33

34 **Abstract**

35 This paper formulates an analytical calculation model for predicting the cracking behavior of
36 reinforced concrete ties to provide more consistent crack width calculation methods for large-
37 scale concrete structures in which large bar diameters and covers are used. The calculation
38 model was derived based on the physical behavior of reinforced concrete ties reported from
39 experiments and finite element analyses in the literature. The derivations led to a second order
40 differential equation for the slip that accounts for the 3D effects of internal cracking by using a
41 proper bond-slip law. The second order differential equation for the slip was solved completely
42 analytically, resulting in a closed-form solution in the case of lightly loaded members and in a
43 non-closed-form solution in the case of heavily loaded members. Finally, the paper provides a
44 solution strategy to facilitate a practical and applicable method for predicting the complete
45 cracking response. Comparison with experimental and finite element results in the literature
46 demonstrated the ability of the calculation model to predict crack widths and crack spacing
47 consistently and on the conservative side regardless of the bar diameter and cover.

51 concrete structures.

52

53 **1. Introduction**

54 Predicting the cracking behavior of reinforced concrete (RC) structures consistently and
55 accurately is not straightforward. This is reflected in the many approaches proposed in the
56 literature (Borosnyói and Balázs 2005). Formulas based on empirical, semi-empirical, elastic
57 analysis, and even fracture mechanics have all been proposed. Mechanical calculation models
58 based on the internal cracking behavior of RC ties have also recently been proposed (Fantilli et
59 al. 2007, Debernardi and Taliano 2016, Kaklauskas 2017).

60

61 The study presented in this paper is part of an ongoing research project with the overall
62 objective of improving crack width calculation methods for the large-scale concrete structures
63 planned for the coastal highway route “Ferry-free E39” in Norway. The Norwegian Public Roads
64 Administration (NPRA) recommends that the design of such structures should follow the
65 guidelines provided in N400 (NPRA 2015), which state that the crack width calculation methods
66 should be in accordance with the provisions in Eurocode 2 (EC2) (CEN 2004). However, Tan et
67 al. (2018a) showed that the crack width formulas recommended by EC2 and the *fib* Model Code
68 2010 (MC2010) (*fib* 2013) predict the cracking behavior of structural elements inconsistently,
69 particularly in cases of large covers and bar diameters. The analytical calculation model
70 presented in this paper was based on solving the second order differential equation (SODE) for
71 the slip when applying a bond-slip law first proposed by Eligehausen et al. (1983) and later
72 adopted by MC2010. Other authors in the literature have used a similar approach (e.g. Russo
73 and Romano 1992, Balász 1993, Debernardi and Taliano 2016), an approach which has
74 recently been acknowledged in the state-of-the-art French research project CEOS.fr (2016) as
75 an alternative way of calculating crack widths for large RC members. The main drawback in
76 using this approach until now was the analytically complex solution of the SODE for the slip,
77 thus resorting to numerical solution techniques instead and by that reducing the practical
78 applicability of the approach. Moreover, the background of the SODE for the slip was never
79 properly elaborated.

80

81 The aim of this research was to provide more realistic and consistent surface crack width
82 calculation methods for large-scale concrete structures, where large covers in combination with

large bar diameters in several layers and bundles are typically used, by deriving and solving the SODE for the slip completely analytically. First, the SODE for the slip was derived. Then, the SODE for the slip was solved analytically, after which a solution strategy for determining the complete cracking response was developed for the purposes of practical application. Finally, the application was demonstrated by comparing analytical predictions with experimental and finite element (FE) results reported in the literature.

The analytical model was derived using the concept of axisymmetry and applies first and foremost to such conditions. However, it will be shown that the model also has the ability to predict the cracking behavior of RC ties that deviate from such conditions by transforming an arbitrary cross section into an equivalent axisymmetric cross section. Moreover, predicting realistic and consistent surface crack widths is an important part of the structural design, and it might also be relevant for the aesthetics of a structure (Leonhardt 1988). On the other hand it is often argued that the crack width at the reinforcement appears more relevant in terms of durability. Predicting the latter, though, becomes rather complicated and was not addressed in this study.

2. The physical behavior of RC ties

A typical deformation configuration of RC ties according to several experimental studies reported in the literature (Watstein and Mathey 1959, Broms 1968, Husain and Ferguson 1968, Yannopoulos 1989, Beeby 2004 and Borosnyói and Snóbli 2010) is depicted in Fig. 1(a). Note that the crack width at the interface between concrete and steel $w_{cr,int}$ is considerably smaller than that on the concrete surface w_{cr} , which according to Goto (1972) and Tammo and Thelanderrson (2009) is due to the rib interaction between concrete and steel. This causes the concrete to crack internally, which allows it to follow the displacement field of steel at the interface almost completely. This reported physical behavior formed the basis for ignoring the crack width at the interface in the FE model of Tan et al. (2018c). This imposed equal longitudinal displacements for concrete and steel at the interface as shown in Fig. 1(b), in which it should be noted that the crack width w_{cr} applies to the concrete surface only. The FE model was validated against the classical experiments of Bresler and Bertero (1968) and Yannopoulos

(1989), where comparison of steel strains, the development of crack widths and the mean crack spacing showed good agreement. Furthermore, the FE model was also used to analyze cylindrical RC ties to better understand the cracking behavior. It was observed that the bond transfer at the interface caused radial displacements of the concrete, which in turn increased hoop stresses and strains. This resulted in internal splitting cracks and inclined cracks, depicted respectively as circles and straight lines in Fig. 1(b), when the principal stresses exceeded the tensile strength of the concrete. Moreover, deriving local bond-slip curves at different positions over the bar length showed that such curves include the effect that internal splitting and inclined cracks had on reducing the bond transfer. In other words, the local bond-slip curve describes how the 3D behavior of an RC tie affects the bond transfer. This shows that a single local bond-slip curve is sufficient to describe the mean bond transfer at the interface between concrete and steel for an arbitrary RC tie.

3. The mechanical crack width calculation model

3.1 Main assumptions

The analytical calculation model was derived based on the physical behavior of RC ties discussed in the previous section. However, some simplifications were made, and at first the concept of axisymmetry was also used for simplicity. Firstly, concrete and steel were both treated as elastic materials. Secondly, the nonlinearity of the internal cracking of the confining concrete was accounted for by lumping this behavior to the interface between the materials using a bond-slip law, i.e. claiming that the three sections in Fig. 2(a), (b) and (c) are statically equivalent. Note that a physical slip u occurs at the interface in Fig. 2(b) and (c) as a result of treating concrete and steel as elastic materials. This means that the total slip s_{tot} in the statically equivalent section in Fig. 2(c) is composed of two parts: the slip at the interface u caused by the formation of internal inclined cracks and the elastic deformations of the concrete caused by axial and shear deformations in the cover s_s . This also conforms to the definition of slip in *fib* bulletin 10 (2000). Assuming that the slip at the interface is equivalent to the deformation caused by internal inclined cracks implies in reality that the crack width at the interface can be ignored in the calculation model, so that the resulting crack width applies to the concrete surface. Furthermore, the Poisson's ratio for concrete can be ignored ($\nu_c = 0$) because the concrete is

143 assumed to be exposed to heavy internal cracking as described in the previous section. Finally,
 144 the displacement field depicted in Fig. 3, which shows the deformed configuration of an arbitrary
 145 section in an RC tie subjected to loading at the rebar ends, can be assumed to apply for an
 146 arbitrary statically equivalent section.

147

148 The continuum concept (Irgens 2008) is hereafter used to formulate the compatibility, material
 149 laws and equilibrium for concrete and steel.

150

151 **3.2 Equations for concrete**

152 *3.2.1 General equations*

153 The SODE for the concrete displacements was derived by using the cylindrical coordinates and
 154 the displacement field depicted in Fig. 3. Concrete strains at the interface ε_{ci} and the specimen
 155 surface ε_{co} were assumed to be related as

156

$$\psi(x) = \frac{\varepsilon_{co}}{\varepsilon_{ci}} \leq 1 \quad (1)$$

157

158 in which

159

$$\varepsilon_{ci} = \frac{dw_{ci}(x)}{dx} \quad (2)$$

160 and

$$\varepsilon_{co} = \frac{dw_{co}(x)}{dx} \quad (3)$$

161

162 where dw_{ci} and dw_{co} are differential displacements at the interface and at the specimen surface
 163 respectively. Note that the inequality in Eq. (1) is because the concrete strains at the specimen
 164 surface cannot exceed the concrete strains at the interface as a consequence of force being
 165 applied at the steel bar ends. The maximum longitudinal displacement of the concrete cover
 166 relative to the concrete interface is

167

$$-\Delta w_{\text{cmax}}(x) = w_{\text{ci}}(x) - w_{\text{co}}(x) \quad (4)$$

168

169 Moreover, longitudinal concrete displacements can be formulated as

170

$$w_{\text{c}}(R, x) = w_{\text{ci}}(x) + \Delta w_{\text{cmax}}(x) \bar{\psi}(R, x) \quad (5)$$

171

172 in which $\bar{\psi}$ is a shape function describing the variation in longitudinal displacements over the

173 section and over the bar length. It was chosen to satisfy the following boundary conditions:

174

$$\begin{aligned} w_{\text{c}}(R_1, x) &= w_{\text{ci}}(x) \\ w_{\text{c}}(R_2, x) &= w_{\text{co}}(x) \end{aligned} \quad (6)$$

175

176 where R_1 and R_2 are the radial coordinates of respectively the interface and the specimen
 177 surface. It should be noted that Fig. 3 omits radial displacements for the concrete, while in the
 178 case of axisymmetry displacements in the hoop direction are non-existent. Omitting radial
 179 displacements contradicts the physical behavior of RC ties discussed previously, but using a
 180 bond-slip law $\tau(u)$, with τ denoting the bond stress, will take into account the 3D-effects that are
 181 excluded when radial displacements for the concrete are omitted. This means that Eq. (5)
 182 suffices in describing the displacement field for concrete. Now, using Green strains for small
 183 displacements yield the following non-zero components in the strain tensor for concrete:

184

$$\varepsilon_{\text{c}} = \frac{\partial w_{\text{c}}(R, x)}{\partial x} = \frac{dw_{\text{ci}}(x)}{dx} + \frac{\partial}{\partial x} [\Delta w_{\text{cmax}}(x) \bar{\psi}(R, x)] \quad (7)$$

185

$$\gamma_{\text{cRx}} = \gamma_{\text{cxR}} = \frac{\partial w_{\text{c}}(R, x)}{\partial R} = \Delta w_{\text{cmax}}(x) \frac{d\bar{\psi}(R, x)}{dR} \quad (8)$$

186

187 where ε_{c} and $\gamma_{\text{cRx}} = \gamma_{\text{cxR}}$ are longitudinal strains and engineering shear strains respectively.

188 Consequently, Eq. (7) and (8), and ignoring the Poisson's ratio for concrete, yield the following

189 non-zero components for the stress tensor:

190

$$\sigma_c = E_c \varepsilon_c \quad (9)$$

191

$$\tau_{cxR} = \tau_{cRx} = \frac{1}{2} E_c \gamma_{cxR} \quad (10)$$

192

193 where σ_c and $\tau_{cRx} = \tau_{cxR}$ are respectively the normal and the shear stresses, while E_c is the
 194 Young's modulus for concrete. Considering equilibrium for the concrete in Fig. 2(c) yields

195

$$\frac{dF_c(x)}{dx} = \tau(u) \sum \pi \phi_s \quad (11)$$

196

197 where τ is the bond stress dependent on the slip at the interface u , and $\sum \pi \phi_s$ is the total
 198 perimeter surrounding the steel bars in a cross section. The concrete force resultant can be
 199 formulated as

200

$$F_c(x) = \int_{A_c} \sigma_c dA_c \quad (12)$$

201

202 where A_c is the concrete area.

203

204 Finally, inserting Eq. (12), (9), (7), (4), (1), (2) and (3) in Eq. (11) successively yields

205

$$E_c \frac{\partial}{\partial x} \int_{A_c} \left\{ \frac{dw_{ci}(x)}{dx} - \frac{dw_{ci}(x)}{dx} [1 - \psi(x)] \bar{\psi}(R, x) - [w_{ci}(x) - w_{co}(x)] \frac{\partial \bar{\psi}(R, x)}{\partial x} \right\} dA_c = \tau(u) \sum \pi \phi_s \quad (13)$$

206

207 which is the SODE for the longitudinal concrete displacements at the interface.

208

209 3.2.2 Simplified equations

210 An analytical solution of Eq. (13) is possible in the case of axisymmetry if both ψ and $\bar{\psi}$ are
 211 known. In most practical situations, however, this is not the case. A practical approach to Eq.
 212 (13) would therefore be to redefine Eq. (1) as

213

$$\psi(x) = \psi = \frac{\varepsilon_{cm}}{\varepsilon_{ci}} \leq 1 \quad (14)$$

214

215 in which

216

$$\varepsilon_{cm} = \frac{dw_{cm}(x)}{dx} = \psi \varepsilon_{ci} \quad (15)$$

217

218 are mean concrete strains and w_{cm} are mean displacements over the section, see Fig. 3, which

219 in this particular case simplifies the shape function to

220

$$\bar{\psi} = 1 \quad (16)$$

221

222 Note that ψ in Eq. (14) is now assumed constant. Edwards and Picard (1972) were the first to
 223 introduce the concept of Eq. (14). This was later investigated more thoroughly by conducting
 224 nonlinear finite element analysis (NLFEA) on cylindrical RC ties in Tan et al. (2018b). It was
 225 concluded that although the shape function $\bar{\psi}$, first defined in Eq. (5) varied with respect to both
 226 R and x -coordinates over the bar length, the ratio in Eq. (14) remained more or less constant
 227 over the bar length except for a small region close to the loaded end. Actually, it was observed
 228 that a constant value of $\psi = 0.70$ over the entire bar length seemed reasonable independent of
 229 geometry and load level. The physical interpretation of Eq. (15) is that *plane sections that do not*
 230 *remain plane* are implicitly accounted for in determining the equilibrium. Now, replacing w_{co} with
 231 w_{cm} in Eq. (13) and inserting Eq. (14) and (16) simplifies the SODE for the longitudinal concrete
 232 displacements at the interface to

233

$$\psi A_c E_c \frac{d^2 w_{ci}(x)}{dx^2} = \tau(u) \sum \pi \phi_s \quad (17)$$

234

235 **3.3 Equations for steel**

236 Longitudinal displacements for steel were assumed uniform over its radius. And since the
 237 Poisson's ratio for concrete was ignored and axisymmetry applied for circular steel rebars
 238 means that Eq. (18)

239

$$w_s(R, x) = w_s(x) \quad (18)$$

240

241 suffices in describing the displacement field for steel. The following normal strain was thus the
 242 only non-zero component in the strain tensor when Green strains for small deformations were
 243 applied:

244

$$\varepsilon_s = \frac{dw_s(x)}{dx} \quad (19)$$

245

246 Moreover, the Poisson's ratio for steel was ignored ($\nu_s = 0$) as the lateral effects it had on bond
 247 were assumed to be included in the bond-slip curve. This led to the following normal stress
 248 being the only non-zero component in the stress tensor:

249

$$\sigma_s = E_s \varepsilon_s \quad (20)$$

250

251 where E_s is the Young's modulus for steel. The equilibrium of steel in Fig. 2(c) yields

252

$$\frac{dF_s(x)}{dx} = -\tau(u) \sum \pi \phi_s \quad (21)$$

253

254 Furthermore, the steel force resultant was obtained as

255

$$F_s(x) = \int_{A_s} \sigma_s dA_s = A_s E_s \frac{dw_s(x)}{dx} \quad (22)$$

256

257 when inserting Eq. (20) and (19) successively. Finally, inserting Eq. (22) in (21) yields

258

$$A_s E_s \frac{d^2 w_s(x)}{dx^2} = -\tau(u) \sum \pi \phi_s \quad (23)$$

259

260 which is the SODE for the steel displacements.

261

262 **3.4 Compatibility**

263 The slip was defined in terms of the displacement field depicted in Fig. 3 as

264

$$-u(x) = w_s(x) - w_{ci}(x) \quad (24)$$

265

266 Differentiating Eq. (24) once and inserting Eq. (2) and (19) provides the first derivative of the slip

267 as

268

$$-u'(x) = \frac{dw_s(x)}{dx} - \frac{dw_{ci}(x)}{dx} = \varepsilon_s - \varepsilon_{ci} \quad (25)$$

269

270 **3.5 The second order differential equation for the slip**

271 Inserting Eq. (23) in (17) provides

272

$$\frac{d}{dx} \left[\frac{dw_{ci}(x)}{dx} + \xi \frac{dw_s(x)}{dx} \right] = 0 \quad (26)$$

273

274 where

275

$$\xi = \frac{\alpha_e \rho_s}{\psi} \quad (27)$$

276

$$\alpha_e = \frac{E_s}{E_c} \quad (28)$$

277

278 and

279

$$\rho_s = \frac{A_s}{A_c} \quad (29)$$

280

281 Inserting Eq. (25) and (23) successively in Eq. (26) yields the SODE for the slip as

282

$$\frac{d^2 u(x)}{dx^2} - \chi \tau(u) = 0 \quad (30)$$

283

284 where

285

$$\chi = \frac{\sum \pi \phi_s}{A_s E_s} (1 + \xi) \quad (31)$$

286

287 By introducing

288

$$\zeta = \frac{\tau_m(u)}{\tau(u, \theta)} \leq 1 \quad (32)$$

289

290 where τ_m and $\tau(u, \theta)$ is respectively the mean and the maximum bond stress around the
 291 circumference of a steel bar in an arbitrary cross section, and further multiplying χ in Eq. (30) by
 292 ζ from Eq. (32) takes into account the bond stress τ not being constant around the
 293 circumference of the steel bar in non-axisymmetric cases, e.g. when the cover to the steel
 294 surface varies in a cross section as depicted in Fig. 2(d). In practice, this implies taking the
 295 distance between rebars into account, a parameter acknowledged by the research of Gergely
 296 and Lutz (1968) to be significant for the crack width. This means that the solution of Eq. (30)
 297 with χ multiplied by ζ from Eq. (32) involves transforming a cross section with an arbitrary
 298 geometry into a circular cross section with a radius r_{eq} such that the area A_c remains the same.

299

300 The analytical solution of Eq. (30) depends on the choice of the bond-slip law and a variety of
 301 choices can be found in the literature (Rehm 1961, Nilson 1972, Martin 1973, Dörr 1978, Mirza

and Houde 1979, Hong and Park 2012). In this study, the local bond-slip law recommended by MC2010 was used:

$$\tau(u) = \tau_{\max} \left(\frac{u}{u_1} \right)^\alpha \quad (33)$$

Eq. (33) and its parameters were originally derived on the basis of pull-out tests of relatively short specimens, in which the concrete was in compression, thus differing considerably from the stress conditions in RC ties where the concrete is in tension (Pedziwiatr 2008). However, the investigation by Tan et al. (2018c) showed that Eq. (33) could be applied to represent the mean bond transfer over the specimen length by using the predefined parameters $\tau_{\max} = 5.0$ MPa, $u_1 = 0.1$ and $\alpha = 0.35$ when comparing it to the local bond-slip curves obtained from the FE analysis of several RC ties, see Fig. 4. Bond-slip curves proposed by other authors are also shown in the same figure. This means that inserting Eq. (33) in Eq. (30) finally yields the SODE

$$\frac{d^2u}{dx^2} - \chi \frac{\tau_{\max}}{u_1^\alpha} u^\alpha = 0 \quad (34)$$

Note that Eq. (34) has been derived and will be solved using the simplified equations for concrete.

4. The analytical crack width calculation model

4.1 General solutions

4.1.1 The slip

Eq. (34) is a non-linear homogenous SODE and can be solved analytically, by successively defining the second term as a function of the slip $f(u)$, moving it to the other side of the equal sign, multiplying both sides with the first derivative of the slip u' , applying the chain rule on the left-hand side of the equal sign and the substitution rule on the right-hand side, and subsequently integrating once, the first derivative of the slip is provided as

$$u' = \frac{du}{dx} = -\sqrt{2(\gamma u^\beta + C)} \quad (35)$$

328

329 where C is an integration constant and

330

$$\beta = 1 + \alpha \quad (36)$$

331 and

$$\gamma = \chi \frac{\tau_{\max}}{\beta u_1^\alpha} \quad (37)$$

332

333 Only the negative sign is included in Eq. (35) for compatibility with Eq. (25). Separating the

334 variables in Eq. (35) and integrating on both sides yields

335

$$x = B - \frac{1}{\sqrt{2}} \int (\gamma u^\beta + C)^{-\frac{1}{2}} du \quad (38)$$

336

337 where B is an integration constant. The integral can now be solved using the method proposed

338 by Russo et al. (1990) and Russo and Romano (1992), where the binomial in Eq. (38) is

339 developed as an infinite series of functions in accordance with Newton's binomial theorem, and

340 then integrating each term. This results in two different general solutions that converge at

341 distinct intervals

342

$$x = B_1 - \frac{1}{\sqrt{2}} \sum_{k=0}^{\infty} \left(-\frac{1}{2} \right) \binom{\frac{1}{2}}{k} \gamma^k \left(\frac{1}{C} \right)^{\left(\frac{1}{2} + k \right)} \frac{u^{1+k\beta}}{1+k\beta} \quad \text{for } 0 < u < u_d \quad (39)$$

343

344 and

345

$$x = B_2 - \frac{1}{\sqrt{2}\gamma} \sum_{k=0}^{\infty} \left(-\frac{1}{2} \right) \binom{\frac{1}{2}}{k} \left(\frac{C}{\gamma} \right)^k \frac{u^{\delta-k\beta}}{\delta-k\beta} \quad \text{for } u > u_d \quad (40)$$

346

347 where B_1 and B_2 are integration constants, and

348

$$\delta = \frac{1 - \alpha}{2} \quad (41)$$

349

350 while

351

$$u_d = \left| \frac{C}{\gamma} \right|^{\frac{1}{\beta}} \quad (42)$$

352

353 is the value discerning Eq. (39) from (40). Note that the general solutions in Eq. (39) and (40)

354 imply that the longitudinal coordinate x is a function of the slip value u as a consequence of

355 splitting the variables in Eq. (35).

356

357 4.1.2 Strains

358 Successively inserting Eq. (2) and (19) in Eq. (26), integrating once, and applying $\varepsilon_{ci} = 0$ and

359 $\varepsilon_s = F/E_s A_s = \varepsilon_{s0}$ at the loaded end, i.e. at $x = 0$, yields

360

$$\varepsilon_{ci} = \xi (\varepsilon_{s0} - \varepsilon_s) \quad (43)$$

361

362 Inserting Eq. (35) and (43) in Eq. (25) yields the steel strains

363

$$\varepsilon_s = \frac{\xi \varepsilon_{s0} + \sqrt{2(\gamma u^\beta + C)}}{1 + \xi} \quad (44)$$

364

365 while, inserting Eq. (44) in (43) provides the concrete strains

366

$$\varepsilon_{ci} = \xi \frac{\varepsilon_{s0} - \sqrt{2(\gamma u^\beta + C)}}{1 + \xi} \quad (45)$$

367

368 4.2 Boundary conditions

Boundary conditions must be established before calculating particular solutions. These are established by considering the concepts of *comparatively lightly loaded members* (CLLM) and *comparatively heavily loaded members* (CHLM) depicted in Fig. 5. Russo and Romano (1992) were the first to introduce these concepts, which were later acknowledged by *fib* bulletin 10 (2000). Briefly summarized, the main difference is that steel and concrete strains become compatible, $\varepsilon_s = \varepsilon_{ci}$, at a certain distance x_r from the loaded end in the case of CLLM, while the strains remain incompatible, $\varepsilon_s \neq \varepsilon_{ci}$, over the entire bar length in the case of CHLM. This further implies, in accordance with Eq. (24), that the slip becomes zero at distance x_r from the loaded end in the case of CLLM and at the symmetry section x_s in the case of CHLM. This yields the following boundary conditions in the case of CLLM behavior:

$$\begin{aligned} -u_r &= 0 \\ -u'_r &= \varepsilon_s - \varepsilon_{ci} = 0 \end{aligned} \tag{46}$$

at $x = x_r$, and in the case of CHLM behavior:

$$\begin{aligned} -u_s &= 0 \\ -u'_s &= \varepsilon_s - \varepsilon_{ci} > 0 \end{aligned} \tag{47}$$

at $x = x_s = \frac{L}{2}$.

4.3 Comparatively lightly loaded members (CLLM)

Applying the boundary conditions in Eq. (46) for Eq. (35) yields

$$C = 0 \tag{48}$$

Inserting Eq. (48) in (38), integrating once and applying the boundary conditions in Eq. (46) again yields the expression for the slip in the case of CLLM behavior

$$u = [\delta\sqrt{2\gamma}(x_r - x)]^{\frac{1}{\delta}} \quad (49)$$

393

394 Inserting Eq. (48) in (44) and acknowledging that $\varepsilon_s = \varepsilon_{s0}$ at $x = 0$, provides the maximum slip at
 395 the loaded end as

396

$$u_0 = \left(\frac{\varepsilon_{s0}^2}{2\gamma} \right)^{\frac{1}{\beta}} \quad (50)$$

397

398 Furthermore, inserting Eq. (50) in (49) for $x = 0$ yields the transfer length as

399

$$x_r = \frac{1}{\delta} \left[\varepsilon_{s0} \left(\frac{1}{2\gamma} \right)^{\frac{1}{2\delta}} \right]^{\frac{2\delta}{\beta}} \quad (51)$$

400

401 Note that the transfer length increases with increasing steel strains $\varepsilon_{s0} = F/E_s A_s$ at the loaded
 402 end. Expressions for the steel and concrete strains can be finally obtained by inserting Eq. (49)
 403 in respectively Eq. (44) and (45)

404

$$\varepsilon_s = \frac{\xi \varepsilon_{s0} + (2\gamma)^{\frac{1}{2\delta}} [\delta(x_r - x)]^{\frac{\beta}{2\delta}}}{1 + \xi} \quad (52)$$

405

$$\varepsilon_{ci} = \xi \frac{\varepsilon_{s0} - (2\gamma)^{\frac{1}{2\delta}} [\delta(x_r - x)]^{\frac{\beta}{2\delta}}}{1 + \xi} \quad (53)$$

406

407 One application of the particular solutions obtained could be in the case of two consecutive
 408 cracks formed with a considerable distance between them. This means that a certain region,
 409 $2(x_s - x_r)$, remains undisturbed as depicted in Fig. 5(a) and (b). This situation occurs typically in
 410 the so-called *crack formation stage*, in which the applied member load is relatively low and the
 411 distance between two consecutive cracks formed is relatively large.

412

413 **4.4 Comparatively heavily loaded members (CHLM)**

414 **4.4.1 Particular solutions**

415 Applying the boundary conditions in Eq. (47) in (35) yields

416

$$u'_s = -\sqrt{2C} \quad (54)$$

417

418 Acknowledging from Eq. (35) and Fig. 5 that u' is a real function yields

419

$$C > 0 \quad (55)$$

420

421 This means that the general solutions of Eq. (39) and (40) apply in the case of CHLM because

422 $C \neq 0$. Now, inserting Eq. (35) in (25) and applying $\varepsilon_{ci} = 0$ and $\varepsilon_s = F/E_s A_s = \varepsilon_{s0}$ at the loaded

423 end, i.e. at $x = 0$, yields

424

$$C = \frac{\varepsilon_{s0}^2}{2} - \gamma u_0^\beta \quad (56)$$

425

426 Furthermore, Eq. (55) and (56) imply that the maximum slip at the loaded end must satisfy

427

$$u_{0,\max} = \left(\frac{\varepsilon_{s0}^2}{2\gamma} \right)^{\frac{1}{\beta}} \quad (57)$$

428

429 Inserting Eq. (56) in (42) and acknowledging that Eq. (37) is a positive value provides

430

$$u_d = \left(\frac{\varepsilon_{s0}^2}{2\gamma} - u_0^\beta \right)^{\frac{1}{\beta}} \quad (58)$$

431

432 Now, applying the first condition in Eq. (47) to (39) yields

433

$$B_1 = \frac{L}{2} \quad (59)$$

434

435 Moreover, applying $u = u_0$ at $x = 0$ for Eq. (40) yields that B_2 can be expressed with binomial
 436 coefficients as

437

$$B_2 = \frac{1}{\sqrt{2\gamma}} \sum_{k=0}^{\infty} \left(-\frac{1}{2} \right)^k \left(\frac{C}{\gamma} \right)^k \frac{u_0^{\delta-k\beta}}{\delta - k\beta} \quad (60)$$

438

439 The particular solutions of Eq. (39) and (40) are now obtained using the integration constants in
 440 Eq. (56), (59) and (60). It should be noted, however, that the integration constants in Eq. (56)
 441 and (60) depend on the slip at the loaded end u_0 , so they must be obtained iteratively. This can
 442 be done conveniently by considering the two cases shown in Fig. 6.

443

444 4.4.2 Case 1

445 The first case involves solving Eq. (39) with respect to the slip at the loaded end in its interval
 446 when $u_0 < u_d$ in accordance with Fig. 6(a). Inserting Eq. (59) in (39) and applying $u = u_0$ at $x =$
 447 0 provides the function

448

$$f_1(u_0) = \frac{L}{2} - \frac{1}{\sqrt{2}} \sum_{k=0}^{\infty} \left(-\frac{1}{2} \right)^k \gamma^k \left(\frac{1}{C} \right)^{\left(\frac{1}{2} + k \right)} \frac{u_0^{1+\beta k}}{1 + \beta k} = 0 \quad (61)$$

449

450 which is valid for the interval

451

$$0 \leq u_0 < \left(\frac{\varepsilon_{s0}^2}{4\gamma} \right)^{\frac{1}{\beta}} \quad (62)$$

452

453 when acknowledging that u_d in Eq. (39) is given by Eq. (58).

454

455 4.4.3 Case 2

456 Case 2 is where $u_0 > u_d$, which means that the solution for the slip u depends on both Eq. (39)
 457 and (40) due to the validity of the equations at its respective intervals, see Fig. 6(b). In other
 458 words, Eq. (39) is valid for slip values below u_d while Eq. (40) is valid for slip values above u_d .
 459 Now, accepting that Eq. (39) is valid for the slip value $u = u_d - du$ at the location $x_d + dx_1$
 460 provides
 461

$$x_d + dx_1 = \frac{L}{2} - \frac{1}{\sqrt{2}} \sum_{k=0}^{\infty} \left(-\frac{1}{2} \right)^k \gamma^k \left(\frac{1}{C} \right)^{\left(\frac{1}{2} + k \right)} \frac{(u_d - du)^{1+\beta k}}{1 + \beta k} \quad (63)$$

462
 463 Similarly, accepting that Eq. (40) is valid for the slip value $u = u_d + du$ at the location $x_d - dx_2$
 464 and inserting Eq. (60) provides
 465

$$x_d - dx_2 = \frac{1}{\sqrt{2}\gamma} \sum_{k=0}^{\infty} \left(-\frac{1}{2} \right)^k \left(\frac{C}{\gamma} \right)^k \frac{u_0^{\delta-k\beta}}{\delta - k\beta} - \frac{1}{\sqrt{2}\gamma} \sum_{k=0}^{\infty} \left(-\frac{1}{2} \right)^k \left(\frac{C}{\gamma} \right)^k \frac{(u_d + du)^{\delta-k\beta}}{\delta - k\beta} \quad (64)$$

466
 467 Note that du is an infinitesimal value for the slip, while dx_1 and dx_2 are infinitesimal values
 468 along the bar length in accordance with Fig. 6(b). Subtracting Eq. (64) from (63) provides the
 469 function
 470

$$f_2(u_0) = \frac{L}{2} - \frac{1}{\sqrt{2}\gamma} \{f_{21}(u_0) - f_{22}(u_0)\} - \frac{1}{\sqrt{2}} f_{23}(u_0) - \Delta x = 0 \quad (65)$$

471
 472 where
 473

$$f_{21}(u_0) = \sum_{k=0}^{\infty} \left(-\frac{1}{2} \right)^k \left(\frac{C}{\gamma} \right)^k \frac{u_0^{\delta-k\beta}}{\delta - k\beta} \quad (66)$$

474

$$f_{22}(u_0) = \sum_{k=0}^{\infty} \left(-\frac{1}{2} \right)^k \frac{\left[\left(\frac{C}{\gamma} \right)^{\frac{k}{\delta-k\beta} + \frac{1}{\beta}} + du \left(\frac{C}{\gamma} \right)^{\frac{k}{\delta-k\beta}} \right]^{\delta-k\beta}}{\delta - k\beta} \quad (67)$$

475

$$f_{23}(u_0) = \sum_{k=0}^{\infty} \left(-\frac{1}{2} \right)^k \frac{\gamma^k \left[C^{\frac{2-\beta}{2\beta(1+k\beta)}} \left(\frac{1}{\gamma} \right)^{\frac{1}{\beta}} - du C^{\frac{\frac{1}{2}+k}{1+k\beta}} \right]^{1+k\beta}}{1 + k\beta} \quad (68)$$

476

477 and $\Delta x = dx_1 + dx_2$. Eq. (65) is valid for

478

$$u_0 > \left(\frac{\varepsilon_{s0}^2}{4\gamma} \right)^{\frac{1}{\beta}} \quad (69)$$

479

480 when acknowledging that u_d in Eq. (40) is given by Eq. (58).

481

482 4.4.4 Solution strategy

483 Russo and Romano (1992) give a convenient way of determining whether Case 1 or Case 2

484 governs by calculating Eq. (61) for a value of u_0 close to the upper limit value in Eq. (62), e.g. as

485 $u_{0\text{check}} = \left(\frac{\varepsilon_{s0}^2}{4\gamma} - du \right)^{\frac{1}{\beta}}$. Case 1 governs if the value calculated is negative. Case 2 governs if the

486 value calculated is positive since the nature of Eq. (61) invokes that u_0 must increase to satisfy

487 Eq. (61), which implies that Eq. (69) governs.

488

489 Newton-Raphson iterations are used to calculate the value of u_0 effectively after determining

490 whether Case 1 or 2 governs

491

$$u_{0,i+1} = u_{0,i} - \frac{f_j(u_{0,i})}{f_j'(u_{0,i})} \quad (70)$$

492

where index i represents the number of iterations and index j represents the function in Eq. (61) for Case 1 or Eq. (65) for Case 2. Furthermore, it is suggested that an initial value of $u_{0,\text{init}} = \left(\frac{\varepsilon_{s0}^2}{4\gamma}\right)^{\frac{1}{\beta}} - du$ is used for Case 1 or $u_{0,\text{init}} = \left(\frac{\varepsilon_{s0}^2}{4\gamma}\right)^{\frac{1}{\beta}} + du$ is used for Case 2 to start the iterations in Eq. (70). The iterated value $u_{0,i+1}$, however, should never exceed Eq. (57) due to the requirement of Eq. (55). Convergence is achieved when $|u_{0,i+1} - u_{0,i}| < Tol$, at which Tol is a chosen tolerance value. Note that the derivatives of the functions in Eq. (61) and (65) are needed to solve Eq. (70) and are provided in Appendix A. Once the value of u_0 is obtained, the particular solutions of Eq. (39) and (40) are used to obtain the corresponding x values for the slip u along the bar length. In summary, CHLM involves determining whether Case 1 or 2 governs using Eq. (61) before the slip at the loaded end u_0 is calculated using Eq. (70).

503

504 4.4.5 Strains

The strain distributions for steel and concrete were obtained by using Eq. (44) and (45) respectively. Moreover, inserting Eq. (45) in (15), and acknowledging that the maximum concrete strains will occur at the symmetry section, i.e. where the slip $u = 0$, provides the maximum mean concrete strains as

509

$$\varepsilon_{\text{cm,max}} = \psi \xi \frac{\varepsilon_{s0} - \sqrt{2C}}{1 + \xi} < \varepsilon_{\text{ct}} \quad (71)$$

510

The violation of Eq. (71) implies that a crack has formed at the symmetry section, meaning a new member with length $L/2$ exists and that the CHLM response should be determined for the newly formed member.

514

515 4.5 Conditions at crack formation

The conditions at crack formation are shown in Fig. 7, where the transfer length increases with increasing load as highlighted for Eq. (51). The steel strain at the loaded end needed to extend the transfer length to the symmetry section is obtained by inserting $x_r = L/2$ in Eq. (51) so that

519

$$\varepsilon_{s0,S} = (2\gamma)^{\frac{1}{2\delta}} \left(\frac{L}{2} \delta \right)^{\frac{\beta}{2\delta}} \quad (72)$$

520

521 Furthermore, the maximum mean concrete strain at the end of the transfer length x_r is obtained
 522 by inserting Eq. (53) in (15) at $x = x_r$ so that

523

$$\varepsilon_{cm,max} = \frac{\psi \xi}{1 + \xi} \varepsilon_{s0} \quad (73)$$

524

525 It is assumed that a crack forms when $\varepsilon_{cm,max} = \varepsilon_{ct}$, which means that the corresponding steel
 526 strain at the loaded end is

527

$$\varepsilon_{s0,cr} = \varepsilon_{ct} \frac{1 + \xi}{\psi \xi} \quad (74)$$

528

529 So inserting Eq. (74) in (51) yields the distance from the loaded end at which a new crack can
 530 form or, expressed more rigorously, the *crack spacing*

531

$$x_{cr} = \frac{1}{\delta} \left[\varepsilon_{ct} \frac{1 + \xi}{\psi \xi} \left(\frac{1}{2\gamma} \right)^{\frac{1}{2\delta}} \right]^{\frac{2\delta}{\beta}} \quad (75)$$

532

533 Eq. (72) to (75) are conceptually visualized in Fig. 7, providing two different conditions for the
 534 cracking response of a member. The continuous lines represent the steel strains, while the
 535 dashed lines represent the corresponding concrete strains. Note that the concrete strain for $\varepsilon_{s0,S}$
 536 in Fig. 7(a) is unrealistic since the concrete tensile strength is exceeded. It is only included to
 537 elucidate the physical concept of Eq. (72). Condition 1 implies that a crack forms at a distance
 538 from the loaded end shorter than half the member length, i.e. $x_{cr} < x_s$, meaning that $\varepsilon_{s0,cr} <$
 539 $\varepsilon_{s0,S}$. This further implies that the cracking response of the member is governed by CLLM
 540 behavior as long $\varepsilon_{s0} < \varepsilon_{s0,cr}$, while CHLM behavior governs the cracking response as soon as
 541 $\varepsilon_{s0} > \varepsilon_{s0,cr}$. Condition 2 implies that a crack can form only at the symmetry section, $x_{cr} = x_s$,

542 because $\varepsilon_{s0,cr} > \varepsilon_{s0,S}$. This means that a CLLM behavior governs the cracking response of the
 543 member as long $\varepsilon_{s0} < \varepsilon_{s0,S}$, while CHLM behaviour governs the cracking response as soon
 544 $\varepsilon_{s0} > \varepsilon_{s0,S}$. The physical interpretation of Condition 1 is that cracking can form at any location
 545 beyond x_r due to the unrestricted length of the member, while Condition 2 means that cracking
 546 can form only at the symmetry section due to the limited length of the member. Appendix B
 547 provides guidelines for determining which condition applies and whether CLLM or CHLM
 548 behavior governs the cracking response based on the a priori loading and the mechanical
 549 properties of the RC tie. For design purposes, however, only Condition 1 is relevant for
 550 determining the cracking response.

551

552 **4.6 The crack width**

553 Finally, the crack width is obtained as

554

$$w_{cr} = 2 \int_{x_r} (\varepsilon_s - \varepsilon_{cm}) dx \quad (76)$$

555

556 Inserting Eq. (15), (44) and (45) in Eq. (76) yields

557

$$w_{cr} = 2 \left(\frac{1}{1 + \xi} \right) [\xi \varepsilon_{s0} x_r (1 - \psi) + u_0 (1 + \psi \xi)] \quad (77)$$

558

559 In summary, the crack width is a function of the applied load $\varepsilon_{s0} = F/A_s E_s$, the transfer length x_r ,
 560 and the slip at the loaded end u_0 . For design purposes, i.e. Condition 1, the crack width is
 561 determined by calculating u_0 and x_r , which in the case of CLLM behavior is obtained by the
 562 closed-form solutions in Eq. (50) and (51). A solution strategy is provided in subsection 4.4.4 to
 563 calculate u_0 efficiently in the case of CHLM behavior, but here x_r is replaced with $\frac{x_{cr}}{2}$, where x_{cr}
 564 is the crack spacing obtained using the closed-form solution in Eq. (75). Note that the crack
 565 width obtained w_{cr} applies to the face at the loaded rebar end, i.e. as depicted in Fig. 1. This
 566 means that the calculation model conservatively assumes that a crack has been formed before
 567 loading, which allows for predicting crack widths regardless of the load level.

568

569 **4.7 Comparison with equivalent calculation models**

570 The calculation model described was evaluated against the equivalent models proposed by
571 Russo and Romano (1992), Balász (1993) and Debernardi and Taliano (2016). The models are
572 equivalent in the sense that the SODE for the slip, i.e. Eq. (34), is solved. However, some
573 significant differences should be highlighted. The models of Balász (1993) and Debernardi and
574 Taliano (2016) neglect the elastic shear deformation over the cover, i.e. they assume $\psi = 1$ in
575 Eq. (14). Another significant difference in Debernardi and Taliano (2016) is that the bond stress
576 distribution over the bar length is altered locally by using a linear descending branch close to the
577 primary crack, which complicates the solution of Eq. (34). These authors assume that internal
578 inclined cracks form in this region and continue to form towards the symmetry section as the
579 load increases. The FE analysis by Lutz (1970) and by Tan et al. (2018c) on RC ties show that
580 a build-up of bond stresses occurs close to a primary crack and that the peak of the bond stress
581 distribution tends to move towards the symmetry section as the load increases, as assumed by
582 Debernardi and Taliano (2016). However, this physical phenomenon is a consequence not of
583 internal inclined cracks, but of internal splitting cracks forming close to the primary crack, which
584 is reflected by the characteristic bond-slip curves at $x \approx 0$ in Fig. 4. In fact, the FE analysis
585 showed that internal inclined cracks also formed beyond the bond stress distribution peak,
586 which means they cannot occur in direct conjunction with the descending branch alone. This
587 also means that a single bond-slip curve should suffice to represent the mean local bond-slip
588 behavior over the bar length, as shown in Fig. 4 and discussed in Section 2, and should already
589 include the total effect of both internal splitting and internal inclined cracks have on reducing the
590 bond transfer.

591

592 The calculation model presented in this paper was particularly inspired by the work of Russo
593 and Romano (1992). However, there are some significant differences: (i) a primary crack is
594 assumed to form when, $\varepsilon_{cm} = \varepsilon_{ct}$, implying that concrete stresses are unevenly distributed even
595 at the zero-slip section in accordance with the observations in Fantilli et al. (2008) and Tan et al.
596 (2018b); (ii) the influence of the distance between steel bars can be accounted for by Eq. (32);
597 and (iii) a completely analytical solution strategy is provided to solve Eq. (34) for practical

598 applications. In addition, the derivations using continuum mechanics formulation yield a
599 mechanically sound model that describes how the 3D behavior of RC ties can be simplified into
600 a 1D model when using a proper bond-slip law. However, the main advantage of the model
601 presented in this paper, and that of Russo and Romano (1992), is that Eq. (34) is solved
602 completely analytically, in contrast to Balász (1993) and Debernardi and Taliano (2016), who
603 only provide analytical solutions in the case of CLLM behavior.

604

605 Using the bond-slip curve recommended by Tan et al. (2018c) implies that the bond stresses
606 should be related to the deformations in the outer surface of the concrete rather than at the
607 steel-concrete interface, which contradicts the compatibility in Eq. (24). However, the elastic
608 shear deformation over the cover is normally considered to be negligible, although it does seem
609 to affect the elastic stress and strain distribution (Braam 1990, Tan et al. 2018b). This justifies
610 the combined use of the chosen bond-slip curve, the compatibility in Eq. (24), and the concept
611 of ψ in Eq. (14).

612

613 **5. Application**

614 **5.1 Comparison with axisymmetric RC ties**

615 *5.1.1 General*

616 This section compares strains and crack widths obtained analytically with the classical
617 experiments of Bresler and Bertero (1968) and Yannopoulos (1989), and the FE analysis of Tan
618 et al. (2018c) on cylindrical RC ties concentrically reinforced with a steel bar loaded at the steel
619 bar ends. The bond-slip parameters, $\tau_{\max} = 5.0$ MPa, $u_1 = 0.1$ mm and $\alpha = 0.35$ were chosen,
620 while $\psi = 0.70$ was adopted in accordance with Tan et al. (2018b). The factor $\zeta = 1$ was chosen
621 due to axisymmetry. The infinite series used for calculating the response in the case of CHLM
622 behavior was truncated after 10 terms, while the parameters $\Delta x = 0.1$ and $du = 5.8 \cdot 10^{-5}$ were
623 chosen in accordance with Russo and Romano (1992).

624

625 *5.1.2 Comparison with experimental data*

626 Bresler and Bertero (1968) measured the strain distribution over the bar length by mounting
627 several strain gauges in a groove cut along the center of several reinforcing steel bars. The

reinforcing steel bars were first cut longitudinally into two halves, after which the groove was milled along the center of the two parts. After mounting the strain gauges in this groove, the two halves were tack-welded together to minimize the impact on the exterior of the reinforcing bars. The specimen investigated, denoted "Specimen H", was 406.4 mm (16 in) long and 152.4 mm (6 in) in diameter concentrically reinforced with a 28.7 mm (1.13 in) deformed steel bar. The length of the specimen was chosen as twice the mean crack spacing of 203.2 mm (8 in) obtained from pilot studies conducted on 1829 mm (72 in) long RC ties with similar sectional properties. A notch was cut around the circumference at mid-length to induce cracking here. The compressive strength, tensile strength, and Young's modulus for the concrete were reported as respectively 40.8 MPa (5.92 ksi), 4.48 MPa (0.65 ksi), and 33165 MPa (4810 ksi), while the yield strength and Young's modulus for the steel were reported as 413 MPa (60 ksi) and 205464 MPa (29800 ksi) respectively. The reduction of the steel area due to the groove was taken into account in the analytical calculations by using the reported steel area $A_s = 548 \text{ mm}^2$ (0.85 in²), while the notch was taken into account by reducing the reported tensile strength by a factor of 0.7. This led to cracking at mid-length in the analytical calculations for higher load levels as shown in Fig. 8(a). It should be noted that the analytical steel strains represent the mean of the experimental steel strains.

645

The six specimens investigated by Yannopoulos (1989) were 76 mm in diameter concentrically reinforced with a 16 mm deformed steel bar and were 100 mm long. The length of the specimens was based on the mean crack spacing of 90 mm obtained from pilot studies conducted on 800 mm long RC ties with similar sectional properties and was chosen to prevent new cracks from forming between the loaded ends. The compressive strength, tensile strength, and Young's modulus for concrete were reported respectively as 43.4 MPa, 3.30 MPa and 32000 MPa, while the yield strength and Young's modulus for steel were reported as 424 MPa and 200000 MPa respectively. The specimen length in the analytical calculations was chosen to be similar to that in the experiments. Fig. 8(b) shows the average crack width development at the loaded ends reported for the six specimens investigated. The analytical calculations predicted slightly larger crack widths. Nevertheless, the comparison shows good agreement.

657

5.1.3 Comparison with FE analysis

Tan et al. (2018c) conducted NLFEA on four cylindrical RC ties denoted $\phi 20c40$, $\phi 32c40$, $\phi 20c90$, and $\phi 32c90$ using axisymmetric elements, with ϕ and c respectively indicating steel bar diameter and cover. The concrete was given material properties corresponding to a concrete grade C35 in accordance with MC2010 and a non-linear fracture mechanics material model based on total strain formulation with rotating cracks. The crack bandwidth was chosen to be dependent on the total area of the finite elements in line with the smeared crack approach. The steel was chosen to have linear elastic material properties with a Young's modulus of 200000 MPa and a Poisson's ratio of 0.3. Furthermore, interface elements were used to allow for radial separation but no physical slip, as depicted in Fig. 1(b). In summary, the approach implied smearing out internal inclined and splitting cracks that would have localized at the tip of each bar rib if they were modelled discretely. This was found to give good agreement in comparison with the steel strains, development of crack widths, and mean crack spacing observed in the experiments.

Fig. 9 shows the comparison of steel strain distributions over the bar lengths at three different stress levels for the specimens, again noting that the analytical model predicts the mean of the experimental steel strains. The first stress level shows the CLLM behavior just before a crack forms at a certain distance from the loaded end, while the two higher stress levels show the CHLM behavior for specimen lengths similar to the crack spacing obtained in the FE analysis, see Table 1. Note that the strain distribution is shown for only half the specimen length due to symmetry. In general, the analytical calculations make conservative predictions of the CLLM behavior, which also is reflected in the comparison of the predicted crack spacing in Table 1. The table also shows that the analytical model predicts crack spacing consistently and on the conservative side regardless of the bar diameter and cover size. The conservative prediction of the crack spacing can be attributed to the bond-slip parameters chosen. Fig. 10 shows the development of crack widths in specimens with lengths similar to the FE analysis crack spacing in Table 1 and indicates that the analytical model makes quite accurate predictions of crack widths for a given specimen length.

Fig. 11 shows comparisons of the development of crack widths based on specimen lengths similar to the crack spacing predicted by the analytical model in Table 1. The analytical model yields Condition 2 and CHLM behavior in general, which allows for cracking at mid-length at higher load levels and occurs for all of the specimens except $\phi 20c90$. The graphs also show that the analytical model predicts crack widths on the conservative side in general.

5.2 Comparison with non-axisymmetric RC ties

The French research project CEOS.fr (2016) conducted experiments on two identical quadratic RC ties identified as Ties 4 and 5 which were pulled in tension. The ties were 355 mm in width and height, had a length of 3200 mm, and were reinforced with eight 16 mm rebars. A concrete grade C40/50 was used, while the yield strength and Young's modulus of steel were reported as 529 MPa and 200000 MPa respectively. The cover to the rebars was 45 mm. Fig. 12(a) shows a comparison of the development of predicted crack widths with the maximum crack widths measured. The analytical calculations were based on using specimen lengths similar to the crack spacing predicted analytically in Table 2. The factor $\zeta = 1$ was chosen for simplicity. The deviation between Tie 4 and Tie 5 in the maximum crack widths measured seems to be due to the difference in maximum crack spacing reported in Table 2. Nevertheless, the maximum crack spacing predictions were conservative, and the crack widths predicted show relatively good agreement with the maximum crack widths measured.

Tan et al. (2018a) conducted experiments on eight quadratic RC ties identified as $X-\phi-c$, where X represents the loading regime the RC tie was exposed to, either at the crack formation stage (F) or the stabilized cracking stage (S), while ϕ and c represent the rebar diameter and cover respectively. The rebar diameter was either 20 mm or 32 mm, while the cover was either 40 mm or 90 mm. The ties were 400 mm in width and height, had a length of 3000 mm, and were reinforced with eight rebars. The concrete compressive and tensile strength were reported as 74.3 MPa and 4.14 MPa respectively, while the Young's modulus was reported as 27.4 GPa. The yield strength and Young's modulus of the steel were reported as 500 MPa and 200000 MPa respectively. Fig. 12(b) shows the comparison of maximum crack widths measured $w_{0.95}$ and crack widths predicted w_{cr} using the concept of modelling uncertainty, i.e. as $\theta = w_{0.95}/w_{cr}$.

718 The crack widths calculated were based on using specimen lengths similar to the crack spacing
719 predicted analytically in Table 2. The factor $\zeta = 1$ was again chosen for simplicity. Both the
720 crack widths and the crack spacing predicted are on the conservative side except for F-32-90
721 and S-32-90, in which the maximum crack widths predicted were slightly underestimated.

722

723 **6. Discussion**

724 The conservative predictions of the crack widths in Fig. 11 are due to the nature of Eq. (75),
725 which, together with the predefined bond-slip parameters, provides an upper limit for the crack
726 spacing or, expressed more rigorously, for the maximum crack spacing. This is equivalent to the
727 concept of calculating the maximum crack widths according to the semi-empirical formulas in
728 EC2 and MC2010. However, unlike EC2 and MC2010, Eq. (75) is not assumed to vary from
729 once to twice this value. Furthermore, Figs. 8b) and 10 show the ability of the model to predict
730 accurate crack widths given a specimen length. The observations in Figs. 8a) and 9 suggest
731 that the analytical model can predict the mean behavior of experimental steel strains, which is a
732 direct result of using just one local bond-slip curve to represent the bond transfer over the
733 specimen length. This means that the effect internal inclined and splitting cracks has on
734 reducing the bond transfer locally is smeared over the specimen length in the analytical model.
735 The consequence of using only one local bond-slip curve is that the bond stresses reach their
736 maximum at the cracked section ($x = 0$), which contradicts the physical behavior of RC ties
737 discussed previously. This is due to the fact that the selected bond-slip curve causes bond
738 stresses to increase with increasing slip as can be observed in Fig. 4. This is elucidated in Fig.
739 13, which shows the corresponding bond stresses to the steel strains predicted in Fig. 9. One
740 solution to this problem would be to use different bond-slip curves depending on the location
741 over the specimen length, but this would substantially complicate the solutions to the analytical
742 model. So, the use of just one local bond-slip curve provides a practical yet mechanically sound
743 calculation model that has proven capable of predicting the development of crack widths and
744 crack spacing consistently and on the conservative side, regardless of the mechanical
745 properties and loading of the RC ties. Another advantage of using a bond-slip curve, as
746 opposed to assuming a constant bond stress distribution e.g. in EC2 and MC2010, is that the
747 mean bond stresses become dependent on the load level and the geometry of RC tie, thus

748 conforming to the theoretical observations made by Tan et al. (2018c). This should provide
749 more realistic predictions of the crack spacing.
750

751 Fig. 14 shows the corresponding concrete strains at the interface, ε_{ci} , to the steel strains
752 predicted in Fig. 9 at load levels 250 MPa and 400 MPa, whereas the dashed lines represent
753 the resultant of concrete strains in a section according to Eq. (15), i.e. as $\varepsilon_{cm} = \psi \varepsilon_{ci}$. It is
754 observed that both the concrete stresses at the interface and the resultants of concrete stresses
755 increase with increasing load level. This is due to the increase of the bond transfer between the
756 load levels of 250 MPa and 400 MPa as represented by the increase of the areas under the
757 curves shown in Fig. 13. Furthermore, this would cause a crack to form at the zero-slip section
758 even in the case of CHLM behavior if the mean concrete strains exceed the tensile strength of
759 concrete, as shown in Fig. 11. This conforms to the discussions of transient cracking of RC ties
760 addressed in *fib* bulletin No. 10 (*fib* 2000). This feature though, can easily be neglected in the
761 calculation model for design situations as a conservative approach. The main reason for
762 including ψ in Eq. (14) was to account for the fact that nonlinear strain profiles occur over the
763 concrete cover (Tan 2018b), which is a mechanical improvement to the assumption of claiming
764 that plane sections remain plane in RC ties as per (Saliger 1936, Balász 1993, CEN 2004, *fib*
765 2013 and Debernadi and Taliano 2016). It can be shown though, that different values of ψ in
766 general have limited effect on the crack width predictions.
767

768 Fig. 12 shows that the analytical model presented can be applied to predict crack widths in non-
769 axisymmetric RC ties as well. In these calculations, simple assumptions were made such as
770 that the whole concrete area contributed in tension $A_{c,ef} = A_c$ and choosing $\zeta = 1$. This led to
771 similar crack spacing predictions for RC ties with similar reinforcement ratios but different
772 covers, which contradicts the experimental data in Table 2. It is well-known that the cover has a
773 significant influence on crack spacing, and therefore crack widths, as reported by Broms (1968),
774 Gergely and Lutz (1968), Caldentey et al. (2013) and Tan et al. (2018a). One approach to taking
775 the cover into account could be to use the provisions in EC2 and MC2010 for calculating an
776 effective reinforcement ratio, $\rho_{s,ef} = A_s/A_{c,ef}$, to predict the cracking behavior.. This is
777 exemplified in Table 3, which shows the crack spacing predictions when the effective height

778 surrounding the rebars, i.e. $h_{c,ef} = \min[2.5(c + \phi/2), h/2]$, is used to determine the effective
 779 reinforcement ratios. Comparison of specimens having similar geometrical reinforcement ratios,
 780 e.g. S-20-40 against S-20-90 and S-32-40 against S-32-90, shows that the crack spacing
 781 predictions increase for specimens having larger covers owing to the difference in effective
 782 reinforcement ratios. However, the increase in crack spacing predictions for specimens with
 783 larger covers is seen to be underestimated compared to the experimental evidence. This could
 784 also be related to assuming $\zeta = 1$, which is questionable particularly for RC ties with 90 mm
 785 cover because the bond stress distribution surrounding the perimeter of the rebars is probably
 786 not uniform, as elucidated in Fig. 2(d). However, determining a proper value for ζ is not
 787 straightforward and requires further study, e.g. by conducting FE analysis of non-axisymmetric
 788 RC ties. Nevertheless, the model with the introduction of the factor ζ and an effective
 789 reinforcement ratio based on the cover size shows great potential in predicting the cracking
 790 behavior of non-axisymmetric RC ties as well.

791

792 The calculation model using the simplified equations for concrete can predict crack widths both
 793 in the *crack formation stage* and the *stabilized cracking stage* through the concepts of CLLM
 794 and CHLM, and is as such different from the calculation methods recommended by EC2 and
 795 MC2010 which apply to the stabilized cracking stage only. Furthermore, assuming ψ not equal
 796 to one implies that the mean concrete strains over the section in general is different from the
 797 concrete strains at the interface further implying that the concrete stresses in each section are
 798 assumed unevenly distributed, even at the zero-slip section, a concept first introduced by
 799 Edwards and Picard (1972). This means that a crack forms when the resultant of concrete
 800 stresses at the zero-slip section is equal to the mean value of the tensile strength as pointed out
 801 for Eq. (74). Finally, using only one bond-slip curve means that bond stresses are different from
 802 null at the cracked section. These assumptions enabled a practical approach to solve the SODE
 803 for the slip.

804

805 The model allows for treating problems such as *imposed deformations*, where the mechanical
 806 loading becomes directly dependent on the crack pattern or, expressed more rigorously, the
 807 stiffness of the member. Moreover, the authors of this paper are also currently working on the

808 application of the analytical model to more general cases, such as non-cylindrical RC ties,
809 tensile zones in structural elements exposed to bending, and RC membrane elements exposed
810 to biaxial stress states at which cracks form at a skew angle to an orthogonal reinforcement
811 grid.

812

813 **7. Conclusions**

814 A new analytical crack width calculation model has been formulated to provide more consistent
815 crack width calculations for large-scale concrete structures, where large covers and bar
816 diameters are typically used. The calculation model was derived based on the uniaxial behavior
817 of axisymmetric RC ties. Furthermore, the model includes the effect of internal cracking on the
818 bond transfer, a non-uniform strain distribution over the concrete area and a non-uniform bond
819 stress distribution surrounding the perimeter of the steel bar in non-axisymmetric cases. The
820 latter accounts for the effect of steel bar spacing in practice.

821

822 The SODE for the slip has been solved completely analytically, yielding closed-form solutions in
823 the case of comparatively lightly loaded member (CLLM) behavior and non-closed-form
824 solutions in the case of comparatively heavily loaded member (CHLM) behavior. One solution
825 strategy and method for determining the complete cracking response has been provided for the
826 purposes of facilitating a practical applicable calculation model, the lack of which has been the
827 major drawback in using previous equivalent models. The comparison with experimental and
828 finite element results in the literature shows that the calculation model predicts an average
829 strain distribution based on using a single local bond-slip curve to represent the bond transfer.

830 The comparisons demonstrate the ability of the calculation model to predict crack widths
831 accurately given a member length. Finally, the model has proven capable of predicting crack
832 spacing and crack widths consistently and in general on the conservative side regardless of the
833 bar diameter and cover, even for non-axisymmetric RC ties.

837 Public Roads Administration as a part of the Coastal Highway Route E39 project.

839 **Appendix A**

840 Function derivatives in the case of CHLM behavior for Case 1.

841

$$f_1'(u_0) = -\frac{1}{\sqrt{2}} \sum_{k=0}^{\infty} \left(-\frac{1}{2} \right)^k \gamma^k \left[\gamma \beta u_0^{\beta-1} \left(\frac{1}{2} + k \right) C^{-\frac{3}{2}k} \frac{u_0^{1+k\beta}}{1+k\beta} + C^{-(\frac{1}{2}+k)} u_0^{k\beta} \right] \quad (78)$$

842

843 Function derivatives in the case of CHLM behavior for Case 2.

844

$$f_2'(u_0) = -\frac{1}{\sqrt{2}\gamma} [f_{21}'(u_0) - f_{22}'(u_0)] - \frac{1}{\sqrt{2}} f_{23}'(u_0) \quad (79)$$

845

$$f_{21}'(u_0) = \sum_{k=0}^{\infty} \left(-\frac{1}{2} \right)^k \left(\frac{1}{\gamma} \right)^k \left[C^k u_0^{\delta-k\beta-1} - \frac{\gamma \beta k C^{k-1}}{\delta - k\beta} u_0^{\beta(1-k)+\delta-1} \right] \quad (80)$$

846

$$\begin{aligned} f_{22}'(u_0) = \sum_{k=0}^{\infty} \left(-\frac{1}{2} \right)^k \left[\left(\frac{C}{\gamma} \right)^{\frac{k}{\delta-k\beta}+\frac{1}{\beta}} + du \left(\frac{C}{\gamma} \right)^{\frac{k}{\delta-k\beta}} \right]^{\delta-k\beta-1} \cdot (-\gamma \beta u_0^{\beta-1}) \\ \cdot \left[\left(\frac{1}{\gamma} \right)^{\frac{k}{\delta-k\beta}+\frac{1}{\beta}} \left(\frac{k}{\delta-k\beta} + \frac{1}{\beta} \right) C^{\frac{k}{\delta-k\beta}+\frac{1}{\beta}-1} \right. \\ \left. + du \left(\frac{1}{\gamma} \right)^{\frac{k}{\delta-k\beta}} \left(\frac{k}{\delta-k\beta} \right) C^{\frac{k}{\delta-k\beta}-1} \right] \end{aligned} \quad (81)$$

847

$$\begin{aligned} f_{23}'(u_0) = \sum_{k=0}^{\infty} \left(-\frac{1}{2} \right)^k \gamma^k \left[\left(\frac{1}{\gamma} \right)^{\frac{1}{\beta}} C^{\frac{2-\beta}{2\beta(1+k\beta)}} - du C^{\frac{\frac{1}{2}+k}{1+k\beta}} \right]^{k\beta} \cdot (-\gamma \beta u_0^{\beta-1}) \\ \cdot \left\{ \left(\frac{1}{\gamma} \right)^{\frac{1}{\beta}} \left[\frac{2-\beta}{2\beta(1+k\beta)} \right] C^{\left[\frac{2-\beta}{2\beta(1+k\beta)} - 1 \right]} \right. \\ \left. + du \left[\frac{\frac{1}{2}+k}{1+k\beta} \right] C^{\left[\frac{\frac{1}{2}+k}{1+k\beta} + 1 \right]} \right\} \end{aligned} \quad (82)$$

848

849 **Appendix B**

850 A method for determining the complete cracking response, in which $\varepsilon_{s0,s}$, $\varepsilon_{s0,cr}$ and x_{cr} are
851 determined by Eq. (72), (74) and (75) respectively, while ε_{s0} is the steel strain at the loaded end.
852 CLLM and CHLM are abbreviations for *Comparatively Lightly Loaded Members* and
853 *Comparatively Heavily Loaded Members* respectively.

| S-20-40 | 163 | 250 | 422 |
| S-32-40 Tan et al. (2018a) | 178 | 240 | 361 |
| S-20-90 | 217 | 290 | 422 |
| S-32-90 | 266 | 320 | 361 |

14 Table 3. Comparison of crack spacing reported in the experiments of Tan et al. (2018a) and
 15 crack spacing predicted using effective reinforcement ratios.

| | Experimental | | Predicted |
|---------|--------------|--------------|-----------------|
| RC tie | Mean [mm] | Maximum [mm] | Analytical [mm] |
| S-20-40 | 163 | 250 | 390 |
| S-32-40 | 178 | 240 | 342 |
| S-20-90 | 217 | 290 | 422 |
| S-32-90 | 266 | 320 | 361 |

1 **Figures**

2

3 Fig. 1(a) Typical deformation configuration of RC ties with deformed steel bars observed in
 4 experiments. (b) FE model with assumptions in accordance with Tan et al. (2018c) showing a
 5 typical deformation configuration and crack plot, where straight lines indicate inclined internal
 6 cracks and circles indicate internal splitting cracks.

7

8 Figure 2(a) Internally cracked section typically observed in physical experiments. (b) The
 9 internal cracking behavior lumped as springs to the interface between concrete and steel. (c)
 10 Statically equivalent section using a bond-slip law for the springs. (d) Equivalent cross sections
 11 when using the second order differential equation for the slip.

12

13 Figure 3. The displacement field of an arbitrary statically equivalent section. The section to the
 14 left hand side shows the undeformed configuration, while the section to the right hand side
 15 shows the deformed configuration for a load applied to the rebar end greater than zero.

16

17 Figure 4. Local bond-slip curves according to Eq. (33) with adjusted parameters proposed by
 18 Russo and Romano (1992), Balász (1993), Debernardi and Taliano (2015) and Tan et al.
 19 (2018c) compared with theoretical local bond-slip curves obtained in the FE analysis of several
 20 RC ties at different positions over the bar length in Tan et al. (2018c).

21

22 Figure 5(a) and (b) Strain and slip distribution in CLLM. (c) and (d) Strain and slip distribution in
 23 CHLM.

24

25 Figure 6(a) Case 1: solution for the slip using Eq. (39), i.e. $u_0 < u_d$. (b) Case 2: solution for the
 26 slip using Eq. (39) for $0 < u < u_d$ and Eq. (40) for $u_d < u < u_0$.

27

28 Figure 7(a) Condition 1. (b) Condition 2.

29

30 Figure 8(a) Comparison of steel strains predicted with steel strains reported in the experiments
31 of Bresler and Bertero (1968) over the bar length. (b) Comparison of crack widths predicted with
32 crack widths reported in the experiments of Yannopoulos (1989) using similar specimen length
33 $L = 100$ mm similar to that in the experiments.

34

35 Figure 9. Comparison of steel strains predicted with steel strains reported over the bar length in
36 the FE analysis of Tan et al. (2018c). (a) Specimen $\phi 20c40$. (b) Specimen $\phi 32c40$. (c)

37 Specimen $\phi 20c90$. (d) Specimen $\phi 32c90$.

38

39 Fig. 10. Comparison of crack widths predicted (in specimens with lengths similar to FE analysis
40 mean crack spacing reported in Table 1) with crack widths reported in the FE analysis of Tan et
41 al. (2018c). (a) Specimen $\phi 20c40$, $L = 105$ mm. (b) Specimen $\phi 32c40$, $L = 109$ mm. (c)

42 Specimen $\phi 20c90$, $L = 260$ mm. (d) Specimen $\phi 32c90$, $L = 272$ mm.

43

44 Fig. 11. Comparison of crack widths predicted (in specimens with lengths similar to crack
45 spacing predicted in Table 1) with crack widths reported in the experiments of Yannopoulos
46 (1989) and the FE analysis of Tan et al. (2018c). (a) Yannopoulos (1989) specimen, $L =$
47 181 mm. (b) Specimen $\phi 20c40$, $L = 224$ mm. (c) Specimen $\phi 32c40$, $L = 207$ mm. (d) Specimen
48 $\phi 20c90$, $L = 470$ mm. (e) Specimen $\phi 32c90$, $L = 434$ mm.

49

50 Fig. 12. Comparison of crack widths predicted (in specimens with lengths similar to crack
51 spacing predicted in Table 2) with crack widths reported in experiments. (a) CEOS.fr (2016). (b)
52 Tan et al. (2018a).

53

54 Fig. 13. Bond stresses corresponding to the steel strains predicted in Fig. 9. (a) Specimen
55 $\phi 20c40$. (b) Specimen $\phi 32c40$. (c) Specimen $\phi 20c90$. (d) Specimen $\phi 32c90$.

56

57 Fig. 14. Concrete strains corresponding to the steel strains predicted in Fig. 9. (a) Specimen
58 $\phi 20c40$. (b) Specimen $\phi 32c40$. (c) Specimen $\phi 20c90$. (d) Specimen $\phi 32c90$.
