THEORY OF THE FLIGHT OF AIRPLANES IN ISOTROPIC TURBULENCE;
REVIEW AND EXTENSION

by

B. Etkin

FEBRUARY, 1961

UTIA REPORT NO. 72
ACKNOWLEDGMENT

This report comprises the written version of an invited paper presented at a meeting of the AGARD Flight Mechanics Panel, Brussels, April 10-14, 1961. Thanks are due to Professor E. D. Poppleton for constructive criticism; and to the National Research Council of Canada for supplying the necessary travel funds.
SUMMARY

(1) Recent experimental information on low-level atmospheric turbulence is reviewed. It is suggested that the assumptions of homogeneity and isotropy customarily adopted for high altitudes are still useful in this regime, and that the integral scale is roughly equal to 9/10 of the altitude up to about 1000 ft. (2) The previously published theory of the "power-series approximation" as applied to the vertical component of the gust is extended to include all three velocity components simultaneously. Fourteen different one-dimensional input power spectra and cross spectra are found of which only 5 are important. Of these five, only one is a cross-spectrum involving two different velocity components (u and v). Formulae for them are calculated and curves are presented. The "gust derivatives" required for calculating airplane response are defined and discussed, and the most important ones are shown to be simply the negatives of classical stability derivatives. Methods of approach for calculating the remaining ones are suggested. (3) Finally it is shown that the dispersion, or probable error of position, is fundamentally different when the controlled variable is velocity or heading than when it is position.

I. INTRODUCTION

The flight of airplanes through turbulent air has been a subject of prime concern to aeronautical engineers since the beginning of flight itself. The attendant problems of structural integrity, flying qualities and performance receive continuing study. The application of statistical methods during the past decade, in particular the methods of power-spectral analysis and the theory of isotropic turbulence, have brought about a significant advance in our understanding of these problems.

The theoretical approaches to analysis fall into two categories, according to the manner of specifying the 'unit' element of the gust. The first uses a 'gust impulse' as the basic element, as shown in Fig. 1. References 1, 2 and 3 are representative of analyses based on this method. The second approach uses the elementary spectral (Fourier) component illustrated in Fig. 2 as the basic element. This is the one which has been taken in Refs. 4, 5 and 6. It should be emphasized that there is no fundamental opposition between the two formulations; both can in principle lead to the same results, the accuracy of which depends not on this choice, but rather on the details of the approximations subsequently made in the analysis. It is the opinion of the author that the second method has some advantages, viz.:

1. The mathematical formulation is simpler, and hence easier to understand and to use.

2. It is easier to separate the elements of the theory that are essentially wing theory from those that are essentially the representation of the turbulence.

3. By using the power-series approximation of Refs. 5 and 6, extended herein, the accumulated knowledge of aerodynamics embodied in stability and flutter derivatives is easily incorporated.

4. Approximations involving certain parts of the frequency spectrum are easily incorporated.

This report presents a brief review of the information on atmospheric turbulence in Sec. II. It follows in Sec. III with a semi-qualitative description of the two basic methods of analysis mentioned above. Section IV contains an extension and generalization of Ref. 6 to cover the case of simultaneous inputs of all three gust components, and Sec. V presents some information on the flight path of a vehicle flying in isotropic turbulence.
II. THE STRUCTURE OF ATMOSPHERIC TURBULENCE

It is obvious that if we wish to study flight in turbulent air theoretically we must know enough about atmospheric turbulence to construct a reasonable mathematical model of it. For this purpose, the atmosphere close to the ground, (in the boundary layer produced by the wind) needs to be considered separately from that higher up.

2.1 Outside the Boundary Layer

There is little to be added to the picture of turbulence at higher altitudes which has already been so competently given by Press and his coworkers at the NASA (Refs. 7 and 8). (An abbreviated account is given in Ref. 5). In short, it is a reasonable approximation to regard high-level turbulence as homogeneous and isotropic in patches of limited extent. The velocity of airplanes is normally sufficiently high that the turbulent field within one of these patches may be regarded as constant during the time of passage; and the statistical properties of the input to the airplane are assumed to be independent of the response of the airplane itself, i.e. they are the same as would be obtained in rectilinear translation at constant speed. (This is not to say that the response of the airplane is neglected in calculating the aerodynamic forces. The forces associated with motion of the airplane are included as usual). The probability distribution of the intensity $\sigma$ of the turbulent patches is dependent on the route, season, altitude etc. The one-dimensional spectrum function for the lateral component of the turbulence which is now widely accepted is

$$\Theta_{33}(k_1) = \Theta_{22}(k_1) = \frac{\sigma^2}{2\pi} \frac{1 + 3 k_1^2}{(1 + k_1^2)^2}$$

(2.1)

According to the theory of isotropic turbulence (Ref. 9) the above is derivable from the more basic energy spectrum-function. The latter is

$$E(k) = \frac{8}{\pi} \sigma^2 \frac{k^4}{(k^2 + 1)^3}$$

(2.2)

In terms of $E(k)$, the one-dimensional spectrum is calculated from the relations

$$\Theta_{ij}(k_1) = \frac{1}{L^2} \int \int \Phi_{ij}(k_1, k_2, k_3) dk_2 dk_3$$

(2.3)

and

$$\Phi_{ij}(k_1, k_2, k_3) = \frac{L^2}{4\pi} \frac{E(k)}{k^4} (k^2 \delta_{ij} - k_i k_j)$$

(2.4)
where \( \delta_{ij} \) is the Kronecker delta. When Eq. 2.2 is substituted into Eq. 2.4 we get

\[
\Phi_{ii}(k_1, k_2, k_3) = \frac{2}{\pi^2} c^2 L^3 \frac{\kappa_i^2 \delta_{ij} - \kappa_i \kappa_j}{(\kappa_j^2 + 1)^3}
\]  

(2.5)

and Eq. 2.3 becomes, for the particular energy spectrum adopted,

\[
\Theta_{ij}(k_1) = \frac{2\sigma^2 \kappa_i^2}{\kappa_j^2} \int_{-\infty}^{\infty} \frac{\kappa_i^2 \delta_{ij} - \kappa_i \kappa_j}{(\kappa_j^2 + 1)^3} \, d\kappa_2 \, d\kappa_3
\]  

(2.6)

From Eq. 2.6, we may also obtain the companion to Eq. 2.1, i.e. the longitudinal one-dimensional spectrum

\[
\Theta_{II}(k_1) = \frac{2\sigma^2 \kappa_i^2}{\kappa_j^2} \frac{1}{1 + \kappa_i^2}
\]  

(2.7)

The cross-spectra \( \Theta_{12}, \Theta_{23}, \Theta_{31} \) are all zero, since for these cases the integrand of Eq. 2.6 is antisymmetrical with respect to one or both of k2, k3.

Unfortunately, there is insufficient information available on the scale \( L \) of the turbulence in the atmosphere. The value \( L = 1000 \) ft. has been assumed by Press and others to be reasonably representative but much more experimental information is needed. It should be pointed out that this is a very important parameter, since it may exert a dominant influence on the energy available at the resonant frequencies of the airplane. This effect is shown in Fig. 3, taken from a Douglas Co. report (Ref. 10). Furthermore, the accuracy of the power-series method (Sec. IV) is dependent on the ratio of airplane size to turbulence scale.

2.2 Near the Ground

At low levels, the turbulence resembles that which occurs in boundary-layers adjacent to rough surfaces and is strongly affected by the terrain. The scale and intensity both vary rapidly with height above the ground, and in general the field is neither homogeneous nor isotropic. A number of measurements have recently been reported of statistical properties of low-level turbulence (Refs. 10, 11, 12, 13) from which two useful general conclusions can be drawn. The first is that Eqs. 2.1 and 2.7 are fair approximations to the lateral and longitudinal one-dimensional spectrum functions. The second is that the scale factor \( L \) in these equations, up to 1000 ft. altitude, may be approximated roughly by

\[
L = 0.9 \, h
\]  

(2.8)
where \( h \) is the altitude. The evidence for these conclusions is given in Figs. 4 to 6. Figures 4 and 5 show comparisons made in the USAF-supported Douglas study between measured spectra, and those given by the equations. The agreement as to shape is encouraging. Figure 6, which contains more detail at the low wave numbers, is another comparison, using \( k_1 \frac{h}{k_1} \) (i.e., \( k_1 \)) as the ordinate, and the ratio altitude/wavelength as abscissa. The experimental data is that of Panofsky (Ref. 11) and the heavy line is Eq. 2.1 with \( L = 0.93 h \). This value of \( L \) corresponds to a maximum of the curve at \( h = 0.25 \). This seems to give the shape of the experimental curves well enough at heights as diverse as 1 metre and 300 metres. No importance should be attached to the actual ordinates of the curves in these Figures, since none of them has been normalized, and there are wide variations in \( \sigma \) (which is the area under the curve when plotted to linear coordinate scales); only the shapes are significant.

Panofsky also gives a semi-empirical formula for the variation of intensity with height and ground roughness under unstable meteorological conditions. This is

\[
\sigma = 0.226 \frac{\bar{V}}{\log h/h_o}
\]

where

\( \bar{V} = \) mean wind at height \( h \)

\( h_o = \) characteristic roughness length.

The questions of homogeneity and isotropy are more troublesome. The evidence shows quite clearly that low-level turbulence reflects the nature of the terrain. If the latter is homogeneous and isotropic, then the turbulence will be closely axisymmetric, i.e., independent of rotation about a vertical axis, and homogeneous with respect to translations in the horizontal plane. However, the scale and intensity in general vary with height, and hence the turbulence is not truly isotropic and the theory leading to the one-dimensional spectrum given in Eq. 2.6 is not valid. In spite of this, there would seem to be no recourse, in the present state of the subject, but to use the isotropic model for the low-level case as well as for high altitudes. The complexity of the problem is even then quite sufficient!

Equation 2.8 indicates that we must be concerned with turbulence having scales as small as 200-300 ft. At such small scales, the variation in gust velocity over the airplane becomes important, and analysis methods of some refinement and complexity are indicated.
III. THE TWO BASIC METHODS OF ANALYSIS

3.1 The "Impulse" Method

Let \( o x_1 \ x_2 \ x_3 \) be a coordinate system so chosen that the mean wind in it is zero, and such that \( o x_1 \) is the mean flight path. Let the airplane be regarded as planar, so that only the distribution of atmospheric motion \((u'_{1}, u'_{2}, u'_{3})\) over the horizontal plane \( o x_1 \ x_2 \) is of interest. The impulsive gust element at point \((x_1, x_2)\) then has components

\[
u'_{1} \ dx_1 \ dx_2 , \nu'_{2} \ dx_1 \ dx_2 , \nu'_{3} \ dx_1 \ dx_2
\]

of which we consider one at a time (as for example in Fig. 1). Now let the airplane come under the influence of the gust element when the c.g. is at position \((\xi, 0, 0)\). Then a typical aerodynamic force or moment associated with it, e.g. the \(Z\) component (the negative of the lift) is

\[
u'_{3} \ dx_1 \ dx_2 \ h(x_{1c.g} - \xi , x_2)
\]

where \(h(\Delta x_1, x_2)\) is the response function for a unit-impulse gust, and is zero for \(\Delta x_1 < 0\). The total force \(Z(x_{1c.g})\) acting on the airplane is then obtained by integrating with respect to c.g. across the span and with respect to \(\xi\) from \(-\infty\) to \(\infty\). The autocorrelation of \(Z(x_{1c.g})\) is next obtained, viz.

\[
R_{zz}(\Delta x_1) = \frac{1}{Z^2} \frac{Z(x_1)}{Z(x_{1} + \Delta x_1)}
\]

and finally the spectral density (which is the quantity sought) is obtained by taking the Fourier Transform of the autocorrelation. This procedure entails some quite complicated mathematics. It is worth noting that the basic aerodynamic information is all bound up in the function \(h(\Delta x_1, x_2)\).

Thus the method does not lend itself readily to incorporating aerodynamic information (experimental or theoretical) which is in the form of stability or flutter derivatives. There is a large body of such information, and to be able to draw on it easily is an advantage. Furthermore, when we wish to extend the impulse method to include the three velocity components simultaneously, the complexity is further increased by the presence of non-vanishing two-point cross-correlations between the \(u'_{1}, u'_{2}\) and \(u'_{3}\) components.

3.2 The "Fourier Component" Method

In this method the basic element of the turbulent velocity field is a wave of shearing motion, described by the expression

\[
e^{i \Omega \cdot x} \ d \Omega(\Omega)
\]
The corresponding distribution of downwash over the $0 x_1 x_2$ plane, for example, is shown in Fig. 7. Once the lift and other relevant aerodynamic forces or moments have been determined for such basic velocity fields, the formalism for writing down the spectra of the inputs to the airplane system is quite straightforward. However, in itself this step does not make the determination of the basic lift element any easier. It replaces the problem of finding $h(\Delta x_1, x_2)$ with that of finding the periodic lift (or other force) associated with a running-wave boundary condition. In fact, the latter solutions may be constructed by a suitable integration of the former. Examples of solutions of this kind of wing-lift problem are found in Refs. 14 and 15.

### 3.2.1 The Power-Series Approximation

A simplifying approximation introduced in Ref. 5 and extended in Ref. 6 is based on representing the gust-velocity field over the airplane by a modified Taylor series. It was shown in Ref. 6 that by keeping terms in the series up to the second order, the velocity distribution can be represented adequately for spectral components whose wavelengths on the two axes ($\lambda_1$ and $\lambda_2$, Fig. 7) exceed twice the corresponding airplane dimension (length or span). It was further shown that the cut-off frequency obtained by excising the higher wave numbers is high enough to allow inclusion of important elastic modes, and that the error due to using a truncated spectrum is not serious provided that the ratio $L/\ell$ is not less than about 3. The value of $\ell$ for a large swept-wing airplane is about 100 ft., so the turbulence scale $L$ may be as small as 300 ft. for such aircraft. For smaller machines, $L$ may be correspondingly less.

It should be noted that it may frequently not be necessary to retain the second order terms in the power-series development. From the examples shown in Ref. 5 it can be seen that cutting off the spectrum at component wave-lengths less than eight times the wing chord and wing span respectively may still provide sufficiently good results for motion in the rigid-body modes. This requires only that the zero order and linear terms of the series be retained. Furthermore, it will be seen in the following that the input spectra associated with the second-order terms are very small.

*It is shown later, Sec. 4.1.1, that the wave-length limitation is actually less restrictive than this.*
IV. EXTENSION OF THE POWER-SERIES APPROXIMATION

In Refs. 5 and 6 only the vertical component of the turbulence ($u_3' = \omega'$) was considered to be present. However, the simultaneous occurrence of all three velocity components must be considered for a complete theory. Thus we take as the description of a single spectral component of the gust field the Taylor series

$$u_i' = (u_i')_0 + \left( \frac{\partial u_i'}{\partial x_j} \right)_0 x_j + \frac{1}{2} \left( \frac{\partial^2 u_i'}{\partial x_j \partial x_k} \right)_0 x_j x_k$$

where the summation convention for repeated suffices is implied. The subscript $o$ denotes the airplane C.G., i.e. the point $(u_o t, o, o)$. Thus $u_i'$ and its derivatives are periodic, with circular frequency $\Omega_1 u_o = \omega$.

As in Sec. 3.1, we consider the airplane to be a planar body, so that only the variations in the $x_1 x_2$ plane are of interest - hence the restriction of $j, k$ to 1, 2 in Eq. 4.1. In Ref. 6 a refinement was included which improved the fit obtained with this approximation to the actual sinusoidal velocity distribution. The refinement was to multiply the linear terms by suitably chosen frequency-dependent factors. This had the same effect on the input spectrum functions as would adding certain third order terms to Eq. 4.1. Although there is certainly some gain in accuracy achieved thereby, this refinement adds undesirable complexity, and is not included herein.

The point of view taken is that each term of Eq. 4.1 (when it is applied to a single spectral component) represents a periodic relative velocity field of simple form, which results in periodic aerodynamic forces and moments. These are expressed quite generally by a set of "gust derivatives" or "gust transfer functions" which are analogous to (some are identical to) the familiar stability and flutter derivatives which have been in use for so long.

Consideration of the symmetry of the velocity distributions represented by the individual terms of Eq. 4.1 permits separation of the associated aerodynamic forces and moments into the usual longitudinal and lateral groups. The following matrix equations serve to define the 'gust derivatives' (note that the gust velocities are now denoted by $u', v', w'$):

$$\{F_1\} = [A_1] \{g_1\} \quad (4.2)$$

$$\{F_2\} = [A_2] \{g_2\} \quad (4.3)$$
where

\[ F_1 = \begin{bmatrix} X \\ Z \\ M \\ H_e \end{bmatrix} \]  
\[ F_2 = \begin{bmatrix} Y \\ L \\ N \\ H_a \\ H_r \end{bmatrix} \]  
\[ g_1 = \begin{bmatrix} u' \\ v' \\ w' \\ x \\ y \\ x' \\ y' \\ u_{xx} \\ v_{xx} \\ w_{xy} \\ u_{yy} \\ v_{yy} \end{bmatrix} \]  
\[ g_2 = \begin{bmatrix} v' \\ v_x' \\ u_y' \\ w_y' \\ x' \\ y' \\ u_{xx} \\ v_{xx} \\ u_{xy} \\ v_{xy} \\ w_{xy} \end{bmatrix} \]

where \( w'_x = \partial w'/\partial x \) etc. It will be seen subsequently that the input spectra associated with \( \tilde{w}'_{xy} \) are negligible, and hence that term may be dropped.
In the above expressions \( \{F_1\} \) and \( \{F_2\} \) are the column matrices of the Laplace Transforms of the longitudinal and lateral aerodynamic forces respectively, \( \{g_1\} \) and \( \{g_2\} \) are the matrices of the Laplace Transforms of the gust-velocity inputs for the longitudinal and lateral equations, and \( \{A_1\} \) and \( \{A_2\} \) are the matrices of 'gust transfer functions' defined by Eqs. 4.2 and 4.3. These transfer functions might frequently be approximated by simple derivatives, e.g. \( Y_{v'} = \partial Y/\partial y' \) (see Ref. 5, Sec. 4.16). The matrices \( \{A_1\} \) and \( \{A_2\} \) are written out above with maximum generality, in which case there are a total of 80 transfer functions! The dashed lines in Eqs. 4.6 to 4.9 indicate those portions of the matrices (to the right of the line) which would be neglected in a first-order theory. The number of transfer functions is then reduced to 40. If only control-fixed conditions are of interest, a further reduction to 27 is effected by dropping all the \( H \) terms. Additional simplifications of the sort common in stability and control work might frequently be order: for example, neglecting the \( X \) force equation altogether in the longitudinal equations of motion, and dropping certain transfer functions which experience or analysis indicate are small.

4.1 The One-Dimensional Input Spectra

Since the 'inputs' \( \{g_1\} \) and \( \{g_2\} \) contain more than one element, the airplane system is subjected to a set of simultaneous random inputs. Figure 8 illustrates the general case, with inputs \( x_i(t) \), \( i = 1 \) to \( n \), output \( y_n(t) \), and transfer functions \( G_{ni}(s) \). The output is given by

\[
\begin{bmatrix}
X_{u'} & X_{w'} & X_{u'}_{x} & X_{w'}_{x} & X_{v'} & X_{u'}_{yy} & X_{w'}_{yy} \\
Z_{u'} & Z_{w'} & Z_{u'}_{x} & Z_{w'}_{x} & Z_{v'} & Z_{u'}_{yy} & Z_{w'}_{yy} \\
M_{u'} & M_{w'} & M_{u'}_{x} & M_{w'}_{x} & M_{v'} & M_{u'}_{yy} & M_{w'}_{yy} \\
H_{u'} & H_{w'} & H_{u'}_{x} & H_{w'}_{x} & H_{v'} & H_{u'}_{yy} & H_{w'}_{yy} \\
\end{bmatrix}
\]

\[
\begin{bmatrix}
Y_{v'} & Y_{v'}_{x} & Y_{u'} & Y_{w'} & Y_{v'}_{xx} & Y_{u'}_{xy} & Y_{w'}_{yy} \\
L_{v'} & L_{v'}_{x} & L_{u'} & L_{w'} & L_{v'}_{xx} & L_{u'}_{xy} & L_{w'}_{yy} \\
N_{v'} & N_{v'}_{x} & N_{u'} & N_{w'} & N_{v'}_{xx} & N_{u'}_{xy} & N_{w'}_{yy} \\
H_{v'} & H_{v'}_{x} & H_{u'} & H_{w'} & H_{v'}_{xx} & H_{u'}_{xy} & H_{w'}_{yy} \\
H_{r'} & H_{r'}_{x} & H_{u'} & H_{w'} & H_{r'}_{xx} & H_{u'}_{xy} & H_{r'}_{yy} \\
\end{bmatrix}
\]
and as shown in Ref. 16, the (one-dimensional) power spectral density of $y_n$ is given by

$$
\Theta_{y_n}(\omega) = \sum_i \sum_j G_{ni}(i\omega) \Xi_{ij}(i\omega) \Theta_{ij}(\omega)
$$

(4.10)

The star denotes the conjugate complex number, so that for example the term $G_{ni}^* G_{ni} \Xi_{ij} = |G_{ni}|^2 \Xi_{ij}$, which is the familiar result for a single input. $\Xi_{ij}$ is the cross-spectrum of $x_i$ and $x_j$, i.e. the spectral distribution of $x_i x_j$, or the Fourier transform of the cross-correlation of $x_i$ and $x_j$. In using Eq. 4.10 it is important to note that

$$
\Theta_{ij}(\omega) = \Theta_{ji}^*(\omega)
$$

(4.11)

If $y_n$ is one of the airplane response quantities such as roll angle, load factor, wing stress, etc., then $G_{ni}(\omega)$ is the overall transfer function relating this particular response to the input $x_i$ (e.g. $w'_y$). The evaluation of these transfer functions is performed by applying the forces $\{F_1\}$ or $\{F_2\}$ to the appropriate equations of motion, e.g. for the horizontal flight of a rigid airplane with six rigid-body and three control system degrees of freedom:

$$
[B_1] \begin{bmatrix}
\ddot{u} \\
\dot{w} \\
\dot{\theta}
\end{bmatrix} = \{F_1\}
$$

(4.12)

$$
[B_2] \begin{bmatrix}
\ddot{v} \\
\dot{\phi} \\
\dot{\psi}
\end{bmatrix} = \{F_2\}
$$

(4.13)

where
The equations do not include any automatic control elements, but the addition of these in particular cases is usually fairly straightforward.

We must now consider the input spectrum functions which occur in Eq. 4.10. These are the cross-spectra of all the inputs that occur in \{g_1\} or \{g_2\}, that is, among the velocity components and their first and second derivatives. Many of these cross-spectra are zero by virtue of the fact that the two quantities involved are uncorrelated (see after Eq. 2.7). However, a number of them remain, and these must be calculated. Let the spectrum function corresponding to any pair of entries in \{g_1\} or \{g_2\} be identified by a corresponding pair of subscripts. For example, \( H_{ux} v_{xy} \) is the cross-spectrum of \( u'_x \) and \( v'_xy \) which
occur in \( \{ g_i \} \). The expression for the three-dimensional cross-spectrum of two scalar components of a vector of the form \((3.1)\) is given by Batchelor (Ref. 9, Eq. 2.5, 5) as

\[
\Phi_{ij}(\Omega) = \lim_{d \Omega \to 0} \frac{dU^*_i(\Omega) dU_j(\Omega)}{d \Omega_1, d \Omega_2, d \Omega_3}
\]  

(4.16)

The cross-spectra of elements containing derivatives can be written down directly from Eq. 4.16. For example, the spectral component of \( u_{x'} \) from Eq. 3.1, is given by the \( x_1 \) derivative of the \( u_1 \) component, viz.

\[
e^{i \Omega \cdot x} (i \Omega_1 dU_1)
\]  

(4.17)

whence for example

\[
\Phi_{u_x v_{xy}}(\Omega) = i \Omega_1^2 \Omega_2 \Phi_{12}(\Omega)
\]  

(4.18)

The general rule is seen to be that for each derivative with respect to \( x_k \) the spectrum function \( \Phi_{ij} \) is multiplied by \( \pm i \Omega_k \). The plus sign is for derivatives of the second subscript velocity component \( v_{xy} \) in Eq. 4.18, and the minus sign is for derivatives of the first \( u_{x'} \). The difference in sign occurs because the conjugate of the first amplitude element is used in Eq. 4.16. The corresponding one-dimensional spectrum function, continuing with the same example, is then (cf. Eq. 2.3)

\[
\Theta_{u_x v_{xy}}(\Omega_1) = i \Omega_1^2 \int_{-\infty}^{\infty} \Omega_2 \Phi_{12}(\Omega) d \Omega_2 d \Omega_3
\]  

(4.19)

or

\[
\Theta_{u_x v_{xy}}(k_1) = i \frac{k_1^2}{L_5^3} \int_{-\infty}^{\infty} k_2 \Phi_{12}(k_1, k_2, k_3) d k_2 d k_3
\]  

(4.20)

In the theory presented herein, we exclude that portion of the spectrum for which \( \Omega_2 > \Omega'_2 \) and \( \Omega_1 > \Omega'_1 \), where \( \Omega'_2 \) and \( \Omega'_1 \) correspond to the wave-length limits for which the power-series approximation is valid. It must be noted that some of the integrals of the type contained in Eq. 4.19 are divergent when the limits are infinite and the truncation is therefore essential, and not a matter of choice. The expression for the truncated spectrum is

\[
\Theta_{u_x v_{xy}}(k_1) = i \frac{k_1^2}{L_5^3} \int_{-k'_2}^{k'_2} k_2 d k_2 \int_{-\infty}^{\infty} \Phi_{12}(k_1, k_2, k_3) d k_3
\]  

(4.20)
With the value of $\Phi_{ij}$ given in Eq. 2.5 this integral, and the others like it which occur in the equations, can all be evaluated quite simply. The integrand in the majority of cases is an odd function of one or both of $k_2$ and $k_3$ and for these the integral is zero. Of those which remain, some can be discarded on the basis of the following order of magnitude analysis.

The general form for $\Theta(k_1)$ (apart from sign) is

$$\Theta(k_1) = \frac{1}{L^{n+2}} \int_{-k_2}^{k_2} \left( i \cdot k_1 \right)^\alpha (i \cdot k_2)^\beta \Phi_{ij} \, dk_3$$

(4.21)

where $n = \alpha + \beta$, and $\alpha$ and $\beta$ are the orders of the two velocity derivatives involved. When the expression for $\Phi_{ij}$ given by Eq. 2.5 is inserted, we get

$$\Theta(k_1) = \frac{2\sigma^2}{\nu^2} \int_{-k_2}^{k_2} \left( i \cdot k_1 \right)^\nu (i \cdot k_2)^\beta \int_{-\infty}^{\infty} k_3^2 \epsilon_{ij} - k_i k_j \, dk_3$$

(4.22)

Depending on the values of $i$ and $j$, the integration with respect to $k_3$ leads to zero, or one or both of the following terms

$$\frac{2\nu}{8} \left( k_1^2 + k_2^2 + 1 \right)^{-1/2} \cdot \frac{\pi}{8} \left( k_1^2 + k_2^2 + 1 \right)^{-3/2}$$

(4.23)

Since we are interested in values of $k_1$ and $k_2$ up to about 100, we see that the magnitude of $\Theta$ is characterized by the numbers

$$L^{1-n} (100)^{n-4} \quad \text{or} \quad L^{1-n} (100)^{n-2}$$

of which the larger one is the second.

Thus the relative values of $\Theta$ with ascending $n$ are characterized by

<table>
<thead>
<tr>
<th>$n$</th>
<th>0</th>
<th>1</th>
<th>2</th>
<th>3</th>
</tr>
</thead>
<tbody>
<tr>
<td>relative $\Theta$</td>
<td>1</td>
<td>0.1</td>
<td>0.01</td>
<td>0.001</td>
</tr>
<tr>
<td></td>
<td>1</td>
<td>0.5</td>
<td>0.25</td>
<td>0.125</td>
</tr>
</tbody>
</table>
On the strength of these values, and noting that $L = 200$ is a rather small scale, we may neglect all cross-spectra for which $n > 2$. The remaining non-zero spectra, (25 in all) have been calculated and are given below.

For the Longitudinal Equations

\[ n = 0 \]

\[ \Theta_{uu} = \frac{\sigma^2}{2\pi} \frac{1}{1 + k_1^2} \frac{k_2^{'2}}{k'} \left[ 1 + \left( \frac{k_2^{'2}}{k'} \right)^2 \right] \]

\[ \Theta_{ww} = \frac{3\sigma^2}{2\pi} \frac{1}{1 + k_1^2} \frac{k_2^{'2}}{k'} \left\{ \frac{1}{3} \left( \frac{k_2^{'2}}{k'} \right)^2 + \frac{k_1^2}{1 + k_1^2} \left[ 1 - \frac{1}{3} \left( \frac{k_2^{'2}}{k'} \right)^2 \right] \right\} \]

\[ n = 1 \]

\[ \Theta_{uu_x} = i \frac{\sigma^2}{2\pi} \frac{k_1 k_2^{'}}{k'(1 + k_1^2)} \left[ 1 + \left( \frac{k_2^{'2}}{k'} \right)^2 \right] \]

\[ \Theta_{ww_x} = i \frac{3}{2} \frac{\sigma^2}{2\pi} \frac{k_1 k_2^{'}}{k'(1 + k_1^2)} \left[ \frac{k_1^2}{1 + k_1^2} - \frac{k_1^2}{1 + k_1^2} \left( \frac{k_2^{'2}}{k'} \right)^2 + \frac{1}{3} \left( \frac{k_2^{'2}}{k'} \right)^2 \right] \]

\[ \Theta_{uu_y} = -i \frac{\sigma^2}{2\pi} \frac{k_1}{1 + k_1^2} \left( \frac{k_2^{'2}}{k'} \right)^3 \]

\[ n = 2 \]

\[ \Theta_{uu_{xx}} = i \ \Theta_{uu_x} \]

\[ \Theta_{uu_{yy}} = \frac{\sigma^2}{2\pi L} \left[ 4 \frac{k_1^2}{k'} + \left( \frac{k_2^{'2}}{k'} \right)^3 - 2 \ln \frac{k' + k_2^{'}}{k' - k_2^{'}} \right] \]

\[ \Theta_{uu_{xy}} = \frac{\sigma^2}{2\pi L} \frac{k_1^2}{1 + k_1^2} \left( \frac{k_2^{'2}}{k'} \right)^3 \]
\[ \Theta u_{xy} = - \Theta u_{xy} \]

\[ \Theta u_{xx} = - \Theta u_{xx} \]

\[ \Theta u_{yy} = \frac{\sigma^2}{2 \pi L} \left[ \frac{k_1^2}{1 + k_1^2} \left( \frac{k_2'}{k'} \right)^3 - \left( \frac{k_2'}{k'} \right) + \frac{1}{2} \ln \frac{k' + k_2'}{k' - k_2'} \right] \]

\[ \Theta \omega_{xx} = -i \frac{k_1}{L} \Theta \omega_{x} \]

\[ \Theta \omega_{yy} = i \frac{k_1}{L} \Theta \omega_{y} \]

\[ \Theta \omega_{xy} = - \frac{3 \sigma^2}{4 \pi L} \left[ \frac{\frac{1}{3}}{1 + k_1^2} \left( \frac{k_2'}{k'} \right)^3 - \frac{2}{3} \left( \frac{k_2'}{k'} \right)^2 + \frac{2}{3} \left( \frac{k_2'}{k'} \right) + \ln \frac{k' + k_2'}{k' - k_2'} \right] \]

For Lateral Equations

\[ n = 0 \]

\[ \Theta u = \frac{3 \sigma^2 L}{2 \pi} \left[ \frac{1}{1 + k_1^2} \frac{k_2'}{k'} \left\{ \frac{k_1^2}{1 + k_1^2} \left[ 1 - \frac{1}{3} \left( \frac{k_2'}{k'} \right)^2 \right] + \frac{1}{3} \right\} \right] \]

\[ n = 1 \]

\[ \Theta u_x = i \frac{k_1}{L} \Theta u_x \]

\[ \Theta u_y = \Theta u_y \]

\[ n = 2 \]

\[ \Theta u_{xy} = - \Theta u_{xy} \]
\[ \Theta_{u^2 x^2} = i \frac{k_1}{k_2} \Theta_{u^2 x} \]

\[ \Theta_{u^2 x y} = \Theta_{u^2 y x} \]

\[ \Theta_{u^2 y^2} = - \Theta_{u^2 y} \]

\[ \Theta_{u^2 u^2} = - \Theta_{u u^2} \]

\[ \Theta_{u^2 v^2} = - \Theta_{u v^2} \]

The spectra given above are plotted against \( k_1 \) for several values of \( k_2 \) in Figs. 9 to 22. It may be noted that none of them are complex - they are either real, or pure imaginaries. There are 25 non-zero power spectra and cross-spectra listed above. Many of these are equal or merely opposite in sign to others, so that there are only fourteen essentially different ones. Of these fourteen, three are zero-order \( (\Theta_{u^2 x^2}, \Theta_{v^2 y^2}, \Theta_{w^2 w^2}) \) four are first-order \( (\Theta_{u^2 x x}, \Theta_{u v y y}, \Theta_{v v^2 x}, \Theta_{w w^2 x}) \) and the remaining seven are all second order. Of the first-order spectra, only one is a cross-spectrum involving two different velocity components, i.e. \( \Theta_{u v y} \). Hence in a first order theory, this remains as the only cross-term between velocity components, and if it is neglected, complete statistical separation of the response to the three components of the turbulence results.

4.1.1 The Wavelength Limitation

Examination of Figs. 9 to 22 and Table I shows that the order of magnitude of the spectrum peak is given by \( L_1^{1-n} \). Now if the basic series giving the velocity, Eq. 4.1, had been extended to include
higher order terms, the effect would simply have been to add additional higher order spectra (n \gg 3) to the list already calculated. It is evident that these higher order spectra would be negligibly small for the frequency range \( k < 1 \) and for the scale \( L > 100 \). In the range \( 1 \leq k \leq 100 \) they would ultimately become large as \( n \) increased indefinitely. Thus it appears that the spectra presented are actually valid for a series representation of the velocity containing terms of at least the third, and probably higher order. The wavelength limitations may therefore reasonably be taken as

\[
\lambda_1' = l_1 \\
\lambda_2' = l_2
\]

where \( l_1 \) is the overall length of the wing. Hence

\[
k_1' = \lambda_1' \frac{1}{\lambda_1} = 2 \pi \frac{1}{l_1} \\
k_2' = \lambda_2' \frac{1}{\lambda_2} = 2 \pi \frac{1}{l_2}
\]

For example, if \( L = 1000 \) and \( b = 100 \), then \( k_2' = 20 \pi = 62.8 \)

Finally it may be remarked that for large \( L \), (i.e. 1000') the second-order spectra are less at medium wave numbers (\( k = 1 \)) by a factor of order \( 10^9 \) then the zero order spectra. Thus, unless relatively high frequency responses are of interest (e.g. elastic modes) the second-order spectra are not at all important.

4.2 The 'Gust Derivatives'

Equations 4.8 and 4.9 indicate that the general second-order theory, when applied to the rigid-body motion of an airplane with three additional control degrees of freedom, involved 80 aerodynamic transfer functions (which we have termed 'gust derivatives'). Should additional elastic degrees of freedom of the airplane be included (as in Ref. 6) then still additional gust derivatives would be required. As has already been mentioned however, substantial simplifications can be made in many practical analyses, such as dropping the X-force equation, keeping only the first-order derivatives, etc. These simplifications must always be determined by the particular circumstances, and it is not within the scope of this paper to anticipate all the possibilities. Neither is it within its scope to present a collection of data on the derivatives, although it is hoped that some research at the Institute of Aerophysics will be directed to that end. Nevertheless, a discussion of the derivatives is given in the following three sections.
4.2.1 The Zero-Order Derivatives

The zero-order derivatives, which are the most important ones, are those with respect to the gust-velocity components themselves, e.g., $M_w'$, $L_v'$ etc. They are the elements of the first two columns of $[A_1]$ and the first column of $[A_2]$. These are simply the aerodynamic transfer functions (stability derivatives) of classical aerodynamic theory, with opposite sign, i.e.

$$Z_{w'} = -Z_w \text{ etc.} \quad (4.49)$$

where $Z_w$ is given by Eq. 4.15(a). The reversal of sign is because $w$ is the velocity of the airplane in the $z$ direction, and $w'$ is the velocity of the air in the same direction; hence the relative motion is given by $(w - w')$. This group of derivatives embodies the major aerodynamic effects of gusty air, and a simplified calculation in which all others are neglected would still be of considerable value, especially for small airplanes in large-scale turbulence.

4.2.2 The First-Order Derivatives

Columns 3 to 5 of $[A_1]$ and columns 2 to 4 of $[A_2]$ contain the elements in which there appears a first-order derivative of the velocity components. These describe the influence of the 'gust gradient' on the airplane, and are no doubt important for large airplanes, especially near the ground in small-scale turbulence. It has already been shown (Ref. 6) that the derivatives with respect to $w'_x$ and $w'_y$ are identical with the classical pitch and roll stability derivatives, viz.:

$$M_{w'_x} = M_q \text{ etc.} \quad (4.50)$$

$$L_{w'_y} = -L_p \text{ etc.}$$

No correspondingly simple interpretation is in general possible for the velocity fields associated with $u'_x$ and $u'_y$. For unswept wings of high-aspect ratio, the derivative $u'_x$ would presumably be significant only in introducing a relative wind at the tail different from that at the c.g., i.e.

$$\Delta u_{rel'} = -u'_x \int_{x}$$

This would modify the tail lift, and hence the lift and pitching moment of the airplane, as expressed in the derivatives $Zu'_x$ and $Mu'_x$. For swept-back high-aspect-ratio wings it introduces a variable (linear) relative wind along the span, which could be treated by a suitably modified lifting-line theory. The same theoretical wing problem is presented by the velocity field associated with $u'_y$, with the difference that the spanwise velocity...
variation associated with the latter exists for all wings, whether swept or not. For the particular case of a straight lifting line, the forces corresponding to \( u'_y \) are just those given by the classical yaw-rate derivatives, viz.:

\[
L_{u'_y} = -L_{\Gamma} \quad \text{etc.}
\]

The effects of the linear velocity fields associated with \( v'_x \) and \( v'_y \) on the contributions of the vertical tail to the aerodynamic forces can readily be estimated, since they merely change the average relative sidewind wind at the tail and hence the angle of attack of the vertical tail. Their effects on the wings are rather more involved. \( v'_x \) would not be expected to be of much importance for unswept wings, but for swept wings \( v'_x \) and \( v'_y \) both have the effect of modifying the wing angle of attack distribution, when it has dihedral, in the manner illustrated in Fig. 23. Again, for high-aspect-ratio wings, lifting line theory could be used to calculate these effects in a rather straightforward manner. For more general cases, lifting surface theory would have to be employed.

When the wing is swept there is, in addition to the \( \alpha \) changes described above, the important variation of the magnitude of the component of the relative wind normal to the line of aerodynamic centres. This is given by

\[
\Delta V_n = \mp v'_n \Delta m \Lambda, \quad \gamma > 0
\]

and the distributions of \( \Delta V_n \) associated with \( v'_x \) and \( v'_y \) have exactly the same form as those shown for \( \Delta \alpha \) in Fig. 23. Thus the two effects will be additive in producing rolling moment, side force and yawing moment.

### 4.2.3 The Second-Order Derivatives

Columns 5 to 10 of \( [A_1] \) and 4 to 8 of \( [A_2] \) contain the second-order elements. By virtue of the assumption made in Sec. 4.1, i.e. neglecting all input spectra having \( n > 2 \), one column of these derivatives is not required. That is the seventh column in \( [A_2] \), containing derivatives with respect to \( \omega'_{xy} \). The reason for this is that the lowest order spectrum function which contains the input \( \omega'_{xy} \) is \( \Upsilon \omega'_{xy} (n = 2) \) and it is identically zero. Hence this particular input is of negligible importance and the associated derivatives are not of interest.

Of the remaining derivatives, those involving \( \omega'_{xx} \) and \( \omega'_{yy} \) have already been discussed in Ref. 6, (using a different nomenclature). They are shown to give the aerodynamic forces resulting from a periodic cambering or chordwise bending of the wing (\( \omega'_{xx} \)) and a flapping or spanwise bending (\( \omega'_{yy} \)). Values of the lift and pitching moment on a two-dimensional wing in incompressible flow are given there for the \( \omega'_{xx} \) case. The calculation of forces due to the \( \omega'_{yy} \) field could be accomplished by a
relatively straightforward application of the appropriate method of wing theory.

The elevator and rudder hinge-moment derivatives contained in $[A_1]$ and $[A_2]$ could all be calculated relatively easily on the assumption that the surface in question experiences an angle of attack or velocity change equal to that at the mean aerodynamic centre of the surface. The calculation of aileron hinge moment derivatives (the 4th row of $[A_2]$) would take more effort except when simple strip theory is acceptable.

Generally speaking, since the input spectra corresponding to $n = 2$ are relatively so weak, it appears that rough estimates of the second-order derivatives will serve well enough for analysis. A note of caution must be sounded in this connection, however, when elastic modes of the aircraft are involved, for then the second order terms may be more important.

V. DISPERSION OF THE FLIGHT PATH

When the aircraft is flown by a human or automatic pilot so as to traverse a specified track (eg. as given by a radio beam), at a specified altitude (eg. as given by an altimeter), then the controlled variables may be considered as $x_3$ (altitude) and $x_2$ (lateral displacement). These will be random variables, having mean-square values which, when used in the normal (Gaussian) probability distribution, give the probability of dispersion of the aircraft from the desired (rectilinear) flight path. In a homogeneous isotropic atmosphere this probability function applies equally well to all portions of the path. However, when the controlled variable is a velocity, rather than a displacement, the situation is fundamentally different. This would normally be the case for the $x_1$ degree of freedom; that is, forward speed not distance flown is the controlled variable. Likewise, if a heading reference only is used for navigation (eg. magnetic compass), then $u_2$ not $x_2$ becomes the random output. In such a case the displacement in a given direction is the integral of the corresponding random velocity component, i.e.

$$x_i = \int_0^t u_i \, dt$$

(5.1)

If we consider a very large number of flight paths through the turbulent field, and take an ensemble average, denoted by $\langle \cdot \rangle$, then

$$\langle x_i \rangle = \int_0^t \langle u_i \rangle \, dt = 0$$

(5.2)

since the ensemble average is equal to the space average. The mean square coordinate, however, does not vanish:
The ensemble average (average over many flights at given time \( t \)) is

\[
\langle x_i^2(t) \rangle = \int_0^t \int_0^t \langle u_i(\alpha) u_i(\beta) \rangle \, d\alpha \, d\beta 
\]

But the mean product \( \langle u_i(\alpha) u_i(\beta) \rangle \) is known from the autocorrelation,

\[
R(\alpha - \beta) = \frac{\langle u_i(\alpha) u_i(\beta) \rangle}{u_i^2} 
\]

Therefore

\[
\langle x_i^2(t) \rangle = \overline{u_i^2} \int_0^t \int_0^t R(\alpha - \beta) \, d\alpha \, d\beta 
\]

The integral can be shown to have the value

\[
2 \int_0^t R(\gamma) \, d\gamma - 2 \int_0^t \gamma R(\gamma) \, d\gamma 
\]

At large values of \( t \) the second term becomes negligible, and we have the final result

\[
\langle x_i^2 \rangle = 2 \overline{u_i^2} A \, t 
\]

where \( A = \int_0^\infty R(\gamma) \, d\gamma \) is the area under the autocorrelation curve of \( u_i(t) \). The latter is directly related to the output power spectrum of \( u_i \), and can be calculated from it, i.e.

\[
R(\gamma) = \int_{-\infty}^{\infty} \Theta_{u_i u_i}(\omega) e^{i\omega \gamma} \, d\omega 
\]

where \( \Theta_{u_i u_i}(\omega) \) is the power spectral density of \( u_i \). The significance of the result given in Eq. 5.8 is that the r.m.s. dispersion \( \langle x^2 \rangle^{\frac{1}{2}} \) varies as \( \sqrt{t} \). This is the same result as in the classical problem of the "random walk". Thus the probable error in the lateral position of a compass-controlled flight path increases with the square root of the time, or distance flown. The same would be true of the distance flown itself in a speed-controlled flight. However since an altitude reference is almost invariably used in the flight of airplanes the probable error in the height remains constant with time. The dispersion of entirely unguided bodies, e.g. ballistic missiles, would vary as \( \sqrt{t} \) in all three coordinates.
