The proposed method used edit distance but this can be replaced with with other sequence-based distances. On the other hand, however, it has already been shown that many studies yield high classification results when sequence alignment techniques are used as a measure of similarity between folk songs [23]. Thus, the high classification performance in this study may reflect the advantages of the alignment method used as the main distance. Therefore, the performance evaluation of the present method as a measure of similarity requires further study to experiment with more data sets and distance measures. Besides, since only segments with the same length are compared and are performed based only on shorter melodies, there is a limitation that some loss of information can occur. There is also a disadvantage that this method is time-consuming because it repeatedly performs calculations among all the segments. Despite several limitations, we believe that this multi-scaled approach provides a wealth of insight that will help us to understand the properties of similarity.

JOSQUINTAB: A DATASET FOR CONTENT-BASED COMPUTATIONAL ANALYSIS OF MUSIC IN LUTE TABLATURE

ABSTRACT

An enormous corpus of music for the lute, spanning some two and half centuries, survives today. Unlike other musical corpora from the same period, this corpus has undergone only limited musicological study. The main reason for this is that it is written down exclusively in lute tablature, a prescriptive form of notation that is difficult to understand for non-specialists as it reveals little structural information. In this paper we present JOSQUINTAB, a dataset of automatically created enriched diplomatic transcriptions in MIDI and MEI format of 64 sixteenth-century lute intabulations, instrumental arrangements of vocal compositions. Such a dataset enables large-scale content-based computational analysis of music in lute tablature hitherto impossible. We describe the dataset, the mapping algorithm used to create it, as well as a method to quantitatively evaluate the degree of arrangement (goodness of fit) of an intabulation. Furthermore, we present two use cases, demonstrating the usefulness of the dataset for both music information retrieval and musicological research. We make the dataset, the source code, and an implementation of the mapping algorithm, runnable as a command line tool, publicly available.

1. INTRODUCTION

An enormous corpus of music for the lute, roughly spanning the sixteenth, seventeenth, and first half of the eighteenth century, and containing an estimated 60,000 individual pieces in circa 860 sources, printed and manuscript, survives today [27]. Although the lute was one of the most widely used instruments during these two and a half centuries, and this corpus is thus extremely rich in information about daily musical practice, up until the present day it has not undergone the same critical musicological study as other musical corpora from the same period. The main reason for this is that the notation used to write down lute music, lute tablature, is notoriously difficult to understand for non-specialists [18, 28]. This is because lute tablature is a purely *prescriptive* form of notation: like all forms of instrumental tablature [12], it merely provides the actions a player must take—in this case, where to place the fingers on the fretboard and which strings to pluck—rather than the sounds and musical edifice these actions produce, which a *descriptive* form of notation does [20, 29]. In practice, this means that lute tablature, as opposed to mensural forms of notation, conveys virtually no information about the structure, polyphonic or other, of the music it encodes, making it hard to comprehend *a prima vista*.

In this paper we propose to address the problem of the marginal position of music in lute tablature within musicological research by providing JOSQUINTAB, a dataset of 64 automatically created *enriched diplomatic transcriptions*—literal transcriptions annotated with voice, key, and mensuration information—of a selection of sixteenth-century lute and vihuela (the lute's Spanish counterpart) *intabulations*, instrumental arrangements of vocal compositions, as well as a mapping algorithm for creating such a dataset, and an implementation thereof, runnable as a command line tool. The proposed dataset enables large-scale content-based computational analysis of music in lute tablature, which, in the absence of some notion of the music's polyphonic structure, has hitherto not been possible. The command-line tool allows researchers to extend the dataset by creating their own transcriptions.

In summary, the main contributions of this paper are:

- a dataset of 64 automatically created enriched diplomatic transcriptions of lute intabulations, each in the original and in an unornamented version;
- a mapping algorithm for creating such a dataset;
- an implementation of the mapping algorithm, runnable as a command line tool.

Furthermore, we provide:

- a method to quantitatively evaluate the degree of arrangement (goodness of fit) of an intabulation, which is incorporated in the mapping algorithm;
- two use cases, demonstrating the usefulness of the dataset for both music information retrieval (MIR) and musicological research.

In the spirit of open science and reproducible research, we aim to make the resources we contribute FAIR (findable, accessible, interoperable, and reusable) [32]. We do so by using *recommended formats*—MIDI and MEI—for the dataset, [1] and by making the dataset, the source code for the mapping algorithm, and the command line tool publicly available.

[1] https://www.loc.gov/preservation/resources/rfs/

The remainder of the paper is structured as follows. In Section 2, we sketch the scholarly and scientific background against which this research is carried out. In Section 3 we describe the contents of JOSQUINTAB and the preprocessing that the data we build on requires, and in Section 4 the mapping algorithm by means of which we create JOSQUINTAB, the method to evaluate the dataset quantitatively, and the command line tool. Section 5 is dedicated to the use cases, and in Section 6, conclusions and directions for future work are presented.

2. BACKGROUND IN MUSICOLOGY AND MIR

2.1 Lute tablature: A brief introduction

When in the late fifteenth century lutenists began playing polyphonic music on their instrument, this entailed a need for an accommodating, score-like, notation. Several approaches were developed simultaneously, crystallising into three principal systems, whose modern names refer to their regions of origin: French, Italian, and German lute tablature [1]. [2] From these three, the French system would outlive the other two, from the seventeenth century on becoming the primary system. The former two systems use letters (French) or numbers (Italian), indicating where on the fretboard the fingers must be placed, on a six-line 'staff', each line of which represents a *course* (string pair) to be plucked. The German system is more abstract—it does not use a staff—and consists of a collection of glyphs (letters, numbers, and special characters, often varying per author) representing unique course-fret combinations.

2.2 Transcription practices

Figure 1, which shows an example of the Italian system, perfectly demonstrates the problem with lute tablature. Below a deceivingly simply notational surface, structurally rather complex music may lie hidden—and it requires a significant amount of expertise to infer the information not notated. The traditional musicological solution to 'unlock' this corpus for research is the preparation of scholarly editions, commonly in paper format, in modern music notation. Some of these are 'literal' or *diplomatic* transcriptions, recording the information given in the source exactly as it appears [17] (i.e., providing only pitch and minimal duration information), thus involving a minimum of interpretation but in turn revealing little about the polyphonic structure of the music, while others are full-fledged polyphonic transcriptions, involving a maximum of interpretation, and therefore often accompanied by a critical apparatus motivating the choices made.

Preparing scholarly editions is time-consuming and specialist work—all the more so in the latter case. This is one of the reasons why recent times have seen attempts at automatic transcription of lute tablature. Computers are ideally suited for fast (and large-scale) literal transcription—in fact, this can be achieved fairly easily with many of the music notation software packages, proprietary or open-source, available today. Automatic *polyphonic* transcription of lute tablature, however, has proven to be quite challenging [8, 13, 14], and in MIR research is still considered an open problem. Thus, despite ongoing efforts in musicology and MIR—both concerning content-based [22, 23] and bibliographical research [11]—only a fraction of the lute repertory has been explored up until the present day, and much work remains to be done.

2.3 Sixteenth-century lute music and intabulations

Sixteenth-century lute music is generally considered to fall into three categories [3]: (i) original compositions, i.e., idiomatic, abstract works in varying degrees of counterpoint, such as fantasias, ricercares, or preludes; (ii) settings of dance tunes; and (iii) intabulations, i.e., instrumental arrangements of vocal compositions. It is the latter category—by far the largest of the three, by itself taking up at least approximately half of the music [3]—we focus on in this paper. Up until today, intabulations have largely escaped in-depth musicological research—mostly on the grounds that as non-original works, they would be inferior compositions, which, especially when heavily ornamented, served no other goal than to demonstrate the player's virtuosity. While it is doubtlessly true that certain arrangements are less exciting than others, a fact that should not be overlooked is that intabulations are highly informative about contemporary compositional and performance practices [6,18,19,26], giving insights into, e.g., ornamentation techniques [4] or the application of *musica ficta*, i.e., chromatic alterations not notated in vocal music [5].

Intabulations generally remain close to their vocal models: contemporary treatises on the subject of intabulating prescribe that the intabulator take over as much of the vocal model as is technically possible on the instrument [24]; several existing in-depth studies of selected intabulations [2, 4, 5, 25, 30] support this. It is exactly the resulting close relation between model and intabulation that facilitates the mapping approach presented in this paper.

3. JOSQUINTAB

As its name reveals, the dataset exclusively contains intabulations of vocal compositions by Josquin des Prez (c. 1450-1521), an earlier-generation composer highly popular among sixteenth-century intabulators [3, 21]. According to the *New Josquin Edition*, no less than 18 chansons, 17 motets (most of them in multiple parts), various parts of 17 mass sections, and even eight complete masses have been intabulated [16]—adding up to at least 60 works, depending on how one counts.

In creating the dataset, which we do by mapping machine-readable tablature encodings (in TabCode format [10, 28]) onto MIDI renderings of editions of the vocal models (as explained in detail in Section 4), [3] we build on two existing, high-quality data repositories. The tablature encodings were retrieved for a previous study [22]

[2] The vihuela players generally adopted the Italian system; vihuela tablature, especially the upside-down variant that equals modern guitar tablature, is sometimes referred to as *Spanish tablature*.

[3] See also `http://www.ecolm.org/`.

Figure 1. Francesco Spinacino, *Intabulatura de lauto, Libro primo* (Venice, 1507), *Adiu mes amours*, first system.

from Sarge Gerbode's Lute Page, [4] a curated repository of encodings made by amateur enthusiasts; the MIDI renderings of editions of the vocal models (as well as scores in PDF format of the same editions, used for reference) are retrieved from the GitHub repository for the Josquin Research Project (Center for Computer Assisted Research in the Humanities, Stanford University), [5] which aims to provide ways to search and analyse scholarly edited scores of polyphonic early music. [6]

Our eventual goal is for the dataset to contain transcriptions of *all* intabulations of Josquin compositions, including all dubious attributions (but excluding the spurious ones). This inclusive approach is taken as scholarly opinion on the matter of the authenticity of a significant number of pieces tends to change constantly [31]. [7] However, while the Josquin Research Project repository provides editions of all vocal models, the Lute Page repository only contains intabulations of nine of the chansons, 10 of the motets (in 21 parts in total), and 12 of the mass sections parts, where approximately half of the chansons and motet parts have been intabulated more than once. (For practical reasons, for now we ignore the eight complete masses, all of which appear in a single print and are therefore somewhat of an exception; moreover, we only look at printed sources, facsimiles of which, needed for error checking, are generally easier to come by.) As Table 1 shows, this yields a dataset of 64 pieces (60658 data points). Each piece is represented by (i) a machine-readable encoding of the tablature in TabCode format; (ii) a MIDI rendering of the vocal model; (iii) a tuple (see below) of MIDI renderings of the created transcription; (iv) a tuple of MEI renderings (containing score and tablature) of the created transcription; and (v) a CSV file with the mapping details. [8]

In many of the intabulations, a 'net' of ornamentation has been added to the original notes, like a superstructure imposed on the music [5]. We provide each transcription both in the ornamented, original version and in a version stripped of the ornamental net (the procedure by which this is done is explained in more detail in Section 4). The latter is expected to be more useful for analysis tasks that are complicated by large amounts of ornamentation, such as the one in Use Case 2 (see Section 5.2). Furthermore, it must be noted that tablature only provides a 'minimum' duration for each note, applying to all notes in a chord (see Figure 1). We have made no attempt at reconstructing the notes' actual duration, i.e., at determining their offset—which is not a trivial problem as it depends on multiple contextual factors (e.g., counterpoint, phrasing, etc.). At this point, it is therefore important to stress that the transcriptions created are not full-fledged editions in the musicological sense of the word, and are not intended as such—rather, they serve to facilitate large-scale content-based computational analysis.

3.1 Preprocessing: Alignment issues

The mapping algorithm takes as input an encoding of the tablature in TabCode format and a MIDI rendering of the vocal model. In order for it to function optimally, these files must be aligned both in terms of pitch (i.e., the appropriate lute tuning must be used) and time (i.e., they must span the same number of bars). [9] In the ideal case, only the tuning needs to be provided—but in practice, most of the tablature encodings require a number of small corrections, and in some cases even additions, all of them necessary to ensure temporal alignment. Currently, these need to be carried out in a manual preprocessing step.

There are four types of *corrections*, three of which apply to the encodings. First, almost all encodings require the mensuration signs used to be adapted in order for the nominal beat level to correspond to that in the MIDI file (in most cases this results in augmentation—e.g., a change of a $\frac{2}{2}$ mensuration to a $\frac{2}{1}$ mensuration—or, conversely, a reduction; but in some cases they are actually incorrect); moreover, a small number of encodings require lacking mensuration signs to be added. Second, a small number of encodings require unspecified triplets to be made specific. Third, a small number of encodings require the correction of syntactic errors that render them non-parsable (technically, this type of correction does not affect any alignment issues). [10] The fourth and last type of correction applies to the MIDI renderings of the vocal models, which all require the key signature meta message to be set.

Furthermore, there is one type of *addition*, which again applies to the encodings only, and which results in lengthening them. A substantial number of encodings—29 in

[4] See `http://www.gerbode.net/`. The files were converted from the proprietary Fronimo format into TabCode.

[9] The standard tuning used for the six-course sixteenth-century lute is one where the courses are tuned in perfect fourths with a major third in the middle. The lowest-sounding course was generally tuned to nominal G or A, but several other tunings occured as well.

[10] We make no attempt at correcting any incorrectly encoded notes.

Table 1. JOSQUINTAB: 36 motet part intabulations (ranging in size from 234–2238 notes; median 1257.5 notes; total 43557 notes); 13 mass section part intabulations (260–1141 notes; median 343 notes; total 5942 notes); 15 chanson intabulations (483–1250 notes; median 686 notes; total 11159 notes). I = number of intabulations.

total—contain fewer bars than their vocal models. In most cases, this is obviously due to an error on behalf of the intabulator, i.e., accidental omission. Given a sequence of bars $\{b_1, ..., b_{n-1}, b_n\}$, where bar b_1 has the same ending as bar b_{n-1}, all bars between b_1 and b_n may easily be skipped unwittingly (a scribal error known as *homoeoteleuton* in manuscript studies [9]). In exceptional cases, however, omission is intentional. Omissions are countered by inserting rests into the intabulation at the appropriate position.

Apart from an encoding and a MIDI rendering, the mapping algorithm must also be given the appropriate tuning, as well as the appropriate *reduction*: the factor by which the durations in the tablature must be multiplied (or divided) in order for its nominal beat level to correspond to that of the vocal model. The reduction can be a positive integer greater than 1, in which case it amounts to an augmentation; a negative integer, in which case it amounts to a reduction; or 1, in which case the durations do not change. Although determining the tuning and reduction is strictly speaking not a preprocessing step, this information must be given as input to the mapping algorithm, and must thus be established—currently, manually—prior to running it.

4. MAPPING ALGORITHM

The mapping algorithm itself is fairly straightforward and traverses the music chord by chord (where a chord is any event that has one or more notes in it), from left to right. Given a tablature encoding and a MIDI representation of the vocal model, first, an ordered list T is made, containing the union of the chord onset times in both tablature and MIDI. Then, two two-dimensional matrices with $|T|$ rows are constructed: the *grid* G, containing, for each onset time T_i, onset, pitch, voice, and duration information for the chord at T_i in the MIDI (or null values when there is no chord); and the *mask* M, containing, for each onset time T_i, onset, pitch, duration and note index information for the chord at T_i in the tablature (or null values when there is no chord). The grid and mask are traversed jointly, row by row, and in the process a list of *voice labels* V is created. A voice label is a binary vector encoding all voices onto which a note is mapped. Let mask row $M_{i,*}$ represent a tablature chord and grid row $G_{i,*}$ a MIDI chord at onset T_i. If $M_{i,*}$ is non-null, i.e., there is a chord in the tablature at T_i, the following steps are taken.

1. If $M_{i,*}$ contains a single note whose duration is less or equal than the *ornamentation threshold* (a pre-set parameter) and $G_{i,*}$ is null, [11] i.e., there is no chord in the MIDI at T_i (see Figure 2, horizontal brackets), the note is flagged as ornamental. Null is added to V, the note is added to a running list O, and Steps 2-4 below are skipped.
2. Each note in $M_{i,*}$ is mapped to a voice by finding the voice that goes with its counterpart in $G_{i,*}$. A note can be mapped to multiple voices.
   (a) If a match is found, a voice label is added to V.
   (b) If no match is found (see Figure 2, single brackets and non-bracketed sharps), null is added to V, and the note is added to U, the list of unmapped notes in $M_{i,*}$.
3. If U is not empty, the notes in it are mapped—in one go—to the available voices (any voices not yet occupied by a note in $M_{i,*}$). To this end, for each available voice in the MIDI, the last note with an onset that is less than T_i in that voice is added as a pitch-voice tuple to a list A. Then, the cheapest mapping of U onto A is calculated, where the cost is based on pitch distance. All corresponding null voice labels in V are replaced, and all mapped notes removed from U. (If, after this process, there are still unmapped notes—which can happen if $M_{i,*}$ contains more notes than there are voices in the model—this step is repeated, now considering *all* voices as avail-

[11] As ornamentation threshold we use the value two levels below beat level (e.g., in $\frac{2}{1}$ or $\frac{3}{1}$ mensuration, a quarter note).

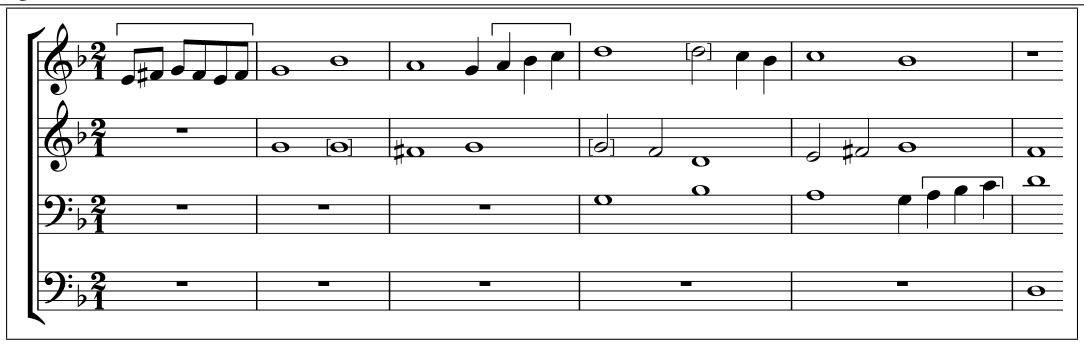

Figure 2. Francesco Spinacino, *Adiu mes amours*, opening bars (see Figure 1). Mapping algorithm output. The tablature contains all notes from the vocal model; bracketed notes and sharps are additions. Full note durations are inferred.

able. As a result, voices can have more than one note mapped onto them.)

4. (Optional.) If $M_{i-1,*}$ is ornamental, the cheapest connection of the last note in O to $M_{i,*}$ is calculated (where the cost is again based on pitch distance), and all notes in O are mapped onto the voice onto which the note in $M_{i,*}$ that yields the cheapest connection has been mapped. In case of a tie, the cheapest connection of the first note in O to $M_{i-1-|O|,*}$ (i.e., the chord immediately before that first note) is decisive. All corresponding null voice labels in V are replaced, and O is cleared.

When the grid and mask have been traversed, the algorithm combines the created list of voice labels V with an internal representation of the tablature created from the encoding, and, retaining the key and mensuration information from the MIDI, returns this as a track-separated MIDI file and an MEI rendering thereof. If Step 4 is included, these contain all ornamentation that is in the tablature; if it is skipped, they remain unornamented.

4.1 Evaluation method

There are four categories of mismatches. If in Step 1 a note is flagged, it is considered an *ornamentation*. Else, if in Step 2(b) no match is found for a note, and in Step 3 it is mapped at cost 0), it is considered a *repetition* (see Figure 2, single brackets); else, if there is a semitone discrepancy between it and a note in A, but they are the same pitch class, it is considered *musica ficta* (see Figure 2, non-bracketed sharps); else, it is considered an *alteration*. These categories are hierarchical and mutually exclusive.

This classification enables us to quantitatively evaluate the degree of arrangement (goodness of fit) of an intabulation in a granular manner. We measure the degree of arrangement by means of the *mapping ratio* $m = \frac{|N|-|M|}{|N|}$, where N is the set of all notes, and M the set of all mismatches. At the highest level of granularity, which results in the lowest m, M is equal to the total of all ornamentations, repetitions, instances of musica ficta, and alterations—i.e., to the total of mismatches across all four categories. It can be argued, however, that not all categories carry the same weight. Repetitions, for example, are idiomatic for lute music because of the instrument's short sustain, and have only little harmonic and melodic impact; and instances of musica ficta, which have a stronger harmonic and melodic impact (but no rhythmic impact), are nothing but inflections, different 'flavours' of the same pitch class. Thus, it makes sense not to include mismatches falling into these categories in M, or at least to weight them differently. We therefore redefine m as

$$m = \frac{|N| - (o|M_o| + r|M_r| + f|M_f| + |M_a|)}{|N|}, \quad (1)$$

where M_o, M_r, and M_f are the sets of all ornamentations, repetitions, and instances of musica ficta; o, r, and f their respective weighting parameters; and M_a is the set of all alterations (N, as above, is the set of all notes).

Genre	Ornamented			Unornamented	
	o, r, f			r, f	
	$1, 1, 1$	$1, 0, 0$	$0, 0, 0$	$1, 1$	$0, 0$
Motets	0.52	0.66	0.92	0.70	0.89
Mass sections	0.70	0.83	0.96	0.80	0.95
Chansons	0.57	0.69	0.94	0.75	0.92
All	0.54	0.68	0.93	0.72	0.90

Table 2. Mapping ratio m at different levels of granularity. Values are weighted averages, where each per-piece ratio is weighted by the number of notes in the piece.

Table 2 shows the mapping ratio, averaged per genre, at the highest level of granularity (i.e., the most strict case, with all parameters set to 1), at an intermediate level (with only o set to 1), and at the lowest level (i.e., the most lenient case, with all parameters set to 0) for the ornamented transcriptions, as well as at the highest and lowest level for the unornamented transcriptions, where the intermediate level does not apply. The table shows that, on average, at least half of the notes ($m = 0.54$) in the ornamented transcriptions, and approximately three quarters ($m = 0.72$) in the unornamented transcriptions, have an exact match in the vocal models. The ratios increase considerably—to 0.68 and 0.90, respectively— if we consider repetitions and musica ficta to be matches as well. The table also shows that, generally, the intabulations are fairly heavily ornamented, as the ratio at the lowest level of granularity ($m = 0.93$) is much higher than that at the other levels.

4.2 Command line tool

The Java implementation of the mapping algorithm, `TabMapper`, [12] can be run as a command line tool. A single transcription is created with the command

```
$ tabmapper tab.tc model.mid <t> <r> -n
```

where `tab.tc` is the TabCode encoding of the intabulation, `model.mid` the MIDI rendering of the vocal model, `<t>` and `<r>` are the tuning and reduction (see Section 3.1), and `-n` is an optional argument indicating that the transcription created should be unornamented. A *set* of transcriptions is created with the command

```
$ tabmapper list.csv -n
```

where `list.csv` is a CSV file specifying, for each piece, the name of the TabCode file, that of the MIDI file, the tuning, and the reduction, and `-n` is again optional.

5. USE CASES

Two use cases demonstrate the usefulness of the dataset for both MIR and musicological research.

5.1 Use Case 1: Voice separation

Use Case 1 shows how the dataset can serve to train machine learning models for voice separation in lute tablature [13, 14], which can be used for automatic polyphonic transcription of music in lute tablature. *Voice separation* can be defined as "the task of separating a musical work consisting of multi-note sonorities into independent constituent voices" [7]. From an MIR perspective, this task is considered an open problem. As with many supervised machine learning tasks in MIR, a lack of labelled data to train and evaluate models on hinders progress. This is a particularly pressing issue in the case of tasks related to music in lute tablature. Apart from our own manually created dataset containing 15 pieces (11641 data points) [13, 14], to our knowledge there currently exist no other datasets of voice-annotated tablature.

Automatic data creation can be a solution. However, data created by means of a rigid algorithm is less consistent in terms of transcription quality than data created manually, where each individual situation can be addressed on its own terms—and this may result in a model having more difficulty learning the task, and consequently, generalising worse. An experiment confirms this. In [13], we train and evaluate neural networks on nine four-voice pieces (8892 data points); our best-performing model achieves a generalisation accuracy of 79.63%. A model with the same architecture [13] trained and evaluated on the 28 four-voice pieces (26215 data points) in JOSQUINTAB yields a generalisation accuracy of only 64.47%. [14] We hypothesise this to be partly due to inconsistencies in the data; however, an analysis of the results reveals that an error propagation issue particular to imitative music, as discussed in [15], also plays a substantial role. As the dataset grows and inconsistencies are ironed out statistically, performance improvement is expected. Despite its current subpar performance, this model can already be reliably used for automatic polyphonic transcription.

5.2 Use Case 2: Cross-corpus melodic matching

Use Case 2 shows how the dataset can be applied for melodic matching across heterogeneous—in this case, instrumental versus vocal—corpora. A major goal of automatic transcription of tablature is the ability to search freely for *musical quotations* occurring between corpora in tablature and in standard notation. Our dataset provides an important stepping stone in this direction. Using the unornamented transcriptions created, we are able to do a further processing step in order to create search strings for Early Music Online Search, [15] a tool that uses OMR to enable full-text searches into sixteenth-century printed music.

Our initial results are promising. Eight pieces exist in both corpora, of which we are able to successfully search and match four. Not only are we able to match the individual pieces, but also the individual voice parts within each piece are correctly identified. In three additional cases, our search matches not with the correct piece, but rather with another piece by the same composer—showing that our search method enables the identification of common stylistic features. This shows the potential of transcribing a larger tablature corpus in order to identify hitherto unknown vocal models.

6. CONCLUSIONS AND FUTURE WORK

In this paper we present JOSQUINTAB, a dataset of automatically created enriched diplomatic transcriptions of 64 lute intabulations. We describe the contents of the dataset, the mapping algorithm used to create it, and we show how we can quantitatively evaluate it. Two use cases illustrate how the dataset can be used for content-based computational analysis within and across corpora, demonstrating its usefulness for MIR and musicological research. We make the dataset, the source code, and an implementation of the mapping algorithm publicly available.

There are many ways in which this work can be extended. One is to further automate the preprocessing (alignment, determination of tuning and reduction) that the data currently requires. Another is to parameterise certain functionality of the mapping algorithm (e.g., the value of the ornamentation threshold) in order to allow more flexibility in the transcription creation. A third is to extend the dataset so that it includes all intabulations of Josquin compositions, and those of other composers as well. It is clear that the work presented opens many new research avenues, which we plan to explore in future work.

[12] `https://github.com/reinierdevalk/tabmapper/`

[13] We now use the backward processing mode [13], and train using a validation set, doubling the number of training iterations and decreasing the amount of regularisation applied by a factor of 10.

[14] Values are cross-validation averages, where the dataset is partitioned along its individual pieces.

ABSTRACT

This work presents a novel dataset comprised of audio and jury evaluations for rhythmic pattern reproduction performances by students applying for a conservatory. Data was collected *in-loco* during entrance exams where students were asked to imitate a set of rhythmic patterns played by teachers. In addition to the *pass* or *fail* grades provided by the members of the jury during the exam sessions, a subset of the data was also evaluated by external annotators on a 4-level scale. A baseline automatic assessment system is presented to demonstrate the usefulness of the dataset. Preliminary results deliver an accuracy of 76% for a simple pass/fail logistic regression classifier and a mean average error of 0.59 for a linear regression grade estimator. The implementation is also made publicly available to serve as baseline for alternative assessments systems that may leverage the dataset.

1. INTRODUCTION

Automatic assessment of music performances is an important audio signal processing application drawing increased attention over the past few years. The *Massive Open Online Course* (MOOC) methodology has recently contributed to the growth of online music courses, attracting a large number of students. In this scenario, automatic assessment methodologies have the potential to largely reduce the instructor load of assessing student submissions. Moreover, due to its subjective nature, the task of evaluating students performances can be very difficult [4, 14, 24], sometimes even preventing different evaluators from reaching an agreement while assessing the same performance [17, 22]. Automatic evaluations may circumvent this obstacle by defining clear and objective goals that must be achieved in order to succeed in a musical performance.

While some authors leverage their evaluation tools using linear measures to quantify similarity between pairs of reference and performance [20], most of the recently proposed assessment systems rely on machine learning based models for this task. Earlier models were trained with labeled data and hand-crafted audio features targeting at the prediction of grades for performances. Such methodology is applied in Nakano et al. [13] for improving the state-of-art for singing voice assessment. The authors gathered data from the AIST-HDB dataset [9] to train a model able to predict *good/poor* classifications for singing performances. Bozkurt et al. [4] have also suggested a supervised learning method for singing voice assessment, but this time conducting their own data collection procedures inside a music conservatory. The collected data containing jury evaluations was fed into a machine learning model whose accuracy was reported as 74% for binary *pass/fail* predictions. Singing assessments following similar methodologies and including classification systems were previously proposed by Schram et al. [16] and Molina et al. [12]. Both authors aimed at the automatic evaluation of voice performances by training machine learning models with audio features and targeted scores.

Recent advances in unsupervised learning led researchers to also rely on learned metrics to support their assessment systems. Unlike the aforementioned supervised procedures, these techniques delegate to the model itself the task of figuring data patterns directly from raw audio data, clustering similar observations into equivalent groups and using such information to predict assessments. Examples of such methodology include the results discussed by Wu and Lerch in [24], where authors modeled a feature learning approach specially designed for assessing percussive performances recorded during band auditions. This very same data source leveraged Pati et al. [14] in their similar study also tackling the problem of modeling music assessment by means of learned features. They have proposed the application of deep neural networks capable of capturing non-linear aspects of performances that would better correlate with reference's features. These recent studies encourage the use of unsupervised feature learning rather than supervised methods, reporting that the former

outperforms the latter in most of the cases.

Audio corpora play a critical role in every assessment system, as the decision functions used for predicting evaluations are trained on the corpora. In their work, Li et al [10] delivered an important contribution by reviewing several commonly-used music datasets made publicly available for MIR tasks. This systematic review also describes important information regarding the nature of each dataset (e.g. available content, total audio durations, types of annotations) and points out to a lack of datasets with annotations related to rhythmic assessment, we argue. Specifically regarding the rhythmic dimension, the dataset provided by the Florida Bandmasters Association (FBA) has been commonly adopted [14,21,23,24] and is, to the extent of our knowledge, the only dataset that currently includes rhythmic performances that are annotated with grades. It is comprised of audio performances from band auditions recorded in the Florida state between 2013 and 2015, including jury assessments for different music aspects (musicality, note accuracy, rhythmic accuracy, tone quality, etc.).

This present work is an effort to address the shortage of music datasets designed for rhythmic assessment. The presented data was collected during the rhythmic sessions of entrance exams based in a music conservatory, where student performances were recorded and evaluated by members of a jury. Data curation procedures were applied over this raw dataset (including 1040 student performance recordings) in order to extract a subset of (80) performances which were submitted to an extra evaluation, this time in a 4-level scale (i.e. grades ranging from 1 to 4). The resulting subset featured with annotated data was fed to a simple machine learning rhythmic assessment system in order to demonstrate the use of the dataset in this scenario. A binary *pass/fail* logistic classifier and a linear regression grade estimator are implemented, the former delivering a maximum accuracy of 76% while the latter pointing to a minimum mean average error of 0.59 when tested over a 5-fold cross validation. Both the complete rhythmic dataset and the re-annotated subset are made publicly available. The implementation of the proposed rhythmic assessment system is also openly shared to serve as baseline for comparisons with similar approaches.

2. THE MAST RHYTMIC DATASET

The Musical Aptitude Standard Test (MAST) Rhythmic Dataset is a collection of rhythmic performances and references recorded in the Istanbul Technical University (ITU) Turkish Music Conservatory during entrance exams. In Turkey, these assessments are commonly applied to support the evaluation of the musical aptitude of applicants, determining whether or not they should be accepted to study in the institution. Categorizations are preferably achieved during jury-assisted exams when students are individually auditioned and evaluated according to multiple musical aspects (e.g. chord recognition, melodic singing, rhythm playing). For the rhythmic session students are asked to imitate reference performances by usually clapping hands or tapping a hard surface.

The rhythmic patterns included in the dataset are taken from the jury based qualification exams of the years 2015 and 2016. The rhythmic assessment portion of the entrance exams in these years was composed of two types of rhythmic pattern reproduction questions; rhythm one in a simple meter (4/4) and rhythm two in a compound meter (7/8, 9/8, 10/8 or a 5/4). In order to ensure the confidentiality of the questions asked in the exam and minimize the chance of a memorization and the leakage of these pattern outside of the examination areas, the applicants chose randomly from 10 different question packages, each package having a different version of the two types of rhythmic patterns stated. Thus, there are 20 different rhythms for each year making up the total of 40 distinct rhythmic patterns in our dataset.

Besides taking into consideration the two types of rhythms, the exam preparation committee designed the questions such that each pattern should be employing similar rhythmic values (quarter-note, eight-note, sixteenth-note and a triplet) and similar number of notes. The applicants were expected to perform above a threshold of success regardless of the package the selected. Later, it was observed that, while there may be differences in terms of difficulty for different packages which might affect an applicant's test score, there wasn't any significant relationship observed between the selected packages and the success of the candidates [1].

The jury committee consists of three members and the candidates are expected to reproduce the rhythmic pattern after it has been played two times by a member of the committee. The jury gives a full grade (10pts) and moves on to the next question if the candidate's performance is an exact reproduction (or nearly). If there are flaws in the reproduction, then the candidate is exercised by performing the rhythmic pattern divided to two halves separately, after which the rhythmic pattern is played for reproduction one last time. The evaluation at this stage may have three outcomes, either the participant receives a partial grade (8pts) if it is an exact reproduction (since he/she couldn't perform an exact reproduction at the beginning), if it still has 1-2 errors the jury gives a minor grade (4 pts), and no points are given if the performance has more than 2 errors. The evaluations of the jury member can show variances at this stage due to individual preferences (e.g. for some a consistent tactus may be more important than missing an attack, for some it is the accentuation and the phrasing). Due to these, in our dataset we have only selected those performances in which there was an unanimously consensus among jury members that it was an exact (or nearly exact) reproduction or a failure (all giving 0 pts.).

In general, to allow reinspection of the execution of these exams, each applicants performance is video recorded by the ITU conservatory directorate. For our purposes – and to ensure anonymity - these recordings were converted to wave files and then cropped so that each recording consisted of the candidates performances only.

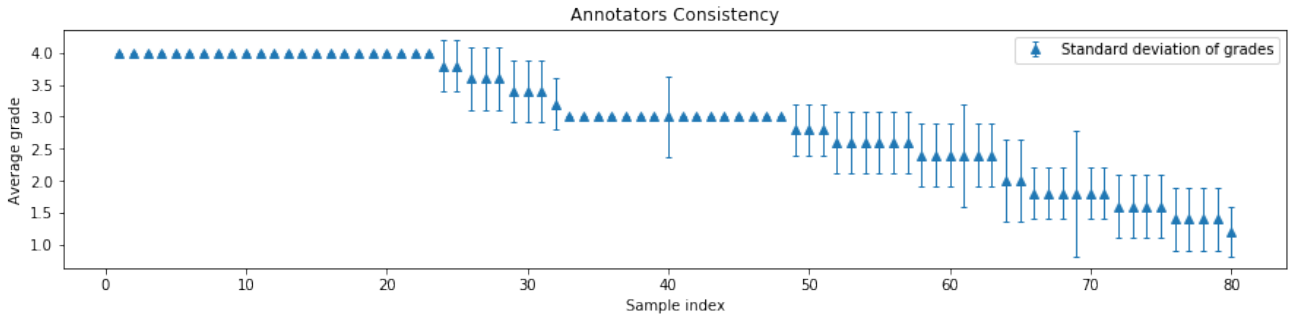

Figure 1. Distribution of grades assigned by the distinct annotators. The x-values indicate the performance index while the y-values stand for the average grade assigned. Error bars describe the standard deviation for all evaluations

3. USER ANNOTATIONS

In order to contribute to a more complete validation over the collected data, the original dataset - which originally only contained *pass/fail* classifications provided by members of a jury - was also annotated with a higher resolution (4-level) grading. Since the re-assessment of all the 1040 student performances comprised by the full dataset would require high human resources, the original data was sampled. This convenience sampling initially filtered 20 references with low rhythmic complexity, followed by the selection of four noise-free student performances for each reference - two from each *pass/fail* class, totaling 80 sampled student performances and 20 jury member performances (that serve as the reference/target rhythmic pattern for grading a student performance via comparison).

This subset of performances (from now on addressed as re-annotated subset) was submitted to evaluation sessions completed by seven annotators (male: six, female: one) and aided by a custom evaluation tool (depicted in Figure 2) developed for a similar data collection task. During these sessions, the annotators could hear in sequence the rhythmic reference and student performance (with a one second silence in-between) as many time as desired until feeling comfortable to choose between one of the available grades: *1 - Completely off, 2 - Major errors, 3 - Minor errors, 4 - Perfect*. Although no advanced music skills were considered mandatory to support the assessment of quite simple rhythmic patterns, authors tried to select annotators with some relevant music background. Besides, the graders were provided with a custom rubric documenting the musical aspects that should be taken into consideration when assigning grades. They were asked to assess the similarity of the student performance to the reference in terms of the beat and duration patterns, discarding tempo differences.

Evaluation sessions could be interrupted and resumed by annotators at any moment using the session control feature provided by the tool. Figure 1 presents the distribution of averaged grades assigned by annotators to all the sampled performances. Nearly half (38) of evaluated performances had unanimous assessments while the rest of them presented some deviations (mean: 0.49, max: 0.97).

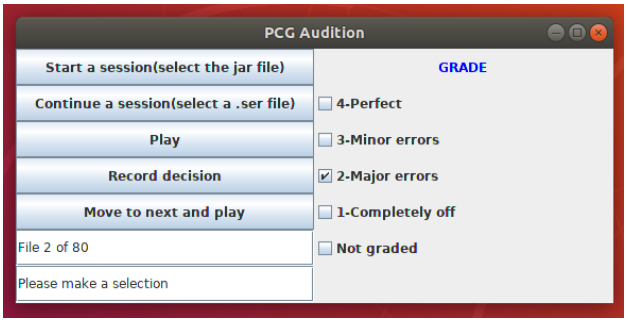

Figure 2. Annotation tool used during the custom evaluation sessions

4. DATA PREPARATION

The detection of rhythmic events is an issue recurrently addressed via extraction of onset times from raw audio [6–8]. Onset features are primarily encoded as onset vectors containing the moments when signal-disturbing events (e.g. chord attack, drum kick) happen. Multiple similarity measures have already been proposed for the comparison of onset vectors, including distance between vectors [18] and error measures [15]. In this present work we propose a hybrid model that benefits from both aforementioned similarity measures to predict rhythmic assessments.

For the onset detection, our audio processing module relies on the *OnsetDetection* algorithm implemented by the Essentia library [3] [1]. All references and performances comprised by the re-annotated subset were sampled at a rate of 44.1kHz and the resulting frames were provided to the onset detection algorithm to allow for feature extraction. The onset extractor is parameterized with default values (window size: 1024 samples, hop size: 512 samples) and three methods for onset extraction are tested and compared: High Frequency Content detection (HFC) [11], Spectral Flux detection (FLUX) [19] and Complex-Domain spectral difference (COMPLEX) [2].

The recordings in the dataset are not aligned in time, nor cropped with a fixed offset before/after the first/last onset. Hence the first and the last onset are considered as boundaries of each performance. For the use of vector distance measures applied to same-sized vectors, binary vectors are

[1] https://essentia.upf.edu

computed applying a fixed-numbered (60) grid on the time axis (i.e. for each recording, the duration between the first and last onset is divided into 60 time bins and a binary value (onset/non-onset) is stored in the vector for each bin). We opted for 60 bins for each rhythmic performance, since this number is divisible by two, three, four, five, and six, which are the common multipliers for most rhythmic patterns.

Figure 3 presents an example of a visual representation for onsets times before and after the quantizing procedures that we have just described. The relative positions for the original onsets are plotted in dashed lines and circle stems, while the quantized information is drawn in solid lines and triangle stems. All the quantized, unquantized onsets and scaling information are also included into the re-annotated dataset for further use.

5. BASELINE ASSESSMENT SYSTEM

This work introduces a baseline automatic assessment system for rhythmic performances of students. Regression models are trained with vector similarities aiming at the modeling of the rhythmic evaluations detailed in the re-annotated subset.

The feature set for both models described below includes eight different similarity measures: two strictly related to the rhythmic domain (beat difference and Percival's similarity [15]), four text-distance approaches (Levenshtein, Damerou-Levenshtein, Jaro and Jaro-Winkler) and two vector-distance measures (Hamming and Yule). This last subset of features was selected according to their reported benefits in comparing vector with boolean data [5]. Since the nature of these measures resulted in different distance ranges, all features were normalized in order to range within a common scale.

Two different types of evaluations are targeted by the proposed assessment systems. A grade estimation is implemented through a linear regression model while categorizations between *pass/fail* classes are predicted by a logistic regression classifier. The overall 'true' grade of a performance is calculated via removing the highest and lowest grades and averaging the rest, which is an approach similar to the one usually applied in music conservatories. Binary categorization is modeled by judging as accepted (*pass*) all performances whose average grades are greater than or equal to three, rejected (*fail*) otherwise.

All machine learning implementations are written in Python 3.6.7 using scikit-learn [2] modules.

6. RESULTS

Both mentioned datasets are now made publicly available for further investigation. The complete rhytmic dataset (MAST rhythm dataset) [3] is a collection of 3721 audio files cropped from recordings of conservatory entrance examinations in Turkey (summer 2015 and summer 2016). 1040 of the recordings are student performances graded by a jury of 3 instructors as pass or fail. The rest of the recordings are jury performances of the same rhythmic patterns in various sessions. The re-annotated subset (MAST rhythm re-annotated subset) [4] is a balanced sample (in terms of pass-fail graded samples) extracted from the complete dataset, assessed by seven annotators in a 4-level grid and onset information for 80 performances, accounting for 20 distinct rhythmic patterns (references). All the code supporting the implementation of our automatic assessment systems is also shared as Jupyter notebooks at Github [5].

Classifier	Ac.	Pr.	Rc.
Logistic Regression (FLUX)	63%	66%	83%
Logistic Regression (COMPLEX)	72%	75%	83%
Logistic Regression (HFC)	**76%**	**79%**	**78%**

Table 1. Performance measures (accuracy, precision and recall) for classifiers trained with different onset features

The designed models are evaluated according to how well they predict assessment for unseen test data. Our evaluation relied on a 5-fold cross validation (test size: 20%) for both models. The performance results for the logistic classifier are summarized in the learning curves shown in Figure 4 and states a maximum accuracy of 76% when trained with HFC data. The complete comparison stating accuracy, precision and recall results from various onset features can also be examined in Table 1.

For the linear grade estimator, the performance analysis consisted of measuring the errors observed between the predicted grades and the expected values. Our estimator was compared with baseline naive versions whose projected evaluations are modeled using uniform and random distributions. Results are summarized in Table 3 and indicate that our approach provides better predictions (yet with a small margin) than the naive estimators regardless of the trained feature, with HFC once again delivering the best performance. As for the influence of specific features over the decision function, the coefficients suggested by the linear regression (Table 2) encourage us to infer that Jaro, Jaro-Winkler and Hamming distances are the features whose influences are higher over grading predictions.

Our final evaluation is carried out by crossing data from the two proposed datasets. Models trained with sampled data from the re-annotated dataset were provided with all performances coming from the complete dataset in order to verify how well the trained assessment systems would behave when asked to predict evaluations for new unseen data. All the 1040 performances comprised by the full dataset were submitted to the same pre-processing steps described in Section 4 and the resulting similarity measures were tested against both the logistic classifier and linear estimator trained with HFC features (since it's the extraction method that delivers the best performance). Here accuracy is calculated according to the number of predic-

Table 3. Comparison between error measures (Mean Average Error, Mean Squared Error and R-squared) observed in predictions for naive estimators and proposed model trained with different features

tions matching the jury evaluations (*pass/fail*). Final results report a matching rate of 65% for the binary predictions while the grade estimator guessed the right class for 70% of the unseen data.

7. CONCLUSIONS

The present study is an attempt to address the lack of data sources designed for automatic rhythmic assessment. Student performances for a set of rhythmic patterns were recorded and evaluated by a jury during entrance exams conducted in a music conservatory. An additional data annotation step was also carried out with seven annotators, this time grading a subset of these performances with grades ranging from one to four. The re-annotated subset trained an automatic assessment system able to predict

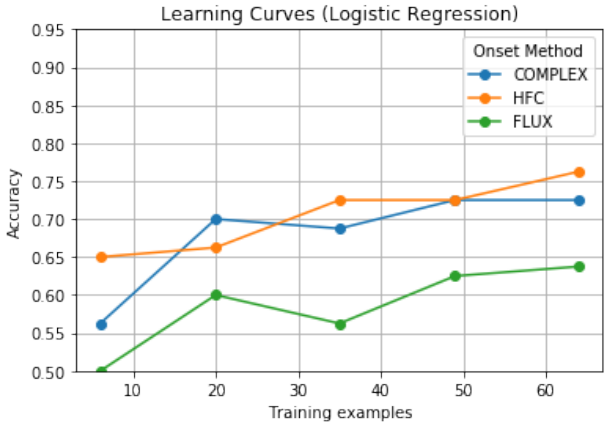

Figure 4. Learning curve for the *pass/fail* logistic classifier

students evaluations for rhythmic tasks. Models delivered a maximum accuracy of 76% for a binary (*pass/fail*) classifier and presented a minimum mean average error of 0.59 when predicting grades in a linear fashion, also pointing to Jaro, Jaro-Winkler and Hamming distances as the best model predictors. When compared with the data remained from the re-annotation process, the baseline assessment system predictions matched the jury-labeled data in about 70% of the cases.

All the aforementioned artifacts are now made public for further investigation. Both the full dataset and the re-annotated subset can be freely accessed and used to support assessment systems that builds on more sophisticated techniques to predict student grades for rhythmic lessons. Besides, the proposed implementation is also made available as Jupyter notebooks that can be examined and used as baseline in comparative studies.

8. ACKNOWLEDGEMENTS

This work was conducted during a visiting scholar period at Universitat Pompeu Fabra, sponsored by the Capes Foundation within the Ministry of Education, Brazil (grant n. 88881.189929/2018-01). The dataset was collected during a project funded by the Scientific and Technological Research Council of Turkey, TUBITAK, Grant [215K017].

ABSTRACT

Neural networks have been used to learn a latent "musical space" or "embedding" to encode meaningful features and provide a method of measuring semantic similarity between two musical passages. An ideal embedding is one that both captures features useful for downstream tasks and conforms to a distribution suitable for sampling and meaningful interpolation. We present two new methods for learning musical embeddings that leverage context while simultaneously imposing a shape on the feature space distribution via backpropagation using an adversarial component. We focus on the symbolic domain and target short polyphonic musical units consisting of 40 note sequences. The goal is to project these units into a continuous low dimensional space that has semantic relevance. We evaluate relevance based on the learned features' abilities to complete various musical tasks and show improvement over baseline models including variational autoencoders, adversarial autoencoders, and deep structured semantic models. We use a dataset consisting of classical piano and demonstrate the robustness of our methods across multiple input representations.

1. INTRODUCTION

Music is inherently complex. A single motif can be described along a multitude of dimensions. Some of these dimensions may describe the motif in broad terms and capture properties that offer a more aggregate representation including tonality, note density, complexity, and instrumentation. Others may consider the sequential nature and temporal facets of music such as syncopation, harmonic progression, pitch contour, and repetition. While these features may describe specific attributes about the music, they are intrinsically related and when combined can be used to predict or classify higher level musical descriptors such as genre, style, or even mood and emotion.

In recent years, neural networks have been used to learn a low dimensional latent "musical space" or "embedding" to encapsulate such features and provide a method of measuring semantic similarity between two musical passages [26]. Ideally, the embedding $f(x) \in \mathbb{R}^d$ for a passage x is learned such that the Euclidean distance $D_{i,j} = ||f(x_i) - f(x_j)||^2$ between two passages describes their semantic relationship. For the task of autonomous music generation learning this space effectively is important in order to influence the generator such that its outputs conform to human expectations. This is particularly true in interactive applications where a machine's response is typically conditioned on a human performer. Thus, an effective embedding is one that is capable of interpreting music in a manner which correlates with human perception.

Previously, musical embeddings have been learned using restricted boltzman machines (RBMs) [9, 22, 27], autoencoders (with various denoising techniques) [2, 3], siamese network models [4,13,23], word2vec models [11], and sequence prediction models [1, 6, 18]. Variational autoencoders (VAEs) have also demonstrated some success with monophonic inputs [25]. VAEs learn a normally distributed latent space which has shown to make sampling and embedding manipulation more effective [15]. Though VAEs are useful for constraining the statistical properties of the learned space, it has also been shown that, like word embeddings in language, improved features can be learned when networks are trained to reconstruct the context. The resulting features perform well on prediction and composer classification tasks [2].

An ideal embedding is one that both captures useful features and conforms to a distribution suitable for sampling and meaningful interpolation. In this work, we present two methods for learning musical embeddings. The methods leverage context and simultaneously impose a shape on the feature space distribution via backpropagation using an adversarial component. We focus on the symbolic domain and target short musical units such as a three second clip or a sequence consisting of a small of number notes. The goal is to project these units into a continuous low dimensional space that has semantic relevance. We evaluate relevance based on the learned features' abilities to complete several music-related tasks. We use a dataset consisting of classical piano and demonstrate that it is possible impose a prior distribution on the embeddings while maintaining the quality of the features.

2. RELATED WORK

One possible scenario for learning a space which encodes semantic similarity is to explicitly label pairs of musical units as being similar and train a model in a supervised fashion, thus, pulling units labeled as similar closer together and pushing non-related units further apart in the latent space. This type of metric learning can be effective, however, the requirement for constructing such a dataset makes it challenging. In this work we focus on self-supervised methods that don't require explicitly labeled data.

RBMs, autoencoders, and prediction are all examples of self-supervised learning paradigms. They rely on what is readily available in the data to serve as a proxy to human labeled data, thus, autonomously constructing the supervising signal. Many of the methods have been inspired from the natural language processing community including skip-gram and language models [20]. For example, both [11] and [18] used skip-gram inspired techniques to embed chords. The learned tonal space had similarities to the circle of fifths. Context is also leveraged in [4] where a Deep Structured Semantic Model (DSSM) is used learn one, two, and four bar embeddings [12]. Such siamese network techniques have proven useful for learning semantic similarity in language. In [21] labeled pairs were used to train siamese networks to effectively learn sentence similarity. A pairwise ranking loss was similarly used for the task of hit song prediction [30].

RBM and autoencoder methods don't leverage context, but have still demonstrated the ability to learn good features compared to manually designed features. This is particularly true in the audio domain [9, 16, 29]. In [7] autoencoders were used to learn a latent space encoding timbre. Autoencoders are particularly useful because they inherently support contain a generative component and if learned effectively the embeddings can be manually manipulated for interactive applications [3]. VAEs, in particular, have shown promise and utility for music because the latent space is regularized in a manner that makes sampling and manipulation more convenient and meaningful [15, 24, 25].

The methods in this work are inspired by adversarial autoencoders [19]. Like VAEs, the goal of this type of autoencoder is to constrain the latent codes to some arbitrary prior distribution. However, instead of using a KL-divergence penalty, the autoencoder incorporates an adversarial method to train the distribution of the latent codes to match that of the prior distribution.

While both VAEs and adversarial autoencoders are useful for generation, it has been shown that autoencoder features are not as effective for downstream tasks compared to methods that include context or prediction [2]. In this work we propose a solution that computes a pairwise loss based on context and includes an adversarial component to regularize the latent space.

3. METHODS

We present two methods. At a high level the embeddings of semantically similar units should be geometrically closer in the latent space than units that are dissimilar. For each method the objective is to learn a space that achieves this by leveraging context while adhering to a predefined distribution. In lieu of explicitly labeled data we train the networks using the assumption that two adjacent units (i.e. two adjacent measures in a composition) are related. In other words the distance between two adjacent units should be smaller than two random units in the database.

3.1 Adversarial DSSM

Our first method is a modified implementation of the DSSM. If $q(z)$ represents the aggregated posterior distribution of all the embeddings of length d generated by the DSSM $f(x)$ for $x \in X$ then the goal here to is match $q(z)$ to a prior distribution $p(z)$ we define as $z_i \sim \mathcal{N}_d(\mu, \sigma^2)$ where $\mu = 0$ and $\sigma^2 = 1$. This is achieved by connecting a discriminator to the last layer of the DSSM as shown in Figure 3. This discriminator is trained adversarially in coalescence with the generator which also happens to be the DSSM itself.

The standard DSSM training procedure is well-suited for metric learning as it explicitly trains parameters to produce embeddings that are closer together (according to a distance metric) for related items while pushing non-related items away. However, the number of negative examples and the ratio of easy to hard examples is usually greatly biased towards the easy-end. This often produces poor performance since many examples can satisfy the constraint with a very small loss that provides no real meaningful update during backpropagation [5]. This typically leads to high inter-class and low intra-class variance making fine grained categorization or meaningful similarity measures (important for music) challenging or impossible.

To address this problem a bootstrapping method was used in [5] in which particularly difficult examples were manually mined from the dataset and used during different stages of training. In this work, the adversarial component naturally helps to mitigate this problem by enforcing the prior distribution. The network parameters must find a way to achieve the desired similarity metric, but adhere to a distribution that does not allow for a learned space in which most examples can easily satisfy the similarity constraint.

The adversarial DSSM is trained in two stages: 1) Using the standard DSSM technique compute a softmax loss with negative examples and 2) Using the adversarial network train the generator and discriminator so that the generator is trained to produce embeddings that look as if they have been sampled from the predefined distribution $p(z)$. Thus, the parameters are being optimized according to two different losses with one learning the similarity metric and the other learning to describe the data such that the aggregated posterior distribution of the embeddings are Gaussian and continuous.

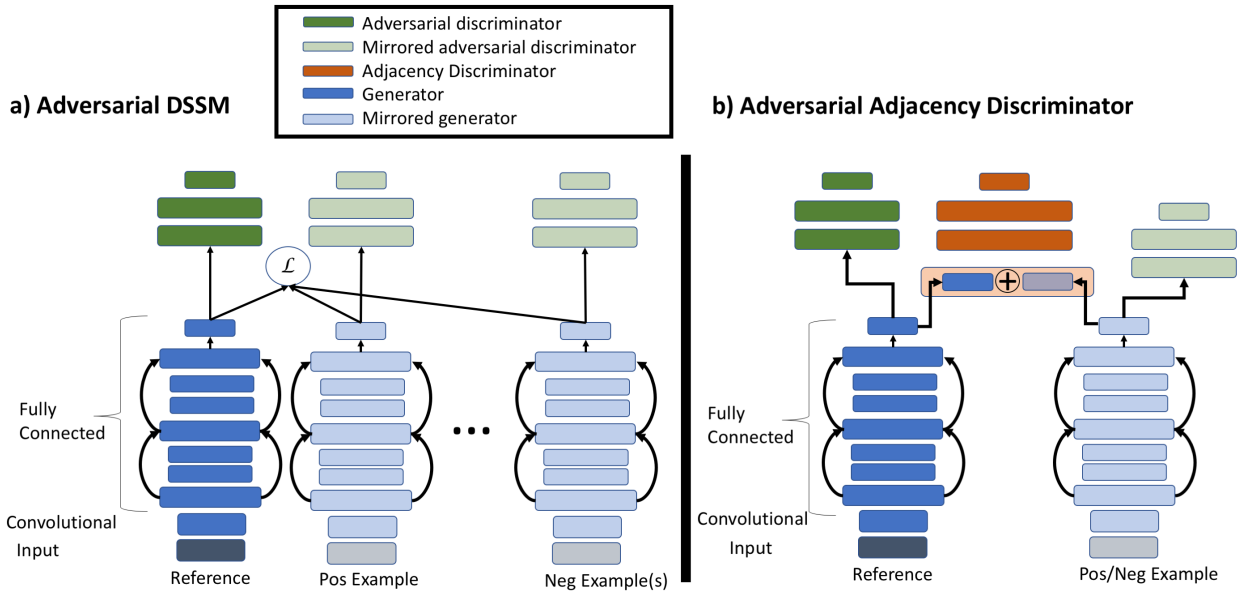

Figure 1. Architectures for a) Adversarial DSSM and b) Adversarial Adjacency Model

For the first part the network is trained using Euclidean similarity.

$$sim(\tilde{X}, \tilde{Y}) = \frac{1}{1 + D(\tilde{X}, \tilde{Y})} \tag{1}$$

Negative examples are included in a softmax function to compute $P(\tilde{R}|\tilde{Q})$ where $\vec{R}$ is the reconstructed vector and $\vec{Q}$ is the input vector.

$$P(\tilde{R}|\tilde{Q}) = \frac{\exp(sim(\tilde{Q}, \tilde{R}))}{\sum_{\tilde{d} \epsilon D} \exp(sim(\tilde{Q}, \tilde{d}))} \tag{2}$$

The network learns the parameters by minimizing the following loss function using gradient descent:

$$\mathcal{L} = -log \prod_{(Q,R)} P(\tilde{R}|\tilde{Q}). \tag{3}$$

For the second part generative adversarial network (GAN) training procedures are used [8]. First, the adversarial discriminator is trained to distinguish between the generated embeddings and vectors sampled from $q(z)$. Second, the generator (also the DSSM or $f(x)$) is trained to fool the discriminator. We use a deterministic version of the GAN where stochasticity comes solely from the data distribution. In other words no additional randomness is incorporated.

Training alternates between the DSSM and GAN procedures until Eqn. 3 converges. We found that a higher learning rate for the GAN procedures (particularly for updating the generator) relative to the DSSM loss was necessary in order to get the desired results. Otherwise, the GAN based updates had very little to no effect resulting in a model with a very similar behavior to the vanilla DSSM without the adversarial component.

3.2 Adversarial Adjacency Model

The second method we propose is also inspired by siamese network paradigms. However, unlike the DSSM, the embeddings are not directly optimized for the desired metric. Instead, a classifier is trained to determine whether two units are related or not. Though, because we use adjacency as the self-supervising surrogate signal in lieu of manually designed similarity labels the classifier is really being trained to determine whether two units would be contiguous or not in a composition.

A simple version of this classifier would concatenate *both* units into a single input and be trained to produce a binary classification from this concatenated vector. Our goal, however, is to be able to embed a *single* unit and having a network which requires two units as input would prevent this. Therefore, we use tied weights in which the lower layers of the network are identical and the embeddings are not concatenated until several layers deep into the network (see Figure 3). In other words the two inputs are embedded independently, but use the same parameters to do so.

A much smaller classifier is attached to the top of the concatenated embeddings to discriminate between related and non-related inputs. By using only a couple layers to perform the actual discrimination most of the good features for classification will need to be learned by the embedding portion. This enforces the network to embed an input in a manner that not only efficiently encodes itself, but also can effectively distinguish itself from unrelated inputs. Our thinking was that hopefully the network would achieve this by embedding related units closer together. (Note, for ease of comparison the architecture of the embedding network here is identical to the DSSM network in the previous section).

Like the previous method we attach an adversarial component to the end of the embedding portion of the network. The goal is the same in that the aggregated posterior distribution of the embeddings should conform to a predefined distribution. The model is trained in two stages: 1) Train the classifier to discriminate between related and non-related inputs and 2) Train the embeddings to fit a

prior distribution using the GAN scheme. Therefore, the embedding portion of the model is updated during both stages.

For the first part the classifier is trained using cross entropy with two classes (related and non-related).

$$-\sum_{c=1}^{M} y'_c \log(y_c) \tag{4}$$

where $M = 2$, y' is the predicted probability and y is the ground truth. The GAN portion is trained similarly to the previous method. We found that this method was inherently more stable than the previous method and much less tuning of the learning rates between the two losses were necessary.

4. EXPERIMENTS

In order to test the various networks and training procedures we used a collection of piano compositions from 27 artists. The distribution of compositions among artists is depicted in Table 4. At least two songs from each artist were held out for testing. We augmented the data by transposing each piece into all keys. This also prevented the networks from simply learning the bias any composers might have had for specific key signatures. We also augmented the data by altering the tempo randomly within a range of .95 to 1.05 of the original.

Table 1. Piano Music Dataset.

4.1 Baseline Models

We compare our methods against four baseline models for a total of six methods:

1. Variational autoencoder (VAE)
2. Adversarial autoencoder (AAE)
3. Deep structured semantic model (DSSM)
4. Adjacency Discriminator (AdjD)
5. Adversarial deep structured semantic model (A-DSSM)
6. Adversarial Adjacency Discriminator (A-AdjD)

4.2 Input Representation

Often performance of a music-based model is ultimately determined by the input representation of the data. Therefore, we test our system using two different input representations.

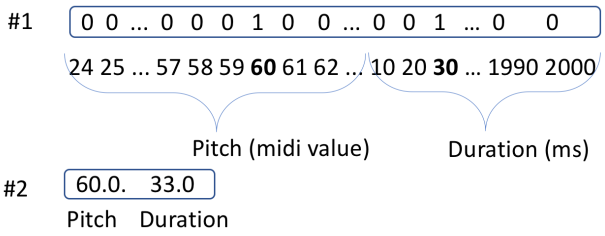

Figure 2. Two representations for encoding middle 'C' (midi note 60) and a 33ms interval to the next pitch. Input representation #1 uses a two-hot encoding that discretizes time in 10ms chunks. Input representation #2 uses a single floating point value for both pitch and time.

The first representation is inspired by Google Magenta's event based method [28] in which each event is one-hot encoded. Because much of the data does not include relevant volume information we do not include it in our representation. We also use only the onset time and use a fixed duration for each note, therefore, it is not necessary to include note off events. This was primarily to simplify the input space and attempt to better interpret the results. Pitch is represented in a one-hot manner on a vector representing midi values 24 to 96. We encode intervals between pitch events discretely in 10ms intervals from 0 to 2000ms, thus, the time portion of the vector consists of 200 values. The single vector for all possible events including pitch and interval has a length of 272. A two-hot encoding method is used so both the pitch and interval before the next pitch is encoded using the 272 values (see Figure 4.2).

The second representation is much less conventional. We represent both pitch and time intervals continuously. The pitch of a note is represented by a single floating point value determined by its midi value and the interval between notes is also represented by a single floating point value determined by the number of milliseconds. Therefore a vector for a single event only has a length of two (4.2).

On the surface, this continuous pitch representation does not make a lot of sense as the Euclidean distance in this space does not really translate to pitch distances

that are particularly meaningful in Western music or piano. An autoencoder trained to reconstruct this input using a Euclidean-based loss is unlikely to learn many relevant musical features. However, the two methods proposed in this work do not compute the loss in the original space. The adversarial DSSM optimizes the latent space by computing the loss directly on the embeddings and the adversarial adjacency model optimizes the latent space through a classification task using a cross entropy loss. Therefore, we hypothesize that our methods should be more robust against varying input representations compared to models that compute a loss in the original space (e.g. autoencoders). Additionally, a method that is robust when using this representation can be useful for styles of music or particular instruments in which continuous pitch representations are more appropriate.

In this continuous representation the pitches and intervals are standardized to a mean of zero and standard deviation of one. In our experiments we did not find a difference in our final results when compared to using non-standardized input vectors, however, the learning was faster using standardized vectors.

We focus on short musical units consisting of exactly 40 notes. This means that the input vector to the network using the first representation has a length of 10880 (40 * 272). The input vector using the second representation has a length of only 80 (40 pitches and 40 intervals). Forty notes was chosen because it provides enough content to capture local structure, yet, the vector length using the first representation is not overwhelmingly large.

4.3 Architectures

The first layer of the network is convolutional using a filter with an input length equivalent to a vector containing one note and one interval (i.e. 272 for the first representation and 2 for the second). The filter is convolved over the entire vector using an equivalent stride length (272 or 2), thus, the filter learns to encode a single pitch and interval. After this initial convolutional layer all remaining layers are fully connected.

For each method the portion of the network which performs the embedding is the same aside from marginal differences in the number of parameters for the first convolultional layer between the two representations. The network encodes the input into a 32-dimensional vector. Each network has eight layers between the final embedding and input vector and uses residual connections [10] as depicted in Figure 3.

It is plausible that higher capacity networks (both wider and deeper) may improve results further, however, the primary objective in this work is to compare various training methods and not architectures. We designed this architecture because it allowed us to leverage the utility of deep learning and specific techniques (e.g. convolution, residual connections, etc.), yet, it is not too large that training time would become problematic during experimentation. Each layer uses LeakyReLU and the parameters are updated using Adam optimization [14, 17].

4.4 Experiments

We perform five different experiments based on music-related tasks. Performance on these tasks will be used to determine the efficacy of the learned latent space and features for the various models.

Ranking The primary measure for evaluation is based on a ranking task. Given a reference unit and a group of 100 units consisting of 99 random units from the database and one unit that is adjacent to the reference (either before or after) the task is to rank all 100 units according to their Euclidean distance to the reference in the latent space. This is repeated for each unit in the test set and a mean rank is reported where the a lower rank indicates a higher similarity. The assumption is that adjacent units should be geometrically closer in the latent space relative to non-adjacent units.

Composer Classification We evaluate how useful the learned features are for classifying the units according to their composers. Using the embeddings as inputs we train a simple two layer network to perform classification. In the test set there are 27 possible composers. Though works by these composers are seen during the training phase, the test set consists of unique compositions that were not available during training.

Pitch Chroma Prediction We evaluate whether the embedding retains enough information about the input units to reconstruct a unit's chromagram representation. We train a two layer network to minimize a softmax function (Eqn. 3) over cosine similarity. Thus, in Eqn. 2 we replace the Euclidean similarity (Eqn. 1) with $sim(\tilde{X}, \tilde{Y}) = \frac{\tilde{X}^T \cdot \tilde{Y}}{|\tilde{X}||\tilde{Y}|}$. The positive example is the true chroma extracted from the unit computed directly from the original input vector. Negative examples come from chroma extracted from random units in the data.

Note Density Regression We evaluate whether the embedding retains enough information about the input units to describe their note density. Because we use a fixed number of notes per unit the network is trained to predict the unit's duration in seconds. We use root mean square error (RMSE) to measure performance.

Forward Prediction We evaluate whether a sequential model can be trained to predict the embedding of the next unit in a composition given a sequence of the previous seven units. This task is related to the first Ranking task, but focused on generation and prediction rather than general distances in the learned manifold. We train two stacked LSTM cells, each with 200 units, to predict the next step of a sequence. Specifically, at each time step, the input to the network is a the 32-dimensional embedding vector of a 40 note unit x_i. We train this network to predict the 8^{th} unit, x_{i+7} given the previous 7 units $x_i, z_{i+1}, \ldots x_{i+6}$. This means that 280 notes of context are provided before the prediction is made.

For each given target x_{i+7} as described above, we create a set of 32 embedding vectors: one is $f(x_{i+7})$, the true embedding for the target. The other 99 vectors are embeddings of randomly selected units in the data set. The Euclidean distance is measured between the output of the

LSTM and the encodings of each unit. The distances are then sorted and ranked similarly to the first Ranking experiment.

5. RESULTS

The results for each experiment are reported in Tables 2-6.

5.1 Discussion

The vanilla DSSM performed relatively poorly on all tasks except for note density regression. Without the adversarial component it learns the most significant feature (in this case note density in time), yet, fails to learn much more beyond this. By fitting the latent space to a prior distribution, the adversarial component seems to do what it was designed for – preventing the model from satisfying the similarity constraint without actually learning too many meaningful features.

Our adjacency discriminator model worked reasonably well even without the adversarial training. We found that without the adversarial component the latent embeddings were naturally fairly close to a Gaussian distribution, thus, adding an adversarial discriminator had much less of an effect than when used with the DSSM. Though the additional fine tuning did improve performance across the tasks albeit marginally.

Finally, the differences in performance for the two input representations were much less pronounced for our methods. This suggests our proposed methods (the Adversarial Adjacency Discriminator in particular) may be useful for non-Western music and instruments capable of continuous pitch spaces.

6. CONCLUSION

In this work we described new approaches to self-supervised metric learning. The learned features showed improved results on downstream tasks over various baseline methods. Most importantly, the quality of the features were either improved or maintained when imposing a prior distribution on the embeddings. The next steps for this work are to: 1) develop decoders from the latent spaces learned from our methods and 2) measure the perceptual significance of the learned space.

ABSTRACT

In this paper, we introduce a method for converting an input probabilistic piano roll (the output of a typical multi-pitch detection model) into a binary piano roll. The task is an important step for many automatic music transcription systems with the goal of converting an audio recording into some symbolic format. Our model has two components: an LSTM-based music language model (MLM) which can be trained on any MIDI data, not just that aligned with audio; and a blending model used to combine the probabilities of the MLM with those of the input probabilistic piano roll given by an acoustic multi-pitch detection model, which must be trained on (a comparably small amount of) aligned data. We use scheduled sampling to make the MLM robust to noisy sequences during testing. We analyze the performance of our model on the MAPS dataset using two different timesteps (40ms and 16th-note), comparing it against a strong baseline hidden Markov model with a training method not used before for the task to our knowledge. We report a statistically significant improvement over HMM decoding in terms of notewise F-measure with both timesteps, with 16th note timesteps improving further compared to 40ms timesteps.

1. INTRODUCTION

The ultimate goal of the task of Automatic Music Transcription (AMT) is to convert an audio signal into some form of human- or machine-readable music notation [2]. This process is divided into two main steps. First, an acoustic model performs multi-pitch detection by converting an input acoustic signal into a *posteriogram*: a pseudo-piano roll matrix which contains the probability of each pitch being present at each timestep according to the acoustic model. Next, a music language model (MLM) is used to enforce some musicality on the results, converting the posteriogram into a human-readable format.

While it is desirable to run these two models jointly—and some systems have been designed in such a way with success, either with relatively simple MLMs (e.g., [19,20]), or for performing a simpler task than AMT (e.g., chord detection [15])—the search space and resulting computation quickly becomes too large to be feasible for more complex probabilistic MLMs which explicitly model musical structure (e.g., [22]). Furthermore, such MLMs have typically been designed to take as input MIDI (or MIDI-like) data which consists of lists of musical notes, rather than the typical posteriogram output of acoustic models.

However, the conversion of a posteriogram into MIDI is not a trivial task, and has not been the focus of much research until recently. A naive approach is simple thresholding of the posteriogram, and a simple two-state (on/off) HMM has also been proposed [17]. Some more sophisticated models have attempted to use neural networks as implicit MLMs to incorporate some prior musical knowledge into their systems (e.g., [21,24]), but often, they bring only modest improvement [21] or the MLM is only used in rare occasions [24] (see Section 2 for a more complete discussion on these and other related systems). The main issues that we identify with these previous attempts to incorporate MLMs are (1) the MLM fails to capture musical features because of an inappropriately short timestep which overemphasizes self-transitions [25], and (2) the MLM is not robust to noise during decoding.

Our main contributions are to:

1. compare the use of a musically-relevant timestep for MLM decoding—specifically a 16th note, as recommended in [25]—to the more standard 40ms.
2. train the MLM with scheduled sampling [3], making it more robust to noise at test time.
3. propose a novel "blending" model which dynamically merges probabilities from the acoustic model and the MLM rather than using a simpler method such as a linear combination.
4. describe a new training method for a previously-proposed post-processing HMM [17], leading to a significant improvement in F-measure over the standard maximum likelihood approach.

For contribution (1), note that in a realistic setting, using a 16th note timestep would require a beat-tracking algorithm. However, in this proof-of-concept experiment, we consider 16th note locations as given, and leave the integration of a noisy 16th note timestep for future work. It should be noted that a 16th note timestep was already investigated in [27] for polyphonic sequence transduction, which concluded that although an improvement is observed when using 16th note timesteps, it is attributed only to the fact

*Authors 1 and 2 contributed equally to this work.

that the resulting outputs are quantized to the ground truth metrical grid. By contrast, we show here that a 16th-note MLM brings improvement for language model decoding beyond quantisation of the output.

We conduct our experiments using a state-of-the-art piano-specific acoustic model [13] (although our system could be applied to a variety of musical instruments and styles). Overall, we show that our full system with the 16th note timestep, scheduled sampling, and the blending model, leads to a significant improvement in F-measure over both the baseline and the proposed HMM, with identical timesteps.

2. RELATED WORK

The most basic strategy for binarizing time-pitch posteriograms is simple thresholding, where outputs below some value are set to 0 while all others are set to 1 (e.g., in [9, 11, 13]). Slightly more sophisticated is to use a two-state (on/off) HMM for each pitch (proposed in [17], used in, e.g., [6, 7]), where results tend to be cleaner with fewer spurious notes using this method. Still, the musicality of such a model is limited, as it considers each pitch independently, and does not consider more than one previous frame for each transition.

Recently, deep learning methods have also been used for this task, typically using some form of RNN. They can be broadly grouped into performing one of two tasks: transduction or language model decoding.

Transduction methods aim to convert one sequence of symbols into another (here, the output of an acoustic model into a binary piano roll). Examples include [5], which uses an architecture combining an RNN with a Restricted Boltzmann Machine (RBM), and [27], which investigated the performance of an LSTM-based model. One drawback of transduction methods is that they require aligned MIDI and audio recordings for training. Similarly, they are trained on one specific acoustic model's outputs, and do not necessarily generalize to other acoustic models.

With *language model decoding* methods, an MLM is trained to assess the likelihood of an output sequence. Importantly, such a model is trained on symbolic data, independent of any acoustic model. For example, [21] uses an RNN-RBM as a language model, combined with various neural acoustic models. Similarly, [24] uses an RNN-RBM language model, but instead of using a fixed framerate, it operates on frames corresponding to detected inter-onset-intervals. Our method belongs to this second category of language model decoders, with the caveat that one component of it, the blending model, requires training on aligned pairs of input and output, though much less than would be needed to train a neural transduction model.

As mentioned, using an MLM has brought only limited improvement to the performance of AMT systems in the above studies. One reason for this lack of substantial improvement in [21] might be the use of an inappropriate timestep for language modelling: the MLM operates on 32ms timesteps, a duration much shorter than the typical duration of a note, and unrelated to the tempo of the piece being analyzed. Indeed, [25] hints at the fact that for polyphonic music sequence prediction, using a small time-step only results in a smoothing effect due to the predominance of self-transitions, and using a musically-relevant time step such as a 16th note allows the network to learn more interesting musical properties. To that end, [24] describes an MLM which uses note-based timesteps. However, the MLM was only used in the rare case that a note onset was detected without a corresponding pitch. Using the MLM over the whole note sequence resulted in decreased performance over simple thresholding, possibly due to the discrepancy between training using perfect inputs and decoding noisy sequences (this issue was also noted in [21]).

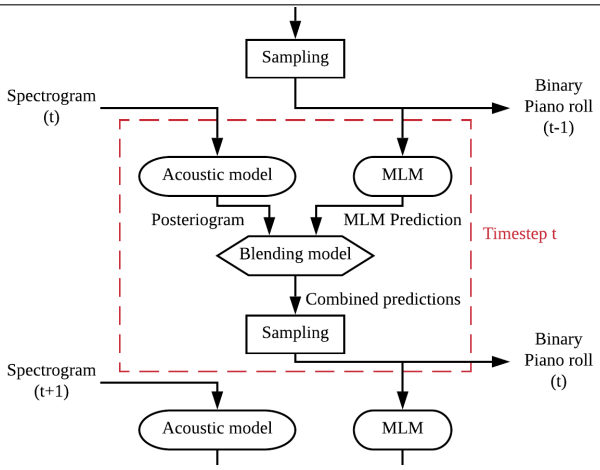

Figure 1. The proposed system.

3. PROPOSED SYSTEM

Our system takes as input a probabilistic piano roll, specifically the output of the acoustic model from [13]. That model is a CNN which takes as input a spectrogram with logarithmically-spaced frequency bins and log-magnitude with a timestep of 40ms, and is a benchmark acoustic model for piano transcription.

Our system's inputs are in the form of matrix $I \in \mathbb{R}^{N_p \times T}$, where T is the length of the input in frames, $N_p = 88$ (one row per key on a piano keyboard), and each element $I_{p,t}$ contains the probability of a pitch p being present at frame t. Our output is the binary matrix $O \in \{0,1\}^{N_p \times T}$, where $O_{p,t}$ is 1 if pitch p is present at frame t, and 0 otherwise.

Our system flow is shown in Fig. 1. It consists of two main components: an LSTM-based language model (see Section 3.1), which predicts the presence of each pitch at a frame given the previous frames; and a blending model (see Section 3.2), which combines the input acoustic prior with the LSTM's priors at each frame, and outputs a final combined probability distribution over pitches at each frame. The search process for finding the most probable output according to our system is detailed in Section 3.3.

3.1 Language Model

The language model has the same architecture as described in [25]. It is a single-layer LSTM, with a hidden layer of

size 256 and sigmoid outputs of size N_p. It is trained to predict which pitches might be present in the next frame of a binary piano roll, given all the previous (binary) frames, using cross-entropy between the output of the network and the actual next frame as training loss. Two different MLMs were trained, one operating on 40ms timesteps, and one on 16th note timesteps. We use $L_{p,t}$ to denote the MLM's output corresponding to pitch p at frame t.

During a typical training procedure, the input sequences from which the network learns are taken directly from the ground truth. Such an MLM learns to make prediction based only on perfect musical sequences. However, during inference, the MLM must make predictions based on potentially noisy sequences, as input frames are obtained from previous predictions and noisy acoustic multi-pitch detections. This discrepancy hinders performance of MLMs, as noted in [21] and [24]. To solve this problem, we use scheduled sampling [3]: during training, at each timestep, instead of always using the ground-truth frame, we randomly choose either the ground-truth frame (with probability p_{GT}), or a frame sampled from predictions made by the MLM at the previous timestep. Training starts with $p_{GT} = 1$, and p_{GT} is decreased as training progresses, allowing the MLM to progressively become more robust to noisy inputs and recover from previous mistakes.

One limitation is that the noise the MLM adapts to is not the same the MLM sees at test time, since samples are drawn using the acoustic model's outputs as well at test time. We could sample from a distribution that does the same during training, but we choose not to, because (1) [3] mentions that even adding uniform noise helps performance, so exactly matching noise distributions is less important, and (2) this would require paired audio and MIDI data for MLM training (as acoustic model predictions must be made from audio), which is available in smaller quantities than MIDI data alone.

3.2 Blending Model

The intuition behind the blending model is that the MLM and the acoustic model might each perform better or worse in certain situations, so combining their probabilities with a constant weight may achieve poor results. The blending model's job is to learn the situations in which each model performs well, and output the combined prior for a pitch at a frame based on both the probabilities from the acoustic model and the MLM, as well as some surrounding context.

It is a feed-forward neural network with l [1] hidden layers with 5 nodes each followed by an output layer with a single sigmoid. For each pitch p at time t, it takes as input: (1) the acoustic and language priors at that pitch and frame ($I_{p,t}$ and $L_{p,t}$), (2) the sample history at that pitch for the previous $hist$ [1] frames ($O_{p,t'}$ for $max(0, t - hist) \leq t' < t$), and (3) nine additional hand-crafted features, described in Table 1, resulting in an input vector of length $11 + hist$.

The sample history allows the model to learn if there are certain situations in which the LSTM performs particularly well or poorly. Features 1–4 model how peaked the output distribution from each model is (and thus how certain it might be) but with different nonlinear properties. Features 5–6 model the expected polyphony, features 7–8 model how fast-changing each model's predictions are, and feature 9 allows the blending model to learn if either model performs better or worse for high or low pitches.

Feature	Description	Equation
1–2	Uncertainty	Eqn. (1)
3–4	Entropy	Eqn. (2)
5–6	Mean	$\sum_{p'<N_p} \frac{I_{p',t}}{N_p}$
7–8	Flux	$I_{p,t} - I_{p,t-1}$
9	Pitch	$\frac{p}{N_p}$

Table 1. The features used for the blending model. For equations written using I, the second feature is calculated identically with L.

$$\text{Uncertainty} = \sum_{p'<N_p} \begin{cases} (1 - I_{p',t})^2 & I_{p',t} > 0.5 \\ (I_{p',t})^2 & I_{p',t} \leq 0.5 \end{cases} \quad (1)$$

$$\text{Entropy} = \frac{1}{log_2(N_p)} \sum_{p'<N_p \wedge I_{p',t} \neq 0} -I_{p',t} log_2(I_{p',t}) \quad (2)$$

We create two versions of the blending model. First, a weight model (WM) which outputs a weight $w_{p,t}$, which is used to calculate a blended prior $P_{p,t}$ as a weighted sum: $P_{p,t} = w_{p,t} I_{p,t} + (1 - w_{p,t}) L_{p,t}$. Second, a prior model (PM) which outputs $P_{p,t}$ directly. The main difference between the two models is that WM can only ever result in a $P_{p,t}$ that lies somewhere between $I_{p,t}$ and $L_{p,t}$, while PM can always output any $P_{p,t}$ between 0 and 1.

3.3 Search Process

Since our model's search space has a branching factor of 2^{N_p} at each frame, we cannot perform a global search. Therefore, we use Viterbi decoding [23] with beam search using a beam of size b and a branching factor k. Specifically, at each frame, we save only the b most probable histories to that point. Then, for each of those at frame t, using the blending model's output distribution $P_{p,t}$, we sample the k most probable samples using Algorithm 2 from [5] (again saving only the top b from the $b * k$ resulting hypotheses). The sample at frame t is denoted S_t, and is a set containing the pitches active at that frame. The probability of a sample S_t, given the blended priors $P_{p,t}$ is:

$$P(S_t) = \prod_{p' \in S_t} P_{p',t} \prod_{p'<N_p \wedge p' \notin S_t} 1 - P_{p',t} \quad (3)$$

Beam search has the drawback that the beam can easily become saturated with only slight variations of the most probable hypothesis. Therefore, similar to [21] and [15], we use a hashed beam search. We consider any two hypotheses which are identical for the past h frames to be duplicates of each other for our purposes, and only save the most probable of them.

The final output O of our system is constructed using the sample history of the most probable state in the beam, such that $O_{p,t}$ is 1 if $p \in S_t$ and 0 otherwise.

[1] See Section 4.5 for details on the training of l and $hist$.

4. EXPERIMENTS

4.1 Data

For our experiments, we use the MAPS dataset [10], which contains MIDI-aligned recordings of various classical music pieces, some as played by an upright Disklavier, and some synthesized using high-quality piano samples. We create the exact same test set as was used in [13] (which was created in the same way as *Configuration II* from [21], with the additional constraint that only the Disklavier recordings were used). We create our training and validation sets slightly differently because the blending model requires a reasonably-sized validation set on which to train. From the remaining synthesized pieces, we choose 20 to become the validation set (counting multiple synthesized recordings of a single piece as only 1), and use the remaining pieces for training. This results in final split sizes of 59 pieces for test, 105 for training, and 32 for validation. The decrease in training set size compared to [13] does not seem to affect the performance of the acoustic model. We train the acoustic model on the whole pieces, but our evaluation is performed on the first 30 seconds of each recording, as is usually done, e.g. in [13].

To train our MLM, we use MIDI files taken from the Piano-midi.de [2] dataset. This dataset currently holds 324 pieces of classical piano music from various composers, with both quantised note durations and expressive timings. Every piece in MAPS can be found in the Piano-midi.de dataset, as these files were used to create MAPS. To avoid training the MLM with pieces later used for testing, we split the dataset using the same pieces as in the MAPS splits: all the pieces in the MAPS test set are used for testing (52 pieces), all the pieces in the MAPS validation set are used for validation (20 pieces), and all the remaining pieces are used for training (252 pieces).

We use two different timesteps in our experiments: 40ms (the resolution of [13]); and 16th-note, in which the input is divided into 16th-note frames based on the metrical grid. For the 16th-note timesteps, we use the metrical annotations from the A-MAPS dataset [26]. To downsample the acoustic prior for the 16th-note timesteps, we take the average of its original 40ms frames for the duration of each new frame. Before evaluation, we upsample our outputs back to 40ms timesteps, assigning each resulting frame the value of the corresponding output frame.

4.2 Metrics

We report both framewise and two versions of notewise precision (P), recall (R), and F-measure (F_1), each of which is averaged across all recordings in the test set. The frame-based metrics are standard as used in the MIREX Multiple-F0 Estimation task [1], comparing the output piano roll to the ground truth piano roll, using 40ms frames (after upsampling when using 16th-note timesteps). Since our model does not output onsets and offsets explicitly, we treat any output 1 not preceded by a 1 as an onset, and any 0 not preceded by a 0 as an offset. We treat the ground truth the same after first converting it into a piano roll. Thus, our "notewise" metrics do not correspond with notes exactly, but rather as close as our output format can get. We leave an analysis using proper notes for future work.

We also perform two post-processing steps for the notewise metrics, for all methods: (1) minimum duration pruning, where we remove any notes shorter than 50ms; and (2) gap filling, where we fill rests shorter than 50ms. Additionally, we report both onset-only (On) and onset-offset (OnOff) notewise results. For On, a note is considered correct if its pitch is correct and its onset time is within 50ms of the ground truth, and for OnOff, we add the constraint that the offset is such that the note duration is within 20% of ground truth (or 50ms, whichever is biggest). Both are as described for note-tracking in [1], and we use `mir_eval` [18] to perform all calculations.

As argued in [12], the most relevant metrics are the notewise metrics. Indeed, a poor transcription system could still score high in terms of framewise F_1 if its only errors correspond to short spurious notes and fragmentation of held notes. When discussing our results, we thus concentrate mainly on the notewise metrics. Furthermore, the onset-only metrics are the most commonly-used ones for the task, and onsets are much more perceptually important (and salient) than offsets [4, 8]. Thus, our main evaluation concentrates on onset metrics, and we discuss the OnOff metrics only in Section 5.4.

4.3 Configurations

Besides the two versions of our blending model described in Section 3.2 (WM and PM), we use a baseline blending model: a constant weight (CW) model, which always calculates $P_{p,t}$ similarly to WM, but using the constant $w_{p,t} = 0.8$ for all p and t (a value set in an ad hoc fashion on the validation set). CW should indicate whether the adaptability of the blending model is important for performance. For each blending model, we train a version both with and without scheduled sampling (using +S to denote its use) for each timestep.

There is a risk with PM that the blending model might choose to dismiss the MLM input completely. With WM, even if the MLM is not used to choose the weight, it will still have an influence on the resulting probabilities, unless the blending model's output is exactly 1. To see whether our improvement comes from the MLM or simply the use of the blending model, we also train a blending model which is identical to configuration PM+S, except that any of its inputs which come from the MLM's predictions are set to 0 at both train time and test time (this includes the MLM prediction itself as well as various features which use the MLM's output). We call this configuration PM-A, and present a brief discussion of its results in Section 5.2.

4.4 Baselines

We compare our models against that of [13], retrained with our training and validation sets. We threshold its output at a 0.5, setting all values ≥ 0.5 to 1 and all others to 0.

We also compare our model against a common HMM baseline [17] where each pitch is represented by a simple 2-state (on/off) HMM, run independently. Typically, the

Table 2. Results of all experiments, with all timesteps, with the best values in bold. CW uses our constant weight model, WM uses the weight model, and PM uses the prior model. +S denotes the use of scheduled sampling in training.

HMM raises precision and lowers recall, removing short spurious notes from the output. In [17], one HMM is trained per pitch class. For transposition invariance, we instead train a single HMM, and use it for all pitches. In previous work, it has been standard to use maximum likelihood estimation (MLE) to set the transition probabilities (by counting transitions in some training set), and to treat the input probabilistic piano roll directly as the observation probabilities. We instead learn the transition probabilities with Bayesian Optimization (BO) [16] to maximize the notewise F_1 on the validation set. There are only two probability values to search for (since $P(\text{off}|S) = 1 - P(\text{on}|S)$). We use the validation set instead of the larger training set so that the HMM has noisier observations during training (for both MLE and BO), and we set the initial state probabilities to a uniform distribution.

The resulting HMM is one which is much more likely to change states: for 40ms timesteps, $P(\text{on}|\text{off})$ is 0.004 with MLE and 0.493 with BO, and $P(\text{off}|\text{on})$ is 0.167 with MLE and 0.196 with BO. 16th-note timesteps see a similar change. Specifically, the probability for transitioning from off to on is much greater, likely because the observed data is much more accurate at note onsets, and thus the model can safely trust those values in most cases. The BO-trained HMM leads to a significant increase in both framewise and notewise F_1 for both timesteps compared to the MLE-trained HMM (MLE results omitted).

4.5 Training

The MLM is trained using the Adam optimizer [14] with a learning rate of 0.001. Piano rolls are cut into smaller sequences of 750 frames for 40ms timesteps and 300 frames for the 16th-note timesteps. We augment the data by transposing each sequence by a number of semitones randomly chosen between -5 and 7 at each epoch, so that each tonality is equally represented without shifting the note range too much. We use early stopping, such that if the cross-entropy evaluated on the validation dataset does not decrease for 200 epochs, training is stopped, and the best model so far is kept. For scheduled sampling, we decrease p_{GT} linearly from 1 to 0.7 over 500 epochs. Validation is done using a fixed value of $p_{GT} = 0.7$, and we use early stopping once the schedule is finished (after 500 epochs).

The blending model is trained on the validation set to maximize On-notewise F_1. Training data is generated by running our MLM on the first 30 seconds of each piece in the validation set with a fixed weight of 0.8 and a beam size of 10. We save a data point—containing the priors, a sample history of length $hist$, and features—for each (frame, pitch, hypothesis) triple for which the acoustic prior differs from the language prior by at least Δ_{min}. Bayesian Optimization for 200 iterations is used to search for the values of Δ_{min} and $hist$ (up to 10 for 16th-note timesteps and up to 50 for 40ms timesteps), and how many hidden layers l to use (1–4 of size 5).

The parameters for the beam search are set in an ad hoc fashion on the validation set. The beam size b and the branching factor k have small effects, where larger values lead to better results, but slower computation, and we use $b = 50$ and $k = 5$ for evaluation. The hash length h has an effect where smaller values force the model to perform a more global search, but with less ability to make decisions based on frames further in the past. We use a value of $h = 12$ for evaluation.

5. RESULTS

Full framewise and On-notewise results are in Table 2. Overall, we can see that for 40ms timesteps, PM+S and WM+S outperform all other models in the On-notewise F_1 ($p < 10^{-3}$ with a paired t-test, which we use for all significance tests), but WM+S does not significantly outperform PM+S. For 16th note timesteps, PM+S is significantly better than all other models for On-notewise F_1 ($p < 10^{-6}$). The baselines achieve the best framewise results—HMM for 16th-note ($p = 0.021$ over PM+S) and [13] for 40ms (not significant). This makes sense, as our blending models are optimised for On-notewise F_1. Moreover, our MLM is designed to take advantage of knowledge of musical structure, which is more clear at the note level.

In the following sections, we investigate the impact of each component of our system: the timestep (5.1), scheduled sampling (5.3), and the blending model (5.2). The OnOff-notewise metrics are presented in Section 5.4.

5.1 Timestep

It is clear that using 16th-note timesteps improves the results (framewise for the baselines and On-notewise for all

methods). Similar results were seen in [27], which showed that the improvement was mainly due to quantisation of the output. Here, the increase in performance of [13] is due entirely to this quantisation. However, when performing the same quantisation procedure to the output of the 40ms-timestep PM+S, we see framewise and On-notewise F_1 of only 63.6 and 62.9 respectively, significantly worse than PM+S with a 16th-note timestep ($p < 10^{-6}$ for both). PM also sees a significant improvement when using a 16th-note timestep directly ($p < 10^{-8}$ for both), as well as WM+S, but for On-notewise F_1 only ($p = 0.01$). Weaker or insignificant effects are seen for our other models, both framewise and On-notewise. This shows that for our MLM, much of its improvement with 16th-note timesteps is due to its ability to learn more musical patterns at that scale, particularly when the full system has the ability to take advantage of that knowledge. In the following sections, therefore, we concentrate on the results with the 16th-note timestep.

5.2 Blending model

The adaptability of WM and PM clearly allow them to outperform CW, and the wider output range of PM leads to improvement over WM ($p = 0.018$ for WM over CW without scheduled sampling, $p < 10^{-6}$ for all other pairs), although WM's precision is greater. For the framewise metrics, a similar pattern is seen, though the effect is weaker ($p < 0.001$ for PM over WM, $p = 0.048$ from WM over CW, and not significant for WM+S over CW+S).

To see whether our improvement comes from the MLM or simply from the use of the blending model, we evaluate the PM-A configuration. This model achieves an On-notewise F_1 of 65.1 with a 16th-note timestep, significantly worse than PM+S ($p < 10^{-9}$), which shows that both the MLM and the blending model play an important part in our system's performance. In the following sections, we concentrate on PM results.

5.3 Scheduled sampling

We can see that PM+S performs significantly better overall than PM for On-notewise ($p < 10^{-7}$), but not framewise F_1 ($p = 0.50$). Looking at the results in a piecewise fashion leads to an interesting conclusion about where that improvement comes from. In Figure 2, we plot the notewise F_1 of [13] (x-axis, a proxy for the noisiness of the input) against the increase in On-notewise F_1 for PM+S over PM (y-axis) for each piece in our test set. Here, it can be seen that PM+S outperforms PM by a greater margin in exactly those cases that we expect scheduled sampling to help: when the input is noisier. This correlation is significant ($p = 0.02$), but with high variance ($R^2 = 0.09$). Overall, we can conclude that scheduled sampling does indeed lead to improved performance with noisy inputs.

5.4 Onset-offset Evaluation

Table 3 presents the OnOff-notewise results for the two baselines and our overall best performing model (PM+S), where it can be seen that our model significantly outperforms the other systems ($p < 10^{-5}$ for both timesteps).

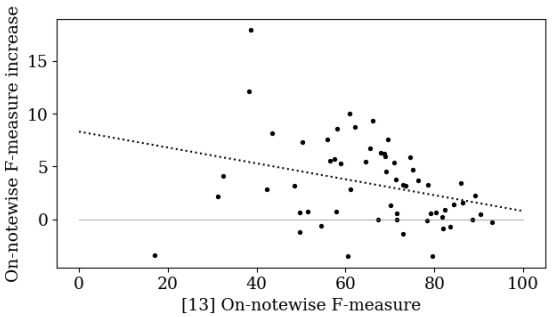

Figure 2. Increase of On-notewise F_1 of PM+S over PM plotted against On-notewise F_1 of [13] for each piece. Dotted line shows linear correlation ($p = 0.02$, $R^2 = 0.09$).

Method	40ms timestep			16th-note timestep		
	P	R	F_1	P	R	F_1
[13]	31.8	37.7	33.8	41.0	37.3	38.5
HMM	37.8	36.5	36.5	41.3	37.5	38.8
PM+S	**41.5**	**43.2**	**41.8**	**47.7**	**43.3**	**45.0**

Table 3. Results using the OnOff-notewise metrics. PM+S uses our prior model with scheduled sampling.

This is promising, and it seems that the MLM might have learned some rhythmic components of musical structure.

6. CONCLUSION

In this paper, we have presented a system for converting a posteriogram output of an acoustic multi-pitch detection system into a binary piano roll. Our system consists of an LSTM-based MLM and a feed-forward neural blending model to combine the MLM outputs with those from the acoustic model. We have shown that our system performs significantly better than thresholding the posteriogram, as well as post-processing it with a new strong baseline HMM. We have further shown that (1) scheduled sampling helps the MLM perform better in the case of noisy inputs, and (2) the use of a 16th-note timestep allows the MLM to learn musical structures better than with a 40ms timestep.

To that end, in future work, we intend to investigate the use of noisy 16th-note labels from a beat-tracking system, rather than the ground truth labels that we have used here. Furthermore, we will perform a systematic ablation study for the input features of the blending model. We also intend to analyze our results in a more qualitative fashion in future work with listening tests. Our own subjective conclusions are that our system does often produce more musical results than the baselines, but a proper listening test would show more objectively whether that is the case throughout the test set, and what aspects of the resulting piano rolls become more musical in which cases. In the meantime, we provide some examples of our model's performance as supplementary material [3], along with the code to reproduce our experiments [4].

ABSTRACT

Hierarchical models of music allow explanation of highly complex musical structure based on the general principle of recursive elaboration and a small set of orthogonal operations. Recent approaches to melodic elaboration have converged to a representation based on intervals, which allows the elaboration of pairs of notes. However, two problems remain: First, an interval-first representation obscures one-sided operations like neighbor notes. Second, while models of Western melody styles largely agree on stepwise operations such as neighbors and passing notes, larger intervals are either attributed to latent harmonic properties or left unexplained. This paper presents a grammar for melodies in North Indian rāga music, showing not only that recursively applied neighbor and passing note operations underlie this style as well, but that larger intervals are generated as generalized neighbors, based on the tonal hierarchy of the underlying scale structure. The notion of a generalized neighbor is not restricted to rāgas but can be transferred to other musical styles, opening new perspectives on latent structure behind melodies and music in general. The presented grammar is based on a graph representation that allows one to express elaborations on both notes and intervals, unifying and generalizing previous graph- and tree-based approaches.

1. INTRODUCTION

North Indian classical music (Hindustani music) provides valuable evidence for theories of syntactic musical organization. Like Western art music, it takes the form of aesthetic communication with an attentive and experienced audience, and is also a subject of theoretical discourse. Like most music outside the Western canon, it is normally unwritten, depending instead on memorization and improvisation. Instead of a system of chordal harmony or polyphony, Indian music comprises a solo melody against a complex background drone (of at least two pitches).

Melodic elaboration is prized as a means of musical extension and aesthetic enhancement: it operates at many levels, from the ornamentation of a single pitch, to the expansion of a phrase, to the architecture of a piece or performance. Melodic coherence is ensured by selecting one of a set of modes (rāga), each comprising a scale, a pitch hierarchy, and a set of licensed pitch transitions; any phrase that evokes a different rāga from the one selected is regarded as an error. It has been noted that Indian music resembles language in several respects [17], and a rāga could be understood as a melodic grammar, in which melodies are constructed by recursive elaboration over a hierarchically organized set of pitches.

The idea of understanding music in a hierarchical fashion goes back to Schenker [21], and has developed through the integration of impulses from generative linguistics and the theory of formal grammars since the 1980s [24, 1, 11, 20, 16]. Approaches most commonly addressed harmonic structure [23, 18, 19, 3, 5] and melody [4, 12]. Several approaches proposed simplified formalizations of Schenkerian theory and corresponding computational implementations [12, 13, 27, 10]. There is still comparably little discussion concerning the extent to which such hierarchical frameworks extend to non-Western forms of music. Narmour's theory of melodic processes is explicitly directed to capture melodies outside the Western canon as well [15]. The application of Schenkerian methods to non-Western music has been discussed by Stock [25]. More recently, it has been proposed to adapt analytical tools from Schenkerian analysis and the GTTM to Indian music [14, 2].

This paper links with this discourse and proposes a generalized formal model of North Indian melodic and phrase structure. A common shortcoming in previous models of melodic elaboration is the treatment of leaps, which are usually either attributed to a latent harmonic structure that is assumed to be known [12, 9], or modelled as probabilistic intervals [4, 6] without explicit restrictions. This paper introduces a formalism for relating leaps in North Indian music to a latent tonal hierarchy that is stated explicitly. With respect to this hierarchy, leaps can be viewed as instances of generalized neighbor- and passing-note relations that take into account the stability of a pitch in a scale. As will be argued, the generalized neighbor idea applies beyond North Indian music to some degree.

A central question for elaborative models concerns the representation of the music. Since formal grammars – the standard formalism for recursive elaboration – operate on

* École Polytechnique Fédérale de Lausanne

Figure 1: Rāga Multānī with pitches in an approximate Western notation. The notated duration denotes the hierarchical level, i.e. relative stability, of each pitch; arrows indicate a constraint on the resolution direction of an unstable pitch.

Figure 2: A short Multānī phrase and its derivation.

$d \in D_M$	1	♭2	♭3	♯4	5	♭6	7
$\delta_M(d)$	↕	↓	↕	↕	↕	↓	↕
$\lambda_M(d)$	4	0	2	1	3	0	2

Table 1: A formal description of the rāga Multānī, showing the direction and hierarchical level of each scale degree (as shown in Figure 1). ♭2 and ♭6 are directed downwards and can therefore only be used before 1 and 5, respectively.

strings of objects, most models of musical elaboration represent music as a sequence of objects, such as notes or chords. As a consequence, these models mostly focus on melodic [4, 6, 12] or homophonic settings [8].

A desirable property of a formal grammar is that it is *context-free*, meaning that elaborations on a single object are independent from the objects around it. Systems that are based on strings of notes have problems with being context-free since some elaboration operations (such as passing notes) depend on two notes [11]. Because of this, more recent approaches have been based on strings of intervals [12, 27, 4], which allow elaborations of both single notes and pairs of notes while remaining context-free. However, in an interval grammar, notes are represented implicitly and redundantly (as part of an incoming and outgoing interval). In addition, all notes generated by elaboration are derived from two parent notes, which is unintuitive for single-sided operations. As a unification and generalization of both approaches, this paper suggests a graph-based representation in which both notes and intervals are represented explicitly, with a graph grammar describing the elaboration rules. This goes beyond descriptions of *derivations* as graphs, which is already an established practice [12, 27, 10].

2. MELODIC OPERATIONS

Melody in Indian music is based on a set of modes called rāgas. A rāga is not only a collection of pitches that may be used, it also establishes a hierarchy of stability among these pitches. Stable pitches are those that can serve as resting points, while less stable pitches tend to move towards their more stable neighbors. Some pitches in a rāga have a preferred resolution direction and must resolve to the closest pitch in that direction. An example of a rāga with its scale, tonal hierarchy, and directional constraints is shown in Figure 1. The relative stabilities indicated in Figure 1 is based on observation of normal practice in this rāga.

The melodic elaboration of a rāga is performed most completely and systematically (though not exclusively) in ālāp: a type of improvisation in which the scale and melodic features of the rāga are gradually exposed in phrases unfolding an arch-shaped trajectory, starting from the root (scale-degree 1) and reaching the octave above (or higher) before finally returning to the root (a process called *vistār* or "scalar expansion" [26]). This background structure is filled and elaborated recursively, generating a complex foreground melody. Elaboration follows mainly two principles, inserting either passing or neighbor notes.

Passing notes fill intervals that are larger than steps. They can occur close to the surface (such as the ♭2 in ♭3 ♭2 1), but can also be understood to characterize dependencies in the background (e.g., filling the top-level interval 1 - 1′ with a 5). Two kinds of passing elaborations can be distinguished: Either a single note is introduced that subdivides the interval, potentially leaving non-step intervals that can be further elaborated; or the interval is filled with all scale notes enclosed by the interval.

Neighbor notes can be inserted before or after an existing note. While passing notes relate to both notes of an interval, neighbors are subordinate to single notes. When embellishing a note with a neighbor, a trade-off can be made between pitch proximity and stability: While unstable neighbors need to be very close to the main note's pitch, more distant neighbors can occur if they are sufficiently stable. In general, a pitch can only be perceived as a neighbor to some reference pitch if no pitch in the interval between the two is more stable than the proposed neighbor in the given mode.

Figure 2 shows the steps needed to derive a phrase using neighbors and passing notes. Starting with a single 1, the note is duplicated and elaborated twice, first with a lower neighbor 7, then with an upper neighbor ♭3. Finally, the space between ♭3 and 1 is filled with a passing ♭2.

3. MODES AND GENERALIZED NEIGHBORS

The idea of modes and generalized neighbors can be given a formal description: A *mode* M is a triple

$$\begin{aligned} M &:= (D, \delta, \lambda) \\ \delta &: \quad D \to \{\uparrow, \downarrow, \updownarrow\} \\ \lambda &: \quad D \to \mathbb{N} \end{aligned}$$

where D_M is a totally ordered set of *scale degrees*, δ_M is a function indicating the *direction* in which a scale degree is allowed to move, and λ_M returns the *hierarchical level* of a scale degree. For example, the rāga Multānī (Figure 1) would be formalized according to Table 1.

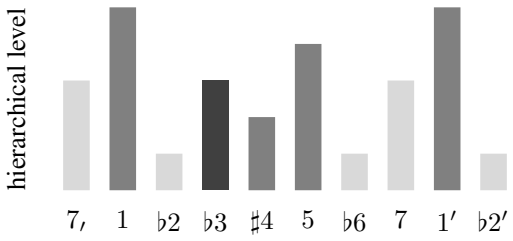

Figure 3: The upper and lower neighbors (dark) of ♭3 (black) in the Multānī rāga. Only pitches that can be reached without skipping a more stable pitch are neighbors. ♭2 is not a neighbor since it is directed downwards and can only be a neighbor to 1.

The same scale degree can be used as a *pitch* in different octaves, so pitches are indicated as scale degrees together with "′" for octaves above and "," for octaves below the default octave. The pitches of adjacent octaves are adjacent as well: $7,$ is directly below 1 and $1'$ is directly above 7. As a result, a mode gives rise to a set of pitches P_M, which corresponds to $\mathbb{Z}$ while scale degrees correspond to $\mathbb{Z}_{|D|}$. For convenience, δ_M and λ_M are assumed to be defined on pitches as well and return the values of the corresponding scale degrees.

The set of pitches *between* a pitch p_1 and a pitch p_2 is the set of pitches in the open interval (p_1, p_2) that agree with the direction of the interval:

$$\Delta_M(p_1,p_2) = \begin{cases} \{p \in P_M \mid & p_1 < p < p_2 \wedge \delta_M(p) \neq \downarrow\} \\ & \text{if } p_1 < p_2 \\ \{p \in P_M \mid & p_1 > p > p_1 \wedge \delta_M(p) \neq \uparrow\} \\ & \text{if } p_1 > p_2. \end{cases}$$

The *neighbors* of a pitch $p \in P_M$ are then all pitches $n \in P_M$ that have a higher level than all pitches *between* p and n. In addition, the direction of n must agree with the direction from n to p:

$$\begin{aligned} nb_M(p) = \{n \in P_M \mid p \neq n \\ \wedge \forall q \in \Delta_M(n,p) : \lambda_M(q) < \lambda_M(n) \\ \wedge\, n \rightarrowtail p\}, \end{aligned}$$

where

$$n \rightarrowtail p = \begin{cases} \delta_M(n) \neq \uparrow & \text{if } p < n \\ \delta_M(n) \neq \downarrow & \text{if } p > n \\ true & \text{otherwise.} \end{cases}$$

Thus, every pitch is a neighbor to p only if it can be reached from the reference pitch without skipping a more stable pitch than the neighbor, as illustrated in Figure 3. Directed pitches can only be inserted as left neighbors since they must move towards their resolution.

When a single passing note is generated, the passing note must be a neighbor to both notes of the interval it is inserted in. However, in this case the inserted note is moving away from the first note, so the direction is not towards the reference note but towards the neighbor. A *reverse neighbor* $r \in rnb_M(p)$ is defined in analogy to a neighbor but with inverted direction:

$$\begin{aligned} rnb_M(p) = \{r \in P_M \mid p \neq r \\ \wedge \forall b \in \Delta_M(p,r) : \lambda_M(b) < \lambda_M(r) \\ \wedge\, p \rightarrowtail r\}, \end{aligned}$$

For example, a passing ♭2 in the sequence ♭3 ♭2 1 is a neighbor to 1 but a reverse neighbor to ♭3, as it is directed away from ♭3 and towards 1.

Finally, a *fill* is the list of all pitches between two pitches p_1 and p_2, sorted according to the direction of the interval (p_1, p_2) and restricted to pitches agreeing with that direction (as given by Δ_M).

$$\mathit{fill}_M(p_1,p_2) = \begin{cases} sort(\Delta_M(p_1,p_2), asc) & \text{if } p_1 < p_2 \\ sort(\Delta_M(p_1,p_2), desc) & \text{otherwise.} \end{cases}$$

4. A FORMAL GRAMMAR OF RĀGA MELODIES

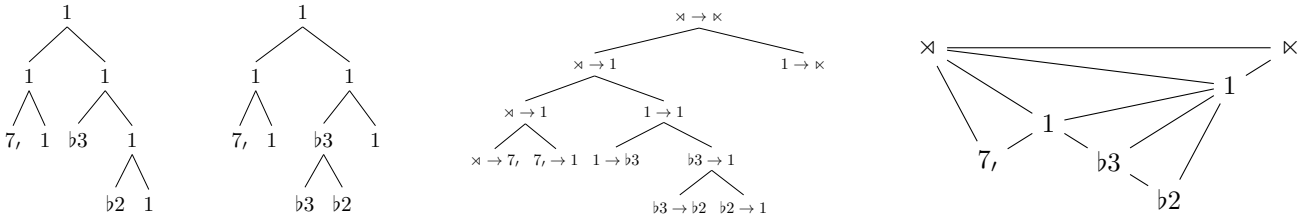
4.1 Representing Melodies as Graphs

As seen in Section 2, the two fundamental elaboration types – passing and neighbor notes – operate on two different musical entities: While neighbors elaborate single notes, passing notes fill intervals between two notes, elaborating both notes at the same time. As a consequence, two main formalisms describing hierarchical elaboration have emerged, note grammars and interval grammars.

Note grammars generate strings of notes, with derivation rules replacing single notes by several new notes. The resulting hierarchical structure is a tree of notes as shown in Figure 4a. However, elaborating single notes is problematic for passing notes, as they elaborate two notes. Not only is the resulting hierarchy ambiguous (the passing note must be attached to either its predecessor or its successor), but from a generative perspective, a passing note can only be derived from one of its parents. Thus, deciding where a passing note may be inserted becomes a context-sensitive problem.

Interval grammars [4, 9, 6, 12] solve the passing note problem (and two-sided operations in general) by elaborating pairs of notes, or intervals. Inserting a new note replaces an existing interval with two new intervals. The melody is then represented as a string of intervals with each note being represented twice, once as the second note of an interval and once as the first. To avoid this redundancy in notation, derivations are usually not given as trees (Figure 4b) but as outerplanar graphs (Figure 4c), giving each note two parents. However, for one-sided operations like neighbors, interval-based elaboration is conceptually misleading, as only one of the parent notes is considered while the other is ignored. This can lead to unwanted subordination of conceptually independent neighbors, as will be argued below.

As a unification and generalization of note- and interval-based systems, a graph-based representation of melodies is suggested here, representing notes as nodes



(a) Two analyses using note elaboration. The passing ♭2 must be attached either to the 1 on its right or to the ♭3 on its left.

(b) An analysis of the phrase using interval elaboration. The passing ♭2 is generated in the interval ♭3 → 1.

(c) The same analysis as in 4b, displayed as an outerplanar graph.

Figure 4: Conventional formal analyses of the phrase in Figure 2.

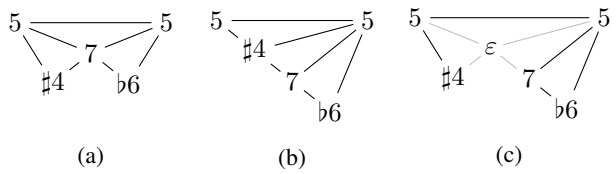


Figure 5: Three possible derivations of 5 ♯4 7♭6 5.

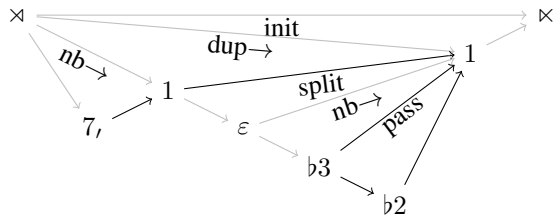

Figure 6: An analysis of the phrase in Figure 2 using the rāga grammar. Dark edges indicate the subgraph induced by removing non-note nodes ($\rtimes, \ltimes, \varepsilon$).

and note transitions as edges. Using graphs as the basis for elaboration has both conceptual and practical implications. Conceptually, graphs represent both notes and note transitions explicitly, which allows the use of both entities as a starting point for elaboration. Practically, while graphs can represent strings of objects (such as melodies) as a special case, they can easily describe much more complex structures, which potentially allows the description of elaboration operations in non-monophonic music. However, special cases such as monophony can still be defined graph-theoretically, ensuring consistency under elaboration. Thus, graphs provide a common framework for both melodic grammars and more complex formalisms.

While graphs in principle allow operations on both nodes and edges, a much simpler and more consistent system is obtained by operating only on edges, resulting in an *edge-replacement graph grammar*. All operations are then defined on edges (i.e., node transitions) with one-sided operations ignoring one node of the edge. One-sided operations still introduce an edge between the unused note and the new one in order to allow further elaboration between them. In order to express the independency between the new and the ignored note, a dummy node (written as ε) can be introduced first between any two notes. A dummy node does not generate a note and is analogous to the empty string in a conventional grammar.

Only strictly one-side operations can be performed on edges adjacent to a dummy node. This restriction expresses the independence between one-sided elaboration notes and their opposite side, and permits a more appropriate hierarchy: Suppose two one-sided neighbors are generated between two 5s, a ♯4, as a right neighbor to the first 5 and a 7 as a left neighbor to the second 5 with a passing ♭6, resulting in 5 ♯4 7♭6 5 (Figure 5). Without a dummy node, either 7 or ♯4 is subordinate to the other, depending on which is generated first (Figures 5a and 5b). By first introducing a dummy node, both neighbors can be derived independently (Figure 5c). Moreover, as dummy nodes are removed after the derivation, the resulting graph structure only retains edges that express elaboration dependence. Thus, dummy nodes allow the derivation to formally follow edge replacement while semantically expressing both one-sided and two-sided operations.

4.2 Formal Definition of the Grammar

A melody is formally represented as a directed linear graph with notes as nodes and transitions between notes as edges directed in time. The beginning and end of the melody are marked with the special nodes $\rtimes$ and $\ltimes$, respectively. The derivation is started from a single 1:

$$\rtimes \to 1_M \to \ltimes,$$

with 1_M indicating the root of mode M.

Derivation rules follow an edge-replacement paradigm: edges can be replaced with new subgraphs, retaining the nodes adjacent to the original edge. Some rules use only one of the adjacent nodes. In this case, a wildcard symbol ($* \in P_M \cup \{\rtimes, \ltimes, \varepsilon\}$) is used for the ignored node. The special symbol ε represents the *empty melody* and can be used to split an edge into two parts that may be elaborated independently. Only one-sided operations can be used on edges adjacent to an ε, $\rtimes$, or $\ltimes$.

For a given mode M the rāga grammar $\mathcal{G}_M^{rāga}$ is defined as the graph grammar $(\mathcal{T}, \mathcal{N}, \mathcal{I}, \mathcal{R})$ with

$$\mathcal{T} := \{n_1 \to n_2 \mid n_1 \in P_M \cup \{\rtimes, \varepsilon\}, n_2 \in P_M \cup \{\ltimes, \varepsilon\}\}$$
$$\mathcal{N} := \{\}$$
$$\mathcal{S} := \rtimes \to \ltimes$$

as terminals $\mathcal{T}$, non-terminals $\mathcal{N}$, and initial graph $\mathcal{S}$; and the following replacement rules $\mathcal{R}$:

initialize:
$(\rtimes \to \ltimes) \Rightarrow (\rtimes \to 1_M \to \ltimes)$

duplicate left: $\forall p \in P_M$:
$(p \to *) \Rightarrow (p \to p \to *)$

duplicate right: $\forall p \in P_M$:
$(* \to p) \Rightarrow (* \to p \to p)$

left neighbor: $\forall p \in P_M, n \in nb_M(p)$:
$(* \to p) \Rightarrow (* \to n \to p)$

right neighbor: $\forall p \in P_M, n \in nb_M(p) \wedge \delta_M(p) = \updownarrow$:
$(p \to *) \Rightarrow (p \to n \to *)$

passing: $\forall p_1, p_2 \in P_M, n \in rnb_M(p_1) \cap nb_M(p_2)$:
$(p_1 \to p_2) \Rightarrow (p_1 \to n \to p_2)$

fill: $\forall p_1, p_2 \in P_M$:
$(p_1 \to p_2) \Rightarrow (p_1 \to f_1 \to \ldots \to f_n \to p_2)$
where $f_1, \ldots, f_n = \mathit{fill}(p1, p2)$

split: $\forall p_1, p_2 \in P_M$:
$(p_1 \to p_2) \Rightarrow (p_1 \to \varepsilon \to p_2)$.

In this description, rules are given as templates that are instantiated for all (combinations of) pitches. A more elegant and efficient description is possible, if rules are considered to be functions on classes of structured symbols [7], allowing them to look inside their inputs.

Since the rāga grammar generates linear graphs, it is still possible to display derivations with outerplanar graphs. Figure 6 shows a derivation of the example phrase from Figure 2 using the rāga grammar. Each operation used to derive the phrase is written in the triangle formed by the old edge it replaces and the new edges it inserts. Later derivation graphs will omit operations and edge directions to remove visual clutter, as both are clear from the context.

In Figure 6, the ε inserted between the two 1s separates them and allows independent generation of neighbors. In particular, it would be possible to generate another right neighbor to the first 1 without subordinating it to the $\flat$3, or vice versa.

While the full derivation graph displays all derivation steps as they are formalized (i.e., as edge replacements), it does not distinguish one-sided and two-sided operations. Removing all non-note nodes ($\rtimes, \ltimes, \varepsilon$) and the adjacent edges induces a subgraph in which two-sided operations still use two edges while one-sided operations adjacent to non-note nodes only use one edge. The resulting graph resembles both note trees and outerplanar graphs in different regions, depending on the type of operation being used there. Thus, using ε nodes is an analytical option that reveals independencies between adjacent parts of the graph.

The graph grammar $\mathcal{G}^{rāga}$ is a special case of a graph grammar that is formally equivalent to a context-free grammar on strings of notes. Therefore, it can parse melodies efficiently. The context-free grammar can be obtained in two steps: First, the graph representation is transformed to an interval representation in all parts of the grammar. Second, a set of rules is added for generating notes from intervals by taking the second note of each interval and generating empty strings (ϵ) where necessary.

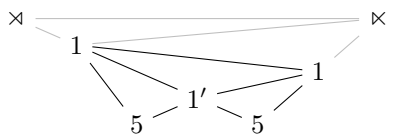

Figure 7: The spine modeling the deep structure of the octave expansion in an ālāp.

In a directed linear graph, edges are totally ordered by their direction, so the graph can be transformed into a sequence of edges (e.g., $a \to b \to c$ becomes $(a, b)(b, c)$). Let e be the function that transforms linear graphs to sequences of edges. Then the context-free melody grammar $G(\mathcal{G}_\mathcal{M}) := (T, N, I, R)$ induced by a melody-graph grammar $\mathcal{G}_\mathcal{M}$ is defined as follows:

$$
\begin{aligned}
T_G :=& P_M \\
N_G :=& (P_M \cup \{\rtimes, \varepsilon\}) \times (P_M \cup \{\varepsilon, \ltimes\}) \\
S_G :=& e(\mathcal{S}_\mathcal{G}) = (\rtimes, \ltimes) \\
R_G :=& \{e(l) \Rightarrow e(r) \mid l \Rightarrow r \in \mathcal{R}_\mathcal{G}\} \cup \\
& \{(x, p) \Rightarrow p \mid p \in P_M, x \in P_M \cup \{\rtimes, \ltimes, \varepsilon\}\} \cup \\
& \{(x, n) \Rightarrow \epsilon \mid n \in \{\varepsilon, \ltimes\}, x \in P_M \cup \{\rtimes, \ltimes, \varepsilon\}\}.
\end{aligned}
$$

5. DISCUSSION

A main motivation for introducing generalized neighbors is that they allow modelling leaps in the background structure of North Indian music. Figure 7 shows the architecture of a typical *ālāp* in rāga Multānī. The melody slowly ascends from 1 to $1'$ via 5 and returns back to 1 (again via 5). The upper $1'$ can be seen as a very stable and distant neighbor of 1 while the 5s in between are (again stable and distant) passing notes. Each stage of this *spine* is then further elaborated by neighbors and passing notes, using increasingly less stable pitches and smaller intervals (Figure 8).

North Indian music is not the only style of music in which melodies are based on hierarchical modes. If other mainly mode-based styles also follow the elaboration principles of passing notes and neighbors, then the grammar defined in Section 4 should permit sensible analyses for these cases. Consider, for example, the melody of *Nun komm der Heiden Heiland* (based on the Dorian mode) and a phrase from the Jazz standard *Moanin'* (based on a Blues scale). Their respective derivations (shown in Figure 9) suggest plausible reductions of the surface melody in both cases. Moreover, the proposed relations between notes match the intuitions of generalized neighbors and passing notes.

A natural generalization of the mode-based approach is to consider the mode as a latent variable that can change over the course of the piece but still organizes elaboration

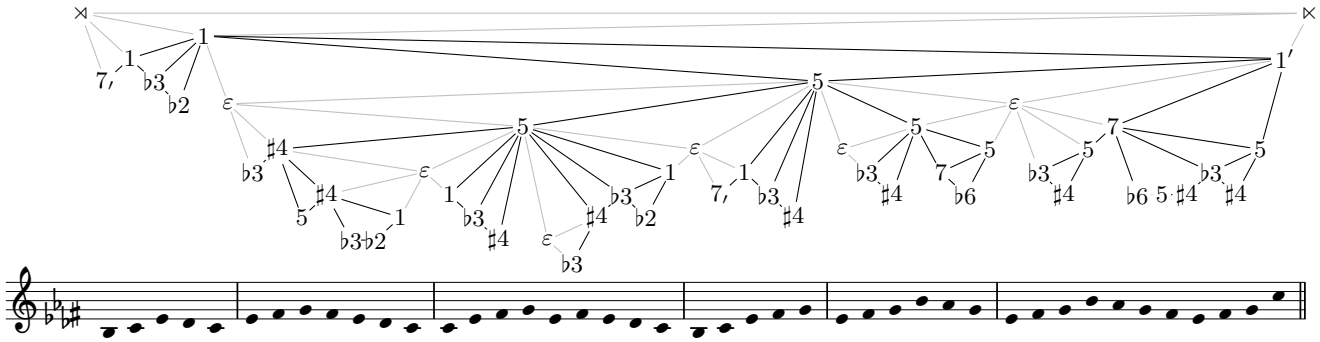

Figure 8: This example represents selected phrases, in order of performance, excerpted from the ascending part of an ālāp in rāga Multānī, recorded by the sitarist Dharambir Singh [22]. For reasons of space, one phrase has been selected for each of the stations between 1, 5 and 1′. Surface ornamentation and rhythmic durations have been omitted.

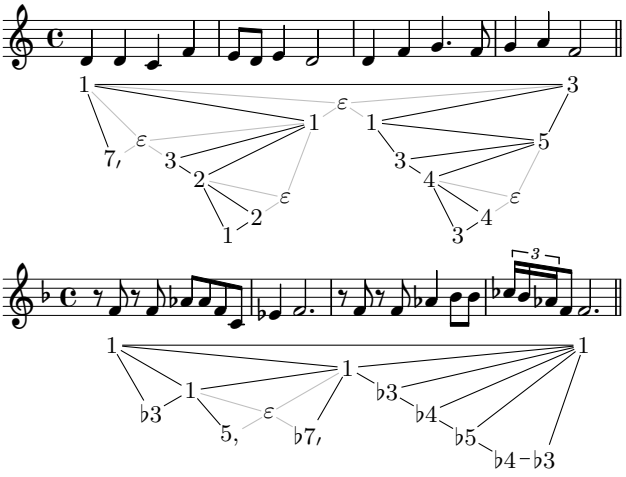

Figure 9: The first two phrases from *Nun komm der Heiden Heiland* and *Moanin'* (without repetitions), and their derivations based on a Dorian and a Blues scale, respectively.

Figure 10: The A part of *Take the A-Train* and a summary of its underlying lines.

locally. Depending on the style, this hierarchy can be constant over longer regions of the piece or change rather frequently. The latter case occurs when harmonies are considered as the latent structure, as they also define a tonal hierarchy, ranging from the root to non-chord notes.

However, there are two issues concerning generalized neighbor elaboration on harmonies. First, when the latent hierarchy changes, it is not obviously clear what should happen at the transition point. This is not an issue when these transitions are rare and elaboration across these boundaries is avoided. However, when harmonies take the role of the latent hierarchy, then transitions occur more often and elaborations frequently cut across harmonic changes. Moreover, as melodic elaboration happens on every level of reduction, it can even be considered to *generate* harmonic change in the background, such as the passing $\hat{2}$ in the *Ursatz*, generating a V harmony.

Second, not all leaps in melodies can be explained as generalized neighbors. The melody of *Take the A-Train* (Figure 10), for example, features several leaps which cannot be consistently explained as neighbors. While the initial G_4 and E_5 might be seen as neighbors to C_5, the descent to E_4 in the end is left unexplained by that. Instead, it is more plausible to assume a set of several independent lines: A higher line descends from E_5 to C_5, a lower line from G_4 to E_4, and an intermediate line that connects G_4 and C_5. Internally these lines behave according to elaboration principles (passing notes in this case), but the surface melody freely switches between the lines. This suggests that the organizing latent structure in this case is a set of implicit lines, although the elaboration and coordination of these lines might still be governed by a mode or a harmonic sequence as another layer of latent structure.

6. CONCLUSION

This paper proposed a generalized graph grammar formalism to model North Indian rāga music. We propose that passing and neighbor note elaborations are both necessary and (in their generalized form) sufficient operations of recursive rāga melody. This strengthens their status as fundamental musical principles across cultures. As the two operations are based on different objects (intervals and notes), models of elaboration should be able to represent both notes and intervals explicitly.

The notion of a generalized neighbor, based on a tonal hierarchy, shows that melodic leaps do not happen arbitrarily but can be related to a latent background structure. Understanding and modelling this background structure is necessary for a deeper understanding of melodic elaboration.

7. ACKNOWLEDGEMENTS

The research presented in this paper is generously supported by the Volkswagen Foundation and Claude Latour. This project has received funding from the European Research Council (ERC) under the European Union's Horizon 2020 research and innovation programme under grant agreement No 760081 – PMSB. We thank Dharambir Singh for the permission to use his recording of an ālāpin rāga Multānī. We also thank the anonymous reviewers for their helpful feedback.

A COMPARATIVE STUDY OF NEURAL MODELS FOR POLYPHONIC MUSIC SEQUENCE TRANSDUCTION

Adrien Ycart* **Daniel Stoller*** **Emmanouil Benetos**

ABSTRACT

Automatic transcription of polyphonic music remains a challenging task in the field of Music Information Retrieval. One under-investigated point is the post-processing of time-pitch posteriograms into binary piano rolls. In this study, we investigate this task using a variety of neural network models and training procedures. We introduce an adversarial framework, that we compare against more traditional training losses. We also propose the use of binary neuron outputs and compare them to the usual real-valued outputs in both training frameworks. This allows us to train networks directly using the F-measure as training objective. We evaluate these methods using two kinds of transduction networks and two different multi-pitch detection systems, and compare the results against baseline note-tracking methods on a dataset of classical piano music. Analysis of results indicates that (1) convolutional models improve results over baseline models, but no improvement is reported for recurrent models; (2) supervised losses are superior to adversarial ones; (3) binary neurons do not improve results; (4) cross-entropy loss results in better or equal performance compared to the F-measure loss.

1. INTRODUCTION

Automatic music transcription (AMT) is a core MIR problem [25]. Its aim is to extract what is played in a music signal into a human-readable score. Much of the literature has focused on the intermediate goal of detecting when and which notes were played, also called multi-pitch detection and note-tracking. It is a long-discussed topic, yet, unless it is constrained to a specific instrument and instrument model [17], it remains a challenging task, in particular in the case of polyphonic music [2].

Many AMT systems use a two-step workflow [3, 13]. First an *acoustic model* estimates the pitches present in each audio frame and produces a non-binary posteriogram representation over time and pitch. Then a post-processing step is applied to obtain a binary piano-roll representation, or a MIDI-like note-based representation (we focus here on piano-roll representation). The former task has been extensively discussed in the literature, but the latter has received much less attention.

Recent transcription and transduction models are commonly neural networks trained with a traditional maximum likelihood framework that assumes pitches to be independent [20, 23, 41]. Although this provides a simple and stable training loss, it can lead to unrealistic estimates as the model tries to cover all the modes of the output probability distribution [35]. More recently, Generative Adversarial Networks (GANs) [18] were proposed to rectify this issue, as they do not rely on an explicit likelihood and tend towards realistic outputs with high likelihood under the true output distribution. In GANs, a *generator* network makes its outputs as realistic as possible while a *discriminator* classifies examples as real (from the training set) or fake (created by the generator), which in turn gives feedback to improve the generator. GANs have made a breakthrough in high-quality image generation and reconstruction [8], and were subsequently also applied to symbolic music generation [39] and singing voice separation [36]. For AMT, GANs could help produce better transcriptions by taking into account correlations across both time and pitch.

The output of neural networks used in previous approaches [20, 23, 41] is real-valued to enable training by gradient descent.To obtain a piano roll at test time, the network outputs are binarised with a threshold as a post-processing step. However, this can lead to overly-fragmented notes, as in [41], when the output values are close to the threshold. Binary neurons [4] offer an alternative by integrating the binarisation of outputs into training while still allowing gradient back-propagation.

In this paper, we perform a comparative study of various neural-network-based methods for polyphonic sequence transduction, focusing on classical piano music. We systematically compare the influence of certain design choices, namely the network architecture, the training loss and the type of outputs. In particular, we introduce a GAN framework and assess its performance by comparing it to simpler training losses such as cross-entropy. We also evaluate whether binary neurons can bring improvements in this context as suggested for symbolic music generation [15] by making generator outputs binary and thus more similar to the real examples. In addition, we propose a method to directly use the F-measure as a training objective by using binary neurons. Each of these methods is evaluated with both a recurrent neural network (RNN) and a novel

*Authors 1 and 2 contributed equally to this work.

convolutional network as transduction model. These design choices are evaluated using inputs from two different multi-pitch detection systems (a piano-specific [23] and a multi-instrument acoustic model [5]). All experiments are conducted using a representation based on 16th note time steps, which can improve results [41] and reduce the input dimensionality compared to regular timesteps in the order of 10ms and thus the required training and test time.

Our paper is organised as follows. In Section 2, we describe previous work. Section 3 presents the dataset used. In Section 4, we detail the architecture used for our various sub-models, and the training objectives are described in Section 5. We present our evaluation metrics in Section 6, and describe our experiments and their results in Section 7. Finally, we discuss the limitations of our proposed methods along with future directions in Section 8.

2. RELATED WORK

2.1 Polyphonic Music Sequence Transduction

AMT acoustic models yield a posteriogram, which is a real-valued time-pitch representation that reflects the likelihood of pitches being present at different points in time, either as probabilities (between 0 and 1) or as saliences (unbounded). Polyphonic music sequence transduction aims to convert these posteriograms into a binary piano-roll representation (also called *note tracking*). Aside from simply thresholding the posteriogram, one of the most popular methods involves pitch-wise Viterbi decoding [31], where each pitch is considered as a 2-state (on/off) hidden Markov model (HMM).

More recently, a series of neural network-based methods has been proposed. In [6], a model combining a Restricted Boltzmann Machine (RBM) with a recurrent neural network (RNN) was proposed for symbolic music modelling. It was later used for AMT [7], using an audio representation from a Deep Belief Network as input. The same architecture was also used as a language model for piano-roll post-processing [34], to evaluate the likelihood of symbolic sequences rather than using it as a transduction model. In [41], a simpler Long Short-Term Memory (LSTM) model achieved improved performance when using musically-relevant time steps, but mostly because resulting outputs are quantized to the ground truth metrical grid.

2.2 Generative Adversarial Networks

Since their introduction in 2014, GANs have enjoyed considerable attention [18]. The main appeal in using GANs is that the model's likelihood only needs to be implicitly defined [29]. In contrast, defining a suitable and tractable likelihood function is difficult for complex output spaces such as the space of natural images, so simplistic assumptions are often made about the output density. In our context, a GAN could generate a coherent segment of music in one pass through the network, while other methods either have to assume independent outputs for each pitch and time-frame [17,20,23,41], or condition each output dimension on all previous ones in an auto-regressive fashion [34], which requires a computationally intensive decoding process.

Applications of GANs are increasing rapidly and cover a wide variety of fields [32, 36]. For music modelling, this includes the C-RNN-GAN [28], which uses an RNN to output note events with continuous duration, onset time, pitch and velocity, instead of the discrete values used in the MIDI representation. The MuseGAN [14] generates discrete piano-roll music representations. Here, a continuous-output generator is used and the training data is simply treated as being continuous despite its discrete nature.

GANs can also be used for conditional prediction models [26, 35, 36], where the output space is complex and high-dimensional and defining a suitable loss function is difficult. For these reasons we investigate GANs for AMT in this paper.

2.3 Binary neurons

Training a network with discrete outputs is challenging because back-propagation does not yield gradients from non-differentiable operations. Various methods have been proposed to solve that issue, such as REINFORCE [27,37], and the straight-through estimator [4, 21]. Binary neurons were used with GANs in the context of music generation [15], as it is very easy for the discriminator to separate binary, real samples from generated ones that have real values between 0 and 1. This can make generator training ineffective, as the discriminator's feedback focuses on only making the real-valued generator outputs more binary. They are reported as improving over a similar system with non-binary outputs [15] by being easier to train and yielding better results. More generally, binary outputs are appealing in our context, as they integrate the thresholding process into the network, removing the need for thresholding real-valued network outputs to obtain a binary piano-roll representation at test time and finding an optimal threshold value on an extra validation set.

3. DATASET

For our experiments, we use the MAPS dataset [16]. It contains MIDI files of polyphonic piano music, along with aligned audio renditions, generated using synthetic pianos and a Disklavier acoustic piano. It contains 238 pieces of classical music (18h total duration), with some pieces performed more than once, on different pianos. We split it into training, validation and test sets similarly to [23], where the test set features only acoustic piano and the training set only synthetic piano recordings, to obtain realistic performance estimates. We also ensure there is no overlap of pieces between the training and test set, and create a validation set by removing 10 random examples from the training set.

Rhythm annotations for this dataset are available in the A-MAPS annotations [40]. We use these annotations, in order to run our experiments using a time step of a 16th note. There are two main reasons for that choice. First, it was shown in [41] that using a 16th note time step can improve transcription performance over time steps of a fixed frame duration in seconds. Moreover, using 16th note time steps instead of fixed steps (usually on the order of 10 ms) results in a much more compact representation and faster training,

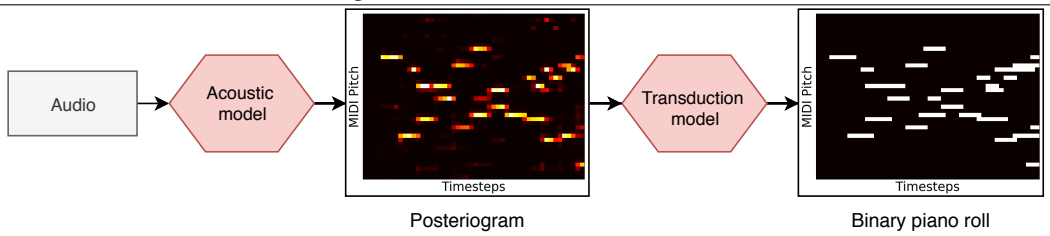

Figure 1. Overview of the whole transcription process. We focus on the second step.

enabling large-scale experiments. However, it introduces some imprecision when dealing with extra-metrical notes and tuples. In addition, the required beat positions are not usually available as annotations and would thus have to be obtained with a beat-tracking algorithm. Since we use beat annotations in our study, lower results than the ones reported here might be obtained in the presence of beat-tracking errors.

4. MODELS

The general workflow for our task is described in Figure 1. First an acoustic model produces a non-binary posteriogram. Then, this posteriogram is converted into a binary piano roll by a transduction model. Although this study focuses on the latter, we present both in this section.

4.1 Acoustic models

We use our transduction models with two different kinds of acoustic model outputs. The first model, described in [23], is a convolutional neural network (CNN) operating on spectrograms with logarithmically-spaced frequency bins and log-magnitude. It was designed specifically for piano transcription, and was trained on the MAPS dataset. At each time step, it outputs predictions for $N_p = 88$ pitches as probabilities between 0 and 1. We call this model *Kelz*.

The second model, described in [5], also uses CNNs, with a custom input representation that stacks harmonically-shifted Constant-Q transform representations of the signal. It was designed as a general multi-pitch detection system, and was trained on a multi-instrument dataset that includes piano. Besides, it has a frequency resolution of 20 cents, and has a smaller frequency span than a piano keyboard. In order to adapt it for piano transcription, we average the frequency bins that correspond to a given MIDI pitch. In this case, $N_p = 73$. It has to be noted that this averaging leads to lower activations. We call this model *Bittner*.

In both cases, outputs are then downsampled to a 16th note time step. To do so, we use the best-performing method in [41] referred to as *step*: let M and N be the original and downsampled posteriograms respectively, p a pitch, n a 16th note step, and i and j the time steps corresponding to n and $n+1$ respectively, we have:

$$s = i + round(\frac{j-i}{4}), \quad N[p,n] = \frac{\sum_{k=i}^{s} M[p,k]}{s-i+1}$$

4.2 Transduction model architectures

Our transduction models take the output of an acoustic model as input and are trained independently from the acoustic models. We compare two different kinds of transduction models. The first model is a Long Short-Term Memory (LSTM) network [22] with the same architecture as described in [41]. It has N_p inputs per time step, one hidden layer with 100 hidden nodes, followed by a fully connected layer with N_p outputs.

The second model is a newly-designed CNN that uses a series of convolutions with filter sizes (1) 5×5, (2) 5×1 with dilation of 12×1, and (3) 5×15, to capture both frequency and temporal correlations. A 1×1 convolution processes the combined output from convolutions (2) and (3), whose output is combined with the output from convolution (1) using another 1×1 convolution. While all above convolutions have 32 channels and use LeakyReLU activations, the final 1×1 convolution has only one filter and does not use an activation. Both models are closely matched in terms of the number of parameters at about $80,000$.

4.3 Real-valued vs. Binary outputs

We use two different strategies to convert the unnormalised, real-valued outputs obtained from the model. The first one is real-valued sigmoid outputs: the output of the network for each pitch is simply sent through a sigmoid. At test time, the outputs are binarised using a single threshold for all pitches, chosen to maximise frame-wise $\mathcal{F}$ on the validation set. The second strategy employs deterministic binary neurons, as described in [14]. Here, the output of the network for each pitch is sent through a sigmoid, and then thresholded at 0.5. This thresholding operation, however, is not differentiable, which makes it impossible to use gradient descent as training method. Therefore, we use the sigmoid-adjusted straight-through estimator [12], that was shown to provide good results [14]. It ignores the thresholding operation during back-propagation and instead multiplies the current gradient by the derivative of the sigmoid function.

4.4 Baseline methods

We compare our system against two baseline post-processing methods. The first binarises all outputs using a threshold optimised as explained in Section 4.3 (as opposed to using a fixed threshold of 0.5 as done in [23]). The second one, introduced in [31], and later used in various systems [10, 11], is to model each pitch by an on/off HMM, and then decode the most likely sequence of hidden states using the Viterbi algorithm. The initial probabilities and

transition parameters are computed from ground truth annotations, one set of parameters per pitch. The observations for 'on' and 'off' states are modelled as beta distributions, each fitted to the acoustic model outputs on the validation dataset. These distributions are fitted using data from all pitches and shared between them due to the rarity of extremely low and high pitches.

5. TRAINING OBJECTIVES

The networks are trained using the Adam optimiser [24] on sequences of 64 timesteps. For cross entropy and F-measure, we use a learning rate of 10^{-2}, as advised in [41]. With GANs, the learning rate is 10^{-3} for the discriminator, and $5 \cdot 10^{-4}$ for the generator. Early stopping is used: after no improvement in validation framewise $\mathcal{F}$ for 30,000 iterations (checked every 1000 iterations), training is stopped and the best model is kept.

5.1 Cross-entropy loss

As a commonly used baseline objective, we use the binary cross-entropy (CE) loss averaged over all entries $\hat{y}_t$ in the predicted piano-roll $\hat{y}$ as loss for the transducer model:

$$\mathbb{E}_{(x,y)\sim\mathbb{P}_d} \frac{1}{N_t N_p} \sum_{p=1}^{N_p} \sum_{t=1}^{N_t} y_{t,p} \log \hat{y}_{t,p} + (1 - y_{t,p}) \log(1 - \hat{y}_{t,p}) \tag{1}$$

where $y_{t,p} \in \{0, 1\}$ indicates whether a note at timestep $t \in [\![1, N_t]\!]$ with pitch index $p \in [\![1, N_p]\!]$ is active, and $\mathbb{P}_d$ denotes the joint distribution of acoustic model outputs and transcriptions. While this loss is conceptually simple and allows fast and stable training, it relies on the strong assumption that each note activity can be determined independently from all others, although some note combinations are more likely to occur than others. Since the model cannot assign high probability to specific note combinations, only to individual notes, it would assign high probability to all involved notes. Unrealistic note combinations might then be obtained when independently sampling from these probabilities.

5.2 F-measure loss

In most cases, transduction and transcription models are trained with CE, but finally evaluated with frame- or note-wise F-measure. To close this gap between training and testing, we propose maximising the F-measure directly during training. However, this requires a binary piano roll instead of real-valued network outputs. As a solution, we employ binary neurons introduced in Section 4.3. By replacing $\mathcal{P}$ and $\mathcal{R}$ in the formula for $\mathcal{F}$ by their complete expressions (see Section 6), simplifying the equation, and using the two identities $\mathrm{TP}(t) = \sum_{p=1}^{N_p} y_{t,p} \cdot \hat{y}_{t,p}$ and $\mathrm{FN}(t) + \mathrm{FP}(t) = \sum_{p=1}^{N_p} |y_{t,p} - \hat{y}_{t,p}|$ where $\mathrm{TP}(t)$, $\mathrm{FP}(t)$ and $\mathrm{FN}(t)$ are the numbers of true positives, false positives and false negatives at time step t, respectively, we obtain

$$\mathcal{F} = \frac{\sum_{t=1}^{N_t} \sum_{p=1}^{N_p} 2 \cdot y_{t,p} \cdot \hat{y}_{t,p}}{\sum_{t=1}^{N_t} \sum_{p=1}^{N_p} \left[2 \cdot y_{t,p} \cdot \hat{y}_{t,p} + |y_{t,p} - \hat{y}_{t,p}|\right]} \tag{2}$$

as our F-measure loss, which only makes use of differentiable operators. The only exception is the absolute value function, whose gradient is undefined only at 0, which occurs in the above equation if $y_{t,p} = \hat{y}_{t,p}$. Since the model output $\hat{y}_{t,p}$ does not need to change in that case, we assign it a gradient of 0. In conjunction with binary outputs, we can thus use gradient descent to maximise $\mathcal{F}$. It has to be noted that a similar, non-binary version of F-measure was proposed as training loss in [30]. We only investigate the binary F-measure here.

5.3 Adversarial loss

We adapt the improved Wasserstein GAN [19] framework for the adversarial loss to our conditional generation case, by using a discriminator network $D_\theta : x, y \to \mathbb{R}$ that takes a transcription y as input with the corresponding acoustic model output x as condition. It is trained to output scalar values that minimise the loss (see Equation (3) in [19]):

$$\begin{aligned} L(\theta) = \mathbb{E}_{x\sim\mathbb{P}_r}[D_\theta(x, G_\phi(x))] - \mathbb{E}_{x,y\sim\mathbb{P}_d}[D_\theta(x, y)] \\ + \lambda\, \mathbb{E}_{x\sim\mathbb{P}_r, \hat{y}\sim\mathbb{P}_i(x)}[(||\nabla_{\hat{y}} D_\theta(x, \hat{y})||_2 - 1)^2], \end{aligned} \tag{3}$$

where $\mathbb{P}_r$ denotes the distribution of real acoustic model outputs. The third term regularises the discriminator network responses to stabilise generator training. It is weighted by the scalar hyper-parameter λ (we use $\lambda = 10$), and involves drawing $\mathbb{P}_i(x)$, which yields $\hat{y} = r \cdot G_\phi(x) + (1 - r) \cdot y$ with a weight r uniformly chosen from $[0, 1]$ that interpolates between the generator output $G_\phi(x)$ and the ground truth transcription y for the input x.

During training, the generator is updated once using the negative of the first term in (3) as loss, before the discriminator is trained on (3) for 5 iterations to re-estimate the Wasserstein distance between real and generator samples.

As discriminator, we use a convolutional network similar to [42]. First, a 5×1 convolution with dilation of 12 and 16 channels is computed to capture relationships between octaves, and concatenated to the input features for further processing. Afterwards, a 3×3 convolution with a stride of two is applied four times, using 16, 32, 64, and 128 filters, respectively. The downsampled feature map is processed by a dense layer with 16 nodes, and by another dense layer with a single output and linear activation. All layers except the final one use LeakyReLU activations.

6. EVALUATION METRICS

We evaluate the performance of our system using the common MIREX transcription metrics [1], in both frame-wise and note-wise configurations. With *frame metrics*, the output and the ground truth are compared frame-by-frame. The metrics are computed directly on the 16th-note-timestep piano-rolls. With *note metrics*, the system output and the ground truth are viewed as a list of notes. A note is correctly detected if its pitch matches the ground truth and its onset is within a tolerance threshold of the correct onset. The threshold usually used is 50ms, however, since we operate on 16th note timesteps, we require that onset times correspond exactly to the ground truth. The offsets are usually

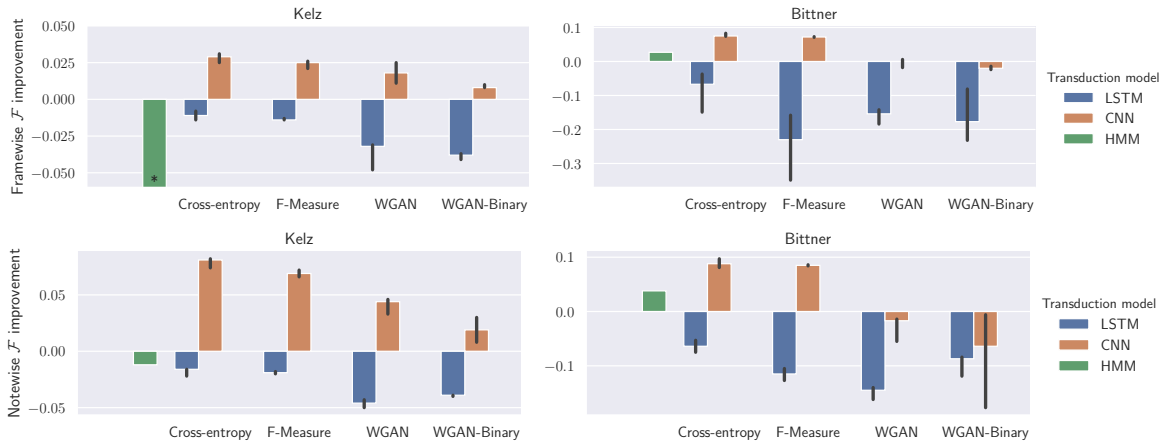

Figure 2. Model comparison across training objectives, transducer and acoustic models. Bars correspond to median improvement over simple thresholding, error bars correspond to maximum and minimum improvement across runs. * means that the bar was truncated for readability purposes.

not taken into account as they are difficult to estimate properly with percussive sounds such as piano notes. We use the `mir_eval` implementation [33] to find the maximal match between the two lists. In both cases, the precision ($\mathcal{P}$), recall ($\mathcal{R}$) and F-measure ($\mathcal{F}$) are computed as per [1]. These metrics are computed for each recording, and then averaged over sets of recordings.

7. RESULTS

We evaluate every possible combination of acoustic and transduction model as well as training loss and output type (continuous or binary neurons). To account for variability in training, we run every experiment 3 times and report results of the model that reaches the median frame $\mathcal{F}$ performance. To assess differences in performance across different conditions, we perform paired Wilcoxon signed-rank tests using the piece-wise results from each median model. All median results are given in Table 1 for Kelz, and Table 2 for Bittner. We also plot the absolute improvement over simple thresholding for frame and note $\mathcal{F}$ in Fig. 2. The error bars show the best and worst of the 3 runs.

7.1 Transduction model and acoustic model

The two transduction models (CNN and LSTM) clearly behave very differently. Most of the time, the CNN model improves the results compared to simple thresholding. On average, across all configurations, the CNN provides an average increase of 2.56% frame-wise and 3.39% note-wise $\mathcal{F}$. In particular, the CE-trained CNN improves for Kelz by 3.1% frame and 8.2% note $\mathcal{F}$, while for Bittner, it reaches 8.3% frame and 9.7% note $\mathcal{F}$. This difference in improvement can be explained by the fact that the Kelz acoustic model overfits a lot on the training set, reaching around 92% frame $\mathcal{F}$ on the training set alone, but only around 81% on the validation set. As a result, it is more difficult for transduction models to generalise with the Kelz model as input, as training and test data differ. The Bittner model is much more stable across subsets with 62% frame $\mathcal{F}$ on the training set, and 63% on the validation set, as it was trained on a completely separate dataset.

On the other hand, the LSTM model performs worse than thresholding in every configuration. This contradicts the improvement in frame $\mathcal{F}$ reported in [41] achieved using an LSTM, although one could argue that the experimental setup is quite different regarding the LSTM inputs, the lengths of training sequences, and dataset splits. We tried using training sequences of 256 instead of 64 timesteps and also tried a bi-directional LSTM to check whether a lack of context explains our result, but results did not improve. Since we observe much better training set than test set performance (e.g. the LSTM with CE loss on the Bittner model achieves about 80% on training but only 57% frame $\mathcal{F}$ on the test set), we suspect that strong overfitting is the sole reason. This effect might be amplified as training and test sets do not share any pieces or pianos, and synthetic pianos are used for training and real pianos for testing. Since the partitions used in [41] do share pianos, the improvement reported therein could be partly due to overfitting to the particular pianos featured in the training set. Our CNN appears to generalise better in this regard.

7.2 Comparing training objectives

Since our LSTM model does not generalise to the test set, we exclude it from the following comparisons between training objectives. It appears that supervised losses consistently outperform adversarial losses ($p < 10^{-9}$ for frame and note $\mathcal{F}$). Additionally, GANs performance varies more between training runs than with supervised losses. This contradicts the expected result that GANs should be more effective. Using binary neurons also failed to improve the performance of our system. In particular, in the context of GANs, non-binary neurons are significantly better than binary neurons for both frame and note $\mathcal{F}$ ($p < 0.02$), except for Bittner in terms of note $\mathcal{F}$ ($p = 0.33$). This shows that the findings of [14] do not generalise to our application, at least when we compare with strong CE-based models. GANs might require more data to realise their potential, better ways of training with discrete outputs, or more perceptually meaningful evaluation metrics to capture the improvement in

Table 2. Results as percentages for median models with Bittner input. Bold corresponds to best values across models.

output quality. Additionally, improvements or alternatives to binary neurons might be needed to stabilise training further, as we observed high variance in training loss between batches compared to using a CE loss.

We find that using our F-measure loss results in slightly worse $\mathcal{F}$ than when using the CE loss with Kelz (decrease of 0.4 in frame- and 1.6 in note-wise $\mathcal{F}$, $p < 0.02$), but no significant differences with Bittner. This might be explained by the use of 16th note timesteps that strongly smooths the inputs and outputs, reducing the risk of fragmented notes substantially. Also, the binary outputs could make training more difficult due to the approximations used to overcome the non-differentiability problem; and because we perform threshold tuning on the validation dataset for the CE setting, thereby giving the CE model the chance to fit its parameters more to the validation set, whereas it is only used for early stopping with the F-measure loss.

The theoretical advantages of binary neurons do not translate into performance improvements, but they are conceptually elegant since they do not require a separate threshold tuning after training. Overall, the basic CE loss remains the best performing for our task.

7.3 Comparison against baseline

We compare the best-performing model on both inputs (i.e. CNN trained with CE loss) with both baseline systems. CNN post-processing improves substantially over both baselines, for both acoustic models, with both frame and note $\mathcal{F}$ ($p < 0.01$). Surprisingly, the HMM post-processing yields significantly worse results than simple thresholding on Kelz for frame $\mathcal{F}$, but not significantly for note $\mathcal{F}$. It seems to be too conservative, outputting a note only when it is long enough and with high enough activation, a problem already noted in [41]. On Bittner however, HMM post-processing significantly improves results over thresholding ($p < 10^{-9}$ for frame $\mathcal{F}$, $p = 0.08$ for note $\mathcal{F}$). This can be attributed to the fact that the thresholded outputs contain a particularly high proportion of fragmented notes, because activations are very low in general, with many values around the threshold. The HMM successfully smooths them.

8. CONCLUSION

In this study, we proved that post-processing a posteriogram with a convolutional network model can improve transcription performance compared to several baseline methods. Various other tasks include similar discretisation problems, such as polyphonic sound event detection [9] or automatic drums transcription [38], and could probably benefit from this finding. We showed that some theoretically-motivated approaches did not actually result in increased performance as evaluated by the F-measure: WGANs do not perform better than a simple CE loss, binary neurons do not improve WGANs for this task, and training directly with the F-measure as loss is not better than using CE and then thresholding outputs as a post-processing step. We also showed that the results obtained in [41] actually do not generalise to the case where the recording conditions of test and training datasets differ, highlighting the importance of carefully selecting dataset partitions in future work.

This study resulted in many unexpected results that prompt us to investigate further. More transduction architectures could be investigated, such as C-RNNs. Data augmentation (e.g. pitch transposition) could provide sufficient data to make GANs worthwhile over CE. The F-measure loss could also improve further with other methods for back-propagating through the binary neurons. The fact that binary neurons seemed to improve results with Kelz and the LSTM model is also a good motivation to keep exploring their use with various architectures. Finally, all these configurations were evaluated with standard metrics. Especially for the WGAN models, it would be interesting to see whether the performance increases in ways that are not captured by the F-measure metric but turn out to be perceptually important in listening tests.

ABSTRACT

Similarity measures are indispensable in music information retrieval. In recent years, various proposals have been made for measuring melodic similarity in symbolically encoded scores. Many of these approaches are ultimately based on a dynamic programming approach such as sequence alignment or edit distance, which has various drawbacks. First, the similarity scores are not necessarily metrics and are not directly comparable. Second, the algorithms are mostly first-order and of quadratic time-complexity, and finally, the features and weights need to be defined precisely. We propose an alternative approach which employs deep neural networks for end-to-end similarity metric learning. We contrast and compare different recurrent neural architectures (LSTM and GRU) for representing symbolic melodies as continuous vectors, and demonstrate how duplet and triplet loss functions can be employed to learn compact distributional representations of symbolic music in an induced melody space. This approach is contrasted with an alignment-based approach. We present results for the Meertens Tune Collections, which consists of a large number of vocal and instrumental monophonic pieces from Dutch musical sources, spanning five centuries, and demonstrate the robustness of the learned similarity metrics.

1. INTRODUCTION

The question of how melodic similarity can be computationally modeled is of crucial importance for various Music Information Retrieval (MIR) tasks [35]. One classic MIR scenario is a user posing a sung or hummed query to a retrieval system in order to retrieve resembling pieces of music from a music collection [6, 24]. This query-by-humming scenario requires melodic matching methods that are robust against different kinds of melodic variation arising from imprecise memory or limited singing skills. Melody matching is also an important aspect in cover-song detection, where the predominant melody contains information for song identification [29]. Musicologists benefit from melodic similarity measures for exploring and mapping folk songs [19, 30], or other collections with monophonic musical material, such as themes from classical compositions [18], or score incipits [34]. Finally, music similarity detection plays an important role in cases of copyright violation [31], where objective similarity measures can support the court in making decisions.

In this paper, we present a Neural Network approach for melodic similarity learning. The neural encoders learn complex mappings from input sequences into distributed melody representations. The primary aim of our system is to be employable for music retrieval. In addition to accurately modeling melodic similarity, desirable properties of a retrieval system are speed and indexability. Neural Networks very well accommodate both. Generally, once trained, a neural network can compute results very fast by making use of GPUs. Moreover, indexability is served by the application of similarity metrics on top of the learned encodings [3].

Various other approaches to melodic similarity have been taken [35], including sequence alignment and other dynamic programming approaches, such as edit distance and dynamic time warping, and, recently, Recurrent Neural network representations [4, 9, 11, 16, 27, 30, 33]. In this study, we contrast our approach with a sequence alignment method that has been successfully applied in the context of folk melodies. Alignment-based methods suffer from at least three drawbacks. First, they typically are first-order, taking into account only adjacent items in sequences. Second, they have quadratic time-complexity. Finally, an alignment score is not a proper metric. Our neural network approach overcomes these disadvantages but does so at the cost of being a supervised learning algorithm.

2. DATA AND FEATURES

2.1 Data sets

The Meertens Tune Collections (MTC) [1] contains a series of data sets with melodic material from Dutch sources (mainly manuscripts, printed sources, and audio recordings), spanning five centuries of music history [20, 22]. These data sets are subsets of the Dutch Song Database, maintained by the KNAW Meertens Institute [21]. The lat-

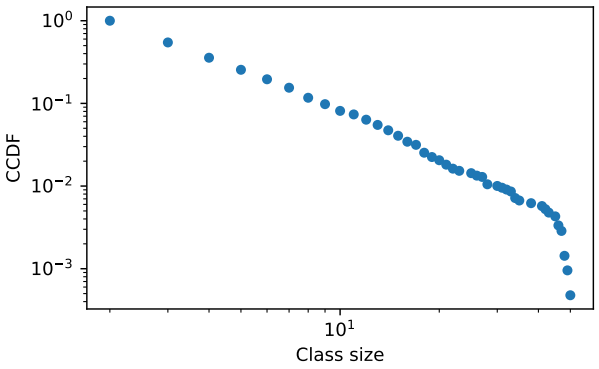

Figure 1. Complementary Cumulative Distribution Function of the tune family sizes in the subset of MTC-FS-INST 2.0 which we use in our experiments.

est release, MTC-FS-INST 2.0, contains 18,109 digitized melodies with rich metadata. Many of these melodies occur in more than one source. Due to oral and semi-oral transmission, these different occurrences typically show melodic variation. As an example, Figure 3 depicts three variant melodies, illustrating the kind and extent of variation. To denote such a group of variant melodies, we adopt the concept of *tune family* from folk song research [1]. In a long-term effort, the collection specialists of the Meertens Institute aim to identify each melody in terms of tune family membership.

In this paper, we use MTC-FS-INST 2.0, which reflects the diversity of the contents of the Dutch Song Database. One main distinction in the data set is between vocal and instrumental music as illustrated in Figure 2. Generally, the instrumental part of the data set dates from the 17th and 18th centuries. It contains melodies that were played in bars and brothels as well as theaters and upper-class private settings. The vocal part of the data set mainly consists of songs from the 19th and 20th centuries. As a whole, the data set provides a rich variety in melodic styles, which renders it a perfect source for training general purpose melodic similarity measures.

To obtain training, development, and test sets, we filter and split the data set. First, we exclude all 5,765 unlabeled melodies and all 3,008 singleton tune families. This leaves a selection of 9,336 melodies in 2,094 tune families. The complementary cumulative distribution function of the class sizes is presented in Figure 1. The distribution of class sizes is heavy-tailed.

An important criterion to measure the level of success achieved by the metric learning approach is its capability to cluster together tune melodies belonging to families unseen during training. In order to make this possible, we perform a controlled test set split, ensuring that all instances from a proportion of tune families do not appear in the training data. The actual proportions of seen and unseen families is shown in Table 1 together with further data set size statistics. [2]

[2] Supplementary material, data sets and code to replicate the experiments are available from `https://github.com/fbkarsdorp/melodic-similarity`.

	# Mel	# TF	# TF in Train	$\mu_{\|TF\|}$	$\sigma_{\|TF\|}$
Train	5,975	1,572		3.80	5.06

Test	1,869	611	287	3.06	1.55

Table 1. Composition of the subsets of MTC-FS-INST 2.0 used for training, development and testing. The table provides the number of melodies (Mel) and tune families (TF) in each set, the number of tune families that are shared with the training set, and mean and standard deviation of tune family sizes.

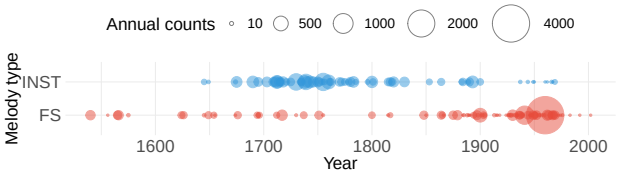

Figure 2. Number of melodies per year in MTC-FS-INST 2.0. The plot displays frequencies for instrumental melodies (INST) and vocal melodies (FS).

2.2 Features

Melodies are represented as sequences of notes, and notes as sets of feature-values. Since the MTC provide a rich melody encoding, including key, meter, and phrase boundaries, we can assemble a diverse feature-set in which various musical parameters are represented: pitch, metric structure, rhythm, tonality, and phrase structure. See the supplementary material for an exact list of features.

3. METHODOLOGY

Our approach is based on two components. First, we deploy distributional melody encoders implemented with Neural Networks. Secondly, we train the encoders with Stochastic Gradient Descent to minimize a Contrastive Loss that we describe below.

3.1 Distributional Encoder

An input melody from the dataset $x_i \in X$ can be represented by a sequence $x_i = [x_{(i,1)}, \ldots, x_{(i,k)}]$ of length $k = |x_i|$, where each $x_{(i,t)}$ is a bundle of m features explained in Section 2.2. For simplicity, we refer to the j^{th} feature of sequence step t as x_t^j, thus dropping data set indices. Our goal is to compute an encoding $h = f(x)$ as a function of the input sequence x, parameterized by a Neural Network $f(x)$.

The encoding process can be described as follows. We first process each time step in the input sequence independently by concatenating all features into a single vector $e_t = [e_t^1; \ldots; e_t^m]$. Categorical features are first encoded into a one-hot vector and projected into their own embedding space with model parameters $W_j \in \mathbf{R}^{JxE}$, where J

Figure 3. Three members of tune family *Daar was laatstmaal een ruiter 2*, showing various kinds of melodic variation.

is the total number of possible values of the j^{th} categorical feature and E is the dimensionality of the embedding space. Continuous features are normalized to have a mean of 0 and standard deviation of 1. For all feature types, the sequences are padded at the beginning and the end using special symbols in the case of categorical features and the feature mean after re-scaling for continuous features. The resulting sequence of input embeddings is fed to a stack of recurrent layers [3] with the t^{th} hidden activation at layer l given by $h_{(t,l)} = RNN_l(h_{(t,l-1)}, h_{(t-1,l)})$.

We also experiment with bidirectional RNNs, which extend each RNN layer with an additional RNN run backwards. In the case of the bidirectional RNN, the final melody embedding is given by the concatenation of the last activations of the forward and backward RNNs at the last layer: $h = [\overrightarrow{h_{(k,|L|)}}; \overleftarrow{h_{(1,|L|)}}]$. In the case of the unidirectional RNN, the embedding is given by a feature-wise max-pooling operation over the sequence of activations at the last layer, with the p^{th} output feature defined by $h_p = max([h_{(1,|L|)}]_p, \ldots, [h_{(k,|L|)}]_p)$. Instead of traditional RNN cells [7], we use LSTM [14] and GRU [5] cells which have been shown to offer stronger performance and better training behavior.

3.2 Contrastive Loss

The goal of our approach is to learn a distributional encoder such that melodic sequences of the same class are embedded into neighboring regions and far from melodic sequences belonging to different families. To this end, we train the encoder using a contrastive loss [12].

3.2.1 Duplet Loss

Let the encodings of two input sequences with tune family labels y_i and y_j be denoted by x_i and x_j. The goal we want to achieve is that the similarity between x_i and x_j is high when y_i and y_j are equal, and low otherwise. More formally, we seek to achieve the following inequality:

$$D(x_i, x_j) < D(x_i, x_k) + \alpha \tag{1}$$

$\forall (x_i, x_j, x_k) \in X \mid y_i = y_j \wedge y_i \neq y_k$, where D is a distance function and α is a pre-specified margin. In order to achieve this goal, we optimize a contrastive loss function defined over input pairs that is therefore known as the duplet loss. The contrastive loss function is decomposed in a positive term L_+:

$$L_+(x_i, x_j) = (\beta) D(x_i, x_j)^2 \tag{2}$$

[3] During preparatory work, we also experimented with convolutional stacks but found no improvements over the recurrent counter-part, which was, therefore, singled out for the purpose of the present study.

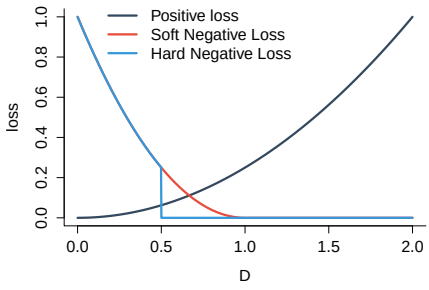

Figure 4. Visualization of the two loss variants with a hard margin and a soft margin.

and a negative term L_-:

$$L_-(x_i, x_j) = \max(0, \alpha - D(x_i, x_j))^2 \tag{3}$$

where β is a parameter used to weight the contribution of the negative term. [4] The two terms can be combined into a single loss function with the help of a variable $Y_{i,j}$ that takes value of 1 for $y_i = y_j$ and 0 when $y_i \neq y_j$:

$$L_D(x_i, x_j) = (Y_{ij}) L_+(x_i, x_j) + (Y_{ij} - 1) L_-(x_i, x_j) \tag{4}$$

For the current study, we restrict ourselves to the cosine distance as defined by Eq. 5:

$$D(x_i, x_j) = 1 - \frac{f(x_i) \cdot f(x_j)}{\|f(x_i)\| \|f(x_j)\|} \tag{5}$$

Naturally, other distance functions are equally applicable, but the two-sided boundedness of the cosine distance (i.e. distances fall between [0, 2]) allows more efficient optimization of the parameters α and β. Moreover, the loss specified above employs a soft margin. By contrast, [28] propose the use of a hard margin, effectively reducing the loss to zero if it falls below some value. With the hard margin, the negative term in Eq. 3 becomes:

$$L_-(x_i, x_j) = \begin{cases} (1 - D(x_i, x_j))^2 & D(x_i, x_j) < \alpha \\ 0 & \text{otherwise} \end{cases} \tag{6}$$

Figure 4 visualizes the two loss variants. In the experiments below, we compare both versions of the loss.

3.2.2 Triplet Loss

The triplet loss [13, 32] differs from the duplet loss in that it considers input example triplets x_i, x_j, x_k consisting of a positive example x_i, a negative example x_j such that

[4] The scaling parameter β and margin α are optimized on a development data set, which we will discuss below.

$y_j \neq y_i$ and an anchor x_k such that $y_k = y_i$. The triplet loss shares the goal of the duplet loss from Eq. 1, but employs anchor positive examples to ensure that the distance between any two instances of the same family is less than the distance to an instance of a different family by at least a pre-specified margin α. More formally, the triplet loss is defined by Eq. 7:

$$L_T(x_i, x_j, x_k) = \max(0, D(x_i, x_k) - D(x_j, x_k) + \alpha) \tag{7}$$

The triplet loss, therefore, presents a more relaxed form than the duplet loss, allowing instances of the same family to occupy larger regions. As opposed to the composite form of the duplet loss, the triplet loss is simple. However, the triplet loss is more heavily dependent on the quality of the sampled negative examples and anchors, which might lead to poorer training dynamics.

3.3 Online Duplet and Triplet Mining

We train our encoder using mini-batches of duplets or triplets from the data set. The number of possible duplets and triplets grows, respectively, quadratically and cubically with the number of instances in the data set, which renders exhaustive training costly. Feasibility aside, training with all possible duplets or triplets is not desirable as a large proportion of the resulting duplets and triplets make it either too easy or too difficult to fulfill the objective of Eq. 4 and Eq. 7. Such examples prevent the network from learning, and lead to slower convergence.

As suggested by [32] in the context of face recognition, efficient and fast converging training can be achieved by online selection of 'hard' duplets or triplets, i.e. the most dissimilar *positive* examples, and the least dissimilar *negative* examples. We apply this approach by first sampling a mini-batch of k instances per each of n sampled unique tune families. Subsequently, using the current model we compute the encodings of all $n \times k$ instances and for each instance we sample positive and negative, or anchor and negative examples from the mini-batch. In the case of the duplet loss, for each instance we select all possible positive examples (i.e. all other instances in the mini-batch from the same family) and an equal number of negative examples from the least dissimilar negatives. In the case of the triplet loss, for each instance x_i we select pairs of anchor x_k and negative example x_j such that the distance between positive and anchor is smaller than the distance between negative and anchor, while the difference between the distances lies inside the margin α:

$$0 < D(x_i, x_k) - D(x_j, x_k) < \alpha \tag{8}$$

In case no negative example can be found that satisfies this condition, we select a random negative.

3.4 Baseline: Alignment

We compare our results with the performance of a previously proposed alignment method [23]. In this method, the Needleman-Wunsch-Gotoh algorithm is used [10], which computes a global alignment score for two sequences of symbols. The alignment is constructed by inserting gaps at appropriate locations in the sequences following a dynamic programming approach. The alignment score is based on a similarity function for symbols and a gap scoring scheme. The Gotoh-variant of the algorithm applies an affine gap scoring function in which the continuation of a gap obtains a different score than the opening of a gap, opposed to the basic variant of the algorithm in which all gaps obtain the same score. We use the best scoring configuration in [23], which uses pitch, metric weight and the position of a note in its phrase.

3.5 Evaluation

We formulate the task of tune family identification as a ranking problem: given a query melody q_i and a data set of melodies $X, q_i \notin X$, the models should provide a ranked list of the melodies in X. To evaluate how well our models solve this problem, we measure the performance of the models by means of three evaluation measures: (i) 'Average Precision', (ii) 'Precision at rank 1', and (iii) 'Silhouette Coefficient'. Each of these measures addresses a different aspect of the performance quality of the models. First, Average Precision (AP) addresses the question whether given a query melody, all or most relevant melodies are high up in the ranking:

$$\text{AP} = \frac{\sum_{k=1}^{N} P(k) \times rel(k)}{\text{number of relevant melodies}}, \tag{9}$$

where k is the position in the ranked list of N retrieved melodies. $P(k)$ represents the precision at position k, and $rel(k) = 1$ if the melody at position k is relevant, $rel(k) = 0$ otherwise. By computing the average AP over all query melodies, we obtain the Mean Average Precision (MAP). As a second ranking measure, we focus on the Precision at rank 1 score (P@1), which computes the fraction of queries for which the highest ranked sequence is relevant. Third and finally, we compare these two ranking based evaluation measures with the Silhouette Coefficient, which is a measure of cluster homogeneity and separation. The Silhouette Coefficient contrasts the mean similarity between a sample and all other samples from the same family with the similarity of that sample with members of other families. By taking the average over all silhouette scores, we obtain a measure of cluster homogeneity ranging from -1 (incorrect clustering) to 1 (perfect clustering). [5]

3.6 Training and Hyper-Parameter Optimization

The networks were trained on the training data sets specified in Table 1. We use the Adam optimizer [17] and stop training after no improvement in MAP score was made on the development data for ten consecutive epochs. The neural network consists of a large number of hyper-parameters, making hyper-parameter tuning expensive and time-consuming. Following [2], we perform a randomized hyper-parameter search, in which we train n differ-

ent models with random hyper-parameter settings sampled from parameter-specific, relatively flat distributions. [6]

4. RESULTS

Table 2 presents the results for the development data set with MAP scores for the best performing models trained with duplet (RNN_D) and triplet loss (RNN_T). The best RNN_D achieves a MAP of 0.72, which is markedly better than the Alignment method (0.69), and slightly better than the best RNN_T (0.71). However, as will be discussed in more detail below, RNN_T models are significantly harder to optimize than RNN_D models (at least for the current data set). The columns 'seen' and 'unseen' represent MAP scores for queries of which the corresponding tune families were either seen or unseen during training. Crucially, the scores are almost equivalent, indicating that the neural networks are capable of actually learning a similarity metric, and not just a clustering or classification procedure, in which the systems learn to assign sequences to known class labels and data points. The performance differences between the models are further expressed by the Silhouette coefficient, which indicates superior performance of the RNN_D model. However, note that for P@1, all systems perform equally well.

The best performing models were employed to encode the melodies in the test set. The test results in Table 3 show a similar picture. Again, RNN_D outperforms the other systems. Note that the performance of RNN_T slightly dropped in comparison to the development results and that the performance difference with respect to RNN_D has become larger. Overall, the RNNs appear to have adequately learned how to form compact distributional representations of symbolic music in an induced melody space. This capability is further illustrated by the two-dimensional projection of the melody space in Figure 5. The left subplot demonstrates that the learned representations clearly separate vocal (FS) from instrumental melodies (INST). The subplot to the right serves as a validation of the clustering capabilities of the encoder. It highlights the positions of a small number of randomly chosen tune families, the members of which all cluster together.

[6] The full list of hyper-parameters and the predefined priors are listed in Section 2 of the Supplementary Materials.

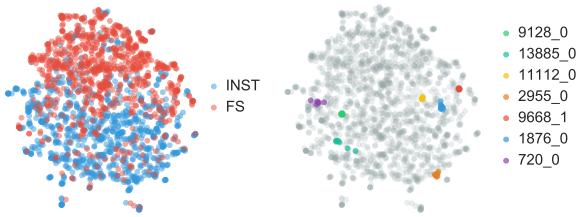

Figure 5. Two-dimensional UMAP [25] projection of the induced melody space obtained with RNN_D. The left subplot visualizes the positions of instrumental melodies (INST) and vocal melodies (FS). The subplot to the right highlights the positions of a small number of randomly chosen tune families.

4.1 Hyper-Parameter Importance

We assess the importance of the different hyper-parameters of the neural networks by modelling their influence on the MAP scores resulting from the randomized parameter search [26]. To this end, we fit the following linear regression model:

$$\text{MAP}_i \sim \mathcal{N}(\mu_i, \sigma) \quad (10)$$

$$\mu_i = \gamma + \beta_l l_i + \beta_m m_i + \beta_h h_i + \beta_d d_i + \beta_b b_i + \beta_c c_i + \beta_{lm} l_i m_i, \quad (11)$$

where Eq. 10 specifies the likelihood function with mean μ and standard deviation σ, and Eq. 11 represents the linear model. Here, γ represents the intercept of the linear model, l_i is the loss type of model i (i.e. triplet or duplet loss), m_i is the margin value α, h_i is the dimension of the hidden layer, d_i refers to the embedding dropout value, b_i dummy encodes whether a model employed bidirectional versus unidirectional RNNs, and c_i is the cell type of the RNN (i.e. LSTM or GRU). Since the margin functions differently in the triplet and duplet loss, we model the interaction between margin and loss type ($\beta_{lm} l_i m_i$). All categorical predictors are dummy encoded, and the continuous predictors are zero centered. β priors are sampled from uninformative Normal distributions, $\mathcal{N}(0, 1)$, and σ is sampled from a weakly regularizing half-Cauchy prior with location 0 and scale 1.

Table 4 presents the posterior distribution estimates of the model along with their estimation errors, their 95% credible intervals (CI_{95}), and the $\hat{R}$ statistic. [7] The mean

[7] Since the linear model is Bayesian, the credible intervals can be interpreted straightforwardly as the 95% probability that the estimates fall in a particular range. The 'No U-Turn Sampler' (NUTS) was used for sampling [15], which is a specific type of Hamiltonian Monte Carlo (HMC).

	Estimate	Error	l-CI$_{95}$	u-CI$_{95}$	$\hat{R}$
γ	0.66	0.00	0.65	0.67	1.0
β_l	-0.08	0.01	-0.09	-0.07	1.0
β_m	0.01	0.01	-0.02	0.04	1.0

β_{lm}	-0.18	0.02	-0.22	-0.13	1.0
σ	0.04	0.00	0.04	0.04	1.0

Table 4. Posterior distribution estimates for the hyper-parameters of the Neural Networks. In addition to the mean estimates, the table provides the estimation errors, 95% Credible Intervals, and the $\hat{R}$ statistic.

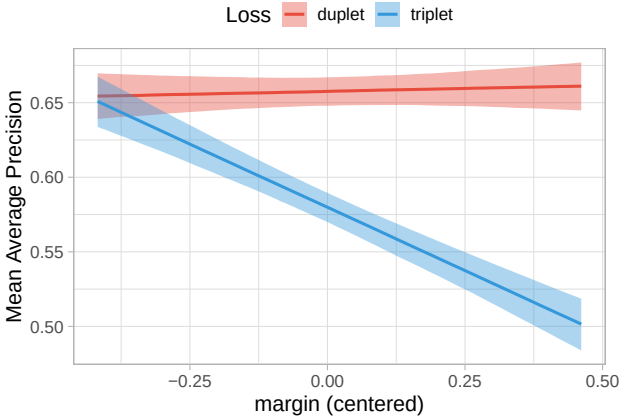

Figure 6. Marginal effects plot showing the interaction between loss type (i.e. Duplet and triplet loss) and the margin α.

intercept $\gamma = 0.66$ represents the mean posterior estimate of MAP values for unidirectional models, fit with GRU cells ($c_i = 0$), duplet loss ($l_i = 0$) and mean (i.e. 0) values for the continuous predictors. Given this base model, several interesting observations can be made. First, as suggested by the negative β_l estimate, triplet loss models markedly underperform duplet loss models with, *ceteris paribus*, a mean drop in performance of 0.08. Second, employing larger hidden dimensions (β_h) and using bidirectional RNNs (β_b) both positively influence the MAP scores. Third, on average adding too much dropout hurts performance ($\beta_d = -0.05$). Fourth, the strong negative posterior distribution estimate for the interaction between the margin α and loss type indicates that careful tuning of α is especially important for the triplet loss. By contrast, different values of α barely impact the performance of duplet loss models. The marginal effects plot in Figure 6 highlights this interaction. Finally, RNNs trained with GRU cells markedly outperform models trained with LSTM cells ($\beta_c = -0.05$). Figure 7 illustrates this performance difference. Additionally, the plot demonstrates the

$\hat{R}$ is a statistic to assess the convergence of the sampler, and should be below 1.1 [8]. For more information about the convergence and parameters, see the Supplementary Information.

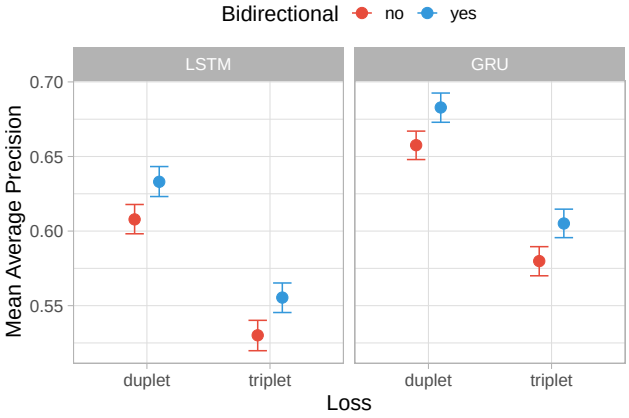

Figure 7. Marginal effects plot of RNN cell type (i.e. LSTM or GRU) and bidirectional versus unidirectional RNNs.

benefits of employing bidirectional RNNs, which consistently outperform unidirectional models.

5. CONCLUSION & FUTURE WORK

This paper proposed a method for end-to-end melody similarity metric learning using deep neural networks. We trained distributional melody encoders to minimize Duplet and Triplet Contrastive loss functions with which we achieve state-of-the-art retrieval performance on a large set of instrumental and vocal melodies. A thorough statistical analysis of the hyper-parameters of the Neural Networks indicates that on average Duplet Loss RNNs are easier to tune and less sensitive to specific hyper-parameter settings. Additionally, RNNs trained with GRU cells consistently outperform LSTM cell implementations. Our system has several major advantages over more traditional, alignment-based methods. First, thanks to its ability to infer complex interactions between input variables, the Neural Network approach is less sensitive to specific feature combinations and feature selection. Second, as shown by our study, the Neural Network approach displays more robustness, achieving similar MAP scores across exclusive sets of tune families (seen vs unseen).

For future work, we have the following three recommendations. First, the applicability of the proposed approach should be carefully examined on more diverse data sets, in order to test for the cross-domain robustness of the learned similarity metrics. Second, a more extensive and thorough comparison (including error analysis) with other existing melodic similarity methods is desired to highlight advantages and possible disadvantages of the neural systems. Finally, we acknowledge that, while successful, the proposed architecture still leaves room for improvement. Inspired by progress in similarity metric learning within the fields of Paraphrase Detection and Semantic Textual Similarity, we would like to experiment with more expressive neural architectures and feature extraction to explore the performance limits of the Neural Network approach on melodic similarity metric learning.

ABSTRACT

We propose a multi-task learning approach for simultaneous tempo estimation and beat tracking of musical audio. The system shows state-of-the-art performance for both tasks on a wide range of data, but has another fundamental advantage: due to its multi-task nature, it is not only able to exploit the mutual information of both tasks by learning a common, shared representation, but can also improve one by learning only from the other. The multi-task learning is achieved by globally aggregating the skip connections of a beat tracking system built around temporal convolutional networks, and feeding them into a tempo classification layer. The benefit of this approach is investigated by the inclusion of training data for which tempo-only annotations are available, and which is shown to provide improvements in beat tracking accuracy.

1. INTRODUCTION

By definition, the music analysis tasks of tempo estimation and beat tracking are highly interconnected. Considering the goal of a beat tracking system is to produce a sequence of time instants that reflect how a human listener might tap their foot in time to a piece of music, we understand the tempo as the rate at which these beats occur, as measured in beats per minute (BPM). With the exception of a specific class of musical recordings which are both perfectly quantised (i.e. adhering strictly to a fixed metronome), and which begin precisely at the onset of a beat, e.g. drum loops, tempo information alone is insufficient to derive the beats since it provides no information about phase. In practice, a more flexible and musically realistic approach to beat tracking is required to contend with deviations from purely isochronous beat sequences without a trivial phase component. These deviations can take the form of continuous changes in tempo and/or timing which are common in expressive musical performances, more abrupt "step" changes in tempo, or short pauses after which a previously established tempo is resumed [21]. The presence and extent of these deviations from isochrony have been identified as contributing to the difficulty of musical examples for computational beat tracking [14] as well as for human annotators annotating ground truth [27].

When reflecting on the history of computational approaches for beat tracking, we consider that the role and usage of data has fundamentally changed. For the earliest work in beat tracking in the 1990s [18, 37], annotated data was scarce. By the mid-to-late 2000s, several beat tracking datasets (both public and private) came into use [12, 19, 20, 22, 24, 29] and were widely adopted as the primary means for reporting beat tracking performance. Even allowing for parameter optimisation or some training to maximise the performance of beat tracking algorithms on given datasets, a closed loop (in a strict end-to-end sense) did not exist between annotated data and beat tracking algorithms until the advent of deep neural network (DNN) approaches [7]. Both the high learning power and explicit use of annotations of DNN approaches led to a significant leap in the state of the art.

Similarly, tempo induction algorithms formerly tried to identify the main periodicity of musical accent features, such as band-passed signals, discrete onsets or a continuous detection function by means of auto-correlation [1, 13, 36], resonating comb filters [29, 37] or Fourier analysis [9], and available data was only used to evaluate the algorithms. The first attempts to learn something meaningful from data for tempo estimation sought to devise ways to choose among multiple tempo hypotheses [15, 16, 26, 38, 45] or to predict the perceptual tempo [35]. Only recently, DNN approaches have been used to infer tempo directly from spectral features [40].

At the present time, DNN approaches are highly prevalent among music analysis and generation research within the music information retrieval (MIR) community, and thus access to large amounts of high-quality annotated data is of paramount importance for the development and training of new models. For beat tracking, the hand annotation of beat locations is particularly arduous due to the need to make several hundred temporally-dependent annotations per full piece of music, and the work-load only increases in the presence of challenging musical and signal conditions [27]. By contrast, global tempo annotation, while still dependent on some approximate beat marking, can typically be created with far less effort. As a result,

there is a far greater amount of tempo annotated data available than for beat tracking.

Our motivation is therefore towards a new approach for beat tracking which can be trained not only on beat annotations but also from tempo-only annotated data. We formulate this as a multi-task learning problem [8] for simultaneous tempo estimation and beat tracking. Our hypothesis is that due to the multi-task nature, we can not only exploit the mutual information of both tasks by learning a common, shared representation, but also improve one by learning only from the other.

We implement our multi-task approach by extending a recent beat tracking system [11] built around temporal convolutional networks (TCNs) [2, 44]. The primary addition in this paper takes the form of globally aggregating the skip connections of the TCN and feeding them into a tempo classification layer. A graphical overview of the inputs and outputs of our system is shown in Figure 1, with details of the architecture in Figure 2.

We evaluate our proposed multi-task system on a wide range of existing beat- and tempo-annotated datasets and compare performance against reference systems in both tasks. Our results demonstrate that the multi-task formulation achieves state-of-the-art performance in both tempo estimation and beat tracking. The most notable increase in performance occurs on a dataset where the network has been trained on tempo labels but whose beat annotations remain totally unseen by the network.

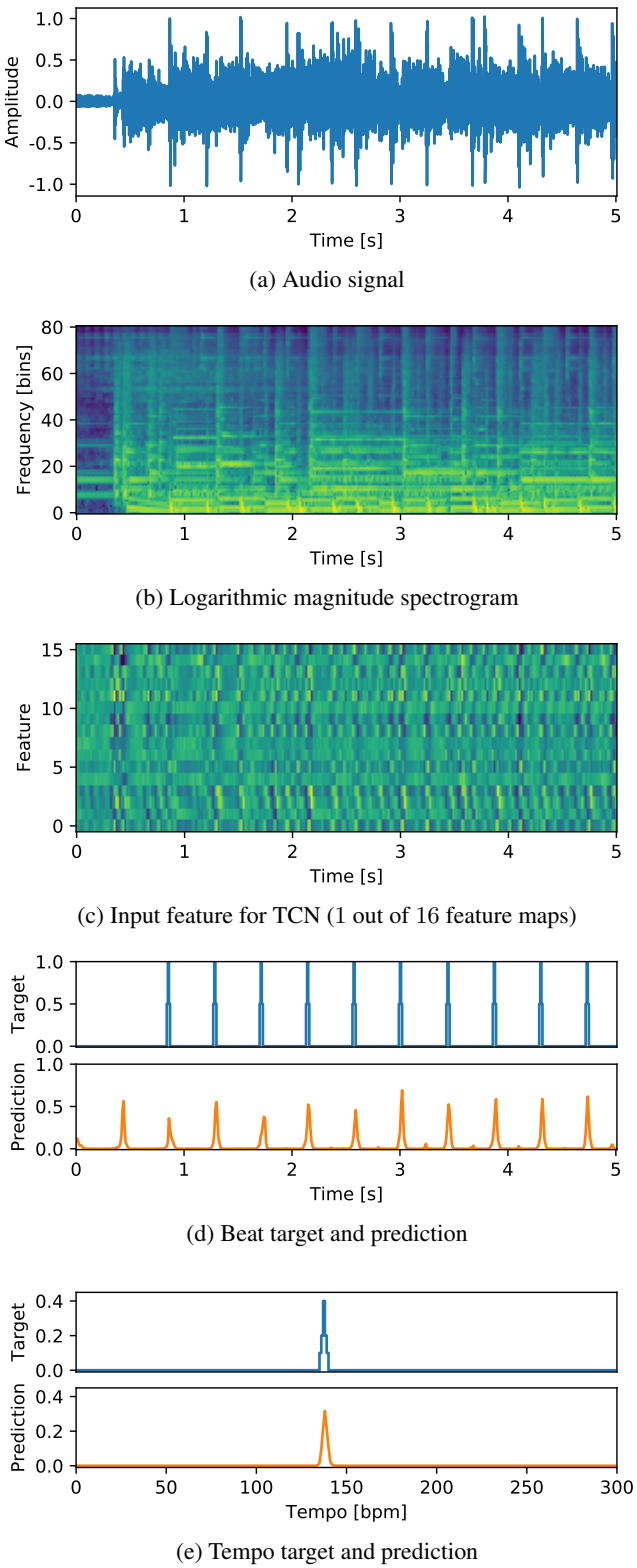
The remainder of this paper is structured as follows. In Section 2 we provide an overview of the existing beat tracking approach and then detail our multi-task formulation. In Section 3 we conduct a rigorous evaluation of beat tracking and tempo estimation. Finally, in Section 4 we discuss the context of the results and propose areas for future work.

2. APPROACH

In this section, we provide an overview of the beat tracking system [11] around which our multi-task learning approach is formulated. Following this, we describe the extension for multi-task learning via the inclusion of an additional output layer which performs tempo classification.

2.1 Beat Tracking Approach

The underlying beat tracking approach is inspired by two well-known deep learning methods: i) the *WaveNet* model [44] which uses dilated convolutions for generative audio synthesis by learning directly on raw audio waveforms, and ii) the current state of the art in musical audio beat tracking [4, 6], which uses a bi-directional long short-term memory (BLSTM) recurrent architecture. Based on the work of Bai et al. [2], who demonstrated improved performance of TCNs over recurrent architectures for numerous sequential data analysis and classification tasks, we developed a TCN approach for musical audio beat tracking [11] which, at a high-level, addressed the substitution of the BLSTM in [4, 6] with a TCN. However, since the



(a) Audio signal

(b) Logarithmic magnitude spectrogram

(c) Input feature for TCN (1 out of 16 feature maps)

(d) Beat target and prediction

(e) Tempo target and prediction

Figure 1: Signal flow of a 5 second audio excerpt through the proposed multi-task system. From the time domain signal (a), a logarithmic magnitude spectrogram is computed (b). This input representation is processed by intermediate convolutional and max pooling layers to obtain a single 16-dimensional feature (c), which is fed into the TCN. Both targets and predictions for beats and tempo are shown in (d) and (e), respectively.

TCN from *WaveNet* is both causal and operates on raw audio, several modifications were required, which are summarised below.

Instead of using raw audio as input, the dilated convolutions are performed on a highly sub-sampled low-dimensional feature representation (cf. Figure 1c). This 16-dimensional feature vector is derived by applying multiple convolution and max pooling operations to a log magnitude spectrogram of the input audio signal. The spectrogram is computed with a window and FFT size of 2048 samples, a hop size of 441 samples (i.e. 100 frames per second for audio sampled at 44100 Hz), and filtered with a bank of overlapping triangular filters with 12 bands per octave covering a frequency range of 30 to $17,000$ Hz (cf. Figure 1b). Alternating convolutional and max pooling layers are applied to slices of 5 frames in length to reduce the dimensionality both in time and frequency to a single dimension. The convolutional layers contain 16 filters each, with kernel sizes of 3×3 for the first two, and 1×8 for the last layer. The intermediate max pooling layers apply pooling only in the frequency direction over 3 frequency bins. A dropout [42] rate of 0.1 is used with the exponential linear unit (*ELU*) [10] as activation function.

The main TCN component from *WaveNet* was modified to operate non-causally, meaning that, for any time frame of the input representation, the dilated convolutions extend in both directions (i.e. back to the past and forward to the future). This provides a receptive field which is centred on the time frame in question, rather than directed solely towards the past.

In terms of the parameterisation of the TCN approach we used 11 layers with 16 1-dimensional filters of size 5 and geometrically spaced dilations ranging from 2^0 up to 2^{10} time frames. The resulting receptive field is ~ 81.5 seconds. We applied spatial dropout with rate 0.1 and used the *ELU* activation function instead of the gated activations of *WaveNet*. As output we used a single *sigmoid* unit. In order to obtain a final beat tracking output, the beat activation function produced by the network was passed to a dynamic Bayesian network, approximated by a hidden Markov model, from [31]. For further details on the TCN approach for beat tracking, see [11].

In this work we slightly changed the architecture of [11] by adding another 1×1 convolution layer with 16 filters into the residual path of the TCN layers (cf. Figure 2). We found that this layer helped to increase tempo estimation performance.

2.2 Multi-Task Extension

We extend this beat tracking system to be able to estimate the tempo of a musical piece by adding a second output branch to the network. As output, a classification layer with linear spacing as in [40] is used. It has 300 units, representing a tempo range from 0 (indicating that the piece has no tempo) up to 300 BPM. This additional output allows for multi-task learning of the whole system, the details of which are outlined in Figure 2. In order to be able to process input sequences of variable length, global average pooling (over time) is used to aggregate the features for the tempo classification layer.

While it is possible to feed the output of the TCN (or indeed the output of any other sequential beat tracking model) directly to the tempo classification layer, in practice we found that using a beat activation function led to reasonable "coarse" tempo estimation performance (i.e. determining whether a musical piece is either fast or slow), but lacked absolute precision. However, utilising skip connections of the TCN boosted tempo estimation accuracy considerably. Our intuition is that this way the subtleties of the intermediate representation of the dilated convolutions (which represent different time scales) are preserved and can be better exploited.

In the original *WaveNet* [44], skip connections were used to speed up convergence and enable training of deep models. Since the TCN beat tracking system [11] has only 11 layers, skip connections were not needed to successfully train a model and thus were not utilised. In this work, we branch off the skip connections at the same location as in *WaveNet* (i.e. from the 1×1 convolutions inside the TCN layers), but use them solely for the tempo branch of the network (cf. Figure 2).

We aggregate the skip connections of the individual layers by summation. Since the 1×1 convolutions have 16 filters each, this results in a single 16-dimensional feature vector for classification. Compared to concatenating the skip connections, this low-dimensional input to the tempo classification layer reliably prevents over-fitting to the training data. We apply dropout [41] with rate 0.5 before feeding this vector in the final tempo classification layer with a *softmax* function. During inference, quadratic interpolation of the output probability distribution is used to determine the final tempo in BPM.

The whole system has only $29{,}901$ trainable parameters, from which the multi-task tempo classification extension accounts for $5{,}100$. We contrast our compact model with the reported $2.9M$ parameters of the current state of the art in tempo estimation [40].

2.3 Network Training

To train the system, we represent annotated beat training data as impulse trains at the same temporal resolution as our input feature (i.e. 100 frames per second). To allow for slight deviations of the annotated beat locations and partially address the imbalance between the number of beat and non-beat frames, we use the neighbouring frames of the annotated beat positions as positive examples, but weight them by a scaling factor of 0.5 (cf. Figure 1d).

Given beat annotations, we derive tempo annotations by counting the inter-beat-intervals (IBI) to build a histogram. We smooth this histogram with a Hamming window of size 15 frames (i.e. 150 ms) to counteract small fluctuations of the beat annotations and determine the most dominant IBI by quadratic interpolation. This interval is then converted to tempo in BPM and mapped to tempo targets representing integer BPM values. In a similar way to the widening of the beat annotations, we smooth the tempo targets, but

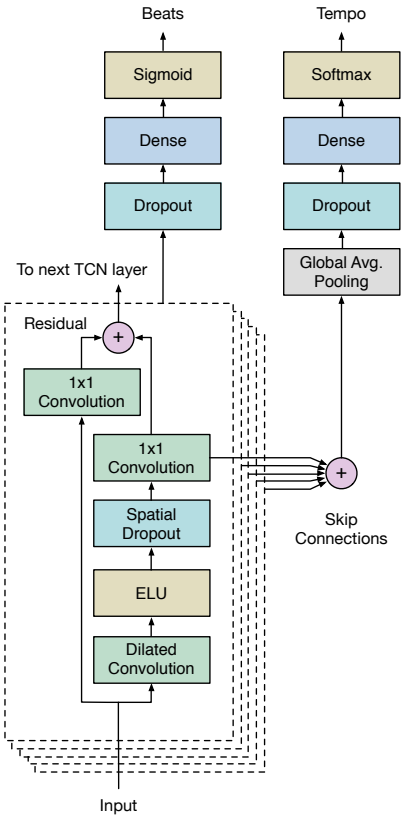


Figure 2: Structure of the neural network with the TCN for beat tracking (left) and the multi-task extension for tempo estimation (right).

extend the range to ± 2 BPM, weighting the neighbouring BPM targets with 0.5 and 0.25, respectively. We then normalise the tempo targets to form a probability distribution (as shown in Figure 1e) in order for it to be usable with the *softmax* activation function.

For training, we combine the cross-entropy losses of both network outputs by weighting them equally. Since the training sequences have different lengths, we train on whole sequences and minimise the combined loss with stochastic gradient descent (i.e. using a batch size of 1). We use *Adam* [28] with an initial learn rate of 0.002, and reduce it by a factor of 5 whenever the validation loss reaches a plateau and stop training if no improvement in validation loss is observed for 50 consecutive epochs or if a maximum of 150 epochs have elapsed. To avoid exploding gradients, we clip the gradients to a maximum norm of 0.5. If only tempo targets are present for training, we mask the loss of the beat tracking output. This way, only the error of the tempo output is backpropagated through the network and used to update the weights. It is important to note, that even in this scenario the shared beat and tempo feature representation gets adapted and optimised.

3. EXPERIMENTS AND EVALUATION

For experiments and evaluation we use the datasets listed in Table 1. Those listed in the upper part are used for training using 8-fold cross validation, and those in the lower part are independent test sets held back for evaluation only. If available, updated annotations are used and indicated by additional references. We chose these datasets in order to be able to compare the performance of our proposed systems to the best performing reference systems for both beat tracking and tempo estimation.

Dataset	files	length
Ballroom [23, 32] [1]	685	5 h 57 m
Beatles [12]	180	8 h 09 m
Hainsworth [24]	222	3 h 19 m
Simac [20]	595	3 h 18 m
SMC [27]	217	2 h 25 m
HJDB [25] $*$	235	3 h 19 m
ACM Mirum [35] $\star$	1410	15 h 05 m
GiantSteps [30, 39] $\star$	664	22 h 05 m
GTZAN [33, 43]	999	8 h 20 m

Table 1: Datasets used for training (upper half), and testing (lower half). The $*$ symbol denotes that only tempo annotations were used during training and beat annotations are used for evaluation only, and the $\star$ symbol indicates those datasets for which only tempo annotations exist.

The *HJDB* (Hardcore, Jungle, Drum & Bass) dataset is used to demonstrate the effectiveness of our multi-task extension w.r.t. its ability to improve beat tracking performance using only the tempo annotations of this set. This dataset was chosen, since its distinct music style is not well represented within any of the other training sets.

3.1 Beat Tracking Evaluation

We compare our proposed multi-task system to existing state-of-the-art beat tracking systems, namely to the underlying TCN approach presented in [11], and the two BLSTM approaches for beat [4] and joint beat and downbeat tracking [6]. Our goal is that the inclusion of the tempo classification layer is never detrimental to the performance of the beat tracking component.

Following the *de facto* standard for beat tracking evaluation, we report a set of different metrics with the parameterisation defined in [12]. We use the standard *F-measure*, as well as the continuity based measures *CMLc* and *CMLt* which require the beats to be tracked at the correct metrical level, as well as *AMLc* and *AMLt* which also allow alternate metrical interpretations such as double/half and offbeat. They either consider only the longest consecutive correctly tracked segment (*xMLc*) or all correctly tracked beats of a musical piece (*xMLt*).

From the results given in Table 2 it can be seen that all systems achieve essentially the same level of beat tracking accuracy, independent of the evaluation method. There are, however, smaller deviations from this general tendency. The beat output of the downbeat tracking system [6] performs slightly better on the *Ballroom* set, which might be

[1] The 13 identified duplicates were removed: `http://media.aau.dk/null_space_pursuits/2014/01/ballroom-dataset.html`

due to the characteristic rhythmic patterns which can be better exploited by explicit modelling of whole bars.

Table 2: Beat tracking results on datasets used for training with 8-fold cross validation (top), and on completely unseen test data (bottom).

Given these results, we infer that the multi-task system achieves at least the same performance as the same system without the multi-task extension.

3.2 Multi-Task Evaluation

In the previous section, our evaluation focused on the use of both tempo- and beat-annotated training data within our multi-task model. In order to test our hypothesis that tempo-only information can indeed lead to improved beat tracking accuracy, and thus demonstrate the ability of multi-task learning to strengthen one target by learning additionally from the other, we perform a further experiment. To this end, we add a new dataset, but only use its tempo annotations for training.

We believe that the effect of this learning strategy should be most visible when performed with data, which is otherwise underrepresented in the training set. In our opinion, the *HJDB* dataset is a perfect fit since it contains musical genres from the early 1990s, namely Hardcore, Jungle, and Drum & Bass, which are characterised by their very distinct rhythmic structure. For the details on this dataset, see [25].

We train our new multi-task approach in two different ways. Once with the data as outlined in Table 1, but without *HJDB* (i.e. as in the previous section), and once including the tempo annotations of this dataset.

Inspection of the first two rows of Table 3 reveals that both the original TCN beat tracking system, and the system with the multi-task extension achieve roughly the same performance across all evaluation methods. However, once the additional tempo information is utilised (last row marked with the $*$ symbol), the performance increases by up to ~ 5 percentage points. The jump in accuracy is best observed in the *CMLc* and *CMLt* evaluation methods. This indicates that the system is able to exploit the additional information to track the beats at the correct metrical level more often than without this information. Within the context of the *HJDB* dataset where the "correct" metrical level is largely unambiguous, we consider this to be an important contribution.

	F	*CMLc*	*CMLt*	*AMLc*	*AMLt*
			HJDB

Multi-task $*$	0.882	0.848	0.858	0.937	0.947

Table 3: Multi-task learning beat tracking results on the *HJDB* dataset. All results obtained with 8-fold cross validation. The $*$ symbol denotes that tempo annotations of the *HJDB* set were used as additional targets during training.

3.3 Tempo Evaluation

Further to the beat tracking oriented evaluation results reported in the previous two sections, we also explore the effectiveness of our proposed approach for the task of global tempo estimation. To discover how our multi-task approach compares to the state of the art, we contrast its performance against four reference systems [5, 17, 36, 40]. Following the established evaluation practice for tempo estimation [23] we report the *Accuracy 1* and *Accuracy 2* scores with a tolerance of $\pm 4\%$ for each of these methods, with the results shown in Table 4.

Given that human perception of tempo is known to be subjective [34], this very reasonably manifests in multiple, valid interpretations of the beat among listeners and thus more than one acceptable tempo. Thus, in the context of automatic tempo estimation, it may not be realistic to expect to obtain near perfect performance on the *Accuracy 1* score on datasets of arbitrary musical makeup. To this end, we rely on the *Accuracy 2* score (which permits so-called "tempo octave errors") to better gauge performance.

On all of the reported datasets in Table 4, our proposed approach is the only one to consistently obtain an *Accuracy 2* greater than or equal to 0.938, which shows the high potential of our method to accurately find tempo across diverse musical data. Even with the stricter *Accuracy 1* evaluation, our method achieves at least a score of 0.697 which is ahead of all other methods, albeit by a small margin. It is important to stress that the *ACM Mirum*, *GiantSteps*, and *GTZAN* datasets are completely unseen by our multi-task approach, and this pattern even holds for *HJDB* when not included in the training set.

Concerning the *HJDB* set, we can observe a different overall pattern of performance compared to the other datasets, with a much smaller gap between *Accuracy 1* and

	Accuracy 1	*Accuracy 2*

Table 4: Tempo estimation results on completely unseen data. The ∗ symbol denotes that tempo annotations of the *HJDB* set were used as additional targets during training, the † symbol results obtained with 8-fold cross validation.

Accuracy 2 for most systems. Echoing the situation in the beat tracking evaluation in Table 3, we believe that this is a direct result of the unambiguous tempo for these styles of music. Looking across the performance of the other algorithms on *HJDB*, we discover that the method of Percival and Tzanetakis [36], while it also obtains a perfect score for *Accuracy 2*, is largely unable to identify the annotated tempo as shown by the disproportionately low score for *Accuracy 1*.

When trained with the additional tempo annotations of the *HJDB* set, our multi-task method is the only one able to detect the correct tempo for all pieces of this dataset for both *Accuracy 1* and then trivially for *Accuracy 2*. Although results are obtained with cross-validation, this was to be expected because of the homogeneity of the dataset. *Accuracy 1* on the *GiantSteps* set also greatly benefits from this additional training material, since this dataset contains a huge proportion of music labelled with the musical genre "drum and bass". On the other hand, having access to this kind of data (the system of Schreiber and Müller [40] was trained on an extended version of the *GiantSteps* dataset) can in turn result in very good scores on the *HJDB* set.

4. DISCUSSION AND CONCLUSIONS

In this paper, we have proposed a novel formulation for the simultaneous estimation of tempo and beat from musical audio signals within a multi-task learning framework. Via an extensive evaluation of both beat tracking and tempo estimation, we have demonstrated that our proposed multi-task approach leads to state-of-the-art performance across a wide variety of test datasets and relevant evaluation methods. Perhaps most critically, we have shown that, within this multi-task learning framework, we can improve the performance of beat tracking by providing it tempo-only annotations. In light of the challenges of obtaining high-quality annotated data for training beat tracking systems, the ability to profit from alternative training data which is both far more prevalent and easier to annotate, may have a significant impact on beat tracking moving forward.

In order to train our model, we made use of all of the available beat and tempo annotations within the allocated training sets in Table 1, and subsequently provided additional tempo-only annotations for evaluation on the *HJDB* dataset. We consider this split between beat and tempo annotated data to be one that is worthy of further exploration, in particular by seeking to understand how little beat annotated data is sufficient to achieve the same performance, assuming we can supplement the model with additional tempo annotations. This reduction of beat information could be posed in two ways, either by a lower number of fully annotated excerpts/pieces, or by restricting the duration of annotated sections across many pieces. If successful, the latter option would offer the possibility to rapidly increase the availability of training data by drastically reducing the burden of annotating long pieces of music—at least for those with roughly constant tempo.

We frame this discussion within the computational context of our proposed multi-task approach and the TCN beat tracker [11] which it extends. As previously stated, our multi-task model is highly effective in terms of objective performance, but with a fraction of the number of weights of other state-of-the-art approaches. This has two particularly beneficial properties. First, it allows for very efficient training (thanks in part to the ease of parallelisation of dilated convolutional models compared to recurrent architectures). Second, the training of networks with very few weights drastically reduces the degrees of freedom of the network, and hence strongly mitigates over-fitting. Thus, when looking beyond the limited domain of existing annotated datasets and considering generalisation capabilities of beat tracking and tempo estimation methods (and the subsequent re-use of this information for end-users) on totally unseen data, we believe that such "compact" deep models are worthy candidates for future research.

CAN WE INCREASE INTER- AND INTRA-RATER AGREEMENT IN MODELING GENERAL MUSIC SIMILARITY?

Arthur Flexer and Taric Lallai
Austrian Research Institute for Artificial Intelligence (OFAI), Vienna, Austria
arthur.flexer@ofai.at

ABSTRACT

We present a pilot study on ways to increase inter- and intra-rater agreement in quantification of general similarity between pieces of music. By using a more controlled group of human subjects and carefully curating song material, we try to increase overall agreement between raters concerning the perceived general similarity of songs. Repeated conduction of the experiment with a two week lag shows that intra-rater agreement is higher than inter-rater agreement. Analysis of the results and interviews with test subjects suggests that the genre of songs was a major factor in judging similarity between songs. We discuss the impacts of our results on evaluation of respective machine learning models and question the validity of experiments on general music similarity.

1. INTRODUCTION

One of the successful applications of Music Information Retrieval (MIR) is the automatic recommendation of music or creation of playlists as is now commonplace and ubiquitous in music streaming services like Spotify, Deezer, Pandora or Tidal. These services often recommend music which is in some way similar to what users have been listening before. Therefore objective assessment of the quality of such services requires a quantification of similarity between recommended songs that mirrors the human perception of music similarity. Previous research [6, 8, 10, 14, 20] has shown that perception of music similarity is highly subjective with low inter-rater agreement. This is especially true for perception of *general* music similarity. Because it is not meaningful to have computational models that go beyond the level of human agreement, these levels of inter-rater agreement present a natural upper bound for any algorithmic approach [6,10,15,22,25]. To overcome this principal problem, a range of solutions have been proposed including better control of subject groups and song material, analysis of more specific aspects of music similarity, personalization of recommendations or holistic evaluation of complete MIR systems in specific use cases [6, 20]. In this paper we present a pilot study on the feasibility to improve inter-rater agreement in modeling music similarity by confining subject groups and carefully curating song material. We also report on levels of intra-rater agreement when the experiment is repeated with a two week time-lag. To the best of our knowledge, levels of intra-rater agreement have never been explored in MIR so far.

2. RELATED WORK

It seems a fundamental fact that human perception of music is highly subjective with potentially low inter-rater agreement. To give one example, if different human subjects are asked to rate the same song pairs according to their perceived similarity, only a certain amount of agreement can be expected due to a number of subjective factors [6, 20] like personal taste, musical expertise, familiarity with the music, listening history, current mood, etc. The same holds for annotation of music where different human subjects will not always agree on genre labels or other semantic tags. It was shown [23] that the performance of humans classifying songs into 19 genres ranges from modest 26% to 71% accuracy, depending on the test subject. A study [14] on transcription of chords found that annotators disagree on about 10% of harmonic annotations. A related study [10] on chord annotation showed that annotators, if given full freedom to choose chords, tend to use different chord-label vocabularies, with overlap among all annotators being less than 20%. Audio-based grounding of everyday musical terms also showed problematic results [1].

Going even further, the argument has been made [29] that music itself does not exist without the psychophysiological effect of a stimulus on humans. Therefore no such thing as an immovable 'ground' exists in the context of music, which itself is subjective, highly context-dependent and not constant. A similar conclusion has been drawn in a study on the feasibility of automatically annotating acousmatic music [9]. The same problem is also well known in general IR, where already fifty years ago it has been documented that the implicit use orientation strongly influences manual rating of retrieved items [4].

Connected to this problem, a certain level of inter-rater agreement naturally presents an upper bound for any algorithmic approach trying to provide models which are valid for a multitude of users. Whenever these models are tested by new users, there will be a certain amount of disagree-

ment making it impossible that these computational models surpass the level of human agreement. This has been documented [6,8,20] for the MIREX [1] tasks of 'Audio Music Similarity and Retrieval' (AMS) and 'Music Structural Segmentation' (MSS). MIREX ('Music Information Retrieval Evaluation eXchange') is an annual evaluation campaign for MIR algorithms [5]. Since our experiment reported in Section 4 is closely connected to the MIREX task of 'Audio Music Similarity and Retrieval' (AMS), we now review previous results concerning rater agreement in the AMS task [6]. The essence of the AMS task was to have human graders evaluate pairs of query/candidate songs according to their general similarity. The query songs were randomly chosen from a test database and the candidate songs are recommendations automatically computed by participating algorithms. The human graders rated whether these query/candidate pairs "sound similar" using both a BROAD ('not similar', 'somewhat similar', 'very similar') and a FINE score (from 0 to 10 or from 0 to 100, depending on the year the AMS task was held, indicating degrees of similarity ranging from failure to perfection).

Only in the year 2006 [2] every query/candidate pair in the AMS task has been evaluated by three different human graders, which makes 2006 the only year inter-rater agreement can be accessed. The average Pearson correlation between pairs of graders was found to be at the rather low level of 0.40. The same authors [6] also derived an upper bound based on ratings within the highest interval of scores, where query/candidate pairs that have been rated between 9 and 10 by one grader have received an average rating of 6.54 by the respective other two graders. This was explained to constitute an upper bound B^{AMS} as the maximum of average scores that can be achieved within the AMS evaluation setting, based on a considerable lack of agreement between human graders. What sounds very similar to one of the graders will on average not receive equally high scores by other graders. For AMS the upper bound has already been reached in 2009 by a number of algorithms [6].

Related results exist for the MIREX 'Music Structural Segmentation' (MSS) task, where an upper bound for MSS has been reported which is already within reach for some genres of music [6]. Additional results for music structure analysis [15, 25] and segment boundary recognition [22] exist. The level of inter-rater agreement has also been explored for melody extraction [2, 3, 18], metrical structure [17], rhythm and timbre similarity [16] as well as chord estimation [12]. An interesting new approach [11] is to use deep learning to account for different annotator styles in the task of chord labeling, essentially personalizing chord labels for individual annotators.

To the best of our knowledge, intra-rater agreement has so far not been explored in MIR, but in general IR it is a well documented fact that items are judged differently over time, even by the same people [19].

3. EXPERIMENT

Our experiment is closely connected to the MIREX task of 'Audio Music Similarity and Retrieval' (AMS) as reviewed in Section 2. We still aim at quantification of general similarity among song pairs by human graders, but try to increase inter- and intra-rater agreement by introducing a number of changes. Essential differences of our experiment include: (i) a more controlled group of human graders; (ii) carefully curated song material; (iii) query/candidate pairs are not results of algorithmic recommendation but of constrained random assignment.

Participants: In selecting test subjects for this study, we were aiming at a more uniform group of persons compared to the MIREX AMS task, where participants were drawn form the larger MIR community without any restrictions and without collecting any personal data. The major selection criteria for taking part in our study was to have had musical training in the past in some way, which should give all participants a comparable background in music. We also selected participants from an essentially young age group, which resulted in all participants having been born after 1984 and their age ranging from 25 to 34 years. The sample consisted of three females and three males. All participants were personal contacts of one of the authors.

Song Material: Contrary to the MIREX AMS task with songs from nine genres, songs in this study belong to only five different genres. The genres are: (i) American **Soul** from the 1960s and 1970s with only male singers singing; (ii) **Bebop**, the main jazz style of the 1940s and 1950s, with excerpts containing trumpet, saxophone and piano parts; (iii) **High Energy** (Hi-NRG) dance music from the 1980s, typically with continuous eighth note bass lines, aggressive synthesizer sounds and staccato rhythms; (iv) **Power Pop**, a Rock style from the 1970s, with chosen songs being guitar-heavy and with male singers; (v) **Rocksteady**, which is a precursor of Reggae with a somewhat soulful basis. The full list of songs can be found here.

The five genres were chosen to have small stylistic overlap. All songs originate between the 1940s and 1980s, making it more unlikely that participants are overly familiar with the music since all of them have been born after 1984. For every genre, we chose 18 songs. To further ensure unfamiliarity of song material to participants, we proceeded as follows. The songs were mainly chosen with the help of the recommendations of similar songs and artists on the music platform Spotify. For each genre, we always started with one stereotypical artist of the genre and then searched for other similar songs using the similar artist function of Spotify, with the goal of finding similar music from rather unknown artists. The criterion for each song's degree of popularity was to have under 50.000 accesses on Spotify. Post-experiment questioning confirmed that very few songs were familiar to the participants. No artists appears more than once on the song list. Within genres, we tried to find a homogeneous set of songs in order to evoke high similarity ratings which are crucial for determination of upper bounds in rater agreement. For presentation in the

questionnaire, 15 seconds of a representative part of every song (usually the refrain) were chosen and normalized to 89db to control for volume effects.

Questionnaire: The study was conducted online at www.soscisurvey.com, which is a free-access platform to compile questionnaires also allowing to include audio files. The first page of the questionnaire contained an introduction that explains the purpose of the study, the expected temporal effort as well as the note that the collection of data is held anonymously. Subsequently, the procedure of the study was explained to the participants. The subjects were asked to "assess the similarity between the query song and each of the five candidate songs by adjusting the slider" and "to answer intuitively since there are no wrong answers". Before starting with the assessment, a test page was shown consisting of one randomly chosen query song and five randomly chosen candidate songs of all five genres. That was done to introduce all five genres and to give an idea of the variation of the song material used in the study.

For the main part of the questionnaire the pairings of query and candidate songs were determined as follows. The complete song material consists of excerpts of 90 songs with a duration of 15 seconds, with 18 songs belonging to each of the 5 genres. We randomly drew 3 songs of each genre as query songs yielding a total of 15 query songs. For every query song we randomly chose five candidate songs with the constraint that at least one of them belongs to the same genre as the corresponding query song. This yields 15 groups of 6 songs each, with the sequential order being held constant for all participants. Each group contains one query song paired with each of the five candidate songs of the group. In sum, comparisons of five pairs had to be made for every group yielding a total of $15 \times 5 = 75$ pairs. The participants were asked to indicate their rating of the similarity on a slider ranging from 0 to 100 %. The more similar a pair was assessed, the higher the percentage was, and the further to the right the slider had to be shifted.

At the end of the questionnaire, data regarding gender, age and musical education and experience was collected. On the last page of every questionnaire, the subjects had the possibility to leave a comment.

About two weeks after filling in the first questionnaire at time point **t1**, all subjects filled in the same questionnaire with identical randomized items a second time (time point **t2**). The test page as well as the questions about the personal experiences with music were omitted in the second round of surveys.

4. RESULTS

First we analyse the degree of **inter-rater agreement** by computing the Pearson correlation ρ between graders for the 75 pairs of query/candidate songs. The correlations between graders S1 to S6 are given in Table 2 for time t1 and in Table 3 for time t2. The correlations range from 0.59 to 0.86, with an average of 0.73 at t1 and 0.75 at t2 (see also Table 1 for an overview of results). This is considerably higher than $\rho^{AMS} = 0.40$ which has been reported for the MIREX AMS task 2006 [6]. The differences in correlation between ρ^{AMS} and correlations in our experiment are also statistically significant at both t1 ($|t| = |8.3322| > t_{95,df=16} = 2.120$) and t2 ($|t| = |8.8519| > t_{95,df=16} = 2.120$). Therefore the inter-rater agreement over the full range of scores in our experiment is increased compared to the MIREX AMS task.

	t1	t2	t1 → t2
ρ	$0.73 \pm .065$	$0.75 \pm .065$	$0.80 \pm .103$
B_{80}	67.7 ± 19.5	57.5 ± 25.6	82.1 ± 14.6
ρ^{AMS}	$0.40 \pm .027$		
B_{80}^{AMS}	61.65 ± 27.0		

Table 1. Overview of results for time points t1, t2 and between t1 and t2 (t1 → t2). Shown are average correlations ρ and upper bounds $B_{80} \pm$ standard deviations, also for MIREX AMS task (last two lines).

Next we explore the level of agreement for specific intervals of scores. We plot the average score of a rater i for all query/candidate pairs, which he or she rated within a certain interval of scores v, versus the average scores achieved by the other five raters $j \neq i$ for the same query/candidate pairs. We therefore explore how human graders rate pairs of songs which another human grader rated at a specific level of similarity. The average results across all raters and for intervals v ranging from $[0, 1], (1, 2]$... to $(9, 10]$ are plotted in Figure 1 for t1 and in Figure 2 for t2. It is evident that there is a certain deviation from the theoretical perfect agreement which is indicated as a dashed line, especially for time t2. Pairs of query/candidate songs which are rated as being very similar (score between 90 and 100) by one grader are on average only rated at around 72.9 by the five other raters at t1 and at only 55.17 at t2. On the other end of the spectrum, query/candidate pairs rated as being not similar at all (score between 0 and 10) receive average scores of 17.4 (t2) and 16.1 (t2) by the respective other raters.

In a previous study [6] an upper bound B^{AMS} has been reported based on scores within the highest interval. Since for our experiment only 4 (out of 75 song pairs × 6 raters = 450) scores are higher than 90 for t1 and only 15 for t2, we compute a broader upper bound based on all scores between 80 and 100. There are 37 such scores for t1 and 47 for t2. This upper bound B_{80} is 67.7 for t1 and 57.5 for t2 (see Table 1). If we multiply scores from AMS 2006 by ten for better comparability and compute a similar upper bound B_{80}^{AMS} this yields 61.65. Since our upper bounds B_{80} are either above (t1) or below (t2) the upper bound B_{80}^{AMS}, we have to conclude that our experiment was not able to raise the upper bound in modeling general music similarity.

Next we looked at **intra-rater agreement** measured between time points t1 and t2. The Pearson correlation ρ between t1 and t2 for the 75 pairs of query/candidate songs for graders S1 to S6 are given in Table 4. The correla-

	S1	S2	S3	S4	S5	S6
S1	1.00	0.77	0.74	0.72	0.74	0.82
S2		1.00	0.72	0.75	0.62	0.83
S3			1.00	0.70	0.67	0.76
S4				1.00	0.64	0.80
S5					1.00	0.64
S6						1.00

Table 2. Inter-rater correlation at time **t1**, with mean $0.73 \pm .065$ standard deviation.

	S1	S2	S3	S4	S5	S6
S1	1.00	0.79	0.73	0.77	0.74	0.83
S2		1.00	0.73	0.74	0.75	0.86
S3			1.00	0.69	0.69	0.80
S4				1.00	0.59	0.79
S5					1.00	0.73
S6						1.00

Table 3. Inter-rater correlation at time **t2**, with mean $0.75 \pm .065$ standard deviation.

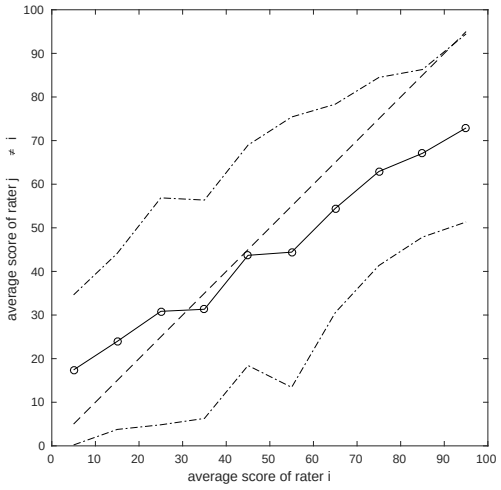

Figure 1. Average score inter-rater agreement for different intervals of scores (solid line) $\pm$ one standard deviation (dash-dot lines) at time **t1**. Dashed line indicates theoretical perfect agreement.

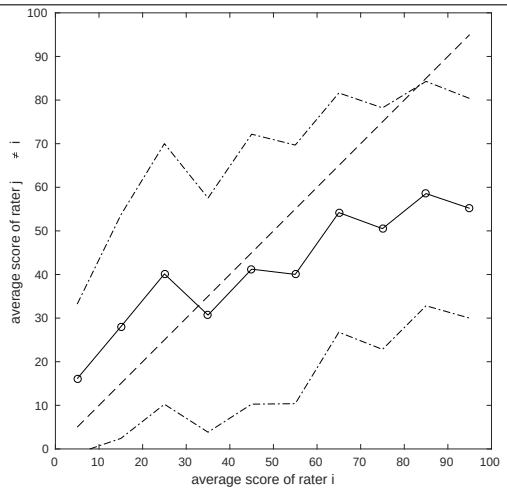

Figure 2. Average score inter-rater agreement for different intervals of scores (solid line) $\pm$ one standard deviation (dash-dot lines) at time **t2**. Dashed line indicates theoretical perfect agreement.

S1	S2	S3	S4	S5	S6
0.81	0.85	0.75	0.81	0.64	0.95

Table 4. Intra-rater correlation between times **t1** and **t2**, with mean $0.80 \pm .103$ standard deviation.

tions range from 0.64 to 0.95, with an average of 0.80, which is somewhat higher than inter-rater correlation of 0.73 and 0.75 at time t1 and t2 (see Table 1). The differences between inter-agreement correlations and intra-agreement correlation are however not statistically significant, neither for t1 ($|t| = |-1.9742| < t_{95,df=19} = 2.093$) nor for t2 ($|t| = |-1.3682| < t_{95,df=19} = 2.093$).

Similar to what we did for inter-rater agreement, we also plotted the average score of a rater i for all query/candidate pairs, which he or she rated within a certain interval of scores v at time t1, versus the average scores achieved by the same rater i for the same query/candidate pairs at time t2 in Figure 3. Compared to Figures 1 and 2, we see better agreement within persons between t1 and t2, with intra-agreement being very close to theoretical perfect agreement (dashed line) for scores ranging from 0 to 50, but also from 90 to 100.

We also computed an upper bound B^{80} based on ratings within the interval $(80, 100]$, where query/candidate pairs that have been rated between 80 and 100 by a grader i at t1 have received an average rating of 82.1 by the same grader i at t2. This is higher than the upper bound for inter-rater agreement at both t1 (67.7) and t2 (57.5). The differences between inter-agreement upper bounds and intra-agreement upper bound are statistically significant, both for t1 ($|t| = |-4.2537| > t_{95,df=220} = 1.960$) and t2 ($|t| = |-5.7121| > t_{95,df=19} = 1.960$) Therefore we conclude that the upper bound within participants measured with a two week time lag is higher then the upper bound based on inter-rater agreement.

Because a number of participants in this study com-

	Soul	Bebop	High Energy	70s Rock	Rocksteady
Soul	**46.9**	16.2	-	38.3	25.1
Bebop	19.3	**73.4**	10.4	6.7	14.3
High Energy	30.4	8.1	**71.2**	32.0	15.5
70s Rock	17.4	-	20.9	**48.2**	11.0
Rocksteady	35.0	-	23.3	13.3	**66.1**

Table 5. Genre confusion matrix at time **t1**, shown are average scores per genre combination.

	Soul	Bebop	High Energy	70s Rock	Rocksteady
Soul	**46.6**	13.5	-	36.4	19.6
Bebop	16.5	**64.7**	10.2	9.5	11.6
High Energy	33.3	5.8	**58.6**	29.8	15.8
70s Rock	18.6	-	16.8	**50.6**	11.0
Rocksteady	26.1	-	15.9	8.8	**62.5**

Table 6. Genre confusion matrix at time **t2**, shown are average scores per genre combination.

mented that the **genre of the songs was an important factor** when evaluating the similarity of songs, we analysed the results with respect to genre also. In Tables 5 and 6 we present genre confusion matrices at times t1 and t2. Just to give one example, the first entry in the first line in Table 5 shows that whenever both query and candidate song were from genre 'Soul', on average such pairs have been judged at 46.9 by the graders. The average score for query songs from 'Soul' and candidate songs from 'Bebop' was 16.2, etc. An entry with a dash ('-') signifies that none such query/candidate pairs existed in our questionnaire. The confusion matrices are not symmetric, since there is a difference whether a song from a certain genre is used as a query or a candidate song.

At both times t1 and t2, average scores in the main diagonals are higher then all off-diagonal entries. This shows that participants indeed rated similarities within genres higher than between genres, at least on average. For both times t1 and t2 average scores are highest within genre 'Bebop', followed by 'Rocksteady' and 'High Energy'. Genre 'Soul' has lowest within genre scores and considerable off-diagonal confusion with e.g. '70s Rock'.

To make clearer how often query/candidate pairs within one genre were rated higher than pairs with mixed genres, we computed average R-precision. In our scenario, for each of the 15 groups of songs (consisting of one query and five candidate songs), R is equal the number of candidate songs with genre identical to the respective query song. For our questionnaire R ranged from 1 to 4. When we order all five candidate songs from highest to lowest score, R-precision is then the fraction of candidate songs with correct genre among the first R candidate songs. Average R-precision across questionnaires of all all six participants is 0.86 for t1 and 0.88 for t2. These high values corroborate self-reports by participants that genre was an important aspect when rating similarity of songs.

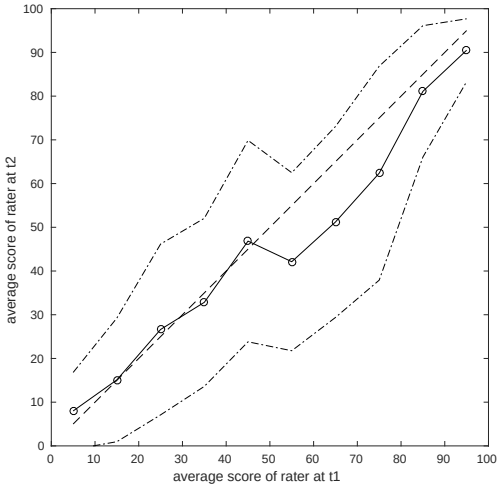

Figure 3. Average score intra-rater agreement for different intervals of scores (solid line) $\pm$ one standard deviation (dash-dot lines) between times **t1** and **t2**. Dashed line indicates theoretical perfect agreement.

5. DISCUSSION

Our principal reason for conducting this research and experiment is the quest to raise the level of rater agreement when judging music similarity. This is needed to quantify the success of computational models of music similarity which are used in automatic music recommendation services. Previous research has criticized the low level of inter-rater agreement and derived an upper bound for algorithms modeling music similarity, which has been reached already in 2009 and has not been outperformed ever since [6]. As a matter of fact, the respective MIREX task (AMS) has been dormant since 2015. In an attempt to improve the AMS task, we have conducted an experiment with a more controlled group of participants and with more carefully curated song material.

The overall inter-rater agreement measured via correla-

tion could indeed be increased compared to the AMS task. However the upper bound, which is only based on higher scores of music similarity, is not improved compared to AMS. Therefore our new version of the AMS task based on more controlled participants and better curated song material is not better suited to measure differences between algorithms that have already reached the AMS upper bound.

One proposal to overcome the problem of upper bounds in measuring music similarity is to personalize models, i.e. to have separate models of music similarity for individual persons. Certainly this is what many commercial services do by offering individual recommendations tailored to their users. This of course brings us to the question how stable assessment of music similarity is within persons, i.e. when the same persons have to judge music similarity repeatedly. The result concerning this intra-rater agreement in our experiment is divided. On the one hand the overall agreement as measured via correlation could not be improved, or at least not sufficiently to allow for statistical significance. On the other hand the upper bound could indeed be raised, opening up the possibility to better measure progress in computational models of personalized music similarity.

For future efforts to improve on the original AMS task design, one should probably rethink which songs from what genre to use. In our experiment, genres were so distinct that at least some participants used membership to a certain genre as the main criterion when assessing similarity between songs. This might impact generalizability of our results when judging music similarity within individual genres. It is also not completely clear, what contribution to improvements our more controlled group of subjects had. We are however convinced that the more uniform group of subjects with a certain musical expertise did lower variation of results. The same holds for the rather young age of participants and the choice of generally not well known song material. Post experiment questioning of participants corroborated that very few songs were known to them, hence less connotations to influence assessment of similarity existed.

One should also point out that this is a pilot study with only six participants. A higher number of test subjects might have allowed for more statistically significant results, e.g. concerning differences between inter and intra-rater correlations. Future work should also explore alternatives to Pearson correlation like generalizations of Kappa measures to the interval scale, which take into account the possibility of rater agreement occurring by chance (e.g. intra-class-correlation [24]). Another open question is whether a time lag of more than two weeks might change results on intra-rater agreement.

A possible route to further improvements is to ask a more specific question than just assessing general music similarity, as in the original AMS task and in the experiment reported in this paper. Criticism of this unclear abstract notion of general music similarity brings us to the concept of 'validity' of our experiment. A valid experiment is an experiment that actually measures what the experimenter intended to measure (see e.g. [27] or [28] for a discussion in relation to MIR). Precisely this intention of the experimenter in the original MIREX AMS task is completely unclear, since it is rather dubious what general music similarity is supposed to mean in the first place. The argument that users apply very different, individual notions of similarity when assessing the output of music retrieval systems has been made before [20]. After all, music similarity is a multi-dimensional notion including timbre, melody, harmony, tempo, rhythm, lyrics, mood, etc, with many of these dimensions meaning different things to different people. It has also been noted before that evaluation of abstract music similarity without reference to a specific usage scenario is not very meaningful [7, 21]. It is therefore our belief that the intention of a music similarity experiment can only be made clearer if it will be tied to a user scenario, e.g. creating a playlist for a specific occasion. Identifying specific use cases has already been advocated as a method for better problem definition [26] in MIR. Previous reviews [13] of user studies in MIR could serve as valuable input for formalization of the use cases.

6. CONCLUSION

We have presented a pilot study aimed at improving experiments to measure general music similarity. By using a more controlled group of subjects and music material from more well defined genres, we were able to improve overall inter-rater agreement but did not succeed in raising an upper bound for models of music similarity, which constitutes an obstructive glass ceiling for any machine learning approach. We did however succeed in raising this upper bound for intra-rater agreement, which corroborates the rationale of personalizing music services. We also discussed the doubtful validity of experiments on general music similarity making it clear that definition of a specific use case might be necessary for conduction of a truly valid experiment. The fact that MIR needs to care much more about the proper design of its experiments is also the main insight going beyond the scope of this paper. Although a small but growing number of publications concerning design and evaluation of MIR experiments exists, they have so far not been able to change the research culture of MIR as a whole.

ABSTRACT

We describe the *AIST Dance Video Database (AIST Dance DB)*, a shared database containing original street dance videos with copyright-cleared dance music. Although dancing is highly related to dance music and dance information can be considered an important aspect of music information, research on dance information processing has not yet received much attention in the Music Information Retrieval (MIR) community. We therefore developed the AIST Dance DB as the first large-scale shared database focusing on street dances to facilitate research on a variety of tasks related to dancing to music. It consists of 13,939 dance videos covering 10 major dance genres as well as 60 pieces of dance music composed for those genres. The videos were recorded by having 40 professional dancers (25 male and 15 female) dance to those pieces. We carefully designed this database so that it can cover both solo dancing and group dancing as well as both basic choreography moves and advanced moves originally choreographed by each dancer. Moreover, we used multiple cameras surrounding a dancer to simultaneously shoot from various directions. The AIST Dance DB will foster new MIR tasks such as dance-motion genre classification, dancer identification, and dance-technique estimation. We propose a dance-motion genre-classification task and developed four baseline methods of identifying dance genres of videos in this database. We evaluated these methods by extracting dancer body motions and training their classifiers on the basis of long short-term memory (LSTM) recurrent neural network models and support-vector machine (SVM) models.

1. INTRODUCTION

The Music Information Retrieval (MIR) community started with standard music information such as musical audio signals and musical scores, and then extended its scope to other types of music-related multimodal information such as images, videos, lyrics, and social-media data. Since dance music – a popular target of MIR research [7, 19, 20, 22, 33, 40, 42, 46, 55, 61, 66, 80] – is originally written for dance and has a strong connection to dance motions, *dance information*, that is, any kind of information related to dance, such as dance music, dance motions, and dancers, can be considered an important aspect of music information that the MIR community should cover. Research on dance motions, however, has not yet received much attention in the community. The goal of this research is to develop a dance information database including original dance videos with copyright-cleared dance music and make it publicly available to the community so that research on dance can attract more attention in the community and new MIR tasks related to dance can emerge in the future.

As a sub-area of MIR research, we propose defining *dance information processing* as meaning various types of processing and research related to dance information.

Figure 1. Snapshots of AIST Dance Video Database (AIST Dance DB), which features **multiple genres** (10 major dance genres), **multiple dancers** (solo and group dancing by 40 professional dancers), and **multiple cameras** (at most 9 video cameras surrounding a dancer). These color snapshots are cropped to enlarge dancers in videos.

First, it is necessary for dance information processing to handle dance music. There have been studies on traditional dance tunes [7, 22, 40, 61], electronic dance music [19, 42, 46, 55, 66, 80, 82], and dance-music classification [20, 33]. Second, it is important for dance information processing to advance research related to dance motions. There have been various related studies such as on dance-motion choreography generation driven by music [2, 28, 29, 32, 52, 53, 73], rhythm estimation from dance motions in dance videos [18], music retrieval by dance motions [75], controlling music tempo by dance motions [37], dance-motion identification [60], and dance-motion genre classification [43]. In addition, research on dance motions could have good synergy with research on performer motions made during musical performances [30, 47, 48, 51, 67] since both deal with music-related human body movements. This emerging field of dance information processing, however, has lacked a large systematic dance information database that is available to researchers for common use and research purposes.

We therefore built the *AIST Dance Video Database (AIST Dance DB)*, the first large-scale copyright-cleared database focusing on street dances (Figure 1). The AIST Dance DB consists of 13,939 original dance videos covering 10 major street dance genres (break, pop, lock, waack, middle hip-hop, LA-style hip-hop, house, krump, street jazz, and ballet jazz) and 60 original pieces of dance music composed for these genres, each having 6 different musical pieces with different tempi. We had 40 professional dancers (25 male and 15 female), each having more than 5 years of dance experience, dance to those pieces. In addition to 13,890 videos for which each of the 10 genres has 1,380 videos, we added 49 videos that cover 3 typical dancing situations (showcase, cypher, and battle) in which a group of dancers enjoy dancing. The database is carefully designed to cover both solo dancing (12,990 videos) and group dancing (949 videos) as well as both basic choreography moves (10,800 videos) and advanced moves (3,139 videos) originally choreographed by each dancer. We used at most nine video cameras surrounding a dancer to simultaneously shoot from various directions.

To the best of our knowledge, such street dance videos have not been available to researchers, so they will become valuable research materials to be analyzed in diverse ways and used for various machine-learning purposes. For example, the AIST Dance DB will foster new MIR tasks such as dance-motion genre classification, dancer identification, and dance-technique estimation. As a basic task of dance information processing, we propose a dance-motion genre-classification task for street dances. We developed four baseline methods for identifying dance genres of a subset of the dance videos in this database and evaluated them by extracting dancer body motions and training their classifiers on the basis of long short-term memory (LSTM) recurrent neural network models and support vector machine (SVM) models. In our preliminary experiments, we tested the methods on 210 dance videos of 10 genres done with 30 dancers and found that dance genres were identified with a high accuracy of 91.4% when a 32-sec excerpt was given; however, the accuracy dropped to 56.6% when a 0.67-sec excerpt was given. These results can be used as a baseline performance for this task.

2. RELATED WORK

Since the importance of research databases has been widely recognized in various research fields, researchers interested in dance have also spent considerable effort on building dance-related databases [62]. For example, the Martial Arts, Dancing and Sports Dataset [82] has six videos for both the hip-hop and jazz dance genres. These videos were shot from three directions, and the video data includes depth information. However, six videos for each genre is not enough for some tasks, and the videos do not contain enough professional dance motions to effectively express the characteristics of each genre. Several relatively small dance datasets have also been published [14, 17, 63, 79].

Some databases not only have dance videos but also provide different types of sensor data. Stavrakis et al. [70] published the Dance Motion Capture Database, which provides high-quality motion capture data as well as dance videos. This database includes Greek and Cypriot dances, contemporary dances, and many other dances such as flamenco, the belly dance, salsa, and hip-hop. Tang et al. [72] also used a motion capture system to build a dance dataset that contains four dance genres: cha-cha, tango, rumba, and waltz. Essid et al. [23] published a dance dataset that consists of videos of 15 salsa dancers, each performing 2 to 5 fixed choreographies. They were captured using a Kinect camera and five cameras. This dataset is unique since all video data contain inertial sensor (accelerometer + gyroscope + magnemeter) data captured from multiple sensors on the dancers' bodies. All these databases, however, do not handle street dance videos performed by multiple dancers and recorded with multiple camera directions.

Although YouTube-8M [1] and Music Video Dataset [65] were not built for research on dance, the former contains 181,579 dance videos and the latter contains 1,600 music videos including dance-focused videos. It is difficult to use these videos for dance information processing because the videos are not organized from this viewpoint. In comparison, the AIST Dance DB contains videos that are systematically recorded and organized to have attributes such as dance genre names, the names of basic dance moves, labels of dance situations, and information on dancers and musical pieces.

3. AIST DANCE VIDEO DB

3.1 Design policy

We designed the AIST Dance DB by considering the following three important points.

- **Suite of video files of original dance and audio files of copyright-cleared dance music**
  To analyze and investigate the relationships between a musical piece and the dance motions that go along

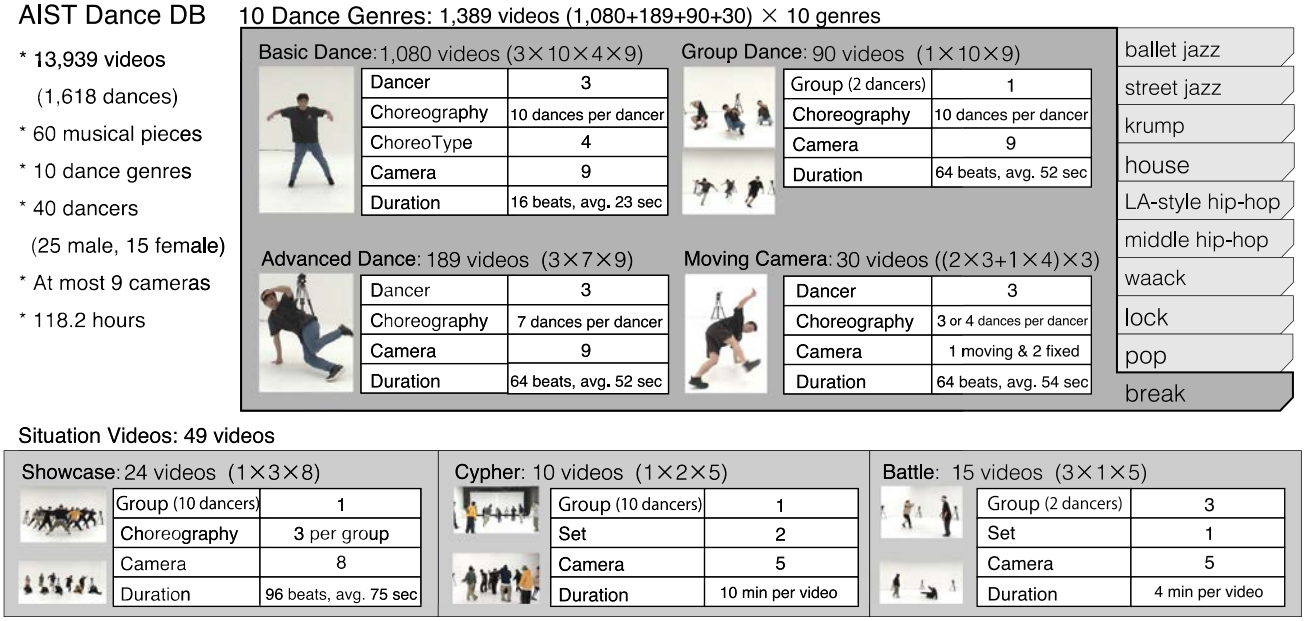

Figure 2. Overview of AIST Dance DB. Each of 10 dance genres has 1,389 videos that consist of 4 categories: **Basic Dance** (120 dances in 1,080 videos for basic genre-specific dance moves with 4 impressions (ChoreoType): intense, loose, hard, and soft), **Advanced Dance** (21 dances in 189 videos for advanced dance moves originally choreographed by each individual dancer), **Group Dance** (10 dances in 90 videos for group dance done with 3 dancers having different original choreographies), and **Moving Camera** (10 dances in 30 dolly-shot videos with moving camera). Other 49 Situation Videos consist of **Showcase** (3 dances in 24 videos assuming stage dance performances done by 10 dancers in front of audiences), **Cypher** (2 dances in 10 videos where 10 dancers line up in a circle and keep dancing in turns), and **Battle** (3 dances in 15 videos where 2 dancers face each other and dance).

with the piece, we first asked professional musicians to create pieces of dance music in different genres for our database, then recorded dance videos in which professional dancers danced while listening to one of the musical pieces. As a result, each video includes not only dance motions but also the musical piece used as background music.

- **Variety of dance genres and choreographies**
  Since processing diverse dance information would require a variety of genres and choreographies, we ensured such a variety by including 10 dance genres, 40 male and female dancers, different numbers of dancers (solo dancing and group dancing), different choreographies, and different levels of difficulty in choreography (basic choreography moves and original advanced moves).
- **Shooting from various directions**
  To analyze the same dance motions from different views and angles, we used multiple video cameras surrounding a dancer so that the cameras can simultaneously shoot from various directions. Even if some body parts cannot be seen from the front camera, they can be seen from the back camera.

3.2 Contents

An overview of the AIST Dance DB is shown in Figure 2. We built it on the basis of the design policy discussed in Section 3.1. The AIST Dance DB consists of 1,618 street dances in 13,939 videos: 13,890 videos of 10 street dance genres and an additional 49 *Situation Videos* of 3 different situations. The dance genres were decided in consultation with experts on street dances and divided into *Old School* styles (break, pop, lock, and waack), which are dance styles from about the 1970s to 1990s, and *New School* styles (middle hip-hop, LA-style hip-hop, house, krump, street jazz, and ballet jazz), which are dance styles since about the 1990s.

The database also includes 60 musical pieces that are categorized into 10 dance genres. The tempi of the 6 pieces for each genre except for house were set to 80, 90, 100, 110, 120, and 130 beats per minute (BPM); the tempi of the 6 pieces for house were set to 110, 115, 120, 125, 130, and 135 BPM since slow tempi are not fitting for house.

To cover choreographic variations within dance genres, we had 40 professional dancers (25 male and 15 female) participate in video recordings in a professional studio. At least three dancers were assigned to each genre. All dancers had more than 5 years of dance experience. All videos were recorded in full color, although dancers mainly wore monotone clothing when dancing.

For each of the 10 dance genres, we recorded a total of 1,380 videos consisting of 1,080 basic choreography dance videos, 189 advanced choreography dance videos, 90 group dance videos, and 30 dance videos with a moving camera for dolly-in and dolly-out shots. All camera positions were fixed except for the moving camera. As shown in Figure

2, we also recorded 49 *Situation Videos* that consist of 24 videos for showcase, 10 videos for cypher, and 15 videos for battle. Dancers were asked to choreograph their dance to fit the given genre. Basically, each choreography was shot in one take; however, it was taken again when there was a clear mistake. The location of the front camera was designed carefully to capture the full body of the dancer, and the other cameras were located to capture as much of the dancer's body as possible except for group dance. This database is available at `https://aistdancedb.ongaaccel.jp`.

4. DANCE-MOTION GENRE CLASSIFICATION

To illustrate the utility of the AIST Dance DB, we tackled the dance-motion genre-classification task. Since genre classification of music is a popular research topic in the MIR community, genre classification of dance motions could be a good starting point, which would also have applications such as personalized dance-video recommendation.

We developed four baseline methods to provide baseline results. We investigated four research questions the answers of which could contribute to research on dance-motion genre classification: (RQ1) *"Can we classify the 10 genres by using their video frames only?"*, (RQ2) *"How many video frames should be used to train a model?"*, (RQ3) *"Is the ease of classification different by dance genre?"*, and (RQ4) *"Can beat positions help improve classification accuracy?"*.

4.1 Experimental Conditions

As a dataset for our experiments, we created a subset of the advanced choreography dance videos. The dataset consists of 210 dance videos shot from the front camera only and covers the 10 dance genres. Each genre has 21 dance videos by 3 dancers, each of whom uses 7 original choreographies. In total, the dataset covers 210 different choreographies by 30 different dancers. The musical piece in each video has 64 beats (4 beats $\times$ 16 measures in four-four time), where the term "beat" denotes a quarter note.

We split 210 dance videos into a training set (126 videos), a validation set (14 videos), and a test set (70 videos). For each genre, 14 videos by two dancers were used for the training and validation sets, and 7 videos by the remaining dancer was used for the test set. Every dancer and every choreography in the training and validation sets thus does not appear in the test set.

4.2 Methods

An overview of our baseline methods is shown in Figure 3. Each method is trained to classify an excerpt of the input video into one of the 10 dance genres. In the first step of motion-feature extraction, we use the OpenPose library [12] to estimate the dancer's skeleton (body pose and motion) in all video frames (60 frames per second). This can reduce the dependency on the AIST Dance DB since the estimated body pose and motion do not have original RGB pixel information.

Since both pose and motion are important elements that characterize dancing, we obtain dancer poses by calculating 21 joint angles from the skeleton per video frame. Each joint angle is then converted into two dimensional values θ_x and θ_y by calculating the sine and cosine of the angles to make the distance calculation between angular values easier. As a result, we convert the 21-dimensional angular values into a 42-dimensional feature vector. Let us represent this feature vector at the n-th frame of the i-th video as $v_\theta^{(i)}(n)(1 \leq n \leq N^{(i)}\ and\ 1 \leq i \leq I)$, where $N^{(i)}$ is the number of frames in the i-th video and I is the number of videos in the dataset. When some joints in the video have not been detected, we substitute zeros for the values that correspond to the undetected joints. Our methods then represent the body motions by calculating the velocity and acceleration between frames. The velocity $v_{\Delta\theta}^{(i)}(n)$ and acceleration $v_{\Delta^2\theta}^{(i)}(n)$ at the n-th frame are calculated as follows:

$$v_{\Delta\theta}^{(i)}(n) = v_\theta^{(i)}(n) - v_\theta^{(i)}(n-1), \tag{1}$$

$$v_{\Delta^2\theta}^{(i)}(n) = v_{\Delta\theta}^{(i)}(n) - v_{\Delta\theta}^{(i)}(n-1). \tag{2}$$

We then concatenate the above three: $v_\theta^{(i)}(n)$, $v_{\Delta\theta}^{(i)}(n)$, and $v_{\Delta^2\theta}^{(i)}(n)$, into one 126-dimensional vector $v^{(i)}(n)$.

In the second step, we aggregate the 126-dimensional vectors representing body motions within a unit (temporal interval) determined if using beat positions or not. All beat positions are automatically determined by the tempo of each musical piece. Below are the details of the two methods:

- Adaptive method: when using beat positions, the vectors are aggregated within four kinds of tempo-dependent variable length units: we used one, two, three, or four beats as one unit. The length L_a corresponding to a beat ranges from 27 to 45 video frames as the tempo ranges from 80 to 135.
- L-fixed method: the vectors are aggregated within various fixed-length units. The length L of one unit is 20, 40, 60, ..., or 500 video frames.

Each method calculates a unit-level feature vector for every unit in the video. It calculates the mean vector and standard deviation vector (126 dimensions each) among body motions from the n_{start}-th to n_{end}-th video frames of every unit and concatenates those vectors into the 252-dimensional unit-level vector of the k-th unit $\tilde{v}^{(i)}(k)$.

In the third step, each method calculates a window-level feature vector. We use five different window lengths to aggregate unit-level feature vectors into a window-level one to see how many video frames are necessary to identify a dance genre. The window-level feature vector is obtained by concatenating all unit-level vectors $\tilde{v}^{(i)}(k)$ within a window of 2, 4, 8, 16, and 32 units, respectively. The window is then shifted by 1 unit to obtain the next window-level feature vector. We thus obtain five different window-level feature vectors.

In the fourth step, we prepare four baseline methods by combining adaptive or L-fixed methods with LSTM-based or SVM-based models. Each method classifies every

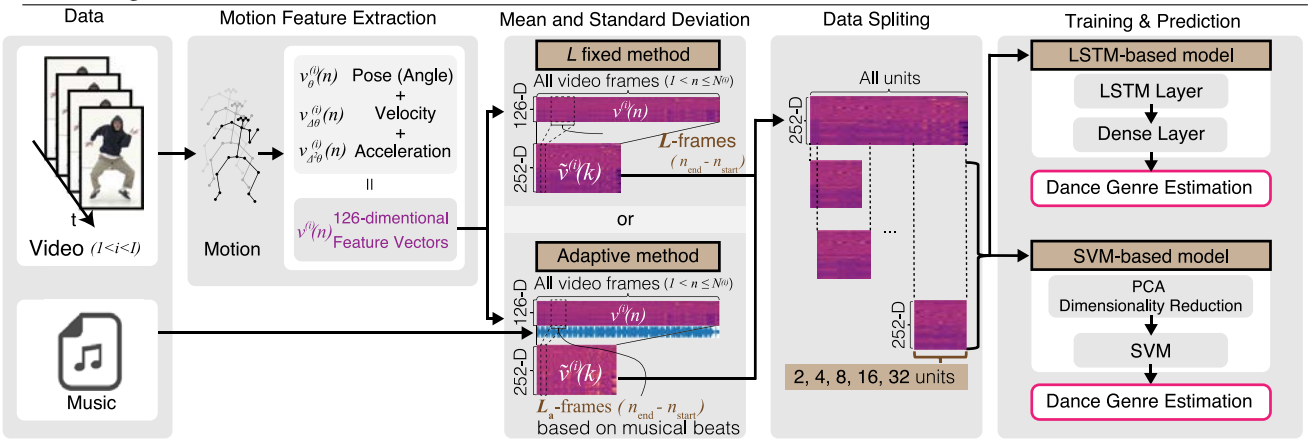

Figure 3. Overview of four baseline methods for dance-motion genre-classification task: (1) L-fixed method with LSTM-based model, (2) L-fixed method with SVM-based model, (3) adaptive method with LSTM-based model, and (4) adaptive method with SVM-based model.

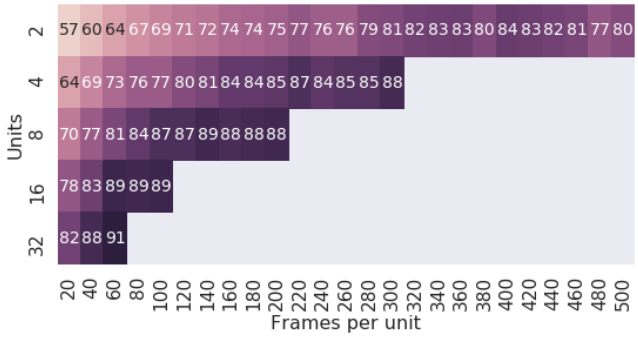

Figure 4. Comparison of the genre-classification accuracy of the L-fixed method with the LSTM-based model with regard to different combinations of the number of frames per unit and the number of units. Blank indicates that combined size of frames exceeds the length of video.

window-level feature vector into the 10 dance genres. For the LSTM-based model, we use a bi-directional recurrent neural network (RNN) with one layer of LSTM [39] cell. The network outputs a 10-dimensional one-hot vector representing dance genres. A rectified linear unit activation function is applied to the output of the LSTM. Batch normalization is applied to the output layer of the dense layers. We use cross entropy as the loss function and a batch size of 10. We train this model with a learning rate of $5e-4$ through 100 epochs and record the trained model at the minimum validation loss. This model is implemented in PyTorch [57]. For the SVM-based model, we first obtain 200-dimensional vectors by using principal component analysis to reduce the dimension of the training data, then train the SVM model. Finally, we estimate the dance genre of every window-level feature vector in a video by using these two models.

5. RESULTS

To answer RQ1 in Section 4, we investigated the accuracy of dance-motion genre classification using three-fold cross-validation (each fold used a different dancer for the test set). We first calculated the ratio of the correct estimation for every dance genre, then averaged over genres to obtain the genre-classification accuracy. The best genre-classification accuracy was 91.4% when we used the L-fixed method with the LSTM-based model where the number of frames was 60 and the number of units was 32. In this dataset, we found that dance genres can be estimated with relatively high accuracy. In the case of the L-fixed method with the SVM-based model, however, the best accuracy was dropped to 84.0%.

To answer RQ2 in Section 4, we analyzed the genre-classification accuracy when the number of frames per unit and the number of units were changed as shown in Figure 4. We found that dance-motion genre classification can be executed with an accuracy of 56.6% by using only 0.67 sec corresponding to 40 frames (20 frames per unit $\times$ 2 units) of a video. This was much shorter than we expected.

To answer RQ3 in Section 4, we conducted an analysis by creating a confusion matrix for the L-fixed method with the LSTM-based model and found that krump is relatively easy to estimate and house is relatively difficult to estimate. We also found that the estimation performance depends on the number of frames per unit and the number of units to calculate the input to the classifiers. With a small number of frames and units, street jazz and ballet jazz were easily confused by the classifier and the estimation accuracy of house dropped. This can be understood from the fact that street jazz and ballet jazz contain similar poses and house contains many movements that are commonly found in other dance genres, such as simple lateral movements.

To answer RQ4 in Section 4, we confirmed that the highest accuracy of the adaptive method using musical beats was 83.4% and that of the L-fixed method was 91.4%, both with the LSTM-based model. In the case of the adaptive method with the SVM-based model, the best accuracy was further dropped to 80.7%. In this way, the preliminary answer to RQ4 was not positive. Since there would be much room for improvement when using beat positions, we leave this for future research.

6. DISCUSSION

6.1 Dance information processing

As shown in Figure 5, dance information processing can be classified into four categories: (a) dance-motion analysis, (b) dance-motion generation, (c) dance-music analysis, and (d) dance-music generation. The goal of (a) dance-motion analysis is to automatically analyze every aspect of dance motions including dance-motion genre classification, dancer identification, dance-technique estimation, structural analysis of choreographies, and dance-mood analysis. A typical research topic of (b) dance-motion generation is to automatically generate motions for dance robots and computer-graphics dancers so that their motions can be natural and indistinguishable from human motions. As described at the beginning of this paper, research related to dance music, including (c) dance-music analysis and (d) dance-music generation, has been popular in the MIR community. There is still room for improvements regarding analyzing and classifying dance music in more depth and generating dance music in various styles and for various purposes.

Furthermore, our research community could investigate various interactions between those categories as well as advance each of the four categories. For example, we could combine (a) dance-motion analysis and (c) dance-music analysis. Analyzed dance motions would be helpful for structural analysis of musical pieces in dance music videos. Analyzed music structure could be used to analyze dance motions in a context-dependent manner. Another interesting topic of research is to find musical pieces suitable for dance motions, which will be useful for developing automatic DJ systems that recommend musical pieces suitable for various dancers on dance floors and at dance events. Analyzing the relationships between dance motions and music in existing dance videos is also important to develop systems for assisting people in creating and editing more attractive music-synchronized videos. We could also combine (a) dance-motion analysis and (b) dance-motion generation. If three-dimensional dance motions can be accurately extracted from a large collection of existing dance videos, they could be useful for automatic dance-motion-generation systems based on machine learning. If dance styles of dancers can be analyzed and modeled, it could become possible to transfer those styles to artificial computer-graphic dancers or robot dancers.

Dance information processing will naturally use multimodal dance information for different research topics. There have been many related studies such as on dance-practice support [3, 8, 11, 15, 16, 24, 36, 49, 68, 71], choreography-creation support [25, 59, 81], dance-performance augmentation [6, 9, 10, 13, 26, 27, 31, 38, 45, 56, 76, 78], dance-group support and analysis [35, 50, 54, 69, 77], dance archive [44, 58, 64, 83], dance performance alignment [21, 34], dance video editing [5, 41, 74], and dance-style transfer [4]. We look forward to advances in this emerging research field of dance information processing.

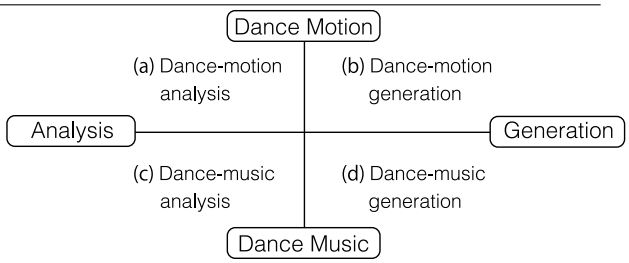

Figure 5. Overview of dance information processing.

6.2 AIST Dance Video Database

We believe that the AIST Dance DB will contribute to the advancement of dance information processing as other research databases have also contributed to the advancement of their related research. In particular, this database will advance research on dance-motion analysis (Figure 5). In addition to the dance-motion genre-classification task we discussed in this paper, it is possible to develop systems that can classify dance videos into advanced dance, basic dance, moving camera, and group dance, as shown in Figure 2. Since various dancers dance to the same musical pieces in this database, their individual differences can be analyzed in depth, and such analyzed results could be useful in developing dancer-identification systems. The basic dance videos could be useful for analyzing subtle individual differences of motions since all the dancers have the same basic motions. By using videos recorded from different directions, systems that can recognize dance motions from any direction could also be developed. As we illustrated in Section 4.2, using image-processing technologies, such as OpenPose, makes it possible to extract dance motions from dance videos for use in machine learning for various purposes including automatic dance-motion generation.

From the viewpoint of the MIR community, it is essential for the AIST Dance DB to include 60 pieces of dance music in synchronization with dance motions. This will lead to various research topics such as dance-music classification with or without using dance motions, dance-motion classification with or without using dance music, and detailed multimodal analysis of the correlation between dance motion and music. Furthermore, since this database is publicly available, it can be used for designing benchmarks of evaluating technologies.

7. CONCLUSION

The main contributions of this work are threefold: 1) we built the first large-scale shared database containing original street dance videos with copyright-cleared dance music, 2) we proposed and discussed a new research area *dance information processing*, and 3) we proposed a dance-motion genre-classification task and developed four baseline methods. We hope that the AIST Dance DB will help researchers develop various types of dance-information-processing technologies to give academic, cultural, and social impact.

MICROTIMING ANALYSIS IN TRADITIONAL SHETLAND FIDDLE MUSIC

ABSTRACT

This work aims to characterize microtiming variations in traditional Shetland fiddle music. These microtiming variations dictate the rhythmic flow of a performed melody, and contribute, among other things, to the suitability of this music as an accompaniment to dancing. In the context of Shetland fiddle music, these microtiming variations are often referred to as *lilt*. Using a corpus of 27 traditional fiddle tunes from the Shetland Isles, we examine inter-beat timing deviations, as well as inter-onset timing deviations of eighth note sequences. Results show a number of distinct inter-beat and inter-onset rhythmic patterns that may characterize lilt, as well as idiosyncratic patterns for each performer. This paper presents a first step towards the use of Music Information Retrieval (MIR) techniques for modelling lilt in traditional Scottish fiddle music, and highlights its implications in the field of ethnomusicology.

1. INTRODUCTION

The Shetland Isles is an archipelago situated 100 miles north of the Scottish mainland (Figure 1). The distinctive music-culture of the Isles reflects a wide range of influences from around the North-Atlantic, including mainland Scottish, Scandinavian, and North-American, in particular. The earliest evidence of a performance tradition on violin, or fiddle, in the Shetland Isles dates from the eighteenth century, but there is also evidence of a pre-violin string-instrument tradition that dates to a much earlier time. However, it was over the course of the nineteenth century and into the twentieth century that the modern instrument established itself as an important component of ceremonies and rituals where dancing often played an important role [3]. The fact that solo fiddle music was used for dancing had a great influence on performance practice, with commentators often referring to the 'lilt' of a musician's performance when describing its suitability as an accompaniment to dancing. Even though a strict definition of lilt does not exist, the term often refers to the rhythmic flow imparted to the music by the performers. The term lilt bears a resemblance to the concept of swing in Jazz performance, where

Figure 1: The Shetland Isles

notated consecutive eighth notes are not played with equal duration, often approximating a tied triplet notation with a 2:1 ratio [4]. Given that an exact definition of lilt does not exist, and that many rhythmic elements could potentially play a role in imparting this dance feel to the music, this paper focuses on understanding general trends in microtiming variations in Shetland fiddle music. With this work we hope to bring a better understanding of what "*playing with lilt*" might entail.

2. RELATED WORK

The first systematic analysis of lilt in Shetland fiddle music was carried out by Peter Cooke in 1986 [3]. In this work, an electrokymograph, an early device used to measure variations in pressure, was used to capture the pitch contour and envelope of sound from a live fiddle performance. This was then used to manually calculate note onsets and approximate note durations. Anecdotal observations made by Cooke show eighth note durations that are rarely equal, with ratios of consecutive eighth notes in the range of 4:3 to 2:1. This *long-short* duration pattern is reminiscent of

swing in jazz performances [4, 6]. The seminal work carried out by Cooke in the 80s has seen a recent resurgence of interest, and has been the focus of recent analysis using state-of-the art computational analysis methods [1].

Swing research in fiddle music has also been carried out in the context of Irish traditional music [9]. In this work, a simple pitch detection and autocorrelation approach was used to estimate note durations and calculate 'swing percentages'. This method was proposed to detect the presence of swing in both synthesized and audio recordings.

Given its central role in the Jazz repertoire, swing has received considerable attention in this domain [2, 4, 6]. In [6], Friberg and Sundström examine the relationship between swing ratio and tempo in a number of popular jazz recordings. Using spectrograms obtained from the cymbal, the swing ratio was calculated based on the timing of successive eighth notes. The reported swing ratio ranged between 3.5:1 at low tempi to 1:1 at high tempi. In a later reexamination of this work, [4] applied automatic techniques to estimate swing ratios from a larger corpus of jazz recordings. The results support the initial findings of Friberg and Sundström with the added benefit that they can be applied at scale. Microtiming variations play an important role in a number of other music traditions including Ragtime syncopation [10], Samba rhythms [7], and Jembe music from Mali [8].

3. METHOD

This work represents an initial step towards the computational analysis of microtiming variations in Shetland fiddle music. As a starting point, it was necessary to compile a relevant fiddle data set. Once the recordings had been selected, all the tunes were transcribed to traditional music notation by an expert musicologist (Sect. 3.1). To be able to extract accurate timing information, each transcription was aligned in time with its corresponding audio track. For the alignment, the transcriptions were exported in MIDI format, and a MIDI-to-audio synchronization algorithm was used (Sect. 3.2). Finally, the time-aligned transcriptions were analyzed to extract timing information in the symbolic domain (Sect. 3.3). In the following sections, we provide a detailed description of all the steps in our analysis.

3.1 Fiddle Corpus

The fiddle corpus compiled in this work comprises 27 recordings of solo fiddle tunes available in the Tobar an Dualchais website.[1] Tobar an Dualchais is a collaborative project aimed at the digitization and preservation of Gaelic and Scottish recordings. The recordings in the corpus are field recordings made on a Nagra III reel-to-reel tape recorder with Sennheiser microphones. These were captured as monophonic wave files at 22.1kHz, 16 bit resolution. Table 1 provides a description of the corpus. Five performers are included, three from Mainland Shetland and two from the island of Whalsay (see Fig.1 for a map of the Shetland Isles). Track IDs from the Tobar and Dualchais collection are also provided to allow future research on the same corpus. For more information on the corpus see our accompanying website.[2]

The entire corpus was transcribed by a musicologist from the University of Aberdeen in Scotland (with expertise on Shetland fiddle traditions), providing us with transcriptions in conventional music notation for each of the 27 tunes.

3.2 MIDI-to-audio Synchronization

To calculate microtiming variations, the 27 transcriptions were exported in MIDI format and synchronized to their corresponding audio tracks. Synchronized MIDI transcriptions allow us to find the exact location in time of note onsets. For the MIDI-to-audio alignment, the method proposed in [5] was used. This method represents both the audio and MIDI streams as a combination of chroma and chroma onset features. The optimal alignment between audio and MIDI is obtained through dynamic time warping (DTW) using dynamic programming. Two difficulties were observed with the automatic synchronization. First, synchronization of the initial bars was inaccurate for some tunes, resulting in noticeably asynchronous audio and MIDI notes. Second, given that the tuning of certain files (or segments of the files) often lays between two consecutive semitones, the algorithm struggled to deal with these pitch variations and resulted in inaccurate alignments. To account for these inaccuracies in the automatic synchronization, the annotations of the complete corpus

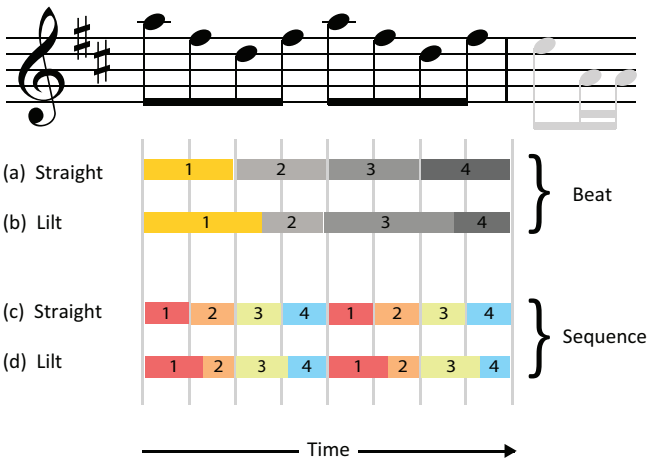

Figure 2: Schematic depiction of our onset-based analysis on a segment of the tune *Clean Pease Strae*. **Beat-level analysis:** (a) Beats of equal length (straight version) (b) Beats with timing deviations (lilt version). **Sequence analysis:** (c) Eighth notes of equal length (straight version) (d) Eighth notes with timing deviations (lilt version).

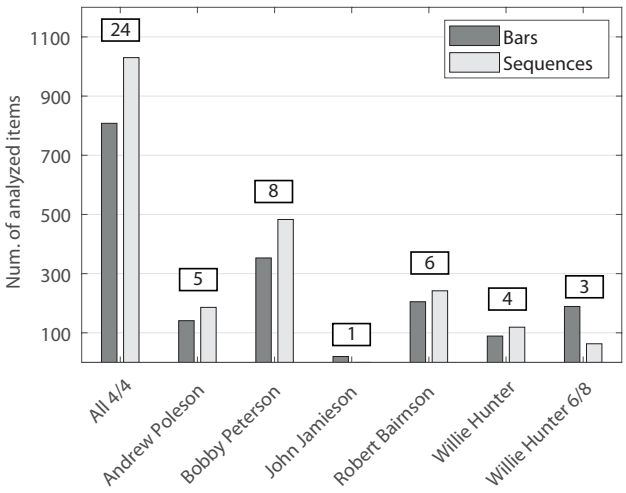

Figure 3: Total number of bars, note sequences and tunes (shown in boxed numbers above) per performer in the Shetland fiddle corpus.

were then manually fine-tuned by two professional musicians using Sonic Visualiser [3] .

3.3 Onset-based Analysis

The synchronized MIDI transcriptions are used to analyze microtiming variation in our corpus. Two different analyses were conducted: (a1) Microtiming variations on the beat level, and (a2) Microtiming variations in eighth note sequences. Given that accurate annotations of the note offsets are not available or easily extracted, we focus on measuring time intervals between onsets in this study. For the beat-level analysis (a1), we calculate time intervals between consecutive beats in the bar. We refer to these intervals as inter-beat-intervals (IBI). For the eighth-note-sequence analysis (a2), we calculate time intervals between consecutive eighth notes in the sequence. We refer to these intervals as inter-onset-interval (IOI).

Our analysis can be better understood by looking at Fig. 2, where a segment of the tune *Clean Pease Strae* is displayed. For the beat level analysis, Fig. 2a shows inter-beat-intervals (IBI) of equal length. This is referred to as the *straight* version of a performance. Our study seeks to understand whether deviations from the straight version exist, and whether performers slightly shorten or stretch the beats when playing with lilt. This scenario is depicted in Fig. 2b, where beats 1 and 3 are slightly longer than beats 2 and 4. Similarly, we analyze sequences of eighth notes in all tunes, and focus on measuring inter-onset-intervals (IOI) for sequences of four eighth notes (for $\frac{4}{4}$ meter), and sequences of three eighth notes (for $\frac{6}{8}$ meter). This can be seen in Figs. 2c and 2d, where the straight and lilt versions of the two eighth note sequences in the bar are shown, respectively. As with the beat-level analysis, we seek to understand whether performers slightly shorten or stretch the eighth notes when playing with lilt. In Fig 2d, the eighth notes 1 and 3 in the sequences are slightly longer than notes 2 and 4.

3.3.1 Practical Considerations

To facilitate the analysis of our corpus, we implemented an algorithm for pattern detection in MIDI files. The algorithm includes methods to detect relevant information such as downbeats, rhythm sequences (eighth notes, quarters, etc), double-stops, pitch sequences, etc. Supported by our pattern detection algorithm, the following considerations were taken: (1) Given that our analysis uses note onsets to detect inter-beat-intervals (IBI), only those bars where an onset was present (a note was played) on each of the beats in the bar were considered. While this means that parts of the performance were discarded in our analysis, it also completely removes the need to perform beat annotations, and relies entirely on the performers' onsets to calculate timing. (2) For the eighth-note-sequence analysis, only complete sequences of four eighth notes in $\frac{4}{4}$ bars, and three eighth notes in $\frac{6}{8}$ bars were considered. We restrict our analysis to sequences whose first eighth note coincides with an on-beat. Here again, we completely rely on the performer's onsets to calculate inter-onset-intervals (IOI) and timing variations. (3) A song-wise mean normalization of IBI and IOI was performed for the beat-level analysis and for the sequence analysis, respectively. This normalization allows us to remove differences in beat and note duration dictated by the different tempi of the tunes, and allows us to make direct comparisons between tunes. (4) In our corpus, only three tunes out of the 27 are written in $\frac{6}{8}$. These three tunes are all performed by Willie Hunter, and hence, conclusions with respect to the usage of timing in $\frac{6}{8}$ bars are restricted to the ones revealed by Willie Hunter's performances. (5) In all tunes where double-stops

were detected, only the onset of the lower note was used in our calculations.

Figure 3 shows a summary of the number of tunes, complete bars found and complete sequences found per performers in the corpus using our pattern detection algorithm.

4. RESULTS

4.1 Annotation reliability

To assess the reliability of the annotations, five of the tracks in the corpus were annotated by the two expert annotators. As a measure of annotator agreement, we use Chronbach's alpha coefficient α. For simplicity, we refer to the annotators as a1 and a2 in the following. The agreement between annotators was extremely high with $\alpha(a1, a2) = 0.9995$. It is important to consider, that the starting point for both annotators was the MIDI synchronization obtained with the method proposed in [5]. Hence, we also calculate the Chronbach's coefficient between the automatic MIDI synchronization M, $a1$, and $a2$, resulting in $\alpha(a1, M) = 0.9999$, and $\alpha(a2, M) = 0.9995$. These results validate both the reliability of our final annotations, and the high accuracy obtained by the automatic synchronization in the first place. Only minor modifications were required in order to obtain the final annotations from the automatically synchronized ones. These results also validate the usage of the method in [5] as an efficient approach for MIDI-to-audio synchronization of fiddle recordings, and opens the possibility to further enlarge our corpus in the future.

4.2 Onset-based analysis

In the following sections, we present our results in a top-down manner, starting with trends observed over the entire corpus, followed by a performer-wise analysis, and concluding with a comparative analysis of the tune *Willafjord* (the only tune performed by two perfomers in our corpus). To summarize the results, boxplots are presented both for the beat-level and sequence analyses. In all the figures, the boxplots represent the minimum and maximum values (whiskers), and the first, second (median) and third quartiles (box). In addition, the mean values for each distribution are displayed with colored circles. We present normalized note and beat durations in our plots (see Sect. 3.3.1).Values smaller than 1 show IOIs and IBIs shorter than that of the mean. Similarly, values larger than 1 show IOIs and IBIs longer than that of the mean.

4.2.1 Corpus analysis

Pairwise differences of the mean IOIs and mean IOBs of the entire corpus are calculated using the Wilcoxon signed-rank test at a 5% significance level (p-value < 0.05). Results for the corpus analysis are presented in Fig. 4 where the contribution of all performers and all tunes in $\frac{4}{4}$ meter are displayed.

Figure 4a shows the results of the beat-level analysis for all performers and tunes in $\frac{4}{4}$ bars. The pairwise comparisons revealed the normalized beat duration of beat 3 to be significantly shorter than 1 and 4. The slight shortening of beat 3 across all performers might indicate an attempt to delineate the on-beats in the $\frac{4}{4}$ bar.

Figure 4b shows the results of the sequence analysis. Note 3 in the sequence is significantly longer than all other eighth notes in a sequence. In addition, we see a significant difference between note 2 and note 4, with note 4 slightly shorter than note 2. In contrast, no significant difference was found between notes 1 and 2 in the sequence, appearing to be performed mostly in a *straight* manner .

4.2.2 Performer-wise analysis

In this section, we analyze possible performer idiosyncrasies both on the beat level and on the note sequence

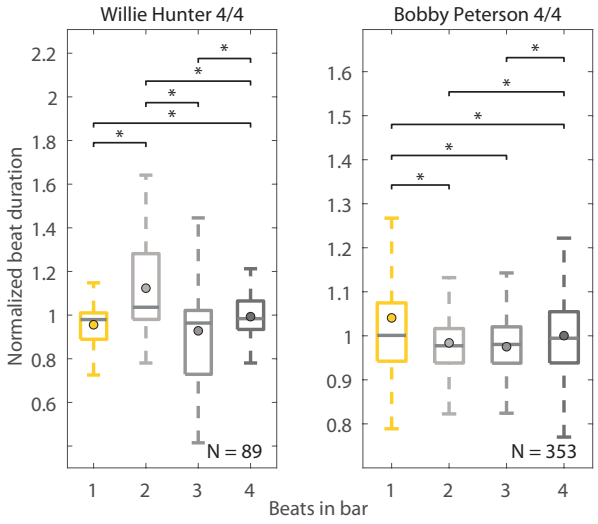

Figure 5: Performer-wise beat-level results. Significant differences are highlighted (* p-value < 0.05: Wilcoxon signed-rank test for pairwise comparisons)

level.

On the beat level, significant differences are evident in only two of the five performers, Willie Hunter and Bobby Peterson, with the other performers mostly showing beats of equal length. As seen in Fig. 5, the general trend in both Hunter and Peterson is to slightly shorten the third beat. These results support the trend observed in the corpus analysis of beats in Fig. 4a. In Willie Hunter, beat 3 is significantly shorter than beats 2 and 4, but beats 1 and 3 appear to be mostly played with the same duration. In contrast, beat 3 in Bobby Peterson is significant shorter than beats 1 and 4, but not than beat 2. Beat 1 in Bobby Peterson appears to be slightly prolonged, showing significant difference with all other beats.

On the note-sequence level, significant differences are evident in five performers as displayed in Fig. 6. John Jamieson only performs one tune in our corpus, and no eighth note sequences were found in it. In this analysis, we also include the results for the three tunes in $\frac{6}{8}$ performed by Willie Hunter. For the $\frac{6}{8}$ tunes, we consider sequences of three consecutive eighth notes. In Willie Hunter's $\frac{6}{8}$ sequences, we see a tendency to slightly shorten note 2. These differences are significant with respect to note 1 and 3. In Hunter's $\frac{4}{4}$ sequences, note 3 is significantly longer than all the others, a pattern that we also observe in Bobby Peterson. However, for Bobby Peterson, we additionally see a slightly shortened note 4 (significant with respect to note 2 and 3), and a tendency to lengthen note 2 with respect to 1. In contrast, Robert Bairnson appears to play mostly straight sequences, with a slightly shorter note 3 with respect to 1. As mentioned by Cooke in [3], the shortening of the 3rd note may be related to bowing: if notes 2, 3, and 4 are played with one bow, the middle note if often shortened and accented. The influence of bowing on lilt falls beyond the scope of this study, but calls for further future investigation. Andrew Poleson on the other hand, shows a consistent shortening of note 2, with significant differences with respect to all other notes.

It appears that a tendency to play pairs of eighth notes (either 1-2 or 3-4) in a long-short (LS) pattern might exist, with Willie Hunter ($\frac{4}{4}$) and Bobby Peterson showing a LS pattern in notes 3-4, and Andrew Poleson in notes 1-2. These results also go in hand with observations made by Cooke in [3].

4.2.3 Comparative analysis of the tune Willafjord

To analyze differences between performers, we compare the two versions of the tune *Willafjord* in our corpus; one performed by Bobby Peterson, the other by Robert Bairnson. Here we focus specifically on the differences at the note sequence level, and perform pairwise comparisons of the four notes sequence. Given that there are differences between the two performances, a direct correspondence between the sequences that we compare cannot be established, and hence, we treat them as unmatched pairs. To do so, the Wilcoxon sum-rank test is performed at a 5% significance level (p-value < 0.05). The tests reveal significant differences in IOIs for all of the eighth note positions, suggesting completely different performing practices by the two fiddlers for the tune *Willafjord*.

Our comparative analysis of the tune *Willafjord* gives a tantalizing insight into the source of such performer idiosyncrasies. These can be further elucidated in the biographies of Bobby Peterson and Robert Bairnson in Peter Cooke's original ethnographic account. Although both men lived on the main island of Shetland (approximately 23 miles apart), Bobby Peterson spent a great deal of his young life as sailor on a whaling ship. There, he was subject to a great many influences including hearing and learning tunes from other sailors from Scotland and Scandinavia. He learned the fiddle mostly be ear, in fact the first tune he ever learned was the focus of our analysis, the tune *Willafjord*. In contrast, Robert Bairnson, although only a short distance away, was fairly isolated as infrastructure on the Shetland Isles in the early 20th century made travelling very difficult. Bairnson also lived in a district where religious attitudes deemed music and dancing sinful. He was taught formally by a local minister, learning notation at the same time. Therefore he lacked the 'indigenous repertory' of other Shetlanders [3, p. 20]. These biographies go some way to explaining why such clear difference can be observed between performers, and in particular, the straight playing of Bairnson versus the more lilting performance of Peterson.

5. CONCLUSIONS AND FUTURE WORK

In this paper we presented microtiming analysis of a corpus of traditional Shetland fiddle music. The corpus, created specifically for this study, was first annotated by expert annotators using automatic MIDI-to-audio synchronization as a starting point. We examined inter-beat-interval timing deviations, as well as inter-onset-interval timing deviations of eighth note sequences to find the elusive qualities of *lilt*. We first analyzed the corpus as a whole, moving to

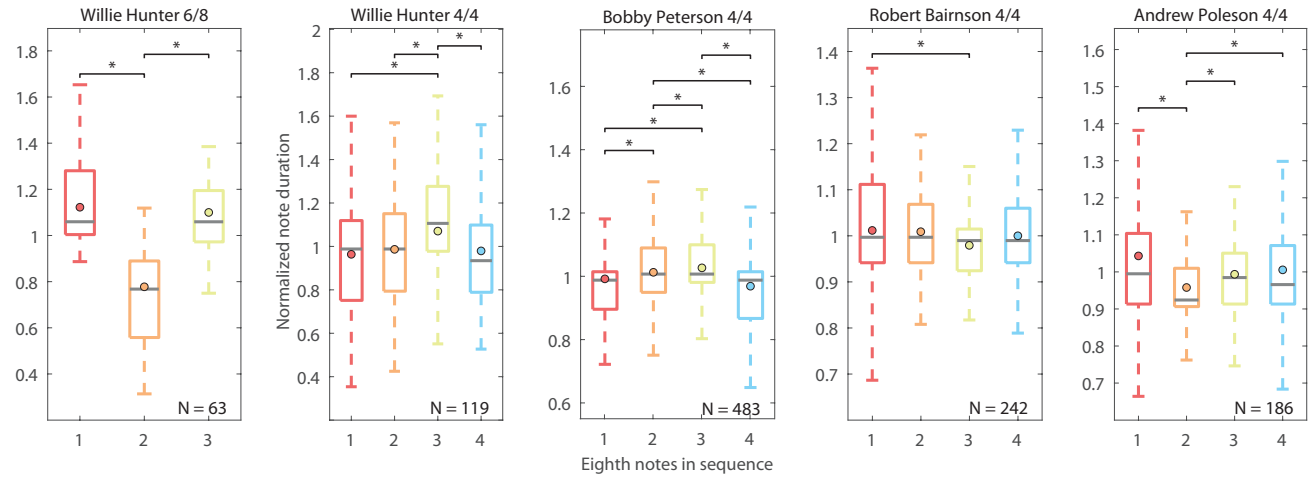

Figure 6: Performer note-sequence results. Significant differences are highlighted (* p-value < 0.05: Wilcoxon signed-rank test for pairwise comparisons)

performer-based analysis, and finalized with a comparative study of a tune played by two performers.

In general, the beat-level analysis indicates a tendency to slight shorten beat 3 in the bar. The note-sequence analysis, suggests the use of long-short patterns in pairs of eighth notes (either 1-2 or 3-4). Even though these emerging patterns in the data may suggest what playing with lilt entails, it is clear that lilt also encompasses idiosyncratic aspect of performance practice. Further investigation is required in order to understand how these patterns relate to other aspects of music performance such as bowing, accentuation, repertoire-specific performing styles, tempo, etc.

With this work, we have reached three important milestones in our research: (1) We have produced high-quality annotations for our corpus that will serve as the foundation and ground-truth for more powerful computational models, (2) we have validated the use of a state-of-the-art MIDI-to-audio synchronization algorithm for the task at hand, and (3) we have revealed microtiming variation patterns in fiddle music from the Shetland Isles.

6. ACKNOWLEDGMENTS

The authors would like to thank the panel of annotators Juan Fernando Alzate and Elissa Sayampanathan, as well as Mr. Ronnie Gibson and Dr. Frances Wilkins at the University of Aberdeen, and Dr. Cathlin Macaulay at the Scottish Studies Archive, School of Literature, Languages and Cultures Celtic & Scottish Studies, University of Edinburgh.

ABSTRACT

This paper describes the digitization process of a large collection of historical piano roll recordings held in the Stanford University Piano Roll Archive (SUPRA), which has resulted in an initial dataset of 478 performances of pianists from the early twentieth century transcribed to MIDI format. The process includes scanning paper rolls, digitizing the hole punches, and translating the pneumatic expression codings into MIDI format to create expressive performance files. We offer derivative files from each step of this process, including a high resolution image of the roll, a "raw" MIDI file of hole data, an "expressive" MIDI file that translates hole data into dynamics, and an audio file rendering of the expressive MIDI file on a digital piano sample. This provides digital access to the rolls for researchers in a flexible, searchable online database. We currently offer an initial dataset, "SUPRA-RW" from a selection of "red Welte"-type rolls in the SUPRA. This dataset provides roll scans and MIDI transcriptions of important historical piano performances, many being made available widely for the first time.

1. INTRODUCTION

1.1 Background

Piano rolls are among the most important historical music storage formats, utilizing holes on a scrolling paper roll to activate keys automatically by a pneumatic mechanism built into a piano. There are many types of piano rolls with varying degrees of autonomous playback prescribed by the roll system. We focus here on the "reproducing roll", one that reproduces automatically notes, timings, and expressive details of a live performance.

By late 1904 the German company Michael Welte and Söhne developed the first "reproducing player piano", the Welte-Mignon [7]. This was a high-end, fully autonomous self-playing instrument capable of reproducing all features of an original performance of a pianist, including details of timing, dynamics and pedaling. The process involved capturing and coding expressive details into the hole punches on the edges of rolls which then cued the pneumatic mechanisms in the piano to alter hammer velocities instantaneously. These codings were created by skilled technicians who made judgements about the expressive effects they could generate using the pneumatic parameters available for manipulation in each system. The resultant playback of a reproducing roll sounds like a recreation of an individual musical performance.

The reproducing player piano quickly became a commercial success that attracted the most important artists of the day to make recordings on the medium. Composers recorded playing their own works on roll include Claude Debussy, Maurice Ravel, Gustav Mahler, Sergie Prokofiev, Sergei Rachmaninoff, Edvard Grieg, Alexander Scriabin, Enrique Granados, Igor Stravinsky, George Gershwin, and Scott Joplin, among others.

A variety of proprietary reproducing roll systems were produced by over a dozen companies , each one incompatible with the others. The most important of these include Welte-Mignon, Hupfeld, Ampico, Duo-Art, and Phillips Duca. Some companies developed multiple formats. Welte maufactured three formats: Welte T-100 (red Welte), Welte T-98 (green Welte), and Welte-Licensee.

1.2 SUPRA

Stanford University's Player Piano Project [13] is a multi-departmental effort begun in 2014 by the Archive of Recorded Sound to address the obstacles faced by researchers who wish to study piano rolls and pneumatic instruments. Stanford now holds one of the largest roll collections in the world, with more than 16,000 rolls and a dozen pneumatic roll playing instruments. The collection includes a variety of roll types, including thousands of reproducing rolls. A dedicated roll scanner was built by the project to generate image scans of rolls for preservation and digitization. The Stanford University Piano Roll Archive (SUPRA) is the online database of roll images generated by the scanning effort. It aims to provide a virtual experience of piano rolls including a high resolution

color image of the roll and a digitally synthesized audio rendition of each roll. In order to create accurate audio files of reproducing rolls, algorithms that model the pneumatic expression systems of each format must be created. This process of "emulation" (i.e. emulating the pneumatic system through a digital means) is important if the expressive content of reproducing rolls are to be accurately transcribed. This paper outlines the end-to-end process undertaken to scan, digitize, and create emulation algorithms for a subset of 478 Welte T-100 reproducing rolls that will be made accessible through the online SUPRA database.

2. PRIOR WORK

Efforts at scanning and digitizing piano rolls have been undertaken by hobbyists and enthusiasts with private collections, but with inconsistent results and incomplete documentation [1, 15, 18]. More recently a number of institutional projects have been initiated [2, 3, 8–10]. Much of this work has focused on non-reproducing rolls, those rolls lacking expression coding [8, 12]. Most institutional efforts do not provide audio file transfers of the rolls at this point [2, 3, 9]. In some cases only documentation of the rolls is offered but not complete roll scans [3].

A number of dedicated roll scanners have been constructed [1,9,12,15,18]. However, some projects utilize flat bed scanners which require images to be stitched together leading to potential errors [8]. Peter Phillips's unique design of a "pneumatic roll reader" offers some advantages, but does not allow for an archival image [14]. Anthony Robinson has done impressive work with scanner design and is able to produce quality roll scans [15]. These are, however, in gray scale and at modest resolution.

There is not much published work on the topic of emulation although there have been some well publicized efforts at utilizing emulations to playback reproducing rolls. Colmnares et al. [6] provide some theory behind the topic and relies on the work of Wayne Stahnke, one of the pioneers in modeling pneumatic roll systems. Stahnke produced two commercially successful emulated transfers of Rachmaninoff's playing on Ampico reproducing rolls that garnered critical acclaim [17], however the algorithms and detailed procedures of his work remain unpublished. Peter Phillips's recent doctoral thesis provides comprehensive documentation and experimental justification for his emulation procedures and is the most thorough discussion published thus far [14]. Our work here follows closely on his effort and also on our prior work to create an emulation for the Welte Licensee format [16].

3. THE SUPRA-RW DATASET

We chose to begin the SUPRA database with Welte T-100 rolls as these were the first reproducing piano rolls made. These important recordings have received very little attention from roll scanning efforts because they require a scanner capable of managing the significantly greater width of these rolls. Expression emulation of Welte T-100 rolls is also among the most complex of reproducing roll formats.

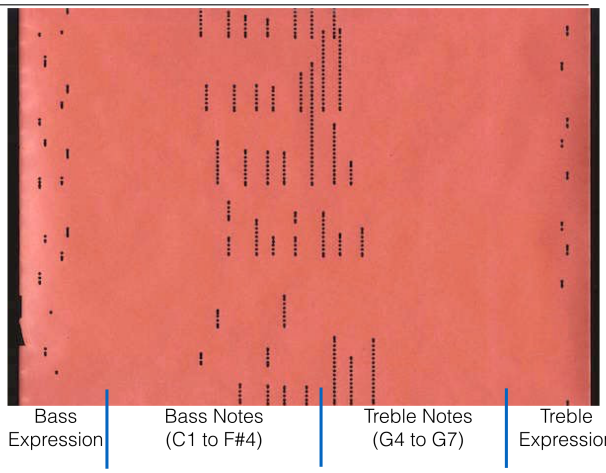

Figure 1: A sample from a red Welte roll. It is divided into four sections: bass expression, bass notes, treble notes, and treble expression.

Welte T-100 rolls are often referred to as "red Welte rolls" because they were generally punched on red paper. They are 12.9 inches (32.8 cm) wide, and have 100 perforation tracks (holes), eight per inch across, evenly spaced. A sample from a red Welte roll is shown in Figure 1. The first and last ten perforation tracks are used for expression, and the middle 80 tracks are used for notes from C1 to G7.

The SUPRA-RW dataset is the result of the digitization of 478 Welte T-100 rolls in Stanford's collection. It consists of about 52 hours of piano roll performances, with an average length of 6 minutes and 32 seconds. The database allows users to search, view images, download and listen to audio emulations of the rolls.

Our digitization procedure results in the following files and derivatives in sequence:

(a) Archival TIFF image at 300 DPI (dots per inch) and 24-bit color.
(b) JPEG files derived from the archival TIFF.
(c) Uncompressed grayscale TIFF file (that utilizes the green color channel of the original scan) allowing efficient access to high resolution detail of the holes.
(d) Raw MIDI file that captures all hole data extracted from the grayscale TIFF file.
(e) Expressive MIDI file that merges multiple holes into single musical notes, applies emulation algorithms to control for individual note dynamics, and adds pedaling. Metadata such as title and composer is also added to this file.
(f) Audio files (WAV and M4A) rendered by running the expressive MIDI file through the Ivory Keys II software synthesizer.

The SUPRA-RW dataset as well as the software are available online [1] at a Creative Commons Attribution-Non-Commercial-ShareAlike 4.0 International license (CC BY-NC-SA 4.0) [2].

4. ROLL DIGITIZATION

4.1 Scanning

Piano rolls are digitized using a dedicated roll scanner built in conjunction with Swope Design Solutions and based on designs by Anthony Robinson [3]. The scanner (Figure 2) uses a line-scan camera (DALSA Spyder3 Color 4k) triggered by a rotary encoder on a glass cylinder that tracks the movement of the paper roll that passes over it. The target resolution of the images is 300 DPI, with the experimentally measured DPI being 301.50 $\pm$ 0.25 across the width of a roll and 300.25 $\pm$ 0.25 along the length of the roll.

The scanner can image a roll up to 5$\times$ playback speed, although the typical acquisition speed is 2–3$\times$. An original uncompressed color image is typically 1–4 GB in size. The line-scan camera takes pictures that are 2 pixels high and 4096 pixels wide. One row of pixels is used to measure the green color channel, and the second row contains interleaved red and blue color pixels. The adjacent images from the camera are 50% overlapped such that a red/blue row from one image is aligned with the green row of the next image. Since the green channel has twice the resolution of the red or blue channels, the green channel is used for hole data extraction from the images.

[3] For more details and a video of the scanner in action, see https://library.stanford.edu/blogs/stanford-libraries-blog/2018/10/piano-roll-scanner-update.

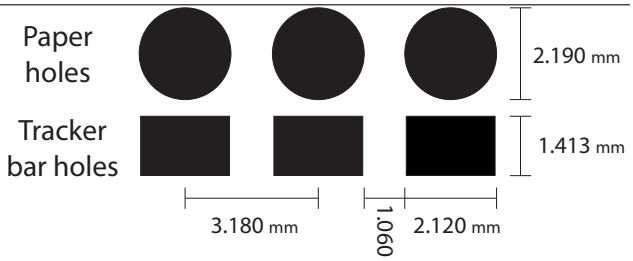

Figure 3: Red Welte paper and tracker bar hole physical dimensions and horizontal spacings (to scale).

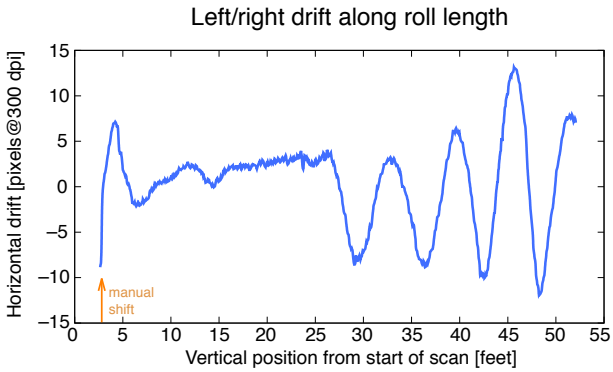

Figure 4: Drift analysis for a sample roll. The total drift range is 25px from left to right. The arrow near the start of the roll indicates a manual shift by the scanner operator.

4.2 Drift Correction and Hole Detection

The paper of an original piano roll can warp due to age and poor storage conditions. In such cases, paper holes may drift and misalign with the corresponding tracker bar hole and trigger the incorrect note. Figure 3 shows the spacing between the rectangular tracker bar holes and the circular holes of the piano roll paper. When the paper shifts by more than one mm (about 13 pixels), a paper hole will start to bleed the vacuum in an adjacent tracker bar hole. If the overlap is large enough, an incorrect note will be triggered on the player piano. Thus, a first step in extracting the musical holes from a roll image involves identifying and cancelling this drift.

Figure 4 plots the drift of a sample roll throughout its length. There is an initial sudden shift of about 15 pixels at the start of the roll caused by the scanning operator moving an adjustment bar. For the next 25 feet the drift is minimal, at only a few pixels. Then starting at around 27 feet, an oscillation with an amplitude of 20 pixels begins to be observed. This oscillation has a frequency of about 5–6 feet and is common in many Welte T-100 scans. We determined this to be due to inconsistencies in the paper, as well as mechanical properties of the scanner relating to the tension and alignment of the supply and take-up spools.

For a sample of 60 red rolls, the average total drift range was 20.8 $\pm$ 10.8 pixels, where the spacing between note columns was 37.75 px. Five of the rolls had a total drift that would cause them to produce incorrect notes if played without correction on a player piano, and 25 had a drift that may cause problems. The largest total drift throughout the

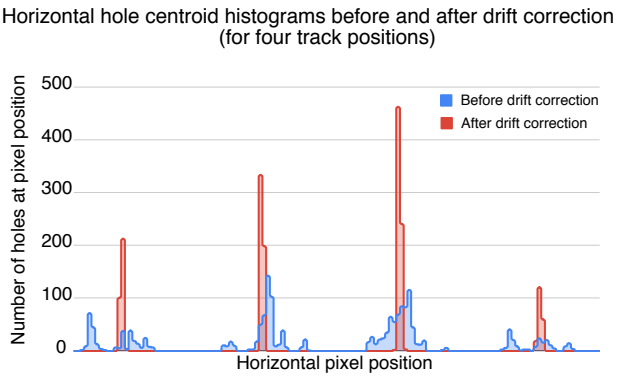

Figure 5: Horizontal positions of hole centroids for four tracks before (blue) and after (red) drift correction.

scan of a roll was 55.7 px, and the smallest was 2.7 px over the length of a roll.

To calculate the drift correction along the length of a piano roll, the edges of the paper are identified, and these edges are low-pass filtered to remove defects such as edge tears from the edge analysis. When the left and right edges of the paper move suddenly in parallel, this indicates that the scanner operator moved the adjustment bar during the scanning process.

This left-right drift is cancelled out by adjusting the horizontal position by the negated drift value at that position on the roll. The centroid (center-of-mass) for each musical hole is identified in the image, and then assigned a corrected position by subtracting the drift offset at the centroid position. Figure 5 shows the results of this drift correction for a single tracker bar position. After adjusting for drift, the hole centroids for a track are clustered within a standard deviation of less than one pixel ($1/300$th of an inch), compared to a range of 18 pixels before the adjustment.

Finally, a Discrete Fourier Transform (DFT) is applied to the drift-corrected hole centroid histogram (window size 4096, zero padding by a factor of 16). The spacing of the hole tracks is obtained by searching for the peak harmonic in the expected region of the DFT. The offset of the spacings is locked to the track position with the most hole punches.

4.3 Defect Analysis

The drift adjustment also allows for increased accuracy in identifying holes that are not quite aligned with any intended tracker hole. Such errors can be removed in this step. Figure 6 illustrates such a problematic hole. In this example, the green-highlighted hole at the bottom left corner of the figure is caused by a tear in the original paper. This hole is not aligned on any of the expected hole centers that are indicated by purple vertical lines. The blue holes indicate alignment as expected.

Other statistical measures of hole shapes are also used to detect aberrant holes. For example, the angle of the major axis of the hole is expected to align with the length of a roll, except for circular single-punch holes. Holes less than $1/6$ of the expected area of a single punch are automatically excluded. These are typically small defects in the

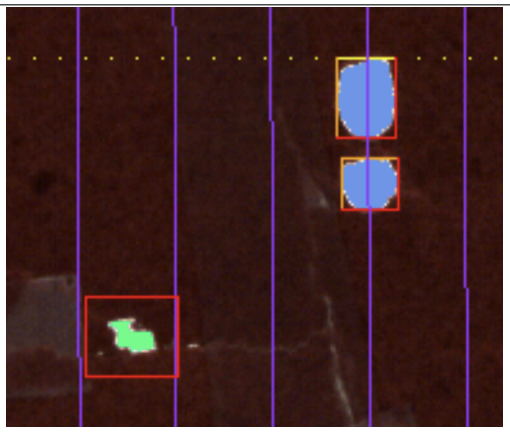

Figure 6: Unintentional hole in paper (bottom left) and intentional holes (upper right).

paper, such as dirt or large pieces of cellulose in the paper that have fallen out over time. Holes wider than the expected spacing between holes are also flagged as potential problems.

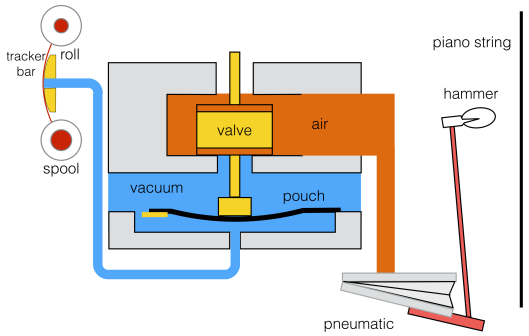
4.4 Bridge Removal

Long holes on piano rolls are often split into several smaller holes to avoid weakening the paper, however they sound as a single longer note when played back on a pneumatic instrument. This process is called “bridging”. Our raw MIDI files retain the bridging information, thus making them suitable for punching new paper copies of the rolls (what are called “recuts") that retain these separations. This detail is also important for master-roll reconstruction analysis. Our expressive MIDI files however remove this bridging to produce the resultant sound of the roll. Adjacent holes are taken to merge into single notes when the spacing between holes is less than $1.37\times$ the diameter of the punches. Figure 6 illustrates such a case where the two blue holes in the upper right corner represent a single note and would be merged.

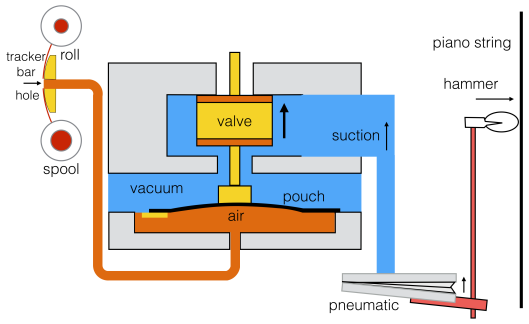
5. ROLL EMULATION

5.1 The Pneumatic System

A player piano is powered by suction, utilizing pneumatic valves that regulate vacuum pressure created by an electric motor. As shown in Figure 7, when a roll passes over the tracker bar, a hole on the paper allows air to leak into the lower section of the valve box, causing the air below to change to atmospheric air pressure. As it moves the valve pouch upwards, the vacuum thus travels to the pneumatic and collapses it, causing the pneumatic to move, which strikes a piano key. However, on a reproducing piano, a further series of pneumatic controls, the “expression box”, regulates the precise rate of change in the suction level of the “dynamic” pneumatic. There is one expression box for each half of the keyboard, thus allowing dynamic changes to only occur on one half at a time, however the changes



(a)



(b)

Figure 7: Basic components in a player piano. (a) When not reading a hole. (b) When reading a hole.

can occur very rapidly over time [4].

Thus, the dynamic pneumatic can do one of the following:

(a) Remain stationary.

(b) Open or close slowly, producing the effect of a slow crescendo or decrescendo (suction level increases or decreases slowly).

(c) Open or close quickly, producing the effect of a fast crescendo or decrescendo (suction level increases or decreases quickly).

5.2 Expression Emulation of Welte T-100 Rolls

The process of emulation involves understanding how the expression box (or equivalent component in other formats) affects suction pressure on the dynamic pneumatics for each key over time. The expression system for Welte T-100 rolls involves ten parameters (including pedals) that can affect independently or in combination the dynamic result at any given time. Table 1 shows the possible parameters and their locations as expression hole tracks. There are parallel holes for each expression regulation on each side of the piano because, as mentioned above, the pneumatic expression mechanism is split in half across the keyboard. The damper (sustain) pedal plays a role in the dynamics because it affects the collective sustain and decay of notes played.

[4] The original technology used by reproducing roll companies to capture dynamic information from the live performer remains unclear. One theory suggests that the dynamics were translated into perforations from expression lines drawn by styli attached to pneumatics that were connected to expression regulators. Others have suggested a combination of electro-pneumatic valves and a dynamic rotor. A more detailed investigation of this question is beyond the scope of this paper but further information can be found in other sources [11, 14].

Bass Section	Treble Section
14: Bass Mezzoforte off	113: Treble Mezzoforte off

22: Motor off	105: Electric cutoff
23: Motor on	104: Rewind
24-66: Notes C1 to F#4	67-103: Notes G4 to G7

Table 1: MIDI note number and corresponding perforation track information (encoded in the raw MIDI files).

We begin by encoding each hole track as a MIDI note number in the raw MIDI file. The function of each hole track on red Welte rolls is summarized in Table 1. Holes of the bass expression tracks (MIDI Note Number 14—19) control the dynamics of notes below F#4 and those of the treble expression tracks (108—113) control the dynamics of notes above G4. Holes for pedal movements (20—21, and 106—107) apply to all notes. Notes (pitches) on the keyboard are holes 24–103.

The "Mezzoforte on" and "Mezzoforte off" hole tracks control a pneumatic hook (which is often referred to as the "mezzoforte hook") that prevents the expression pneumatic from fully opening or closing. The damper (sustain) pedal and una corda (soft) pedal are controlled by lock-and-cancel valves: holes in one track turn on the valve, and holes in an adjacent track turn it off, allowing the hole to have a continuing effect once triggered.

The "Crescendo forte" and "Crescendo piano" hole tracks produce slow crescendos (increasing dynamics). They are also controlled by lock-and-cancel valves. This means once a perforation of "Crescendo forte" is triggered, the dynamic will increase until it is cancelled by "Crescendo piano". The "Forzando forte" and "Forzando piano" produce fast crescendos and decrescendos. They are controlled by a single continuous roll perforation, unlike lock-and-cancel valves, so the pneumatic is powered for the length of the perforation. When the crescendo and forzando tracks are not activated, a steady slow decrescendo results. In fact, a slow decrescendo is effectively constantly activated due to its connection to ambient air pressure.

To calculate the rate at which the crescendo or decrescendo operates, we examined original Welte T-100 test rolls, manuals and other sources [5, 14]. A test roll contains a number of specific note and dynamic tests that allow a technician to adjust the fine regulation of the player piano. The slow crescendo, slow decrescendo, fast crescendo, and fast decrescendo rates are regulated by test 3 through 6 in the T-100 test-roll manual. Test 3 regulates the slow crescendo rate to the mezzoforte hook. Test 4 regulates the fast crescendo and decrescendo. Test 5 regulates the re-

Crescendo type	Travel between	Time (ms)
Slow Crescendo	min. to mezzoforte	1190
Slow Decrescendo	mezzoforte to min.	2380
Fast Crescendo	min. to mezzoforte	200 to 300
Fast Decrescendo	max. to min.	70 to 210

Table 2: Crescendo type and the time it takes to travel between two dynamic levels.

lease from fortissimo touch to piano touch. Test 6 regulates the combination of crescendo and decrescendo. These tests would have been used in conjunction with the judgement of a trained technician. Even as specified, they allow for a small range of results to the tests.

Based on this research, we chose rates for these parameters as shown in Table 2. We have chosen to model pneumatic pressure changes during execution of the slow crescendo and decrescendo as a non-linear function (one-pole filter), whereas that of the fast crescendo and decrescendo is modelled as a linear function. We apply the following constraints to map pneumatic pressures to MIDI velocity levels: the mininum velocity (softest level) is 35, mezzoforte (medium level) is 65, and the maximum (loudest level) is 90. In addition, the overall velocity of bass notes are assigned to be about 5 velocity levels lower than the treble notes.

5.3 Tempo Configuration

Most piano rolls formats are played with a speed written at the start of a roll by the manufacturer; however, Welte T-100 rolls do not have this indication. Test rolls and manuals do suggest that these rolls are to be played at single set speed, however Welte player instruments curiously come with a speed-adjustment lever. It has been theorized that this lever may have allowed for small adjustments needed by poorly regulated instruments. We deduce the general set tempo from an examination of test rolls and sources to be approximately 9.46 ft./min., but accept a potential range of $\pm$ 0.5 ft./min.

Timings of notes in image-extracted MIDI files are expressed in delta-time ticks (pulses) that represent one pixel row in the original image. This allows notes in the MIDI file to be linked to their source locations in the scanned rolls. To translate roll speed into MIDI playback speed, we first set the initial MIDI tempo to 60 BPM. Then we calculate ticks (or pulses) per quarter note (TPQ, or PPQ, in the file header) by multiplying the roll speed with a factor that converts ft./min. into pixels/sec.:

$$\text{factor} = \frac{\text{feet}}{\text{min}} \times \frac{300\text{pixel}}{\text{inch}} \times \frac{12\text{inch}}{\text{feet}} \times \frac{1\text{min}}{60\text{second}} = 60$$

So a speed of 9.46 ft./min. is used to set the TPQ value in the MIDI header to 568.

5.4 Paper Acceleration

The take-up spool on a player piano rotates at a constant speed, while the diameter of the spool increases as paper is wound around it. This causes an acceleration of the paper

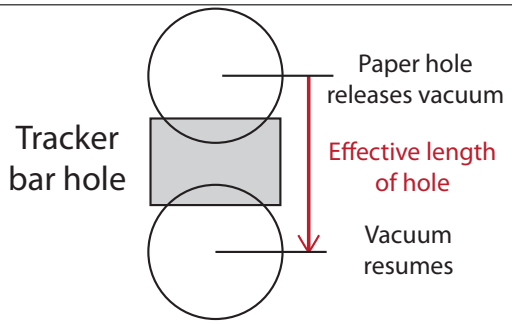

Figure 8: Schematic of paper hole moving across trackbar (not to scale).

over time. Since the MIDI file time unit represents spatial distance on the roll, tempo changes are given in the MIDI file to emulate this acceleration. Based on our research and sources, we set this to be a 0.22% acceleration rate per foot [4]. The result is a more accurate tempo across the length of the roll.

5.5 Hole Extension

Another correction we apply concerns the effective length of paper holes over the tracker bar. The pneumatic valve is actually triggered before the paper hole completely lines up with the tracker bar hole, as enough of the ambient air pressure is generated by a portion of the hole. Thus the effective length of the hole is actually longer than it is on the paper, as illustrated in Figure 8. Compensating for this extension is especially important for the forzando piano and forte expression tracks because they are fast-acting and sensitive to small variations in time. We approximate the extra time the valve is open by measuring the length of a Welte-Mignon tracker bar hole and multiplying it by 0.75.

5.6 Audio Rendition

We provide high-quality audio transfers of the expressive MIDI files in SUPRA-RW by rendering them through Synthogy Ivory II Pianos in Steinberg Cubase. The resulting wav and m4a files should generate a result that compares favorably to a Welte T-100 roll played on an original Welte-Mignon pneumatic instrument.

6. CONCLUSION

In this paper, we describe the creation of the SUPRA-RW dataset which includes scanning, symbolic music extraction, pneumatic system modeling, and performance rendering via emulation. These procedures will apply with some variation (especially in emulation algorithms) to other reproducing roll formats and should be useful for those working to digitize large collections.

There is much work to do with reproducing (and non-reproducing) rolls. Our project will continue to study pneumatic expression mechanisms and we plan to create emulations for other roll formats. This will support online access to the thousands of rolls in Stanford's collection and will grow the SUPRA database.

7. ACKNOWLEDGEMENT

We thank Anthony Robinson for contributing his roll scanner design and expertise to the project. Brett Swope of Swope Design Solutions built the scanner for this project. We thank Peter Phillips and Wayne Stahnke for their generous advice and consultation. The Stanford University Library staff provided expertise in many areas for which we would like to thank Tony Calavano, Doris Cheung, Frank Ferko, Nathan Coy, Jill Sison, Kristen St. John, Peter Crandall and Andree Clair Bonnepart. This project is funded partially through the generosity of an anonymous donor.

ABSTRACT

Autoregressive neural networks, such as WaveNet, have opened up new avenues for expressive audio synthesis. High-quality speech synthesis utilizes detailed linguistic features for conditioning, but comparable levels of control have yet to be realized for neural synthesis of musical instruments. Here, we demonstrate an autoregressive model capable of synthesizing realistic audio that closely follows fine-scale temporal conditioning for loudness and fundamental frequency. We find the appropriate choice of conditioning features and architectures improves both the quantitative accuracy of audio resynthesis and qualitative responsiveness to creative manipulation of conditioning. While large autoregressive models generate audio much slower than real-time, we achieve these results with a more efficient WaveRNN model, opening the door for exploring real-time interactive audio synthesis with neural networks.

1. INTRODUCTION

Expressive musical instruments, whether digital or acoustic, enable players to use relatively low-dimensional gestures to control perceptual qualities of audio such as pitch, dynamics, and timbre in real time [5, 10]. Progress in *Neural Audio Synthesis*, directly rendering audio with deep neural networks, has revolutionized the field of speech synthesis [13, 15, 18, 19] by replacing hand-designed functions with data-driven design, and is similarly poised to create a brand new class of expressive musical instruments [1, 3, 4, 6, 12].

Much of this progress is due to deep autoregressive models, such as WaveNet [18] and Tacotron [15, 19]. While these models can generate a wide range of realistic audio, using them as expressive musical instruments is not straightforward as they require fine-grained domain-specific conditioning information, such as phonemes [18] or mel-spectrograms [15] for speech, and are prohibitively slow at generating audio.

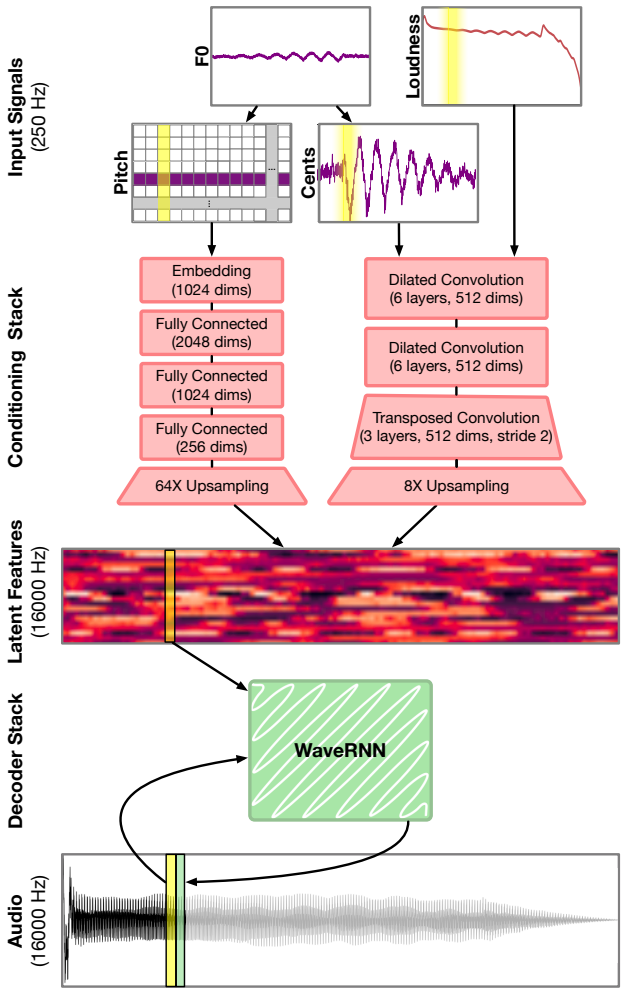

Figure 1. Real-time neural synthesizer architecture. Fundamental frequency (F0) and loudness features are fed through a conditioning stack and upsampled to audio rate. Using our Pitch/Cents representation, F0 is split into pitch one-hot embeddings and continuous deviations in cents. The latent features are concatenated and fed into a WaveRNN which generates audio autoregressively. Audio samples can be heard in the online supplement [1].

In this paper, we make progress in overcoming these challenges by using domain-specific conditioning features to drive a simpler and more efficient WaveRNN [7] model to generate audio of musical instruments. We explore a variety of conditioning features and architectures and demonstrate that a WaveRNN-based model driven by time-distributed and fine-scale musical features is capable of synthesizing realistic audio faster than real time. Our key

findings include:

- *Fine-grain control over loudness.* By conditioning on extracted loudness features, WaveRNNs can resynthesize audio that closely matches the original loudness, from long attacks and decays to fast changes like a tremolo.
- *Fine-grain control over pitch.* By conditioning on extracted fundamental frequency features, WaveRNNs can resynthesize audio that closely matches the original frequencies, from a constant pitch, to subtle vibratos and large glissandos.
- *Feature selection.* Conditioning on perceptual loudness consistently outperforms using amplitude energy, while conditioning on discrete pitches and continuous cents outperforms using a single continuous frequency feature.
- *Real-time generation*. Since the models are built around WaveRNN, even unoptimized kernels synthesize audio faster than real-time in batch mode. We show our results hold for casaul conditioning stacks, opening the door for low-latency interactivity with a properly optimized implementation.

Audio for all examples shown in this paper can be found in the online supplement [1] .

2. RELATED WORK

2.1 Musical Conditioning

WaveNet autoencoders can infer a latent conditioning signal from raw audio [4]. This enables unique opportunities for timbre transfer and morphing [2,12], but the latent code is relatively high dimensional and unintuitive to manipulate due to entanglement of perceptual attributes.

Discrete pianorolls can serve as an intuitive intermediate representation to control generation of realistic polyphonic audio in focused domains such as solo piano performance [6,9]. However, many instruments have dynamic pitch and volume that cannot be captured with discrete pianorolls. In contrast, this work examines using continuous pitch and loudness conditioning to create a synthesizer capable of such dynamic control.

2.2 Fast Synthesis

A successful approach to speeding up generation is rendering audio in parallel. Parallel Wavenet [17] distills a teacher WaveNet model into a student network that generates audio in parallel using inverse autoregressive flows. This dramatically reduces inference latency but requires training several networks and carefully tuning several heuristic losses. Other flow-based models such as WaveGLOW [14] can train audio generation flows directly, but so far have only been successful at inverting spectrograms. Generative adversarial networks provide another approach to parallel generation and GANSynth [3] recently proved four orders of magnitude faster than WaveNet baselines by generating magnitudes and phases in the spectral domain. However, these models are not capable of handling fine-scale conditioning or variable-length sequences considered here.

The streaming nature of autoregressive models makes them uniquely suited for real-time performance. WaveRNN and LPCNet [7,16] are single-layer recurrent neural networks that reduce complexity to generate 24kHz 16-bit speech at speeds up to 4×real time, even on mobile device CPUs. These models can also run inference in a streaming fashion; a critical requirement for interactive and live applications.

WaveRNN in particular, achieves its performance through a set of architectural and engineering innovations, including 1) the representation of 16-bit audio as a tuple of two 8-bit integers, which enables efficient parameterization of the neural network using a dual-softmax layer, 2) special GRU cells for the two 8-bit integers which achieves high quality synthesized audio, and 3) custom kernels on GPUs and CPUs for dense and sparse models respectively.

3. EXPERIMENTAL DETAILS

3.1 Dataset

We focus our work on a smaller subset of the NSynth dataset [4] identical to GANSynth [3]. These total 70,379 examples, comprising mostly of strings, brass, woodwinds and mallets with pitch labels within MIDI range 24-84 (F0 of ∼32-1000 Hz). Each sample is 4 seconds long and sampled at 16KHz, resulting in 64,000 dimensions.

3.2 WaveRNN

Our WaveRNN model consists of a 1280-unit GRU, two 640×512 fully connected layers (projection) and two 512×256 fully connected layers (logits). The output has two size-256 softmax layers, each predicting 8 bits of the audio (16 bits in total). The model size is on par with WaveRNN for speech synthesis [7]. Compared to other fast audio synthesis models (Parallel WaveNet [17], GANSynth [3], and WaveGlow [14]), WaveRNN has a simpler training setup: the training loss is simply negative log-likelihood and the set of hyper-parameters to tune is small.

3.3 Conditioning

Our work explores conditioning with fine-grain pitch and amplitude control. Details of the conditioning architecture are shown in Figure 1. Below we motivate the choice of representation, followed by the choice of conditioning architecture.

3.3.1 Amplitude Representation

We experiment with two representations for amplitude: Root Mean Square (RMS) *Energy* and an A-weighted Log Amplitude *Loudness*.

[1] `http://bit.ly/2GcCPNV`

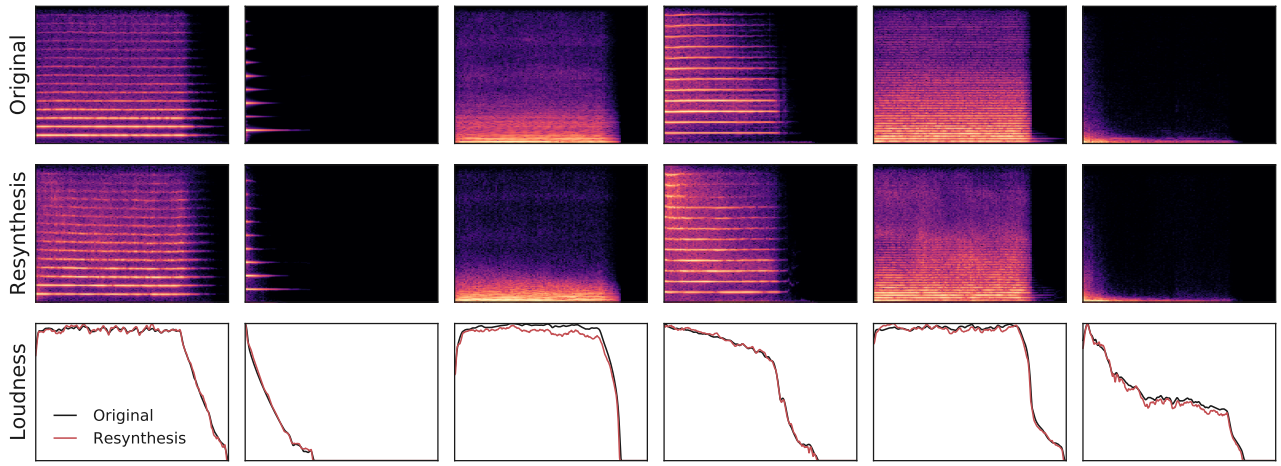

Figure 2. Audio resynthesized from extracted features. Spectrograms of examples from the NSynth dataset and and audio resynthesized from audio features (loudness and fundamental frequency) extracted from the original audio. The bottom row shows the loudness features of the original audio and resynthesized audio. Spectral and loudness contours, and fundamental frequency contours (not shown), are largely reproduced by the resynthesized audio. These samples, and those in the other Figures, were produced with the best performing Loudness + Pitch/Cents conditioned model.

Energy: Energy is computed from the STFT of the waveform with `hop_length=64` and `n_fft=2048`, yielding energy vectors of length 1000 for 4 seconds of audio (250 Hz). For training, we normalize these values across the entire dataset.

Loudness: There are many detailed psychometric models of perceived loudness [11]. For clarity, we opt for a simple A-Weighting of the power spectrum, which places greater emphasis on higher frequencies, followed by log-scaling. The loudness vector is centered and has equal length to energy. The exact computational steps are included in the Appendix.

3.3.2 Amplitude Conditioning

Wave2Midi2Wave [6] successfully conditioned a WaveNet to generate realistic piano audio based on a convolutional stack encoding a pianoroll. We adopt a similar architecture for encoding amplitude. The conditioning network consists of a stack of 12 dilated convolution layers (with dilations 1, 2, 4, 8, 16, 32, 1, 2, 4, 8, 16, 32), followed by three transposed convolutions with stride 2. All convolution layers have 512 filters with kernel size 3. For causal conditioning, we simply zero-pad and shift the receptive fields to not include future context.

3.3.3 Fundamental Frequency

We use CREPE [8], a recent and data-driven pitch tracking model with state-of-the-art performance. With hop size of 64, CREPE produces a vector of frequencies of length 1000. We convert these into MIDI pitch using librosa's `hz_to_midi()` function. From this point, we explore different representations of pitch.

Normalized Frequency: Dividing the vector of MIDI values by 127.0 yields a normalized vector representing pitch on a linear scale.

Octaves/Notes/Cents: We experiment with splitting the F0 vector into an octave one-hot $\mathbb{R}^5$, note one-hot $\mathbb{R}^{12}$ and a continuous vector of floats for cents. Each component is a vector of length 1000.

Pitches/Cents: Our most effective representation consists of a pitch one-hot $\mathbb{R}^{60}$ and a continuous vector of floats for cents. Each component is a vector of length 1000.

3.3.4 Fundamental Frequency Conditioning

For normalized frequency, we use the same convolutional stack as for amplitude features.

For Octave/Notes/Cents and Pitches/Cents, we use separate conditioning stacks for the one-hot component and continuous component (shown in Figure 1). The vector of continuous cents is encoded using the same convolutional stack as amplitude features.

For one-hot features, we use a mulitilayer perceptron (MLP) encoder network. The one-hots first pass through an embedding layer and then projected via a series of fully connected (FC) layers with RELU non-linearity into a final target dimensionality. For Octave/Notes/Cents, the two branches of encoders for octave and notes each use embedding units 1024 and FC units 2048, 1024, 512. The final octave and note activations are concatenated to produce a tensor of shape (1024, 1000). For Pitches/Cents, a single pitch encoder is used with embedding units 1024 and FC units of 2048, 1024 and 256. The final activation shape is (256, 1000). Unlike the convolutional stacks, the one-hot MLP encoding stacks are causal by definition.

3.4 Conditioning the WaveRNN

All conditioning features are time-series with lower sampling frequency (250Hz) than audio. To be used as local conditioning vectors by WaveRNN they are upsampled via

replication to 16 KHz, concatenated and added as an additional bias term in the GRU gate equations.

3.5 Training

During training, the model is tasked with resynthesizing the high dimensional audio as accurately as possible, combining the low dimensional conditioning inputs and teacher-forced previous "outputs" to autoregressively make next-step predictions. We minimize the negative log-likelihood loss of the WaveRNN's coarse and fine logits, which is computed via softmax cross-entropy.

The system was implemented in TensorFlow and each model trained on 1 Million steps. We use the ADAM optimizer with epsilon of 1e-8, momentum of 0.9, max gradient norm of 1.0 and an exponential moving average rate of 0.9999. Learning rate decay is 0.7 for every 100k steps. We fine-tuned models over batch sizes of 128, 256 and 512 and learning rates of either 9e-5 or 1e-4, and report best performing models.

4. METRICS

Resynthesis: Since log-likelihood is not a direct measure of sample quality, we quantitatively evaluate our models through the task of resynthesis. Audio features are extracted from the source audio and used to synthesize a new sound with the same features. Some examples of resynthesis are shown in Figure 2. We take the L_1 distance of extracted features between the orignal and resynthesized audio to be the fine-scale perceptual error in resynthesis. Aditionally, since the NSynth dataset has labels for pitch and instrument family (a proxy for timbre), we use these labels to train a classifer which we use to evaluate the global similarity of the resynthesis. The classifier has identical structure to the ones implemented in [4] and [3], and we provide complete details in the Appendix. We calculate each metric on resynthesized audio from the full test set of 17,600 samples.

Loudness L_1 distance: The loudness vector is extracted from the synthesized audio and L_1 distance computed against the input's conditioning loudness vector (ground truth). A better model will produce lower L_1 distances, indicating input and generated loudness vectors closely match. Note this distance is *not* back-propagated through the network as a training objective.

F0 L_1 distance: Pitch tracking using CREPE, like with any pitch tracker, is not completely reliable. Instabilities in pitch tracking, such as sudden octave jumps at low volumes, can result errors not due to model performance and need to be accounted.

CREPE outputs a useful confidence in its prediction of F0 for every frame. By examining the accuracy of pitch tracking on ground truth audio, we found that applying a confidence threshold of 0.85 filtered out areas of unreliable pitch tracking and yielded the best trade-off against false positives. Only F0 from time frames above this threshold are considered in our analysis. For models representing pitch using Octaves/Notes/Cents and Pitches/Cents, we recompute the equivalent normalized frequency. The F0 L_1 distance is reported in MIDI space for easier interpretation; an average F0 L_1 of 1.0 corresponds to a semitone difference.

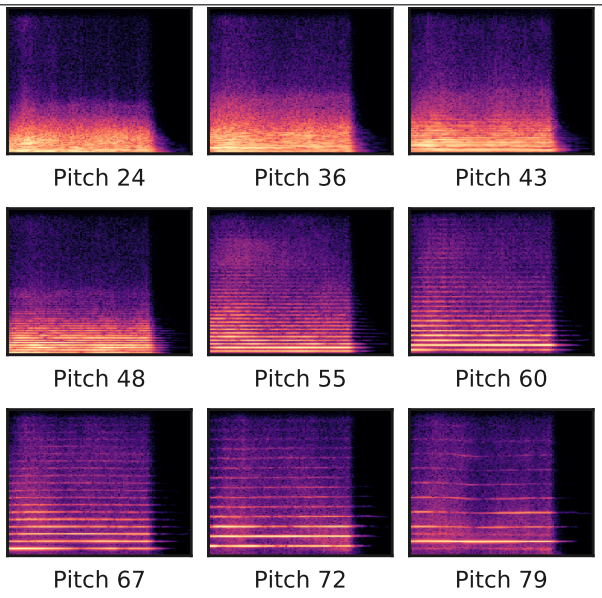

Figure 3. Synthesizing audio at different pitches with the same loudness envelope.

F0 Outliers: Audio examples with F0 confidence below 0.85 for the full length of the example indicate a failure of pitch tracking and are considered "outliers" of the measurement. 398 *ground truth* audio samples in the test set are categorized as outliers, producing a baseline for this metric of $398/17600 = 0.02$. For *generated* audio, examples completely below the 0.85 confidence threshold, are similarly removed. By inspection, we also found L_1 distances above an octave to correspond to pitch tracking failures and remove the samples as outliers. Better performing models have lower values close to the 0.02 baseline.

Pitch Error: The classifier pitch prediction gives a more global measurement of pitch correspondence during resynthesis. On ground truth samples, the classifier has a 0.06 error rate, which is the best that generated samples can hope to achieve.

Instrument Family Error: Instrument family labels are a rough measure of timbral similarity. We assume that if the original and resynthesized audio have similar timbre then they should be classified as the same instrument family. Although the classifier is not perfect, with an error rate of 0.22, it is state-of-the-art for the task and dataset, providing a rough measure of relative performance between models.

5. RESULTS AND DISCUSSION

5.1 Resynthesis

Table 1 shows the quantitative metrics for models with different conditioning on the resynthesis task. Models with causal conditioning are given in parentheses next to their non-causal equivalents.

	Signal Processing	CREPE		NSynth Classifier	
	Loudness (L_1)	**F0 (L_1)**	**F0 Outliers**	**Pitch Error**	**Family Error**
Loudness	0.14 (0.33)	6.20 (6.89)	0.57 (0.66)	0.98 (0.99)	0.75 (0.85)
Loudness + Normalized Frequencies	0.16 (0.24)	1.42 (4.17)	0.07 (0.15)	0.35 (0.81)	0.60 (0.82)
Loudness + Octave/Note/Cents	0.11 (0.14)	1.21 (1.81)	0.07 (0.08)	0.33 (0.25)	0.61 (0.78)
Loudness + Pitch/Cents	**0.10** (**0.10**)	**0.94** (**1.00**)	**0.06** (**0.07**)	**0.16** (**0.12**)	**0.53** (**0.72**)
Ground Truth	-	-	**0.02**	**0.06**	**0.22**

Table 1. Ablation study showing detailed conditioning improves resynthesis accuracy. Loudness is extracted directly from the audio as described in Section 3.3.1. CREPE is used for tracking fundamental frequency (F0), and a classifier pretrained on the NSynth dataset is used to predict pitch and instrument family (see Appendix). Models with causal convolutions in their conditioning stacks have their numbers in parentheses, while the rest use non-causal convolutions. Conditioning on F0 in Pitch/Cents tuples outperforms both Octave/Note/Cents tuples and frequencies as normalized floats, and the trend holds for both causal and non-causal conditioning.

F0 representations: A clear trend is present across all metrics: performance improves as F0 conditioning moves from Normalized Frequency, to Octave/Note/Cents, to Pitch/Cents representations. Interestingly, this improvement is not only present in the frequency-based metrics (*F0 L_1, F0 Outliers, Pitch Error*), but in the metrics for volume and timbre as well (*Loudness L_1, Family Error*).

Qualitatively, we found the models to have different failure modes. Models trained with Octaves/Notes/Cents conditioning held correct fundamental frequencies more reliably than Normalized Frequency, but would on rare occasions be completely offset by a large and erroneous interval for the length of the note. This ambiguity seems to arise from discontinuities at octave boundaries, such as between MIDI notes B2 and C3 that are close in absolute frequency. While Normalized Frequency does not suffer from this effect, we found many models trained on this representation produced audio that would dip "flat" in frequency. This could be due to the reduced effective range of input, which needs to cover the entire range of frequencies on a normalized continuous scale. Unlike speech, slight deviations in frequency are perceived as notes being out of tune.

Non-causal vs Causal: The trends in F0 conditioning are reinforced by the fact they are shared between both causal and non-causal variants of the models. Non-causal conditioning allows incorporating future information into current predictions which helps performance in almost cases. Despite this, the best performing models see less of a performance drop, which is promising for future low latency applications. Increasing the capacity of the causal encoder stack may achieve parity in performance.

Energy vs Loudness: Table 1 in the Appendix justifies the preference for loudness over energy as a conditioning signal. We compare variants of the best performing model (Loudness + Pitch/Cents vs. Energy + Pitch/Cents) and find the loudness-conditioned model outperforms the energy-conditioned model on all metrics. It is worth emphasizing that Loudness L_1 is a fair evaluation metric in this case because it is not used as a loss during training and is more aligned to human perception.

Missing Conditioning: Finally, Table 1 in the Appendix also compares a model conditioned only with Loudness to one conditioned only with Pitch/Cents. Predictably, each does better than the other on their respective metrics, and fails on the other complementary metrics, demonstrating that both levels of conditioning are required. Interestingly, the Instrument Family Error is lower for the loudness-conditioned model, indicating aspects of timbre are likely more highly correlated with loudness contours than pitch contours.

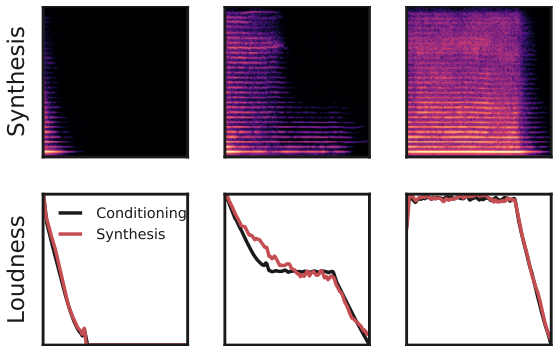

Figure 4. Interpolating in loudness conditioning.

Timbre: In the absence of timbre conditioning, the models learns to correlate timbre with pitch and loudness contours in the NSynth dataset. For example, the combination of a short decay and high F0 vector is a mallet-like sound whereas a long decay and low F0 vector is a cello-like sound. This is evidenced by the reduced Instrument Family Error in tandem with lower Loudness and F0 L_1 distances. Naively adding instrument family conditioning and spectrogram conditioning did little to improve the metrics or control of generated timbre. We believe exploring new methods of timbre control is a rich area for future research and would enable applications like interactive instrument morphing.

5.2 Creative Conditioning

We perform qualitative studies with modified out-of-dataset conditioning vectors. All examples are generated with the Loudness + Pitch/Cents model, and audio for all examples can be found in the online supplement [1] .

Interpolation of Loudness vectors: On the bottom row of of Figure 4, we show three loudness vectors. The left and right vectors were selected from the test set to

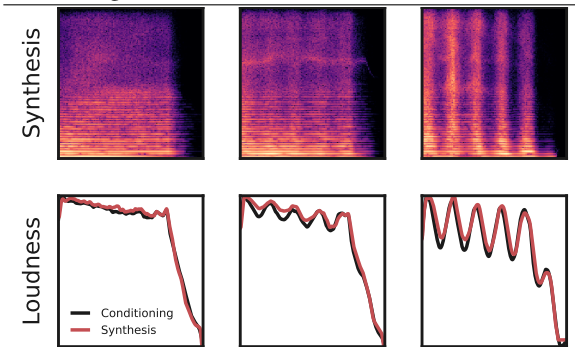

Figure 5. Applying tremolo to loudness conditioning.

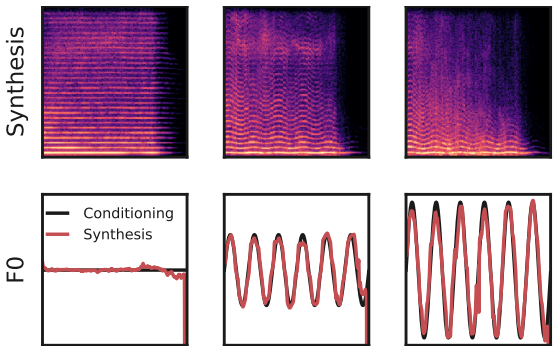

Figure 6. Applying vibrato to frequency conditioning. F0 extracted with CREPE.

demonstrate two extremes: fast decay (left) and long sustain (right). The middle is a synthetic linear interpolation of the two vectors. The top row shows spectrograms for audio synthesized by our model conditioned on each of these loudness vectors with the same F0 vector held at constant pitch. The model is able to closely adhere to the loudness curves even for the interpolated example. More importantly, the spectrogram reveals how loudness conditioning functions more than a naive "amplitude envelope", since the harmonic content changes non-linearly with the loudness signal. This rich behavior draws an analogy to the behavior of real acoustic instruments, where varying excitation introduces rich non-linear changes to the harmonic spectra based on the characteristics of the instrument.

Tremolo: Figure 5 shows the spectrogram (top) and extracted loudness vector (bottom) for an example with increasing an increasing intensity of tremolo (left-to-right) added to the original loudness vector. The generated audio closely tracks the loudness contours through diverse modulation of harmonic content. Note how the reduction in power is uneven across the frequency spectrum, dampening higher harmonics more than fundamental frequencies. A naive multiplicative tremolo would reduce power equally across all frequency bands.

Vibrato: Figure 6 shows audio synthesized from a baseline F0 vector with constant pitch. The middle vector adds a tremolo of a semitone while the rightmost vector adds a tremolo of about 2 semitones. The loudness vector is held constant in the synthesized audio. As seen by oscillations in frequency of the corresponding spectrograms, the model can generate audio reflective of increasing intensities of vibrato.

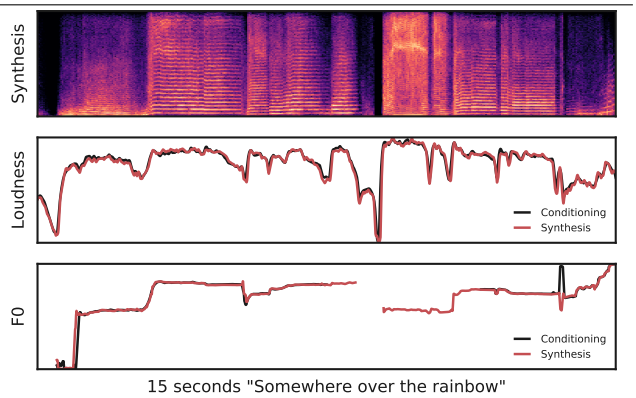

Figure 7. Re-synthesis of out-of-domain input contours extracted from a live vocalist singing "Somewhere over the rainbow". Break in F0 corresponds to silence.

Out-of-domain inputs: Figure 7 shows audio re-synthesized from conditioning signals extracted from a vocalist singing "Somewhere Over the Rainbow". The model was never trained on sequences longer than 4 seconds, nor samples with fast-moving amplitude and pitch variations such as the jump in "Some-*where*". Nonetheless, the model is able to generalize and synthesize audio tightly following these modulations. This opens the door for a variety of interactive applications. The user can provide input contours extracted from live singing, guitar playing or generate these directly from a MIDI Polyphonic Expression (MPE) controller or touchscreen interface.

5.3 Generation Speed

For this work, we draw the distinction between *"real-time throughput"* (producing x seconds of audio in wall time less than or equal to x seconds), and *"low-latency generation"* (producing audio with little to no delay from a conditioning input).

The original WaveRNN paper [7] achieved both through systems optimizations of the underlying kernels. These optimizations motivate our use of WaveRNN for future applications, but are not yet implemented in this paper. Despite this, even with unoptimized kernels, we see dramatic speedups over traditional WaveNet models and are able to achieve faster than real-time throughput speeds for batches of audio on commonly available hardware. For example, our best performing model generates 82 seconds of audio (batch size 21) in 60 seconds on an NVIDIA GTX 1080 GPU ($\sim 1.4\times$ real time).

6. CONCLUSION

In this work, we demonstrate state-of-the-art synthesis of musical instrument sounds with fine-grain temporal control over loudness and pitch. The model learns tight correlations between loudness and pitch, being able to introduce non-linear spectral modulations beyond a naive tremolo or vibrato. The comparable performance between non-causal and causal models points towards streaming applications such as a low-latency re-synthesis guitar pedal or live vocal effect.

ABSTRACT

A vital aspect of Indian Classical Music (ICM) is *Raga*, which serves as a melodic framework for compositions and improvisations alike. Raga Recognition is an important music information retrieval task in ICM as it can aid numerous downstream applications ranging from music recommendations to organizing huge music collections. In this work, we propose a deep learning based approach to Raga recognition. Our approach employs efficient prepossessing and learns temporal sequences in music data using Long Short Term Memory based Recurrent Neural Networks (LSTM-RNN). We train and test the network on smaller sequences sampled from the original audio while the final inference is performed on the audio as a whole. Our method achieves an accuracy of 88.1% and 97 % during inference on the *Comp Music Carnatic dataset* and its 10 Raga subset respectively making it the state-of-the-art for the Raga recognition task. Our approach also enables sequence ranking which aids us in retrieving melodic patterns from a given music data base that are closely related to the presented query sequence.

1. INTRODUCTION

Carnatic and Hindustani music are the two main branches of Indian Classical Music (ICM), which underlies most of the music emanating from the Indian subcontinent. Owing to the contemplative and spiritual nature of these art forms and varied cultural influences, a lot of emphases is placed on melodic development. Raga, which governs various melodic aspects of ICM, serves as a framework for compositions and improvisations. Krishna et al. [20] define a Raga as the "collective melodic expression that consists of phraseology which is part of the identifiable macro-melodic movement". A major portion of contemporary Indian Music including film, folk and other forms of music heavily draw inspiration from ICM [10, 12].

Numerous melodic attributes make Ragas distinctive in nature, such as the *svara* (roughly, a musical note), the *gamaka* (for example oscillatory movement about a given note, slide from one note to another etc [17]), *arohana* and *avarohana* (upward and downward melodic movement) and melodic phrases/ motifs [12, 20]. Emotion is another attribute that makes Ragas distinctive. Balkwill et al. [2] conducted studies on the perception of Ragas and observed that even an inexperienced listener is able to identify emotions portrayed by various Ragas. Given the importance of Raga in ICM, Machine Learning (ML) based automatic raga recognition can aid in organizing large audio libraries, labeling recording in the same, etc.

We believe automatic raga recognition has tremendous potential in empowering content-based recommendation systems pertaining to ICM and contemporary Indian music. However, Raga recognition is not a trivial problem. There are numerous examples where two or more Ragas have the same or a similar set of notes but are worlds apart in the musical effect they produce due factors like the gamaka, temporal sequencing (which has to abide by the constraints presented in the arohana and avarohana), as well as places of svara emphasis and rest. Raga identification is an acquired skill that requires significant training and practice. As such, automatic Raga classification methods have been widely studied. However, existing methods based on Pitch Class Distributions (PCD) disregard the temporal information and are highly error-prone, while other methods (reviewed in detail in Section 2) are highly dependent on preprocessing and hand made features, which limit the performance of such methods.

In this work, we introduce a deep learning based solution to Raga recognition and Raga content-based retrieval. First, we reformulate the problem of Raga recognition as a sequence classification task performed using an LSTM RNN based architecture with attention. We then show that the same network, with minimal fine-tuning based on the triplet margin loss [27], can be used for sequence ranking. We introduce sequence ranking as a new sub-task of automatic Raga recognition. In this configuration, the model can be used to perform Raga content-based retrieval. A user provides the model with a query sequence and the model returns sequences that are very closely related to the presented query. This can aid in downstream applications like recommendation systems and so on.

Deep learning has proven to be an indispensable asset due to its flexibility, scalability, learning abilities, end to end training, and most importantly, unprecedented success in modeling unstructured spatial and temporal data over the past few years. Our work draws inspiration from the

successes in [26, 27] introduce a convolutional neural network based recommendation system for music which overcomes and outperforms various drawbacks of traditional recommendation systems like collaborative filtering, a bag of words method, etc. It also leverages LSTM-RNN and attention based models which have proven to be extremely effective in tasks like sequence classification, sequence to sequence learning, neural machine translation, image captioning task, etc., all of which directly deal with sequences.

To summarize, the main contributions of our work are as follows :

- We present a new approach to Raga recognition using deep learning using LSTM based RNN architecture to address problem of Raga recognition.
- With our approach we obtain 97.1 % on the 10 Raga classification task and 88.1 % accuracy on the 40 Raga classification task on the Comp Music Carnatic Music Dataset (CMD), hence improving the state-of-the-art on the same.
- We introduce sequence ranking as a new sub task of Raga recognition, which can be used in creating Raga content based recommendation systems.

Note that we refer to our Raga recognition (i.e sequence classification) model as SRGM1 and the sequence ranking model as SRGM2 throughout the paper.

2. RELATED WORKS

Broadly speaking, ML methods for Raga classification can either be PCD based or sequence based. Many of the previous works have focused on PCD based methods for Raga recognition [6, 7, 18] with Chordia et al. [4], currently holding the best performing results for PCD based methods with an accuracy of 91%. [17] presents an in-depth study of various distribution based methods for Raga classification. Although an intuitive and an effective approach, the major shortcoming of PCD based methods is that it disregards temporal information and hence is error prone. To overcome this, previous works have used Hidden Markov Models based approach [19], convolutional neural networks based approach [21], arohana avarohana based approach [23] among various other methods.

[9, 24] employ Raga phrase-based approach for Raga recognition. [11] use an interesting phrase-based approach inspired by the way in which seasoned listeners identify a Raga. This method is currently the state-of-the-art on a 10 Raga subset of CMD. [12] introduces Time Delayed Melodic Surface(TDMS) which is a feature based on delay co-ordinates that is capable of describing both tonal and temporal characteristics of the melody given a song. With TDMS, the authors achieve state-of-art performance on the CMD.

While the PCD based methods ignore the temporal information, many works like assume that the audio is monophonic. Works like [19,23] attempt to take advantage of the temporal information by extracting arohana and avarohana.

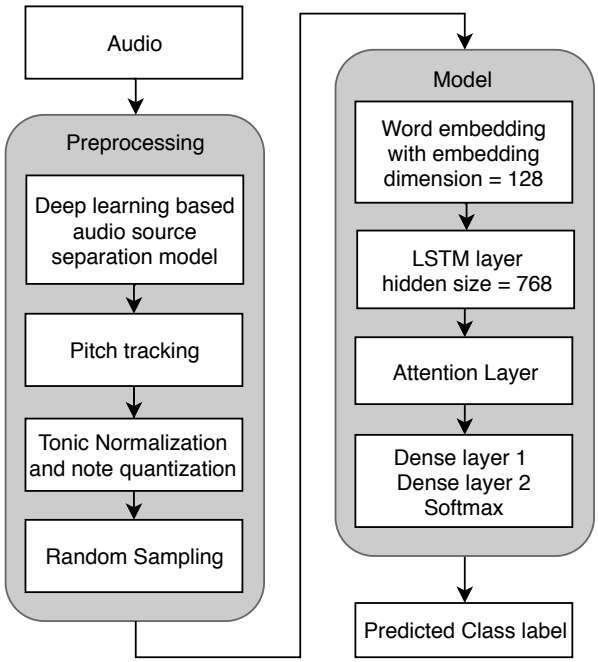

Figure 1. Figure shows various preprocessing steps and model architecture for SRGM1 (refer Section 3)

Although arohana and avarohana are critical components to identifying a Raga, they do not contain as much information as the audio excerpt itself. Most previous works heavily rely on prepossessing and feature extraction, most of which are handcrafted, which can prove to be a limitation as it only gets harder to devise ways to extract complex and rich features.

3. RAGA RECOGNITION AS A SEQUENCE CLASSIFICATION PROBLEM (SRGM1)

Sequence classification is a predictive modeling problem where an input, a sequence over space or time, is to be classified as one among several categories. In modern NLP literature, sentiment classification is one such example, where models predict sentiments of sentences. We argue that the Raga recognition is closely related to the task of sequence classification, since any audio excerpt in ICM involving vocals/melody instruments, can be broken down as a sequence of notes spread over time. To reformulate Raga recognition as a sequence classification task, we treat the notes obtained via predominant melody estimation as words, the set of all words form the vocabulary and each Raga as a class. We detail our approach to raga recognition as below.

3.1 Preprocessing

3.1.1 Deep Learning based audio source separation

Audio recordings available as part of CMD accurately represent live ICM concerts with vocalists accompanied by various string, wind, and percussion instruments. How-

ever, for the purposes of raga recognition, analyzing the vocals is sufficient. We believe that the presence of other elements in the audio interferes with the performance of the classifier and hence we include audio source separation as a preprocessing step. We use Mad-TwinNet [8], a deep neural network based approach capable of recovering vocals from a single channel track comprised of vocals and instruments. It uses a Masker Denoiser architecture combined with twin networks (a technique used to regularize recurrent generative networks). We use the pre-trained model made publicly available by the authors.

3.1.2 Pitch tracking

Our model analyzes the melody content of audio excerpts to perform Raga recognition, hence pitch tracking is an essential preprocessing step. To perform pitch tracking, we use the python API [15] for Praat [3] which is an open source software for the analysis of speech and sound.

3.1.3 Tonic Normalization and note quantization

ICM utilizes a relative scale that is based on the Tonic note of the performer. Since the Tonic can vary in different renditions of the same raga, recognizing and accounting for the tonic note is extremely important. [11] have made numerous features, including Tonic of audio excerpts, available as part of CMD. We normalize the pitch tracked array of every audio in CMD by using the following:

$$f_n = 1200 * log_2(f/T) \tag{1}$$

where f is the frequency after pitch tracking (in Hz), T is the frequency of the Tonic (in Hz) and f_n is the tonic normalized frequency. The above expression results in 100 cents in a half step, for instance, E and F. Empirically we observe that it is sufficient to have just 5 levels in a half step. However, we leave this as a hyperparameter on the model. Hence the expression for obtaining a tonic normalized note is given by:

$$f_p = \text{round}(1200 * log_2(f/T) * (k/100)) \tag{2}$$

where k is number of desired levels in a half step. For instance, $k = 5$ when number of desired levels between two consecutive notes are 5.

3.1.4 Random sampling

The pitch tracked sequences of audio excerpts from CMD have a length of at least $5 * 10^5$ steps. It is impractical to train a Recurrent neural network on sequences with such length as it increases training time considerably. Also, the network would struggle to retain information over such large sequences. Hence, we train the network on *subsequences*, which are smaller sequences randomly sampled from the pitch tracked audio excerpt. It is random in that the start index is randomly selected. We sample N_r number of times from every audio excerpt. Length of the subsequence is chosen carefully as it impacts the models training considerably. We observe that smaller sequences tend to confuse the model. An ideal value for the length of the subsequence is 4000-5000 steps.

3.1.5 Choosing an appropriate value for N_r

Eq (3), determined empirically, gives the appropriate value for N_r, based on the length of the subsequence L_r and maximum of the set of lengths of all pitch tracked audio excerpts L_{max}.

$$N_r = \lceil 2.2 * L_{max}/L_r \rceil \tag{3}$$

3.2 Model Architecture

At the core of our model (refer figure 1) is the LSTM [13, 22] based recurrent neural network, which is a popular choice for sequence classification and sequence to sequence learning tasks. We experiment with various configurations for the LSTM block and emperically find that a single LSTM layer with a hidden size of 768 works the best. The word embedding layer, which appears prior to the LSTM layer, converts each note that appears in the subsequence into a 128-dimensional vector. The LSTM block is followed by an attention layer. Our implementation closely follows soft alignment as described in [1]. The attention layer is followed by two densely connected layers, the first of which has 384 hidden units and the second one has hidden units equal to the number of classes represented in the training dataset. This is followed by a softmax layer, which converts the output of the final dense layer into a probability distribution over the given number of classes i.e, a vector of length equal to the number of classes and sums to one.

3.3 Model training and Optimization

We train the model for over 50 epochs, with a batch size of 40 (i.e, 40 subsequences are fed to model at each training step) and an initial learning rate of 0.0001. We employ dropout [25] in the dense layer and batch normalization [14] after the LSTM layer to reduce over fitting.

3.3.1 Loss Function

Since we are dealing with a classification problem with number of classes greater than 2, the categorical cross entropy is the best suited loss function. The categorical cross entropy loss (CCE) is computed as follows:

$$\text{CCE} = -\sum_{i=1}^{N} y_{i,j} * log(p_i) \tag{4}$$

Where N is the number of classes, $y_{i,j}$ is an indicator function which is 1 only when $i = j$, j is the training label for the given subsequence, p_i is the i^{th} entry of the probability vector (which is the output of the model).

3.3.2 Optimization

Random sampling dramatically increases the size of the data set (the size would be 480*N_r, where 480 is the number of recordings in CMD). This makes it hard to fit all these samples on a single computer. Hence we use the Distributed asynchronous stochastic gradient descent training algorithm [5]. We use the Adam [16] optimizer to update the gradients during training.

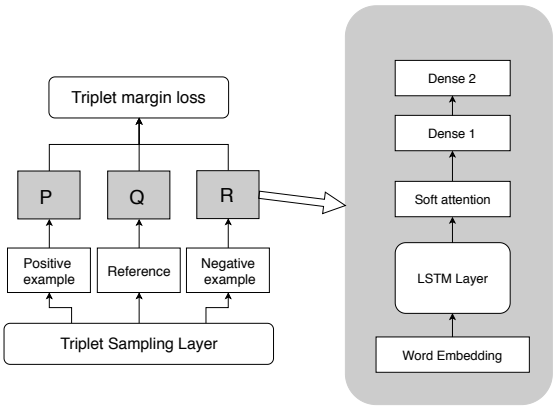

Figure 2. Schematic diagram for the sequence ranking algorithm. P, Q and R are the copies of the same model and hence have the same architecture.

4. SEQUENCE RANKING AND RETRIEVAL (SRGM2)

A fully trained sequence ranking model will be able to create feature embeddings such that the L2 distance between the feature embeddings of a pair of sequences is directly proportional to how similar the sequences are. In this work we fine tune a pre-trained Raga recognition model (SRGM1, from the previous section) using the triplet margin loss and evaluate its ability in retrieving subsequences similar to query subsequence. The demonstrated ability to retrieve similar sounding musical pieces is a unique and highly useful feature of our method.

4.1 Preprocessing

The preprocessing steps used in the training of SRGM1 apply to sequence ranking. We start with audio source separation followed by pitch tracking, tonic normalization and finally random sampling.

4.2 Model architecture

The network architecture of the sequence ranking model is shown in 2. P, Q, and R are modified copies of pre-trained SRGM1 network (Note: the diagram shows P, Q, and R as different blocks. However, in practice, the triplets are passed through the same network one after the other). The modifications being, 1) absence of softmax activation at the end of the network 2) Dense 2 is altered to have 600 hidden units in place of 40 (or 10 depending on the dataset it was trained on).

4.3 Triplet sampling

The triplet sampling layer supplies the model with triplets such that one pair is similar to each other and the other pair is dissimilar. We consider two sequences to be similar if they are from the same raga and are dissimilar if they are from different ragas. The procedure for sampling triplets is as follows:

- From the collection of all subsequences, sample a subsequence P_{ref} randomly (uniform random).
- Let P_{ref} belong to raga R_i
- Select another phrase P_+ from the same raga R_i randomly (uniform random) such that $P_+ != P_{ref}$
- Randomly (uniform random) choose another Raga R_j such that $R_j != R_i$ from the set of all Ragas R
- Sample P_- from Raga R_j randomly (uniform random).

4.4 Model training and Optimization

Similar to the training of SRGM1, we employ dropout on the dense layers of the model. Since we are fine-tuning SRGM1, we do not have to train the word embeddings and the LSTM layers. Triplet sampling can be offline (before training) or online (during training). Although it reduces training time, offline sampling is extremely inefficient as it requires a lot of memory (RAM). Hence we sample triplets as and when required. The sequence ranking model is optimized based on the triplet margin loss, given by:

$$\mathscr{L} = min(D(\mathscr{P}_+, \mathscr{P}_{ref}) - D(\mathscr{P}_-, \mathscr{P}_{ref}) + M, 0) \quad (5)$$

where P is the feature embedding obtained for any input P using the model. D(.) is a distance function (the most common choice is the Euclidean distance) and M is the margin (common choice 1). Similar to SRGM1, we use distributed asynchronous stochastic gradient descent for training the model with Adam optimizer.

5. DATASET, INFERENCE AND EVALUATION METHODOLOGY

5.1 Dataset

In this work, we use the Carnatic Music Dataset [11] made available by the Comp Music group. The Comp Music data set consists of high-quality recordings of live ICM concerts. This dataset comprises of 124 hours of 480 commercially available recordings that are stored in the mp3 format.

The dataset contains 12 full-length recordings per Raga and features 40 different Ragas (hence 480 recordings). These recordings feature numerous artists, a wide variety of compositions and a diverse set of Ragas. The ragas are diverse in terms of their melodic attributes (refer to Section 1). Therefore, we believe that training and evaluating the model on this dataset would allow us to assess how well the model would perform in near real-world scenarios.

5.2 Comparison with prior works

We compare our results with three prior works, [4, 11, 12] of which [12] is the current state of the art for the Raga recognition task on the CMD dataset and [11] is the current state of the art for Raga recognition on the 10 Raga subset of CMD dataset. Gulati et al. [12] provides a summary of

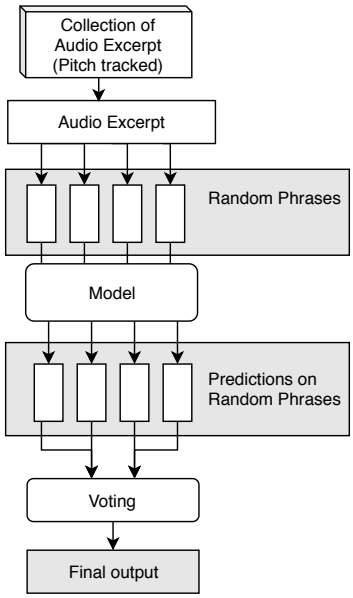

Figure 3. Figure gives an overview of the inference process for SRGM1 as described in Section 5.3.1

the performance of all of these the three methods on the CMD dataset. To ensure a fair comparison, we follow the evaluation strategy as provided in [12] (described in 3.3.1).

5.3 Inference

5.3.1 SRGM1

Although the model is trained on subsequences, during inference, we are interested in determining the Raga of the audio as a whole. Thus, follow the procedure as shown in figure 3. First, we split the audio excerpt into numerous subsequences and obtain the predictions for each of these. We then perform voting to determine the majority class. Note, that if the majority class has less than 60% of the votes we label the classification as incorrect.

5.3.2 SRGM2

For SRGM2, we are interested mostly in the sequences the model retrieves rather than inference on the audio as a whole. However, if one desires to make inference on the audio as a whole, we can adopt the procedure described in section 3.3.1.

5.4 Evaluation strategy

5.4.1 Evaluation strategy for SRGM1

CMD consists of 12 recordings per Raga. Since we train the model on subsequences, we have a total of 12*N_r subsequences in every class. Therefore, this is a balanced classification problem and accuracy is a suitable metric for evaluation. Authors in [12] use leave-one-out cross-validation strategy for evaluation where one of the 12 recordings for every Raga is used as test data and the remaining 11 are used as the training data. We adopt the same approach to evaluate our model as it enables us to make fair comparison of our results with previous works. We also present a confusion matrix for the observed results to further investigate the performance of SRGM1.

Gulati et al. [11] use stratified 12 fold cross-validation. To be able to compare our results to theirs on the 10 Raga subset of CMD, we adopt the same strategy. As an alternative evaluation strategy, we hold out 5 of the 12 recordings from every class as the test set and train the model on the rest.

Method	**CMD-10 Ragas**	**CMD-40 Ragas**
SRGM1	95.6%	84.6%
SRGM1 Ensemble	**97.1**%	**88.1**%
$\mathscr{M}_F$	-	81.5 %
$\mathscr{M}_{KL}$	-	86.7 %
$\mathscr{M}_B$	-	86.7 %
$\mathscr{E}_{VSM}$	91.7 %	68.1 %
$\mathscr{E}_{PCD}$	82.2 %	73.1 %

Table 1. Table summarizes performances of various models on the CMD dataset and its 10 Raga subset. Refer to Section 6.1

5.4.2 Evaluation strategy for SRGM2

A suitable evaluation metric for SRGM2, a sequence ranking model, is the "precision at top-k" measure which is popular score used to evaluate information retrieval systems. Precision at top k is defined as the proportion of retrieved items in the top-k set that are relevant to the query. We consider a retrieved subsequence to be relevant when it belongs to the same Raga as the query subsequence. The expression for precision at top-k hence becomes :

$$P_k = \frac{\sum_{i=1}^{k} I_{y_i,c}}{k} \tag{6}$$

$$P_{avg} = \frac{\sum_{i=1}^{n} P_{k_i}}{n} \tag{7}$$

Where P_k is precision at top k evaluated on one query sample, I_{y_i} is an indicator function which is 1 only when y_i which is the Raga of the i^{th} retrieved sample is same as c which is the Raga of the query sample. P_{avg} is the top-k precision averaged over the complete dataset.

6. RESULTS AND DISCUSSION

We present a summary of results in table 1 where we compare the performance of our model with [12], [11] and [4]. $\mathscr{M}_F$, $\mathscr{M}_{KL}$ and $\mathscr{M}_B$ represent 3 variations of TDMS [12] which uses euclidean distance, KL divergence and Bhattacharya distance respectively. $\mathscr{E}_{VSM}$ represents vector space model [11] for Raga recognition while $\mathscr{E}_{PCD}$ represents pitch class distribution based method presented in [4].

We observe that our method performs better than the current state-of-the-art on both 10 Raga subset of CMD and the CMD as a whole. We obtain an improvement of 6 % on the 10 Raga subset of CMD and improvement of

Figure 4. Figure shows the confusion matrix for the predictions obtained using SRGM1.

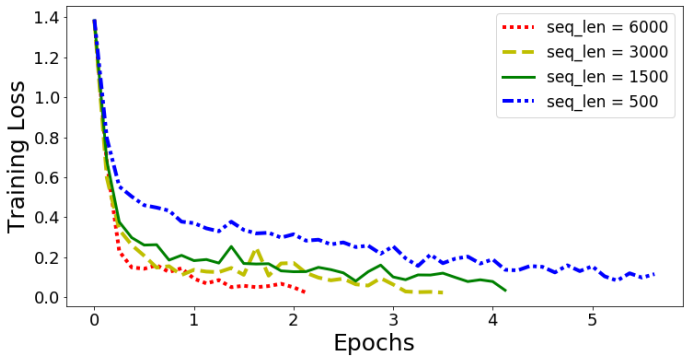

Figure 5. The above graph depicts variation in the "training loss vs epochs" plot with changing subsequence length.

Subsequence length	Num epochs to converge	Time per epoch in sec (Wall Time)	Hold out test set accuracy
500	12	32	88.86
1500	6	58.4	95.5
3000	5	120.1	95.63
6000	3	241.5	97.34

Table 2. Summary of our findings for the study on variation of model training and performance based on subsequence length

Metric	top-30 precision	top-10 precision
Score	81.83 %	81.68 %

Table 3. Summary of performance of sequence ranking on the top-10 and top-30 precision metrics

2% on CMD using the SRGM1-Ensemble model. The Ensemble model was created using 4 sets of weights for the same model architecture. For each test sample, we obtain output from each of the 4 models and then combine them by summing the log of the outputs of the model to obtain the final prediction vector for that sample.

The confusion matrix for SRGM1 trained on CMD (40 Ragas) is as shown in figure 4. Note that the confusion matrix is presented for the results obtained on a subsequence level and not on the audio excerpt level i.e, these are results before performing inference (refer to Section 4.3.1). There are no patterns apparent from the confusion matrix. However, on closely observing the samples on which the model performs poorly, we see that these samples have very little information, which can be attributed to events like to long pauses during the performance, sustaining a particular note for a prolonged interval, etc.

To further investigate the effect of subsequence length on the training of a model, we devise an experiment by using a 4 Raga subset of CMD. We use 36 recordings as the training set and 12 recordings as the test set. We train the network until the categorical cross entropy loss reduces to 0.02. Figure 5 shows a plot of the training loss vs the number of epochs. It is clearly visible that a model that is trained on subsequences of length 6000 converges in lesser number of epochs and has a smooth descent while the model using subsequences of length 500 makes the training very noisy and the network takes as long as 12 epochs to attain the same value of the loss. A summary of our findings has been tabulated in table 2.

We evaluate the sequence ranking model on the metrics described in section 5.4.2, namely top-10 precision and top-30 precision. Our findings have been summarized in table 3. SRGM2 obtains a top-30 precision of 81.83 % and top-10 precision of 81.68 %. We also conduct a qualitative analysis of the retrieved samples by inspecting various aspects like the range of svaras (notes) observed in the query to that in the retrieved sample, checking for similar note progressions, etc. We observe that the sequences retrieved by the model are similar to the ones in the query. We attach several samples of query subsequences and retrieved sequences as part of the supplementary material.

7. CONCLUSION AND FUTURE WORK

In this work, we proposed a novel method to address the problem of Raga recognition. Through various experiments and validation, we are able to demonstrate the capability of our approach in tackling the problem of raga recognition. We also introduce sequence ranking as a new sub-task of raga recognition. We present numerous query - retrieved subsequence pairs (as part of supplementary material) which demonstrates the effectiveness of this approach to mine databases for similar sequences.

We believe that deep learning based approaches have tremendous scope in MIR pertinent to ICM. As part of future work, we would like to further explore the idea of sequence ranking as we feel it can be used for tasks like joint recognition of tonic and Raga. An exciting future research direction would be to explore the possibility of using deep learning for generative modeling tasks in ICM. It would definitely be interesting to see if deep learning models can replicate the intricate improvisation aspects of ICM.

afriberg@kth.se

ABSTRACT

This paper presents a convolutional neural network (CNN) that uses input from a polyphonic pitch estimation system to predict perceived minor/major modality in music audio. The pitch activation input is structured to allow the first CNN layer to compute two pitch chromas focused on different octaves. The following layers perform harmony analysis across chroma and time scales. Through max pooling across pitch, the CNN becomes invariant with regards to the key class (i.e., key disregarding mode) of the music. A multilayer perceptron combines the modality activation output with spectral features for the final prediction. The study uses a dataset of 203 excerpts rated by around 20 listeners each, a small challenging data size requiring a carefully designed parameter sharing. With an R^2 of about 0.71, the system clearly outperforms previous systems as well as individual human listeners. A final ablation study highlights the importance of using pitch activations processed across longer time scales, and using pooling to facilitate invariance with regards to the key class.

1. INTRODUCTION

1.1 Modality

Minor and major modality is a function of scale, harmony and tonality and is perceptible even to very young children [20]. However, the rich variability of music harmony renders many compositions hard to classify into a minor or major mode. Researchers have therefore investigated modality as a continuous variable in listening tests, producing more or less uniformly distributed averages with high internal consistency. Such a continuous variable, ranging from minor to major, has interchangeably been referred to as *modality* [12-14, 28, 34], *mode* [1], *key mode* [33], *mode majorness* [33], and *majorness* [2, 28, 33]. We will mainly use the term "modality" or "minor/major modality".[1] This paper aims to improve on previous methodologies for predicting perceived modality, designing a CNN that is able to model associated intricacies of musical harmony.

In a listener study [14], rated modality had a significant correlation (0.3-0.6) with rated *speed*, *articulation*, *pitch* (low/high) and *timbre*/*brightness* – happy tunes in major mode are likely more often performed with a higher articulation (staccato). This means that a system can be designed to predict perceived modality simply by picking up aspects in the audio not directly associated with harmony. Music information retrieval (MIR) systems relying on such confounding factors of variation have been challenged by Sturm [37]. The CNN architecture proposed in this study tries to minimize these interactions by specifically targeting properties directly linked to modality, as expanded upon, e.g., in Section 2.4.

1.2 Previous Studies Predicting Modality

Two previous studies have attempted to predict perceived modality from music audio. The first study [14] used partial least squares regression applied to audio features from the MIR toolbox [28, 29]. Two models were tried, the first using dedicated modality features and the second also including other spectral features. They were evaluated on the same two datasets used in the present study (Section 5.1), reaching an R^2 of 0.43 (0.38) and 0.47 (0.53) respectively (results for the second model in parenthesis).

A second study [1] have instead used the Inception v3 architecture [38] applied to a mel-frequency spectrogram. Results on a dataset of 5000 15 seconds (s) excerpts with lower ground truth consistency was $R^2 = 0.23$ (based on the Pearson's correlation coefficient of 0.48 reported in an additional/supplemental paper [2]). The model was developed to handle numerous perceptual features and may not be ideal for modality; the pooling operations applied across mel-frequency obfuscates tonal interrelationships at ranges larger than the pooling kernels. Since the filters span the time dimension, the model may to some extent instead make predictions from other aspects of the audio that covaries with modality, as outlined in Section 1.1.

1.3 Pitch Chroma and Deep Layered Learning

Chroma features, imposing spectral energies across a wide frequency range onto the twelve pitch classes of a musical octave, have a long tradition in MIR [15, 17, 35]. Pitch chromas have also been derived both from MIDI data and estimated through the autocorrelation function in the past [39]. A problem with the chroma is that it often is affected by interferences and becomes noisy [23]. Researchers have used various techniques to mitigate these issues, including harmonic percussive source separation [40] and cepstral whitening [31]. A multilayer perceptron (MLP) has also been used, with chord annotations defining ground truth pitch classes [23]. In this paper, we instead use the output from a high accuracy/resolution polyphonic pitch tracking system [8]. The pitch transcription is reshaped and fed as input to a CNN so that several pitch chromas emphasizing

[1] Since "mode" and "modality" have a wider scope, perhaps "modalite" could be a useful nomenclature for future studies.

different octaves can be learned within its first layer. The full architecture thus uses intermediate targets to restructure the learning problem according to the inherent organization of music. Such a "deep layered learning" approach [6], learning intermediate equivariant music representations, has been used for various MIR problems in recent years [e.g., 5, 19, 26].

1.4 CNNs and Ensemble Learning

The CNN proposed in this study use filter kernels operating across pitch/pitch class, pitch octaves and time scales, applying the same processing to each time frame. Previous CNNs for harmony processing have instead used filter kernels operating across time and frequency, for tasks such as key estimation [22, 25] and chord recognition [18, 24].

A CNN trained two times with randomly initialized parameters will generally produce two different predictions to the same input data. This is something that makes neural networks useful for ensemble learning [16]. The average (ensemble) prediction from several models containing more or less decorrelated errors will be better than randomly choosing one of them [32, 36]. Ensemble learning is used in this paper, as specified in Section 4.

1.5 Overview of the Paper

This paper presents a pitch chroma CNN architecture for predicting perceived modality. Section 2 describes how the pitch activation input to the CNN is computed and structured. In Section 3, the network architecture and training procedure is outlined. Section 4 describes how several CNNs were combined into an ensemble, and how a global prediction was made using additional features in an ensemble of MLPs. The two datasets and the evaluation procedure is described in Section 5, and results presented in Section 6. Section 7 presents an ablation study, testing how the design of the model affect predictive performance, and Section 8 offers conclusions.

2. PREPARING THE INPUT REPRESENTATION

2.1 Defining a Start and End Time for Each Excerpt

A start and end time were first determined for each musical excerpt (ME) so that the CNN would not have to make any predictions for silent parts in the beginning and end. A magnitude log-frequency spectrogram with 60 bins per octave was computed as described in [8] (pre-filtering). Let x be a vector representing the frequency response in time frame i. The overall magnitude of that time frame, across all frequency bins, was then defined as

$$m_i = \sqrt{\overline{x^2}}, \tag{1}$$

using the elementwise square and arithmetic mean, and forming m as a vector across time. The signal level was defined as $L_i = 20 \log_{10} m_i$, and the resulting vector filtered with a Hann window of width 61 frames (0.35 s). The *average* signal level of the ME was instead defined as $L_a = 20 \log_{10} \overline{m}$. The first time frame with a signal level within 10 dB of L_a defined the start, and the last frame within 10 dB of L_a defined the end of the ME.

2.2 Pitchogram

The input to the CNN was extracted from the *Pitchogram* representation computed with an existing machine learning system [8]. That system uses two stages to compute the Pitchogram. First, a sparse filter kernel operates across a log-frequency spectrogram to compute activations corresponding to tentative fundamental frequencies (f_0s), upsampled through parabolic interpolation to a centitone resolution. These tentative f_0s are then analyzed in a deeper network and computed activations inserted at the corresponding pitch bin in the Pitchogram. The Pitchogram thus contains f_0 activations and has a pitch resolution of 1 cent/bin and a time resolution of 5.8 ms/frame.

2.3 Extracting Semitone-spaced Pitch Vectors

The Pitchogram was down-sampled to 1 bin/semitone before processing by the modality CNN. To do this, a Hann window of height 141 bins (cents) was first applied across pitch to smooth the pitch response. Then, to adjust MEs that deviate globally from standard tuning (specifying A4 to a frequency of 440 Hz), the Pitchogram of each ME was "tuned". This was especially important for some of the MEs from the film music datasets (Section 5.1), where the orchestral performances had different tunings. The tuning was achieved by locating the maximum activation in a vector v of length 100, where each element corresponds to the sum of pitchogram activations at a specific cent value (i.e., all bins 47 cents above standard tuning were summed as the 47th entry of the vector). Only one vector was computed for each ME (i.e., global tuning). The whole Pitchogram was then shifted $\pm$50 cent based on the index of the maximum element. Finally, semitone-spaced activations were extracted between MIDI pitch 26-96, resulting in a pitch vector for each frame of height 71.

2.4 Varying Time Scales

We assume that listeners use pitch information at varying time scales to form an overall impression of the modality of a piece of music. At the shortest time scale, concurrent tones can form harmonic relationships that sound more like a major chord or a minor chord. At slightly longer time scales, tones played in succession may together imply the mode of the chord. At even longer time scales, the combination of tones and their relative activation may resemble key profiles/tonal hierarchies [27] that are more or less indicative of a major or minor tone scale. We wanted to develop a model that was agnostic to various factors that may covary with modality, such as accentuation (see Section 1.1), in the hope that our model would then generalize better to other datasets lacking these covariations. This precluded many models tracking variations in pitch activations across time (e.g., recurrent neural networks). Therefore, in order to still account for tonal relationships evolving over time, the pitch response was smoothed across time with filters of varying width, producing pitch vectors responding at varying time scales. The smoothing was done with Hann windows of width

$$w = 10 \times 3^n + 1 \tag{2}$$

where *n* varied between 1-5. The shortest Hann window therefore had a width of 31 frames (0.18 s) and the longest a width of 2431 frames (14.1 s). Since the unfiltered pitch vector was also included, the processing was applied at six different time scales. The smoothed pitch vectors were finally stacked across width, as shown in the left pane of Figure 1. This enabled the system to combine them during processing with a filter of width and stride 6 (Section 3.1).

2.5 Octave Spaced Depth (Chroma)

The proposed CNN computes a pitch chroma within its first layer. To facilitate this, the pitch vector was divided into 5 overlapping sections spaced an octave apart, each covering 23 semitones. The sections were concatenated across depth, resulting in aligned pitch classes (facilitating chroma processing within the CNN with filters extending across depth). This depth dimension is illustrated for a single time frame in the right pane of Figure 1. The CNN input of each time frame was thus prepared. It can be understood as a $23 \times 6 \times 5$ three-dimensional tensor, where height (23) represents pitch class, width (6) represents different time scales and depth (5) represents pitch octaves.

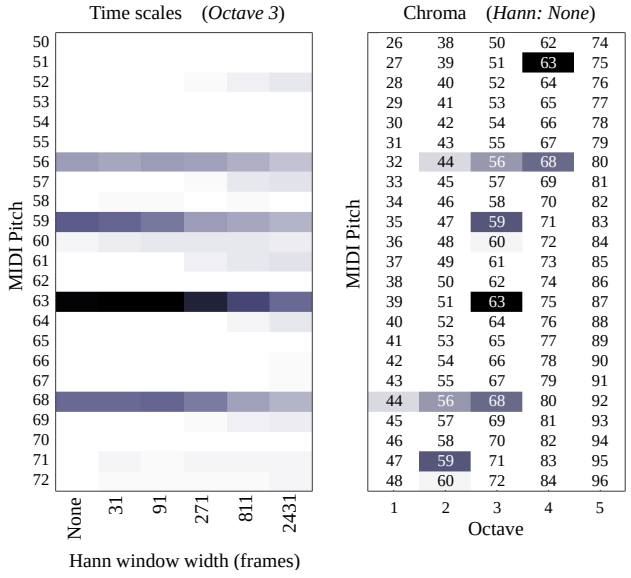

Figure 1. Two dimensions of the 3D-tensor input to the CNN for a single time frame, consisting of pitch activation from [8] restructured across pitch, time scale and pitch class. The time frame is taken 8 seconds into ME No 4 in the film clips dataset, where a G ♯ minor chord was played. The left pane consists of activations at varying time scales in the third octave. The right pane consists of the different pitch octaves, shown at the shortest time scale.

2.6 Segmentation

Each ME was divided into 6 overlapping segments of length 9 seconds (1550 time frames). Since no ME was longer than 54 seconds, these segments spanned the entire ME. Each segment of an ME was assigned the same ground truth annotation that had been established from listener ratings (Section 5.1). Since each frame (input tensor) had $23 \times 6 \times 5 = 690$ input values, each segment had slightly above a million input values (690×1550).

3. CNN ARCHITECTURE AND TRAINING

3.1 CNN Architecture

The CNN that was applied to each 9 seconds segment is shown in Figure 2. The same processing architecture was applied to each time frame of the segment. Convolutional filters always operated across unspanned dimensions, and zero-padding was never utilized, thereby shrinking the output space when applying the filters. Rectified linear units (ReLUs) were used as activation functions. Since the dataset in the study was small (203 MEs), it was important (and a challenge) to keep the number of learnable parameters small while retaining the ability to model the intricacies of musical harmony. The network had a total of 413 learnable parameters, including parameters for the batch-normalization that was applied after each ReLU layer.

As shown in the figure, the first *chroma layer* is used for converting input tensors to pitch chromas. Two filters learn weights for each octave, operating across pitch (height) and time scales (width). The two resulting pitch chromas are split into two branches, and processed with 1 and 5 filters respectively in the subsequent *harmony analysis* layer. This was done to reduce the total number of parameters while still achieving the following objectives:

- Allow the system to use two pitch chromas so that it could, for example, independently filter and account for information in the bass and higher pitches.
- Output 6 different activations for each time scale and pitch class from the *harmony analysis* layer using only $12 \times 6 + 6 = 78$ filter parameters.

Each filter used for harmony analysis spans an octave so that all pitch classes are taken into account when computing an activation (attempts at dividing the harmony analysis into two layers with shorter filters gave slightly lower results). Since the input has a height of 23, each filter is applied at 12 positions when operating across pitch, one for each pitch class. Thus, the input and filter sizes are the minimum sizes for which the same combination of all pitch classes at various keys can be subjected to the same filters. The two branches were concatenated across depth and the next filter (orange) then spanned the various *time scales*. The subsequent *max pooling* filter (purple) provides invariance with regards to the key class that the music was performed in, since it spans all 12 pitch/key classes. Based on the max pooling design, it can be expected that the previous layers of the CNN learn to either react to minor or major chords, minor or major tonal hierarchies, or various combinations thereof. The strongest indications of both major and minor modality across key are then passed to the subsequent *fully connected* (locally) layer (orange) for further processing. This layer is implemented as 7 filters that span the entire local input space (a fully connected layer would instead span the entire segment, something that is not desirable). A second filter (orange) combines the previous activations into a single *frame prediction*.

Finally, *average pooling* (purple) of the frame predictions is applied across the entire 9 seconds segment to produce a *segment prediction* (red) as a regression output.

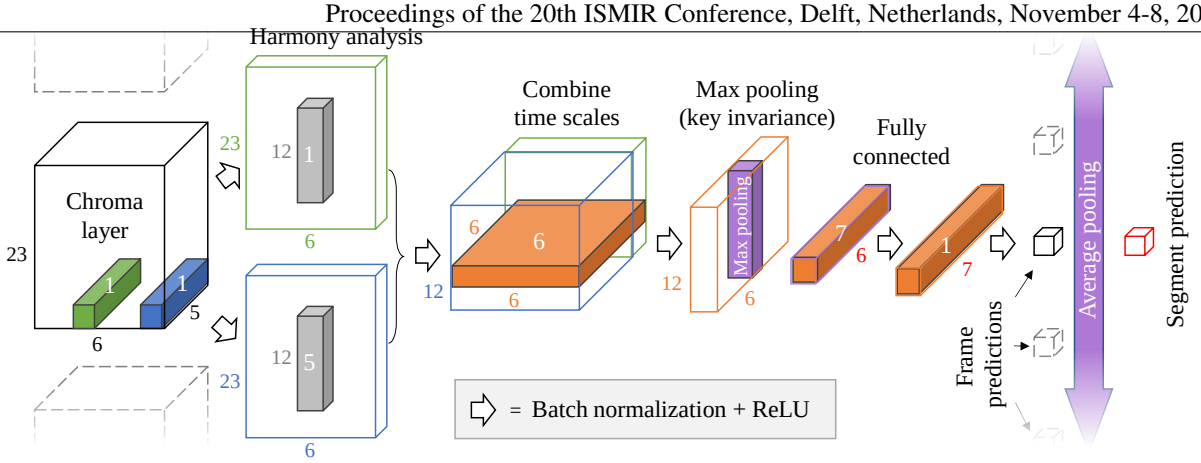

Figure 2. The CNN architecture for predicting perceived modality, shown for a single input tensor (time frame). Neighboring time frames are faded and dashed. All dimensions (except singleton) are indicated with black or colored numbers, and the number of filters is indicated with white numbers. White arrows indicate batch normalization followed by ReLUs. In the chroma layer, two filters (green and blue) compute pitch chromas from the input. The two chromas are processed to analyze the relationship between different pitch classes. Various time scales are then combined through six filters (orange), and max pooling applied (purple) to provide invariance with regards to the key class of the music. A fully connected layer is implemented through filters (orange) that span the entire feature space for a specific time frame. Finally, one filter is used to compute a frame prediction, and average pooling is applied to generate a prediction for the entire segment (red).

3.2 Training

The system was evaluated with 10-fold cross-validation, (Section 5.2). For each fold, the CNN was trained with the Adam optimizer [21], using the mean-squared-error loss function, an initial learning rate of 0.01, and a drop factor (every epoch) of 0.98. The gradient decay factor was set to 0.9 and the factor for L_2 regularization was set to 0.0001. A mini-batch size of 32 (segments) was used, shuffling the training data every epoch. The CNN was trained for 25 epochs. If the computed R^2 on the *training split* (the tracks used for training in each of the ten folds) was below 0.83 after 25 epochs, the network was reinitialized and training restarted (to avoid networks stuck in a local minimum). This happened in around 3 % of the cases. We tested the main model without the restarting condition in the ablation study (Section 7.1), which produced a minimal difference. Note that there was no validation stopping, for the same reasons as outlined in [10]: small validation sets are unreliable performance indicators, and maximizing performance for individual networks will not necessarily maximize performance of ensembled (Section 4) networks.

4. GLOBAL ESTIMATES AND ENSEMBLING

Two different global estimates were computed for each ME, one estimate from an ensemble of the CNN (ECNN), and one estimate from an ensemble of MLPs (EMLP) refining the output activations from each CNN.

4.1 CNN

The CNN modality prediction for each ME was computed as the average of all frame predictions (see Figure 2). This means that the local CNN architecture up until average pooling was applied to each frame at run-time.

We used ensemble learning to improve the accuracy of the CNN predictions (Section 1.4). Ten CNNs were trained for each fold, and the average of their predictions was used.

4.2 Additional MLP

In addition, another global estimate was computed for each ME with an EMLP, using the global CNN prediction and input features from the Pitchogram and spectrogram. The intention was to use and examine the effect of various (potentially confounding) features in the audio that the CNN was designed to not model.

Pitch activations in the tuned Pitchogram were averaged across time and summed to a vector, indexing into the vector based on each bins' distance to the closest semitone (0-50 cents). The 6 first discrete cosine transform (DCT III) components of the vector were then extracted as features. These features capture the extent and shape of micro-tuning deviations (PT) across the track (e.g., from vibrato).

We also computed both a vibrato suppressed (VS) and vibrato enhanced (VE) spectral flux (SF), using the max-filtering processing strategy first described in [9], developed to model perceived speed from onset densities in pitched instruments. The processing was applied to the whitened log-frequency signal level spectrogram computed as described in [8]. The VE SF was computed by subtracting the VS SF from the regular half-wave rectified bin-wise SF, thereby retaining energy only in the bins suppressed in the VS SF. For both versions, we computed the mean across time after half-wave rectification, producing an SF vector across frequency. The 6 first DCT components were extracted from these vectors as features. We then used the same log-frequency spectrogram, computed the mean across time, and extracted the first 6 DCT components of the resulting vector (spectral distribution, SD).

The average CNN output activation from all frames (Section 4.1) was also used as an input feature (naturally, this was the most important feature). In summary, the MLP had $1 + 6 \times 4 = 25$ input features, divided into four feature groups (PT, VS, VE and SD) and one CNN prediction.

The MLP was rather small and resembled the MLP developed for predicting performed dynamics in [10]. It had two hidden layers each consisting of 8 neurons. The network was trained for 5 epochs with the Levenberg-

Marquadt optimization [30]. Hyperbolic tangent (tanh) units were used as activation functions in all layers except for the last linear output activation. Each input feature was normalized by its minimum and maximum value to the range ± 1. Ensemble learning was used, taking the average prediction of 20 MLP models. Since the ECNN consisted of 10 CNNs, and since one EMLP was trained for each CNN, the final prediction in each fold was computed as an average of $10 \times 20 = 200$ MLP models.

5. DATASETS AND EVALUATION PROCEDURE

5.1 Datasets

The dataset for the study was assembled from two music audio datasets. The first dataset (D_1) consists of 100 audio excerpts of popular music (average length 30 s) that were produced from MIDI [14]. The second dataset (D_2) from [4] consists of 110 audio excerpts of film music (average length 15 s). As previously noted [7], the film music dataset contains duplicates. Seven duplicates were found and removed, reducing the size of D_2 down to 103 MEs. The MEs are polyphonic and use a wide range of instruments.

The overall modality had previously been rated by two groups of 19 and 21 listeners for the two datasets. Listeners were asked to rate the modality of each excerpt on a quasi-continuous scale between minor (1) and major (10), listening on high-quality loudspeakers. The ratings were averaged across listeners, producing a single ground truth rating of perceived modality for each ME. Reliability was relatively high, with a standardized Cronbach's alpha (CA) [3, 11] of 0.94 and 0.97 for the two datasets.

The datasets were pooled into a single dataset (203 MEs), which was used for training and testing.

5.2 Evaluation Procedure

The accuracy of the model was computed with the coefficient of determination, R^2, between predictions and ground truth annotations. We used the square of Pearson's correlation coefficient (including an intercept).

The models were evaluated with 10-fold cross-validation, using a stratified sampling so that each training set contained about the same number of MEs from D_1 and D_2. To improve the reliability of the results, the *complete experiment* was repeated ten times, re-partitioning the validation split each time.[2] To get 95 % confidence intervals (CIs), ten results (R^2s) were sampled with replacement and the mean computed, repeating the procedure 10^6 times. The resulting distribution of mean R^2s could then be used for extracting CIs; it indicates the reliability of the test results based on its variation over test runs.

6. RESULTS

6.1 Main Results

The final result for the ECNN and the ECNN in combination with the global EMLP is presented in Table 1.

[2]Running the main 10-fold cross-validation experiment ten times took about 5.5 days, training the ECNN with a GeForce GTX 1080 GPU (5 days; $10 \times 10 \times 10 = 1\,000$ CNNs) and the EMLP using 5 parallel i7-6700K CPU threads (0.5 days; $10 \times 20 \times 10 \times 10 = 20\,000$ MLPs).

Model	R^2	95 % CI	D_1	D_2
ECNN	0.672	0.665-0.679	0.645	0.710
ECNN+EMLP	0.716	0.710-0.722	0.710	0.745

Table 1. Squared correlation (R^2) between the ground truth ratings of perceived modality in music audio and the predictions of the two proposed models; also measured individually within the two datasets (D_1 and D_2).

The full system reached an R^2 of 0.716 for the predictions of perceived modality in the two datasets (corresponding to a correlation, r, of 0.846). The predictions from the CNN ensemble without the subsequent EMLP, minimizing contributions from confounding factors of variation, were almost as accurate, with an R^2 of 0.672.

As seen in Table 1, the second dataset (D_2) consisting of film clips was easier to predict than the first one (D_1). This difference is in line with results of the previous study on the same datasets that reported an R^2 of 0.43 (full model, 0.38) for D_1 and 0.47 (full model, 0.53) for D_2. The higher CA (Section 5.1) for this dataset indicates that listeners also had stronger agreement when rating it. Figure 3 shows predictions in relation to ground truth annotations.

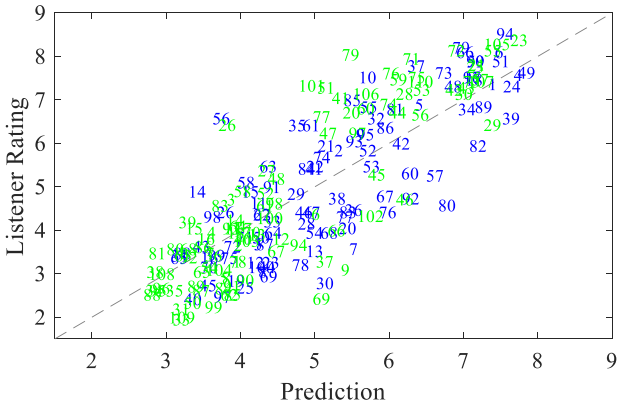

Figure 3. Predicted modality (x-axis) in relation to rated modality (y-axis) for datasets D_1 (blue) and D_2 (green) in one of the test runs ($R^2 = 0.706$) for the ECNN+EMLP. The dashed grey line indicates perfect prediction. Numbers indicate the index of each ME for future comparisons.

6.2 Comparison with Previous Systems and Humans

Figure 4 provides context regarding the prediction accuracy. The proposed system (blue bars) clearly outperforms previous systems (Section 1.2, white bars). Note that [1] was tested on a different dataset, so differences in predictive performance should be interpreted with caution. Human performance (circles) was computed from the listeners of the original listening test using a similar strategy as proposed in [10]. The performance of n listeners was derived by sampling (with replacement) n listeners and computing the R^2 between their mean rating and the mean rating from the non-sampled listeners. The procedure was repeated 10^5 times, using the 10^5 results to compute a mean and 95 % CIs. For $n = 1$, sampling is not applicable, and the 95 % CIs were defined as the listener with the second lowest and second highest R^2.

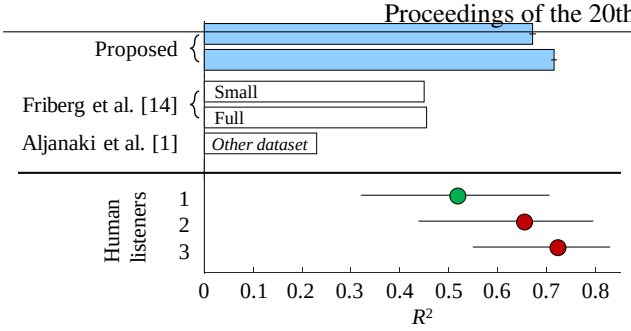

Figure 4. Modality estimation results (R^2) of the proposed system (blue), previous systems (white), individual human listeners (green circle), and ensembled human listeners (red circles). Black lines indicate 95 % CIs.

7. ABLATION STUDY

7.1 CNN

Important stages of the CNN architecture were examined by training the ECNN with various alterations of the CNNs. The different stages/properties tested were:

Time scales: *None-2431* – All different time scales (Section 2.4) were tested separately.

Key class invariance pooling (Pool): *Avg* – A CNN using average pooling instead of max pooling. *Conv* – A fully convolutional architecture that instead reduced the pitch dimension through four layers with two filters of height {5 4 3 3}, followed by a single filter of height 1.

Input: *Mag* – Using a magnitude log-frequency spectrogram as input, computed as described in [8] (pre-filtering). *dB* – Using the whitened log-frequency signal level spectrogram from [8]. For both versions, the spectrum covered the same range of 71 semitones, using overlapping triangular filters to reduce the frequency resolution.

Pitch chroma (PC): *Mean* – The mean of the five octaves was computed directly and passed as input, using 6 harmony analysis filters in the first layer

Results relative to the main CNN model are shown in Figure 5 and conclusions of the experiment provided in Section 8. The same validation split was used for all tests to increase consistency. This split was also used for the main model for computing a performance reference.

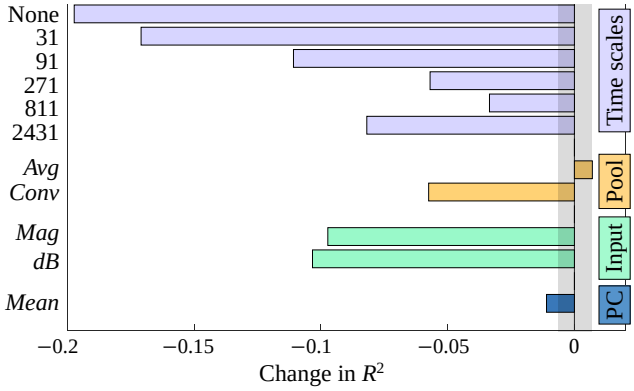

Figure 5. The variation in R^2 for different CNN settings in relation to the main CNN model. The 95 % CIs (±0.007) from the main experiment are indicated by the grey area.[3]

[3]Note that these CIs define the 95 % range within which the mean of *ten* complete 10-fold cross-validation runs varies. The ECNN ablation study used *one* complete 10-fold cross-validation run per architecture.

7.2 MLP

We also tested various combinations of EMLP input features.[4] The results shown in Figure 6 indicate that a combination of SF features with vibrato suppression (VS) and vibrato enhancement (VE) was important.

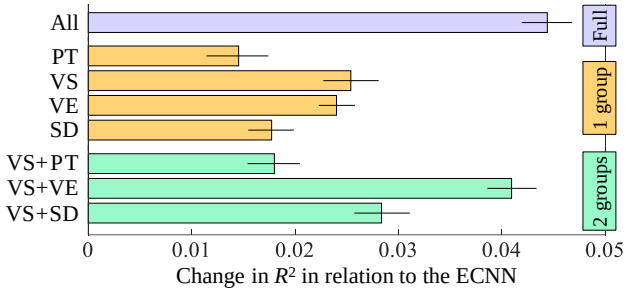

Figure 6. The change in R^2 in relation to the ECNN results, when using various EMLP feature groups (Section 4.2). Black lines indicate 95 % CIs for the relative improvement over the ECNN in each test run.

8. CONCLUSIONS

A convolutional neural network for predicting perceived modality in music was implemented. Its predictive performance was well above that of previous systems as well as the average human listener, performing better than around 95 % of the human annotators. It requires the combined ratings of 3 listeners to reach the same predictive performance as the model. The CNN used pitch activations from a pitch tracking system as input; the ablation study showed that this input representation improves performance substantially in relation to spectral input (*Mag* and *dB*). The methodology of max pooling across key classes to provide invariance seems beneficial since it improved performance in relation to a fully convolutional model. However, average pooling, in which the network instead has to rely on earlier ReLUs to discard irrelevant activations in certain key classes seems to be an equally attractive, or even better, option for achieving key class invariance.

The CNN was restricted from using filters operating across time, to reduce the influence of irrelevant confounding factors of variations, such as accentuation and spectral fluctuations. Instead, the CNN received input filtered to account for different time scales. The ablation study indicates that a time scale of around 4-5 seconds is the most relevant and that instantaneous time scales, only using harmonic information from concurrent tones, significantly reduces performance. Performance only dropped slightly when the pitch chroma layer of the CNN was discarded and the mean (across octaves) pitch chroma instead used as input (*Mean* PC, Figure 5). The small size of the dataset likely reduces the importance of this CNN layer; tracking interactions between pitches in different registers requires more learnable parameters, which requires more input data for generalization.

We hope that the results can inspire further development of CNN architectures accounting for musical invariances, including, and beyond, key class and pitch class.

[4]All feature groups were tested with the *same* global CNN activation as an additional feature, and evaluated across the full ten experimental runs.

ABSTRACT

This paper investigates end-to-end learnable models for attributing composers to musical scores. We introduce several pooled, convolutional architectures for this task and draw connections between our approach and classical learning approaches based on global and n-gram features. We evaluate models on a corpus of 2,500 scores from the KernScores collection, authored by a variety of composers spanning the Renaissance era to the early 20th century. This corpus has substantial overlap with the corpora used in several previous, smaller studies; we compare our results on subsets of the corpus to these previous works.

1. INTRODUCTION

Models for attributing composers to musical scores have been extensively studied in the music information retrieval community. The composer classification question has been posed for a variety of corpora, from Renaissance composers [2,3], to the narrow (and challenging) case of Haydn and Mozart string quartets [5, 8, 12, 22], and to various collections of classical era composers (most of the other papers discussed in Section 2). In this work we study an expansive collection of scores, from 13th century sacred music by Guillaume Du Fay to 20th century ragtimes by Scott Joplin.

A major challenge of this task is learning from limited data. While the corpus considered here is larger than most, this is largely due to the number of composers considered (19): for specific composers, we have at most 466 scores (Bach) and as few as 22 (Japart). Small datasets are an inherent problem for composer classification: the corpus used in this work contains, for example, all of the Bach chorales and all of the Mozart string quartets. We cannot resurrect these composers and have them write us more scores to include in our corpus. This situation contrasts starkly with many learning problems, where substantial progress can be made by collecting massive datasets and exhaustively training an expressive model (usually a deep neural network) with "big data."

Further complicating this task, an individual score is itself a high dimensional object: the average score in our corpus consists of thousands of notes, each of which is encoded as a high dimensional vector to represent its pitch and value. Learning from a small number of examples in a high dimensional space is a formidable problem; thus much work on composer classification focuses on feature engineering, feature selection, dimensionality reduction, or some combination of these approaches to construct low-dimensional representations of scores to learn from.

In this paper we take a different approach: we dispense with feature engineering and explore end-to-end classifiers that operate directly on full scores. Specifically, we investigate shallow convolutional neural networks with an aggressive pooling operation. In this setting, all but the most impoverished linear classifiers achieve 100% training accuracy. We rely on implicit regularization introduced by the network structure and first-order optimization with early stopping to avoid overfitting to training data. While theoretical understanding of such an approach is in its early stages [18], we find empirically that this works quite well for composer classification.

2. RELATED WORK

The earliest works on composer classification [3, 15] analyzed highly preprocessed corpora of melodic fragments. Much of the subsequent work on classification focuses on engineering features to summarize full scores. These approaches can be broadly categorized, using the terminology of [7], into "global" summarization approaches that compute small sets of summary statistics as a feature set for each score [2, 5, 6, 10, 12, 16, 22] and local "event" featurizations that extract n-gram counts of a score as features [8, 9, 11, 24, 25]. There is also a line of work that applies compression-based dissimilarity metrics [1, 19, 20] to this task, which offers a substantially different perspective on classification problems.

The present work is most similar in spirit to [3] and [23]. Like [3], we adopt an end-to-end approach to feature learning using neural architectures. In contrast with [3], we learn on full scores with minimal preprocessing and consider a multi-class classification task over a broad variety of composers; this approach is made possible by modern hardware unavailable to researchers in 2002. We also take a more systematic approach to architecture exploration, and identify effective architectures that are simpler than

hybrid convolutional-recurrent approach taken in [3].

Like [23], we exploit structure in musical scores using convolutional models. But where [23] use a fixed Morlet or Gaussian convolution filters, the convolutional filters in this work are parameterized and learned from the data to maximize classification accuracy. We also explore multi-layer "deep" convolutional models and demonstrate improvements using such architectures versus the single layer of convolutions explored in [23].

Comparing to the substantial body of work that emphasize feature-engineering, the present work can be seen as an unified framework for learning global and event features. We will draw analogies between linear convolutional filters and n-gram features, and also demonstrate how convolutional models can express many popular global features. We will also introduce a global pooling operation that can be interpreted as an counter that tracks the number of occurrences of learned features, which is directly analogous to the count and ratio statistics that comprise the bulk of metrics used in human-engineered featurizations.

3. CORPUS AND DATA REPRESENTATION

We train and evaluate models on a corpus of 2,500 scores spanning five centuries of choral, piano, and chamber compositions from the KernScores collection [17]. An overview of this collection is provided in Table 1. In this work, we consider each movement of a multi-movement composition to be a distinct score. Our models extract only the note data (pitch, note-value, and voicing) from scores, ignoring all other markings such as time signatures, key signatures, tempo markings, instrumentation, and movement names. For the Renaissance composers in this collection (Du Fay through Japart) we shorten the length of all note-values by a factor of 4 to crudely account for the shift in duration conventions between mensural and modern notation [4].

We represent a score by lossless encoding of its pitch, voice, and note-value contents, transcoded from a **kern file to a binary representation suitable for input to a neural network. Specifically, we encode a score S as a binary tensor $\mathbf{x} \in \mathcal{S} = \{0,1\}^{T \times P \times (N+D+1)}$ where T, P, N, D are defined as follows:

- T - The number of rows of pitch/note-value data in the score S.
- P - The maximum number of concurrent **kern columns (spines): 6 for this corpus.
- N - The range of note pitches: 78 for this corpus, ranging from C1 to F#7.
- D - The number of distinct note values (i.e. durations): 55 for this corpus.

For each $t \in \{0, \ldots, T-1\}$, $p \in \{0, \ldots, P-1\}$, $n \in \{0, \ldots, N-1\}$, and $d \in \{0, \ldots, D-1\}$ we set

$\mathbf{x}_{t,p,n} = 1$ iff pitch n occurs at time t in spine p,
$\mathbf{x}_{t,p,N+d} = 1$ iff note-value d occurs at time t in spine p,
$\mathbf{x}_{t,p,N+D} = 1$ iff pitch n continues at time t in spine p.

Composer	Dates	Sub-Collection	Scores
Du Fay	1397-1474	Choral	35
Ockeghem	1410-1497	Choral	98
Busnois	1430-1492	Choral	68
Martini	1440-1497	Choral	122
Compere	1445-1518	Choral	27
Josquin	1450-1521	Choral	423
de la Rue	1452-1518	Choral	178
Orto	1460-1529	Choral	43
Japart	1474-1507	Choral	22
Corelli	1653-1713	Trio Sonatas	188
Vivaldi	1678-1741	Concertos	33
Bach	1685-1750	Chorales	370
		Well-Tempered Clavier	96
D. Scarlatti	1685-1757	Keyboard Sonatas	59
Haydn	1732-1809	String Quartets	209
Mozart	1756-1791	Piano Sonatas	69
		String Quartets	82
Beethoven	1770-1827	Piano Sonatas	102
		String Quartets	67
Hummel	1778-1837	Preludes	24
Chopin	1810-1849	Preludes and Mazurkas	76
Joplin	1868-1917	Ragtimes	47

Table 1. Details of the KernScores collection used for training and evaluation in this paper.

For example, consider how we would encode line 28 of the **kern excerpt shown in Figure 1. This is the 5th row of pitch/note-value data in the score, so we will encode data from this line into $\mathbf{x}_5$. The periods "." in columns (i.e. spines) 0 and 1 indicate that a note or (in this case) a rest is continued from a previous line, so we set $\mathbf{x}_{5,0,N+D} = 1$ and $\mathbf{x}_{5,1,N+D} = 1$. Two notes are indicated in spine 2: 8a and 8f. The number "8" indicates an eighth-note value. Each unique note-value is assigned an (arbitrary) index; we assign index 15 to the eighth-note value, so we set $\mathbf{x}_{5,2,N+15} = 1$. The letters "a" and "f" indicate the pitches A3 and F4, which lie 33 and 41 semitones above C1 (the base of our note range) respectively. Therefore we set $\mathbf{x}_{5,2,33} = 1$ and $\mathbf{x}_{5,2,41} = 1$. Finally, spine 3 indicates an eighth-note F5 so we set $\mathbf{x}_{5,3,53} = 1$ and $\mathbf{x}_{5,3,N+15} = 1$.

The encoding defined about is an essentially verbatim transcoding of the **kern text data to a binary structured format. Converting from text to this structured format will allow us to write convolution operations along the time and pitch axes of the data tensor $\mathbf{x}$. Encoding pitches with binary indicators in N-dimensional vectors is consistent with piano roll representations [23] but departs from the example of [3], which encodes pitch as a single numerical magnitude. The binary pitch encoding is required to support convolutions along the pitch domain, which we will introduce later in models (8) and (9).

The binary note-value encoding also differs from the numerical magnitude encoding used in [3]. We will not introduce models that convolve over durations (there is no translation invariant structure to exploit) so the motivation above for representing pitches with indicators does not ap-

Figure 1. Left: An excerpt from a **kern encoding of of Haydn's Opus 33, No 1, consisting of the first 6 beats of the first movement. Right: A visual rendering of the first two measures of the same score as sheet music. In the **kern format, time proceeds from top to bottom, whereas in traditional notation time proceeds left to right. The contents of the beginning of the 6th beat is highlighted (red) in each format to aid comparison between the **kern format and sheet music.

ply to durations. Rather, we are motivated by the observation that note-values of similar duration may not be more alike in any musical sense than note-values with less similar duration. We avoid imposing this notion of similarity a-priori by encoding durations as categorical indicators: in this encoding, all note-values are equally distant in the Euclidean sense.

We also contrast our note-value encodings with piano roll representations, such as the representation used in [23]. In a piano roll representation, time is discretized: the value of a note is indicated implicitly by the number of discrete time-slices over which it is sustained. We choose an explicit representation of note-values because it more directly reflects the contents of a written score, and results in shorter time series overall than discretized representations.

4. PROBLEM FORMULATION

Our aim is to learn a classifier that predicts a composer y given a score $\mathbf{x}$. There are $C \equiv 19$ composers in our corpus: we assign each composer a label from 0 to $C-1$. We will construct a model $f_\theta : \mathcal{S} \to \{0,1\}^C$ that assigns vector $f_\theta(\mathbf{x})$ to a score $\mathbf{x}$ where each component $f_\theta(\mathbf{x})_i$ indicates model's (un-normalized) confidence that composer i wrote score $\mathbf{x}$. We predict $\hat{y}_\theta(\mathbf{x}) \equiv \arg\max_i f_\theta(\mathbf{x})_i$, the composer the model has most confidence in.

We evaluate our models via accuracy on holdout sets $\mathbf{x}^{\text{holdout}}$, where accuracy is the zero-one loss defined by

$$\text{Accuracy}(\mathbf{x}^{\text{holdout}}) = \frac{1}{n}\sum_{i=1}^{n} \mathbf{1}(\hat{y}_\theta(\mathbf{x}_i^{\text{holdout}}) = y_i).$$

Here $\mathbf{1} : \text{Bool} \to \{0,1\}$ is the indicator function: $\mathbf{1}(p) = 1$ if the proposition p is true, otherwise $\mathbf{1}(p) = 0$. The results in Section 6 report 10-fold cross validated accuracies. It is standard practice in the machine learning community to report results on a single holdout set. But for for the small datasets considered in composer classification, cross-validating is essential to cut down the variance of estimated accuracy.

Given a collection of labeled scores (training data) $\{(\mathbf{x}_1, y_1), \ldots, (\mathbf{x}_n, y_n)\}$ and a parameterized family of models $\{f_\theta : \theta \in \Theta\}$ we learn an optimal model f_θ by empirical risk minimization of the negative log-likelihood under the softmax-normalized probability distribution of model outputs:

$$\min_{\theta\in\Theta} \sum_{i=1}^{n} -\log\left(\frac{\exp(f_\theta(\mathbf{x}_i)_{y_i})}{\sum_{k=1}^{C}\exp(f_\theta(\mathbf{x}_i)_{y_k})}\right). \qquad (1)$$

For each of iteration of 10-fold cross-validation, in addition to the holdout fold $\mathbf{x}^{\text{holdout}}$, we hold out a second fold as validation data and optimize the objective (1) on the remaining 8 folds. We train our models using the Adam optimizer [13], regularizing with retrospective early stopping at the point with best accuracy on the validation fold.

5. MODELS

Every model class f_θ that we consider in this paper takes the following general approach.

1. Compute a set of local features at or around each time index in the score.
2. Average these features across time ("pool" the features, in neural networks parlance) into a single global feature vector.
3. Construct a linear classifier on top of this global feature vector to predict the composer of the score.

The approach above is motivated by the need to manage the high-dimensionality of a score: given even the first 5 indices of the score tensor $\mathbf{x}$ described in Section 3, we can easily fit a classifier that achieves 100% training accuracy but fails to generalize to new data. As discussed in Section 2, the classical approach to this overfitting phenomenon is to reduce a score to a low-dimensional summary of pre-determined features and fit a classifier to this summary. The present work aims to learn features from scratch, but if we permit our model to learn any features it wants then it will simply overfit to the training data.

We therefore cripple our models in two ways. First, step 1 of the general approach above limits our model to learn features that are local in scope. We will allow our

models to learn features that are sensitive to correlations between co-occurring notes (harmony), or between short sequences of notes (melody, rhythm). But by construction, our models will not be able to learn features that capture correlations between (for example) the first and last notes of a score. This precludes us from learning certain high-level patterns that could have predictive power (e.g. Mozart is more likely to repeat a section verbatim than Bach) but saves of us from learning a multitude of spurious patterns that appear to have predictive power on the training data but fail to generalize to new observations.

Second, step 2 of the general approach prevents our model from learning features that occur at fixed time locations. As discussed above, even knowing the first 5 indices of the score tensor is enough to easily identify every score in the corpus. By pooling features together across time, we force our models to classify based on the overall prevalence of the features it learns, rather than the occurrence of a particular feature at a particular time.

Note that classical approaches to feature engineering largely follow the same modeling restrictions outlined above. The engineered features used in e.g. [6] (Table 1, page 7) or [2] (Table 1, page 2) consist primarily of overall frequencies, prevalences, and rates of occurrence. These features capture properties of either a single time index or short sequences, aggregated across an entire score. The use of n-gram features also fits this mold: an n-gram is by definition a local feature of n time indices, and an n-gram featurization computes aggregate (i.e. pooled) counts of the occurrences of each particular n-gram across a score. The use of genuinely non-local features is rare. They are used in [12]: see for example the "maximum fraction of overlap with opening material within first half of movement" feature. The use of these features may account for the effectiveness of [12] in the Haydn versus Mozart classification task, which our models underperform on.

5.1 Sub-sampling Scores

The approach outlined above requires us to average features across entire scores. Each score in our corpus has a unique length, ranging from 10 to 4000 time indices. As a practical matter, it is difficult to deal with such variable-length data in machine-learning systems; our tools are designed to operate efficiently on homogeneous batches of data. One solution to this problem is to sub-sample scores; for example, [23] train models on the first s quarter notes where $s = 70$ or $s = 400$. Those authors found that the larger sample consistently outperforms the smaller one. We confirm this finding with the experiments in Table 2, which show that our models consistently perform better with larger samples of the score.

We therefore make the following compromise between using all available information from a score and operating on homogeneous inputs: we sample the first s, middle s, and last s indices from our score $\mathbf{x}$, resulting in $3s$ time indices sampled from each score. We use $s = 500$ for all experiments except the experiments in Table 2 that explore how models behave as we vary this hyperparameter. The average score in our corpus has 534 time indices, so for most scores this means we sample the entire score (for scores shorter than 500 time indices we pad out our sample with zeros). Only for scores longer than $1,500$ time indices (there are 117 in our corpus) do we lose any information with this approach.

	Sample Size					
Model	10	20	50	100	250	500
Histogram (Eqn 2)	50.0	59.0	62.0	63.0	66.1	64.2
Voices (Eqn 5)	60.0	61.6	63.9	72.0	75.5	76.9
Hybrid (Eqn 9)	59.3	62.1	68.9	77.1	79.9	81.7

Table 2. Comparison of model accuracies using a variety of samples sizes: accuracy uniformly increases with larger samples of the scores. See referenced equations (Eqn) for formal definitions of the models.

5.2 Histogram Models

The simplest models we consider are histogram models. Averaging the input data $\mathbf{x}$ over voices and time gives us a histogram vector $h \in \{0,1\}^{N+D+1}$:

$$h(\mathbf{x};\theta) = \frac{1}{TP}\sum_{t=1}^{T}\sum_{p=1}^{P}\mathbf{x}_{t,p}.$$

Multiplying this histogram by a weight matrix $W_\theta \in \mathbb{R}^{(N+D+1)\times C}$ with parameterized entries gives us a simple linear model:

$$f_\theta(\mathbf{x}) = W_\theta^\top h(\mathbf{x};\theta). \tag{2}$$

No features are learned in this model; all that is learned are the linear weights W_θ on the histogram features. The model can be interpreted as a simplified version of the global feature models discussed in Section 2. In this case, the global features are the prevalences at which each of the $N + D + 1$ note and duration symbols occur in a score.

5.3 Voice Convolutional Models

Now let's consider a simple neural model inspired by n-gram features. Let k be a number of features we desire to learn and n be a number of time indices. Define the function relu : $\mathbb{R} \to \mathbb{R}$ by $t \mapsto t\mathbf{1}(t > 0)$. Given a weight matrix $W_\theta^1 \in \mathbb{R}^{n(N+D+1)\times k}$ we can construct a "convolutional" feature representation $h_{t,p} \in \mathbb{R}^{T\times P\times k}$ at each time index t in each voice p defined by

$$h_{t,p}(\mathbf{x};\theta) = \text{relu}\left((W_\theta^1)^\top \mathbf{x}_{t:t+n,p}\right). \tag{3}$$

We define $\mathbf{x}_{t:t+n}$ to be a slice of $\mathbf{x}$ from index t to index $t + n$ (non-inclusive); when $t + n > T$, we pad $\mathbf{x}$ with zeros. We then pool these features across voices and time to construct a single, global feature representation $h \in \mathbb{R}^k$, to which we can apply a linear classifier with weights $W_\theta \in \mathbb{R}^{k\times C}$:

$$\begin{aligned} h(\mathbf{x}_t;\theta) &= \frac{1}{TP}\sum_{t=1}^{T}\sum_{p=1}^{P} h_{t,p}(\mathbf{x};\theta), \\ f_\theta(\mathbf{x}) &= (W_\theta)^\top h(\mathbf{x};\theta). \end{aligned} \tag{4}$$

This is a non-linear model (because of the non-linear relu "activation") and we can view h as a learned feature representation of the score $\mathbf{x}$. The weights ("filters") W_θ^1 learn to extract k relevant patterns of length n from voices, analogous to–but more expressive and compact than–classical n-gram featurizations. In our experiments we set $k = 500$ and $n = 3$; the choice of n is consistent with the pervasive use of 3-grams features in prior work [8, 9, 12, 24].

5.4 Deeper Representations

A natural way to extend the convolutional feature extraction discussed in Section 5.3 is to compose multiple layers of convolutions. Given the feature representation $h_{t,p}$ given by Equation 3 and a parameterized weight tensor $W_\theta^2 \in \mathbb{R}^{nk_1 \times k_2}$, we can construct a second layer of features

$$h_{t,p}^2(\mathbf{x};\theta) = \text{relu}\left((W_\theta^2)^\top h_{t:t+n,p}(\mathbf{x};\theta)\right).$$

We can loosely interpret such a representation as building hierarchical features of features. In principle we can build arbitrarily deep stacks of features in this way; in our experiments, we were unable to realize significant gains using architectures with more than two convolutional layers.

Building a classifier over these features proceeds identically to the shallower models:

$$\begin{aligned} h_{\text{conv}}(\mathbf{x};\theta) &= \frac{1}{TP}\sum_{t=1}^{T}\sum_{p=1}^{P} h_{t,p}^2(\mathbf{x};\theta) \\ f_\theta(x) &= (W_\theta)^\top h_{\text{conv}}(\mathbf{x};\theta). \end{aligned} \tag{5}$$

For this model we set $n = 3$, $k = 300$, and $k_2 = 300$.

5.5 Full-Score Convolutional Models

The models considered in Sections 5.3 and 5.4 are largely monophonic: they extract features from individual voices (although they classify based on a pool of these features gathered from all the voices). Notably, those models have no ability to capture harmonic patterns in the interactions between voices. We now consider a model that can capture these interactions.

Let $W_\theta^1 \in \mathbb{R}^{nP(N+D+1)\times k}$, $W_\theta^2 \in \mathbb{R}^{nk\times k_2}$ and consider the model

$$\begin{aligned} h_t(\mathbf{x};\theta) &= \text{relu}\left((W_\theta^1)^\top \mathbf{x}_{t:t+n}\right) \in \mathbb{R}^{T\times k}, \\ h_t^2(\mathbf{x};\theta) &= \text{relu}\left((W_\theta^1)^\top h_{t:t+n}\right) \in \mathbb{R}^{T\times k2}, \\ h(\mathbf{x}_t;\theta) &= \frac{1}{T}\sum_{t=1}^{T} h_t^2(\mathbf{x};\theta), \\ f_\theta(\mathbf{x}) &= (W_\theta)^\top h(\mathbf{x}_t;\theta). \end{aligned} \tag{6}$$

We parameterize this model with $n = 3$, $k = 300$ and $k_2 = 300$. This model is strictly more expressive than the part-wise models (4) or (5), capable of capturing patterns that the part models can't. However, the underperformance of this model (6) relative to less expressive models (4) and (5) suggest that it is prone to capture spurious patterns, leading to overfitting (compare results in Table 3).

5.6 Harmonic Models

All the models considered so far treat pitch classes as categorical data. We recognize, for example, that C4 is distinct from E4 or G4, but not that C4 is 4 semi-tones below E4 and 7 semi-tones below G4. This section introduces a model that exploits this structural order of pitch-classes, by convolving along the pitch-axis of the input tensor.

For notational convenience, we decompose the input tensor $\mathbf{x} = \mathbf{f} \oplus \mathbf{d}$ into separate pitch components $\mathbf{f} \in \{0,1\}^{T\times P\times N}$ and note-value components $\mathbf{d} \in \{0,1\}^{T\times P\times(D+1)}$. Let $W_\theta^1 \in \mathbb{R}^{jP\times k}$ and convolve along the pitch-axis to construct a features $h_{t,n}(\mathbf{f};\theta) \in \mathbb{R}^{T\times N\times k}$:

$$h_{t,u}(\mathbf{f};\theta) = \text{relu}\left((W_\theta^1)^\top \mathbf{f}_{t,:,u:u+j}\right).$$

Here j is a hyper-parameter indicating the height of the convolution; analogous to the width-n hyperparameter in our time-domain convolutions for models (4), (5), and (6). Unlike the time domain, we find that setting a large value of j (in our models, $j = N/2$) is desirable; a similar phenomenon is observed for frequency-domain convolutions in [21].

We proceed to pool the features $h_{t,u}$ together across the pitch domain to construct $h_t \in \mathbb{R}^{T\times k}$:

$$h_t(\mathbf{f};\theta) = \frac{1}{N}\sum_{u=1}^{N} h_{t,u}(\mathbf{f},\theta). \tag{7}$$

The idea of this pooling is to construct a feature-set that is invariant to pitch translation. We are interested in learning features such as, for example, the occurrence of general major chords rather than the occurrence of a particular major chord such as the one rooted at A3. The pooling operation above precludes us from learning the latter type of feature.

We then construct a second layer of features to integrate the harmonic features h_t together with the note-value features $\mathbf{d}_t$. Using weights $W_\theta^2 \in \mathbb{R}^{k\times k_2}$ and $W_\theta^3 \in \mathbb{R}^{(D+1)\times k2}$ we build $h_t^2(\mathbf{x};\theta) \in \mathbb{R}^{T\times k_2}$. We then pool the representations h_t^2 across time and construct a linear classifier on the resulting representation:

$$\begin{aligned} h_t^2(\mathbf{x};\theta) &= \text{relu}\left((W_\theta^2)^\top h_t(\mathbf{f};\theta) + (W_\theta^3)^\top \mathbf{d}_t\right), \\ h_{\text{harmonic}}(\mathbf{x}_t;\theta) &= \frac{1}{T}\sum_{t=1}^{T} h_t^2(\mathbf{x};\theta), \\ f_\theta(\mathbf{x}) &= (W_\theta)^\top h_{\text{harmonic}}(\mathbf{x}_t;\theta). \end{aligned} \tag{8}$$

We parameterize this model with $k = 64$ and $k_2 = 500$.

5.7 Hybrid Models

Looking back at the models we've introduced, observe that the voice models (4) and (5) exploit temporal structure within voices, but pool away any harmonic patterns between voices. In contrast, the harmonic model (8) exploits harmony between voices but pools away any sequential patterns across time indices. The full-score convolutional model can capture both types of structure, but is prone to capture spurious patterns and overfit.

This motivates the introduction of our final, hybrid model that weakly combines temporal and harmonic models to increase predictive power without overfitting. The idea is to feed the input tensor separately through temporal and harmonic models to construct features representations h_{conv} (5) and h_{harmonic} (8) respectively. We combine these features in a final, linear layer using weights $W_\theta^c \in \mathbb{R}^{k_2 \times C}$ and $W_\theta^h \in \mathbb{R}^{k_2 \times C}$ to make a prediction:

$$f_\theta(\mathbf{x}) = (W_\theta^{\text{c}})^\top h_{\text{conv}}(\mathbf{x};\theta) + (W_\theta^{\text{h}})^\top h_{\text{harmonic}}(\mathbf{x};\theta). \quad (9)$$

Because temporal and harmonic information are only combined in the final linear layer, this model is unable to learn expressive relationships between these features, such as the classical XOR relationship [14]. As we see in Table 3, this combination increases accuracy over either the temporal or harmonic models on their own.

6. RESULTS AND CONCLUSIONS

The results of all models discussed in this paper, evaluated on the full corpus, are presented in Table 3. We sort the rows in this table by the number of scores for each composer; we observe a trend towards increasing accuracy when we have more data (with some outliers).

	Models

Table 3. Results of the 19-way classification problem on the full corpus for each model considered in this paper.

To compare with previous work, we train additional models on subsets of the corpus. We invite comparisons between the results in Table 4 and the results of [2], and between the results in Table 5 and the results of [6]. These comparisons are imperfect: neither [2] nor [6] report the precise scores used in their experiments. Nevertheless our corpus is derived from the same KernScores sources as [2] and [6], and contains a comparable number of scores to the counts reported in [6]. Therefore we believe our subsets are similar to the corpora used in these works and that comparison is meaningful. For future reference, the exact dataset used for the present work can be found online. [1]

For the popular Haydn versus Mozart string quartet classification task [5, 8, 12, 22], we were unsuccessful. The standard evaluation metric for this task is LOOCV, which we could not perform due to the computational expense of our models. With 10-fold cross validation, we observed exceedingly high variance upon repeat optimizations of the same model. However none of our optimizations exceeded 80%. Due to imbalance between Haydn and Mozart quartets (209 versus 82 scores) a classifier that simply predicts Haydn given any input achieves 71.8%.

Overall, we conclude that the convolutional models proposed in this paper perform quite well. We find this notable, given that success in neural modeling is often associated with much larger datasets. Furthermore, we do not believe that the potential of these methods has been exhausted; further investigation may yield even better convolutional architectures for composer classification.

ABSTRACT

Early musical sources in white mensural notation—the most common notation in European printed music during the Renaissance—are nowadays preserved by libraries worldwide trough digitalisation. Still, the application of music information retrieval to this repertoire is restricted by the use of digitalisation techniques which produce an uncodified output. Optical Music Recognition (OMR) automatically generates a symbolic representation of image-based musical content, thus making this repertoire reachable from the computational point of view; yet, further improvements are often constricted by the limited ground truth available. We address this lacuna by presenting a symbolic representation in original notation of *Il Lauro Secco*, an anthology of Italian madrigals in white mensural notation. For musicological analytic purposes, we encoded the repertoire in **mens and MEI formats; for OMR ground truth, we automatically codified the repertoire in agnostic and semantic formats, via conversion from the **mens files.

1. INTRODUCTION

White and black mensural notations are both defined by the use of strictly measurable unambiguous characters, a codification system introduced for the first time around 1280 in the *Ars cantus mensurabilis* [15]. Yet, white notation, unlike its predecessor black notation, passed through minimal changes during its period of existence (aprox. 1450–1600), thus becoming a consolidated European notation system typical of Renaissance vocal polyphonic music [1]. Furthermore, the development of relatively standardised musical sources in white mensural notation was also encouraged by the advancement of new printing technologies [12], which led at that time to a prolific production of early music prints, many of them still available nowadays.

The high cultural and historical value of these musical sources led to libraries worldwide utilising digitalisation mechanisms to preserve them. [1] Considering the often low quality of such scanned sources, this created a new challenge for Optical Music Recognition (OMR) systems. Much effort has already been made on symbolically representing this repertoire by developing suitable storage and encoding formats [28, 31] as well as improving OMR performance [5, 19, 24, 34]. Still, OMR technology is not yet reliable enough to accurately extract the musical content of some sources [28], making manual encoding—which provides the ground truth needed to improve the systems—often necessary. Despite this, digital editions of early music in original notation, as that presented in the *Measuring Polyphony Project*, [2] are still an exception [9, 20, 29].

We present a diplomatic edition and OMR ground truth of the anthology *Il Lauro Secco*—originally printed in 1582 in white mensural notation, previously encoded in original notation in Lilypond format by [20], and also transcribed in modern notation in **kern and MEI formats by [21]. To encode the anthology in the original (white mensural) notation, we considered **mens [28] and MEI [31] formats, chosen as the most adequate for manual encoding and storage, respectively. We also encoded the repertoire in the so-called 'agnostic' and 'semantic' formats, chosen as adequate to provide OMR ground truth [6, 27]. These were automatically generated from the **mens files through the `mens2agnostic` and `mens2semantic` converters, which we present as a way to reduce human efforts. A total of 660 codified scores, 150 engraved images, 150 original prints, and the converters are freely available. [3]

The paper is laid out as follows: in Section 2, an overview of related work is given; Section 3 describes our methodology; Sections 4 and 5 discuss the encoding criteria; finally, in Sections 6 and 7, we deal with limitations of our work, conclusions, and future directions.

2. PREVIOUS WORK

Manuscripts and prints, since the only remaining source of Renaissance music, have great value for the conservation and understanding of this music and its historical context,

[1] *Gallica* (Bibliothèque Nationale de France) and *Early Music Online* (British Library) have digitised around 600 musical sources from the 16^{th} century which are freely accessible and downloadable online.

[2] `http://measuringpolyphony.org/`

[3] `https://github.com/SEILSdataset/SEILSdataset`

a process in which digital technology plays a fundamental role [13]. Despite symbolic codification of the musical content is essential for a systematic study of the considered repertoire, the lack of a common methodology across the available digital collections makes their comparison difficult and might even bias research outcomes [8]. Furthermore, although initiatives such as *Tasso in Music Project* [26], [4] *Gesualdo Online Project*, [5] *Marenzio Online Digital Edition* (MODE), [6] *Josquin Research Project*, [7] or *The Lost Voices Project* [8] have as a main goal the codification of early musical sources in machine-readable formats, those preserving the original notation during the symbolic representation process are still rare [9, 20, 29]. In addition, despite the limitations of editing music in book format [35], even recently published—carefully curated—diplomatic editions of early music present transcriptions in modern notation of the musical content [10], without providing any symbolically codified support.

Music XML, considered the best music notation interchange format [11], is commonly used to transfer codified music across different platforms; still, Music XML might present limitations when working with early music, e. g., in the codification of different notations. In this regard, the Music Encoding Initiative (MEI) has been established [30], not only covering the encoding of a wide range of notations but also providing a set of features especially suited to the digital edition of music such as the inclusion of critical comments [22]. However, conversion routines between user-friendly encoding formats which support early notation, as, e. g., Lilypond [18] [9] and MEI, are still missing. Indeed, only recently suitable formats for manual encoding and conversion into MEI, such as the Humdrum representation scheme **kern [17], have been adapted for mensural notation, i. e., the representation scheme **mens [28], which as well as MEI can be rendered with the dedicated music engraving library Verovio [23] and through the online platform Verovio Humdrum Viewer (VHV [33]).

OMR has been progressively improved, e. g., by processing inconsistently notated handwritten scores [16, 25] and low quality early printed sources [24, 34]. Still, for all the machine learning systems, an adequate ground truth is essential to properly set-up an OMR framework. The so-called 'annotated dataset' or ground truth is a version of the evaluated data in which every instance (musical character) is identified with the label expected to be predicted. From a musicological prospective, a digital diplomatic edition [14], i. e., a symbolically codified source that faithfully mirrors the original print, would be the most appropriate approach to encode OMR ground truth of early music.

3. METHODOLOGY

We present a digital diplomatic edition of the anthology encoded in two open community driven formats with the capability to codify white mensural notation: **mens (a Humdrum representation scheme which presents a user-friendly encoding syntax [28]), and MEI (which has a specific module to encode mensural notation [31] and is considered to be the most appropriate storing format [28]). For OMR applications, we encoded the anthology's 'ground truth' in agnostic and semantic formats, i. e., two symbolic representations originally presented for western modern notation [6] but considered also as being appropriate to codify early notated sources [27].

3.1 Data description

The *Il Lauro Secco* anthology is a collection of 30 madrigals—secular polyphonic a cappella compositions—for five voices, [10] which has been published in a set of separate 'partbooks', i. e., according to a printing format in which each vocal part is presented in a different book [12]. This means that for each of the 30 madrigals in the anthology, five 'parts', i. e., individual scores presented in the corresponding partbooks (we will use the Italian term *particella(s)* to refer to these) are presented; no 'choral score', i. e., a score in which all the voices are displayed over-imposed in the same sheet, is available. Since the anthology encompasses 150 *particellas* (30 madrigals x 5 voices), and we considered four encoding formats—**mens, MEI, agnostic, and semantic—a total of 600 symbolically codified *particellas* are presented.

For the diplomatic edition, the 150 *particellas* were encoded in **mens and MEI (i. e., a total of 300 files), which present a faithful representation of the original source. The MEI files were also engraved with Verovio [23] and saved as images in pdf format (i. e., 150 files). Additionally, one choral score with the five voices over-imposed, from the lower to the higher in the same sheet, was also encoded in **mens and MEI for each madrigal (i. e., a total of 60 files). Still, the choral scores are only presented to encourage / facilitate analysis and performance; thus, they should not be considered as part of the diplomatic edition: They do not respect the original's editorial choice (i. e., partbook printing), and, contradicting the original print, lyrics normalisation and musical corrections to preserve vertical alignment were applied to them.

For the OMR ground truth, the 150 *particellas* were encoded in agnostic and semantic format, yielding a total of 300 files. The agnostic encoding gives the sequential representation of the musical symbols by indicating their exact position within the staff but without providing any musical meaning [6]. Differently, the semantic representation gives a simplified version of the scores while still keeping the musical meaning, e. g., the indication FM (F major) for modern notation implies that a flat is considered in the key-signature [6]. To the best of our knowledge, lyrics have not been considered in any of these formats, neither for mensural [27] nor for modern [6] notation; thus, the *particellas* in agnostic and semantic formats do not contain lyrics. In the future, these might be required to perform Optical

[10] Note that the polychoral madrigal composed by Luca Marenzio is not taken into account [20].

Character Recognition (OCR) and OMR together. Then, the codified lyrics and their musical alignment can be retrieved from the *particellas* in **mens and MEI.

3.2 Data conversion and manual encoding

Even though the *Il Lauro Secco* anthology has already been codified in original notation [20], since this work employed the encoding format Lilypond—mostly used as a 'final' encoding choice rather than an interchange format [27]—direct conversion to **mens or MEI was not possible. Considering this, as starting codified version of the anthology, we chose the modern notated transcription encoded in **kern format [21], which contains a choral score for each madrigal (i. e., 30 **kern files in total). We converted the 30 choral scores from **kern to **mens by compiling the filter `kern2mens` [11] implemented in the Verovio Humdrum Viewer [12] (VHV [33]). Conversion errors were corrected (cf. Section 3.3), and aspects exclusive for mensural notation—thus missing in the **kern files, as e. g., colorature or ligatures—were manually integrated in the **mens choral scores (cf. Section 4.1).

When the musical content of the 30 choral scores in **mens was edited according to the original sources—note, as already mentioned, that a few musical corrections were required in order to preserve vertical alignment across voices—these were split into the individual parts. The extraction of the voices in separated files was performed with the Humdrum Toolkit, [13] through the command `extractx` of the Humdrum extras, [14] by that generating five **mens files per madrigal with two spines (one for music and another for lyrics) each. After that, the lyrics of the 150 *particellas* in **mens were manually 'unnormalised', i. e., corrected according to the original source (cf. Section 4.2), and the few musical corrections in the choral scores to preserve vertical alignment were also made according to the original. Finally, the **mens *particellas* were automatically converted into MEI syntax through the Verovio command-line interface. [15]

For the encoding of the agnostic and the semantic files, two Python scripts to convert from **mens to both formats, `mens2agnostic` and `mens2semantic`, were created. Even though agnostic and semantic representations have already been considered to encode Spanish white mensural notation [27], the repertoire in this notation, unlike the music prints considered by us, is handwritten, thus presenting many differences with respect to the white mensural notation of printed sources [29]. Due to this, for the agnostic and semantic encoding, we followed specific criteria (cf. Sections 5.1 and 5.2), which were developed from those originally presented for modern western notation [6]. Since lyrics were not considered for these representations, before automatically converting the 150 **mens *particellas*, they were removed by extracting the spines with musical content as individual files.

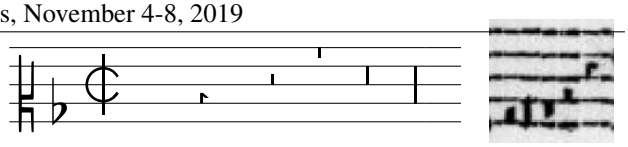

Figure 1. At left, a codified representation of mensural notation engraved in VHV presents (from left to right) the following symbols: C2 clef, B flat, 𝔠 time signature, and rests of *semiminima* in line 2 (L2), *minima* (L3), *semibrevis* (L5), *brevis* (L3), and *longa* (L3). At right, an extract of a original print taken from the *Basso* part of Belli's madrigal presents (from left to right) rests of: *minima* in line 1 (L1), *brevis* (L1), *semibrevis* (L2), *minima* (L2), and *semiminima* (L3). Rests position (standard in **mens) is given considering their proximity to the center of the staff (L3).

3.3 Data post-processing

Musical aspects specific of mensural notation, e. g., 'proportions' (transcribed in modern notation with triplets), were not interpreted in the conversion from **kern to **mens. Thus, manual post-processing of the **mens files was required to address the following conversion issues: (i) 16^{th} notes in **kern were converted in **mens as *semibrevis* instead of *semifusas*; (ii) triplets, used in **kern to transcribe *proportio tripla* of *tempus imperfectum* [1], i. e., the *diminution* of the *prolatio* (reduction of the subdivision values) by changing from a time signature with binary meter and binary subdivision (e. g., 𝐂 and 𝔠) to another with binary meter and ternary subdivision (e. g., `3` and $\mathbf{C}\frac{3}{2}$), were not recognised in the conversion, yielding compilation failure of the **mens files.

Although 'coloration' and 'custos' can be encoded in MEI, these are not yet implemented in VHV for **mens (cf. Section 4.1). Due to this, in the conversion from **mens to MEI, these were not recognised, but manually encoded in MEI. Similarly, since lyrics linked to rests are not supported in VHV (cf. Section 4.2), these were not recognised in the conversion from **mens to MEI, but also manually encoded. In **mens representation, unlike in the original source, rests are indicated in a standard position within the staff (cf. Figure 1); yet, in the agnostic representation the original position of the rests should be indicated. The same applies for accidentals, which in **mens, unlike in the original source (cf. Figure 3), are displayed in the same staff position of the note they refer to. Since in the conversion from **mens to agnostic, the specific position of rests and accidentals was missing, this was manually encoded in the agnostic files (cf. Section 5.1).

4. CRITERIA FOR DIGITAL DIPLOMATIC EDITIONS OF WHITE MENSURAL NOTATION

While MEI is a suitable encoding format for storage, **mens is more appropriate for manual encoding [28]. The following criteria will refer mainly to the codification in **mens; manual interventions in MEI will only be described when required. For white mensural notation encoding guidelines in **mens, cf. [28]; [16] for MEI, cf. [32]. [17]

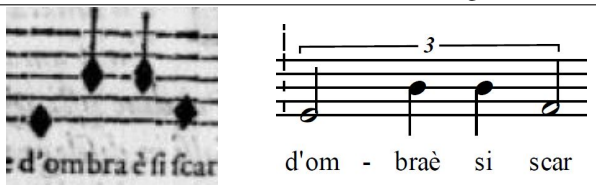

Figure 2. At left, the rhythmic sequence *semibrevis*, *minima*, *minima*, *semibrevis* (all blackened), which should be interpreted as *minor color*; at right, the transcription of this fragment of Belli's madrigal in modern notation [20].

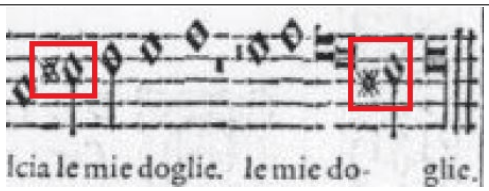

Figure 3. Two different representations of the accidental sharp displayed in Marenzio's madrigal. The first in the standard position, i. e., aligned to the note; the second not.

4.1 Musical encoding criteria

Unlike the anthology codified in Lilypond [20], where different musical aspects are modified w.r.t. the original source to encourage the analysis and performance of the repertoire, the present encoding in **mens and MEI tries to represent the original source as much as possible. For this, the following criteria were considered:

(i) In previous symbolic versions of the anthology [20, 21], rests have often been encoded in shorter length than in the original source. This was due to the use of barlines, which made it impossible to display rests longer than a measure. In **mens and MEI encoding, the exact duration of the rests indicated in the original source was considered; yet, as in these formats the position of rests within the staff cannot be defined, the default position displayed in the images engraved with VHV might not always coincide with that given in the original print (cf. Figure 1).

(ii) Stems up to the third staff line (included) are generally displayed upwards, while above the third space (included), they are displayed downwards. This applies always when engraving codified scores in VHV; yet, for melodic reasons, notes in the third line of the original source might also present downwards stems. Thus, the direction of the stems which did not follow the standard disposition in the original source was manually specified in the **mens encoding. Furthermore, since *Longa*'s stems in VHV are always engraved downwards, these were also specified, when needed, according to the original.

(iii) Coloration or 'blackening' [1]—used to indicate rhythms with ternary subdivision (i. e., *perfect prolatio*)—is an attribute unique of white mensural notation; thus, it was not indicated in the modern notated transcription in **kern [21]. Due to this, coloration was manually encoded in **mens according to [28] by indicating '∼'. Since coloration is not yet implemented in VHV, this is not displayed when engraving **mens files, and it was also not correctly converted from **mens to MEI; thus, coloration was manually encoded in MEI by specifying the note attribute 'colored="true"' [32]. As blackened *minimas* appear graphically as *semiminimas*, it depends on the musicological interpretation whether such a character should be encoded as the former or the latter. To prevent interpretation bias, coloration was only indicated for *brevis* and *semibrevis*, i. e., the notes which do not have an already existing equivalent when blackened. Still, from a musicological prospective, the so-called *minor color*—a *semibrevis* followed by a *minima* both blackened that must be performed as a triplet of whole and half notes [1]—should be considered; thus, in some cases, *semiminimas* might be interpreted as blackened *minimas* (cf. Figure 2).

(iv) *Ligatures*—symbols that in mensural notation represent a combination of two or more notes [1]—were indicated according to the VHV documentation, [18] i. e., notes within the ligature are delimited with brackets: square brackets were used for *recta ligatures*, angle brackets for *obliquous ligatures*. However, since the rhythmic stems of *ligatures* are not yet implemented in VHV, they are not displayed when engraving **mens and MEI encoding.

(v) *Custodes* (singular: custos)—a symbol at the end of a staff indicating the pitch of the first note in the next staff [1]—are not yet implemented for **mens encoding. Considering this, we introduced the indication `*custos` in the *particellas* in **mens, which although is not engraved, indicates the exact position where the custos is displayed, i. e., the end of each staff as shown in the original source. This might be similar to the indication `!!linebreak:original`, typically used in **kern encoding. Unlike in **mens, *custodes* are already implemented in MEI encoding [32]; thus, these were manually indicated by adding the event `<custos/>`, in which the exact position of the symbol is also indicated by the attributes pitch name (`pname`) and octave (`oct`).

(vi) Accidentals in mensural notation present differences w.r.t. modern notation; e. g., single sharps in mensural are indicated with 'x', while this symbol indicates double sharp in modern notation. Furthermore, unlike in modern notation, accidentals in mensural are not always aligned—displayed in the same vertical staff position—to the note they precede (cf. Figure 3). Still, since in **mens encoding accidentals' position cannot be specified, these are displayed, when engraved in VHV, according to the default alignment; [19] thus, their position in the engraved images may not coincide with that of the original source.

(vii) Measures were considered in the *particellas* to indicate staff breaks, i. e., after each `*custos`, a new measure was indicated to break the musical content according to the distribution displayed in the original source. [20]

(viii) Clefs, key, and time signatures were indicated at the beginning of the score (first staff) and within staves, [21] but not at the beginning of consecutive staves, since automatically engraved in VHV. In mensural notation, unlike

[18] `http://doc.verovio.humdrum.org/humdrum/mens/`

[19] Despite in MEI the specific position of the accidentals can be specified, this was not yet performed due to time-constraints.

[20] In the 'choral scores', in order to facilitate interpretation and analysis, the numbers of measures are given regularly to fragment the music.

[21] Since verovio and VHV are still in development, repetitions within a staff of the same clef and some time signatures might not be engraved.

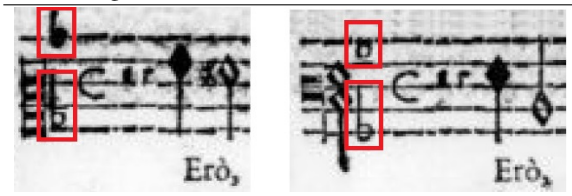

Figure 4. B–flat showed twice for C2 (left) and F3 (right) clefs, in the *Canto* and *Basso* parts of da L'Occa madrigal.

Figure 5. Two different representations of the letter 's' in the word *lassi*, displayed in Fiorino's madrigal.

in modern, when having a flat in key signature, this is displayed twice for C2 and F3 clefs (cf. Figure 4); yet, only one is engraved by VHV for **mens and MEI encoding.

4.2 Textual encoding criteria

The lyrics of the *particellas* encoded in **mens were 'unnormalised' w.r.t. the standardised transcription in **kern format [21], i. e., they were rewritten according to the original source. In this process, punctuation was introduced when missing, and modified or removed when needed. Contractions (e. g., *altrov'adopra*), abbreviations (e. g., *hãno*, *pche*, or *ij*), and the *tironian* symbol '&', previously transcribed as 'et', were indicated as in the original. The arbitrary use of diacritic marks (e. g., *più* and *piu*), letters (e. g., *verde* and *uerde*), links between words (e. g., *invano* and *in vano*), and letter capitalisation was kept inconsistent across voices as in the original partbooks.

Unlike in the transcription encoded in **kern [21], lyrics linked to long rests at the beginning of a voice were encoded in the *particellas* in **mens and MEI; still, since these are not supported in VHV, they are not displayed in the engraved images. Indeed, even though lyrics might be printed under rest in the original source, these should not be sung—they are given for performance reasons, to indicate verse sung by the other parts to voices which start with long rests. Finally, due to graphical limitations, the two different spellings of the letter 's' (cf. Figure 5) were indicated with the unique graphical symbol 's'.

5. ENCODING CRITERIA FOR OMR GROUND TRUTH OF WHITE MENSURAL NOTATION

The vocabularies for agnostic and semantic encoding of modern notation [6] were adapted to the characteristics of white mensural notation. Thus, aspects typical of modern notation, such as slurs or dynamics, were not considered, while elements characteristic of mensural notation, e. g., 'ligatures' and 'coloration', were taken into account. Division and addition dots were indicated as shown by [6] for modern notation. Note that in white mensural notation, the following notes are used [1]: *maxima*, *longa*, *brevis*, *semibrevis*, *minima*, *semiminima*, *fusa*, and *semifusa*.

5.1 Criteria for agnostic encoding

Since in the agnostic format, musical symbols are encoded as graphical objects without musical meaning, for each element, its position within the staff (line or space) is indicated. Lines and spaces are enumerated from the bottom to the top: the five lines from L1 to L5, the additional line below the staff L0, the one above L6; the four spaces from S1 to S4, the space below the staff S0, the one above S5.

(i) The position of rests within the staff is not standardised in mensural notation (cf. Figure 1); thus, all the possible positions were considered in the vocabulary. Still, since in the conversion from **mens to agnostic, such a position was not indicated (cf. Sections 3.3 and 4.1–i), this was manually encoded in the agnostic files.

(ii) The stems whose direction in the original source did not follow the standard rule (cf. Section 4.1–ii), were marked with back-slash '\' or slash '/', to indicate downwards and upwards directions, respectively, e. g., 'note.semifusa\-L3'. Note that this does not apply to *brevis* and *semibrevis*, i. e., notes without stem.

(iii) Coloration (cf. Section 4.1–iii) was indicated for *brevis*, *semibrevis*, and ligatures by adding '∼' when applicable, e. g., 'note.breve∼-S3' or 'ligature∼.start-L5'.

(iv) Ligatures (cf. Section 4.1–iv) were indicated by the word 'ligature' instead of 'note'. Since the considered anthology presents only *recta* ligatures of two notes, in the vocabulary, only the starting and final notes of the ligature, without distinction between *recta* and *obliqua*, were indicated, e. g., 'ligature.start-L2'. Still, middle notes, ligature type, and other attributes could also be defined if needed.

(v) *Custodes* (cf. Section 4.1–v) were indicated by the word 'custos' followed by their position, e. g., 'custos-S3'.

(vi) The position of accidentals is not always standardised in mensural notation (cf. Figure 3); still, since in **mens encoding this cannot be specified (cf. Section 4.1–vi), in the conversion from **mens to agnostic, the accidentals' default position was indicated and manually modified in the agnostic files when required (cf. Sections 3.3).

(vii) Clefs, key, and time signatures were encoded as in the original source, i. e., also at the beginning of each staff—note that the agnostic encoding might be split in staves by introducing a break-line after each custos, if needed. B–flat in key signature, displayed twice for some clefs, was also codified, e. g., C2 clef with a B–flat in key signature (cf. Figure 4) would be encoded in agnostic as 'clef.C-L2 accidental.flat-L5 accidental.flat-S1'.

5.2 Criteria for semantic encoding

In the semantic encoding, each element is intended with its musical meaning; thus, no position markers such as staff line or stem direction are given, since implicitly indicated.

(i) Renaissance music can be grouped into two systems, *durus* and *mollis*, which together with the cleffing, i. e., the use of standard (up to C1) or high (up to G2) clefs, were the common criteria used by publishers in the 16^{th} cen-

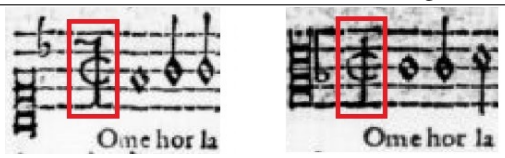

Figure 6. Representations of the time signature 𝔠 showed in the *Canto* (left) and *Alto* (right) of Fronti's madrigal.

tury to group madrigals in different collections [7]. *Durum*, in Latin, corresponds to B–natural in modern terminology while *molle* corresponds to B–flat [12]; thus, madrigals in *durus* system (i. e., with B–*durum* in key signature) would use the Lydian scale while those in *mollis* (i. e., with B–*molle* in key signature) would use the F major scale [1]. In the semantic encoding, the words 'mollis' and 'durus' were considered to indicate B–flat and no alteration in key signature, e. g., 'keySignature-durus'.

(ii) Accidentals in mensural notation must be interpreted according to the musical context, e. g., a sharp might indicate that a note is natural (instead of sharp) if it previously was flat, and altered notes might be notated without accidentals. Indeed, in early music—specially from the 14^{th} century—there was a tendency to use many altered notes for performance (the so-called *musica ficta*); still, often it was not allowed to indicate such altered notes in written music, since these did not follow the 'guidonian rule' of the hexachords (the so-called *musica retta*) written music was based upon at that time [15]. The theorisation on this topic creates great interest in the research community [2], and due to its complexity—which goes beyond the purpose of this paper—we only encode the accidentals printed in the original source without further interpretations; for a transcription in modern notation which contains 'editorial accidentals' of the *musica ficta*, cf. [20].

(iii) Unlike modern notation, where—except for dotted notes—each note is always divided in two equal neighbour smaller notes (e. g., a quarter note is divided by two eighth notes), in mensural notation a non dotted note might be divided not only in two, but also in three neighbour smaller notes, depending on its 'mensuration' [1]. The mensuration of *brevis* and *semibrevis* (so-called *tempus* and *prolatio*) is indicated by the time signature, e. g., 𝐂 indicates *tempus imperfectum cum prolatione imperfecta* [1], i. e., a duple metre with binary subdivision. While imperfect *prolatio* would be the equivalent of a simple metre in modern notation (i. e., binary subdivision of each bit), perfect *prolatio* would be the equivalent of a compound metre (i. e., ternary subdivision of each bit). [22] In the semantic encoding, mensuration was indicated by adding '_imperfect' or '_perfected' to each note, rest, and ligature, e. g., 'note-D4_minima_imperfect'.

6. LIMITATIONS

Beyond the already discussed aspects that might differ between the engraved images, i. e., the visual representation of **mens and MEI files engraved by VHV, and the original source, such as different position of accidentals and rests, or missing elements (e. g., custos, ligature stems, or clefs, time, and key signatures in specific cases), other differences between the presented diplomatic edition and the original print should be mentioned. One is the time signature so-called, the *alla breve* [1], i. e., 𝔠, which indicates, as well as 𝐂, *tempus* and *prolatio* imperfect. Although in the original source, this time signature presents two graphical variants (cf. Figure 6), this is displayed by a unique symbol in the engraved images (cf. Figure 1). Another element which is not included in the engraved images is the use of descriptive or decorative initials, which gained great relevance in printing music collections since, unlike ordinary text editions, music prints required normally one or even two woodcut initials for every page [3]. Since the *Il Lauro Secco* anthology was the first music collection published by Baldini as ducal printer in the court of Alfonso II d'Este, ornamental elements as the initials (cf. Figure 7) received special attention in the luxurious collection [4]. [23]

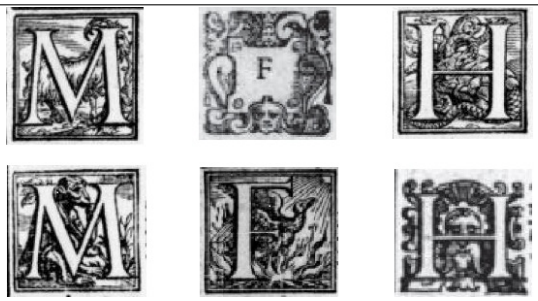

Figure 7. The anthology presents two different sets of decorative initials, which also contemplate variations of the same letter. In the musical parts two alternatives of the initials 'M' (left), 'F' (middle), and 'H' (right) are displayed.

7. CONCLUSIONS AND FUTURE WORK

We symbolically codified the *Il Lauro Secco* anthology in white mensural notation. For analytic and performance purposes, a diplomatic edition, encoded in **mens and MEI formats as well as its engraved images in pdf format, is provided. For OMR applications, ground truth in agnostic and semantic formats is presented, and the converters required to automatically generate such files from **mens encoding are also freely available. The recent development of a user-friendly encoding format for mensural notation (**mens) and a suitable encoding interface (VHV) made this work possible. Yet, given the novelty of these tools, specific aspects of mensural notation are still being developed, e. g., the lack of rests' and accidentals' position markers, or a custos indicator. By evaluating these aspects, we aim at encouraging a further development of the available tools. Due to the higher standardisation—w.r.t. handwritten and black mensural notation—of white mensural notated printed sources, and to the vast array of available scanned copies, we want to apply the methodology presented in this work to similar repertoires, thus stimulating further advance of OMR technology for early music.

[22] In modern notation, a dot must be added to the quarter note (bit note) in compound metre while in mensural notation this would not be required.

[23] Given the importance of decorative initials in Renaissance prints, the possibility to include them in VHV might be something to consider.

ABSTRACT

We introduce the Harmonix set: a collection of annotations of beats, downbeats, and functional segmentation for over 900 full tracks that covers a wide range of western popular music. Given the variety of annotated music information types in this set, and how strongly these three types of data are typically intertwined, we seek to foster research that focuses on multiple retrieval tasks at once. The dataset includes additional metadata such as MusicBrainz identifiers to support the linking of the dataset to third-party information or audio data when available. We describe the methodology employed in acquiring this set, including the annotation process and song selection. In addition, an initial data exploration of the annotations and actual dataset content is conducted. Finally, we provide a series of baselines of the Harmonix set with reference beat-trackers, downbeat estimation, and structural segmentation algorithms.

1. INTRODUCTION

The tasks of beat detection [8], downbeat estimation [2], and structural segmentation [34] constitute a fundamental part of the field of MIR. These three musical characteristics are often related: downbeats define the first beat of a given music measure, and long structural music segments tend to begin and end on specific beat locations – frequently on downbeats [10]. The automatic estimation of such information could result in better musical systems such as more accurate automatic DJ-ing, better intra- and inter-song navigation, further musicological insights of large collections, *etc*. While a few approaches exploiting more than one of these musical traits have been proposed [2, 11, 25], the amount of human annotated data containing the three of them for a single collection is scarce. This limits the training potential of certain methods, especially those that require large amounts of information (e.g., deep learning [18]).

In this paper we present the Harmonix set: human annotations of beats, downbeats, and functional segmentation for 912 tracks of western popular music. These annotations were gathered with the aim of having a significant amount of data to train models to improve the prediction of such musical attributes, which would later be applied to various products offered by Harmonix, a video game company that specializes in musically-inspired games. By releasing this set to the public, our aim is to let the research community explore and exploit these annotations to advance the tasks of beat tracking, downbeat estimation, and automatic functional structural segmentation. We discuss the methodology to acquire these data, including the song selection process, and the inclusion of standard identifiers (AcoustID and MusicBrainz) and a set of automatically extracted onset times for the first 30 seconds of the tracks to allow other researchers to more easily access and align, when needed, the actual audio content. Furthermore, we present a series of results with reference algorithmic approaches in the literature with the goal of having an initial public benchmark of this set.

The rest of this work is organized as follows: Section 2 contains a review of the most relevant public datasets of the tasks at hand; Section 3 discusses the Harmonix set, including the data gathering, their formatting, and various statistics; Section 4 presents numerous benchmarks in the set; and Section 5 draws some final conclusions and discusses future work.

2. BACKGROUND

Several datasets with beat, downbeat, and/or segment annotations have been previously published, and in this section we review the most relevant ones.

2.1 Beat and Downbeat Tracking Sets

Over the last 15 years, many annotated datasets for beat and downbeat tracking have appeared in the literature whose primary purpose has been to allow the comparison of newly proposed and existing algorithms. However, the well-known difficulties of sharing the audio component of large annotated datasets has led to a rather ad-hoc usage of different datasets within the literature, and to a lesser extent, the choice of which evaluation metrics are selected to report accuracy. Conversely, the MIREX evaluation campaign provides a more rigid model for evaluation, by withholding access to private test datasets, and instead relying on the submission of the competing algorithms in order to compare them under controlled conditions. To this end, MIREX can be a useful reference point to consider these two music analysis tasks from the perspective of annotated data.

The MIREX Audio Beat Tracking (ABT) task [1] first appeared in 2006 and ran on a single dataset [28,30] with the performance of the submitted algorithms determined using one evaluation metric, the P-Score. After a brief hiatus, the task reappeared in 2009 with the addition of a dataset of Chopin Mazurkas [36], and the inclusion of multiple evaluation metrics [5]. The task continued to run in this way until the incorporation of the SMC dataset [16] in 2012, from which point it has remained constant. In 2014, the Audio Downbeat Estimation (ADE) task [2] was launched which comprised six different datasets from diverse geographic and stylistic sources: The Beatles [24]; Hardcore, Jungle, Drum and Bass (HJDB) [15]; Turkish [41]; Ballroom [21]; Carnatic [42]; and Cretan [17], with the evaluation conducted using the F-measure. While the datasets contained with these two MIREX tasks are by no means exhaustive, they provide a useful window to explore both how the audio data is chosen and how the annotation is conducted for these MIR tasks. To this end, we provide the following breakdown of different properties including reference to both MIREX and non-MIREX datasets.

Duration: Unlike the task of structural segmentation, beat and downbeat tracking datasets can be comprised of musical excerpts [14, 15, 21, 28] rather than full tracks [9,12,13,24]. **Number of annotators**: The initial MIREX beat tracking dataset [28] was unique in that it contained the annotations of 40 different people who tapped the beat to the music excepts. Conversely, other datasets used multiple annotators contributing across the dataset [16], a single annotator for all excerpts [14], or even deriving the annotations in a semi-automatic way from the output of an algorithm [24]. **Annotation post-processing**: Given some raw tap times or algorithm output, these can either be left unaltered [28] or, as is more common, iteratively adjusted until they are considered perceptually accurate by the annotator(s) [14–16]. **Style-specificity**: While some datasets are designed to have broad coverage across a range of musical styles [13, 14, 23], others target a particular group of styles [15, 21], a single style [9], the work of a given artist [12, 24] or even multiple versions of the same pieces [36]. **Western / Non-Western**: Similarly, the make up of the dataset can target underrepresented non-western music [33,41,42]. **Perceived difficulty**: Finally, the choice of musical material can be based upon the perceived difficulty of the musical excerpts, either from the perspective of musical or signal level properties [16].

2.2 Structural Segmentation Sets

The task of structural segmentation has been particularly active in the MIR community since the late 2000s. Similarly to the beat tracking task, several datasets have been published, and some of them have evolved over time. This task is often divided into two subtasks: segment boundary retrieval and segment labeling. All well-known published datasets contain both boundary and label information. One of the major challenges with structural segmentation is that this task is regarded as both *ambiguous* (i.e., there may be more than one valid annotation for a given track [26]) and *subjective* (i.e., two different listeners might perceive different sets of segment boundaries [4]). This has led to different methodologies when annotating and gathering structural datasets, thus having a diverse ecosystem of sets to choose from when evaluating automatic approaches.

The first time this task appeared on MIREX was in 2009, [3] where annotations from The Beatles dataset (which also includes beat and downbeat annotations, as previously described) and a subset of the Real World Computing Popular Music Database (RWC) [13] were employed. These sets contain several functional segment annotations for western (The Beatles) and Japanese (RWC) popular music. These segment functions describe the *purpose* of the segments, e.g.: "solo," "verse," "chorus." A single annotation per track is provided for these two sets. The Beatles dataset was further revised at the Tampere University of Technology, [4] and additional functional segment annotations for other bands were added to The Beatles set, which became known as the Isophonics Dataset [24]. No beat or downbeat annotations were provided to the rest of the tracks in Isophonics, and the final number of tracks with functional structural segment annotations is 300. The number of annotated tracks in RWC is 365.

To address the open problems of ambiguity and subjectivity, further annotations per track from several experts could be gathered. That is the case with the Structural Annotations for Large Amounts of Music Information (SALAMI) dataset [39], where most of its nearly 1,400 tracks have been annotated by at least 2 musical experts. Similarly, the Structural Poly Annotations of Music (SPAM) dataset [32] provides 5 different annotations for 50 tracks. These two sets not only contain functional levels of annotations, but also large and small scale segments where only single letters describing the similarity between segments are annotated. Thus, these can be seen as sets that contain *hierarchical* data, which pose significant chal-

[1] https://www.music-ir.org/mirex/wiki/2006:Audio_Beat_Tracking
[2] https://www.music-ir.org/mirex/wiki/2014:Audio_Downbeat_Estimation
[3] https://www.music-ir.org/mirex/wiki/2009:Structural_Segmentation
[4] http://www.cs.tut.fi/sgn/arg/paulus/beatles_sections_TUT.zip

lenges, since ambiguity and subjectivity span across multiple layers [26] and remain largely unexploited in the MIREX competition [7,40]. As opposed to Isophonics and RWC, these two sets contain highly diverse music in terms of genre: from world-music to rock, including jazz, blues, and live music.

The following properties typically define segmentation datasets: **Number of annotators**: This can help when trying to quantify the amount of disagreement among annotators [26, 32], or when developing approaches that may yield more than one potentially valid segmentation. **Hierarchy**: The levels of annotations contained in the set. It typically contains functional, large, and/or small segment annotations. When only one level of annotations is provided, these are typically called *flat* segment annotations.

3. THE HARMONIX SET

In this section we present the Harmonix set, including the methodology of acquiring the data, its motivation, its contents, and a set of annotation statistics. The Harmonix set is publicly available on-line. [5]

3.1 Data Gathering

The primary motivation of this work is based on the need to create gameplay data for rhythm-action games (also known as beat matching games). Many such games exist, from early pioneers like Parappa The Rapper and Beatmania, to the rock simulation games Guitar Hero and Rock Band, as well as community-based games like OSU and more recently, VR games like Beat Saber. In most cases the gameplay data (also referred to as beatmaps), consisting of note locations in a song, are hand-authored. In certain games, additional control data may be desirable. For example, in the rock simulation games, where a 3D depiction of a rock concert is rendered, it can be desirable to simulate flashing lights (on the beat) or lighting color palette changes (on section boundaries). Again, these data tend to be hand-authored.

Harmonix's desire was to implement a suite of automatic music analysis tools that estimate certain musical attributes in order to expedite the process of hand-authoring gameplay data, or in some cases, to fully automate the process of creating these data. The songs of the Harmonix set were gathered and hand-annotated to create a ground-truth dataset for training and testing these algorithms.

The mix of genres in this corpus were chosen to be typical of ones used in the rhythm-action games, with a somewhat higher tendency towards EDM and popular songs suitable for dancing (see Figure 1 for the full genre distribution). As such, most tend to have a very stable tempo and a 4/4 time signature. However, we also added a selection of songs that may not be typical of dance or pop music to increase variety. Some of these (Classic Rock, Country, Metal) may have less stable tempo (where drums are played by actual musicians as opposed to drum-machines

[5] https://github.com/urinieto/harmonixset

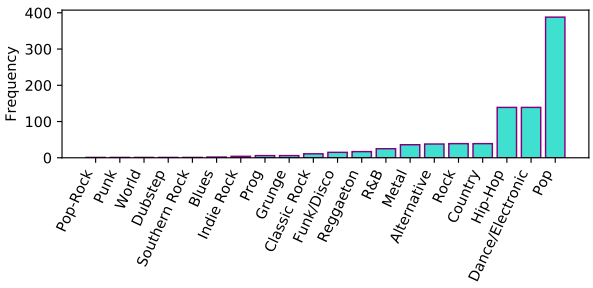

Figure 1. Genre distribution of the Harmonix set.

or DAW-based productions) and may deviate from a strict 4/4 meter.

All songs were annotated by trained professional musicians who regularly work in music production environments. As the project went on, the majority of annotation work fell to only a few individuals who became specialized in this task. Annotations were created in Digital Audio Workstation software (such as Reaper or Logic). First, a MIDI tempo track was established that corresponded to the song audio. Then beats, downbeats, and sections were coded into the MIDI track using note events and text events. MIDI files were then exported and automatically converted to a text-based representation of beats, downbeats, and named section boundaries. Every song was verified once by the original annotator.

3.2 Dataset Contents

The Harmonix set contains manual annotations for 912 western popular music tracks, thus being the largest published dataset to date containing beats, downbeats, and function structural segmentation information. The annotations and some of the song-level metadata are distributed via JAMS [19] files, one per track. This format is chosen given its simplicity when storing multi-task annotations plus song- and corpus-level metadata. Each JAMS file contains the beat, downbeat, and functional segmentation annotations, plus a set of estimated onsets for the first 30 seconds of the audio. These onsets are intended to help aligning the audio in case researchers obtain audio data with different compression formats that might include certain small temporal offsets. This onset information was computed using librosa [27], with their default parameters. [6]

For the sake of transparency and usability, we also publish the raw beats, downbeats, and segmentation data as space-separated text files, two per track: one for beats and downbeats, and the other for segments. We also distribute the code that converts these raw annotations into unified JAMS files. Furthermore, we provide other identifiers with the aim of easily retrieving additional metadata and/or audio content for each song. These identifiers include:

- **MusicBrainz** [7] : open music encyclopedia including

[6] librosa 0.6.3, using Core Audio on macOS 10.13.6.
[7] https://musicbrainz.org/

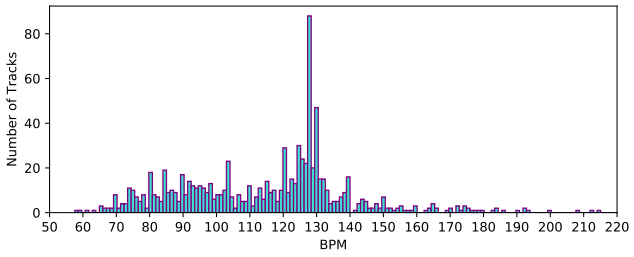

Figure 2. Tempo distribution of the tracks in the set.

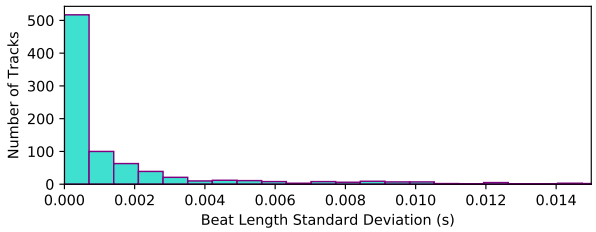

Figure 3. Standard deviation of the tempo distribution.

unique identifiers for recordings, releases, artists, etc.

- **AcoustID** [8] : open source fingerprinting service to easily match audio content, typically associated with MusicBrainz identifiers.

Finally, we provide a single CSV file including additional metadata information such as genre, time signature, and BPM.

3.3 Data Statistics

In this subsection we provide several data insights obtained from the annotations to give an objective overview of the set. In Figure 2 we show the estimated tempo distribution in beats-per-minute (BPM) per track. These estimations were computed using the track-level median inter-beat-interval (IBI) for each of the annotated beats in a given track. There is a clear peak at 128 BPM, which could be explained by being the most common tempo in electronic dance music [29]. Furthermore, in Figure 3 we plot the standard deviation of the IBI. We can clearly see that the tempo is remarkably steady in this dataset, which is expected given the type of musical genres it spans.

In terms of segment statistics, we show data based on certain attributes described in a MIREX meta-analysis of the segmentation task [40]. In Figure 4 we plot track-level histograms for the number of segments, and the number of unique segments (i.e., those with the same associated label). Both distributions seem to be unimodal and centered around 10 and 11 for the number of segments per tracks, and around 6 and 7 for the number of unique labels per track. This differs from the number of unique segments in The Beatles dataset, which is centered around 4 per track [31].

[8] https://acoustid.org/

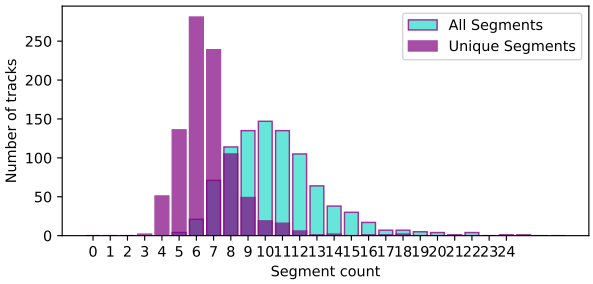

Figure 4. Number of segments per track, based on their segment labels.

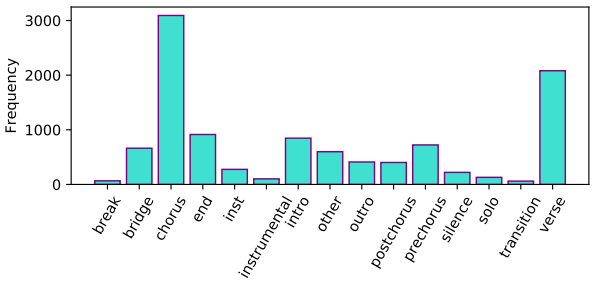

Figure 5. Most common segment labels.

Figure 5 shows the frequency in which the most common segment labels appear in the set. The labels "chorus" and "verse" dominate the distribution, as these functional parts are common in western popular music. The plot also shows potentially repeated labels like "inst" and "instrumental." A further inter-song analysis of the labels might be necessary to potentially merge certain labels and thus unify the vocabulary of the set.

We plot in Figure 6 the distribution of the segment lengths, in seconds, across the entire dataset. As we showed in Figure 2, there is a majority of tracks at 128 BPM, for which a duration of 15 seconds would correspond to a segment of exactly 32 beats. This, in the common 4/4 time signature, would result in 8 bars per each 15-second segment in that tempo, and 8 bars are common in electronic dance music [29].

Finally, and thanks to having access to the annotated downbeats, we show in Figure 7 the number of segments

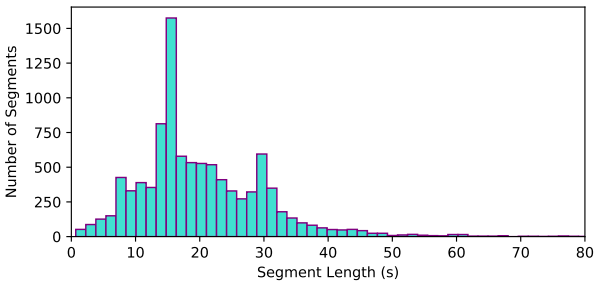

Figure 6. Segment length distribution.

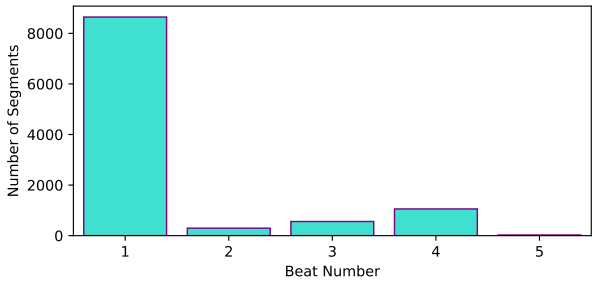

Figure 7. Number of segments based on their starting beat position within a bar.

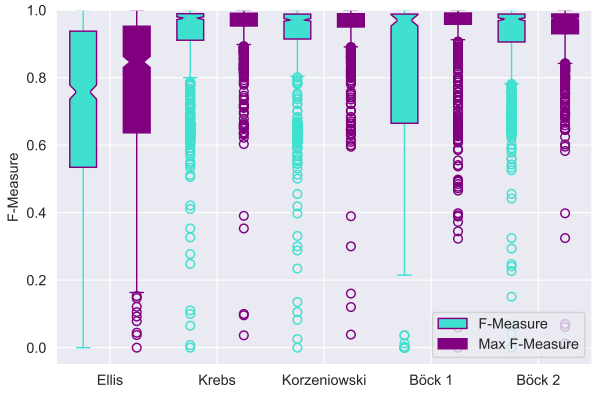

Figure 8. Beat tracking performance over the Harmonix set, for the algorithms Ellis [8], Krebs [22], Korzeniowski [20], Böck 1 - the "BeatDetector" technique from [3], and Böck 2 - the "BeatTracker" technique from [3].

starting at a specific beat within a given bar. We can see that the vast majority of segments (81.1%) start in a downbeat. Interestingly, several segments (10%) start in position 4, thus showing that 1-beat count-ins are more common than other types of count-ins on this dataset (a popular example of a 1-beat count-in song is Hey Jude by The Beatles, where the (1) is on the Jude and Hey is the (4) of the previous bar).

4. RESULTS

4.1 Beat Results

In order to establish performance baselines over the dataset for the task of beat-tracking, we have evaluated a number of openly available beat tracking algorithms on the dataset [3,8,20,22]. Each of these algorithms can be found in either the madmom [1] or librosa python libraries. [9] By running these algorithms in other datasets with the same metrics, a comparison of datasets could ultimately be performed. The results are also included in the dataset repository in CSV format. This is intended as a convenience for any future work that wishes to evaluate novel algorithms against these benchmarks.

The beat tracking results for the aforementioned algorithms are displayed in Figure 8. They are evaluated across two metrics, F-Measure, and Max F-Measure, where the latter refers to the maximum F-Measure obtained per track when evaluated across double and half-time metrical variations in the annotated beats provided with this dataset. In all experiments a tolerance window of ± 70 ms was employed in order to compute the F-Measure. For half-time metrical variations, both the downbeat and upbeat alignments were tested for a maximum F-Measure value. While [8] is the most computationally efficient of the algorithms, we see clear gains in the more recently developed methods. When investigating the types of errors present in the beat position estimates from [8], it was found the most common error was the alignment of beat phase. Often beat positions landed on the half beat or quarter beat, resulting in an F-Measure of 0 when this misalignment is consistent throughout the track. When comparing F-Measure and Max F-Measure metrics, it can be seen that with this dataset both [8] and the "BeatDetector" algorithm from [3] have a significant number of double-half time errors, compared to the other algorithms evaluated. Unlike the "BeatTracker" algorithm in [3], the "BeatDetector" algorithm assumes constant tempo.

4.2 Downbeat Results

Unfortunately, the availability of open source downbeat estimation libraries is limited. In order to provide a baseline for downbeat detection performance with the Harmonix set specifically, results have been evaluated with the downbeat detection algorithms available in [1] in addition to Durand's algorithm [6] [10], making three algorithms in total. The algorithms from the madmom python package [1] include the method proposed in [2] using the annotated beat positions as input, and the dynamic Bayesian bar tracking processor using the input from the RNN bar processor activation function. The results can be seen in Figure 9 in terms of F-Measure with a tolerance window of ± 70 ms. The superior performance of [2], which has oracle annotated beat information, highlights the importance of reliable beat tracking for downbeat estimation performance, and the interdependence between the beat tracking and downbeat estimation tasks.

4.3 Segmentation Results

There are several open source structural segmentation algorithms available in the Music Structure Analysis Framework (MSAF) [32]. [11] We run the best performing ones on the Harmonix set: (i) Structural Features [38] to identify boundaries, and (ii) 2D-Fourier Magnitude Coefficients (2D-FMC) [31] to label the segments based on their acoustic similarity. Constant-Q Transforms [37] are the selected

[9] We used madmom 0.16.1 and librosa 0.6.3. We noticed a bias in this librosa version where beats were offset by a consistent number of milliseconds. More specifically, we employed librosa's `beat.beat_track` method with default arguments on macOS 10.13.6.

[10] Not open source, shared via private correspondence.

[11] MSAF version dev-0.1.8.

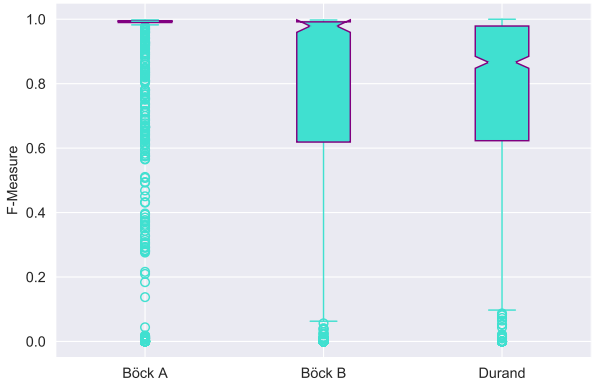

Figure 9. Downbeat tracking performance over the Harmonix set, for the algorithms Böck A [2] and Böck B - a dynamic Bayesian network provided within the madmom package [1], and Durand [6].

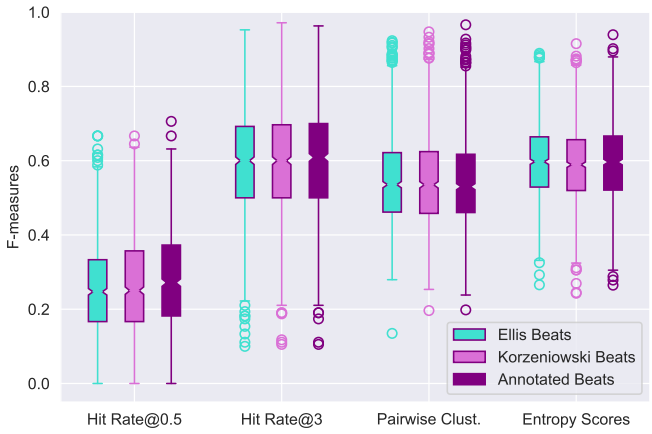

Figure 10. Segmentation results over the Harmonix set, using Structural Features for boundaries, 2D-FMC for the labeling process, and three types of beat information.

audio features given their ability to capture both timbral and harmonic content, and the default parameters in MSAF are the ones employed when computing these results. We use `mir_eval` [35] to evaluate these algorithms, and report the F-measures for the most common metrics: Hit Rate with 0.5 and 3 second windows for boundary retrieval, and Pairwise Frame Clustering and Entropy Scores for the labeling process. These algorithms can use beat-synchronized features, and we ran each algorithm three times, depending on the following beat information: (i) Ellis' estimations, (ii) Korzeniowski's estimations, and (iii) annotations from the Harmonix set. Thus, we are able to assess the segmentation results when employing the worst and best performing beat trackers from our previous study, plus those computed using human annotated beats. Song-level results for these three different runs are available as CSV files in the dataset repository disclosed above.

In Figure 10 all segmentation results are shown. The results in turquoise boxplots (on the left side) display the metrics of the algorithms when running on Ellis' beat-synchronized features, those in light pink (in the middle) correspond to the results computed with Korzeniowski's beats, while the purple boxplots (on the right) show those using annotated beats instead. Given how related boundary retrieval is with respect to precise beat placement, it is not unexpected to see an improvement in the boundary metrics (Hit Rates) when using more accurate beat data. The boxplots further show that the smaller the time window used in the Hit Rate metrics the more accurate the beat information should ideally be. In other words, Korzeniowki's beats yield very similar results than those from human annotations when using a 3 second window, but there is clearly room for enhancement (in terms of beat tracking) when using 0.5 second windows, where the segmentation results using human annotated beats outperform any of the others that employ estimated ones. On the other hand, it is worth noting that the label results do not seem to depend as much on the quality of the beats in order to produce their outcomes, as the three different runs yield similar results for the Pairwise Frame Clustering and Entropy Scores metrics. As mentioned in Section 2.2, structural segmentation is a challenging task especially due to ambiguity, subjectivity, and hierarchy, and this is reflected in the overall results, which exhibit notable room for improvement.

5. CONCLUSIONS

We presented the Harmonix set, the largest dataset in terms of human annotations containing the following three types of music information: beats, downbeats, and function structural segments. This set contains mostly western popular music, with strong emphasis on Pop, EDM, and Hip-Hop. We provide metadata in terms of genre, song title, and artist information along with standard identifiers such as MusicBrainz and AcoustID plus predicted onset information to allow easier matching and alignment with audio data. We discussed a set of results using current algorithms in the literature in terms of beat tracking, downbeat estimation, and structural segmentation to disclose an initial public benchmark of the set. Given the rather large nature of the set and the three different types of music information contained in it, it is our hope that researchers employ these data not only to further advance one of these three MIR tasks individually, but also to potentially combine them to yield superior approaches in the near future.

6. ACKNOWLEDGMENTS

We would like to thank Simon Durand for sharing his downbeat estimation implementation. Matthew E.P. Davies is supported by Portuguese National Funds through the FCT-Foundation for Science and Technology, I.P., under the project IF/01566/2015.

FMP NOTEBOOKS: EDUCATIONAL MATERIAL FOR TEACHING AND LEARNING FUNDAMENTALS OF MUSIC PROCESSING

Meinard Müller, Frank Zalkow
International Audio Laboratories Erlangen, Germany
{meinard.mueller, frank.zalkow}@audiolabs-erlangen.de

ABSTRACT

In this paper, we introduce a novel collection of educational material for teaching and learning fundamentals of music processing (FMP) with a particular focus on the audio domain. This collection, referred to as FMP notebooks, discusses well-established topics in Music Information Retrieval (MIR) as motivating application scenarios. The FMP notebooks provide detailed textbook-like explanations of central techniques and algorithms in combination with Python code examples that illustrate how to implement the theory. All components including the introductions of MIR scenarios, illustrations, sound examples, technical concepts, mathematical details, and code examples are integrated into a consistent and comprehensive framework based on Jupyter notebooks. The FMP notebooks are suited for studying the theory and practice, for generating educational material for lectures, as well as for providing baseline implementations for many MIR tasks, thus addressing students, teachers, and researchers.

1. INTRODUCTION

Music information retrieval (MIR) is an exciting and challenging area of research. Music not only connects people but also relates to many different research disciplines including signal processing, information retrieval, machine learning, musicology, and psychoacoustics. In its beginnings, research in MIR has borrowed many ideas and concepts from more established disciplines such as speech processing or computer linguistics. After twenty years, the MIR field has matured to an independent research area that has many things to offer to signal processing and other research disciplines [16]. In particular, thanks to the rich and challenging domain of music, there are many MIR tasks that can serve as motivation application scenarios for introducing, explaining, and studying techniques for audio processing, time-series analysis, and information retrieval.

In this paper, we introduce the **FMP notebooks**, which provide educational material for teaching and learning fundamentals of music processing. One primary goal of these notebooks is to give an exciting and easy-to-understand introduction to MIR with a particular focus on audio-related analysis and retrieval tasks. Following the textbook [13], the notebooks treat many well-established MIR tasks as summarized in Figure 1. Within each MIR task, fundamental algorithmic approaches and techniques are discussed in detail. Going beyond and complementing traditional toolboxes, the FMP notebooks closely combine textbook-like explanations with Python code examples. Interleaving technical concepts, mathematical details, code examples, illustrations, and sound examples within a unifying and interactive Jupyter notebook framework helps to bridge the gap between theory and practice. Furthermore, the notebooks can be easily adapted to generate educational material (such as figures and sound examples) for lectures and to realize baseline approaches for many MIR tasks. The FMP notebooks (as well as HTML exports) are accessible under a Creative Commons license at: https://www.audiolabs-erlangen.de/FMP

There are some excellent software toolboxes such as essentia [2], librosa [12], madmom [1],

Figure 1. Overview of FMP notebooks.

Marsyas [20], or the MIRtoolbox [7], which provide open source software for MIR and music processing applications. We will give an overview of related toolboxes in Section 2. While such toolboxes aim at implementing a wide range of MIR functionalities, the main goal of the FMP notebooks is to promote the understanding of MIR concepts. Therefore, rather than providing compact and efficient code, the programming style used in the FMP code examples is simple and explicit with a flat functional hierarchy (at the cost of having some redundancy). The mathematical notation and the naming conventions used in the FMP notebooks are carefully matched to establish a close relationship between theory and practice. Furthermore, the notebooks allow a user to generate appealing multimedia objects such as figures and sound examples, which may be useful for lectures and scientific publications. In summary, educational and didactic considerations are the main guide in the development of the FMP notebooks. As such, we hope that these notebooks nicely complement existing open source toolboxes, fostering education and research in MIR.

The remainder of the paper is organized as follows. In Section 2, we review related software frameworks and toolboxes for audio and music processing. Then, in Section 3, we deal with the structure, content, and implementation of the FMP notebooks. In Section 4, we give some concrete examples of how the FMP notebooks can be used for learning and teaching music processing and MIR. Conclusions can be found in Section 5.

2. RELATED WORK

As said before, the main aim of the FMP notebooks is to help users to gain a deeper understanding of essential MIR techniques. Providing explicit and simple code examples (by consciously introducing redundancies), the notebooks are not intended to form a toolbox in a stricter sense. Instead, the FMP notebooks reimplement, integrate, and apply various functions that are also provided by existing toolboxes. In the following, we give a summary of open-source toolboxes that have been specifically designed for supporting MIR research.

There are a number of comprehensive and well-document toolboxes that provide modular source code for processing and analyzing music and audio signals. Prominent examples are the Marsyas toolbox [20], the MIRtoolbox [7], the jAudio toolbox [10], and the essentia library [2]. All these collections provide code for audio feature extraction as well as for MIR applications including music classification, melody extraction, beat tracking, and structure analysis.

There are also various toolboxes that focus on specific MIR applications such as the Chroma Toolbox [14] for chroma feature extraction, the Constant-Q Toolbox [19] for computing time-frequency transforms, the TSM Toolbox [3] for time-scale modification, the Tempogram Toolbox [5] for tempo and pulse tracking, and the SM Toolbox [15] as well as the MSAF toolbox [17] for audio structure analysis. While most of these toolboxes cover more traditional MIR techniques, the recent Python library madmom [1] also offers code for MIR approaches that employ deep learning techniques. Other useful toolboxes provide code for the evaluation of MIR approaches such as the mir_eval library [18] or for data augmentation such as the Audio Degradation Toolbox [9] or the muda library [11]. Other useful sources are the MIR notebooks [1] provided by Steve Tjoa as well as the companion website [2] of the textbook [8] on audio content analysis, which offers code for hands-on experience in audio and music processing. Furthermore, Xambó et al. [22] introduce a browser-based learning environment for teaching MIR and programming in high-schools.

In particular, we want to draw attention to the Python package librosa [12], which provides basic functions as well as advanced processing pipelines for several music and audio analysis tasks. librosa also comprises a gallery of advanced examples [3], which nicely illustrate how to use the package for approaching MIR tasks such as onset detection, music synchronization, harmonic-percussive separation, and audio structure analysis. The FMP notebooks are inspired by librosa and integrate, extend, and complement elements offered by this package. While librosa is designed to be an easy-to-use toolbox with convenient presets, the emphasis of the FMP notebooks is on the educational side providing detailed explanations of theoretical and practical aspects. We hope that the FMP notebooks serve as a good basis for carrying on with more advanced techniques as provided by powerful toolboxes such as librosa, essentia, or madmom.

3. STRUCTURE OF NOTEBOOKS

The FMP notebooks are structured in ten parts as shown by the table of Figure 1. **Part 0** (also containing this table) is the starting notebook, which is opened when calling https://www.audiolabs-erlangen.de/FMP. Besides giving an overview, this notebook also provides information on the license (Creative Commons Attribution-NonCommercial-ShareAlike 4.0 International License), the main contributors, and some links to related toolboxes. **Part B** provides **basic** introductions to the Jupyter notebook framework, the Python programming language, and other technical concepts underlying these notebooks (see Section 3.1). The main body of the FMP notebooks, which covers different music processing and MIR scenarios, consists of **Part 1** to **Part 8** (closely following the eight chapters of the textbook [13]). These parts are described in Section 3.2.

3.1 Technical Framework

The notebooks of **Part B** serve different purposes. First, these notebooks describe the main tools used for developing the FMP notebooks. Second, they give short intro-

[1] https://musicinformationretrieval.com/

[2] https://www.AudioContentAnalysis.org

[3] https://librosa.github.io/librosa/advanced.html

ductions of the relevant technical concepts while providing links to more detailed tutorials. Third, the notebooks give examples for best practices in programming as well as for generating and using code, figures, and sound elements. In the following, we describe the technical framework underlying the FMP notebooks while summarizing the content of **Part B**.

3.1.1 Jupyter Notebook

The FMP notebooks are based on the Jupyter notebook framework. This open-source web application allows users to create documents that contain live code, text-based information, mathematical formulas, plots, images, sound examples, and videos. Jupyter notebooks are often used as a publishing format for reproducible computational workflows [6]. They can be exported to a static HTML format, which makes it possible to generate web applications that can be accessed through standard web browsers with no specific technical requirements. **Part B** introduces some relevant elements of the Jupyter framework including practical aspects such as the most important Jupyter operators and keyboard shortcuts.

3.1.2 Installation

To run the FMP notebooks, one needs to install Python, Jupyter, and additional Python packages. In **Part B**, we introduce the Anaconda Python distribution with its package and environment manager, which allows for quickly installing, running, and updating the required software packages. Furthermore, we provide a file which specifies an environment called `FMP`. This environment comprises all packages (specified by name and version number) needed for the FMP notebooks. Giving a step-by-step description, we explain how to use Anaconda to set up this environment.

3.1.3 Multimedia

One notebook of **Part B** gives a short overview of how to integrate multimedia objects (in particular, audio, image, and video objects) into a Jupyter notebook. Rather than being comprehensive, we only give a selection of possibilities as used in the other parts of the FMP notebooks. In particular, we discuss two alternatives: a direct integration of images, video, and audio elements using HTML tags as well as an integration using the Python module `IPython.display`.

3.1.4 Python

In the FMP notebooks, we use Python as the programming language. The reason for this choice is that Python is a open-source general-purpose language, which is widely used in scientific computing and offers plenty of resources in data sciences and machine learning. Furthermore, being a beginner-friendly language, it suits the didactic orientation of the FMP notebooks well. **Part B** contains a short introduction to Python summarizing the most important data types, control structures, and functions as occurring in later parts of the FMP notebooks. One of our design principles is to keep the required programming skills at an elementary level. Furthermore, one finds code examples that illustrate how to create appealing figures, process audio files, and program interactive plots.

3.1.5 Numba

As one side topic, we also give a short introduction to the Python package `Numba`, which offers an open source just-in-time (JIT) compiler that translates a subset of Python code into fast machine code. Even though not crucial from a functionality point of view, this package can be used to significantly speed up (sometimes a factor of 100) some of the implementations offered by the FMP notebooks.

3.1.6 Further Topics and Summary

Further topics covered by **Part B** are descriptions of relevant Python libraries, some basic information of the version control system Git, and links to tools that are helpful for music processing and MIR.

In summary, with having the notebooks of **Part B**, our goal is to make the FMP notebooks self-contained (at least, to a high degree). Rather than trying to be comprehensive, we give useful and instructive code examples that become relevant in the other parts. Furthermore, **Part B** also motivates and documents how the FMP notebooks were created.

3.2 Music Processing and MIR Scenarios

The main music processing and MIR topics covered by the FMP notebooks are organized in eight parts, which follow the eight chapters of the textbook on Fundamentals of Music Processing [13]. The notebooks include introductions for each MIR task, provide important mathematical definitions, and describe computational approaches in detail. One primary purpose of the FMP notebooks is to provide audio-visual material as well as Python code examples that implement the computational approaches described before. Additionally, the FMP notebooks provide code that allows a user to experiment with parameters and to gain an understanding of the computed results by suitable visualizations and sonifications. These functionalities also make it easily possible to input different music examples and to generate figures and illustrations that can be used in lectures and scientific articles. This way, the FMP notebooks complement and go beyond the textbook [13], where one finds a more mathematically oriented approach to MIR. In the following, we summarize the main content of the music processing and MIR scenarios covered by the FMP notebooks.

Part 1 (Music Representations). Musical information can be represented in many different ways. In this part, we cover three widely used music representations: sheet music, symbolic, and audio representations. Besides introducing basic terminology that is used throughout the following FMP notebooks, we provide Python code to study musical and acoustic properties of audio signals including aspects

such as frequency, pitch, dynamics, and timbre. For example, there are code snippets for comparing different tuning systems (equal-tempered, Pythagorean, harmonic series) and for generating Shepard tones.

Part 2 (Fourier Analysis of Signals). In this part, we approach the Fourier transform (used as the main signal processing tool in these notebooks) from various perspectives. We provide code to better understand complex numbers and exponential functions, which form the basis for the discrete Fourier transform (DFT). Also, the fast Fourier transform (FFT)—an algorithm of great beauty and high practical relevance—is covered in theory and practice. As another important topic, we discuss the short-time Fourier transform (STFT). In this context, we address issues such as sampling, padding, and axis conventions—issues that are often neglected in theory—from a practical perspective.

Part 3 (Music Synchronization). The objective of music synchronization is to temporally align different versions of the same underlying piece of music. Considering this scenario, we provide code examples for generating chroma-based music features, which capture properties that are related to harmony and melody. In this context, we also address issues of high practical relevance including tuning, logarithmic compression, as well as spectral and temporal resolution—aspects that have a significant influence on the features' properties. Furthermore, we study an alignment technique known as dynamic time warping (DTW), a concept that is applicable for the analysis of general time series. For its efficient computation, we discuss an algorithm based on dynamic programming—a widely used method for solving a complex problem by breaking it down into a collection of simpler subproblems.

Part 4 (Music Structure Analysis). In this part, we address a central and well-researched area within MIR known as music structure analysis. Given a music recording, the objective is to identify critical structural elements and to segment the recording according to these elements. Within this scenario, we discuss fundamental segmentation principles based on repetitions, homogeneity, and novelty—principles that also apply to other types of multimedia beyond music. In particular, we provide code for generating, visualizing, and understanding self-similarity matrices and for modifying their structural properties using a variety of enhancement strategies. The notebooks also cover classical approaches for novelty detection and audio thumbnailing. Finally, we introduce scape plot representations and demonstrate how this concept can be used to generate beautiful visualizations of time-dependent properties in a compact and hierarchical way.

Part 5 (Chord Recognition). Another essential and long-studied MIR task is the analysis of harmonic properties of a piece of music by determining an explicit progression of chords from a given audio recording—a task often referred to as automatic chord recognition. Within this scenario, we first discuss some basic theory of harmony including concepts such as intervals, chords, and scales. To better understand these musical concepts, the notebooks provide code for generating and interacting with suitable sound examples. Furthermore, we introduce a simple baseline system for chord recognition based on a template-based matching procedure. This system is then extended by hidden Markov models (HMMs)—a concept of central importance for the analysis of temporal patterns in time-dependent data streams including speech, gestures, and music. Besides algorithmic aspects and their implementation, we use the chord recognition scenario to illustrate the importance of feature design choices and the effect of temporal smoothing strategies. Such issues become of crucial importance when comparing, understanding, and exploring the potential of more involved chord recognition systems (e. g., based on deep learning).

Part 6 (Tempo and Beat Tracking). Tempo and beat are fundamental properties of music. In this part, we introduce the basic ideas on how to extract tempo-related information from audio recordings. A first task, known as onset detection, aims at locating note onset information by detecting changes in energy and spectral content. The notebooks not only introduce the theory but also provide code for implementing and comparing different onset detectors. To derive tempo and beat information, note onset candidates are analyzed concerning quasiperiodic patterns. This second step leads us to the study of general methods for local periodicity analysis of time series. In particular, we introduce two conceptually different methods: one based on Fourier analysis and the other one based on autocorrelation. Furthermore, the notebooks provide code for visualizing time-tempo representations, which deepen the understanding of musical and algorithmic aspects. Finally, the FMP notebooks cover fundamental procedures for predominant local pulse estimation and global beat tracking.

Part 7 (Content-Based Audio Retrieval). A central topic in MIR is concerned with the development of search engines that enable users to explore music collections in a flexible and intuitive way. In this part, we discuss audio retrieval strategies that follow the query-by-example paradigm: given an audio query, the task is to retrieve all documents that are somehow similar or related to the query. Within this scenario, we discuss the issue of specificity, which refers to the degree of similarity between the query and the database documents. First, we deal with the problem of audio identification (a retrieval task of high specificity), where the objective is to identify the particular audio recording that is the source of the query. In particular, we introduce the main ideas of an audio identification system based on spectral peaks—a technique used in many commercial applications such as Shazam [21]. Then, the notebooks cover two related retrieval tasks of lower specificity referred to as audio matching and version identification, where the goal is to identify recordings with performance variations and other versions (e. g., cover songs). The main goals of the notebooks are to provide code for baseline systems and for gaining a better understanding of

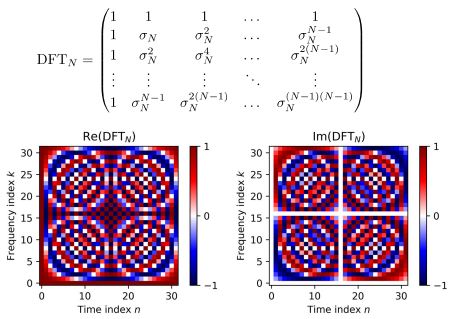

Figure 2. The matrix DFT_N and a visualization of its real and imaginary parts for the case $N = 32$.

the practical requirements of the different retrieval tasks.

Part 8 (Musically Informed Audio Decomposition). In the final part on audio decomposition, the notebooks cover challenging research directions that are related to source separation. Within this wide research area, we consider three subproblems: harmonic–percussive separation, main melody extraction, and score-informed audio decomposition. Within these scenarios, the notebooks offer detailed explanations and implementations of essential techniques including instantaneous frequency estimation, fundamental frequency (F0) estimation, spectrogram inversion, and nonnegative matrix factorization (NMF). These techniques are useful for a variety of general multimedia processing tasks beyond source separation and music processing. Besides algorithmic and computational aspects, we again encounter in this part of the notebooks a variety of acoustic and musical properties of audio recordings. Providing tools and instructive scenarios for gaining a good understanding of such properties is a central and overarching objective of the FMP notebooks.

4. EXAMPLES

In this section, we give some short examples that illustrate some of the educational aspects of the FMP notebooks.

We start with a classical signal processing topic. Given a discrete signal $x = (x(0), x(1), \ldots, x(N-1))^\top \in \mathbb{R}^N$ of length N, the discrete Fourier transform (DFT) is defined by $X(k) := \sum_{n=0}^{N-1} x(n) \exp(-2\pi i k n/N)$ for $k \in [0 : N-1]$. The vector $X \in \mathbb{C}^N$ can be interpreted as frequency representation of the time-domain signal x. The FMP notebooks approach the DFT in various ways, including the usage of inner products and their geometric interpretation. Defining the complex number $\sigma_N := \exp(-2\pi i/N)$, Figure 2 shows the matrix DFT_N (given by $\mathrm{DFT}_N(n,k) = \sigma_N^{nk}$ for $n, k \in [0 : N-1]$) along with a visualization of its real and imaginary parts. Furthermore, the notebooks explain how to evaluate the DFT efficiently using the fast Fourier transform (FFT). The general idea of the FMP notebooks is not to shy away from mathematics. Instead, the notebooks provide rigorous introductions to the theory, which are interleaved with code examples that further explain, implement, and visualize abstract concepts.

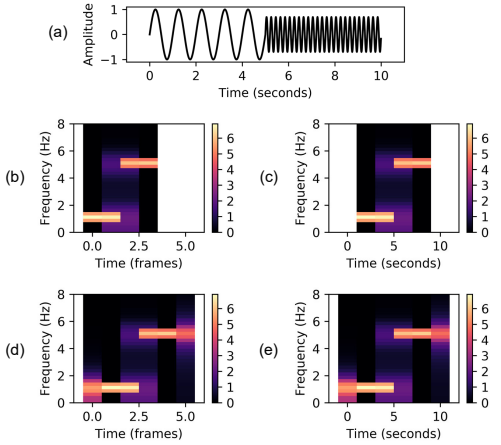

Figure 3. Time-domain signal (a) and its STFT without padding (b/c) and with zero-padding (d/e).

To recover time information hidden in the Fourier domain, the main idea of the short-time Fourier transform (STFT) is to consider only small sections of the signal. These sections are obtained by multiplying shifted versions of a window function with the original signal and by computing a Fourier transform for each of the resulting windowed signals. This results in a sequence of spectral vectors, also called frames. In practice, the correct physical interpretation of discrete objects such as samples, frames, and spectral coefficients can be tricky. Also, there are many different conventions when applying windowing. Figure 3 shows a signal (two subsequent sinusoids of 1 Hz and 5 Hz, respectively) and its STFT. In the FMP notebooks, we explain how to correctly interpret discrete parameters, discuss different windowing conventions (including padding), and show how to correctly visualize feature representations (taking a centric view).

For Western music, one often uses a twelve-tone equal-tempered scale, where the 12 pitch classes correspond to the twelve chroma values $\{\mathrm{C}, \mathrm{C}^\sharp, \mathrm{D}, \mathrm{D}^\sharp, \ldots, \mathrm{B}\}$. Aggregating all spectral information that relates to a given pitch class into a single coefficient, a spectrogram can be transformed in a chromagram, see Figure 4. This example also demonstrates how to generate accurate and visually appealing figures, which can be a tricky and time-consuming effort. In the FMP notebooks, we give numerous examples on how to enhance, place, and align figure elements. In Figure 4, for example, a waveform (given in samples) and a chromagram (given in frames) are visually aligned using a common time axis (given in seconds). Furthermore, using an adapted colormap enhances essential structures in the chromagram. Finally, the size and the placement of the three subplots are controlled using a grid structure.

Such chromagram representations, which particularly capture harmonic and melodic properties of an audio recording, have turned out to be a powerful tool for various MIR tasks. One such task is music synchronization, where the objective is to automatically link different versions of the same piece of music. Figure 5 shows a synchronization result when aligning two different recordings of the be-

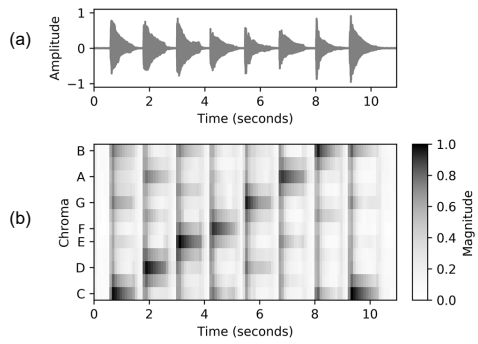

Figure 4. Waveform (a) of a C-major scale and resulting chromagram (b).

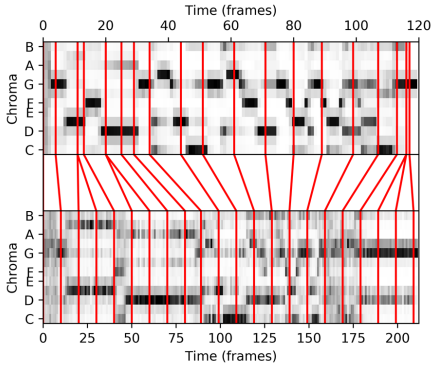

Figure 5. Chromagram representations of two different recordings of the beginning of Beethoven's Fifth Symphony and resulting synchronization result (aligned time positions are indicated by red lines).

ginning of Beethoven's Fifth Symphony. Using a chroma-based alignment procedure based on dynamic time warping as an example approach, the FMP notebooks provide a detailed treatment of music synchronization including a musically informed motivation, algorithmic descriptions, implementation details, graphical representations, and application scenarios.

Chromagrams are also commonly used representations for tasks such as structure analysis and chord recognition. Figure 6 shows the annotated score as well as a chord recognition result obtained from an audio recording of the The Beatles' song "Let It Be." The FMP notebooks not only describe and implement computational approaches, but also discuss the results in a musically informed fashion by looking at real-world music and audio examples. Furthermore, common evaluation measures such as precision, recall, and F-measure are introduced including a discussion of their benefits and limitations within concrete MIR scenarios.

In our final example, we consider a task that is often referred to as harmonic–percussive separation (HPS), where the goal is to decompose a given audio signal into two parts: one consisting of the harmonic and another one of the percussive events of the original signal [4]. Since this task is very instructive from an educational point of view, it was included in the FMP notebooks. First, the task is suited to reflect on acoustic qualities of sound sources, see

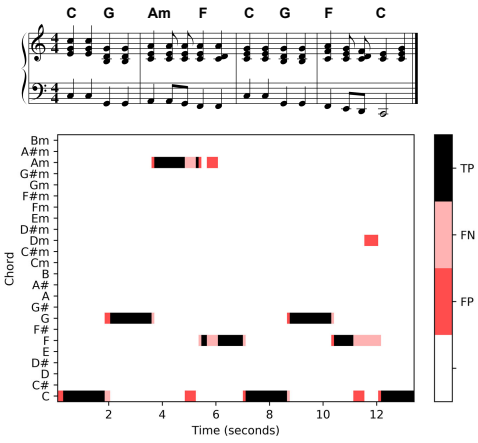

Figure 6. Chord recognition result for the first measures of The Beatles' song "Let It Be."

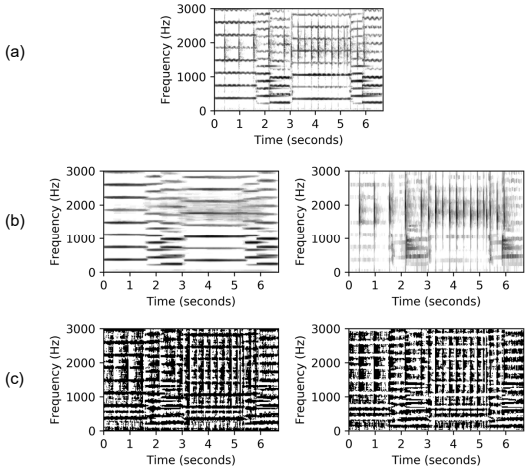

Figure 7. Spectrogram (a) of a recording consisting of violin sounds (harmonic components) superimposed with castanet clicks (percussive components). Furthermore, the figure shows filtered spectrograms (b) and derived binary masks (c).

Figure 7a. Second, the HPS approach discussed involves fundamental (vertical and horizontal) filtering techniques applied to a spectrogram representation, see Figure 7b. Third, it involves spectral masking techniques related to Wiener filtering, see Figure 7c. Finally, one requires signal reconstruction techniques by inverting a modified STFT. The FMP notebooks deal with these central topics using the HPS scenario as motivation and illustration.

5. CONCLUSIONS

The FMP notebooks put together a package for studying central MIR tasks providing detailed explanations, mathematical details, code examples, instructive sound examples, and illustrative figures within a unifying framework. While going hand in hand with existing toolboxes such as `librosa` [12], the FMP notebooks complement existing MIR resources with the aim to bridge the gap between theory and practice and by providing educational material useful for teaching and learning fundamentals of music processing.

ABSTRACT

Sight-reading requires a musician to decode, process, and perform a musical score quasi-instantaneously and without rehearsal. Due to the complexity of this task, it is difficult to assess the proficiency of a sight-reading performance, and it is even more challenging to model its human assessment. This study aims at evaluating and identifying effective features for automatic assessment of sight-reading performance. The evaluated set of features comprises task-specific, hand-crafted, and interpretable features designed to represent various aspect of sight-reading performance covering parameters such as intonation, timing, dynamics, and score continuity. The most relevant features are identified by Principal Component Analysis and forward feature selection. For context, the same features are also applied to the assessment of rehearsed student music performances and compared across different assessment categories. The results show potential of automatic assessment models for sight-reading and the relevancy of different features as well as the contribution of different feature groups to different assessment categories.

1. INTRODUCTION

Sight-reading, also known as *prima vista*, describes the task of reading and performing an unknown piece of music from its musical score with little or no preparation. It is a challenge to most students who are learning a musical instrument.

Sight-reading performance reflects the player's ability in different aspects including reading music, applying fingering and playing techniques, and interpreting music in a relatively short time. As an important skill for musicians, sight-reading is often part of school curricula as well as auditions for professional orchestras [6]. The assessment of sight-reading in auditions and teaching environments faces multiple difficulties. While there are efforts to make human assessments comparable and "less subjective," for example by using grading rubrics, the fairness of the assessment can be impacted by bias effects (gender, ethnicity, general appearance, etc.), fatigue effects after hours of listening and assessing, as well as individual preferences and tolerances for various error types. An automatic assessment system can potentially provide objective, repeatable, and unbiased assessments. Thus, it could be helpful both as a tool available to judges to inform their decisions as well as a tutoring system for students providing feedback in individual practice sessions. It can also help understand the important performance parameters of sight-reading assessment and how they compare to the assessment of general (student) music performances.

In this study, we create a prototype and investigate the feasibility of a sight-reading assessment system by designing interpretable features for the task and evaluating the system on a large database of professionally rated recordings. We also inspect commonalities and differences of feature sets for the assessment of sight-reading vs. prepared performances of sheet music. More specifically, we perform feature selection and detailed feature analysis on a score-aligned hand-crafted feature set, identify the most effective features for sight-reading assessment and observe the difference in the assessment ratings of sight-reading and a rehearsed performance.

The paper is structured as follows: the related work on sight-reading assessment is introduced in Sect. 2 and the evaluated features are presented in Sect. 3. Section 4 explains the experiments and discusses the results of the feature analysis. The final Sect. 5 gives concluding remarks and outlines future work.

2. RELATED WORK

2.1 Sight-reading skills and parameters

Sight-reading involves coordination of auditory, visual, spatial, and kinesthetic systems to produce an accurate and musical performance [11]. In sight-reading exercises, multiple layers of visual information are processed simultaneously when reading the score while playing the instrument. Besson et al. has demonstrated distinct processing between melodic and rhythmic information [2]. This indicates that pitch accuracy and rhythmic accuracy can be treated as two independent assessment categories. Elliott found a strong positive relationship between wind instrumentalists' general sight-reading ability and the ability to sight-read rhythm patterns [5]. This suggests that features containing rhythmic information are important for assessing a sight-

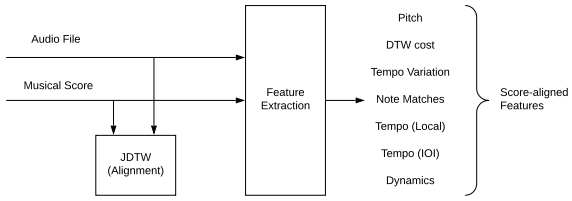

Figure 1. Feature extraction

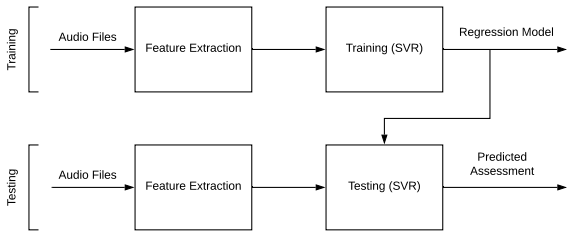

Figure 2. Flow chart of training and testing

reading performance. While intonation, rhythm, and tone quality are typical properties to be assessed, in many cases only an overall rating is given without details on individual properties [1, 4].

2.2 Automatic assessment

There is only a limited number of publications for the automatic assessment of sight-reading. Cheng et al. developed a real-time system for sight-reading evaluation of piano music [4]. The real-time system transcribes the polyphonic music and detects wrong notes. Commercial interest is shown by the existence of systems such as *Sight Reading Practice and Assessment* [1] and *SightReadPlus* [2], which aims at assessing a student playing and tracking the progress of sight-reading.

The automatic assessment of sight-reading has many similarities to the assessment of music performance in general. Therefore, we should expect similar features to be relevant for both tasks and take advantage of the broader spectrum of publications in general performance assessment. Abeßer et al. designed a feature set consisting of 138 features based on the pitch contour of students' vocal and instrumental performances, applied feature selection and used the selected features to train a Support Vector Machine (SVM) [1]. They found that features describing the similarity of score and audio, and the variability of note durations are the most impactful features. Fukuda et al. presented a piano tutoring system which applied non-negative matrix factorization for transcription and DTW for audio-to-score alignment [8]. They basically use, similar to Cheng et al. [4], the number of detected mistakes as core information for performance assessment. Wu et al. proposed assessing a performance independent of the musical score using features based on pitch, amplitude, and rhythm histograms [16]. Vidwans et al. extracted a set of pitch, dynamics, and tempo features after aligning the performance to the score with Dynamic Time Warping (DTW) [15]. Their work is followed by Gururani et al., who investigated the impact of hand-crafted descriptors for the assessment of student alto saxophone technical exercises by feature selection [9]. The results reveal that score-aligned features have a higher correlation with human assessments than score-independent features.

More recently, deep learning methods have been applied to automatic performance assessment [14]. Although deep learning might be a useful tool to achieve better performance for the prediction, the current success of such approaches is often impeded by the available dataset sizes which are often insufficient to train the models properly. A maybe even more important drawback of deep learning is that the interpretability is lost in the hidden layers, so that systems based on deep learning might not be able to give meaningful detailed feedback to a student. This is the main reason why we focus on hand-crafted, knowledge-based features in this study.

3. FEATURE EXTRACTION

3.1 Overview

The flow chart of feature extraction process is shown in Figure 1. [3] Given a recording of a student's sight-reading exercise, the pitch contour is extracted by pYIN [12] from the audio signal (sample rate 44.1 kHz, window and hop size 1024 and 256 samples, respectively). This pitch contour is then aligned to the score of that piece using a modified DTW algorithm which we refer to as Jump-enabled Dynamic Time Warping (JDTW), a DTW variant which can account for repeated score passages. After the alignment, features that capture pitch, rhythmic, and dynamics properties are extracted. The following sections will introduce JDTW, the extracted features, and the inference model.

3.2 Jump-enabled Dynamic Time Warping

Intuitively, we expect the main difference between sight-reading and the performance of a rehearsed piece of music, besides a higher likelihood of errors and more variability in tempo, to be in a higher probability of the student stopping and restarting from a preceding score position after a pause. The frequent occurrence of these jumps has been verified through informal dataset analysis. As standard alignment approaches such as DTW cannot properly handle such jumps, a modification of the DTW algorithm is necessary to properly align the audio sight-reading performance to the score (in our case in MIDI format). Therefore, we propose a Jump-enabled Dynamic Time Warping (JDTW) which is able to handle these repetitions in the students' sight-reading performance. The approach is inspired by Fre-

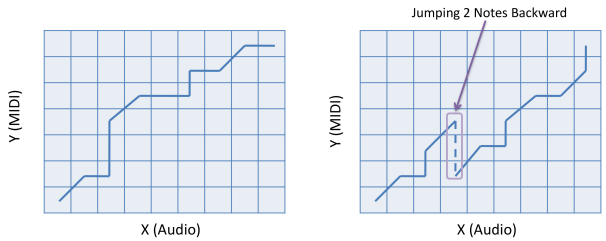

Figure 3. Illustration of paths of index pairs for a sequence X of length N = 9 and a sequence Y of length M = 7. Left: original DTW; Right: JDTW.

merey et al.'s jumpDTW [7] but uses different constraints in terms of potential jump positions and jump lengths.

Dynamic Time Warping (DTW) is a commonly used path finding technique based on dynamic programming to find an optimal alignment between two time series through a pair-wise distance matrix [13]. It has been widely used in speech recognition and musical information retrieval. It only allows sequential alignment, which means that we can neither walk back in a sequence nor jump in time. Given the two sequences $X := (x_1, x_2, ...x_N)$ (audio) of length $N \in \mathbb{N}$ and $Y := (y_1, y_2, ...y_M)$ (midi) of length $M \in \mathbb{N}$, the recursion formula of the accumulated cost matrix D of the classical DTW is as follows:

$$D(n,m) = \min\{D(n-1,m-1), D(n-1,m), D(n,m-1)\} + c(x_n, y_m) \quad (1)$$

for $1 < n \leq N$ and $1 < m \leq M$; $c(x_n, y_m)$ is a measure of distance between x_n and y_m.

The modified accumulated cost matrix D_J for JDTW introduces an additional cost term $J(n,m)$ as follows:

$$D_\text{J}(n,m) = \min\{D_\text{J}(n-1,m-1), D_\text{J}(n-1,m), D_\text{J}(n,m-1), J(n,m)\} + c(x_n, y_m) \quad (2)$$

in which $J(n,m)$ is the minimum accumulated cost for a path jumping to point (n,m):

$$J(n,m) = \begin{cases} \min\limits_{i \leq I}\{D_\text{J}(n-1, m+i) + p\}, & \text{pause before n} \\ \infty, & \text{otherwise} \end{cases} \quad (3)$$

for $1 < n \leq N$ and $1 < m \leq M$, where I is the largest distance in notes allowed for a jump and p is the penalty for jumps. Figure 3 illustrates the paths of the original DTW and the JDTW for an example.

3.2.1 Parametrization and implementation

The adjustment of two JDTW parameters is essential: I, the maximum length of a jump in notes, and p, the penalty of the jump itself. The parametrization with the lowest accumulated cost is found empirically from a simulated validation set of 120 synthesized sound files, leading to the values of $I = 3$ and $p = 3 \cdot \text{mean}(C)$, in which C is the cost matrix between X and Y (meaning that the penalty depends on the average cost).All other DTW-related parametrizations follow standard settings.

Two details are noteworthy in the context of the current implementation: (i) after obtaining the pitch contour from the audio and before computing the alignment, silent frames are temporarily removed from both pitch contour and MIDI sequence, and (ii) the distance between pitch contour x_n and MIDI pitch y_m is computed after tuning frequency adjustment as the octave-independent *wrapped* distance to eliminate pYin's frequent octave errors, however, a small penalty of 1 is added for distances equal or higher than 12 to account for possible octave jumps in the score. After successful application of JDTW, each audio frame is aligned to a note in the MIDI sequence.

Index	Group	Description
1–8	Pitch	Mean and std of pitch dev. (mean, std, max, min)
9–11	DTW cost	Cost of whole path, jumped path and correct path
12–14	Tempo var.	Slope dev., number and distance of jumps
15–16	NIR, NDR	% of silence inserted % of short notes
17–18	Tempo (local)	Inversed tempo per note (mean, std)
19–24	Tempo (IOI)	Crest, bin resolution, skewness, kurtosis, roll-off, power ratio of the IOI histogram
25–32	Dynamics	amplitude envelope and amplitude spikes (mean, std, max, min)

Table 1. Overview of extracted features.

3.3 Feature set

The evaluated feature set can be divided into seven categories: pitch, DTW cost, tempo variation (DTW-based), note matches, tempo (local), tempo (Inter-Onset-Interval-based), and dynamics. Table 1 lists all 32 features explained below with their feature indices.

- **Pitch** ($d = 8$)**:** For each note, the mean and the standard deviation of the pitch deviation from the MIDI pitch is computed. Then, these features are aggregated over the whole performance using mean, standard deviation, maximum, and minimum of each series. The resulting eight features are used to capture intonation accuracy.
- **DTW cost** ($d = 3$)**:** As a result of the alignment, we can compute three cost metrics from the path. The first one is the overall cost of the whole JDTW path. The second cost is the cost of the discarded parts, i.e., the accumulated cost of all the repeated parts except the last run. The third cost is the overall cost of the path ignoring these discarded parts. These three cost features are normalized by the length of the overall

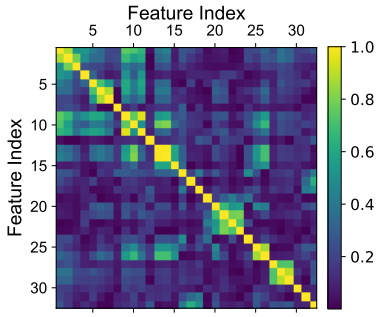

Figure 4. The covariance matrix among features.

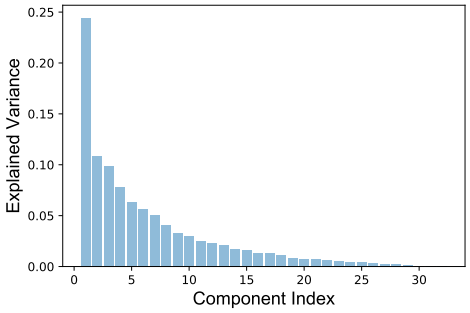

Figure 5. Explained variance for each principle component.

path, and are a measure of pitch similarity between the two sequences.

- **Tempo variation (DTW-based)** ($d = 3$)**:** In addition to the cost-based features, additional features can be extracted from the alignment path. We extract the deviation of the path slope from the diagonal of the matrix, the number of jumps, and the total accumulated distance of jumps.
- **Note matches** ($d = 2$)**:** The Note Insertion Ratio (NIR) is a feature representing additional notes in the student performance, and the Note Deletion Ratio (NDR) represents the missing notes in the performance. As the alignment is performed on pitch contour after removing all the silent frames, these frame have to be inserted back. It is possible that a note is split into multiple notes and that very short (less than 3 frames) notes occur. The NIR is the duration ratio of the inserted silence to the total duration of pitched region. The NDR is the duration ratio of very short notes to the duration of pitched region.
- **Tempo (local)** ($d = 2$)**:** The mean and the standard deviation of the inverse of the tempo per note is an estimate of the overall (inverse) tempo and its variability. For example, an eighth note lasting 1 s results in an inverse local tempo of $\frac{8\,\text{notes}}{1\,\text{s}}$.
- **Tempo (IOI-based)** ($d = 6$)**:** From the histogram of Inter-Onset-Intervals, the crest factor, bin resolution, skewness, kurtosis, roll-off, and the peak power ratio (ratio of the sum of the peak values to the sum of all histogram values) are extracted. These features describe general tempo characteristics.
- **Dynamics** ($d = 8$)**:** For every note, the standard deviation of the envelope as well as amplitude spikes (number of sharp amplitude changes within a note) is computed. Similar to the pitch features, the mean, standard deviation, maximum, and minimum are aggregated over all notes. The resulting eight features are used to capture the dynamic properties of the performance.

4. METHODOLOGY

Our assessment system follows a general machine learning setup as visualized in Figure 2. Our evaluation aims at not only investigating the general feasibility of assessing sight-reading automatically, but also an analysis of which features are most relevant. Furthermore, a general music performance assessment is compared with sight-reading assessment in order to identify similarities and differences between the two tasks.

This section first introduces the dataset used. Then, feature analysis is performed with Principal Component Analysis and forward feature selection. Finally, the performance and features of sight-reading assessment and general music performance assessment is studied.

4.1 Dataset

The dataset used for this study is provided by the Florida Bandmasters Association (FBA). It consists of audio recordings of Florida All-State auditions of middle and high school students in the three years 2013, 2014, and 2015. Each recording consists of exercises such as etudes, scales, and sight reading and provides one expert assessments per exercise in four categories: *musicality*, *note accuracy*, *rhythmic accuracy*, and *tone quality*. For this study we focus on the first three categories. Only a subset of this dataset is used: we are focusing on the sight-reading exercise played by middle school student performers for the instrument Alto Saxophone. The recordings of technical exercise are used to compare sight-reading assessment with the assessment of prepared and rehearsed performances. There are a total of 391 students' audition recordings in the 3 years. Each recording contains technical exercise, sight-reading exercise, and other sections. The total lengths of technical and sight-reading exercise recordings are 192 minutes and 344 minutes, respectively. As the rating scales differ over years and categories (most of the ratings are given within 0–10, others have the ranges 0–5, 0–15, and 0–20), they are all linearly mapped to our target range $[0, 1]$.

The musical score of the sight-reading exercise has been transcribed manually after reviewing multiple highly-rated performances from the three years.

4.2 Principal Component Analysis

Principal Components Analysis is a method to linearly transform a set of possibly correlated variables into a set of uncorrelated variables (components). For the presented analysis, we will use both the covariance matrix of the features and the PCA loading matrix.

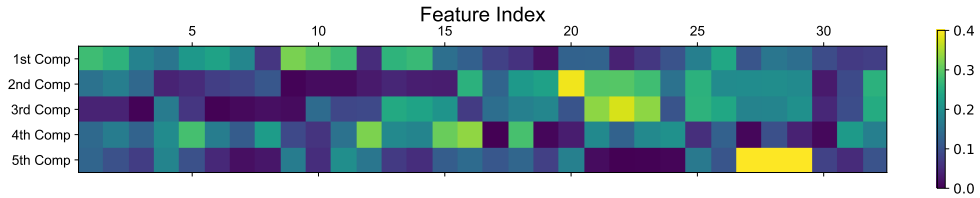

Figure 6. The PCA loading matrix.

The covariance matrix of the features is shown in Figure 4. It can be observed that —unsurprisingly— features are correlated with each other within groups. This is true for pitch features (1–3) and (5–7), DTW cost features (9–11), Tempo variation features (13,14), Tempo (IOI) features (20–23), as well as Dynamics features (25,26) and (27–29). This expected result shows that features within one group carry similar information and verifies that the proposed feature grouping is reasonable.

In addition to high correlation within each feature group, some high correlation is observed across groups. The pitch features (1–7), for instance, are highly correlated with DTW cost features (9–11). This is the case because the DTW-cost features are the accumulated difference between the pitch being played and the reference pitch. The cost of the jumped path (10) is highly correlated with number and distance of jumps (13,14). All of these three features are a measure of the amount of jumps in the performance. The std of the amplitude envelope (26) is also correlated with the jump features. One possible reason for this is that a high number of pauses and jumps might significantly impact the amplitude variation. Other feature correlations are less interpretable; for example, the correlation between min of amplitude spikes (32) and mean of the inverse local tempo (17) is not easily explained.

Figure 5 displays the explained variance by principal components. The eigenvalue of the first component is considerably higher than that of the following components. The first five components explain 60% of the total variance. The loading matrix, shown for these first five components in Figure 6, indicates that the first component is mostly a combination of pitch features (1–7) and the pitch-related DTW cost features (9–11). Both the second and the third component are combinations of rhythmic IOI features with the second focusing on tempo (20) and the third component mostly describing tempo variation (21–23). While the interpretation of the fourth component is difficult, the fifth component clearly represents dynamics (27–29).

4.3 Inference

A SVM Regression model is trained using the extracted features. As a linear kernel gave comparable results to an RBF kernel, the linear kernel was chosen for sake of simplicity. Libsvm [3] is used as implementation.

4.4 Forward Feature Selection

While the PCA gives us insights into feature correlation and which features contribute most to explaining the variance in the feature set, it is of limited use in deciding which features contribute most to the assessment task. In order to identify these, we apply forward feature selection [10]. As this selection approach 'wraps' the target regression algorithm, the selected features will be task-relevant. Forward feature selection is performed on the SVR model with 5-fold cross-validation. The used metric to evaluate success is the R-squared value, which is a common metric for the evaluation of regression systems.

The result of the selection process is a list of features ordered according to their relevance for the task. The indices of the first 10 selected features for each assessment category are listed in Table 2. This table also compares the selected feature sets for sight reading with the sets for a rehearsed student performance. The R-squared results depending on the number of selected features, comparing the sight-reading exercise with the technical exercise, are shown in Figure 7.

4.4.1 Discussion

Figure 7 shows that the R-squared value starts to converge after about 10 iterations of the feature selection. The highest R-squared for musicality and rhythmic accuracy is higher for the practiced performance, while that for note accuracy is higher for sight-reading.

Of the selected features listed in Table 2, two of the dynamics features (25,26) rank high for both practiced performance and sight-reading for all three assessment categories. These two features are the mean and std of the amplitude standard deviation per note. Apparently, the steadiness of loudness plays an important role in assessing the performance.

Looking closer into the Note Accuracy row of Table 2,

Category	Practiced	Sight-reading
Musicality	25,16,21,15,5, 26,11,1,6,18	25,6,32,15,29, 7,26,5,24,23
Note Acc.	9,20,17,3,28, 14,25,21,26,23	26,6,32,15,7, 23,2,9,3,11
Rhythm Acc.	25,21,16,13,26, 18,5,11,2,1	25,6,32,23,15, 29,31,8,20,1

Table 2. The first 10 selected features in forward feature selection. Colors represent different feature groups: **cyan** for pitch, **purple** for DTW cost, **grey** for tempo variance, **apricot** for note matches, **orange** for tempo (local), **pink** for tempo (IOI) and **green** for dynamics.

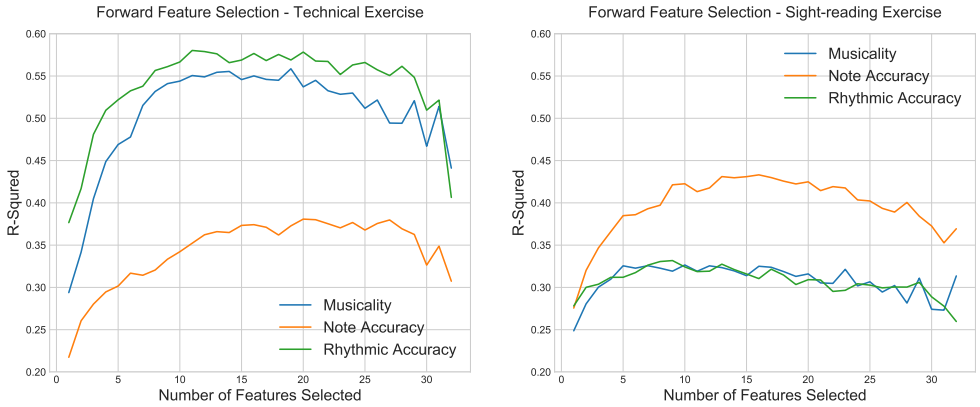

Figure 7. The R-squared curves in feature selection.

we can observe that six of the ten selected features (2,3,6,7,9,11) for sight-reading are features which contribute highly to the first (pitch-related) PCA component. This is not the case for technical exercise, indicating that the pitch features contain more relevant information for sight-reading than for practiced performance. This is also indicated by feature 6 ranking highly in all three assessment categories for sight-reading but not for practiced performance. This feature is one of the aggregated features (standard deviation of absolute differences between played pitch and reference pitch) and is thus a measure of pitch steadiness.

For the assessment categories Musicality and Rhythmic Accuracy, more dynamics features are selected for sight-reading exercise than for the practiced performance. The reason for this might be a different expectation for the two exercises. It might be that, either due to the low complexity of the score or little time for preparation, a dynamically steady performance is preferred by the judges.

During feature selection, the R-squared curve reaches its maximum at about 10–20 iterations and drops dramatically when nearly all the features are selected. This is unexpected behavior for an SVM. A possible reason may be that the dataset is not large enough to train an SVR with all the features or that there might be some 'misleading' features in the feature set.

According to the results above, the automatic assessment of sight-reading is even more challenging than assessing a practiced performance, which performs in the range that we expect (compare [9]) but not so well that it could be considered solved. The higher R-squared for Note Accuracy indicates that our features, especially the intonation features, model this category better for sight-reading than for technical exercise. The low R-squared values for Musicality and Rhythmic Accuracy indicate that we essentially cannot model the human assessments either due to irrelevant features or noisy ground truths. It means that the judges assess the two kinds of exercises differently for these categories and that our regression model fails to capture the information important for sight-reading.

5. CONCLUSION

We presented a feature set of 32 hand-crafted features for the assessment of sight-reading and evaluated them for middle school alto saxophone performances. The feature analysis included PCA and forward feature selection based on the R-squared of the output from an SVR. We can identify the relevant assessment dimensions in the first few principal components and find that the assessment of sight-reading in general is highly influenced by dynamics, and that the assessment of Note Accuracy is mostly focused on pitch-related features. Judging from the absolute results, we can see that the automatic assessment of sight-reading is still an unsolved problem and that the presented features can model a human assessment only imperfectly. In order to be usable in a realistic scenario, we need to either identify additional, more relevant features or move towards state-of-the-art, uninterpretable feature learning solutions. As compared to a practiced and prepared performance, we can identify some commonalities and some differences in the set of relevant features, but the most striking difference is the gap of model performance between assessment categories. Further work is needed to identify where the cause for this gap can be found.

It is likely that rehearsed and sight-reading exercises do not share the same assessment criteria even if the categories are named identically. The performance, as imperfect as it might be, is not assessed by score deviations alone, so that our feature might not represent all critical factors. An additional complication is that in our dataset, we only have the assessment from one judge for each performance. The effect of possible subjectivity and uncertainty makes are complicated task even more challenging. More effort is needed to be able to explain the logic behind the assessment given by judges with quantitative and interpretable indicators before they can be used in music education.

6. ACKNOWLEDGEMENT

We would like to thank the Florida Bandmasters Association (FBA) for providing the dataset used in this work.

SUPERVISED SYMBOLIC MUSIC STYLE TRANSLATION USING SYNTHETIC DATA

Ondřej Cífka **Umut Şimşekli** **Gaël Richard**

{ondrej.cifka, umut.simsekli, gael.richard}@telecom-paris.fr

ABSTRACT

Research on style transfer and domain translation has clearly demonstrated the ability of deep learning-based algorithms to manipulate images in terms of artistic style. More recently, several attempts have been made to extend such approaches to music (both symbolic and audio) in order to enable transforming musical style in a similar manner. In this study, we focus on *symbolic music* with the goal of altering the 'style' of a piece while keeping its original 'content'. As opposed to the current methods, which are inherently restricted to be unsupervised due to the lack of 'aligned' data (i.e. the same musical piece played in multiple styles), we develop the first fully *supervised* algorithm for this task. At the core of our approach lies a *synthetic data* generation scheme which allows us to produce virtually unlimited amounts of aligned data, and hence avoid the above issue. In view of this data generation scheme, we propose an encoder-decoder model for translating symbolic music *accompaniments* between a number of different styles. Our experiments show that our models, although trained entirely on synthetic data, are capable of producing musically meaningful accompaniments even for real (non-synthetic) MIDI recordings.

1. INTRODUCTION

Artistic style transfer has become a well-established topic in the computer vision literature and is becoming of increasing interest in other areas of computer science, especially music and natural language processing. More generally, we are dealing with a family of *style transformation* tasks, where the goal is to alter the *style* of a piece of data (e.g., an image, a musical piece, a document) while preserving – to some extent – its *content*. In the music domain, a solution to these problems would have exciting industrial applications, not only as a way to generate new music automatically (as an alternative to fully automatic music composition, which still seems to be a distant goal), but also as a tool for music creators, allowing them to easily incorporate new styles and ideas into their work.

In computer vision, the most popular task in this direction is *style transfer*, where the algorithm has two inputs: the 'content' image to transform and a 'style' image, bearing the style that we wish to impose on (or *transfer* to) the content image. On the other hand, work done on music so far has mostly focused on a different task, which we refer to as *style translation*. Contrary to style transfer, only the 'content' input is given, and the goal is to render it in a target style which is known in advance and usually *learned* from a large set of examples. Note that although this second task is often also referred to as 'style transfer' in the context of music and text generation, we claim that this conflicts with how the term is traditionally understood [11,13,38], and that the term 'translation' is more appropriate and in line with other prior work [17, 24, 28, 40].

The focus of our work is on the latter task, and more specifically, on *accompaniment style translation* for *symbolic music*. In particular, given a piece of music in a symbolic representation, our goal is to generate a new accompaniment for it in a different arrangement style while preserving the original harmonic structure. Even though our approach is generic, to narrow down our scope, we focus on generating bass and piano tracks.

A major difficulty of the music style translation task is that there are no publicly available 'aligned' or 'parallel' datasets (containing examples of the same music played in different styles). As a result, recent works closely related to ours [4, 5] have adopted unsupervised learning frameworks – variational autoencoders (VAE) [19] and CycleGANs [40] – and applied them to genre-labeled datasets. However, these extensions to symbolic music have not yet permitted to obtain results as compelling as those on images [22, 40], text [20, 39], and music audio [28].

In this study, we adopt a different strategy to overcome the lack of aligned data, which is to *synthesize* it. Synthetic training data has proven useful for music information retrieval tasks such as chord recognition [21] and fundamental frequency estimation [25, 32], and is also popular for tasks like semantic segmentation in computer vision [30, 36]. In our case, synthetic data opens up the possibility for supervised learning techniques known from the machine translation field. Moreover, it allows us to work with fine-grained style labels, as opposed to genre labels, which may be too vague or ambiguous for such purposes.

Our main contributions are as follows:

- We propose a supervised, end-to-end neural model for symbolic music style translation, along with a

training data generation scheme.

- Our model is able to translate into a large number of different styles by conditioning a single decoder on the target style. To our knowledge, this is the first time this technique has been applied to music translation with some success.
- To evaluate the performance of our model, we propose an objective metric of music style similarity.
- We show that an approach to music style translation based entirely on synthetic data is viable and generalizes well to more 'natural' inputs, even in unrelated styles.

We believe that our approach will foster new directions in this line of research; some of these will be briefly discussed in the conclusion. The source code of our system, built using TensorFlow, is available online. [1]

2. RELATED WORK

The work performed so far in the area of music style transformation is relatively small in volume but fairly diverse, since, as noted in [8], the transformations can work with different music representations as well as on different conceptual levels.

To our knowledge, the only work on music style transfer – in the original sense, as discussed in the introduction – has been done on audio. Some approaches [9, 35] combine signal decomposition techniques with *musaicing* [41] (a form of concatenative synthesis). In [14], the authors attempt to transfer 'sound textures' from a recording by means of techniques adapted from image style transfer, but without specific focus on the musical aspects. In both cases, the transformation is largely limited to timbre.

The problem of unsupervised music audio translation is tackled in [28], where the authors train a neural network to translate between a number of domains. For symbolic music, style translation is studied in [4, 5], adapting unsupervised learning techniques from computer vision. A different approach is proposed in [23], consisting in training a model on the target style only and then using pseudo-Gibbs sampling to transform a given piece of music.

Finally, we should mention more 'constrained' problems from the symbolic music domain which can also be framed as style translation tasks, e.g. (re-)harmonization [16,29] and expressive performance generation [12,24,37].

3. SYNTHETIC DATA GENERATION

Since we are in a supervised setting, our approach requires a large amount of *paired* examples where each pair consists of one musical fragment arranged in two different styles. Given that no such dataset is currently available, we created a synthetic one, generated using RealBand from the Band-in-a-Box (BIAB) software package [2].

First, we downloaded chord charts of around 3.5K songs in the BIAB format from a popular online archive [3]. We used BIAB to generate arrangements of these songs in different styles and filtered the resulting MIDI files to keep only those in $\frac{4}{4}$ or $\frac{12}{8}$ time. [2] We then chopped those files into segments of 8 bars, splitting notes that overlap segment boundaries.

We selected a total of 70 styles from the '0 MIDI' and '1 MIDI' style packs included in Band-in-a-Box 2018, representing a wide variety of popular music genres. Each style contains up to 5 accompaniment tracks (drums, bass, piano, guitar, strings). [3] We generated each song in 3 randomly picked styles, providing $2 \times \binom{3}{2} = 6$ training pairs per segment, or around 658K training examples in total. An example of a possible training pair is shown in Fig. 1.

In all experiments, we used 2,809 songs for training, 46 songs as a validation set and 46 songs for evaluation, each in 3 examples in different styles. The song names, along with the styles used for each song, are included in the supplementary material [7].

4. PROPOSED MODEL

We propose an architecture based on RNN encoder-decoder sequence-to-sequence models with attention [1], commonly employed in machine translation and other areas of natural language processing. This choice is motivated by the successes of RNNs on symbolic music generation [10, 15, 33, 34] and by the ability of the attention mechanism to condition the generation on arbitrary input data without a prior alignment.

Our model is designed so that it is capable of translating music between a potentially large number of different styles. This is achieved by conditioning the decoder on the target style. An obvious advantage of this design is efficiency: to translate between n styles, we only need to train a single model, compared to n models (one for each target style; possibly with a shared encoder as in [28]) or even $\Theta(n^2)$ models (one for each pair of styles, e.g. [4,5]). Other implications of this choice are investigated in Section 6.2.

On the other hand, to simplify the task and facilitate evaluation, we train a dedicated model for each target instrument track. Our output representation and decoder architecture are chosen accordingly and would not necessarily be suitable for generating several independent tracks.

Input and output representation. A common choice of representation of symbolic non-monophonic music for neural processing is a piano roll. We use a binary-valued piano roll with 128 pitches and 4 columns per beat (quarter note) to encode our input.

For representing the output (and also as an alternative input representation), we opted for a MIDI-like encoding, which – unlike a piano roll – is straightforward to model using an RNN decoder. Specifically, following [33], we encode the music as a sequence of 3 types of events, each with one integer argument:

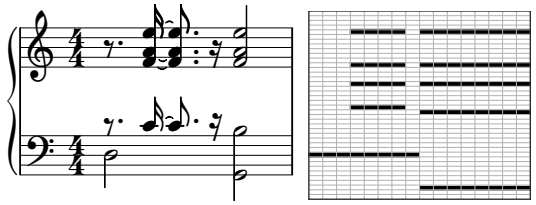
- `NoteOn(`*`pitch`*`)` : start a new note at the given pitch;

[1] `https://git.io/musicstyle`

[2] The time signature depends on the style as well as on the song itself. A song originally in $\frac{4}{4}$ may have a $\frac{12}{8}$ arrangement and vice versa.

[3] These 5 labels are not always accurate; for example, some styles have two guitar tracks, one of which is labeled as piano.

Figure 1: Six bars of an accompaniment (piano and bass) for a 12-bar blues, generated using BIAB in a 'jazz swing' style (top) and a 'samba' style (bottom). The timing is only approximate. The input chord sequence is displayed at the top.



```
NoteOn(50) TimeShift(9) NoteOn(60) NoteOn(65)
NoteOn(69) NoteOn(76) TimeShift(12) NoteOff(60)
NoteOff(65) NoteOff(69) NoteOff(76) TimeShift(3)
NoteOff(50) NoteOn(43) NoteOn(59) NoteOn(65)
NoteOn(69) NoteOn(76) TimeShift(24) NoteOff(All)
```

Figure 2: A bar of music, represented as a piano roll (top right) and as a sequence of 20 event tokens (bottom).

- `NoteOff(pitch)`: end the note at the given pitch;
- `TimeShift(delta)`: move forward in time by the specified amount, measured in 12ths of a beat.

`NoteOn` and `NoteOff` take values in the range 0–127, whereas `TimeShift` is within 1–24.[4] In contrast to [33], our representation is tempo-invariant and we do not model dynamics. Fig. 2 illustrates both representations.

Model architecture and training. The proposed model consists of an encoder and a decoder; the former serves to compute a dense representation of the input, while the latter generates the output event sequence, conditioned on the encoded input and the target style.

The architecture of the encoder depends on the type of input representation:

- If the input is a piano roll, we use a two-layer convolutional network (CNN), followed by a bidirectional RNN with a gated recurrent unit (GRU) [6]. The CNN serves to compress the input, resulting in a sequence of 1280-dimensional vectors with 2 vectors per bar. The bidirectional GRU then adds the ability to incorporate information from a wider context.
- If the input is a sequence of tokens, we use an embedding layer, also followed by a bidirectional GRU.

We refer to the two variants of the model as 'roll2seq' and 'seq2seq', respectively.

The decoder is also implemented using a GRU, conditioned on the target style and equipped with a feed-forward

[4] When encoding the piano track, we compress the sequences by also including a `NoteOff(All)` event which ends all currently active notes.

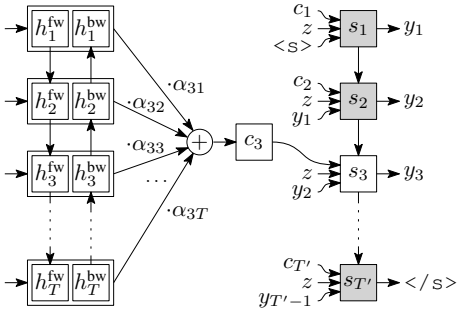


Figure 3: The attention-based decoder. During the i-th decoding step (here $i = 3$), a set of coefficients α_{ij} is computed and used to weight the encoder states $h_j = [h_j^{\text{fw}}, h_j^{\text{bw}}]$ to obtain the context vector c_i, which in turn is used as input for the decoder cell to compute the next state, s_i.

attention mechanism [1] acting on the encoder outputs. More precisely, as illustrated in Fig. 3, the i-th decoder state s_i is computed as

$$s_i = \text{GRU}([c_i, W^{\text{s}}z, W^{\text{e}}y_{i-1}], s_{i-1}),$$

where $[\cdot]$ denotes concatenation, z and y_{i-1} respectively denote the one-hot encoded representations of the target style and the previous output event, $W^{\text{s}}, W^{\text{e}}$ are the corresponding embedding matrices, and c_i is the context vector. The latter is a weighted average of the encoder outputs, computed by the attention mechanism. The purpose of attention is to provide an *alignment* between the encoder and decoder states. The need for this alignment arises from the fact that the positions in the output sequence are not linear in time (due to the chosen encoding), and the decoder therefore needs to be able to move its focus flexibly over the input. For a complete description of attention, see [1].

The training pipeline is portrayed in Fig. 4b. Each training example consists of a song segment x in one style (the source style) along with the corresponding segment y in a different style (z, the target style). We train the model by minimizing the loss on y while passing x to the encoder and conditioning the decoder on z.

The models are trained using Adam [18] with learning rate decay and with early stopping on the development set. Our configuration files with complete hyperparameter set-

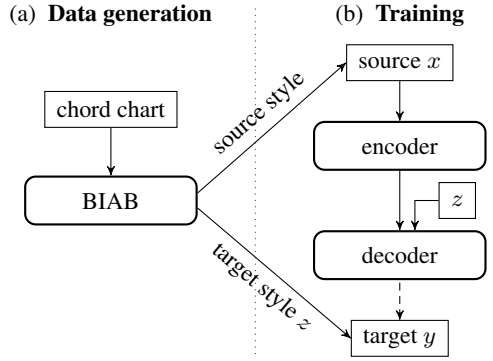

Figure 4: A scheme of the training pipeline. (a) We use BIAB to generate each song in different arrangement styles (see Section 3). (b) The model is trained to predict the target-style segment y given a source segment x and the target style z (see Section 4).

tings are included with the source code.

Once the model is trained, we perform style translation using greedy decoding, i.e. by taking the most likely output token at every step (and using that as input in the next step). We also explored random sampling with different softmax temperatures, but found that this leads to a higher number of errors (i.e. invalid sequences or incorrect timing) and does not significantly improve the quality of the outputs.

5. EVALUATION METRICS

When evaluating a style transformation, we need to consider two complementary criteria: how well the transformed music fits the desired style (*style fit*) and how much content it retains from the original (*content preservation*). Note that it is trivial (but useless) to achieve perfect results on either of these two criteria *alone*, so it is essential to evaluate both of them.

In this section, we describe 'objective', automatically computed metrics for both criteria. Even though we believe these metrics are sound and well-motivated, we acknowledge the limitations of automatic metrics in general and encourage the reader to listen to the provided example outputs [7] to get a real sense of their quality.

Content preservation. We use a content preservation metric similar to the one proposed by [23], computed by correlating the chroma representation of the generated segment with that of the corresponding segment in the source style. This is motivated by the fact that we expect the output to follow the same sequence of chords as the input. More precisely, we compute chroma features for each segment at a rate of 12 frames per beat and smooth each of them using an averaging filter with a window size of 2 beats (24 frames) and a stride of 1 beat (12 frames). Finally, we calculate the average frame-wise cosine similarity between the two sets of chroma features.

Style fit. In some of the recent music style transformation works [4,5], the quality of a transformation is measured by means of a binary style classifier trained on a pair of styles. However, the merit of such evaluation is limited, since a high classifier score merely demonstrates that the output has some of the distinguishing features of the target style, and not necessarily that it actually fits the style. For this reason, we aim for a more interpretable metric of style fit.

As observed by [16, 26, 31], musical style is well captured in pairwise statistics between neighboring events. Drawing inspiration from the features proposed in [26], we devise a key- and time-invariant style representation which we call the *style profile*.

To compute the style profile, we consider all pairs of note onsets less than 4 beats apart and at most 20 semitones apart, and record the time difference and interval for each pair. In other words, we define the following multiset of ordered pairs:

$$\mathcal{S} = \{(t_b - t_a,\ p_b - p_a) \,|\, a, b \in \text{notes},\ a \neq b,\\ 0 \leq t_b - t_a < 4,\ |p_b - p_a| \leq 20\},$$

where t_x is the onset time of the note x (measured in fractional beats) and p_x is its MIDI note number. We then obtain the style profile as a normalized 2D histogram of $\mathcal{S}$ with 6 bins per beat and one bin per semitone, and flatten it to get a 984-dimensional vector.

Finally, to quantify the style fit of a particular set of outputs, we compute their style profile and measure its cosine similarity to a reference profile. Note that an 8-bar segment may not be sufficient to obtain a reliable style profile; instead, we always aggregate the statistics over a number of segments. In particular, we put forward two variants of the style fit metric, obtained as follows:

(a) Compute a style profile aggregated over all outputs of a model in a given target style and measure its cosine similarity to the reference.

(b) Compute a style profile for each translated song separately and measure its cosine similarity to the reference. We report the mean and standard deviation over all songs.

We refer to (a) and (b) as 'macro-style' and 'song-style', respectively. In both cases, the reference style profile is extracted from the training set, separately for each track.

While we do not claim that this metric is able to distinguish between broad style categories (such as genres), yet it can definitely capture the differences and similarities between specific 'grooves', which makes it well-suited for our purpose. This is illustrated in Fig. 5, showing the pairwise similarities between the profiles of the bass tracks of different BIAB styles, with clearly visible clusters of jazz, rock or country styles.

6. EXPERIMENTAL RESULTS

In our experiments, we focus on generating the bass and piano tracks, and we train a dedicated model for each of them. For each track, we consider two scenarios: generating the track given only the corresponding source track (BASS→BASS, PIANO→PIANO), and using all non-drum accompaniment tracks from the input (ALL→BASS, ALL→PIANO).

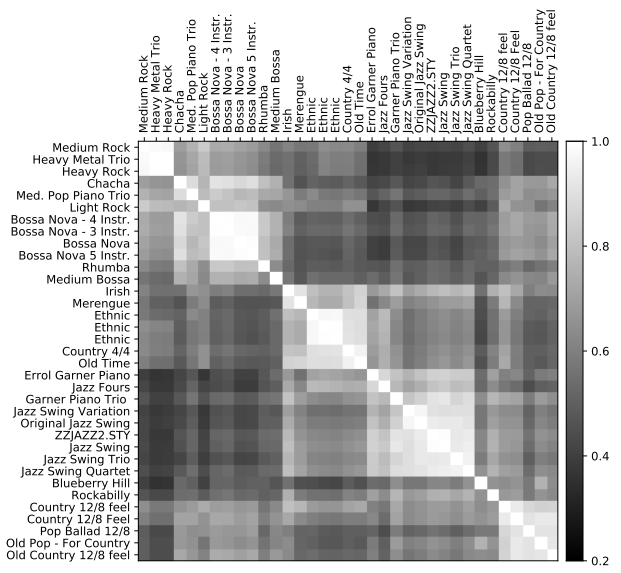

Figure 5: Pairwise cosine similarities of selected style profiles computed on training bass tracks. The styles are ordered based on a hierarchical clustering of the profiles.

For BASS→BASS, we compare the seq2seq and roll2seq architectures defined in Section 4. For all other pairs, where the input is non-monophonic, we only employ roll2seq, since the sequential representation grows disproportionately in length in these cases and the computational cost of the attention mechanism becomes too heavy.

We evaluate our models on our synthetic test set generated by BIAB and on the Bodhidharma MIDI dataset [27]. The latter is a diverse collection of 950 MIDI recordings annotated with genre labels. We filtered and pre-processed the dataset in the same way as the synthetic test set and we extracted the bass and piano tracks. [5]

We also made extensive attempts to train the recent models of [4, 5, 23] on our data using the source code published by the authors, but unfortunately without success. This has prevented us from comparing these models with our proposal. Nonetheless, the provided outputs [7] can serve as a basis for perceptual comparison.

6.1 Evaluation

For a comprehensive evaluation of each model, we translated all inputs to all 70 styles and calculated the content preservation and style fit metrics. The results (averaged) are presented in Fig. 6.

We provide two baselines for each track (bass and piano): 'source', which is simply the same track before the translation, and 'reference', which is a track generated by BIAB based on the chord chart (only available for the synthetic test set). As expected, the style fit is low for the source track (measured with respect to the target style) and close to 1 for the reference track. Our models' outputs generally do not fit the target style as perfectly as the reference does, but still score high compared to the source.

[5] To form the bass track, we retrieve all notes assigned to any Bass instrument. For the piano track, we use the Piano and Organ classes.

As for content preservation, we can notice that the reference value is quite low (0.78 for BASS and 0.79 for PIANO). This should not be too surprising, since we are comparing accompaniments in two different styles, which might have different pitch-class distributions; moreover, there is some random harmonic variation within each style (see e.g. bars 5–6 in Fig. 1). The results achieved by our models on the synthetic test set are very close to the reference. To illustrate the value range of the metric, we provide the results obtained by a 'randomized' baseline (shown as 'random' in Fig. 6), where we randomly permuted the reference segments for each style (obtaining a reference with the correct style, but the wrong content). The resulting value is very low (0.16 for BASS and 0.31 for PIANO) compared both to the true reference and to our models, indicating that the metric is useful and the models are performing well.

On Bodhidharma, content preservation is generally weaker than on the synthetic test set. One interpretation can be that the encoder simply fails to extract the content information accurately, since it was trained on a different domain. However, we also find that the models often make timing errors on Bodhidharma inputs, leading to misalignment between the input and the output, which may also cause the content preservation metric to drop.

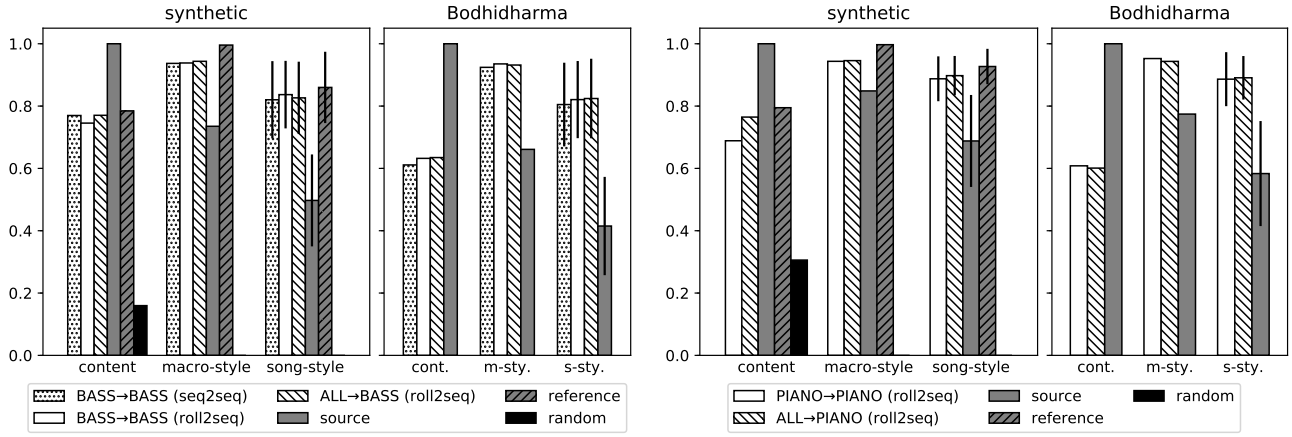
On the other hand, the style fit on Bodhidharma is close to the results on the synthetic test set (and not consistently lower or higher), and the difference to 'source' (i.e. the corresponding input track) is more marked, perhaps reflecting a higher style variability in the Bodhidharma data.

Upon listening, we clearly observe that the outputs are musical and seem to both fit the target style and follow the harmonic structure of the inputs. Besides, even though the piano and the bass tracks are generated independently, they sound surprisingly coherent. However, as mentioned above, we also observe occasional timing errors (especially in heavily syncopated grooves), which become more prominent when the bass and piano tracks are combined. A potential remedy for this issue would be to modify the encoding to make it more robust, e.g. by representing the timing in a beat-aware manner.

We also note that the single-track models output harmonically incorrect notes more often than the ALL models; this is expected, since their *input* is less harmonically rich. This effect is clearly audible (especially in BASS, where important scale degrees are often missing in the input), but cannot be captured by the content preservation metric, which is computed against the same input.

6.2 Comparison with a single-pair model

All models presented so far were trained on music in 70 different styles, as opposed to a single style pair. To investigate the effect of this choice, we picked a pair of fairly dissimilar styles – ZZJAZZSW ('Jazz Swing Variation') and TWIST ('Twist Style', categorized as 'Lite Pop') – and generated a new training, validation and test set with each song rendered in these two styles only. To increase the amount of data, we performed this twice for each song (with different results), obtaining $2 \times 2 = 4$ training pairs



(a) BASS (b) PIANO

Figure 6: Evaluation results on content preservation and style fit. 'Source' is the original track (bass or piano), 'reference' is a track generated by BIAB in the target style and 'random' is a random permutation of the references. For 'song-style', we plot the mean and the standard deviation over all songs and target styles.

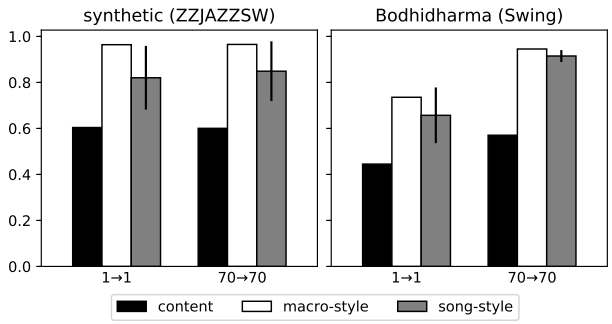


Figure 7: Comparison of a single-style-pair model (1→1) and a full model (70→70) on the ZZJAZZSW→TWIST style pair.

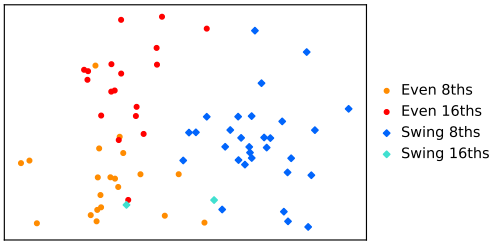

Figure 8: Style embeddings learned by the ALL→PIANO model, labeled with 'feel' annotations provided by BIAB. Dimensionality reduction was performed using linear discriminant analysis (LDA) with the feel labels as targets.

per segment.

We used this new dataset to train single-style-pair versions of all models (in the ZZJAZZSW→TWIST direction only), preserving the original architectures except for the conditioning on the target style. We compare these '1→1' models to the full versions (70→70) on two sets of inputs:

- the synthetic test set in the ZZJAZZSW style;
- the 'Swing' section of Bodhidharma (23 songs).

In Fig. 7, we show the results for the two variants of the ALL→BASS model. While the performance on the synthetic data seems to be the same, the scores of the 1→1 model drop considerably on the Bodhidharma data, suggesting that the model is overfitted to the 'synthetic' swing style. On the other hand, the performance of the 70→70 model stays high, showing that training on many different styles helped the model generalize to real swing.

6.3 Style embedding analysis

Neural representation spaces are often found to exhibit a meaningful geometry, and our learned style embedding space is no exception. As an example, Fig. 8 shows a projection of the embeddings labeled by the 'feel' of each style, with 'even' and 'swing' feel styles being clearly separated. We include more plots in the supplementary material and also make available an interactive visualization. [6]

7. CONCLUSION

In this study, we focused on symbolic music accompaniment style translation. As opposed to the current methods, which are inherently restricted to be unsupervised due to the lack of aligned datasets, we developed the first fully supervised algorithm for this task, leveraging the power of synthetic training data. Our experiments show that our models are capable of producing musically meaningful accompaniments even for real MIDI recordings.

We believe that these results point to interesting research directions. First, synthetic data seem to be an excellent resource for music style translation, and could be used as a starting point even for unsupervised learning, allowing to validate a given approach before moving on to more challenging, unaligned datasets. Second, our supervised approach could be used to address more general music transformation tasks, and we are already working on an extension in this direction.

ABSTRACT

Analogy-making is a key method for computer algorithms to generate both natural and creative music pieces. In general, an analogy is made by partially transferring the music abstractions, i.e., high-level representations and their relationships, from one piece to another; however, this procedure requires *disentangling* music representations, which usually takes little effort for musicians but is non-trivial for computers. Three sub-problems arise: extracting latent representations from the observation, disentangling the representations so that each part has a unique semantic interpretation, and mapping the latent representations back to actual music. In this paper, we contribute an explicitly-constrained variational autoencoder (EC^2-VAE) as a unified solution to all three sub-problems. We focus on disentangling the *pitch* and *rhythm* representations of 8-beat music clips conditioned on chords. In producing music analogies, this model helps us to realize the imaginary situation of "*what if*" a piece is composed using a different pitch contour, rhythm pattern, or chord progression by borrowing the representations from other pieces. Finally, we validate the proposed disentanglement method using objective measurements and evaluate the analogy examples by a subjective study.

1 Introduction

For intelligent systems, an effective way to generate high-quality art is to produce analogous versions of existing examples [15]. In general, two systems are analogous if they share common abstractions, i.e., high-level representations and their relationships, which can be revealed by the paired tuples *A : B :: C : D* (often spoken as A is to B as C is to D). For example, the analogy "the hydrogen atom is like our solar system" can be formatted as *Nucleus : Hydrogen atom :: Sun : Solar system*, in which the shared abstraction is "a bigger part is the center of the whole system." For generative algorithms, a clever shortcut is to make analogies by solving the problem of "*A : B :: C : ?*". In the context of music generation, if A is the rhythm pattern of a very lyrical piece B, this analogy can help us realize the imaginary situation of "what if B is composed with a rather rapid and syncopated rhythm C" by preserving the pitch contours and the intrinsic relationship between pitch and rhythm. In the same fashion, other types of "what if" compositions can be created by simply substituting A and C with different aspects of music (e.g., chords, melody, etc.).

A great advantage of *generation via analogy* is the ability to produce both *natural* and *creative* results. Naturalness is achieved by reusing the representations (high-level concepts such as "image style" and "music pitch contour") of human-made examples and the intrinsic relationship between the concepts, while creativity is achieved by recombining the representations in a novel way. However, making meaningful analogies also requires *disentangling* the representations, which is effortless for humans but non-trivial for computers. We already see that making analogies is essentially transferring the abstractions, not the observations — simply copying the notes or samples from one piece to another would only produce a casual re-mix, not an analogous composition [11].

In this paper, we contribute an explicitly-constrained conditional variational autoencoder (EC^2-VAE), a conditional VAE with explicit semantic constraints on intermediate outputs of the network, as an effective tool for learning disentanglement. To be specific, the encoder extracts latent representations from the observations; the semantic constraints disentangle the representations so that each part has a unique interpretation, and the decoder maps the disentangled representations back to actual music while preserving the intrinsic relationship between the representations. In producing analogies, we focus on disentangling and transferring the *pitch* and *rhythm* representations of 8-beat music clips when chords are given as the condition (an extra input) of the model. We show that EC^2-VAE has three desired properties as a generative model. First, the disentanglement is *explicitly coded*, i.e., we can specify which latent dimensions denote which semantic factors in the model structure. Second, the disentanglement does not sacrifice much of the reconstruction. Third, the learning does not require any analogous examples in the training phase, but the model is capable of making analogies in the inference phase. For evaluation, we propose a new metric and conduct a survey. Both objective and subjective evaluations show that our model significantly outperforms the baselines.

2 Related Work

2.1 Generation Via Analogy

The history of generation via analogy can trace back to the studies of non-parametric "image analogies" [15] and "playing Mozart by analogy" using case-based reasoning [29]. With recent breakthroughs in artificial neural networks, we see a leap in the quality of produced analogous examples using deep generative models, including music and image style transfer [7, 13], image-to-image translation [18], attribute arithmetic [3], and voice impersonation [12].

Here, we distinguish between two types of analogy algorithms. In a *broad* sense, an analogy algorithm is any computational method capable of producing analogous versions of existing examples. A common and relatively easy approach is supervised learning, i.e., to directly learn the mapping between analogous items from labeled examples [18, 27]. This approach requires little representation learning but needs a lot of labeling effort. Moreover, supervised analogy does not generalize well. For example, if the training analogous examples are all between lyrical melodies (the source domain) and syncopated melodies (the target domain), it would be difficult to create other rhythmic patterns, much less the manipulation of pitch contours. (Though improvements [1, 21, 32] have been made, weak supervision is still needed to specify the source and target domains.) On the other hand, a *strict* analogy algorithm requires not only learning the representations but also disentangling them, which would allow the model to make domain-free analogies via the manipulation of any disentangled representations. Our approach belongs to this type.

2.2 Representation Learning and Disentanglement

Variational auto-encoders (VAEs) [22] and generative adversarial networks (GANs) [14] are so far the two most popular frameworks for music representation learning. Both use encoders (or discriminators) and decoders (or generators) to build a bi-directional mapping between the distributions of observation x and latent representation z, and both generate new data via sampling from $p(z)$. For music representations, VAEs [2,9,24,30] have been a more successful tool so far compared with GANs [31], and our model is based on the previous study [30].

The motivation of representation disentanglement is to better interpret the latent space generated by VAE, connecting certain parts of z to semantic factors (e.g., age for face images, or rhythm for melody), which would enable a more controllable and interactive generation process. InfoGAN [5] disentangles z by encouraging the mutual information between x and a subset of z. β-VAE [16] and its follow-up studies [4,20,30] imposed various extra constraints and properties on $p(z)$. However, the disentanglement above are still *implicit*, i.e., though the model separates the latent space into subparts, we cannot define their meanings beforehand and have to "check it out" via *latent space traversal* [3]. In contrast, the disentanglement in Style-based GAN [19], Disentangled Sequential Autoencoder [23], and our EC^2-VAE are *explicit*, i.e., the meanings of different parts of z are defined by the model structure, so that the controlled generation is more precise and straightforward. The study Disentangled Sequential Autoencoder [23] is most related to our work and also deals with sequential inputs. Using a partially time-invariant encoder, it can approximately disentangle dynamic and static representations. Our model does not directly constrain z but applies a loss to intermediate outputs associated with latent factors. Such an indirect but explicit constraint enables the model to further disentangle the representation into pitch, rhythm, and any semantic factors whose observation loss can be defined. As far as we know, this is the first disentanglement learning method tailored for music composition.

3 Methodology

In this section, we introduce the data representation and model design in detail. We focus on disentangling the latent representations of pitch and rhythm, the two fundamental aspects of composition, over the duration of 8-beat melodies. All data come from the Nottingham dataset [10], regarding a $\frac{1}{4}$ beat as the shortest unit.

3.1 Data Representation

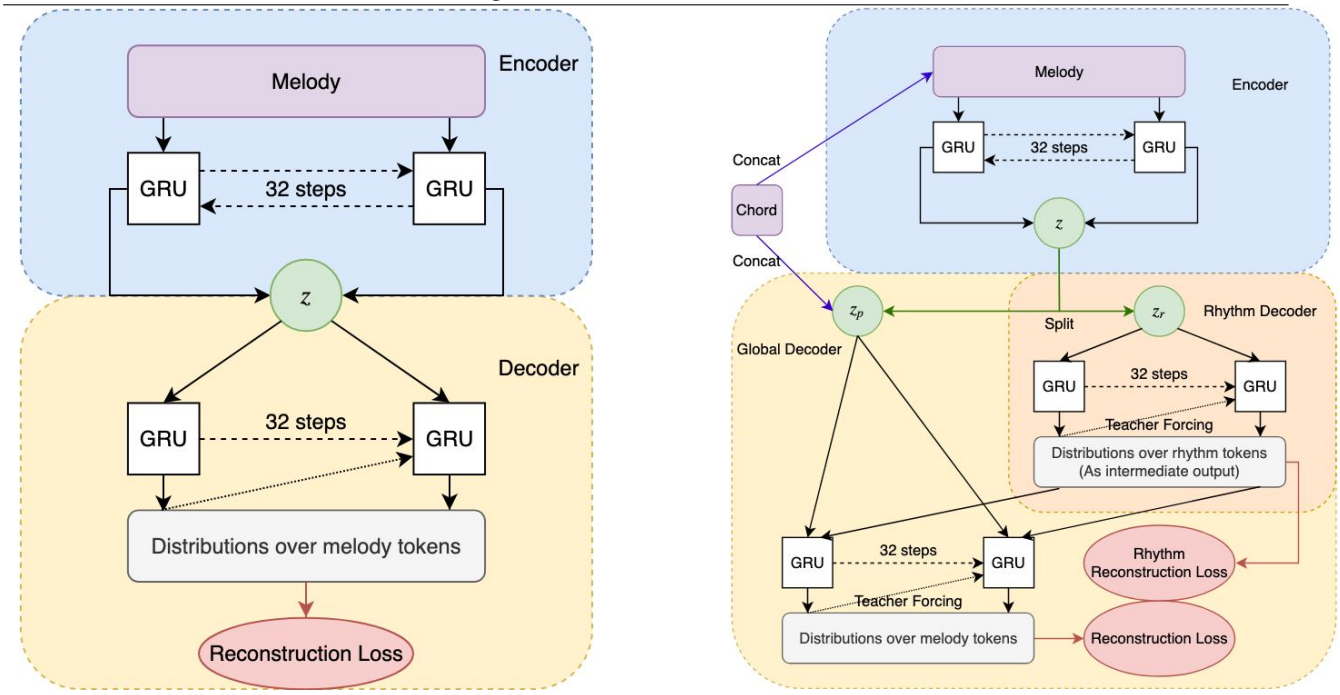
Each 8-beat melody is represented as a sequence of 32 one-hot vectors each with 130 dimensions, where each vector denotes a $\frac{1}{4}$-beat unit. As in [24], the first 128 dimensions denote the *onsets* of MIDI pitches ranging from 0 to 127 with one unit of duration. The 129^{th} dimension is the *holding* state for longer note duration, and the last dimension denotes *rest*. We also designed a rhythm feature to constrain the intermediate output of the network. Each 8-beat rhythm pattern is also represented as a sequence of 32 one-hot vectors. Each vector has 3 dimensions, denoting: an onset of any pitch, a holding state, and rest.

Besides, chords are given as a condition, i.e., an extra input, of the model. The chord condition of each 8-beat melody is represented as a chromagram with equal length, i.e., 32 multi-hot vectors each with 12 dimensions, where each dimension indicates whether a pitch class is activated.

3.2 Model Architecture

Our model design is based on the previous studies of [24, 30], both of which used VAEs to learn the representations of fixed-length melodies. Figure 1 shows a comparison between the model architectures, where Figure 1(a) shows the model designed in [30] and Figure 1(b) shows the model design in this study. We see that both use bi-directional GRUs [6] (or LSTMs [17]) as the encoders (in blue) to map each melody observation to a latent representation z, and both use uni-directional GRUs(LSTMs) (with teacher forcing [26] in the training phrase) as the decoders (in yellow) to reconstruct melodies from z.

The key innovation of our model design is to assign a part of the decoder (in orange) with a specific subtask: to disentangle the latent rhythm representation z_r from the overall z by explicitly encouraging the intermediate output of z_r to match the rhythm feature of the melody. The other



(a) Vanilla sequence VAE.

(b) EC^2-VAE model.

Figure 1: A comparison between vanilla sequence VAE [30] and our model with condition and disentanglement.

part of z is therefore everything but rhythm and interpreted as the latent pitch representation, z_p. Note that this explicitly coded disentanglement technique is quite flexible — *we can use multiple subparts of the decoder to disentangle multiple semantically interpretable factors of z simultaneously* as long as the intermediate outputs of the corresponding latent factors can be defined, and the model shown in Figure 1(b) is the simplest case of this family.

It is also worth noting that the new model uses chords as a condition for both the encoder and decoder. The advantage of chord conditioning is to free z from storing chord-related information. In other words, the pitch information in z is "detrended" by the underlying chord for better encoding and reconstruction. The cost of this design is that we cannot learn a latent distribution of chord progressions.

3.2.1 *Encoder*

A single layer bi-directional GRU with 32 time steps is used to model $Q_\theta(z|x,c)$, where x is the melody input, c is the chord condition, and z is the latent representation. Chord conditions are given by concatenating with the input at each time step.

3.2.2 *Decoder*

The global decoder models $P_\phi(x|z,c)$ by multiple layers of GRUs, each with 32 steps. For disentanglement, we split the latent representation z into two halves z_p and z_r, each being a 128-dimensional vector. As a subpart of the global decoder, the rhythm decoder models $P_{\phi_r}(r(x)|z)$ by a single layer GRU, where $r(x)$ is the rhythm feature of the melody. Meanwhile, the rhythm is concatenated with z_p and chord condition as the input of the rest of the global decoder to reconstruct the melody. We used cross-entropy loss for both rhythm and melody reconstruction. Note that the overall decoder is supposed to learn non-trivial relationships between pitch and rhythm, rather than naively cutting a pitch contour by a rhythm pattern.

3.3 Theoretical Justification of the ELBO Objective with Disentanglement

One concern about representation disentanglement techniques is that they sometimes sacrifice reconstruction power [20]. In this section, we prove that our model does not suffer much of the disentanglement-reconstruction paradox, and the likelihood bound of our model is close to that of the original conditional VAE, and in some cases, equal to it.

Recall the Evidence Lower Bound (ELBO) objective function used by a typical conditional VAE [8] constraint on input sample x with condition c:

$$\begin{aligned}\text{ELBO}(\phi,\theta) &= \mathbb{E}_Q[\log P_\phi(x|z,c)] \\ &\quad - \mathbb{KL}[Q_\theta(z|x,c)||P_\phi(z|c)] \leq \log P_\phi(x|c)\end{aligned}$$

For simplicity, $\mathcal{D}$ denotes $\mathbb{KL}[Q_\theta(z|x,c)||P_\phi(z|c)]$ in the rest of this section. If we see the intermediate rhythm output in Figure 1(b) as hidden variables of the whole network, the new ELBO objective of our model only adds the rhythm reconstruction loss based on the original one, resulting in a lower bound of the original ELBO. Formally,

$$\begin{aligned}&\text{ELBO}^{\text{new}}(\phi,\theta) \\ &= \mathbb{E}_Q[\log P_\phi(x|z,c)] - \mathcal{D} + \mathbb{E}_Q[\log P_{\phi_r}(r(x)|z_r)] \\ &= \text{ELBO}(\phi,\theta) + \mathbb{E}_Q[\log P_{\phi_r}(r(x)|z_r)]\end{aligned}$$

where ϕ_r denotes parameters of the rhythm decoder. Clearly, ELBO$^{\text{new}}$ is a lower bound of the original ELBO because $\mathbb{E}_Q[\log P_{\phi_r}(r(x)|z_r)] \leq 0$.

Moreover, if the rest of global decoder takes the original rhythm rather than the intermediate output of rhythm decoder as the input, the objective can be rewritten as:

$$\begin{aligned}
&\text{ELBO}^{\text{new}}(\phi,\theta)\\
&=\mathbb{E}_Q[\underbrace{\log P_\phi(x|r(x),z_p,c)+\log P_\phi(r(x)|z_r,c)}_{\text{with } x \perp\!\!\!\perp z_r|r(x),c \text{ and } r(x)\perp\!\!\!\perp z_p}]-\mathcal{D}\\
&=\mathbb{E}_Q[\log P_\phi(x,r(x)|z,c)]-\mathcal{D}\\
&=\mathbb{E}_Q[P_\phi(x|z,c)+\log P_\phi(r(x)|x,z,c)]-\mathcal{D}\\
&=\text{ELBO}(\phi,\theta)
\end{aligned}$$

The second equal sign holds for a perfect disentanglement, and the last equal sign holds since $r(x)$ is decided by x, i.e., $P_\phi(r(x)|x,z,c)=1$. In other words, we show that under certain assumptions ELBO$^{\text{new}}$ with disentanglement is identical to the ELBO.

4 Experiments

We present the objective metrics to evaluate the disentanglement in Section 4.1, show several representative examples of generation via analogy in Section 4.2, and use subjective evaluations to rate the artistic aspects of the generated music in Section 4.3.

4.1 Objective Measurements

Upon a successful pitch-rhythm disentanglement, any changes in pitch of the original melody should not affect the latent rhythm representation much, and vice versa. Following this assumption, we developed two measurements to evaluate the disentanglement: 1) Δz after transposition, which is more qualitative, and 2) F-score of an augmentation-based query, which is more quantitative.

4.1.1 Visualizing Δz after transposition

We define F_i as the operation of transposing all the notes by i semitones, and use the L_1-norm to measure the change in z. Figure 2 shows a comparison between $\Sigma|\Delta z_p|$ and $\Sigma|\Delta z_r|$ when we apply F_i to a randomly chosen piece (where $i \in [1,12]$) while keeping the rhythm and underlying chord unchanged.

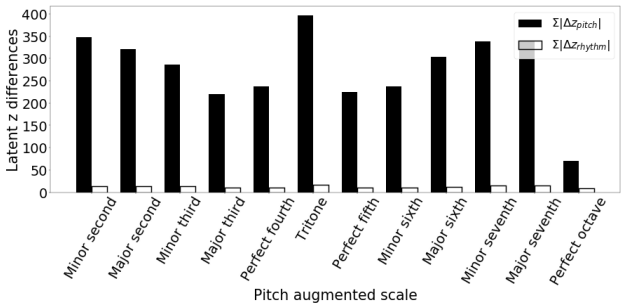


Figure 2: A comparison between Δz_p and Δz_r after transposition.

Here, the black bars stand for $\Sigma|\Delta z_p|$ and the white bars stand for the $\Sigma|\Delta z_r|$. It is conspicuous that when augmenting pitch, the change of z_p is much larger than the change of z_r, which well demonstrates the success of the disentanglement.

It is also worth noting that the change of z_p to a certain extent *reflects human pitch perception*. Given a chord, the change in z_p can be understood as the "burden" (or difficulty) to memorize (or encode) a transposed melody. We see that such burden is large for tritone (very dissonant), relatively small for major third, perfect fourth & fifth (consonant), and very small for perfect octave.

Due to the space limit, we only show the visualization of the latent space when changing the pitch. According to the data representation in Section 3.1, changing the rhythm feature of a melody would inevitably affect the pitch contour, which would lead to complex behavior of the latent space hard to interpret visually. We leave the discussion for future work but will pay more attention to the effect of the rhythm factor in Section 4.3.

4.1.2 F-score of Augmentation-based Query

The explicitly coded disentanglement enables a new evaluation method from an *information-retrieval* perspective. We regard the pitch-rhythm split in z defined by the model structure as the *reference* (the ground truth), the operation of factor-wise data augmentation (keeping the rhythm and only changing pitch randomly, or vice versa) as a *query* in the latent space, and the actual latent dimensions having the largest variance caused by augmentation as the *result set*. In this way, we can quantitatively evaluate our model in terms of precision, recall, and F-score.

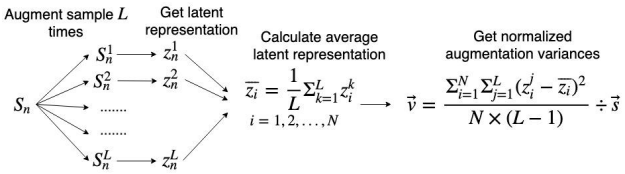

Figure 3: Evaluating the disentanglement by data augmentation.

	Pitch			Rhythm		
	pre.	rec.	F-s.	pre.	rec.	F-s.
EC^2-VAE	**0.88**	**0.88**	**0.88**	**0.80**	**0.80**	**0.80**
Random	0.5	0.5	0.5	0.5	0.5	0.5

Table 1: The evaluation results of pitch- and rhythm-wise augmentation-based query.

Figure 3 shows the detailed query procedure, which is a modification of the evaluation method in [20]. After pitch or rhythm augmentation for each sample, $\vec{v}$ is calculated as the average (across the samples) variance (across augmented versions) of the latent representations, normalized by the total sample variance $\vec{s}$. Then, we choose the first half (128 dimensions) with the largest variances as the result set. This precision, recall and F-score of this augmentation-based query result is shown in Table 1. (Here, precision and recall are identical since the size of the result set equals the dimensionality of z_p and z_r.) As this is the first tailored metric for explicitly coded disentanglement, we use random guess as our baseline.

4.2 Examples of Generation via Analogy

We present several representative "what if" examples by swapping or interpolating the latent representations of different pieces. Throughout this section, we use the following example (shown in Figure 4), an 8-beat melody from the Nottingham Dataset [10] as the source, and the target rhythm or pitch will be borrowed from other pieces. (MIDI demos are available at `https://github.com/cdyrhjohn/Deep-Music-Analogy-Demos`.)

Figure 4: The source melody.

4.2.1 Analogy by replacing z_p

Two examples are presented. In both cases, the latent pitch representation and the chord condition of the source melody are replaced with new ones from other pieces. In other words, the model answers the analogy question: *"source's pitch : source melody :: target's pitch : ?"*

Figure 5 shows the first example, where Figure 5(a) shows the piece from which the pitch and chords are borrowed, and Figure 5(b) shows the generated melody. From Figure 5(a), we see the target melody is in a different key (D major) with a larger pitch range than the source and a big pitch jump in the beginning. From Figure 5(b), we see the generated new melody captures such pitch features while keeping the rhythm of the source unchanged.

(a) Target's pitch and chord.

(b) The generated target music, using the pitch and chord from (a) and the rhythm from the source.

Figure 5: The 1st example of analogy via replacing z_p.

(a) Target's pitch and chord.

(b) The generated target, using the pitch and chord from (a) and the rhythm from the source.

Figure 6: The 2nd analogy example via replacing z_p.

Figure 6 shows another example, whose subplots share the same meanings with the previous one. From Figure 6(a), we see the first measure of the target's melody is a broken chord of Gmaj, while the second measure is the G major scale. From Figure 6(b), we see the generated new melody captures these pitch features. Moreover, it retains the source's rhythm and ignores the dotted eighth and sixteenth notes in Figure 6(a).

4.2.2 Analogy by replacing z_r

Similar to the previous section, this section shows two example answers to the question: "*source's rhythm : source melody :: target's rhythm : ?*" by replacing z_r. Figure 7 shows the first example, where Figure 7(a) contains the new rhythm pattern quite different from the source, and Figure 7(b) is the generated target. We see that Figure 7(b) perfectly inherited the new rhythm pattern and made minor but novel modifications based on the source's pitch.

(a) Target's rhythm pattern.

(b) The generated target music, using the rhythm of (a) while keeping source's pitch and chord.

Figure 7: The 1st example of analogy via replacing z_r.

(a) Target's rhythm pattern.

(b) The generated target music, using the rhythm of (a) while keeping source's pitch and chord.

Figure 8: The 2nd analogy example via replacing z_r.

Figure 8 shows a more extreme case, in which Figure 8(a) contains only 16th notes of the same pitch. Again, we see the generated target in Figure 8(b) maintains the source's pitch contour while matching the given rhythm pattern.

4.2.3 Analogy by Replacing Chord

(a) Changing all the chords down a semitone, resulting in the key change from G major to Bb minor.

(b) Changing the key from G major to G minor.

Figure 9: Two examples of replacing the original chord.

Though chord is not our main focus, here we show two analogy examples in Figure 9 to answer "what if" the source melody is composed using some other chord progressions. Figure 9(a) shows an example where the key is Bb minor. An interesting observation is the new melody

contour indeed adds some reasonable modification (e.g. flipping the melody) rather than simply transposing down all the notes. It brings us a little sense of Jazz. Figure 9(b) shows an example where the key is changed from G major to G minor. We see melody also naturally transforms from major mode to minor mode.

4.2.4 *Two-way Pitch-Rhythm Interpolation*

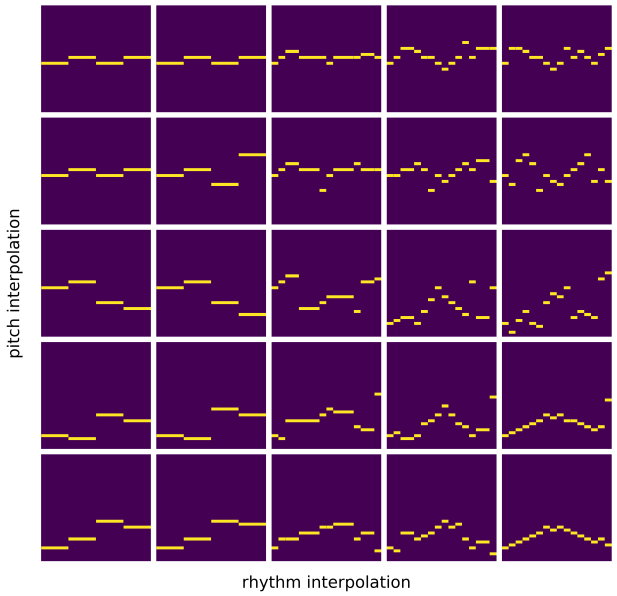

Figure 10: An illustration of two-way interpolation.

The disentanglement also enables a smooth transition from one music to another. Figure 10 shows an example of two-way interpolation, i.e., a traversal over a subspace of the learned latent representations z_r and z_p along 2 axes respectively, while keeping the chord as NC (no chord). Here, each square is a piano-roll of an 8-beat music. The top-left (source) and bottom-right (target) squares are two samples created manually and everything else is generated by interpolation using SLERP [28]. Note that the rhythmic changes are primarily observed moving along the "rhythm interpolation" axis, and likewise for pitch and the vertical "pitch interpolation" axis.

4.3 Subjective Evaluation

Besides objective measurement, we conducted a subjective survey to evaluate the quality of generation via analogy. We focus on changing the rhythm factors of existing music since this operation leads to an easier identification of the source melodies.

Each subject listened to two groups of five pieces each. All the pieces had the same length (64 beats at 120 bpm). Within each group, one piece was an original, human-composed piece from the Nottingham dataset, having a lyrical melody consisting of longer notes. The remaining four pieces were variations upon the original with more rapid rhythms consisting of 8^{th} and 16^{th} notes. Two of the variations were produced in a rule-based fashion by naively cutting the notes in the original into shorter subdivisions, serving as the *baseline*. The other two variations were generated with our EC^2-VAE by merging the z_p of the original piece and the z_r decoded from two pieces having the same rhythm pattern as the baselines but with all notes replaced with "do" (similar to Figure 8(a)). The subjects always listened to the original first, and the order of the variations was randomized. In sum, we compare three versions of music: 1) the original piece, 2) the variation created by the baseline, and, 3) the variation created by our algorithm. The subjects were asked to rate each sample on a 5-point scale from 1 (very low) to 5 (very high) according to three criteria:

1. *Creativity*: how creative the composition is.
2. *Naturalness*: how human-like the composition is.
3. *Overall musicality*.

A total of 30 subjects (16 female and 14 male) participated in the survey. Figure 11 shows the results, where the heights of bars represent means of the ratings the and error bars represent the MSEs computed via within-subject ANOVA [25]. The result shows that our model performs significantly better than the rule-based baseline in terms of creativity and musicality ($p < 0.05$), and marginally better in terms of naturalness. Our proposed method is even comparable to the original music in terms of creativity, but remains behind human composition in terms of the other two criteria.

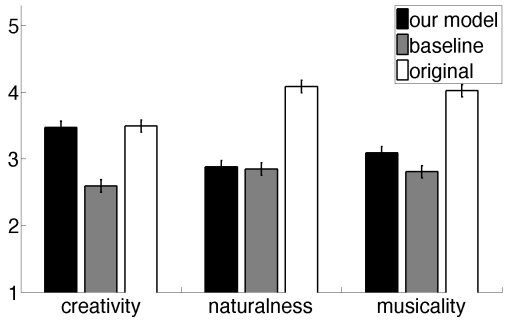

Figure 11: Subjective evaluation results.

5 Conclusion

In conclusion, we contributed an explicitly-constrained conditional variational autoencoder (EC^2-VAE) as an effective disentanglement learning model. This model generates new music via making analogies, i.e., to answer the imaginary situation of "what if" a piece is composed using different pitch contours, rhythm patterns, and chord progressions via replacing or interpolating the disentangled representations. Experimental results showed that the disentanglement is successful and the model is able to generate interesting and musical analogous versions of existing music. We see this study a significant step in music understanding and controlled music generation. The model also has the potential to be generalized to other domains, shedding light on the general scenario of generation via analogy.

ABSTRACT

Cross-modal retrieval learns the relationship between the two types of data in a common space so that an input from one modality can retrieve data from a different modality. We focus on modeling the relationship between two highly diverse data, music and real-world videos. We learn cross-modal embeddings using a two-stream network trained with music-video pairs. Each branch takes one modality as the input and it is constrained with emotion tags. Then the constraints allow the cross-modal embeddings to be learned with significantly fewer music-video pairs. To retrieve music for an input video, the trained model ranks tracks in the music database by cross-modal distances to the query video. Quantitative evaluations show high accuracy of audio/video emotion tagging when evaluated on each branch independently and high performance for cross-modal music retrieval. We also present cross-modal music retrieval experiments on Spotify music using user-generated videos from Instagram and Youtube as queries, and subjective evaluations show that the proposed model can retrieve relevant music. We present the music retrieval results at: `http://www.ece.rochester.edu/~bli23/projects/query.html`.

1. INTRODUCTION

Music retrieval has been explored for many cross-domain inputs such as text [27], image [5], location [41], video [32], vocal imitation [42], and sheet music [29]. To our knowledge there are few reports focusing on cross-modal music retrieval given videos from unconstrained sources. With the proliferation of smart phones, people capture short videos to communicate moments from their everyday lives. Learning relationships between music and real-world videos has many applications including novel music query scenarios where a playlist is recommended to fit user's surrounding scenes, or automatically soundtrack selection to complement and enhance visual messages on social media, e.g., Snapchat, Instagram, and Facebook.

Real-world videos can contain any form of video including edited or raw content, and music is an inherently diverse content as well [8]. Thus associating music with such videos is more challenging than common sounds and objects, e.g., barking to a dog [1], which has explicit connection on semantic level. One way to bridge real-world videos and music is via elicited emotions. Previous work addresses this problem after recognizing each modality independently as hand-labeled emotion features [5, 32], but this is not sufficient since hand-labeled emotions (e.g., several human-defined emotion tags) are prone to bias and subjectivity [39], and bottleneck each modality into a limited non-learnable space. Thus no scalable solution has been proposed to query from large music databases. Later a two-stream network structure is proposed for music query by music videos [12], where cross-modal embeddings are learned directly from music-video pairs. However, it requires intensive training on music videos (MV) where the videos were originally created for specific songs, and the music retrieval performances given videos from more varieties of sources are not systematically evaluated.

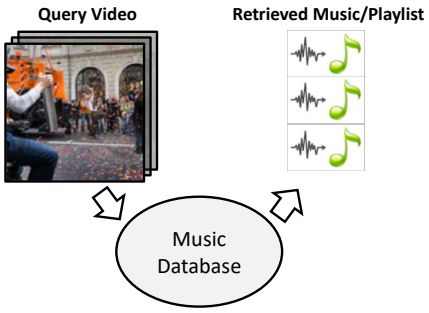

Figure 1. A large music database can be queried by real-world videos from unconstrained sources.

In this paper, we address the music retrieval task on videos in the wild (Figure 1). Different from previous work that models each modality independently, we propose a two-stream network structure to learn the cross-modal distance in an end-to-end fashion using music-video pairs, while emotion tags are applied on each branch to form latent emotion space. Each branch is pre-trained as audio/video emotion tagging sub-network before feeding music-video pairs to both for cross-modal distance learning. This strategy requires fewer music-video pairs for training, and makes it possible to collect crowdsourced pairs of music and videos from independent sources. Note that the tags are only used during training phase to facilitate the convergence of cross-modal distance learning, and not necessary during model inference of music query. When a video queries the system, the model ranks every item of

an existing music database by Euclidean distance to the input video on the cross-modal embedding. The top ranked results represent the best matches to the input.

The main contributions of this paper are :

- A first system to address music retrieval from videos in the wild via learnable emotion space.
- A two-stream network structure and training strategy with emotion tags as joint constraints to learn cross-modal embeddings from fewer music-video pairs.
- Subjective evaluations showing promising retrieval results on real-world datasets.

2. RELATED WORK

2.1 Music, Videos and Emotions

The emotions associated with music and videos have been thoroughly studied. It has been suggested that emotions are one of the primary reasons people engage with music [15], and psychological studies reveal that people have emotional reactions on visual stimuli as well [7]. Therefore a natural way to retrieve music for videos is through the associations with emotion.

Categorical and dimensional representations have been used to represent emotion in music [18]. Discrete categorical tags include terms such as *calmness*, *sadness*, *anger*, and more. Gracenote [1] has performed a major effort around tagging the mood in music and provides mood taxonomies consisting of over 300 categories organized hierarchically. One work finds that the number of mood categories does not reflect the richness of emotions perceived by humans, or the taxonomy is inherently ambiguous [15]. Dimensional labels typically represent music on a 2-D plane of valence and arousal [30]. This continuous representation does not have the taxonomy problem, but has trouble distinguishing some psychology and emotion concepts such as *nostalgia*.

Emotion associated with images and videos have been also represented categorically [44] and dimensionally [24], similar to music. Seven emotion tags have been associated with videos of facial expressions [16, 17]. Eight basic emotion tags, with 3 variations on each tag are introduced for labeling unconstrained videos [38]. Movie scenes have been characterized in the valence-arousal space [3]. In [11], "Dominance" is introduced as an additional dimension for characterizing video emotions.

2.2 Cross-modal Audio-Visual Retrieval

Cross-modal retrieval has received increasing attention in the recent years. One work proposes a two-stream network structure for audio-vision cross-modal retrieval of common objects and their respective sounds, such as an image of a clock paired with the sound of an alarm [1]. This work has curated a large training dataset of common objects and sounds from publicly available sources. The cross-modal correspondence is learned from audio-visual pairs. Similar work has been described with additional modalities of text [2] and speech [26].

Related work for music includes cross-modal localization [43], association [20, 22], and generation [21] of music performances. Earlier work for cross-modal music retrieval involves extracting distance measurement between low-level features from video and music segments [40]. Some approaches synchronize video and music after representing each modality as sequence of 2-D valence-arousal features [23, 31, 32]. One work uses stochastic emotion space to bridge video and music [36], and another reports recommended music for still photo albums by defining a cross-modal graph on which synsets of mood tags from images and music are associated [5]. Pairing in these approaches recognizes each modality as explicit symbolic representations independently (e.g., hand-labeled emotions) before learning the association. Also, these systems mostly emphasize temporal inter-dependence, focusing on pairing a soundtrack to match the visual event with less demand on learning deep semantic representations on emotions.

Learning cross-modal embeddings end-to-end using cross-modal pairs could result in a deep representations of the relationships and improved performance at scale in a music retrieval setting. As presented in [12], music/video cross-modal retrieval has been modeled by learning from music-video pairs and presented on music and their respective music videos, where the videos were intentionally created as MV. Without constraining the cross-modal learning space, it requires intensive training on music-video pairs, e.g., existing music videos, and is not systematically evaluated on the retrieval results for videos from more sources. In this paper we also learn the embedding space in an end-to-end fashion using pairs of video and music, but constrain the learning space with emotion tags to form latent emotion space for each modality.

3. APPROACH

3.1 Network Architecture

3.1.1 Video Branch

The video branch consists of a feature extraction module followed by fully-connected layers for emotion tagging, left stream in Figure 2. We use pre-trained Inflated-3D model (I3D) [4] as the visual feature extractor. I3D was originally proposed for human action recognition from videos and was trained on the Kinetics dataset [4]. This pre-trained network has been successfully used for other video understanding tasks such as video captioning and audio-visual localization [34].

We input only the RGB frames and ignore optical flow. The system outputs a concatenation of the inception modules. We take a global average pool resulting in a 1024-D feature vector for each whole video of any duration. Next, we add fully connected layers. Each layer is followed by a ReLU nonlinearity, except that the output layer is followed by a sigmoid nonlinearity. Input video frames are resized to 224×224, and the RGB values are normalized to [-1,

[1] www.gracenote.com

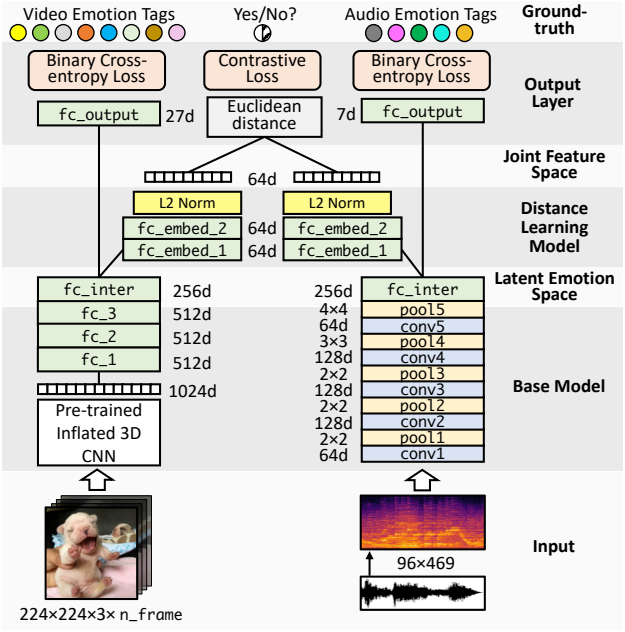

Figure 2. The two-stream network architecture with emotion constraints on each branch. The dimensions of fully-connected layer (fc), channel numbers of convolutional layer (conv), and pool sizes are marked aside each block. The kernel size for all the convolutional layers is 3×3.

1]. The video network is pre-trained with 27 emotion tags using binary cross-entropy loss.

3.1.2 Audio Branch

The audio branch consists of a ConvNet structure as a general audio tagging framework analogue to [6], right stream in Figure 2. Each convolutional layer is followed by a batch normalization and ReLU nonlinearity, and the output fully-connected layer has a sigmoid nonlinearity. Audio is trimmed to 10-sec with a sample rate of 12 kHz. Log mel-spectrograms are computed from input audio with a frame length of 42.7 ms (with 50% overlapping) and 96 mel-scale filter banks. The audio network is pre-trained with 7 emotion tags using binary cross-entropy loss.

3.1.3 Cross-modal distance learning

The cross-modal distance learning network is designed to embed the video and audio into the cross-modal embeddings (i.e., the joint feature space in Figure 2) so they can be directly compared as vector distance. This network takes the two 256-D penultimate layers from the video and audio branches to predict if the input music-video pair match, as a binary classification problem. The 256-D layers represent latent emotion space that is learned from the training pairs. The classifier is trained with the contrastive loss [10] on the Euclidean distance between each modality's 64-D cross-modal embedding, after L2 normalization.

3.2 Training

We first pre-train the audio and video branches independently as multi-label classifiers to predict emotion tags for each modality. The training stops when validation loss does not decrease for 5 consecutive epochs. Then the cross-modal distance learning framework is trained jointly while each branch predicts emotion tags. The network is jointly constrained and the three loss functions are equally weighted. This strategy constrains the learning space using emotion tags, and enables cross-modal distance learning from fewer music-video pairs. We use Adam optimizer [19], a stochastic gradient descent method, to minimize all the loss functions. When the model is trained, in practice all tracks in a music catalog are indexed by the embedding vector from the cross-modal joint feature space. Given any query video, the tracks in the database can be ranked by the Euclidean distance to the embedding vector calculated from the video. This creates a fast retrieval setup for large catalogs.

4. DATA

4.1 Training Data

The audio and video branches are pre-trained on independent music and video datasets with emotion labels. To train the cross-modal network we reuse the data from different modalities to create music-video pairs according to crowdsourced annotations about how well each pair matches.

4.1.1 AudioSet

We use the AudioSet [9] to pre-train the audio branch. AudioSet has human-labeled 10-second sound clips drawn from YouTube videos. We use data from "Music Mood" Ontology which contains music excerpts that are labeled with one of 7 music mood categories. We use AudioSet's official *Unbalanced Train* data where we randomly sample roughly 800 clips from each category for a total of 5.6K samples. We split it randomly where 80% is used for training and 20% is used for validation. We use AudioSet's official *Eval* data as the test set which consists of 354 samples, roughly 60 for each class, barring invalid download links. We do not use the videos from AudioSet for cross-modal distance learning because most contain a specific type of edited content, which is not suitable for the objective of retrieving music for videos from unconstrained sources.

4.1.2 Cowen2017

We use the Cowen2017 dataset [7] to pre-train the video branch. The dataset includes over 2K data samples including video clips from daily life, movies, cartoons, game scenes, artistic work, and more. Each video is annotated by several subjects who could select up to 27 emotion tags for each video. The annotations are aggregated so that each video's label is 27 emotion tags with a confidence value between 0 and 1. We split it randomly where and 80% is used for training and 20% is used to create the test set.

4.1.3 Music-video Pairs

To our knowledge there are no publicly available datasets that connect diverse videos with music, and contain the

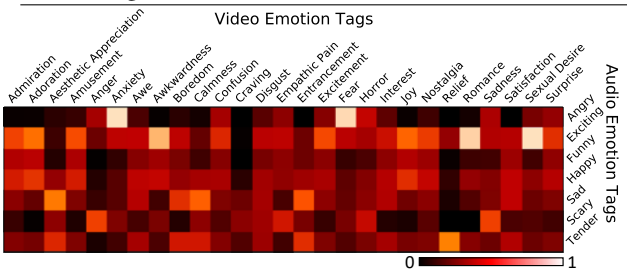

Figure 3. Visualizations of the emotion tags for the annotated music-video pairs from crowdsourced annotations. The color shows normalized counts.

respective emotion labels. Our goal is to construct a generalizable dataset that matches samples from one modality to the other while all samples have emotion labels. So we apply crowdsourcing to create music-video pairs from the same samples in AudioSet and Cowen2017. We follow the respective splits of training and test set as before so clips from one set do not appear in the other.

Training a cross-modal network requires positive and negative music-video pairs. The positive pairs are created by collecting binary crowdsourced judgments for randomly paired music and video clips until we have 1000 matches. Detailed crowdsourcing setup is described in Section 4.3. The negative samples are created from random un-annotated music-video pairs. In total we have class-balanced training set of 2000 pairs. We then perform the same process to collect another 1000 pairs on the test set. In Figure 3, we present a heatmap visualization of the relationship between the emotion tags of the positive audio-video pairs from the two modalities.

4.2 Real-world Data

To estimate how the system will perform on real-world data we curate videos and music from popular social media and music streaming platforms.

4.2.1 Spotify's Popular Music

We create a dataset of popular music from Spotify, an international music streaming platform. We identify popular Gracenote level 1 worldwide genres where at least 1000 tracks are streamed per day on Spotify. From each of the 30 most popular genres we select 40 of the most popular songs. The audio is downloaded from Spotify, which results in 1195 music clips.

4.2.2 The Moments in Time Dataset

We use video clips from the *Moments in Time* dataset [28] where each clip is a 3-second video snippet. The dataset was created for the tasks of action recognition and event understanding. We pick the first 100 moment categories (sorted alphabetically) from the *Moments in Time Mini* (a subset). From each category we select the first 5 video samples, totaling 500 video clips as the query videos.

4.2.3 Instagram Videos

Instagram is a social media platform for sharing photos and short videos. From a new account without search history we curate the top 20 videos from common photo post categories [13] : *Friends*, *Food*, *Gadget*, *Pets*, *Activities*, *Selfies*, *Fashion*, and we exclude *Captioned Photos* because the text may bias annotators' judgments and the system is currently not trained to process text. This results in 140 user uploaded short video clips.

4.3 Crowdsourcing Setup

Crowdsourced judgments are collected to create music-video pairs in the training and test datasets for cross-modal distance learning, and for subjective evaluations of music retrieval performance on real-world datasets. Experiments are run on the Figure-eight [2] platform which minimizes malicious activity during annotations and ensure high quality judgments for researchers.

Annotators are sourced from an international pool and each annotator is allowed to answer at most 10 questions, so that relevance judgments would not be overfit to any small group. Every question is randomly presented to at least 3 annotators. If the agreement among annotations is less than 65% per question, the number of annotators is dynamically increased up to 5 or until there is at least 65% agreement. Annotators are instructed to "listen in a quiet place, wear headphones, and watch the entire clip". The instructions for each audio-video pair are: "Please tell us if there is a common emotion theme in the video and the music, try not to focus on whether you like the music or the video." Possible responses are: "yes they match", "no they do not match", and "I am not sure".

To avoid biasing the pool of contributors we do not use gold standard screening questions that resemble the annotation questions, a common practice on Figure-eight. Instead to monitor annotation quality and attentiveness, we monitor whether any annotator's responses consistently deviate from the responses of other annotators. If an annotator's responses are different from the average annotation in more than 3 questions we flag that individual to analyze their contributions. We do not find any annotators fall into this group. In total we have collected thousands of annotations from subjects from 12 countries. Approximately 71% of the questions have greater than 66% agreement on "yes" and "no" responses. The remaining has responses split between "yes", "no", and "not sure", and for this work we consider the responses as "no" because annotators do not perceive relevance.

5. EXPERIMENTS

The model performance is evaluated numerically on the tasks of 1) predicting emotion tags from each branch independently, 2) predicting if the input audio-video pairs match, and 3) cross-modal music retrieval, on the annotated datasets. The music retrieval performances are also

[2] https://www.figure-eight.com

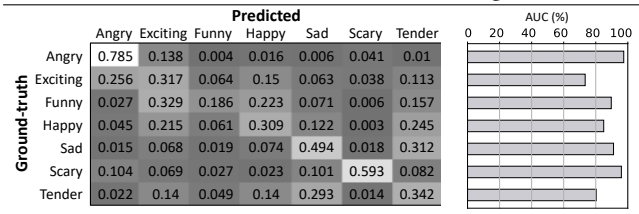

Figure 4. Performance of the audio branch for predicting emotion tags after pre-training. Results are presented as confusion matrix (left), and AUC on each category (right).

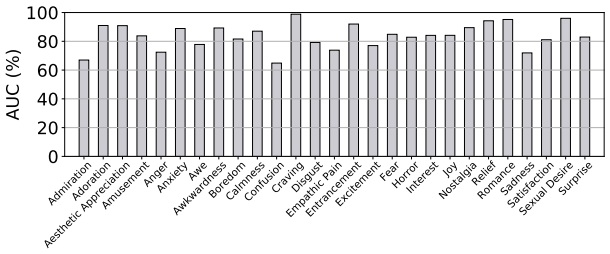

Figure 5. Performance of the video branch for predicting emotion tags after pre-training. AUCs are calculated using a score margin at 0.25.

evaluated on real-world data using crowdsourced subjective judgments.

5.1 Predicting Audio Emotion Tags

We evaluate the pre-trained audio branch using the labeled heldout data from AudioSet. The music emotion tagging result is evaluated using multi-class classification metrics. Figure 4 presents the confusion matrix, where *Angry* and *Scary* are likely to get high true positive rates, while the boundaries between *Exciting*, *Funny*, and *Happy* are blurred. We observe that angry music is generally noisy with strong percussion, while scary music has strong inharmonic components, as more distinct characteristics.

We also evaluate the model using the area under the receiver operating characteristic curve (AUC), a statistical metric that summarizes model's performance regardless of classification threshold. Equivalently, it measures the performance of binary classifiers (measuring each tag independently) by ranking scores, i.e., the probability that a randomly chosen positive is ranked ahead of a randomly chosen negative. The performance on each emotion tag is shown in Figure 4, with an average of **87.88**%.

5.2 Predicting Video Emotion Tags

The pre-trained video tagging branch is evaluated using heldout data from Cowen2017. Similar to scored AUCs [35, 37], we set a score margin on soft ground truth labels to report the performance. This metric assesses how well relative differences between video samples in the dataset can be predicted. It compares the sign of the differences between any two predictions to sign of the differences of the respective ground truth ones. Performance is measured only when the two data points have sufficiently large ground truth differences, e.g., 0.25 as used here. The average AUC for all tags is **83.79**%, as shown in figure 5 on each tag.

Method	2-stream	emotion [32]	emtoion [5]	proposed
Result	38.1%	36.0%	46.8%	**68.0**%

Table 1. Music retrieval performances on the labeled datasets compared with three baseline methods.

5.3 Predicting Audio-video Pairs

We also evaluate the cross-modal network to understand overall performance on cross-modal distance learning and the effects of the emotion tags which constrain the video and audio branches during cross-modal training. The cross-modal network predicts the input audio-video pairs as either positive or negative (matched or not) on the 1000 pairs from test set, and is evaluated as a binary classifier with a threshold of 0.5. We create a baseline model with the same two-stream network structure but without pre-training the branches on emotion tags or joint loss functions. The two models are trained and evaluated with the same dataset, described in Section 4.1.3. The accuracy of the proposed model is **79.00**% while the baseline achieves **63.30**%. Note that this baseline system is a general two-stream cross-modal distance learning network, e.g., [1], which usually requires intensive training on a large number of training pairs. The results indicate that pre-training and joint constraints on emotion tags is important for cross-modal distance learning when the training data is limited and the task includes data with highly diverse.

5.4 Cross-modal Music Retrieval

We reuse the heldout data from Cowen2017 and Audioset as query videos and the pool of music, respectively, where for each query video there are on-average 16.2 music samples from the pool are annotated as ground-truth retrieval. The music retrieval performance is evaluated by counting the number of videos that can retrieve a relevant song. For each query video only the top retrieval is considered, after ranking all the 354 music tracks. The proposed model retrieves relevant music for **68.0**% of query videos.

We also compare the performance to three baseline models, as presented in Table 1. The first baseline model is the same baseline as illustrated in Section 5.3, which share the same network structure but without emotion tags and pre-traning to form latent emotion space. It only achieves satisfactory retrieval for **38.1**% of videos.

The second baseline models each modality as continuous emotion representation on the valence-arousal (V-A) space, analogue to [32]. We implement this by adapting the proposed model structure, where the output layer from each branch is replaced with 2-D states to represent valence and arousal constrained by mean squared error (MSE) from the ground-truth values as a regression problem, without the two-stream structure for learning the cross-modal embeddings. The audio model achieves R^2

Video source	Moments in Time	Instagram
Result	58.2%	64.3%

Table 2. Music retrieval performance on Spotify music using query videos collected from new sources.

statistics of 53%/36% for arousal/valence when trained and evaluated on the *1000Song* dataset [33]. The video model achieves R^2 of 75.04%/60.28% for arousal/valence when trained and evaluated on the AudioSet videos using annotated labels. Both models achieve higher performance than the original work on emotion prediction [32]. We map the two modalities in the A-V space and the model achieves relevant retrievals for **36.0**% videos.

The third baseline matches modalities according to hand-labeled emotion tags, analogue to [5]. To implement this we modify the model structure to build the cross-modal distance learning structure from the predicted emotion tags from each branch, instead of the 256-D latent emotion space. This model achieves relevant retrievals for **46.8**% videos.

These experiments show that the proposed approach outperforms three baseline solutions. Two of the baselines join the modalities directly on predicted emotion states: arousal-valence values or explicit emotion tags. It suggests that our model learns deeper relationships between the modalities in the cross-modal space. Comparing to the other baseline, the results indicate that when the model is not constrained with emotion tags, only 2000 audio-video pairs as training set is too small for the network to learn the cross-modal embeddings to represent underlying the relationships between the cross-modal inputs.

5.5 Performance on Real-world Data

We assess how well our proposed model works on real-world data by collecting human judgments using the crowdsourcing setup in section 4.3. We use the 500 samples from the *Moments in Time* dataset and 140 user-generated videos from Instagram to retrieve music from a pool of music clips downloaded from Spotify. The model can successfully retrieve music for **58.2**% and **64.3**% videos, respectively. Music retrieval performance is better on Instagram than *Moments in Time*.

Note that Instagram videos are uploaded by users to visually share an experience or a mood that incites an emotion [14]. Instead, *Moments in Time* was created to capture different actions objectively without capturing sentiment [28]. This difference may explain why performance is higher on the Instagram videos.

5.6 Qualitative Analyses

We qualitatively analyze the latent emotion space learned from the two-stream model. We take the latent emotion space from the audio branch and create a t-SNE visualization [25], as plotted in Figure 6, to study how the matched videos localize in this 2-D space. Each dot represents a music sample from AudioSet, and we color the ones with the original label "Tender" in grey. Among these samples, we randomly select some from different regions and they are presented using different colors and with the thumbnails of the paired videos from model output. It indicates that samples close together with similar granular emotions are usually associated with similar videos. For example, samples in yellow represent music that sounds serene or soothing, and associated with outdoor nature scenes. This suggests that the proposed framework constrained with emotion tags enables the model to learn a interpretable emotion space and cross-modal correspondence including nuances that are no represented in the original tags.

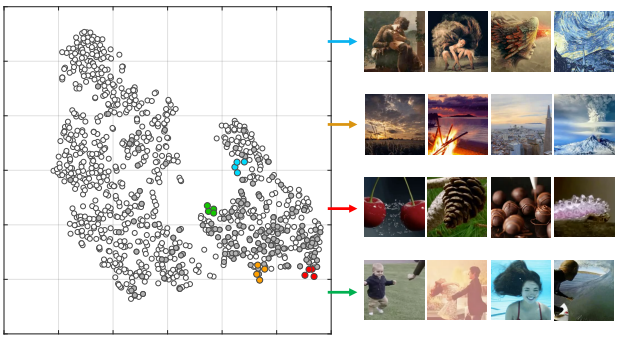

Figure 6. The t-SNE visualization of the latent emotion space from the audio branch. Samples from the "Tender" tag are in gray. Four randomly selected regions for tender music are presented in colors representing different emotion concepts: gloomy, ambient, delicate, sweet, each with the thumbnails of the paired videos displayed.

We also investigate some failure retrieval cases and find most are due to incorrect predictions of video emotions. Also, several retrievals are matched on emotions but mismatched on cultural signals. For example, a video with people bowing to Beyonce as she wears a crown is paired with music that sounds "mystical" or "heavenly", which is annotated as "mismatch" likely because annotators recognize Beyonce and they are expecting her music. If cultural signals are ignored these retrievals may have been reasonable matches. Overall, the results indicate that the system is effective for music retrieval, and we expect improvements by incorporating more signals such as culture or genres.

6. CONCLUSION

We have addressed the problem of music retrieval using real-world videos from unconstrained sources. We haved proved that emotion tags can constrain the learning space and enable cross-modal distance learning from fewer annotated cross-modal pairs. Experiments show that our model can retrieve promising results for user-generated query videos. As an application, this model can offer novel music query solutions for daily life videos which can enhance visual messages to make sharing more enjoyable. We also expect this work to have product implications in the music streaming business. In the future we plan to personalize the music that is retrieved for users' tastes.

ABSTRACT

Western classical music comprises a rich repertoire composed for different ensembles. Often, these ensembles consist of instruments from one or two of the families woodwinds, brass, piano, vocals, and strings. In this paper, we consider the task of automatically recognizing instrument families from music recordings. As one main contribution, we investigate the influence of data normalization, pre-processing, and augmentation techniques on the generalization capability of the models. We report on experiments using three datasets of monotimbral recordings covering different levels of timbral complexity: isolated notes, isolated melodies, and polyphonic pieces. While data augmentation and the normalization of spectral patches turned out to be beneficial, pre-processing strategies such as logarithmic compression and channel-energy normalization did not lead to substantial improvements. Furthermore, our cross-dataset experiments indicate the necessity of further optimization routines such as domain adaptation.

1. INTRODUCTION

In classical music, there are compositions for a variety of distinct instrumentations. Chamber music, for example, comprises ensembles of different size, which often consist of instruments from a specific instrument family such as woodwinds, brass, piano, vocal, or strings. Typical examples are brass quintets, piano duos, choirs, or string quartets. While the automatic classification of such *monotimbral* recordings w.r.t. the instrument family is a simplification of general instrument recognition, it still constitutes a challenging task. Successfully tackling this problem could help to organize and browse classical music collections. Furthermore, recognizing instrument families from monotimbral recordings constitutes the first step towards handling more complicated scenarios such as orchestra recordings, where we often find passages featured by specific instrument families.

In this paper, we approach the task of music instrument family recognition from classical music recordings. For our experiments, we consider three scenarios using datasets of monotimbral recordings with different levels of timbral complexity. We start with analyzing recordings of isolated notes (`IN`) played by an individual instrument. Furthermore, we test on isolated, monophonic melodies (`IM`) with a natural variety of note durations. For the third scenario, we consider monotimbral, mostly polyphonic music recordings (`MP`), where one or more instruments of the same instrument family are playing simultaneously. In Section 3, we describe these datasets in detail.

To approach the instrument family recognition task, we make use of a state-of-the-art instrument recognition algorithm [8] based on convolutional neural networks using spectrogram segments as input. As our main contributions, we apply this method to the instrument family scenario. For the `MP` scenario, we investigate how the model performance can be improved using strategies for data augmentation and pre-processing. We systematically test the generalization capability of the trained models to previously unseen datasets in a sequence of cross-dataset experiments.

2. RELATED WORK

Traditional algorithms for automatic instrument recognition (AIR) rely on audio features measuring instrument-specific timbral properties of music signals. Fuhrmann [4] provides a comprehensive overview of such techniques. As an example with a focus on classical music, Eggink & Brown [3] propose a system to recognize five wind and string instruments based on partial frequency and magnitude features combined with a Gaussian classifier.

Due to the rapid proliferation of deep-learning techniques, most recent publications mainly focus on data-driven algorithms, which are the focus of this literature review. These algorithms are trained to learn a direct mapping from low-level signal representations such as mel-spectrograms to higher-level attributes such as instrument labels. While data-driven approaches require less domain knowledge, they usually need large amounts of training data in order to learn models that generalize well to unseen

datasets. However, popular AIR datasets such as MedleyDB [1], IRMAS [2], or MusicNet [21] are still of limited size. As a consequence, authors often apply data augmentation techniques such as pitch shifting [7] to virtually enlarge the number of audio files.

Concerning the generalization capability, AIR approaches based on deep neural networks (DNNs) show good performance on particular datasets, but cross-dataset experiments (as we present in Section 5.2) are rarely performed. Such experiments are crucial for better understanding to which extent DNN models generalize to unseen datasets with different characteristics. In the related field of audio event recognition, researchers often observe this limitation of data-driven algorithms and suggest additional domain adaptation steps [5]. Another challenge is the entanglement between perceptual attributes such as pitch and timbre in spectrogram representations. Lostanlen et al. [14] propose weight-sharing strategies for DNN models in order to derive pitch-invariant representations, which still maintain good timbre discriminability.

Typical model architectures used in recently proposed AIR systems are convolutional neural networks (CNNs) [6–9, 12, 17, 20] and hybrid convolutional-recurrent neural networks (CRNNs) [7]. Most of the CNN architectures comprise several convolutional layers for feature learning and a set of dense layers for classification. Han et al. [8] proposed such a CNN architecture to recognize the predominant instrument in polyphonic and multitimbral recordings. The authors evaluate different late-fusion techniques to aggregate frame-level model predictions in order to obtain song-level instrument labels. This model has been used and extended in recent AIR literature [6, 20]. Takahashi et al. [20] show in a comparative experiment that using horizontal and vertical filter shapes instead of symmetrical ones improves recognition performance, but requires more training time. Hung & Yang [9] tested an alternative CNN model, which includes residual blocks with additional skip connections to allow for reducing the vanishing-gradient problem during training.

Concerning the input representation, most DNN-based AIR systems process mel-spectrogram segments (*patches*). As alternative, Hung & Yang test constant-Q spectrograms and harmonic-series features as input to the models [9]. Li et al. [12] propose an end-to-end-learning approach using a CNN architecture that directly processes raw audio data. Hung & Yang [9] show that using score information as an additional cue leads to small improvements in the frame-level recognition of seven classical instruments.

3. DATASETS

In this section, we describe three datasets that we use for our instrument family recognition experiments. Regarding the level of difficulty, the isolated-note scenario (`IN`) constitutes the simplest task represented by the Studio On Line Dataset (`DB-SOL`) presented in Section 3.1. A scenario with increased level of difficulty comprises isolated melodies (`IM`), represented by the University of Rochester Multi-modal Music Performance Dataset (`DB-URMP`) described in Section 3.2. As our most complicated scenario, we consider monotimbral polyphonic recordings of classical music realized in the Monotimbral Classical Dataset (`DB-MTC`), which comprises recordings of monotimbral, mostly polyphonic classical pieces (`MP`, see Section 3.3). Table 1 summarizes the properties of the three datasets.

Table 1: Number of audio files, spectral patches, and average patches per file for each dataset and experiment.

Dataset	Files	Patches	Patches / file (avg)
Original Datasets (with silent patches)			
`DB-MTC`	50	38078	762
`DB-MTC`$^+$	400	304624	762
`DB-URMP`	149	33693	226
`DB-SOL`	20604	225273	11
Experiment 1 (silent patches removed)			
`DB-MTC`	50	34163	683
`DB-MTC`$^+$	400	281841	705
Experiment 2 (3 classes, silent patches removed)			
`DB-MTC`	30	20900	697
`DB-URMP`	149	31236	210
`DB-SOL`	20604	202486	10
`DB-M/U/S`	20783	254622	12

3.1 Studio On Line Dataset (`DB-SOL`)

The Studio On Line dataset [1], recorded in 2002 at IRCAM (Paris), comprises over 25000 isolated note recordings from 16 different instruments covering the instrument families woodwinds, brass, and strings. Recognizing the instrument family of such isolated note recordings (`IN`) constitutes a relatively simple scenario since there is no spectral overlap of multiple notes. However, the large variety of instrument playing techniques—in particular, frequency modulation techniques such as vibrato and trill—makes the recognition task more complex. For our experiments, we discarded recordings from `DB-SOL` that only comprise mechanical instrument sounds without a clear pitch as well as breathing and speaking sounds.

3.2 University of Rochester Multi-modal Music Performance Dataset (`DB-URMP`)

The University of Rochester Multi-modal Music Performance (URMP) Dataset [11] was originally published to study audio-visual music performance analysis. The dataset comprises 44 ensemble pieces including duets, trios, quartets, and quintets, most of which are arrangements of popular classical pieces. For all pieces, multitrack recordings are available with a total of 149 isolated instruments tracks. Within each track, one melody instrument from the families woodwinds, brass, and strings is recorded in isolation. We use these individual tracks as the basis for our isolated-melodies (`IM`) scenario.

[1] Freely available as part of the Orchids software at `http://forumnet.ircam.fr/product/orchids-en/`. In [13], the dataset was used for evaluating an instrument recognition system.

3.3 Monotimbral Classical Dataset (DB-MTC)

To test the instrument family recognition task on a realistic scenario, we compiled a dataset consisting of 50 tracks from commercial recordings. The data comprises mostly polyphonic classical pieces composed for instruments of one family. For each of the five families, we included ten audio files, each from a different CD. The total duration in minutes for each instrument family is 63.2 (woodwinds), 37.6 (brass), 75.1 (piano), 51.4 (vocal), and 82.8 (strings).

The woodwind class mainly comprises chamber music works such as wind quintets by Cambini, Danzi, Hindemith, Nielsen, and Reicha, as well as a quartet by Rossini and a sextet by Janacek. Furthermore, we consider a serenade by W. A. Mozart, an excerpt from Dvořak's Ninth symphony (*New World*), and a partita for wind ensemble by Krommer. We are aware of the problem that wind ensembles often include a french horn, which is a brass instrument. While this is a typical situation in classical music, it might influence our recognition experiments. For the brass selection, we use brass ensemble music for five to ten players. We consider pieces by ten different composers, played by Canadian Brass, German Brass, Mnozil Brass, and other ensembles. Into the piano class we placed solo sonatas and fugues by Beethoven, Berg, C. P. E. Bach, and others, played by different pianists. Regarding vocal music, we include music for solo voice—such as Berio's *Sequenza III*—and choirs. The choir pieces comprise a renaissance composition by Allegri, romantic pieces by Bruckner and Janacek, modern pieces by Ligeti and Scelsi, and more. The strings class consists of several string orchestra pieces by Barber, Hindemith, Lutosławski, Penderecki, and Rawsthorne. Additionally, we include chamber music such as string quartets, a quintet by Schubert and a sextet by Brahms. [2]

4. SYSTEM OVERVIEW

In the following, we present our system for instrument family recognition, which consists of three main components. The first component (Section 4.1) transforms the audio signal of a music recording into a mel-based time–frequency representation. The second component (Sections 4.2 and 4.3) applies pre-processing techniques such as normalization or compression to the time–frequency representation. The third component (Section 4.4) consists of a CNN that outputs class probabilities and is trained in a supervised fashion. Figure 1 summarizes the main processing steps together with additional details regarding the network architecture (second and third columns of the figure).

4.1 Mel-spectogram Representation

For computing the time–frequency representation of the recordings, we follow the work by Han et al. [8]. We resample the audio signals to a sample rate of f_s = 22050 Hz and compute the mel-spectrogram [3] using 128 mel-bands, a hop size of 512 samples, and a window size of 1024 samples. Then, we normalize the magnitude in each frequency band of the mel-spectogram via dividing by the number of mel-bands. For each recording, we further segment the resulting mel-spectrogram representation into time–frequency patches with a length of 43 frames (approx. one second) with an overlap of 21 frames (approx. 0.5 seconds). This results in a tensor $X \in \mathbb{R}^{N \times 43 \times 128}$, where N indicates the total number of computed patches. In order to remove potential silent parts in the recordings, we discard a patch as soon as the mean of its magnitude values is below 5% of the entire file's maximal magnitude.

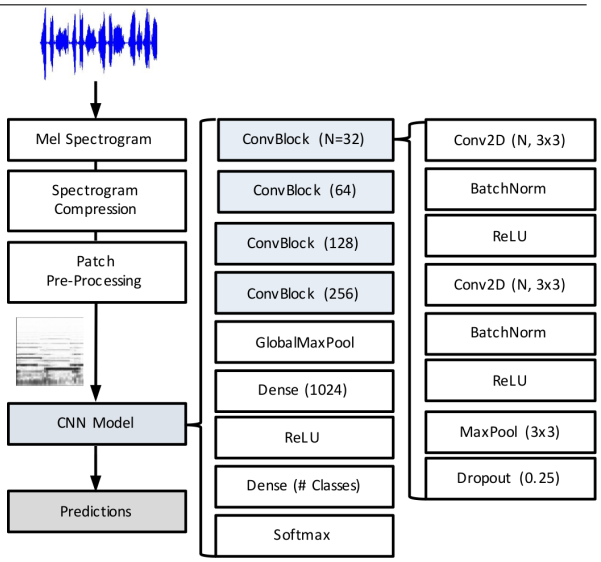

Figure 1: Reference model proposed by Han et al. [8] with slight modifications as discussed in Section 4.4. Spectrogram patches are processed by successive pairs of convolutional layers followed by batch normalization and ReLU activation function, max pooling (MaxPool), and global max-pooling (GlobMaxPool).

4.2 Spectrogram Dynamic Range Compression

Classical music recordings commonly exhibit a large dynamic range. To account for this, we investigate the effect of pre-processing strategies for compressing the dynamic range of the mel-spectrograms. In the following, we compare four different approaches for dynamic compression.

The first strategy, denoted as `NO`, does not apply any dynamic range compression. In this case, we directly use the mel-spectrogram as input to the model. The second strategy applies logarithmic compression defined by $X \leftarrow \log(1 + \gamma X)$. For our experiments, we consider two settings with $\gamma = 1$ (denoted as `LC 1`) and $\gamma = 10000$ (denoted as `LC 10000`), respectively. As the fourth strategy, we employ Per-Channel Energy Normalization (`PCEN`) proposed in [22] and further studied in [15]. `PCEN` ap-

[2] Due to copyright issues, we cannot publish the audio files. Instead, we publish the spectrogram patch tensors and corresponding targets to allow for reproducibility of our experiments under `https://doi.org/10.5281/zenodo.3258829`.

[3] We use the implementation from `librosa` (`https://librosa.github.io/librosa/`), version 0.6.2.

plies a first-order Infinite Impulse Response (IIR) filter, which controls the gain of the spectral representation, followed by dynamic range compression [22]. In principle, PCEN enhances prominent spectral characteristics (such as onsets), while attenuating low-energy frequency bands that are correlated with reverberation or corrupted by noise [22]. As the main benefit, the resulting spectral representation is robust against effects of reverberation and additive noise. For our experiments, we use PCEN as implemented in the librosa[3] Python library with default parameters (gain=0.98, bias=2, power=0.5, time_constant=0.4).

4.3 Patch Pre-processing

After the dynamic range compression step of the mel-spectrogram, we apply another pre-processing technique in order to normalize the spectral patches before we feed them to the CNN model. For this *patch pre-processing* step (not to be confused with the batch normalization within the CNN), we compare four different approaches. Let mean$(\cdot)$ and std$(\cdot)$ denote the computation of the average and standard deviation, respectively. $X_{:,:,f}$ denotes a slice of the given tensor $X \in \mathbb{R}^{N\times 43\times 128}$ for a fixed frequency index $f \in \{1,\ldots,128\}$. Similarly, $X_{p,:,:}$ denotes a slice of the tensor X for a fixed patch index $p \in \{1,\ldots,N\}$. Based on this, we define the four approaches as follows:

The first approach (A) performs frequency-based Zero-Mean and Unit-Variance (ZMUV) normalization following early approaches for efficiently training DNNs [10]. For each $f \in \{1,\ldots,128\}$, it is computed via:

$$X_{:,:,f} \leftarrow \frac{X_{:,:,f} - \text{mean}(X_{:,:,f})}{\text{std}(X_{:,:,f}) + \epsilon}. \quad (1)$$

The second approach (B) applies global ZMUV normalization to the tensor X, following the work presented in [18]:

$$X \leftarrow \frac{X - \text{mean}(X)}{\text{std}(X) + \epsilon}. \quad (2)$$

The third approach (C) employs local patch pre-processing, where each patch $p \in \{1,\ldots,N\}$ is normalized individually in the following way:

$$X_{p,:,:} \leftarrow \frac{X_{p,:,:} - \text{mean}(X_{p,:,:})}{\text{std}(X_{p,:,:}) + \epsilon}. \quad (3)$$

The fourth approach (denoted as "–") does not apply any pre-processing: The mel-spectral representation is provided directly to the CNN model.

For the approaches A and B, we apply ZMUV normalization to the validation and test set using mean and standard deviation as computed from the training set.

4.4 CNN Model

For our experiments, we adopt a CNN architecture proposed by Han et al. [8], illustrated in Figure 1. The model is based on a VGG-type architecture [19] and consists of four blocks that perform convolution operations. Each block contains a pair of 2D convolutional layers, each comprising K kernels of size 3×3. After each convolutional layer, we apply batch normalization (BatchNorm) followed by the Rectified Linear Unit (ReLU) activation function. At the end of each convolutional block, we use 3×3 max-pooling and dropout (with probability 0.25). Between subsequent convolutional blocks, we increase the number of channels K by a factor of two.

After the fourth convolutional block, we use a global max-pooling layer in order to flatten the latent representation. We give the flattened representation to a fully-connected feed-forward layer with 1024 units, followed by the final feed-forward layer that uses a soft-max activation function. We extend the architecture presented by Han et al. [8] using additional batch normalization layers after each convolutional layer. The batch normalization layers perform ZMUV normalization across each batch of mel-spectrogram patches. We train the model using categorical cross-entropy loss, the Adam optimizer with a learning rate of 10^{-4}, and a batch size of 128. In order to reduce overfitting, we implement early stopping during model training with a patience of 20 epochs. Since the audio files in DB–MTC substantially differ in length, we use a class-weighting scheme during training to compensate for class imbalance, which is computed as an inverse proportion of the number of training items per class.

5. EXPERIMENTS

In this section, we present our experiments on instrument family recognition. For Experiment 1 (Section 5.1), we consider polyphonic, monotimbral recordings using the DB–MTC dataset and test the improvement strategies discussed in Section 4. In Experiment 2 (Section 5.2), we investigate the generalization capabilities of the trained models in a cross-dataset experiment using the three datasets described in Section 3. As evaluation measure, we report the micro-average F-score. The F-score is computed as the harmonic mean between precision and recall on a patch-level and is not affected by potential class imbalance.

5.1 Experiment 1: Instrument Family Classification in Monotimbral Classical Music Recordings

In this experiment, we evaluate whether data augmentation, spectrogram compression, and patch pre-processing techniques lead to an improved classification performance. We focus on the MP scenario using the DB–MTC dataset.

5.1.1 Data Augmentation

Due to the small number of 10 audio files per instrument family in DB–MTC (see Section 3.3), we enlarge the dataset using the data augmentation techniques shown in Table 2. We apply algorithms taken from the Audio Degradation Toolbox [16] that implement brown and white noise, two room impulse responses, dynamic range compression, and two kinds of signal attenuation. In total, we create seven augmented versions of each audio file in the dataset, thus increasing the size of the dataset from 50 to 400 files. We refer to this augmented dataset as DB–MTC$^+$.

Table 2: Overview of applied data augmentation methods. *(def)* indicates where default presets from [16] are used.

Abbr.	Augmentation Type	Approach
Noi	Noise	Brown noise, SNR -6 dB
		White noise, SNR +22 dB
Imp	Impulse Response	Great Hall *(def)*
		Classroom *(def)*
Dyn	Dynamic Range Compression	*(def)*
Att	Attenuation	-3 dB
		-6 dB

Table 3: Confusion matrix for the best parameter configuration in Experiment 1 including all augmentations (DB-MTC$^+$), averaged over three folds. The overall F-score is 0.89.

True \ Predicted	woo	bra	pia	voc	str
woodwinds (woo)	**0.92**	0.06	0.02	0.00	0.00
brass (bra)	0.20	**0.70**	0.07	0.00	0.03
piano (pia)	0.01	0.01	**0.97**	0.01	0.01
vocal (voc)	0.09	0.00	0.01	**0.82**	0.08
strings (str)	0.00	0.02	0.02	0.02	**0.94**

5.1.2 Evaluation Procedure

We systematically evaluate 96 combinations of data augmentation, spectrogram compression, and patch pre-processing methods as listed in Table 4. For each configuration, we perform three validation runs and report the mean F-score. In each run, we randomly split the dataset on file level into training (40%), validation (30%), and test set (30%). We use the additional augmented versions of the files for the training and validation sets and test only on the clean, non-augmented signals.

5.1.3 Results

In Table 4, we show the results of Experiment 1. We observe the highest F-score of 0.89 for a system using no compression of the mel-spectrogram (NO), frequency-based patch normalization (A), and a fully augmented training set. Independent of the applied data augmentation, the results show that a normalization of spectral patches before model training is very beneficial if no (NO) or only mild spectrogram compression (LC 1) is applied. In contrast, strong compression (LC 10000) elevates the results for systems without patch pre-processing (−) much closer to the regions with pre-processing: Strong spectrogram compression and the patch normalization techniques have a similar effect, with the latter tending to have an even greater impact. At least one of the methods should be considered for usage. The simple logarithmic compression strategies outperform the PCEN strategy, which we apply using default parameters. We assume that using a trainable PCEN front-end instead seems to be more promising for future work.

In Table 3, we show a confusion matrix for this experiment using the ideal parameter combination. While the piano class is recognized best, confusions mainly occur between vocal and woodwinds or strings, and between woodwinds and brass. Concerning the latter confusion, both families are wind instruments and, therefore, exhibit certain timbral similarity. Furthermore, the presence of french horns in both classes (as discussed in Section 3.3) might be problematic.

5.1.4 Baseline System

To compare the CNN-based results to a simple baseline system relying on standard audio features, we extract 20 mel-frequency cepstral coefficients (MFCC) per spectral patch $X_{p,:,:}$ and average them over the patch duration. This way, each spectral patch is represented by a 20-dimensional MFCC feature vector. We train a random forest classifier with 50 estimators obtaining an F-score of 0.75. This result—which could be further improved by using data augmentation and more diverse audio features—indicates that the benefit of our deep learning strategy over standard approaches is only weak when using datasets of limited size such as DB-MTC.

5.2 Experiment 2: Cross-Dataset Evaluation

In this experiment, we evaluate how well the CNN model generalizes to unseen datasets that represent different levels of timbral complexity. Ideally, we expect the model to learn spectro-temporal patterns that are unique to particular instrument families so that these patterns are recognized independent of a dataset's acoustic characteristics.

5.2.1 Evaluation Procedure

We split all three datasets DB-MTC, DB-SOL, DB-URMP and, additionally, a combination of them called DB-M/U/S, into individual training, validation, and test sets and perform cross-dataset evaluations. Concretely speaking, we train a model using training and validation sets taken from one dataset and evaluate using the test set of another dataset. Due to differences between the datasets, we restrict ourselves in this experiment to the three instrument families woodwinds, brass, and strings which are consistently present over all datasets. Consequently, we discard piano and vocal recordings from DB-MTC. Data augmentation and a comparison with the MFCC-based baseline system are not part of this experiment as we solely focus on the cross-dataset performance of the models.

We compare two approaches for splitting datasets into training, validation, and test sets. We either randomly select patches (patch-based) or split patches based on files (file-based) in order to avoid overfitting due to patches from the same file ending up in both the training and test sets. For the patch-based approach, we identify the smallest amount of available patches per class among the datasets. The smallest class is the brass class in DB-MTC with 4397 patches. Therefore, for the patch-based evaluation, we sample the same amount of patches from all other classes and datasets. We then use a split ratio of 40%–30%–30% to create training, validation, and test sets. Hence, each dataset finally consists of

Table 4: Mean F-scores for the parameter optimization on the DB-MTC dataset (Experiment 1) described in Section 5.1. The abbreviations for data augmentation methods (first four columns) are introduced in Table 2. The spectrogram compression methods LC 1, LC 10000, and PCEN, as well as the patch pre-processing methods −, A, B, C in the remaining columns are described in Section 4.2 and Section 4.3, respectively. The optimal parameter configuration (NO, A, full data augmentation) is highlighted using gray background color. The average standard deviation between F-scores over all three validation runs is 0.03 (min: 0.003, max: 0.15).

13191 patches. We create the fourth dataset DB-M/U/S by equally sampling patches from the other datasets.

For the file-based approach, we split each dataset using the same ratio of 40%–30%–30% on a file level, i. e., patches from one file will exclusively end up in one of the subsets. Here, no further steps are taken to balance out the amount of patches. Since this procedure leads to class imbalance, we use class weights as discussed in Section 4.4. The file-based version of DB-M/U/S is generated by accumulating all subsets over all datasets. Table 1 summarizes all datasets used in this experiment. For model training, we pick the parameters that lead to the best result in Experiment 1, namely no compression (NO) and patch pre-processing method C. We do not include any augmentations in this experiment.

5.2.2 Results

Table 5 shows the results for the cross-dataset evaluation on the patch-based data split. Due to the split strategy, the classifier overfits to the training set and naturally achieves high F-scores on the corresponding test set when patches are randomly mixed. This overfitting effect is supported by the fact that adding additional training data from a different dataset in DB-M/U/S even degrades the performance for testing on DB-MTC and DB-SOL.

Table 6 shows the results for the file-based data split. Due to its large size, DB-SOL has the highest impact on the model performance in the mixed dataset DB-M/U/S. When comparing the performance for training and testing on DB-MTC, the F-score drops by 0.12 for the file-based split strategy. This confirms our expectations since the DB-MTC dataset has a small number of files per class and a large variance of file durations.

As a general observation for both split strategies, the CNN approach for instrument family recognition shows only a limited capability to generalize well towards unseen data, which becomes apparent for all cross-dataset combinations in both tables (high values on the diagonal).

Table 5: Resulting F-scores for cross-dataset evaluation using patch-based dataset split. The rows and columns of the table indicate the training and test sets for each configuration, respectively.

Training \ Test	DB-MTC	DB-URMP	DB-SOL	DB-M/U/S
DB-MTC	**0.96**	0.70	0.62	0.77
DB-URMP	0.49	**0.96**	0.61	0.70
DB-SOL	0.64	0.78	**0.95**	0.79
DB-M/U/S	0.95	**0.97**	0.91	0.94

Table 6: Resulting F-scores for cross-dataset evaluation using file-based dataset split.

Training \ Test	DB-MTC	DB-URMP	DB-SOL	DB-M/U/S
DB-MTC	**0.84**	0.60	0.68	0.68

6. CONCLUSIONS

In this paper, we investigated a state-of-the-art convolutional neural network model for automatic instrument family recognition in Western classical music recordings. Focusing on monotimbral, polyphonic recordings, we showed that increasing the amount of training data via augmentation techniques leads to improved classification performance. We also found that pre-processing is of central importance for achieving a good system. Combining patch normalization with dynamic compression or per-channel energy normalization does not further improve the results, but these techniques may compensate the effect of patch normalization to some degree. Given that a simple MFCC-based baseline system already achieves good performance in Experiment 1, the possible superiority of more complex data-driven methods such as CNNs needs to be assessed carefully. In a cross-dataset experiment, we further tested how well the CNN model generalizes towards unseen data. Our results indicate that current CNN models lack generalization capability across different datasets, thus indicating the need for applying further optimization methods such as domain adaptation [5].

ABSTRACT

Chord recognition is an important task since chords are highly abstract and descriptive features of music. For effective chord recognition, it is essential to utilize relevant context in audio sequence. While various machine learning models such as convolutional neural networks (CNNs) and recurrent neural networks (RNNs) have been employed for the task, most of them have limitations in capturing long-term dependency or require training of an additional model.

In this work, we utilize a self-attention mechanism for chord recognition to focus on certain regions of chords. Training of the proposed bi-directional Transformer for chord recognition (BTC) consists of a single phase while showing competitive performance. Through an attention map analysis, we have visualized how attention was performed. It turns out that the model was able to divide segments of chords by utilizing adaptive receptive field of the attention mechanism. Furthermore, it was observed that the model was able to effectively capture long-term dependencies, making use of essential information regardless of distance.

1. INTRODUCTION

The goal of chord recognition task is to output a sequence of time-synchronized chord labels when a raw audio recording of music is given as input. Chords are highly abstract and descriptive features of music that can be used for a variety of musical purposes, including automatic lead-sheet creation for musicians, cover song identification, key classification and music structure analysis [4, 24, 26]. Since manual chord annotation is labor intensive, time consuming and requires expert knowledge, automatic chord recognition system has been an active research area within the music information retrieval community.

Automatic chord recognition is challenging due to the fact that 1) not all the notes played are necessarily related to the chord of the moment and 2) simple one-hot encoding of chord labels cannot represent the inherent relationship between different chords. Most traditional automatic chord recognition systems consist of three parts: feature extraction, pattern matching and chord sequence decoding. The most common strategy was to rely on hidden Markov models (HMMs) [3] for sequence decoding. Recently, many studies have explored various deep neural networks such as convolutional neural networks (CNNs) or recurrent neural networks (RNNs) [23] for chord recognition.

Recently, a novel attention-based network architecture named Transformer was proposed in [33]. It performs well without any recurrence or convolution and the use of Transformer has become popular in various domains. For example, a bi-directional Transformer model called BERT achieved state-of-the-art results on eleven natural language processing (NLP) tasks [10]. In the domain of music, [13] applied Transformer to a music generation task and succeeded in creating music with complex and repetitive structure.

In this paper we propose BTC (Bi-directional Transformer for Chord recognition). In contrast to the other chord recognition models that depend on training of separate feature extractors or adopting additional decoders such as HMMs or Conditional Random Fields (CRFs) [22], BTC requires only a single training phase while being able to obtain results comparable to them. We also visualize how the model works through attention maps. The attention maps demonstrate that BTC is able to 1) divide segments of chords by utilizing its adaptive receptive field and 2) capture long-term dependencies.

2. RELATED WORK

2.1 Automatic Chord Recognition

In the past, most automatic chord recognition systems were divided into three parts: feature extraction, pattern matching and chord sequence decoding. After applying transformation such as short-time Fourier transform or constant-q transform (CQT) to an input audio signal, features are extracted from the resulting time-frequency domain. Some examples of such hand-crafted features include chroma

vectors and the "Tonnetz" [11] representation. For pattern matching and chord sequence decoding, Gaussian mixture models with feature smoothing [6, 7] and HMMs [28, 32] have been the most popular choices, respectively.

With the recent wide acceptance of deep learning in research communities, there have been many studies applying it to chord recognition task in various ways. The very first deep-learning-based chord recognition system was proposed by [14] where they trained a CNN for major-minor chord classification. Attempts to apply deep learning to feature extraction include [16] and [19], where the former employed a CNN to extract Tonnetz features from audio data and the latter adopted a deep neural network (DNN) to compute chroma features. CNN and HMM were combined for chord recognition in [15] and [35].

In addition to CNN, another popular network architecture for chord recognition is RNN. [5] and [31] explored an RNN as chord sequence decoding method, relying on deep belief network and a DNN, respectively. Another branch of RNN-based chord recognition systems utilize a language model which predicts only the sequence of chords without considering their durations. This might be helpful when the number of chord labels is large (e.g. large vocabulary type, explained in Section 4.1). A large-scale study of language models for chord prediction was conducted in [18]. Without audio data, the authors trained just a language model with the chord progression data only and showed that RNNs outperformed N-gram models. In their succeeding work [21], they combined the RNN-based harmonic language model with a chord duration model to complete the chord recognition task.

Another RNN-based approach is presented in [34] which trained a CNN feature extractor with large MIDI (Musical Instrument Digital Interface) data and combined BLSTM (Bi-directional Long-Short Term Memory) with CRF for sequence decoder. This BLSTM-CRF model achieved good performance but has a drawback that its training procedure involves complex MIDI pre-training. The model that we propose, on the other hand, is much simpler to train.

2.2 Attention-based Models

The attention mechanism, first introduced by [2], can be described as computing an output vector when query, key and value vectors are given. In sequence modelling tasks such as machine translation, query and key correspond to certain elements of the target sequence and the source sequence respectively. Each key has its own value. The output is computed as a weighted sum of the values where the weights are computed from the query and key. Self-attention refers to the case when query, key and value are computed from the same input.

Transformer is an attention-based network that relies on attention mechanism only and does not include recurrent or convolutional architecture. Utilizing multi-head attention together with position-wise fully-connected feed-forward network, it showed significantly faster training speed and achieved better performance than recurrent or convolutional networks for translation tasks.

Transformer used scaled dot-product as an attention function:

$$Attention(Q, K, V) = softmax(\frac{QK^T}{\sqrt{d_K}})V \quad (1)$$

where Q, K and V are matrices of query, key and value vectors respectively, and d_K is the dimension of key.

The use of Transformer has become very popular, achieving the state-of-the-art results in various domains. A well-known example is bi-directional encoder representations from Transformers (BERT) [10]. BERT is a pre-training model based on masked language model for language representations that achieved state-of-the-art results on eleven NLP tasks. In the domain of music, [13] proposed music Transformer for symbolic music generation. Music Transformer employed relative attention to capture long-term structure effectively, which resulted in music compositions that are both qualitatively and quantitatively better structured than existing music generation models.

3. BI-DIRECTIONAL TRANSFORMER FOR CHORD RECOGNITION

3.1 Bi-directional Transformer

Making use of appropriate surrounding frames is essential for successful chord recognition [7, 8]. This context-dependent characteristic of the task is the motivation for applying the self-attention mechanism. With some modification to the original Transformer architecture, we present a bi-directional Transformer for chord recognition (BTC). [1]

The structure of BTC is shown in Figure 1. The model consists of bi-directional multi-head self-attentions, position-wise convolutional blocks, a positional encoding, layer normalization [1], dropout [30] and fully-connected layers. The model takes a CQT feature of 10 second audio signal (Section 4.1) as input. The results of adding positional encoding are given as input to two self-attention blocks with different masking directions, indicated as dotted boxes in Figure 1(b). The outputs are concatenated and are fed into a fully-connected layer so that the output size is the same as the original input. A stack of N bi-directional self-attention layers is followed by another fully-connected layer that outputs logit values. The size of the logit values is the same as the number of chord labels. These logits are used to predict the chord and calculate the loss.

The loss function is a negative log-likelihood and all the model parameters are trained to minimize the loss given by the following equation (2).

$$L = -\sum_{t=1}^{T}\sum_{c\in V} y_c(t) log(\hat{y_c}(t)) \quad (2)$$

T is the number of total time frames and V is the chord label set. $y_c(t)$ is 1 if the reference label at time t is c and 0 otherwise. $\hat{y_c}(t)$ is the output of the model, representing the probability of the chord at time t being c.

[1] https://github.com/jayg996/BTC-ISMIR19

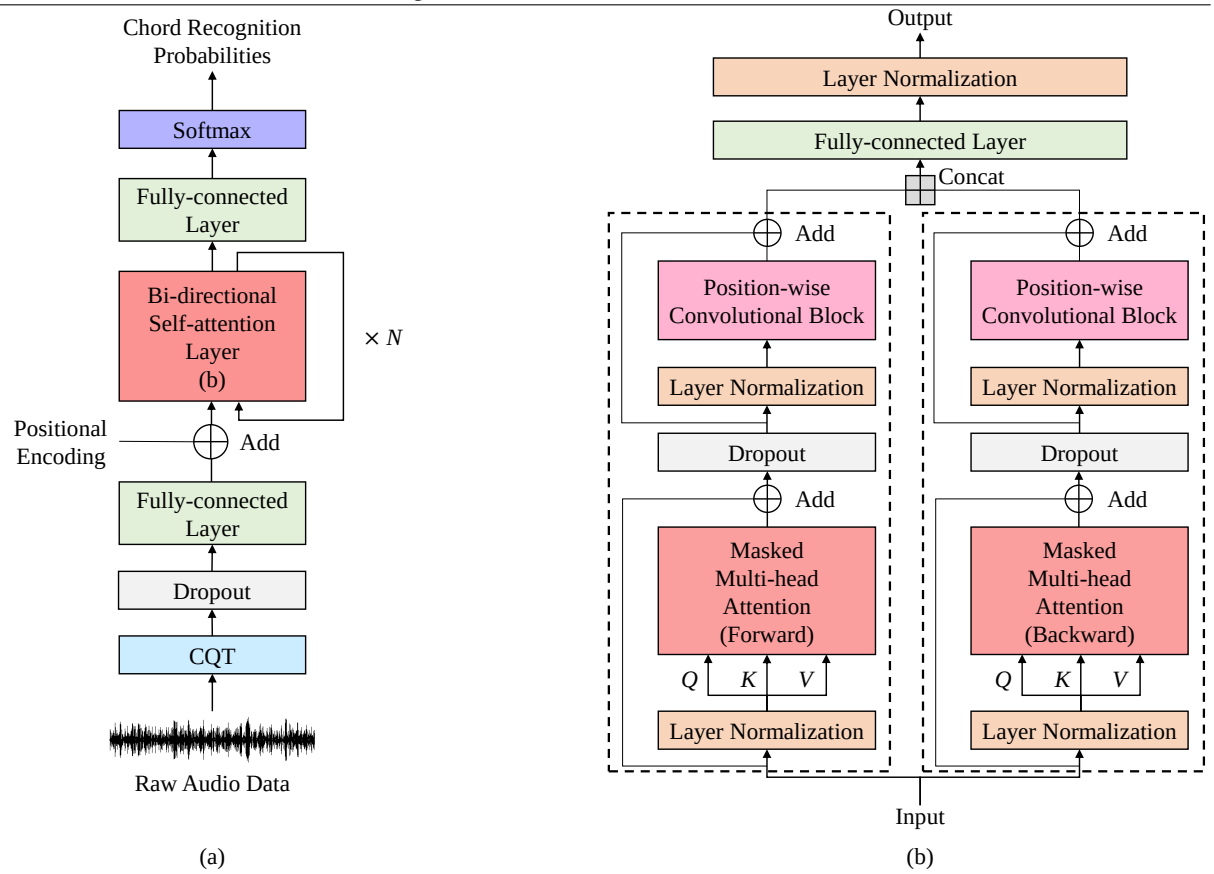

Figure 1. Structure of BTC. (a) shows the overall network architecture and (b) describes the bi-directional self-attention layer in detail. Dotted boxes indicate self-attention blocks.

3.1.1 Bi-directional Multi-head Self-attention

BTC employs multi-head self-attention as in the original Transformer. For each time frame, the input features are split into n_h pieces and provided as input to the multi-head self-attention with the number of heads, n_h. Given I as an input matrix, the multi-head self-attention can be computed as (3):

$$Multihead = Concat(head_1, ..., head_{n_h})W_O \quad (3)$$

$Q_j = (IW_Q)_j, K_j = (IW_K)_j$ and $V_j = (IW_V)_j$ are given as input to the attention function (1) to produce $head_j$ for $j = 1, ..., n_h$. W_Q, W_K and W_V are fully-connected layers that project the input to the dimension of Q, K and V, respectively. W_O is also a fully-connected layer that projects the concatenated output of dimension $(n_h \times d_{V_j})$ to the dimension of the final output. Dropout is applied to the softmax output weights when computing each $head_j$.

In BTC, self-attention can be interpreted as determining how much attention to apply to the value of the key time frame when inferring the chord of the query time frame. To prevent the loss of information due to the attention being performed to the entire input at once, we employed bi-directional masking. The forward / backward direction refers to masking all the preceding / succeeding time frames. The same masked multi-head attention module as the Transformer decoder was adopted. The bi-directional structure enables BTC to fully utilize the context before and after the target time frame.

Since the multi-head attention is performed on every time frame in the sequence, information about the order of the sequence is lost. We employed the same solution proposed by Transformer to address this issue: adding positional encoding results to the input, which are obtained by applying sinusoidal functions to each position. Since relative positions between two frames can be expressed as a linear function of the encodings, positional encoding helps the model learn to apply attention via relative positions.

3.1.2 Position-wise Convolutional Block

To utilize the adjacent feature information in a time frame, we replaced the position-wise fully-connected feed-forward network from the original Transformer architecture with a position-wise convolutional block. The position-wise convolutional block consists of a 1D convolution layer, a ReLU (Rectified Linear Unit) activation function and a dropout layer, where the whole sequence of layers is repeated n_C times. Input and output channel size were identical to keep the feature size and sequence length constant. With the position-wise convolutional block, we anticipate to search the boundary and smooth the chord sequence by exploring adjacent information at each time frame.

3.2 Self-attention in Chord Recognition

For chord recognition, it is important to utilize not only the information from the target time frame but also from other related frames, which we call the context. The network architectures such as CNNs or RNNs can also explore the context, but self-attention is more suitable for the task because of the following reasons.

First, self-attention has selective usage of attention. In other words, the receptive field can be adaptive unlike CNNs where the kernel size is fixed. For example, assume that the labels for 16 frames are Cs for the first four frames, Gs and Fs for the next eight frames and Cs for the last four frames (see Figure 2). Consider the situation of recognizing Gs in frames 5 to 8. As for a CNN with kernel size of 3, when recognizing the chord of frame 7, the receptive field (frame 6 to 8) would be informative enough since all the frames contain the same chord. However, when inferring frame 5, the receptive field of frame 4 to 6 contains not only G but also C. With self-attention, on the other hand, the model can pay attention to the section of frame 5 to 8 regardless of the target frame's position.

Another advantage of attention mechanism is its ability to capture long-term dependency effectively. RNNs can also utilize distant information but direct access is not possible. For CNNs, there are two ways to access distant frames: by stacking layers in depth or by increasing the kernel size. The former has the same drawback as RNNs and the latter has the disadvantage that the weight sharing becomes less effective. Unlike these, self-attention has direct access to other frames no matter how far they are. Specifically, when recognizing the chord of frame 13, performing attention to first four frames would be helpful since they all contain C. With RNNs or deep CNNs, information that the first four frames were C would inevitably be diluted while passing through frames 5 to 12.

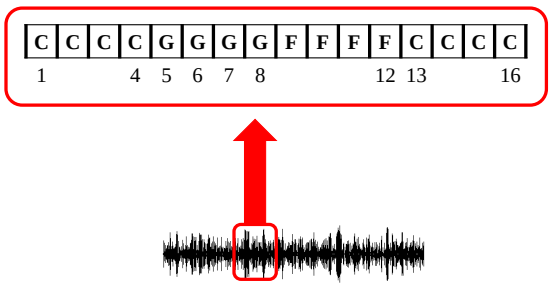

Figure 2. Chord sequence example

4. EXPERIMENTS

4.1 Data and Preprocessing

BTC and other baseline models were evaluated on the following datasets. A subset of 221 songs from Isophonics [2]: 171 songs by the Beatles, 12 songs by Carole King, 20 songs by Queen and 18 songs by Zweieck; Robbie Williams [12]: 65 songs by Robbie Williams; and a subset of 185 songs from UsPop2002 [3]. These datasets consist of label files that specify the start time, end time and type of the chord. Due to copyright issue, these datasets do not include audio files. The audio files used in this work were collected from online music service providers (e.g. Melon [4]), which do not always provide the same audio files corresponding to the songs in the datasets. Since it was not possible to get exactly the same audio files, there were subtle differences in the chord start time of the label file and audio file. Accordingly we manually matched the labels to the audio file by shifting the whole label file back and forth, which resulted in no more than adding or deleting some "No chord" labels.

Each 10-second-long audio signal (consecutive signals overlapping 5 seconds) was processed at the sampling rate of 22,050Hz using CQT with 6 octaves starting from C1, 24 bins per octave, and the hop size of 2048 [34]. The CQT features were transformed to log amplitude with $S_{log} = ln(S + \epsilon)$ where S represents the CQT feature and ϵ is an extremely small number. After that, global z-normalization was applied with mean, variance from the training data.

Pitch augmentation was also employed to the audio file with pyrubberband [5] package and labels were changed with pitch variation. Pitch augmentation between -5 $\sim$ +6 semitones were applied to all the training data.

Two different label types were used: maj-min and large vocabulary. The maj-min label type consists of 25 chords (12 semitones $\times$ {maj, min} and "No chord") [20]. The large vocabulary label type consists of 170 chords (12 semitones $\times$ {maj, min, dim, aug, min6, maj6, min7, minmaj7, maj7, 7, dim7, hdim7, sus2, sus4} and "X chord : the unknown chord", "No chord") [25]. From the label files, we extracted the chord that matches the time frame of input feature and transformed it to the appropriate label type.

4.2 Evaluation Metric

The evaluation metric was weighted chord symbol recall (WCSR) score and 5-fold cross validation was applied to the entire data. When separating the evaluation data from the training data, there was no song included in both. The WCSR score can be computed as (4), where t_c is the duration of correctly classified chord segments and t_a is the duration of the entire chord segments.

$$WCSR = \frac{t_c}{t_a} \times 100(\%) \tag{4}$$

Scores were computed with mir_eval [27]. Root and Maj-min scores were used for the maj-min label type. Root, Thirds, Triads, Sevenths, Tetrads, Maj-min and MIREX scores were used for the large vocabulary label type. To calculate the score with mir_eval, the chord recognition results were converted into label files.

Table 1. WCSR scores averaged over the same 5 folds. Numbers next to the scores denote the standard deviations.

4.3 Results

Specific hyperparameters of BTC are summarized in Table 2. The hyperparameters with the best validation performance were obtained empirically after applying in 5-fold cross validation. Adam optimizer [17] was used with initial learning rate of 10^{-4}. Learning rate was decayed with rate 0.95 when validation accuracy did not increase. Training was stopped if the validation accuracy did not improve for over 10 epochs.

Since existing studies of chord recognition were evaluated on different datasets, it is difficult to say that a particular model is the state-of-the-art. Among the models that were trainable with our datasets, we chose three baseline models with good performance: CNN, CNN+CRF and CRNN. CNN is a VGG [29]-style CNN and CNN+CRF has an additional CRF decoder [20]. CRNN is a combination of CNN and gated recurrent unit [9], named "CR2" in [25]. The input was preprocessed as mentioned in Section 4.1 for BTC and CRNN. For CNN+CRF and CNN, a single label was estimated with a patch of 15 time frames, in a similar way to [20].

Table 1 shows the performance comparison results of the baseline models and BTC for two label types. The best value for each metric is represented in bold. Among the models without a CRF decoder, BTC showed the best performance for all metrics. Including models with a CRF decoder, CNN+CRF obtained the best result in most of the metrics. Still, BTC shows comparable performance to CNN+CRF, performing better in Sevenths and Maj-min metrics for the large vocabulary label type.

The main purpose of training a CRF decoder is to smooth the predicted chord sequences that are often fragmented. The performances of CRNN+CRF and BTC+CRF are also presented in Table 1 for comparison. Performance improvements due to the introduction of CRFs are evident in CNN but not in BTC and CRNN. This indicates that outputs of CNN were fragmented and an additional decoder training is necessary for better performance. On the other hand, BTC and CRNN can be trained with only CQT features and chord labels. That is, BTC requires only a single training phase while achieving the performance comparable to that of CNN+CRF.

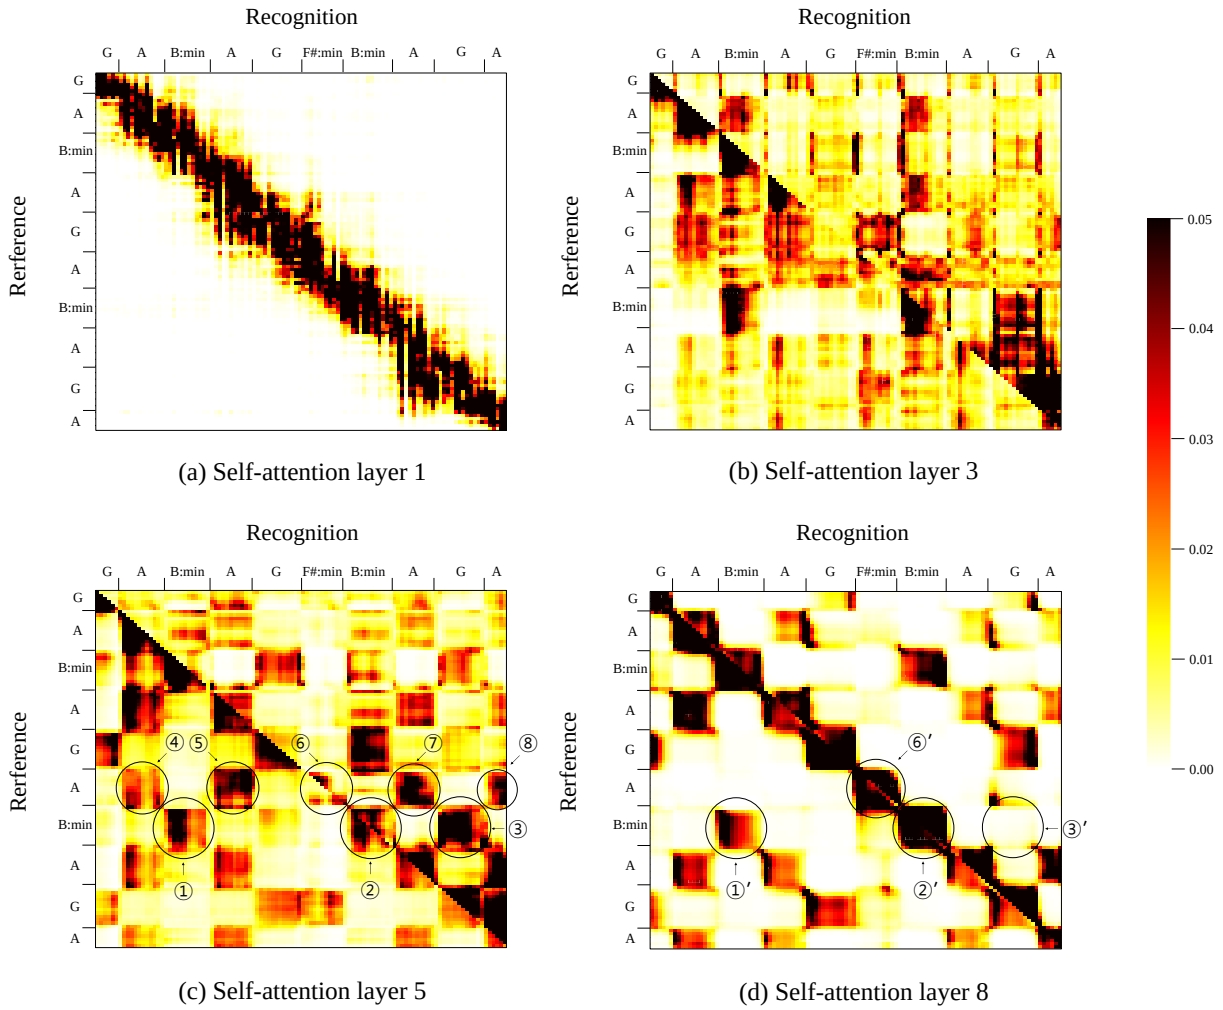
4.4 Attention Map Analysis

Attention maps demonstrate that each self-attention layer has different characteristics. Figure 3 shows the attention map of self-attention layers 1, 3, 5 and 8, trained with the maj-min label type. The lower / upper triangle of each attention map represents the attention probability of the forward / backward direction self-attention layer. The labels of the vertical axis and the horizontal axis are the reference chord and the chord recognition result of the target time frame, respectively. The cell of i-th row and j-th column represents the attention probability to the j-th time frame when inferring the chord of the i-th time frame.

At the first self-attention layer, only neighboring frames are used to construct the representation of the target frame. For the third layer, the attention is widely spread over all time frames, yet still with higher probabilities for nearby frames than distant frames. At the fifth layer, several adjacent time frames form a group, which appears in a rectangular region in the attention map. This means that the model divides the whole input into some sections, which is possible due to the adaptive receptive field. The network focuses only on a few important sections to identify the target frame, regardless of the distance between section and the frame. Unlike the fifth layer, attention is more dense in certain regions at the eighth layer. In particular, the boundary of the high probability region matches that of the final recognition result.

Specifically, at the fifth layer in Figure 3(c), the reference chord for region ② is B:min. Region ① shares the same reference chord B:min and the network assigns high attention probabilities to region ① for time frames in region ②. This phenomenon is similar in layer 8 between ①′ and ②′(Figure 3(d)), which results in the correct final chord recognition of B:min. In contrast, for region ③ where the reference chord is G, the attention probability is



(a) Self-attention layer 1

(b) Self-attention layer 3

(c) Self-attention layer 5

(d) Self-attention layer 8

Figure 3. The figures represent the probability values of the attention of self-attention layers 1, 3, 5 and 8 respectively. The layers that best represent the different characteristics were chosen. The input audio is the song "Just A Girl" (0m30s ∼ 0m40s) by No Doubt from UsPop2002, which was in evaluation data.

high at layer 5 but not for region ③′ at layer 8. This can be attributed to G and B:min sharing two notes in common, since G and B:min consist of (G,B,D) and (B,D,F#) respectively. In other words, attention at layer 5 can be seen as attention to partial features of chords sharing the same notes. None the less, the final recognition result after the last layer is not G but B:min. This is possible because of the multi-head attention structure: the other heads might lower the attention probability even if the attention to a wrong chord is active, leading to the correct result.

On the other hand, there are cases where the recognition results are wrong in a similar situation. The reference chord for regions ⑥ and ⑥′ is A. At layer 5, the attention mechanism seems to work well with high attention probabilities to region ④,⑤,⑦ and ⑧, where the reference chords are all As. However, the attention to those regions cannot be seen at the last layer, and the final recognition result is not A but F#:min. This recognition failure can be regarded as a result of two notes of F#:min (F#,A,C#) overlapping with A (A,C#,E).

To summarize, for each target frame in the input audio, the model uses only neighboring frames at first. At the middle layers, the model gradually broadens the receptive field and selectively focuses on time frames with characteristics similar to that of the target frame. Finally, at the last layer, the attention is performed on only essential information for chord recognition.

5. CONCLUSION

In this paper, we presented bi-directional Transformer for chord recognition (BTC). To the best of our knowledge, this paper was the first attempt to apply Transformer to chord recognition. The self-attention mechanism was appropriate for the task that attempts to capture long-term dependency by effectively exploring relevant sections. BTC has an advantage in that its training procedure is simple and it showed results competitive to other models in most of the evaluation metrics. Through the attention map analysis, it turned out that each self-attention layer had different characteristics and that the attention mechanism was effective in identifying sections of chords that were crucial for chord recognition.

ABSTRACT

In the last few years, several datasets have been released to meet the requirements of "hungry" yet promising data-driven approaches in music technology research. Since, for historical reasons, most investigations conducted in the field still revolve around music of the so-called "Western" tradition, the corresponding data, methodology and conclusions carry a strong cultural bias. Music of non-"Western" background, whenever present, is usually underrepresented, poorly labeled, or even mislabeled, the exception being projects that aim at specifically describing such music. In this paper we present SAMBASET, a dataset of Brazilian *samba* music that contains over 40 hours of historical and modern *samba de enredo* commercial recordings. To the best of our knowledge, this is the first dataset of this genre. We describe the collection of metadata (e.g. artist, composer, release date) and outline our semiautomatic approach to the challenging task of annotating beats in this large dataset, which includes the assessment of the performance of state-of-the-art beat tracking algorithms for this specific case. Finally, we present a study on tempo and beat tracking that illustrates SAMBASET's value, and we comment on other tasks for which it could be used.

1. INTRODUCTION

Machine-learning-based systems in music information retrieval (MIR) are becoming increasingly complex to cope with the also expanding number of tasks and the challenges they propose. In turn, estimating the parameters of these large models requires more and better data [29], especially because such data must often be separated into training, test, and validation sets. Although data augmentation can be used to alleviate this bottleneck [29], this kind of strategy is not able to solve the cultural bias still present in existing MIR data, methodologies, and conclusions [38].

Indeed, a great part of the research in this field focuses on musical traditions usually labeled as "Western". This is worrying, since by doing so we risk not being able to fully evaluate and reproduce specific musical properties found in some cultures [38]. Some datasets attempt to be universal and to cover a large number of music styles, but end up sacrificing the very representation of what they are trying to portray. This is the case, for example, of the well-known Ballroom and Extended Ballroom datasets, whose "Samba" class contains a mixture of songs of different origins, of which only a few examples correspond to Brazilian rhythms, specifically identifiable as *bossa-nova*, *pagode*, and others [28]. In other datasets, music from non-"Western" traditions is given generic labels as "Latin", or "World" [28]. This underscores the importance of increasing the efforts towards the study of non-"Western" traditions found throughout the multicultural world we live in.

1.1 Other Culture-Specific Datasets

Here we review some of the existing datasets devoted to non-"Western" music traditions. One of the biggest projects today is CompMusic [38], which focuses on five particular music cultures: Arab-Andalusian, Beijing Opera, Turkish-makam, Hindustani, and Carnatic. Several annotations are provided, including melody (e.g. singer tonics, pitch contours), rhythm and structure (e.g. tala cycles), scores (e.g. for percussion patterns), and lyrics.

There are also some datasets of Latin-American music launched with MIR in mind. For instance, the dataset released in [32] comprises annotated audio recordings of Uruguayan *candombe* drumming, suited for beat/downbeat tracking. Aimed at music genre classification, the Latin Music Database [39] has Brazilian rhythms—*axé*, *forró*, *gaúcha*, *pagode*, and *sertaneja*—and music from other traditions: *bachata*, *bolero*, *merengue*, *salsa*, and *tango*. Closer to the topic of this article, two datasets focus exclusively on Brazilian music: intended for music genre classification, the Brazilian Music Dataset [40] includes *forró*, rock, *repente*, MPB (Brazilian popular music), *brega*, *sertanejo*, and disco; meant for beat/downbeat tracking and rhythmic pattern analysis, the BRID [28] consists of typi-

cal rhythmic patterns of *samba*, *samba de enredo*, *partido-alto* and other styles played on Brazilian instruments.

1.2 Our Contributions

In this paper, we present SAMBASET, the first large dataset of annotated *samba de enredo* recordings. Besides describing the dataset contents and detailing the beat and downbeat annotation process, we highlight one possible (musicological) use of this dataset through a study on recordings' tempo across the years, and briefly discuss how its results agree with expert knowledge about the evolution of *sambas de enredo* over the last few decades. Finally, we draw our concluding remarks and point out other challenges that can be tackled with SAMBASET.

1.3 Notes on *Samba*

Samba plays a special role in Brazil's image overseas. And every year, the country receives millions of tourists for Carnival activities in cities such as Salvador and Rio de Janeiro. Being Brazil's quintessential rhythm, *samba*'s development is closely related to that of Brazil itself.

Samba's roots can be traced back to dance and religious practices from the Afro-Brazilian diaspora [1, 20] and, as Araujo [1] points out, to the accommodation efforts made by people of African descent to maintain their heritage and cultural identity despite slavery and persecution. In many of these cultural practices, participants would form a *roda* (circle) and accompany one or more dancers (positioned at the center of the *roda*) by clapping, singing, and occasionally playing instruments [1, 37]. These traditions gave origin to different cultural manifestations, collectively associated with the term *samba*, [1] for example: *coco*, *samba de roda*, *partido-alto*, *samba de terreiro*, *pagode*, among others. In the post-Abolition period, *samba* overcame prohibition to become Brazil's national rhythm.

In the 1930s, the genre evolved to the rhythmic framework that still defines it today—generally characterized by duple meter (i.e., binary division of the periodically perceived pulsations) and strong syncopation. However, the idea of syncope—momentary contradiction of the prevailing meter or pulse [36]—can only be adequately applied to "Western" music, creating a fundamental problem in music traditions where this disruption of the pulse is the norm, and not the exception. That is why some authors prefer to resort to the concepts of commetricity and contrametricity [37], which indicate respectively when the surface rhythm confirms or contradicts the underlying meter, a terminology more commonly used in African music studies [2, 24, 37]. Therefore, it is more appropriate to say that *samba* presents a strong tendency towards contrametricity.

Later developments in *samba* led to, arguably, the most internationally famous of all its subgenres, the *samba de enredo*. These are *sambas* subject to an *enredo* (plot) composed in the context of an *escola de samba*—popular association for the practice of *samba*, strongly connected to a specific community—, and presented at parades in an organized competition annually held along a so-called Sambadrome during Carnival. At the core of every *escola de samba* lies the *bateria* (percussion ensemble). During a performance, the rhythmic aura of a *bateria* is created by the superposition of several cyclical individual parts, assigned to each multi-piece instrument set, similarly to what is observed in percussion ensemble practices throughout sub-Saharan Africa [1]. The *bateria* sets the mood of *samba*, but recent studies have observed an increase in the average tempo of *bateria* performances, an effect attributable to stricter parading time constraints [12, 22, 34].

[1] Possibly a variation of *semba*, word for a kind of circle dance practice in the Angolan Kimbundu language [37].

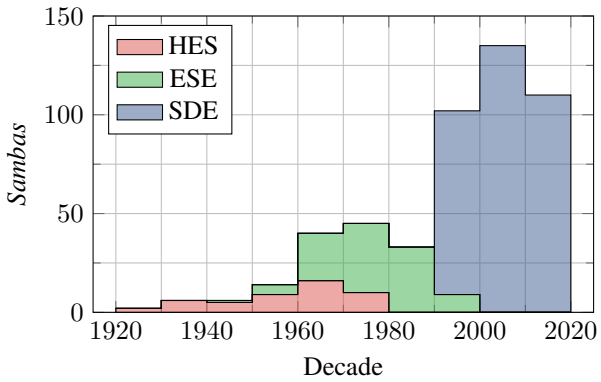

Figure 1: Recordings per decade of first performance.

2. DATASET OVERVIEW

Sambas de enredo are well documented in the phonographic industry. Apart from historical collections, since 1968 the yearly *sambas de enredo* that competing *escolas de samba* will perform at the carnival parade have been professionally recorded and marketed. Initially available as LP records, these official compilations began to appear as CDs in 1990. Since then, the amount of musicians (instrumentalists and choir) in each track has only increased.

Currently comprised of audio recordings, annotations and metadata, SAMBASET covers different eras, from later renditions of old classics to the most recent *sambas de enredo* just out of the Sambadrome. Figure 1 indicates the distribution of *sambas* w.r.t. the year they were first performed (typically, the parading year). Three major collections make up the dataset; in chronological order:

História das Escolas de Samba (HES): a collection of historical *sambas*, composed between 1928 and 1974, from four major *escolas de samba*, arranged and interpreted by the instrumentalists of each *escola*. Recorded in 1974, published in four LPs by Discos Marcus Pereira (redistributed as CDs in 2011), their 48 tracks also include a few *sambas de quadra/de terreiro* and *partidos-altos*.

Escolas de Samba – Enredos (ESE): a collection of historical *sambas*, composed between 1949 and 1993, from ten traditional *escolas de samba* in the voices of many idols from *samba*'s history, accompanied by a selected ensemble of instrumentalists and choir. There are a total of 100 tracks recorded and released in 1993 by Sony Music. This

Figure 2: Metadata file excerpt.

collection includes a couple of tracks from different subgenres (*samba de terreiro* and *samba-exaltação*).

Sambas de Enredo (SDE): official compilations of *sambas de enredo* recorded by members of the top *escolas* from Rio de Janeiro, for each carnival parade between 1994 and 2018. The 25 CDs gather 338 tracks, published by RCA/BMG/Sony BMG (1994–2006) and by Universal Music (after 2007), with one *samba de enredo* per track.

Table 1 gives the number of tracks for each *escola de samba* featured in the dataset, by genre. In total, there are 493 recorded sambas in 486 audio tracks, [3] resulting in over 40 hrs 30 min of content. All files are stereo with a sampling rate of 44.1 kHz and 16-bit resolution. Not only the three different collections allow for the coverage of different time periods, but they also have distinct sonorous characteristics. In HES, tracks feature only a few musicians playing very naturally and with great expression, as if they were in a *roda*. For several tracks in the official compilation (SDE), on the other hand, more than fifty instrumentalists play simultaneously while a choir of around the same size accompanies the main singer. Finally, ESE presents smaller ensembles and less expressiveness.

3. METADATA AND ANNOTATIONS

Metadata for albums and tracks were carefully curated and organized in an XML file. The information therein described was primarily obtained from CD booklets and later cross-checked with both the *União Brasileira de Compositores* [4] (lit. Brazilian Union of Composers, UBC) and the *Instituto Memória Musical Brasileira* [5] (Brazilian Musical Memory Institute, IMMuB). Whenever corresponding information was available, data was also checked against online database services such as FreeDB, MusicBrainz or Discogs. Finally, we consulted *samba*-oriented forums and websites for additional, conflicting or missing information.

All XML tags can be seen in Figure 2. While most of these labels are straightforward (e.g. title, composer), some require further clarification. First, the album_code refers to a unique code given to each album in the dataset. Albums from the HES and ESE collections were sequentially numbered, i.e., they are referred to by the codes HES1 to HES4 and ESE1 to ESE10, respectively. For SDE, albums were specified via the publishing year, which is also present in the album's title (i.e., SDE1994–SDE2018). The track_number is used with the album_code to name all audio files (e.g. the metadata in Figure 2 corresponds to file HES1.06.wav). Track's start_time and end_time indicate the time each *samba* starts and ends, respectively. This is invaluable since many *samba de enredo* recordings are preceded by a short introductory speech or song motivating the performance, or succeeded by a "farewell" shout after the music has already stopped. The checksum attributes were filled with the MD5 hash of the track's WAV file, to allow the verification of audio data integrity. Finally, mean bpm values were estimated from the beat annotations described in the following.

As of the writing of this paper, SAMBASET has annotations of beat and downbeat produced according to a semi-

[2] Some imbalance can be observed in the distributions of both genres and *escolas*. However, ST/SQ and OT tracks were only kept for the completeness of the dataset in regard to the CD collections, and the *escolas*' playing styles are not so heterogeneous as to make this imbalance critical.

[3] Some tracks in the ESE collection contain more than one *samba*.

[4] http://www.ubc.org.br/

[5] https://immub.org/

automatic procedure, after the results of the experiment described in Section 4. First, automatically-generated beat annotations were obtained for all audio files using the DBNBeatTracker system, which is available in the `madmom` package [3]—deemed a good candidate for providing reliable beat estimations (cf. Section 4). In a second step, these estimations were checked and manually corrected by one of the authors, who addressed eventual phase errors, and missing/extra beats. Since *samba de enredo* is always in duple meter, downbeats could be manually selected during this second phase. This two-step procedure greatly reduced the amount of manual work necessary to annotate beats and downbeats for this entire dataset.

4. ANALYSIS OF BEAT TRACKERS' PERFORMANCE

In this section, we provide a performance analysis of different state-of-the-art beat tracking systems, which were applied on a subset of short (30-second) excerpts from SAMBASET. Samples were selected according to a criterion based on the mean mutual agreement between beat estimation sequences generated by the algorithms under analysis, inspired by the approach of Holzapfel et al. [21]. This subset was manually annotated using Sonic Visualiser [11] by an expert with an engineering background, knowledgeable of audio technologies, and with many years of experience as a practicing musician, in particular of *samba*. Estimations were evaluated against this ground truth using three different types of metrics.

4.1 State-of-the-art Algorithms Considered

Fourteen algorithms (seen in Table 2) were used for sample selection and performance evaluation. We replaced eight of the algorithms originally featured in Holzapfel et al. [21] with six other algorithms released in following years, most notably those provided in the `madmom` package [3].

The algorithms are implemented in different programming languages and, in a few cases, require different operating systems. We used the Python implementations of AUB (version 0.4.9), ELL (provided by the librosa package [30] version 0.6.2), DEG and MFT (Essentia package [8] version 2.1-beta5-dev), BO1, BO2, and BO3 (madmom package [3] version 0.16.1); and the available releases of DIX (in Java, version 0.5.8), DAV (Vamp plugin in conjunction with the Sonic Annotator [10]), IB1 and IB2 (version 1.0 binaries). Finally, the C++ implementation of KLA was kindly provided by the author.

4.2 Evaluation Measures

Since there is currently no consensus on the evaluation metrics for the beat tracking task [13], with choices depending on the type of application, in this work we adopted the following methods [6]:

F-measure [17]: It is defined as the harmonic mean between precision (ratio between correctly detected and estimated beats) and recall (ratio between correctly detected and annotated beats). Generally, an estimated beat is considered correct if within ± 70 ms around an annotation.

Continuity-based measures [19]: Here, an estimated beat is considered correct if it is within a small tolerance around an annotation, the previous estimation has also been deemed correct, and the inter-beat interval is consistent with the inter-annotation interval within another tolerance—both generally set to 17.5% of the inter-annotation interval. CMLt ("correct metrical level") is the ratio between correct and annotated beats; accepting phase errors of half a beat period or octave errors in estimation yields the AMLt ("allowed metrical level").

Information Gain [14]: Defined as the Kullback-Leibler divergence between the observed beat error histogram (considering the timing errors of all estimated beats within a beat-length window around the annotations) and a uniform one (accounting for a pair of unrelated beat sequences), it spans the range $[0, \log_2(K)]$ bits, where K is the number of bins in the histograms (usually 40).

4.3 Selection of Ground Truth Excerpts

In [21], Holzapfel et al. presented a method for selecting challenging music examples for the beat tracking task without ground truth annotations. To do so, they first calculate the mean mutual agreement (MMA) between sequences estimated by a group of state-of-the-art beat trackers. The mutual agreement between two estimated beat sequences $\{i, j\}$ output by different beat tracking systems is given by the Information Gain in bits:

$$\mathrm{MA}_{i,j} = \mathrm{InfGain}(i, j), \quad i \neq j. \tag{1}$$

For a committee of N beat trackers, they then calculate the $N(N-1)/2$ different mutual agreements and average them all to obtain the MMA. The researchers show how a low mean mutual agreement coincides with perceptual and musical properties that make tapping difficult for humans. They build a challenging dataset by selecting samples with MMA < 1 bit, given a committee of five beat trackers.

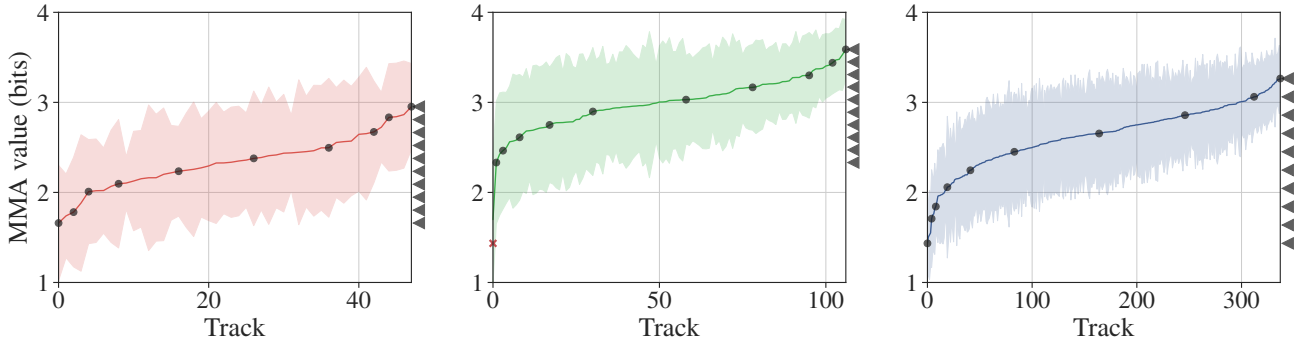
Later, in [42], they calculate the MaxMA, i.e., the algorithm whose output presents the maximum mutual agreement with the rest of the committee, showing that it provides the most reliable estimation for that given music example. They conduct subjective listening tests to determine a perceptual threshold for acceptable quality of this chosen output. This threshold is found to be 1.5 bits, for the same committee of five beat trackers. Their results also show a correlation between the test ratings and the MMA.

In this work, we followed a similar approach to select samples of various difficulties to the state-of-the-art algorithms. As mentioned in 4.1, we collected implementations of 14 beat tracking systems, removing some (the unavailable ones) featured in the original work [21], and adding others that were presented after its publication. We then extracted 30-second excerpts from all the different *sambas de enredo* in SAMBASET, and computed the MMA between estimations yielded by the beat trackers for all these 493 files. Figure 3 presents the ordered MMA values for excerpts from the three collections (HES, ESE, and SDE).

[6] Computed with standard settings using mir_eval [35] version 0.5.

Beat Tracker	CMLt (%)	AMLt (%)	F-meas. (%)	Inf. Gain (bits)
Aubio (AUB) [9]	59.4	65.6	61.9	2.30
BayesBeat-HMM (KR1) [25, 26]	42.7	65.6	67.6	2.27
BayesBeat-PF (KR2) [25, 27]	47.6	52.9	58.0	2.25
*BeatRoot (DIX) [17]	79.4	82.8	86.4	3.15
Davies (DAV) [15]	97.2	97.2	97.5	3.66
*Degara (DEG) [16]	88.3	91.2	89.7	3.40
*Ellis (ELL) [18]	76.9	76.9	78.7	3.35
IBT causal (IB1) [33]	83.4	83.4	86.2	2.45
*IBT non-causal (IB2) [33]	51.1	90.8	80.0	2.49
*Klapuri (KLA) [23]	61.3	63.7	63.1	3.09
BeatTracker (BO1) [5, 7]	98.1	98.1	98.6	3.78
DBNBeatTracker (BO2) [4, 26]	**99.5**	**99.5**	**99.5**	**3.80**
DBNDownBeatTracker (BO3) [6]	94.0	97.3	97.1	3.68
MultiFeature (MFT) [41]	86.4	86.4	86.8	3.55
Mean	76.1	82.2	82.2	3.09

Table 2: Ground truth performance of each beat tracking algorithm on the audio excerpts of SAMBASET. The best performance for each metric is highlighted in bold. The five-member committee proposed in [21] is indicated by an asterisk.



(a) HES collection (b) ESE collection (c) SDE collection

Figure 3: Collections sorted by MMA mean (solid line), with standard deviation (shaded region). Annotated samples (solid circles) were chosen as the closest to ten evenly spaced MMA values (solid triangles). One sample was treated as an outlier (cross) in (b).

For each collection, using the curve obtained from its excerpts, we determined P evenly spaced MMA values (including the maximum and minimum points), and selected the excerpts closest to each of these values to annotate. The reasons for this procedure are twofold: first, by selecting the same number of samples from each collection, we compensate for the large imbalance between them (e.g. in SDE there are nearly seven times more excerpts than in HES), while ensuring that their unique characteristics will be equally represented in the subset (recalling the variability in HES is much higher than that in ESE, or SDE); second, we guarantee that the algorithms will be compared within a group of samples to which they share different levels of consensus (and that would possibly provide a human annotator with a gamut of challenges). In total, thirty files were manually annotated ($P = 10$, i.e., ten from each collection), totalling just over 1 900 beats. It should be noted that a moderate number of annotated samples is sufficient, since we are dealing with a single music genre, which considerably limits the range of variations between them.

4.4 Discussion of Results

We see in Figure 3 that, in general, the fourteen beat tracking systems show more agreement in estimations for tracks in the ESE collection, followed by those in SDE, with HES in last. In fact, for over 50% of the tracks in ESE, the algorithms presented MMA > 3 bits, against slightly under 12% for SDE tracks and 0% in HES tracks in the same conditions. Considering an MMA > 2.5 bits, those percentages grow to 95%, 70% and 23%, respectively. This agrees with the authors' overall impression that the HES collection is the most "flavorful", whereas ESE is less expressive.

Regarding the test with the sampled subset, Table 2 gives the accuracy values for all algorithms, averaged over the thirty samples. Seven beat trackers perform better than the mean in all metrics, some of them outperforming the others by a large margin. In the end, the four best algorithms for our dataset are BO2, BO1, DAV, and BO3.

For the sake of comparison, we also evaluated the 493 excerpts with the five-member committee proposed in [21] and used in [42]: for 98.6% of the set the committee shows

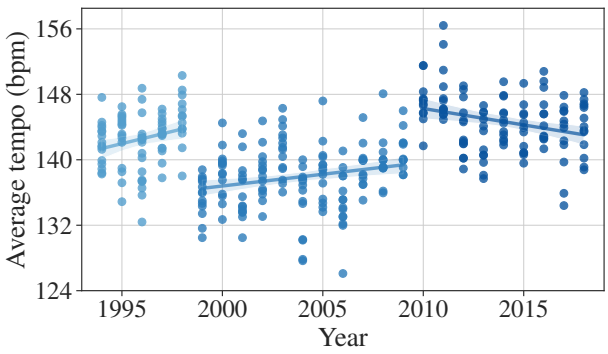


Figure 4: Variation of average tempo across the SDE collection with trend lines for three distinct regions and respective confidence intervals (shaded areas).

MMA > 1.5 bits; a single excerpt has MMA < 1 bit. This indicates that, overall, SAMBASET excerpts are not very challenging to the algorithms in this committee, which would provide a good number of acceptable estimations. Indeed, the good results shown by committee members in the ground truth performance suggests likewise. This analysis of state-of-the-art algorithms indicates a safe approach to semiautomatically annotating beats in this dataset.

5. MUSICOLOGICAL INSIGHTS

Here we investigate the evolution of average tempo in *samba de enredo* recordings across the years as represented in the SDE collection. For each excerpt, we compute the average tempo in beats per minute (bpm) as the inverse of the mean inter-beat interval, using the automatically detected beats. Figure 4 shows the average tempo for every track in SDE, plotted against the release year.

Although no clear trend is apparent from the whole data, we can readily verify the existence of local trends in three different regions of the graph. The first region accounts for the years of 1994 through 1998, and corresponds to the end of an era of "live" recordings in the *Teatro de Lona* (Barra da Tijuca), a large circus-like tent. As Moehn reveals on his essay "The Disc is not the Avenue" [31], by then the recordings were being made with a large number of musicians from each *escola* (around sixty) as well as large choirs from the respective community.

A radical change took place in the production of the 1999 disc: the entire process was moved to the studio and the number of *escola* members was reduced, not only to cut costs, but also to regain control over the sound organization [31]. Producers wanted the disc to sound "clear" and, thus, constrained the creative liberties of the *bateria*'s directors (e.g. they were not allowed to choose the tempo of the performance or to follow certain musical conventions that are common in a live performance). This was an attempt to recover the disc's marketability (sales had been dropping in previous years), despite distancing it from the actual phenomenon of the *samba de enredo* [31]. In 2010, "live" recordings were resumed, this time in the *Cidade do Samba* (Gambôa). Producers retreated in their interference on the soundscape creation, and the *escolas* were able to reclaim the final saying in some aspects of the recording, such as the tempo. The larger space provided by the *Cidade do Samba* also lead to an increase in the number of musicians taking part in the recordings: more than 8 000 for the 2014 CD against 1 500 in the 1998 recording [31].

Therefore, the first and third regions of Figure 4 more closely represent actual *samba de enredo* performances. In particular, notice that the average bpm in the third region is above the averages in the other two regions. This can be seen as a direct translation to the digital media of the decisions to accelerate the live performances (and the marching pace), so that the *escolas* satisfy changes in parading time limits, as reported by many specialists [12, 22, 34].

6. CHALLENGES

It would be very interesting to enrich this dataset with other types of annotations. In particular, one could think of generating ground truths for section boundaries (e.g. verses and the two different choruses that are very common in *samba de enredo* compositions), chord annotations (for instruments such as the *cavaquinho*), and instrument activity. As in the case of the CompMusic project [38], pitch contour annotations for soloist voices could be produced, as well as time-aligned lyrics and percussion transcription.

With these annotations, SAMBASET can provide many challenges to state-of-the-art algorithms in different MIR tasks. Tracks (specially in SDE) contain a plethora of simultaneous sounds of different qualities and textures, e.g. harmonic and percussive instruments, soloists and choirs. These could pose hard problems to vocal F0 or chord estimation systems. Also, singing voice annotation and lyrics could allow the study of soloist's interpretation as to phrasing, preferred ornaments, or characteristic syncopation; along with the metadata provided, it would be possible for example, to work on singer classification.

7. CONCLUSION

In this paper, we presented SAMBASET, a large *samba de enredo* dataset with rich metadata, beat and downbeat annotations. We provided a detailed overview of its contents [7] and reported a study on the performance of a group of state-of-the-art beat trackers over the set. We also motivated one musicological use of the dataset, i.e., the study of changes in *samba de enredo*'s rhythmic properties across several years. We expect that SAMBASET allows for technical improvements in traditional MIR tasks via new perspectives on problem solving that arise from contemplating cultures different from those to which we are accustomed.

8. ACKNOWLEDGEMENTS

Authors would like to thank CNPq and CAPES-ANII-CNRS (STIC AmSud program) for funding this work.

ABSTRACT

It has been shown that the harmonic series at the tempo frequency of the onset-strength-function of an audio signal accurately describes its rhythm pattern and can be used to perform tempo or rhythm pattern estimation. Recently, in the case of multi-pitch estimation, the depth of the input layer of a convolutional network has been used to represent the harmonic series of pitch candidates. We use a similar idea here to represent the harmonic series of tempo candidates. We propose the Harmonic-Constant-Q-Modulation which represents, using a 4D-tensors, the harmonic series of modulation frequencies (considered as tempo frequencies) in several acoustic frequency bands over time. This representation is used as input to a convolutional network which is trained to estimate tempo or rhythm pattern classes. Using a large number of datasets, we evaluate the performance of our approach and compare it with previous approaches. We show that it slightly increases Accuracy-1 for tempo estimation but not the average-mean-Recall for rhythm pattern recognition.

1. INTRODUCTION

Tempo is one of the most important perceptual elements of music. Today numerous applications rely on tempo information (recommendation, playlist generation, synchronization, dj-ing, audio or audio/video editing, beat-synchronous analysis). It is therefore crucial to develop algorithms to correctly estimate it. The automatic estimation of tempo from an audio signal has been one of the first research carried on in Music Information Retrieval (MIR) [11]. 25 years later it is still a very active research subject in MIR. This is due to the fact that tempo estimation is still an unsolved problem (outside the prototypical cases of pop or techno music) and that recent deep-learning approaches [3] [37] bring new perspectives to it.

Tempo is usually defined as (and annotated as) the rate at which people tap their foot or their hand when listening to a music piece. Several people can therefore perceive different tempi for the same piece of music. This is due to the hierarchy of the metrical structure in music (to deal with this ambiguity the research community has proposed to consider octave errors as correct) and due to the fact that without the cultural knowledge of the rhythm pattern(s) being played, it can be difficult to perceive "the" tempo (or even "a" tempo). This last point, of course, opens the door to data-driven approaches, which can learn the specificities of the patterns. In this work, we do not deal with the inherent ambiguity of tempo and consider the values provided by annotated datasets as ground-truth. The method we propose here belong to the data-driven systems in the sense that we learn from the data. It also considers both the tempo and rhythm pattern in interaction by adequately modeling the audio content. The tempo of a track can of course vary along time, but in this work we focus on the estimation of constant (global) tempi and rhythm patterns.

In the following section, we summarize works related to tempo and rhythm pattern estimation from audio. We refer the reader to [12, 32, 44] for more detailed overviews.

1.1 Related works

Tempo estimation. Early MIR systems encoded domain knowledge (audio, auditory perception and musical knowledge) by hand-crafting signal processing and statistical models (hidden Markov, dynamic Bayesian network). Data were at most used to manually tune some parameters (such as filter frequencies or transition probabilities). Early techniques for beat tracking and/or tempo estimation belong to this category. Their overall flowchart is a multi-band separation combined with an onset strength function which periodicity is measured. For example, Scheirer [36] proposes the use of band-pass filters combined with resonating comb filters and peak picking; Klapuri [18] uses the resonating comb filter bank which is driven by the bandwise accent signals, the main extension is the tracking of multiple metrical levels; Gainza and Cole [8] propose a hybrid multiband decomposition where the periodicities of onset functions are tracked in several frequency bands using autocorrelation and then weighted.

Since the pioneer works of [11], many audio datasets have been annotated into tempo. This therefore encourages researchers to develop data-driven systems based on machine learning and deep learning techniques. Such machine-learning models are K-Nearest-Neighbors (KNN) [40], Gaussian Mixture Model (GMM) [33, 43], Support Vector Machine (SVM) [4, 9, 34], bags of classifiers [20], Random Forest [38] or more recently deep learning models. The first use of deep learning for tempo estimation

was proposed by Böck et al. [3] who proposed a deep Recurrent Neural Network (bi-LSTM) to predict the position of the beats inside the signal. This output is then used as the input of a bank of resonating comb filters to detect the periodicity and so the tempo. This technique still achieves the best results today in terms of Accuracy2. Recently, Schreiber and Müller [37] proposed a "single step approach" for tempo estimation using deep convolutional networks. The network design is inspired by the flowchart of handcrafted systems: the first layer is supposed to mimic the extraction of an onset-strength-function. Their system uses as input Mel-spectrograms and the network is trained to classify the tempo of an audio excerpt into 256 tempo classes (from 30 to 285 BPM), it shows very good results in terms of Class-Accuracy and Accuracy1.

Rhythm pattern recognition. While tempo and rhythm pattern are closely interleaved, the recognition of rhythm pattern has received much less attention. This is probably due to the difficulty of creating datasets annotated in such rhythm pattern (defining the similarity between patterns — outside the trivial identity case — remains a difficult task). To create such a dataset, one may consider the equivalence between the rhythm pattern and the related dance (such as Tango): *Ballroom* [12], *Extended-ballroom* [24] and *Greek-dances* [14]. Systems to recognize rhythm pattern from the audio are all very different: Foote [7] defines a beat spectrum computed with a similarity matrix of MFCCs, Tzanetakis [42] defines a beat histogram computed from an autocorrelation function, Peeters [32] proposes a harmonic analysis of the rhythm pattern, Holzapfel [15] proposes the use of the scale transform (which allows to get a tempo invariant representation), Marchand [23, 25] extends the latter by combining it with the modulation spectrum and adding correlation coefficients between frequency bands. For a recognition task on the Extended-ballroom and Greek-dances, Marchand can be considered as the state-of-the-art.

1.2 Paper proposal and organization

In this paper we present a new audio representation, the Harmonic-Constant-Q-Modulation (HCQM), to be used as input to a convolutional network for global tempo and rhythm pattern estimation. We name it **Deep Rhythm** since it uses the **depth** of the input and a **deep** network. The paper is organized as follows. In §2, we describe the motivation for (§2.1) and the computation details of (§2.2) the HCQM. We then describe the architecture of the convolutional neural network we used (§2.3) and the training process (§2.4). In §3, we evaluate our proposal for the task of global tempo estimation (§3.1) and rhythm pattern recognition (§3.2) and discuss the results.

2. PROPOSED METHOD

2.1 Motivations

From Fourier series, it is known that any periodic signal $x(t)$ with period T_0 (of fundamental period $f_0 = 1/T_0$) can be represented as a weighted sum of sinusoidal components which frequencies are the harmonics of f_0: $\hat{x}_{f_0,\underline{a}}(t) = \sum_{h=1}^{H} a_h \sin(2\pi h f_0 t + \phi_h)$.

For the voiced part of speech or pitched musical instrument, this leads to the so-called "harmonic sinusoidal model" [26, 39] that can be used for audio coding or transformation. This model can also be used to estimate the pitch of a signal [21]: estimating the f_0 such that $\hat{x}_{f_0,\underline{a}}(t) \simeq x(t)$. The values a_h can be estimated by sampling the magnitude of the DFT at the corresponding frequencies $a_{h,f_0} = |X(hf_0)|$. The vector $\underline{a}_{f_0} = \{a_{1,f_0} \cdots a_{H,f_0}\}$ represents the spectral envelope of the signal and is closely related to the timbre of the audio signal, hence the instrument playing. For this reason, these values are often used for instrument classification [29].

For audio musical rhythm, Peeters [30] [31] [32] proposes to apply such an harmonic analysis to an onset-strength-function . The period T_0 is then defined as the duration of a beat. a_{1,f_0} then represents the DFT magnitude at the 4^{th}-note level, a_{2,f_0} at the 8^{th}-note level, a_{3,f_0} at the 8^{th}-note-triplet level, while $a_{\frac{1}{2},f_0}$ represent the binary grouping of the beats and $a_{\frac{1}{3},f_0}$ the ternary one. Peeters considers that the vector $\underline{a}$ is representative of the specific rhythm and that therefore $\underline{a}_{f_0}$ represents a specific rhythm played at a specific tempo f_0. He proposes the following harmonic series: $h \in \{\frac{1}{4}, \frac{1}{3}, \frac{1}{2}, \frac{2}{3}, \frac{3}{4}, 1, 1.25, 1.33, \ldots 8\}$ Using this, he shows - in [32] that given the tempo f_0, the vector $\underline{a}_{f_0}$ can be used to classify the different rhythm pattern; - in [30], that given manually-fixed prototype vectors $\underline{a}$, it is possible to estimate the tempo f_0 (looking for the f such that $\underline{a}_f \simeq \underline{a}$); - in [31] that the prototype vectors $\underline{a}$ can be learned (using simple machine-learning) to achieve the best tempo estimation f_0.

The method we propose in this paper is in the continuation of this last work (learning the values $\underline{a}$ to estimate the tempo or the rhythm class) but we adapted it to the deep learning formalism recently proposed by Bittner et al. [2] where the depth of the input to a convolutional network is used to represent the harmonic series $\underline{a}_f$. In [2], a constant-Q-transform (time τ and log-frequency f) is expanded to a third dimension which represent the harmonic series $\underline{a}_f$ of each f (with $h \in [\frac{1}{2}, 1, 2, 3, 4, 5]$). When $f = f_0$, $\underline{a}_f$ will represent the specific harmonic series of the musical instrument (plus an extra value at the $\frac{1}{2}f$ position used to avoid octave errors). When $f \neq f_0$, $\underline{a}_f$ will represent (almost) random values. In [2], the goal is to estimate the parameters of a filter such that when multiplied with this third dimension $\underline{a}_f$ it will provide very different values when $f = f_0$ or when $f \neq f_0$. This filter will then be convolved over all log-frequencies f and time τ to estimate the f_0's. This filter is trained using annotated data. In [2], there is actually several of such filter; they constitute the first layer of a convolutional network. In practice, in [2], the $a_{h,f}$ are not obtained as $|X(hf)|$; but by stacking in depth several CQTs each starting at different minimal frequencies $hf_{\min}$. The representation is denoted by Harmonic Constant-Q Transform (HCQT): $X_{hcqt}(f, \tau, h)$.

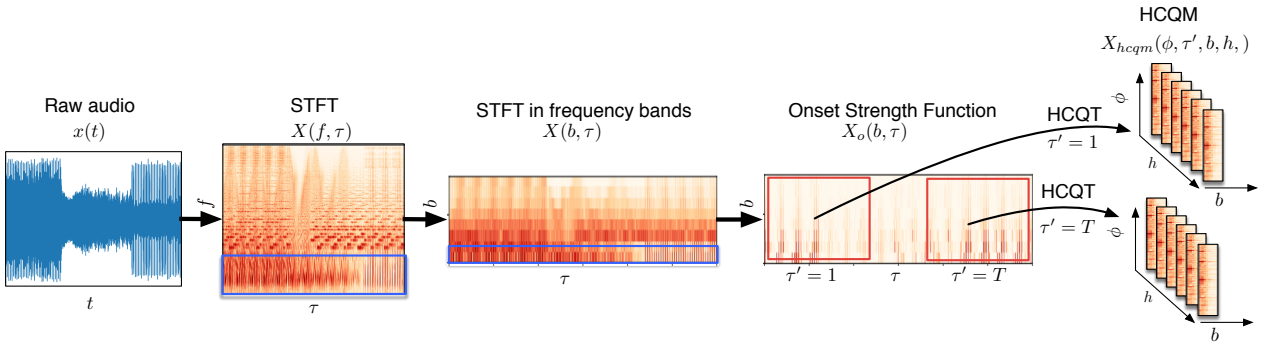

Figure 1. Flowchart of the computation of the Harmonic-Constant-Q-Modulation (HCQM). See text for details.

2.2 Input representation: the HCQM

As mentioned our goal is here to adapt the harmonic representation of the rhythm proposed in [30] [31] [32] to the deep learning formalism proposed in [2]. For this, the HCQT proposed by [2] is not applied to the audio signal, but to a set of Onset-Strength-Function (OSF) which represent the rhythm content in several acoustic frequency bands. The OSFs are low-pass signals which temporal evolution is related to the tempo and the rhythm pattern.

We denote our representation by **Harmonic-Constant-Q-Modulation (HCQM)**. As the Modulation Spectrum (MS) [1] it represents, using a time/frequency (τ'/ϕ) representation, the energy evolution (low-pass signal) within each frequency band b of a first time/frequency (τ/f) representation. However, while the MS uses two interleaved Short-Time-Fourier-Transforms (STFTs) for this, we use a Constant-Q transform for the second time/frequency representation (in order to obtain a better spectral resolution). Finally, as proposed by [2], we add one extra dimension to represent the content at the harmonics of each frequency ϕ. We denote it by $X_{hcqm}(\phi, \tau', b, h)$ where ϕ are the modulation frequencies (which correspond to the tempo frequencies), τ' are the times of the CQT frames, b are the acoustic frequency bands and h the harmonic numbers.

Computation. In Figure 1, we indicate the computation flowchart of the HCQM. Given an audio signal $x(t)$, we first compute its STFT, denoted by $X(f, \tau)$. The acoustic frequency f of the STFT are grouped into logarithmic-spaced acoustic-frequency-bands $b \in [1, B = 8]$. We denote it by $X(b, \tau)$. The goal of this is to reduce the dimensionality while preserving the information of the spectral location of the rhythm events (kick patterns tend to be in low frequencies while hit-hat patterns in high frequencies). For each band b, we then compute an Onset-Strength-Function over time τ, denoted by $X_o(b, \tau)$.

For a specific b, we now consider the signal $s_b(\tau) = X_o(b, \tau)$ and perform the analysis of its periodicities over time τ. One possibility would be to compute a time-frequency representation $S_b(\phi, \tau')$ over tempo-frequencies ϕ and time frame τ' and then sample $S_b(\phi, \tau')$ at the positions $h\phi$ with $h \in \{\frac{1}{2}, 1, 2, 3, 4, 5\}$ to obtain $S_b(\phi, \tau', h)$. This is the idea we used in [32]. However, in the present work, we use the idea proposed by [2]: we compute a set of CQTs [1], each one with a different starting frequency $h\phi_{\min}$. We set $\phi_{\min}$=32.7. Each of these CQTs gives us $S_{b,h}(\phi, \tau')$ for one value of h. Stacking them over h therefore provides us with $S_b(\phi, \tau', h)$. The idea proposed by [2] therefore allows to mimic the sampling at the $h\phi$ but provides the correct window length to achieve a correct spectral resolution. We finally stack the $S_b(\phi, \tau', h)$ over b to obtain the 4D-tensors $X_{hcqm}(\phi, \tau', b, h)$. The computation parameters (sample rate, hop size, window length and FFT size) are set such that the CQT modulation frequency ϕ represents the tempo value in BPM.

Illustration. For easiness of visualisation (it is difficult to visualize a 4D-tensor), we illustrate the HCQM $X_{hcqm}(\phi, \tau', b, h)$ for a given τ' (it is then a 3D-tensor). Figure 2 [Left] represent $X_{hcqm}(\phi, b, h)$ on a real audio signal with a tempo of 120 bpm. Each sub-figure represent $X_{hcqm}(\phi, b, h)$ for a different value of $h \in \{\frac{1}{2}, 1, 2, 3, 4, 5\}$. The y-axis and x-axis are the tempo frequency ϕ and the acoustic frequency band b. The dashed rectangle super-imposed to the sub-figures indicates the slice of values $X_{hcqm}(\phi = 120bpm, b, h)$ which corresponds to the ground-truth tempo. It is this specific pattern over b and h that we want to learn using the filters W of the first layer of our convolutional network.

2.3 Architecture of the Convolutional Neural Network

The architecture of our network is both inspired by the one of [2] (since we perform convolutions over an input spectral representation and use its depth) and the one of [37] (since we perform a classification). However, it differs in the definition of the input and output.

Input. In [2], the input is the 3D-tensor $X_{cqt}(f, \tau, h)$ and the convolution is done over f and τ (with filters of depth H). In our case, the input could be the 4D-tensors $X_{hcqm}(\phi, \tau', b, h)$ and the convolution could be done over ϕ, τ' and b (with filters of depth H). However, to simplify the computation, we reduce $X_{hcqm}(\phi, \tau', b, h)$ to a sequence over τ' of 3D-tensors $X_{hcqm}(\phi, b, h)$ [2]. The convolution is then done over ϕ and b with filters of depth H.

Our goal is to learn filters W narrow in ϕ and large in b which represents the specific shape of the harmonic con-

[1] For the STFT and CQT we used the librosa library [27].

[2] Future works will concentrate in performing the convolution directly using the 4D-tensors; which would allow to perform smoothing over time.

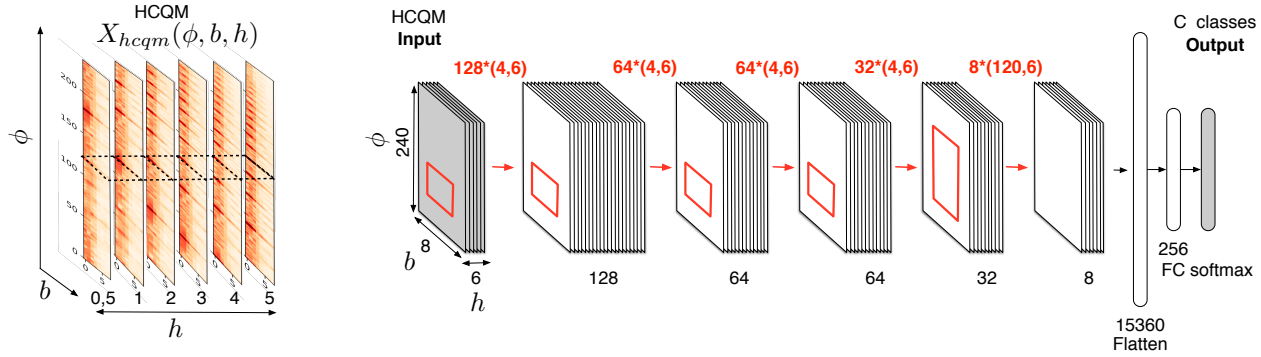

Figure 2. [Left] Example of the HCQM for a real audio with tempo 120bpm. [Right] Architecture of our CNN.

tent of a rhythm pattern. We do the convolution over b because the same rhythm pattern can be played with instrument transposed in acoustic frequencies.

Output. The output of the network proposed by [2] is a 2D representation which represents a saliency map of the harmonic content over time. In our case, the outputs are either the $C = 256$ classes of tempo (as in [37] we consider the tempo estimation problem as a classification problem into 256 tempo classes) or the $C = 13$ (for extended-ballroom) or $C = 6$ (for Greek-dances) classes of rhythm pattern. To do so, we added at the end of the network proposed by [2] two dense layers, the last one with C units and a softmax activation.

Architecture. In Figure 2 [Right], we indicate the architecture of our network. The input is a 3D-tensor $X_{hcqm}(\phi, b, h)$ for a given time τ'. The first layer is a set of 128 convolutional filters of shape $(\phi = 4, b = 6)$ (with depth H). As mentioned, the convolution is done over ϕ and b. The shape of these filters has been chosen such that they are narrow in tempo frequency ϕ (to precisely estimate the tempo) but cover multiple frequency acoustic bands b (because the information relative to the tempo/ rhythm cover several bands). As illustrated in Figure 2 [Left] the goal of the filters is to identify the pattern over b and h specific to $\phi =$ tempo frequency.

The first layer is followed by two convolutional layers of 64 filters of shape $(4, 6)$, one layer of 32 filters of shape $(4, 6)$, one layer of 8 filters of shape $(120, 6)$ (this allows to track down the relationships between the modulation frequencies ϕ). The output of the last convolution layer is then flattened and followed by a dropout with $p = 0.5$ (to avoid over-fitting [41]), a fully-connected layer of 256 units, a last fully-connected layer of C units with a softmax activation to perform the classification into C classes. The softmax activation vector is denoted by $\underline{y}(\tau')$. The Loss function to be minimized is a categorical cross entropy.

All layers are preceded by a batch normalization [16]. We used Rectified Linear Units (ReLU) [28] for all convolutional layers, and Exponential Linear Units (eLU) [5] for the first fully-connected layer.

2.4 Training

The inputs of our network are the 3D tensors HCQM $X_{hcqm}(\phi, b, h)$ computed for all time τ' of the music track. On the other side, the datasets we will use for our experiments only provide **global** tempi [3] or **global** rhythm classes as ground-truths. We therefore have several HCQMs for a given track which are all associated with the same ground-truth (multiple instance learning).

To fix the network hyper-parameters, we split the training set into a train (90%) and a validation part (10%). We used the ADAM [17] optimizer to find the parameters of the network with a constant learning rate of 0.001, $\beta_1 = 0.9$, $\beta_2 = 0.999$ and $\epsilon = 1e - 8$. We used mini-batches of 256 HCQM with shuffle and a maximum of 20 epochs with early-stopping.

2.5 Aggregating decisions over time

Our network provides an estimation of the tempo or rhythm class at each time τ'. To obtain a **global** value we aggregate the softmax activation vectors $\underline{y}(\tau')$ over time by choosing the maximum of the vector $\underline{y}$ computed as the average over τ' of the $\underline{y}(\tau')$.

3. EVALUATION OF THE SYSTEM

We evaluate our proposed system for two tasks: - **global tempo estimation** (§3.1), - **rhythm pattern recognition** (§3.2). We used the same system (same input representation and same network architecture) for the two tasks. However, considering that the class definitions are different, we performed two independent trainings [4] .

3.1 Global tempo estimation

Training and testing sets. To be able to compare our results with previous works, we use the same paradigm (cross-dataset validation [5]) and the same datasets as [37] which we consider here as the state-of-the-art. The **training set** is the union of

[3] It should be noted that this does not always correspond to the reality of the track content since some of them have a tempo varying over time (tempo drift), have a silent introduction or a break in the middle.

[4] Future works, will consider training a single network for the two tasks or applying transfer learning of one task to the other.

[5] Cross-dataset validation uses separate datasets for training and testing; not only splitting a single dataset into a train and a test part.

- *LMD tempo*: it is a subset of the Lack MIDI dataset [35] annotated into tempo by [38]; it contains 3611 items of 30s excerpts of 10 different genres
- *MTG tempo* it is a subset of the GiantSteps MTG key dataset (MTG tempo) [6] annotated using a tapping method by [37]; it contains 1159 items of 2min excerpts of electronic dance music;
- *Extended Ballroom* [24]: it contains 3826 items of 13 genres (it should be noted that we removed from the Ballroom test-set the items existing in the Extended Ballroom training-set).

The total size of the training set is 8596. It covers multiple musical genres to favor generalization.

The **test-sets** are also the same as in [37] (see [38] for their details): - *ACM-Mirum* [33] (1410 items), - *ISMIR04* [12] (464 items), - *Ballroom* [12] (698 items), - *Hainsworth* [13] (222 items), - *GTzan-Rhythm* [22] (1000 items), - *SMC* [14] (217 items), - *Giantsteps Tempo* [19] (664 items). We also added the *RWC-popular* [10] (100 items) for comparison with [3]. As in [37], *Combined* denotes the union of all test-sets (except RWC popular).

Evaluation protocol. We measure the performances using the following metrics:

- **Class-Accuracy:** it measures the ability of our system to predict the correct tempo class (in our system we have 256 tempo classes ranging from 30 to 285bpm);
- **Accuracy1:** it measures if our estimated tempo is within $\pm 4\%$ of the ground-truth tempo
- **Accuracy2:** is the same as Accuracy1 but considering octave errors as correct

Results and discussions. The results are indicated in Tables 1, 2 and 3.

Validation of B and H. We first show that the separation of the signal into multiple acoustic-frequency-bands $b \in [1, B = 8]$ and the use of the harmonic depth H is beneficial. For this, we compare the results obtained using
- $B = 8$ and $h \in \{\frac{1}{2}, 1, 2, 3, 4, 5\}$ (column "new")
- $B = 8$ but $h \in \{1\}$ (column "h=1")
- $B = 1$ and $h \in \{\frac{1}{2}, 1, 2, 3, 4, 5\}$ (column "b=1").

Results are only indicated for the "Combined" test-sets. For all metrics (Class-Accuracy, Accuracy-1 and Accuracy-2), the best results are obtained using $B = 8$ and $h \in \{\frac{1}{2}, 1, 2, 3, 4, 5\}$.

Comparison with state-of-the-art. We now compare our results with the state-of-the-art represented by the 3 following systems: - **sch1** denotes the results published in [38], - **sch2** in [37] and - **böck** in [3].

According to these Tables, we see that our method allows an improvement for two test-sets: - *Ballroom* in terms of Class-Accuracy (73.8) - *Ballroom* and *Giantsteps* in terms of Accuracy1 (92.6 and 83.6) and Accuracy2 (98.7 and 97.9). This can be explained by the fact that the musical genres of these two test-sets are represented in our training set (by the *Extended-Ballroom* and *MTG tempo* respectively). It should be noted however that there is no intersection between the training and test sets. For the *ISMIR04* and *GTZAN* test-sets, our results are very close (but lower) to the one of **sch1**. For the *RWC popular* test sets, our results (73.0 and 98.0) largely outperforms the ones of **böck** in terms of Accuracy-1 and Accuracy-2. Finally, if we consider the *Combined* dataset, our method slightly outperforms the other ones in terms of Accuracy1 (74.4).

The worst results of our method were obtained for the *SMC* data-sets. This can be explained by the fact that the *SMC* data-sets contains rhythm patterns very different from the ones represented in our training-sets.

While our results for Accuracy2 (92.0) are of course higher than our results for Accuracy1 (74.4), they are still lower than the ones of **böck** (93.6). One reason for this is that our network (as the ones of sch1 and sch2) is trained to discriminate BPM classes, therefore it doesn't know anything about octave equivalences.

3.2 Rhythm pattern recognition

Training and testing sets. For the rhythm pattern recognition, it is not possible to perform cross-dataset validation (as we did above) because the definition of the rhythm pattern classes is specific to each dataset. Therefore, as in previous works [25], we perform a 10-fold cross-validation using the following datasets:

- *Extended Ballroom [24]:* it contains 4180 samples of C=13 rhythm classes: 'Foxtrot', 'Salsa', 'Viennesewaltz', 'Tango', 'Rumba', 'Wcswing', 'Quickstep', 'Chacha', 'Slowwaltz', 'Pasodoble', 'Jive', 'Samba', 'Waltz'
- *Greek-dances [15]:* it contains 180 samples of C=6 rhythm classes: 'Kalamatianos', 'Kontilies', 'Maleviziotis', 'Pentozalis', 'Sousta' and 'Kritikos Syrtos'

Evaluation protocol. As in previous works [25], we measure the performances using the average-mean-Recall R[6]. For a given fold f, the mean-Recall R_f is the mean over the classes c of the class-recall $R_{f,c}$. The average mean-Recall R is then the average over f of the mean-Recall R_f. We also indicate the standard deviation over f of the mean-Recall R_f.

Results and discussions. The results are indicated in Table 4. We compare our results with the ones of [25], denoted as **march**, considered here representative of the current state-of-the-art.

Our results (76.4 and 68.3) are largely below the ones of **march** (94.9 and 77.2). This can be explained by the fact that the "Scale and shift invariant time/frequency" representation proposed in [25] takes into account the interrelationships between the frequency bands of the rhythmic events while our HCQM does not.

To better understand these results, we indicate in Figure 3 [Top] the confusion matrices for the *Extended Ballroom*. The diagonal represents the Recall R_c of each class c. We see that our system is actually suitable to detect the majority of the classes: $R_c \geq 88\%$ for 9 classes over 13. ChaCha, Waltz and WcSwing make R completely drop. Waltz is actually estimated 97% of the

[6] The mean-Recall is not sensitive to the distribution of the classes. Its random value is always $1/C$ for a problem with C classes.

time as Pasadoble. This can be explained by the fact that our current harmonic series $h \in \{\frac{1}{2}, 1, 2, 3, 4, 5\}$ does not represent anything about the 3/4 meter specific to Waltz which would be represented by $h = \frac{1}{3}$. To verify our assumption, we redo the experiment using this time exactly the same harmonic series as proposed in [32]: $h \in \{\frac{1}{4}, \frac{1}{3}, \frac{1}{2}, \frac{2}{3}, \frac{3}{4}, 1, 1.25, 1.33, \dots 8\}$. The corresponding confusion matrix is indicated in 3 [Bottom] where Waltz is now perfectly recognized (97%), however SlowWaltz is now recognized as Waltz in 97% of the cases which makes (while the system is better) the average mean-Recall actually decreases to 74.6%. The low results of Wcswing can be explained by the (too) small number of training examples (23).

4. CONCLUSION

In this paper we have presented a new approach for global tempo and rhythm pattern classification. We have proposed the Harmonic-Constant-Q-Modulation (HCQM) representation, a 4D-tensor which represents the harmonic series at candidate tempo frequencies of a multi-band Onset-Strength-Function. This HCQM is then used as input to a deep convolutional network. The filters of the first layer of this network are supposed to learn the specific characteristic of the various rhythm patterns. We have evaluated our approach for two classification tasks: global tempo and rhythm pattern classification.

For tempo estimation, our method outperforms previous approaches (in terms of Accuracy1 and Accuracy2) for the *Ballroom* (ballroom music) and *Giant-steps tempo* (electronic music) test-sets. Both test-sets represent music genres with a strong focus on rhythm. It seems therefore that our approach works better when rhythm patterns are clearly defined. Our method also performs slightly better (in terms of Accuracy1) for the Combined test-set.

For rhythm classification, our method doesn't work as well as the state of the art [25]. However, the confusion matrices indicate that our recognition is above 90% for the majority of the classes of the *Extended Ballroom*. Moreover, we have shown that adapting the harmonic series h can help improving the performances.

Among future works, we would like to study the use of the HCQM 4D tensors directly, to study other harmonic series and to study the joint training of (or transfer learning between) tempo and rhythm pattern classification.

ABSTRACT

While audio chord recognition systems have acquired considerable accuracy on small vocabularies (e.g., major/minor chords), the large-vocabulary chord recognition problem still remains unsolved. This problem hinders the practical usages of audio recognition systems. The difficulty mainly lies in the intrinsic long-tail distribution of chord qualities, and most chord qualities have too few samples for model training.

In this paper, we propose a new model for audio chord recognition under a huge chord vocabulary. The core concept is to decompose any chord label into a set of musically meaningful components (e.g., triad, bass, seventh), each with a much smaller vocabulary compared to the size of the overall chord vocabulary. A multitask classifier is then trained to recognize all the components given the audio feature, and then labels of individual components are reassembled to form the final chord label. Experiments show that the proposed system not only achieves state-of-the-art results on traditional evaluation metrics but also performs well on a large vocabulary.

1. INTRODUCTION

Large-vocabulary chord transcription is a difficult task, as the number of chord qualities is large, and the distribution of training chord classes is extremely biased. For example, the Billboard dataset [2], a human-annotated dataset, contains 230 different chord qualities, or equivalently, 2,749 distinct chord classes [1]. While the first 10% chord qualities cover 93.86% of the data, the last 50% chord qualities only cover 0.35% of the data altogether [2]. Such a long-tailed chord distribution makes it extremely hard to model rare chord qualities.

To bypass the problem, former systems typically adopt two kinds of strategies: chord quality simplification and chord structure representation. The first approach maps complex chord qualities into simpler ones (e.g., to map `C:maj7`, `C:maj9`, `C:maj11` etc. all to `C:maj`), and therefore suppress the number of different chord classes. Then, a classifier is trained based on the simplified chord vocabulary. The most common mapped chord vocabulary is the major/minor vocabulary, which consists of merely 12 major chords, 12 minor chords, and a non-chord label. However, this is often an over-simplification, especially for some pop and jazz chords with richer expressions than major/minor chords do.

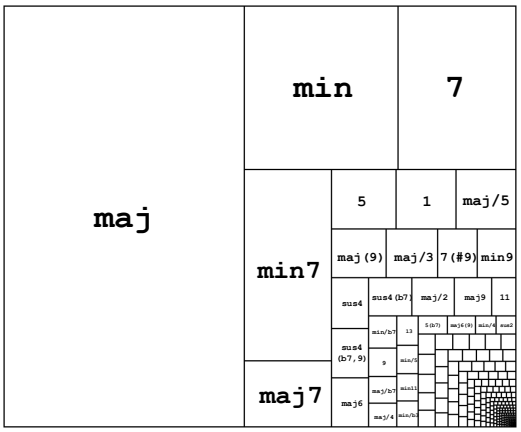

Figure 1. A visualization of chord quality distribution in our collected chord dataset. Each chord quality is denoted by a block whose size is proportional to its number of appearances. Labels for small blocks are omitted.

The second approach, instead, turns chord label classification into a structured estimation problem, and this study belongs to this category. To achieve this, a unified structure representation of chord symbols is required. Chromagram-like representations are often adopted for chord recognition as it is a direct reflection of acoustic features and often led to a good performance in practice [16, 20].

However, Chromagram-like representations miss some of the musical semantics that are important references for human transcribers. One example features two chords `E:min7/b3` and `G:maj6` which are very similar in the chromagram as they share the same chord notes {G, B, D, E} and bass G. However, they are quite different in musical

[1] We here assume that each chord quality can be combined with all possible 12 roots except for the `N` chord.

[2] In calculation, the chord quality counts are weighted by their durations.

semantics as one is a major chord and the other is minor. Moreover, in audio chord recognition, some chord degrees are more important than others. For example, a wrong triad is regarded as a more severe problem than a wrong ninth or other extensions. Such intuition is not directly reflected in a chromagram-like representation of a chord.

We believe that structured representation is the key to large-vocabulary chord recognition, yet a more musically meaningful representation is needed. In this paper, we propose a new representation method by chord structure decomposition. We also present a multitask classification model comprised of a Convolutional Recurrent Neural Network (CRNN) and a Conditional Random Field (CRF), that utilize such representation into the audio chord recognition system.

2. RELATED WORK

Audio chord recognition is an important task for content-based music information retrieval and has been actively studied for 20 years [22]. Audio chord recognition systems typically follow a two-stage process: feature extraction and chord sequence decoding. For traditional models, chromagram [19, 22, 23] is the most widely used feature for chord recognition as it reflects the acoustic properties of a chord. There are also other attempts for handcrafted features, such as the tonnetz feature [12]. For the sequence decoding model, template matching and Hidden Markov Models (HMMs) [24, 27] are adopted to decode the most likely chord sequence. Considering the relationship of chord labels and other musical concepts (e.g., beats, keys), complex HMMs and other Dynamic Bayesian Networks (DBNs) are also used for joint decoding [19, 23].

With the development of deep learning, recent studies begin to focus more on features extracted by neural networks, such as feed-forward Deep Neural Networks (DNNs) [16] and Convolutional Neural Networks (CNNs) [10, 17]. For the sequence decoding phase, beam search and the Viterbi algorithm are widely used [1,18,28]. While early papers in this area adopt a small and fixed vocabulary like the major/minor vocabulary [1,16,17], recent work focuses more and more on larger vocabularies [7, 8, 20].

Strategies for structured representation of chords has been widely discussed in the field of music generation and analysis [4, 9], but not all of them are helpful in the context of chord recognition problem. In audio chord recognition, the HPA system [23] uses two latent variables, the root-position form and the bass note, to model a chord in a Hidden Markov Model. McFee and Bello [20] adopt a 36-D vector to represent a chord, denoting a binary encoding of its root, bass and chord degrees respectively. Then, a plain 170-class classifier is adopted to decode chord symbols from the features.

3. PROPOSED METHOD

3.1 Chord Structure Representation

Most chord symbols can be regarded as a collection of musically meaningful components: root, bass (for possible inversions), a triad type, and a set of extra notes, which usually include certain 7^{th}, 9^{th}, 11^{th} and/or 13^{th} degrees above the root. Different combinations of these components form the large chord vocabulary that musicians use. However, the possible choices for each component are pretty limited. For example, the 7^{th} degree of a chord, if exists, is most likely to be one among `7`, `b7` and `bb7` (in `dim7` chords). This property is very helpful under the context of audio chord recognition, as the number of classes for chord label classification can be greatly reduced if we break down the chords into these components and perform classification on each component instead.

Chord	Root	Triad	Bass	7th	9th	11th	13th
G:maj	G	maj	G	N	N	N	N
G:maj7	G	maj	G	7	N	N	N
G:7(b9)	G	maj	G	b7	b9	N	N
G:min7/b3	G	min	Bb	b7	N	N	N
B:hdim7	B	dim	B	b7	N	N	N
A:sus4(b7)	A	sus4	A	b7	N	N	N
C:9(13)	C	maj	C	b7	9	N	13
N	N	N	N	N	N	N	N

Table 1. Some examples of chord structure decomposition.

We now formally introduce our chord representation method. We first define the chord components and their possible labels:

$$\begin{aligned}
\text{Root} &\leftarrow \{\text{N}, \text{C}, \text{C\#/Db}, \text{D}, ..., \text{B}\} \\
\text{Triad} &\leftarrow \{\text{N}, \text{maj}, \text{min}, \text{sus4}, \text{sus2}, \text{dim}, \text{aug}\} \\
\text{Bass} &\leftarrow \{\text{N}, \text{C}, \text{C\#/Db}, \text{D}, ..., \text{B}\} \\
\text{Seventh} &\leftarrow \{\text{N}, 7, \text{b7}, \text{bb7}\} \\
\text{Ninth} &\leftarrow \{\text{N}, 9, \#9, \text{b9}\} \\
\text{Eleventh} &\leftarrow \{\text{N}, 11, \#11\} \\
\text{Thirteenth} &\leftarrow \{\text{N}, 13, \text{b13}\}
\end{aligned}$$

Notice that we ignore incomplete triads like `C:(1,5)` and `C:(1)`, so these qualities will not appear in the triad category. To make other chord degrees (e.g., the major 6^{th} in `maj6` and `min6`) compatible with the representation, we here adopt octave equivalent versions of these degrees that match the form of the chord extensions listed above (e.g., 6^{th} to 13^{th}).

By enumerating distinct labels for these components, we can map the component labels into numeral values. The enumerated values are all indexed from 1. We now define the chord vector, the encoded form of chord used by our models. The chord vector $\mathbf{c} = (c_1, ..., c_6)$ of a chord C is defined as a 6-dimension vector. For non-chord class `N`, all $c_i = 1$. For any other chord label C, we have:

$$\begin{aligned}
c_1 &= (\text{TriadIndex}(C) - 1) \cdot 12 + \text{RootIndex}(C) + 1 \\
c_2 &= \text{BassIndex}(C) \\
c_3 &= \text{SeventhIndex}(C) \\
c_4 &= \text{NinthIndex}(C) \\
c_5 &= \text{EleventhIndex}(C) \\
c_6 &= \text{ThirteenthIndex}(C)
\end{aligned}$$

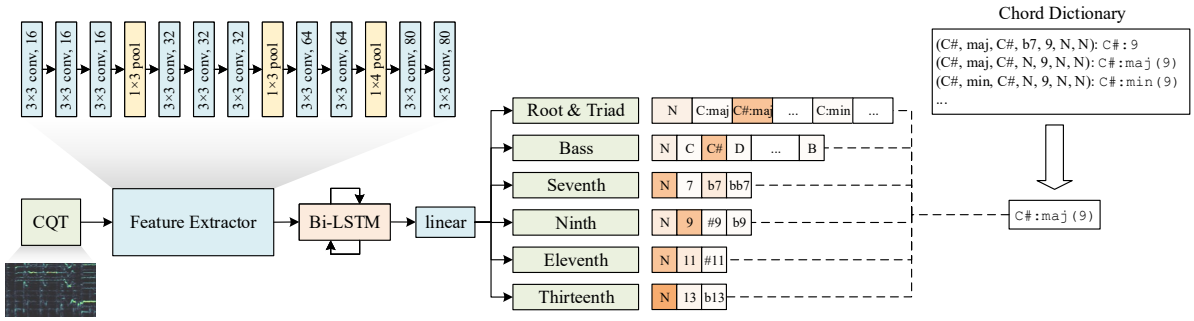

Figure 2. An overview of the system.

3.2 Model Architecture

The proposed chord recognition system consists of two parts, the feature processor and the decoding model. The feature processor transforms the low-level audio features to the frame-wise activations for each chord component value. The decoding model then decodes the final chord sequence given the activations. An overview of the system is shown in Figure 2.

3.2.1 Feature Processor

We first apply the Convolutional Recurrent Neural Network (CRNN), a powerful architecture for audio feature processing [3, 6, 20], to the input spectrogram. The audio feature is first fed into convolutional layers. After each convolutional layer, we perform batch normalization and then a rectified linear function to introduce non-linearity. Each convolutional layer adopts a 3×3 kernel size with 1×1 zero padding to the input, except for the last two layers where no padding is applied on the frequency axis, in order to reduce the feature size.

After that, we apply a Bi-directional Long Short-Term Memory (Bi-LSTM) layer to introduce temporal context for chord recognition. Each direction has a hidden size of 96. Then, for each frame t, a linear unit transforms the hidden states for both directions into six vectors $\mathbf{s}^{(t,1)}...\mathbf{s}^{(t,6)}$. The softmax function is performed on each vector to get the activation $\mathbf{a}^{(t,1)}...\mathbf{a}^{(t,6)}$ for each component of the chord vector:

$$a_k^{(t,i)} = \frac{\exp(s_k^{(t,i)})}{\sum_{k'=1}^{N_i} \exp(s_{k'}^{(t,i)})} \; \forall i = 1...6, \forall k = 1...N_i \quad (1)$$

Here, N_i denotes the vocabulary size of the i-th component category. The loss of the neural network given the ground-truth chord sequence $\mathbf{C} = \{C^{(1)}, ..., C^{(T)}\}$ is defined as weighted cross-entropy loss:

$$L = -\sum_{t=1}^{T}\sum_{i=1}^{6}\sum_{k=1}^{N_i} w_k^{(i)} \mathbb{I}[k = c_i^{(t)}] \log(a_k^{(t,i)}) \quad (2)$$

Here, $\mathbb{I}[\cdot]$ is the indicator function, and $c_i^{(t)}$ denotes the i-th component of the chord vector of $C^{(t)}$. $w_k^{(i)}$ is the class weight factor for index k of the i-th component. We will further explain it in section 3.3.

3.2.2 Chord Decoding Model

To decode the final chord sequence from the activation vectors $\mathbf{a}$, an intuitive way is to pick the class with the largest activation values for each component and each frame. However, this approach tends to produce excessive chord changes as there is no transition penalty between two frames. Also, it will be hard if we want to control the output chord vocabulary V. Therefore, we propose a decoding model by a linear Conditional Random Field (CRF).

The linear CRF takes the following form:

$$P(\mathbf{C} \mid \mathbf{F}) \propto \phi(C^{(1)}, \mathbf{F}) \prod_{t=2}^{T} \phi(C^{(t)}, \mathbf{F}) \psi(C^{(t-1)}, C^{(t)}) \quad (3)$$

Here, $\mathbf{F}$ is the audio feature of the whole song and $\mathbf{C} = \{C^{(1)}, ..., C^{(T)}\}$ is the target chord sequence with each $C^{(i)} \in V$. The observation potential function ϕ takes the form:

$$\phi(C^{(t)}, \mathbf{F}) = \exp \sum_{i=1}^{6}\sum_{k=1}^{N_i} \mathbb{I}[k = c_i^{(t)}] \log a_k^{(t,i)} \quad (4)$$

where $\mathbf{a}^{(t,i)}$ are the activation vectors given by the Convolutional Recurrent Neural Network (CRNN) and $\mathbf{c}^{(t)}$ is the encoded chord vector for $C^{(t)}$.

The transition potential function ψ takes the form:

$$\psi(C^{(t-1)}, C^{(t)}) = \exp\left(-d \cdot \mathbb{I}[C^{(t-1)} \neq C^{(t)}]\right) \quad (5)$$

where $d = 30$ is a hyper-parameter that controls the degree of transition penalty. A larger d penalize more on chord transition and vice versa.

3.3 Class Re-weighting

Although we do not directly perform classification on distinct chord labels, the problem of class imbalance still persists during model training. For example, some chord extensions are very infrequent in the training set, leading to

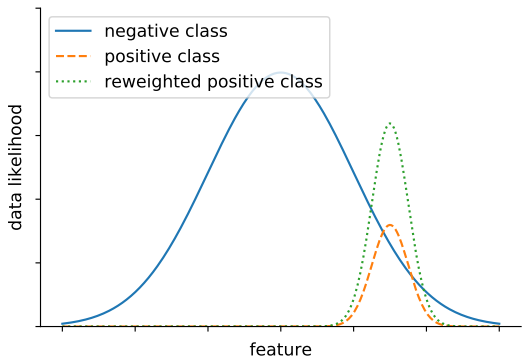

Figure 3. An illustration of why ambiguous class labeling causes problems. In this example, the class boundaries of the positive class and the negative class cross each other. Under the maximal likelihood principle, the accuracy of the positive class (with smaller prior than the negative class) is greatly harmed as its data likelihood is mostly covered by the negative class. Class re-weighting alleviates this problem to some extent.

excessive negative samples and insufficient positive samples for training. Generally, imbalanced training samples make the training process biased as the model tends to focus more on optimizing classes with more samples.

We here stress another issue that potentially aggravates this bias in learning-based automatic chord recognition systems. Audio chord annotation is an ambiguous problem even for human experts [11]. This means that the "ground truth" chord label of a fixed audio piece may contain uncertainty if annotated by different experts [15]. This may cause class boundaries for different labels to cross each other. In this case, we inevitably suffer from accuracy loss for the ambiguity between classes, and classes with small priors often suffer most (see Figure 3 for an example).

To make up for the bias, we introduce the class re-weighting strategy by introducing a class-wise weight factor $w_k^{(i)}$ for each possible chord component value in equation (2). By the re-weighting term, we want classes with fewer training samples to gain larger weights. We adopt the following weight term:

$$w_k^{(i)} = \min\left\{\left(\frac{n_k^{(i)}}{\max_{k'} n_{k'}^{(i)}}\right)^{-\gamma}, w_{max}\right\} \qquad (6)$$

Here, $n_k^{(i)}$ denotes the number of training samples for class k for the i-th component. γ and w_{max} are hyper-parameters, where $0 \leq \gamma \leq 1$ is the balance factor and $w_{max} \geq 1$ is the clamping value. A smaller γ will result in a more balanced weights and vice versa.

4. EXPERIMENTS

As previous chord recognition systems adopt smaller chord vocabularies compared to us, it is hard to make a direct comparison between different systems. Therefore, we divide the experiment results into two parts.

In the first part, we will compare the performance of our system on traditional chord evaluation metrics, most of which perform evaluations on simplified chord vocabularies. The evaluation metrics are calculated by the python package `mir_eval` [26]. In the second part, we will directly evaluate the system performance on larger chord vocabularies.

4.1 Datasets

We use 1217 songs from Isophonics, Billboard and MARL collections collected by Humphrey and Bello [11, 20] to form the dataset. To make a fair comparison, we adopt the 5-fold cross-validation with the same train/validation/test splits (60% for training, 20% for validation and 20% for testing) as in [20].

4.2 Pre-processing

We extract the Constant-Q Transform (CQT) spectrogram from the audio by the librosa [21] package with a sample rate of 22050 and a hop length of 512. We use the pitch range from midi note C1 (inclusive) to C7 (exclusive) with 36 filter banks per octave (252 CQT filter banks in total).

Data augmentation is performed by the pitch-shifting operation (from -5 semitones to +6 semitones) on the training set. Augmented features are directly calculated by shifting CQT spectrograms. The annotated chord labels are shifted accordingly.

4.3 Model Training

We use the Adam optimizer [14] to optimize the neural network parameters with a scheduled learning rate adjustment. To begin with, we use a learning rate 1e-3. If the validation loss does not improve in 5 epochs, we decrease the learning rate by 90%. We stop training after the learning rate drops below 1e-6.

In each epoch, a 1000-frame segment (approximately 23.2 seconds) is randomly selected from each song. 24 such segments form a mini-batch for gradient calculation.

4.4 Comparative Results

We first evaluate the performance of our system under traditional metrics proposed by [25]. For different metrics, the model outputs and ground truth chords are first mapped to some small vocabularies by removing extra notes and/or inversions. The scores are calculated by their matching percentages. The adopted metrics are: root only, root and thirds, major/minor chords, basic triads, sevenths, tetrads and MIREX (at least three correct notes between reference and estimated chords). All of these scoring methods ignore extended chord degrees (e.g., ninth, eleventh and thirteenth).

To evaluate the effect of our chord representation versus a plain classifier, we also perform evaluations on a modified version of the model, which contains a linear layer and a *flat* softmax output layer for all possible combinations of roots and chord types present in the dataset. The model is denoted by "Flat" in Figure 4. Other compared models are (1) Ours: the proposed model without re-weighting; (2) Ours+R: the proposed model trained with re-weighting factors ($\gamma = 0.5, w_{max} = 10$); (3) ACE18: an early design

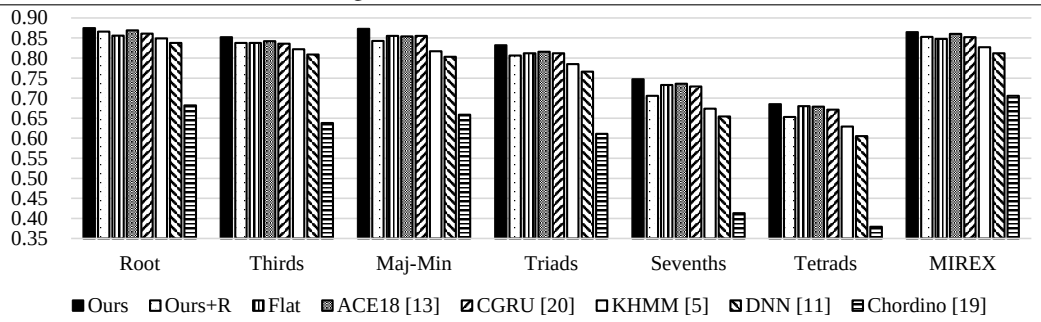

Figure 4. Comparison of median weighted recall scores.

of our model submitted to the MIREX 2018 contest [13] trained on the full vocabulary without beat alignment post-processing; (4) CGRU: A Convolutional Gated Recurrent Units (CGRU) model by [20]; (5) KHMM: A k-stream HMM by [5]; (6) DNN: A deep convolutional network by [11]; (7) Chordino: the classic baseline with template matching and HMM by [19].

In the results, Our system outperforms the baseline systems in all metrics, indicating that our system has a good performance on simplified chord vocabularies, even if the system is not trained for these vocabularies on purpose.

We can also see that the model with class re-weighting actually does not outperform the model without class re-weighting. The main reason is that class re-weighting assumes a more balanced class distribution, which is not the case of our test dataset. We will show in section 4.5.1 that class re-weighting actually has a better performance if we penalize the misclassification error of different classes equally, regardless of their frequency in the test dataset.

4.5 Performance on Large Chord Vocabulary

4.5.1 Evaluation on Common Chord Labels

To evaluate the chord recognition system on a large chord vocabulary, we first evaluate the system performance on common chord labels. We construct the target chord vocabulary V that includes the following chord qualities:

- Basic triads: `maj`, `min`, `aug`, `dim`
- Inverted triads: `maj/3`, `maj/5`, `min/b3`, `min/5`
- Seventh chords: `maj7`, `7`, `min7`, `dim7`, `hdim7`
- Extended chords: `maj9`, `9`, `min9`, `11`, `13`
- Suspended chords: `sus4`, `sus2`, `sus4(b7)`
- Slash chords: `maj/2`, `maj/b7`, `min/2`, `min/b7`
- Non-chord class: `N`

All chord qualities except `N` can be applied to 12 roots, resulting in 301 distinct chord classes. Under such a constraint, the model will not output other chord classes. To define the evaluation metrics, we use D to denote all pairs of estimated chords and reference chords (in vocabulary V) over the test dataset on the same frame. The per-class accuracy $\mathrm{acc}_{\mathrm{chord}}(C)$ for chord class $C \in V$ can be defined as:

Model	Frame-wise Acc.	Class-wise Acc.
No Re-weighting	**0.7719**	0.3475
(0.3,10.0)	0.7609	0.3745
(0.5,10.0)	0.7459	**0.4022**
(0.7,20.0)	0.7146	0.3738
(1.0,20.0)	0.6577	0.3832

Table 2. Mean frame-wise accuracy and mean class-wise accuracy for the proposed model with different class re-weighting factors (γ, w_{max}) for training. The re-weighting factors are shown in the model column.

$$\mathrm{acc}_{\mathrm{chord}}(C) = \frac{\sum_{(C_{\mathrm{est}},C_{\mathrm{ref}})\in D} \mathbb{I}[C_{\mathrm{est}} = C]\mathbb{I}[C_{\mathrm{ref}} = C]}{\sum_{(C_{\mathrm{est}},C_{\mathrm{ref}})\in D} \mathbb{I}[C_{\mathrm{ref}} = C]} \tag{7}$$

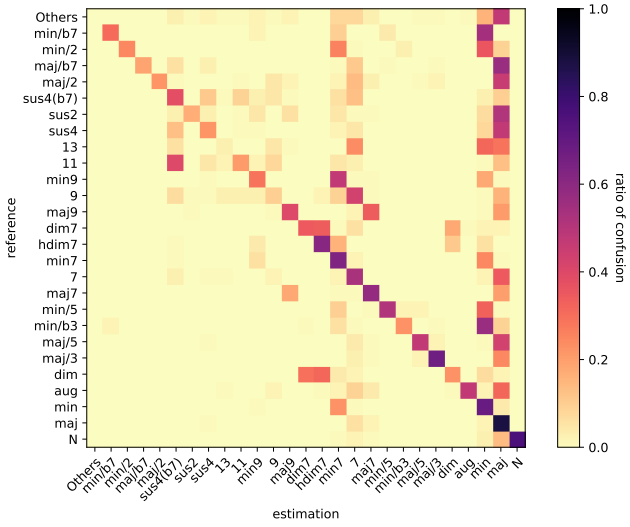

Figure 5. The quality confusion matrix of model trained with re-weighting factors $\gamma = 0.5, w_{max} = 10$.

We believe that a good chord recognition system should have high frame-wise accuracy, as well as a low bias among different chord classes. For example, a system with high bias may recognize all samples of one chord class C into another, resulting in a low score for $\mathrm{acc}_{\mathrm{chord}}(C)$. Therefore, we want the average of $\mathrm{acc}_{\mathrm{chord}}(C)$ over all chord classes as high as possible in the class-wise measurement. Formally, we define the mean frame- and class-wise

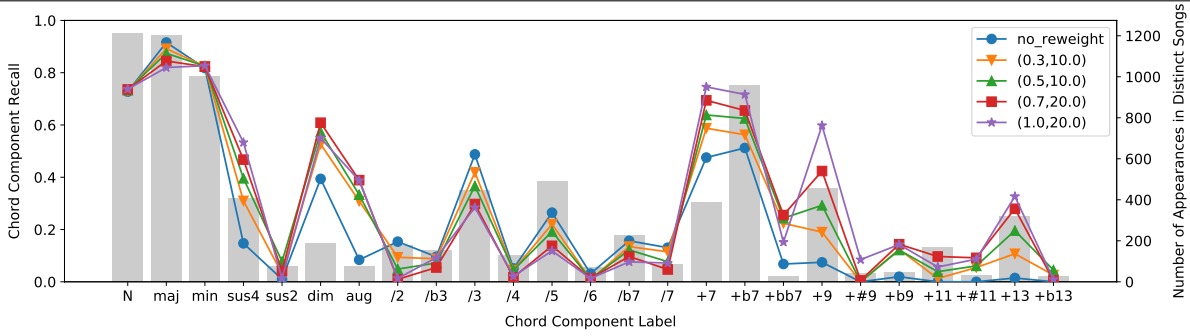

Figure 6. Recall values for different chord components on test sets (denoted by lines) and song-level component counts in the whole dataset (denoted by bars). Different lines denote the models trained with different re-weighting factors (γ, w_{max}).

accuracy as:

$$\text{acc}_{\text{frame}} = \frac{1}{|D|} \sum_{(C_{\text{est}}, C_{\text{ref}}) \in D} \mathbb{I}[C_{\text{est}} = C_{\text{ref}}] \quad (8)$$

$$\text{acc}_{\text{class}} = \frac{1}{|V|} \sum_{C \in V} \text{acc}_{\text{chord}}(C) \quad (9)$$

We evaluate our system with different class re-weighting parameters under these two metrics. The results are shown in Table 2. From the results, we can see that all models with class re-weighting have a lower mean frame-wise accuracy and a higher mean class-wise accuracy compared to the model without class re-weighting. This indicates that class re-weighting alleviates the class bias problem to some extent while leading to a trade-off that the frame-wise accuracy is harmed.

We also show the within-root quality confusion matrix (i.e., quality confusion matrix when the estimated root is correct) of the model trained with re-weighting factors ($\gamma = 0.5, w_{max} = 10$) in Figure 5 for error analysis. Two major trends can be observed. First, most quality errors are from mapping complex chord qualities to simpler ones. For example, `maj9`, `9` and `min9` are mapped to `maj7`, `7` and `min7`; tetrads are mapped to triads. Second, certain extended chord qualities like `13` and `11` are hard to be detected. Despite of the label bias, we also suspect that annotated extended qualities may omit some degrees in practice (e.g., a missing eleventh in a `13` chord) but the omission is not always annotated in the test set. The misclassification of `11` chords to `sus4(b7)` is also reasonable as a `11` chord without a third and a ninth has the same pitch classes as a `sus4(b7)` chord.

4.5.2 *Evaluation on Chord Components*

To further evaluate the system's performance on a large chord vocabulary, we adopt a full chord vocabulary (i.e., a chord vocabulary containing all chord qualities present in the dataset) for the decoding process and evaluate the class-wise accuracy for each chord component. For the root and bass category, we are interested in if their relationship (chord inversion) is correctly detected. The slash notation is defined as the interval between bass and root. For example, In the chord quality `maj/5`, the fifth of the chord is the bass note. Accuracy on slash notations reflects the model's ability to detect chord inversions.

Also, we want to evaluate how class re-weighting affects the accuracy of rare chord component labels. Therefore, we experiment with different hyper-parameters for class re-weighting and make a comparison as shown in Figure 6.

In Figure 6, it is clear to show that the model with no re-weighting declines to predict certain extensions including `11` and `13`. When class re-weighting is adopted, we can observe an accuracy boost for these components. However, the trade-off of class re-weighting is the fact that it harms the accuracy of some other classes as well as providing false positive predicts.

Also, it can be observed that the accuracy for a specific component class has a positive correlation with the number of its appearances in the dataset. Some label components surely have too few samples for the model to learn the correct acoustic and semantic properties, resulting in a low accuracy even if class re-weighting is performed.

5. CONCLUSION

In this paper, we propose a method to perform audio chord recognition on a large chord vocabulary. The core idea of the model is to recognize each chord component instead of the whole chord label itself, and each chord component has a much smaller vocabulary that is easier for the model to handle. We show by experiment that the model acquires state-of-the-art performance on traditional chord evaluation metrics. Also, we demonstrate its ability to detect rare chord component values.

However, the model still has several unsolved issues. First, the model still has strong class bias even if we adopt the re-weighting strategy, and the model performance on some rarest chord component values are still not satisfactory. Second, the proposed representation is not yet perfect. More theoretical analysis and experiments are required to design the best chord representation method for the audio chord recognition task.

We also stress the class ambiguity issue with regard to the datasets. Although a class-balanced dataset is nearly unfeasible in the realm of audio chord recognition, we would like to call for datasets with more precise annotations as well as a more thorough analysis of currently available datasets.

ABSTRACT

In this paper, we propose a recurrent neural network (RNN)-based MIDI music composition machine that is able to learn musical knowledge from existing Beatles' music and generate full songs in the style of the Beatles with little human intervention. In the learning stage, a sequence of stylistically uniform, multiple-channel music samples was modeled by an RNN. In the composition stage, a short clip of randomly-generated music was used as a seed for the RNN to start music score prediction. To form structured music, segments of generated music from different seeds were concatenated together. To improve the quality and structure of the generated music, we integrated music theory knowledge into the model, such as controlling the spacing of gaps in the vocal melody, normalizing the timing of chord changes, and requiring notes to be related to the song's key (C major, for example). This integration improved the quality of the generated music as verified by a professional composer. We also conducted a subjective listening test that showed our generated music was close to original music by the Beatles in terms of style similarity, professional quality, and interestingness. The generated music samples can be downloaded at `https://goo.gl/uaLXoB`.

1. INTRODUCTION

Automatic music composition has been an active research area for the last several decades, and researchers have proposed various methods to model many different kinds of music. [7,8,12,23,26] used rules and criteria developed by professional musicians to generate songs. These methods usually relied heavily on the input of music experts, handcrafted rules, consistent intervention during the process of composition, and fine-tuning the generated music in the post-processing stage. Although the quality of the composed music may be quite satisfactory, the composition process can be time-consuming and the composed music can be biased toward a particular style. Recently, agnostic approaches that do not depend on expert knowledge have been emerging [9]. Instead of relying on music experts, these methods employ a data-driven approach to learn generalizable theory and patterns from existing pieces of music, and this approach has proven to be effective. For example, [2,15] trained a hidden Markov model from music corpora and [10] modeled polyphonic music from the perspective of the graphic model. With the recent progress made in deep learning, there have been many research efforts that have tried to compose music using neural networks: [27] used a deep convolutional network to generate a melody conditioned on 24 basic chord triads found in each measure; [19] generated the drum pattern for songs using an RNN [13]; [9, 14, 17, 18] described RNN approaches to modeling and harmonizing Bach-style polyphonic music; and [5] proposed a multi-layer RNN to model pop music by encoding drum and chord patterns as one-hot vectors.

While most of the aforementioned machine-learning methods were able to generate music in some categories such as Bach chorale and folk music, we found that it is challenging to use their methods to model songs by the Beatles. Formed in 1960, The Beatles are arguably one of the most influential bands of all time. Their primary songwriters, John Lennon and Paul McCartney, were considered masters and many of their songs are still well known today. The Beatles music drew on elements of 50s rock and roll, and their musical style can be characterized by catchy vocal melodies, unique chord progressions, and an upbeat, energetic sound. The standard instrumentation of the Beatles contains vocals, two electric guitars, bass, drums, and occasional piano.

One difficulty of replicating the Beatles' music is that all the component parts depend on each other but have different characteristics. For example, the bass line is often monophonic while the guitar chords are polyphonic, and the guitar chords are likely to contain certain notes found in the bass part. The model needs to be able to generate different instrumental parts within a uniform musical structure. In addition, the style of the musical features of-

*This work was done when Yichao Zhou was an intern at Snap Inc.

ten changes between songs. For example, many Beatles' songs use monophonic vocal melodies while others use polyphonic, two-part vocal melodies. The chords in the Beatles' music often contain a lot of non-standard combinations of notes that are different from the common chord triads, with the added complexity that certain chords may be incomplete and missing one or more of their component parts. They can be played by either a piano or a guitar, each of which uses different chord spacing. All of these variations are challenging to model for a machine learning algorithm. Moreover, the Beatles are known for using complex harmonies that can be difficult to classify, with the added complication that certain chords may be incomplete or missing one or more of their component parts. Thus it may not be appropriate to encode the chord progression aspect of the music as one-hot vectors [27], as they treat two similar harmonies differently.

To overcome these difficulties, we introduce BandNet, an RNN-based, Beatles-style multi-instrument music composition machine. We exploit the song structures that can be commonly found in pop music to generate complete songs without relying too much on labeled data. Our system requires little expert knowledge to use and it can be successfully trained on a relatively small corpus. We explain the proposed approach in Section 2 and evaluate the performance of our algorithm in Section 3.

2. METHODS

2.1 Data Representation

Our BandNet uses MIDI files as input and output and utilizes the same data processing pipeline from Magenta [4]. For each Beatles' song, we consider the three most important channels: the vocal melody, guitar chords, and bass part. All the channels are allowed to be polyphonic, to maximize the flexibility of the model.

In our dataset, we include all the songs that use a 4/4 time signature, which means that a quarter note is felt as the beat, and each measure (a.k.a one bar, a short segment of music whose boundaries are shown by vertical bar lines in the score) has four beats. It is reasonable to discretize note lengths into sixteenth notes. We call the duration of a sixteenth note a *step*. Therefore, each measure is discretized into 16 steps and each beat is discretized into 4 steps.

Because a song may be played by different instruments with different pitch ranges, we first transpose the pitch by octave so that the average pitch of each channel in each song is as close as possible to the global pitch average of that channel. Next, we transpose each song by -5 to 6 semitones to augment the training data 11 times so that it is able to generate music in all possible keys. Other approaches, such as transposing each song to the same key, C major for example, do not work well for the Beatles' music because we have yet to find a reliable way to detect the key of each song.

Figure 1: An example showing how we encode an excerpt from *I Want to Hold Your Hand (1964)*. Notes are quantized to eighth notes rather than sixteenth notes for demonstration purposes. The sheet music example is shown at the top where the scan lines are marked in blue. The encoded sequence of the sheet music is shown at the bottom.

2.2 Score Encoding

BachBot [17] and Magenta [4] convert polyphonic MIDI music into a sequence of symbols so that RNN can be used to model the probabilistic distribution of such a sequence. We expand their schemes to music with multiple channels.

Figure 1 gives an example showing how we encode the music score. We create a new type of symbol `NXT_CHNL`, along with the three existing categories: `NEW_NOTE`, `CNT_NOTE`, and `NXT_STEP`. The strategy is to scan the score in a left to right (time dimension), top to bottom (channel dimension), zig-zag fashion. Each time we meet a note during the scan, we will first check whether it is a new note or a continuation of a previous note (e.g., the second sixteenth interval of an eighth note). We will then either emit a `NEW_NOTE` or a `CNT_NOTE` symbol depending on the case, followed by the pitch of that note. When a channel is polyphonic, the note with higher pitch will al-

ways be in front of the notes with lower pitch according to this strategy. When the scan line comes across the boundary of a channel, we will emit a `NXT_CHNL` symbol, and when the scan line comes across a time step, we will emit a `NXT_STEP`. Unlike other common methods where each symbol will represent all the notes inside a time step, we decompose them into multiple symbols and the advancement of the time step is explicitly expressed using the symbol `NXT_STEP`.

2.2.1 Note Features

With the previous encoding mechanism, we can encode any of the Beatles' songs into a sequence $S = \{S_i\}_{i=0}^{N}$. Here $S_i \in \mathcal{S}$ in which $\mathcal{S}$ is the set of all the possible symbols. We have $|\mathcal{S}| = |T| * 2 + 2$, where T is the set of possible pitches.

Because the training data is limited, it is helpful to incorporate additional features for each symbol to help the neural network learn the theory and patterns of the music. We pair each symbol S_i with its feature F_i when we feed the encoded sequence into the RNN. We designed two features for BandNet, i.e., $F_i = (B_i, G_i)$. The feature $B_i \in \{0, 1\}^5$ contains the beat information. $B_i = 1$ if and only if the global time step of ith symbol is a multiple of 2^i. We find that this feature is helpful for the RNN to keep the style of the chord channel consistent inside a measure. The second feature $G_i \in \{0, 1\}$ represents whether the melody will be generated at the current time step. Without this feature, we find that sometimes BandNet will not generate a vocal melody due to silences in the melody channel of the training data (usually because of an instrumental or guitar solo section). By setting this variable to one or zero, we can easily control whether we want to generate the vocal part in a given section of music.

2.3 Network Structure

Figure 2 shows how a classical multi-layer LSTM-RNN [13] models the probabilistic distribution of the symbol sequence. At the bottom layer, each LSTM cell takes the symbol S_i in its one-hot vector form together with the corresponding binary feature vector F_i as its input I_i. These LSTM cells are chained so that they will apply nonlinear transformations to the previous cell state C_{i-1}^1 and input I_i and produce the current hidden state h_i^1 and cell state C_i^1, respectively. In order to increase the nonlinearity of the model, we make the network deep by stacking multiple layers of LSTM cells. Starting from the second layer, each cell will take the hidden state from the previous layer as input. Finally, we apply a linear transformation to the hidden states in the last layer with softmax to compute the conditional probability $P_\Theta(S_{i+1} \mid I_{\{1\cdots i\}})$, where Θ contains the parameters of the network. We use BPTT [20] to find the parameters that locally maximizes the likelihood of the training data.

2.4 Keeping Notes in the Key

By using the LSTM-RNN and the encoding schemes from previous sections, our generative model is able to compose multi-instrument music. During the test, we find that the melody channel generated by the LSTM occasionally contained some unexpected notes. We found that many of these notes are dissonant because they are not in the key of the music. We speculate that this is because the Beatles often used notes in their music that deviated from conventional practices of other popular music. These notes may work well under some conditions, but the amount of data does not allow our neural network to learn how to use these notes in the right context. Therefore, in order to improve the quality of our music, it is reasonable to filter them out in BandNet, i.e., restricting the notes that are not in the song's key during the generating stage. This can be achieved by applying a mask to the probability distributions returned by the neural network and re-normalizing them so that they all sum to unity.

2.5 Generating a Complete Song

Most of the Beatles' music has a repetitive and sectional song structure. Figure 3 shows an example of the structure in the song *Yesterday (1965)*. This song uses an *AABABA* structure, where the A section is called the *verse* and the B section is called the *chorus*. The verse section is repeated four times, with each repetition being exactly the same or having only minor differences. It is hard for the RNN to learn this phenomenon because the distance between two sections is as long as eight measures, i.e., 128 time steps. RNN normally cannot carry hundreds of symbols in its memory across a span of that long. Folk-RNN [25] used a data format called ABC notation that has an annotation for repeating sections so that they do not need to deal with this problem. We do not have such fine-level annotation in our dataset. Instead, we use a template-based method to generate structured music. Users of BandNet will first select a predefined song structure template, e.g., AABA or ABABCBB, and then BandNet can generate a clip for each section whose length can vary from 4 to 16 measures. After that, we assemble the generated clips to form a complete song. Because we do not model the drum pattern in this work, we assign a precomposed drum pattern for each section of music, which is beneficial as we can select different styles of drum patterns for different sections of the song.

The well-known DeepBach [9] and BachBot [17] can generate a new harmony or re-harmonize an existing melody from a single instrument, i.e. piano. BandNet can generate a song with multiple instruments, e.g. guitar, keyboard, bass, and drum. Because we do not have a melody to condition on, BandNet needs a short sequence of notes, also known as a *seed*, to begin a section. Although in theory it is possible not to condition on any seeds, we found that the resulting music was often unsatisfactory. In order to avoid depending on a professional musician to compose note sequences as seeds, we adopt the following strategy: First, we let BandNet generate long sequences of music without conditioning on any seeds. Second, we can listen to these randomly generated segments and mark the clips that sound most compelling to us. Third, we use these clips

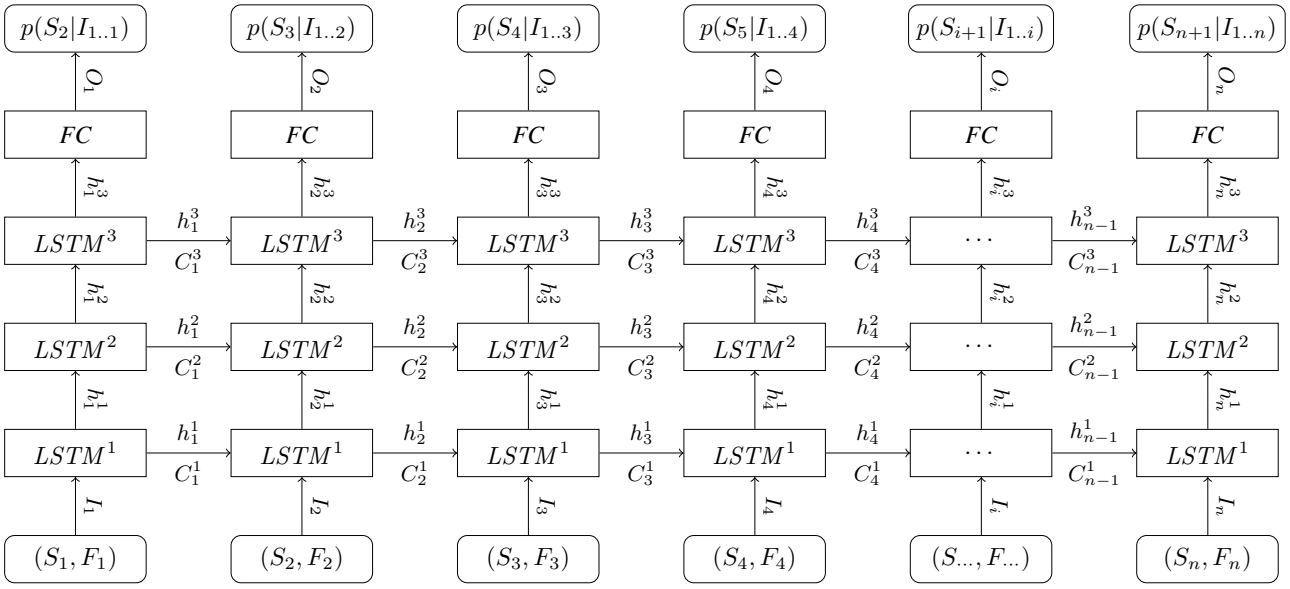

Figure 2: A diagram showing how an unrolled 3-layer LSTM-RNN works for music composition. Here, symbol S_i and feature F_i are encoded to the vector I_i. $LSTM^j$ represents an LSTM cell in the jth layer. Cells in the same layer share the same parameter. C_i^j and h_i^j are the cell state and hidden state of the ith cell in the jth layer. FC represents a fully-connected layer and its output O_i is fed into a softmax function to produce a distribution over all the possible symbols.

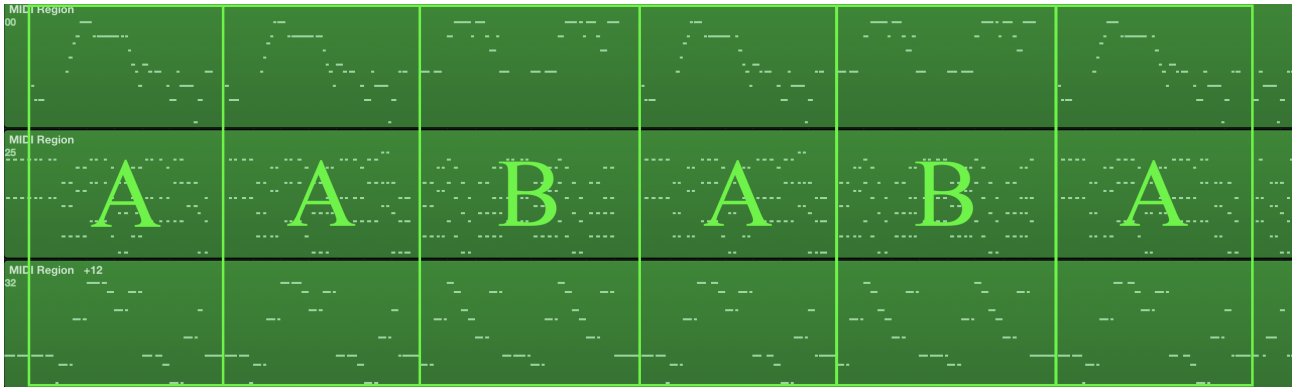

Figure 3: The piano roll of the song *Yesterday (1965)*. It has a song structure AABABA, whose sections are labeled in green in the Figure. The channels from top to bottom are melody, chords, and bass line.

as seeds for BandNet to generate all the sections of the song.

3. EXPERIMENTS

3.1 Settings and Datasets

We collected 183 Beatles MIDI songs from the Internet as our training dataset. We removed 60 songs from the dataset because they were either divergent in musical style when compared with other Beatles' songs, or were missing important components such as a clear vocal melody or bass line. We found that MIDI files in the wild can be messy. For example, the chords may be divided across three channels in some MIDI files, while there can be up to eight channels used for instrumental decoration in others, which is not necessary for our purposes. We cleaned this dataset by deleting the unnecessary channels and merging the fragmented channels.

Due to the number of songs that the Beatles composed, the size of our dataset is smaller compared to those used in the literature [5, 17, 27], but we found that it is sufficient to train a reasonably good model. Aside from its influence in popular music history, there are two reasons why we choose to use the Beatles' catalog as our training dataset: First, the style of the Beatles' music is relatively consistent when compared to other categories of pop music, and therefore it is easier for the RNN to learn its underlying structures. Second, most of the Beatles' music contains the elements required by our music generation pipeline, such as distinct melody, chord, and bass parts, as well as repeating song structures, which can be missing in genres such as classical and folk music.

The two most important parameters of the recurrent neural network were the dimension of LSTM cells and the number of layers. We found that a 3-layer RNN in which each LSTM cell had 256 hidden units worked well in practice.

Our implementation was based on Magenta [4] and Tensorflow [1] for processing the MIDI files and training the RNN. Because the number of parameters in our network was large, we applied dropout [24] to alleviate overfitting. We trained our model using the Adam optimizer [16], which is a variant of stochastic gradient descent that is not sensitive to the global learning rate. We used 10% songs in our dataset for cross validation and we stopped the training process when the error on the validation dataset no longer decreased. During the training, we clipped the gradients so that their L2-norms were less than or equal to 1. This technique was proposed in [24] to alleviate the gradient explosion problem.

3.2 Quality Scoring by a Professional Composer

In this section, a professional music composer evaluated the music generated by each subsequent version of BandNet. The composer gave two scores for each individual channel (melody, chords, and bass) based on their musical content and structure. The Content Quality (CQ) was defined as how well the notes and rhythms in the generated music function according to music theory principles consistent with the music of the Beatles, and the Structure Quality (SQ) was defined as to what extent the music sample exhibits an organizational structure. All scores were given on a scale of 1 to 5. In addition, we designed two overall scores to evaluate the overall quality of each multiple-channel song. The Averaged Content and Structure Quality (ACSQ) were calculated through averaging the CQs and SQs of all the channels, and the Group Synergy Quality (GSQ) score evaluated how well the individual channels work together to make a unified whole.

The results are shown in Table 1. The score was an average across five songs under each setting. We found that model BN was on par with Magenta's melody and polyphony generators [4] in terms of content and structure scores, which is reasonable because models from Magenta were designed to model melody and chords (as in polyphonic music) separately, and modeling them jointly in the case of BandNet would not improve the score of each individual channel. After introducing the silence feature, the GSQ of BandNet increased from 2.6 to 2.95 because we were able to exclude unusual silences in the melody. By adding the beat feature, BandNet continued to receive rewards in SQs for the melody and chord channels; a possible explanation for this is that the beat feature gave the RNN measure and section information, which helped it learn the structure of the music more efficiently. Both of these features also improved GSQs, as the normalization of each individual channel also improved the alignment between individual parts. Finally, the greatest improvement in both metrics was from the key restriction feature. This significantly improved the CQs of individual channels by removing "wrong" notes, and also improved SQs and GSQs by reducing the amount of notes that were dissonant with one another across individual channels.

3.3 Subjective Listening

We also conducted a subjective listening experiment to evaluate the quality of our generated songs from the perspective of amateurs. We received 17 responses in this user study: 16 said that they had never received formal musical training. In this test, we asked users to listen to 15 songs. All of the songs were in AABA structure and each section had a length of 8 measures. The first 5 songs, labeled as group A, were composed by BandNet using randomly generated seeds; the next 5 songs, labeled as group B, were composed by BandNet using professionally composed seeds. Each seed was 2 measures in length, with BandNet generating the remaining 6-measure clip for each section. Songs in group A and B were generated randomly without human selection. The last 5 songs, labeled as group C (the control group), included relatively unknown Beatles' songs, with the intention that listeners had likely never heard them before. We shuffled the order of the songs so that listeners could not guess whether a song was composed by BandNet prior to listening. We also modified the drum patterns for the group C Beatles' songs,

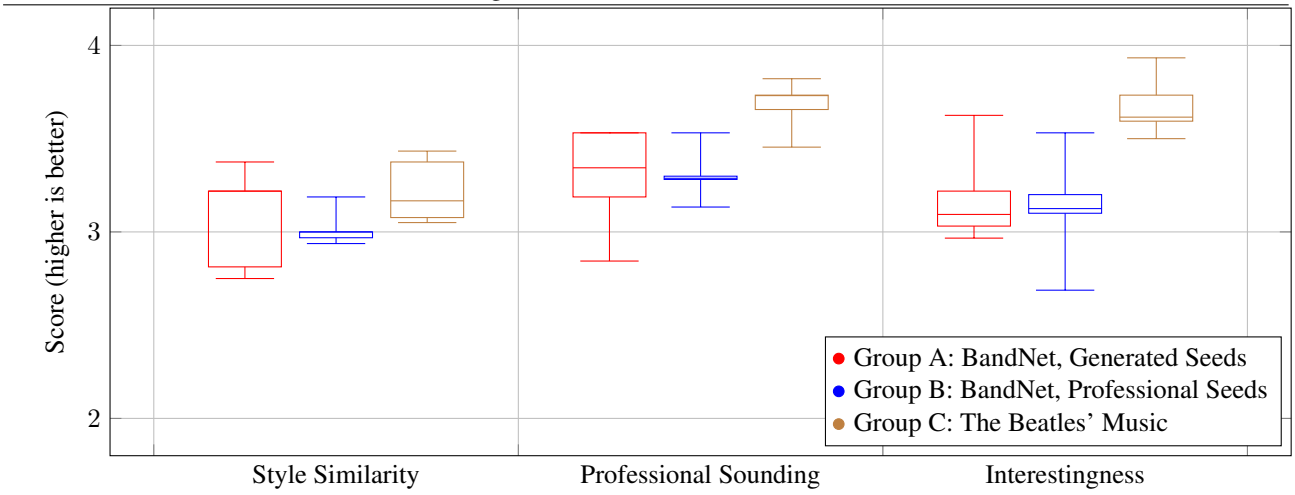

Figure 4: Result of a user study that evaluates the performance of different ways to generate music. The x-axis represents the sources of the music and the y-axis represents the score. The box plot shows the distribution of the average score of each song rated by the listener. From bottom to top, the horizontal lines of each box show the minimum, the first quartile, the median, the third quartile, and the maximum of the average score, respectively.

so that listeners could not distinguish them from BandNet-composed songs based on differences in the drum pattern.

At the beginning, we asked subjects to listen to 5 well-known songs by the Beatles, such as *I Want to Hold Your Hand (1964)*, in order to familiarize them with the Beatles musical style. Next, we asked them to listen to the 15 songs mentioned above and to answer the following 4 questions for each song:

Q1: Have you heard this song before?
Q2: Does it sound similar to the music of the Beatles?
Q3: How likely is it that this music was professionally composed?
Q4: How interesting is this music?

We asked listeners to only choose between "Yes, definitely!" and "No/Not sure" in Q1; if they answered "Yes", we removed their scoring of that song from our results. This is because a subject may be biased to give a song a higher score if he had heard it song before. For Q2, Q3, and Q4, we let users grade each song using a scale from 1 to 5 with an increment of 0.5. Figure 4 shows the distribution of those scores from 17 responses. The labels in the horizontal axis, Style Similarity, Professional Sounding, and Interestingness correspond to Q2, Q3, and Q4, respectively. Each sample in the box plot represents the average score over 17 responses to a question for a particular song.

For Q1, about 13.3% of responses indicated that they had heard those little-known Beatles' songs, while the percentages were only 0% and 1.3% for BandNet-generated songs using automatically-generated seeds and professional seeds, respectively. This could be an indicator showing that we did not overfit the training data and just replicated some clips from the original Beatles' music. For the rest of the questions, we found that the authentic Beatles' songs constantly outperformed the BandNet-generated songs, but only by a small margin. In particular, the average Style Similarity scores for songs in group A, B, and C are 3.08, 3.02, and 3.22, respectively. The score difference of Q2 between the authentic and generated songs was less than 0.202, which showed that BandNet was able to imitate the style of the Beatles relatively well. The average Professional Sounding scores were 3.29, 3.16, and 3.68, and the average Interestingness scores were 3.19, 3.13, and 3.68 for songs in group A, B, and C, respectively. The score gaps of Q3 and Q4 between authentic and generated songs were approximately 0.5. The musical knowledge that BandNet learned came primarily from The Beatles, and in theory may be difficult for an RNN-based machine learning algorithm to generate more professional and interesting music than The Beatles. Concerning the seeds used in generation, our experiments have shown that using professionally-composed seeds did not have a significant advantage over selecting from randomly-generated seeds in terms of subjective listening evaluation. This means that we may no longer need a composer in the loop for generating a complete song and an amateur would be able to "compose" a Beatles-style song without the guide of a professional by using BandNet.

4. CONCLUSIONS AND FUTURE WORKS

In this paper, we propose an RNN-based, multi-instrument MIDI music composition machine, which learns musical knowledge from existing Beatles' music and automatically generates music in the style of the Beatles with little human intervention. We also integrate expert knowledge into the data-driven based learning process. We prove that our method is effective in both professional evaluation and subjective listening tests. Our future work includes explicitly modeling the drum parts, designing a better neural network structure, employing Gibbs sampling, improving the evaluation metrics, and testing BandNet for other genres of music on a larger dataset.

ABSTRACT

Few prior studies on music recommendations investigate the context in which users receive the recommendations, and what impact the recommendation has on the user. In this paper, we aim to better understand the factors that affect people's decisions as to whether they choose to listen to music recommendations and how the recommendations impact their music-listening behaviors. We conducted an online survey asking about people's past experiences on giving and receiving music recommendations. We found that in addition to the aesthetic qualities of music and the respondent's taste, expectations regarding the delivery (e.g., timing, persistence) of the recommendations, familiarity, trust in the recommender's abilities, and the rationale for suggestions were important factors. We discuss the implications for the design of music recommenders based on the findings, including better rationale for and accessibility of recommended music, improved saving options, and more targeted delivery at specific times. The data also suggests disparities in how people wish to receive music recommendations and what will influence them to listen to recommendations, versus how they would like to offer recommendations to others. In addition, the findings highlight the importance of music recommendations in people's existing social relationships and their role in building/improving new relationships.

1. INTRODUCTION

Music recommendation has been a well explored topic in the field of music information retrieval over the past few decades. Much of the recent research related to music recommendation focuses on improving recommendations for individual users or user groups by using various data or methods; for instance, user characteristics [22], tags or metadata [20, 21], or collaborative filtering [24]. In addition to more traditional content-based approaches, user behavior [6] and social/contextual features [20, 22] have also been explored to improve recommendation results.

However, few studies explore the broader process of users receiving music recommendations and what happens after the recommendations have been made. What kinds of contextual factors affect people to choose whether they listen or not listen to the music recommendations? Are there any changes that could be made in the way that people or music recommendation systems make the suggestions to improve the likelihood of someone listening to them? What kind of impact do music recommendations have on the user and the social relationships of recommenders and recommendees?

This paper aims to gain a deeper understanding of the user context where music recommendations happen, and the interaction between music recommendations and underlying social relations. We address the following research questions in this study:

RQ1: When people do not listen to recommendations, what are the reasons they do not do so?
RQ2: What can be done to improve the chances that people will listen to recommendations?
RQ3: What happens after the music recommendations? What are the perceived impacts of music recommendations on people's music listening behavior or social life?

We conclude the study by presenting a set of implications for designing music recommendation systems based on what we learned about people's post-recommendation behavior.

2. LITERATURE REVIEW

2.1 Music Recommendations

There is little literature about what happens after a user receives a recommendation, and how the chances of a user listening to the recommendation might be increased. Prior research seeks to understand the motivations behind sharing [12], but it has not necessarily examined *what comes next*, with regards to the recommendation's impact on a user's music listening behavior, social practices, and other aspects of their lives.

As commercial music streaming services become the primary way that many people access music, machine recommendation systems have become an important way to help music listeners find what they want to hear [19]. Jun et al. [11] proposed that there are two primary issues with providing "efficient music recommendation" (p. 1934). These issues are how accurately a recommender system can predict user preference and how accurately a system can assist with searching for new music [11]. The researchers identified that the flow, or sequence, of songs provided

by recommender systems could be improved and suggested blending related recommendations into one seamless clip that takes a user's temporal-spatial information into account [12].

Studies like Lee et al.'s 2011 paper [12], one of the first studies on music sharing behavior via social networks, discusses the motivations behind why users share music. They examined social music practices on Korean social networks like Cyworld and Tisory, finding that "self-expression, ingratiation, altruism, and interactivity" are the main "social motivation factors" driving sharing behaviors on social media platforms (p. 716). Previously, most studies about online sharing music focused on piracy and the motivations behind those behaviors (p. 717). Understanding users' motivations for sharing music and the connections they make to their music may help in improving the likelihood that a recommendation is heard.

Su et al. [19] set out to examine the reliability of collaborative filtering recommender systems. They proposed a system called Recommendation by Tag-driven Item Similarity (RTIS), which takes both "play counts as implicit ratings and item tags as semantic preferences" into account (p. 304). Wang et al. [23] examined the effectiveness of a sequence-based recommender system that takes contextual information into account when providing recommendations, as "people usually have different [music] preferences and requirements under different contexts" (p. 231).

Zhang et al. [25] posit that music recommendation systems should, to the extent possible, simulate the kind of music recommendation that a friend might provide. Listeners are more likely to listen to recommendations from sources they trust, like friends. They built a recommendation framework called Auralist that used four identified factors relating to successful music recommendations: accuracy, diversity, novelty and serendipity. It was found that increasing serendipity in machine-based music recommendation improves user reception of recommendations.

In order for a music recommendation framework to be successful, Schedl [16] believes that recommendation systems must work at three levels: music content, music context, and user context (p. 1). Schedl's study focuses primarily on user-centric models in MIR and uses of geospatial location data for music recommendation. Based on their findings, they present an adaptable mobile player that automatically adjusts the playlist given user context.

2.2 Impact of Music Recommendations on Users

Music can have a memorable, sometimes lasting, impact on one's everyday life. Leong and Wright [14] examined social music practices in the home and the impact that various music technologies have on "people's sociality and in turn how various social practices affect people's interactions with technology" (p. 951). They found that participants that "explore and discover music together… provided opportunities for bonding, with new discoveries and insights into their shared interests in music" (p. 955).

Boer et al. [3] found that one's music preferences can help facilitate social bonding between strangers. Selfhout et al. [17] found that social music rituals and shared music preferences can contribute to adolescents' development of friendships. Boer and Abubakar [2] published a study to expand the evidence of the positive effects social music activities can have on "social cohesion and emotional well-being" (p. 1). They examined music listening behaviors in families and peer groups in four countries: Philippines, Kenya, New Zealand, and Germany. They found that "across four cultures music listening in families and peer groups contributes to family and peer cohesion, respectively" (p. 10).

North, Hargreaves, and Hargreaves' 2004 study [15] of everyday listening among 346 people provided "initial normative data on who people listen with, what they listen to (and what their emotional responses to this music are), when they listen, where they listen, and why they listen" (p. 41). Notably, this study indicated that users' music preferences are situationally dependent, and shifted based on where users are and who they are with. It also highlighted that music was most often accessed during activities independent of deliberate music listening, which we define in our study as passive listening.

Our study seeks to build upon the research of Lee and Price [13] on user personalities and personality characteristics and their relation to music information systems. Lee and Price identified seven personas that exemplified specific user music-listening attitudes, behaviors, and traits. User personas were indicative of how a user might access or curate music, as well as how that user might react to a music recommendation. In this study, we will specifically explore user behavior and how different personas may manifest in the context of music recommendation.

3. STUDY DESIGN AND METHOD

In order to understand user attitudes and behavior post-music recommendation, we designed a web-based survey. Links to the survey were shared via flyer in St. Petersburg, FL and Seattle, WA, posted online across various social media platforms, and disseminated in-person at local band events in St. Petersburg, FL. We received 219 total responses, with 92% of respondents from the United States, 2% from Canada, and 6% from other countries. 42% of respondents were male and 53% were female, with the remaining 6% identifying as other genders or preferring not to answer. The average respondent was 28 years old, with a youngest age of 15 and an oldest of 70 years old (Median: 27; Std dev: 9.71). We asked participants when and for how long they listened to music in their daily life. Respondents answered that they actively listen to music for 1-2 hours (Mean: 1.44 hours; Median: 1 hour; Std dev: 2.01) and passively listen to music for 3-4.5 (Mean: 4.43 hours; Median: 3 hours, Std dev: 3.69) a day. 95% of respondents typically listened to music through a streaming service like YouTube (72%), Spotify (64%), or Pandora (27%). Participants listened to music, actively or

passively, during a wide range of activities. 89% of respondents listened to music while driving or commuting, 77% while working or studying, 74% while exercising, 73% while cleaning, and 63% while cooking.

We also asked respondents open-ended questions about what happens when they receive or give recommendations. Respondent answers were subject to multiple-coder grounded theory analysis [5]. Researchers looked for patterns in the answers given by respondents, and proposed qualitative codes to describe those patterns. The researchers generated a codebook for each question, though some questions were similar enough that certain codes could be used across multiple questions. The definition of each code and the rules for its usage were refined through an iterative process. Once codebooks were finalized, the codes were applied to responses using a consensus code model [9, 10]. Researchers coded answers independently, then met and discussed the applicability of codes until there was agreement between the three researchers for each code usage. The number of codes assigned to a response was not limited; some answers could be captured by a single code, while others were complex enough to require up to half a dozen codes. A copy of the codebook can be accessed at: https://tinyurl.com/ISMIR2019LeePritchardHubbles.

4. RESULTS AND DISCUSSION

4.1 Reasons for Not Listening to Recommendations

We asked respondents what influenced their decisions when they decided not to listen to a recommendation. Responses varied significantly depending on whether the recommendation came from an automated service or from another human being. Three general assessment categories were noted: recommendations tended to be rejected because the recommendation was aesthetically displeasing, because the recommender strategy was suboptimal, or because of external factors out of the control of the recommender.

For automated recommender services, respondents most often tended to judge whether or not to take recommendations based on aesthetic factors such as personal taste (71 respondents, 32.42%) or their level of familiarity with the artist, song, or genre (69, 31.51%). Respondents often rejected recommendations or suggested playlists that include artists/songs they know they hate. Other aesthetic factors included deciding against the recommendation based on descriptive information such as song title, lyrics, or style keywords (22, 10.05%). A few respondents also judged based on the artist's general popularity or based on visual cues like album art or band photography. Some commented on also relying on reviews or their perception of the artist (e.g., "*If I have heard bad reviews from peers or online, or think the band is against my values or promotes things I'm particularly against.*" (P20)). Several respondents stated that they will make a quick judgment as to whether they will continue to listen to the song or not after listening to a short snippet of a song, for about 10-20 seconds (20, 9.13%).

"*The beginning of the piece. If it doesn't sound catchy or doesn't have a decent layout of tone and rhythm, I'll skip it. I try to give all music a fair chance but sometimes I only have a certain window of listening time and I want to use it wisely*." (P192)

Factors external to the recommender system also played a substantial role in rejecting suggestions from automated services. Some respondents simply prefer a listening experience that does not involve recommendations (47, 21.46%). Other respondents mentioned not being in the right mood for the recommendation (34, 15.53%), alluding to the situationally-dependent music preferences of users [14]. A few also mentioned not having enough time to investigate recommendations or having inertia or a lack of interest.

"*This is my default state. I have to want to listen to a suggestion which really means that I'm in an exploratory mood*." (P163)

"*My mood mostly. I'm generally resistant to trying new things, but I always want to. Conditions must be perfect*." (P104)

Relatively few respondents criticized the recommendation strategy. Some chose not to listen based on whether the recommender service had given poor suggestions in the past (22, 10.05%), and a few mentioned annoying or inconvenient means of delivering suggestions, problems accessing the recommendations, getting too many recommendations, or simply needing an easy way to remember the suggestions.

"*The frequency of the suggestions making them easy to ignore and pin as spam.*" (P42)

"*I'd love it if I could choose to add recommended music to a, 'listen later,' or, 'recommend to me again later,' list, just with the touch of a button*." (P196)

In some cases, the reasons people do not listen to music had nothing to do with the content of the music, but more with the context of the song or artist. Several users suggested that content-based music recommendations provided by recommender services will inherently be limited in their ability to predict the likelihood of someone listening to the music recommendation.

"*Honestly, a lot of reasons I won't listen to something is outside the sphere of music. How would a music streaming service know I don't want those recs because the fanbase is full of white supremacists or because the singer is a sexual predator?*" (P7)

For recommendations that came from other human beings, the recommendation strategy was the most important consideration in deciding whether or not to listen. The most common human factor was whether the recommender was reliable, or had given good or bad

recommendations in the past (62, 28.31%); this consideration was much more prominent for human recommenders than for automated systems.

"*Whether or not I think they understand the very specific type of music I have asked them to suggest to me. Or if I have not solicited them if I will listen if I generally like the music they listen to and consider them to have 'good tastes'."* (P49)

The underlying social relationship that a respondent had with a human recommender often played an important role in determining what the recomendee did with the music. In some cases, the feelings toward the recommender overrode other factors like the recommendee's taste in assessing the value of the recommendation.

"*It really depends on the person that gives me the recommendation. If it is someone I know I have a similar preference as, then I am definitely going to listen to it. Similarly, if it is someone I am friends with or just in general like, I will listen to it even if I don't know their music preferences that well. I won't listen to a song if I don't like the person or I know they like a kind of music I don't.*" (P38)

"*If I don't like the person I don't listen. If they're a jerk but I know they have good taste I check it out but I don't get back to them. I tend to associate my favorite songs with people I care about who introduced me to them originally*." (P208)

Many respondents also mentioned that they easily forgot recommendations given by other people, and needed a means by which to remember them (34, 15.53%). A few mentioned annoying or inconvenient recommendation delivery tactics, or difficulty accessing the songs.

"*When people recommend music to me, it's also often not convenient. When I'm already using a streaming music, I'm already relying on them to suggest me new music. That's what they are for. However, when a friend recommends me music, it may come at a time when I'm not in the mood to explore but want to listen to some familiar favorites*. (P178)

Aesthetic considerations were also important in evaluating human recommendations. Familiarity (47, 21.46%) and taste (29, 13.24%) factors also played significant roles in deciding to skip recommendations from people, but were less prominent than with machine suggestions. External factors were also less prominent; quite a few respondents said they often did not have time to explore recommendations (24, 10.96%), and some also mentioned not being in the mood, having a lack of interest, or not wanting to take recommendations in general.

4.2 Things That Can Improve the Chance of People Listening to Recommendations

Additionally, we asked respondents what, if anything, could be done differently to make them more likely to listen to recommendations from streaming services or from other people, and responses were not dramatically different between the two. Two important considerations arose. One was the design or delivery strategy of the recommender or recommendation service. The recommender's design (broadly conceived for both services and people - when, where, and how the recommender or service chose to deliver suggestions) was important to respondents (services 36, 16.44%; people 43, 19.63%), as were components like whether information about the artist or song was provided with the recommendation, why the recommender made the suggestion, whether a clip was available for listening, and whether incentives for listening were provided. For recommender systems, the ability to manually change parameters was important, as respondents felt that they could receive more personalized recommendations.

"*I would be more interested if I would understand why those certain songs are being recommended to me (are the recommended songs based on similar tunes or because people who listen to my type of music like those recommended songs?). I would also probably listen to the recommended songs more if the recommendations were personal (such as seeing what types of people are listening to it, where it's being listened, what kinds of playlists it often appears in).*" (P13)

"*Maybe a better attempt at explaining why it was recommended (e.g., same scene, era, lyrical themes, mood, instrumentation, etc. of what I was already listening to)*." (P66)

For human recommenders, how often or how enthusiastically recommenders persisted in pushing recommendations, and whether the respondent's friends or acquaintances also liked the music being recommended, were also important factors that influenced people's decision to listen or not listen to music.

"*They could mention specific aspects of what I'd like. For example, 'I know you love Neko Case. This singer has a similar voice'."* (P4)

"*A good description: the story behind the track creates an emotional connection to it and makes you listen more attentively. A direct link to the track (preview) available from everywhere. Even better if it can be previewed right in the messenger.*" (P120)

The social connection between the recommender and recommendee was mentioned repeatedly as a factor that might encourage to listen to the music: "*Make me like them? Or at least be charismatic enough and not a horrible garbage person.*" (P208); "*Make me better friends with those other people.*" (P26).

Second, respondents mentioned the importance of the content of the recommendations. Whether the recommendations were similar to personal taste - what the respondent likes or listens to - was most important (services 47, 21.46%; people 40, 18.26%). Respondents also mentioned basing recommendations on artist or genre/style similarity - i.e., musical similarity, rather than closeness to what the

recommender likes. Other content factors included whether the person or system had a deep, intimate knowledge of the respondent; problems with older and newer listening desires conflicting (e.g., recommenders making recommendations based on old preferences); a desire for new songs unfamiliar to the recommendee; recommendations based on general popularity (or deliberately avoiding popular songs); and the ability to compartmentalize - to separate out genres or styles and get siloed recommendations for each. Additionally, some users desired contextual information about music and artists that may influence whether they would listen.

"*If they told me WHY they recommended a particular artist, or gave me some kind of cool "family tree" of the piece they're recommending (e.g., it featured a musician I liked).*" (P79)

"*If some of the algorithmic rationale was a bit more transparent in the messaging to the user (e.g. 'You might like this artist because they feature their bassist and you like other bass-forward bands' or 'Here is a collaboration between an artist you like and a different artist from a genre/label you like').*" (P161)

"*Essentially I'd like to feel like I'm geeking out about the music and somehow digging deeper into things (like the feeling of researching things on Wikipedia) rather than automatically thrown into a new radio station or a recommendation with no context.*" (P174)

Some respondents also talked about social features that aggregate people with similar music tastes or leverage the existing social connections among the listeners: "*Maybe tag artists that many of my friends listen to, sort of indirect friend suggestion.*" (P68); "*Aggregate 'listeners like you' - functionality where I can see what others with tastes similar to me like or are listening to.*" (P179).

We additionally asked what could be done to make it more likely that others would listen to music suggestions the respondent gave. A broad spectrum of responses materialized from this question. Common responses included providing a means for the person to listen (42; 19.18%), having similar music preferences (38; 17.35%), having a deep knowledge of the recommendee's personality or music preferences (34; 15.53%), pushing the recommendation hard or ginning up excitement about it (30; 13.70%), talking in person about the recommendation as opposed to via distance communication (29; 13.24%); and giving context or rationale for why the recommendation was made (24; 10.96%). In general, we noticed an asymmetric relationship between how participants felt about music recommendations from other people versus the music recommendations that they were giving to others. Most participants were able to articulate with specificity the different criteria they use to decide *not* to listen to music recommendations given to them, yet they generally exhibited high confidence that their recommendations to others were in fact listened to (further discussed in 4.3).

4.3 Post-Recommendation

We asked respondents about moments where giving or receiving recommendations led them to have more music-related interactions with another person. 102 (46.58%) said conversations followed about the song, artist, lyrics or genre, which often led to the discovery of mutual musical interests (50; 22.83%) and additional sharing of music (49, 22.37%). 41 (18.72%) described the opening up of a bond or deepening of a friendship with the recommendee, and an equal number talked about having shared experiences with the recipient, such as going to a concert, checking out a record store, or listening to music together at home or on trips. Several respondents talked about the depth and lasting impact of this kind of experience.

"*Once I shared a particular song with an acquaintance and we sat in rapt silence as we listened together, and the song ended up sparking one of the best conversations I had in my teens. Even now, whenever I hear even one song from that album, I remember what it was like when it was 'in the air' so to speak.*" (P27)

"*A friend I had spoken to about music prior had talked to me about an album and asked me to come over so that we could both listen to it on their record player. I was so moved listening to the entire album I started crying and talked to my friend about it, thus leading to a really deep meaningful conversation that deepened our relationship and understanding of each other. We eventually became best friends and this person is now really important to me*." (P82)

We also asked respondents whether they had shared a song, artist, or album with someone they knew in the past three months; whether they knew if the person to whom they had provided the recommendation actually listened to it; and how they knew the recommendation had been listened to. 148 (67.58%) of respondents responded both that they had made a recommendation and that the recommendee had listened to it. By far, the most common means of verifying this was through discussion. Of those who said the recommendee had listened, 103 (69.59%) said they had talked with the recommendee about the recommendation in person or via messaging or social media. 43 (29.05%) mentioned playing the song for the recipient or listening to the songs together, and a few mentioned making follow-up inquiries, singing the song for the recipient, or checking in on the recipient's listening or streaming activity within an application.

5. CONCLUSION AND FUTURE WORK

In this study, we investigated the contexts in which music recommendations occur, in order to improve understanding of the impact of music recommendations on people's lives and social relationships (and vice versa). The main design implications for recommendation systems based on our data analysis are as follows:

Needs for providing and receiving recommendations are asymmetric: In general, it seemed as if respondents were more comfortable broadcasting recommendations than receiving them. The systems and strategies that users would like designed for themselves to receive music differed from those they would build to recommend to others. They seemed more willing to be forward and persistent about pushing the recommendations out than they would prefer for recommendations aimed at them.

Music is an important tool for building social relationships: "Companionship (willingness to engage in social aspects of music listening)" [13] continued to be an important aspect related to music recommendations. Servicing people recommendations that come from their friends may help introduce a desired human element into the systems. Facilitating exchange of individual songs between people, and presenting these exchanges explicitly as recommendations, may improve the user experience beyond algorithmic or expert-curated recommendations. Automated suggestions drawn from friends' listening patterns or notifications of friends' activity ('Your friend just listened to: Track X') may not sufficiently substitute for intentional sharing of recommendations. This intention seems to be important, as the importance of a social relationship often overrode factors like musical tastes and preferences. People paid extra attention to music recommendations that came from people they cared about. Sometimes they were willing to listen to music that they personally had no interest in because they perceived it as an opportunity to spark an interesting conversation or have a shared experience and potentially improve their relationship with the recommender.

The co-listening experience was also important to many of our respondents. Co-listening was a factor that Spinelli et al. [18] identified as a significant social music behavior. Hagen & Lüders [7] noted that users on commercial streaming services might choose to follow each other to deepen interpersonal relationships, not necessarily because of "shared music preferences alone" (p. 10). Brown and Sellen [4] also discussed the social aspects of consuming music and how users can form or deepen relationships through listening to music together. Our findings enrich this literature by showing that our respondents viewed co-listening not simply as a way to ensure or verify that the recommendee listens to the recommendation, but also because that is how shared bonding experiences are created [14]; the recommendation could become the foundation or catalyst of the social relationship between recommender and recommendee. In music recommendation systems, perhaps a feature to support co-listening remotely (e.g., 'Your friend X is listening to Y. Would you also like to listen to it together?' and the system informing friend X that another user chose to co-listen to the song), rather than just providing the recommendation, might encourage people to be more willing to listen to the recommended song.

People desire for more personalized and contextualized recommendations: While the underlying social interaction is important, there is also a persistent desire for better algorithmic curation, over and above simple suggestions from friends. While recommendation systems have gotten more sophisticated and individualized over time, a variety of different recommendation requests surfaced - better matched to users' tastes, better matched to specific musical styles, better attuned to popularity and extramusical cultural associations, or compartmentalized based on different listening sessions. This kind of personalization could help meet the needs of the users in the long tail, who have stronger needs and wants regarding music recommendations (those labeled with the "music epicurean" persona by Lee & Price [13]). The context of the recommendation was also important to many respondents; they wanted to understand why the song was recommended to them, see the musical and social connections between the songs and artists, and know which friends were also listening to or interested in the music recommended to them. This desire for more contextual knowledge was a common theme for both machine and human based recommendations. While there is a fair amount of research available to support context-based music recommendation systems [1, 8, 11, 16], few have examined what might happen if users are provided insight into why an algorithm recommended something.

Some people are simply less interested in recommendations: In designing services, it may be valuable to note a significant recalcitrant population that is unreachable for recommendations, either because they do not want new music at all, or because they do not want new music from the service specifically (persona labeled as "Non-believer" in [13]). Part of this population still seems to respond to recommendations provided by people they know, especially if they feel like they can trust them. This trust was based on two factors: positive past recommendation experience, and how well the recommender understood the recommendee's musical taste. Designing a system to incorporate this social aspect of recommendation may help reach out to this reluctant population.

Many contextual factors need to be further investigated to gain a comprehensive understanding of the impact of music recommendations. In our future work, we plan to dive deeper into people's social music behaviors and explore perceptions of the value of specific social features such as collaborative playlists, co-listening, and music recommendations via videos and other audiovisual media.

ADVERSARIAL LEARNING FOR IMPROVED ONSETS AND FRAMES MUSIC TRANSCRIPTION

Jong Wook Kim, Juan Pablo Bello
Music and Audio Research Lab, New York University
{jongwook,jpbello}@nyu.edu

ABSTRACT

Automatic music transcription is considered to be one of the hardest problems in music information retrieval, yet recent deep learning approaches have achieved substantial improvements on transcription performance. These approaches commonly employ supervised learning models that predict various time-frequency representations, by minimizing element-wise losses such as the cross entropy function. However, applying the loss in this manner assumes conditional independence of each label given the input, and thus cannot accurately express inter-label dependencies. To address this issue, we introduce an adversarial training scheme that operates directly on the time-frequency representations and makes the output distribution closer to the ground-truth. Through adversarial learning, we achieve a consistent improvement in both frame-level and note-level metrics over Onsets and Frames, a state-of-the-art music transcription model. Our results show that adversarial learning can significantly reduce the error rate while increasing the confidence of the model estimations. Our approach is generic and applicable to any transcription model based on multi-label predictions, which are very common in music signal analysis.

1. INTRODUCTION

Automatic music transcription (AMT) concerns automated methods for converting acoustic music signals into some form of musical notation [4]. AMT is a multifaceted problem and comprises a number of subtasks, including multi-pitch estimation (MPE), note tracking, instrument recognition, rhythm analysis, score typesetting, etc. MPE predicts a set of concurrent pitches that are present at each instant, and it is closely related to the task of note tracking, which predicts the onset and offset timings of every note in audio. In this paper, we address an issue in the recent approaches for MPE and note tracking, where the probabilistic dependencies between the labels are often overlooked.

A common approach for MPE and note tracking is through the prediction of a two-dimensional representation that is defined along the time and frequency axes and contains the pitch tracks of notes over time. Piano rolls are the most common example of such representations, and deep salience [5] is another example that can contain more granular information on pitch contours. Once such representation is obtained, pitches and notes can be decoded by thresholding [23] or other heuristic methods [17, 25].

To train a model that predicts a two-dimensional target representation $\hat{\mathbf{Y}} \in \mathbb{R}^{P \times T}$ from an input audio representation $\mathbf{X}$, where P is the number of pitch labels and T is the number of time frames, a common approach is to minimize the element-wise sum of a loss function $\mathcal{L}$:

$$\text{minimize } \mathcal{L}(\hat{\mathbf{Y}}, \mathbf{Y}) = \sum_{p=1}^{P} \sum_{t=1}^{T} \mathcal{L}(\hat{\mathbf{Y}}_{pt}, \mathbf{Y}_{pt}), \tag{1}$$

where $\mathbf{Y} \in \mathbb{R}^{P \times T}$ is the ground truth. In a probabilistic perspective, we can interpret $\mathcal{L}$ as the negative log-likelihood of the model parameters ϑ of a discriminative model $p_\vartheta(\mathbf{Y}|\mathbf{X})$:

$$p_\vartheta(\mathbf{Y}|\mathbf{X}) = e^{-\mathcal{L}(\hat{\mathbf{Y}}, \mathbf{Y})} = \prod_{p=1}^{P} \prod_{t=1}^{T} e^{-\mathcal{L}(\hat{\mathbf{Y}}_{pt}, \mathbf{Y}_{pt})} = \prod_{p=1}^{P} \prod_{t=1}^{T} p_\vartheta(\mathbf{Y}_{pt}|\mathbf{X}) \tag{2}$$

which indicates that each element of the label $\mathbf{Y}$ is conditionally independent with each other given the input $\mathbf{X}$. This encourages the model to predict the average of the posterior, making blurry predictions when the posterior distribution is multimodal, e.g. natural images [10].

Music data is highly contextual and multimodal, and the conditional independence assumption does not hold in general. This is why many computational music analysis models employ a separate post-processing stage after sequence prediction. One approach is to factorize the joint probability using the chain rule and assume the Markov property:

$$p_\vartheta(\mathbf{Y}|\mathbf{X}) \approx \prod_{p=1}^{P} \prod_{t=1}^{T} p_\vartheta(\mathbf{Y}_{pt}|\mathbf{Y}_{\cdot(t-1)}, \mathbf{X}). \tag{3}$$

This corresponds to appending hidden Markov models (HMMs) [36] or recurrent neural networks (RNNs) [17,39] to the transcription model. The Markov assumption is effective for one-dimensional sequence prediction tasks, such as chord estimation [35] and monophonic pitch tracking [32], but when predicting a two-dimensional representation, it still does not address the inter-label dependencies along the frequency axis.

There exist a number of models in the computer vision literature that can express inter-label dependencies in two-dimensional predictions, such as the neural autoregressive distribution estimator (NADE) [27], PixelRNN [43], and PixelCNN [42]. However, apart from a notable exception using a hybrid RNN-NADE approach [7], the effect of learning the joint posterior distribution for polyphonic music transcription has not been well studied.

To this end, we propose a new approach for effectively leveraging inter-label dependencies in polyphonic music transcription. We pose the problem as an image translation task and apply an adversarial loss incurred by a discriminator network attached to the baseline model. We show that our approach can consistently and significantly reduce the transcription errors in *Onsets and Frames* [17], a state-of-the-art music transcription model.

2. BACKGROUND

2.1 Automatic Transcription of Polyphonic Music

Automatic transcription models for polyphonic music can be classified into frame- or note-level approaches. Frame-level transcription is synonymous with multi-pitch estimation (MPE) and operates on tiny temporal slices of audio, or frames, to predict all pitch values present in each frame. Note-level transcription, or note tracking, operates at a higher level, predicting a sequence of note events that contains the pitch, the onset time, and optionally the offset time of each note. Note tracking is typically implemented as a post-processing stage on the output of MPE [3], by connecting and grouping the pitch estimates over time to produce discrete note events. In this sense, we can say that MPE is at the core of polyphonic music transcription.

Two categories of approaches for MPE have been most successful in recent years: matrix factorization and deep learning. Factorization-based models for music transcription [40] use non-negative matrix factorization (NMF) [29] to factorize a time-frequency representation $\mathbf{X} \in \mathbb{R}^{F \times T}$ as a product of a dictionary matrix $\mathbf{D} \in \mathbb{R}^{F \times K}$ and an activation matrix $\mathbf{A} \in \mathbb{R}^{K \times T}$, where K is the number of pitch labels to be transcribed, e.g. 88 keys for piano transcription. This allows for an intuitive interpretation of each matrix, where each column of $\mathbf{D}$ contains a spectral template for a pitch label, and each row of $\mathbf{A}$ contains the activation of the corresponding pitch over time. Various extensions of factorization-based methods have been proposed to leverage sparsity [1], adaptive estimation of harmonic spectra [14, 44], and modeling of attack and decay sounds [2, 12]. In all of these approaches, an iterative gradient-descent algorithm is used to minimize an element-wise divergence function between the matrix factorization $\mathbf{DA}$ and the target matrix $\mathbf{X}$ [13].

Deep learning [28] methods for music transcription are increasingly popular [3], as larger labeled datasets and more powerful hardware become accessible. These approaches use neural networks (NN) to produce music transcriptions from the input audio. An early work [34] used deep belief networks [20] to extract audio features which are subsequently fed to pitch-wise SVM-HMM pairs to predict the target piano rolls. More recent approaches are based on convolutional [5, 23] and/or recurrent neural networks [6, 17, 39], which are also optimized with gradient descent to minimize an element-wise loss of predicting the target time-frequency representations.

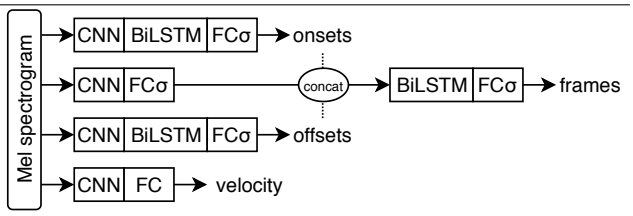

Figure 1. The Onset and Frames model. CNN denotes the convolutional acoustic model taken from [23], FC denotes a fully connected layer, and σ denotes sigmoid activation. Dotted lines mean stop-gradient, i.e. no backpropagation.

Onsets and Frames [17] is a state-of-the-art piano transcription model that we use as our baseline. It uses multiple columns of convolutional and recurrent layers to predict onsets, offsets, velocities, and frame labels from the Mel spectrogram input, as shown in Figure 1. Predicted onset and frame posteriors are then used for decoding the note sequences, where a threshold value is used to create binary onset and frame activations, and frame activations without the corresponding onsets are disregarded.

As discussed above, most NMF- and NN-based methods, including Onsets and Frames, use an element-wise optimization objective which does not consider the inter-label dependencies. This motivates the adversarial training scheme that is outlined in the following subsection.

2.2 Generative Adversarial Networks and `pix2pix`

Generative adversarial networks (GANs) [16] refer to a family of deep generative models which consist of two components, namely the generator G and the discriminator D. Given a data distribution $\mathbf{x} \sim p(\mathbf{x})$ and latent codes $\mathbf{z} \sim p(\mathbf{z})$, GAN performs the following minimax game:

$$\min_G \max_D \underbrace{\left[\mathbb{E}_{\mathbf{x}} \log D(\mathbf{x}) + \mathbb{E}_{\mathbf{z}} \log(1 - D(G(\mathbf{z})))\right]}_{\mathcal{L}_{\text{GAN}}(G,D)}. \quad (4)$$

G and D are implemented as neural networks trained in an adversarial manner, where the discriminator learns to distinguish the generated samples from the real data, while the generator learns to produce realistic samples to fool the discriminator. GANs are most renowned for their ability to produce photorealistic images [22] and have shown promising results on music generation as well [9, 11, 45]. We refer the readers to [8, 15] for a comprehensive review of the techniques, variants, and applications of GANs.

The second term in Equation 4 has near-zero gradients when $D(G(\mathbf{z})) \approx 0$, which is usually the case in early training. To avoid this, a non-saturating variant of GAN is suggested in [16] where the generator is trained with the following optimization objective instead:

$$\max_G \mathbb{E}_{\mathbf{z}} \log D(G(\mathbf{z})). \quad (5)$$

The non-saturating GAN loss is used more often than the minimax loss in Equation 4 and is implemented by flipping the labels of fake data while using the same loss function. Least-squares GAN [31] is an alternative method to address the vanishing gradient problem, which replaces the cross entropy loss in Equations 4-5 with squared errors:

$$\begin{aligned} &\min_D \ \Big[\mathbb{E}_{\mathbf{x}}(D(\mathbf{x})-1)^2+\mathbb{E}_{\mathbf{z}}D(G(\mathbf{x}))^2\Big], \\ &\min_G \ \mathbb{E}_{\mathbf{z}}(D(G(\mathbf{z}))-1)^2. \end{aligned} \tag{6}$$

While the default formulation of GAN concerns unconditional generation of samples from $p(\mathbf{x})$, conditional GANs (cGAN) [33] produce samples from a conditional distribution $p(\mathbf{y}|\mathbf{x})$. To do this, the generator and the discriminator are defined in terms of the condition variable $\mathbf{x}$ as well:

$$\min_G \max_D \underbrace{\Big[\mathbb{E}_{\mathbf{x},\mathbf{y}}\log D(\mathbf{x},\mathbf{y})+\mathbb{E}_{\mathbf{x},\mathbf{z}}\log(1-D(\mathbf{x},G(\mathbf{x},\mathbf{z}))\Big]}_{\mathcal{L}_{\text{cGAN}}(G,D)}. \tag{7}$$

`pix2pix` [21] is an image translation model that learns a mapping between two distinct domains of images, such as aerial photos and maps. A `pix2pix` model takes paired images $(\mathbf{x},\mathbf{y})$ as its training data and minimizes the conditional GAN loss along with an additional L1 loss:

$$\mathbb{E}_{\mathbf{x},\mathbf{y},\mathbf{z}} \left\| \mathbf{y}-G(\mathbf{x},\mathbf{z}) \right\|_1, \tag{8}$$

which encourages the conditional generator to learn the forward mapping from $\mathbf{x}$ to $\mathbf{y}$. It can be thought that the GAN loss in Equation 7 is fine-tuning the mapping learned by the L1 loss in Equation 8, resulting in a predictive mapping that better respects the probabilistic dependencies within the labels $\mathbf{y}$.

In this paper, we adapt this approach to music transcription tasks and show that we can indeed improve the performance by introducing an adversarial loss to an existing music transcription model.

3. METHOD

We describe a general method for improving an NN-based transcription model G that performs prediction of a two-dimensional target $\mathbf{Y}$ from an input audio representation $\mathbf{X}$. Say the original model G is trained by minimizing the loss $\mathcal{L}_{\text{task}}(G(\mathbf{X}),\mathbf{Y})$ between the predicted target $\hat{\mathbf{Y}}=G(\mathbf{X})$ and the ground-truth $\mathbf{Y}$. The main idea of our method is to adapt `pix2pix` [21] to this setup, by introducing an adversarial discriminator D during the training process. The adversarial training objective includes the conditional GAN loss $\mathcal{L}_{\text{cGAN}}$ (Equation 7):

$$\min_G \max_D \mathbb{E}_{\mathbf{X},\mathbf{Y}}\Big[\nu\mathcal{L}_{\text{task}}(G(\mathbf{X}),\mathbf{Y})+\mathcal{L}_{\text{cGAN}}(G,D)\Big], \tag{9}$$

where ν is a hyperparameter that controls how much the conditional GAN loss contributes to the gradient steps relative to the discriminative loss $\mathcal{L}_{\text{task}}$. Figure 2 illustrates how the two components are connected in the computation graph and how the loss terms are calculated.

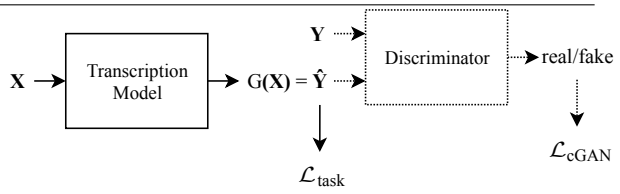

Figure 2. A computation graph showing how a discriminator is appended to the original model. The appended parts are shown as dotted components.

Adversarial training with $\mathcal{L}_{\text{cGAN}}$ allows the model to learn the inter-label dependencies as desired, even when $\mathcal{L}_{\text{task}}$ is defined only in terms of element-wise operations between $\hat{\mathbf{Y}}$ and $\mathbf{Y}$, as in Equation 1. In the next subsection, we describe a neural network architecture for the cGAN discriminator that leverages prior knowledge on music.

3.1 Musically Inspired Adversarial Discriminator

Following `pix2pix`, we use a fully convolutional architecture [30] for the discriminator. By being fully convolutional, the discriminator has translation invariance not only along the time axis (as in HMMs and RNNs) but also along the frequency axis. Since the discriminator determines how realistic a polyphonic note sequence is, the translation invariance enforces that the decision does not depend on the musical key, but only on the relative pitch and time intervals between the notes. This effectively implements a music language model (MLM) [7, 39] and biases the transcription toward more realistic note sequences.

Unlike the image-to-image translation problem, the input representations (e.g. Mel spectrograms) and the output representations (e.g. piano rolls) of a music transcription model can have different dimensions. This makes combining $\mathbf{X}$ and $\mathbf{Y}$ in a fully convolutional manner difficult. For this reason, we make the discriminator a function of $\mathbf{Y}$ only, simplifying the objective in Equation 7 to:

$$\mathcal{L}_{\text{cGAN}}(G,D)=\mathbb{E}_{\mathbf{Y}}\log D(\mathbf{Y})+\mathbb{E}_{\mathbf{X}}\log(1-D(G(\mathbf{X}))). \tag{10}$$

Note that $\mathbf{z}$ is also omitted in Equation 10, as we follow [21] and implement the stochasticity of $\mathbf{z}$ only in terms of dropout layers [41], without explicitly feeding random noises into the generator. This causes a mode collapse problem where the learned $p(\mathbf{Y}|\mathbf{X})$ is not diverse enough, but it does not harm our purpose of producing more realistic target representations.

3.2 TTUR and *mixup* to Stabilize GAN Training

Although an ideal GAN generator can fully reconstruct the data distribution at the global optimum [16], training of GANs in practice is notoriously difficult, especially for high-dimensional data [15]. This led to the inventions of a plethora of techniques for stabilizing GAN training, among which we employ the two-timescale update rule (TTUR) [19] and *mixup* [47]. TTUR means simply setting the generator's learning rate a few times larger than that of the discriminator, which has been empirically shown to stabilize GAN training significantly.

The other technique, *mixup*, is an extension to empirical risk minimization where training data samples are drawn from convex interpolations between pairs of empirical data samples. For a pair of feature-target tuples $(\mathbf{X}_i, \mathbf{Y}_i)$ and $(\mathbf{X}_j, \mathbf{Y}_j)$ sampled randomly from the empirical distribution, their convex interpolation is given by:

$$\begin{aligned}\tilde{\mathbf{X}} &= \lambda \mathbf{X}_i + (1-\lambda)\mathbf{X}_j \\ \tilde{\mathbf{Y}} &= \lambda \mathbf{Y}_i + (1-\lambda)\mathbf{Y}_j\end{aligned} \tag{11}$$

where $\lambda \sim \text{Beta}(\alpha, \alpha)$, and α is the *mixup* hyperparameter which controls the strength of interpolation. When $\alpha = 0$, the Beta distribution becomes Bernoulli(0.5) which recovers the usual GAN training without *mixup*.

mixup is readily applicable to the binary classification task of GAN discriminators. In our conditional GAN setup, we have an additional advantage of having paired samples of a real label $\mathbf{Y}$ and a fake label $\hat{\mathbf{Y}} = G(\mathbf{X})$, which allow us to replace Equation 10 with:

$$\min_G \max_D \mathbb{E}_{\mathbf{X},\mathbf{Y},\lambda}\Big[-\ell(D(\lambda \mathbf{Y} + (1-\lambda)G(\mathbf{X})), \lambda)\Big]. \tag{12}$$

where $\ell(p, y) = -y \log p - (1-y)\log(1-p)$ is the binary cross entropy (BCE) function. With this *mixup* setup, the discriminator now has to operate on the convex interpolation between the predicted representation and the corresponding ground truth. This makes the discriminator's task even more difficult when the prediction gets close to the ground truth, which is desirable because the discriminantor should be inconclusive (i.e. $D = \frac{1}{2}$ everywhere) at the global optimum [16].

Algorithm 1 details the procedure of training the conditional GAN using *mixup*, based on Equations 10 and 12. Note that for training the generator network, we perform label flipping in $\mathcal{L}^G_{\text{cGAN}}$ similarly as in Equation 5. Also, to train a least-squares GAN (Equation 6) instead, we can simply replace ℓ with a mean squared error (MSE) loss.

Input: Generator $G_\vartheta(\mathbf{X})$ with initial parameters ϑ, learning rate η, and loss function $\mathcal{L}_{\text{task}}(\hat{\mathbf{Y}}, \mathbf{Y})$, discriminator $D_\varphi(\mathbf{Y})$ with initial parameters φ, learning rate β, and loss function $\ell \in \{\text{BCE}, \text{MSE}\}$, batch size m, training data distribution $p(\mathbf{X}, \mathbf{Y})$, `pix2pix` weight ν, *mixup* strength α.

Output: Trained conditional generator $G_\vartheta(\mathbf{X})$.

while *φ and ϑ have not converged* **do**
- $\{(\mathbf{X}_i, \mathbf{Y}_i)\}_{i=1,\cdots,m} \leftarrow m$ samples from $p(\mathbf{X}, \mathbf{Y})$
- **for** $i = 1, \cdots, m$ **do**
  - $\hat{\mathbf{Y}}_i \leftarrow G_\vartheta(\mathbf{X}_i)$
  - $\lambda_i \leftarrow$ sample from $\text{Beta}(\alpha, \alpha)$
  - $\tilde{\mathbf{Y}}_i \leftarrow \lambda_i \mathbf{Y}_i + (1-\lambda_i)\hat{\mathbf{Y}}_i$
- **end**
- $\mathcal{L}^D_{\text{cGAN}} \leftarrow \sum_{i=1}^M \ell(D_\varphi(\tilde{\mathbf{Y}}_i), \lambda_i)$
- $\varphi \leftarrow \varphi - \beta \cdot \nabla_\varphi \mathcal{L}^D_{\text{cGAN}}$
- $\mathcal{L}^G_{\text{cGAN}} \leftarrow \sum_{i=1}^M \ell(D_\varphi(\tilde{\mathbf{Y}}_i), 1-\lambda_i)$
- $\vartheta \leftarrow \vartheta - \eta \cdot \nabla_\vartheta \Big[\sum_{i=1}^m \nu \mathcal{L}_{\text{task}}(\hat{\mathbf{Y}}_i, Y_i) - \mathcal{L}^G_{\text{cGAN}}\Big]$

end

Algorithm 1: Training of a *mixup* Conditional GAN.

4. EXPERIMENTAL SETUP

To verify the effectiveness of our approach, we compare Onsets and Frames [17], a state-of-the-art piano transcription model, with variants of the same model that are trained with the adversarial loss. We also aim to evaluate the choices of the GAN loss and the *mixup* strength α.

4.1 Model Architecture

We use the extended Onsets and Frames model [18] which increased the CNN channels to 48/48/96, the LSTM units to 256, and the FC units to 768. The extended model has total 26.5 million parameters. We do not use the frame loss weights described in [17] in favor of the offset stack introduced in the extended version (see Figure 1). During inference, we first calculate the posteriors corresponding to overlapping chunks of audio, with the same length as the training sequences, and perform overlap-add using Hamming windows to obtain the full-length posterior. This is because the effects of adversarial learning do not continue further than the training sequence length when we let the recurrent networks continue to predict longer sequences.

The input to the discriminator has two channels for the onset and frame predictions. The discriminator has 5 convolutional layers: `c32k3s2p1`, `c64k3s2p1`, `c128k3s2p1`, `c256k3s2p1`, `c1k5s1p2`, where the numbers indicate the number of output channels, the kernel size, the stride amount, and the padding size. At each non-final layer, dropout of probability 0.5 and leaky ReLU activation with negative slope 0.2 are used. The mean of the final layer output along the time and frequency axes is taken as the discriminator output.

4.2 Hyperparameters

Table 1 summarizes the hyperparameters used during the experiments, which are mostly taken directly from [17] and [21]. Also following [17], we use Adam [26] and apply learning rate decay of factor 0.98 in every 10,000 iterations, for both the generator and the discriminator. We examine two types of GAN losses, the non-saturating GAN (ℓ = BCE) and the least-squares GAN (ℓ = MSE). For each GAN loss, multiple values of *mixup* strengths are compared with $\alpha = 0$, i.e. no *mixup*. Training runs for one million iterations, and the iteration that best performs on the validation set are used for evaluation on the test set.

Hyperparameter	Values
Generator learning rate η	0.0006
Discriminator learning rate β	0.0001
Discriminator loss function ℓ	{BCE, MSE}
Batch size m	8
`pix2pix` weight ν	100
mixup strength α	{0, 0.2, 0.3, 0.4}
Activation threshold τ	0.5
Training sequence length	327,680

Table 1. Hyperparameters used during the experiments.

4.3 Dataset

We use the MAESTRO dataset [18], which contains Disklavier recordings of 1,184 classical piano performances. The dataset consists of 172.3 hours of audio, which are provided with 140.1, 15.3, and 16.9 hours of train/validation/test splits such that recordings of one composition only appear in the same split. We resample the audio to 16 kHz and down-mix into a single channel. Following [17], an STFT window of 2,048 samples is used for producing 229-bin Mel spectrograms, and a hop length of 32 ms is used. Training sequences sliced at random positions are used, unlike the official implementation which slices training sequences at silence or zero crossings.

4.4 Evaluation Metrics

The Onsets and Frames model perform both frame-level and note-level predictions, and their performance can be evaluated with the standard precision, recall, and F1 metrics. For multi-pitch estimation, we also report the error rate metrics defined in [36], which include total error, substitution error, miss error, and false alarm error. We use the `mir_eval` [37] library for all metric calculations. For the note-level metrics, we use the default settings of the library, which use 50 ms for the onset tolerance, 50 ms or 20% of the note length (whichever is longer) for the offset tolerance, and 0.1 for the velocity tolerance.

5. RESULTS

5.1 Comparison with the Baseline Metrics

Table 2 and 3 summarize the transcription performance, clearly showing a consistent improvement in the conditional GAN models over the Onsets and Frames baseline. Table 2 shows that both non-saturating GAN and least-squares GAN achieve the highest frame and note F1 scores when the *mixup* strength $\alpha = 0.3$ is used, and they both outperform the baseline. The binary piano rolls are easy to distinguish from the non-binary predictions, which may cause imbalanced adversarial training. *mixup* allows non-binary piano rolls to be fed to the discriminator, making its task more challenging and leading to higher performance.

Table 3 shows an important trend of the cGAN results compared to the baseline that cGAN trades off a bit of precision for a significant improvement in recall; this is a side effect of the cGAN producing more confident predictions, as will be discussed in the following subsections.

	Baseline	GAN type	*mixup* strength α 0	0.2	0.3	0.4
Frame F1	0.899	Non-Saturating	0.664	0.912	**0.914**	0.907
		Least-Squares	0.904	0.903	0.906	0.898
Note F1	0.942	Non-Saturating	0.717	0.953	**0.956**	0.951
		Least-Squares	0.944	0.947	0.950	0.943

Table 2. Frame and note F1 scores are the highest when the non-saturating GAN loss and $\alpha = 0.3$ are used.

While the percentage differences are moderate, our method achieves statistically significant improvements in F1 metrics on the MAESTRO test dataset ($p < 10^{-14}$ for all 4 metrics, two-tailed paired t-test). The distribution of per-track improvement in each F1 metric is shown in Figure 4, which indicates that the improvements are evenly distributed across the majority of the tracks. These improvements are especially promising, considering that Onsets and Frames is already a very strong baseline.

5.2 Visualization of Frame Activations

To better understand the inner workings of the conditional GAN framework, we visualize the frame posteriorgrams created by the baseline and the best performing conditional GAN model in Figure 3. In contrast to the baseline posteriorgrams which have many blurry segments, the posteriorgrams generated by our method mostly contain segments with solid colors, meaning that the model is more confident in its prediction. Figure 5 shows that the proportion of frame activation values in $(0.1, 0.9)$ is noticeably higher in the baseline, thus making the output less sensitive to the threshold choice. This is because indecisive predictions are penalized by the discriminator, since they are easy to distinguish from the ground-truth which contains only binary labels. The generator is therefore encouraged to output the most probable note sequences even when it is unsure, rather than producing blurry posteriorgrams that might hamper the decoding process. This allows for an interpretation in which the GAN loss provides a prior for valid onset and frame activations, and the model learns to perform MAP estimation based on this prior.

5.3 Training Dynamics and The Generalization Gap

Figure 6 shows the learning curves for the frame F1 and note F1 scores, where the scores on the training dataset are plotted in dotted lines. It is noticeable in the figure

	mixup strength α	Frame Metrics							Note Metrics			Note Metrics with Offsets			Note Metrics with Offsets & Velocity		
		F1	P	R	E_{total}	E_{subs}	E_{miss}	E_{fa}	F1	P	R	F1	P	R	F1	P	R
Baseline		.899	.946	.857	.179	.013	.130	.036	.942	.990	.899	.802	.842	.765	.790	.830	.755
Non-Saturating GAN	0.3	**.914**	.931	.898	**.156**	.012	.089	.054	**.956**	.981	.932	**.813**	.835	.793	**.802**	.823	.782
Least-Squares GAN	0.3	.906	.942	.875	.167	.013	.113	.042	.950	.988	.916	.810	.841	.781	.799	.830	.771

Table 3. Summary of transcription performance using *mixup* strength $\alpha = 0.3$. The non-saturating GAN loss has the highest performance across all F1 metrics. The average metrics across the tracks in the MAESTRO test dataset are reported, and the model checkpoint where the average of frame F1 and note F1 is the highest on the validation dataset is used.

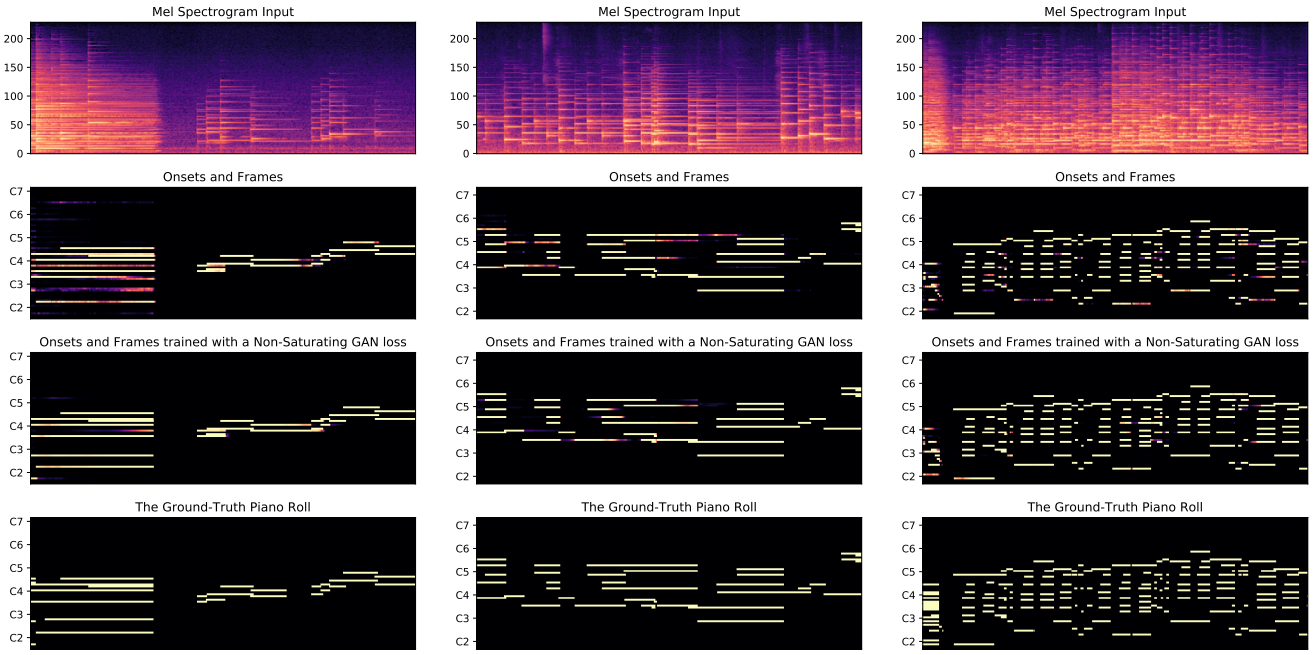

Figure 3. Comparisons of the frame activation posterior predicted by the baseline and our model (ℓ = BCE, $\alpha = 0.3$), on three example segments. The input Mel spectrograms and the target piano rolls are shown together. The GAN version produces more confident predictions compared to the noisy baselines, leading to more accurate predictions.

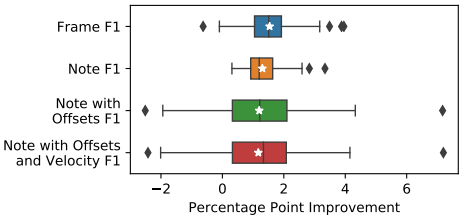

Figure 4. F1 score improvements over the baseline, tested on the MAESTRO test tracks.

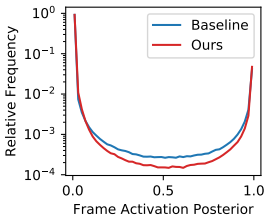

Figure 5. Distribution of frame activation values.

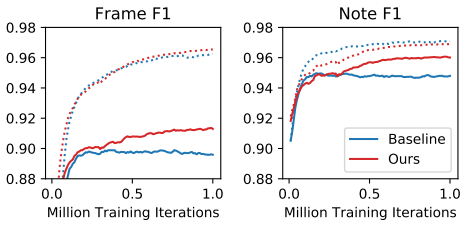

Figure 6. Learning curves showing the generalization gaps; training curves are dotted.

that the validation F1 scores for the baseline stagnate after 300k iterations, while the F1 scores of our model steadily grow until the end of 1 million iterations. Thanks to this, the generalization gap — the difference between the training and validation F1 scores — is significantly smaller for the conditional GAN model. This means that the GAN loss works as an effective regularizer that encourages the trained model to generalize better to unseen data, rather than memorizing the note sequences in the training dataset as LSTMs are known to be capable of [46].

6. CONCLUSIONS

We have presented an adversarial training method that can consistently outperform the baseline Onsets and Frames model, using the standard frame-level and note-level transcription metrics and visualizations that show how the improved model predicts more confident output. To achieve this, a discriminator network is trained competitively with the transcription model, i.e. a conditional generator, so that the discriminator serves as a learned regularizer that provides a prior for realistic note sequences.

Our results show that modeling the inter-label dependencies in the target distribution is important and brings measurable performance improvements. Our method is generic, and any model that involves predicting two-dimensional representation should be able to benefit from including an adversarial loss. These approaches are common not only in transcription models but also in speech or music synthesis models that predict spectrograms as an intermediate representation [24, 38].

Our results do not include the effects of using data augmentation [18], which is orthogonal to our approach and should bring additional performance improvements when applied. As discussed, the discriminator imposes the prior on the target domain whereas data augmentation enriches the input audio distribution. This implies that our method would be less effective when the majority of errors are due to the discrepancy in the audio distribution between the training and test datasets. How to apply adversarial learning for better generalization on the input distribution is a potential future research direction.

ABSTRACT

Converting an acoustic music signal into music notation using a computer program has been at the forefront of music information research for several decades, as a task referred to as automatic music transcription (AMT). However, current AMT research is still constrained to system development followed by quantitative evaluations; it is still unclear whether the performance of AMT methods is considered sufficient to be used in the everyday practice of music scholars. In this paper, we propose and carry out a user study on evaluating the usefulness of automatic music transcription in the context of ethnomusicology. As part of the study, we recruited 16 participants who were asked to transcribe short musical excerpts either from scratch or using the output of an AMT system as a basis. We collect and analyze quantitative measures such as transcription time and effort, and a range of qualitative feedback from study participants, which includes user needs, criticisms of AMT technologies, and links between perceptual and quantitative evaluations on AMT outputs. The results show no quantitative advantage of using AMT, but important indications regarding appropriate user groups and evaluation measures are provided.

1. INTRODUCTION

Automatic music transcription (AMT) is the process of transferring an music audio signal to a symbolic representation using computational methods [14, p.30]. Engineering research has been developing AMT methods for a number of decades now (see *e.g.* [17] for an early example), and it represents a recurrent theme in the discourse in the field of music information retrieval (MIR). In the field of comparative musicology – the historical predecessor of ethnomusicology – the idea of using automatic methods to obtain a graphical representation (not necessarily symbolic) from a music recording attracted interest from the early days of audio recording technology [7]. This long history of interest in AMT technology in two rather remote fields motivates us to investigate what the current state of the art in AMT may have to offer for (ethno)musicologists transcribing a piece of music.

In the field of MIR, recent AMT research has mostly focused on automatic transcription of piano recordings in the context of Western/Eurogenetic music (see [3] for a recent overview). The vast majority of proposed methods aim to create systems which can output a MIDI or MIDI-like representation in terms of detected notes with their corresponding onsets/offsets in seconds. Such methods are typically evaluated quantitatively using multi-pitch detection and note tracking metrics also used in the respective MIREX public evaluation tasks [2]. Methods that can automatically convert audio into staff notation include the beat-informed multi-pitch detection system of [8] in the context of folk music (the dataset of this work is also used in the present user study) and the multi-pitch detection and rhythm quantization system of [15], which was applied to Western piano music. Recently, methods inspired by deep learning theory have also attempted to automatically convert audio directly into staff notation [5, 18], although these methods are mostly constrained to synthesized monophonic excerpts using piano soundfonts.

Within ethnomusicology, transcription may take a large variety of forms, depending on analytic goals and the analyzed musical context [20]. An early study of the commonalities and discrepancies between transcriptions of the same piece by several experts was conducted by List in 1974 [12]. The study investigated transcriptions of three pieces by up to eight transcribers, and documented higher consistency in the notation of pitch than in duration. An estimated pitch curve was provided as well, and the study demonstrated that only small corrections were conducted by the transcribers. The value of user studies has been recognized in MIR [9, 10, 19, 21], and MIR user studies have been conducted, for instance, in the context of applying music to achieve certain emotional states [6] and therapeutic applications [11]. However, to the best of our knowledge, since [12] no user studies have been conducted that study a larger group of transcribers in their interaction with the output of an AMT system.

In the context of AMT, the research questions that can be approached by a user study are manifold. In this study, we investigate the relations between the output of a state-of-the-art AMT system and manual transcriptions, the validity of quantitative evaluation metrics when comparing manual transcriptions, and the question of whether using an AMT as a starting point for transcription provides ad-

vantages of any kind. To this end we conducted a study with 16 experienced transcribers, and asked them to transcribe eight excerpts of a particular musical style with a specific analytic goal. Transcriptions were either to be performed completely manually, or using an AMT output as a starting point. Our results document a range of insights into the qualities and problems of AMT and evaluation metrics. Even after decades of development of AMT systems, our study cannot reveal a clear advantage of using AMT to inform manual transcription, but our results indicate promising avenues for future development.

The outline of this paper is as follows. Section 2 presents the method, and Section 3 the results of the study. Sections 4 and 5 provide discussion and conclusions, respectively.

2. PROPOSED STUDY

2.1 Subjects

Participants for the proposed study were recruited from the Institute of Musicology in Vienna, Austria, from SOAS University of London, UK, and from City, University of London, UK. In total, 16 subjects participated in our study, nine male and seven female. The criteria for the participation in the study were being an advanced student or recent graduate in a musicology or ethnomusicology program, having attended training on music transcription / musical dictation and being recommended by a member of faculty as being good transcribers. Apart from these students, two musicology lecturers also participated as subjects.

The participants had 16 years of music training on average, with a standard deviation of 9 years. In terms of their interests, 6 participants closely identified with Western classical music, and 10 participants identified with world/folk/traditional music. In terms of their professional practice, 9 participants engaged with Western classical music, and 8 with world/folk/traditional music. In terms of software for music notation and transcription, 7 participants were familiar with MuseScore, 6 with Transcribe!, 5 with Sibelius, and 2 with Sonic Visualiser.

2.2 Material

For this study, we use audio recordings and corresponding transcriptions collected as part of the Crinnos project [1], which were also used as part of the *Sousta Corpus* for AMT research in [8]. All recordings used in this study were recorded in 2004 in Crete, Greece, and all regard a specific dance called *sousta*. Recordings selected for this study were transcribed by ethnomusicologists in Western staff notation as part of the Crinnos project.

These recordings were chosen for the present study for several reasons. They provide a dataset that is highly consistent in terms of musical style, thus appropriate for an AMT user study consisting of multiple excerpts. The sousta dance is usually notated in 2/4 meter and has a relatively stable tempo, again providing consistency for human transcribers. The instrumental timbres are likewise highly consistent, with one Cretan lyra (a pear-shaped fiddle) playing the main melody, and usually two Cretan lutes playing the accompaniment.

Eight audio excerpts from the *Sousta Corpus* were selected for the present study. The length of each excerpt was set to 4 bars, which results in a duration of 7-8 seconds per excerpt. The number of excerpts and their duration were determined through pilot studies, with the goal to constrain the duration of the proposed study for each participant to 2 hours. The position of the 4 bars within each piece was chosen as such to provide study participants with a complete musical phrase, in order to aid transcription. The corpus of [1] also contains corresponding reference transcriptions in musicXML format, which were used for quantitative evaluations. [1]

We did not assume that participants are familiar with the music culture used in this study. Therefore, one complete recording from the corpus of [8] was also selected in order to familiarize participants with the music culture prior to the start of the study.

2.3 AMT methods

For the purposes of this study, an AMT method is needed that can convert an audio recording into machine-readable Western staff notation, suitable for audio recordings from the particular music culture employed for this study. In terms of academic research, the pool of candidate AMT methods for audio-to-staff music transcription is limited to the beat-informed matrix factorization-based system used for the same corpus in [8], the two-stage piano-specific polyphonic transcription system from [15], plus preliminary works for end-to-end piano-only transcription using synthesized audio [5, 18]. In terms of commercial AMT software, a partial list is included in [3], out of which only a small subset (ScoreCloud, Sibelius' AudioScore plugin) produces transcriptions in staff notation.

We selected the beat-informed matrix factorization-based AMT method [8] from the above list of candidate AMT methods, because of its suitability for the present corpus. In terms of commercial tools, we selected ScoreCloud [2], given its competitive performance in monophonic transcription of violin recordings, an instrument with timbre characteristics similar to the Cretan lyra. Based on quantitative AMT evaluations of both systems (shown in Section 3.1), it was decided to use the ScoreCloud AMT system for the present user study.

Since the objective of this study is for participants to transcribe the main melody and not to focus on accompaniment and ornamentations, the automatic transcriptions produced by the systems of [8] and ScoreCloud were modified as to remove the bass staff (if it exists) along with all transcribed notes in that staff; all ornamentations (e.g. trills, grace notes) and note groupings were deleted. We also changed sharp or flat symbols in the automatic transcriptions as to have consistent accidentals for each excerpt.

[1] The excerpts and reference transcriptions can be obtained at `https://bit.ly/2ZKhmnY`

[2] `https://scorecloud.com/`

2.4 Procedure

Experiments took place in quiet rooms; participants were provided with a laptop (if they did not have their own), headphones, printed or digital automatic transcriptions (as desired by participant), manuscript paper, and the study questionnaire. Participants were video recorded in order to assist with the subsequent annotation process.

Participants were asked to transcribe the main melody for each excerpt and to not transcribe the accompaniment or ornamentations. The purpose of this specification was to clarify the analytic goal of the transcription. Participants were free to use the music notation software of their preference or to transcribe on manuscript paper. The study consisted of 8 excerpts per participant, with 4 excerpts to be manually transcribed, and 4 excerpts to be accompanied with AMT outputs in printed and machine-readable format, to be used as a starting point for transcriptions. The order of manual and edited transcriptions was interleaved, and participants were either asked to start transcribing their first segment manually or to edit an automatic transcription. The order of the 8 excerpts exposed to participants was randomized. Fig. 1 shows an example automatic transcription produced using ScoreCloud, compared with a reference and a study participant transcription.

Following the study, a short conversation with participants took place, in order to obtain qualitative feedback as well as information on their experience with automated tools for the task. All participant transcriptions that were produced on manuscript paper were re-transcribed by the authors in machine-readable music notation using MuseScore, in order to carry out quantitative evaluations.

2.5 Evaluation Metrics

2.5.1 Participant Questionnaire

Participants were asked to quantify their effort for every excerpt towards producing the transcription on a scale 1-10 (1: no effort, 10: very high effort). In addition, for every excerpt to be edited from an automatic transcription, participants were asked to rate the quality of the AMT (on a scale 1-10, with 10 being excellent). After completing the experiment, participants were asked to specify the most crucial mistakes present in the automatic transcriptions, and to comment on the possible value of AMT as a starting point towards producing manual transcriptions.

2.5.2 Quantitative metrics

In order to evaluate the performance of the automatic transcription methods, as well as to compare the participants' transcriptions with the reference transcriptions, we use the quantitative metrics for complete AMT proposed in [15] [3] . We chose to compare with these particular reference transcriptions, because their transcribers had extended experience with both transcription and the musical style.

These quantitative metrics are based on an automatic alignment of the estimated score to the reference score using the method of [16]. Following alignment, we are able to identify correctly detected notes, notes with pitch errors (also called *pitch substitution errors*), extra notes, and missing notes. Based on the above definitions, the following error rates are used, as per [15]: pitch error rate E_{p}, extra note rate E_{e}, missing note rate E_{m}, and onset time error rate E_{on}. We also define an average error metric E_{mean} as the arithmetic mean of all 4 aforementioned metrics. As additional quantitative metric, we also measured the time taken by each participant to transcribe each excerpt.

[3] Noting that typical metrics used in multi-pitch detection and note tracking [2] are not suitable for evaluating transcriptions in staff notation.

3. RESULTS

3.1 AMT system evaluation

Excerpt#	E_{p}	E_{e}	E_{m}	E_{on}	E_{mean}
1	18.75	18.18	15.62	48.15	25.18
2	10.71	3.85	10.71	36	15.32
3	20.69	28.57	31.03	45	31.32
4	10	29.03	26.67	18.18	20.97
5	2.5	38	22.5	25.81	22.20
6	7.69	7.14	0	23.08	9.48
7	13.64	3.12	29.54	61.29	26.90
8	40.91	41.18	9.09	70	40.29
Average	15.61	21.13	18.15	40.93	23.96

Table 1. AMT quantitative evaluation scores using ScoreCloud.

Excerpt#	E_{p}	E_{e}	E_{m}	E_{on}	E_{mean}
1	12.5	66.67	66.67	75	55.21
2	21.05	22.22	26.31	35.71	26.33
3	0	100	100	0	50.00

5	17.39	39.13	39.13	21.43	29.27
6	12.5	16.67	16.66	35	20.21
7	33.33	0	25.64	31.03	22.50
8	38.46	53.57	0	53.85	36.47
Average	17.37	47.00	44.02	37.75	36.54

Table 2. AMT quantitative evaluation scores using the method of [8].

Tables 1 and 2 depict the error rates for all eight examples used in the experiments, using ScoreCloud and the AMT system of [8], respectively. The ScoreCloud system performs significantly better than the system of [8] (based on a paired-sample t-test, $p < 0.05$) for the extra- and missing note rates, and for the mean error rate E_{mean}.

Ranking of the examples looks quite inconsistent between ScoreCloud and the method of [8]. Segment 6 has lowest error rates for both, but the highest error rates are for Segment 8 for ScoreCloud, and Segment 1 for [8]. However, when calculating the average E_{mean} of both algorithms, one could identify Segment 3 as the most challenging (2nd highest error rate for both algorithms).

Figure 1. Transcriptions for bars 85-88 of segment 114 from the corpus of [8]. (a) Reference transcription. (b) Automatic transcription using ScoreCloud. (c) Manual transcription created by one of the expert participants.

3.2 Participant transcription evaluation

Table 3 depicts the transcription error rates obtained for each piece, averaged over all participants. The lowest mean error rate E_{mean} is obtained for Excerpt 6, and the highest for Excerpt 3, which is consistent with the ranking obtained from the two automatic transcription algorithms.

In Table 3, error rates with statistically significant differences (based on one-sample t-tests) to the error rates obtained from the ScoreCloud AMT (Table 1) are underlined. In addition, significantly lower error rates are emphasized using bold numbers. For the overall average (last row of Table 3), the only significant differences are increases in error rates (E_e, E_m) for the participant transcriptions, which indicates that participants' transcriptions include a larger number of extra and missing notes compared to the ScoreCloud transcriptions. Regarding significant changes of error rates for the individual pieces, four out of five for E_p, three out of five for E_{on}, and one out of two for E_{mean} are decreases in error rate. This indicates that at least some participant transcriptions were more consistent with the reference regarding meter (E_{on}) and pitch (E_p), compared to the ScoreCloud automatic transcriptions.

The inconsistent tendencies observed for the various metrics depicted in Table 3 motivate to investigate further which of the metrics most accurately reflect the notion of the quality of a transcription. Based on the quality ratings that the participants provided for each AMT, a conclusion was obtained which of the five error rates depicted in Tables 1 to 3 most correlated with the rated quality of a transcription. The highest correlation with the participants' stated AMT quality ratings was obtained for E_{mean} ($r = -0.91, p = 0.0019$). Correlations for E_p and E_{on} were still significant ($p < 0.05$), but correlations with both E_e and E_m were not. This motivates to focus on E_{mean} as the main metric for the rating of transcription quality in this paper, and to rather consider E_e and E_m as indicators for the chosen level of detail in the manual transcription.

Excerpt#	E_{p}	E_{e}	E_{m}	E_{on}	E_{mean}
1	14.58	42.15	24.42	40.85	30.50
2	**4.76**	20.07	15.37	**21.49**	15.42
3	**7.97**	54.05	48.45	45.83	39.07
4	18.16	38.50	35.61	44.13	34.10
5	19.52	33.75	16.52	37.16	26.74
6	**1.75**	18.84	11.50	16.90	12.25
7	17.53	15.33	30.68	**41.20**	26.18
8	**20.25**	37.81	13.97	**47.22**	**26.81**
Average	12.96	32.75	24.47	36.70	26.72

Table 3. Average error rates over all participant transcriptions. Underlined values emphasize statistical significant difference to the value in Table 1 (one-sample t-test, $p < 0.05$); bold values emphasize significant decrease in error rates over AMT.

3.3 Differences depending on the subject

Group	T(s)	Eff.	E_p	E_e	E_m	E_{on}	E_{mean}
Experts	430.33	4.1	**9.71**	31.58	28.60	**28.49**	24.60
Other	803.96	5.4	13.99	**33.12**	23.16	39.29	**27.39**

Table 4. Comparison of mean transcription times, T(s), rated efforts (Eff.), and error rates between experts and other participants. Statistically significant differences between experts and others are underlined (Welch's t-test, $p < 0.05$), and significant differences to average error rates in Table 1 are emphasized using bold numbers.

Based on the participant information, participants were grouped into experts and non-experts. The group of experts comprises three participants, who were either instructors of transcription courses, or had several decades' experience in transcribing folk music. Table 4 depicts the mean transcription times, rated transcription efforts, and error rates obtained from the transcriptions of these two groups. Whereas the expert group's transcription times

and effort ratings were significantly lower, the results regarding the quantitative error rate metrics remain inconclusive. Only regarding the onset error rate (E_{on} - which assesses the metrical correctness of the transcriptions when compared with the reference), the expert group had significantly better values that the non-expert group. In comparison with the average error rates obtained using the ScoreCloud algorithm (Table 1), the other transcribers have significantly higher error rates for E_e and E_{mean}, whereas the experts have significantly lower error rates regarding E_p and E_{on}. This implies that the tendency towards decreased error rates in the latter two metrics observed in Table 3 is more emphasized among the expert group.

3.4 Differences between editing and manual transcription

Case	T(s)	Eff.	E_p	E_e	E_m	E_{on}	E_{mean}
AMT	733.14	4.98	11.91	29.51	21.58	36.02	24.75
Man.	695.44	5.20	14.02	35.99	27.35	37.37	28.68

Table 5. Comparison of mean transcription times, T(s), rated efforts (Eff.), and error rates between AMT editing and manual transcription. None of the differences between the cases were found statistically significant (Student's t-test, all p-values > 0.18).

Table 5 shows the error rates over all participant transcriptions when editing automatic transcriptions as a starting point and when carrying out manual transcriptions, respectively. In order to address the question if any difference in the quality of the obtained participant transcriptions exists between the manual transcriptions and the editing of the automatic ones, the distributions of the error rates from the two cases were compared using two-sample t-tests. However, no significant differences were observed, indicating that the transcription times, efforts, and quality neither improved, nor deteriorated by using automatic transcriptions as a starting point. Significantly decreased variances were observed for two error rates (E_p, E_m) when using the AMT as a starting point (two-sample F-test, $p < 0.05$). This indicates that the usage of AMT as a starting point – at least in our experiments – led to transcriptions that are more similar, which may be interpreted as a bias imposed on the transcribers by using the AMT.

Since we observed in Table 4 that experts transcribe generally faster, we investigated if some gain in using AMT in terms of transcription time and effort can be observed at least for particular participants. To this end, we computed the relative changes in transcription time comparing manual transcription with editing per participant, and the absolute differences in the effort ratings per participant. For each participant, negative values for transcription time difference indicate that editing AMT was faster, whereas negative values for rating difference imply less effort when editing AMT. Figure 2 shows a correlation between the differences in effort and transcription times, which indicates that participants who had a tendency to rate a decreased effort in editing tend also to be those spending less time when editing. The approximately equal number of points in the lower-left and the upper-right quadrant reflects the absence of an overall effect of using AMT on transcription times and effort. The fact that all three expert transcribers (emphasized by circles) spend longer when editing AMT may indicate that providing AMT is not of practical use for experienced transcribers, a point further discussed in the following Section.

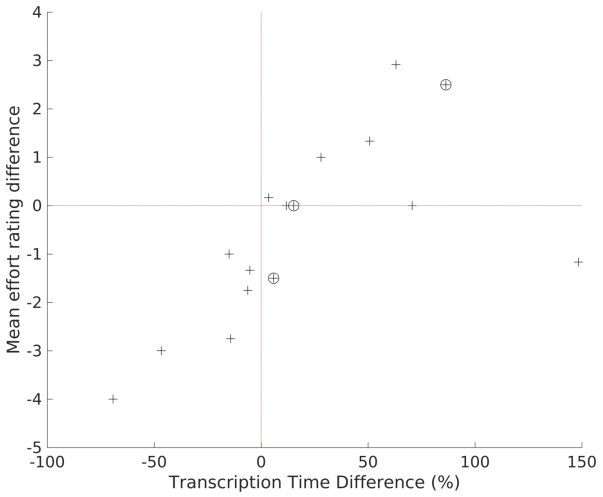

Figure 2. Scatter plot of absolute differences in the effort ratings and change in transcription time. Expert participants are emphasized by a circle.

3.5 Qualitative Results

The experiment was designed to be flexible in terms of providing the participants with exactly those tools for transcription that they would normally use outside of the context of this experiment. Therefore, the choices regarding these tools provide valuable insights into the transcription practice in the context of musicology. Out of the 16 participants, eight decided to transcribe the segments on paper, using mainly the software *Transcribe!* as a tool to loop certain phrases, and to decrease the speed of the playback. The other eight transcribers used notation software, four of them *MuseScore*, and four of them *Sibelius*; the latter exclusively applied by transcribers based in the UK, which indicates differences between the transcription practices based on the local musicology education.

Even though many participants transcribed on paper, all but one participant provided a positive response to the question if AMT tools are able to provide a valuable starting point for a manual transcription. Four of the participants expressed their opinion that use of AMT would be helpful mainly for inexperienced transcribers, and another four explicitly mentioned the potential to save time when using AMT.

A thematic analysis [4] was applied to the questionnaire responses in order to obtain the main reasons for criticism and appraisal of AMT. Four main themes emerged as depicted in Figure 3, three expressing criticism, and one expressing the value of AMT. Most frequently, participants

criticized rhythmic aspects of the AMT, referring most of the time to note durations contained in the AMT. The participants' second most frequent criticism concerns the omission of notes sounding in the recordings, and the addition of notes not heard by the transcriber, with omissions and additions being similarly frequent in the comments. Finally, participants criticized the simultaneous notation of notes, resulting from the notation either of accompaniment notes played on the lute or of overtones of the main instrument. Despite the fact that our questions focused on criticism of the AMT, one positive theme emerged as well, as participants emphasized the value of the AMT to obtain an understanding of the overall shape of the melody.

Summing up the qualitative observations, the most important finding is that current AMT technologies in the context of musicology may have a generally positive value for inexperienced transcribers in terms of pitch information. This value is, however, diminished by the frequent problems related to rhythm, addition/omission of notes, and poor separation of main melody and accompaniment.

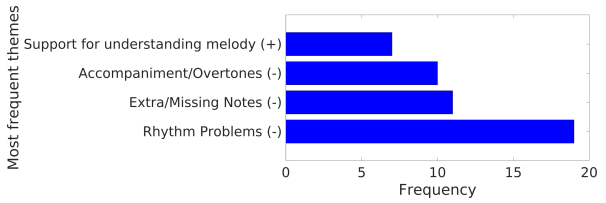

Figure 3. Most frequent themes in the discussions of qualities (+) and problems (-) of the AMT.

4. DISCUSSION

There are several aspects of the proposed study that need to be taken into account before making any claims on the usefulness of AMT in the context of (ethno)musicology. Firstly, the sample size in terms of participants is relatively small, which indicates the difficulty in locating subjects who are trained in transcription and are willing to work with automated methods. It is also difficult to rate the participants' transcription skills: future work could enlist the assistance of transcription instructors and to ask them to rate the participants' transcriptions. Another aspect to take into account is the bias introduced by the AMT system when asking participants to edit transcriptions.

The quantitative evaluation metrics proposed in [15], which were used as part of this study are not error-free: they rely on automatic score-to-score alignment that has been designed to align performance MIDI with reference scores. In particular, the symbolic alignment step could fail in the case of "abstract" transcriptions which could only focus on transcribing notes that are on strong beats, e.g. ignoring any passing notes. Therefore, additional work can be done towards improving the automatic symbolic alignment approach of [16] towards supporting the alignment automatic and manual transcriptions with reference scores.

Additionally, it should be stressed that the present study is focused on the usefulness of AMT in the context of (ethno)musicology, thus not taking into account potential uses of AMT in other application domains. The focus of this study was also on monophonic transcription (despite the presence of polyphony in certain segments); therefore, the usefulness of polyphonic AMT, and also of multiple-instrument AMT technologies, remains to be explored.

Finally, the question posed in the study on the value of AMT could be viewed as suggestive and could have biased participants towards providing a positive answer. There might also be a bias on participants who agreed to take part in the study, since their participation could indicate their general interest into the subject of automatic music transcription, and more generally on the use of technology in the transcription process.

5. CONCLUSIONS

This paper presented a user study on AMT in the context of ethnomusicology. Participants were asked to manually transcribe four segments of folk dance tunes, and to transcribe four different segments of the same style using the output of an AMT system as a starting point. Quantitative analysis shows: a comparative quality between automatic and manual transcriptions; differences between expert and non-expert transcribers, in terms of the time required to carry out transcriptions and also on the metrical quality of the resulting transcriptions; a correlation between the differences in stated effort between manual and edited transcriptions and transcription times; and a correlation between AMT quality ratings and some of the employed quantitative metrics. Finally, qualitative results show support for AMT to obtain an understanding of the overall melodic shape, although combined with criticism of the AMT related to harmonic errors, missing/extra notes, and rhythmic problems. Importantly, however, using an AMT output as a starting point for a transcription did not result in any quantifiable differences regarding quality, transcription time, or effort.

Future work will investigate similarity/dissimilarity of participants' transcriptions, in particular between those by the expert participants and the reference transcriptions, and will liaise with transcription instructors towards grading the resulting transcriptions. We will investigate ways to improve the quantitative metrics of [15] towards a more robust symbolic alignment of automatic and manual transcriptions with reference scores, and conduct evaluations using the newly-proposed metrics of [13]. Exploring whether the conclusions of this paper hold more broadly across other AMT systems and musical repertoires will have important impact on AMT research and on the applicability of AMT in ethnomusicology. We believe that this paper provides a viable and effective framework for user-based evaluation of AMT methods.

LakhNES: IMPROVING MULTI-INSTRUMENTAL MUSIC GENERATION WITH CROSS-DOMAIN PRE-TRAINING

ABSTRACT

We are interested in the task of generating multi-instrumental music scores. The *Transformer* architecture has recently shown great promise for the task of piano score generation—here we adapt it to the multi-instrumental setting. Transformers are complex, high-dimensional language models which are capable of capturing long-term structure in sequence data, but require large amounts of data to fit. Their success on piano score generation is partially explained by the large volumes of symbolic data readily available for that domain. We leverage the recently-introduced *NES-MDB* dataset of four-instrument scores from an early video game sound synthesis chip (the NES), which we find to be well-suited to training with the Transformer architecture. To further improve the performance of our model, we propose a pre-training technique to leverage the information in a large collection of heterogeneous music, namely the Lakh MIDI dataset. Despite differences between the two corpora, we find that this transfer learning procedure improves both quantitative and qualitative performance for our primary task.

1. INTRODUCTION

In this paper, we extend recent results for symbolic piano music generation [1] to the multi-instrumental setting. Both piano and multi-instrumental music are *polyphonic*, where multiple notes may be sounding at any given point in time. However, the generation of multi-instrumental music presents an additional challenge not present in the piano domain: handling the intricate interdependencies between multiple instruments. Another obstacle for the multi-instrumental setting is that there is less data available than for piano, making it more difficult to train the types of powerful generative models used in [1].

Until recently, music generation methods struggled to capture two rudimentary elements of musical form: long-term structure and repetition. Huang et al. [1] demonstrated that powerful neural network *language models*, i.e., models which assign likelihoods to sequences of discrete tokens, could be used to generate classical piano music containing these elusive elements. In order to adapt this method to the multi-instrumental setting we incorporate instrument specification directly into our language-like music representation. However, this strategy alone may be insufficient to generate high-quality multi-instrumental music, as the results of [1] also depend on access to large quantities of piano music.

To begin to address the data availability problem, we focus on an unusually large dataset of multi-instrumental music. The *Nintendo Entertainment System Music Database* (NES-MDB) [2] contains 46 hours of *chiptunes*, music written for the four-instrument ensemble of the NES (video game system) sound chip. This dataset is appealing for music generation research not only for its size but also for its structural homogeneity—all of the music is written for a fixed ensemble. It is, however, smaller than the 172 hours of piano music in the *MAESTRO Dataset* [3] used to train Music Transformer.

The largest available source of symbolic music data is the *Lakh MIDI Dataset* [4] which contains over 9000 hours of music. This dataset is structurally heterogeneous (different instruments per piece) making it challenging to model directly. However, intuition suggests that we might be able to benefit from the musical knowledge ingrained in this dataset to improve our performance on chiptune generation. Accordingly, we propose a procedure to heuristically map the arbitrary ensembles of music in Lakh MIDI into the four-voice ensemble of the NES. We then pre-train our generative model on this dataset, and fine-tune it on NES-MDB. We find that this strategy improves the quantitative performance of our generative model by 10%. Such transfer learning approaches are common practice in state-of-the-art natural language processing [5, 6], and here we develop new methodology to employ these techniques in the music *generation* setting (as opposed to analysis [7]).

We refer to the generative model pre-trained on Lakh MIDI and fine-tuned on NES-MDB as *LakhNES*. In addition to strong quantitative performance, we also conduct multiple user studies indicating that LakhNES produces strong qualitative results. LakhNES is capable of generating chiptunes from scratch, continuing human-composed material, and producing melodic material corresponding to human-specified rhythms. [1]

2. RELATED WORK

Music generation has been an active area of research for decades. Most early work involved manually encoding musical rules into generative systems or rearranging fragments of human-composed music; see [8] for an extensive overview. Recent research has favored machine learning systems which automatically extract patterns from corpora of human-composed music.

Many early machine learning-based systems focused on modeling simple *monophonic* melodies, i.e., music where only one note can be sounding at any given point in time [9–11]. More recently, research has focused on *polyphonic* generation tasks. Here, most work represents polyphonic music as a *piano roll*—a sparse binary matrix of time and pitch—and seeks to generate sequences of individual piano roll timesteps [12, 13] or chunks of timesteps [14]. Other work favors an *event-based* representation of music, where the music is flattened into a list of musically-salient events [1, 15, 16]. None of these methods allow for the generation of multi-instrumental music.

Other research focuses on the multi-instrumental setting and seeks to provide systems which can *harmonize* with human-composed material [17–20]. Unlike the system we develop here, these approaches all require complex inference procedures to generate music without human input. Recent work [21–23] attempts multi-instrumental music generation from scratch, but these methods are limited to generating fixed lengths, unlike our method which can generate arbitrarily-long sequences. There is also music generation research that operates on the audio domain [24, 25], though this work is largely unrelated to symbolic domain methods. The work described in this paper is methodologically similar to MuseNet [26], which was concurrent with our work.

3. DATASETS AND TASK

The *NES Music Database* (NES-MDB) [2] consists of approximately 46 hours of music composed for the sound chip on the Nintendo Entertainment System. This dataset is enticing for research in multi-instrumental music generation because (1) it is an unusually large corpus of music that was composed for a fixed ensemble, and (2) it is available in symbolic format.

3.1 NES ensemble preliminaries

The ensemble on the NES sound chip has four monophonic instrument voices: two pulse waveform generators (P1/P2), one triangle waveform generator (TR), and one noise generator (NO). [2] The first three of these instruments are melodic voices: typically, TR plays the bass line and P1/P2 are interchangeably the melody and harmony. The noise instrument is used to provide percussion.

The various instruments have a mixture of sound-producing capabilities. For example, the range of MIDI pitches which P1/P2 can generate is 33–108, while the range of TR extends an octave lower (21–108). The noise channel can produce 16 different "types" of noise which correspond to different center frequencies and bandwidths. Each instrument also has a variety of dynamics and timbral attributes. It is shown in [2] that these expressive attributes can be estimated from the score post-hoc, and hence we ignore them in this study to focus on the problem of modeling composition rather than expressive performance.

Each chiptune in NES-MDB is stored as a MIDI file, and the constituent MIDI events are quantized at audio rate (44100 *ticks* per second). Paired with code which synthesizes these MIDI files as NES audio, the files contain all of the information needed to synthesize the original 8-bit waveforms.

[2] There is an additional fifth voice capable of waveform playback that the authors of NES-MDB excluded.

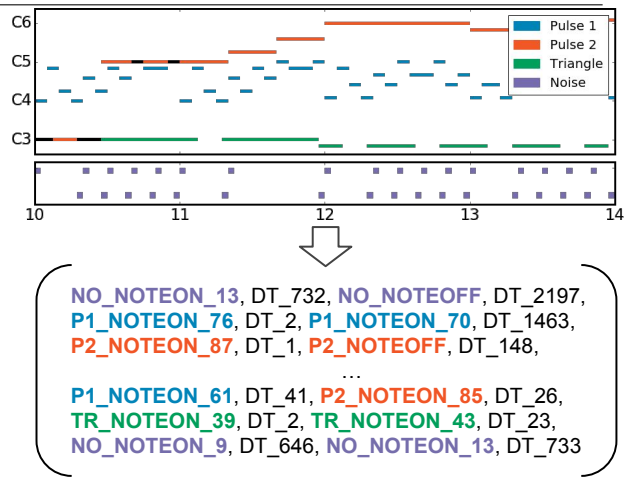

Figure 1. A visual comparison between the piano roll representation of the original NES-MDB paper [2] (**top**) and the event representation of this work (**bottom**). In the piano roll representation, the majority of information is the same across timesteps. In our event representation, each timestep encodes a musically-meaningful change.

3.2 Event-based task

In our original work on NES-MDB [2], we operated on a *piano roll* representation of the data, i.e., the MIDI information decomposed into a sparse grid across time, pitch, and instrument (top of Figure 1). Because no tempo or beat information exists in the dataset, the authors chose to discretize the time axis at a rate of 24 timesteps per second. This high rate is necessary for capturing nuanced timing information in the scores but results in much of the information being redundant across adjacent timesteps. This represents a challenge as long-term dependencies are a barrier to success for sequence modeling with machine learning.

To circumvent these issues, we design an *event-based* representation (bottom of Figure 1) similar to that used for single-instument music in [15]. Specifically, we convert each NES-MDB MIDI file into a time-ordered sequence of events, so that every entry in the sequence corresponds to a musically-salient occurrence.

To handle the rhythmic information, we add time shift (ΔT) events which represent time advancing by some dis-

Event description	Event ID(s)
Start or end of sequence	0
ΔT for 1–100 ticks (short)	1–100
ΔT for 100–1000 ticks (medium)	101–190
ΔT for $>$ 10000 ticks (long)	191–370
P1 Note Off/On	371–447
P2 Note Off/On	448–524
TR Note Off/On	525–613
NO Note Off/On	614–630

Table 1. Schematic for our event-based representation of NES-MDB, reminiscent of the one used in *Performance RNN* [15]. The 631 events in our representation are distributed among time-shift (ΔT) events (which allow for nuanced timing), and note off/on events for individual instruments (as in typical MIDI).

crete number of ticks (each tick is $\frac{1}{44100}$th of a second). To keep the number of events in our representation tractable, we quantize ΔT events in the real data to fixed gratings. We embed the multi-instrumental aspect of our problem directly into this representation by using separate note on/off events for each instrument. Contemporaneous events are always listed in the following instrument order: P1, P2, TR, NO. Our final representation consists of 631 events, of which about half encode time-related events and half note-related (Table 1). Apart from minor timing quantization, this format is a lossless transformation of the original MIDI score.

4. METHODOLOGY

To model the event sequences outlined in the last section, we adopt a *language modeling* factorization. We factorize the joint probability of a musical sequence consisting of N events $(E_1, \ldots, E_N)$ into a product of conditionals:

$$P(E_1) \cdot P(E_2 \mid E_1) \cdot \ldots \cdot P(E_N \mid E_1, \ldots, E_{N-1}). \quad (1)$$

This factorization is convenient because it allows for a simple left-to-right algorithm for generating music: sampling from the distribution estimated by the model at each timestep (conditioned on previous outputs). The goal of our optimization procedure is to find a model configuration which maximizes the likelihood of the real event sequences. Motivated by the strong results for piano music generation from the recent *Music Transformer* [1] approach, we also adopt a Transformer [27] architecture.

4.1 Transformer architecture

The Transformer [27] is an attention-based neural network architecture. In our context, this means that the model has a mechanism which explicitly biases its predictions based on a subset of musical events that have happened in the past. The model's design gives it the ability to learn which subset of past musical events to pay attention to when predicting the current event. This mechanism may be especially useful for learning patterns of repetition in music across large gaps of time.

The original Transformer architecture [27] was an encoder-decoder model designed for language translation. In this paper, we are only concerned with the decoder portion of the Transformer. Our work uses a recent extension of Transformer called Transformer-XL [28], which is designed specifically to handle longer sequences. Transformer-XL builds upon the Transformer architecture by augmenting it with a recurrence mechanism. The recurrence mechanism enables Transformer-XL to use information beyond its training segment by learning how to incorporate recurrent state from previous segments. In contrast, the original Transformer is only able to alter its predictions based on the current training segment, hence the available system memory during training is a bottleneck to its ability to learn long-term dependencies. In order to effectively use its recurrent state, Transformer-XL adopts a sophisticated position-aware mechanism so the model can generalize to different amounts of recurrent memory during generation.

The Music Transformer [1] is a different Transformer variant that also attempts to tackle long-range dependencies by using a mechanism which reduces the quadratic memory cost of attention, enabling training on longer sequences. Although similar in goal to Transformer-XL, its method is orthogonal and could, in theory, be combined with the recurrent mechanism of Transformer-XL. For simplicity, we focus on the Transformer-XL architecture as its recurrence mechanism alone is sufficient to learn long-term dependencies. Additionally, code to reproduce the Music Transformer method is unavailable.

4.2 Pre-training

Transformers are extremely high-dimensional models, and accordingly they can learn effective strategies for extremely large datasets [6]. One barrier to their application in the music domain is that most symbolic music datasets are either too small or too structurally heterogeneous. For example, the popular Bach chorales dataset [29] is structurally homogeneous (all chorales have four voices), but small (only 306 chorales). In contrast, the Lakh MIDI dataset [4] is enormous (175k songs) but heterogeneous (varying numbers of instruments per piece). The NES-MDB dataset we use in this work represents a middle ground (large and structurally-homogenous), but is still substantially smaller than the MAESTRO dataset [3] used to train Music Transformer (46 hours vs. 172 hours).

We hypothesize that we can improve the performance of our model on our NES music generation task by leveraging the musical information in the larger Lakh MIDI dataset. To test this, we propose a two-step procedure. First, we map each structurally-heterogeneous Lakh MIDI file into one which can be performed by our NES ensemble. Then, we pre-train a Transformer on this dataset, and fine-tune this pre-trained model on the NES-MDB dataset. Such transfer learning procedures are common methodology in other areas of machine learning [30], but remain hitherto unexplored in music generation research. One possible

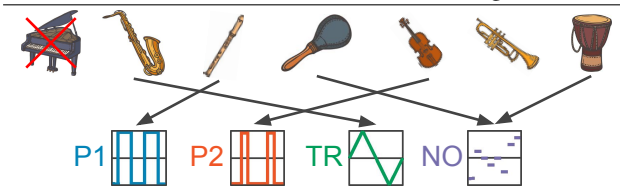

Figure 2. Illustration of our mapping heuristic used to enable transfer learning from Lakh MIDI to NES-MDB. We identify monophonic instruments from the arbitrary ensembles in Lakh MIDI and randomly assign them to the fixed four-instrument ensemble of NES-MDB.

reason for the lack of investigation into this strategy is that mapping music from one domain to another requires careful consideration of musical invariants, and hence is less straightforward than analogous methodology for other tasks (e.g., language). We consider this transfer learning protocol to be a primary methodological contribution of this work.

4.2.1 Mapping Lakh MIDI to the NES ensemble

Here we describe our protocol for mapping Lakh MIDI data into a score suitable for the four monophonic instruments of the NES ensemble. For a given example from Lakh MIDI, we first identify all of its monophonic melodic instruments (skipping the example if it has no such instruments). Then, we filter out instruments which fall outside of the range of MIDI notes that the NES ensemble is capable of producing (Section 3.1). We randomly assign these instruments to the three melodic instruments of the NES (P1/P2/TR) (Figure 2). Because there are a variable number of instruments in each Lakh MIDI example, there are potentially many possible assignments. Hence, we output multiple examples for each input Lakh MIDI example.

In addition to this strategy for melodic instruments, we also design a strategy for mapping percussive instruments in Lakh into the percussive noise instrument of the NES ensemble. We first identify percussive instruments in each Lakh MIDI example. Then, each individual percussive voice (e.g., snare drum, hi-hat) is randomly assigned to a noise "type" (1–16), emulating how the noise instrument is used by human composers to encode syncopated rhythms.

From the 175k MIDI files in Lakh MIDI, our mapping procedure produces 775k examples suitable for performance by the NES ensemble. It is straightforward to imagine similar mapping procedures for other ensembles (e.g., string quartet, vocal choir), and thus it is possible that music generation research in other domains could reuse this procedure to enable transfer learning.

5. EXPERIMENTS

We first conduct an experiment to train Transformer-XL [28] on our event representation (Section 3.2) of NES-MDB. We train the model on excerpts from the training data of 512 events; each excerpt represents around 9 seconds of music on average. Because of the recurrent attention mechanism in Transformer-XL, the model effectively has access to twice this length in its history.

We use the smaller configuration of Transformer-XL which has 12 attention layers each with 8 heads. The learning rate $2e{-}4$ used to train this model on text was found to be too high for our musical application, so we lowered it to $2e{-}5$. Training was stopped when the performance of the model on the validation data stopped improving. We trained the model using four NVIDIA Titan X GPUs with minibatches of size 30, and it reached its early stopping criteria in less than a day. [3]

5.1 Data augmentation and pre-training

To improve the performance of our model further, we employed standard music data augmentation methods as well as ones which we developed specifically for the multi-instrumental setting:

1. (Standard) Transpose melodic voices by a random number of semitones between -6 and 5 (inclusive).
2. (Standard) Adjust the speed of the piece by a random percentage between $\pm 5\%$.
3. Half of the time, remove a random number of instruments from the ensemble (leaving at least one).
4. Half of the time, shuffle the score-to-instrument alignment for the melodic instruments only (e.g., TR performs P2's part).

Finally, we experimented with pre-training our model on the Lakh MIDI dataset mapped to the NES ensemble (Section 4.2.1). To conduct this experiment, we first split the Lakh data into training and validation subsets. We then trained the model for a week on the training set (with data augmentation) and monitored performance on the validation set. Because of the extreme size of the dataset, the model only completed four epochs of training. Even after a week, the model was underfitting the training data (validation performance was still improving). We then fine-tuned this pre-trained model on the NES-MDB training data, again performing early stopping based on the validation performance. Both our pre-training and fine-tuning experiments use the same hyperparameters outlined in the previous section.

5.2 Baselines

We also measure the performance of competitive baselines on our event-based representation of NES-MDB. Our simplest baselines consist of n-gram models, i.e., statistics gathered directly from the training data of how often certain length-n sequences appear. Specifically, we build unigram (1-gram) and 5-gram models, using backoff for the latter to provide a likelihood for 5-grams which are not present in the training data. We also compare to an LSTM [31] recurrent neural network, which is a popular model for music generation. Our LSTM is configured so

[3] Full hyperparameter description and pre-trained models: `https://github.com/chrisdonahue/LakhNES`

Model	Params	Epochs	Test PPL
Random	0	0	631.00
Unigram	631	1	198.14
5-gram	9M	1	37.25
LSTM [31]	40M	18	14.11
+Data augmentation		35	12.64
Transformer-XL [28]	41M	76	3.50
+Data augmentation		350	2.74
+Pre-train (LakhNES)		250	**2.46**

Table 2. Quantitative performance of various models trained on the event-based representation (631 event types) of NES-MDB. *Params* indicates the number of parameters of each model. *Epochs* is the number of data epochs the model observed before early stopping based on the validation data. *Test PPL* represents the perplexity of the model on the test data, i.e., the exponentiation of its average negative log-likelihood on the test data. A lower perplexity indicates that the model better fits this unseen data.

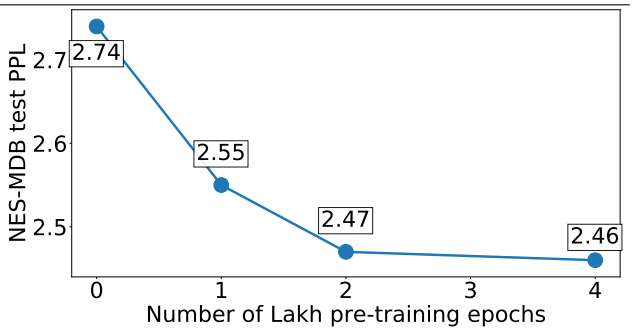

Figure 3. Measuring the performance improvement when doubling the amount of Lakh MIDI pre-training before fine-tuning Transformer-XL on NES-MDB. Each datapoint represents the result of a fine-tuning run starting from 0, 1, 2, or 4 epochs of Lakh MIDI pre-training. Additional amounts of pre-training appear to improve performance, though with diminishing returns.

that it has approximately the same number of parameters as our Transformer-XL model (1 layer, 3072 units).

6. QUANTITATIVE ANALYSIS

We report the *perplexity* (PPL) of each model on the test set in Table 2. Perplexity is calculated by first averaging the negative log-likelihood of each model across the test data, then exponentiating the average, i.e., $e^{\frac{1}{N}\sum_{i=1}^{N} -\log q_i}$, where q_i is the likelihood assigned by a given model to the i-th event. A lower perplexity on the test set indicates that a model is a good fit for unseen data, and hence increases our confidence in its ability to generate new music.

We find that Transformer-XL dramatically outperforms both the n-gram and LSTM baselines on the NES-MDB event-based task (PPL of 3.5 vs. 37.2 and 14.1 respectively). Data augmentation improves the performance of both the LSTM and Transformer-XL (by 10% and 22% respectively), and also increases the number of epochs before the models overfit. We observe that LakhNES (Transformer-XL pre-trained on Lakh MIDI and fine-tuned on NES-MDB with augmentation), achieves 10% better performance than training with data augmentation alone.

We also conduct an experiment to measure the performance effect of using different amounts of Lakh MIDI pre-training before fine-tuning on NES-MDB. Specifically, we measure the performance on the NES-MDB fine-tuning task after 1, 2, and 4 epochs of Lakh MIDI pre-training. We plot the test PPL of each model after fine-tuning in Figure 3. The results agree with our expectation that increasing the amount of pre-training improves the fine-tuned model's performance, though with diminishing returns.

7. USER STUDY

While perplexity is a useful quantitative metric for model comparison, it is not necessarily correlated with human judgements. Since we ultimately seek models which produce music that is convincing to humans, we conduct two user studies on Amazon Mechanical Turk to compare the performance of various models. In both of our user studies we compare four models (rows 3, 5, 7, 8 from Table 2): (1) 5-gram model, (2) LSTM trained with data augmentation, (3) Transformer-XL trained with data augmentation (TXL), and (4) Transformer-XL with data augmentation and Lakh MIDI pre-training (LakhNES).

7.1 Turing test

This study seeks to determine the ability of humans to distinguish between real (human-composed) and fake (computer-generated) chiptunes in a "Turing test" setting. We present human judges with pairs of examples where one example is real and the other fake, and ask them to identify the real example between the two.

We first amass collections of 5-second audio clips from all of our methods and from the real data by selecting random slices from the variable-length music. Then, we create pairs of examples where one example is real and the other fake (randomly chosen from our four methods). Given that Mechanical Turk studies are notoriously noisy, we also create control pairs where the fake data comes from a random model (i.e., we generate "music" by selecting events uniformly at random—row 1 in Table 2).

We ask human judges to annotate 800 batches each consisting of 10 randomly-ordered pairs, where fake data in 2 of the pairs came from the control set and fake data in 8 of the pairs came from our four methods. For their judgments to be included in our results, workers were required to complete at least 3 batches and achieve 100% accuracy on the 6 control examples in those batches—a worker answering randomly would only be included 1.6% of the time. After filtering, each method was evaluated around 180 times. We report accuracy in Figure 4.

In this setting, a lower accuracy indicates that a given model's results sound more human-like, because they were incorrectly identified as human-composed more often. An

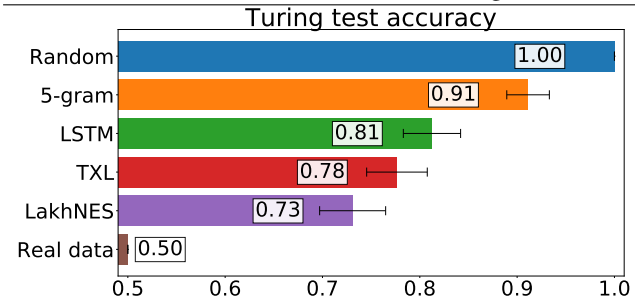

Figure 4. Human accuracy at distinguishing computer-generated examples from human-composed ones (error bars are standard error). Users were presented with pairs of clips (one human, one computer) and tasked with identifying which was composed by a human. Random examples are used as a control and we filtered annotators with accuracy less than 1 on those pairs. A lower accuracy is better as it indicates that the annotators confused a particular model with the real data more often.

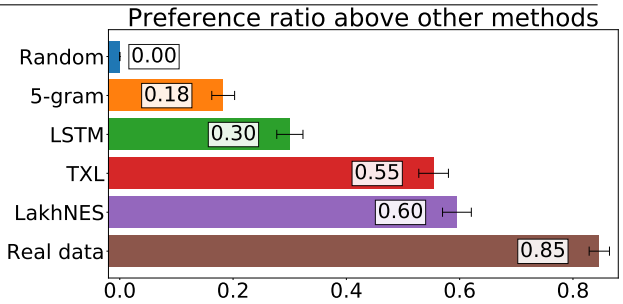

Figure 5. Proportion of comparisons where humans preferred an example from each model over an example from another random model (error bars are standard error). Users were presented with pairs of clips from different methods and asked which they preferred. Pairs of random data and human-composed clips are used as a control and we filtered annotators who preferred random. A higher ratio is better as it indicates that the annotators preferred results from that method more often than another.

ideal generative model would achieve 50% accuracy (although it is possible in theory to generate music which sounds "more human" than human-composed music). We find that LakhNES (Transformer-XL with pre-training) was mistakenly identified as human more often than both our 5-gram model ($p < .0001$ by t-test with normal approximation) and our LSTM ($p = .07$). It also outperformed Transformer-XL without pre-training, but the difference was not statistically significant ($p = .32$).

Overall, these results suggest that there is still a sizable gap between human-composed and computer-generated chiptunes. Subjectively speaking, we feel that the melodies and harmonies produced by LakhNES are promisingly human, but its inability to maintain rhythmic consistency is often a dead giveaway in a Turing test. We suspect that our model could be improved by using a beat-based event representation, however the current model can be bootstrapped with human-specified rhythmic material to manually address rhythmic consistency issues (Section 8).

7.2 Preference test

In addition to our Turing test, we also conduct a preference-based user study, given that human-ness is not necessarily a predictor of general preference. We present human judges with pairs of examples from two different methods, and ask them which of the two they "prefer".

Here we construct pairs of 10-second clips from two different (randomly-chosen) methods. These clips are twice as long as those used in Section 7.1 allowing longer-term structure to influence preference decisions. As in our Turing test, we construct randomly-ordered batches consisting of 10 pairs. In each batch, 8 of the pairs are created by sampling two methods without replacement from a set of five (four computer-generated and the real data), while 2 pairs always compare randomly-generated clips to real data (control). We ask human judges to assign preference to these batches, filtering out workers who even once indicated that they preferred random examples to real data.

After filtering, each of the five methods was involved in around 400 comparisons in total. We report the ratio of "wins" for each method in Figure 5, i.e., the proportion of times a method was preferred over any of the other four.

We find that LakhNES outperforms all other generative methods, though is preferred significantly less often than the real data. Human judges preferred chiptunes generated by LakhNES over the real data in 26% of comparisons (vs. only 10% of the time for the LSTM). We find this to be a promising indicator of Transformer's potential on this task.

8. PAIRING LAKHNES WITH HUMANS

In addition to generating chiptunes from scratch, LakhNES can be used for a number of tasks to assist human composers. For example, LakhNES can be "primed" on human-composed material and then asked to continue the material, providing a method for composers to quickly expand on their ideas. Composers can also provide fixed rhythmic material and use LakhNES to generate the rest of the score. We explore these use cases in our sound examples: `https://chrisdonahue.com/LakhNES` . When generating all of our sound examples (besides those in our user study), we found that limiting the entropy of the model by using a sampling temperature of .95 and top-k sampling [32] with $k = 32$ improved results qualitatively.

9. CONCLUSION

In this paper we presented LakhNES, a method for learning to generate multi-instrumental music. We developed an event-based representation suitable for this task. Training powerful language models on this representation results in compelling multi-instrumental music generation. We show that we can further improve results both quantitatively and qualitatively by pre-training on a cross-domain dataset. LakhNES can be used to both generate chiptunes from scratch and collaborate with human composers.

10. ACKNOWLEDGEMENTS

Thanks to Cheng-Zhi Anna Huang, Cheng-i Wang, and Jennifer Hsu for helpful discussions regarding this work. This work was supported by UC San Diego's Chancellors Research Excellence Scholarship program. GPUs used in this research were donated by NVIDIA.

TAKING FORM: A REPRESENTATION STANDARD, CONVERSION CODE, AND EXAMPLE CORPUS FOR RECORDING, VISUALIZING, AND STUDYING ANALYSES OF MUSICAL FORM

Mark Gotham
Cornell University
Department of Music

Matthew T. Ireland
University of Cambridge
Sidney Sussex College

ABSTRACT

We report on new specification standards for representing human analyses of musical form which enable musicians to represent their analytical view of a piece either on the score (where an encoded version is available) or on a spreadsheet. Both of these representations are simple, intuitive, and highly human-readable. Further, we provide code for converting between these formats, as well as a nested bracket representation adopted from computational linguistics which, in turn, can be visualised in familiar tree diagrams to provide 'at a glance' introductions to works. Finally, we provide an initial corpus of analyses/annotations in these formats, report on the practicalities of amassing them, and offer tools for automatic comparison of the works in the corpus based on the content and structure of the annotations. We intend for this resource to be useful to computational musicologists, enabling study of form at scale, and also useful pedagogically to all teachers, students, and appreciators of music from whom projects of this kind can be rather disconnected. The code and corpus can be found at `https://github.com/MarkGotham/Taking-Form`

1. INTRODUCTION

Marking up scores is a fundamental part of life for any musician working in a score-based medium including – but not entirely limited to – Western classical music. The specifics vary widely from analytical observations to instrument fingerings, but the wider goals can be understood in the same terms: commenting on the music to clarify, visualise, remind, and reinforce a particular understanding of the music in question or plan for its execution.

Regrettably, these annotations are rarely stored, kept, and shared effectively. For instance, an ensemble may assiduously mark up a set of parts, but at the end of the hire period, publishers require them to erase those annotations. (Admittedly this is routinely flouted.) Some conductors travel with their own sets of parts for this reason; others waste rehearsal time conveying markings that could well have been in the score in the first place.

Those score markings represent one of many forms of siloed knowledge that we cannot easily share and repurpose. The same is true of most musical analysis which is published in articles and monographs which time-pressed musicians for the most part simply do not read, and from which the information is hard to extract automatically.

The digital age presents potential solutions to many of these problems, and computational musicology is beginning to answer the call with solutions that centre on representing musico-analytical information in a structured fashion. For instance, formats designed to enable the representation, study, and re-purposing of Roman-numeral analyses include the 'TAVERN', 'ABC', and 'RomanText' projects among others [5, 13, 19]; Automated extraction of performance data include [6, 7], and 'Tuttitempi'; [1] and even pencil-on-paper performers' markings have become an extricable dataset [1].

A key part of the equation here is the opportunity for musical visualization; prior work in this area sees a close relationship between efforts to create format standards for representing musical structure on the one hand, and visualising those structures on the other. This has included handling note-by-note annotations ab initio (such as Dezrann [8] and Verovio [14]) as well as a range of ad hoc visualizations for other research projects like the 'Ribbon' formal analysis of the Josquin Research Project [16]. [2]

This expands the more established practice of visualizing audio analysis in which Fourier or wavelet transforms visualise spectral content (routine in commercial softwares); beat trackers visualise the micro-timing of performed tempo; [3] and even the recorded waveform itself visualises the dynamic profile (an easily forgotten, but eminently useful resource). [4]

2. FORM

Form is a particularly pertinent candidate for stronger representation. The range of use cases includes computational study and visualizations for education in the widest sense:

[1] `https://tuttitempi.com/`
[2] `http://josquin.stanford.edu/`
[3] For instance, see Sonic Visualiser [2]
[4] See [4] for a summary of other relatively recent audio visualizations.

not only of those formally involved in traditional modes of teaching and learning, but anyone seeking to attain or maintain a stronger grasp of the work in question.

Discussion of form necessarily involves comparisons across the full range of the work in question. Keeping all of this information in mind is a challenge and thus form is a parameter particularly in need of schematic representations: while a harmonic or melodic device can often be reproduced exactly, that is almost never possible with form. This has led to a range of creative representations of large-scale structures with clear, at-a-glance summaries.

This paper reports on an attempt to represent formal analyses such that they can be stored, visualised, and studied effectively. We accommodate any number of internal divisions, and envisage this being used to mark up analytical views of everything not specified in the score: that is divisions right down to the level of hypermetrical / phrase groupings. In principle, this could be continued further, to represent the structure of the measure level and beat groupings. [5] That may well be useful for metrically complex works; we include one example in the 'Miscellany' corpus (see Section 3) but do not explore it further here as those details are usually clear from the notation in the common practice repertoire we are primarily targetting. Instead we focus on representing analytical views of those un-notated, hypermetrical and formal levels above the single measure.

We propose three similarly expressive standards for representing analyses, and we provide code for converting between those representations. *On-score mark-up* (Section 2.2) forms the most natural user interface for musicians accustomed to making such annotations; *Abstract syntax trees* (Section 2.1) present a final visualization format; and the *tabular standard* (Section 2.3) is a flexible intermediary encoding useful for overcoming some of the complexities inherent in annotating a score with labels that denote position in a hierarchical structure. We now begin at the 'extremes', as it were, with the (final) visualization format and (initial) on-score mark-up, before proceeding to 'join the dots', discussing the intermediary standard.

2.1 Abstract Syntax Trees (ASTs)

In dealing with form, we face the specific problem of representing hierarchical information, and thus we respond to an explicit call from [15] for a 'Standard Format' for 'Hierarchical Analyses and Representations', including form. Previous work includes Craig Sapp's automation and visualization of 'Hierarchical Key Analysis' [18], and the 'Variations Audio Timeliner' [6] approaches form specifically (though it not open source). There is also a well established precedent for using 'tree' structures (borrowed from computational linguistics) to represent this hierarchical information in music.

Perhaps the most famous linguistics-music cross-over, 'A Generative Theory of Tonal Music' [11], applied a

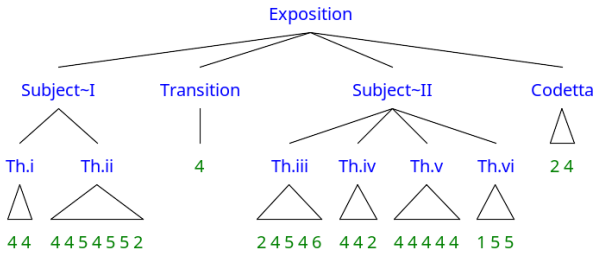

Figure 1. Example tree visualisation: the exposition from the first movement of Schubert's Symphony No.8. The abbreviations are 'Subject' for 'Subject Group', and 'Th.' for 'Theme'.

version of ASTs to discuss metrical and grouping well-formedness and preference at the note level in Schenkerian terms. [17] has applied the same logic to the different 'levels' of harmonic identity, from the chord symbol (such as 'C') through Roman-numerals ('I') to Riemannian functions ('T'). [7]

Figure 1 provides an example of such an AST representation of a passage of musical form: the exposition from the first movement of Schubert's Symphony No.8. The figure includes structural groupings from the highest level down to the level of measure grouping: the numbers of the lowest level refer to the number of measures in each successive phrase grouping.

This paper provides a specification format for producing such visualisation on the basis of well-structured representations of form and phrase in music, as well as code for converting between this representation format, various kind of tree visualizations, and, crucially, encoded scores. With these tools, we can mark observations directly onto scores (which is pedagogically invaluable) and keep them in a structured format for representations and analysis.

In the specification format proposed, each mark-up annotation (labelled on a score) maps directly to a node in the AST. The level (distance from the root node) in the AST must be explicitly encoded within the annotation.

2.2 On-score mark-up

There are many ways to encode this information. This paper reports on a single standard for doing so which is highly flexible both in terms of the types and terms of divisions used, and also the input method. We begin with perhaps the most user-friendly method: marking formal divisions directly onto encoded scores. All that is required is a music notation software which will export to the interoperable standard musicXML. Most notation software support this, including both commercial and free/open-source options like MuseScore.

To enter a marking, simply create a 'stave text' as described in the following instructions which combine the

[5] Our computational framework could be extended to calculate and visualise any arbitrary summary statistic, measuring any lowest level divisions.

[6] variations.sourceforge.net/vat/

[7] For more on datasets for and visualisations of GTTM and Schenkerian reductions see [10, 12] and the work of Masatoshi Hamanaka, Keiji Hirata, and Satoshi Tojo, including [9] and Masatoshi Hamanaka's XML markups of musical examples from (and using the tree structure representation of) GTTM [11] `http://gttm.jp/gttm/`

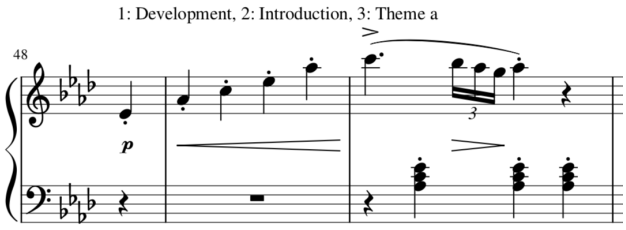

Figure 2. Example file markup in the first movement of Beethoven's Piano Sonata op.2 no.1.

definition of the minimal well-formedness constraints with 'how to' style instructions. Figure 2 illustrates what this looks like on a score.

- First, click on any note at the right measure and beat position for the marking you want to enter.
- Enter a new textual marking at that position (most software provide CMD+T (Mac) / CNTRL+T (Windows) as a shortcut for this).
- Begin each on-score mark-up with an initial character to specify a 'level number' for the marking in question, followed by a colon. For instance, 'Exposition', 'Development' and 'Recapitulation' will all be on the top level of division (number 1) in sonata form movements, so '1: Exposition'. All other levels continue the divisions from here, (e.g. '2: First Subject Group').
- Where you wish to indicate a division, but have no name for the span in question, use the correct level number and a placeholder text like '4: X'.
- In practice, many entries like '1: Exposition' and '2: First Subject Group' will begin at the same time. To indicate these multiple, simultaneous level entries, insert one text entry with all the component parts divided by a comma (','). For instance, many sonatas will begin with the long string: '1: Exposition, 2: First Subject Group, 3: Theme a, 4: Sentence, 5: Presentation, 6: Basic Idea'.

All entries are relative to each other, so level numbers are given by finding the directly relevant parallel. These will fall into a few basic types of comparison:

- A span and its first phrase-division will generally be used together, with the division at +1 level. For a phrase, we might have '4: Period, 5: Antecedent'.
- The next division of that phrase ('Consequent') is at the same level of the first division ('Antecedent'), thus '5: Consequent'.
- The next phrase outside of this span returns to the initial level, so '4: Period'.
- When we eventually get to larger structural boundary then we have to find an entry at a comparable level, which will involve proportionately wider view. For the 'Recapitulation' we're starting again from the top level (so '1: Recapitulation'), while for the second subject group it's level 2 ('2: Second Subject Group').

Note that while the numbers assigned to the top levels will be consistent within and even across pieces ('Exposition', 'Development' and 'Recapitulation' will almost always appear as a set at level 1), those at lower levels will vary depending on the number of level divisions above them. For instance, the same phrase grouping structure may appear at multiple levels across a piece: at lower levels in a long and richly-structured exposition, but at nominally 'higher' levels in a short Coda with fewer divisions (see Figure 1).

This system has been designed to minimise the potential for confusion. Among the alternatives we considered and rejected was a system of multiple comparative marks with '+' for breaking up the existing span, '-' backing up one level, '=' for the same level and '*' for reverting to the highest level. This may appear to be an improvement until you try to indicate the start of a development, for instance, and have to work out the number of successive '-'s needed to reach the right level.

Further work could explore the possibility of encoding similar annotations within a formal context-free grammar. In that case, the user would specify the start of the scope of each annotation, allowing a top-down parser to infer the AST structure without the user having to explicitly specify the depth of each annotation. Informal user trials suggested this recursive mark-up format to be less intuitive and less flexible than the format proposed above, and so we have not explored it further in this initial work.

In any case, the process is necessarily somewhat complicated. To keep everything in order, some users may prefer to work directly on spreadsheets (for which instructions follow in the next section) or at least to keep an informal spreadsheet on the go at the same time.

2.3 Tabular standard

See `https://www.github.com/MarkGotham/Taking-Form` for code to extract these score markings and set them out in a tabular format that is also (perhaps even more) human-readable. Equally, some users will prefer to work directly on spreadsheets. In our experience, the tabular format provides a faster and more flexible user interface for adding, deleting, and especially for modifying annotations.

In the tabular standard:

- Generally, there is one row per measure. Exceptions include the relatively common case of 1st / 2nd time bars (for which use measure 'numbers' 112a / 112b etc.) and the extremely rare case where two structural boundaries fall within the same measure (use multiple rows).
- Each text entry indicates the start of a span. Again, we suggest using text like 'Exposition' where a

```
Sentence    Presentation    Basic Idea      [Exposition
                            Basic Idea          [Subject~I
            Continuation    Fragmentation           [Th.i 4 4]
                            Cadence                 [Th.ii 4 4 5 4 5 5 2]
                                                ]
                                                [Transition 4]
                                                [Subject~II
                                                    [Th.iii 2 4 5 4 6]
                                                    [Th.iv 4 4 2]
                                                    [Th.v 4 4 4 4 4]
                                                    [Th.vi 1 5 5]
                                                ]
                                                [Codetta 2 4]
                                            ]
```

Figure 3. An example of the tabular representation format, setting out a generic division of a sentence (level N) into presentation and continuation phases (level N+1) which, in turn, divide into two 'Basic Idea's in the first case, and 'Fragmentation' and 'Cadence' in the latter (all at level N+2).

Figure 4. An example of the tabular representation format, setting out form, theme, and phrase groupings in the exposition of Schubert 8/i (corresponding to Figure 1).

name is appropriate, and 'X' for any moment that begins a new span, but is not so easily labelled.

- That marking entry remains in effect until a change in the same column (e.g. replacing 'Exposition' with 'Development' or one 'Period' with another 'Period', for instance).
- The columns go from larger to smaller units and users may employ as many columns as needed to get from the large formal architecture (e.g. expositions of c.50 bars) down to few-bar groupings. We make no assumptions here. While a '4' grouping will often divide into 2+2, it might be better expressed as an undivided 4 (and occasionally as an asymmetric 3+1). Assuming that '4' indicates 2+2 would leave us without a description for the undivided 4.
- Again, the final levels of grouping will appear in different columns of the document, depending on the number of intervening levels.
- The 'beat' column is available for registering exactly where a new theme starts, accommodating anacruses for instance. When inputting directly to tabular, the user may wish to indicate beats with negative numbers to indicate both the basic measure range and the exact beat position at a glance. If in doubt, we advise using the downbeat ('beat 1'), especially if the accompaniment part begins there (the accompaniment is a part of the span too, after all). The code for converting to bracket representation involves a simplification that eliminates beat information.

The representation standard (in both the on-score and tabular entry systems) also accepts 'equal division', which may be useful for sections which need two labels for exactly the same span. For instance, a section might be listed as 'A' but also consist entirely of a 'Compound Period'. Similarly, the 'First theme' may very well be a 'Sentence'. Assign these designations consecutive level numbers (columns) even though they represent the same span.

Finally, while the standard accommodates any naming system, we recommend naming themes successively, and not restarting the count for the second subject group (continuing instead with 'Theme C', for instance) in order to enable succinct and unambiguous reference back to these themes later on.

2.4 Nested Bracket Notation

The linguistics standard for representing syntax trees is a system of nested brackets. Figure 4 sets out an example of this applied to musical form. In this format, the first entry in a bracket is the parent node, labelling the overall span, and each subsequent entry is a child node (an internal division). These child nodes may divide further with additional brackets recursively.

Our specification requires only:

- Matched brackets: each open '[' must be paired with a closing ']'.

There are no further, formal constraints.

Our converter outputs this as a simple string, which is all that's required to meet the syntax criteria for the various existing code libraries for visualising nested bracket notation with trees. However, once again, some users may wish to begin directly at this level, in which case we would advise one additional constraint for readability:

- Add a new level of indentation to the bracket file to indicate the structural level in question.

Figure 4 reflects this more visually graspable version.

3. CORPUS

We complement this new standard and code base with a corpus of examples. The preparation of that corpus warrants comment as a potential model for other projects of this kind.

The analyses began in the classroom, with students each assigned their own movement(s) to work on. The instructors then marked those student analyses, providing a 'corrected' version based on the student work as well as written feedback, drawing their attention to important moments and considerations. This process thus created a corpus of student-initiated, instructor-corrected analyses which went

through a final round of finessing and proof-reading to ensure grammatical accuracy and also consistency before release.

Future projects could extend this to a final round explicitly consolidating one scholar's analyses for additional internal consistency and quality control. In any case, the process benefits from involving a large number of people in suitable capacities and in a time-effective manner. Students get high-quality feedback from highly invested researcher-teachers, as well as direct integration into research projects. Researcher-teachers, in turn, benefit from knowing that their marking time is more than doubly valuable: they are providing great feedback and building a corpus at the same time.

The corpus combines tabular and nested-bracket representations to illustrate the range outlined above. The tabular representations consist of:

- Beethoven's 'first period' piano sonatas (nos1–15): 15 sonatas, 54 movements. [8]
- The first movements of all the Mozart piano sonatas (15 sonata movements).

The nested-bracket format demonstrates that format alternative, as well as other formal representations of the music. Specifically, while the tabular representations represent measures by number, these bracket representations register the number of measures within the spans in question directly (the conversion code accommodates both).

We are keen to stress that the standard supports any analyses and terminologies consistent with the minimal formal constraints itemised above. As discussed, we have elected in this corpus to name the themes alphabetically here to minimise confusion with the numbered levels, but again, this format supports any naming system the user cares to apply or devise. We provide a more miscellaneous set of repertoire and formal ideas in the corpus' 'Miscellany' folder to this effect. For instance, the analysis of the first movement from Bach's Brandenburg Concerto No.6 uses this template to set out the form in terms of changes to the canon distances.

Yet more importantly, we emphatically do not intend the analyses themselves to be in any way definitive, but rather a proof of concept, and a first offering. We welcome multiple analyses of the same work to focus our disciplinary discussion of what gives rise to formal labels and to the shifting balance of priorities. That said, creating more analyses of different works is probably a keener priority at the outset of this field. [9]

4. APPLICATIONS

The existence of tree structure representations based on formal analyse enables a number of applications in the visualisation of musical form and the comparison of form between scores. Both the visualization and the automated comparison help to focus questions of divergence between two analyses.

In this project, we have primarily focused on off-score visualizations to enable at-a-glance overviews and the development of global intuitions for structure. Equally, these formal observations could be returned to scores for different kinds of visual clarification. For instance, they enable the automated marking-up of phrase-ending barlines more strongly in scores, which is a popular annotation type among conductors. Moreover, we can toggle these annotations on and off at will: this is an important, and fundamentally digital-age flexibility.

Turning to automated comparisons, a distance metric between trees can be defined, which in turn enables clustering of scores with similar form. That process is discussed in the following section.

4.1 Tree edit distance and clustering

Zhang and Shasha [20] provide an algorithm for calculating the edit distance between two trees, t_1 and t_2. This metric is based on the minimum number of *insert*, *delete* and *update* operations (each of which have an associated cost for a given node) required to transform t_1 into t_2. We adopt their approach but allow the user to specify a function to describe the cost of each operation for a particular node, to enable the distance metric to be tuned for a particular corpus. In the examples that follow, the cost of inserting, deleting or updating a node is weighted more highly for nodes closer to the root of the tree. The cost function should also use the semantics of each node: the default comparator function in the code provided weights operations on a placeholder node '[X]' lower than the equivalent operation on any other node. Thus inserting a placeholder node '[X]' at level 6 in the tree is less costly than inserting a 'Coda' at level 1 in the tree, for example.

The concept of tree edit distance has been applied to a range of problems such as automated melody recognition, plagiarism detection in software, and finding similarities between sequences of RNA and DNA. We have explored two applications of tree edit distance, involving comparisons between two analyses, and between N analyses. We set these out in turn.

Between two analyses. A summary of the differences in tree structure up to some depth (l_{max}) can be collapsed into strings in a simple language. We base our notation on a language proposed by Cunningham for summarising control structures in programming languages. [10] Figure 5 illustrates how this simplified version of nested-bracket notation (without labels) can be used to visualise differences in form up to a given depth (l_{max}) in the tree.

In our simplified language: '||' denotes the divisions between nodes at level 1 in the tree; '.' represents a structure at level 5, or l_{max} if $l_{\text{max}} < 5$; '{' and '}' denote the start and end (respectively) of the span of a node at level 2 (if level $2 < l_{\text{max}}$); '[' and ']' denote the start and end (respectively) of the span of a node at level 3 (if

[8] Of these 15 sonatas, 9 are in 4 movements, 6 are in 3.

[9] [3]'s BPS-FH dataset of first movements from Beethoven Piano Sonatas. BPS-FH focusses on harmony but also includes some formal designations, and thus a balance between the potential benefits of cross-referencing and of extending the collective corpus.

[10] http://c2.com/doc/SignatureSurvey/

ANALYSIS 1 {..}{..}{..}{..}‖ {..}{....}{..}
ANALYSIS 2 {..}{.. .}{..}‖'{..}{....}{..}

Figure 5. Two analyses encoded as strings in a simple language. This enables edit distance-based comparison of their musical form up to level 3 in the abstract syntax tree.

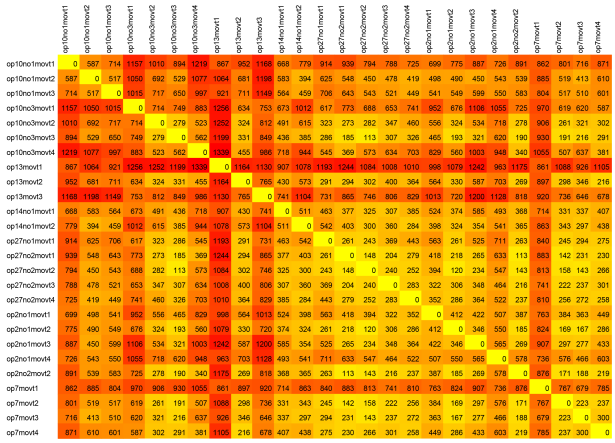

Figure 6. Heat map of tree edit distance between a selection of works in the corpus provided. The colour scale ranges from yellow (most similar/lowest tree edit distance) to red (most different/highest tree edit distance).

level $3 < l_{\max}$); '(' and ')' denote the start and end (respectively) of the span of a node at level 4 (if level $4 < l_{\max}$); ' denotes an anacrusis or longer introductory passage.

The process of calculating the tree edit distance allows correct alignment of the two strings. Our current analysis code highlights in green those nodes that are present in one analysis but not the other, and in red those nodes for which differences exist at a level greater than $l_{\max}$.

Between N analyses. Expanding this principle further, tree edit distance can be used to compare the form of all N scores in a corpus. Pairwise similarities in form can thus be identified. Figure 6 shows the tree edit distance between a selection of works in the corpus provided, visualised as a heat map.

5. SUMMARY AND OUTLOOK

This paper reports on a new specification standard for representing musical form, a corpus of example movements, and a set of code for converting between a range of representation and visualisation formats, handling score annotation to tabular or nested bracket representation, and tabular to nested bracket representation.

Among the possible improvements to this model, we envisage developments to both the user-interface and the representation structure. We consider the current opportunity to work on free and open source notation software to be a radical improvement to the student experience, enabling them to work directly on 'the music', listening back to it at will, and recording their observations in a digital format. That said, we are still limited to the availability of encoded scores and this is one musical area in which working with PDFs would be helpful, and could be practical.

As projects such as PeachNote exemplify, while OMR cannot yet reliably generate performance-ready scores, it is generally robust enough to support use cases like score-to-audio matching. Thus, as long as we still have many more PDFs than encoded scores available, it would be worth considering an alternative user-interface which offers a drag-and-drop system, for placing annotation labels onto the score. Here, we only need OMR robust enough to extract measure lines accurately and pair them with the annotation. Using pre-made (rather than free-text) labels would also solve the issue of ambiguous user-entries, though it would also limit the range of possible answers.

Turning to the representation standard, one priority for improvement is the inclusion of ambiguity. At present, we cannot admit multiple variant readings in a single file (though nothing stops analysts from producing multiple variant files). Formal judgments can arise through identification of melodic and / or harmonic closure, textural and / or dynamic changes, and much more besides. When forced into a single reading, we have to make difficult decisions between these competing priorities.

Furthermore, this ambiguity motivates a second direction for computational research based on this kind of corpus: while we can clearly pursue questions exploring proportions and the like, taking the analyses at face value, we can also explore which score elements correlate most strongly with formal designations, where analyses (dis)agree, and what gives rise to these shifts in priority.

This paper began with an overview of some recently implemented representation and visualization formats for other musical parameters; a key frontier in this field will be the combination of those standards. Given the lack of a consensus over a primary successor to XML for score encodings (MNX, MEI, ...), this much more sparsely populated field of analytical representations may be doubly slow in determining its future direction. That said, representations of harmony and form by reference to their measure and beat positions are easy to combine, perhaps representing harmonies as leaf nodes (assuming they change at least as frequently as formal sections).

Finally, we also motivated this research with its potential breadth of appeal to musicians outside the scholarly, computational community. This should be a key consideration for determining future research priorities. Integrating diverse groups in the production of corpora (also featured in this text and project) may be one way to road test new ideas for ease and popularity of use at the outset. We invite other researchers building corpora to experiment with variants on this process and whatever the exact standards they use, to focus on building up a large and versatile meta-corpus for the benefit of all.

6. ACKNOWLEDGEMENTS

This research was supported by a grant from Cornell University's Active Learning Initiative (ALI). We wish to thank the ALI, and all Cornell students who took part.

ABSTRACT

Learning features from data has shown to be more successful than using hand-crafted features for many machine learning tasks. In music information retrieval (MIR), features learned from windowed spectrograms are highly variant to transformations like transposition or time-shift. Such variances are undesirable when they are irrelevant for the respective MIR task. We propose an architecture called Complex Autoencoder (CAE) which learns features invariant to orthogonal transformations. Mapping signals onto complex basis functions learned by the CAE results in a transformation-invariant "magnitude space" and a transformation-variant "phase space". The phase space is useful to infer transformations between data pairs. When exploiting the invariance-property of the magnitude space, we achieve state-of-the-art results in audio-to-score alignment and repeated section discovery for audio. A PyTorch implementation of the CAE, including the repeated section discovery method, is available online. [1]

1. INTRODUCTION

Learning from audio data most commonly involves some prior processing of the raw sound signals. The most popular features are derived from a spectrogram, which consists of the magnitude values of the Fourier transform of a windowed signal of interest. In a Fourier transform, a signal is projected onto sine and cosine functions of different frequencies. One of the main reasons for the spectrogram to be more useful than the usage of the Fourier coefficients in their complex form is the fact that the magnitude spectrum of a signal is invariant to a translation of the original signal.

This invariance to translation, desirable for most learning problems in audio, results from the fact that cosine and sine represent the real and imaginary parts, respectively, of the *complex eigenvectors* of translation. More generally, the eigenvectors of an orthogonal transformation (e.g., translation, rotation, reflection, but most general all permutations - "shuffling pixels") constitute an orthonormal basis of complex vectors with corresponding eigenvalues of magnitude 1. Hence, as we shall see in detail, the absolute value of a signal's coefficients with respect to this basis is invariant to that transformation. We harness this invariance property for learning representations invariant to different orthogonal transformations.

In particular, transposition-invariance is an essential property for several MIR tasks, including alignment tasks, repeated section discovery, classification tasks, cover song detection, query by humming, or representations of acapella recordings with pitch drift. Different methods have aimed at learning transposition-invariant representations. For example, in [33] close time steps in chromagrams are cross-correlated in order to calculate distances between pitch classes, and in [20], successive n-grams of constant-Q transformed (CQT) representations of audio are compared using a Gated Autoencoder (GAE) architecture. Most similar to our approach, the transposition-invariant magnitudes of Fourier transformations applied to chromagram-like representations of audio are facilitated in [3] and [23]. However, instead of using 2D Fourier transforms with fixed basis functions, we learn the relevant basis functions starting from CQT representations of audio. This learning of basis functions has some advantages over using pre-defined bases. For example, the number of basis elements necessary to discriminate between signals can be reduced compared to a common Fourier transform (e.g., for transposition- and time-shift invariance we use $M = 256$ basis functions for input dimensionality $N = 3840$, while usually $N = M$). Furthermore, our approach is generic and has the potential to learn other musically interesting invariances (e.g., towards tempo-change, diatonic transposition, inversion, or retrograde).

The contribution of this paper is a simple training method for learning invariant representations from data pairs and its application to two MIR tasks. First, we show that when using the features learned by the Complex Autoencoder (CAE) from audio in CQT representation, we can improve the state-of-the-art in a transposition-invariant repeated section discovery task in audio. Second, the CAE

[1] https://github.com/SonyCSLParis/cae-invar

features prove useful in an audio-to-score alignment task, where we show that most of the time, they yield better results than Chroma features and features calculated with a GAE. We also compare the CAE with a GAE in classifying rotated MNIST digits, based on rotation-invariant features learned by the CAE. The reason we also perform experiments on MNIST is that it allows us to show the efficacy of the model with respect to rotation-invariance. Furthermore, the class labels available in the MNIST dataset help to highlight the different clusters in the rotation-invariant space (see Figure 4).

In particular for translations, the model can be interpreted as measuring distances in the data. Training the CAE for transposition and time-shift invariance on short windows of audio in CQT representation, therefore, leads to representations of rhythmic structures and tonal relationships present in the windows, what we exploit in the repeated section discovery task. Representing rhythmic structures is less critical in music alignment tasks; it can even be disadvantageous when the aligned signals differ in tempo. We show in the alignment task that it is sufficient to train the CAE only for transposition-invariance (i.e., time-shift transformation) on rather short n-grams of audio in CQT representation. This is because compared to repeated section discovery, where rhythmic patterns can help to identify similar parts, in the alignment task, a dynamic time-warping algorithm keeps track of the respective positions in the music pieces.

The CAE can be trained in an unsupervised manner on data pairs obeying the relevant transformations. Thereby, we obtain a "magnitude space" and a "phase space", as it is known from a Fourier transform. The "magnitude space" of the CAE is invariant to all the learned transformations. Remarkably, the *phase shifts* a projected signal undergoes during a transformation (i.e., the relative vector in the "phase space" of the CAE) are discriminative with respect to the type and the distance of a transformation. This is an interesting property which could be exploited for determining types of relations between musical fragments in structure analysis tasks.

The paper is structured as follows. In Section 2 existing work related to the proposed method is discussed. In Section 3 we describe the model and its mathematical background and Section 4 describes the general training procedure. In Section 5, we show results on three different tasks: discovery of repeated themes and sections, audio-to-score alignment, and classification of MNIST digits. We end the paper with a conclusion and a discussion of possible directions for future work (Section 6).

2. RELATED WORK

Generally, mid-level representations in neural networks are highly variant to transformations in the input. The most common and well-known way to obtain shift-invariance in convolutional architectures is max-pooling [4]. However, full shift-invariance can only be achieved step-wise by applying max-pooling over several layers. A whole line of research therefore aims to obtain representations invariant to different kinds of transformations using other approaches. Inspiration for the proposed model was drawn from [25], where complex basis functions are learned using a GAE. An approach similar to ours is to facilitate harmonic functions or wavelets, either in weight initialization [29, 37], for modulating learned filters using Gabor functions [22], or for using fixed wavelets in scattering transforms [5, 32]. Similarly, harmonic functions can be pre-defined, e.g., to obtain rotation invariance in convolutional architectures [36], or learned, e.g., by assuming "temporal slowness" of features in videos [21, 28], while pitch-invariant timbral features are learned in [30] by enabling convolution through the frequency domain.

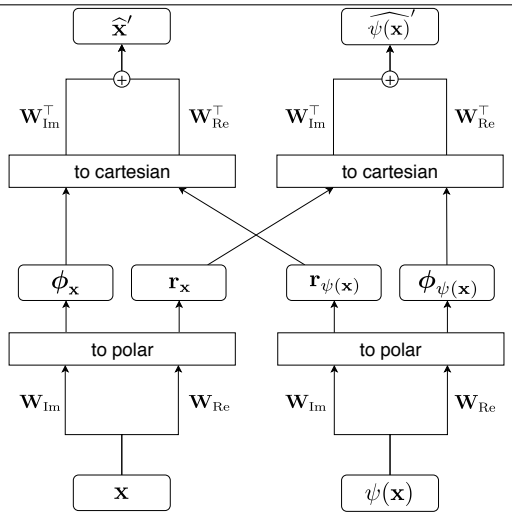

Figure 1: Schematic illustration of reconstruction during training. Both the input $\mathbf{x}$ and its transformed counterpart $\psi(\mathbf{x})$ are projected onto complex basis pairs $\{\mathbf{W}_{\mathrm{Re}}, \mathbf{W}_{\mathrm{Im}}\}$ and expressed in polar form. Then, using the swapped magnitude vectors $\{\mathbf{r}_{\psi(\mathbf{x})}, \mathbf{r}_{\mathbf{x}}\}$ and the original phase vectors $\{\boldsymbol{\phi}_{\mathbf{x}}, \boldsymbol{\phi}_{\psi(\mathbf{x})}\}$, the data is reconstructed by performing the inverse operations.

Most of the approaches mentioned so far (including our approach) aim at invariances to relatively simple, affine transformations. Invariances to more complex, non-linear transformations are usually achieved by redundancy (e.g., an object is presented from different camera angles or under different lighting conditions), which typically requires bigger architectures. That way, invariance can be learned by an explicit transformation of the input [16], by enforcing similarity in the latent space [24], or by using a Siamese architecture and pre-defined transformation sets [18]. Other methods involve rotating convolution kernels during training [38] and dealing with input deformations using learned, dynamic convolution grids [8]. In [9] an end-to-end CNN which acts on raw audio learns Gabor-like filters similar to those extracted by the CAE, see Figure 2.

3. MODEL AND MATHEMATICAL BACKGROUND

We aim at learning orthogonal transformations encoding certain invariances of a class of signals which are known or

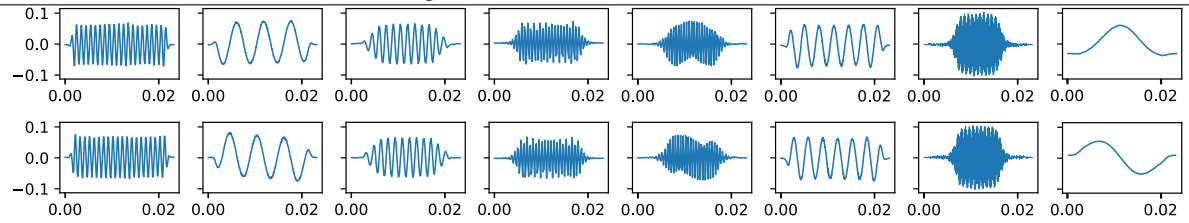

Figure 2: Some examples of real (top) and imaginary (bottom) basis vectors learned from audio signals (time in seconds).

assumed to be useful for a particular learning task at hand. To this end, we leverage the particular properties of orthogonal transformations, which we now describe. A transformation $\psi : \mathbb{R}^N \to \mathbb{R}^N$ is orthogonal if $\langle \psi(\mathbf{x}), \psi(\mathbf{y}) \rangle = \langle \mathbf{x}, \mathbf{y} \rangle$ for all $\mathbf{x}, \mathbf{y} \in \mathbb{R}^N$. By $\langle \mathbf{x}, \mathbf{y} \rangle$ we denote the inner product on $\mathbb{R}^N$ or $\mathbb{C}^N$, respectively. Orthogonal transformations are distinguished by the fact that they possess a diagonalization with eigenvalues which all have absolute value 1. Hence, in any non-trivial case, the eigenvalues are complex and so are the corresponding eigenvectors. More precisely, if ψ is orthogonal, there exists a unitary matrix [2] $\mathbf{W}$ and eigenvalues λ_j, $j = 1, \ldots, N$, with $|\lambda_j| = 1$ for all j, such that

$$\psi(\mathbf{x}) = \mathbf{W}^* \mathbf{D} \mathbf{W} \mathbf{x} \tag{1}$$

Here $\mathbf{D}$ denotes the diagonal $N \times N$ matrix with the eigenvalues λ_j in the diagonal. We hence have the following statement.

Proposition 1. *If an orthogonal transformation $\psi : \mathbb{R}^N \to \mathbb{R}^N$ is diagonalised by a unitary matrix $\mathbf{W}$, then the feature vector given by $|\mathbf{W}\mathbf{x}|$ for all $\mathbf{x} \in \mathbb{R}^N$ is invariant to ψ. In other words, we have $|\mathbf{W}\mathbf{x}| = |\mathbf{W}\psi(\mathbf{x})|$ for all $\mathbf{x} \in \mathbb{R}^N$.*

Proof. According to (1) and since $\mathbf{W}\mathbf{W}^*\mathbf{x} = \mathbf{x}$, we have

$$\mathbf{W}\psi(\mathbf{x}) = \mathbf{D}\mathbf{W}\mathbf{x}, \tag{2}$$

which can be written coordinate-wise as

$$\langle w_j, \psi(\mathbf{x}) \rangle = \lambda_j \langle w_j, \mathbf{x} \rangle, \; j = 1, \ldots, N,$$

where w_j denotes the $j-$th row of the complex, unitary matrix $\mathbf{W}$. Hence, since $|\lambda_j| = 1$ for all j, we have $|\langle w_j, \psi(\mathbf{x}) \rangle| = |\langle w_j, \mathbf{x} \rangle|$ for all $\mathbf{x} \in \mathbb{R}^N$ and thus $|\mathbf{W}\mathbf{x}| = |\mathbf{W}\psi(\mathbf{x})|$ as claimed. □

In CAE-learning, we can only deal with real weights and are usually interested in learning less than N basis vectors. Hence, we split an $M \times N$-dimensional submatrix of the unitary, complex matrix of eigenvectors $\mathbf{W}$ into a real and an imaginary part $\mathbf{W}_{\text{Re}} \in \mathbb{R}^{M \times N}$ and $\mathbf{W}_{\text{Im}} \in \mathbb{R}^{M \times N}$ which map $\mathbf{x}$ onto the real and imaginary part of $\mathbf{W}\mathbf{x}$, respectively. The complex data $\mathbf{W}_{\text{Re}}\mathbf{x} + i\mathbf{W}_{\text{Im}}\mathbf{x}$ is then expressed in its polar form by a phase vector $\boldsymbol{\phi}_{\mathbf{x}} \in [0, 2\pi)^M$ and a magnitude vector $\mathbf{r}_{\mathbf{x}} \in \mathbb{R}^M_{\geq 0}$.

According to Proposition 1, assuming that $\mathbf{W}_{\text{Re}} + i\mathbf{W}_{\text{Im}}$ consist of orthonormal eigenvectors of ψ leads to the magnitude of projections of a signal $\mathbf{x}$ and a transformed version $\psi(\mathbf{x})$ onto these eigenvectors to be equal. This property is imposed during training by expressing $\mathbf{W}\mathbf{x}$ and $\mathbf{W}\psi(\mathbf{x})$ in their respective polar forms

$$\boldsymbol{\phi}_{\mathbf{x}} = \text{atan2}(\mathbf{W}_{\text{Re}}\mathbf{x}, \mathbf{W}_{\text{Im}}\mathbf{x}), \tag{3}$$

and

$$\mathbf{r}_{\mathbf{x}} = \sqrt{(\mathbf{W}_{\text{Re}}\mathbf{x})^2 + (\mathbf{W}_{\text{Im}}\mathbf{x})^2}, \tag{4}$$

and swapping the magnitude vectors before reconstruction.

Accordingly, we reconstruct $\mathbf{x}$ given its own phase representation $\boldsymbol{\phi}_{\mathbf{x}}$ and the magnitude representation of the transformed signal $\mathbf{r}_{\psi(\mathbf{x})}$ as follows (see Figure 1):

$$\widehat{\mathbf{x}}' = \mathbf{W}_{\text{Re}}^\top(\mathbf{r}_{\psi(\mathbf{x})} \cdot \sin \boldsymbol{\phi}_{\mathbf{x}}) + \mathbf{W}_{\text{Im}}^\top(\mathbf{r}_{\psi(\mathbf{x})} \cdot \cos \boldsymbol{\phi}_{\mathbf{x}}). \tag{5}$$

Likewise, we reconstruct the transformed signal $\psi(\mathbf{x})$ as

$$\widehat{\psi(\mathbf{x})}' = \mathbf{W}_{\text{Re}}^\top(\mathbf{r}_{\mathbf{x}} \cdot \sin \boldsymbol{\phi}_{\psi(\mathbf{x})}) + \mathbf{W}_{\text{Im}}^\top(\mathbf{r}_{\mathbf{x}} \cdot \cos \boldsymbol{\phi}_{\psi(\mathbf{x})}). \tag{6}$$

The CAE is then trained by minimizing the symmetric reconstruction error

$$\frac{1}{N}\sum_i^N (x_i - \widehat{x}'_i)^p + \frac{1}{N}\sum_j^N (\psi(x_j) - \widehat{\psi(x_j)}')^p, \tag{7}$$

where $p \in \{1, 2\}$ has shown to work well in practice. Training on sufficiently many transform pairs thus leads to learning the weights of the unitary matrix $\mathbf{W}$, which diagonalises ψ. While the magnitudes of the coefficient vectors $\mathbf{W}\psi(\mathbf{x})$ are equal to $\mathbf{W}\mathbf{x}$, the transformation itself is then represented by the differences in the phase vectors $\Delta\boldsymbol{\phi} = \boldsymbol{\phi}_{\mathbf{x}} - \boldsymbol{\phi}_{\psi(\mathbf{x})}$ (see Figure 4(b)). As an example of complex basis vectors learned by the CAE, see Figure 2, where the CAE was trained on time-shifted audio signals in the time domain, yielding complex Gabor-like filters.

4. TRAINING

For all the experiments described below, we choose 256 complex basis vectors and train the model for 500 epochs with a learning rate of 1e-3. We use a batch size of 1000, and we sample 100k transformations per epoch, generally picking random instances from the train set to be transformed. The training data is standardized, and 50% dropout is used on the input. We set $p = 1$ (see Equation 7) for the audio experiments, and $p = 2$ for the MNIST experiment. In the alignment experiment, we also penalize the mean of norms of all basis vectors and the deviation of the individual basis vectors' norms to the average norm over all basis vectors. In the MNIST experiment, the norm of all basis vectors is set to 0.4 after every batch. For information about the training data see the respective experiment section below.

[2] A complex matrix $\mathbf{W}$ is unitary, if $\mathbf{W}^* = \mathbf{W}^{-1}$.

Table 1: Different precision, recall and f-scores (adopted from [34], details on the metrics are given in [6]) of different methods in the Discovery of Repeated Themes and Sections MIREX task, for symbolic music and audio. The $\mathbf{F_3}$ score constitutes a summarization of all metrics.

5. EXPERIMENTS

5.1 Discovery of Repeated Themes and Sections

In the MIREX task "Discovery of Repeated Themes and Sections", [3] the performance of different algorithms to identify repeated (and possibly transposed) patterns in symbolic music and audio is tested. The commonly used JKUPDD dataset [6] contains 26 motifs, themes, and repeated sections annotated in 5 pieces by J. S. Bach, L. v. Beethoven, F. Chopin, O. Gibbons, and W. A. Mozart. We use the audio versions of the dataset and preprocess them the same way as the training data described below.

The CAE is trained on 100 random piano pieces of the MAPS dataset [12] (subset MUS) at a sampling rate of 22.05 kHz. We choose a constant-Q transformed spectrogram representation with a hop size of 1984. The range comprises 120 frequency bins (24 per octave), starting from a minimal frequency of 65.4 Hz. The spectrogram is split into n-grams of 32 frames. The set of transformations applied to the data during training $\Psi_{\text{pshift, tshift}}$ contains transposition by $[-24, 24]$ frequency bins and time shifts by $[-12, 12]$.

After training, all n-grams of the JKUPDD dataset are projected into the transformation-invariant magnitude space. Using these representations, a self-similarity matrix is built for each piece using the reciprocal of the cosine distance. The matrices are then filtered with an identity matrix of size 10×10. Then, their main diagonals are set to zero. Finally, the matrices are first normalized and then centered by subtracting their medians.

For finding repeated sections, the method proposed in [20] is adopted, which finds diagonals in a self-similarity matrix using a threshold. As we normalized the matrices to zero median, the threshold chosen in this experiment is close to zero (i.e., 0.01).

5.1.1 Results and Discussion

Table 1 shows the results of the experiment. Using our method, we could slightly outperform the Gated Autoencoder approach proposed in [20]. By visual inspection of the self-similarity matrix, we noted very precise diagonals at repetitions, while almost no similarity is indicated on other parts (this is different from the self-similarity plots provided in [20]). This selectivity, which may also result from the cosine distance, probably contributes to the slightly higher precision of the proposed method.

5.2 Invariant Audio-to-Score Alignment

The task of synchronising an audio recording of a music performance and its score has already been studied extensively (see e.g. [10, 11, 14, 15, 17, 26]). Here, we compare synchronisation results using the proposed method (CAE) to traditional Chroma features and the GAE features introduced in [20], which were used for music alignment in [2].

For the alignment experiments we follow [2], using the same setup and the same data (see Table 2 for a summary). *CB* and *CE* consist of 22 recordings of excerpts of the Ballade Op. 38 No. 1 and the Etude Op. 10 No. 3 by Chopin [13], *MS* contains performances of the first movements of the piano sonatas KV279-284, KV330-333, KV457, KV475 and KV533 by Mozart [35], and *RP* consists of three performances of the Prelude Op. 23 No. 5 by Rachmaninoff [1]. Finally, *B3* and *M4* are annotated recordings of Beethoven's 3^{rd} and Mahler's 4^{th} symphonies. Note that CB, CE, MS, and RP consist of piano music, while B3 and M4 consist of orchestral music, but we will use the same model for the whole data set, which was trained on piano music only.

The scores are provided in the MIDI format, with the global tempi set such that the scores roughly match the average length of the given performances, i.e., both representations have the same average tempo, but there still exist substantial differences in local tempi. The scores are then synthesized with the help of *timidity* [4] and a publicly available sound font. The resulting audio files are used as score representations for the alignment experiments. To compute the alignments, a multi-scale variant of the dynamic time warping (DTW) algorithm (see [26] for a detailed description of DTW) is used, namely FastDTW [31] with the radius parameter set to 50.

The CAE is trained the same way and on the same data as described in Section 5.1 but here we choose a CQT hop size of 448. Furthermore, for this experiment, we use an

The rightmost column shows the average result of alignments of the original performances to scores in 12 different transpositions.

n-gram size of 8. The set of transformations applied to the data during training Ψ_{pshift} are transpositions by $[-24, 24]$ frequency bins.

5.2.1 Results and Discussion

In the alignment experiments, we compare the proposed CAE features to the results presented in [2], where Chroma features and features computed via a gated autoencoder (GAE) were compared to each other. Table 3 gives an overview of the results. The first three columns show that the proposed CAE features consistently outperform the other two methods in the normal alignment setting (i.e., without any transpositions). Additionally, the rightmost column shows that for CAE, the results essentially stay the same, even when the alignment is computed with transposed versions of the score. This demonstrates the invariance to transpositions, which is a serious advantage over the Chroma features.

As has been shown in [2], the GAE features are highly sensitive to tempo differences between the score representation and the performance. To see if the proposed CAE features suffer from the same problem, we repeated this experiment and performed alignments on artificially slowed-down and sped-up score representations. The results are shown in Table 4. For all tested features, the degree to which the tempi of the score representation and the performance match influences the alignment quality. The experiments suggest that CAE is less sensitive to differences in tempi than GAE, but the Chroma features still have the advantage over GAE in this matter. We also conducted experiments with more extreme tempi, which further confirmed this trend. The reason for the higher robustness to tempo differences of the CAE features over the GAE features may be found in the way the GAE features are computed. In a GAE, two inputs $\{\mathbf{x}_{t-n,\dots,t}, \mathbf{x}_{t+1}\}$ are compared to one another, and the features are sensitive to the position and order of events in $\mathbf{x}_{t-n,\dots,t}$. When training a CAE only for transposition-invariance, the resulting features represent mainly distances in the frequency-dimension of the input and tend to be invariant to the position of events in time.

5.3 Classification of MNIST digits

We test the ability of the CAE to learn rotation-invariance in 2D images using randomly rotated MNIST digits (the dataset was first described in [19]). Given the set of rotations Ψ_{rot} with rotation angles $[0, 2\pi)$ about the origin of the images. For any MNIST instance $\mathbf{x}_k$, we create a rotated version $\psi_i(\mathbf{x}_k)$ and a further rotated version $\psi_j(\psi_i(\mathbf{x}_k))$, where $\psi_i, \psi_j \in \Psi_{\text{rot}}$, resulting in pairs $\{\psi_i(\mathbf{x}_k), \psi_j(\psi_i(\mathbf{x}_k))\}$. After the CAE is trained on 50k such pairs, single randomly rotated instances are projected into the magnitude space. On these projections, a logistic regression classifier is trained to predict the class labels. We test different train set sizes (sampled from the main train set with balanced class distribution). 50-fold cross-validation is used, where evaluation is always performed on 10k test instances, independent of the train set size. For comparison, we perform k-nn classification on the randomly rotated images (i.e., the input space), and unrotated images directly. We choose logistic regression for the magnitude space and k-nn classification for the input space because they showed the overall best results for those representations. This choice, as well as the overall experiment setup, reflects that in [25].

5.3.1 Results and Discussion

Figure 3 shows the results of the rotated MNIST classification task. The error rates of *magnitudes GAE* were obtained by a GAE architecture which was extended to learn basis functions, as reported in [25]. Classification on the magnitude space of the CAE (*magnitudes CAE*) leads to substantially better results than those of the GAE, even though only 256 basis elements are used in the CA, compared to 1000 in the GAE. This is probably due to the explicit training of the CA to learn an invariant magnitude space, while the magnitude space of the GAE is learned indirectly during the learning of transformations. Overall, classification on the rotation-invariant magnitude spaces performs much better than on the input space of rotated images in particular for small train set sizes. The difference in performance between *images (original)* and *magnitudes CA* reflects the gap between a theoretically optimal rotation-invariant representation (as *images (original)* are

DS	Metric	Chroma			GAE			CAE		
		$\frac{2}{3}$ T.	Base T.	$\frac{4}{3}$ T.	$\frac{2}{3}$ T.	Base T.	$\frac{4}{3}$ T.	$\frac{2}{3}$ T.	Base T.	$\frac{4}{3}$ T.
CB	Error $\leq$ 50 ms	54%	64%	67%	47%	83%	33%	**80%**	**84%**	**85%**
	Error $\leq$ 250 ms	82%	85%	85%	87%	**94%**	84%	**91%**	**94%**	**94%**
CE	Error $\leq$ 50 ms	69%	71%	73%	40%	87%	38%	**85%**	**90%**	**88%**
	Error $\leq$ 250 ms	90%	94%	94%	**93%**	**96%**	80%	**93%**	**96%**	**95%**
MS	Error $\leq$ 50 ms	79%	85%	75%	84%	90%	74%	**86%**	**91%**	**76%**

	Error $\leq$ 250 ms	**83%**	88%	**82%**	–	90%	–	82%	**91%**	**82%**
M4	Error $\leq$ 50 ms	**26%**	27%	**24%**	–	25%	–	24%	**29%**	22%
	Error $\leq$ 250 ms	**75%**	73%	**71%**	–	66%	–	72%	**75%**	65%

Table 4: Results on score representations with different tempi (higher is better). *Base T.* refers to a globally set tempo that ensures that the duration of the score representation is roughly equal to the duration of a typical performance. $\frac{2}{3}$ *T.* and $\frac{4}{3}$ *T.* refer to score representation with the tempo set to $\frac{2}{3}$ and $\frac{4}{3}$ of the base tempo. The two metrics used are the percentage of events that are aligned with an error lower or equal 50 ms and 250 ms (i.e. higher is better). The missing numbers for GAE were not provided in [2].

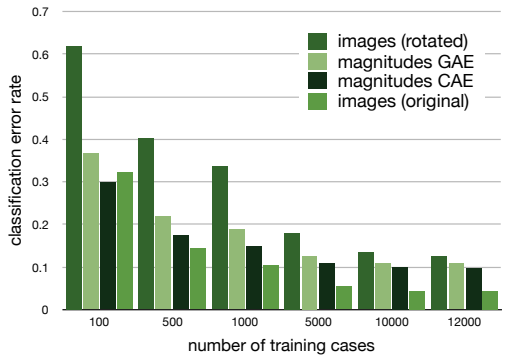

Figure 3: Classification error rates in the input space (images) and the magnitude space (magnitudes) on the rotated MNIST dataset with different train set sizes. "Images (original)" denotes the results of the unrotated MNIST dataset for comparison.

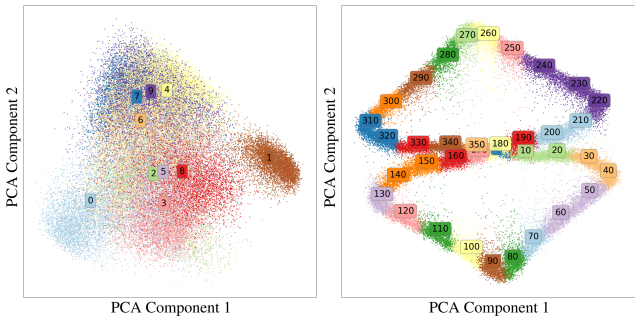

(a) (b)

Figure 4: PCAs of rotated MNIST digits in the magnitude space (a) and the phase-difference space (b) (best viewed in color). The magnitude space represents the data in the absence of the transformations leading to clusters of the digit classes (colored and labeled accordingly). The phase-difference space represents the transformations between images, independent of their identity (colors and labels denote rotation angles quantized into 36 bins).

not rotated), and the representations learned by the CA. On 100 training cases, logistic regression would outperform the k-nn classification on the input spaces, while for all other train set sizes k-nn is superior over logistic regression. Thus, we obtain slightly worse classification performance of *images (original)* on 100 training cases compared to *magnitudes CA*.

Figure 4 shows PCAs of the randomly rotated MNIST digits projected into the magnitude space and the phase-difference space of the CAE. The clusters in the magnitude space indicate that images with the same content (i.e., class label) yield similar projections, independent of their rotations. The clusters in the phase-difference space show that phase differences clearly represent the transformations in the data.

6. CONCLUSION AND FUTURE WORK

The empirical results in this work show that for music alignment, structure analysis, and invariant classification tasks, the features learned by the CAE have advantages over other features, like Chroma features, and features learned by a GAE. As opposed to Chroma features, the CAE features are transposition-invariant, and generally perform better in the alignment task. Compared to the features learned by a GAE, the CAE features are more robust to differences in tempo between alignment data.

Future work should involve investigating the use of the "phase-difference" space of the CAE. For example, qualifying transformations between sections in music could lead to a richer musical structure analysis (e.g., determining mutually transposed parts, or finding sections with similar rhythm but different tonality).

The learned bases could also be used in scattering transforms (i.e., as convolutional filters). As opposed to conventional scattering transforms, where the bases are fixed in general, learned bases may help reducing model sizes or to cover different invariances. Using rotation-invariant filters in convolutional settings may lead to rotation-invariant architectures, similar to what is proposed in [36].

ABSTRACT

In the past years, deep learning has produced state-of-the-art performance in timbre and instrument classification. However, only a few models currently deal with the recognition of advanced *Instrument Playing Techniques* (IPT). None of them have a real-time approach of this problem. Furthermore, most studies rely on a single sound bank for training and testing. Their methodology provides no assurance as to the generalization of their results to other sounds. In this article, we extend state-of-the-art convolutional neural networks to the classification of IPTs. We build the first IPT corpus from independent sound banks, annotate it with the JAMS standard and make it freely available. Our models yield consistently high accuracies on a homogeneous subset of this corpus. However, only a proper taxonomy of IPTs and specifically defined input transforms offer proper resilience when addressing the "*minus-1db*" methodology, which assesses the ability of the models to generalize. In particular, we introduce a novel *Folded Constant Q-Transform* adjusted to the requirements of IPT classification. Finally we discuss the use of our classifier in real-time.

1. INTRODUCTION

Throughout modern history, western composers have diversified and refined *Instrument Playing Techniques* (IPTs) in order to foster innovation in the timbre space [14]. In folklore and oral traditions, IPTs sometimes stand out as a distinctive feature of the musical style [16, 22]. Therefore, their identification could contribute to the more general task of style recognition in the process of browsing in music databases. Moreover, interactive computer music systems (for instance in the field of improvisation or score-following) could hugely benefit from the development of real-time IPT classifiers [24].

In the last two decades, the MIR community has produced a lot of research in the field of timbre recognition, but there has been little effort in IPT classification, often considered as its *last frontier* [17].

One major cause of this gap in research is the lack of IPT sound banks. Lostanlen [17] has recently addressed the question of IPT recognition but limited his experiment to samples from isolated notes in a unique sound bank.

Here, our aim is to build a real-time classifier of IPT from solo recordings. Our system should be reactive to possibly rapid changes in the technique. Therefore, the preprocessing of the audio has to maintain temporal coherence and induce as little latency as possible. For instance, any segmentation of the audio (such as proposed by [21]) in order to subsume our task into a problem of classification of isolated notes would be irrelevant. Our study focuses on the cello but the methodological issues we raise are similar for other instruments and the process we use to build and train the classifier could be generalized as long as the IPTs of these instruments are included in a sufficient number of sound banks.

We show that trying to categorize cello IPTs in a unidimensional way produces weak results. The classifier performs well on homogeneous sets of data but generalizes poorly. Therefore we introduce a taxonomy of the playing techniques of the cello along 4 axes (named *exciter/vibrator*, *left-hand*, *waveform*, and *interaction position*). We aim to build a single network which classifies audio sequences in a multi-task [4] manner according to these axes. Then, we implement a rule-based system on top of this network, in order to simplify the model and yield a classification along the 18 main IPT categories.

In order to train our classifier, we produce a large corpus of labeled synthetic data with 5 IPT sound banks and their proprietary samplers. This corpus is annotated using the JAMS standard [11]. We make it available to the MIR community.

We adapt state-of-the-art models successfully used for instrument classification [11,16] to the multi-task and low latency requirements of IPT recognition. Front-end classifiers along the 4 IPT dimensions are built as fully-connected (FC) or recurrent layers on top of deep convolutional neural networks (CNNs). All tested system configurations achieve high accuracies on homogeneous subsets of our annotated corpus. This alone provides no indication of their ability to generalize to other databases or actual solo recordings. Therefore, we adapt the *minus-1db* methodology presented by Livshin [15] to the needs of our system. When subject to this methodology, we

show that RNN front-ends generalize better than FC. Our adapted *Folded Constant-Q Transform (FCQT)* also yields more stable performance than Log-Mel-Spectrograms. Finally, we assess the reactivity of our models for each of the 4 IPT dimensions.

2. RELATED WORK

2.1 Deep Learning and MIR

Following their success in the field of computer vision [10], deep learning techniques have been quickly adopted by the MIR community. Instead of using sets of hand-designed audio descriptors [1,7,15], these techniques rely on basic representations of the audio signal and let the algorithm learn suitable features for a given task. Convolutional (CNN), recurrent (RNN) neural networks and their combinations have been among the most popular architectures used in MIR. Convolutional layers seek local correlations within their input by training sets of convolutional kernels. CNNs are built by stacking such layers with *pooling* layers[1] at increasingly bigger scales. Therefore, they can detect large and complex patterns while being computationally efficient. RNNs have been developed in order to forecast or classify temporal sequences. As their hidden units have connections from one time step to the next, they can carry information through various temporal states. Long Short-Term Memory (LSTM) units, where gates enable to control this flow of information, have been proficiently used in MIR [6].

2.2 Instrumental Timbre Classification

Early research in instrument classification relied on samples of isolated notes played with ordinary techniques. In most studies, experiments were performed with a single sound bank. This practice overlooked variability related to the instrument model, player or recording environment. A detailed review of generalization issues by Livshin [15] shows that the performance of classifiers trained and tested with a single sound bank gives no hint on their accuracy when confronted to new sounds. He suggests to use several independent sound banks, pick one for testing while training the classifier on the rest joined together. Then, the experiment has to be repeated with all the possible test banks. This methodology named *minus-1db* provides more reliable indications on the ability of the classifier to generalize. In the case of instrument classification from solo recordings, it translates into a *leave-1-CD-out* policy.

To our knowledge, very few studies follow the methodological principles of Livshin, and, as such, can be regarded as being state-of-the-art in this matter.

Patil and al. [21] proposed a classifier built upon a support vector machine applied to spectro-temporal receptive fields. Trained on isolated notes of the RWC database to classify 6 instruments, this model reached 98.7% accuracy. Its resilience was assessed on a proprietary database of soli, which were first segmented using a harmonicity-based method. With the *leave-1-CD-out* methodology, accuracy still reached 88.1%.

Lostanlen and Cella [18] used two separate solo instrument databases to train and test a deep CNN to classify 8 instruments. Their network relied on the CQT of the audio signal. Through proper optimization of their convolution strategy, their system reaches average accuracies of 74%, against 61.4% for a decision tree forest applied to a large set of audio descriptors.

Regarding predominant instrument classification in polyphonic textures, Han and al. [11] achieved state-of-the-art F1-scores with a deep CNN applied to log-mel-spectrograms. This study was performed with two independent subsets of the IRMAS database for training and testing.

2.3 IPT Classification

IPT classification studies have been carried out on the clarinet [19], the snare drum [27], and the electric guitar [5]. The first two studies pose methodological issues since they perform training and evaluation with a single database. Chen and al. [5] focus on the detection in electric guitar solos of five techniques which all have an impact on the melodic contour. This feature is key to the design of their classifier. Therefore, their research can hardly be generalized to other IPTs.

Lostanlen and al. [17] tackle the issue of IPT recognition in a transversal manner. They work with samples from isolated notes belonging to 143 IPTs from 16 instruments. Their query-by-example system relies on a variant of the *k-nearest neighbors* algorithm where the metric used is subject to a training process. Applied to Mel-Frequency Cepstral Coefficients enriched by second-order scattering coefficients, it reaches *rank-5* accuracy of 61%. Yet, again, they train and test their system on a single sound bank.

3. IPT TAXONOMY

As we will show in Section 5., trying to classify IPTs without taking into account their multi-dimensional structure results in a poor ability to generalize. This motivates our newly introduced taxonomy.

3.1 Theoretical Background

A proper IPT taxonomy requires identifying what exciter, vibrator and resonator are selected (Schaeffer [26]), and what modification and excitation movements are undertaken (Cadoz [3]). Taking the example of the cello and following Feron [8] :

- among the possible exciters are the bow hair, bow wood, as well as various parts of the hand (finger, nail, knuckle). The natural vibrators are the four strings, but the body can be involved[2];
- modification movements are mainly the ornaments and other IPTs realized by the left hand (e.g. *vibrato*, *glissandi*, *harmonics*);

1 Pooling reduces the size of the output of the convolution (*called a feature map*) by downsampling ; generally, the maximum value of a local neighborhood is taken (*max-pooling*)

2 The *resonator* is assumed to remain unchanged (body).

- excitation movements should be characterized by their position (e.g. *sul tasto* or *ponticello),* length (e.g. *staccato*), eventual periodicity (e.g. *jettato, tremolo*), and the amount of speed and pressure involved (e.g. *flautando* vs. *pressured*).

3.2 Availability of Data

Proper definitions of all these IPTs should then be provided in order to annotate a recorded corpus of audio in a consistent manner.

However, the cost of such a study would be prohibitive. Therefore, we decided to rely upon available sound banks and their IPT definitions.

We identified 5 IPT sound banks which had different players and recording setups: EastWest Quantum Leap (EWQL), Vienna String Library (VSL), IRCAM Solo Instruments (ISI), Virtual Orchestra (VO) and ConTimbre (CONT). These banks suffer from two drawbacks. First, as expected, the absence of standardized definitions causes gaps in the realization of given IPTs between them, even for such a basic feature as the vibrato of an *ordinario* class. Second, each of the sound banks includes only a fraction of all the technical possibilities mentioned above. Several IPT combinations, albeit perfectly playable, are not available (e.g. *harmonic trills*).

3.3 Proposed Taxonomy

We match the list of IPTs in our sound banks with the theoretical approach in section 3.1. Bearing in mind our real-time constraint, we want to prevent an inflation of the number of classifiers and parameters in our model.

Therefore, we retain only 4 dimensions in our taxonomy (see Table 1). The first axis refers to the *exciter/vibrator* couple, which has a strong impact on the harmonicity and noisiness of the resulting sound. The second axis refers to how the *left hand* shapes the pitch contour. The third axis, called *waveform*, classifies IPTs depending on the nature and length of the bow/string interaction. The last axis refers to the *position* of the *interaction* with the string, which induces different spectral envelopes in the sound.

Axis 1 *Exciter/Vibrator*	Axis 2 *Left-hand*	Axis 3 *Waveform*	Axis 4 *Int. Position*
bow hair/string (*ordinario*)	NONE	NONE	NONE
bow wood/string (*con legno*)	*vibrato*	sustained	ordinario
finger/string (*pizzicato*)	non *vibrato*	*staccato*	*sul tasto*
finger/string+body (*pizz. Bartok*)	*glissando*	*spiccato, battuto*	*sul ponticello*
pressured bow/string	trill	*marcato, sfz*	harmonics
hand or knuckle hit on body		*tremolo*	

Table 1. IPT taxonomy (axes, classes) proposed in this study. This taxonomy is partly hierarchical in the sense that classification along Axes 2-4 is optional and dependent upon classification on Axis 1. When no classification is desirable, the *NONE* class is used in the training process[3].

3 For instance, a pizzicato will never be classified along the 3rd (waveform) axis. But it still could be classified along the 2nd axis (e.g. glissando) or the 4th (e.g. harmonics).

Some IPTs which would require a separate axis (should we aim at an exhaustive taxonomy for musicological purposes) were forced onto an existing dimension. Pressured bowing was included in axis 1 as it results in strong inharmonicity and noisiness. Harmonics, both natural and artificial, were included in axis 4, as they are most commonly played *sul ponticello*, but imply specific spectral envelopes. Finally, string classification[4] was excluded from the taxonomy, as well as the use of mutes.

On each dimension, each class of the taxonomy had to be represented at least in two sound banks for the *minus 1-Db* methodology to be implemented.

4. EXPERIMENTS

4.1 Building the Databases

4.1.1 Sequence Generation Principles

Bearing in mind our goal to generalize to actual solo recordings, we have generated series of audio sequences which simulate such recordings. This simulation tool was developed as a series of Max/Msp patches[5] controlling the proprietary samplers[6] of our 5 sound banks. The generated sequences include randomly generated notes and chords of all available IPTs. The chords are bounded by the playability of the instrument (as presented in [28]) and the specific ranges of the sound banks.

In the remainder of this article, we will use the term *database X* to designate the sequences which were generated with this process applied to the *sound bank X.*

4.1.2 Data Augmentation

We augment the data to increase the robustness of the classifier to variations in the recording environment and tuning of the instrument. Therefore, we generate sequences with a randomly detuned reference A4 in a 20Hz range around 440Hz (through transposition of the original samples). We also use various levels and types of reverb in the samplers. Finally, we average the stereo channels provided by the sampler to get the final signal.

After augmentation, the sequences represent 13.5 hours of music and over 4 Gb of AIF files sampled at 44100Hz and encoded at 16 bits PCM.

4.1.3 JAMS Standard Annotation

Our simulation tool exports both the annotation files with the JAMS format [13] and the corresponding audio. IPT classification along the 4 axes is provided with the *tag_open* namespace. Onset times and note/chord pitches were added when available, using *onset* (resp. *pitch_contour*) namespaces. Both audio and annotation files are made available to the MIR community[7].

4 All notes above G2 can be played on several strings. String change is regarded as a component of intra-class variability.

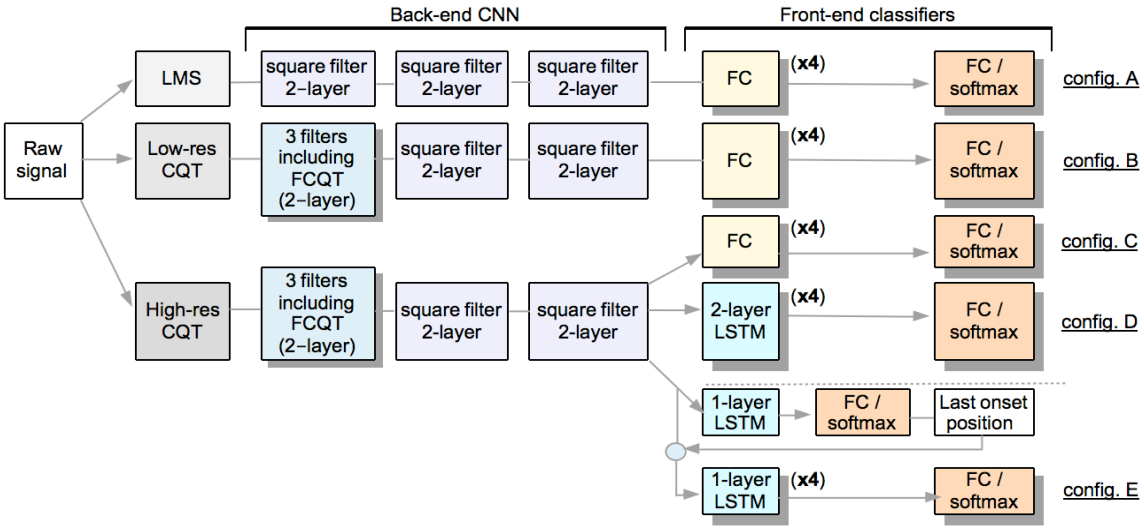

Figure 1. System architecture (incremental configurations A to E). A is directly inspired by [11]. B introduces CQT along with adapted filtering in the convolutional process. The resolution of CQT is increased in C. Recurrent layers process the output of the CNN in D. Finally, in configuration E, we experiment with the joint classification of onsets.

4.2 System Architecture and Configuration

4.2.1 Preprocessing

As shown in Figure 1, we have tested several possibilities[8] for the spectral transform.

Log-mel-spectrograms (LMS): following [11], we first downsample the signal to 22,050Hz, then compute LMS on 128 bins, with FFT windows of 2048 samples and hopsize of 512 samples (~23ms).

Adapted low-res CQT: following [18], we compute a 12 bin-per-octave CQT from C3(~130Hz)[9] to B10(~15.8kHz). Hop size is 1024 samples (~23ms). Only the logarithm of the amplitude of the CQT is retained. In order to preserve the temporal coherence of the preprocessed signal, we halve the Q-factor of the bins in the C3-B3 octave. In our adapted CQT, the size of the analysis windows are limited to 2850 samples (~64ms).

Adapted high-res CQT: to better account for IPTs such as *glissandi* and *vibrato*, we also experiment with a doubled bin-per-octave resolution above C5. The total number of bins of the CQT increases from 84 to 144. Since analysis windows are bounded, we cannot extend this resolution to the lower two octaves without deteriorating further the corresponding Q-factors.

In all configurations, we filter out low-energy frames (with average LMS or CQT < -79dB), normalize the data and cut it into fixed-length sequences of 60 frames (~1.4 s). Short sequences are less likely to include the attack of long notes, which is critical information for the network. A sequence length of 60 frames is an empirical compromise between this loss of information and the computing cost of longer sequences.

4.2.2 Folded Constant Q-Transform (F-CQT)

We introduce *F-CQT* as a generalization of the *pitch spiral* method [18] in order to capture efficiently the spectral envelope of a signal. It is obtained by first changing the pitch order of the CQT chromatic bins to match the cycle of fifths. The reshuffled CQT is then folded in 2 dimensions so as to put successive octaves on adjacent lines, in the same manner as the pitch spiral.

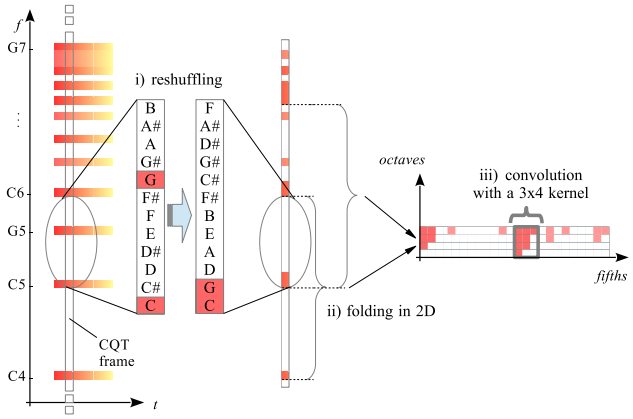

Figure 2. *F-CQT* example for a C4 note: (i) each CQT frame is reshuffled on an octave-per-octave basis, folded (ii) using 2-octave wide half-overlapping bands, in order to avoid side effects. A kernel (iii) of size 12 captures 8 out of the first 12 harmonics including the fundamental.

As shown in Figure 2, bins related to the harmonics $f_{2^i 3^j} = f_1 2^i 3^j$ of a given fundamental f_1 remain in its close neighborhood. Therefore, a small convolutional kernel of 3 *fifths* x 4 *octaves*[10] will capture 8 out of the first 12 harmonics. This is achieved without resorting to a computationally expensive harmonic-CQT [2]. Convolution with such a kernel can be seen as a 1D frequency-wise convolution of the usual CQT with a disjoint filter: the *F-CQT filter*. To capture the same

8 We use the Librosa [20] implementation for LMS and CQT.

9 It has been assumed that the lower octave of the cello would be analyzed with enough detail without the fundamental frequency being reported.

10 Tradeoff between the number of harmonics captured and the size of the kernel. A higher number of octaves results in blurring the picture with several harmonics on the same bin.

harmonics with a regular 1D-kernel would require a much bigger kernel size (43 parameters instead of 12).

4.2.3 CNN Back-end

We assume that the nature of our task is somewhat similar to the recognition of instruments in a challenging environment such as polyphonic textures. Therefore, we follow the main characteristics of the CNN architecture presented in [11], while adapting its capacity to our data.

The proposed CNN is made of 3 modules which operate at increasing scales. In each module we stack two identical convolutional layers, with batch normalization and *Rectified Linear Unit* (ReLU) activation. A max-pooling layer and dropout at 0.25 probability are implemented at the output of the module. Following the architecture design of [11], we use as baseline square (3x3) filters[11] for all layers. However it has been suggested in recent research [23] that domain-specific filtering could improve CNN performance, especially in the deeper layers. Therefore, we evaluate the use of three separate filters, namely our *F-CQT*, the baseline (3x3) and a (6x2) filter; the latter is designed to capture longer patterns such as *vibrato* or *trills*. The concatenation of 8 feature maps for each filter is used as input of the second module. Max-pooling layers are in charge of downsampling the features while the number of feature maps increases[12]. The output of the CNN is a 10 step long sequence of 64 maps with a single feature (one step equals six frames ~125ms).

4.2.4 IPT Classifiers (Front-end)

In configurations A to C, IPT classifiers are built with a fully-connected (FC) layer of 32 neurons with *ReLU* activation, followed by another FC layer with *softmax* activation. The latter comprises as many neurons as there are classes in the corresponding axis [10].

In configuration D (resp. E), we replace the first FC layer with a double (resp. single) layer of 32 unidirectional LSTM cells with an input of 64 features per temporal step.

In configuration E, following [12], an additional classifier with the same design is jointly trained to locate the attack of the last note of the sequence. Its eleven classes coincide with the 10 steps of the sequence plus one: this additional class is used to categorize sequences of long notes where the attack occurs prior to the beginning of the sequence. The prediction of this onset classifier is concatenated with the original features and used as input to the 4 IPT classifiers.

A rule-based system computes an 18-class linear classification from the network predictions along the 4 IPT axes. The same rules are applied to the ground truth. An 18-class accuracy is provided as an additional assessment of the performance of the system.

11 2D filters are noted: N *time frames* x M *frequency bins*.

12 Detailed architecture available here:https://drive.google.com/open?id=1GvS6VQ3iJP6e9MBajEPL0VOXva-iuUmS

4.3. Training Configuration

The system is trained by minimizing the sum of the cross-entropy loss function of the classifiers. Mini-batch gradient descent is performed with ADAM optimization [10] and exponential decay of the learning rate[13].

5. RESULTS

5.1 Direct classification (18 classes)

We first attempted to build directly a classifier among 18 cello IPTs, chosen simply because they were the most represented IPTs in our data. Our network architecture (called A_{18}) was similar to configuration A, but with a single 18-class classifier front-end. This effort resulted in excellent accuracies when the classifier was tested on homogeneous subsets of our corpus (see Table 2). However, these results collapsed when the *minus-1db* methodology was implemented. Not only average accuracies dropped below 50% but they were very irregular from one test base to the other. This indicated a poor ability to generalize.

Database excluded from training	18-class accuracy	
	Homogeneous corpus	Heterogeneous corpus *(minus-1db)*
CONT	92,9%	49,9%
EWQL	94,0%	30,3%
ISI	95,2%	51,1%
VSL	97,3%	44,0%
VO	93,4%	32,4%
Average A_{18}	94,6%	41,5%

Table 2. 18-class accuracy of configuration A_{18} with a single 18-class IPT classifier front-end. Results are given for 5 different training/testing subsets and averaged on 3 alternative learning schedules.

5.2 Introduction of our taxonomy

Trained and tested on 5 homogeneous subsets of our data, our models still yield in average 18-class accuracies over 90% in all the configurations (see Table 3). In the framework of the *minus-1db* methodology, they now exhibit much greater resilience. Their 18-class accuracies, averaged on all test bases, are above 50% in most configurations. These accuracies are also less sensitive to the choice of the test base, as shown by Figure 3 in the case of configuration D.

Configuration	Parameter count	18-class accuracy	
		Homogeneous corpus	Heterogeneous corpus *(minus-1db)*
A (LMS)	184K	93,5%	49,6%
B (Low-res CQT)	180K	90,1%	52,2%
C (High-res CQT)	181K	91,2%	54,3%
D (2 layers LSTM)	150K	91,3%	57,6%
E (Joint onset class.)	142K	91,7%	57,6%

Table 3. Parameter count and 18-class accuracy of configurations A-E, averaged on 5 different homogeneous or heterogeneous training/testing subsets and 3 alternative learning schedules.

On all axes but the *interaction position*, whatever the resolution, CQT with adapted filtering performs better than 128 bins log-mel-spectrograms (see Table 4). For

13 Detailed training parameters available at the same URL as 12.

instance, configuration C achieves better average and 18-class accuracy than A with roughly the same parameter count (Student t-test resp. p=0.046 and 0.004).

Accuracy / Configuration	Average on all axes	Exciter/ vibrator	Left-hand	Wave-form	Int. Position
A (LMS)	72,6%	84,2%	66,6%	77,1%	62,7%
B (Low-res CQT)	73,6%	85,6%	71,1%	78,1%	59,7%
C (High-res CQT)	74,7%	86,0%	72,6%	78,6%	61,7%
D (2 layers LSTM)	**76,0%**	**87,0%**	73,4%	**79,9%**	**63,5%**
E (Joint onset class.)	75,6%	86,7%	**73,8%**	79,5%	62,2%

Table 4. *Minus-1db* framework : per-axis and average accuracies in each configuration, for all 5 test databases and 3 alternative learning schedules.

We hypothesized that increasing the resolution of the CQT beyond the tempered scale would improve system accuracy for such IPTs as *vibrato* or *glissando*. Our experiment confirms that configuration C yields better average accuracies than configuration B on the *left-hand* axis (p=0.023). This results in better 18-class accuracy (p=0.045).

Configuration D with a 2-layer LSTM front-end achieves better average and 18-class accuracy than C with a fully-connected front-end (resp. p=0.039 and 0.02). Configuration E with joint onset classification but single-layer LSTMs also achieves better 18-class accuracy than C (p=0.016) with even lower parameter count. In both configurations E and D, all axes exhibit average improved performance compared to C but detailed results show discrepancies from one test base to the other.

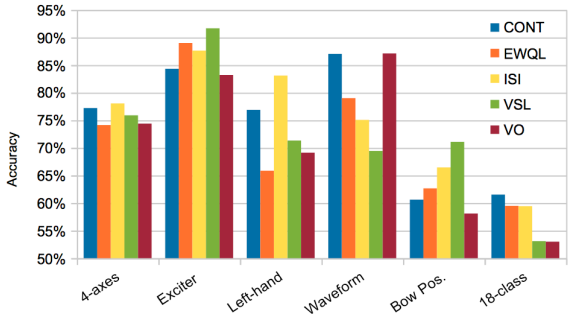

Figure 3. Accuracy per base and axis (configuration D).

In all tested configurations, the best accuracies are observed on the *exciter/vibrator* axis, while the worst-performing axis is *interaction position*. This statement is valid across most test databases, as seen in Figure 3 for configuration D. Bow position classification is likely to be a very difficult task even for a human expert. In the medium register, the choice of the string has a strong impact on the timbre, which makes the bow position harder to guess. In the higher register, *sul tasto* (with stronger emphasis or lower rank harmonics) and *ordinario* may be hard to distinguish. Finally, this is the axis where variability due to the instrument model is likely to be most perceivable.

5.3 Reactivity study

Our real-time classifier has to be as reactive as possible to sudden changes in the play of the cellist. To assess that reactivity, we select sequences in our test database where a change of IPT just occurred on the last note (or chord) of the sequence. We compute the average accuracy of the system as each time frame goes by. As Figure 4 exhibits, *exciter* is the axis where the classifier is most reactive, achieving >70% accuracy within 70ms of the attack. Unsurprisingly, it takes much longer for the network to categorize *left-hand* activity (e.g. *vibrato, trills)* or discriminate between *waveforms,* which often requires the note to be released (e.g. *staccato*). Finally, not only the *bow-position* axis yields poorer overall accuracy, but it is also the least reactive.

When the attack of the note gets out of the 60 frame-wide analysis window (see Figure 4, right side), the system has to categorize IPTs without information about the attack. However, its performance is not harmed as one could expect. Indeed, the actual length of the note provides information about the technique used. Longer notes tend, for instance, to be produced with the bow and to be vibrated or trilled.

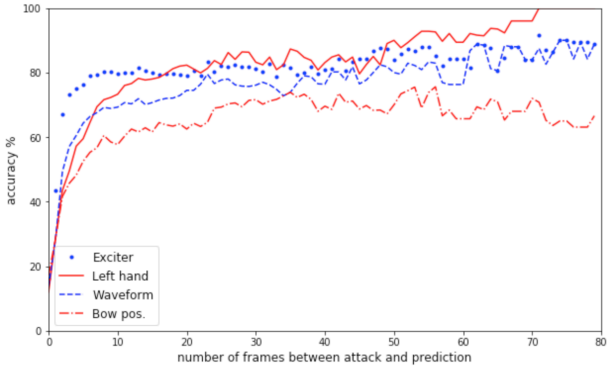

Figure 4. Average accuracy for sequences with an IPT change vs. time lapsed between change and prediction (10 frames~0,23s). Test base: ISI, configuration D.

6. CONCLUSIONS

In this article, we have extended state-of-the-art methods regarding instrument recognition to the real-time classification of IPTs from cello solo recordings. First experiments in the framework of the *minus-1db* methodology show a good resilience of models which are based on a meaningful taxonomy and process an adapted CQT through the proper combination of deep CNN and LSTM layers. Our methodology, from the realization of the databases to the architecture and training of the networks, can be extended with little effort to other string instruments. Other orchestral instruments first require an adaptation of the IPT taxonomy, which could be grounded on the same principles as ours [3,8,26].

To further assess the ability of our models to generalize, a database of contemporary cello solo recordings has been built, some of which will be annotated with the JAMS standard and used for testing. Finally, several unsupervised adaptation techniques, such as Maximum Classifier Discrepancy [25] or back-propagation through Gradient Reversal Layer [9], will also be tested in this environment.

HUMDRUMR: A NEW TAKE ON AN OLD APPROACH TO COMPUTATIONAL MUSICOLOGY

Nathaniel Condit-Schultz
Georgia Institute of Technology
natcs@gatech.edu

Claire Arthur
Georgia Institute of Technology
claire.arthur@gatech.edu

ABSTRACT

Musicology research is a fundamentally humanistic endeavor. However, despite the productive work of a small niche of humanities-trained computational musicologists, most cutting-edge digital music research is pursued by scholars whose primary training is scientific or computational, not humanistic. This unfortunate situation is prolonged, at least in part, by the daunting barrier that computer coding presents to humanities scholars with no technical training. In this paper, we present `humdrumR` ("hum-drummer"), a software package designed to afford computational musicology research for both advanced and novice computer coders. Humdrum is a powerful and influential existing computational musicology framework including the *humdrum syntax*—a flexible text data format with tens of thousands of extant scores available—and the Bash-based *humdrum toolkit*. `HumdrumR` is a modern replacement for the humdrum toolkit, based in the data-analysis/statistical programming language R. By combining the flexibility and transparency of the humdrum syntax with the powerful data analysis tools and concise syntax of R, `humdrumR` offers an appealing new approach to would-be computational musicologists. `HumdrumR` leverages R's powerful metaprogramming capabilities to create an extremely expressive and composable syntax, allowing novices to achieve usable analyses quickly while avoiding many coding concepts that are commonly challenging for beginners.

1. INTRODUCTION

Though digital musicology has been a productive area of research for several decades (e.g., [2, 8, 12, 16, 18–20, 22–24, 26, 28, 29]), it remains a niche field within the musical-side of academia. In fact, most cutting-edge, scientific music research has been pursued by researchers with primary training in computer science and psychology. Fortunately, recent years have seen a flourishing of "digital humanities" research in general, with increasing numbers of traditional humanities scholars adopting computational approaches. Humanist music scholars' deep, nuanced knowledge of musical culture, structure, and practice could be an invaluable asset to the computational/empirical music research community. Unfortunately, the training necessary for fruitful computational scholarship is absent from most music curricula, which cover neither the fundamental methodological principals of empirical research nor the necessary coding skills. The need to assist, and convince, music scholars to learn programming has been an area of active discussion for some time [7], in particular there is a need for software tools crafted to support their learning and research goals [32].

To make computational research truly appealing and accessible to traditional humanists and seasoned computational researchers alike, we must juggle three conflicting factors: flexibility, power, and usability. User-friendly interfaces like the Josquin Research Project's Analysis Tools [1], Theme Finder [2], or rapscience.net's Visualizer [3] can be utilized by scholars with no special training. However, such tools allow only variations of hard-coded analyses applied to limited, fixed databases. On the opposite extreme, any skilled programmer can code their own symbolic music data formats and analysis/parsing software "from scratch"—as many computational projects [4, 11] have done—, allowing for the unlimited power of the programming language of their choice, but requiring substantially more effort and experience. The most prominent modern computational musicology toolkit—`music21` [10]—, in our estimation, falls too close to the later extreme, proving quite daunting to novice coders.

This paper describes `humdrumR` ("hum-drummer"), a software toolkit for symbolic musicological data analysis intended to be appealing and accessible to traditional musicologists while also being useful to more experienced computational researchers. Learning lessons from the successes and failures of existing tools, `humdrumR` strikes a powerful new balance between flexibility, power, and usability:

1. Using the humdrum data syntax, `humdrumR` is extremely flexible and general in scope, allowing users to study any type of performance-art data that can be represented symbolically—musical scores, dance steps, trumpet fingerings, etc.

[1] http://josquin.stanford.edu/search/
[2] http://www.themefinder.org/
[3] http://rapscience.net/Analysis/gui.html

2. Based in the R programming language, `humdrumR` is extremely powerful, capable of complex data manipulation and interfacing with R's statistics, visualization, and machine learning libraries.

3. `humdrumR` is designed to present a relatively low barrier of entry for non-technical researchers, offering a concise, expressive syntax for applying music analyses while avoiding difficult coding paradigms.

In 2005, musicologist and psychologist Nicholas Cook observed that to truly engage in computational musicology "proper," scholars must achieve "sufficient understanding of the symbolical processing and data representation on which it's based" [7]. We believe that the combination of humdrum and R represents an ideal avenue for computational novices to develop this "sufficient" understanding: enough to pursue quality computational research but without having to engage with general coding paradigms that are irrelevant to their research.

In this paper, we first review the relevant philosophical and technical features of humdrum and R, noting how `humdrumR` incorporates these features (sections 2 and 3). We next contrast humdrum(R) coding philosophy and style with that of `music21` (section 4). Finally, we describe the principle features of the `humdrumR` package and `humdrumR` syntax (section 5), including numerous code examples.

2. HUMDRUM

Humdrum [4] is a system for computational musicology research, created by David Huron [17] (circa 1995) and maintained by Craig Sapp at Stanford's Center for Computer Assisted Research in the Humanities. Though no one digital musicology framework has ever truly dominated the field, humdrum is certainly among the most widely used and influential systems, being cited as the direct inspiration for some of its most successful competitors—`music21` [10] and MusicXML [13]—and with tens of thousands of scores available in humdrum format. Humdrum actually has two distinct components: the humdrum syntax and the humdrum toolkit.

The *humdrum toolkit* is a collection of Unix command-line tools for parsing and analyzing humdrum data, largely written in Bash and AWK but with more recent "extra" commands written in `C++`. [5] The humdrum toolkit is fundamentally entwined with the Bash shell, in particular the `grep` and `sed` commands, which rely heavily on *regular expressions* to parse and filter tokens. The humdrum toolkit also includes a number of analysis tools, notably the sophisticated windowing and n-gram tool `context` and the pattern finder `patt`. Using the toolkit, basic parsing and analysis can be achieved quickly and easily in Bash command pipes, but true Bash scripting is required for even mildly complicated tasks. In practice, after initial parsing, humdrum users must transition into a higher-level programming environment (Python, R, MATLAB, Julia, etc.) to achieve more complex data manipulation, statistical testing, or data visualization. The burden of parsing and manipulating humdrum data in the higher-level language falls on the user, substantially increasing the need for coding skills and prolonging the workflow. To make matters worse, installation of the humdrum toolkit can be fairly complicated, especially for Windows users, who must install a Unix emulator to use the toolkit at all.

`HumdrumR` is a successor to the humdrum toolkit, replacing all the original toolkit's functionality while adding significantly more. However, `humdrumR` uses the original humdrum syntax specification, and is thus compatible with all existing humdrum data. In fact, both the technical design and methodological philosophy of the humdrum syntax are fundamental to `humdrumR`.

2.1 The Humdrum Syntax

The humdrum syntax is an extremely general scheme for representing musicological data in plain-text. The syntax is basically tabular (tab-delineated columns) but with a few additional complexities:

- Columns of data are interpreted as *spines*, which can dynamically start, end, split, or merge, creating *spine paths*. Spine paths allow the syntax to represent many complex cases from music notation: For example, if the upper staff of a piano score splits temporarily into two voices (one with beams up, the other with beams down), this can be encoded by splitting the spine representing that staff into two columns (with a `*^` token) before merging them again after the split passage (`*v` tokens).

- Humdrum records are tagged as *interpretation records* (representing local metadata) or *data records* (notes, chords, etc.). By simply interspersing interpretation and data records, metadata can be concisely associated with specific data points, passages, or sections. For example, key information can be quickly read, edited, or added to scores by simply inserting lines containing tokens like `*f#:` (f# minor). This approach contrasts with the more verbose, hierarchical attributes and tags used in XMLs.

- Finally, each "cell" (i.e., each line-column coordinate) in a humdrum file can contain multiple data tokens—a feature commonly used to represent chords but with myriad other potential use cases.

The humdrum syntax provides a data *structure* but says nothing about how information is actually encoded in data tokens. Rather, specific *interpretation* schemes must be defined. A few well-specified interpretations for music are widely used, most notably the `**kern` representation. However, users can freely define new interpretations, with the appropriate degree of rigour/precision/complexity for the task at hand. Thus, humdrum is not limited to traditional Western notation, but rather affords the study of non-Western, vernacular, or avant-garde musics, as any type of

[4] http://www.humdrum.org

[5] Sapp also maintains a `C++` development library for humdrum tools called humlib (https://humlib.humdrum.org/).

musical feature, data, or metadata to be easily encoded in the same place. This presents a stark contrast with nearly all other music encoding schemes, including *MuseData* [15], abc [30], TinyNotation [9, ch. 16], LilyPond [25], and MusicXML, all of which are limited to representing music as, or in terms of, Western *music notation*—for instance, representing diatonic note names. Though `**kern` represents music in similar terms, the humdrum syntax in general has no such limitation. [6] Though the actively developing MEI [14] encoding standard *can* be extended to incorporate arbitrary music information, the emphasis of the MEI community is nonetheless representing music notation(s) for purposes of library science and score preservation and dissemination, not analysis.

Data encoding schemes inevitably balance read/writeability with power and flexibility [9, ch. 16]). Notation systems such as abc notation and TinyNotation achieve nearly effortless human read/writeability, but with severely limited representational possibilities. [7] On the opposite extreme, MusicXML and MEI can encode extremely complex, sophisticated score information, but are difficult to read/write directly. Humdrum achieves a balance between these extremes: though not quite as extendable as MEI, the humdrum syntax nonetheless affords a huge variety of approaches to encoding data. On the other hand, though `humdrum`'s top-down, tab-delineated format certainly makes editing slightly more cumbersome than editing abc or TinyNotation, most humdrum interpretations are comparably readable.

Like other easy notation schemes (abc, tinyNotation, LilyPond), humdrum interpretations often embed multiple pieces of information in each token. For instance, the `**kern` token `(4.aL/` encodes information about slurs (`(`), rhythm (`4.`), pitch (`a`), beaming (`L`), and stem direction (`/`). This "dense" approach allows a large window of musical time (for instance, several measures of multipart music) can be seen on a single screen. This contrasts with, for instance, MEI which spreads specific pieces of information across nested tags, making it impossible to see more than a few notes in a single screen. Such complicated tokens can also be written and edited rapidly, once you are familiar with the encoding. However, `kern`'s "dense" approach is but one option given humdrum's flexible syntax: information can be spread across multiple spines/columns (like *MuseData*) in whatever manner is most appropriate for data analysis. For example, the MCFlow corpus of rap transcriptions [6] encodes eight pieces of information across eight separate spines.

Human read/writeability is not just important to the process of data creation and curation, but is in fact essential to humdrum's entire methodological philosophy: humdrum emphasizes epistemological transparency by forcing users to engage directly with their symbolic data representations, even as they are filtered and transformed. Indeed, in traditional humdrum work flows, we apply repeated transformation to humdrum data tokens while maintaining, and visualizing the simple, readable humdrum syntax with each transformation. This dramatically improves the process of debugging and makes the series of steps from input to output clearer for novice users. Humdrum, thus, truly supports Cook's [7] call for a direct understanding of symbolic representations and processes. Consistent with this philosophy, `humdrumR` commands also reconstruct and display readable humdrum data even as the data is manipulated, maintaining a clarity and transparency which is easily lost when coding with complex data structures.

Though alternative data encodings have proven highly useful in contexts of research (*MuseData*, abc, MEI), file interchange (MusicXML), composition and engraving (TinyNotation, LilyPond, MEI), and performance (MIDI), the humdrum syntax offers an optimal combination of flexibility, read/writeability, and epistemological transparency, and is thus an ideal target for a new computational musicology toolkit. Fortunately, our focus on a single encoding scheme is not a limiting factor, as software to translate between `**kern` and most important representations—including MIDI, MusicXML, and MEI—is already available. In fact, fruitful cross-fertilization between musical data ecosystems is common: for instance, MEI's extraordinary Verovio score viewer has already been adapted as the Verovio Humdrum Viewer [8], making it easier than ever to visualize and edit humdrum data.

3. R

R [27] is a free, cross-platform, open-source "environment for statistical computing and graphics"—a domain specific programming language designed specifically for data analysis. R has a large ecosystem of data-analysis and statistics packages, most available through the Comprehensive R Archive Network (CRAN); As of now, the only programming environment with a comparable ecosystem for data analysis is Python. However, being less popular than Python for *general* programming, R's ecosystem is comparatively focused and uncluttered, with a higher quality floor. R's standard library ("base" R) itself contains analysis and visualization features which will satisfy the needs of many musicological research projects. Even when using external libraries, R users rarely encounter dependency issues—in fact, the process of installing R, `humdrumR`, and its dependencies is trivial on any operating system, even for beginner programmers, with no need for external package managers, virtual environments, "sandboxes," etc.

R excels at exploratory, ad hoc data analysis in short scripts or in the read-eval-print loop (REPL), making it easy to quickly manipulate, filter, and visualize data "on the fly." Indeed, a focus on simple scripting and "constrained" projects, without concern for more general software development issues, is core to R (and `humdrumR`) philosophy, making R an excellent avenue for learning programming purely for data analysis. This coding paradigm

[6] Conversely, humdrum/`**kern` is not as optimized for representing the details of music engraving as LilyPond, MEI, or MusicXML.

[7] However, `music21` includes an API for extending TinyNotation, useful to those with the requisite coding skills.

[8] http://verovio.humdrum.org/

is well suited to the constrained, stand-alone projects typical of theory-driven musicological research projects. The R ecosystem also includes a number of useful, free, software tools for enhancing the productivity, reproducibility, and presentation/sharing of research conducted in R. Notably, RStudio is a free, high quality integrated development environment for R. R is also one target of the Jupyter project [21], with RStudio too incorporating a suite of mark-up, notebook, and presentation tools. Finally, RStudio's `shiny` package [5] provides an easy means of creating interactive R data visualizations in the browser.

Though R is generally best suited to a combination of procedural and functional styles of programming, it nonetheless includes Object-Oriented Programming features suitable for defining simple classes. R's `S4` object system is oriented around multiple dispatch—generic functions can be defined which call specific methods based on the types of any or all of the function's arguments, not just their first argument. In languages featuring multiple dispatch (Julia, Common Lisp, Smalltalk, etc.), methods are not bound within classes. As a result, the object system operates in the background: novice users benefit from the features afforded by the object system—for instance, common functions like `summarize` can be applied to nearly any type of R object, getting useful results—without ever having to consciously engage with the system.

One of the core philosophies of R is "vectorization": treating data collections (especially vectors and arrays) as conceptually singular objects. `HumdrumR` leans into this philosophy, allowing users to think and operate on `humdrumR` data collections holistically. One concrete realization of this approach is that `humdrumR` users can completely avoid explicit iteration (i.e., loops): Iteration is abstracted by the `humdrumR` API, allowing users to decide solely *what* processes to apply to data tokens, not *how* to apply them to each token. `HumdrumR` defines a number of useful data classes, yet the R approach makes these classes an implementation detail that novice programmers need not understand.

3.1 Metaprogramming

The final key to the R ecosystem's concise data analysis syntax is its subtle use of metaprogramming [31, ch. 17–21]. In particular, numerous R packages use a shared domain specific language for specifying statistical models using R "formula" [31] objects.[9] Created using the `~` operator, R formulae capture ("quote") surrounding R expressions as well as their local namespace. R's metaprogramming features allow the programmatic manipulation of these formulae, for instance, using the `update` routine. Again, though metaprogramming is essential to R code, only advanced developers will ever need to explicitly engage with metaprogrammming concepts.

[9] For example, `Y ~ X*Z + (1|G)` describes a linear model predicting the variable `Y` using predictors `X` and `Z`, and the interaction between `X` and `Z`, with random-effect intercepts specified for each level of the grouping factor `G`.

4. music21

`Music21` is a Python library for symbolic music generation and analysis, with an extensive set of tools extending well beyond the capabilities of the humdrum toolkit, and which easily integrates with Python's extensive ecosystem (statistics and graphics libraries, etc.). Though `music21` and `humdrumR` overlap significantly in use case, `humdrumR` offers a fundamentally different coding philosophy and style.

Python syntax is famously simple to read/learn, yet the Pythonic coding style of `music21` nonetheless presents challenges to would-be computational musicologists. Working with `music21` requires one to engage directly with a hierarchy of complex classes (with *numerous* attributes and methods) and write many explicit control and looping structures, including (in typical analyses) multiple nested `for` loops. In contrast to humdrum, which relies on plain-text strings to encode information, `music21` parses musical scores into numerous complex data objects. Notably, `music21.Note` contains a rich set of attributes and methods for describing "notes." This complexity, though highly useful to experienced coders, is a barrier to entry for novices, for whom the practical reality of carrying out a computational musicology project is all but impossible. This is in part due to the style of `music21`'s User's guide, which necessarily gets bogged down explaining detailed functionality of how to represent, extract and manipulate low-level features (e.g., parts, notes, etc.) at the expense of explaining larger-scale processes like, for instance, how to search through a corpus of music to compare n-grams. Finally, `Music21`'s object hierarchy primarily represents musical score features—representations for arbitrary extra-musical data (e.g., dance steps, fingerings) or musical metadata (e.g., formal labels, manual annotations) is not supported.

`Music21`'s *Stream*-based object model is (purposely) extremely flexible [1]. As discussed above, the humdrum syntax includes some scope for flexible variation (using spine paths, for instance), yet `humdrumR`'s data backend (section 5.1) nonetheless always has the same structure; thus, one can always assume the same data structure and thus that certain commands/routines will always work. In contrast, `music21` users must always first determine the Stream-hierarchy of their data: are notes nested within measures, within parts, or within chords, etc? Similarly, `music21`'s highly sophisticated data classes (like `music21.Note`) are fairly inflexible, whereas humdrum's plain-text tokens are completely flexible. Again, this later approach is consistent with `humdrumR` philosophy, forcing users to think about and grapple with the transparent details of how their musical information is encoded and *not* about details of data structure.

As dynamically typed, interpreted languages, explicit loops in either R or Python are notoriously slow. However, whereas `music21` makes much explicit use of `for` loops, `humdrumR` enables users to exclusively use "vectorized" R and an optimized split-apply-combine backend, to achieve fast execution of most commands. As a re-

sult, humdrumR is generally much faster than music21.

5. HUMDRUMR

The humdrumR library defines a number of data object classes and a suite of functions for manipulating these classes. Most significant is the humdrumR class itself, which encapsulates a corpus of parsed humdrum files, and serves as the primary interface through which users interact with humdrum data. HumdrumR includes a complete humdrum syntax parser, which reads any valid humdrum data—including all valid spine paths—into a humdrumR data object. Invalid humdrum files are automatically flagged and skipped, with line-by-line syntax error reports generated on request. Consistent with the humdrumR philosophy, the syntax for reading files is concise and powerful: users simply specify one or more regular expressions matching files on their local disc. For instance, the command

```
readHumdrum("Bach/Chorales/chor.*krn")->chor
```

validates, reads, and parses all files matching the regular expression "chor.*krn" in the directory "Bach/Chorales" (370 files on our machine), wraps them in a humdrumR corpus object, and assigns this object to the variable chor. A set of summary functions are included to quickly describe the size, content, and structure of a loaded humdrumR data objects. In addition, an extensive suite of functions and classes for representing and manipulating pitch and rhythm data is also included—these tools reproduce much of the functionality of the original humdrum toolkit—as well as music21's core class hierarchy—, with some significant improvements and additions.

A great strength of the original humdrum toolkit is its use of the Bash | ("pipe") operator to concisely chain a series of operations—a syntax that is highly accessible to novice programmers. In recent years, the piping approach has become popular in R [3], especially magrittr's %>% pipe operator. HumdrumR too incorporates a pipe operator—%hum>%—which appears in all our subsequent code examples.

5.1 Data Model

R's primary native data structure is the tabular data.frame. HumdrumR utilizes a popular extension of the base R data.frame, the data.table [10]: an optimized data.frame which achieves database manipulation performance comparable to Python's Pandas module, including an extremely fast split-apply-combine routine. The HumdrumR class stores humdrum data in a list of data.tables, with each individual data token assigned to a single row. Data and metadata for each token are encoded in named columns of the data.table, called *fields*. The original string is encoded in the Token field, with global and local metadata associated with that token spread across other fields. Additional fields encode the "location" (which file, spine, path, record, etc.) of each token, encoding the structure of the original humdrum data so that it can be reconstructed for visual inspection after each modification. Users can freely create new fields; for instance, **kern tokens can be parsed into various pieces of information, each saved into a separate field: For example, the commands

```
chor %hum>% as.recip -> chor$Duration
chor %hum>% as.midi  -> chor$MIDI
```

create two new fields—Duration and MIDI—by applying the functions as.recip [11] and as.midi to the default Token field. These new fields can then be referenced like any other field in subsequent calls.

5.2 API

Much of R's expressive power arises from a subtle usage of metaprogramming to manipulate data.frames: Several base R functions—including subset, with, and within—allow users to input arbitrary R expressions which are then *evaluated within the data set* using the table's named fields as a local namespace. HumdrumR extends this paradigm to humdrum data, allowing users to apply arbitrary expressions to humdrum data stored in the underlying data.table back-end. Users capture expressions as R formulae and humdrumR API applies them to the data. These expressions can refer to any field in the data, including fields created by the user. The command

```
chor %hum>% ~table(MIDI[Duration == "4"])
```

(using the MIDI and Duration fields defined in the previous code block) extracts all MIDI values where the corresponding rhythm is a quarter note—using the standard R indexing ([]) operator—and then applies the base R table function, to tabulate these MIDI values. In a sense, this approach is an abstraction of function definition: One creates an expression—equivalent to the *body* of a function—but specifies no function arguments, as all data fields from the humdrum data are automatically passed into the expression if referenced.

The true power of the humdrumR arises through special *keyword* formulae which modify the API's behavior. Most notably, the by keyword can be used to split-apply-combine humdrum data. For instance, the command

```
chor %hum>% c(~table(MIDI[Duration == "4"]),
              by ~ File)
```

applies the exact same processing as the previous code block except the expression is applied separately to each file in the corpus, creating 370 separate tables. Since the humdrumR data fields include all data and metadata in the dataset, *any* field can be used to group data.

Other keyword formulae afford complex windowing, including n-grams, overlapping fixed-length windows, and various dynamic windowing possibilities. Finally, another set of keywords can be used to directly manipulate R's built-in visualization settings. Since formulae (including keyword formulae) are first-class objects in R, all of these expressions can be easily saved, composed, manipulated,

[10] https://cran.r-project.org/web/packages/data.table/index.html

[11] "Recip" is short for "reciprocal"—the humdrum term for standard Western duration categories (eighth-notes, sixteenth-notes, etc.).

and combined. For instance, we could save the tabling expression used above and use it in combination with various keyword formulae:

```
tabQuarters <- ~table(MIDI[Duration == "4"])
chor %hum>% c(tabQuarters, by ~ File)
chor %hum>% c(tabQuarters, by ~ Spine)
chor %hum>% c(tabQuarters, by ~ Clef)
```

The humdrumR API also includes routines for filtering and indexing a humdrum corpus. The standard R indexing operators ([] and [[]]) can be used to select pieces, records, or spines, either numerically or by matching regular expressions. More sophisticated filtering can be achieved through the use of humdrumR formulae: For instance, the command

```
filterHumdrum(chor,
              ~Token %~% '[EeAa]-',
              by ~ File)
```

selects all the files in the data set which contain the notes E♭ or A♭.

To bring it all together, a simple, yet complete humdrumR analysis script might look like this:

```
readHumdrum("Bach/Chorale/chor.*krn")->chor
chor %hum>% (~ as.midi(Token))
     %hum>% (~ Pipe - 60)
     %hum>% c(doplot ~hist(Pipe,
                           title = Clef,
                           xlim = c(30, 80)),
              by ~ Clef,
              mfcol ~ c(2,2))
```

These commands load the Bach chorale dataset, convert the original data tokens to MIDI numbers, subtract these numbers by 60 (to center them on middle C), then create a separate histogram for each clef in the data (in a 2x2 grid [12]). Note the use of the base R hist (histogram) function, including the use of the title and xlim (x-axis limits) arguments to give each plot a meaningful title and place all plots on the same scale.

5.3 Developer Tools

HumdrumR is designed to be highly extensible. Even novice users can quickly begin to create and save their own routines as R functions, or simpler yet, as combinations of humdrumR formulae. However, humdrumR also includes several features to support development by more sophisticated coders. All humdrumR data classes are intended to serve as extensible bases for further development—for instance, developers might choose to implement counterpoint analysis algorithms using humdrumR's basic tonalInterval class and its wealth of useful methods (transposition, inversion, etc.). However, the most significant tool for developers is humdrumR's Regular-Expression Method Dispatch System (REMDS). Interacting with humdrum data requires extensive string manipulation, typically using regular expressions, as one works to extract the information one is interested in from humdrum's "dense" character tokens. Using the REMDS, developers need only define normal R functions to manipulate the information they are concerned with and regular expressions to match that information. The REMDS can then be used to create generic functions which read an input string and dispatch the appropriate method based on matching regular expressions—what's more, these methods can (optionally) be applied "in place," only affecting the substring which matches the desired regular expression. For example, the humdrumR pitch module defines a number of functions which translate specific pitch encodings (note names, solfege, intervals, etc.) to/from humdrumR's common tonalInterval pitch representation. The REMDS is then used to generate generic pitch translation functions which call the desired method when a specific regular expression is matched. For instance, the function as.midi can be applied to strings containing a variety of pitch representations, even when embedded with other information (i.e., rhythm, beaming):

```
as.midi("4.cc#J") # "cc#" => **kern  =>  73
as.midi("4.C#5J") # "C#5" => **pitch =>  73
as.midi("4.-M9J") # "M9"  => **mint  => -14
as.midi("4.soJ")  # "so"  => **solfa =>  7
```

This approach allows users to use humdrumR functions without having to explicitly manipulate strings or use regular expressions, one of the major barriers to learning in the original humdrum toolkit. Many of humdrumR's own functions (like as.midi) are written using the REMDS, and developers can utilize it to significantly reduce coding effort when defining new functions.

6. FUTURE

The package source of HumdrumR 0.3.0 is currently available on github (natsguitar/humdrumR); when development solidifies, version 1.0.0 will be made available on CRAN under the terms of the GNU General Public License. However, releasing code is not enough to support humanist scholars interested in coding—it is imperative to provide high quality documentation and learning materials in a style that is digestible for users who may be new to computer programming. The most important contribution of the original humdrum project was neither the syntax nor the toolkit, but Huron's extensive user guide [17]. [13] The Humdrum User Guide offers a gentle introduction to empirical/computational research from a humanistic perspective, walking readers through the practical and philosophical details and challenges of digital humanities work and the conceptual transformations necessary to convert humanistic thought into concrete code, using examples from real musicology projects. HumdrumR too will ultimately be accompanied by a *humdrumR User Guide*, including interactive online content. Our goal is to not just teach the mechanics of operating software in a friendly, hands-on format, but also the conceptual framework needed to think about music as data, introducing key scientific principles/methods (data sampling, statistics, hypotheses, etc.) while maintaining a holistic, humanistic perspective.

[12] The keyword mfcol is a base R graphics parameter which controls the layout of plots in a grid.

ABSTRACT

Music is well established as a means of social connection. In the age of streaming platforms, personalized playlists and recommendations are popular topics in music information retrieval. We bring the focus of music enjoyment back to social connection and examine how technologies can enhance interpersonal relationships, specifically through the context of the collaborative playlist (CP). We conducted an exploratory study of CP users and non-users ($N = 65$) and examined speculative and experienced purposes and outcomes of CPs, as well as general perspectives on music and social connectedness. We derived a CP Framework with three purposes—Practical, Cognitive, and Social—and two connotations—Utility and Orientation. Both users and non-users shared similar perspectives on music-related activities and CP user outcomes. Projected and actual CP purposes differed between groups, however, as did perception of music's role in connectedness in recent years. These results highlight the importance of music-based social interactions for both groups.

1. INTRODUCTION

Music has traditionally prompted social cohesion through mutually engaging properties such as cooperation and group empathy [26]. The importance of music's social implications is underscored by research on social interactions in online music sharing [8], in specific social contexts [2, 12, 13, 33], and in prototype designs [32, 34]. Social aspects are even highlighted in research with broader scopes. In exploring music information needs and behaviors through a large-scale user survey, researchers find "there is a strong social component to people's experience of and interaction with music" [39]. Such studies underpin the importance of technology's mediation in music. Yet, there is a relative dearth of research in current collaborative technologies for our most intimate and social experiences in music. Moreover, music's socially engaging traits are increasingly jeopardized by technologies that propagate individualized music consumption [17, 22].

Collaborative playlists (CPs), made possible through access-based consumption (i.e., streaming), are increasingly gaining traction [3]. For one, Spotify has allowed users to co-create and co-modify a playlist since 2008 [19]. Despite the importance of music's social qualities and increasing popularity of music co-consumption platforms, there is little research looking explicitly at today's phenomenon of collaborative playlisting. In contrast to related topics on recommendation systems and personal playlists, we lack an understanding of how CPs are used and enjoyed. Therefore, we can neither evaluate nor improve current systems in terms of meeting user needs and desires. Given these social benefits, and the fact that 86% of individuals in large music markets are purported to consume music via streaming platforms [24], characterizing the current state of how users feel about and interact with collaborative music platforms in an effort to bring "social" back into music is certainly a relevant topic in MIR research.

To address these needs, we explored the perception and experience of CP engagement by building upon prior work that identified behaviors and sentiments related to CPs [36]. We analyzed responses to selected questions from a larger survey to address the following research questions:

- RQ1: What are the distinct purposes and outcomes of CPs?
- RQ2: How do purposes and outcomes differ from those non-users predict CP usage would engender?
- RQ3: How do music perceptions, values, and habits differ between CP users and non-users?

Ultimately, an understanding of designing HCI through music co-consumption with better characterization of collaborative behaviors and needs from a user-centered perspective can help build HCI principles that can influence the landscape of human collaborations.

2. RELATED WORK

In the past, music listening was almost inevitably a social activity, through jukeboxes, radio, or the family record player in the living room. Only when music playback devices became more affordable and portable did music listening become an activity that could be enjoyed individually [17, 18, 22]. But these new practices did not displace

social practices around music. Research shows that music is still enjoyed socially (i.e., used as a social agent) to reinforce existing relationships and establish new ones [15,22]. Music preferences, especially during adolescence, play an important role in identity formation individually but also as a group of friends [18]; they convey information about a person's or group's values and beliefs. Music social practices are not limited to listening with others. They also include talking about music with friends and introducing them to new music [7]. When music collections were essentially or at least primarily physical, people shared music and prepared compilations with or for their friends [7], and mostly shopped for albums in music stores with others rather than alone [14]. Now that music has migrated online, have these social practices migrated too? Have music streaming services' collaborative and sharing features given rise to new social practices?

The advent of peer-to-peer (P2P) file sharing services (e.g., Napster, Gnutella) marked a turning point in music distribution and consumption. Researchers examined the social practices of users in these "online communities". Although these services offered ways for users to connect (e.g., chatrooms), few users "actively [sought] out chat or information sharing" [16]; interactions between users were "relatively infrequent"; and ties between them were mostly weak [37]. Brown and Sellen [7], who compared music sharing online and offline, concluded that when music was shared online, the social component of the activity was "stripped away". A study on iTunes sharing revealed that design decisions—such as partial user identification, and using a subnet ecosystem rather than P2P or in-person—impacted how social aspects of music sharing were supported [42].

More recently, music streaming services have enabled ubiquitous access-based consumption [3], and consequently have fueled research focused on selection, discovery, and listening through personal music collections [11, 20, 27, 39]. Streaming services have also provided many new affordances for supporting social music practices, one being the possibility of creating CPs. Even works on general music enjoyment and practices highlight "the growing need for tools to support collaborative music seeking, listening, and sharing" [29]. As such, works on creating social music technologies have been particularly numerous. Prototypes that aim to heighten the "extensive social functions" that music serves have been developed in the form of physical devices [32, 35] and digital platforms [5, 23, 25, 30, 31, 34]. Other works consider music recommendation based on group preferences [6, 9, 10] or integrate the collaborative functionality with other social components, such as interpersonal conversations [4], conflict management [41], and synchronous enjoyment [40]. These studies provide insights into the various aspects tackled or addressed in designing CP products. However, to the best of our knowledge, there have been no user studies on collaborative playlists or literature that considers long-term usage and outcomes relating to commercially available CP platforms. Therefore, we know very little about how CPs are used and perceived.

3. METHODS

3.1 Survey Design

Building upon past work [36], we designed a survey comparing CP users and non-users. We defined a CP as "a list of songs that multiple users have created using a digital platform"; CPs are distinguished from personal playlists in that they are also modified by other users. Our survey comprised open-ended and multiple-choice questions on perceived or experienced CP motivations, purposes, and outcomes; changes in behavior resulting from CP engagement; characteristics of users' favorite CPs; and impacts of CPs and music on social connectedness. We recruited participants through an introductory university music class, online music communities (e.g., Music group on Reddit), and social media (e.g., Twitter, Facebook). Anyone 18 years or older and fluent in English was eligible to participate. We provided no compensation for participating. Ethics approval was obtained from the Institutional Review Board of Stanford University.

3.2 Analyses

We focused on a subset of questions regarding CP purposes and outcomes, as well as music-related activities and music's role in social connectedness (questions are listed in Table 1). A three-step approach was used to analyze free-text responses (Q1). First, we decomposed each response into individual ideas and used affinity diagrams to group ideas in a data-driven fashion. We then categorized and labeled each of the groupings that emerged. Finally, the original responses were re-coded based on the identified groupings, and we computed counts and percentages of CP user and non-user responses that fell into each grouping. Quoted responses reference participants as "U" for users and "N" for non-users, followed by anonymized numbers.

Statistical analyses and data visualizations were conducted in R [38]. Differences between CP users' and non-users' word counts (Q1) and ordinal responses (Q2–Q4) were assessed using two-tailed Wilcoxon rank-sum tests. For Q2–Q4, each question comprised multiple responses (Table 1), so these p-values were corrected for multiple comparisons, on a per-question basis, using False Discovery Rate (FDR). We report significant ($p < 0.05$) and marginally significant ($0.05 \leq p < 0.10$) results, and FDR-corrected p-values.

4. RESULTS

We collected complete responses from 65 participants; 58% ($N = 38$) were CP users. Of users 42% were female ($N = 16$), and of non-users 41% were female. Participants ranged in age from 18–64 years (median 21 years); 89% ($N = 58$) resided in North America, with remaining participants from Europe ($N = 4$), Asia ($N = 2$), and South America ($N = 1$); and 86% ($N = 56$) were students. All CP users used Spotify to engage in CP activities, and Spotify was dominant among this group for other music consumption activities. Non-users were more varied in their choice of platforms (e.g., Apple Music, Pandora).

	Topic	Question	Response	Respondents
Q1	Purposes	What purpose(s) does/might a collaborative playlist serve for you?	Free-text	Users, interested non-users
Q2	Outcomes	Collaborative playlist(s) have/could... (10 statements, e.g., Diversify music library, Require less effort to enjoy music, Influence music taste positively).	Ordinal	Users, all non-users
Q3	Social connection through music	Please select the option that best represents your opinion on the following statements over the past 5 years: (4 statements, e.g., Personally, connecting with others through music has declined).	Ordinal	Users, all non-users
Q4	Importance of music activities with others	How important are these activities to your social relationships? (6 statements, e.g., Listening to recorded music with others, Sharing music with others).	Ordinal	Users, all non-users

Table 1. Survey topics, questions, response types, and respondents.

4.1 Purposes (Q1)

In answering RQ1 and RQ2, we unpacked free-text responses on CP purposes from all users as well as non-users who expressed interest in joining and/or initiating a CP (total $N = 55$).[1] Five main categories emerged from the affinity diagramming analysis (Figure 1): Three categories relating to purpose (Practical, Cognitive, and Social) and two relating to connotation (Utility and Orientation). Every response could be classified under at least one category, and many responses implicated multiple categories (i.e., category membership was not mutually exclusive). The subcategories emerged from our set of responses but are not exhaustive, and therefore may be expanded further.

Responses categorized as **Practical** implicated both the playlist object itself (the *artifact*) and the experience of playlist creation (the *process*). Users cited specific events (e.g., "party" (U21), "road trip" (U3)) or themes (e.g., "workout" (U16), "Christmas music" (U17)) as CP purposes; one non-user response ("serve as an outlet for entertainment" (N8)) suggested CP creation could itself be intrinsically enjoyable. **Cognitive** responses involved learning and discovery, both about music and about others, and thus centered around the user *receiving* information. Here, music discovery responses ranged from broad statements (e.g., "discover new music" (various)) to discovery specifically within or outside of established tastes (e.g., "get exposed to new music within my general musical interest" (N29) versus "finding interesting new music, particularly in genres I'm less familiar with" (U36)). Learning and discovery about others tended to focus on either listening habits or musical preferences of family and friends. **Social** responses reflected purposes directed *outward* from users. Responses around *sharing* ranged from very general (e.g., "share my music" (various)) to sharing with specific others (e.g., "sharing music with friends" (U1), "share music with a significant other" (U45)), and to sharing based on others' preferences (e.g., "allocate all of the songs that we think each other would like to listen to" (U24)). Other Social responses mentioned *bonding* (e.g., "I use it to bond with friends, especially friends who live far away" (U12), "connect to another person through song" (U40)).

In **Utility** responses, CPs are described as a means of reducing *effort* and increasing *efficiency* (e.g., "I don't have to do as much work to create a playlist" (N15), "creator wants help creating the playlist in a shorter deadline" (U19)). **Orientation** refers to delivery of benefits to the *self* or *others* (e.g., "allows me to receive music recommendations" (U31) serves the self, while "a place to allocate all of the songs that we think each other would like to listen to" (U24) connotes benefits to others).

Counts and percentages of responses from each participant group in categories are summarized in Table 2. While a single response could be classified under multiple purposes, the reported percentages still suggest insights into which categories were emphasized by users versus non-users. For example, more CP users tended to report Practical and Social purposes, while a greater percentage of non-users reported Cognitive purposes, as well as Utility and Orientation connotations.

While responses from CP users did not contain significantly more words than those of non-users ($p = 0.25$), they tended to be more diverse. One manifestation of this is in the variety of responses. For example, non-users' statements relating to social events all involved parties, while users also mentioned holidays, road trips, workouts, and dorm events. Users also highlighted ways in which CPs serve other eventual goals (i.e., an intermediary purpose), for example a CP created in preparation for a concert or

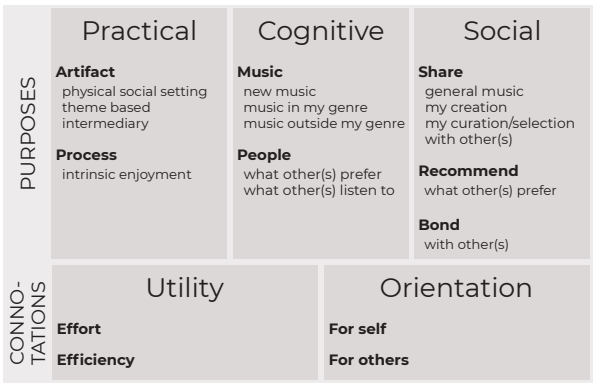

Figure 1. CP Framework: Purposes and Connotations.

[1] Non-user interest was assessed in a previous question. For Q1 we did not request responses from non-users ($N = 10$) who expressed no desire to participate in CPs for personal and/or logistical reasons.

	CP user	CP non-user	Total
Purposes			
Practical	**25 (66%)**	5 (29%)	30 (55%)
Cognitive	12 (32%)	**11 (65%)**	23 (42%)
Social	**25 (66%)**	6 (35%)	31 (56%)
Connotations			
Utility	6 (16%)	**4 (24%)**	10 (18%)
Orientation	23 (61%)	**14 (82%)**	37 (67%)

Table 2. Counts and percentages of user and non-user responses that reference CP purposes and connotations (Q1).

to centralize candidate repertoire for an a cappella group. CP users were also more descriptive and provided more specific use cases (e.g., "we have a playlist called 'Sharing Sundays' that we update weekly with a new song that we've been enjoying that week and then send the group a little message explaining why we chose that song" (U22)). Finally, the most nuanced responses spanning multiple purposes and connotations came from users:

- "A way to share songs and music tastes [Social]—both for the satisfaction of having others enjoy the same music I listen to [Orientation], and to find cool new music my friends share with me that I hadn't heard before [Cognitive]" (U7).
- "I use it to share music and to create larger playlists for team workouts or get-togethers with friends [Practical, Utility]. Oftentimes the playlist is for an upcoming event and whoever creates the playlist wants input from attending people in order to make the music maximally inclusive [Practical, Social]. Sometimes the playlist needs to be a few hours long and the creator wants help creating the playlist in a shorter deadline [Utility]" (U19).
- "Allows friends/ family to put songs on a playlist for everyone to enjoy and listen to [Practical, Orientation] and allows for others to share their music in a closed space with selective people [Social]. Also somewhat acts [as] a bonding experience and allows for people to bond over a mutual interest of music [Social]" (U30).

Furthermore, the frequency of updates could be inferred from the practical function the CP served: CPs for physical social settings and intermediary functions were usually created for one-off scenarios, whereas theme-based function connoted updates throughout the CP usage.

4.2 Outcomes (Q2)

Participant responses on actual (users) or speculative (non-users) CP outcomes were also considered for RQ1 and RQ2. Visualized results of medians and quartiles (Figure 2A) show that responses ranged from slight disagreement to slight agreement for decrease in time and effort to enjoy and manage music, whereas responses tended more toward agreement for "Diversify music library", "Increase ways of music discovery", and "Positively influence music taste". Median calculations across all participant responses show "Somewhat agree" as the dominant answer for most categories except decrease in time and effort to enjoy and manage music as well as "More open to new experiences", for which medians were "Neutral". As the plots suggest, responses between groups for "Decrease time and effort to manage music" (users $>$ non-users), "Increase ways of music discovery" (non-users $>$ users), and "Make listening to music more enjoyable" (users $>$ non-users) differed significantly when calculated independently, but were not significant after FDR correction.

4.3 Social Connection Through Music (Q3)

For RQ3, we found that users and non-users differed in their perception of music's social role (i.e., connecting with others), personally and in general (Figure 2B). Most participants disagreed that connections through music have declined, and agreed that music fosters connection. Users disagreed more strongly than non-users that personal connections through music have declined ($p = 0.03$). As marginally significant findings, users were more likely than non-users to report that music helps them to personally connect with others ($p = 0.05$); and non-users were more likely than users to report that in general, connecting with others through music has declined ($p = 0.08$).

4.4 Importance of Music Activities with Others (Q4)

Also related to addressing RQ3, participants rated the importance of musical activities to their social relationships (Figure 2C). With the exception of "Perform or create music", most responses fell between "Neither" (neutral) and "Very important". Inspection of the plot suggests distributional differences between users and non-users regarding discussing music, experiencing musical events, listening to recorded music, and sharing music with others. Quantitatively, differences between groups were marginally significant for "Listen to recorded music with others" ($p = 0.05$) and "Share music with others" ($p = 0.09$), with users reporting higher importance.

5. DISCUSSION

In this study, we analyzed survey responses from CP users and non-users. Analysis of free-text responses on speculative and actual CP purposes revealed three purposes (Practical, Cognitive, and Social) and two connotations (Utility and Orientation). Analyses of responses on CP usage outcomes, perspectives on social connection through music, and importance of music activities with others revealed similarities and differences between groups.

5.1 Similarities Between Users and Non-Users

Taking a holistic view across questions, we see similarities across participant groups. For example, both users and non-users were represented in each category of purposes and connotations identified from text responses to Q1 (Table 2); likewise, for Q2–Q4, overall patterns of responses were comparable across groups (Figure 2). These similarities could be attributed to non-users' awareness—of benefits and probable outcomes from CP usage—which

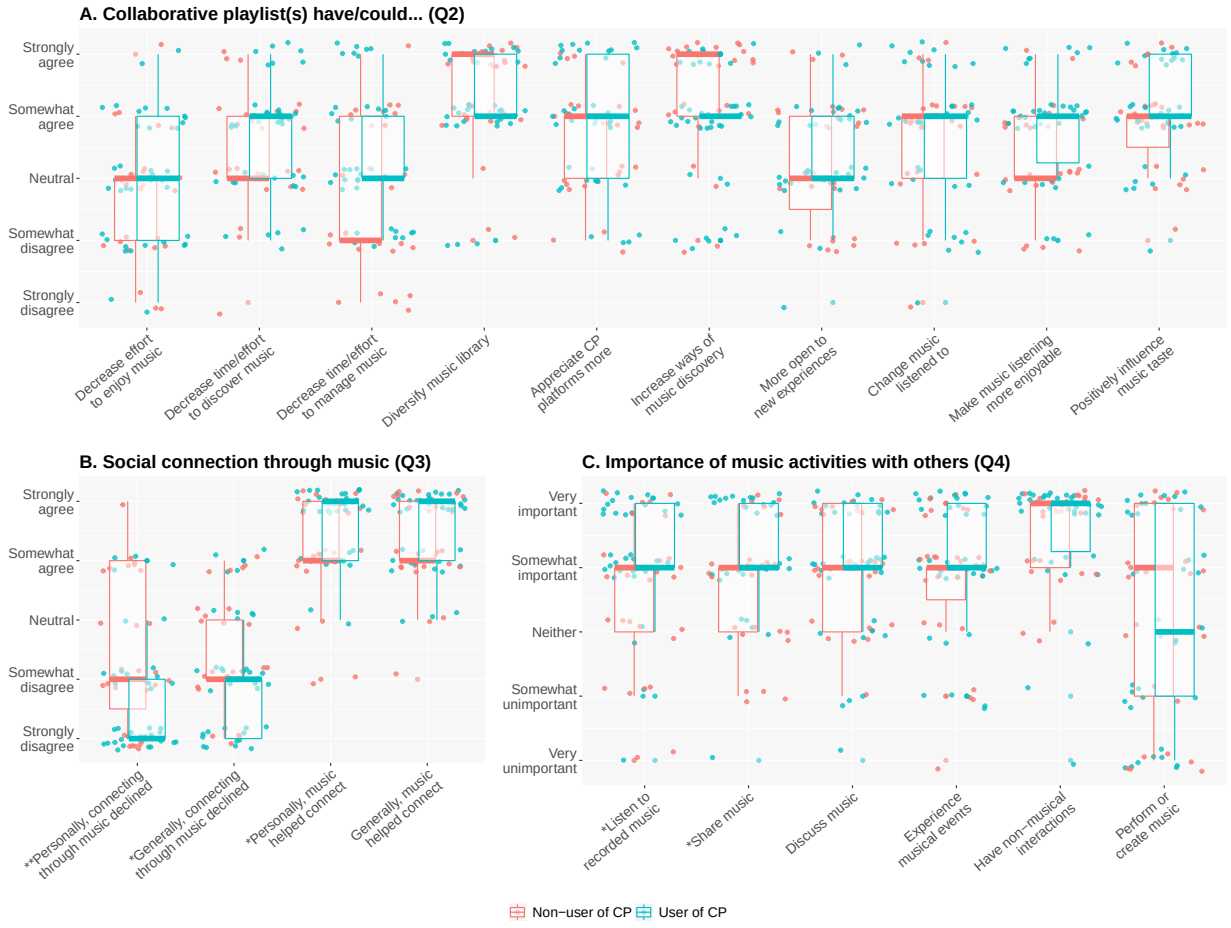

Figure 2. Boxplots of results for Q2–Q4: (A) Speculative and actual outcomes of CP usage (B) Social connection through music over the past 5 years (C) Importance of activities with others to social relationships (*$0.05 \leq p < 0.10$, **$p < 0.05$).

enabled them to be relatively accurate in their perceptions. While there were extreme responses outside the quartiles, most responses on music's social benefits were favorable. As observed in previous studies, we surmise that this was due in part to self-selection of survey participants [20] and recruitment through music-related channels [39].

5.2 Diverging Perspectives on Discovery

We also observed high-level differences between groups. Open-ended responses (Q1) show that a greater percentage of non-users' responses implicated Cognitive purposes (discovery, information seeking). Moreover, discovery was marginally more agreed-upon as a speculated purpose in Q2 by non-users than as an actual purpose by users. We propose several possible interpretations for these findings. One is that non-users might naturally translate discovery benefits offered in music personalization to the social playlist setting, whereas Practical and especially Social purposes are more specific to social music curation. Or, in actual CP usage, discovery is not as easy or actualized as speculated (e.g., if collaboration caters to shared tastes of a group [6, 9]), resulting in lower-than-expected outcomes for music discovery. Another possibility is that lower discovery outcomes for users stem from their CP purposes lying more in Practical and/or Social realms; hence users do not see a marked difference in their ways of discovery. Finally, users may perceive CP purposes or outcomes relative to one another; if Practical or Social purposes turn out to be most rewarding, they may serve as more dominant reasons for engaging in CPs and were thus reported more by users. Regardless of users' lower response to "Increase ways of music discovery", they still report that CPs have diversified and positively influenced their music taste. Therefore, while discovery may not be the prominent purpose for CPs, it is still an outcome.

5.3 Distinct Social Purposes

Compared to non-users, a higher percentage of CP users mentioned Social purposes (Q1). CP users also reported more personal connection through music (Q3) and higher quartiles for importance of music-related social activities (Q4). This might be due to reasons mentioned in §5.2, whereby non-users focus more on Cognitive purposes and users find Social outcomes of CPs more rewarding.

While we cannot attribute causality with certainty, we see that the Social purpose relates to valuing and experiencing connections with others, thereby distinguishing users from non-users. As anticipated, this is the biggest factor distinguishing CPs from personal playlists. This aspect has been reported in previous studies on social music curation, for example on bonding over shared music tastes [31, 34] or in creation and consumption of collabora-

tively curated playlists [8, 35]. Detailed comparisons with personal playlists are provided in §5.4.

Last but not least, the median "Somewhat agree" signal for "Appreciate CP platforms more" corroborates the statement made in prior work that "there is a strong social component to people's experience of and interaction with music, and music services that successfully incorporate such social features are well received" and lead to greater appreciation [29]. Perhaps CP platforms seeking to attract new users could highlight these attributes that were less reported by non-users.

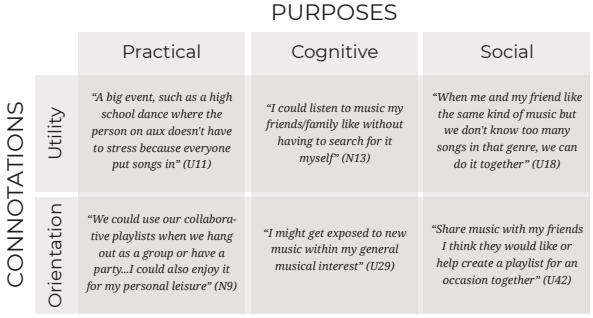

Figure 3. Collaborative Playlist Framework populated with example responses from participants.

5.4 CP Framework and Applications

Our purposes and connotations culminate in a Collaborative Playlist Framework (shown in Figure 3 with participant quotes). The framework co-articulates holistically one's reasons for engaging in CPs. The CP Framework can be applied to all responses in our study, and is also applicable to participant quotes from existing literature on social music. For example, "It would be very handy if you could ask the participants of your party to create the playlist to the party together" [31] expresses Practical purposes of CPs and Utility connotations of convenience.

We find the CP Framework to also be applicable to personal playlists, with Practical and Cognitive purposes and Orientation toward self being dominant. For example, a user from past literature described adding songs identified through Shazam to their Spotify playlist automatically [11], pointing to the discovery purpose. These songs then went into a "maybe playlist" from which the songs, depending on enjoyment, were moved into the "sometimes playlist", "officially [added] to my music collection", or deleted. These point to Practical purposes of personal playlists, also apparent in others' work [21].

We also observed similarities of Practical purposes between personal playlists and CPs. As discussed in §4 the similar contexts emerge from investigation on personal playlists, and in doing so reflect similar levels of detail as in the CP context [21]. Furthermore, we find that the update frequency implied from the playlist (artifact) type is consistent between personal and social playlists [1, 20, 21].

Just as one can have many reasons for engaging in an activity, CPs can be created with multiple purposes and connotations. These can evolve within and across the dimensions we have articulated, and can also facilitate one another. For example, suppose a group of friends decides to share the effort of creating a CP to play at a party [Utility, Practical]. The act of creating the CP provides an opportunity for social bonding [Social]. Collective consumption of the playlist at the party enables sharing and discovery [Social, Cognitive], ultimately bringing about further bonding [Social]. Facilitation can also occur within-category. While CPs may be created to fulfill a particular function for an event [Practical-artifact], the process itself of selecting music for a CP can be an intrinsically enjoyable activity [Practical-process], a phenomenon that has been reported in previous research [28, 34]. At times, sharing and suggesting music [Social-share/recommend] can in fact bring about the separate purpose of bonding [Social-bond]. We also already have hints of "with whom" participants (expect to) engage in CPs. Some create CPs with these personal connections in mind, while others might create CPs based on or in search of shared musical tastes [31]. Text responses indicate that such ensuing purposes, however, are not always sought by participants.

We acknowledge some shortcomings in the present work. A larger sample size could improve interpretability of results and also provide further insights into CP usage. In addition, by grouping responses based solely on CP usage, we may be overlooking valuable insights relating to other demographic factors; a larger sample size will help here as well. Finally, there are many other facets (e.g., ownership, group dynamics) through which this topic can be approached, and we are continuing our work through identification of CP usage patterns.

6. CONCLUSION AND FUTURE WORK

Our findings indicate that CPs have distinct purposes and outcomes (RQ1); non-users' speculation of CP usage outcomes do not differ greatly from actual user outcomes (RQ2); and differences in music perceptions, values, and habits exist between the groups (RQ3). These discoveries have direct implications for CPs, which are increasingly integrated into music consumption platforms. They are indicative of why users engage with CPs and what they gain from doing so. Consumption platforms may choose to heighten or make more conspicuous the features from which users derive the greatest benefits and be informed of other music-related activities to be integrated.

We continue to collect data and unpack the larger survey results to identify platform usage patterns of users and non-users. For CP users specifically, we analyze their survey responses and conduct semi-structured interviews to gain a nuanced understanding of their personal experiences and interactions with CPs. Our findings were predominantly based upon users in North America; we envision carrying out this study in other countries as well to examine cross-cultural perspectives. We will also be able to verify the validity of our CP Framework in other contexts and across time. Finally, informed by our findings, we aim to derive design implications for the kind of collaborative interfaces that users desire.

7. ACKNOWLEDGMENTS

We thank Jonathan Berger, Stanford's Music Engagement Research Initiative, and Stanford's Center for Design Research for helpful feedback and contributions.

ABSTRACT

We present a framework based on neural networks to extract music scores directly from polyphonic audio in an end-to-end fashion. Most previous Automatic Music Transcription (AMT) methods seek a piano-roll representation of the pitches, that can be further transformed into a score by incorporating tempo estimation, beat tracking, key estimation or rhythm quantization. Unlike these methods, our approach generates music notation directly from the input audio in a single stage. For this, we use a Convolutional Recurrent Neural Network (CRNN) with Connectionist Temporal Classification (CTC) loss function which does not require annotated alignments of audio frames with the score rhythmic information. We trained our model using as input Haydn, Mozart, and Beethoven string quartets and Bach chorales synthesized with different tempos and expressive performances. The output is a textual representation of four-voice music scores based on **kern format. Although the proposed approach is evaluated in a simplified scenario, results show that this model can learn to transcribe scores directly from audio signals, opening a promising avenue towards complete AMT.

1. INTRODUCTION

Automatic music transcription (AMT) aims to convert acoustic music signals into any sort of music notation. Most of the music we listen today is polyphonic, where simultaneous sound events produced by different audio sources (i.e., instruments) are combined in a single acoustic waveform. This aggregation process entails loss of information, making the transcription task very challenging even for trained musicians. Moreover, the different sound events are highly correlated in time and frequency due to the rhythmic and harmonic patterns usually found in music, which complicates sound separation even further as we cannot rely on the statistical independence of the source signals. Therefore, in order to produce a proper music score from an audio signal, multiple complex sub-tasks must be involved such as multi-pitch estimation, note onset/offset detection, source separation, as well as other musical context information retrieval tasks like metering and tonality estimation.

As pointed out by [2], there are many approaches to tackle AMT, yet most works focus on solving only one intermediate goal of the whole problem. Frame-level transcription, also known as multi-pitch estimation, aims to detect which fundamental frequencies are present at each time step of the input signal. Note-level transcription goes a step further by estimating the notes characterized by their pitch and clock-time duration (onset and offset times), producing a piano-roll representation of the music. Stream-level transcription extends the note-level approach by associating each note with its originating instrument based on its timbre. Lastly, the notation-level transcription is the final goal of AMT, aiming to produce a music score with enough information to interpret the original recording.

In this work, we denote the notation-level transcription as Audio-to-Score (A2S) task, where the audio signal is processed to be converted into a symbolic music score. Even with a perfect transcription, the output of any A2S system cannot faithfully represent the music that was originally played. It must be considered that musical audio signals are often expressive performances, rather than simple mechanical translations of notes read from a staff. A particular score can be performed by a musician in many different ways, and similarly there are several ways to represent the same musical excerpt with standard music notation (e.g., a dotted half note is "the same" as a half note tied to a quarter note). Music scores can only be seen as guides to aid musicians, highly correlating but never fully explaining musical experience. This makes A2S a rather ill-defined problem without unique solutions.

Despite the above, our work aims to demonstrate that the A2S task can be performed in a single step. To this end, we make use of a deep neural network that is trained in an end-to-end fashion to produce a sequence of musical symbols that describes a feasible polyphonic score out of the input audio. Our experiments are conducted using Haydn, Mozart, and Beethoven string quartets and Bach chorales synthesized with different tempos and expressive performances. [1] Although the analysis of the current performance requires a deeper reasoning regarding evaluation

[1] The source code and data are available at https://github.com/mangelroman/audio2score.

metrics, we provide some results that account for the good performance of the proposed model and allow us to be optimistic about this line of research.

1.1 Related Work

There are recent AMT approaches using deep neural networks for the multi-pitch detection task [8, 11, 12]. For this, Short-Term Fourier Transform (STFT), log-frequency STFT or Mel spectrograms are usually fed to Convolutional Neural Networks (CNN) to extract piano-roll representations as output. Other works focus on producing music scores from unquantized MIDI representation [4].

One of the few methods aiming to extract a complete score directly from audio is that of [14]. In this work, a multi-pitch detection method with note tracking is used to get a piano-roll representation that is further converted into a quantized MIDI file by using a rhythm quantization method [15]. Afterwards, a score typesetting software such as MuseScore can be used to get a MusicXML file from the MIDI output.

To the best of our knowledge, there are only two approaches that perform A2S in a single stage, directly converting the input audio into any music notation format. This has the advantage that a wrong detection in a given stage (such as the multi-pitch detection) is not propagated through the next processing stages, avoiding error cascading. The only works addressing notation-level AMT in an end-to-end manner are those of [3] and [17]. Both works follow a supervised learning approach with deep neural networks to solve the AMT task in one step. Although they bring promising results, the proposed models include several limitations (e.g. monophonic audio in [17] and fixed input length in [3]) that cannot be disregarded when addressing the notation-level AMT problem as a whole.

In [3], authors show how a Convolutional-Recurrent Neural Network architecture (CRNN) [19] can learn all the basic tasks involved in notation-level AMT, but it is only a very limited proof of concept that cannot address most of the possible scores. In the second of these works [17], the AMT problem was addressed as an Automatic Speech Recognition (ASR) problem. By using monophonic audio as input and a sequence of symbols (analogously to the written language characters) as output, several methods that were originally developed for ASR can be used. In particular, [17] adopted an architecture inspired in DeepSpeech2 [1], which learns to map audio frames to a sequence of characters without any alignment.

Training with unaligned data, i.e. without needing the input audio frames to be aligned with the music symbols, is a clear advantage as much more data can be gathered without going through the tedious task of manually annotating the location of the output symbols in their corresponding input audio frames. Nevertheless, monophonic audio transcription does not exhibit the essential challenge coming from simultaneous sound events. The present work goes one step beyond by showing that a similar formulation can also be reliable for polyphonic music.

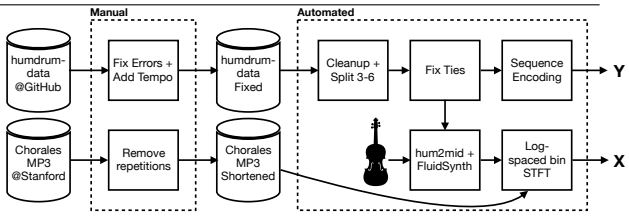

Figure 1: Data acquisition pipeline showing the manual and automated steps required to build the ground truth.

2. DATA

Our notation-level AMT approach, namely A2S, seeks to estimate which music score, modeled as a structure containing symbols from a fixed alphabet of music notation, would likely define that audio.

Let $\mathcal{X}$ be the domain of audio files and Σ the alphabet of music score symbols. The aim of our A2S is to compute a function that maps any audio file into a sequence of symbols, i.e., a function $f : \mathcal{X} \rightarrow \Sigma^*$.

2.1 Input Representation

The input representation of our model is the spectral information of the raw audio waveform over time, based on the STFT with log-spaced bins and log-scaled magnitude. In this type of spectrogram, frequency bins are aligned with equal-tempered music scales using 440Hz as the reference for A4 pitch. The sampling rate of the input audio files was 22,050Hz, and STFT was calculated with a Hamming window with size 92.88ms (2048 samples) and a hop of 23.22ms (512 samples). Only frequencies between pitches C2 and C7 were considered, extracting 48 bins per octave.

2.2 Output Representation

The output music notation of our model is a single sequence of symbols that can be used to render a multi-part western music score. These symbols represent both notes and rests with their corresponding duration, barlines, ties between notes, and fermatas. It is important to remark that in the context of the A2S task, notes are not the same as pitches. For example, pitch 349.23Hz can be represented as F4, E♯4 or G♭♭4 depending on the key signature.

We are not including clefs in our output representation, as they are only intended to aid in the score visualization and do not carry any musical information we can extract from the audio. For the sake of simplicity, we are also not including time signatures in the output sequences assuming they can be inferred from the predicted barlines for the type of scores in our training set. By the same rationale, key signatures are neither included assuming they can also be inferred from the predicted notes. Moreover, since most of our samples are made of fragments of much longer scores, they may not carry enough information to predict the correct key signature, therefore misleading the training process. Other music notation symbols such as slurs, grace notes, ornaments, and articulations marks are also left out of the scope of this work.

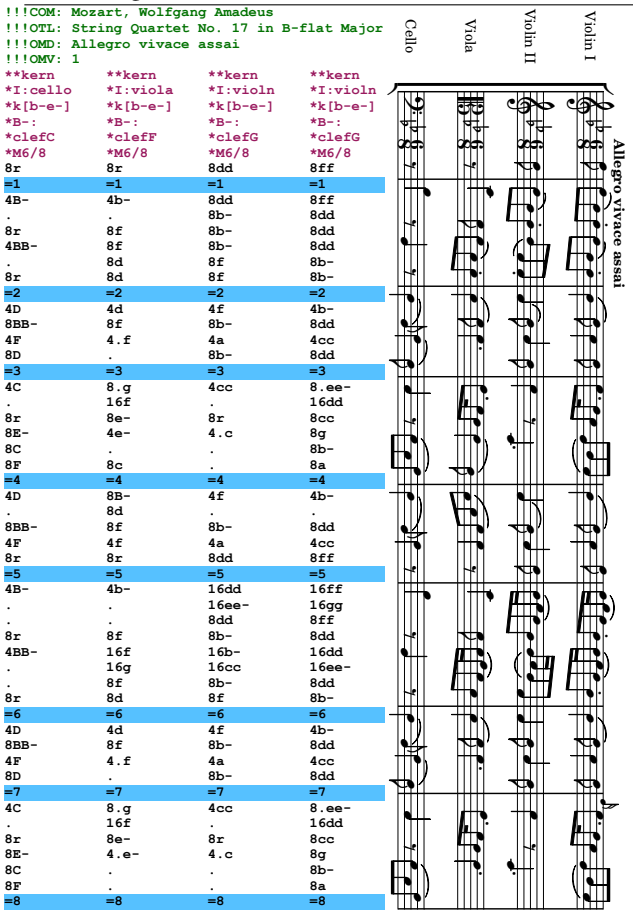

Figure 2: Example of one score in **kern format (left) representing the output of our model and the rendered western music score (right).

2.3 Data Preparation

As previously mentioned, the fact that we do not require data alignments is a clear advantage to easily build the ground truth needed to train our model. However, the majority of scores available in the public domain are usually in printed form, so we cannot automatically obtain the symbolic representation we need unless we make use of an Optical Music Recognition system. A lot of progress has been made in this area of study but unfortunately it is still insufficient to meet our precision needs, driving us to look for existing text based scores instead. After some analysis of the various types of music encoding formats within reach, we chose the humdrum toolkit [9] due to its versatility to represent polyphonic music.

The humdrum file format is a general-purpose human-readable 2D representation of music information intended to assist music researchers. The columns of the text file, separated by the tab character, represent the sources of information that produce music-related events. The lines of the text file represent the evolution of those events over time. The humdrum syntax defines the skeleton that contains other higher level schemes of music notation, like the **kern format our ground truth is based on. The **kern format is designed to encode the semantics of a western musical score, rather than the visual aspects of its printed

	Chorales	**Quartets**
Number of samples	352	34,512
Total duration	5.79h	20.25h
Max duration	120s	30s
Data Augmentation	No	Yes
Polyphony voices	4	4
Instruments	Pipe organ	Cello Viola Violin Flute
Pitch range	C2-A5	C2-E7
Shortest note	$1/16^{th}$	$1/64^{th}$
Irregular groups	None	Triplets
Tempo	♩ $\approx [60, 70]$	♩ $= [40, 200]$
Vocabulary Size	99	143
Train-test split %	80/20	70/30
Batch size	4	16

Table 1: Summary of the datasets' characteristics.

realization, matching nicely with the purpose of this work.

An example of a music excerpt encoded in **kern notation is shown in Figure 2 along with its associated sheet music excerpt. In this format, columns are called spines and they are associated with instruments, just like a pentagram in western sheet music. Spines may contain one single sound event or the combination of various sound events with the same canonical duration, namely a chord. Spines can also be split into two spines when two independent voices (excluding chords) occur for the same instrument. The newly created spine can be rejoined back to the original spine when the extra voice is no longer needed. This level of flexibility gives almost no restrictions to the kind of music it can support, making **kern a good candidate to endure future work.

We created two datasets out of the **kern files available in the humdrum-data repository [18]: the chorales dataset, containing 370 chorales of Bach, and the quartets dataset, containing most of the string quartets of Haydn, Mozart and Beethoven. In the chorales dataset we take each chorale as one training sample, and we use audio from expressive MIDI files synthesized with a high quality pipe organ soundfont [7]. As we did not synthesize the audio, we had to manually remove repetitions to ensure that samples are not unnecessarily long. In the quartets dataset we randomly split the scores in fragments of 3-6 measures each, and we synthesized the corresponding MIDI file obtained from the hum2mid tool, which converts **kern to MIDI using dynamic spines and articulation marks when available in the original **kern file. We removed grace notes and ornaments from the score as they cannot be properly synthesized. We also removed split spines and upper notes of all chords to ensure no more than 4 simultaneous voices were present at any given time. Samples with double dots, double sharps or double flats are out of the scope of this work and therefore discarded. On the training set only, we allow overlapping of fragments as a means of data augmentation technique. Table 1 summarizes the main characteristics of both datasets used in this work.

Figure 1 depicts the data acquisition pipeline we implemented to build our ground truth. The major inconvenience

Largo Assai	40	Allegro Moderato	120
Largo	50	Poco Allegro	124
Poco Largo	60	Allegro	130

Andante	92	Vivace	150
Andantino	100	Allegro Vivace	160
Menuetto	112	Allegro Vivace Assai	170
Moderato	114	Poco Presto	180
Poco Allegretto	116	Presto	186
Allegretto	118	Presto Assai	200

Table 2: List of metronome markings chosen for classical music tempo annotations, given in number of quarter notes per minute.

was dealing with multiple errors present in the **kern files, such as invalid ties, wrong canonical duration of notes and rests, and missing metronome markings. While these errors do not prevent musical analysis of the scores, they become noisy labels that hinder our training process. For that reason, we had to revise all the scores manually to correct these errors and label the missing metronome markings, with the help of existing tempo annotations and the conversion shown in Table 2. Adding metronome markings ensured the synthesized audio perform at reasonable speeds according to the composer's intention. Additionally, a random scaling factor in the $\pm 6\%$ range was applied to each metronome marking to ensure tempo variability in all training samples.

The resulting **kern scores after the preprocessing stage were then encoded in a special symbolic notation intended to reduce the number of characters and ease the training process. Accordingly, each canonical duration for notes and rests including their dotted version were encoded with just one symbol of the vocabulary. Likewise, note pitches were also encoded with one symbol condensing name and octave. In our **kern dataset, barlines are always repeated for all spines, so only one barline is maintained in the output representation referring to all spines. The rest of characters are preserved in the output representation in the same way, i.e. tabs, new lines, tie symbols, fermatas and the "dot" character, which indicates that the previous note/rest still affects the current row.

3. METHOD

Once the input and output representations are defined, we can formulate the A2S task as retrieving the most likely sequence of score symbols $\hat{\mathbf{s}}$ given an audio file $\mathbf{x} \in \mathcal{X}$:

$$\hat{\mathbf{s}} = \arg\max_{\mathbf{s} \in \Sigma^*} P(\mathbf{s}|\mathbf{x}) \tag{1}$$

where Σ represents the set of characters necessary to encode the output as explained in the previous section (for instance, including "tab", "new-line" and "dot", among others). Additionally, Σ includes an *"empty"* symbol, denoted by ϵ, that is necessary to separate two or more instances of the same symbol that occur in consecutive frames.

Following successful approaches in other pattern recognition duties of similar formulation, we address this A2S with a holistic approach based on statistical models. Specifically, for learning the posterior probability provided in Eq. 1, we resort to Convolutional Recurrent Neural Networks (CRNN).

A CRNN is composed of one block of *convolutional* layers followed by another block of *recurrent* layers [19]. The convolutional block is in charge of learning how to extract relevant features from the input and the recurrent layers interpret these features in terms of sequences of musical symbols. The activations in the last convolutional layer can be seen as a sequence of feature vectors representing the input audio file, $\mathbf{x}$. Let W be the width (number of frames) of the input sequence $\mathbf{x}$. The length of the resulting features after the convolutional layer will be $L = \gamma W$, where $\gamma \leq 1$ is implicitly defined by the specific configuration of the convolutional block (which usually includes some type of down-sampling to reduce dimensionality).

The output activations of the convolutional block are then fed to the first layer of the recurrent block, and the activations of its last layer can be considered proper estimates of the posterior probabilities per frame:

$$P(\sigma \mid \mathbf{x}, j), \;\; 1 \leq l \leq L, \;\; \sigma \in \Sigma \tag{2}$$

3.1 Training

Convolutional neural networks can be trained through gradient descent using the well-known *Back Propagation* algorithm. RNN networks can be trained similarly by means of *Back Propagation Through Time* [21]. Therefore both the convolutional and recurrent blocks of a CRNN can be jointly trained by providing audio files annotated at the frame level.

In this work, however, we follow a holistic or "end-to-end" approach, which means that for each audio file we only provide its corresponding target transcript into score symbols, without any kind of explicit information about its segmentation into frames. A CRNN can be uniformly trained without this information by using the so-called Connectionist Temporal Classification (CTC) loss function [6]. The CTC training procedure is a form of Expectation-Maximization, similar to the backward-forward algorithm used for HMM training [16], that distributes the loss among all the frames to maximize Eq. 1 with respect to the ground-truth sequence.

3.2 Decoding

In order to solve Eq. 1, the most likely symbol is computed for each input feature vector of the recurrent block l, also referred as greedy decoding:

$$\hat{\sigma}_l \;=\; \arg\max_{\sigma \in \Sigma} P(\sigma \mid \mathbf{x}, l), \;\; 1 \leq l \leq L \tag{3}$$

Then, a pseudo-optimal sequence of musical symbols is obtained as $\hat{\mathbf{s}} \approx \mathcal{D}(\hat{\sigma})$, where $\hat{\sigma} = \hat{\sigma}_1 \dots \hat{\sigma}_L$ and $\mathcal{D} : \Sigma^\star \rightarrow \Sigma^\star$ is a function which first merges all the consecutive frames with equal symbol, and then deletes all "empty" symbols [6].

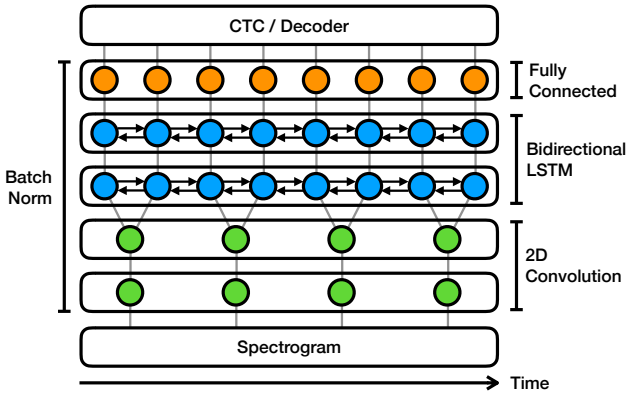

Figure 3: High-level architecture of the Convolutional-Recurrent Neural Network used in our experiments.

3.3 Architecture

The main building blocks of the CRNN considered for our experiments is illustrated in Figure 3.

The first two convolutional layers receive a 2D array containing the audio spectrogram described in section 2.1 and apply 16 filters of 3×3 with a stride of 2 in the frequency axis. We use filter striding to reduce the input dimensionality without the need of pooling layers.

For the Quartets dataset, output frames from the convolutional block are split in half, effectively doubling the number of frames feeding the next recurrent block. This is necessary to comply with the CTC loss function precondition for which the number of input frames must be greater or equal to the number of output symbols. Considering the high number of symbols per second in our sequence-based representation of a polyphonic score of the Quartets dataset, we apply this frame doubling technique at a lesser computational cost than increasing the density of the input spectogram.

The next two recurrent layers are based on Bidirectional Long Short-Term Memory (LSTM) cells, with 1024 hidden units each. The fully connected layer at the end of the recurrent block converts the output per-frame predictions to the size of the output representation vocabulary.

With the purpose of reducing overfitting, Batch Normalization layers [10] are added between any other layer excluding the input and output layers, as well as Dropout layers [20] added after all the convolutional layers and after the last recurrent layer, with a drop probability of 0.1 for the Quartets dataset and 0.2 for the Chorales dataset. A higher drop probability is required for the Chorales dataset since less data is available for training, which increases the risk of overfitting.

4. EXPERIMENTS

To the best of our knowledge, there are few specific evaluation metrics to measure the performance of a notation-level AMT method. In [14] an evaluation metric for note-level AMT is discussed, but it still cannot be directly applied to our task (e.g. we do not have note onsets and offsets). [17] adapts this metric to the A2S task by defining note duration errors instead of onsets/offsets errors. However, we believe this metric is still insufficient to properly evaluate a notation-level AMT method since, for instance, it does not take into account barlines and their effect in subsequent predictions of note durations and ties. The MV2H metric (Multi-pitch detection, Voice separation, Metrical alignment, note Value detection, and Harmonic analysis) was introduced in [13]. This metric is closer to our needs, although its source code uses timing information in seconds that is not provided by our method. We leave it as an open point for future work to establish a proper notation-level AMT metric.

In order to validate our method accuracy during training, we adopt the evaluation metrics from the ASR task as in [17], namely Word Error Rate (WER) and Character Error Rate (CER). They are defined as the number of elementary editing operations (insertion, deletion, or substitution) needed to convert the predicted sequences into the ground-truth sequences, at the word and character level respectively. Even though WER and CER are not specific to AMT, they provide a good indication of how close our score is to the ground-truth score.

In the context of our A2S task, we define words as any group of characters representing notes (including ties), rests and barlines in the output score. The "tab" and "new line" characters act as word separators, and only contribute to the CER calculation.

4.1 Training process

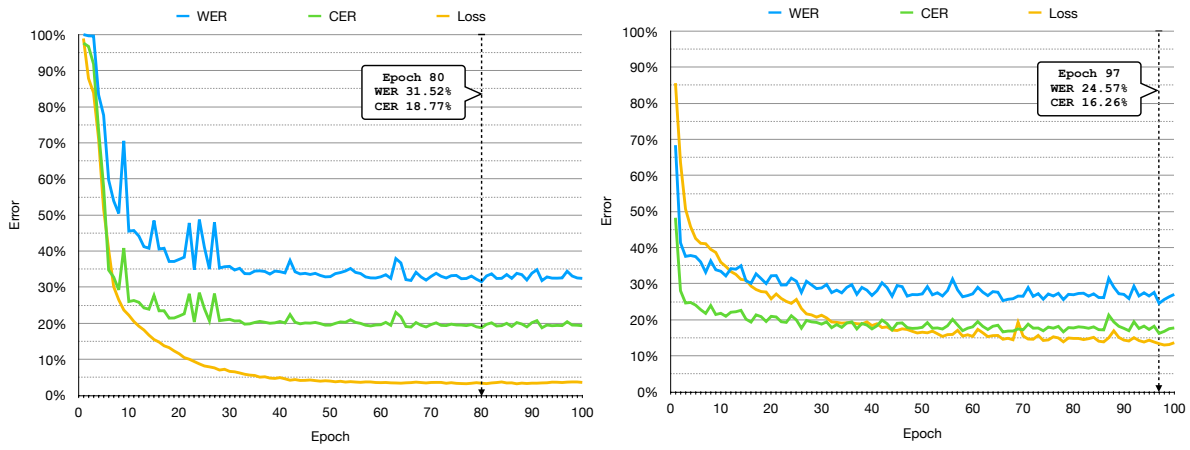
The models were trained for 100 epochs using mini-batch Stochastic Gradient Descent (SGD) optimizer, with Nesterov momentum of 0.9. Our learning rate scheduling consists of 2 cycles of 50 epochs each, starting at 0.0003 and annealing by 1.1 at every epoch. After each epoch, the WER and CER are calculated for the validation set, and the model with the lowest WER is appointed as the best model for testing purposes.

The Chorales dataset, whose samples are full-length chorales, is trained with a batch size of 4. The Quartets dataset, whose samples are small excerpts extracted from the full-length quartets, is trained with a batch size of 16. Figure 4 shows the evolution of the CTC loss, WER and CER at training time on both datasets. Each figure also highlights the epoch where the best model was obtained.

4.2 Results

The best model obtained after the training process is then evaluated against the test set for both the Chorales and Quartets datasets, giving a WER of 30.96% and CER of 18.10% for Chorales, and WER of 21.02% and CER of 13.53% for Quartets.

After analyzing all test predictions, we observe that the model occasionally generates sequences that do not comply with the **kern format. Nevertheless, we believe these formatting errors can be solved by providing more samples to the training set or imposing syntax constraints. As shown in Figure 5, most of the errors arise from wrongly



(a) Chorales dataset.

(b) Quartets dataset.

Figure 4: Evolution of loss, validation WER and CER during 100 epochs of training with a) Chorales dataset and b) Quartets dataset. Chorales WER is 30.96% and CER is 18.10%. Quartets WER is 18.10% and CER is 13.53%.

estimated note durations and barlines. Exchanging notes between voices is another common mistake our model makes, specially when voice pitches are too close or even when two voices cross their melodic lines.

The model struggles at predicting ties and triplets, which requires further analysis to determine whether it is related to barline errors, to the output representation format based on **kern, or to the lack of enough samples in the training set (i.e., ties and triplets are very infrequent in our training data compared to other symbols).

5. CONCLUSIONS

In this work, we focus on the A2S task, a hardly explored formulation consisting of extracting a full score from an audio file. Note that A2S resembles what a human would expect to get if it intends to visualize the input audio as a music score (e.g., MusicXML), unlike what most authors consider AMT where the output sequence format is intended to be further processed by a computer (e.g., MIDI).

The proposed methodology which performs the A2S task has the following advantages over other AMT methods: 1) Frame-level alignment of the ground truth is not needed; 2) The end-to-end approach avoids propagating errors from one stage to the other; 3) The output of our model is based on **kern format and can be straightforwardly translated to a valid music score.

We are aware this simplified scenario used for evaluation does not include real audio and some score symbols, but we argue the results provide the basis to open a new path of research towards notation-level AMT.

One of the main limitations of the proposed approach is the maximum-length of input sequences due to memory constraints. For example, this prevents an end-to-end training with complete songs, only allowing fragments of 2 minutes at a maximum on a typical training infrastructure. For this, we plan in a future work to explore other architectures such as the Transformer XL [5], a sequence-to-sequence model that can deal with much longer sequences. Other future works include defining an evaluation metric for A2S and building a dataset from real audio to validate the approach with actual music performances.

GENERALIZED METRICS FOR SINGLE-F0 ESTIMATION EVALUATION

Rachel Bittner*, Juan J. Bosch*

*Equal contribution

ABSTRACT

Single-f_0 estimation methods, including pitch trackers and melody estimators, have historically been evaluated using a set of common metrics which score estimates frame-wise in terms of pitch and *voicing* accuracy. "Voicing" refers to whether or not a pitch is active, and has historically been regarded as a *binary* value. However, this has limitations because it is often ambiguous whether a pitch is present or absent, making a binary choice difficult for humans and algorithms alike. For example, when a source fades out or reverberates, the exact point where the pitch is no longer present is unclear. Many single-f_0 estimation algorithms select a threshold for when a pitch is active or not, and different choices of threshold drastically affect the results of standard metrics. In this paper, we present a refinement on the existing single-f_0 metrics, by allowing the estimated voicing to be represented as a continuous likelihood, and introducing a weighting on frame level pitch accuracy, which considers the energy of the source producing the f_0 relative to the energy of the rest of the signal. We compare these metrics experimentally with the previous metrics using a number of algorithms and datasets and discuss the fundamental differences. We show that, compared to the previous metrics, our proposed metrics allow threshold-independent algorithm comparisons.

1. INTRODUCTION

Single-f_0 estimation algorithms, including pitch trackers and melody or bass extraction algorithms, predict fundamental frequency (f_0) over time for an audio file. However, there can be time intervals where there is no (target) f_0 value present, for example during silent regions. To account for this, single-f_0 estimation methods additionally estimate the *voicing* over time - i.e. when a given frame contains an active pitch or not. Choosing when the estimated voicing should be active/voiced (1) or inactive/unvoiced (0) often involves choosing a threshold on a confidence value. Single-f_0 estimation algorithms are evaluated by comparing the accuracy of the estimated f_0 and voicing sequence against a reference f_0 and voicing sequence. The choice of threshold to estimate voicing has a critical effect on the resulting metrics; the threshold is often treated as a hyperparameter and is chosen on a validation set. Any confidence information used to determine voicing is discarded and not considered in the evaluation metrics.

The perceptual salience of a pitch is affected by a number of factors, including the volume, the frequency content, the duration and the presence of interference from other sources [12, 18, 21, 27]. In some cases, the brain can perceive a pitch even when the f_0 is not physically present, for example when one short time segment in the middle of a longer pitch sequence is set to be silent [9]. The effect of these factors can be different for each listener, making the task of "objectively" determining if a pitch is present or not a difficult one. Additionally, in polyphonic mixtures, a pitch can be masked by other sources. In the current metrics, algorithms are equally penalized for mistakes on salient and non-salient f_0 values.

We propose a generalization of the existing metrics which (1) allows an algorithm to report voicing as a continuous value (between 0 and 1), and (2) allows frames to be weighted by a reward, which more heavily penalizes mistakes in frames where the energy of the source producing the f_0 is high compared to the rest. These changes remove the need for making a strict decision on whether or not a pitch is present, allowing threshold-independent algorithm comparisons, and allow an optional weighting to be added to reflect frame importance. We also show that when the provided voicing is binary, the proposed metrics are equivalent to the existing metrics. The proposed metrics are to be seen as complementary to the classic ones, which remain useful for measuring performance for applications where a binary threshold is needed in practice. However, binary thresholds are not needed for a number of applications, including pitch informed source separation or melodic similarity.

Additionally, generalized metrics would also help mitigate non-uniformity in decisions made when annotating datasets (e.g. inclusion of delays and reverb as part of the annotation or not), by rewarding correct pitch estimations proportionally to the energy of the pitched signal to be detected. Furthermore, they provide information about the confidence of the estimators, which is useful for many applications.

For reproducibility, the code used for this in this paper is available online [1].

2. VOICING DETERMINATION

Historically, single-f_0 estimation methods need to determine whether a given frame contains a pitch or not. To perform this binary decision, algorithms have commonly used a (static or dynamic) threshold on e.g. energy, salience or pitch likelihood [1, 3, 13–15, 23]. For instance, melody extraction algorithms may exploit pitch contour salience distributions and use heuristics [24], or a threshold on melody contour probabilities produced by a discriminative model [4, 7]. Durrieu et al. [14] first perform source separation on the melodic source, and subsequently estimate the energy of the separated signal frame by frame; frames with energy above a threshold are determined to be voiced. The threshold is empirically selected such that 99.95% of the leading instrument energy is contained in voiced frames. Fuentes et al. [15] also use an energy threshold (of -12dB) on a low-pass filtered separated melody signal. The ideal threshold typically depends on the difference in intensity between melody and accompaniment.

Some methods bypass the use of an explicit threshold and deal with voicing estimation using a classifier, for instance by adding an "unvoiced" class to the set of possible pitch outputs [2]. Other approaches model singing voice detection separately from pitch estimation, and even try to exploit information from neighboring frames (e.g. with LSTMs) for making a decision on the presence of melody on a given frame [17, 23]. Finally, some of the state of the art algorithms provide a measure of confidence on their estimations. However, traditional evaluation metrics do not consider this information.

3. CLASSIC EVALUATION METRICS

Pitch estimation methods have commonly been evaluated using metrics derived from information retrieval, commonly focused on pitch-related accuracy and seldom consider voicing [11, 16]. Melody extraction algorithms are evaluated using similar metrics to pitch estimation, but voicing also takes an important role.

Symbol	Description
n	sample index $\in \{0, \ldots, N-1\}$
f_n	reference frequency (Hz) at sample n
v_n	reference voicing $\in \{0, 1\}$ at sample n
r_n	pitch estimation reward $\in [0, 1]$ at sample n
$\hat{f}_n$	estimate frequency (Hz) at sample n
$\hat{v}_n$	estimate voicing $\in [0, 1]$ at sample n

Table 1. Definition of symbols.

For melody estimation in particular, several metrics are commonly used in the literature [22, 26]. Raw Pitch Accuracy (RPA) and Raw Chroma Accuracy (RCA) measure pitch-related estimation quality. Let the reference and estimate f_0 and voicing sequences be defined as in Table 1. RPA measures the percentage of melody frames in the reference for which the estimated pitch is considered correct (usually within half a semitone of the reference). RCA also measures pitch accuracy, but both estimated and reference pitches are mapped into one octave, forgiving octave mistakes.

$$\mathtt{RPA} = \frac{\sum_{n=0}^{N-1} v_n \mathcal{T}_{\hat{f}_n, f_n}}{\sum_{n=0}^{N-1} v_n}, \; \mathtt{RCA} = \frac{\sum_{n=0}^{N-1} v_n \mathcal{O}_{\hat{f}_n, f_n}}{\sum_{n=0}^{N-1} v_n} \tag{1}$$

where the "correct pitch" indicator function is defined as:

$$\mathcal{T}_{\hat{f}_n, f_n} = \begin{cases} 1 & |d_s(\hat{f}_n, f_n)| \leq 0.5 \\ 0 & |d_s(\hat{f}_n, f_n)| > 0.5 \end{cases} \tag{2}$$

and the difference d_s between two frequency values in semitones is defined as:

$$d_s(\hat{f}_n, f_n) = 12 \log_2 \left(\frac{\hat{f}_n}{f_n} \right) \tag{3}$$

Similarly, the "correct chroma" indicator function is defined as:

$$\mathcal{O}_{\hat{f}_n, f_n} = \begin{cases} 1 & |d_o(\hat{f}_n, f_n)| \leq 0.5 \\ 0 & |d_o(\hat{f}_n, f_n)| > 0.5 \end{cases} \tag{4}$$

and the single-octave pitch difference d_o is defined as:

$$d_o(\hat{f}_n, f_n) = d_s(\hat{f}_n, f_n) - 12 \left\lfloor \frac{d_s(\hat{f}_n, f_n)}{12} + 0.5 \right\rfloor \tag{5}$$

Voicing estimation is evaluated with Voicing Recall rate (VR) and Voicing False Alarm rate (VFA). VR measures the percentage of frames labeled as voiced in the reference which are also estimated as voiced by the algorithm. On the other hand, VFA measures the percentage of frames labeled as un-pitched in the reference that are mistakenly estimated as melody frames by the algorithm.

$$\mathtt{VR} = \frac{\sum_{n=0}^{N-1} \hat{v}_n v_n}{\sum_{n=0}^{N-1} v_n}, \; \mathtt{VFA} = \frac{\sum_{n=0}^{N-1} \hat{v}_n (1 - v_n)}{\sum_{n=0}^{N-1} (1 - v_n)} \tag{6}$$

Finally, Overall Accuracy (OA) is used as a single aggregate measure to evaluate algorithms, as it accounts for both pitch and voicing estimation accuracy. In particular, OA measures the percentage of frames that were correctly labeled in terms of both pitch and voicing.

$$\mathtt{OA} = \frac{1}{N} \sum_{n=0}^{N-1} v_n \hat{v}_n \mathcal{T}_{\hat{f}_n, f_n} + (1 - v_n)(1 - \hat{v}_n) \tag{7}$$

In order to allow each of the metrics to give insights about different aspects of methods, the traditional evaluation methodology allows algorithms to report "negative" pitch values, which are only considered for the computation of RPA and RCA. This was an attempt to evaluate voicing estimation performance separately from pitch estimation performance, and therefore make the result of RPA

Metric	**Classic** ($r_n = v_n$, binary $\hat{v}_n$)	**Generalized** (continuous r_n and $\hat{v}_n$)
RPA	average pitch accuracy in voiced frames	weighted average pitch accuracy in voiced frames
RCA	average chroma accuracy in voiced frames	weighted average chroma accuracy in voiced frames
VR	fraction of voiced frames estimated as voiced	average voicing likelihood in voiced frames
VFA	fraction of unvoiced frames estimated as voiced	average voicing likelihood in unvoiced frames
OA	fraction of frames with correct voicing and pitch	weighted average correctness of each frame

Table 2. Description of the meaning of the metrics in the classic and generalized cases. Note that two possible cases are not described: binary $\hat{v}_n$ with a continuous reward r_n, and continuous $\hat{v}_n$ with $r_n = v_n$.

and RCA independent of the voicing estimation. However, many algorithms do not actually report negative pitches, and furthermore due to the inner functioning of some methods (e.g. Melodia [24]), increasing the number of reported pitches (either positive or negative) not only has an effect on voicing estimation accuracy but also on pitch accuracy.

Other metrics have been proposed to give further insights, such as the continuity of the correctly estimated pitches (either in pitch or chroma), which is relevant for tasks such as automatic transcription, source separation or visualization [8]. Metrics related to user satisfaction have also been studied in the context of melody extraction: different kind of errors have a different impact in the quality perceived when users listen to synthesized melodies that have been extracted automatically [20]. However, most single-f_0 estimation literature does not consider the influence of the energy of the signal under study (or its relation to the accompaniment) in the evaluation. Some exceptions [6, 25] present an evaluation of pitch salience functions, which are commonly correlated to the energy of the signals. Bosch et al. [8] also study the influence of the predominance of the melody over the accompaniment for different algorithms in the context of symphonic music, and monophonic pitch estimators have been evaluated in the presence of different noise levels [16, 28]. However, in the classic single-f_0 estimation metrics, all frames contribute equally to the results, even though in many cases the presence or absence of a (melody) pitch may be unclear for both humans and algorithms.

4. GENERALIZED METRICS

This section presents a generalization of the traditional metrics, in order to deal with the previously introduced limitations: voicing estimates must be binary, and all frames receive equal importance. The proposed metrics (1) allow algorithms to report voicing $\hat{v}_n$ as a *continuous* rather than a binary quantity, representing the likelihood that the frame is voiced, and (2) optionally weight the pitch accuracy in voiced frames using a reward $r_n \in [0, 1]$, allowing mistakes in less important frames to count less than mistakes in important frames.

In the following metrics, we require that (1) $r_n = 0$ if and only if $v_n = 0$, (2) $v_n = 0$ if $f_n = 0$ and (3) $\hat{v}_n = 0$ if $\hat{f}_n = 0$. Note that we may have $\hat{f}_n \neq 0$ and $\hat{v}_n = 0$, allowing the metrics to score pitch accuracy when voicing mistakes are made.

Equation 8 presents the proposed generalization of RPA and RCA, which aggregate the pitch/chroma accuracy proportional to the reward r_n. This makes the generalized metrics more forgiving on unimportant frames, and more demanding on important frames in comparison to previous metrics.

$$\mathtt{RPA} = \frac{\sum_{n=0}^{N-1} r_n \mathcal{T}_{\hat{f}_n, f_n}}{\sum_{n=0}^{N-1} r_n}, \quad \mathtt{RCA} = \frac{\sum_{n=0}^{N-1} r_n \mathcal{O}_{\hat{f}_n, f_n}}{\sum_{n=0}^{N-1} r_n} \tag{8}$$

Generalized versions of VR and VFA remain the same as in Equation 6, however $\hat{v}_n$ need not be binary. In both cases, VR is simply the average of $\hat{v}_n$ in voiced frames ($v_n = 1$), and similarly VFA is the average of $\hat{v}_n$ in unvoiced frames ($v_n = 0$).

Finally, we propose a generalized version of OA in Equation 9, which scores voiced frames proportionally to $\hat{v}_n$, weighted by r_n, and scores unvoiced frames proportionally to $1 - \hat{v}_n$. Let $V = \sum_{n=0}^{N-1} v_n$, the number of voiced frames in the reference annotations. The generalized OA becomes:

$$\mathtt{OA} = \frac{V \frac{\sum_{n=0}^{N-1} r_n \hat{v}_n T_{\hat{f}_n, f_n}}{\sum_{n=0}^{N-1} r_n} + (N - V) \frac{\sum_{n=0}^{N-1} (1 - v_n)(1 - \hat{v}_n)}{\sum_{n=0}^{N-1} (1 - v_n)}}{N} \tag{9}$$

In this generalized OA, voicing "mistakes" are penalized according to the confidence of the estimator, which is softer than in the binary case where mistakes are "all or nothing". When $r_n = v_n$ (equal reward in all voiced frames) and $\hat{v}_n$ is binary, each of the generalized metrics is equivalent to the metrics defined in the binary case. For RPA, RCA, VR and VFA the equivalence is straightforward. For OA, substituting r_n by v_n, plugging in the given equation for V, and simplifying the resulting quantity shows equivalence. Table 2 gives summaries of the metrics in the classic and generalized cases.

4.1 Behavior on Artificial Examples

Figure 1 shows the behavior of the proposed metrics for a few simple examples. For instance, the different results obtained in plots (a), (b), (e) and (f) show that if the pitches are correct, VR and OA get the best results with highly confident estimations. Plot (a) also shows that errors in the

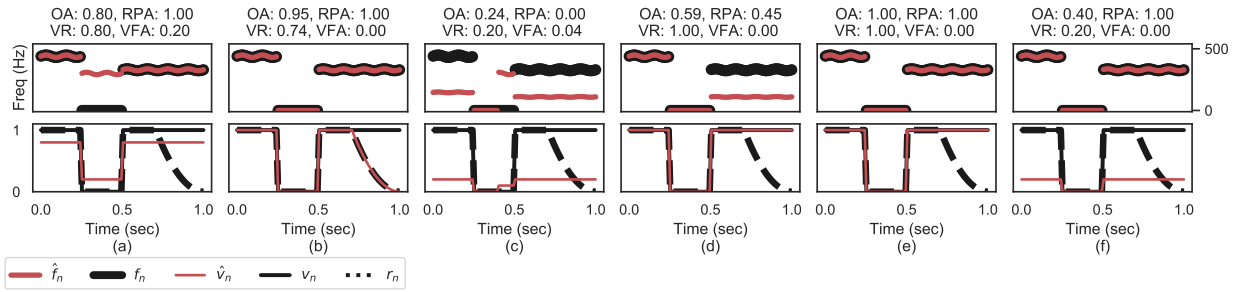

Figure 1. Artificial examples of different combinations of f_n, r_n, $\hat{f}_n$, and $\hat{v}_n$, and the behavior of the generalized metrics.

voicing estimation are less penalized if the estimate confidence is low. In this example, VFA is relatively low (0.2), while if the algorithm had used a very low threshold to determine a binary voicing value $\hat{v}_n$, VFA would be equal to 1 (the worst possible score), since all unvoiced frames would have been estimated as voiced. Plot (d) shows the effect of having perfect voicing estimation but incorrect pitch estimation – the estimator is penalized in OA and RPA. Plot (c) shows a completely wrong pitch estimation, which gets a small score for voicing recall, due to the low estimated confidence. In the same plot, VFA is very low due to the correctly identified unvoiced frames, and the errors between 0.4 and 0.5 s are not heavily penalized due to the low reported confidence.

5. COMPUTING PITCH ESTIMATION REWARDS

In order to create the pitch estimation reward (r_n) for single f_0 datasets, we propose the computation of Root-Mean-Square (RMS) energy in frames over time. The first step is to compute the RMS of the source producing the f_0 (RMS_{f_0}) and the RMS of the mixture (RMS_m) in frames. The second step deals with a frame-wise normalization, in order to obtain a reward signal: $r_n = (\text{RMS}_{f_{0_n}})/(\max(\text{RMS}_{f_0})+\text{RMS}_{m_n})$, where n corresponds to the index of the frame. In frames where there is no pitch annotation ($f_n = 0$), we set $r_n = 0$, as illustrated in Figure 2.

A mismatch between the energy of the melodic source and the voicing derived from pitch annotations (if the f_0 is non zero) could happen due to several factors. One of them is the fact that there may be energy due to a melodic instrument but actually no pitch, for instance in transient percussive sounds, or with unpitched vocal sounds (e.g., many of the consonants). Another possible factor is that the procedure followed during the annotation did not consider echos or reverberation, while they might be clearly present in the signal.

5.1 Isolated Sources

For datasets where isolated sources are available, we can simply compute the frame-wise RMS of the signals over time. For instance, in a melody extraction dataset, we would use the RMS of the source playing the melody in each frame to derive RMS_{f_0}. Note that this is compatible with multiple melody definitions, even allowing different

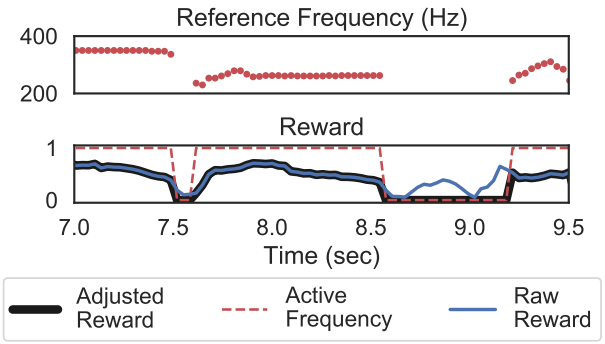

Figure 2. The reference frequency and the estimated reward values. Frames where no reference frequency is provided may have non-zero reward estimates (in blue) - in these cases the reward is set to 0 (in black).

instruments to play the melody sequentially in a given music excerpt [5,8]. RMS_m is computed from the instruments which are not playing the melody pitch in each frame, and the reward computed following the methodology from section 5. A simpler case corresponds to monophonic pitch estimation datasets, where RMS_m is zero, so the raw reward in each frame is equal to the RMS_{f_0}, normalized by its maximum RMS value in the example.

5.2 Sources in Polyphonic Mixtures

When isolated sources are not available, it is more difficult to compute RMS_{f_0} and RMS_m. For these cases, we propose the use of pitch-informed source separation [8, 14] in order to obtain an estimate of the energy of the source and accompaniment. We test the effectiveness of this approach using the iKala dataset by comparing the difference in the reference reward when computing it using isolated vocals, and using the results of pitch informed source separation on the mixture signal.

Figure 3 shows the results of "Melody-A" (see Section 6, for all metrics, with the confidence computed both using source separation and in the ideal case (having access to the isolated sources). As we can observe, VR and VFA have the same values, and OA, RPA, and RCA present some small differences but which are statistically significant, according to a paired t-test ($\alpha = 0.05$). However, in Figure 3 (right) we see that for each metric, the distribution of differences in comparison to "Melody-B" is very

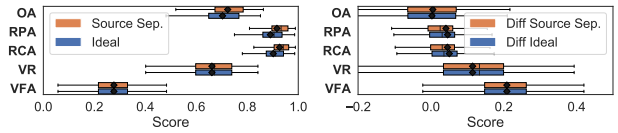

Figure 3. (Left) Metrics for "Melody-A" on iKala for confidence computed using both source separation and in the ideal case. (Right) The difference in score between "Melody-A" and "Melody-B" per track for both confidence measures on iKala.

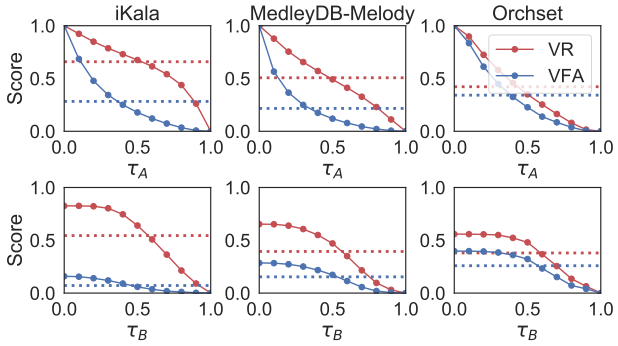

Figure 4. Classic voicing metrics (VR - red, VFA - blue) as a function of threshold. Dashed horizontal lines show the value of the generalized metrics computed with continuous $\hat{v}_n$. (Top) Threshold τ_A for "Melody-A" (Bottom) Threshold τ_B for "Melody-B".

similar when using confidence computed on both the ideal case and with source separation. This suggests that using source separation as a proxy to get the confidence measure would not have an impact on the ranking of algorithms, and therefore the methodology proposed would be useful to compare different algorithms. We leave the improvement of pitch-informed source separation for obtaining a better reward, i.e. more similar to the values obtained if the isolated sources were available, as future work.

6. PROPOSED METRICS ON REAL DATA

In order to show the behavior of the metrics with real data and algorithms, we create variants of four established algorithms: two monophonic pitch estimators "Pitch-A" (based on CREPE [16]) and "Pitch-B" (based on pYIN [19]) and two melody extraction algorithms "Melody-A" (based on Deep Salience [3]) and "Melody-B" (based on Melodia [24]). Note that the main objective is not to actually evaluate/compare these algorithms, but show the behaviour and give further insights about the proposed metrics. Therefore the arbitrarily taken decisions about the estimators such as the normalization, or using default parameters, should not be regarded as important.

In order to test our metrics, we need each algorithm to produce a continuous voicing estimate $\hat{v}_n$. "Pitch-A" and "Melody-A" predict confidence values as part of the algorithm, which we use directly as $\hat{v}_n$. "Pitch-B" and "Melody-B" do not directly predict confidence values, but determine which frames are voiced and unvoiced using thresholds on signals computed internally. We derive a value of $\hat{v}_n$ for these algorithms using normalized versions of these signals (the maximum probability of the pitch candidates for "Pitch-B", and the contour confidence measure for "Melody-B"). Note that not all algorithms currently provide a confidence value as an output, but all of them determine voicing at some level, and the steps used to make this decision can typically be used to create a measure of voicing confidence.

We use three melody extraction datasets in our experiments: iKala [10], MedleyDB [5] and Orchset [8]. iKala comprises 252 30-second excerpts sampled from 206 songs. MedleyDB contains 108 melody annotated files, which are mostly full-length songs between 3 and 5 minutes long, and cover a variety of instrumentation and genres. For our experiments, we use the melody 2 definition: the f_0 curve of the predominant melodic line drawn from multiple sources. Finally, Orchset contains 64 short audio excerpts (between 10 and 30 s.) of symphonic music. For pitch tracking, we use a dataset derived from MedleyDB, with 103 tracks of solo, monophonic instruments. In the two datasets for which we have isolated sources readily available, MedleyDB-Pitch and iKala, we compute the reference reward using the method described in Section 5 using a hop size of 256 and a window size of 4096 for a sample rate of 44100 Hz.

6.1 Voicing Estimation Metrics

We first examine the difference in the generalized versus the classic metrics for VR and VFA. In the classic metrics, the choice of voicing threshold has a major effect on VR and VFA. Figure 4 shows the classic metrics as a function of the voicing threshold as dots for VR (red) and VFA (blue) for "Melody-A" and "Melody-B" on the three melody datasets. The dashed horizontal lines show the value of the generalized metric, which is computed independently of the threshold. We see that the value of the generalized metrics is close to the average value of the metrics for all thresholds.

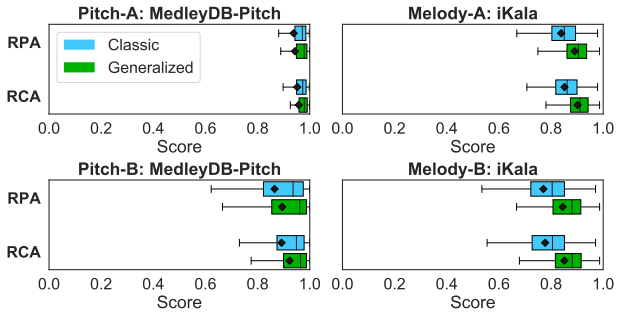

Figure 5. Generalized vs Classic RPA and RCA for four algorithms. r_n is used for the reference datasets. Boxplots show statistics across tracks for each metric.

6.2 Pitch Accuracy Metrics

Figure 5 shows the generalized and classic RPA and RCA on iKala (for "Melody-A" and "Melody-B") and MedleyDB-Pitch (for "Pitch-A" and "Pitch-B"). We can see that the values of the generalized metrics are higher in all cases, which confirms that algorithms commonly make more errors when the reference reward is lower (more difficult cases). The difference between the classic and generalized metrics is larger on "Melody-B" (+0.08 on average for RPA) than "Melody-A" (+0.05 on average for RPA), which suggests that "Melody-A" is less prone to pitch estimation errors when the melody is less predominant.

6.3 Overall Accuracy

Finally, we compare the generalized metrics with the classic metrics for OA. It is most often used as a single measure to compare the performance of two algorithms, but in the classic metric, the choice of each algorithm's voicing threshold can change the relative ranking of OA. In Figure 6, the middle and right columns show the classic OA as a function of threshold for two algorithms, and the left column shows the relative ranking of the classic OA for each combination of thresholds; when a cell is red, the algorithm in the middle gets a higher value for this metric, and vise versa when a cell is blue. We see that for all datasets, a pair of threshold values can be chosen which rank one algorithm higher than the other. This makes the comparison of two algorithms in terms of the classic OA highly dependent on the choice of threshold.

We see that when algorithms are ranked based on the generalized OA, the algorithm which is ranked higher is always the algorithm which is also more often ranked higher for the classic OA (i.e. the dominant color in Figure 6, left). The ordering of the generalized OA is also consistent with the highest possible value of the classic OA (the "star" marker in Figure 6). This suggests that the generalized OA provides a threshold independent way to fairly rank algorithms. Comparing the generalized metrics with and without r_n (Figure 6, horizontal dashed and solid lines), we see that overall the behavior of OA is similar, but harsher when r_n is not used.

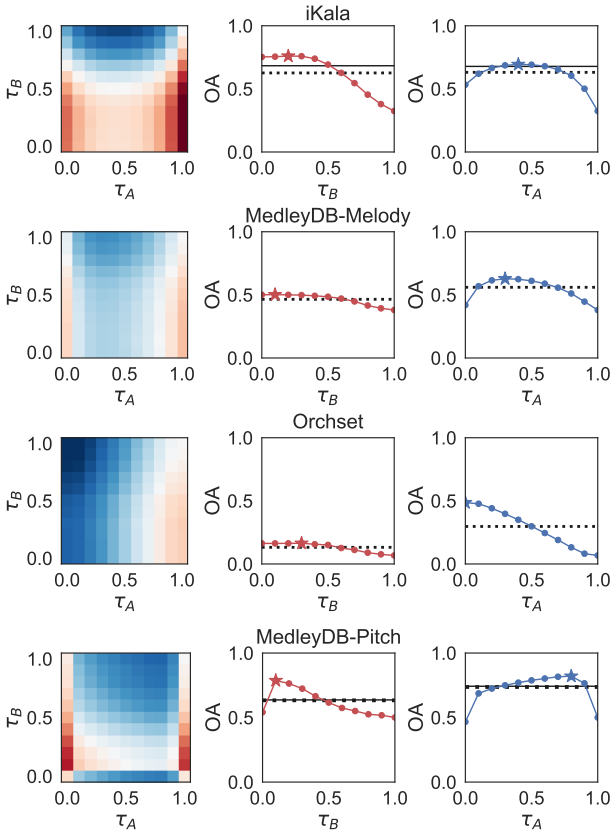

Figure 6. (Left column) difference in overall accuracy between two algorithms. Red: algorithm B gets a higher OA, Blue: algorithm A gets a higher OA, White: They are the same. (Middle and Right Columns) OA as a function of threshold for "Melody-B" (middle) and "Melody-A" (right) for rows 1-3, and for "Pitch-B" (middle) and "Pitch-A" (right) in row 4. Dashed lines show the generalized OA computed with $r_n = v_n$ and continuous $\hat{v}_n$, solid lines show the generalized OA computed with continuous r_n and continuous $\hat{v}_n$. Solid lines are missing for two datasets because the isolated melody sources are not available so we cannot accurately compute continuous r_n.

7. CONCLUSIONS

This paper presents a generalization of traditional single-f_0 estimation metrics, which allows estimators to provide a continuous voicing estimate and introduces a weighting on pitch accuracy. We perform an experimental comparison of the proposed metrics using both monophonic pitch estimators and melody extraction algorithms and show that the generalized metrics provide a threshold-independent way of comparing algorithms. Additionally, we propose a methodology for the annotation of the reference reward r_n based on the energy of the isolated sources and also propose a promising variant for the case when only polyphonic mixtures are available, based on pitch-informed source separation. One of the limitations of the proposed method for estimating the reference reward is that it does not explicitly consider aspects related to pitch perception, which we leave for future work. Finally, the proposed evaluation framework could also be extended to multiple pitch estimation metrics. The concept of confidence and reward, in this case, would be related to each of the individual pitches present, and the methodology would still hold.

While this paper focuses on the generalization of the classic metrics, we also foresee the creation of new metrics, including the adaptation of metrics from the Information Retrieval literature (such as the ROC-AUC score). The current work only considers voicing confidence for estimators and a kind of "pitch confidence" for references, however pitch confidence for estimators and voicing confidence for references could also be incorporated. Future work could also experiment with metrics based on different types of rewards r_n, such as metrics that examine pitch accuracy in difficult frames.

ABSTRACT

In this paper, we learn disentangled representations of timbre and pitch for musical instrument sounds. We adapt a framework based on variational autoencoders with Gaussian mixture latent distributions. Specifically, we use two separate encoders to learn distinct latent spaces for timbre and pitch, which form Gaussian mixture components representing instrument identity and pitch, respectively. For reconstruction, latent variables of timbre and pitch are sampled from corresponding mixture components, and are concatenated as the input to a decoder. We show the model's efficacy using latent space visualization, and a quantitative analysis indicates the discriminability of these spaces, even with a limited number of instrument labels for training. The model allows for controllable synthesis of selected instrument sounds by sampling from the latent spaces. To evaluate this, we trained instrument and pitch classifiers using original labeled data. These classifiers achieve high F-scores when tested on our synthesized sounds, which verifies the model's performance of controllable realistic timbre/pitch synthesis. Our model also enables timbre transfer between multiple instruments, with a single encoder-decoder architecture, which is evaluated by measuring the shift in the posterior of instrument classification. Our in-depth evaluation confirms the model's ability to successfully disentangle timbre and pitch. [1]

1. INTRODUCTION

A disentangled feature representation is defined as having disjoint subsets of feature dimensions that are only sensitive to changes in corresponding factors of variation from observed data [2, 27, 32]. Deep generative models [13, 19, 25, 33] have been exploited to learn disentangled representations in different domains. In the visual domain, studies are focused on learning independent representations for data generative factors such as identity and azimuth [5, 14, 26]. In natural language generation, efforts have been made to generate texts with controlled sentiment [10, 18, 36]. Also in the speech domain, we have witnessed successful attempts in controllable speech synthesis by disentangling factors such as speaker identity, speed of speech, emotion, and noise level [15, 17, 35]. There has been relatively little research on learning disentangled representations for music. In this paper, we disentangle the pitch and timbre of musical instrument sound recordings.

Pitch and timbre are essential properties of musical sounds. Given that one pitch can be played with different instruments, we assume they can be separated. From the perspective of music analysis, disentangled representations of pitch and timbre can be regarded as timbre- and pitch-invariant features which could be exploited for downstream tasks [29,30]. From the synthesis point of view, disentangled representations enable the generation of musical notes with identical pitches (timbres) and different timbres (pitches). Recently, Hung *et al.* presented the first attempt to learn disentangled representations of pitch and timbre for synthesized music by using frame-level instrument and pitch labels based on encoder-decoder networks [21]. Even though the authors managed to change instrumentation to some extent without affecting pitch structure, the approach was restrictive, as it worked with MIDI-synthesized audio and relied on clean frame-level labels, which are scarce to find. Disentangled representations allow for several applications, including music style transfer. Brunner *et al.* proposed a model based on variational autoencoders (VAEs) [25] to generate music with controllable attributes [4]. While genre was factorized by an auxiliary classifier, other musical properties were entangled. Besides the aforementioned models based on MIDI, research on audio has focused on translating between different domains of instrumentation [3,7,20,28]. None of them, however, has addressed learning disentangled latent variables of both pitch and timbre.

This research distinguishes itself from others by disentangling instrument sounds into distinct sets of latent variables (i.e., pitch and timbre), with a framework based on Gaussian Mixture VAEs (GMVAEs). We model the gener-

[1] Example audio files and code at `http://bit.ly/2Dbyt9j`

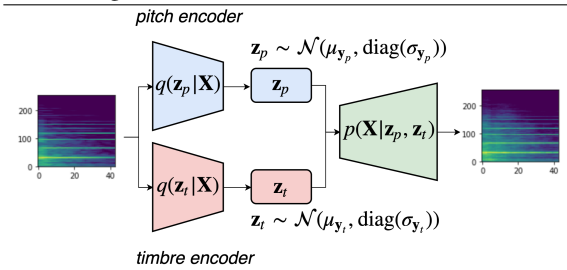

Figure 1. The proposed framework includes separate encoders for pitch and timbre, and a shared decoder.

ative process of an isolated musical note by independently sampling pitch and timbre (instrument) categorical variables. Note that the two factors are actually dependent in a sense that range of pitch is instrument-dependent, however, we verify the model's capability to disentangle them under this simplified assumption of independence. Conditioned on these categorical variables, Gaussian-distributed latent variables are then sampled that characterize variation in the sampled pitch and instrument, respectively. Finally, the data are generated conditioned on the two latent variables. We favor the proposed framework over vanilla VAEs [8, 9] for its more flexible latent distribution compared to a standard Gaussian. In addition, it allows for unsupervised or semi-supervised clustering, which can learn interpretable mixture components and corresponding Gaussian parameters. More importantly, such a framework facilitates the applications in this research: controllable synthesis of instrument sounds, and many-to-many transfer of instrument timbres. Our proposed framework differs from previous studies on timbre transfer, in that we achieve transfer between *multiple instruments* without training a domain-specific decoder for each instrument (e.g. [28]), and we infer both the pitch and timbre latent variable without requiring categorical conditions of source pitch and instrument as in [3]. We evaluate our model by visualizing both the latent space and the synthesized spectrograms, and explore the classification F-scores of classifiers trained in an end-to-end fashion. The results confirm the model's ability to learn disentangled pitch and timbre representations. The rest of the paper is organized as follows: in Section 2, we discuss the proposed framework, and Section 3 describes the dataset and experimental setup. Experiments and results are reported in Section 4. We conclude our work and provide future directions in Section 5.

2. PROPOSED FRAMEWORK

In this section, we briefly describe VAEs and GMVAEs, and elaborate on the proposed framework and architecture.

2.1 Gaussian Mixture Variational Autoencoders

VAEs [25] are unsupervised generative models that combine latent variable models and deep learning [12]. We denote the observed data and the latent variables respectively by $\mathbf{X}$ and $\mathbf{z}$. A graphical model, corresponding to $\mathbf{z} \rightarrow \mathbf{X}$, is trained by maximizing the lower bound of the log marginal likelihood $p(\mathbf{X})$. The intractable posterior $p(\mathbf{z}|\mathbf{X})$ is approximated by introducing a variational distribution $q(\mathbf{z}|\mathbf{X})$ parameterized with neural networks. In regular VAEs, a common choice for the prior distribution $p(\mathbf{z})$ is an isotropic Gaussian, which encourages each dimension of the latent variables to capture an independent factor of variation from the data, and results in a disentangled representation [14]. Such a unimodal prior, however, does not allow for multi-modal representations. GMVAEs [6,22,24] extend the prior to a mixture of Gaussians, and assume the observed data are generated by first determining the mode from which it was generated, which corresponds to learning a graphical model $\mathbf{y} \rightarrow \mathbf{z} \rightarrow \mathbf{X}$. This introduces a categorical variable $\mathbf{y}$, and $q(\mathbf{y}|\mathbf{X})$, which infers the classes of data. This enables semi-supervised learning [24] and unsupervised clustering [6, 22] in deep generative models. In the speech domain, Hsu *et al.* used two mixture distributions to separately model the supervised speaker and unsupervised utterance attributes, which allowed for extra flexibility in conditional speech generation [17]. We build upon this idea to learn separate latent distributions to represent the pitch and timbre of musical instrument sounds. More importantly, to facilitate downstream creative applications such as controllable synthesis and instrument timbre transfer in music, we propose to model supervised pitch representations and semi-supervised timbre representations, with labels of pitch and instrument identity. As such, the mixture components in latent space of pitch and timbre can be clearly interpreted as the classes, i.e., pitch and instrument identity.

2.2 Model Formulation

The latent variables of pitch and timbre for an isolated musical note $\mathbf{X}$ are denoted as $\mathbf{z}_p$ (*pitch code*) and $\mathbf{z}_t$ (*timbre code*), respectively. To represent Gaussian mixture latent distributions, two categorical variables are introduced: an M-way categorical variable $\mathbf{y}_p$ for pitch, where M is the number of recorded pitches in the dataset, and a K-way categorical variable $\mathbf{y}_t$ for timbre, where K is the number of instrument classes. We consider $\mathbf{y}_p$ to be observed (fully supervised), which assumes the availability of pitch labels during training, and is reasonable as we model isolated instrument sounds in this research. For $\mathbf{y}_t$, we investigate both unsupervised and semi-supervised learning, i.e., using varying numbers of instrument labels for training. It is shown in Section 4 that our model can efficiently leverage the limited number of labels. Without loss of generality, we denote $\mathbf{y}_t$ as unobserved (unsupervised) as in [17]. The joint probability of $\mathbf{X}$, $\mathbf{y}_t$, $\mathbf{z}_t$ and $\mathbf{z}_p$ is written as:

$$\begin{aligned} p(\mathbf{X}, \mathbf{y}_t, \mathbf{z}_t, \mathbf{z}_p|\mathbf{y}_p) = \\ p(\mathbf{X}|\mathbf{z}_p, \mathbf{z}_t)p(\mathbf{z}_p|\mathbf{y}_p)p(\mathbf{z}_t|\mathbf{y}_t)p(\mathbf{y}_t), \end{aligned} \tag{1}$$

where $p(\mathbf{y}_t)$ is uniform-distributed, i.e., we do not assume to know the instrument distribution in the dataset. Both the conditional distributions $p(\mathbf{z}_p|\mathbf{y}_p) = \mathcal{N}(\boldsymbol{\mu}_{\mathbf{y}_p}, \mathrm{diag}(\boldsymbol{\sigma}_{\mathbf{y}_p}))$ and $p(\mathbf{z}_t|\mathbf{y}_t) = \mathcal{N}(\boldsymbol{\mu}_{\mathbf{y}_t}, \mathrm{diag}(\boldsymbol{\sigma}_{\mathbf{y}_t}))$ are assumed to be diagonal-covariance Gaussians with learnable means and constant variances. This amounts to both the marginal prior $p(\mathbf{z}_p)$ and $p(\mathbf{z}_t)$ being Gaussian mixture models

(GMMs) with diagonal covariances. Ideally, each mixture component in the former (*pitch space*) uniquely represents the pitch of $\mathbf{X}$, while that in the latter (*timbre space*) is interpreted as the instrument identity. As we will see in Section 4.1, however, moderate supervision is essential to learn a timbre space that groups instruments perfectly. For creative applications such as the synthesis and timbre transfer of instrument sounds, the proposed model has numerous merits: 1) the learnt representations are not restricted to be unimodal, which offers a more discriminative timbre space than regular VAEs (Section 4.1 and 4.2); 2) direct and intuitive sampling from pitch and timbre space allows for consistent and controllable synthesis of instrument sounds, attributed to the fact that Gaussian parameters of each interpretable mixture component are readily available after training (Section 4.3); and 3) simple arithmetic manipulations between means of mixture components facilitate many-to-many transfer between instrument timbres (Section 4.4). For the training objective, we closely follow the derivation in [17] and train the model by maximizing the evidence lower bound (ELBO) as follows:

$$\begin{aligned}\mathcal{L}(p,q;\mathbf{X},\mathbf{y}_p) = &\mathbb{E}_{q(\mathbf{z}_p|\mathbf{X})q(\mathbf{z}_t|\mathbf{X})}[\log p(\mathbf{X}|\mathbf{z}_p,\mathbf{z}_t)] \\ &- D_{KL}(q(\mathbf{z}_p|\mathbf{X})||p(\mathbf{z}_p|\mathbf{y}_p)) \\ &- \mathbb{E}_{q(\mathbf{y}_t|\mathbf{X})}[D_{KL}(q(\mathbf{z}_t|\mathbf{X})|p(\mathbf{z}_t|\mathbf{y}_t)] \\ &- D_{KL}(q(\mathbf{y}_t|\mathbf{X})||p(\mathbf{y}_t)),\end{aligned} \tag{2}$$

where $p(\mathbf{X}|\mathbf{z}_p,\mathbf{z}_t)$, $q(\mathbf{z}_p|\mathbf{X})$, and $q(\mathbf{z}_t|\mathbf{X})$ are parameterized with neural networks, referred to as the *decoder*, *pitch encoder* [2] , and *timbre encoder*, respectively. Instead of using another neural network, we approximate $q(\mathbf{y}_t|\mathbf{X})$ by $\mathbb{E}_{q(\mathbf{z}_t|\mathbf{X})}[p(\mathbf{y}_t|\mathbf{z}_t)]$. Readers interested in detailed derivation are referred to Appendix A in [17].

2.3 Architecture

Our model is composed of a shared decoder and separate encoders for pitch and timbre, as illustrated in Figure 1. Specifically, we reshape the T-by-F spectrogram to have number of channels $C = F$, each of which is a T-by-1 vector, where T and F refer to time and frequency. Each encoder contains two one-dimensional convolutional layers, each with 512 filters of shape 3×1, and a fully connected layer with 512 units. A Gaussian parametric layer follows and outputs two $L-$dimensional vectors which represent mean and log variance. $\mathbf{z}_p$ and $\mathbf{z}_t$ are sampled from the Gaussian layer with the reparameterization trick [25], which enables stochastic gradient descent, and are then concatenated for the decoder to reconstruct the input. The architecture of the decoder is symmetric to the encoder. Batch normalization followed by the activation function `relu` are used for every layer except for the Gaussian and the output layer. We use the activation function `tanh` for the output layer as we normalize the data within $[-1, 1]$.

[2] A common alternative is conditioning the model with categorical pitch labels such that one does not have to train a pitch encoder [3, 7]. It, however, requires the pitch of the inputs to be known a priori to performing tasks such as timbre transfer [3], and also prohibits the model from extracting pitch features for downstream tasks. By training this extra encoder, we also demonstrate how one can extend the model to possibly learn multiple interpretable latent variables.

3. EXPERIMENTAL SETUP

In this section, we describe the experimental setup, including details of the dataset, input representations, and model configurations.

3.1 Dataset

Inspired by Esling *et al.* [8], we use a subset of Studio-On-Line (SOL) [1], a database of instrument note recordings. [3] The dataset contains 12 instruments, i.e, piano (`Pno`, 246), violin (`Vn`, 138), cello (`Vc`, 147), English horn (`Ehn`, 128), French horn (`Fhn`, 214), tenor trombone (`Trtb`, 63), trumpet (`Trop`, 194), saxophone (`Sax`, 99), bassoon (`Bn`, 251), clarinet (`Clr`, 180), flute (`Fl`, 118) and oboe (`Ob`, 107). There are 1,885 samples in total. All recordings are resampled to 22,050Hz, and only the first 500ms segment ($T = 43$) of each recording is considered. We extract Mel-spectrograms with 256 filterbanks ($F = 256$), derived from the power magnitude spectrum of the short-time Fourier transform (STFT). To compute STFT, we use a Hann window with window size of 92ms and hop size of 11ms. As a result, the input representation is a 43-by-256 Mel-spectrogram. The dataset is split into a training (90%) and validation set (10%), each containing the same distribution of instruments. The magnitude of the Mel-spectrogram is scaled logarithmically, and the minimum and maximum values in the training set are used for normalizing the magnitude within $[-1, 1]$ in a corpus-wide fashion to preserve differences in dynamics.

3.2 Hyperparameters

In order to train both the GMMs in pitch and timbre space, we initialize the means of mixture components using Xavier initialization [11]. We set constant standard deviations, rather than trainable ones, for pitch and timbre space. For pitch space, $\boldsymbol{\sigma}_{\mathbf{y}_p} = \mathbf{e}^{-\mathbf{2}}$ for all mixture components, which is relatively small, as each mixture component represents a pitch, and we do not expect a large variance over recordings that play the same pitch. For timbre space, we let $\boldsymbol{\sigma}_{\mathbf{y}_t} = \mathbf{e}^{\mathbf{0}}$ for all mixture components, which captures the timbre variation of each mixture component, i.e., instrument identity. The dimensionality of the latent space is $L = 16$, and the numbers of mixture components are $M = 82$ and $K = 12$, equivalent to the numbers of classes of pitch and instrument, respectively. For all experiments, a batch size of 128 is used, model parameters are initialized with Xavier initialization and are trained using the Adam optimizer [23] with a learning rate of 10^{-4}.

In addition to the proposed model (M_{GMVAE}), we consider a baseline (M_{VAE}) that substitutes the timbre space with an isotropic Gaussian as in regular VAEs. Training such a model amounts to optimizing Eqn (2) with the last two terms replaced with $D_{KL}(q(\mathbf{z}_t|\mathbf{X})||p(\mathbf{z}_t))$, where $p(\mathbf{z}_t) = \mathcal{N}(\mathbf{0}, \boldsymbol{I})$. The experimental results in Section 4.1 and Section 4.2 show that $\mathrm{M_{GMVAE}}$ learns a more discriminative and disentangled timbre space than $\mathrm{M_{VAE}}$.

[3] Access to the dataset was requested from [8].

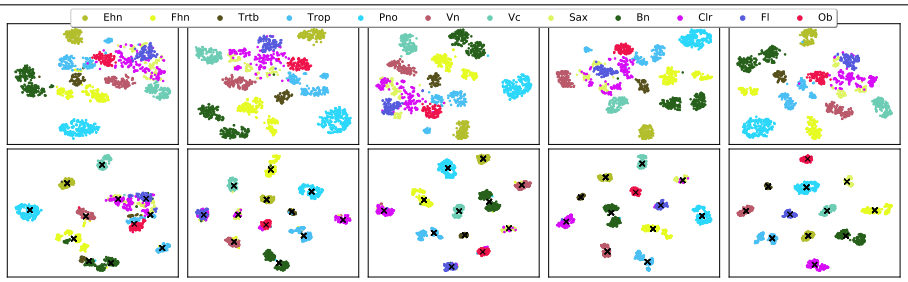

Figure 2. Timbre space visualization of $\mathrm{M}_{\mathrm{VAEs}}$ (top) and $\mathrm{M}_{\mathrm{GMVAEs}}$ (bottom). From left to right: models trained with 0, 25, 50, 75, or 100% of instrument labels, respectively.

	Instrument Classification					Pitch Classification

Table 1. The F-scores of instrument and pitch prediction by linear classifiers and CNNs. N (%) refers to the percentage of instrument labels used to train the models. Columns $\mathbf{z}_t$ and $\mathbf{z}_p$, respectively, refer to the F-scores obtained using the learned timbre and pitch code to train the down-stream linear classifier.

3.3 Semi-Supervised Learning

We exploit a moderate number of instrument labels to learn a timbre space in which the clusters clearly represent instrument identity. Similar to Kingma *et al.* [24], in the semi-supervised training for $\mathrm{M}_{\mathrm{GMVAE}}$, we *guide* the inference of instrument labels $q(\mathbf{y}_t|\mathbf{X})$ by leveraging limited amounts of supervision. This is done by adding an additional loss term which measures the cross entropy between the inferred and true instrument labels. Because we do not infer $\mathbf{y}_t$ in $\mathrm{M}_{\mathrm{VAE}}$, we use $\mathbf{z}_t$ to train an auxiliary classifier to predict $\mathbf{y}_t$. It has two 128-unit fully-connected layers, and is jointly optimized with $\mathrm{M}_{\mathrm{VAE}}$. We consider varying numbers of instrument labels N = 0 (unsupervised), 25, 50, 75, and 100% (fully supervised) of the total number. We randomly sample and let the label distribution match the distribution of instruments.

4. EXPERIMENTS AND RESULTS

The experiments and the results are presented in this section. We first visualize the timbre space, and quantitatively evaluate the disentangled representations. We then demonstrate the applications of controllable synthesis and many-to-many timbre transfer. Finally, we identify the particular latent dimension that is sensitive to the distribution of the spectral centroid, which allows for finer timbre controls.

4.1 Visualization

Figure 2 visualizes the timbre space using t-distributed stochastic neighbor embedding (t-SNE) [34], a technique that projects vectors from high- to low-dimensional space. We first observe that $\mathrm{M}_{\mathrm{GMVAE}}$ learns a Gaussian-mixture distributed timbre space, with means of mixture components marked as crosses in the figure. Second, attributed to the pitch encoder which addresses pitch variations, both $\mathrm{M}_{\mathrm{VAE}}$ and $\mathrm{M}_{\mathrm{GMVAE}}$ are able to form clusters of instrument identity even without being trained with instrument labels (the leftmost column). We observe that the wind family (e.g., saxophone, clarinet and flute) forms an ambiguous cluster. Such an ambiguity remains in the $\mathrm{M}_{\mathrm{VAE}}$ even with increased N, while it is less present in the $\mathrm{M}_{\mathrm{GMVAE}}$ latent space, due to the multi-modal prior distribution. As we will confirm in Section 4.2, $\mathrm{M}_{\mathrm{GMVAE}}$ outperforms $\mathrm{M}_{\mathrm{VAE}}$ in learning a more discriminative and disentangled timbre space. Note that in $\mathrm{M}_{\mathrm{GMVAE}}$, $p(\mathbf{y}_t)$ is assumed to be uniformly distributed over 12 classes of instruments, i.e., mixture components are equally weighted. As a result, instruments with larger within-class variances (e.g., bassoon and trumpet) are assigned to more than one cluster when $N = 0$. In future work we aim to improve the performance of the unsupervised clustering of instruments.

4.2 Pitch and Instrument Disentanglement

A disentangled pitch (timbre) representation should be discriminative for pitch (instrument identity), and at the same time non-informative of instrument identity (pitch). Therefore, we evaluate $\mathbf{z}_p$ and $\mathbf{z}_t$ by means of classification. We train linear classifiers to map $\mathbf{z}_p$ and $\mathbf{z}_t$ to predict both pitch and instrument labels with one fully connected layer. For comparison, we train an end-to-end convolutional neural network (CNN), whose architecture is the same as the encoder and is a strong baseline, to map the original input Mel-spectrograms to either pitch or instrument labels.

Table 1 shows the results. The CNN achieves high F-scores on both instrument and pitch classification; note that N is the supervisory percentage of the total number of *instrument* labels, and we always use all pitch labels to train the models, which is reasonable as we model isolated notes

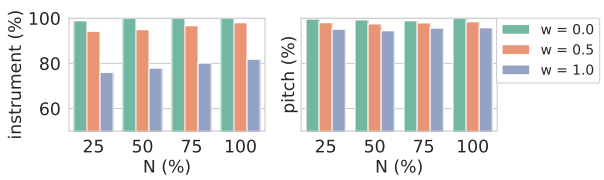

Figure 3. The F-scores for predicting instrument (left) and pitch (right) labels from the synthesized spectrograms.

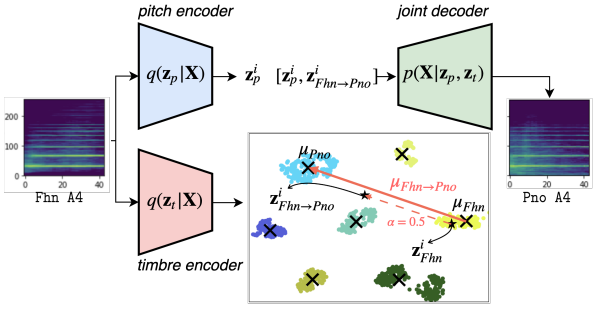

Figure 4. Many-to-many timbre transfer. The ith sample of the `Fhn` is transferred to the `Pno`, with vector arithmetic in the (partially shown) timbre space.

in this work. In instrument classification, using $\mathbf{z}_t$ as the feature representations outperforms $\mathbf{z}_p$ by a large margin, as expected. Specifically, in both models, the $\mathbf{z}_t$ learned with unsupervised learning ($N = 0$) is already discriminative enough to predict instruments with linear classifiers. While the F-score of M_{GMVAE} improves with increased N, that of M_{VAE} does not. Moreover, the linear classifier trained with $\mathbf{z}_t$ outperforms the CNN when $N < 75$. The timbre space of M_{GMVAE} displays the most discriminative power among the models. We attribute the F-scores of instrument classification attained by $\mathbf{z}_p$ to the fact that the piano covers all possible pitches in the dataset, while other instruments account for a smaller pitch range. As a result, $\mathbf{z}_p$ of notes that were only recorded by piano are correctly classified. Future work can be done to decorrelate particular pitches and instruments by data augmentation and adversarial training as in [16]. In pitch classification, $\mathbf{z}_p$ outperforms $\mathbf{z}_t$ as expected, and both models achieve comparable results. More importantly, M_{GMVAE} performs better than M_{VAE} in terms of disentanglement, as $\mathbf{z}_t$ results in lower F-scores when predicting pitch with increased N.

4.3 Controllable Synthesis of Instrument Sounds

As shown in Figure 2, M_{GMVAE} learns a timbre space $p(\mathbf{z}_t)$, whose mixture components are clearly interpreted as instrument identity when trained with moderate supervision. Meanwhile, mixture components in $p(\mathbf{z}_p)$ represent pitch. As Gaussian parameters are readily available after training, we can achieve controllable sound synthesis by sampling $p(\mathbf{z}|\mathbf{y})$. To synthesize the target pitch y_m and instrument y_k, we first sample $\mathbf{z}_p \sim \mathcal{N}(\boldsymbol{\mu}_{y_m}, w \cdot \text{diag}(\boldsymbol{\sigma}_{y_m}))$ and $\mathbf{z}_t \sim \mathcal{N}(\boldsymbol{\mu}_{y_k}, w \cdot \text{diag}(\boldsymbol{\sigma}_{y_k}))$, where the multiplier $w \in \{0, 0.5, 1.0\}$ serves to examine the effect of sampling latent variables that deviate from the modes. The decoder then synthesizes the Mel-spectrogram by consuming $[\mathbf{z}_t, \mathbf{z}_p]$. For evaluation, the CNNs (trained on the original dataset) are used to test whether the synthesized spectrograms are still recognized as belonging to the desired instrument and pitch. High F-scores therefore indicate high controllability of the model in sound synthesis. We use the sound samples in the validation set as the targets to synthesize, and repeat the sampling 30 times for each target.

The F-scores for pitch and instrument classification are reported in Figure 3. We first note that increasing w degrades classification performance. This is expected, as a sample which is synthesized using a latent variable far from its corresponding mean of mixture component deviates more from the intended instrument or pitch distribution. Moreover, the fact that the CNN was trained on the original samples while tested on the synthesized ones also contributes to the inferior performance. Second, increasing N improves instrument classification performance. Finally, the high F-scores across all N's when $w \in \{0, 0.5\}$ indicate accurate and consistent synthesis of instrument sounds with intended pitches and instruments, even with a timbre space trained using a limited number of instrument labels. This implies that M_{GMVAE} efficiently exploits the instrument labels, and learns a discriminative mixture distribution of timbre, which is consistent with the visualization in Figure 2 (bottom row, $N \geq 25$). We do not explore the timbre space resulting from unsupervised learning ($N = 0$) in this experiment, as the instrument identity of each mixture component is not directly available. We can, however, infer the instrument identity of each mixture component by sampling and synthesis, and expect reasonably good performance for controllable synthesis if the clustering of instruments shown in the bottom left of Figure 2 is improved. This will be explored in future work.

4.4 Many-to-Many Transfer of Timbre

In this experiment, we demonstrate many-to-many transfer of instrument timbre. In Mor *et al.*, a domain-specific decoder was trained for each target [28]. To achieve timbre transfer with a single encoder-decoder architecture, Bitton *et al.* proposed to use a conditional layer [31] which takes both instrument and pitch labels as inputs [3]. On the other hand, our model infers $\mathbf{z}_t$ and $\mathbf{z}_p$, and only uses a single joint decoder. As illustrated in Figure 4, timbre transfer is achieved by decoding $[\mathbf{z}_{transfer}, \mathbf{z}_p]$, i.e., transferring timbre while keeping pitch unchanged, where $\mathbf{z}_{transfer} = \mathbf{z}_{source} + \alpha\boldsymbol{\mu}_{source\to target}$, $\boldsymbol{\mu}_{source\to target} = \boldsymbol{\mu}_{target} - \boldsymbol{\mu}_{source}$, and $\alpha \in [0, 1]$. Once again, we rely on the trained CNNs in Table 1 for evaluation. More specifically, we examine the posterior shift in instrument prediction of the CNN, before and after transferring from source to target instruments with $\alpha = \{0, 0.25, 0.5, 0.75, 1.0\}$. For simplicity, the most frequent instruments (i.e., French horn, piano, cello, and bassoon) of the four families are selected as the representatives, and we perform timbre transfer using the samples in the validation set as the source. For example, consider `Fhn` as the source and `Pno` as target, as shown in Figure 4. We modify the timbre code as $\mathbf{z}^i_{Fhn\to Pno} = \mathbf{z}^i_{Fhn} + \alpha\boldsymbol{\mu}_{Fhn\to Pno}$, where $\mathbf{z}^i_{Fhn}$ is the timbre code of the ith `Fhn` sample, and $i = \{1, 2, \ldots, \text{N}_{\text{Fhn}}\}$.

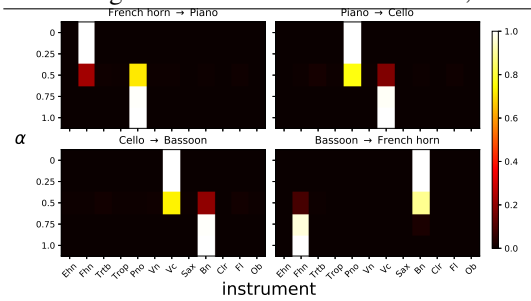

Figure 5. The averaged posterior (color) shift in instrument prediction of the CNN, caused by timbre transfer.

We decode as described earlier and report the averaged posterior (over N_{Fhn}) of instrument prediction of the CNN.

For simplicity, in Figure 5, we report the results of the source-target pairs $Fhn \rightarrow Pno$, $Pno \rightarrow Vc$, $Vc \rightarrow Bn$ and $Bn \rightarrow Fhn$. Each subfigure refers to a source-target pair, and represents the averaged posterior shift of instrument classification of the CNN, with varying α. For all pairs, the biggest posterior shift (hence the prediction change) happens when $\alpha = 0.5$. This also applies to the rest of the possible instrument pairs not shown in the figure. Meanwhile, by using pitch classification, we examine if the pitches are the same before and after timbre transfer, and we use the original pitch labels as ground-truths. We find that, except in the case where the source is piano, all source-target pairs attain a perfect F-score in terms of pitch. This confirms the ability of the model to successfully perform many-to-many timbre transfer. A special case arises when piano is the source. The F-scores before transfer, after transfer to French horn, to cello, and to bassoon, are 0.958, 0.750, 0.791, and 0.791, respectively. As described earlier in Section 4.2, lower F-scores can be attributed to the fact that the range of piano is much larger than that of the target instruments, or the classifier fails to predict the synthesized samples that have unseen combinations of pitch and instrument. The other possible reason is the model falls short of generalization. Nevertheless, this only happens in some cases when the source is piano; as demonstrated in Figure 6, the model is able to transfer `Pno G6` to cello (the first row), which is an example of generalizing to an out-of-range pitch for the target instrument. In the first and third row, the high-frequency components appear with increased α, and the energy distributes over the segment without decay. The model, however, falls short in

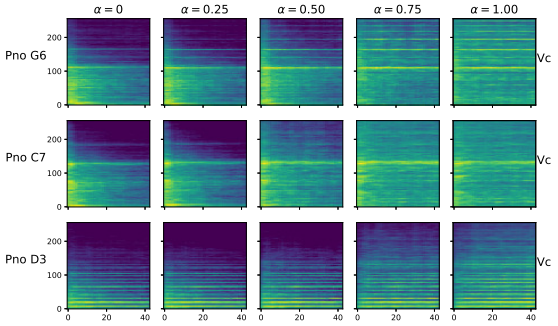

Figure 6. Examples of timbre transfer $Pno \rightarrow Vc$. The top two rows are tones outside of the cello range.

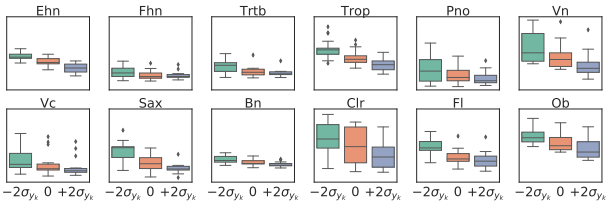

Figure 7. Spectral centroid values in response to z_t^{13}.

generalizing to the higher pitch, i.e., `Pno C7` (the second row), where the energy remains focused at the onset, and high-frequency components are smeared. In the future, we could improve the model generalizability by performing data augmentation and adversarial training as in [16].

4.5 Spectral Centroid Disentanglement

A diagonal-covariance Gaussian prior encourages the model to learn disentangled latent dimensions [14]. This applies to all mixture components in our model. In particular, we identify a latent dimension that correlates with the spectral centroid. we modify the 13th dimension of $\mathbf{z}_t$, z_t^{13}, of each sound sample in the validation set by $\pm 2\sigma_{y_k}$, where $\sigma_{y_k} = e^0$ for all instruments, and then synthesize the spectrograms, for which we then calculate the spectral centroid. Figure 7 shows the distributions of the spectral centroid before and after the modifications. The two-tailed t-test indicates significant differences ($p < 0.05$) between $-2\sigma_{y_k}$ and $+2\sigma_{y_k}$ for all instruments. As demonstrated in Figure 8, we observe that increased z_t^{13} reduces the energy of high-frequency components and results in lower spectral centroid values. In future research, we will further investigate disentangling specific acoustic features for finer control of sound synthesis beyond pitch and instrument.

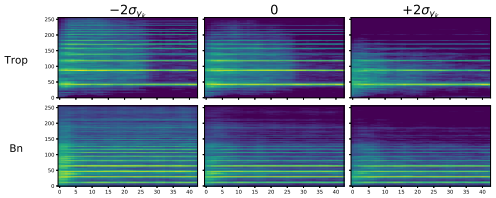

Figure 8. Latent dimension traverse of z_t^{13}.

5. CONCLUSIONS AND FUTURE WORK

We have proposed a framework based on GMVAEs to learn disentangled timbre and pitch representations for musical instrument sounds, which is verified by our experimental setup. We demonstrate its applicability in controllable sound synthesis and many-to-many timbre transfer. In future work, we plan to conduct listening tests for a more comprehensive evaluation of the applications, and further disentangle both low- (e.g., acoustic features) and high-level (e.g., playing techniques) sound attributes, enabling finer control of synthesized timbres. By using supervised and unsupervised learning in a deep generative model, the framework can be easily adapted to learn interpretable mixtures such as singer identity, music style, emotion, etc., which facilitates music representation learning and creative applications.

ABSTRACT

Ever since the first International Symposium on Music Information Retrieval in 2000, the proceedings have been made publicly available to interested researchers. After 20 years of annual conferences and workshops, this number has grown to an impressive amount of almost 2,000 papers. When restricted to linear search and retrieval in a document collection of this size, it becomes inherently hard to identify topics, related work and trends in scientific research. Therefore, this paper presents and evaluates a map-based user interface for exploring 20 years of ISMIR publications. The interface visualizes k-nearest neighbor subsets of semantically similar papers. Users may jump from one neighborhood to the next by selecting another paper from the current subset. Through animated transitions between local k-nn maps, the interface creates the impression of panning a large global map. Evaluation results of a small user study suggest that users are able to discover interesting links between papers. Due to its generic approach, the interface is easily applicable to other document collections as well. The search interface and its source code are made publicly available. [1]

1. INTRODUCTION

Music Information Retrieval (MIR) has been a steadily growing field of research as documented by the official statistics from the International Society of Music Information Retrieval (ISMIR). [2] For the 20th anniversary of the annual ISMIR conference, the number of published papers at this event is expected to exceed 2,000. This work aims to make this great resource more accessible for researchers who would like to familiarize themselves with the field of MIR.

The classical search interface based on keyword search and result lists is well suited for users who know what they are looking for. However, in other scenarios, this might not be the ideal search approach and the amount and diversity of papers and topics can be overwhelming. Exploratory information retrieval systems support users with vague or evolving information needs by providing special user interfaces and interaction models. The ISMIR Cloud Browser [3] [4], last updated in 2013, allows browsing through links of related terms. Our new web-based search interface, the ISMIR Paper Explorer, takes a different – more visual – approach to exploration using similarity-based two-dimensional maps. It can be accessed at https://ismir-explorer.ai.ovgu.de.

Section 2 covers related and prior research that led to or inspired our approach. Details on the underlying dataset and preprocessing are provided in Section 3. We then describe the user interface in Section 4 and present the results from a usability study of our first prototype in Section 5. Furthermore, we also provide insights gained from analyzing the cumulative ISMIR proceedings to detect trends like shifts in topics and methods, and demonstrate whether and how these findings show in the visual search interface (Section 6). Finally, Section 7 offers conclusions.

2. RELATED WORK

In contrast to keyword-based search or recommendation, the goal of exploration is not only to present relevant or related items, but to allow the user to learn about the information space and its properties. This is often desirable when dealing with large document collections and when an overview over a collection is preferred over a pinpoint search.

A common problem when designing interfaces for exploratory search is the typically very high-dimensional feature space used to describe the contents of the respective documents. Considering the task of exploring text documents such as scientific papers, the document contents is commonly expressed as a (weighted) vector of term frequencies (tf-idf). Depending on the selected vocabulary, these often gather up to thousands of dimensions, which are hard to be displayed on a common computer display. Thus, map-based visualizations of inter-document similarities requires projection of these features into a two-dimensional display space. The neighborhood relations in high-dimensional space, however, should be

[1] https://doi.org/10.6084/m9.figshare.8342594
[2] https://www.ismir.net/stats.html
[3] http://dc.ofai.at/browser

preserved throughout the projection so that similarity can be easily perceived by the user.

In order to reduce the dimensionality of the feature spaces, different dimension reduction techniques have been proposed (a comprehensive survey is given in [2]). Popular approaches for dimensionality reduction are Self-Organizing Maps (SOMs) [6], Principle Component Analysis (PCA) [5] and Multidimensional Scaling (MDS) techniques [8].

Inevitably, any reduction of dimensionality will also reduce the information conveyed. None of the aforementioned methods is capable of fully preserving the structure of the collection (unless the collection already has a 2-D structure). A projection will cause errors in a sense that documents, whose feature vectors are very close in high-dimensional space might be projected at large distances from each other and documents that are very dissimilar are placed next to each other respectively. Most dimension reduction techniques try to minimize this error (e.g. stress optimization in MDS), however, a complete resolution is impossible due to the nature of the error. In [13] the authors reviewed and compared different dimensionality reduction algorithms for the visualization of music collections. Based on a user study, MDS was favored as best layout algorithm when the collection undergoes changes due to newly added items.

Although applied in the context of image retrieval, Rubner et al. [11] were among the first to propose multidimensional scaling for iterated search in large document collections. The authors suggest to compute a *local* MDS on the top ten best matching images for a given query. Follow-up queries are emitted by using a representative image of a specific area in the MDS as the next query. A *global* MDS is suggested by the authors to provide a broad overview of the entire collection. While this global approach gave good results for rather small sets of images (the authors tested with a 2-D map of 500 images) it can be easily seen that very large collections (such as the collection of all ISMIR papers) cannot be reasonably presented at a time. Moreover, the number of projection errors will increase with increasing number of documents to be displayed.

A different approach to local MDS is given in [14]. The authors discuss the problems of dimension reduction and introduce the measures of *trustworthiness* (closest neighbors of a document in display space are also neighbors in original space) and *continuity* (all proximities in original space are visualized in display space). The proposed method to local multidimensional scaling is different from the one suggested by [11] in that it allows to parameterize and adjust the compromise between trustworthiness and continuity using an adapted cost function. The MDS is computed on varying neighborhood sizes and trustworthiness as well as continuity are reported to decrease with increasing neighborhood size. In a subsequent work the authors present an unsupervised and a supervised approach to optimize both measures [15].

As discussed, naturally, none of these approaches is capable of actually solving the problems of dimension reduction. In this paper, we therefore follow the idea of reducing the projection error itself rather than trying to attenuate the errors that occur from dimension reduction. Similar to [11] we compute a local MDS on a small subset of the entire collection. Our approach followed in this paper takes these ideas one step further by computing a significantly larger virtual map using MDS of which only a small subset is actually displayed. By selecting one of the displayed documents as follow-up query document, the user can navigate through the collection. Thus, we increase the overlap of any two consecutive maps and thereby increase continuity throughout the navigation process. Furthermore, as suggested in [13] we use Procrustes analysis [3] to better align newly generated maps with their respective predecessors, which leads to a reduced confusion of users when navigating with aligned maps.

3. DATASET PREPARATION

We collected all accessible papers from the years 2000 to 2018 [4] by scraping the respective conference websites, the DBLP index [5] and the recently established Zenodo repository. [6] From a total of 1822 URLs, 28 were broken. We were able to retrieve 16 of these papers through a manual web search. 12 papers are still missing. Meta-data such as paper title and authors, publication year and abstract was retrieved from DBLP. In order to obtain paper citation counts, Google Scholar [7] was queried.

All papers were pre-processed in order to extract the plain text from the originating PDFs (where possible). For several older papers, we had to apply OCR techniques because they only contained the text as image or used obscure font encodings – possibly to hamper copying text from the paper. We experimented with several text extraction tools and eventually settled for *pdftotext* as provided by the Xpdf PDF viewer and toolkit [8] which consistently provided good extraction results. 3 PDFs turned out to be corrupted, leaving 1807 paper to be indexed.

As the meta-data is missing abstracts for most of the papers, we automatically extracted abstracts from the texts using simple heuristics. Furthermore, a preview image of the first page of each paper was extracted using *pdftopng* provided by Xpdf. For imports of future proceedings, scripts have been created to automate the process.

4. PROPOSED USER-INTERFACE FOR VISUAL BERRYPICKING

In classic information retrieval, *berrypicking* refers to the process of finding relevant information through a series of modified search queries [1]. With each query the user inspects a new set of search results and gains a better understanding of the underlying document space as well as his or her information need. Due to this incremental learning process the user is able to formulate new search terms and continue searching.

The proposed user interface adapts this pattern from a list-based presentation of search results to a map-based visualization. Instead of sorting results by relevance with respect to search terms, they are arranged in a similarity preserving two-dimensional projection. Additionally, the burden of having to formulate search terms is substituted by a query-by-example

[4] We aim to update the explorer until the 2019'th ISMIR conference in order to provide access to all 20 years of ISMIR publications.

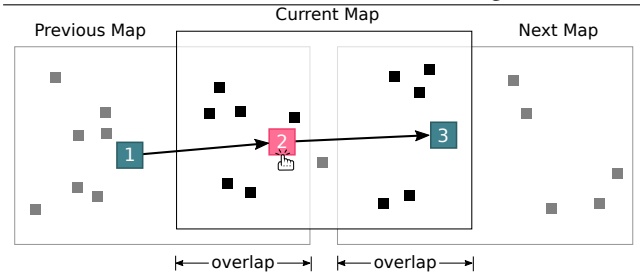

Figure 1. Similarity-based projection of nearest neighbors (squares) using three seed items (colored squares 1,2,3). Common neighbors (black squares) overlap between consecutive maps and are used for alignment when navigating from one item to the next.

search strategy. Such a user interface is hypothesized to be more in line with the goal of learning about the document space.

4.1 General Approach

Instead of trying to visualize the whole proceedings collection in a single similarity-based two-dimensional map, we visualize only the set of k-nearest neighbors for a given seed document in a small map [9]. This circumvents the challenge of the degrading projection quality (c.f. Section 2) and the increasing computational costs for on-the-fly map generation. By selecting a new seed document amongst the k-nearest neighbors, the user is able to hop from one neighborhood map to another. Consecutive maps are aligned as illustrated in Figure 1 to create a consistent transition that is, ideally, perceived as panning a large (global) map. Users are able to transfer knowledge about the content and the relevance of documents accumulated during the exploration process from one visualization to the next. This allows the user to navigate step-by-step through the whole collection.

4.2 Methods

We apply Multi-dimensional Scaling (MDS) [8] for dimensionality reduction. By limiting the number of documents used to compute the projection, we reduce the impact of projection errors and thus visualizations become more reasonable. Transitions between consecutive maps are animated. In order to make these transitions as consistent as possible, we align consecutive maps on their common neighbors. We use Procrustes analysis [3] to reduce the sum of the squared distances between the two sets of images that remain visible during the transition.

As preparation within the Python-based backend, all extracted texts are indexed using the Whoosh library. [9] We also pre-compute pairwise document similarities (stored in a distance matrix) using the tf-idf vector space model [12] considering the 1,000 most frequent terms after applying a Porter Stemmer [10]. This pre-computation allows to quickly retrieve k-nearest neighbors and the corresponding distance matrix for the MDS projection.

The front-end is implemented in HTML5 based on the jQuery [10] javascript library. Cookies are used to store pinned and highlighted papers as well as the user interface settings (cf. Section 4.3). They also allow to track individual sessions for evaluation purposes.

4.3 User Interface

The user interface as shown in Figure 2 consists of three major components: a search bar on top that provides a keyword search interface and access to the settings for the visualization, the map visualization on the left and a details pane that displays the meta-data and the abstract or a preview image for the paper that is currently in focus.

A search can be started by clicking on one of the initially displayed papers or by typing query terms into the search bar. This will generate a map of the k most relevant ISMIR papers for the query. The matching query terms used to populate the initial view are highlighted in the presented information on the map as well as in the details pane. The parameter k is initially set to 30 but can be altered by the user. By clicking on any paper, it will gain focus (indicated by a blue border) and the map will change to display the k most similar ISMIR papers using this paper as new query. A paper can also gain temporary focus (without map update) by hovering the mouse pointer over it. As alternative to the default map visualization, the papers can be arranged in a grid layout that preserves similarities and, in addition, avoids overlaps, see Figure 6 (right).

On the map, each paper is visualized as a rectangle with the title and the last names of the first and last author inside. The fill color saturation visualizes the citation count whereas the border color highlights the current paper in focus (in strong blue) as well as the recent history of focused papers (in light blue). On hovering over a paper, functions for pinning and highlighting become available which are visualized by a landmark pin and a star respectively as explained in Figure 3. Both become permanently displayed in yellow if selected. Pinning keeps a paper on the map, even if it no longer belongs to the k-nearest neighbors of the paper in focus. This can be especially helpful when identifying related work and using the map to visualize similarity relations between the found papers. Highlighted papers are easy to spot because of the star and the additional yellow border color. This function can, for instance, be used to help orientation on the map. Furthermore, papers can be bookmarked using the bookmarking function built into the web browser. The browser's back and forward buttons allow to step through the search history.

The details pane on the right displays the meta-data of the paper in focus comprising the title, the full list of authors, the publication year, and the citation count at the top. Below are two tabs containing the abstract and a preview of the first page of the PDF respectively. Clicking on the title opens the PDF. There is further a link to the DBLP BibTeX record. The content of the details pane can be temporarily changed by hovering over a paper on the map. This allows to inspect paper details without having to focus the paper which would imply a map update.

A first user interface prototype with the functions described above was evaluated in a usability study as described in Section 5. Afterwards, several additional functions were introduced to support a historical analysis of the cumulative ISMIR proceedings for the 20th anniversary. To visualize the year of publication for papers displayed on the map, the fill color hue

[9] https://bitbucket.org/mchaput/whoosh/
[10] https://jquery.com

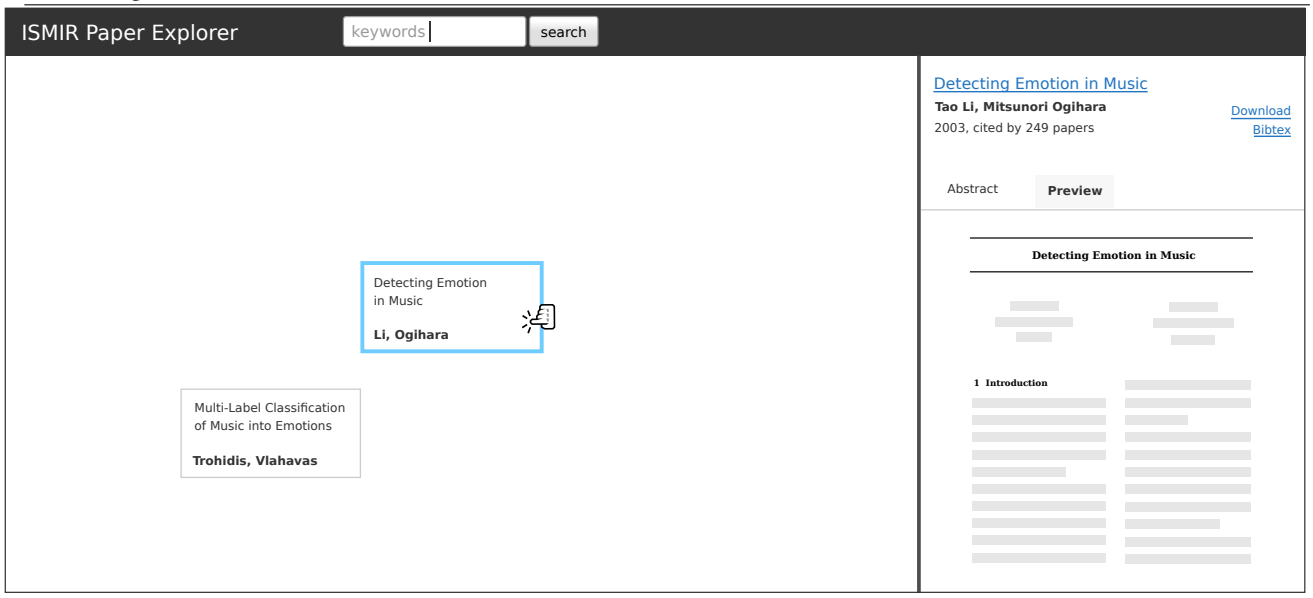

Figure 2. User interface schematic.

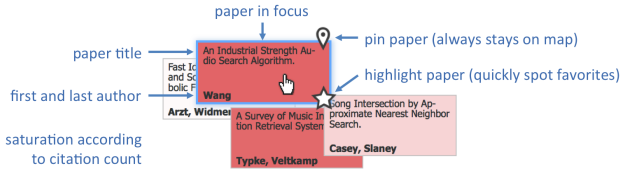

Figure 3. Explanation of the visual elements used in the map (accessible through a help button in the search bar at the top of the user interface).

was adapted. To this end, a continuous color map was divided into 20 steps representing the years. This is compatible with the original coloring to indicate the citation count as this only relies on the color saturation. Furthermore, instead of starting with a random paper in focus and its k-nearest neighbors, we now start with the k most cited papers which naturally cover a wide range of topics addressed in MIR. This makes for a nice starting point to explore the different sub-fields of MIR.

5. EVALUATION

Based on the prototypical implementation of the exploration interface described above, we conducted a small anonymous user study with the aim to evaluate user satisfaction with the presented design. Study participants were asked to compare the explorer interface with available traditional linear paper browsing interfaces for the ISMIR proceedings. Specifically, we asked about experiences using DBLP [5], the Cumulative ISMIR Proceedings browser [11] as well as the ISMIR Cloud Browser [3] [4]. Furthermore, participants were also free to mention tools apart from these. We were interested to see whether the prototype helped to identify related literature and discover additional related topics, which were the fundamental goals when designing the interface. We also wanted to know whether the prototype helped to efficiently find what the user was looking for.

Furthermore, we asked the participants about their overall satisfaction with regard to the proposed interface. Here, we were mainly interested to see whether a fundamentally different approach to paper exploration is still considered as *easy to use*. A key aspect of the interface is the exploitation of the 2-D map to spatially arrange similar papers. We therefore wanted to know whether the spatial grouping helped to *infer relevance* for unknown papers and whether the user were able to effectively *refine the topic focus* during navigation. Finally, as mentioned above, applying the MDS to a restricted neighborhood may result in some confusion when changing the views. We were interested to understand whether the arrangement of papers during navigation was still perceived as *plausible*.

Finally, the users were able to enter additional comments and proposals for improvements in free text.

5.1 Evaluation Results

We received a total of 20 valid responses. Figure 4 presents the aggregated results of all responses. Out of the 20 participants, 13 users were experienced with some of the alternative search tools for finding relevant ISMIR papers. 2 participants mentioned Google or Google Scholar as alternative tools for browsing, which are both linear search and retrieval tools. For users, who were not experienced in any other alternative method for ISMIR paper exploration, we rated their answers regarding the comparison with the proposed protoype as neutral.

In general, the prototype was rated very positively by the study participants. We were pleased to see that a majority of the participants (65%) agreed that the proposed approach helped them to identify literature related to their topic of interest. An overwhelming majority of 90% of the participants furthermore agreed or strongly agreed to the claim that the interface was easy to use, which surprised us due to the fundamentally different browsing experience. Furthermore, according to the results of the study, the suggested spatial alignment helped 70% of the participants to infer the relevance of unknown papers based on the grouping of the neighborhood. As could have been expected, a small number of participants (20%) were not satisfied with the arrangement of the papers

[11] http://www.ismir.net/proceedings/index.php

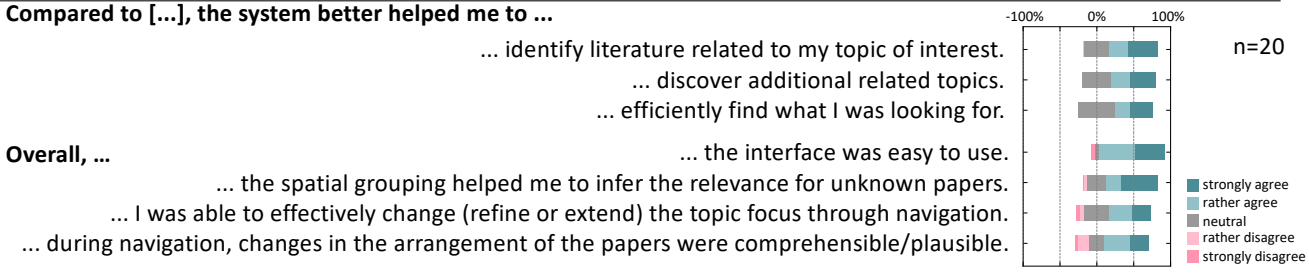

Figure 4. Evaluation results presented in diverging stacked bar charts showing the percentage of participants rating the proposed interface according to the respective statements.

during navigation as it was not considered comprehensible.

A number of participants asked us to publicly release the source code for future development. A few other comments were made with suggestions to further improvements of the usability. One participant mentioned that it is currently not possible to retrieve a list of bookmarked papers, which is a valuable feature for a future release. A few users mentioned that a persistently visible tutorial or legend would help a novice to better use the interface. Finally, an issue was raised about the overlapping surrogates in the non-grid view, which make it sometimes hard to reach them with the mouse. While we encourage the use of the grid view in these cases, we are aware that the grid layout also breaks the spatial alignment of the papers.

6. EXPLORATORY SEARCH

To identify interesting trends in the dataset, we first followed a conventional approach. We binned the publications into 5-year spans and performed a basic bi-gram analysis on the paper abstracts. Table 1 shows the most frequent bi-grams for each bin. Next, we applied a simple heuristic proposed in [7] to detect the most popular methods by assuming that the name of the method appears after phrases like "based on" or "using."

Having identified the most prominent methods, we counted all papers per year mentioning them. For this, we also considered variations like acronyms or slightly different ways of spelling. A plot for the most popular methods is shown in Figure 5 (top). The rise of deep learning since about 2012 cannot be overlooked here. The middle plot in Figure 5 shows the development for select MIR topics like query-by-humming (QBH) which was particularly popular in the early 2000s, optical music recognition (OMR) which has been of constant interest, the development of graphical user interfaces (GUIs) which peaked in 2004 and 2008 mainly driven by approaches based on self-organizing maps (SOMs), and music recommendation which gained massive popularity around the turn of the decade and has leveled off slightly since then. Finally, Figure 5 (bottom) shows the popularity of selected music features over time. Here, the increasing use of chroma features and the slow development of MIR research addressing emotions stand out. At the same time, melody had a very high initial popularity (likely due to a focus on symbolic music representations and QBH in early years) that it lost to some extend over time but may gain back thanks to recently sparked interest in generative models for music. This trend could also explain the emergence of "symbolic music" as a top-5 bi-gram in most recent paper abstracts.

Next, we wanted to see, whether we can make similar

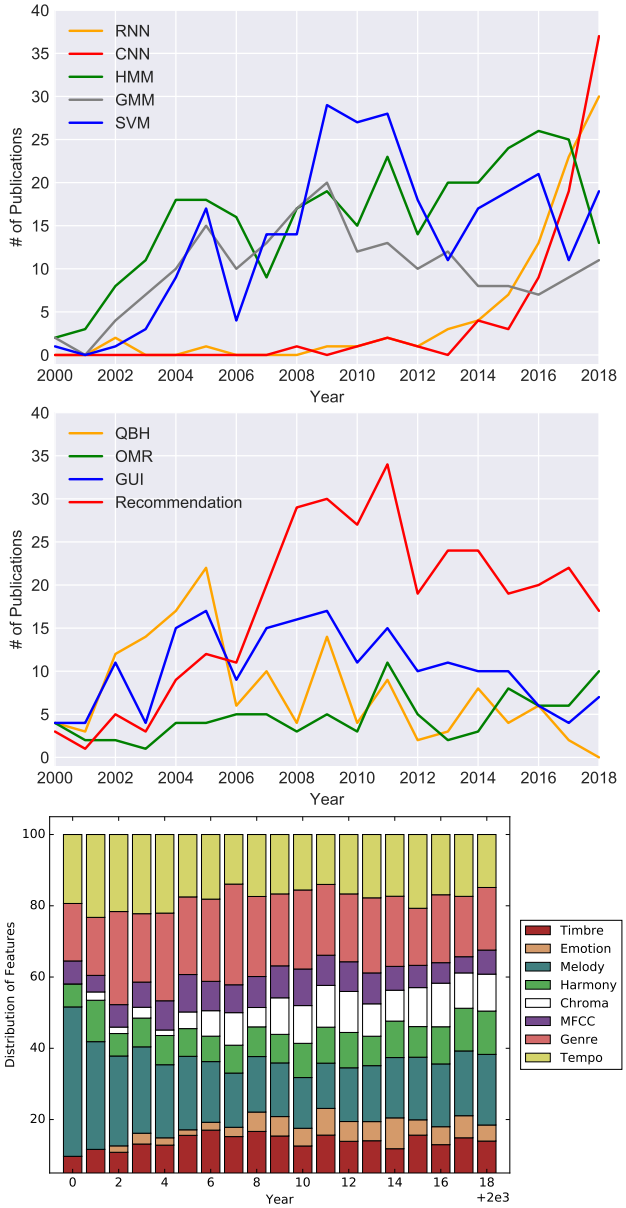

Figure 5. Examples for development over time. Top: popular machine learning techniques. Middle: selected MIR topics. Bottom: selected aspects/features of music.

observations with our exploratory search interface. Here, the same data is used in the back but only a small part of it is shown at a time to not overwhelm the user. Figure 6 (left) visualizes the top-30 papers for the query "query by humming." Based on the dominating orange and green hues, most of

Table 1. Top-5 bi-grams for each 5-year bin. Numbers correspond to the frequency of each bi-gram within paper abstracts.

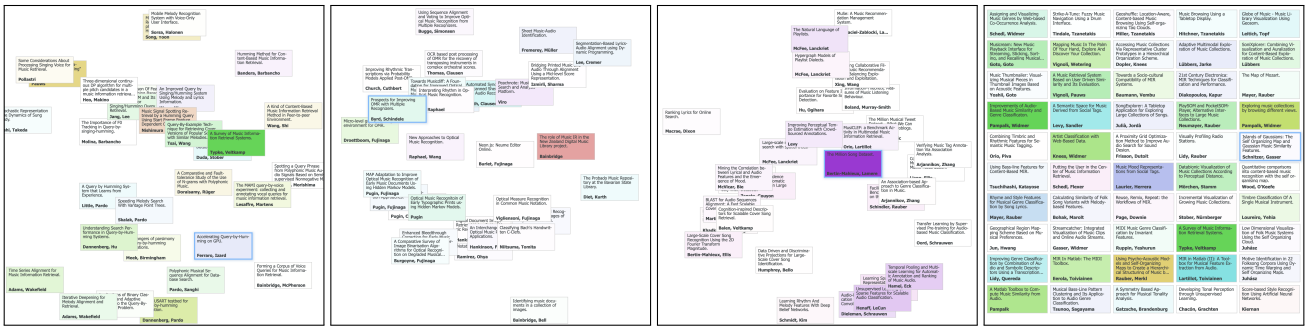

Figure 6. Map visualizations for selected initial search queries – from left to right: "query by humming", "OMR", "million song dataset", "SOM". All except the rightmost sub-figure show the top-30 results. The rightmost sub-figure shows the top-50 results for "SOM" in grid mode. The color saturation is proportional to the citation counts and the hue corresponds to the year starting with red in 2000 and continuing in equal steps through the spectrum.

the papers come from the early-to-mid 2000s with the by far most-cited paper being a survey of MIR systems from 2005. This matches the respective plot in Figure 5 (middle). The advantage in the view is that clusters can be identified like the aspects of singing in the top left, alignment in the lower left or system performance at the bottom.

For the topic OMR (second map from the left in Figure 6), there are some highly-cited papers around 2010 but there is also plenty of coverage in recent years which is in line with Figure 5 (middle). Recognizable clusters comprise, for instance, alignment (top right), applications in libraries (middle right) and old data (bottom).

The third map from the left in Figure 6 shows papers mentioning the Million Song Dataset. As can be seen easily, these are all fairly recent papers with the original publication standing out clearly due to its high citation count. This visualization nicely illustrates the different ways this dataset has been used in research since its publication. There are, for instance, clusters on cover songs (lower left), training deep neural networks (lower right), and on playlists and recommendation (top).

Finally, the rightmost map in Figure 6 shows the top-50 papers for the query "SOM." They are displayed in grid mode to avoid clutter which starts to become an issue at this setting of k for typical screen resolutions. Nevertheless, the 50 papers can still be displayed comfortably in grid mode. This visualization covers almost all relevant papers for this topic. Here, the most-cited papers can be attributed to the period between 2005 and 2010 which was a time of high popularity for this technique being used in a large variety of graphical user interfaces. This also correlates with the two peaks around this time for GUI in Figure 5 (middle).

These are just a few examples about what can be discovered by exploring the cumulative ISMIR proceedings using our proposed user interface.

7. CONCLUSION AND OUTLOOK

In this paper, we presented and evaluated a novel map-based user interface to explore the past 20 years of ISMIR publications. The proposed approach uses an MDS dimensionality reduction on a locally-restricted neighborhood of a query paper in order to project a high-dimensional feature space into 2-D while at the same time keeping projection distortions at a minimum. Consecutive maps are aligned in order to create a consistent impression of panning a global map.

Based on the interface, the user is able to find out a number of interesting topics in the ISMIR collection that would be hard to identify using a linear search interface. As an example, the topic "query by humming" almost disappeared in the early 2010's after having peaked in the early 2000's. While this fact would be hard to extract manually from a linear search interface, it is revealed at a single glance using the proposed prototype.

Besides updating the data to include recent ISMIR publication, one possibility for extension is to consider MIR-related papers not published at ISMIR. Respective candidates could be discovered by analyzing the reference sections. This would also allow an additional co-reference analysis which could enrich the interface further. We will also provide support to integrate the ISMIR Explorer into the official ISMIR website.

8. ACKNOWLEDGMENTS

We would like to thank all participants of the user study and the reviewers for their constructive feedback.

PATTERN CLUSTERING IN MONOPHONIC MUSIC BY LEARNING A NON-LINEAR EMBEDDING FROM HUMAN ANNOTATIONS

Timothy de Reuse, Ichiro Fujinaga

ABSTRACT

Musical pattern discovery algorithms find instances of repetition in symbolic music, allowing for some user-specifiable amount of variation between identified repetitions; however, they can yield an intractably large number of discovered patterns when allowing for even small amounts of variation. This is commonly addressed by defining some heuristic notion of pattern significance, and returning only the most significant patterns. This paper develops a method of pattern discovery that models human judgement of what constitutes a significant pattern by incorporating annotations of repeated patterns, avoiding the need to design heuristics.

We take pattern discovery as a clustering task, where the input is a set of passages of monophonic music, represented as vectors of extracted features, and the output clusters correspond to discovered patterns. The human annotations are used to train a neural network to learn a low-dimensional embedding of the feature space that maps passages of music close together when they are occurrences of the same ground-truth pattern. The results of this approach match up with the annotations significantly better than the results of an approach using clustering without subspace learning. We provide examples of the types of patterns that this method tends to discover and discuss its feasibility and practicality as a tool for extracting useful information about repetitive structure in music.

1. INTRODUCTION

To discover patterns in a piece of music is, loosely speaking, to find passages that are similar to other passages, and to cluster these passages into inter-related groups. This is done with the goal of producing motivic analyses [34], automated composition systems [6], or as a single step to provide information for some larger Music Information Retrieval application [17]. Humans can perceive repetition between two musical passages even when the passages vary somewhat, so it is important to incorporate some allowable margin of variation between members of a single pattern; unfortunately, this causes a combinatorial explosion, returning many more patterns than are useful for any application. Inexact repetition simply occurs in music too often by chance; as [29] put it, "Most repetitions in music are not interesting." For this reason, discovery of patterns cannot be reduced to the problem of finding passages of music within a single piece that are similar to one another. Limiting the number of patterns found by a pattern discovery algorithm in a systematic way means explicitly or implicitly defining some measure by which one pattern can be judged as "more significant" than another; we refer to these as *pattern significance* measures.

Previous work by Collins et al. [10] suggests that analysts judge pattern significance consistently, based on quantifiable features of the musical surface. By analyzing ground-truth significant patterns, we can simultaneously learn a sense of what metric of melodic similarity the annotators used (by comparing occurrences of a single pattern) and a sense of the metric of pattern significance used (by comparing significant patterns to insignificant patterns), and use these findings to inform a pattern discovery method. We use these insights to model pattern discovery as a cluster analysis problem, where the input data points are a set containing all possible passages of music from the piece under investigation, and the output clusters correspond directly to discovered patterns. There are parallels between common issues in cluster analysis and pattern discovery that make this a sensible choice of technique: it is rarely known in advance how many clusters (or patterns) are present in a dataset (or piece), and validity measures for particular clusterings (or sets of discovered patterns) are the subject of ongoing investigation [15]. The goal here is that our clustering approach learns some criteria of what makes the particular patterns in the ground truth significant, and uses that criteria to return a limited number of patterns. Ideally, the model should be able to rediscover all the ground truth patterns from the songs that contain them, and not too many more.

The terms used to refer to sets of repeating musical passages vary widely throughout the literature. We will define a *pattern* as any set of musical excerpts, and refer to these excerpts as the pattern's *occurrences*. Each pattern is labelled as either *significant* or *trivial*. We ascribe no external meaning to a pattern's significance; if an analyst deems a pattern "significant," we assume that to mean nothing more and nothing less than "this analyst would consider this pattern to be of particular interest in this piece."

2. RELATED WORK

Early musical pattern discovery algorithms were string-based, dealing primarily with monophonic inputs [3, 12, 16, 22, 33, 34]. Geometric pattern discovery approaches were developed to deal with polyphonic music, most often representing music as sets of (onset time, MIDI pitch) or (onset time, morphetic pitch) pairs [5, 9, 21, 29, 36].

There are many proposed methods of reducing the number of patterns that are discovered. An early heuristic was based on the concept that patterns are more significant when they are unexpected, and so should be given more weight if their occurrences are statistically unlikely given the distribution of pitches and duration values elsewhere in the piece [11]. Other heuristics take inspiration from information theory, reasoning that a pattern is significant if it can be said to explain a great deal of the redundancy of the piece containing it [**?**, 1, 23, 26–28]. Research by Lartillot has attempted to emulate the cognitive processes that cause a listener to associate present material with past material stored in memory [18–20]. Velarde et al. use the Haar wavelet transform to analyze symbolic music for purposes of pattern discovery by considering the pitch of a monophonic melody as a signal; implicit in this approach is the assumption that this transform allows access to a higher-level musical property that is more relevant to perception of melodic similarity than raw pitch data [39, 40]. Clustering-based approaches are relatively uncommon, often using the clustering aspect for some form of visualization [2,4,17]. Directly comparing the performance of these algorithms is not straightforward. Evaluation against a set of human annotations is standard for the MIREX task in this area [8], but the ground truth used for evaluation there is sparse and taken from several different areas, making it difficult to extrapolate the accuracy of a single method to the method's quality as a whole.

The largest study that investigated human annotations of pattern importance was performed by Collins et al. [10], who asked 20 musically trained subjects to classify patterns in one of Chopin's Mazurkas based on how likely they would be to discuss each pattern if asked to write an essay analysing the whole piece. Principal findings from this study were that a small number of features could be used to explain 70% of the variation between the patterns' importance ratings. The results from this study do not constitute a pattern discovery method in and of themselves, but they speak to the possibility that human significance judgements might be consistent enough to inform a pattern discovery method.

3. APPROACH

This section describes the setup necessary to define our proposed approach. Three main steps are necessary: assembly and feature extraction on the data set, defining a training method that learns an embedding of our feature space, and clustering on the embedded data set.

3.1 Dataset Assembly

The dataset under investigation is the Meertens Tune Collection Annotated Corpus (MTC-ANN) [38], which comprises 93 patterns among 360 monophonic Dutch folk songs in 26 tune families. Each pattern has, on average, 17.8 occurrences, and the average length of an occurrence is 4.14 notes. The small size of the occurrences in this corpus is worth concern; out of the 1657 total occurrences identified across all patterns, 433 of them are three notes long, and 323 of them contain only two notes. It is not obvious that such short snippets of music permit the extraction of useful information about pattern significance. Additionally, these patterns were found as part of a larger annotation process which emphasized finding features of songs that are useful in separating the songs into tune families [37, 41]; our approach uses the assumption that the same implicit significance measure was used for all annotations, but the annotators may have changed their criteria depending on the tune family under consideration. Still, the high number of occurrences per pattern is beneficial for our clustering method, since it is in general easier to detect a denser cluster than a sparser one. Since MTC-ANN contains only segment-like occurrences (i.e., occurrences that contain every note within a single time interval) we will deal only with this type of occurrence. Section 5 discusses how more general subsets of notes might be used instead.

We must find some trivial patterns to compare with this set of significant patterns. We operate under the assumption that any pattern not specified as significant in MTC-ANN is implicitly judged to be trivial. The SIARCT-C (Structure Induction Algorithm for R superdiagonals with Compactness Trawling and Categorization) algorithm, described in [9] and distributed in the PattDisc software toolkit [7], will be used to generate a set of negative examples. In MTC-ANN, patterns are discovered between songs that lie in the same tune families; to match this, and to avoid dealing with the gargantuan number of patterns that would be found looking in 360 songs at once, we find our trivial patterns strictly within the bounds of each tune family. In this process, SIARCT-C will likely find some of the motifs that were identified in MTC-ANN. We remove any pattern from our collection of trivial patterns if it matches one of the significant patterns too closely, where a match is registered if at least half of the occurrences are identical.

We stated previously that pattern discovery could be defined as a clustering problem by considering the input to be "all possible passages of music" extracted from a given input. The occurrences of these discovered trivial patterns will serve as a stand-in for this set of all possible passages to avoid having to work with it directly. This should not cause any loss of generality, since the huge number of patterns returned by SIARCT-C does not significantly help us narrow down the search space. This run of SIARCT-C can be interpreted as a pre-processing step on the set of all possible musical passages from the dataset, where passages are removed if they do not repeat often enough to have a chance at being part of a significant pattern.

3.2 Feature Extraction

Instead of representing each occurrence of our patterns as an ordered sequence of notes and durations, we represent them as feature vectors, to allow the inclusion of information about the context of each occurrence; for example, we quantify how much its pitch range differs from that of the song containing it. Most of the features we extract are defined in the documentation of jSymbolic2, a software tool for extraction of features from symbolic music files [24, 25], but others were devised in previous work specifically for the purpose of extracting useful information from very short passages of music [13]. They fall into five broad categories, here listed with the number of features each contains:

- **Pitch-Related:** Features relating solely to the ordered pitch values of each note (n = 21).
- **Rhythm-Related:** Features relating solely to the ordered duration values and metrical positions of each note (n = 10).
- **Contour-Related:** Features using both pitch and duration values to describe how the sequence changes over time (n = 6).
- **Histograms:** Multi-valued features indicating the raw number of notes with a particular pitch class or duration (n = 31).
- **Context-Related:** Features comparing properties of the occurrence to properties of the song containing it (n = 38).

All together, this yields a feature set of size 106. A detailed list of features and their definitions is provided in the supplementary material to this paper.

3.3 Learning an Embedding

We now have a dataset containing 11,471 short passages of music, each represented as a 106-dimensional feature vector. 1,657 of these are categorized into one of 93 significant patterns, where all members of a single pattern are considered similar to one another and dissimilar to members of any other pattern. 9,814 of our data points are from trivial patterns, and we consider each of these to be dissimilar to every other data point.

The neural network used to learn the embedding is a fully-connected feed-forward network with two hidden layers, each containing 100 nodes, using dropout and batch normalization, and an output layer of size five. The training process for this network takes pairs of data points as input. We use three types of pairs, in equal measure: pairs where both points are members of the same ground-truth pattern (labelled as similar), where both points are members of different ground-truth patterns (labelled as dissimilar), and where one point is from a ground-truth pattern and one is from a trivial pattern (labelled as dissimilar). Both data points are fed separately through the hidden layers, transforming them both into lower-dimensional vectors of length 5, and then their difference is taken; the L1 norm of this difference is the output of the network. Training implements a hinge loss that encourages the output to be near zero if the two input data points are labelled as similar, and encourages the output to be above some margin value (here set to 1) if the points are labelled as dissimilar. Training is halted when the loss on a validation set does not decrease for 1,000 epochs.

The effect of this process is to train the network to learn an embedding of the 106-dimensional feature space into a 5-dimensional space where occurrences of significant patterns are clustered together, and all clusters are placed far away from one another.

3.4 Clustering

We use the DBSCAN (Density-Based Spatial Clustering of Applications with Noise) algorithm to cluster our transformed data points [14]. DBSCAN labels sparser areas of the dataset as containing unlabelled noise, which is ideal for this application, as we expect that most data points will represent musical content not part of significant patterns.

DBSCAN takes two parameters; a minimum cluster size, which we set to 3 based on the size of the smallest patterns in our ground truth, and a value ϵ which, roughly, characterizes how close together points must be near the centers of the discovered clusters. Choosing an optimal ϵ is not straightforward; too high and the data will be partitioned into a few large clusters, but too low and most points in the dataset will be taken as noise. The designers of the algorithm recommend the use of a *k-dist graph* to estimate an optimal value. The k-dist graph of a dataset is formed by finding the k-th nearest neighbor of each data point, calculating the distance between each point and its identified neighbor, and sorting these distances in descending order. On a dataset well-suited to clustering, this sequence of distances should form a curve with a single sharp bend; to one side of this bend, where the distances are high, most points are noise points not part of any cluster, and on the other side of the bend, most points are close to their k-nearest neighbor and are likely members of well-defined clusters. The recommended value for ϵ is the value of the graph at this point of bending. Since most points in our dataset might be considered noise, we will evaluate our method over a range of values for ϵ that are further down the curve than this bending point, which will force clusters to be more tightly packed.

An image of the k-dist graph for one of the experiments run in Section 4 is included in the supplementary material to this paper.

4. EVALUATION

We use cross-validation to evaluate the method's performance. The data is split into training / validation / testing sets based on tune family, to ensure that we train the clustering method on the patterns contained in a particular set of songs and then test that method by discovering patterns in a totally separate set of songs. Each set includes all pat-

	Num. Clusters Ratio	Median Cluster Size	All Points		Significant Points	
			Homogeneity	Completeness	Homogeneity	Completeness
Embedding						
ϵ_5	**2.14 ± 0.39**	**6.50 ± 0.40**	0.25	0.12	0.37	0.62
ϵ_{10}	4.76 ± 1.02	5.90 ± 0.21	0.44	0.13	0.63	**0.67**

ϵ_{25}	10.96 ± 2.33	4.40 ± 0.22	0.52	0.12	0.63	0.62

Table 1: Results of the experiments described in Section 4. Plus-minus signs (±) indicate the standard error of a statistic over the five test sets. Standard errors for the homogeneity and completeness statistics are consistently $\ll 0.05$ and are omitted for readability.

terns, significant and trivial, that lie in its designated tune families.

The training and validation sets must be assembled into pairs before the neural network can take them as input. We generate three sets of pairs corresponding to the categories defined in section 3.3. We take all possible unique pairs of the first category that our training set permits—that is, all possible pairs involving two distinct occurrences of the same significant pattern—and reduce the next two categories to the same size as the first through random sampling without replacement. The total number of data point pairs generated via this process varies depending on which tune families are selected from MTC-ANN for validation and training, since every tune family has a different number of identified patterns, but in practice this number lies in the range from $20,000$ to $40,000$.

Once the network has been trained on this set of pairs, we use it to reduce the test set into vectors that lie in the learned subspace. We run DBSCAN with five different values of ϵ, which are estimated by building a k-dist graph on the test set with k=3. For all test sets, this graph has a very sharp bend near the 5th percentile. Denoting the value at the nth percentile of the k-dist graph as ϵ_n, we test DBSCAN with values of $\epsilon_5, \epsilon_{10}, \epsilon_{15}, \epsilon_{20}$, and ϵ_{25}. Each of these clusterings can finally be compared directly with the patterns in the test set.

We contrast this method with one that uses Principal Component Analysis (PCA) to reduce the dimensionality of the dataset instead of a learned embedding. The test sets are processed with PCA and the five components of highest magnitude are retained. DBSCAN is used to cluster the result, with the same procedure for estimating ϵ as before, using a k-dist graph built on the PCA-reduced data.

Testing proceeds with 5-fold cross-validation. This does not evenly divide the number of tune families (26), but each tune family has a different number of patterns, and each pattern has a different number of occurrences, so no truly equitable division is possible anyway. The neural network is implemented using PyTorch 1.0 [30], while the implementation of DBSCAN is from scikit-learn [31]. Code for running these experiments is available at `https://github.com/timothydereuse/musical-pattern-clustering`.

4.1 Results

In Table 1, the *Num. Clusters Ratio* column compares the number of clusters obtained in each experiment to the number of ground-truth patterns in each test set. The *Median Cluster Size* represents the median number of occurrences within each pattern, averaged over all test sets. This somewhat awkward metric is necessary because using a straight average would skew too high to accurately represent the data; on every test set, both the PCA and embedding approaches tend to return one or two large patterns with hundreds of "noisy" occurrences, a phenomenon further discussed in Section 4.2.

Traditional metrics of classification accuracy such as precision and recall are not applicable in a clustering task where the number of classes is itself being predicted. The metrics used here are *homogeneity* and *completeness*, two complementary measures of clustering validity which compare a clustering to a ground-truth [35]. The homogeneity of a clustering measures the degree to which clusters in the output are comprised of a single class, assigning a score of 1 if every pattern in the output contains data points from only a single ground-truth pattern, even if some patterns are split apart. Similarly, the completeness measures the degree to which classes in the input are mapped to a single cluster of the output, assigning a score of 1 if every pattern in the input stays unbroken when mapped to patterns in the output, even if some patterns get merged together. We evaluate these two metrics against the ground truth in two different ways: first, considering all points in the test set, and then considering only the points

Figure 1: These four two-note occurrences are part of different patterns in MTC-ANN, but the embedding method merges all of their patterns into one.

(a) Three occurrences from a pattern in MTC-ANN erroneously included in a large, noisy cluster by the embedding method.

(b) Three occurrences from the same pattern in MTC-ANN correctly clustered together by the embedding method.

Figure 2

Figure 3: This pattern found by the embedding method is not present in MTC-ANN; however, there is a short three-note pattern (marked by boxes) included in MTC-ANN whose occurrences lie *within* this pattern.

that correspond to significant patterns in the ground truth. Note the very low score for completeness across both the embedding and PCA methods; because the majority of the points in the dataset are labelled as noise, misclassifying any of them into clusters effectively "breaks up" the noise class and lowers the completeness. If we ignore the noise and focus solely on where significant patterns are clustered, we note that they are mostly preserved. The supplementary material to this paper contains an additional table showing the effects of excluding individual feature categories (as defined in Section 3.2) on the clustering.

4.2 Examples

We pick one of the test sets from the row ϵ_{15} of Table 1 to investigate further. This particular clustering finds 21 patterns within six tune families that together contain a total of 77 songs; within these six tune families, MTC-ANN notes 18 significant patterns. Most of the 21 patterns in this clustering do not correspond to patterns in MTC-ANN. In particular, two of the patterns have over 800 occurrences each, almost entirely containing longer occurrences from trivial patterns, with some longer occurrences from significant patterns scattered in as well. In each figure, occurrences are marked with black notes, whereas greyed-out notes show the context in which each occurrence lies.

Only six of the 21 identified patterns have significant overlap with the patterns in MTC-ANN. One reason for this low number is that the clustering method has merged some of the identified patterns together. Figure 1 shows four occurrences from one of these six clusters; all four of these occurrences lie in different patterns of the ground truth, and the full cluster (not shown here, for lack of space) comprises the union of these four original ground-truth patterns. Since all of these occurrences contain only two notes, it is likely that these particular patterns were designated as significant due to their metrical placement in their original songs. It is incorrect that these patterns were merged together, but the fact that *only* these patterns were merged together is notable. The trivial patterns found by SIARCT-C have no shortage of descending intervals that the algorithm might have added to this particular cluster, and yet it contains only descending intervals that were marked as significant by human annotators. This suggests that our subspace-learning neural network has learned something from the "context-related" features mentioned in Section 3.2 that relates to how the human annotators decided which two-note intervals in the original songs merited significance: not enough to separate these four patterns from each other, but enough to separate them from the rest of the dataset as a group.

Figure 2b shows another notable error made in this clustering. One of the ground-truth patterns in this test set is quite large and heterogeneous, comprising 20 occurrences each containing eight or nine notes. Where the occurrences have a relatively simple contour, the clustering correctly groups them together, but it groups the more complicated occurrences with other unclassifiable, long passages in the size-800 clusters mentioned above. It is likely that, given the small size of the dataset, the learned subspace does not encode a particularly complex conception of melodic similarity, which means that longer patterns are unlikely to cluster together unless their similarities are quite pronounced. Compare the three occurrences in Figure 2a to those in Figure 2b, which were successfully clustered into a single pattern, likely as a result of their more uniform contour, and those in Figure 3, where similarity in contour appears to have caused the embedding method to *extend* a pattern existing in MTC-ANN.

5. CONCLUSIONS

We have demonstrated an approach to discovering patterns in symbolic music that maps passages of music onto a low-dimensional subspace where significant patterns form clusters, using an embedding learned from human annotations of repeated patterns. This method outperforms a traditional dimensionality reduction algorithm on common metrics used to validate clustering results against ground truth. There is evidence that the method is capable of learning some notions of pattern significance from the human annotations; though the agreement is far from perfect, and the number of returned patterns is still high, the current state of the art in pattern recognition struggles to agree with human annotations at all [32]. To more rigorously validate this approach in future research, it would be informative to compare a clustering learned from human annotations with a clustering that uses a distance measure derived from an existing melodic similarity metric.

If we continue to restrict ourselves to segment-like occurrences, then extending this approach to polyphonic music would require only a feature set capable of encoding information about polyphonic occurrences. However, to be able to find patterns within polyphonic sources more generally, we must consider occurrences as subsets of notes instead, which is combinatorially infeasible; for a piece of music with n note onsets, there are $O(n^2)$ possible segments, but $O(2^n)$ possible subsets. To address this, it would be necessary to impose limits on the time-extent and number of notes in each occurrence, or to use an existing polyphonic pattern discovery algorithm as a p reprocessing step, as we do here with SIARCT-C.

More ground-truth annotations would undoubtedly increase the accuracy of this approach, but annotations of repeated patterns are expensive to acquire, and information from one set of annotations might not generalize well to other genres. The ability to extract useful information from small sets of repeated patterns would be a more valuable tool for development of practical pattern significance measures. A hypothetical use case for this research would be an interactive pattern-discovery interface where, in lieu of changing the parameters of a manually designed heuristic, users could view a list of patterns and mark some as significant, whereupon the algorithm would re-train on that small set and use its findings to reduce the number of patterns returned to the user.

ABSTRACT

Quantitative analysis of commonalities and differences between recorded music performances is an increasingly common task in computational musicology. A typical scenario involves manual annotation of different recordings of the same piece along the time dimension, for comparative analysis of, e.g., the musical tempo, or for mapping other performance-related information between performances. This can be done by manually annotating one reference performance, and then automatically synchronizing other performances, using audio-to-audio alignment algorithms. In this paper we address several questions related to those tasks. First, we analyze different annotations of the same musical piece, quantifying timing deviations between the respective human annotators. A statistical evaluation of the marker time stamps will provide (a) an estimate of the expected timing precision of human annotations and (b) a ground truth for subsequent automatic alignment experiments. We then carry out a systematic evaluation of different audio features for audio-to-audio alignment, quantifying the degree of alignment accuracy that can be achieved, and relate this to the results from the annotation study.

1. INTRODUCTION

An increasingly common task in computational musicology – specifically: music performance analysis – consists in annotating different performances (recordings) of classical music pieces with structural information (e.g., beat positions) that defines a temporal grid, in order then to carry out some comparative performance analyses, which require time alignments between the performances. As manually annotating many recordings is a very time-consuming and tedious task, an obvious shortcut would be to manually annotate only one performance, and then use automatic audio-to-audio matching algorithms to align additional recordings to it, and thus also be able to automatically transfer structural annotations.

The work presented here is part of a larger project on the analysis of orchestral music performance. In this musicological context, it is crucial to understand the level of precision one can expect of the empirical data collected. The present study attempts to answer two specific questions: (1) what is the precision / consistency we can expect from human time annotations in such complex music? and (2) can automatic alignment be precise enough to be used for transferring annotations between recordings, instead of tediously annotating each recording manually? We will approach this by collecting manual annotations from expert musicians, on a small set of carefully selected pieces and recordings (Section 3), analyzing these with statistical methods (Section 4) – which will also supply us with a ground truth for the subsequent step –, then performing systematic experiments with different audio features and parameters for automatic audio-to-audio alignment (Section 5), quantifying the degree of alignment precision that can be achieved, and relating this to the results from the previous annotation study (Section 6).

2. RELATED WORK

[13] presented a case study of opera recordings that were annotated by five annotators, at the bar level. The authors used the mean values over the annotators as ground-truth values for the respective marker positions and the variance to identify sections possibly problematic to annotate, and offered a qualitative analysis of the musical material and sources for error and disagreement between annotators.

[6] deals with the alignment of recordings with possibly different structure. Their contribution is relevant for our endeavor in so far as they evaluated different audio features and parameters ranges for an audio-to-audio alignment task on a data set of, among others, symphonies by Beethoven, which matches our data set very well. [7] evaluated audio features for the audio-to-audio alignment task using several different data sets.

While many studies of alignment features do not use real human performances but artificial data, we only use ground-truth produced from human annotations (by averaging over multiple annotations per recording) of existing recordings for the evaluation of the alignment task. Furthermore, the results of our analysis of manual annotations (Step 1) will inform our interpretation of the automatic alignment experiments in Step 2 (by relating the observed

alignment errors to the variability within the human annotations), leading to some insights useful for quantitative musicological studies.

3. ANNOTATION AND GROUND-TRUTH

3.1 Annotation vs. Tapping

Our primary goal is to map the musical time grid as defined by the score, to one or more performances given as audio recordings. Due to expressiveness performance, these mapped time points may be very different between different recordings. Following [4], we will call the occurrence of one or more (simultaneous) score notes a *score event*. In our case, we were interested in annotating regularly spaced score events, for instance, on the quarter note beats.

Different methods can be employed for marking score events in a recording. One possibility is to tap along a recording on a keyboard (or other input device) and have the computer store the time-stamps. We will refer to a sequence of time-stamps produced this way as a *tapping* in the following. Producing markers this way has been termed "reverse conducting" by the Mazurka project [1] .

This is to be distinguished from what we will call an *annotation* throughout this paper. In that case, markers are first placed by tapping along, or even by visually inspecting the audio waveform, and then iteratively corrected on (repeated) critical listening. In general, we assume corrected annotations to have smaller deviations from the "true" time-stamps than uncorrected tappings, especially around changes of tempo.

3.2 Pieces, Annotators, and Annotation Process

The annotation work for this study was distributed over a pool of four annotators. Three are graduates of musicology and one is a student of the violin. The pieces considered are: Ludwig van Beethoven's Symphony No. 9, 1st movement; Anton Bruckner's Symphony No. 9, 3rd movement; and Anton Webern's Symphony Op. 21, 2nd movement (see Table 1 for details). The first two are symphonic movements, played by full classical/romantic period orchestra. The third is an atonal piece where the second movement is of a "theme and variations" form, and requires a much smaller ensemble (clarinets, horns, harp, string section). While the first two pieces can be considered to be well known even to average listeners of classical music, the Webern piece was expected to be less familiar to the annotators. It is rhythmically quite complicated, with many changes in tempo and many sections ending in a fermata. We expected it to be a suitable challenge for the annotators as well as the for the automatic alignment procedure.

The quarter beat level was chosen as (musically reasonable) temporal annotation granularity, in all three cases. The annotators were asked to mark all score events (notes or pauses) at the quarter beat level, using the Sonic Visualiser software [2], and then to correct markers such that they coincide with the score events when listening to the playback with a "click" sound together with the recording of the piece. They also had to annotate "silent" beats (i.e. general pauses) or even single or multiple whole silent bars with the given granularity. It is clear that this may create large deviations between annotators at such points, as the way to choose the marker positions is not always obvious or even meaningfully possible in these situations.

Each recording was annotated by three annotators, giving us a total of 21 complete manual annotations [2] .

Composer	Piece	Part	Section	# Events
Beethoven	Sym. 9	1st mov.	complete	1093
A. Bruckner	Sym. 9	3rd mov.	150 - end	371
A. Webern	Sym. Op. 21	2nd mov.	complete	198

Table 1. Annotated works/parts, and number of events. Granularity in all cases: quarter notes.

Composer	Conductor	Orch.	Year	Dur.	Med. SD
Beethoven	Karajan	VPO	'47	16:00	32
	Karajan	BPO	'62	15:28	32
	Karajan	BPO	'83	15:36	27
A. Bruckner	Karajan	BPO	'75	09:30	68
	Abbado	VPO	'96	10:40	52
A. Webern	Boulez	LSO	'69	03:08	47
	Karajan	BPO	'74	03:28	63

Table 2. Annotated recordings. VPO = Vienna Philharmonic Orchestra, BPO = Berlin Philharmonic, LSO = London Symphony Orchestra. Each recording was annotated by three annotators. Med. SD is the median value of standard deviations of the annotations (in milliseconds, rounded to nearest integer), for details see Sec. 4.

4. EVALUATION OF ANNOTATIONS

For a statistical analysis of this rather small number of human annotations, we need to make some idealizing assumptions. We assume that there is one clear point in time that can be attributed to each respective score event, i.e. there are "true" time-stamps τ_n, $n = 1, 2, \ldots$ for the score events we sought to annotate. If each score event is annotated multiple times, the annotated markers θ_n will show random variation around their true time-stamps, with a certain variance σ_n^2. It seems reasonable to assume the respective markers to be realizations of random variables Θ_n, each following a normal distribution, i.e. $\Theta_n \sim \mathcal{N}(\tau_n, \sigma_n^2)$.

Thus, for each event to be annotated we would expect (a large number of) annotations to exhibit a normal distribution around some mean τ_n. This is schematically illustrated in Figure 2.

However, for estimating the parameters of these distributions, rather large numbers of annotations would be required.

[2] Supplemental material to this publication is available online at 10.5281/zenodo.3260499

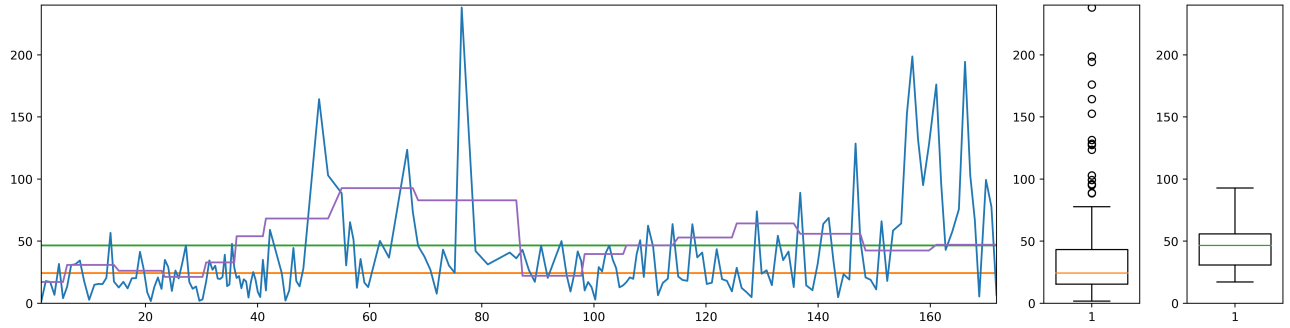

Figure 1. Standard deviations of annotations along a performance, Webern Op21-2, Boulez. Blue: computed from three markers per score event. Magenta: computed from pooled differences (details see text). Orange: median standard deviation (SD), green: median of SD from pooled differences (see boxplots right). Right: boxplots for SD (summary of blue curve) and for SD of pooled values (summary of magenta curve), central quartile is median.

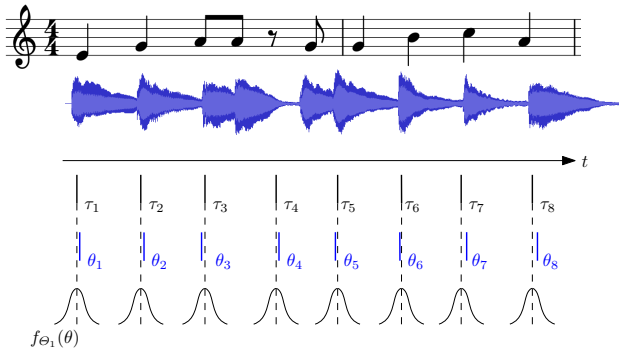

Figure 2. Modeling annotations as random variables. Musical score and waveform of a performance. Hypothetical true time-stamps τ_n. Annotation markers θ_n. Bottom row: pdfs of random variables Θ_n, each of mean τ_n.

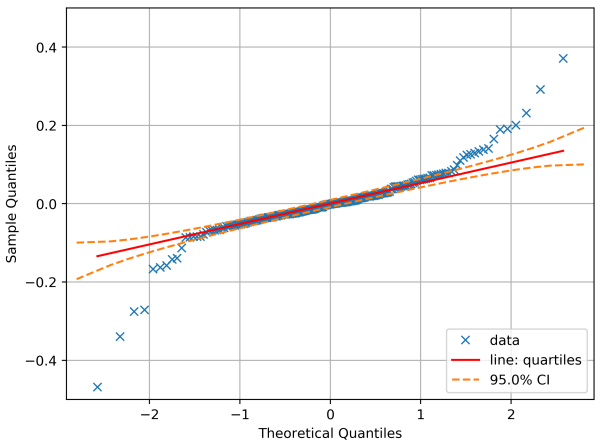

Figure 3. Webern Op21-2, Boulez. Quantile-quantile plot of the differences of a pair of annotation sequences for the whole piece. Solid red line fitted to first and third data quartile, dashed lines show ±95% confidence around this line. Non-normal data deviate strongly from area enclosed by dashed lines.

[3] has shown that with some additional assumptions, the distribution can be estimated from as little as two sequences of markers.

We follow [3] in the derivations below. If the variance σ^2 of the time stamps is assumed to be constant over time (across the whole piece or part to be annotated), subtracting two sequences θ_n^1, θ_n^2 of markers for the same score events, i.e.

$$\Delta_n = \Theta_n^1 - \Theta_n^2, \tag{1}$$

yields the variable $\Delta_n \sim \mathcal{N}(0, 2\sigma_\Theta^2)$. Note that if the mean of Δ_n is not zero, we can force it to be by suitably offsetting either Θ_n^1 or Θ_n^2 by $\bar{\Delta}_n$ – since we assume both sequences to mark the same events with mean zero, a total mean deviation can be viewed as a systematic offset by either annotator. One could then use the differences $\delta_n = \theta_n^1 - \theta_n^2$ to estimate the variance σ_Θ^2 around the true time-stamps:

$$\hat{\sigma}_\Theta^2 = \frac{1}{2N} \sum_{n=1}^{N} (\theta_n^1 - \theta_n^2)^2. \tag{2}$$

In [3], two example analyses of tap sequences were presented that support these assumptions.

We analyzed our annotation data according to these ideas. First, for each annotated recording, we calculated the time-stamp differences between each pair of annotations, according to Eq. (1), and tested the resulting distributions for normality, using the Shapiro-Wilk test. However, for all annotations created, none of the distributions is normal according to these tests. On visual inspection of the distributions of differences of annotation sequences δ_n using quantile-quantile plots (see Fig. 3), the tails of the distributions turned out to be typically significantly heavier than for a normal distribution.

We suspect that this discrepancy to the results given in [3] is most likely due to the higher complexity of our musical material, with large orchestras playing highly polyphonic and rhythmically complex music in varying tempi. It seems intuitively clear that for some sections, the deviations among annotated markers will be much smaller than in complex parts. Additionally, as we asked also silent

beats to be annotated, even during whole silent bars, we should expect substantial deviations for at least a few such events in every recording. We therefore conclude that at least the assumption of identical variance across a whole piece should be dropped (for more complex material) when more detailed information about local uncertainties of the annotation is desired.

However, it is interesting to note that locally, when the differences for only a few consecutive (around 20-30) annotated time-stamps are pooled, they conform to a normal distribution quite well. This means that the assumption of about equal variance for the annotation of score events tends to hold for short blocks of time, but rather not globally (for a whole piece), at least for the musical material considered here.

As estimating the standard deviation (as a measure of uncertainty) of each time-stamp's markers is not reliable given only few annotations, we used an alternative based on the above observation. For blocks of 24 consecutive score events (with a hop size of 12), the differences of a pair of annotation sequences were *pooled* and used to estimate the standard deviation for each respective block. The resulting, block-wise constant curve of standard deviations is shown in Fig. 1 (magenta), along with the simple standard deviation per score event, calculated from three markers (blue), for a specific recording and pair of annotations. The median of these per-block estimated standard deviations is used as a global estimate of the precision of the annotations for the respective performance, and is given for the respective performance as the right-most column in Table 2. As can be seen, the values differ substantially across the pieces as well as within the pieces, for different performances. The right-most boxplot in Fig. 1 shows a summarization of the per-block estimated standard deviations. Interestingly, for the 1st movement of Beethoven's Symphony 9 (with its relatively constant tempo), the estimated standard deviation is close to the value presented in [3], but it is considerably larger for the other pieces that exhibit more strongly varying tempo.

5. AUTOMATIC ALIGNMENT

As mentioned above, annotating a large number of performances of the same piece is a time-consuming process. A more efficient alternative would be to automatically transfer annotations from one recording to a number of unseen recordings, via audio-to-audio alignment.

5.1 Alignment Procedure and Ground-truth

The method of choice for (off-line) audio-to-audio alignment is *Dynamic Time-warping (DTW)* [10]. Aligning two recordings via DTW involves extracting sequences $X \in \mathbb{R}^{L \times D}$ and $Y \in \mathbb{R}^{M \times D}$ of feature vectors, respectively. Using a distance function $d(x_l, y_m)$, the DTW algorithm finds a path of minimum cost, i.e. a mapping between elements x_l, y_m of the sequences X, Y. An alignment is thus a mapping between pairs of feature vectors (from different recordings), each vector representing a block of consecutive audio samples. As each audio sample has an associated time-stamp (an integer multiple of the inverse of the sample rate), each feature vector, say x_l, can be associated with a time-stamp t_l^X as well, (here) representing the center of the block of audio samples. The matching of sequence elements is schematically illustrated in Fig. 4, for the "direction" $X \rightarrow Y$ (note that direction here refers to the evaluation, as will be illustrated next). For each block of X, the matching block of Y is found, and its associated time-stamp t_m^Y is subtracted from the ground-truth time-stamp g_n^Y. This produces the pairwise error sequence $e_n^{X \rightarrow Y}$. As we have ground-truth annotations for both recordings of a pair available, we can also calculate an error sequence for the "reverse" direction $Y \rightarrow X$.

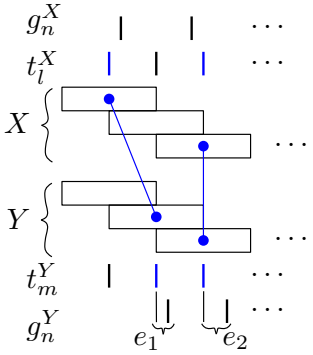

Figure 4. Matching feature vectors through DTW, and calculating errors between associated time-stamps t_m^Y and ground-truth time-stamps g_n^Y, for direction $X \rightarrow Y$. This yields the error sequence $e_n^{X \rightarrow Y}$.

The sequences of ground-truth time-stamps were produced from the multiple annotations discussed above (Section 3), by taking for each annotated score event the sample mean across the three annotations per recording. For computing the alignments, an implementation of FastDTW [12] in python was used.

5.2 Choice of Audio Features

The actual alignment process is preceded by extracting features from the recordings to be aligned. Different features have been proposed and evaluated for this task in the literature. We decided to choose only features that have proven to yield highly accurate alignments and thus small alignment errors.

[6] evaluated several different audio features separately on data sets of different music genres, among them symphonies by Beethoven. They achieved the best results overall by using 50 MFCC (in contrast to 13 or even 5 as used in [7]), for two different block lengths. As the results on these corpora, which are similar to ours, were dominated by MFCC, we decided to use these with similar configurations for our experiments. Additionally, we included a variant of MFCC (in the following addressed as "MFCC mod") following an idea described in [11], where 120 MFCC are extracted, then the first n_{skip} are discarded and only the remaining ones used. However, in contrast to their proposal we skip the subsequent extraction of chroma

information and use the MFCC directly.

The second family of features that has proven successful for alignment tasks are chroma features, which were tested as an alternative. For extracting the feature values, the implementations from LibROSA [9] were used. Besides "classical" chroma features, the variants chroma_cqt (employing a constant-Q transform) and chroma_cens were used. We decided not to include more specialized features that include local onset information, like LNSO / NC [1], or DLNCO (in combination with chroma), as they would seem to give no advantage on our corpus as suggested from the results in [6] and [5].

5.3 Systematic Experiments Performed

In order to find the best setup for audio-to-audio alignment for complex orchestral music recordings, we carried out a large number of alignment experiments, by systematically varying the following parameters:

- FFT sizes: 1024 to 8192 (chroma), up to 16384 (MFCC)
- Hop sizes MFCC: half of FFT size, for 16384 fixed to 4096
- Hop sizes Chroma: 512 and 1024, for each FFT size; additionally 2048 for chroma_cens and chroma_cqt
- Number of MFCC: 13, 20, 30, 40, 50, 80, 100
- MFCC mod: 120 coefficients, first 10, 20, ..., 80 discarded
- Distance measures: Euclidean (l_2), city block (l_1) and cosine distance.

Note that the audio signals were not down-sampled in any of the cases, but used with their full sample rate of 44.1 kHz.

All in all, a total number of 312 different alignments were computed and evaluated for each performance pair. Each alignment of each pair of performances was evaluated in both directions. As it is impossible to display all results in this paper, we will only report a subset of best results in Section 6.

6. EVALUATION OF ALIGNMENTS

6.1 Alignment Accuracy

For quantifying the alignment accuracy, we calculated pairwise errors e_n between the ground-truth time-stamps g_n for the respective recording and the matching alignment time-stamps t_l (see Fig. 4). Per pair of recordings, two error sequences are obtained, one for each evaluation direction, i.e. $e_n^{X \to Y}$ and $e_n^{Y \to X}$. As a general global measure of the accuracy of a full alignment, the mean absolute error is used, where the maximum absolute error can be seen as a measure for lack of robustness.

For reporting of the best results, we first ranked all alignments whose absolute maximum errors are below 5 seconds by their mean absolute errors. As large maximum error is taken as lack of robustness, the worst performing settings were thus discarded. For each pair of recordings, from the remaining error sequences (from originally 312 alignments per pair, each with 2 directions of evaluation), the 10 best results, in terms of mean absolute error, were then kept for further analysis. The error values for both directions of each specific alignment were then pooled, i.e. the error values were collected and analyzed jointly. A one-way ANOVA (null hypothesis: no difference in the means) was conducted for the 10 best alignments per pair of recordings, where for all cases the null hypothesis could not be rejected (recording pair with smallest p-value: $F = 0.6, p = 0.8$). Thus, as the different settings of the 10 best alignments do not result in significant differences in terms of mean error performance, the error sequences for those 10 best alignments were collected, to estimate a distribution of the absolute errors. Fig. 5 shows the empirical cumulative distribution function of the pairwise absolute errors for all 5 alignment (performance) pairs, where each curve is obtained from the 2 error sequences (both evaluation directions) of each of the 10 best alignments for the respective performance pair.

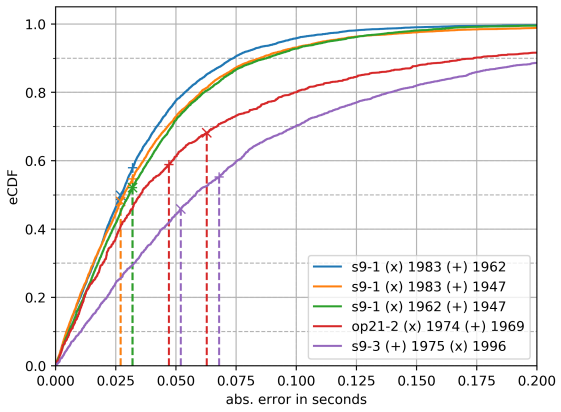

Figure 5. Cumulative distribution of absolute pairwise errors. Each curve represents pooled errors of 10 best alignments (mean absolute error) for both evaluation directions, per pair of recordings. s9-1: Beethoven, S.9, 1st Mov., s9-3: Bruckner, S.9, 3rd Mov., op21-2: Webern, Op21, 2nd Mov. (+) and (x) markers for median standard deviation of annotation, cf. Table 2.

In the following, the settings and results, in terms of mean absolute error and maximum absolute error, for the 10 best alignments are presented. For the Beethoven piece, we restricted the reporting to one pair of recordings (BPO 1962 vs. VPO 1947) due to limited space (Table 3). As can be seen from Fig. 5, the other two pairs do not differ substantially in terms of error performance, and the settings for obtaining these results are almost identical to the ones presented in the table, with an even stronger favor of the MFCC mod feature. Tables 5 and 4 show the results for the Webern and Bruckner pair of recordings, respectively.

As can be seen from the tables, best results are achieved with either MFCC or the modified MFCC. There does not seem to be a very clear pattern of which parameter setting gives best results, even within one pair of recordings. A slight advantage of medium to large FFT sizes is observed, as is a larger number of MFCC ($\geq$ 80, a number much

Feature	#MFCC	#skip	fft size	dist.	mean err.	max. err

larger than what is suggested in the literature for timbre related tasks). For the modified MFCC, skipping the first 20 to 40 out of the 120 coefficients seems a good suggestion. Interestingly, there seems to be no clear relation to the FFT size.

6.2 Relation to Human Alignment Precision

We would like to relate the accuracy achieved by automatic alignment methods to the precision with which human annotators mark score events in such recordings. This will enable us to judge the errors in the alignment methods in such a way that we cannot only say which is best, but which are probably sufficiently good for musicological studies (in relation to how precise human annotations tend to be).

Feature	#MFCC	#skip	fft size	dist.	mean err.	max. err
MFCC	80	-	2048	l_1	62	1049
MFCC	40	-	2048	l_1	65	1026

MFCC	80	-	2048	cos	77	980
MFCC	100	-	8192	l_1	78	1026
MFCC mod	120	20	2048	cos	82	956

Table 5. Settings and results for top 10 alignments, Webern Op.21-2. Errors in ms, rounded to nearest integer.

By comparing the global measures of variation of the annotations (Table 2) with the mean errors obtained from the alignment study, the following can be stated. We would like the errors introduced by the alignments to be in the range of the variation introduced by human annotators. If, for example, the above estimated standard deviations are used for describing an interval (e.g. $\pm$ 1 SD) around the ground-truth annotations, then markers placed by the DTW alignment within such an interval can be taken to be as accurate as an average human annotation. However, as Tables 3 to 5 reveal, on average, the absolute errors are at least slightly (or even much in case of the Bruckner performances) larger than the estimated standard deviations, but still in a reasonable range, even for larger proportions of the score events (see Figure 5).

7. DISCUSSION AND CONCLUSIONS

Given our results, we expect the presented feature settings to be quite suitable as a first step for developing further musicological questions related to comparing multiple performances of one piece. With careful annotation of one recording, transferring the score event markers to other recordings of the same piece should yield not much worse accuracy than what is to be expected from human annotations. Detailed analyses of e.g. tempo may still need a moderate amount of manual correction, however.

An interesting application we consider is the exploration of a larger corpus of unseen recordings. Being able to establish, within a reasonable uncertainty, a common musical grid for a number of performances allows for search of (a first impression of) commonalities and differences across performances, for parameters such as tempo, or features extracted directly from the recording, such as loudness, mapped to the musical grid. This will e.g. allow the pre-selection of certain performances for more careful human annotation and further more detailed analyses. Recently, performance related data have been presented for a larger corpus in [8].

We hope to have presented some new insights with the data on annotation precision, and the applied methods for their quantification. Further work could make use of estimates of typical uncertainty of annotations to estimate, or give bounds for, the uncertainty of data derived from these. One way would be to use simple error propagation to quantify uncertainty of tempo representations, and automatically find (sections of) performances of significantly different tempo within a large corpus of recordings.

8. ACKNOWLEDGMENTS

This work was supported by the Austrian Science Fund (FWF) under project number P29840, and by the European Research Council via ERC Grant Agreement 670035, project CON ESPRESSIONE. We would like to thank the annotators for their work, as well as the anonymous reviewers for their valuable feedback. Special thanks go to

Martin Gasser for fruitful discussions of an earlier draft of this work.

MAPPING TIMING STRATEGIES IN DRUM PERFORMANCE

ABSTRACT

How do drummers express different timing styles? We conducted an experiment in which we asked twenty-two professional drummers to perform a simple rhythmic pattern while listening to a metronome. Here, we investigate the strategies they employed to express three different instructed timing profiles for the same pattern: "On", "Pushed" and Laid-back. Our analysis of the recordings follows three stages. First, we compute sixteen boolean features that capture the microtiming relations of the kick, snare and hi-hat drum onsets, between each other and with regards to the metrical grid. Second, we construct a microtiming profile (mtP) for every performance by averaging the boolean features across the recording. An mtP codifies the frequency with which the various features were found in a performance. Third, through a "similarity profiles" hierarchical clustering analysis, we identify groups of recordings with significant similarities in their mtPs. We found distinct strategies to express each intended timing profile that employ specific combinations of relations between the instruments and with regards to the meter. Finally, we created a map that summarizes the main characteristics of the strategies and their relations using a phylogenetic tree visualization.

1. INTRODUCTION

In groove performance, it has been assumed that musicians can apply different timing 'feels' to a given pattern by, amongst other things, subtly altering the temporal location of events at the 'micro-rhythmic' level by playing either slightly early ('pushed') or late ('laid-back') in relation to other players' rhythm, a metronomic beat reference or simply their own internal pulse [1, 3, 6, 7, 9, 10, 15, 19]. Typical reported values of microtiming deviations in performance range from 0 ms (no displacement) to 50 ms or more, depending on instrument, tempo and genre [2, 11, 13, 22] An instructed timing experiment by Danielsen et al. [9] showed that drummers were able to consistently play a snare-drum pattern with laid-back and pushed feel significantly behind- and ahead-of an instructed on-beat performance, respectively, with similar values. In polyphonic drumkit performance, expert drummers are able to control the degree of onset timing asynchrony between the various constituent drum instruments. These inter-instrument onset asynchronies may play a role in the production and perception of groove timing feel, since both magnitude and order of onset asynchrony between near-simultaneous events have been previously shown to affect judgements of timing in perceptual experiments with musical stimuli [12, 14, 25].

In order to explore potential interactions between instructed timing feel and various audio/motion features in drum-kit performance, a series of experiments was conducted by Câmara et al. [4] where participants played a simple 'back-beat' pattern with On-beat, Pushed and Laid-back timing feel along to a metronome. In the present study, we analyze the data from one of these experiments, limiting our focus towards investigating the extent to which professional drummers employed different strategies in order to achieve the instructed timing feel in terms of the magnitude and order of onset asynchrony between the instruments of the drum-kit themselves, as well as in relation to a metrical reference grid. We hypothesize that drummers chose different elements (read: instruments) of the rhythmic pattern to produce in sync, late and early timing performance for the On, Laid-back and Pushed timing condition, respectively. For example, in order to achieve the same timing instruction, one group of participants may have focused on the relation between two drum instruments, where one led and the other followed, while another group instead on the relation between both instruments and the metrical grid, and yet another group may have incorporated a combination of two such approaches. In other words, for the same timing instruction, drummers may produce different combinations of microtiming onset strategies in order to communicate the same intended timing feel. This article focuses on the novel analysis we developed which aims at mapping and identifying these potentially different strategies.

At the core of our analysis lie the microtiming profiles – structures that effectively codify the onset asynchronies of the instruments as the probabilities or frequencies with which they occur in the performances of the participants. A hierarchical classification of the performances based on their microtiming profiles reveals specific timing strategies, which are summarized as microtiming archetypes that capture the main characteristics of the clusters in a symbolic form. Finally, a visualization of the clustering result as a phylogenetic tree enables us to better understand and identify these strategies.

The rest of the article is divided in four sections. In section 2, we describe the experiment. In section 3, we describe the analysis method, the microtiming profiles in 3.1 and their clustering in 3.2. In section 4, we present the results of our analysis. In the final section 5, we discuss methodological issues.

2. EXPERIMENT

22 male drummers, 22-64 years of age [M = 36, SD = 11] participated in the experiment. All of them were active part-time or full-time musicians and had between 4 and 40 years of professional performance experience [M = 16, SD = 11]. All were familiar with at least one groove-based performance tradition, typically either jazz, funk/soul/R&B, hip-hop, rock, or reggae. Two participants' data were excluded from the analysis: one due to technical issues during the recording process, and the other was deemed to not have successfully understood the task based on responses from a follow up interview.

The participants were instructed to play a standard 'back-beat' pattern (see) ubiquitous in groove music and highly familiar to drummers. They performed along to a metronome (woodblock) track at a tempo deemed comfortable in a pilot of the experiment (96 b.p.m) in 3 different timing style conditions:

1. in a *laid-back* manner, i.e. behind-the-beat (condition: Laid-back)
2. in a *pushed* manner, i.e. ahead-of-the-beat (condition: Pushed)
3. in an o*n-the-beat* manner, (condition: On)

At the beginning of the experiment, a practice round was given to in order to allow for participants to accustom themselves to the following timing style conditions ('Laid-back', 'On', and 'Pushed'), which were subsequently randomized. Each timing condition trial lasted for approximately 70 seconds where participants began to play as soon as they had entrained with the timing reference track. This resulted in approximately 200 hi-hat and 50 snare and kick drum strokes captured per trial.

For our drum instrumental setup, we used the following equipment: a Gretsch acoustic metal snare drum (Gretsch Drums, CT), 7 in. deep, 14 in. wide, with a Remo Emperor X drumhead (Remo, CA) with a thin plastic muffle ring; a Gretsch 21-in. bass drum with Remo FA batter drumhead; a Pearl hi-hat stand with 14" Yamaha cymbals.

Pilot tests of the sound recordings revealed that close-microphone techniques with dynamic microphones led to too much leakage between the different drum signals, therefore AKG C411 contact microphones (AKG, Austria) were used instead and placed on the top skins of the kick and snare, and on the top cymbal of the hi-hat.

Figure 1: Standard back beat grove pattern in 4/4 meter. Upper notes in the score denote hi-hat cymbal; the middle notes, the snare drum; the bottom notes, the kick drum

3. ANALYSIS

Since the focus of this investigation is the microtiming relations of the drum instruments, we create microtiming profiles (mtPs) of the performances for all participants and instructed timing condition trials, comprised of set of features that capture those relations. Based on how similar the mtPs are, we group them using a hierarchical clustering algorithm and construct archetypes that summarize the main characteristics of each group. Finally, we map the relations between the groups' recordings using a phylogenetic tree visualization.

Our analysis and all following computations are based on the temporal location of onsets of individual strokes from each instructed timing condition recording that were calculated using an adaptation of an existing onset detection algorithm of the MIRtoolbox [17] which will be detailed in a forthcoming publication of our group.

We describe the mtPs and the measurements we use to obtain them in subsection 3.1, then present the clustering results and their visualization in subsection 3.2.

3.1 Microtiming Profiles

To obtain the mtP of a recording we first extract a set of sixteen boolean features that capture the microtiming relations between the strokes of the snare, kick drum and hi-hat cymbals relative to each other, as well as to the location of the metrical grid. The boolean features are calculated for each 4/4 measure of a timing condition trial while the mtP is calculated as the average of the boolean features across all measures of a trial. The mtPs were inspired by the motion templates designed by Müller and Röder [20] to describe geometric relations of the human body for the purpose of the analysis of body movements.

Kick on beat 1	x2 features per instrument late/early relative to the hi-hat cymbal
Snare on beat 2	
Kick on beat 3	
Snare on beat 4	
Kick + Hi-hat on beat 1	x2 features per beat both instruments late/early relative to the metrical grid
Snare + Hi-hat on beat 2	
Kick + Hi-hat on beat 3	
Snare + Hi-hat on beat 4	

Table 1: Summary of the sixteen boolean features extracted from the recordings for each bar.

Each feature tests whether an instrument is late or early with respect to a certain reference time point. The first eight features use the onsets of the hi-hat strokes as a reference and the other eight features use the metrical grid as a reference. For instance, feature 1 tests whether the kick drum follows the corresponding hi-hat cymbal,

while feature 9 tests whether both the kick and hi-hat occur after the position of the respective beat. Table 1 summarizes the sixteen binary features extracted from the recordings of each trial.

The above features depend on "tolerance" thresholds with which two instrument's strokes are considered synchronous with each other (for features 1 to 8) or with which the instruments' strokes are considered to occur late or early relative to the beat of the metrical grid (for features 9 to 16). For instance, when the inter-onset interval (IOI) between a pair of kick and hi-hat strokes is greater than the respective synchronicity threshold, feature 1 (kick later than hi-hat) is *true*. In the opposite case where IOI is sub-threshold, both features 1 and 5 (kick later and earlier than hi-hat) are *false*, since the pair is considered to be synchronous.

Furthermore, to determine the relation between the three drum strokes and the metrical grid with which drummers used as a beat reference, we need first to determine the location of this grid. Although one might intuitively assume that the onset of the sounding metronome would correspond to that location, it has been repeatedly observed that people tend to tap to a steady pulse systematically earlier than the actual pulse—a phenomenon known as negative mean asynchrony (NMA) [8]. As such, it may be assumed that the internal pulse scheme with which drummers operate with, that is, their subjective metrical grid, is slightly anticipated.

Even though percussionists and drummers tend to display lower NMA than other musicians in both in-phase synchronous tapping [21] and drumming [11] experiments, NMAs still tends to vary significantly between individuals [8]. Therefore, it is difficult to assume a single global NMA value for all the drummers. Similarly, the two thresholds values described above cannot easily be set universally. In what follows, we will describe how we obtain individual values for these parameters for each drummer based on the performance of their On timing condition, essentially turning the On recordings into a baseline reference. We will discuss the reasoning behind this choice as well as some of its implications in section 5.

For the synchronicity threshold values used in features 1-8, i.e. the tolerance with which two coinciding drum strokes are considered synchronous or not, we use the variability of the IOI between the hi-hat and coinciding kick or snare strokes on each of the four main quarter-note beats of the 4/4 metre (kick + hi-hat on beats 1 and 3, snare + hi-hat on beats 2 and 4). For each drummer, we first calculate the standard deviation of the inter-instrument IOIs of the corresponding beats in each measure of their respective On condition recording. This yields four separate values, two for each hi-hat + kick, and hi-hat + snare, feature. To be conservative, the synchronicity threshold for a drummer is chosen as the maximum of these four values, then multiplied by 2. Thus, a kick or snare stroke is considered to occur as either asynchronously late or early relative to its coinciding hi-hat stroke when their onsets satisfy the following inequalities:

Late: $Onset(i,j) - HiHat(i,j) > SyncThr(i)$

Early: $Onset(i,j) - HiHat(i,j) < -SyncThr(i)$

$SyncThr(i) = 2 \times \max_{k=1}^{4}\{STD_{ON}^{i}(IOI\ at\ beat\ k\}$

where *j* is the beat number from a recording of drummer *i*.

The synchronicity threshold used in features 9 – 16 on the other hand, i.e. the tolerance with which a stroke is considered to occur late or early relative to a corresponding subjective metrical beat, is based on the timing variability of the hi-hat strokes in the On condition. The hi-hat is chosen because it can be considered more of a 'timekeeper' instrument than the other drums, thus serving more aptly as a proxy for the beats of the drummers' subjective metrical reference. To account for the commonly observed anticipation of the beats of the metronome (henceforth abbreviated as AoB), we first calculate the mean position of the hi-hat strokes relative to the metronome in the On recordings for each drummer. 18 out of 20 drummers displayed NMA of hi-hat strokes relative to the actual metronome, consequently yielding negative AoB values. Two participants displayed either no NMA or minutely positive mean asynchrony, and in these cases the AoB was set to 0 (no anticipation). Finally, we consider any drum stroke as occurring asynchronously late or early in relation to the beats of the metrical grid according to the following inequalities:

Late: $Onset(i,j) - beat(j) - AoB(i) > 2 \times STD_{ON}^{i}(HiHat)$

Early: $Onset(i,j) - beat(j) - AoB(i) < -2 \times STD_{ON}^{i}(HiHat)$

where *j* is a drum stroke of drummer *i*, $beat(j)$ is the corresponding position of the metronome, and $STD_{ON}^{i}(HiHat)$ is the standard deviation of the IOI of the hi-hat from the respective metrical beat positions in the On recording of the same drummer. For one of the features 9-16 to be *true*, the onsets of both strokes—hi-hat and kick or snare—must be either early or late. In all other cases, including when one stroke is early and the other late, the corresponding features would be *false*.

Two main observations must be made about the boolean features. First, all boolean features form mutually exclusive pairs. For instance, feature 9 (strokes on beat 1 are early) and feature 13 (strokes on beat 1 are late) cannot be both *true* for the same bar of a recording. However, they can both be *false*, in which case the combination of the two strokes is considered on the beat. Second, features 1-8 (kick and snare relative to hi-hat) and features 9-16 (onsets relative to metrical grid) are independent. For instance, a kick onset can be early relative to the respective hi-hat onset (feature 5 *true*) while at the same time they are both late relative to the beat position (feature 9 *true*).

The final microtiming profiles (mtPs) of the recordings are calculated by averaging the boolean features across each timing condition recording for all drummers. As the boolean features take either *true* (1) or *false* (0) values, averaging them results in values in the range [0, 1], which represent the frequency with which a feature was

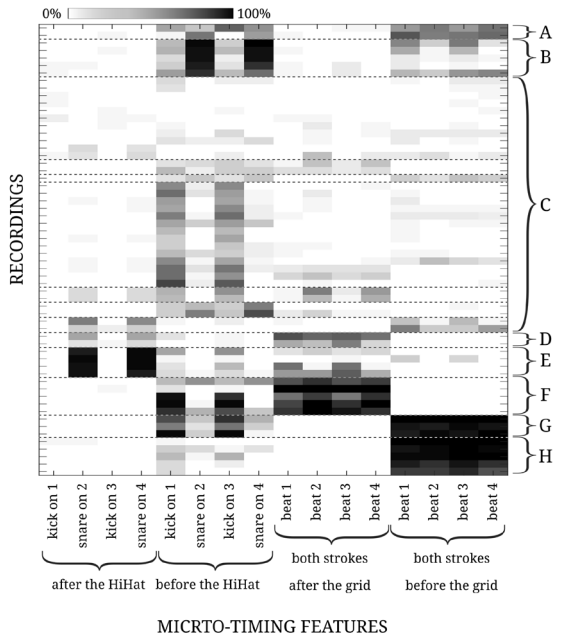

Figure 2: Microtiming profiles (mtPs) for all recordings shown as a greyscale image representing the probability or frequency with which a feature is encountered in a recording. Features are laid along the horizontal axis. On the vertical axis, recordings are sorted and grouped based on the proximity of the SIMPROF clusters (see section 3.2 and Figure 3). Horizontal dashed lines represent the cluster boundaries. The corresponding group mt archetypes are marked on the right with the letters A-H.

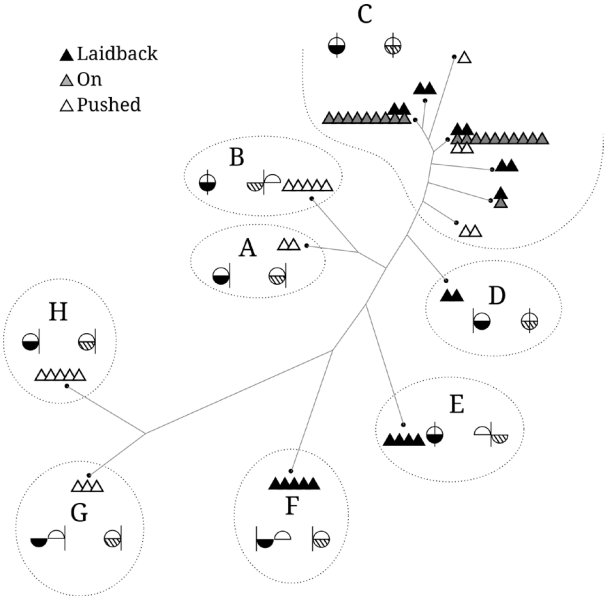

Figure 3: Hierarchical clustering presented as a phylogenetic tree (unrooted, equal daylight visualization). Each triangle corresponds to the microtiming profile of a single recording. Letters A-H are used to label the clusters. Next to each cluster the corresponding mt-Archetype is shown. Label C is assigned to a group of proximal clusters which correspond to the same mt archetype.

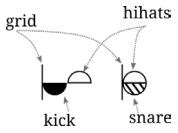

Figure 4: Explanation of an mt-Archetype symbol.

encountered in a recording. The mtPs of all the recordings are visualized in matrix form in Figure 2.

3.2 Hierarchical clustering

We sought to identify the extent to which drummers implemented distinct microtiming strategies for different timing conditions and whether they formed different groups. To this end, we used an agglomerative, hierarchical cluster analysis of the mtPs. A hierarchical clustering was preferred to other clustering methods, like k-means, since it is flexible in that it does not require an a-priori number of clusters to be determined, nor does it impose restrictions on the distribution of the data. Its only requirement is a similarity metric between the data points. We treated the mtPs as arrays of variables, where the similarity between two mtPs is the Euclidian distance between them.

Hierarchical agglomerative algorithms result in dendrograms by successively joining neighboring data points or groups of previously joined points. A linkage criterion determines the distance between groups of points as a function of the pairwise distances of the points themselves. In this study, we used the common Unweighted Group Average linkage (UPGMA) [18, p. 352].

To create clusters of similar data points, one generally "cuts" the dendrogram at different heights. Here, we borrowed methods from the fields of bioinformatics andecology to identify clusters of mtPs. We used the similarity profiles (SIMPROF) method [5]—as implemented in the Fathom Toolbox for Matlab [16]—to test the statistical significance of the branches' internal structure. SIMPROF takes the form of a series of permutation tests. Beginning at the top of a precalculated hierarchy, thesetests stop the ever finer partitioning into subgroups. When a branch in the hierarchy is deemed to have no internal structure and is therefore homogenous, it is no longer subdivided. Thus, a cluster is formed that is comprised of recordings with "exchangeable" features.

For the permutation test, we set the number of iterations to 1000 and the significance level alpha to 0.05—the probability value at which the hypothesis of an internal structure is rejected. We used the Bonferroni correction [18, p. 745] to progressively adjust the probability values for multiple simultaneous tests (see also parameter mc=*true* of the `f_disprof_clust` function of the Fathom toolbox [16]).

The results of the clustering analysis are shown in Figure 2. The dashed horizontal lines cut the mtP matrix into clusters of recordings that show statically significant similarities. In Figure 3, we present the same result as an unrooted phylogenic tree. Recordings of the various Laidback, On and Pushed performances are represented as

black, grey or white triangles, respectively, while the distance between the clusters of recordings corresponds to the UPGMA linkage criterion [18, p. 352].

As our aim is to identify distinct timing strategies in the recordings, we summarize the main characteristics of each cluster into microtiming archetypes. An archetype is computed by first averaging the probabilities of the features that belong in beats 1 and 3 (where the kick strokes occur) as well as the ones that belong in beats 2 and 4 (where the snare strokes occur). The two groups of probabilities describe the relation of the kick/hi-hat and snare/hi-hat combinations of strokes between them and in relation to the meter. Those relationships are reduced into archetypes according to whether the average probability of each feature is above or below 50%. An example of such an archetype is shown in Figure 4. In this example, the average probability of both a kick and corresponding hi-hat stroke to be late relative to the beat is above 50%. At the same time, the average probability of a kick stroke being ahead of the corresponding hi-hat stroke is also above 50%. In contrast, the snare strokes have a probability below 50% to either occur ahead or after the corresponding hi-hat stroke. In other words, most of the snare strokes are considered as synchronous with their corresponding hi-hat strokes.

Clusters with common microtiming archetypes that are relatively proximal in the phylogenetic tree are grouped together to create an overall map of strategies. In Figure 2, these groups are labeled with the letters A to H and in Figure 3 the same groups are annotated with their corresponding archetype.

4. RESULTS

The classification of the mtPs shows that the majority of the Laid-back and Pushed performances form separate homogenous clusters. The purely Laid-back clusters are characterized by generally late timing while the Pushed ones by early timing, as expected. However, the analysis reveals that drummers implemented distinct strategies to express a given timing feel by focusing on different rhythmic elements. The microtiming archetypes assigned to the various group clusters highlight those elements.

More specifically, there are 5 purely Laid-back clusters which comprise 15 out of the 20 Laid-back performances. However, 4 of those recordings (split into 2 clusters in group C) are proximal to the two On clusters and are thus subsumed by the very same archetype. The other 11 are split in three clusters each forming a separate group (D, E and F). All three groups are characterized by late strokes. On the one hand, in group E, the snare stroke is late in relation to the hi-hat and in F, both hi-hat and snare are played late relative to the metrical beat. On the other hand, in group F, the combined kick/hi-hat strokes are late relative to the beat, while the kick additionally precedes the hi-hat.

The Pushed performances are mainly found in purely Pushed clusters (18 out of the 20). However, in similar fashion to the Laid-back condition, a small portion (3) are found proximal to the On clusters in group C. 15 of the remaining Pushed performances form 4 distinct groups (A, B, G and H). All of them are characterized by the early timing of the snare strokes. In group B, the snare precedes the hi-hat although the snare/hi-hat combination is considered as synchronous with the beat. Group B exhibits the inverse pattern of the Laid-back group E (snare early in relation to hi-hat). Similarly, the Pushed group G has its counterpart in the Laid-back group F, with both instruments being early in relation to the beat instead of late but the kick still precedes the hi-hat.

In groups A and H the rhythmic pattern appear to be simply shifted early in relation to the beat. However, although the two groups correspond to the same archetype, they are relatively distant on the tree. A closer look at their mtPs in Figure 2 reveals that in group A, the strokes are anticipating the beat significantly less often than in group H. This can also be seen in the proximity of the group A to group C which is dominated by the On recordings. The similar proximity of the Laid-back group D to the On group C reflects the analogous weak late timing features of the mtPs in comparison with the other Laid-back groups (E, F).

The On performances are all found in Group C which is characterized by synchronous on-the-beat stroke onsets. Within the group, the On recordings are split into two clusters. Examining their mtPs, we see their difference stem from the tendency of some musicians to play the kick drum ahead of the hi-hat.

5. DISCUSSION

In this study, we present findings of an experiment in which professional drummers performed the same rhythmic pattern with an On, Laid-back and Pushed timing feel. We found that participants used more than one distinct onset microtiming pattern for each intended timing instruction (see section 4). A more in-depth discussion of the timing strategies and their musicological implications will be undertaken in an upcoming publication. In the present discussion, we will focus on methodological issues concerning, first, the various parameters of the analysis and their implications, and second, the interpretation of the clustering results.

Our analysis begins with the encoding of the onset asynchronies found in the performances of the drummers into sets of boolean features. Microtiming profiles of the performances are calculated then by averaging those features over the respective recordings. The mtPs codify the probability or frequency with which each feature was encountered in a recording. Finally, by clustering the mtPs we discover the recordings with similar features and group them together.

The boolean features, however simple in their definitions, depend on parameters and thresholds which are crucial to the outcome of the analysis and are closely related to the research questions. In this study, we chose to use individual values for each drummer instead of setting

global ones across all participants. This decision partly reflects the fact that phenomena such as negative mean asynchrony (NMA) typically varies between individuals. and, at the same time, naturally follows from our research question that seeks to identify individual strategies that musicians employ. The three parameters used for calculating the boolean features reflect mechanisms relevant to the perception and production of the subtle asynchronies we are studying. Therefore, setting individual values in our analysis corresponds to adopting the 'point of view' of each separate musician independently, whereas global values might instead correspond better to the perception of a 'typical' listener.

The way in which individual values are assigned to each parameter can significantly impact results depending on how the research question is formalized. In our current approach, we chose to derive the individual parameters for each musician based on their respective On performances, essentially rendering the On condition into a baseline from which the other timing conditions were compared against. For instance, whether a stroke is considered as 'on-the-beat' or not depends on whether it was performed late or early relative to the average hi-hat stroke in the On condition. In this case, the research question could perhaps be interpreted instead as "how do musicians differentiate their Laid-back or Pushed from an On timing feel".

Consequently, one might assume that the mtPs of the On recordings contain no meaningful information since, after all, they cannot be different from themselves! Nevertheless, the On performances should not be excluded from the analysis: firstly, their mtPs can still exhibit significant enough differences between the performances to classify them separately (see group C), though those differences can solely be obtained from the onset relations between the instruments themselves, and not with respect to the metrical grid. Secondly, the proximity of the Laid-back and Pushed clusters to the two On clusters in the phylogenetic visualization of Figure 3 is informative insomuch as it is telling of the strong tendency for drummers to differentiate these asynchronous timing feels from the On timing feel.

The further hierarchical clustering of the derived mtPs proved an effective means of identifying several key timing strategies implemented by the drummers. The method groups and sorts the recordings according to their similarity, revealing their relations without the need for a-priori hypotheses about the existence of specific strategies. Although in principle it is possible to analyze the data using more conventional multivariate statistical approaches, it would be difficult to formalize the hypotheses to be tested, especially considering the variety of strategies that the musicians seem to exhibit. However, in future studies, the two approaches could eventually complement each other: hierarchical clustering can assist in formalizing concrete hypotheses while conventional analyses provide more robust statistical results.

The similarity profiles method (SIMPROF) permits the clustering of statistically similar performances together. It should be noted that other techniques such as bootstrapping [23, 24] may be used as statistical means to define the boundaries of clusters in the mtPs matrix (Figure 2). We leave the exploration of these alternative techniques for a forthcoming publication.

An important parameter in SIMPROF is the significance level (alpha) with which the null hypothesis (that the differences in the mtPs inside a cluster are the result of random combination of the various features) is rejected. The value of alpha, together with the Bonferroni correction for multiple simultaneous tests, determines the level of detail of the final classification, or in other words, the size and scope of the clusters. For instance, if we do not adjust the p-values for multiple tests (Bonferroni correction parameter set to *false* in the `f_disprof_clust` function of the Fathom toolbox [16]), groups B and F are split into three and two subclusters respectively. Looking at the mtPs in Figure 2, we see that for group B this is due to the subtle tendency of some performances to play ahead of the beat. In group F, it is due to the relation of the kick and hi-hat strokes. In the more common approach to hierarchical clustering, in which dendrograms are cut horizontally, this level is controlled by the height that a dendrogram is cut.

The way mtPs are clustered together plays central role in the creation of archetypes and therefore in the characterization of the various timing strategies. Archetypes are calculated as averages of the mtPs in each cluster which are further reduced into eight boolean values. For example, if group F was to be split into two sub-clusters, they would not correspond to the same archetype but would form distinct groups. In contrast, the sub-clusters of group B discussed above correspond to the same archetypes.

Exploring and understanding the results of the clustering analysis requires a side-by-side examination of the mtP matrix (Figure 2) and the phylogenetic tree (Figure 3). The two visualizations combined offer an overview of the performances allowing for a closer examination of the finer timing relation details between the different strategies. This simultaneous multilevel view of the recordings enables us to draw conclusions about the timing strategies which would otherwise be obfuscated or oversimplified.

In conclusion, the encoding of the drum performances into boolean features and the hierarchical classification of the derived microtiming profiles effectively cluster the performances into meaningful groups. The further phylogenetic visualization and the symbolic representation of the groups through microtiming archetypes is an efficient way of mapping drummers' main timing strategies, providing an easily interpretable overview of the results. Our analysis simultaneously brings to the surface higher level rhythmic aspects common to the performances as well as the finer details that differentiate them without the one occluding the other.

ABSTRACT

This paper proposes an improved singing aid system for laryngectomees that converts electrolaryngeal (EL) speech produced using an electrolarynx to a more naturally sounding singing voice. Although the previously proposed system employing a noise suppression process and a rule-based pitch control approach has achieved preliminary success in converting EL speech into a singing voice, there are still two major limitations. First, the converted singing voice still sounds mechanical and unnatural owing to the adverse impacts of spectrograms extracted from EL speeches, also making the effect of pitch control limited. Second, the capability and flexibility of the rule-based pitch control in modeling various singing styles are insufficient, causing the converted singing voices to lack variety. To address these limitations, this paper proposes an improved system that uses 1) a statistical voice conversion approach to convert spectrograms extracted from EL speeches into those of natural speeches and 2) a deep generative model-based approach called VAE-SPACE for pitch modification, which generates pitch patterns in a data-driven manner instead of following manually designed rules. The experimental results revealed that 1) the conversion of spectrograms was effective in improving the naturalness of singing voices, and 2) the statistical pitch control approach was able to achieve comparable results with the rule-based approach, which was very carefully designed to be specialized in singing.

1. INTRODUCTION

The voice is an essential tool used by most of people to communicate with others or express themselves. However, it is difficult for laryngectomees whose larynxes have been removed in surgery to speak or sing in a common manner since they are unable to generate glottal excitation sounds owing to the loss of their vocal folds. In consequence, this vocal disorder may significantly degrade the quality of life of laryngectomees. One popular approach that enables laryngectomees to speak again is to use an external medical device called *electrolarynx* to produce intense mechanical vibrations as an alternative to glottal excitation sounds. Electrolaryngeal (EL) speech produced using an electrolarynx is noteworthy for its intelligibility, and furthermore, it is easy for laryngectomees to learn how to use an electrolarynx, even for people with low physical fitness. However, the perceived naturalness of EL speech is unsatisfactory owing to the use of mechanically generated source excitation sounds, the fundamental frequency (F_0) contours of which are usually flat or given as predetermined patterns. This further limits the capability of the electrolarynx to assist laryngectomees in singing, where F_0 contours play an important role in providing both melodic information and details related to the naturalness and singing style [1].

To develop singing aid systems for laryngectomees, it is essential to suitably control the pitch of EL speech, i.e., F_0 contours. One existing approach is to set F_0 contours corresponding to melodies of predetermined songs and embed them in advance into the electrolarynx as a function to allowing these songs to be sung. However, the flexibility in singing with this approach is unsatisfactory because the number of embedded songs is limited and laryngectomees are solely allowed to sing in predetermined styles.

To achieve a more flexible singing aid, a system based on pitch control has recently been proposed [2]. With this system, laryngectomees are allowed to freely control melodic information such as musical scores and tempo by playing a musical instrument themselves while singing with an electrolarynx. Singing voices are then generated by applying a voice conversion approach that converts EL speeches into singing voices containing well-sung F_0 contours that are modified from the inputted musical scores according to a set of manually predefined rules [3, 4]. Furthermore, noise suppression [5] is employed to reduce the source excitation signals emitted from the electrolarynx. Although this system has achieved preliminary success as a singing aid, there are still two limitations. First, the effect of pitch control in improving the naturalness of singing voices was limited because of the fluctuations originating from the spectral features extracted from EL speeches [2], which resulted in the converted singing voices still sounding mechanical and unnatural. Second, both the capability and flexibility of the rule-based pitch control approach in modeling various singing styles are insufficient. Once the rules are determined, the system outputs certain F_0 pat-

terns containing similar characteristics without considering the personalities and emotions of singers, which is an undesirable property of singing aid systems.

To develop a system that is capable of aiding laryngectomees to sing naturally and distinctly, this paper proposes an improved system that uses 1) a statistical voice conversion (VC) approach based on the Gaussian mixture model (GMM) [6, 7] to convert spectral features extracted from EL speeches into those of natural speeches to alleviate the fluctuation problem and 2) a deep generative model-based approach called VAE-SPACE [8] to generate F_0 contours of singing voices from input musical scores. As a data-driven approach, it is expected that VAE-SPACE can learn the rules for generating natural F_0 contours from data automatically, making it possible to model different singing styles and expressions with a unified model.

2. OVERALL FRAMEWORK OF SINGING AID SYSTEM FOR LARYNGECTOMEES

Fig. 1 shows an overview of the conventional singing aid system proposed in [2] that takes a sequence of musical scores $\boldsymbol{N} = [n_1, \ldots, n_t, \ldots, n_T]$ provided by playing an instrument as melodic information in addition to an EL speech $\boldsymbol{S} = [\boldsymbol{s}_1, \ldots, \boldsymbol{s}_t, \ldots, \boldsymbol{s}_T]$. Here, $\boldsymbol{s}_t = [s_t(1), \ldots, s_t(f), \ldots, s_t(F)]^\mathsf{T}$ denotes the short-time Fourier transform (STFT) coefficients of the EL speech at frame t, and f and $(\cdot)^\mathsf{T}$ denote the frequency index and transpose operator, respectively. The system mainly consists of three modules, namely, for voice quality enhancement, pitch control, and synthesis. With this system, singing voices are generated by a vocoder-based synthesis approach [9] that takes phonetic information and pitch information as inputs, where the former is extracted from the EL speech $\boldsymbol{S}$ enhanced by the voice quality enhancement module and the latter is obtained by modifying the input musical scores $\boldsymbol{N}$ via the pitch control module.

Note that this system can also serve laryngectomees who do not play instruments by allowing them to sing with played accompaniments, where a sequence of predetermined musical scores is given in synchronization with the accompaniments. Different from the method of embedding preset F_0 patterns into an electrolarynx and controlling the pitch by pushing a button, this system can obtain more natural singing voices since singing voices obtained with the former method are usually interrupted when the musical score changes owing to the limitation of mechanical excitation generation, and those obtained in the latter way are converted from more fluent EL speeches.

3. CONVENTIONAL SYSTEM WITH NOISE SUPPRESSION AND RULE-BASED PITCH CONTROL

3.1 Noise suppression

It is important to enhance the quality of both phonetic information and pitch information to achieve a better transformation. To obtain correct phonetic information from

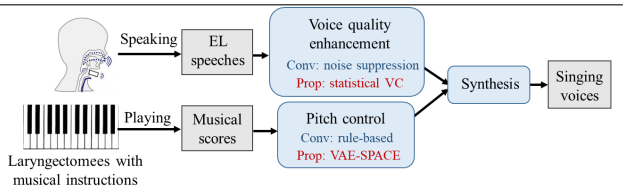

Figure 1. Flowchart of singing aid system.

an EL speech, which is usually mixed with a noisy source signal that radiates from the position of the EL attachment, the aforementioned system employs a spectral subtraction (SS) method [5] to enhance the voice quality of the recorded EL speech. A prototype noise amplitude spectrum $|l(f)|$ is calculated by averaging the amplitude spectra of the EL noise recorded with a close-talking microphone in advance. The enhanced EL speech is obtained with the enhanced amplitude spectrum $|\hat{s}_t(f)|$ and the noisy phase spectrum, where

$$|\hat{s}_t(f)| = \begin{cases} |s_t(f)| - 2|l(f)|, & (|s_t(f)| > 2|l(f)|), \\ 0, & (\text{otherwise}). \end{cases} \quad (1)$$

The phonetic information used for synthesis, i.e., spectral features and aperiodic components, is obtained by analyzing the enhanced EL speech with fixing F_0 at a constant value and using the on/off information of the electrolarynx as unvoiced/voiced information.

3.2 Rule-based pitch control

For pitch control, a rule-based F_0 modification technique [3, 4] is applied to add overshoot, vibrato, preparation, and fine fluctuation, which are four characteristics typically observed in F_0 contours of natural singing voices, into the musical scores n_t. Specifically, overshoot, vibrato, and preparation are added by applying the following infinite impulse response filter to the musical scores:

$$H(s) = \frac{k}{s^2 + 2\zeta\omega s + \omega^2}, \quad (2)$$

where ω, ζ, and k denote the natural frequency, damping coefficient, and proportional gain, respectively. Overshoot and preparation are expressed as the second-order damping model ($0 < |\zeta| < 1$), while vibrato is expressed as the second-order oscillation model ($|\zeta| = 0$). The fine fluctuation is generated from white noise that is high-pass-filtered with the cutoff frequency set at 10 Hz followed by a normalization. The modified F_0 contour can be expressed as $o_t = n_t + e_t$, where o_t and e_t denote the generated F_0 and the component including all four characteristics that is finally added to the musical score at frame t, respectively.

3.3 Limitations

The effectiveness of this system in converting EL speech into a singing voice was experimentally confirmed in [2]. However, it was also reported that undesirable fluctuations reside in F_0 contours of synthesized singing voices that

may have originated from the spectral features extracted from the enhanced EL speeches, which cause the singing voices to still sound mechanical and unnatural. The upper figure in Fig. 6 shows an example of the reanalyzed F_0 contour of a singing voice obtained with the system. Another limitation originates from the rule-based pitch control. Although the system allows laryngectomees to sing an arbitrary song with the desired melody, it is difficult for this framework to further improve the capability to express various singing styles or to generate expressive singing voices.

4. PROPOSED SYSTEM WITH STATISTICAL VC AND VAE-SPACE

To remove these indefinite spectral components affecting F_0 contours, one of the promising approaches is to transform the spectral features of EL speeches of songs into those of natural singing voices not containing these components. Statistical VC techniques [6, 7] have the potential to be used for developing such a transformation based on training data consisting of utterance pairs of the source and target voices, namely, singing voices sung using an electrolarynx (EL speeches) and in a natural way. Furthermore, it is expected that EL noise can be reduced together by training a model with the source voice being noisy EL speech.

To address the second limitation, motivated by the high flexibility of a statistical approach in modeling different voice characteristics and singing styles [10–12], we propose using a statistical parametric model for pitch control instead of the rule-based approach. Specifically, we employ VAE-SPACE [8], which uses a variational autoencoder (VAE) as an analysis-synthesis model to discover the structure of an F_0 generating process for the singing voice in a data-driven manner as well as an inverse process for estimating the underlying musical scores.

4.1 Statistical VC for converting EL speech into singing voice

Let $\boldsymbol{x}_t = [x_t(1), \ldots, x_t(d), \ldots, x_t(D)]^\mathsf{T}$ denotes the D-dimensional spectral feature extracted from EL speech $\boldsymbol{s}_t$ at frame t, where d denotes the index of the feature dimension. The aim of VC is to estimate the spectral features, F_0 contours including unvoiced/voiced (U/V) information, and aperiodic components of the corresponding natural singing voice, which are denoted by the same variable $\boldsymbol{y}_t = [y_t(1), \ldots, y_t(d), \ldots, y_t(D)]^\mathsf{T}$ for simplicity, from the noisy spectral sequence $\boldsymbol{x}_t$.

In the training step, a joint probability density function (p.d.f.) of the joint acoustic feature vectors $[\boldsymbol{X}_t^\mathsf{T}, \boldsymbol{Y}_t^\mathsf{T}]^\mathsf{T}$ is modeled with a GMM as follows:

$$P\big(\boldsymbol{X}_t, \boldsymbol{Y}_t \big| \boldsymbol{\Theta}^{(\mathrm{X,Y})}\big) = \sum_{m=1}^{M} \alpha_m \mathcal{N}\big([\boldsymbol{X}_t^\mathsf{T}, \boldsymbol{Y}_t^\mathsf{T}]^\mathsf{T}; \boldsymbol{\mu}_m^{(\mathrm{X,Y})}, \boldsymbol{\Sigma}_m^{(\mathrm{X,Y})}\big). \quad (3)$$

Here $\boldsymbol{X}_t$ denotes spectral segment feature vectors that are obtained by performing principal component analysis (PCA) for the joint vectors concatenating the spectral feature vectors of the current frame, preceding L frames, and succedding L frames extracted from source voices. $\boldsymbol{Y}_t = [\boldsymbol{y}_t^\mathsf{T}, \Delta\boldsymbol{y}_t^\mathsf{T}]^\mathsf{T}$ denotes vectors combining static and dynamic features extracted from target voices. $\boldsymbol{\Theta}^{(\mathrm{X,Y})}$ denotes a parameter set of the GMM, which consists of the weights α_m, mean vectors $\boldsymbol{\mu}_m^{(\mathrm{X,Y})}$, and convariance matrices $\boldsymbol{\Sigma}_m^{(\mathrm{X,Y})}$ of all the mixture components. Moreover, the p.d.f. of the global variance (GV) [13] of the target static feacture vectors over an utterance $\boldsymbol{v}(\boldsymbol{y}) = [v(1), \ldots, v(D)]^\mathsf{T}$ is also modeled with a Gaussian distribution, which is expressed with a set of parameters $\boldsymbol{\Theta}^{(v)} = \{\boldsymbol{\mu}^{(v)}, \boldsymbol{\Sigma}^{(v)}\}$ as

$$P\big(\boldsymbol{v}(\boldsymbol{y}) \big| \boldsymbol{\Theta}^{(\boldsymbol{v})}\big) = \mathcal{N}\big(\boldsymbol{v}(\boldsymbol{y}); \boldsymbol{\mu}^{(v)}, \boldsymbol{\Sigma}^{(v)}\big). \quad (4)$$

Here, the GV $\boldsymbol{v}(\boldsymbol{y})$ of a time sequence of the target static feature $\boldsymbol{y} = [\boldsymbol{y}_1^\mathsf{T}, \ldots, \boldsymbol{y}_T^\mathsf{T}]^\mathsf{T}$ is calculated utterance by utterance as

$$v(d) = \frac{1}{T}\sum_{t=1}^{T}\big(y_t(d) - \frac{1}{T}\sum_{\tau=1}^{T} y_\tau(d)\big)^2. \quad (5)$$

In the conversion process, a time sequence vector of the converted static feature vectors $\hat{\boldsymbol{y}} = [\hat{\boldsymbol{y}}_1^\mathsf{T}, \ldots, \hat{\boldsymbol{y}}_T^\mathsf{T}]^\mathsf{T}$ is determined by maximizing the product of the conditional p.d.f. of $\boldsymbol{Y}$ given $\boldsymbol{X}$ and the p.d.f. of the GV as

$$\hat{\boldsymbol{y}} = \underset{\boldsymbol{y}}{\operatorname{argmax}}\ P\big(\boldsymbol{Y} \big| \boldsymbol{X}, \boldsymbol{\Theta}^{(\mathrm{X,Y})}\big) P\big(\boldsymbol{v}(\boldsymbol{y}) \big| \boldsymbol{\Theta}^{(v)}\big)^\lambda, \quad (6)$$

$$\text{subject to } \boldsymbol{Y} = \boldsymbol{W}\boldsymbol{y}, \quad (7)$$

where $\boldsymbol{X} = [\boldsymbol{X}_1^\mathsf{T}, \ldots, \boldsymbol{X}_T^\mathsf{T}]^\mathsf{T}$ and $\boldsymbol{Y} = [\boldsymbol{Y}_1^\mathsf{T}, \ldots, \boldsymbol{Y}_T^\mathsf{T}]^\mathsf{T}$ are time sequence vectors of the source and target feature vectors, respectively. $\boldsymbol{W}$ denotes a $2DT$-by-DT matrix that extends a time sequence vector of the static feature vectors into that of the joint static and dynamic feature vectors [14], and λ is a weight parameter, which is commonly set to $2T$. By adopting an approximation with a suboptimum mixture component sequence $\boldsymbol{m} = \{m_1, \ldots, m_T\}$, the converted static feature vector sequence is determined as follow [7]:

$$\hat{\boldsymbol{y}} = \underset{\boldsymbol{y}}{\operatorname{argmax}}\, P\big(\boldsymbol{Y} \big| \boldsymbol{X}, \hat{\boldsymbol{m}}, \boldsymbol{\Theta}^{(\mathrm{X,Y})}\big) P\big(\boldsymbol{v}(\boldsymbol{y}) \big| \boldsymbol{\Theta}^{(v)}\big)^\lambda. \quad (8)$$

The enhanced EL speech is generated by filtering the mixed excitation signal, which is designed according to the F_0 values, U/V information, and aperiodic components estimated from the spectral segment feature vectors, with the converted spectral features.

4.2 VAE-SPACE for pitch control

VAE-SPACE [8] has been proposed as a generative model that can represent and generate F_0 contours of both speeches and singing voices. Let $\boldsymbol{z}$ denotes a sequence of parameters governing the generating process of F_0 contours $\boldsymbol{o} = [o_1, \ldots, o_T]^\mathsf{T}$. VAE-SPACE uses an encoder to estimate the parameters of a conditional distribution $q_\phi(\boldsymbol{z}|\boldsymbol{o})$ of the latent variable $\boldsymbol{z}$ given an F_0 contour $\boldsymbol{o}$, and a decoder to estimate the parameters of a conditional distribution $p_\theta(\boldsymbol{o}|\boldsymbol{z})$ of the F_0 contour $\boldsymbol{o}$ given the latent variable $\boldsymbol{z}$. The encoder and decoder are trained simultaneously so that $q_\phi(\boldsymbol{z}|\boldsymbol{o})$ becomes consistent with the true

posterior distribution $p_\theta(\boldsymbol{z}|\boldsymbol{o}) \propto p_\theta(\boldsymbol{o}|\boldsymbol{z})p(\boldsymbol{z})$. The parameters of the networks ϕ and θ can be trained by maximizing the following variational lower bound [15]:

$$\mathcal{L}(\theta, \phi; \boldsymbol{o}) = \mathbb{E}_{\boldsymbol{z}\sim q_\phi(\boldsymbol{z}|\boldsymbol{o})}[\log p_\theta(\boldsymbol{o}|\boldsymbol{z})] - D_{KL}[q_\phi(\boldsymbol{z}|\boldsymbol{o})||p(\boldsymbol{z})], \quad (9)$$

where $D_{KL}[\cdot||\cdot]$ denotes Kullback-Leibler (KL) divergence. In VAE-SPACE, the latent variable $\boldsymbol{z}$ is associated with a set of interpretable parameters so that the decoder can be seen as a generative model for synthesizing F_0 contours and the encoder can be seen as an inverse problem solver that analyzes the underlying parameters of an observed F_0 contour. In the case of speech, $\boldsymbol{z}$ is associated with a phrase/accent command sequence defined in the Fujisaki model [16], while in the case of a singing voice, it is associated with a sequence of musical scores. The name "VAE-SPACE" comes from the former case, where the VAE-based method is designed to perform statistical phrase/accent component estimation (SPACE).

A typical way of modeling $q_\phi(\boldsymbol{z}|\boldsymbol{o})$ and $p_\theta(\boldsymbol{o}|\boldsymbol{z})$ is to assume a Gaussian distribution

$$q_\phi(\boldsymbol{z}|\boldsymbol{o}) = \mathcal{N}\big(\boldsymbol{z}|\boldsymbol{\mu}_\phi(\boldsymbol{o}), \operatorname{diag}\boldsymbol{\sigma}^2_\phi(\boldsymbol{o})\big), \quad (10)$$

$$p_\theta(\boldsymbol{o}|\boldsymbol{z}) = \mathcal{N}\big(\boldsymbol{o}|\boldsymbol{\mu}_\theta(\boldsymbol{z}), \operatorname{diag}\boldsymbol{\sigma}^2_\theta(\boldsymbol{z})\big), \quad (11)$$

where $\boldsymbol{\mu}_\phi(\boldsymbol{o})$, $\boldsymbol{\sigma}^2_\phi(\boldsymbol{o})$ are the encoder outputs and $\boldsymbol{\mu}_\theta(\boldsymbol{z})$, $\boldsymbol{\sigma}^2_\theta(\boldsymbol{z})$ are the decoder outputs. While the prior distribution $p(\boldsymbol{z})$ is typically modeled as a standard Gaussian distribution with zero mean and unit variance, VAE-SPACE designs it as a specific form based on the assumption that $\boldsymbol{z}$ indicates the underlying musical scores of an F_0 contour in the case of a singing voice. Specifically, in a supervised setting where pairs of F_0 contours and musical scores are availiable, we can train the VAE by maximizing the following loss function, whici tends to maximize the likelihood of $\boldsymbol{z}$, instead of minimizing the KL divergence since the prior distribution of $\boldsymbol{z}$ is known:

$$\mathcal{L}(\theta, \phi; \boldsymbol{o}) = \mathbb{E}_{\boldsymbol{z}\sim q_\phi(\boldsymbol{z}|\boldsymbol{o})}[\log p_\theta(\boldsymbol{o}|\boldsymbol{z})] + \mathbb{E}_{(\boldsymbol{o},\boldsymbol{z})\sim p_D(\boldsymbol{o},\boldsymbol{z})}[\log q_\phi(\boldsymbol{z}|\boldsymbol{o})], \quad (12)$$

where $\mathbb{E}_{(\boldsymbol{o},\boldsymbol{z})\sim p_D(\boldsymbol{o},\boldsymbol{z})}[\cdot]$ denotes the sample mean over the training data. In the generation process, a $\boldsymbol{z}$ sampled from a Gaussian distribution with the musical scores $\boldsymbol{N}$ as the mean and a variance matrix with a small constant value in the diagonal is used as the input of the trained decoder. The generated F_0 contour is then used to replace that obtained by VC to generate the excitation signal with the U/V information estimated by VC.

For network architectures, a gated convolutional neural network (CNN) [17] is used to construct the encoder and decoder to capture long- and short-term dependencies in F_0 contours. The gated CNN uses a data-driven gate called gated linear unit (GLU) $\sigma(\mathbf{H}_{l-1} * \mathbf{W}^{\mathrm{g}}_l + \mathbf{b}^{\mathrm{g}}_l)$ as a nonlinear activation function to control the information passed on in the hierarchy, where $\mathbf{H}_{l-1}$ denotes the output of the $(l-1)$-th layer, $\mathbf{b}^{\mathrm{f}}_l$ and $\mathbf{b}^{\mathrm{g}}_l$ are the weight and bias parameters of the l-th layer and σ is the sigmoid function.

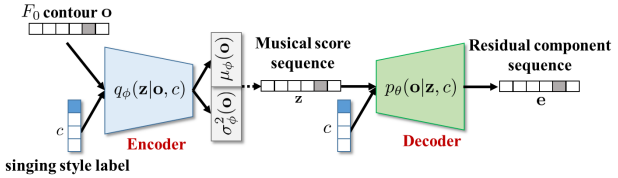

Figure 2. An overview of conditional VAE-SPACE.

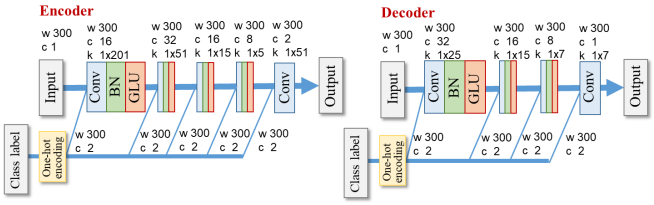

Figure 3. Network architectures of encoder and decoder used for cVAE. VAE used the same architecture excluding the class label inputs. "w", "c" and "k" denote the width, channel number and kernel size, respectively. "Conv", "BN" and "GLU" denote 1D convolution, batch normalization and gated linear unit, respectively.

To improve the performance of VAE-SPACE in modeling F_0 contours and minimize the cost of preparing pair data, we investigate two specific implementation-level problems in this paper: 1) whether a score-level alignment is necessary to train a supervised VAE-SPACE and 2) whether the performance can be improved by fine-tuning the trained decoder with the real musical score sequences generated by a sampling process during VAE pretraining. Furthermore, aiming to model different singing styles in a controllable manner, we also attempt to adopt a conditional CNN with GLUs to construct networks, which takes labels of singing styles c represented as one-hot vectors as additional inputs. The criterion of training a conditional VAE (cVAE) can be obtained merely by extending (12) [15].

5. EXPERIMENTAL EVALUATIONS

5.1 Experimental conditions

We prepared two datasets containing different pairs of data. *Dataset1* consists of EL speech samples of 21 Japanese children's songs recorded by a laryngeal speaker using an electrolarynx and the corresponding natural singing voices. 17 songs were manually segmented into 157 short phrases and used to train GMMs, and the other 4 songs were segmented into 19 phrases, and used as a test set. Each phrase was about 3∼8s long. *Dataset2* includes two versions of one Japanese song (about 4min 30s long), which were sung by a female person in normal and expressive singing styles. We segmented each song into 53 phrases and manually took alignments at the phrase and score levels, which were referred to as "unaligned" and "aligned" data, respectively.

We used the amplitude spectra as spectral feature vectors of EL speeches, and STRAIGHT analysis [9] to extract acoustic features of normal singing voices. The shift

Table 1. RMSE and standard deviation of VAE with different implementation conditions. "ft" denotes fine-tuning.

Models	RMSE
VAE-unaligned	26.1031 ± 5.5028
VAE-aligned	22.7670 ± 5.2874
VAE-aligned-ft	**21.3409 ± 5.3566**
cVAE-aligned-ft	22.2933 ± 6.3934

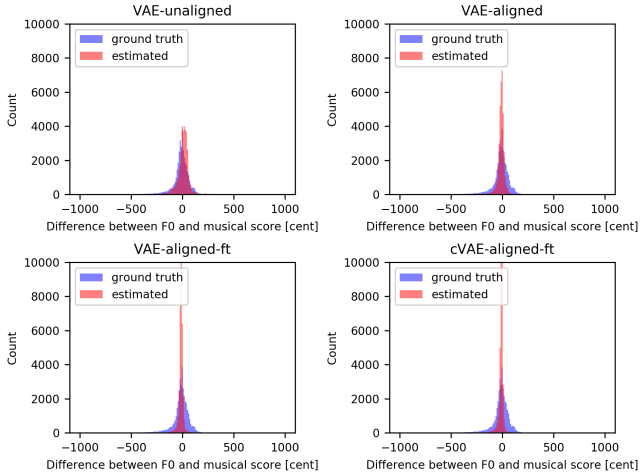

Figure 4. Histograms of the residual components e_t.

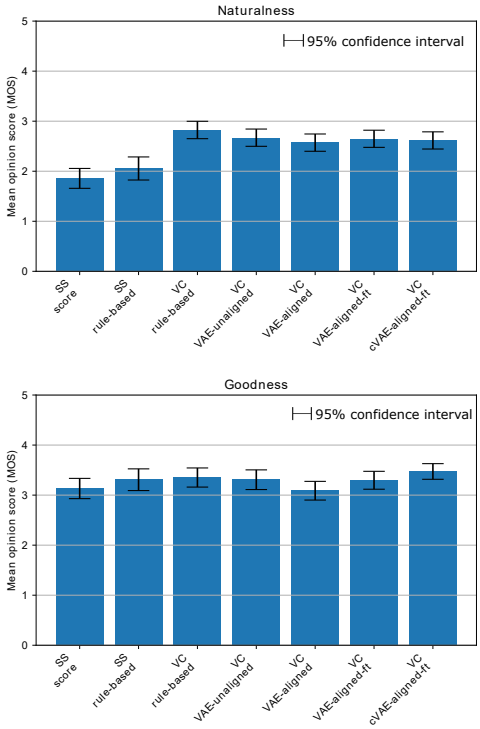

Figure 5. MOS in terms of naturalness and goodness.

length was 5 ms. The 0th through 24th mel-cepstral coefficients were used as spectral features of normal singing voices. As excitation features, a log-scaled F_0 value and aperiodic components on five frequency bands (i.e., 0-1, 1-2, 2-4, 4-6, and 6-8 kHz) were used. To obtain segmental feature vectors at each frame, we concatenated spectral feature vectors with the adjacent frames by setting $L = 4$ and performed PCA to reduce the feature dimension to 50. The numbers of mixture components of the GMMs used to estimate spectral features, aperiodic components, and F_0 including U/V information were all set at 16. Following the original VAE-SPACE paper, the output of the decoder was designed to be a sequence of residual components $\boldsymbol{e} = [e_1, \ldots, e_T]$, as shown in Fig. 2. Fig. 3 shows the architectures of the encoder and decoder. To train VAE, we used the songs sung in a normal style in *Dataset2*, and those sung in an expressive style were used as additional data for training the cVAE.

5.2 Objective evaluation

We first conducted an objective evaluation to demonstrate the performances of VAE-SPACE with different implementation conditions. We divided the songs into 7 folds and performed cross-validation. Root mean square error (RMSE) between the estimated and target F_0 contours was used as a metric to evaluate the estimation accuracy of F_0 generation. Table 1 shows the results. The objective results show that applying a score-level alignment and fine-tuning the decoder were effective in improving the accuracy of generating the target F_0 contours. However, the histograms of the residual components e_t shown in Fig. 4 reveal that both the alignment and fine-tuning decreased the dynamics of the generated F_0 contours.

Table 2. p-values calculated for method c).

	naturalness	goodness
SS+score	2.25E-11	0.1257
SS+rule-based	5.64E-07	0.7673
VC+VAE-unaligned	0.2223	0.7551
VC+VAE-aligned	0.0460	0.0561
VC+VAE-aligned-ft	0.1677	0.3413
VC+cVAE-aligned-ft	0.0976	0.3413

5.3 Subjective evaluation

To further investigate the performances of VAE-SPACE with different implementations and demonstrate the effectiveness of VC, we conducted a subjective evaluation that compared 7 methods, namely, a) SS+musical scores (SS+score), b) SS+rule-based F_0 modification (SS+rule-based), c) VC+rule-based F_0 modification (VC+rule-based), d) VC+VAE-SPACE using unaligned data (VC+VAE-unaligned), e) VC+VAE-SPACE using aligned data (VC+VAE-aligned), f) VC+VAE-SPACE using aligned data and fine-tuning (VC+VAE-aligned-ft), g) VC+cVAE-SPACE using aligned data and fine-tuning (VC+cVAE-aligned-ft). 13 evaluators participating in the experiments scored the converted singing voices in terms of the naturalness of the song and the goodness of singing using a 5-point opinion scale. The mean and 95% confidence interval of the two criteria are shown in Fig. 5 and the p-values calculated for method c) are shown in Table 2.

The results show that VC significantly improved the

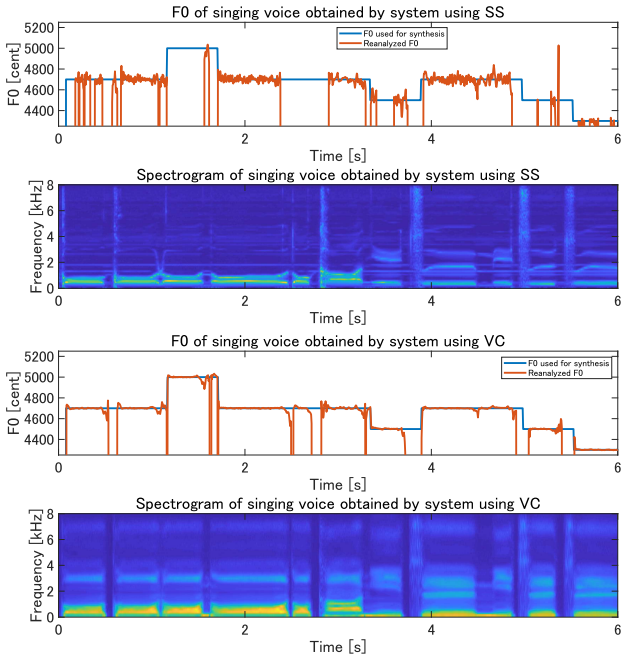

Figure 6. Examples of reanalyzed F_0 contours and spectrograms of synthesized singing voices obtained by employing SS (upper) and VC (bottom).

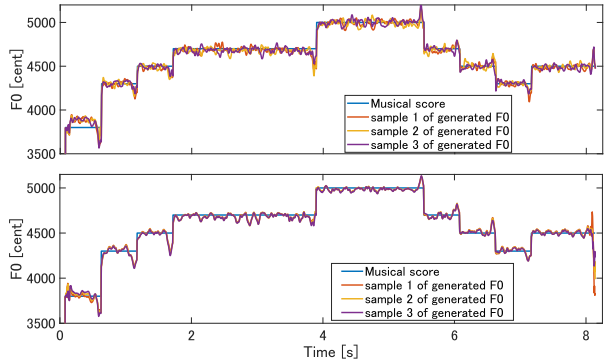

Figure 7. Generated F_0 contours with various $\boldsymbol{z}$ (upper) and class labels (bottom).

quality of converted singing voices in terms of the naturalness, which confirmed the effectiveness of the VC approach in removing the undesirable spectral components. An example of the reanalyzed F_0 contour and spectrogram is shown at the bottom of Fig. 6, which also confirmed this result. VAE-SPACE implemented with a conditional CNN achieved comparable results to the rule-based pitch control with carefully designed rules, and showed a high potential for contributing to the system. Compared with the method using unaligned data and the cVAE, the subjective results for the method using aligned data and fine-tuning were slightly lower, exhibiting the same tendency as the results shown in Fig. 4. This suggests that alignment and fine-tuning are not important in our system. We also investigated the variety of the F_0 contours generated with different sampled $\boldsymbol{z}$ and style class labels, the results of which are shown in Fig. 7. We observed some reasonable differences between the F_0 contours generated with various sampled $\boldsymbol{z}$. However, there was no notable difference observed between the F_0 contours generated with different class labels, which may have been due to the high ability of the networks to model the conditional distributions while ignoring the class labels [18, 19]. This issue will be addressed in future work.

6. DISCUSSION AND REUSABLE INSIGHTS

From the above results, it is concluded that spectrogram modification is useful and must be considered as well as F_0 control to improve the quality of singing voices. On the other hand, data alignment and fine-tuning are not essential, which means that we can increase the number of pair data at a relatively low cost to improve the estimation accuracy and the variety of styles. Furthermore, since the amount of pair data required for the VC approach is small and VAE-SPACE allows semi-supervised training with unlabeled data in addition to labeled data [8,15], it is expected that the entire system will be allowed to play its potential data efficiently, which is important for such a data-driven framework. Although cVAE-based implementation failed to represent different styles in the experiments, the framework for modeling various styles with a unified model provides us with a simple and straightforward way to control singing styles and apply style interpolation/morphing. Note that although we applied the method to model singing voices, it can also be used with other audio signals such as to generate suitable F_0 contours of musical instruments from musical instrument digital interface (MIDI) information. In addition to modeling various styles, we can extend this method to generate the F_0 contours of multiple instruments.

7. CONCLUSIONS

This paper proposed an improved singing aid system for laryngectomees based on a previously proposed system that converts EL speeches into singing voices according to the additionally inputted melodic information. The proposed system uses a statistical VC approach to transform the phonetic information extracted from EL speeches into those of natural speeches, and VAE-SPACE to perform pitch control. We investigated the importance of well-aligned pair data and the fine-tuning process for improving the performance and a conditional version of VAE-SPACE for modeling multiple singing styles with a unified model. The experimental results demonstrated that 1) the VC approach was effective in significantly improving the naturalness of singing voices, 2) the effectiveness of well-aligned pair data and fine-tuning was limited, and 3) VAE-SPACE was able to achieve comparable results to a carefully designed rule-based approach in generating F_0 contours.

1. ABSTRACT

To make music composition more approachable, we designed the first AI-powered Google Doodle, the Bach Doodle [1], where users can create their own melody and have it harmonized by a machine learning model (Coconet [22]) in the style of Bach. For users to input melodies, we designed a simplified sheet-music based interface. To support an interactive experience at scale, we re-implemented Coconet in TensorFlow.js [32] to run in the browser and reduced its runtime from 40s to 2s by adopting dilated depthwise separable convolutions and fusing operations. We also reduced the model download size to approximately 400KB through post-training weight quantization. We calibrated a speed test based on partial model evaluation time to determine if the harmonization request should be performed locally or sent to remote TPU servers. In three days, people spent 350 years worth of time playing with the Bach Doodle, and Coconet received more than 55 million queries. Users could choose to rate their compositions and contribute them to a public dataset, which we are releasing with this paper. We hope that the community finds this dataset useful for applications ranging from ethnomusicological studies, to music education, to improving machine learning models.

2. INTRODUCTION

Machine learning can extend our creative abilities by offering generative models that can rapidly fill in missing parts of our composition, allowing us to see a prototype of how a piece could sound. To celebrate J.S. Bach's 334th birthday, we designed the Bach Doodle to create an interactive experience where users can rapidly explore different possibilities in harmonization by tweaking their melody and requesting new harmonizations. The harmonizations are powered by Coconet [22], a versatile generative model of counterpoint that can fill in arbitrarily incomplete scores.

Creating this first AI-powered doodle involved overcoming challenges in user interaction and interface design, and also technical challenges in both machine learning and in infrastructure for serving the models at scale. For inputting melodies, we designed a simplified sheet music interface that facilitates easy trial and error and found that users adapted to it quickly even when they were not familiar with western music notation.

As most users do not have dedicated hardware to run machine learning models, we re-implemented Coconet in TensorFlow.js [32] so that it could run in the browser. We reduced the model run-time from 40s to 2s by adopting dilated depth-wise separable convolutions and fusing operations, and we reduced the model download size to ∼400KB through post-training weight quantization. To prepare for large-scale deployment, we calibrated a speed test to determine if a user's device is fast enough for running the model in the browser. If not, the harmonization requests were sent to remote TPU servers.

Users in 80% of sessions explored multiple harmonizations, and 53.8% of the harmonizations were rated as positive. One complaint from advance users was the presence of parallel fifths (P5s) and octaves (P8s). We analyzed 21.8 million harmonizations and found that P5s and P8s occur on average 0.365/measure and 0.391/measure respectively. Furthermore, P5s and P8s were more common when user input was out of distribution, and fewer P5s and P8s were correlated with positive user feedback.

3. RELATED WORK

Machine learning has been used in algorithmic music composition to support a wide range of musical tasks [5, 13, 19, 28, 29]. Melody harmonization is one of the canonical tasks [7, 11, 20, 26], encourages human-computer interaction [3, 14, 21, 25, 33], and is particularly approachable for novices. Different interfaces and tools have been developed to make the interaction experience more accessible. For example, in MySong [31], users can sing a melody and have the system harmonize it. In Hyperscore [12], users can draw multiple levels of "motifs" on a graphical sketchpad and have them harmonized according to the tension curve they specified. Startups such as JukeDeck and Amper Music offer APIs that allow users to describe a piece through timing and mood tags. Opensource libraries such as Magenta.js [30] allow machine learning models to be

used in digital audio work stations. For score-based interaction, FlowComposer [27] offers an augmented lead-sheet based interface, while DeepBach [17] demonstrates interactive chorale composition in MuseScore which uses standard music notation.

4. THE BACH DOODLE

4.1 A walk through of the user experience

The Bach Doodle user experience begins by demonstrating 4-part harmony using two measures of a Bach chorale, *Ach wie flüchtig, ach wie nichtig, BWV 26*. By playing the soprano line alone, followed by soprano and alto, and then all four voices, users are shown how the harmony enhances the melody. Users are then presented with two measures of blank sheet music, in the treble clef, with a key signature of C major, in standard time. There are four vertical lines in each measure to indicate the beats which give the user visual cues on where to put notes.

The user enters a monophonic melody using quarter and eighth notes. The note duration is automatic. If a note is entered on a beat, it is a quarter note by default. However, if a note is added after the beat, the existing quarter note becomes an eighth note. This simple interface makes it easy for users with no musical knowledge to input a composition, and can be seen in Figure 1. If the user clicks on the "star" button on the left-hand side of the sheet music, they can enter "advanced mode". This allows the user to input sixteenth notes anywhere on the staff. It also enables a control where the key can be changed to any of the 12 key signatures. This mode is hidden because it can be overwhelming for new users. It is also easier to make less enjoyable music this way, for example by going off key, or making the music overly complex.

Clicking the "Harmonize" button sends the generation request to either TensorFlow.js or the TPU server. When the response is ready, it is presented to the user one voice at a time, listing them out: "Soprano", "Alto", "Tenor", "Bass". The voices are color-coded to illustrate the harmonization in relation to the soprano input notes (Figure 2).

Figure 1. The user interface of the Bach Doodle, where users can input a melody and then click on the green "Harmonize" button on the bottom right to request a harmonization.

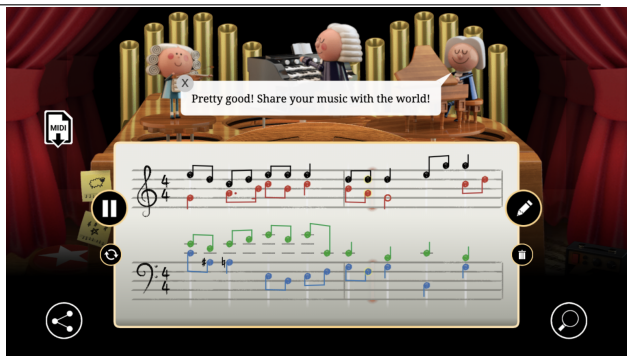

Figure 2. The harmonization returned by Coconet is notated in color, carrying the alto, tenor, and bass voices.

4.2 Design challenges

Celebrating J.S. Bach's birthday using machine learning presented many unique design opportunities as well as some user experience challenges. One of the main goals was to empower people with the feeling that they could augment their own creativity in ways not previously thought possible, by allowing them to directly collaborate with a machine learning model. Another important goal was to convey the message that machine learning is not "magical" or incomprehensible, but rather a science that can be understood. Finally, a notable challenge was to ensure that these aims would be met for a large diversity of individuals, from children who have not yet learned to read to experts of music and technology.

In order to acquire early feedback on the design, user tests were employed. Over the course of the project, dozens of people were asked to play the demos and comment on their experience through both pre-defined questions and open comments. The first user test in the development process revealed that many people do not fully understand the concept of harmony, but fortunately, further testing showed that short animated musical examples were enough for people to comprehend these concepts quickly. Also, user tests indicated that only a small subset of people could read standard music notation. Our intuition was that using standard notation, rather than a grid based interface would be intuitive and frictionless to anybody only if the user interface (UI) was responsive with animations and sound and also if the note input interface was kept simple. Further user testing of the standard notation input UI proved this to be correct.

In order to accommodate people of all ages and experiences, a common technique employed is to remove any advanced feature or unexpected delight from the core experience and instead integrate them as "easter eggs". This allows people of all skill levels to experience the full core experience without feeling frustrated, while also giving the rarer advanced user more features. While the core experience primarily allows eighth notes and tempo changes, clicking on a special button in the background additionally allowed the user to add sixteenth notes and change the key – two features that are very confusing to those without musical backgrounds.

4.3 Reusable insights

For future projects, we have shown that if the technology being used is unfamiliar or perceived as "scary" to those who know little about it, tethering the experience to a familiar story and visuals can be a successful strategy. Most people have a limited understanding of musical concepts such as harmony and standard notation, but it is possible that people of all ages can quickly acquire an intuitive understanding of musical concepts through carefully designed animated audiovisuals and a simple and responsive UI. Additionally, injecting content into loading screens could not only make loading times feel shorter but also be an excellent space for educational content. Finally, user testing is crucial when trying to create an experience using new technology that encompasses a large and diverse audience – it can reveal serious issues and shortcomings that are not obvious due to the team's own background and domain knowledge.

5. TECHNICAL CHALLENGES

In order for users to interact with Coconet via a web interface, we needed to either port it to run client-side on the user's device or host the model on a server with sufficient speed and capacity to support the number of requests we were expecting. In fact, we did both: we ported the model to TensorFlow.js (TF.js) so that it could run on user devices and added support for Tensor Processing Units (TPU) so that it could be served on Google Cloud. By running a simple test on users' devices to determine the speed of core tensor operations, we were able to determine whether to use the TF.js implementation locally, or fall back to a TPU server to handle the computation. In the end, 47.4% of all harmonizations were done locally, in TF.js.

5.1 Background: Coconet

Coconet [22] [1] is a versatile generative model of musical counterpoint that can fill in arbitrarily incomplete scores, as illustrated in Figure 3.

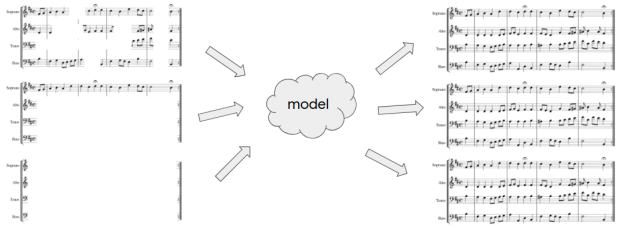

Figure 3. Coconet can be used in a wide range of musical tasks, such as completing partial scores, harmonizing melodies and generating from scratch.

Coconet represents counterpoint as a stack of piano rolls encoded in a binary three-dimensional tensor $\mathbf{x} \in \{0,1\}^{I \times T \times P}$, where I, T, and P denotes the number of instruments, time steps, and pitches respectively. $\mathbf{x}_{i,t,p} = 1$ if the ith instrument plays pitch p at time t. Each instrument is assumed to play exactly one pitch at a time, therefore $\sum_p \mathbf{x}_{i,t,p} = 1$ for all (i,t) positions. We also focus on four-part Bach chorales as used in prior work [2, 4, 8, 16, 18, 24], and assume $I = 4$ throughout.

Conventional approaches often factorize the joint distribution $p(\mathbf{x})$ into conditional distributions of the form $p(\mathbf{x}_k \mid \mathbf{x}_{<k})$, where k indexes a sequence in some predetermined ordering such as chronological. In contrast, Coconet is an instance of orderless NADE [34, 35] and offers direct access to all conditionals of the form $p(\mathbf{x}_{i,t} \mid \mathbf{x}_C)$, where C selects a fragment of a musical score $\mathbf{x}$ and $(i,t) \in \neg C$ is in its complement (i.e. the missing parts). To train Coconet, we sample a training example $\mathbf{x}$, choose uniformly how many variables to erase, i.e. $|\neg C| \sim U(1, D)$, and then choose uniformly the particular subset of variables $\neg C$ to erase. The input $\mathbf{X} \in \{0,1\}^{2I \times T \times P}$ is obtained by erasing the piano rolls $\mathbf{x}$ to obtain incomplete piano rolls $\mathbf{x}_C$ and concatenating this with the corresponding masks, as shown in Figure 4 (top left) where the yellow gaps indicate erased positions with all pitches set to zero.

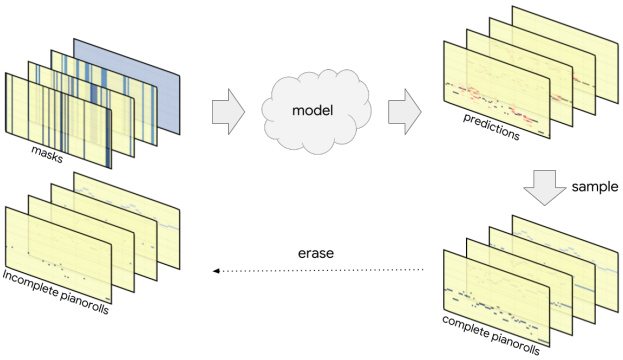

Figure 4. Coconet's generation loop using Gibbs sampling, alternating between (top) filling in the missing parts and (bottom) erasing random parts to improve the score through rewriting.

The output predictions for each (i,t) position is a softmax over the set of pitches P (top right of Figure 4). The negative loglikelihood loss is given below, which involves reweighing by the number of variables erased to ensure that all conditionals are trained equally.

$$\mathcal{L}(\mathbf{x}; C) = -\frac{1}{|\neg C|} \sum_{(i,t) \in \neg C} \sum_p \mathbf{x}_{i,t,p} \log p(\mathbf{x}_{i,t,p} \mid \mathbf{x}_C, C)$$

In contrast to generating from left to right in one pass, Coconet uses Gibbs sampling to improve sample quality through rewriting (see [22] for convergence analysis). Figure 4 shows how the procedure iterates between filling in missing parts and then erasing other parts so that they could be rewritten given the updated context.

5.2 Improving and speeding up Coconet

The original Coconet uses dense convolutions, where filter weights and their mixing weights W are fully connected (Equation 1). This makes it unable to fully leverage GPU parallelization in TF.js (see Section 5.3.2).

[1] Blog post: https://magenta.tensorflow.org/coconet Code: https://github.com/tensorflow/magenta/tree/master/magenta/models/coconet

Let s, q index the pitch and time dimension in filters, and i, j the input and output channels. In dense convolutions, each output position (p, t, j) indexed by pitch, time and output channel is a sum over the resultant input channels and also over the positions in each filter (given by the neighbourhood function). For a 3-by-3 filter this summing is over the 9 positions.

In contrast, depthwise separable convolutions [6], shown in Equation 2, factorizes the dense tensor W into a depthwise tensor V and a pointwise U. As a result, the multiplications between V and X can be parallelized over the input channels i in the inner sum of Equation 3.

$$Y^{\text{dense}}_{p,t,j} = \sum_i \sum_{s,q \in \text{neighborhood(p, t)}} W_{s,q,i,j} X_{s,q,i} \quad (1)$$

$$Y^{\text{dsep}}_{p,t,j} = \sum_i \sum_{s,q \in \text{neighborhood(p,t)}} U_{i,j} V_{s,q,i} X_{s,q,i} \quad (2)$$

$$= \sum_i U_{i,j} \sum_{s,q \in \text{neighborhood(p,t)}} V_{s,q,i} X_{s,q,i} \quad (3)$$

To further speed up Coconet, we adopt dilated convolutions to grow the receptive field exponentially to reduce the number of layers needed. As in [36], where in each block the dilation factors double in each layer for both the pitch and time dimension and then the block repeats.

The original Coconet was trained on eight measures (T=128). However, the Bach Doodle is designed for two measures (T=32), so we retrained the model with the original architecture and saw that the loss increased from 0.57 to 0.62 (show in Table 1), possibly because there is less context. Switching from dense to depthwise separable convolutions reduced the loss, requiring more filters but fewer layers. Since Tensorflow.js allows for parallelization across filters, this still resulted in much faster generation (see Section 5.3.2). Dilated convolutions reduced both the number of layers and number of filters and also reducing the loss. The particular scheme we used is 7 blocks of dilation rates $(1, 2, 4, 8, 16, 16)$ for the pitch dimension and $(1, 2, 4, 8, 16, 32)$ for the time dimension.

Table 1. Comparing frame-wise negative loglikelihood (NLL) on the 16th-note resolution as in [22] and the generation time (in seconds) when model was ported to Tensorflow.js (see Section 5.3.2 for details). The bottom three rows are all trained on two-measure (T=32) random crops.

Convolution type	NLL	run time
Dense (T=128), 64L, 128f	0.57	
Dense (T=32), 64L, 128f	0.62	> 40s
Depthwise separable, 48L, 192f	0.59	7s
Dilated, 45L (7 blocks), 128f	0.58	∼4s

5.3 Porting Coconet to the Browser

JavaScript is the standard language for browser-based computation, but native JavaScript is too inefficient to handle the the amount of computation required by Coconet in a reasonable time for the interaction we desired. TF.js is a javascript library for GPU-accelerated machine learning. It makes use of WebGL [2] to leverage the parallel processing power of GPUs to speed up machine learning operations, supporting the development and training of models, as well as deployment of trained models on web browsers. By enabling users to run trained models directly in their web browsers, it alleviates the need for remote servers to run those models. This can enable faster, more interactive experiences between a user and a machine learning system.

While some models can easily be ported to TF.js using a conversion script, Coconet's Python TensorFlow implementation used some ops that did not yet exist in TF.js (e.g., `cumsum`), and we also needed the flexibility to optimize the performance of the model for our use case. We therefore manually re-implemented Coconet in TF.js ourselves and have made the code opensource [3] . We also contributed missing ops to TF.js with WebGL fragment shader code for GPU acceleration.

5.3.1 UI Challenges

TF.js makes use of the async/await pattern for access to outputs of models and individual TensorFlow operations. During inference, users receive a callback for when GPU operations have completed and the result is ready to be consumed. In this way, there is no blocking of the UI while waiting for model results. In practice, with large models like Coconet (which includes many repeated sampling steps of a deep network), it is still important to cede control back to the UI explicitly during the course of the model operations, which can be done with the `tf.nextFrame()` operation. Our op-by-op code port of the network allowed us to add these occasional UI breaks, which avoided a poor user experience where the page would freeze for multiple seconds during model prediction.

5.3.2 Performance Challenges

The initial port of Coconet to TF.js took over 40 seconds to do one harmonization. For a satisfying user experience, we needed to lessen this latency to below 5 seconds. While TF.js is able to take advantage of GPU acceleration, WebGL does not directly support the types of tensor operations used in deep learning. Instead, these operations must be implemented as shader programs, which were originally intended to compute the color for pixels during graphics rendering. This mismatch leads to inefficiencies that sometimes vary by operation. It turned out that the (unavoidably) inefficient shader implementation of convolutional layers were the main culprit. By switching to depthwise-separable convolutions, however, we were able to avoid many of these performance issues, reducing generation time to 7 seconds.

As we run Coconet through 64 Gibbs sampling steps, any improvement to operations that are used in this loop

[2] `https://developer.mozilla.org/en-US/docs/Web/API/WebGL_API`

[3] `https://tensorflow.github.io/magenta-js/music/classes/_coconet_model_.coconet.html`

could lead to a significant saving. We wrote a custom operation using WebGL shaders to fuse together the operations used in our initial TF.js implementation of the annealing schedule. This schedule by [37] is a sequence of simple element-by-element operations that is run on every sampling step during harmonization. Because of the simplicity of the operations (a scalar subtraction, multiplication, division, and a max operation), we were able to easily fuse them into a single operation that avoided the overhead of executing multiple shader programs on the GPU, speeding up inference by about 5%. The combined savings of adding depthwise-separable convolutions, shrinking the model by using dilated convolutions, and using the fused schedule operation resulted in a reduction of the model latency from 40s to 2s.

5.3.3 Download Size

Due to the number of users we intended to reach as well as the variety of locations, devices, and bandwidth limits they would have, we needed to ensure the download size of the model weights was as small possible. To achieve this goal, we implemented support for post-training weight quantization and contributed it to TF.js. This quantization compresses each `float32` weight tensor by mapping the full range of its dimensions down to 256 uniformly-spaced buckets in order to represent them as `int8` values, which are then stored along with `float32` min and scale values used to recover the range. During model initialization, the weights are converted back to `float32` tensors using linear interpolation. By using these quantization, we were able to reduce the size of the downloaded weights by approximately 4, resulting in a payload of $\sim$ 400KB without any noticable sacrifice in quality.

5.4 Balancing Load Between Tensorflow.js and TPU

We ideally wanted to run the harmonization model completely on end-user devices using TF.js to avoid the need for serving infrastructure, which adds cost, effort, and additional points of failure. But the speed of harmonization differs by user device, with older and lower-end devices taking longer to run the TF.js model code. For devices where harmonization take more than a few seconds, the harmonization is instead done by the cloud-served model. The first step in checking if a device can run harmonization locally is to check if WebGL is supported on the device, since that is required for using GPU-acceleration through TF.js. If WebGL is supported then we perform a speed test on the model, running a sample melody through its first four layers. If the latency of this model inference is below a set threshold, then the TF.js version is used. As there is overhead on the first inference of a model in TF.js, due to initial loading of the model weight textures onto the GPU, we actually run the speed test twice and use the second measurement to make the decision.

6. DATASET RELEASE AND ANALYSIS

6.1 Data structure

Every user who interacted with the Bach Doodle had the opportunity to add their composition to a dataset. We make this entire dataset available at `https://g.co/magenta/bach-doodle-dataset` under a Creative Commons license. Of more than 55 million requests, the user contributed dataset contains over 21.6 million miniature compositions. The compositions are split across 8.5 million sessions. Each session represents an anonymous user's interaction with the Bach Doodle over a single pageload and may contain multiple data points. Each data point consists of the user's input melody, the 4-voice harmonization returned by Coconet, as well as other metadata: the country of origin, the user's rating, the composition's key signature, how long it took to compose the melody, and the number of times the composition was listened to.

6.2 Analysis

We present some preliminary analysis of the dataset to shed some light on how users interacted with the doodle. Out of the 21.6 million sequences in the dataset, about 14 million (or 65.7%) are unique pitch sequences, that are not repeated anywhere in the dataset (without considering timing information). Overall, the median amount of time spent composing a sequence was 25.5 seconds, and sequences were listened to for a median of 3 loops, with a total of 78.2 million loops listened across the entire dataset.

The sequences come from 109 different countries, with the United States, Brazil, Mexico, Italy, and Spain ranking in the top 5. Countries that had a small number of sequences were all grouped together in a separate category, to minimize the possibility of identifying users. While many sessions ($\sim$20%) contained only one request for harmonization (shown in Figure 5), most sessions had 2 or more harmonizations, either of the same melody, or of a different one. As shown in Figure 6, more than 5 million of the input sequences used the maximum number of notes in the default version of the doodle, which is 16. It is interesting to note that despite being an Easter egg, 7.6% of user sessions discovered the advanced mode that allowed them to enter longer sequences.

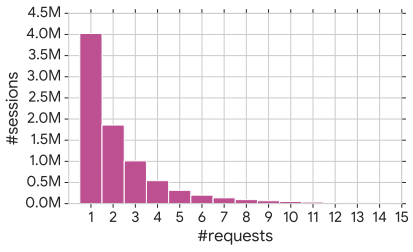

Figure 5. Histogram: number of requests per session

The doodle has 3 presets: *Twinkle Twinkle Little Star*, *Mary had a Little Lamb*, and the beginning to *Bach's Toccata and Fugue in D Minor, BWV 565*, which are the 3 most repeated sequences. However, there are also shows

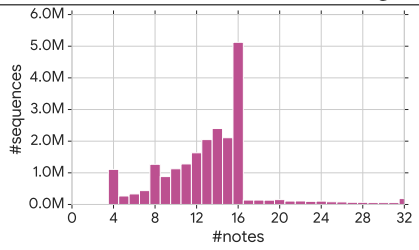

Figure 6. Histogram: length of sequences

some surprising runner ups, such as Beethoven's *Ode to Joy*, and *Megalovania*, a popular song from the game *Undertale*, as well as some regional hits [4]. Overall, users enjoyed their harmonizations, with 53.8% of all compositions rated as "Good". Figure 7 gives the breakdown of user ratings.

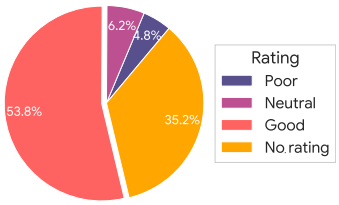

Figure 7. Breakdown of user ratings on harmonized compositions.

6.3 Parallel Fifths and Parallel Octaves

The Coconet model that powered the Bach Doodle was trained to produce harmonizations in the style of Bach chorales, and one well known characteristic of Bach's counterpoint writing is how carefully he followed the rule of avoiding parallel fifths (P5s) and parallel octaves (P8s). However, one complaint from advanced users of the app was the presence of P5s and P8s in the output of the model. Here, we present some analysis of how frequently and under what circumstances such outputs occurred. To identify the P5 and P8 occurrences, we used *music21* [9].

First, we looked at how frequently P5s and P8s appeared in our training data. We were surprised to find that in the 382 Bach chorale preludes we used in our train and validation sets, there were 132 instances of P5s (0.023/measure) and 51 instances of P8s (0.009/measure). Given this prevalence, the model may learn to output this kind of parallel motion. However, many of these instances can be "excused" because they occur under special circumstances such as at phrase boundaries or when using non-chord tones [10, 15]. Unfortunately, our training data does not include key signatures, time signatures, or fermatas, so the model likely learned to treat P5s as more permissible than was actually the case in Bach's music.

We then examined the output of the model to see if P5s/P8s occurred more frequently when user input was outside the training distribution and if the absence of

[4] Visit `https://g.co/magenta/bach-doodle-dataset` to interact with visualizations of the top repeated melodies overall and in each region, as well as regional unique hits.

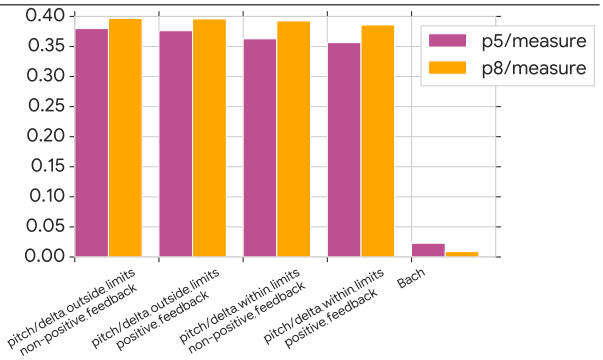

Figure 8. Parallel fifths and octaves per measure

P5s/P8s was correlated with positive user feedback. We first split the output based on whether users gave positive feedback or not (non-positive feedback includes neutral, negative, and the absence of feedback). Next, we split based on whether user input was within the same pitch range as the soprano lines in the training data (MIDI pitches from 60 through 81) and whether the maximum delta between consecutive pitches exceeded that of the training data (1 octave).

In total, we found 15,816,599 P5s (0.365/measure) and 16,949,818 P8s (0.391/measure) in the model output. Results split into the four categories are shown in Figure 8. As hypothesized, P5s/P8s were more common when user input was out of distribution, and their absence correlated with positive user feedback. A Kruskal-Wallis H test for both the number of P5s and P8s showed that there is at least one statistically significant difference between the four categories with $p < 1\text{e}{-4}$. Further, Mann-Whitney rank tests between the categories showed significant differences, each with $p < 1\text{e}{-4}$. The correlation between fewer P5s/P8s and positive user feedback is particularly interesting. This could either indicate that users prefer music with fewer P5s/P8s or it could simply mean that when the model produces poor output, P5s/P8s tend to be a feature of that output. In any case, the presence of P5s/P8s seems to be a useful proxy metric for model output quality. In future work, it could be a useful signal during training (similar to [23]), evaluation, or perhaps even during inference where it could trigger additional Gibbs sampling steps.

7. CONCLUSION

The Bach Doodle enabled large-scale participation in baroque-style counterpoint composition through an intuitive sheet music interface assisted by machine learning. We hope this encourages more creative apps that allow novices and artists to interact with music composition and machine learning in approachable ways. With this paper, we are releasing a dataset of 21.6 million instances of human-computer collaborative miniature compositions, along with meta-data such as user rating and country of origin. We hope the community will find it useful for ethnomusicological studies, music education, or improving machine learning models.

8. ACKNOWLEDGEMENTS

Many thanks to Ann Yuan, Daniel Smilkov and Nikhil Thorat from Tensorflow.js for their expert assistance. A big shoutout to Pedro Vergani, Rebecca Thomas, Jordan Thompson and others on the Doodle team for their contribution to the core components of the Doodle. Thank you Lauren Hannah-Murphy and Chris Han for keeping us on track. Thank you to Magenta colleagues for their support. Thank you Tim Cooijmans for co-authoring the blog post.

SCALABLE SEARCHING AND RANKING FOR MELODIC PATTERN QUERIES

ABSTRACT

We present the design and implementation of a scalable search engine for large Digital Score Libraries. It covers the core features expected from an information retrieval system. Music representation is pre-processed, simplified and normalized. Collections are searched for scores that match a melodic pattern, results are ranked on their similarity with the pattern, and matching fragments are finally identified on the fly. Moreover, all these features are designed to be integrated in a standard search engine and thus benefit from the horizontal scalability of such systems. Our method is fully implemented, and relies on ELASTICSEARCH for collection indexing. We describe its main components, report and study its performances.

1. INTRODUCTION

We consider the problem of searching large collections of digital scores encoded in a symbolic format, typically MusicXML [14], MEI [22, 28], or the forthcoming format of the W3C Music Notation Group [23]. These encodings are now mature and stable, and we can expect to witness in the near future the emergence of very large Digital Score Libraries (DSL). A representative example of such endeavors is the OpenScore initiative, which aims at publishing high-quality encoding of public domain sheet music. This potentially represents millions of scores, and gives rise to strong needs in terms of collection management tools tailored to the peculiarities of music representation.

In the present paper, we focus on the *content-based retrieval* problem. We consider the search mechanism where a user submits a monophonic *query pattern* in order to retrieve, from a very large collection of scores, those that contain one or more fragments "similar" to this pattern. We further require the search system to be *scalable*.

With this objective in mind, we propose two main contributions. First, we expose the design of the core modules of a search engine, namely pre-processing and data normalization, pattern-based search, ranking, and on-line identification of fragments that match the pattern query. Second, we propose a list of guidelines for integrating these modules in a standard information retrieval system, with two main benefits: reduction of implementation efforts, and horizontal scalability.

Our approach is summarized by Figure 1. Pre-processing, matching, occurrence extraction and ranking are standard steps in text-based information retrieval systems, adapted here to the specificities of music representation. Tokenization, stemming and lemmatization [21] are, in our case, replaced by a so-called *normalization* that simplifies the representation and improves the robustness of the result. The *matching step* operates on the normalized representation (query pattern and score content). Normalization and matching are detailed in Section 3.

Obtaining a full score in the result would be of little use if we were not able to identify all the fragments that actually match the pattern, called *pattern occurrences*. This is necessary, for instance, to highlight them in the user interface. The algorithm is described in Section 4.

Finally, the set of matching scores are sorted according to the similarity of their occurrences to the pattern. While pattern matching mostly relies on the melodic profile, the ranking method focuses on the rhythm (Section 5). Their combination produces results with highly relevant scores.

The rest of the paper (Section 6) covers our second contribution, namely the integration of our music retrieval components in a standard search engine. For the sake of concreteness, we detail this integration with ELASTICSEARCH (https://elastic.co).

We finally position our work with respect to the state of the art and lists some useful extensions that could enrich the search functionalities (Section 7).

2. PRELIMINARIES: SCORES, FRAGMENTS, AND PATTERNS

Given a *melodic pattern* P as input, the *pattern matching operation* retrieves all the *scores* such that at least one *fragment* matches P. Our approach focuses on the pitch and duration features, generally considered as the most important parameters for melodic similarity [27]. We model a score as a synchronization of *voices*, and each voice as a sequence of elements $< e_1, e_2, \cdots, e_n >$ with e_i in $\mathcal{E} \times \mathcal{D}$, where $\mathcal{E}$ is the domain of musical "events" (notes, chords, rest) and $\mathcal{D}$ the musical duration.

Figure 1. Overview of the main indexing and matching steps

Figure 2. Voice V_I

Let us take the example of a voice V_I (Fig. 2). The blue fragment, denoted by F in the following, is used to illustrate the matching operation. V_I encodes a melody beginning with a G4 (semi-quarter), followed by a D5 (idem), a D5 (dotted half), etc. Using some pitches encoding mechanism, for instance the chromatic notation (number of semitones from the lowest possible sound), one obtains the representation of this voice as a sequence of pairs:
$V_I =< (34,8);(41,8);(41,3);(34,8);(42,8);(42,6);(39,8);\cdots >$

Given a voice V, we can derive other representations thanks to *transformation* functions. We consider two main categories of transformations: *simplifications* and *mutations*. They will be used in the normalization process.

Definition 1 (Simplifications) *A voice V can be transformed by the following simplification functions: $\epsilon(V)$, the sequence of pitches, $\pi(V)$ the sequence of pitch intervals between events in $\epsilon(V)$, and $\rho(V)$ the sequence of duration (without events) of V.*

Intuitively, $\epsilon(V)$ captures the melodic profile (sequence of note heights), $\pi(V)$ the relative evolution of pitches' heights, and $\rho(V)$ the rhythmic profile of a voice. Applied to V_I one obtains:

1. $\epsilon(V_I) =< 34,41,41,34,42,42,39,36,\ldots >$
2. $\pi(V_I) =< 7,0,-7,8,0,-3,-3,\ldots >$
3. $\rho(V_I) =< 8,8,3,8,8,6,8,6,\ldots >$

Definition 2 (Mutations) *A mutation $M_{I_1 \to I_2}$ maps an interval I_1 to another interval I_2. A* mutation family *is a set of mutation functions.*

For example, $\mathcal{M}_D = \{M_{1\to2}, M_{3\to4}, M_{8\to9}\}$ denotes a subset of the family of *diatonic mutation* that transforms a minor second, third or sixth in, respectively, their major counterpart, and conversely.

Finally, a *fragment* is any subsequence of a voice. We will use the word "pattern" to denote the fragment supplied by some user as a search criteria.

3. NORMALIZATION AND MATCHING

The matching operation is a Boolean procedure that tells whether the pattern P and a fragment F are similar to one another. This similarity concept is subject to a trade-off between the precision (relevant part of the result) and the recall (global relevant scores over the result). This is a traditional information retrieval issue. Let us examine how it is translated in the realm of symbolic music representation.

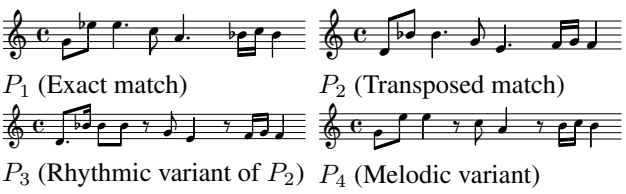

Figure 3. Several matching interpretations

3.1 Discussion

Fig. 3 shows several pattern variants, candidates to match with the fragment F of V_I (blue note heads in Fig. 2).

Exact Match. The strictest matching definition requires both the sequence of pitches (resp. $\epsilon(F)$ and $\epsilon(P)$) and the sequence of durations (resp. $\rho(F)$ and $\rho(P)$) to be identical. If we stick to this definition, F matches only with pattern P_1. The precision is then maximal but we will miss results that seem intuitive. F will not match for instance with the transposed pattern P_2, all other things being equal. This is probably too strict for most applications.

Transposed Match. Accepting transposition means that we ignore the absolute pitch and focus only on intervals, i.e., we compare $\pi()$ and $\rho()$, introducing flexibility in the melodic correspondence. In that case P_2 matches F.

Rhythmic Match. Next, consider pattern P_3 (Fig. 3), a rhythmic variant of P_2 that does not match F by exact rhythmic matching. Again, this definition seems too strict, since short rests, or slight duration adjustments, can typically be added or removed from a voice to denote a specific articulation, without severely affecting the music itself. P_3 matches F if we compare only $\pi(P_3)$ and $\pi(F)$, and ignore $\rho()$. Note that rhythmic changes involve not only rests and durations, but also repeated notes.

Melodic Match. Finally, P_4 is a pattern where intervals have been mutated. The initial minor sixth is replaced by a major sixth. Since such mutations can be found in imitative styles (e.g., counterpoint), it can make sense to accept them as part of the matching definition.

How far are we ready to go in the transformation process? Fig. 4 shows two extreme examples. Pattern P_5 matches F with respect to the sequence of intervals ($\pi(P_5) = \pi(F)$), whereas pattern P_6 is a rhythmic match ($\rho(P_5) = \rho(F)$). It seems clear that these patterns are quite far from the considered fragments and that, at the very least, they should not be given the same importance in the result set than the previous ones.

Music similarity has been studied for decades now. It seems obvious that there is no ideal solution that would suit all situations [12, 15] since similarity judgments depend on many aspects. However, our goal here is *not* to compute all the similarities, but to provide a filtering mechanism that gets rid of the scores that do not match the query pattern.

P_5 (Melodic matching) P_6 (Rhythmic matching)

Figure 4. Two examples that match F on one dimension

F and P_1 P_2, P_3, P_5

Figure 5. Voice normalization.

Algorithm 1 Voice normalization

```
1: procedure VNORM(V)
2: Input: A voice V
3: Output: A voice V', normalization of V
4:     V' ← V
5:     Normalize all note durations in V' to a quarter.
6:     Merge repeated notes from V'.
7:     Remove rests from V'
8:     return V'
```

This mechanism should be simple, efficient, and plugable in a standard search engine. It does not require to apply a costly similarity function to the whole collection.

In this perspective, matching-based retrieval is a first step operated to filter out a large part of the collection. A simplified similarity function can be used to top rank relevant scores. It is then easy to develop further investigations (*e.g.,* specialized similarity function) on the result set.

3.2 Normalization

It is generally considered that rhythm plays a prominent role in the perception of similarity. We therefore rank the result according to the rhythmic likeness of each retrieved fragment with the pattern. Filtering is based on the melodic profile, and its impact depends on how we simplify this profile in the normalization step. Two extreme choices are either to keep the exact sequence, increasing the precision, or to extract the melodic contour, increasing the recall.

In information retrieval systems, normalization is part of pre-processing steps, usually called *analyzers* and can be tuned by the administrator. This flexibility should be adopted for the symbolic music retrieval as well.

Our current implementation relies on the VNORM() algorithm (Alg. 1), applied to both the pattern and each voice in the corpus. Fig. 5 shows the voice normalization applied on patterns F, P_1 (top) and P_2, P_3, P_5 (bottom). In both cases the sequence of intervals obtained by $\pi()$ on the normalization is <6,-3,-3,1,2,-2>.

3.3 Matching

Definition 3 *A score S* matches *a pattern P iff, for* at least *a voice v in S, and* at least *a pair $[b, e], e > b$ of offsets (positions) in v, where the set of voice fragments $v[b] \cdots v[e]$ that match P are called the* matching occurrences *of S.*

$$\pi(\text{VNORM}(P)) = \pi(\text{VNORM}(v[b] \cdots v[e]))$$

4. FINDING MATCHING OCCURRENCES

Once matching scores have been extracted from the repository, it is necessary to identify the corresponding sequences of pitches that match the given query pattern (on normalized *n*-grams). For this, we need to look forward to exact match between intervals in the query pattern, and pitches in score's voices. Algorithm 2 produces a list of matching pitches which will be ranked in the next section.

Algorithm 2 Finding matching occurrences

```
1: procedure FINDINGOCCURRENCES(V, Q)
2: Input: A voice V, a query Q of intervals
3: Output: A set L of fragments
4:     for p in LCS(V, Q) do        ▷ List of matching patterns
5:         L ← L ∪ p
```

This procedure processes a voice V with a given query pattern Q. The `LCS` [1, 20] algorithm (*Longest Common Subsequence*) will give in output each matching pattern in V. It will verify if the pattern Q matches any interval between two successing pitches from V. The LCS algorithm iterates on each pitch of V to check each eligible subsequence, especially for matching patterns contained into repeating subfragments in Q.

5. RANKING

Given a set of fragments that match a pattern P, we now want to sort them according to a similarity measure, and put on top the ones that are closest to P. Assume that the search pattern is our previous F (Fig. 2, blue heads) and that the result set is $\{P_1, P_2, P_3, P_5\}$. For all, function $\pi()$ composed with the normalization VNORM yields <6,-3,-3,1,2,-2>. Intuitively P_1 and P_2 should be ranked first, and P_5 should be ranked last.

It is important to note that this ranking applies to fragments that have an identical melodic pattern. We take advantage of this specificity to operate at two levels. The first level measures the similarity of the "melodic rhythm", i.e., the respective duration of pairwise intervals in each fragment. To this end we define the notion of *blocks*.

Definition 4 *Let F be a fragment such that $\pi(\text{VNORM}(F)) = < I_1, \cdots, I_n >$. By definition of π and* VNORM*, each interval $I_j, j \in [1, n]$ is represented in F by a sequence $< p_1^i, e_2^i, \cdots, e_{k-1}^i, p_k^i >$ such that:*

- *p_1^i and p_k^i are two distinct pitches, and $interval(p_1^i, p_k^i) = I_i$*
- *each $e_l^i, l \in [2, k-1]$ is either a rest, or a pitch such that $e_l^i = p_1^i$*

We call $< p_1^i, e_2^i, \cdots, e_{k-1}^i >$ the block *B_i of I_i in F.*

A block is the largest subsequence of a fragment that covers a non-null interval. The concept of block is illustrated by Fig. 6 for P_1, P_3 and P_5.

The first level of the ranking function evaluates the similarity of two fragments F_1 and F_2 by comparing the blocks

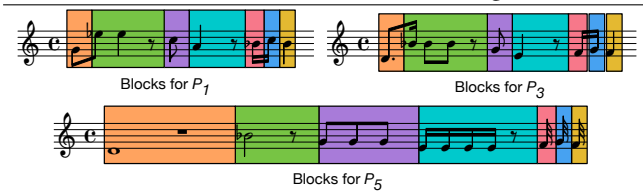

Figure 6. Blocks for P_1, P_3, and P_5

Algorithm 3 Ranking procedure

procedure RANKING(F_1, F_2)
Input: F_1, F_2, such that $\pi(\text{VNORM}(F_1))$=$\pi(\text{VNORM}(F_2))$
Output: a similarity $s \in [0, 1]$
  $s \leftarrow 0$; $d_1 \leftarrow duration(F_1)$; $d_2 \leftarrow duration(F_2)$
  for $i := 0$ **to** n **do** ▷ Loop on the blocks
    $s \leftarrow s + |dur(B_i^1)/d_1 - dur(B_i^2)/d_2|$
  if $s = 0$ **then** $s \leftarrow TieBreaking(F_1, F_2)$
  return $s/2$ ▷ Euclidian normalization [19]

pairwise durations. The rationale is that if these durations are similar, the only difference lies in either repeated notes or rests inside each block. Fig. 6 shows for instance that block durations in P_1 and P_3 are exactly the same, which makes them almost identical. The difference is internal to each block (for instance block 2, in green). On the other hand, P_1 and P_5 turn out to be quite dissimilar.

The RANKING function is simple and efficient (Algorithm 3). We first normalize the fragment duration, and sum up the difference of durations between pairs of blocks.

If it turns out that all block durations are pairwise identical, a tie-breaking function has to be called. This is the only situation where we might have to examine internal of blocks. By definition of blocks, this internal representation only consists of rhythmic data: rests and repeated notes. Any standard text comparison method (edit distance, Levhenstein distance) can be used.

6. INDEXING

We now describe how our functions can be integrated in a search engine. For the sake of concreteness, our description relies on ELASTICSEARCH, but the method works for any similar system (e.g., Solr) that uses inverted index.

6.1 Encoding

An index in ELASTICSEARCH is built on JSON documents. Each field in such a document can be either *indexed*, *stored* or both. Indexing a field means that ELASTICSEARCH supports full-text searches on the field's content. Storing a field means that the field's content is stored in the index. Our index features an *n*-gram field for searching, and a `sequence` field for the ranking.

Given a voice V and the sequence of intervals of its normalization $\pi(\text{VNORM}(V)) =< I_1,\cdots,I_k >$, we compute the list of n-grams $\{<I_i, \cdots, I_{i+n-1} >, i \in [1, k-n+1]\}$, where n, the n-gram size, is an index configuration parameter. If, for instance, the sequence of intervals is <6,-3,-3,1,2,-2>, the list of 3-grams is {<6,-3,-3>, <-3,-3,1>, <-3,1,2>, <1,2,-2>}.

Each n-gram is then encoded as a character string which constitutes a *token*. These tokens are finally concatenated in a large character string, separated by a white space. Positive integers are encoded with `a`, `b`, `c`, etc., and the minus sign by `m`, as illustrated in the following:

```
{"query": {"match_phrase":
  {"ngram": "fmcmc mcmca mcab abmb"} } }
```

6.2 Searching

We can then run keyword queries and, more importantly, *phrase queries* where ELASTICSEARCH retrieves the fields that contain a list of tokens that appear in a specific order. The previous query shows the"*match_phrase*" query which searches the *n*-gram sequence.

The search engine then does the rest of the job for us. It finds all the indexed documents such that the *n*-gram field contains the phrase. However, by default, ranking is based on textual features that do not match what we expect. We therefore need to replace the default ranking method.

6.3 Ranking

Ranking functions can be overridden in ELASTICSEARCH [32, 35]. To this end, we must provide a Java function that implements the ranking method exposed in Section 5. This function is called at query time and produces a similarity score for each voice. The result is sorted on this value, and made accessible to the client application via an iterator-like mechanism [11] called *SearchScript*.

Our ranking function operates on a voice to identify the matching occurrences, and to measure the similarity between the search pattern and each occurrence. We must store in ELASTICSEARCH an encoding of the voice that can be accessed during the query evaluation.

6.4 Query expansion

Our method relies on a strict matching of a sequence of intervals. Since accepting unbounded melodic transformations would likely return the whole database, we can consider those that can be seen as meaningful from a musical point of view. For instance, diatonic mutations of intervals (e.g., accepting both minor and major thirds or sixths in the matching operation) probably makes senses and can improve significantly the recall of our method.

We have integrated the synonym query expansion feature of ELASTICSEARCH engine (e.g., the ability to map "car" to "vehicle") to implement this feature. To achieve this, we decided to produce a list of synonyms for major thirds or sixths. These means that an interval '`c`' can be similar to '`d`' or interval '`h`' to '`i`'. The following *n*-grams are then considered to be: similar`cbh, dbh, dbi, cbi`

In order to integrate the list of synonyms to ELASTICSEARCH, it is given to the index as an analyzer *"melodic_transformation"* (illustrated in the query Section 6.5) and matching *n*-grams are merged at query time.

To find the matching occurrences, we need to modify Algorithm 2 in order to integrate the synonyms where intervals (in the `LCS` algorithm) for major third and sixth

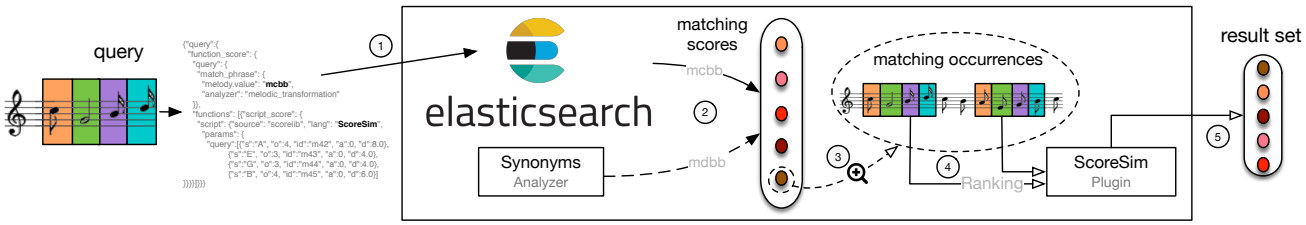

Figure 7. `ScoreSim` integration in ELASTICSEARCH

can be authorized, then: $1.5 \sim 2$ and $3 \sim 3.5$. ELASTICSEARCH can be further enhanced by taking into account a similarity measure between those synonyms (*e.g.*, oriented graph weighted with similarity values between synonyms).

6.5 Implementation

The integration of our approach in ELASTICSEARCH needs to preprocess musical scores to normalize them, and to compute the ranking in the search engine on query-time.

The first step consists in a Python scripts that normalizes voices from scores (Alg. 1), extracts *n*-grams, and produce JSON documents sent to the ELASTICSEARCH REST API. Documents also contain corpus and opus ids, syllables from lyrics voices which can be queried.

Second, to take into account synonyms in ELASTICSEARCH, the list of *n*-gram synonyms needs to be set offline. We have generated the list of all combinations of third and sixth transformation for each possible *n*-gram available in the repository. This list is imported in ELASTICSEARCH and then processed on-the-fly for each query.

The third step integrates the `ScoreSim` scoring module as a Java program in ELASTICSEARCH. For this, a *SearchScript* needs to be inherited in order to produce a plugin for ELASTICSEARCH. This plugin takes queries' parameters and instantiates a scoring function which will process every matching scores. The scoring function `ScoreSim` implements Algorithms 2 and 3.

The query below integrates all features that are proposed in our approach: *n*-gram search (*melody.value*), synonyms analyzer (*melodic_transformation*), and the `ScoreSim` function (*script_score*). In the latter, the parameter "*query*" gives the list of pitches used in order to produce the score value from Algorithm 3. The query params gives the sequence of the music items (octave, pitch and duration) that constitutes the pattern in order to provide distances and rank the result set.

```
{"query":{ "function_score": {
    "query": { "match_phrase": { "melody.value": "mcbb",
                    "analyzer": "melodic_transformation"}},
    "functions": [{"script_score": {
      "script": {"source": "scorelib", "lang": "ScoreSim",
        "params": {"query":[
            {"s":"A", "o":4, "id":"m42", "a":0, "d":8.0},
            {"s":"E", "o":3, "id":"m43", "a":0, "d":4.0},
            {"s":"G", "o":3, "id":"m44", "a":0, "d":4.0},
            {"s":"B", "o":4, "id":"m45", "a":0, "d":6.0}]}}}}]}}}
```

Figure 7 shows the querying process with the following steps: **1)** transform the melodic pattern into the ELASTICSEARCH DSL (Domain Specific Language), **2)** ELASTICSEARCH gets all the matching score corresponding to the given *n*-gram and eventually to their synonyms, **3)** instantiate the `ScoreSim` plugin and process every score, **4)** extract occurrences on each instance and then its score value, **5)** and finally, ELASTICSEARCH sorts the whole result-set according to the produced scores and sends the result.

	q1	q2	q3	q4
Querying pattern	`demc`	`mcmcmc`	`bmbb`	`bmbmc`
Nb of matching scores	204	719	877	2,225
Nb with query expansion	242	1867	877	2,236

Table 1. Query patterns

6.6 Performance

In order to study the impact of our approach on the computation time, we apply different queries on our corpora. The corpora size varies by cumulating several corpus, representing up to 4,950 polyphonic scores. It is composed of the whole corpora available here [1] composed of *Francœur, Méthodes, Motet, Psautiers, Sequentia, Timbres*, etc.

To study the effect of the matching process, we have chosen four different queries to apply with various patterns, from infrequent to more frequent ones, based on the popularity of the stored *n*-grams. Table 1 gives for each query pattern the corresponding total number of matches in the corpora and the number after applying the query expansion (synonyms). We can see that query q2 is clearly expanded since `mcmcmc` has 7 synonyms and produces a large number of matches (2.5 times more). At the opposite, query q3 has no synonyms and do not enlarge its result-set.

Figure 8 shows the evolution of the number of matching scores wrt the corpus size. It gives both matching scores for normal (plain lines) and expanded queries (dashed lines). According to the synonyms, we can see that q1 and q4 provide few more matchings, while q2 witnesses a different behavior where the number of matchings grows proportionally with the number of synonyms.

The execution time is plotted in Figure 9 for the 4 different queries. It shows both normal pattern queries (plain lines) and expanded queries (dashed lines). This allows to investigate both the robustness with respect to various results sizes, and issues related to false positives.

Each query is sub-linear in the result size. Query q4 is a frequent pattern which returns 2,225 matching scores (45% of the corpora). It is executed in 277 ms. The small number of synonyms has few impacts on the global processing time. At the opposite, q1 is extremely efficient due to its

[1] NEUMA repertory: `http://neuma.huma-num.fr/home/`

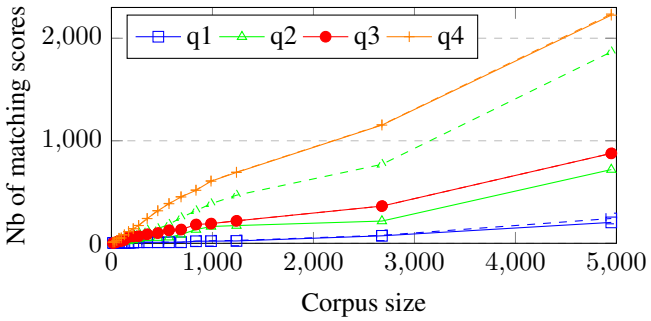

Figure 8. Nb of matching with and without synonyms

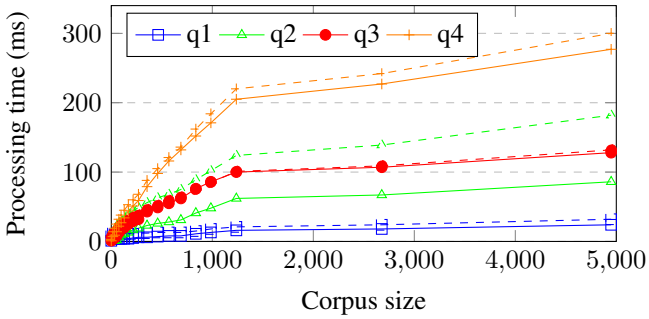

Figure 9. Execution time with and without synonyms

selectivity. It produces 204 scores in 22 ms. One interesting effect can be seen for query q2 where the number of matching synonyms leads to more computation time but it only 2.1 times more (for 2.5 times more matching scores).

Those experiments show that the ranking function takes less than 0.12 ms to process each score on a single ELASTICSEARCH node (server). The corpus can be spread on several nodes in order to scale it up horizontally.

7. RELATED WORK

Our approach combines similarity searches based on textual music encoding, scalable search, and rhythm-based ranking. The novelty of this approach is their association in a consistent setting. The rather trivial implementation makes, in our opinion, our solution quite attractive.

Music similarity has been an active MIR research topic over the last decades [5]. The general goal is to evaluate the likeness of two musical sequences. A major problem raised by this definition is that similarity judgments are highly dependent on both the content being compared and on the user taste, culture, and experience [12, 15]. A recent survey [34] summarizes the recent trends observed in the SMS track of the MIREX competition.

A similarity method is characterized by the choice of musical parameters. Pitches and durations are generally considered as expressive enough. Using sequences to represent both parameters is primarily motivated by our objective to integrate our methods in a standard search engine, and to benefit from an index structure. Some important parameters, e.g., metric accent, structure or harmonic are ignored because they often lead to tree-based encodings that are hardly indexable. Geometric approaches, such as [33], are also less suitable in this indexing perspective. Multidimensional structures are complex, and their performances are known to fall down as the dimension increases [29], and not yet integrated to off-the-shell search engines.

Textual encoding of symbolic music representation is an attractive idea in order to use text algorithms. The *HumDrum* toolkit [17] relies on a specialized text format and adapts Unix file inspection tools for music analysis. Exact and approximate string matching algorithms for melody matching have been used in *ThemeFinder* [18,30] or *Musipedia* [26]. Many algorithms for efficient computation of similarity matching through exhaustive searches have been proposed [2–4, 7]. Specialized rhythm similarity functions are proposed and compared in [31].

Text-based approaches are simple solutions, with two important limitations. First, combining pitches and rhythm in a single character string for instance is not easy, and small music variants may result in important syntactic differences. Second, these methods do not scale since the whole database has to be inspected for each query. Several indexing methods have been suggested for the edit distance [8, 24]. The *Dynamic Time Warping* distance is another popular method, for which sophisticated indexing structures have been proposed [13, 16]. None of them is available beyond research prototypes.

The easiest way to benefit from an inverted index is to split musical sequences in n-grams. This has been experimented in several earlier proposals [6, 9, 10, 25]. Each n-gram plays the role of a "token" and search methods apply.

Ranking is an essential part of an information retrieval system. We believe that our proposal, which combines **1)** a pre-processing normalization step, **2)** a melodic profile search and **3)** a rhythmic profile ranking, completes earlier attempts to adapt text-based retrieval to music retrieval, and results in a complete workflow which achieves a satisfying trade-off between the filtering impact, the ranking relevancy and the overall efficiency.

8. CONCLUSION

We described in this paper a practical approach to the problem of indexing pattern-based searches in a large score library. Our solution fulfills three major requirements for an information retrieval system: (i) it supports search with a significant part of flexibility, (ii) it proposes a ranking method consistent with the matching definition, and (iii) it brings scalability thanks to its compatibility with the features of state-of-the-art search engines. We fully implemented our solution, including the internal ranking function for ELASTICSEARCH, and we will be pleased to supply our software components to any interested institution that wishes to propose a content-based search mechanism.

Score analyzers extension. Alg. 1 with the normalization of voices can be extended with ad hoc music *analyzers*: management of grace notes, the simplification of melodic profiles, treatment of repeated notes, or cross-voice melodies, to name a few.

Acknowledgments. This work is funded by the French ANR project MUNIR

ABSTRACT

Vibratos, tremolos, trills, and flutter-tongue are techniques frequently found in vocal and instrumental music. A common feature of these techniques is the periodic modulation in the time–frequency domain. We propose a representation based on time–frequency scattering to model the inter-class variability for fine discrimination of these periodic modulations. Time–frequency scattering is an instance of the scattering transform, an approach for building invariant, stable, and informative signal representations. The proposed representation is calculated around the wavelet subband of maximal acoustic energy, rather than over all the wavelet bands. To demonstrate the feasibility of this approach, we build a system that computes the representation as input to a machine learning classifier. Whereas previously published datasets for playing technique analysis focus primarily on techniques recorded in isolation, for ecological validity, we create a new dataset to evaluate the system. The dataset, named CBF-periDB, contains full-length expert performances on the Chinese bamboo flute that have been thoroughly annotated by the players themselves. We report F-measures of 99% for flutter-tongue, 82% for trill, 69% for vibrato, and 51% for tremolo detection, and provide explanatory visualisations of scattering coefficients for each of these techniques.

1. INTRODUCTION

Expressive performances of instrumental music or singing voice often abound with vibratos, tremolos, trills, and flutter-tongue. A common feature of these four playing techniques is that they all result in some periodic modulation in the time–frequency domain. However, from a musical standpoint, these techniques convey distinct stylistic effects. Discriminating between these spectrotemporal patterns requires a compact and informative representation that remains stable to time shifts, time warps, and frequency transpositions. Time–frequency scattering [2] provides such mathematical guarantees. Besides the local invariance to translation and stability to deformation provided by the scattering transform [1, 10], time–frequency scattering goes further by applying frequential scattering along the log-frequency axis. This operation provides invariance to frequency transposition and captures regularity along log-frequency dimension.

Prior work in the representation of vibrato and tremolo can be divided into three broad categories: F_0-based representations [4, 14, 20], template-based techniques [5], and modulation spectra [13, 15, 17]. The error-prone stage of fundamental frequency estimation hinders the performance of F_0-based methods. Template-based methods may work for vibratos with a large modulation extent (frequency variation), while for subtly-modulated vibratos, both the definition of templates and the matching between templates and test segments are problematic. The modulation spectra is another well-known representation for modulated sounds, which is averaged on the audio clip level [17]. It may work well for long-term music information retrieval tasks such as genre classification or instrument recognition, but struggling with providing temporal positions for short-duration playing technique recognition. To our knowledge, there is not yet any computational research that compares and discriminates between these periodic modulations in real-world music pieces.

Besides the question of coming up with an adequate signal representation, there is a critical need for human-annotated playing techniques in audio recordings. Up to now, most of the available research literature has focused on playing techniques that have been recorded in highly controlled environments [8, 16, 19]. Yet, recent findings demonstrate that, in the context of a music piece, playing techniques exhibit considerable variations as compared to when they are played in isolation [18]. For periodic modulations, these variations are more evident in folk music, which highly depends on the interpretation of the performer. Such inter-performer variability in folk music performance necessitates data collection with full pieces.

This paper includes three contributions: representation, application, and dataset. We propose a representation based on time–frequency scattering to model the inter-

class variability for fine discrimination of vibrato, tremolo, trill, and flutter-tongue. Rather than decomposing all the wavelet bands as the scattering transform, we calculate a time–frequency scattering around the wavelet subband of maximal acoustic energy, i.e. the transform is calculated adaptively on the predominant frequency. On the application side, to our knowledge this is the first attempt at creating a system for detecting and classifying periodic modulations in music signals. To evaluate our methodology, we create a dedicated dataset of the Chinese bamboo flute, also known as the *dizi* or *zhudi*, and thereafter abbreviated as CBF. This dataset, named CBF-periDB, contains full-length solo performances recorded by professional CBF players and has been thoroughly annotated by the players themselves.

The rest of this paper is organised as follows. The characteristics of each periodic modulation and how this information can be represented by an adaptive time–frequency scattering are described in Section 2. Section 3 shows details of the feature extraction process and the proposed recognition system. The dataset, evaluation methodology, and results are discussed in Section 4. Section 5 presents our conclusions and directions for future research.

2. SCATTERING REPRESENTATION OF PERIODIC MODULATIONS

Prior to discriminating between the four periodic modulations, we analyse characteristics of each modulation in Section 2.1. A short introduction of the scattering transform is provided in Section 2.2. Section 2.3 describes the proposed representation for modelling periodic modulations.

2.1 Characteristic Statistics of Periodic Modulations

The characteristic statistics of each modulation in discussion are shown in Table 1. As can be seen, flutter tonguing has a much higher modulation rate as compared to the other three modulations; thus, the modulation rate can be used as a main feature to distinguish it from others. For the other three techniques with similar modulation rate, the discriminative information lies in the modulation extent and shape of the modulation unit. The *modulation unit* refers to the unit pattern that repeats periodically within the modulation. It can be one-dimensional, either amplitude modulation (AM) or frequency modulation (FM), or two-dimensional as a spectro-temporal modulation. This can be intuitively observed from the partially enlarged spectrograms given in Fig. 1. Trills are note-level modulations, for which the frequency variations are larger than one semitone. This extent of modulation is much larger than vibratos and tremolos. The shape of the modulation unit for trill is more square-like rather than sinusoidal ones which vibratos and tremolos exhibit. The difference between vibrato and tremolo is that vibratos are FMs, while tremolos are AMs. We show later how this discriminative information is encoded into the proposed representation in Section 2.3.

Type	**Rate** (Hz)	**Extent**	**Shape**
Flutter-tongue	25-50	< 1 semitone	Sawtooth-like
Vibrato	3-10	< 1 semitone	Sinusoidal (FM)
Tremolo	3-8	$\approx$ 0 semitone	Sinusoidal (AM)
Trill	3-10	Note level	Square-like

Table 1. Characteristic statistics of four periodic modulations in music signals.

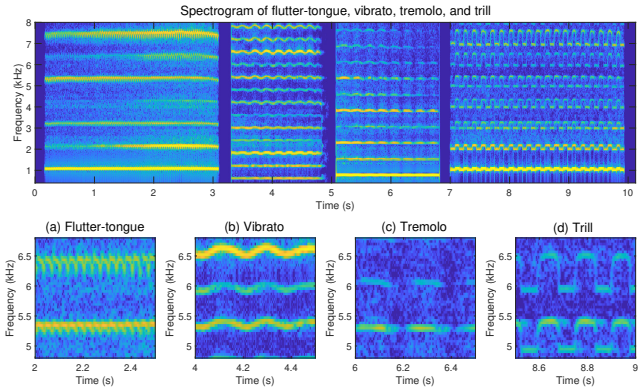

Figure 1. Visual comparison of four periodic modulations. Top: Spectrogram of flutter-tongue, vibrato, tremolo, and trill; bottom: partially enlarged spectrogram of each modulation for detailed comparison.

2.2 Scattering Transform

Proposed by [10], the scattering transform is a cascade of wavelet transforms and nonlinearities. Its structure is similar to a deep convolutional network. The difference is that its weights are not learnt but can be hand-crafted to encode prior knowledge about the task at hand. Since little energy is captured by the scattering transform with orders higher than two [2], we focus in this paper to the second order.

Let ψ_λ denote the wavelet filter bank obtained from a mother wavelet ψ, where λ is the centre frequency of each wavelet in the filter bank. Likewise, ψ_{λ_m} refers to the wavelet filter bank of the m^{th}-order scattering transform, for $m \geq 1$. The second-order temporal scattering transform of a time-domain signal x is defined as:

$$\left| \left| x \overset{\text{t}}{*} \psi_{\lambda_1} \right| \overset{\text{t}}{*} \psi_{\lambda_2} \right| \overset{\text{t}}{*} \phi_T, \tag{1}$$

where $\overset{\text{t}}{*}$ is the wavelet convolution along time. $|x \overset{\text{t}}{*} \psi_{\lambda_m}|$ is the modulus of the m^{th}-order wavelet transform, which hereafter we refer to as the m^{th}-order wavelet modulus transform. The temporal scattering coefficients are obtained by an averaging at a time scale T by means of a low-pass filter ϕ_T.

In addition to the invariance to time-shifts and time-warps provided by the scattering transform, time–frequency scattering provides frequency transposition invariance by adding a wavelet transform along log-frequency axis [7]. The specific time–frequency scattering we apply is a *separable* scattering proposed in [3]. Here,

separable refers to separate steps of temporal and frequential operations of wavelet scattering, arranged in a cascade. The separable scattering representation comprises a second-order temporal scattering and a first-order frequential scattering. The latter is calculated by another wavelet transform along the log-frequency dimension on top of the second-order temporal scattering:

$$\left|\left|\left|x \overset{t}{*} \psi_{\lambda_1}\right| \overset{t}{*} \psi_{\lambda_2}\right| \overset{t}{*} \phi_T \overset{fr}{*} \psi_{\gamma_1}\right| \overset{fr}{*} \phi_F. \quad (2)$$

where $\overset{fr}{*}$ is the wavelet convolution along log-frequency. ψ_{γ_1} is the wavelet filter bank applied in the first-order frequential scattering. The frequential scattering coefficients are obtained by an averaging of the frequential wavelet modulus transform with transposition invariance of F (in octave unit) using a low-pass filter ϕ_F. All scattering coefficients in this paper are normalised and have their logarithm calculated, to capture only the temporal structure and to motivate auditory perception [2]. Hereafter, we use Morlet wavelets throughout the whole scattering network for wavelet convolutions. This is because Morlet wavelets have an exactly null average while reaching a quasi-optimal tradeoff in time–frequency localisation [9]. Our source code is based on the ScatNet toolbox [1].

2.3 Scattering Representation of Periodic Modulations

Periodic modulation recognition, as suggested by the analysis above, is a pitch invariant task. The core discriminative information is based on the modulation itself, which is indicated by its modulation rate, extent, and shape. Fig. 2 shows respectively (a) the spectrogram, (b) the second-order temporal scattering representation, and (c) the first-order frequential scattering representation of a series of periodic modulation examples in CBF-periDB. The spectrogram used here is only for illustration purposes. The first four examples are regular cases (modulations based on stable pitch or with constant parameters): vibrato, tremolo, trill, and flutter-tongue. The last three are cases with time-varying parameters (modulations based on time-varying pitch or with time-varying rate, extent, or shape): rate-changing trill, rate- and extent-changing trill, and flutter-tongue with time-varying pitch. We use these examples to show how the characteristic information of each pattern is captured and discriminated by a separable scattering transform, which consists of a second-order temporal scattering and a first-order frequential scattering transform.

2.3.1 Second-order temporal scattering

Different from a standard two-order temporal scattering transform, we do not decompose all the frequency bands (exchangeable with wavelet bands) in the first-order wavelet modulus transform. As can be observed from Fig. 2 (a), the patterns of these modulations, either in the regular case or time-varying case are similar for each harmonic partial. This indicates that the decomposition of one partial is sufficient to capture modulation information. Fig. 2 (b) shows the second-order temporal scattering representation decomposed only from the frequency band with the highest energy. Flutter-tongue is the most discriminable one with the highest modulation rate. For the other three patterns with close modulation rate value, other characteristic information is considered. By dominant band decomposition, the trill can also be discriminated because of its large modulation extent. This can be interpreted by filters with bandwidth larger than one semitone, which blurs other subtle modulations.

To specifically detect vibrato or tremolo, frequency bands less than one semitone should be obtained. We then make use of their modulation shape information by introducing a *band-expanding* technique. Assume we have frequency bands of 1/16 octave bandwidth in the first-order wavelet modulus transform. Ideally for tremolo, the modulation information is contained only in the dominant frequency band since it is an AM. This is verified by the second example in Fig. 2 (b), which has almost only the fundamental modulation rate with no upper harmonics in the second-order temporal scattering representation. However, vibratos are FMs, which means the modulation information spreads over neighbouring frequency bands. Decomposing neighbouring frequency bands above or below the dominant band provides additional information to distinguish vibrato from tremolo. All this discriminative information can be visualised from the fundamental modulation rate and the richness of the harmonics in the second-order temporal scattering representation in Fig. 2 (b).

2.3.2 First-order frequential scattering

The temporal scattering transform is sensitive to attacks and amplitude modulations, which results in the high en-

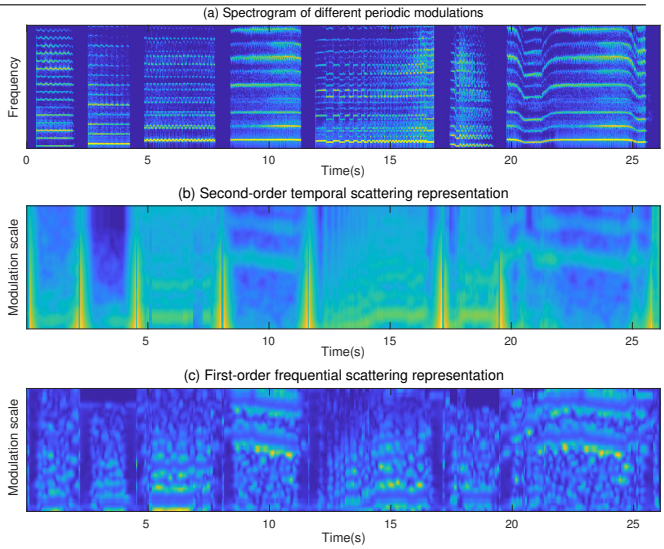

Figure 2. Separable scattering representation of different periodic modulations. From left to right, the first four are regular cases: vibrato, tremolo, trill, flutter-tongue based on stable pitches; the last three are time-varying cases: rate-changing trill, rate- and extent-changing trill, flutter-tongue with time-varying pitch.

[1] https://www.di.ens.fr/data/software/scatnet/

ergy part of the boundaries as clearly observed in Fig. 2 (b). To suppress this noisy information while retaining the frequential structure offered by the second-order temporal scattering, we use frequential scattering along the log-frequency axis on top of Fig. 2 (b). Frequential scattering has a similar framework as temporal scattering while the former captures regularity along log-frequency. As shown in Fig. 2 (c), we obtain a clearer representation without reducing the discriminative information necessary for the task. Although the last example is flutter-tongue bounded to time-varying pitch, its modulation rate is relatively stable. This verifies our method of using just the dominant frequency band or expanded frequency bands from the first-order wavelet modulus transform. The rate-changing and rate-extent changing cases show that the time-varying modulation rates are also captured.

3. PERIODIC MODULATION RECOGNITION

With the proposed representation prepared, we build a recognition system consisting of four binary classification schemes that each predicts one modulation type. Section 3.1 describes the feature extraction process. The calculated features are then fed to a machine learning classifier illustrated in Section 3.2.

3.1 Feature Input

As described in Section 2.3, we adapt the scattering transform by decomposing the dominant and its neighboring frequency bands in the first-order wavelet modulus transform. The feature extraction process of dominant band decomposition is shown in Fig. 3. Using a waveform as input, we first obtain the first-order wavelet modulus transform, where the frequency band with the highest energy for each time frame is localised. Decomposing these bands, we obtain a second-order temporal scattering. A first-order frequential scattering is then conducted on top of the second-order temporal scattering coefficients. Concatenating the two representations in a frame-wise manner, we obtain the feature input to the classifiers. For expanded band decomposition, additional features are calculated similarly by decomposing the neighbouring frequency bands around the dominant band.

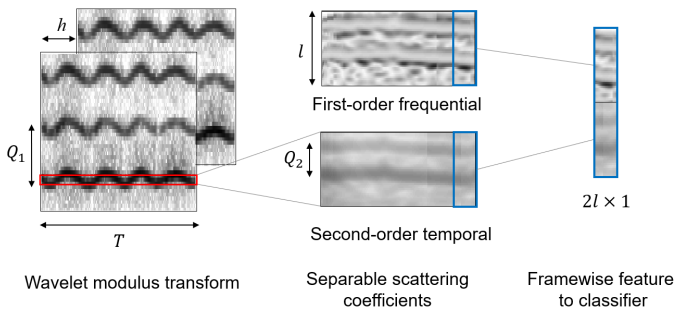

Figure 3. Feature extraction process.

Table 2 gives the parameters which encode the core discriminative information for the recognition. T is the averaging scale for the temporal scattering coefficients. This parameter is useful for discriminating modulations with large differences on modulation rate, for example, on distinguishing flutter-tongue from other low-rate periodic modulations. Averaging scales covering at least four unit patterns are recommended for reliable estimation of the modulation rate. Q_1 are the filters per octave in the first-order temporal scattering transform. Since the modulations discussed here are all oscillatory patterns, setting Q_1 should ensure that each of the modulations are not blurred in the first-order wavelet modulus transform. Here, we use $Q_1 > 12$ for the first-order temporal scattering to support subtly-modulated vibratos and tremolos, of which the modulation extent is less that one semitone. N is the number of neighbouring frequency bands besides the dominant band decomposed from the first-order wavelet modulus transform. $N = 0$ refers to dominant band decomposition only while $N > 0$ means expanded band decomposition. This is a key parameter to encode the unit shape information of subtle modulations. However, if the task at hand is only to detect modulations with high modulation rate or with large extent, this parameter is not necessary.

Parameter	Notation	Main information encoded
Averaging scale	T	Modulation rate
Filters per octave	Q_1	Modulation extent
Expanded bands	N	$= 0$, temporal shape
		> 0, spectro-temporal shape

Table 2. Parameters encoding modulation information in the adaptive time–frequency scattering framework.

Other parameters involved in the feature calculation include frame-size h, filters per octave Q_2 in the second-order scattering decomposition, frequency bands l extracted from the second-order temporal scattering. For frequential scattering, we apply a single scale wavelet transform. The frame size is inversely log-proportional to the oversampling parameter α by $h = T/2^{\alpha}$ (samples), which is designed to compensate for the low temporal resolution resulting from the large averaging scales. Since these parameters carry little discriminative information, we set them consistently for all classification schemes, with $\alpha = 4$, $Q_2 = 8$, and $l = 2Q_2$ based on experimental results. A general example with $T = 2^{15}$ corresponds to frame size of $h = T/2^{\alpha} = 2048$ samples (46ms, assuming the sampling rate is 44.1kHz). The dimensionality of the final representation at each time frame equals to $(N + 1) \times 2l = 4(N + 1)Q_2$.

3.2 Recognition System

Due to the existence of combined playing techniques, such as the combination of flutter-tongue and vibrato, and the combination of tremolo with trill, one frame of the input may have multiple labels. Multi-label classification is considered beyond the scope of this paper and is regarded as future work. Here, we conduct binary classifications for

each modulation, which enables us to explicitly encode the characteristic information specifically for the corresponding pattern. Four binary classifiers are constructed using support vector machines (SVMs) with Gaussian kernels. The model parameters to be optimized in the training process are the error penalty parameter and the width of the Gaussian kernel [6]. The best parameters selected in the validation stage are used for testing. The input feature to the classifiers is the proposed adaptive time–frequency transform of the current time frame.

Taking flutter-tongue as an example, its relatively high modulation rate (25-50Hz) can be emphasized by setting $T = 8192$ (sampling rate is 44.1kHz). The modulation extent which is less than one semitone is interpreted by setting $Q_1 = 16$. Fig. 4 shows the detection result of flutter-tongue from a piece in CBF-periDB using dominant band decomposition ($N = 0$), which can be clearly observed from the harmonic structure in Fig. 4 (a). This is then enforced by removing the noisy attacks using a frequential scattering transform as shown in Fig. 4 (b). Concatenating the two representations, we form frame-wise separable scattering feature vectors with $(N + 1) \times 2l = 32$ dimensions and frame size of $h = T/2^{\alpha} = 512$ samples (12ms). Fig. 4 (c) visualises the binary classification result of flutter-tongue compared with the ground truth for an example excerpt. Overall it can be seen that the proposed approach is successful at detecting flutter-tongue, even in short segments, although occasionally the output is over-fragmented. Similarly, binary classifiers can be implemented for detecting vibratos, tremolos, and trills, with parameters fine-tuned to the corresponding modulations.

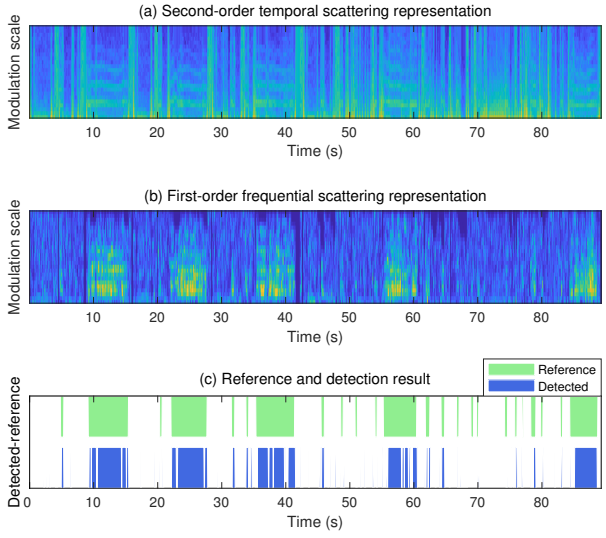

Figure 4. Binary classification result of flutter-tongue in an example excerpt of the CBF-periDB.

4. EVALUATION

4.1 Dataset

To verify the proposed system, we focus on folk music recordings which have more inter-performer variations than Western music. The proposed periodic modulation analysis dataset, CBF-periDB, comprises monophonic performances recorded by ten professional CBF players from the China Conservatory of Music. All data is recorded in a professional recording studio using a Zoom H6 recorder at 44.1kHz/24-bits. Each of the ten players performs both isolated periodic modulations covering all notes on the CBF and two full-length pieces selected from *Busy Delivering Harvest* «扬鞭催马运粮忙», *Jolly Meeting* «喜相逢», *Morning* «早晨», and *Flying Partridge* «鹧鸪飞». Players are grouped by flute type (C and G, the most representative types for Southern and Northern styles, respectively) and each player uses their own flute. This dataset is an extension of the CBF-glissDB dataset in [18], with ten pieces containing periodic modulations added. The playing techniques are thoroughly annotated by the players themselves. Details of both isolated techniques and full-piece (performed) recordings are shown in Table 3. The dataset and annotations can be downloaded from `c4dm.eecs.qmul.ac.uk/CBFdataset.html`.

Isolated		**Performed**	
Type	Length	Piece, number	Length
Flutter-tongue	4.9	Mo, 3	16.0
Vibrato	7.3	BH, 7	28.0
Tremolo	5.0	JM, 4	12.4
Trill	12.3	FP, 6	51.9

Table 3. Length of both isolated techniques and full-piece recordings in CBF-periDB (Mo=*Morning*; JM=*Jolly Meeting*; BH=*Busy Delivering Harvest*; FP=*Flying Partridge*; all numbers for length are measured in minutes).

In the recognition implementation process, the dataset is split into a 6:2:2 ratio according to players (players are randomly initialised) and a 5-fold cross-validation is conducted. This way of data splitting ensures a non-overlap between players in the train, validation, and test sets. Since each player uses their own flute during recording, there is no overlap across flutes. Due to the limited piece types, non-overlap of pieces is not feasible at the current stage. We regard this as future work with a dataset expansion plan to address piece diversity.

4.2 Metrics

Due to the short duration and periodic nature of vibratos, tremolos, trills, and flutter-tongue, feature dependencies over sequential frames are slightly required. The precision $\mathcal{P} = \frac{TP}{TP+FP}$, recall $\mathcal{R} = \frac{TP}{TP+FN}$, and F-measure $\mathcal{F} = \frac{2\mathcal{P}\mathcal{R}}{\mathcal{P}+\mathcal{R}}$ are used here for frame-based evaluation, where TP, FP, FN are true positives, false positives, and false negatives respectively [12]. Assigned labels by SVMs are then compared to the ground truth annotations in a frame-wise manner.

4.3 Baseline

According to our knowledge, there is not yet any previous work on discriminating between these four periodic mod-

Type	Dominant band						Expanded band					
	Temporal scattering			Separable scattering			Temporal scattering			Separable scattering		
	$\mathcal{P}(\%)$	$\mathcal{R}(\%)$	$\mathcal{F}(\%)$	$\mathcal{P}(\%)$	$\mathcal{R}(\%)$	$\mathcal{F}(\%)$	$\mathcal{P}(\%)$	$\mathcal{R}(\%)$	$\mathcal{F}(\%)$	$\mathcal{P}(\%)$	$\mathcal{R}(\%)$	$\mathcal{F}(\%)$
Flutter-tongue	96.1	99.8	97.9	96.3	99.8	98.0	96.7	99.6	98.1	97.8	99.5	**98.7**
Trills	87.1	66.7	75.1	87.4	68.2	76.2	89.5	73.3	80.4	89.8	76.3	**82.3**
Vibrato	75.2	17.5	26.4	72.2	33.1	45.3	75.9	59.4	66.5	75.1	64.7	**69.3**
Tremolo	92.5	1.21	2.2	80.9	6.7	10.6	70.8	38.5	49.1	67.6	41.4	**50.7**

Table 4. Performance comparison of binary classification for flutter-tongue, vibratos, tremolos, and trills in CBF-periDB using separable scattering and temporal scattering representations based on the dominant frequency band and expanded frequency band decomposition ($\mathcal{P}$=precision; $\mathcal{R}$=recall; $\mathcal{F}$=F-measure).

ulations; thus we compare the proposed systems against a state-of-art detection method for vibrato. The filter diagonalisation method (FDM), which efficiently extracts high resolution spectral information for short time signals, was first applied to vibrato detection in erhu performance [20]. Based on the high similarity of the music style between erhu and CBF, both being traditional Chinese instruments, we use FDM as a baseline method for vibrato detection. Using automatically estimated fundamental frequency by pYIN [11] as input for FDM, we try different parameter ranges for vibrato rate and extent based on the vibrato characteristics of the CBF. The best result we obtain based on a 256ms-frame-wise evaluation is $\mathcal{P}$=36.5%, $\mathcal{R}$=58.7%, $\mathcal{F}$=45.0%. The rate range and extent range we use are 3-10 Hz and 5-20 cent, respectively.

4.4 Results

In order to explicitly show information captured in each classification task, a small set of parameter settings for T, Q_1, and N is used. Besides the different meta-parameter settings specifically designed for each modulation classification, we run further experiments by using the same parameters for all four binary classification processes: $T = 2^{15}$, $Q_1 = 16$, and $N = 6$ frequency bands symmetrically expanded around the dominant band. This corresponds to frame size of 46ms and feature dimension of 224. Note that for specific modulation detection, meta parameters of the scattering transform can be fine-tuned to have a much lower feature dimension, as the flutter-tongue detection example demonstrated in Section 3.2. The binary classification results for each pattern are given in both the dominant band decomposition and expanded band decomposition, as shown in Table 4. The detection results using the second-order temporal scattering coefficients only as feature are also provided. The comparison between temporal scattering and separable scattering verifies our analysis in Section 2.3 that for periodic modulation recognition, frequential scattering in the separable scattering representations provides additional discriminative information by removing noisy information. Better performance for flutter-tongue and trill detection shows that for modulations with high modulation rate and large extent, decomposition of the dominant band is sufficient. For discriminating between temporal modulation and spectro-temporal modulation, expanded band decomposition works much better.

Generally, detection performance on vibrato and tremolo is worse than that for flutter-tongue and trill detection. Identifying the errors in the original audio, we find that in most cases these are combined techniques, i.e. subtle frequency variations are accompanied with amplitude modulations or vice versa. In the case of CBF, such combinations are common because of the instrumental gestures of vibrato and tremolo. Vibrato can be generated by fingering or tonguing, while tremolos are commonly produced by breathing variations. Performers are also expressively intended to add tremolo effects on top of other playing techniques.

5. CONCLUSIONS AND FUTURE WORK

Periodic modulation recognition is a pitch invariant task and should only capture modulation information. This is realised by calculating a time–frequency scattering around the wavelet subband of the maximum acoustic energy. We found that the proposed representation decomposed from the dominant band is sufficient to detect modulations with high modulation rate (flutter-tongue) and large modulation extent (trill), while expanded band decomposition captures subtle frequency modulations (vibrato and tremolo). We introduce the ecologically valid dataset, CBF-periDB, to evalate the recognition system. Results show that the proposed representation captures discriminative information between vibratos, tremolos, trills, and flutter-tongue in real-world pieces.

The current work only considers continuous periodic modulations; other periodic patterns, such as tonguing, will be considered as future work due to their noncontinuous nature and more complicated parameter variations. Inspired by research on polyphonic music transcription, current work may be expanded to polyphonic periodic modulation detection. Additional comparison of the current result with other equivalent representations such as the modulation spectra, will be conducted. We conclude that the scattering transform presents a versatile and compact representation for analysing periodic modulations in performed music and opens up new avenues for computational research on playing techniques.

CONTROLLING SYMBOLIC MUSIC GENERATION BASED ON CONCEPT LEARNING FROM DOMAIN KNOWLEDGE

Taketo Akama
Sony Computer Science Laboratories, Tokyo, Japan

ABSTRACT

Machine learning allows automatic construction of generative models for music. However, they are learned from only the succession of notes itself without explicitly employing domain knowledge of musical concepts such as rhythm, contour, and fragmentation & consolidation. We approximate such musical domain knowledge as a function, and feed it into our model. Then, two decoupled spaces are learned: the *extraction space* that captures the target concept, and the *residual space* that captures the remainder. For monophonic symbolic music, our model exhibits high decoupling/modeling performance. Controllability in generation is improved: (i) our *interpolation* enables concept-aware flexible control over blending two musical fragments, and (ii) our *variation generation* enables users to make concept-aware adjustable variations.

1. INTRODUCTION

Listeners not only perceive the succession of notes itself, but also respond to higher-level concepts in music. Two critical components in melodic perception and memory are scale and contour [5]. It is said that similarity between musical fragments is important in listeners' emotional arousal responses to music [18]. Listeners sense those similarities through perceiving patterns of music constructs or transformations such as rhythm, interval, and fragmentation & consolidation (F&C) [20].

Music data processing, especially music generation and analysis have attracted much attention. One of the major methods exploits models that learn the *latent space* [1, 6, 9, 16, 27–29]. These models learn compressed but informative feature vectors of data samples and distribute them in the multi-dimensional latent space. The spacial arrangement represents the relation of data samples. Also, numerous intermediate features—corresponding to samples hopefully not in the dataset—are yielded to fill in the "holes" in the latent space. Then generation and analysis are performed by bidirectional mapping of the latent space and the data space. The latent space is, however, learned from raw musical data without supervision. Therefore, the musical notions or concepts that are important for people are not sufficiently organized on the latent space. Hereinafter, we refer to such notions or concepts as *musical concepts*, examples of which include rhythm, contour, and F&C, as mentioned above.

How do we organize those musical concepts on the latent space? People possess domain knowledge about musical concepts, although even the major concepts are not necessarily defined clearly. In fact, various musical concepts can be approximated as a *function* of raw musical sequences. We input such domain knowledge to our model in the form of a function, and then our model learns latent spaces that capture the corresponding musical concepts.

Our model is called ExtRes (Extraction-Residual Latent Space Decoupling Model), and it aims at learning decoupled latent spaces, each of which is associated with a musical concept. In other words, each musical concept is learned as a *latent-space concept* that occupies a part of the dimensions in the multi-dimensional latent space. The concept-wise decoupled latent spaces allow us to measure similarity between musical fragments in terms of each concept. The similarity is then used for e.g., pattern discovery in a musical piece [17]. In generation, the control over concept-wise latent features helps us to create musical phrases as imagined or to compose patterns/structures in a musical piece [23].

Our ExtRes has the following characteristics. (I) **Knowledge based**: musical concepts can be incorporated as function approximations on the basis of domain knowledge. For monophonic musical sequences, various important musical concepts can be incorporated such as rhythm, chromatic/diatonic interval or pitch, step-leap/signed contour, and F&C. This is possible because given an input sequence, these concepts can be approximated as other sequences with rules or algorithms [2, 19] to construct the functions. (II) **Complex concept and active learning**: complex concepts are actively learned without obtaining attributes first [3, 4, 12, 14], where a set of attributes is a concept. (III) **Extraction-residual**: aiming at comprehending complex data by repeatedly analyzing "one concept versus the rest." The rest (residual) may capture the useful concepts (e.g., scale for contour and "pitch order" for rhythm). (IV) **Coexisting latent spaces**: depending on the input domain knowledge, corresponding concepts are captured in latent spaces. Users can exploit multiple models of ours—wherein latent spaces with different concepts *coexist*—for handling many concepts.

We apply our ExtRes to improving controllability in interactive music generation. (i) **Concept-axes interpolation**: this mechanism helps users to create musical phrases as imagined. Users first input two musical fragments into the system. Prior methods allow users to adjust the *blending* ratio of the two fragments uniformly regardless of concepts [27, 28], whose blending is more musically meaningful than the naive data space blending. Our concept-axes interpolation offers more flexibility: enabling users to blend only the factor of the desired concept in musical fragments and to also adjust the blending ratio for each target/residual concept. (ii) **Concept-aware variation generation**: given a musical fragment, this mechanism allows users to obtain variations, where the amount of variation for each concept is adjustable. When generating a long structured piece of music, this mechanism helps to faithfully realize either of the instructions of a song template [23] or the user intention.

2. METHODOLOGY

2.1 Outline

We propose ExtRes, a generative model that allows learning reusable representation (as latent features and embedding vectors) for a user-specified concept, given a function based on domain knowledge on the concept (Sec.2.2). We then instantiate our proposed ExtRes model for sequence datasets (Sec.2.4). In Sec.2.5, musical concepts are approximated as functions on the basis of domain knowledge. For applications of our ExtRes, we focus on meaning-level controllability in generation. We consider the following kinds of control: (i) altering in relation to other samples (e.g., interpolation), (ii) altering a sample to another sample with similar but not the same meaning (e.g., variation), and (iii) altering individual concepts. ExtRes not only puts (iii) into practice by free explorations in concept spaces, but also allows hybridizing the meaning-level controls (i-iii) for more intended controllability: Sec.2.3 Concept-Axes Interpolation is for bridging (i) and (iii), Sec.2.3 Concept-Aware Variation Generation is for bridging (ii) and (iii).

2.2 Extraction-Residual Latent Space Decoupling Model (ExtRes)

Let us consider a dataset $\mathcal{D} = \{x^{(n)}\}_{n=1}^{N}$, consisting of N i.i.d. samples of stochastic variable $x \in \mathcal{X}$. Given $f_{ext}\colon \mathcal{X} \to \mathcal{Y}$ that extracts information of a target concept as $y \in \mathcal{Y}$ from x, ExtRes is for learning latent spaces $\mathcal{Z}_e$ and $\mathcal{Z}_r$ that correspond to f_{ext}. $\mathcal{Z}_e$ is called an *extraction space*, which captures the extracted target concept, and $\mathcal{Z}_r$ is called a *residual space*, which is expected to be decoupled from $\mathcal{Z}_e$, aiming at capturing a concept corresponding to all the rest. Figure 1 summarizes our model.

f_{ext} can be obtained e.g., by constructing rules or algorithms on the basis of the data domain knowledge (for musical sequences, see [2, 19]). Specific examples based on musical domain knowledge are shown in Sec.2.5.

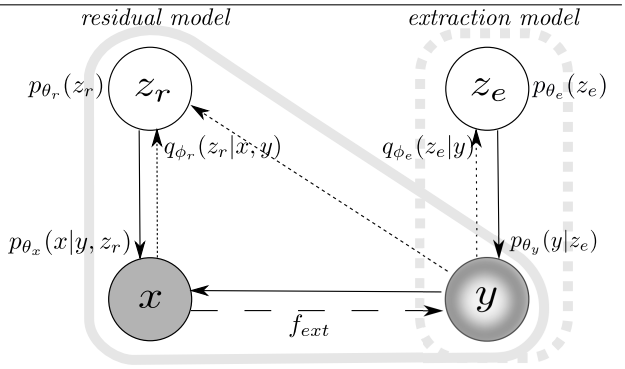

Figure 1: Graphical model of ExtRes.

First, we conduct *data derivation*: augmenting the dataset $\mathcal{D}$ to obtain $\mathcal{D}_{drv} = \{(x^{(n)}, y^{(n)})\}_{n=1}^{N}$, through the mapping $y = f_{ext}(x)$. Then, our approach is to learn a generative model involving two latent variables: $z_e \in \mathcal{Z}_e$ for capturing variability in y and $z_r \in \mathcal{Z}_r$ for variability in x given y. We assume the dataset is generated from the following process: (i) $z_e^{(n)} \sim p_{\theta_e^*}(z_e)$, $z_r^{(n)} \sim p_{\theta_r^*}(z_r)$, (ii) $y^{(n)} \sim p_{\theta_y^*}(y|z_e^{(n)})$, and (iii) $x^{(n)} \sim p_{\theta_x^*}(x|y^{(n)}, z_r^{(n)})$. Then we model this generative process by maximizing marginal log likelihood $\log p_\theta(\mathcal{D}_{drv}) = \sum_{n=1}^{N} \log p_\theta(x^{(n)}, y^{(n)})$ with each term rewritten as:

$$\log p_\theta(x,y) = \log \int p_{\theta_x}(x|y,z_r) p_{\theta_r}(z_r) dz_r \,, \\ + \log \int p_{\theta_y}(y|z_e) p_{\theta_e}(z_e) dz_e. \quad (1)$$

Since this is computationally intractable in general, we derive an evidence lower bound (ELBO) [16]:

$$\log p_\theta(x,y) \geq \mathcal{L}_{res} + \mathcal{L}_{ext}, \quad (2)$$

$$\text{where } \mathcal{L}_{res} = \mathbb{E}_{q_{\phi_r}(z_r|x,y)}\left[\log p_{\theta_x}(x|y,z_r)\right] \\ - D_{KL}\left(q_{\phi_r}(z_r|x,y)||p_{\theta_r}(z_r)\right), \quad (3)$$

$$\text{and } \mathcal{L}_{ext} = \mathbb{E}_{q_{\phi_e}(z_e|y)}\left[\log p_{\theta_y}(y|z_e)\right] \\ - D_{KL}\left(q_{\phi_e}(z_e|y)||p_{\theta_e}(z_e)\right). \quad (4)$$

Here, D_{KL} denotes the Kullback-Leibler (KL) divergence.

We maximize the data likelihood of right hand side of Eq.(2) for optimizing parameters $\{\theta_x, \theta_y, \theta_r, \theta_e, \phi_r, \phi_e\}$. We refer to the models corresponding to Eq.(3) and Eq.(4) as the *residual model* and *extraction model*, respectively.

2.3 Controlling Generation

Concept-Axes Interpolation. With our decoupled latent spaces, interpolation can be done for each latent space $\mathcal{Z}_e$ and $\mathcal{Z}_r$. In the simplest linear case, interpolation between two latent vectors $[z_e^{(i)}; z_r^{(i)}]$ and $[z_e^{(j)}; z_r^{(j)}]$ produces samples $x(\alpha_e, \alpha_r) \sim p_{\theta_x}(x|y(\alpha_e), z_r(\alpha_r))$ with $y(\alpha_e) \sim p_{\theta_y}(y|z_e(\alpha_e))$, where $z_r(\alpha_r) = z_r^{(i)} + \alpha_r(z_r^{(j)} - z_r^{(i)})$ and $z_e(\alpha_e) = z_e^{(i)} + \alpha_e(z_e^{(j)} - z_e^{(i)})$ with $(\alpha_r, \alpha_e) \in [0,1] \times [0,1]$.

Variation Generation Approach. Finding the *boundary*, in a latent space, between *variations* and *non-variations* is semi-automatically learned by defining that *variations* of a given data sample are the samples that contain enough information in terms of reconstruction error ϵ,

in expectation. For our ExtRes, the error ϵ can be adjusted by introducing trade-off parameters in Eq.(3) and Eq.(4) (see Sec.4.2). Intuitively, the latent vectors capture *high-level* features for the corresponding data samples, and given a data sample $\hat{x}$, the learned inference distributions $q_{\phi_r}(z_r|\hat{x}, f_{ext}(\hat{x}))$ and $q_{\phi_e}(z_e|f_{ext}(\hat{x}))$ specify feature-wise similar/dissimilar (i.e. *variations*/*non-variations*) *boundaries* of the given sample. Therefore, our approach is to generate variations $x^{(i)}$ of $\hat{x}$ in accordance with the *boundaries* as follows: $x^{(i)} \sim p_{\theta_x}(x|y^{(i)}, z_r^{(i)})$ with $y^{(i)} \sim p_{\theta_y}(y|z_e^{(i)})$ and $z_r^{(i)} \sim q_{\phi_r}(z_r|\hat{x}, f_{ext}(\hat{x}))$, where $z_e^{(i)} \sim q_{\phi_e}(z_e|f_{ext}(\hat{x}))$.

Concept-Aware Variation Generation. We also propose how to generate variations $x^{(i)}$ in a concept-wise manner when the inference models are normal distributions. The amount of variation is controlled for each concept in either of the following ways: simply changing the ratio of the covariance scales of inference distributions, or ordering the samples $z_e^{(i)}$ or $z_r^{(i)}$ on the basis of Mahalanobis distances:

$$
\begin{aligned}
&D_M(z^{(i)}, \hat{z}) = \sqrt{(z^{(i)} - \hat{z})^{\mathrm{T}} \Sigma^{-1} (z^{(i)} - \hat{z})}, \qquad (5)\\
&\text{for } (z^{(i)}, \hat{z}, \Sigma) \in \{(z_e^{(i)}, \hat{z}_e, \Sigma_e), (z_r^{(i)}, \hat{z}_r, \Sigma_r)\},\\
&\quad \text{where} \quad q_{\phi_e}(z_e|f_{ext}(\hat{x})) = \mathcal{N}(z_e|\hat{z}_e, \Sigma_e),\\
&\quad \text{and} \quad q_{\phi_r}(z_r|\hat{x}, f_{ext}(\hat{x})) = \mathcal{N}(z_r|\hat{z}_r, \Sigma_r).
\end{aligned}
$$

Here, $\mathcal{N}$ denotes normal distribution.

2.4 Instantiation of ExtRes for Sequences

Throughout the rest of this paper, we consider the case where x consists of a sequence of discrete variables s_t i.e. $x = (s_1, ..., s_T)$. Here, each s_t has a distribution over the elements of a finite alphabet set $\mathcal{A}$. Let f_{ext} be a function that maps a sequence of length T to that of length T, i.e. $f_{ext}\colon \mathcal{A}^T \rightarrow \mathcal{B}^T$, where $\mathcal{B}$ is another alphabet set. First, we conduct *data derivation* using $f_{ext}(x^{(n)}) = y^{(n)} = (a_1^{(n)}, ..., a_T^{(n)})$. The given dataset $\mathcal{D} = \{x^{(n)}\}_{n=1}^N$ can be augmented to become $\mathcal{D}_{drv} = \{(x^{(n)}, y^{(n)})\}_{n=1}^N$, where $x^{(n)} = (s_1^{(n)}, ..., s_T^{(n)})$ and $y^{(n)} = (a_1^{(n)}, ..., a_T^{(n)})$. We refer to $(a_1^{(n)}, ..., a_T^{(n)})$ as an *abstract sequence* of $(s_1^{(n)}, ..., s_T^{(n)})$. Now, the inference models are

$$
\begin{aligned}
&(h_{z_e,t}, c_{z_e,t}) = \mathrm{LSTM}(\mathrm{E}(a_t), h_{z_e,t-1}, c_{z_e,t-1}), \qquad (6)\\
&q_{\phi_e}(z_e|a_{1:T})\\
&\quad = \mathcal{N}(z_e|\mathrm{MLP}(h_{z_e,T}), \mathrm{diag}(\exp(\mathrm{MLP}(h_{z_e,T})))), \qquad (7)\\
&(h_{z_r,t}, c_{z_r,t})\\
&\quad = \mathrm{LSTM}([\mathrm{E}(s_t); \mathrm{E}(a_t)], h_{z_r,t-1}, c_{z_r,t-1}), \qquad (8)\\
&q_{\phi_r}(z_r|s_{1:T}, a_{1:T})\\
&\quad = \mathcal{N}(z_r|\mathrm{MLP}(h_{z_r,T}), \mathrm{diag}(\exp(\mathrm{MLP}(h_{z_r,T})))), \qquad (9)
\end{aligned}
$$

where LSTM, E, and MLP denote a long short-term memory RNN (first, second, and third arguments of LSTM are input, hidden state, and cell state, respectively) [13], embedding layer, and multi-layer perceptron, respectively. The generative model for the *abstract sequence* is

$$
\begin{aligned}
&p_{\theta_e}(z_e) = \mathcal{N}(z_e|\mathbf{0}, \mathcal{I}), \qquad (10)\\
&(h_{a,1}, c_{a,1}) = \mathrm{LSTM}([Ea_0; z_e], \mathrm{MLP}(z_e), c_{a,0}), \qquad (11)\\
&(h_{a,t}, c_{a,t}) = \mathrm{LSTM}([\mathrm{E}(a_{t-1}); z_e], h_{a,t-1}, c_{a,t-1}), \qquad (12)\\
&p_{\theta_y}(a_t|a_{1:t-1}, z_e) = \mathrm{Cat}(a_t|\sigma(\mathrm{MLP}(h_{a,t}))), \qquad (13)\\
&p_{\theta_y}(a_{1:T}|z_e) = \textstyle\prod_{t=1}^T p_{\theta_y}(a_t|a_{1:t-1}, z_e), \qquad (14)
\end{aligned}
$$

where Cat and σ denote the categorical distribution and softmax function, respectively. Note that we use notation $p_{\theta_y}(a_1|a_{1:0}, z_e) = p_{\theta_y}(a_1|z_e)$ for brevity. The generative model for the original sequence is

$$
\begin{aligned}
&p_{\theta_r}(z_r) = \mathcal{N}(z_r|\mathbf{0}, \mathcal{I}), \qquad (15)\\
&(h_1, c_1) = \mathrm{LSTM}([Es_0; \mathrm{E}(a_1); z_r], \mathrm{MLP}(z_r), c_0), \qquad (16)\\
&(h_t, c_t) = \mathrm{LSTM}([\mathrm{E}(s_{t-1}); \mathrm{E}(a_t); z_r], h_{t-1}, c_{t-1}), \qquad (17)\\
&p_{\theta_x}(s_t|s_{1:t-1}, a_{1:t}, z_r) = \mathrm{Cat}(s_t|\sigma(\mathrm{MLP}(h_t))), \qquad (18)\\
&p_{\theta_x}(s_{1:T}|a_{1:T}, z_r) = \textstyle\prod_{t=1}^T p_{\theta_x}(s_t|s_{1:t-1}, a_{1:t}, z_r), \qquad (19)
\end{aligned}
$$

where we use the following notation for brevity: $p_{\theta_x}(s_1|s_{1:0}, a_{1:1}, z_r) = p_{\theta_x}(s_1|a_1, z_r)$.

2.5 Formulating Musical Domain Knowledge

On the basis of musical domain knowledge, we approximate musical concepts as $f_{ext}(x)$ for monophonic sequences. As mentioned in Sec.1, given an input musical sequence, many *abstract sequences* expressing important musical concepts can be derived [2, 19]. Among these, we demonstrate formulating two examples: *rhythm* and *contour*. Our finding is that a concept of musical transformations—fragmentation & consolidation, which is the main characteristic of similarity in musical sequences [20]—can also be approximated as a function, and we demonstrate it. We use the real name of musical notes as symbols ('C3', 'D#4', etc.) and use 'R' to represent a rest symbol. We add an extra symbol '__' representing that a note is held and not replayed [11]. Then the alphabet set $\mathcal{A}$ becomes a set of symbols listed above. Let $\mathcal{O}$ be a set of symbols that has no pitch, i.e., $\mathcal{O} = \{\text{'__'}, \text{'R'}\}$. We use the notation $\mathcal{S}_{1:t-1} = \{s_1^{(n)}, ..., s_{t-1}^{(n)}\}$.

Rhythm. Let 'N' denote a symbol that represents any note. Then the *rhythm* sequence for $(s_1^{(n)}, ..., s_T^{(n)})$ is defined as $(a_1^{(n)}, ..., a_T^{(n)})$, where

$$
a_t^{(n)} = \begin{cases} s_t^{(n)} & (s_t^{(n)} \in \mathcal{O}) \\ \text{'N'} & (\text{otherwise}) \end{cases}
$$

Thus, $\mathcal{B} = \mathcal{O} \cup \{\text{'N'}\}$. Now we define f_{ext} for *rhythm* as: $f_{ext}(x) = (a_1, ..., a_T)$.

Contour. In this paper, we refer to a chromatic signed contour with rhythm information as *contour*. Formally, the *contour* sequence for $(s_1^{(n)}, ..., s_T^{(n)})$ can be defined as $(a_1^{(n)}, ..., a_T^{(n)})$, where

$$
a_t^{(n)} = \begin{cases} s_t^{(n)} & (s_t^{(n)} \in \mathcal{O}) \\ \text{'SP'} & (s_t^{(n)} \notin \mathcal{O} \wedge \mathcal{S}_{1:t-1} \subset \mathcal{O}) \\ \mathrm{sgn}(\mathrm{Interval}(s_t^{(n)})) & (\text{otherwise}) \end{cases}
$$

Here 'SP' stands for Starting Pitch, sgn is a real sign function, and Interval is a function that calculates the chromatic pitch difference between the symbol of its argument and the previous symbol that has pitch. Then $\mathrm{sgn}(\mathrm{Interval}(s_t^{(n)}))$ outputs whether the pitch of $s_t^{(n)}$ is higher than ('1'), lower than ('-1'), or the same as ('0') the last symbol that has pitch. Thus, the alphabet set $\mathcal{B}$={'__', 'R', 'SP', '1', '-1', '0'}. Now we define f_{ext}

for *contour* as: $f_{ext}(x) = (a_1, ..., a_T)$.

Fragmentation and Consolidation (F&C). Fragmentation involves replacing one long note with several shorter notes, whereas consolidation conversely involves replacing several shorter notes with a single long note [20]. Formally, the *F&C*-invariant sequence for $(s_1^{(n)}, ..., s_T^{(n)})$ can be defined as $(a_1^{(n)}, ..., a_T^{(n)})$, where

$$a_t^{(n)} = \begin{cases} \text{'FC'} & (s_t^{(n)} \in \mathcal{O} \vee s_t^{(n)} = \text{LSP}(s_t^{(n)})) \\ s_t^{(n)} & (\text{otherwise}) \end{cases}$$

Here LSP stands for Last Symbol with Pitch, and $\text{LSP}(s_t^{(n)}) = s_{t_l}^{(n)}$, where $t_l = \max\{u\colon s_u^{(n)} \in \mathcal{S}_{1:t-1} \wedge s_u^{(n)} \notin \mathcal{O}\}$. Thus, the alphabet set $\mathcal{B} = \{\text{'FC'}\} \cup \mathcal{A} \setminus \mathcal{O}$. Now we define f_{ext} for *F&C* as: $f_{ext}(x) = (a_1, ..., a_T)$.

3. RELATED WORK

Conditional Models. Conditional deep generative models are widely studied especially in the image domain [15,22]. Although our *residual model* is similar to this family of models, their methods are different from ours in that (i) the problem setting itself is different: data for conditioning variable y is given in their method, (ii) condition y is not as structured as ours (usually labels), and (iii) the latent space of condition $\mathcal{Z}_e$ is not learned (i.e., their method has no *extraction model* of ours). In the music domain, conditions of notes or chords are used for factoring out those information from latent variables [7,28,29].

Disentangled Latent Spaces. In the image domain, some approaches successfully disentangle latent space [3,4,14]. The popular approach is regularizing each latent dimension to be independent, hoping to obtain interpretable factors as attributes. Meanwhile, an approach that permits disentangling a latent space applicable to symbolic music has been proposed [10], although this method assumes an attribute has order.

Exploring Latent Space in Music. After learning the latent space, some methods attempt to discover a meaningful direction in a latent space [8, 27]. These methods are also useful for exploring within our individual concept spaces.

Variation Generation in Music. The differences between our *concept-aware variation generation* and the variation mechanism proposed by Pachet et al. [23] are (i) their method is based on a Markov model; (ii) their method controls variation generation in terms of edit operations, while our method controls it in terms of musical concepts; (iii) our ExtRes tries to learn the notion of *variation* (see Sec.2.3). Difference (iii) also differentiates our method from the previous VAE method for generating melody variation, wherein simply Gaussian noises are added to the latent vector to create perturbed latent vectors [29], although their method could produce more diverse variations. One can also use their method within our concept spaces.

Regularizing Latent Space in Music. Human dissimilarity ratings on timbre are utilized to regularize the latent space for bridging audio analysis, perception, and generation [9].

4. EXPERIMENTS

4.1 Dataset

We conduct experiments using a leadsheet dataset introduced by Pachet et al. [24] with more than 12,000 songs, by hundreds of famous songwriters, covering several genres of popular music: jazz, blues, pop, and rock. The dataset has been used in music generation studies [21, 23, 25,26]. We extract all monophonic melody parts with time signature 4/4, which are transposed in all possible keys if the transposition remains within the midi pitch range of $[55, 84]$. We choose to discretize time with 24 symbols in a bar, where every beat has six symbols whose note-on timings in one beat are $\{0, 1/4, 1/3, 1/2, 2/3, 3/4\}$. We then extract all consecutive subsequences of length $T = 24$ (1 bar) or $T = 96$ (4 bars). The total dataset is split into proportion of $\{0.85, 0.1, 0.05\}$ for train, validation, and test data respectively.

4.2 Implementation Details

The numbers of dimensions for z_e or z_r are chosen to be $(16, 32)$ for the $T = (24, 96)$ model. 2-layer stacked LSTMs are employed. We introduce trade-off parameters β_1 for Eq.(3) and β_2 for Eq.(4) to weight the second terms [9, 27, 28]. Intuitively, the amount of information required for each latent variable depends on the target concepts: *rhythm*, *contour*, and *F&C*. Therefore, we conduct a hyper-parameter search using the validation dataset such that β_1 and β_2 are the maximum subject to reconstruction accuracies being sufficiently high. Then, β_1 and β_2 for *rhythm*, *contour*, and *F&C* are chosen to be $(\beta_1, \beta_2) = (0.7, 0.7)$, $(1.0, 0.7)$, and $(0.9, 0.7)$, respectively. The number of training epochs is set to 20, KL-annealing is used [1,9], and teacher forcing is not used.

4.3 Model Performance

Decoupling Performance. We first sample sequences $\{x^{(i)}\colon i \in \{1, ..., I\}\}$ and $\{x^{(i,j)}\colon (i, j) \in \{1, ..., I\} \times \{1, ..., J\}\}$, following the sampling procedure:

$$x^{(i)} \sim p_{\theta_x}(x|y^{(i)}, z_r^{(i)}),\ x^{(i,j)} \sim p_{\theta_x}(x|y^{(i)}, z_r^{(j)}),$$
$$\text{with } z_r^{(i)} \sim p_{\theta_r}(z_r),\ z_r^{(j)} \sim p_{\theta_r}(z_r), \text{ and}$$
$$y^{(i)} \sim p_{\theta_y}(y|z_e^{(i)}), \text{ where } z_e^{(i)} \sim p_{\theta_e}(z_e).$$

For $x^{(i)}$ and $x^{(i,j)}$, we count

$$N_{i,j} = |\{t \in \{1, ..., T\}\colon f_{ext}(x^{(i)})_t = f_{ext}(x^{(i,j)})_t\}|, \quad (20)$$

which is how many elements of the same index are the identical symbol between *abstract sequences* of $x^{(i)}$ and $x^{(i,j)}$. Then, we define the accuracy for a pair $(x^{(i)}, x^{(i,j)})$ as $N_{i,j}/T$.

Figure 2 illustrates the results of cumulative decoupling accuracies for $I = 1000$ and $J = 100$. *F&C* accuracies are almost perfect. Even for *rhythm* and *contour*, $(T = 24, T = 96) = (99.6, 97.5)\%$ and $(85.0, 37.6)\%$ of the samples have perfect accuracies, respectively. Interestingly, for *rhythm* and *contour*, the cumulative percentage of samples grows sharply if one symbol mistake

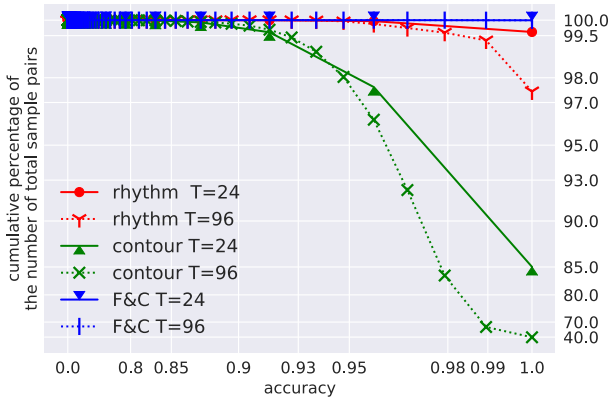

Figure 2: Decoupling accuracy.

	NLL		Accuracy	
	T=24	T=96	T=24	T=96

is allowed. For instance, the percentage for *contour* grows from $(85.0, 37.6)\%$ to $(97.6, 66.3)\%$.

Modeling Performance. Table 1 shows negative log-likelihoods (NLLs; per symbol and lower bound) and reconstruction accuracies (accuracies) for the test dataset. We compare baseline variational auto-encoders (VAEs) [16] (its model implementation and the training algorithms are the same as our *residual model* without the condition y except that the number of dimensions for the latent variable is doubled for fair comparisons) with our three proposed models. Each of our models is divided into two models (*residual/extraction model* (see Sec.2.2)), whose individual NLLs and accuracies are shown in the table. The additions of two NLLs for the *residual/extraction model* are comparable to the NLLs for the baseline VAE. The multiplications of two accuracies for the *residual/extraction model* are also comparable to the accuracies for the baseline VAE.

4.4 Concept-Axes Interpolation

As depicted in Fig.4, given two musical fragments (top-left and bottom-right) in each subfigure with 5×5 fragments, the other 23 fragments "in between" are yielded using *concept-axes interpolation*, whereas the interpolation in a traditional latent space [27, 28] would produce only the three diagonal fragments. In these figures, horizontal axes are the *extraction space* $\mathcal{Z}_e$ axes, and moving towards the axes smoothly changes the extracted target concepts (i.e., *rhythm*, *contour*, and *F&C*-invariant), while generally not changing the *residual* concepts. On the other hand, vertical axes are the *residual space* $\mathcal{Z}_r$ axes, showing smooth change in *residual* concepts and little change in target concepts. Note that here we only show 5×5, but interpolation of the two fragments could be arbitrarily finer/coarser (at any positions of the subfigure) upon users' demand. In Fig.4a, *rhythm* direction preserves "pitch appearing order," showing that the $\mathcal{Z}_r$ successfully captures concepts that are important but might be difficult to learn in $\mathcal{Z}_e$. In Fig.4b, in non-*contour* direction, fragments tend to transpose to match the "pitch set" of the bottom-right fragment without changing *contour*, which captures the scale-like concept. In *contour* direction, the fragments gradually adopt the descending-like contour. In other words, only the descending-like feature is retrieved from the bottom-right fragment to generate fragments in the first row. For Fig.4c, in *F&C*-invariant direction, the gradual altering of fragmenting or consolidating notes is observed. Similar analyses can also be done in longer sequences: Figure 3 shows results for $T = 96$ in piano roll representation with each subfigure consisting of 3×3 musical fragments.

4.5 Concept-Aware Variation Generation

In Fig.5, our variation generation approach is applied to ExtRes/VAE, which are for concept-aware/-unaware variation generations, respectively. In each column of the figure, the generated variations are sorted from top to bottom in the ascending order of learned Mahalanobis distance (see Sec.2.3). Figure 5a depicts the variations for *rhythm*. The second column shows the *extraction space* $\mathcal{Z}_e$ variations, where various rhythms are produced without changing the other factors. In contrast, *residual space* $\mathcal{Z}_r$ variations (the third column) all keep the rhythm unchanged, whereas the other factors such as the "order of used pitches" change. Variations by VAE (the fourth column) mix factors of rhythm/non-rhythm, without drastic change in rhythm. Figure 5b depicts the variations for *contour*. $\mathcal{Z}_e$ variations have various contours without changing other factors. In contrast, $\mathcal{Z}_r$ variations all keeps the contour unchanged, whereas the scale-like concept "set of used pitches" changes. VAE yields relatively conservative variations with mixed contour/scale-like factors. Lastly, variations for *F&C* are in Fig.5c. For the $\mathcal{Z}_e$ variations, melodies with different pitches are generated, while fixing the concept of "the consecutive notes with the same pitch" except the third row from the bottom. As for the $\mathcal{Z}_r$ variations, F&C of notes are observed, which is not the case in the fourth column except the second row from the bottom, indicating that our ExtRes successfully captures the notion of F&C. Note that the variations by ExtRes are generated with simply $(0, 1)$ or $(1, 0)$ variance scales for two spaces to clearly explain the capabilities of ExtRes, but one could interactively change the scale ratio to obtain

variations with desired mixing proportions of the concepts.

5. CONCLUSION AND FUTURE WORK

We presented a latent space decoupling model for learning concept spaces using domain knowledge. For monophonic symbolic music, we experimented on three musical concepts. Controllability in generation was improved by *concept-axes interpolation* and *concept-aware variation generation*. In future, other musical concepts mentioned in Sec.1 should also be tested on ExtRes. We believe that this paper opens up possibilities for learning models with concept-aware inference/generative processes to be used for different information retrieval tasks or more controlled and flexible generations.

UNMIXER: AN INTERFACE FOR EXTRACTING AND REMIXING LOOPS

Jordan B. L. Smith **Yuta Kawasaki** **Masataka Goto**
National Institute of Advanced Industrial Science and Technology (AIST), Japan

ABSTRACT

To create their art, remix artists would like to have segmented stem tracks at their disposal; that is, isolated instances of the loops and sounds that the original composer used to create a track. We present Unmixer, a web service that will analyze and extract loops from any audio uploaded by a user. The loops are presented in an interface that allows users to immediately remix the loops; if users upload multiple tracks, they can easily create mashups with the loops, which are automatically matched in tempo. To analyze the audio, we use a recently-proposed method of source separation based on the nonnegative Tucker decomposition of the spectrum. To reduce interference among the extracted loops, we propose an extra factorization step with a sparseness constraint and demonstrate that it improves the source separation result. We also propose a method for selecting the best instances of the extracted loops and demonstrate its effectiveness in an evaluation. Both of these improvements are incorporated into the backend of the interface. Finally, we discuss the feedback collected in a set of user evaluations.

1. INTRODUCTION

Professional and amateur composers across the world enjoy creating remixes and mashups. Remixes are pieces of music that are composed, in whole or in part, using snippets of another audio recording, whereas mashups juxtapose snippets of two or more recordings [8]. Creators of official remixes usually have access to the stem tracks for a recording, but these resources are not typically available to amateur remixers. Unofficial remixes, sometimes called 'bootlegs', can still be created using clips of the down-mixed recording of the song [8], but this presents two challenges: first, it is time-consuming to manually segment an audio track to select the most prominent or interesting bars or sounds. Second, because the sources in the original audio recording are down-mixed, the artist may have to use equalization (i.e., filtering out certain frequencies) to achieve a simple separation of sources.

We present Unmixer [1], an interface that accomplishes both of these tasks for the user, using a source separation technique instead of equalization (see Fig. 1). The interface allows a user to upload any song; it then processes the audio and returns a set of loops. The user can then play with the loops on the spot, re-combining the loops live. If the user uploads more songs, they can also juxtapose loops from different songs, which are automatically tempo-matched, to create live mash-ups. Finally, users can download the loops to remix offline.

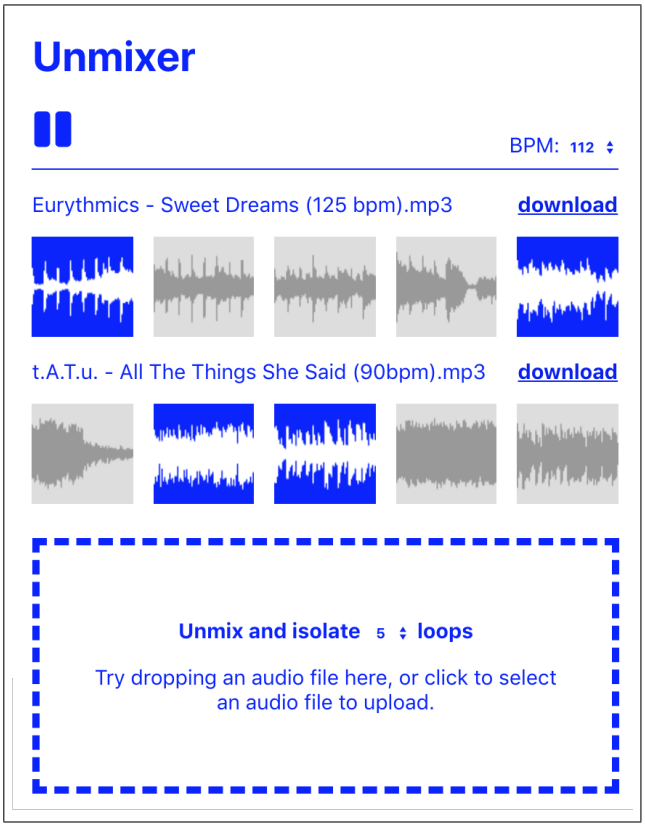

Figure 1. Screenshot of Unmixer interface with two songs loaded. In its current state, two loops from each song are playing.

The website was inspired in part by Adventure Machine [2], a Webby-nominated site designed to promote an album by the musician Madeon. That site allowed visitors to remix stem samples from a Madeon track, and it attracted significant traffic, according to the designers [3]. The thought that inspired us was: what if visitors could populate a remixing interface with samples from any track

[1] Available at: `https://unmixer.ongaaccel.jp`

[2] `https://www.madeon.fr/adventuremachine`

[3] `https://developers.google.com/web/showcase/2015/adventuremachine`

they own? With Unmixer, we aim to achieve this vision.

In the next subsection, we discuss alternative methods of extracting loops. In Section 2, we explain the features of the interface and some design considerations. In Section 3, we explain the algorithm which supports it [22] and propose an extension and improvement to it. Both contributions are evaluated. In Section 4, we present a usability study, and we end with a discussion (Section 5).

1.1 Tools for extracting loops and creating remixes

Existing interfaces for creating live remixes from a library of samples include AdventureMachine and Beat-Sync-Mash-Coder [7], but these do not allow you to populate the interface with automatically extracted loops. The web application *Girl Talk in a Box*[4] cuts any song into chunks for a user and offers novel resequencing options, but does not separate sources or allow the users to play multiple chunks at once. Advanced users can always use a Digital Audio Workstation (DAW), which is the most powerful and flexible way to compose a remix, but they will need to do the work of extracting loops on their own. That said, software exists to support this tedious task, such as [3] and [18], both of which require users to guide the algorithm by indicating regions of the spectrum to ignore or focus on. In sum, we are not aware of another interface that, given an input song, extracts source-separated loops and presents them to the user for remixing.

To extract repeating patterns, two broad approaches are popular: kernel-additive modeling [10], including harmonic-percussive source separation (HPSS) [4] and REPET, a method of foreground-background separation that models a looping background, and its variants [17]. However, these are binary separations: only two sources are obtained. The family of non-negative matrix factorization (NMF) approaches includes NMF [21], NMF deconvolution [19], and non-negative tensor factorization (NTF) [5]. All take advantage of redundancies in the signal—repeating spectral templates, transpositions, stereo dependence, etc. By applying NMF iteratively, [20] separated layers of electronic music that built up progressively, but did not model the extracted sources in terms of loops. This is a drawback shared by all of these algorithms: they produce full-length separated tracks. To obtain short, isolated loops, some extra step is required. However, a recent NTF system [22] models the periodic dependencies in the signal and is thus suitable for extracting loops directly; it forms the basis for our system and is described in Section 3. An orthogonal approach to extracting loops is that of [12], which seeks only to extract drum breaks (short drum solos that are desirable for remixes) by devising a percussion-only classifier.

2. WEB SERVICE AND INTERFACE

The purpose of the interface is to allow users to remix and mash-up the songs they love, and to perform automatically the work of isolating loops, normally done through editing and equalization or source separation.

The interface has just a few, simple features, all visible in the screenshot (see Fig. 1). To begin, a user must upload a song from their hard drive, using the box at the bottom of the page. They may adjust the number of loops to extract using the drop-down list, with possible values between 3 and 10. The audio is processed on the web server using the algorithm outlined in Section 3; once the audio has been analyzed, the interface is populated with a set of loop 'tiles', each tile bearing a waveform sketch. The possible actions are then:

1. click on loop tiles to activate or deactivate them;
2. change the global tempo (drop-down list at top-right of the interface);
3. pause playback (button at top-left);
4. download a zip archive containing all the loops for a given song;
5. choose an additional song (and number of loops to extract) using the box at the bottom of the page.

Uploading and processing a new file can take a while (currently between 5 and 10 minutes), but users can still use the other functions (playing tiles and changing the tempo) while waiting for the next batch of tiles. Users can add any number of songs to a single workspace.

All the loops have the same duration (equivalent to two bars of audio), and the playback of the loops is synchronized so that the downbeats align, no matter when the user activates them. When a user uploads the first song, the global tempo is set to the detected tempo. New songs added to the workspace are tempo-shifted to match the global tempo.

The interface was built as a web application using React[5], making it available on any web-accessible device through a browser. To handle audio playback, we use the Web Audio API, making it easy to synchronize playback of all the tiles and control the playback rate. The audio analysis is run on our server, using the algorithm described in the next section. The web server keeps a log of uploaded audio files and the analysis computed for each. To save time, if the system recognizes an uploaded audio file, it re-uses the old analysis. However, it does not re-use the old audio; it re-extracts the component loops from the new audio to return to the user, thereby avoiding any copyright issues related to redistributing audio.

3. LOOP EXTRACTION

Our approach to extracting loops is based on [22], but we make two contributions: first, we suggest and evaluate methods for selecting individual loops; second, we propose and evaluate an extra "core purification" step.

3.1 Review of NTF for source separation

The pipeline for our system, based on the work of [22], is shown in Fig. 2. First, the mono spectrogram X is di-

[4] http://girltalkinabox.playlistmachinery.com

[5] https://reactjs.org/

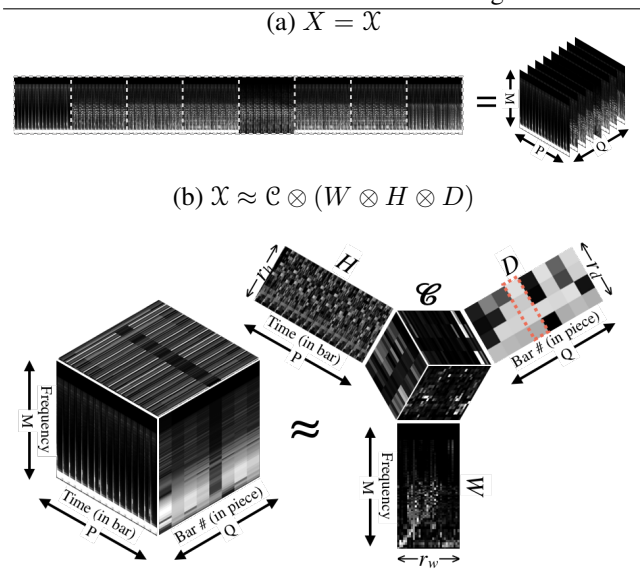

Figure 2. Overview of system, using example '125_acid' [11]. (a) Spectrum of 8-bar song reshaped into tensor. (b) Tucker decomposition expresses song as product of frequency templates W, rhythm templates H, repetition templates D, and a core tensor $\mathcal{C}$. In this example, $(M, P, Q) = (1025, 661, 8)$ and (r_w, r_h, r_d) = (32,20,4).

vided into downbeat-sized windows using a beat-tracker. (Unmixer uses the madmom system [1], but the illustrated example uses the known downbeats.) The $M \times P$-shaped spectrogram windows (one for each bar) are stacked into a new dimension, creating an $M \times P \times Q$ tensor $\mathcal{X}$ (Fig. 2a). Then, using Tensorly [9], we compute the non-negative Tucker decomposition (NTD) with ranks (r_w, r_h, r_d), approximating the tensor as the outer product $\mathcal{X} \approx \mathcal{C} \otimes (W \otimes H \otimes D)$ (Fig. 2b). In plain terms, the NTD models the spectrum with three meaningful components: a set of spectral templates W (the *sounds*), a set of within-bar time-activation templates H (the *rhythms*), and a set of loop-activation templates D (the *layout*, i.e., the arrangement of loops in the song). In Fig. 2b, a decomposition of an artificial 8-bar ($W = 8$) stimulus [11] has been approximated using $r_d = 4$ loop templates, giving a good estimate of the layout of the piece (shown in Fig. 6). The templates are diverse: some sounds are monophonic, others polyphonic; some rhythms are percussive, others sustained.

The sparse core tensor is $\mathcal{C}$; a non-zero element $\mathcal{C}_{[i,j,k]}$ indicates that sound i is played with rhythm j, and this pattern is repeated according to layout template k. To separate the contribution of the k^{th} loop, use the k^{th} row of D to take the outer product $\mathcal{C} \otimes (W \otimes H \otimes D_k) \approx \mathcal{X}_k$, and unfold the tensor into X_k. The reconstructed real-valued spectrum X_k is not sufficient to recreate the signal; we must apply softmasking (as outlined in [17] and implemented in librosa [13]) and use the original phase:

$$y_k = \text{ISTFT}(\text{phase}(X) \cdot \text{mag}(X) \cdot \frac{X_k^p}{X_k^p + X^p}) \quad (1)$$

where p is the power of the softmask operation. As noted

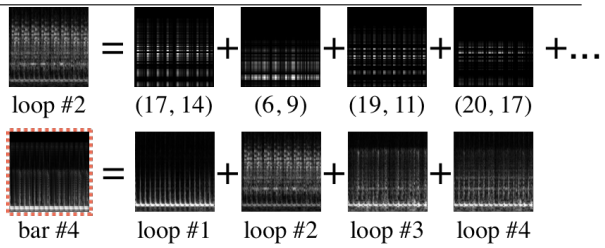

Figure 3. Example reconstruction of spectrum for a single loop (#2) from multiple (freq, rhythm) combinations (above), and for a single bar (#4, also indicated in Fig. 2) from multiple loops (below).

by [6], using softmask filters is convenient, although not necessarily optimal, for non-negative approaches like ours.

The core tensor can be interpreted as a set of "recipes" for building the loops, the recipe for the k^{th} loop being the $r_w \times r_h$ slice of the core tensor $\mathcal{C}_{[:,:,k]}$. To see how, note that $W_i \otimes H_j$, the outer product of the i^{th} sound with the j^{th} rhythm, is an $M \times P$ spectrum of a single bar. The outer product $\mathcal{C}_{[:,:,k]} \otimes (W \otimes H)$ thus represents a sum of such one-bar spectra, leading to the k^{th} loop template. Fig. 3 shows how the 2^{nd} loop template is the sum (in descending order of magnitude) of individual $W_i \otimes H_j$ components. Each bar in the piece will be a superposition of several loops: the bottom part of the figure shows how the 4^{th} bar consists of copies of each loop.

3.2 Loop selection

The output of the algorithm in [22] is a set of full-length tracks, each corresponding to the contribution of one loop. For remixing purposes, we only want a bar-length version of each loop, as cleanly separated as possible. The plain approach is to extract the full-length track, then excerpt a single bar, but the question is then: which bar to select?

There are at least two factors to consider: how loud a given loop instance is, and how strongly that instance stands out from the other parts. Loudness can be maximized by choosing the bar that takes the maximum value in the loop activation matrix: i.e., to select the best bar for the k^{th} loop, choose argmax($D_{[k,:]}$). To minimize cross-talk, we consider two approaches. First, we may normalize the columns of D by choosing argmax($D_{[k,:]} - \bar{D}$), where $\bar{D}$ is a vector of the column means of D.

Alternatively, the coefficients from the softmask operation could estimate how prominently a given loop stands out from the background. In this approach, we compute the softmask coefficients for each bar (i.e., the fractional part of Equation 1), and then select the bar which maximizes the total value of the mask. That is, if $M_{k,i}$ gives the softmask matrix for the i^{th} bar for the k^{th} loop, we select argmax($\sum M_{k,:}$). Finally, we may combine any or all of these decision criteria.

Evaluation To determine the most reliable selection method, we tested them on a set of stimuli assembled by [11]. The test set contains 7 compositions, each containing 4 loops arranged in the same 8-bar layout (shown

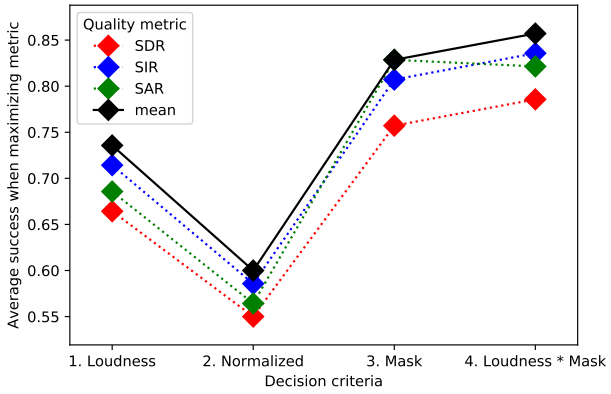

Figure 4. Main effect of bar selection strategies.

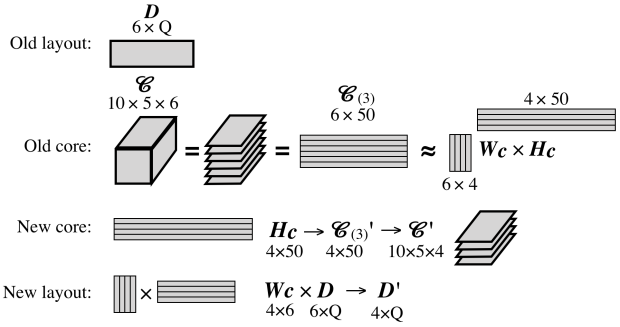

Figure 5. Illustration of core tensor purification. W_C and H_C are estimated using NMF with H_C constrained to be sparse.

in the bottom part of Fig. 6). We ran the NTD algorithm on all the stimuli (with $(r_w, r_h, r_d) = (32, 40, 4)$), and then measured the reconstruction quality of each loop in each bar. We measured reconstruction quality using SDR, SIR and SAR, the source-to-distortion, -interference, and -artefact ratios, respectively, calculated using mir_eval [16]. (For each metric, higher is better.) Then, we tested how frequently the optimal bars were selected by maximizing each criterion. The four tested criteria were: loudness only ($D_{[k,:]}$); normalized loudness ($D_{[k,:]} - \bar{D}$); mask only ($M_{[k,:]}$); and loudness times mask ($D_{[k,:]} \cdot M_{[k,:]}$).

The main effect of the choice of criterion is shown in Fig. 4, which shows how often a given strategy (e.g., "select the loudest bar") correctly found the bar that maximized a given metric. Using loudness alone (1), the optimal bar was selected at least two-thirds of the time. Normalizing the matrix D to diminish cross-talk (2) was too coarse, with the best bar selected less than 60% of the time. However, multiplying the loudness by the mask (4) to diminish cross-talk led to the best overall result, with the optimal bar selected around 80% of the time. The choice of criterion depends slightly on the quality metric (SDR, SIR or SAR) being maximized: if the priority is to maximize SAR, using the mask alone (3) may be advised, but using the loudness-and-mask criterion worked best overall, and it is the criterion used in the Unmixer system.

3.3 Loop purification

As reported by [22], a problem with the algorithm is that the extracted loops can be redundant. For example, suppose a song contains a drum pattern A and a synth pattern B, which are independent, but where B never occurs without A. Instead of modeling the independent patterns A and B, the algorithm is likely to learn one pattern for A and another for $A + B$. This error is not fixed by changing the number of loop templates that the model should learn.

The problem would be avoided if the core tensor were estimated with a sparsity constraint. Note that sparsity is only desired in the 3^{rd} dimension, to prevent the $r_w \times r_h$ slices (the loop 'recipes') from being too similar. Denseness is still desirable in the other dimensions; indeed, allowing different sources (frequency templates) to share rhythms (time activation templates), and vice versa, was a motivation to use NTD to begin with, since it allows an accurate and meaningful reconstruction without the model size becoming infeasibly large.

Algorithms for sparsity-constrained tensor factorizations exist [14], but we are not aware of any existing tensor decomposition packages that implement them. [6] Therefore, we propose to follow regular NTD with a "core-purification" step, using sparsity-constrained NMF to simplify the core tensor.

The process is illustrated in Fig. 5, supposing a decomposition of initial rank $(10, 5, 6)$. First, we take $\mathcal{C}_{(3)}$, the third-dimension unfolding of the core tensor $\mathcal{C}$, so that each horizontal slice of $\mathcal{C}$ is reshaped into a row in $\mathcal{C}_{(3)}$. Then, we apply sparse NMF (using the SNMF function in Nimfa [23]) to model $\mathcal{C}_{(3)} \approx W_C \times H_C$, imposing sparsity on H_C only. (It is also possible to use simple NMF, without the sparsity constraint; this is tested later as a baseline.) The rows of H_C give a new set of maximally independent vectors; when the matrix H_C is refolded, it gives $\mathcal{C}\prime$, a set of maximally independent recipes. The matrix W_C tells us in what proportion to add the previous 6 templates to each other to obtain the new set of 4 templates; hence, we use it to transform the original layout D into $W_C \times D = D'$.

An example showing the promise of this method is shown in Fig. 6. First, we computed the NTD of a song using ranks $(10, 5, 4)$; second, we computed a new NTD with ranks $(10, 5, 6)$, and purified the core so that the final shape was $(10, 5, 4)$. The 4 slices of each core are shown in parts (a) and (b) of the figure, along with the corresponding layouts: first, the loop activation matrix D; second, the revised matrix D'. Each is an estimate of the ground truth layout at bottom. Whereas there is a clear redundancy among loops 2 and 3 in the first set (plain NTD), the redundancy has been reduced in the second (NTD with purification). The reconstruction error for the second set is actually a little higher (0.186 compared with 0.185), but the separated audio will be of higher quality. In the actual example (where we used ranks $(32, 40, 4)$ and $(32, 40, 6)$), the mean SDR and SIR for the 4 estimated loops climbed from 1.98 and 9.96 to 6.85 and 16.16, respectively, while

[6] NB: factorization of 'sparse' tensors is often a supported feature, but not the estimation of sparse outputs.

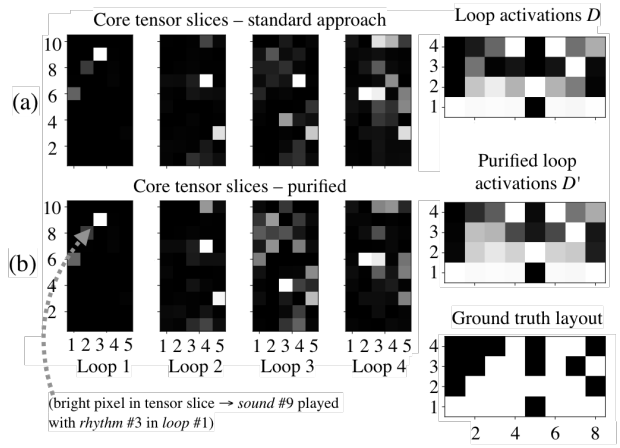

Figure 6. Comparison of (a) core estimated with plain NTD vs. (b) NTD with purification (core purified from 6 to 4), using stimulus '125_acid' [11]. The pixel at $(4, 7)$ which appears redundantly in loops 2–4 in (a) has been subdued in (b). Each subfigure's pixels are linearly scaled between its min and max.

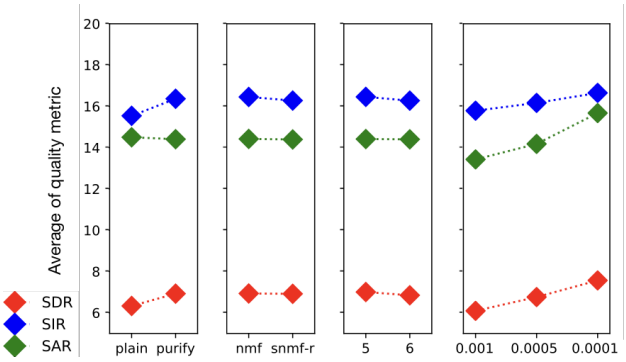

Figure 7. Main effect of loop purification and runtime strategies.

SAR only decreased from 17.97 to 17.38. (These metrics are explained in the next section.)

Evaluation We evaluated the effectiveness of the proposed purification approach on the same dataset used in Section 3.2. We ran a fully-factorial design, exploring the following parameters and settings:

1. Plain NTD vs. purification;
2. Purification method: unconstrained NMF vs. the proposed SNMF approach;
3. Initial rank: 5 or 6 for purification methods only;
4. Tolerance: stopping criterion for computation of initial tensor (0.001, 0.0005 or 0.0001).

We use the known downbeat locations, and the final rank was always set to 4, the true number of loops in the examples. Although these must be estimated in a real-life scenario, we can still evaluate the impact of the purification method, initial rank, and tolerance. The reported metrics are SDR, SIR and SAR, as before.

Fig. 7 shows the main effects. We see that the purification step increased SDR and SIR, with only a minor decrease in SAR. This was the hoped-for result: less interference among the extracted signals (SIR), even if some reconstruction quality is sacrificed (more artefacts, SAR). However, we found that there was little difference between the proposed SNMF-R approach and a simpler NMF approach. We also see that purifying an estimate to rank 4 from rank 5 gave slightly better results than from rank 6. To put these effects in context, we also show the effect of reducing the tolerance, i.e., allowing the tensor factorization to run for longer. The purification step increased SIR nearly as much as did reducing the tolerance by 90%.

4. USER EVALUATIONS

To assess the usability of the system and solicit feedback about the audio quality and enjoyability of app, we conducted a user evaluation. We solicited 8 participants (4 men and 4 women), all between 25 and 40 years old. The study had three components:

1. A background questionnaire covering: their musical training (using the standard Goldsmiths MSI short test [15]); their experience with audio editing interfaces and audio production; and their familiarity with the songs used in the study.
2. A 10-minute test of the interface. Participants were asked to upload a song, familiarize themselves with the interface, then upload 2–5 more and explore the combinations of sounds.
3. A feedback questionnaire with Likert-scale and free-text questions focused on usability, audio quality, enjoyment, and potential new features. Usability questions were adapted from the standard Systems Usability Scale [2]).

We limited participants to a set of 11 audio files that the system had already seen, which greatly sped up the processing time: users did not have to wait the typical 5–10 minutes for the Tucker decomposition to converge; they only needed to wait for the system to receive the audio, use the pre-existing decomposition to extract new audio files, and load said audio files into the interface, all of which takes roughly 30 seconds per file. Otherwise, the system they used is the same that is available live, now at `unmixer.ongaaccel.jp`. The ranks of the analysis are $(r_w, r_h, r_d) = (50, 40, 30)$ (with r_d purified to 25 using SNMF-R), and the NTD is solved with tolerance 0.0001.

User background: The 8 user testers included musical experts and novices: 5 played musical instruments, and 6 had experience editing audio files. Of those 6, 4 also had some experience either using a DAW or creating a remix or mashup. According to the MSI test, the musical sophistication of 4 users was within a standard deviation of average [15], with 1 user above this range and 3 below.

Usability: There was unanimous agreement that the system was "easy to use" and that users thought "most people would learn to use this system very quickly." In fact, in the free response, ease of use was cited by 7 users as one of the best things about Unmixer, especially for "musical novices" or "a beginner [like] myself". One aspect of the

interface that users found inconvenient, though, was the inability to anticipate what a loop would sound like. One wrote that "you need to guess what's in each loop based on the waveform and sometimes it's not what you expected or wanted", and suggested a short text label (e.g., 'vox', 'drum', 'synth') to indicate the content; another suggested visual hints. One user also noted that they did not know what the impact on the loop content or quality would be if they changed the number of loops to extract.

Sound quality: Asked whether "the sound quality of the loops was poor", users were divided, with 4 each agreeing and disagreeing. However, one disagreer later explained that while "audio quality of some samples was not great, ...it was possible to find good quality ones." The quality of source separation was appreciated: 6 agreed that "most loops isolated a single source (e.g., drums, vocals, synth, bass)", and 5 agreed that "loops within one song had a nice variety" (with 2 disagreeing). No one agreed that the "loops from different songs were too similar".

Enjoyment: 6 agreed that "the combination of loops was often interesting", and 4 agreed that they would "like to use Unmixer frequently" (with 2 disagreeing). The interface struck users as novel: none agreed that the "interface was similar to others I've used before". Four agreed that "a remix artist could build a good song from these loops" (with 2 disagreeing); however, among users with experience using DAWs or creating mashups, opinion on this was split 2-against-2. Users saw different reasons to enjoy the interface: one "enjoyed the experience of doing something new"; another wrote that "it was very easy to try out new ideas very quickly". Opinon also varied on what users would use Unmixer for, with responses including: generating mashups "for interludes or as backing music"; "using it to prototype [remix] ideas quickly"; "having fun at a house party—home-DJ style"; creating "nice effects for a video"; and "taking some of my own music" and generating "new ideas from it."

Potential features: To understand what future developments for the interface would be most desirable, we polled users' opinions on a list of 7 suggested features: controls for (1) loudness, (2) pitch-shifting and (3) equalization (e.g., to boost the bass or mid-range); (4) keyboard shortcuts for activating loops; (5) allowing more than 10 loops; and colour-coding loops by (6) type (e.g, vocals, synth) or (7) tonality. Users expressed broad approval for all of these except for (5), although if loops were colour-coded, it might become more desirable to have more loops available. Almost all users indicated that they had already thought of feature (1). When asked what change in Unmixer would make it more usable or useful, two users suggested a timeline functionality so that repeating sequences of loops could be made; two also wanted to be able to 'save' or 'download' the combinations they had created.

5. DISCUSSION

Our user feedback confirmed for us the usability of the system: without supervision, all participants completed the steps of the user study. The positive comments assure us that the app holds promise as a tool for exploring interesting remix possibilities. However, to be most useful and engaging, we need to improve the sound quality of the extracted audio. The interface as it is may even be *too* simple: we expect that with a few changes, like adding keyboard shortcuts and having the tiles give some visual hint as to their content, we can increase user enjoyment and satisfaction. On the other hand, we should not implement all of the features discussed; to do so would be to program an in-browser, fully-functional DAW, whereas our focus is to provide users with loops extracted from songs and allow them to experiment with combinations.

The user study differs from the live experience in a few ways: (1) It allowed a choice among 11 pre-selected tracks, although real users are free to choose any music from their library; and (2) it featured a streamlined experience with minimal waiting for the system to analyze the files. We must collect more feedback from realistic scenarios to understand the system usability. If we cannot speed up the algorithm, we may need to adjust the interface to maintain the feeling of interactivity. For instance, we could provide the user with a quick-and-dirty set of extracted loops, and refine them in the background while the user experiments. Also, the current version kept fixed the ranks of the analysis and the amount of purification. We hope to make these tuneable, or have the system predict the optimal values.

There remain several ways to improve the source separation quality. We have reconstructed the signals using softmask filtering, but we could realize further improvements, and even speed up the algorithm, by using newer masking methods, such as the divergence-based masks proposed by [6]. To improve the system's output, we could use equalization to refine the separated loops. As noted in the introduction, creators of unofficial remixes often use equalization to separate sources in lieu of source separation algorithms. We could blindly apply equalization or HPSS to create, say, bass, treble and percussive versions of each loop, or use a set of instrumentation-detection functions (similar to [12]) to select the best ones.

To evaluate these proposed improvements, it is important to collect more expansive test sets. The small test set of [11] was sufficient to assess the best bar-picking strategy and whether the purification step was useful. However, future work on this task ought to treat more diverse stimuli—more genres, loops per song, and loop layouts—to gauge how the system copes with realistically complex pieces.

6. CONCLUSION

We developed Unmixer, a web-app where users can upload music, extract loops, remix them, and mash-up loops from different songs. Expert and novice users found it easy to use; many also found it a novel way to develop remix ideas, although higher-quality audio output may be required for polished remixes. The backend uses the NTD-based source separation algorithm from [22]; we proposed and tested techniques to select the best reconstructed loop excerpts, and techniques to refine the loop layout, measurably improving on the baseline system output.

QUANTIFYING DISRUPTIVE INFLUENCE IN THE ALLMUSIC GUIDE

ABSTRACT

Understanding how influences shape musical creation provides rich insight into cultural trends. As such, there have been several efforts to create quantitative complex network methods that support the analysis of influence networks among artists in a music corpus. We contribute to this body of work by examining how disruption happens in a corpus about music influence from the All Music Guide. A disruptive artist is one that creates a new stream of influences; this artist builds on prior efforts but influences subsequent artists that do not build on the same prior efforts. We leverage methods devised to study disruption in Science and Technology and apply them to the context of music creation. Our results point that such methods identify innovative artists and that disruption is mostly uncorrelated with network centrality.

1. INTRODUCTION

What is disruption? To understand the concept, let us consider the careers of two famous Jazz musicians whose careers started in the 1940's: Bud Powell and Sun Ra. According to the *All Music Guide* [1], both artists have been highly influential. The AllMusic biography of Bud Powell states that: "One of the giants of the jazz piano, Bud Powell changed the way that virtually all post-swing pianists play their instruments.". Similarly, the guide describes Sun Ra as a major innovator, both in his music and in his style: "[Sun Ra] surrounded his adventurous music with costumes and mythology that both looked backward toward ancient Egypt and forward into science fiction.".

Disruption, as explored in this paper, is focused on differentiating artists like these even though they share similar backgrounds. While both artists may seem alike in terms of influence, the network of future artists citing them as a past influence sets these two great Jazz musicians apart by their network structure. Again according to the AllMusic guide, both artists have Thelonious Monk and Art Tatum as former influences. However, while future musicians influenced by Bud Powell also cite these two artists as influences, those following Sun Ra do not cite Thelonious Monk and Art Tatum; they are mostly influenced by Sun Ra in isolation when compared to Sun Ra's past influences. In this sense, Sun Ra is primarily self-sufficient, and as a consequence, disruptive. In contrast, Bud Powell's contribution is more related to developing and consolidating an ongoing field of work. Figure 1 depicts this concept.

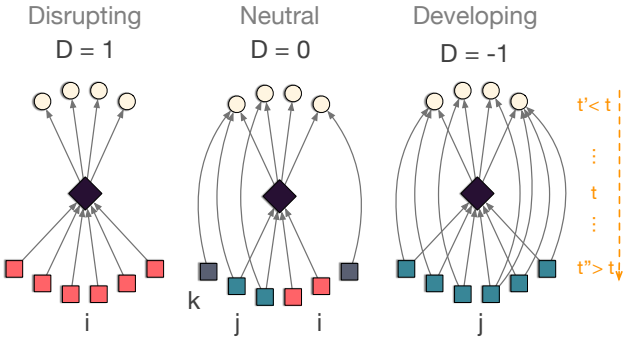

Figure 1: Reference networks of different focal works (diamonds), with their preceding references (circles) and posterior work (squares). i nodes (in red) reference the focal work but none of its predecessors; j nodes (in blue) reference both the focal node and its predecessors, and k nodes (in grey) link only to the focal node's references.

The figure shows an influence network and exemplifies disruption from the standpoint of the central, diamond-shaped, focal work. Links represent influence or citations. In this network, an overall influential innovator will be a node with a high in-degree, and both Bud Powell and Sun Ra fit this definition. In contrast, a disruptive node ($D = 1$) is singled out and thus self-sufficient compared to it's past. In our example, the focal node is cited by other nodes that tend to refer only to this single node as an influence.

To formalize the metric, let us call the focal, diamond-shaped node, as a (for artist). There are n_i nodes that reference a's work and at least one of its predecessors, while n_j nodes reference a but none of its predecessors. There are also n_k nodes do not reference a but reference at least one of its predecessors. Funk and Owen-Smith's [5] disruption index, here called D, is measured as:

$$D = \frac{n_i - n_j}{n_i + n_j + n_k} \quad (1)$$

D ranges from -1 to 1. The negative extreme captures a developing work, one that is mostly cited in conjunction with its own influences (i.e., $n_i = 0$ and $n_k = 0$). The positive extreme captures disruption (i.e., $n_j = 0$ and $n_k = 0$).

[1] http://www.allmusic.org. Quotations from June 16th 2019.

Motivated by recent demonstrations of the utility of D in other fields [5, 18], our work uses this index to examine disruptiveness of music artists using the AllMusic Guide. While several authors have tackled the task of understanding innovative artists, songs, and lyrics [2–4, 12, 15, 16], to the best of our knowledge, no prior effort exists that explores the disruptiveness of artists.

We opt to explore the AllMusic Guide as such a dataset has been used as a *gold standard* to other methods focused on influence [12, 16]. The guide contains a human-curated network of artists that influenced one another. This network provides us the contrasting example of Bud Powell and Sun Ra as a motivator to the importance of considering disruption. While both artists are influential, analyzing disruption unveils that one of them consolidates a stream of influences, while the other destabilizes this stream, shifting attention towards a different direction.

Our main contributions are (i) providing evidence that disruption measures provide insight when analyzing music corpora based on artist metadata, and (ii) describing disruption topologies that characterize how disruption happens in different contexts included in our corpus.

2. BACKGROUND AND RELATED WORK

Before presenting our dataset and results, we discuss previous work that explored different corpora to understand musical influence (Section 2.1). Next, we describe the metric that captures disruption (Section 2.2).

2.1 Influence Analysis in Music Corpora

Understanding musical influence is not a new endeavor [2–4, 12, 13, 15–17]. Several works have leveraged large datasets of audio and metadata to investigate historical trends in music creation quantitatively. Notably, Serrà and collaborators [15] use the Million Song Dataset to unveil historical regularities and changes in pitch transition, timbre usage, and loudness in pop music.

Several researchers have used the Billboard charts of songs most played on radios and streaming as a corpus representing western pop music. The audio and metadata about songs and artists in these charts have been used to characterize trends related to innovation, for example in lyrics [2], songs [16], and artists [16]. In particular, we point out the work of Mauch et al. [11] used timbral, tone, and harmonic information to analyze the sonic dynamics in the Billboard charts from 1960 to 2010. Their results point to three historical inflection points in the evolution of this corpus: 1964, 1983 and 1991.

A complementary approach to the analysis of aggregate trends is to examine individual artists or songs who have innovated in their context. Shalit et al. [16] use a dynamic topic model learned from audio and metadata to evaluate influence and innovation in songs from the Billboard charts. Their model identifies innovative songs and periods and suggests that overall, there is no correlation between how innovative and how influential a song is, with exceptions during the early 70s and mid-90s. For this analysis, Shalit operationalizes innovative songs as songs hard to account for by a model trained with data from the past. On the other hand, a song is influential if its language is used by subsequent work. Authors have also studied influence for particular settings such as Electronic Dance Music [4].

2.2 Measuring Disruptive Influence/Innovation

Our work is inspired by the network measure proposed by Funk and Owen-Smith [5] to study technological change. Funk and Owen-Smith propose a network model and the D index, which "quantifies the extent to which an invention consolidates or destabilizes the subsequent use of the components on which it builds" [5]. The index (detailed in Eq (1)) is built on the notion that disruption should be measured by more than the number of references an invention has in subsequent work. Besides that, a measure of disruption must consider the structure of previous and subsequent work that form the context of the invention.

In their original work, the authors leverage a comprehensive database of patents to validate that their index quantifies how consolidating or destabilizing inventions are and that this information is uncorrelated with the sheer impact of innovations. More recently, Wu et al. [18] validate this same index in datasets of scientific papers and software products. Moreover, Wu et al. show that in the context of papers, software, and patents, disruptive innovation is more associated with smaller teams and work that cites prior efforts further in the past.

3. METHODOLOGY

To describe how we measure disruption in the AllMusic guide, we first detail how we identified artist pages and influence edges from the AllMusic website (Section 3.1).

Different from other datasets where disruption has been measured [5, 18], the AllMusic guide presents a human-curated graph of influences. While from one perspective this is an advantage (e.g., provides explicit opinions of music editors), it is apparent that the information about influences is not complete, and it is likely less complete than in datasets created from of patents and scientific papers. One other particularity of our network is that it widely suffers from biases towards modern occidental musicians who achieved considerable success. To tackle the disadvantages related to sparse counts, we employ a Bayesian approach to measure disruption (Section 3.2).

3.1 Crawling the AllMusic Guide

AllMusic is a comprehensive catalog of artists, albums and songs. The AllMusic website contains Artist Profile pages that detail an artist's biography, discography, genres, styles and links to other related artists, among other information. The list of related artists details those that are similar, have influenced, followed, or have worked with the owner of the profile page. Artists said to influence a given artist according to the site are those "that have had a direct musical influence on, or were an inspiration to, the selected artist,

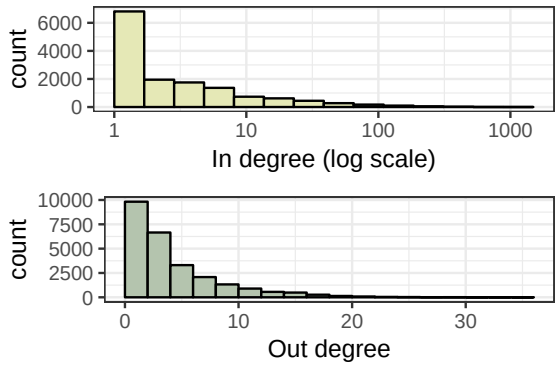

Figure 2: Distribution of in and out node degree in the AllMusic influences dataset. For in degrees, 18,281 nodes with zero inbounding edges are ommitted.

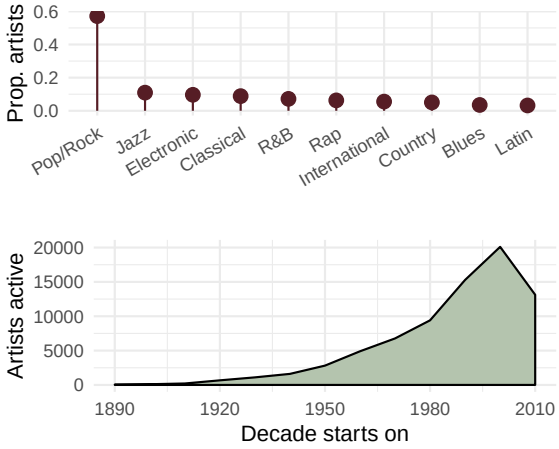

Figure 3: Proportion of artists with either in or out degree different from zero tagged with the 10 most popular genres, and number of artists active per decade.

as determined by our music editors"[2]. Being a human-curated graph, there are several situations an artist influences a contemporary musician, band or singer.

We use AllMusic to create a network of influences among artists. Data were obtained by exhaustively crawling the website. The crawler started with a list of approximately 73,000 thousand AllMusic URLs present in the open MusicBrainz[3] database. We note that not all of these URLs were valid artist page addresses (e.g., some were wrong or deleted links). Nevertheless, we crawled the correct ones and followed their links in a snowball approach [7]. In particular, we followed links to every related artist until crawling we found no new artists. Even though we only use the influence edges in our analysis, to gather as much artists as possible, we crawled all of the similar, influenced, followed, member of egdes.

For each visited artist page, the crawler saves the artist's name, decades of activity, genre, style, and list of influencers. The resulting set of artists from the crawler has 162,971 members, connected by 119,961 directed edges.

[2] https://www.allmusic.com/faq/topic/influencedby

	Cited a	Did **not** cite a
Cited a's influences	n_j	n_k
Did **not** cite a's influences	n_i	everything else

Table 1: 2x2 Contigency Table used for Computing D

After filtering out artists with no influencers cataloged in AllMusic, our dataset comprises of 32,568 artists connected by 119,961 directed links, where a link from artist a to b denotes that a has been influenced by b. When we consider the weakly connected components of the graph, 96% (3,1279) of the nodes are in the giant component. This indicates that there is an undirected path of influence between most nodes. This is expected as major hubs, such as The Beatles, will lead to a mostly connected graph.

To characterize our graph, the in and out-degree distributions of nodes are shown in Figures 2. Complementary, in Figure 3 we show the genre distributions and active decades of the artists. Both the distribution of in and out degrees are skewed, with the distribution of in degrees being considerably more skewed and spanning a more extensive range. It is likely that influences (outgoing edges) of an artist are entered manually by editors and are kept to customary size. Bands or musicians influencing most artists are The Beatles (indegree 1,492), Bob Dylan (784), and The Rolling Stones (636), and there are 18,281 artists with no incoming edges. On the other hand, those with most extensive lists of influencers (outdegree) are Grateful Dead (36), Sonic Youth (35) and Jimi Hendrix (35). Concerning genre and epoch, our sample is biased towards Pop/Rock and artists active from the 80s to the present.

3.2 Measuring Disruption in Sparse Data

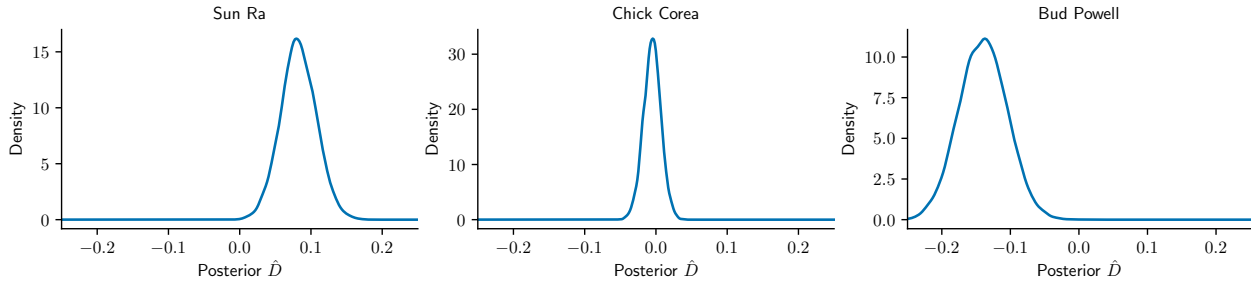
One challenge we tackle while computing disruption is how discuss results regarding D with statistical significance. Considering a focal artist a, recall that other artists may either: (1) cite a only, thus increasing n_i; (2) cite a and a's past influences, thus increasing n_j; (3) cite a's past influences only, increasing n_k; or, (4) do cite a nor past influences. These choices are shown Table 1.

In some of our initial exploratory analysis, we computed disruption in the AllMusic influence graph *as is* (i.e., with no filters nor priors), and found that Eq. (1) would lead to either very high ($D \approx 1$) or very low ($D \approx -1$) scores when n_i, n_j and n_k were very small. One example is the extreme case where $n_i = 1$, $n_j = n_k = 0$. Here, the metric will unveil a biased D due to the small numbers.

To explain our Bayesian approach, initially note that Eq. (1) captures the difference between two proportions:

$$D = p_i - p_j = \frac{n_i}{n_i + n_j + n_k} - \frac{n_j}{n_i + n_j + n_k} \qquad (2)$$

Here p_i, p_j and p_k (unused) are proportions. Furthermore, the counts may be captured by a Multinomial distribution $I, J, K \sim Multinomial(p_i, p_k, p_k, n)$, where $n = n_i + n_k + n_j$. Here, I, J and K are random variables modelling the respective counts n_i, n_j and n_k.



(a) Over 95% Credible and Disruptive (b) Neutral (c) Over 95% Credible and Developing

Figure 4: Posterior $\hat{D}$ for three Jazz Artists. On the left we have a disruptive were 95% of posterior samples are above zero; in the middle a neutral artist; on the left a developing artist where 95% of posterior samples are below 0.

To model D, one approach would be to use the closed form for the probability mass function for $D = I - J$. One negative aspect of this approach is that it also requires some assumption on the joint distribution of I and J or that both are independent. Another approach would be use statistical tests (see [1] for details). Here, classical approaches like the Binomial test for proportions have issues with small samples or assume independence in the choices that lead to the contingency table. Other options such Fisher's or McNemar's test focus on comparing either rows/columns or the off-diagonal of the 2x2 table. In our setting, n_j shares a column with n_i (see Table 1). Our Bayesian approach, discussed next, has the advantage that it that does not require such closed forms or assumptions.

Given that proportions captured by a Multinomial distribution, for each node of the graph, we can apply a conjugate Dirichlet [6] prior on such a Multinomial distribution. Being a conjugate prior, the posterior will also be a Dirichlet distribution from which we can sample proportions: $\hat{p}_i, \hat{p}_j, \hat{p}_k \sim Dirichlet(n_i + \alpha_i, n_j + \alpha_j, n_k + \alpha_k)$. Here, α_i, α_k, and α_j are prior hyper-parameters. These can be fine tuned by an analyst to capture prior beliefs. By sampling from this distribution, we are left with a posterior estimate of disruption that is defined as: $\hat{D} = \hat{p}_i - \hat{p}_j$.

Suppose we perform 10,000 of such samples. Let, $\hat{\boldsymbol{D}}$ be the vector os estimates. The average score of this vector will lead to similar results as the original one ($mean(\hat{\boldsymbol{D}}) \approx D$). However, using these samples, we are able to measure the *credibility* of our estimates [6]. This credibility comes from what is called the *credible-interval*, a Bayesian analogous of the confidence-interval. While a confidence-interval measures the probability that some true population statistic will fall into the range of the interval, the credible-interval is determined by the posterior samples.

To explain how we capture credibility, consider the case where $n_i = 1$ and $n_j = n_k = 0$. Moreover, consider the particular choice priors (discussed later), $\alpha_i = \alpha_k = \alpha_j = 10$. If we measure the fraction of posterior samples greater than zero $P(\hat{D} > 0)$, this value is only of 0.58, even if $p_i = 1$ and $p_k = 0$. Thus, our estimate is 58% credible. Credibility is thus captured by: (1) $P(\hat{D} > 0)$ when $D > 0$; and, (2) $P(\hat{D} < 0)$ when $D < 0$. In other words, simply the fraction of posterior samples when D that are either positive of negative depending on the value of D. If this fraction is above 0.95, we are over 95% credible for either the positive (disruptive) or negative (developing) case. Figure 4 shows three examples of posterior samples of $\hat{D}$ for three artists, illustrating the cases when of disruption and development, and neutrality.

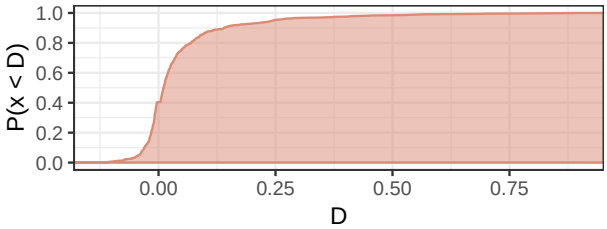


Figure 5: CDF of the disruption D for artists where our estimation has a minimum confidence of 0.95.

We set our hyper-parameters to the non-informative case of $\alpha_i = \alpha_j = \alpha_k = 10$. This choice is based on synthetic samples, where we estimated our credibility scores for different values of $n_i - n_j$ and $n_j - n_i$. Via simulations using different values of n_i, n_j and n_k, we found that with these our choices credibility is over 95% only when $|n_i - n_j| \approx 10$. Moreover, one can notice that these priors do not bias results towards positive nor negative values of $\hat{D}$ (i.e., $\alpha_i = \alpha_j$). We argue that this is adequate as it imposes a minimum difference between n_i and n_j to have some credibility in our estimates. Furthermore, we present disruption values D only in cases where our credibility is over 95%, using 10,000 samples per node.

Finally, being a human-curated guide, some artists will suffer from missing given the limited knowledge of the AllMusic editors. To avoid discussing such cases, we limit the analysis to nodes with at least three incoming and outgoing edges *after disruption is computed*.

4. DISRUPTIVE ARTISTS

We now explore the most and least disruptive artists in our data. Figure 5 shows the distribution of disruptiveness D. This distribution is concentrated around a median value close to zero (0.01), with a longer right tail – there are more highly destabilizing artists than highly consolidating ones.

Artist	D	AM Genre	n_i	$n_j + n_k$
King Sunny Ade	0.90	International	9	1
Édith Piaf	0.86	Vocal	51	6
Frankie Knuckles	0.70	Electronic	30	13
The Clark Sisters	0.68	Religious	13	6
Mstislav Rostropovich	0.68	Classical	13	6
Los Tigres del Norte	0.57	Latin	14	9
John Cage	0.56	Classical	141	64
Tiësto	0.45	Electronic	10	12
Alfred Brendel	0.45	Classical	13	16
Scott Asheton	0.41	Pop/Rock	16	18
Bernard Herrmann	0.41	Stage & Screen	23	28
Converge	0.40	Pop/Rock	32	45
K.M.D.	0.38	Rap	9	15
Too $hort	0.36	Rap	70	104
Darkthrone	0.35	Pop/Rock	15	28

Table 2: Most disruptive artists in AllMusic with at least three influences catalogued.

Artist	D	AM Genre	n_i	$n_j + n_k$
Teddy Wilson	-0.13	Jazz	7	163
John Coltrane	-0.11	Jazz	103	1307
Bud Powell	-0.11	Jazz	23	358
Philly Joe Jones	-0.10	Jazz	8	121
Geto Boys	-0.10	Rap	33	474
Sarah Vaughan	-0.09	Jazz	23	495
Pete Seeger	-0.09	Folk	22	335
Sonny Rollins	-0.08	Jazz	31	641
The Stanley Brothers	-0.08	Country	11	308
Augustus Pablo	-0.08	Reggae	1	212
Buddy Guy	-0.07	Blues	8	611
Roy Acuff	-0.07	Country	25	204
Jimmy Reed	-0.07	Blues	32	515
Oscar Peterson	-0.07	Jazz	15	411
Master P	-0.07	Rap	12	530

Table 3: Most consolidating artists in AllMusic with at least three influences catalogued.

Overall, we also find disruption does not correlate with the influence of an artist. This measure is captured here by the number of other artists influenced by a certain artist (in-degree). This was measured using the linear correlation coefficient is $\rho = -.001$. Correlations between disruption and centrality are further detailed in the next section.

Next, in Table 2 show the 15 most disruptive in our dataset. None of the most disruptive artists are among the most influential of AllMusic, and their communities in the network are very diverse. For example, King Sunny Ade is a Nigerian musician credited for a significant contribution in the popularization of juju music worldwide. According to AllMusic, he has been influenced by other juju and highlife artists such as I. K. Dairo & His Blue Spots and Rex Lawson, while he has influenced artists from a diverse stream including Talking Heads and Trey Anastasio, both from the US. Édith Piaf is a famous French singer with a similar network structure, bridging influences from earlier French singers and an assorted group of followers spanning several decades and countries.

The remaining artists in Table 2 illustrate multiple other types of destabilizing innovation in various genres. For example, Frankie Knuckles and Too $hort are acknowledged as pioneers of house music and gangsta rap, respectively.

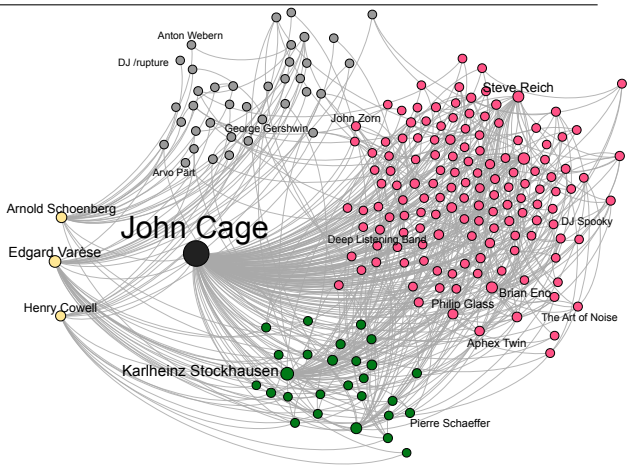

Figure 6: Network with John Cage as the focal node. Preceding artists are in yellow, while i, j and k nodes are pink, green and grey, resp.

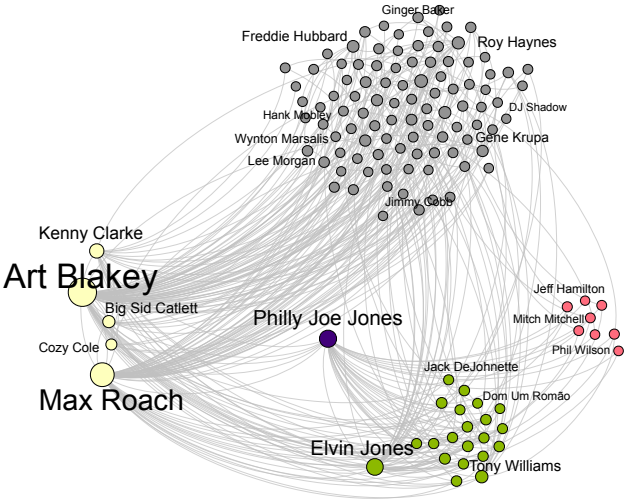

Figure 7: Network with Philly Joe Jones as the focal node. Preceding artists are in yellow, while i, j and k nodes are pink, green and grey, resp.

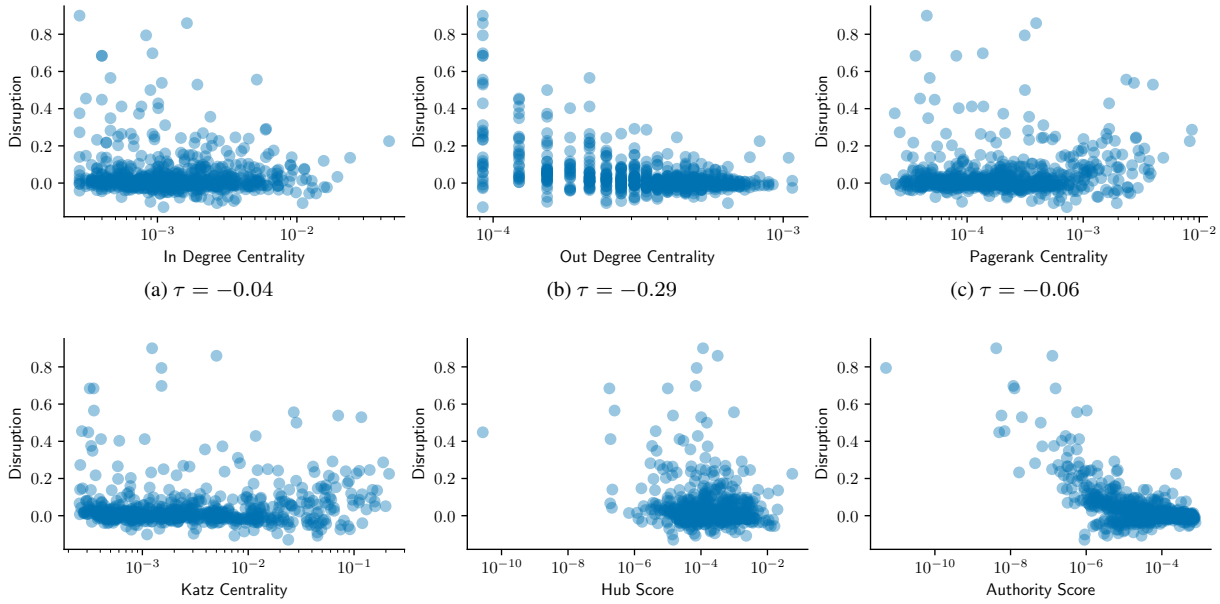
The most influential artist in this list is John Cage, a highly inventive composer who, according to AllMusic, has influenced generations of composers, writers, dancers, and visual artists. Figure 6 shows how the three classical composers cataloged as influences of John Cage are not influences of many of his followers.

On the opposite side of the spectrum of disruption, Table 3 lists the 15 most consolidating artists, according to D. There is a predominance of jazz artists, who are 6 of the ten most consolidating artists. Jazz instrumentalists and singers whose career started after the 1930s are often characterized by our method as consolidators building on a stream of shared influences. These artists share a set of influences with many others. Figure 7 illustrates one such case for the jazz drummer Philly Joe Jones, who shares the influences of Art Blakey and Max Roach with a large number of other jazz drummers, including most subsequent work. Geto Boys and Augustus Pablo have a similar neighborhood structure in the Rap and Reggae genres.



(a) $\tau = -0.04$ (b) $\tau = -0.29$ (c) $\tau = -0.06$

(d) $\tau = -0.01$ (e) $\tau = -0.11$ (f) $\tau = -0.36$

Figure 8: Correlation of Disruption with six node importance measures.

Overall, the examination of artists identified as most and least destabilizing points to the expressiveness of this method. This approach highlights artists who have not necessarily influenced a large number of other artists, so this information is not readily available based on a direct quantification of impact. Moreover, our face validity analysis promptly links high valuations of disruptiveness with widely known stories of innovation. Most interestingly, these stories are diverse in their geography, genre, and epoch, even if mined from a considerably biased dataset.

5. DISRUPTION VS CENTRALITY

We now investigate to what degree the disruption scores provides information that is not already available through other metrics of network topology. To do so, we measure six different node importance scores using our full graph: the Indegree Centrality (normalized indegree), Outdegree Centrality (normalized outdegree), Pagerank [14], Katz [8] Centrality, Hub Scores [10], and Authority Scores [10].

We correlated each score with the disruption index of artists. Figure 8 presents the relation of each score with D together with Kendall's rank correlation (τ) for each case. We resort to Kendall's coefficient, τ, as it addresses ties (e.g., nodes with the same in degree) and is able to uncover both linear as well as non-linear relationships [9].

The patterns in the figure and τ scores point that most metrics do not correlate with disruptiveness. The only cases were moderate negative correlations were uncovered were: Out degree centrality ($\tau = -0.29$) and Authority score ($\tau = -0.36$). A small negative relation also exists for Hub scores ($\tau = -0.11$). Nevertheless, these scores are moderate at best. Such a result is relevant, as it shows that disruptiveness values are not easy to recover using standard node scores from complex networks.

In summary, our results in this section combined with our discussion in the previous section, point to the relevance of measuring disruptiveness. The D index unveils insightful patterns on the AllMusic corpus that are not trivially explained by other network centrality scores.

6. DISCUSSION AND FUTURE WORK

In this paper, we present the first in-depth analysis of disruption in a music corpus. More importantly, we argue in favor of a Bayesian disruption index. While our analysis is limited to a dataset, the approach we here discuss is general enough to be used in other settings. In particular, we note data analysts may tune choices of hyper-parameters to their prior-beliefs for different datasets.

Our contributions bring two main implications. First, our examination of the validity of the disruption index suggests it can be applied to music corpora. Second, our analysis of disruptive artists in the AllMusic guide shows new information about artists in this guide that may be taken into account in musicological analyses.

At the same time, both of these directions call for relevant future work. In particular, further validation of the disruption index with other contexts seems very relevant, to understand its applicability to other musical traditions or to networks formed by albums or songs, for example. In complement to this direction, musicological analyses that use disruption to provide deeper insight leveraging this data is necessary to further validate the usefulness of the approach we here presented.

Reproducibility: We point out that our source code for data collection, analysis and for the figures and tables in this paper, as well as the dataset used, is available at: `http://github.com/flaviovdf/allmusic-disruption`.

ABSTRACT

Prevalent efforts have been put in automatically inferring genres of musical items. Yet, the propose solutions often rely on simplifications and fail to address the diversity and subjectivity of music genres. Accounting for these has, though, many benefits for aligning knowledge sources, integrating data and enriching musical items with tags. Here, we choose a new angle for the genre study by seeking to predict what would be the genres of musical items in a target tag system, knowing the genres assigned to them within source tag systems. We call this a translation task and identify three cases: 1) no common annotated corpus between source and target tag systems exists, 2) such a large corpus exists, 3) only few common annotations exist. We propose the related solutions: a knowledge-based translation modeled as taxonomy mapping, a statistical translation modeled with maximum likelihood logistic regression; a hybrid translation modeled with maximum a posteriori logistic regression with priors given by the knowledge-based translation. During evaluation, the solutions fit well the identified cases and the hybrid translation is systematically the most effective w.r.t. multilabel classification metrics. This is a first attempt to unify genre tag systems by leveraging both representation and interpretation diversity.

1. INTRODUCTION

Music genres have been long studied as semantic dimensions of artists and tracks [8]. Rooted in musicology, music experts have mainly undertaken this endeavour. With digitization of music and prevalence of Internet music consumption, online communities have also shown increasing interest in annotating musical items with genres (e.g. creating folksonomies such as Lastfm). In addition, crowdsourced, web-based encyclopedias that describe and structure music-related knowledge including genres, have been created and openly disseminated [4, 37, 41].

Apart from ontologically describing musical items, genres are also among the most common attributes of tracks, albums and artists to which the users of music streaming services relate [21]. Users resort to genres to discover music, create playlists, define their profiles, foster interactions with other users, etc. Hence, being able to correctly infer music genres as metadata is central to such tasks.

Music genre is a challenging concept to model and highly subjective. Past studies [11, 18, 33, 36] convey how difficult it is to agree upon shared definitions and interpretations, even for popular genres. People interpret genres differently, influenced by their culture, personal preferences or acquired musicological knowledge [11, 18, 33]. Genre representations within tag systems vary [31] with respect to: the level of detail (how specialized genres can get); the coverage (which genres are considered); the genre interpretation (*pop/rock* could be distinctly defined and interpreted across sources); how genres are related (*blues rock* is a subgenre of *rock*, but not of *blues* in the MuMu dataset [16, 22]). Divergences also result from the spelling variability (e.g. *alternative rock* vs. *alt. rock*).

The research question we address in this work is: given annotations with genre tag systems of multiple sources, how to infer the equivalent annotations within a target tag system? We refer to this as a translation task, but we do not necessarily seek to translate tags between languages.

When relying only on the definition of the sources and target tag systems, this task could be solved using taxonomy mapping [27, 29]. A taxonomy is a classification schema with concepts organized from general to specialized. The goal of taxonomy mapping is to align the concepts of the source and target taxonomies. Related works integrate commercial catalogues [24,29], align multi-lingual taxonomies [34,35,43] or restructure existing taxonomies [26,27,38] in supervised or unsupervised manners. Ontology mapping [23] is a similar task, in which additional relation properties and axioms can be exploited.

A solution focused on taxonomy mapping is nonetheless incomplete as it does not consider the application of the taxonomies in practice, which could reveal divergences in genre interpretation. Thus, we hypothesize that a robust translation is built not only on the definitions of genre tag systems, but also on their use for annotations. In accordance with the terminology of the Automatic Machine Translation domain [9], we call a corpus of items jointly annotated by multiple sources a parallel corpus.

The contribution of the current work is a translation system that effectively leverages knowledge-based and statistical methods for genre translation in three cases:

1. A cold-start case, when genre tag systems of the target

and sources are known, but there is no parallel corpus. We address this case with a Knowledge-Based (KB) system based on taxonomy mapping (Section 3).

2. Many parallel annotations are available allowing to learn mappings between genre interpretations (e.g. when some sources use *alternative rock* the target tends to use *alt. rock* and *indie rock*). To deal with this case, we use a simple linear multilabel classifier, namely a logistic regression model trained with Maximum Likelihood (ML) (Section 4.1).
3. The case in-between when less annotations are available and some target tags may be missing in the parallel corpus. We tackle this scenario with an hybrid Bayesian approach that leverages the KB translation as a prior for the logistic regression model trained with Maximum A Posteriori (MAP). This case, presented in Section 4.2, is the most general. Finding an effective solution for it has multiple positive implications for practice.

We release the code of these methods for reproducibility [1] .

The Music Information Retrieval (MIR) community has extensively studied the automatic genre annotation of musical items by exploiting the content (e.g. audio, lyrics) [10, 16, 22]. Other genre representations, tackled in [2, 20, 31, 41], create genre graphs from multiple knowledge sources. Yet, to our knowledge, there is no past work translating music genres from one tag system to another (e.g. from Discogs to Wikipedia) by leveraging the diversity of both genre representations and interpretations.

We resort to item annotation to assess the proposed translation methods. To reflect a real-life context [7], we consider a musical item annotated with multiple source tag systems; having multiple labels and not only broad genres such as *rock*, but also very detailed subgenres, which results in predicting among hundreds of possibilities. Lastly, combining multiple tag predictors in a Bayesian framework was done before [10, 39]. However, these works aggregate information from different predictors in the same tag system while we consider several tag systems.

2. NOTATIONS AND PROBLEM FORMULATION

In this work, we denote matrices by bold capital letters, $\mathbf{M}$; vectors by bold lower case letters, $\mathbf{v}$; the n-th row vector of matrix $\mathbf{M}$ by $\mathbf{m}_n$; scalars by italic lower case letters, x; the coefficient at row i and column j of matrix $\mathbf{M}$ by m_{ij}; the i-th element of vector $\mathbf{v}$ by v_i. Calligraphic font is used for sets of sets (e.g. $\mathcal{S}$) and capital letters for sets (e.g. S).

Let $\mathcal{D}$ be a set of tag systems, $\mathcal{S}$ a subset of $\mathcal{D}$, henceforth referred to as source tag systems, and $T \in \mathcal{D}, T \notin \mathcal{S}$ henceforth referred to as a target tag system. Further, we refer to a tag system as a tag set, but we stress that it may contain broader information such as relations between genres (e.g. taxonomies or ontologies). The research problem we address is: given $\mathcal{S}, T$ and a set of tag annotations (e.g. associated with a given musical item) taken from $\mathcal{S}$, what would have been the corresponding tag annotations if the tags had been taken from T. We note $S = \cup_{E \in \mathcal{S}} E$ the union of the source tag systems, and $|S|$ its cardinality.

The approach we adopt consists in defining a translation scoring function $f : \mathcal{P}(S) \rightarrow \mathbb{R}^{|T|}$, where $\mathcal{P}$ denotes partitions over S, that predicts translation scores for every target tag from a set of source tags. Estimating such a scoring function is a standard setting for multilabel classification.

3. KNOWLEDGE-BASED GENRE TRANSLATION

We propose a translation method based on multiple genre taxonomies brought together under a genre graph. Section 3.1 introduces the graph types of concepts and relations and presents the genre taxonomies. In Section 3.2, we show how we create the links between the genre taxonomies using advanced normalization and tokenization. In Section 3.3, we define the translation scoring function f by exploiting the genre graph structure and its relations.

3.1 Building a knowledge-based genre graph

We automatically derive an undirected genre graph by aggregating multiple genre tag systems (e.g. taxonomies, ontologies or social tags), created by either experts or non-experts as in [2, 20, 31, 34]. Its modular design allows to easily integrate new sources through a normalization pipeline that addresses much more variability of genre strings than the existing works [30, 41] (presented in Section 3.2). The knowledge sources used to build the current version of the genre graph are: DBpedia (English, 12443 genres), and Lastfm (327 genres), Tagtraum (296 genres) and Discogs (296 genres)–the taxonomies released in the 2018 MediaVal AcousticBrainz Genre Task [7]. The Discogs genre taxonomy is pre-defined by experts. The Lastfm and Tagtraum genre taxonomies are automatically inferred from social tags with the approach proposed by Schreiber [30], followed by a manual processing [7].

The types of relations between genres vary across sources. In DBpedia, the retrieved types for each genre are: subgenres, origins, aliases–various spellings of the same genre, and derivatives–genres which are influenced by this genre, but could not be considered subgenres. The other knowledge sources contain only subgenre relations.

Each genre tag system becomes a graph by adding a source node that connects all the genre tags as in Figure 1. Then, to connect these decentralized graphs, a normalized graph is produced from all available tags. Each original tag is connected to its normalized form in the normalized graph. The description of how we normalize genres and create the normalized graph is continued in Section 3.2.

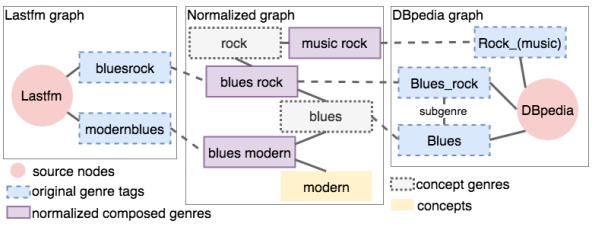

Figure 1: Genre graph extract. Dashed edges link the original genre tags to their normalized versions.

[1] https://github.com/deezer/MusicGenreTranslation

3.2 Normalizing genre tags

We create a more robust normalization pipeline compared to the related works [29,30,35,41] that, apart from basic tokenization and normalization, also separates words written together (e.g. *poprock* in *pop* and *rock*). The basic tokenization splits tags by non-alphanumeric characters (e.g. "-", "_"). The basic normalization converts tags to lower case and brings tags containing "&", "+" and "'n'" to the same form (e.g. *d+b*, *drum'n'bass* and *drum and bass*).

For the advanced tokenization, we use a modified trie [12] and a probabilistic tokenization built on Wikipedia unigrams [3]. A trie is a tree data structure that efficiently stores and retrieves strings. Each node has a char and a flag to mark if the path from the root to it forms a word. We modify the way we populate the trie as follows. At first, we sort the tokens obtained from the basic tokenization and normalization, ascendingly by length. Then, we add the tokens of DBpedia with less than l letters directly to the trie [2] . For the others, we attempt to split them using the trie and only the unknown words are added to the trie.

The tokenization using the trie is a recursive greedy algorithm that aims at matching the longest possible words in the trie. If a recursion fails, we explore the path with the next best previous word instead. If we assess the split output as incorrect, meaning that it results in too many short words, in short suffixes, or fails to split a large tag, then we use the probabilistic tokenization.

The probabilistic tokenization uses dynamic programming to find the words best maximizing their probability product. The frequency of each word, assuming that they are independently distributed, is approximated using the Zipf's law [44] to $\frac{1}{nlog(N)}$, where n is the word rank [42] and N is the total number of Wikipedia unigrams. We again assess the split output. Some extra conditions are added besides those presented in the previous paragraph: a Wikipedia split is incorrect if there are single letters as middle words and if no word is already contained in the trie [3] . If this tokenzation fails, we add the token as it is.

Finally, we transform the obtained tokens in nodes in the normalized graph (see Figure 1). There are three types of nodes: 1) normalized composed genres (e.g. *altern rock*, *deep house*), 2) concepts which are words that do not represent genres but are part of the name of multiple genres (e.g. *nu* in *nu jazz* and *nu metal*); 3) concept genres which are standalone genres but can be also part of composed genres (e.g. *punk* in *post punk*). If a genre is tokenized, its tokens are sorted and concatenated becoming a composed genre node as in [30] (e.g. *music rock* in Figure 1). This node is then connected to its concept and concept genre nodes.

3.3 Translating Genres through DBpedia Mapping

Using intermediate mapping spaces such as taxonomies or pivot languages has been explored in past works to match multi-lingual [35, 43], multi-cultural [27] or e-commerce [26, 29] taxonomies. Similar to [27], we use DBpedia, an ontology derived from Wikipedia infoboxes [19] as it has the highest genre coverage and quite high quality. However, to map a genre to DBpedia genres, we avoid using string similarity as it can be very noisy (e.g. *pop* vs. *bop*). Instead, we leverage genre knowledge to create a mapping strategy as we further present. Most related works rely on the structure of taxonomies for mapping the source and target concepts [24,27,29,35,43]. Our solution uses structural information too, but differently. Specifically, we use the neighbours of the source and target concepts and the structure of the directed DBpedia graph.

We map each genre of the source and target tag system, to the genres of the DBpedia ontology: $B \in \mathcal{D}$. We assume $B \notin \mathcal{S}$ and $B \neq T$. For each input tag system D, with $D \in \mathcal{S}$ or $D = T$, the output of the mapping is a matrix $\mathbf{Z}^D \in \mathbb{R}^{|D|\times|B|}$, where each row represents the relatedness of a genre tag from D to the DBpedia genres. We compute the mapping matrix $\mathbf{Z}^D$ by applying the following steps for each tag $s \in D$:

1. Normalize s with the process described in Section 3.2 (*e.g. Rock/Pop* becomes *pop rock*).
2. Check if the normalized s equals any normalized genre of B. If true, all entries in $\mathbf{Z}_D$ linked to the DBpedia aliases of the found genres are set to 1 and all others to 0 (e.g. *acid house* is mapped to *Acid_house*, with aliases *Acid_(electronic_music)*, *Warehouse_music*, etc.).
3. If the normalized s is not in B, then map it using its context genres in D: compound s with each parent tag in D and check if the normalized compounded tag equals any normalized genre of B (inspired from [43]). If true, proceed as in Step 1. (e.g. *stoner* has parent *rock* in Lastfm; search by *rock stoner* and map it to *Stoner_rock*).
4. If Steps 2 and 3 are unsuccessful, consider two cases:
   (a) s is a concept genre as defined in Section 3.2. First, retrieve the DBpedia directed subgraph composed of the nodes which contain the normalized s as a substring in their normalized form. Second, map s to the nodes with the highest in-degree centrality [5] in this subgraph. The intuition is that concept genre nodes are more likely fundamental music genres; hence they tend to have many subgenres or related genres. Third, assign to the selected DBpedia genres and their aliases a score of 1 divided by the number of selected nodes, and to the others 0 (e.g. *rock* does not exist as is in DBpedia. To map it, we retrieve all tags that contain it such as *Punk_rock*, *Art_rock*, *Rock_music*, etc. We observe that *Rock_music* is the most connected node in the subgraph with the genres containing *rock*. As only one node is selected, we assign to it and its aliases a score of 1).
   (b) s is a composed genre as defined in Section 3.2. First, select from the normalized genres in B those that share the greatest number of words with s. Second, select from this list, the genres with the highest number of shared concept genres–if it is 0, then the initial selection is kept unchanged. Third, assign scores as in Step 4(a).

[2] DBpedia seeds the trie as it has the highest coverage and we set l=7.

[3] As we already added to the trie short genre and concept tags from multiple sources, we assume the probability of all words to be new is low.

5. For each genre in B associated to s in Steps 1–4, propagate half of the value of its score to its neighbors in B. The intuition is that parent genres or subgenres could be relevant and sometimes specified by other sources.

For each s not mapped in the previous process, we compute its scores by averaging the rows in $\mathbf{Z}^D$ of its related genres in the input taxonomy D (e.g. for *aor* which is not found in DBpedia, we compute the scores by assigning it the scores obtained for *rock*, its parent genre in Discogs). Finally, the relatedness of a source genre $s \in S$ and a target $t \in T$ is computed using cosine similarity between their corresponding rows $\mathbf{s} = \mathbf{z}_s^S$ and $\mathbf{t} = \mathbf{z}_t^T$ in the mapping matrices, $\mathbf{Z}^S$ and $\mathbf{Z}^T$. We define $\mathbf{W}^{KB} \in \mathbb{R}^{|T|\times|S|}$ such that $w_{ts}^{KB} = \frac{\mathbf{s}^T\mathbf{t}}{||\mathbf{s}||_2||\mathbf{t}||_2}$. The translation scoring function is:

$$f_t(\{s_1, s_2, \ldots, s_K\}) = \sum_{k=1}^{K} w_{ts_k}^{KB} = \mathbf{x}^T \mathbf{w}_t^{KB}, \quad (1)$$

where $\mathbf{x}$ is the binary encoded vector of $\{s_1, \ldots, s_K\}$.

4. DATA-INFORMED GENRE TRANSLATION

In this section, we consider that a parallel corpus is available and present two statistical approaches: ML that relies only on annotations (Section 4.1), and MAP that leverages the KB results as a prior knowledge (Section 4.2).

4.1 Maximum Likelihood logistic regression

In statistical approaches to the tag translation task, we seek to train a parametric mapping to model the probability $P(\mathbf{y}|\mathbf{x})$ of having a collection of target tags (encoded as a binary vector $\mathbf{y} \in \{0,1\}^{|T|}$) given the source tags (encoded as a binary vector $\mathbf{x} \in \{0,1\}^{|S|}$). We assume the independence of the target tags, and only seek to model the conditional probabilities $P(y_t|\mathbf{x})$. This comes down to training $|T|$ binary classifiers, also known as binary relevance. There are more elaborated settings for doing multilabel classification without the target tag independence assumption. We notably also tested classifiers chain [28], but it did not result in significant improvement over the results presented in Section 5.3, while increasing the system complexity. We propose to implement binary relevance with logistic regression [40]. Logistic regression models the probability of having the t-th target tag y_t given the source tags $\mathbf{x}$ and the parameters of the logistic regression $\theta = \{\mathbf{W}, \mathbf{b}\}$, $\mathbf{W} \in \mathbb{R}^{|T|\times|S|}$ $\mathbf{b} \in \mathbb{R}^{|T|}$; as:

$$P(y_t = 1|\mathbf{x}, \theta) = \sigma(\mathbf{w}_t^T\mathbf{x} + b_t) \quad (2)$$

where $\sigma(x) = \frac{1}{1+\exp(-x)}$. $\mathbf{W}$ is called the weights matrix and $\mathbf{b}$ the bias. Note that, for the statistical approaches, the scoring function f introduced in Section 2 is defined here as $f(\{s_1, s_2, \ldots, s_K\}) = \big(P(y_1 = 1|\mathbf{x}, \theta), \ldots, P(y_{|T|} = 1|\mathbf{x}, \theta)\big)$. To train a logistic regression model we maximize the log-likelihood of the targets, given the source tags, w.r.t. the parameters θ:

$$\mathcal{L} = \log P(\mathbf{Y}|\mathbf{X}; \theta) = \sum_{n=1}^{N} \mathbf{y}_n^T \log(\sigma(\mathbf{W}\mathbf{x}_n + \mathbf{b})) + (\mathbf{1} - \mathbf{y}_n)^T \log(\mathbf{1} - \sigma(\mathbf{W}\mathbf{x}_n + \mathbf{b})) \quad (3)$$

where N is the size of the parallel corpus; $\mathbf{X} = [\mathbf{x}_1, ..., \mathbf{x}_N]^T \in \{0,1\}^{N\times|S|}$; and $\mathbf{Y} = [\mathbf{y}_1, ..., \mathbf{y}_N]^T \in \{0,1\}^{N\times|T|}$. In practice the regularization term $\frac{1}{2}||\mathbf{W}||_F^2$ is added to $\mathcal{L}$ in the objective, where $||\cdot||_F$ denotes the Frobenius norm on matrices, to limit overfitting.

4.2 A unified translation model

While ML logistic regression can be expected to work well with large amounts of parallel annotations, they will not adapt well to settings where no or little parallel data is available. In a real-life scenario, the size of the parallel corpus can range from zero to tens of thousands of samples, which precludes systematically favoring one or the other. Defining a criterion for when to switch from KB to statistical translation is arduous since this criterion would depend on the number of source and target tags as well as on their distribution. Ideally, we would like to have knowledge-based performances when no parallel data is available, and a smooth way to transition towards more data-abundant settings. This leads us to consider the translation table $\mathbf{W}^{KB}$ given by the KB system as a prior in a Bayesian framework, using the MAP [6] objective. Instead of maximizing the likelihood of the target tags, given source tags and parameters, we maximize the posterior probability of the parameters given the source and target tags:

$$P(\theta|\mathbf{x}, \mathbf{y}) \propto P(\mathbf{y}|\mathbf{x}; \theta)P(\theta|\mathbf{x}) = P(\mathbf{y}|\mathbf{x}; \theta)P(\theta). \quad (4)$$

By assuming, for each target tag t a normal distribution for $\mathbf{w}_t$ centered around $\mathbf{w}_t^{KB}$ with a precision matrix $\mathbf{\Lambda} = \lambda^2\mathbf{I}$ (λ is independent of t), we can write the logarithm of the prior distribution as:

$$\log(P(\theta)) = \frac{\lambda^2}{2}||\mathbf{W} - \mathbf{W}^{KB}||^2 + \text{cte}. \quad (5)$$

We also consider a centered Gaussian prior on the bias (corresponding to a l^2 regularization). We then define:

$$\mathcal{L}_{\text{prior}} = \frac{\lambda^2}{2}||\mathbf{W} - \mathbf{W}^{KB}||^2 + \nu||\mathbf{b}||^2. \quad (6)$$

Using (3), (4) and (6), the final MAP objective becomes $\mathcal{L}_{\text{MAP}} = \mathcal{L} + \mathcal{L}_{\text{prior}}$, where the first term is the loss of Eqn (3), and the second can be seen as a regularization term on the weight matrix $\mathbf{W}$ that penalizes its straying away from the priors. $\mathcal{L}$ depends on the number of training samples, while $\mathcal{L}_{\text{prior}}$ does not. Therefore, $\mathcal{L}$ becomes the predominant term in the loss as the size of the training data grows, leading to an objective function very close to the one of the logistic regression of Section 4.1. Conversely, when little data is available, we can expect the performances to be close or better than those of the KB system.

When a large parallel corpus is available, we can choose λ with grid search on a validation set. This is computationally expensive, and does not adapt well when the parallel corpus is small. For the sake of adaptability, we hereby propose a principled way inspired by [15] to choose λ, that does not require a lot of data while achieving top results. The rationale builds on the limited effective range of the logistic regression parameters. A shift of 5 of w_{ts} in the logit scale can move the probability associated with the target tag t from 0.5 to 0.99 or from 0.01 to 0.5. Hence, we would tend to choose λ in such a way that bigger shifts in the predicted probability of the target tag, which is the result of the added shifts for each annotated source tag, are unlikely. If we note $\bar{N}_S$ the average number of source tags per sample (which can be estimated with a few samples), this would mean restricting the coefficients w_{ts} from shifting by more than $\frac{5}{\bar{N}_S}$. For a normal variable $X \sim \mathcal{N}(\mu, \frac{1}{\lambda})$ we have $P(X \in [\mu - \frac{2}{\sqrt{\lambda}}, \mu + \frac{2}{\sqrt{\lambda}}]) \approx 95\%$, we therefore propose to choose precision λ such that:

$$\frac{2}{\sqrt{\lambda}} \approx \frac{5}{\bar{N}_S} \tag{7}$$

5. EXPERIMENTS

We report the performances of the proposed models on a recording-based tag translation task. This also serves as an indirect evaluation of the DBpedia mapping, which, in a work dedicated to taxonomy mapping, could have been assessed by experts. Due to its novelty, we do not benchmark our work against other genre-related research from MIR.

5.1 Dataset

The dataset used in the experiments was created from the dataset used in the 2018 AcousticBrainz Genre Task, part of the MediaEval benchmarking initiative [7]. The dataset in its original form was aimed at testing the automatic genre annotation from content-based features of musical items in a more challenging setup compared to past works. For each item, annotations from different sources were available, each source taxonomy was much more detailed with hundreds of genres-subgenres, and the overall task was modeled as a multi-label classification. The sources were already introduced in Section 3.1. We further describe how the provided dataset was created. In Discogs, the release annotation was propagated to tracks. In Lastfm and Tagtraum, each track was annotated with music genres and subgenres from the derived taxonomies [7]. We present an overview of the dataset in Table 1.

Dataset	Discogs	Lastfm	Tagtraum
Annotation type	Expert	User	User
Items	1,098,337	686,979	589,584
Number genres	315	327	296

Table 1: Description of the dataset [7].

Although the data was already split between development, validation and test [7], we brought several modifications to accommodate the translation task. We created a large dataset comprising the original development and validation data. In order to assess a notion of confidence on the computed metrics, we resorted to K-Fold cross validation [14]. For each possible target, we splitted the data in 4 folds using stratified sampling. First, we filtered out the items which were not annotated in the target tag system. Then, we used an altered version of the iterative stratification algorithm in [32] in order to ensure that the proportion of items for each target label was roughly the same across folds. Following [13], we added the constraint that items belonging to the same artist had to be assigned to the same fold. For that, we used MusicBrainz artist ids retrieved from the recording ids provided in the MediaEval data.

5.2 Evaluation setup

The presented models output a score for each target tag that relates to the confidence of this tag being used in the target annotation. We evaluated these outputs with a ranking metric called Area Under the receiver operating characteristic Curve (AUC), as commonly done in multilabel classification [22]. The (*macro*) averaging is over target tags and measures the ability of the system to rank higher a positive tag than a negative one. Specifically, shifting the values in a column by the same factor (or changing the values of $\mathbf{b}$ in the logistic regression) does not change the AUC macro score, being in that sense, unaffected by item popularity.

We evaluated the logistic regression models on each fold and trained on the three others. We uniformly subsampled the training data to simulate low data availability and chose subsampling factors as powers of 2 between 2^{-13} and 1. Consequently, for the smallest subsampling factors, some source and target tags may not be present in the training data. We used scikit-learn [25] implementation for ML logistic regression, with L-BFGS as the solver. We wrote a Tensorflow [1] implementation of MAP logistic regression. The Adam optimizer [17] was used, with a learning rate of 0.5. We trained the model for 500 epochs with batches of size 100000 or with the full training set if there were less samples. λ was chosen using Eqn 7.

5.3 Results

Figure 2 illustrates how the ML translation eventually outperforms the KB model when enough data is available, while the latter performs much better when little data is available. The MAP translation successfully builds on the KB translation to yield the best results across the whole data availability spectrum. A simple baseline based on tag Levenshtein distance is also shown. Using only a source instead of two (e.g. only Lastfm) led to the same kind of behavior. While we currently proposed one method to obtain the KB translation table, we could also imagine it replaced by an expert-created one, if desired.

The fact that the MAP logistic regression performs consistently well on all the translation tasks is favorable evidence towards the choice of λ given in Eqn 7 as a good default, which we also confirmed using a grid search. Furthermore, we see that the MAP logistic regression lever-

(b) Translation from Discogs and Tagtraum to Lastfm

Figure 2: AUC scores for the three models per amount of training samples (log-scale). The width of the area around the lines marks the standard deviation computed on folds. KB yields a constant value as it is data-independent.

ages even low amounts of training data to improve over the KB model, and even more so when applying regularization on the bias. We further explain this effect by analyzing how the AUC scores compare on a per-tag basis.

Figure 2 shows that MAP logistic regression with bias regularization can achieve better AUC scores than the KB translation, even on target tags absent during training. We argue that this is due to the regularization term on the bias that enables to learn negative correlations between tags. When no bias regularization is used, the optimal set of parameters for a tag t missing from the training data is: $(\mathbf{w}_t^\star, b_t^\star) = (\mathbf{w}_t^{\text{KB}}, -\infty)$. Indeed, we see in Figure 3 that the MAP results are very close to those of the KB model. This is not true anymore with bias regularization. The gradient of the cost function w.r.t. $\mathbf{w}_t$ can be written as:

$$\frac{\partial \mathcal{L}_{\text{MAP}}}{\partial \mathbf{w}_t} = [\hat{s}\sigma(w_{ts} + b_t) + \lambda^2(w_{ts} - w_{ts}^{\text{KB}})]_{1 \leq s \leq |\mathcal{S}|} \quad (8)$$

where $\hat{s}$ is the number of times (possibly 0) the source tag s appears in the training set. We therefore see that as w_{ts} gets closer to w_{ts}^{KB}, the term $\hat{s}\sigma(w_{ts} + b_t)$ will start to outweigh the second. Applying a gradient step will tend to decrease w_{ts}, away from w_{ts}^{KB}, and even more so when $\hat{s}$ is large (popular tags) and b_t is close to 0 (controlled by the regularization term), hence the negative correlation.

Finally, it is worthwhile to mention that the AUC metric relies on occurrences and is thus arguably biased towards statistical methods. We end this section by taking a qualitative look at how statistics modified the similarities between source and target tags, in particular for those with

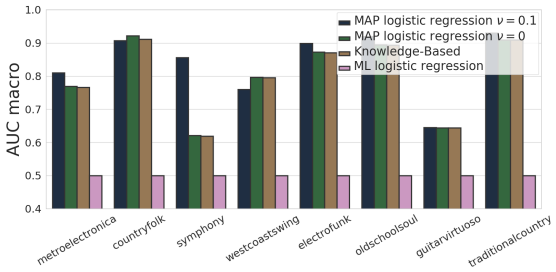

Figure 3: AUC scores for tags that were not in the training set, subsampled by a factor of 2^{-12} with Lastfm as target.

very different KB and ML AUC scores. These differences fall under four explanations:

- Annotation noise: Statistical models learn a very high similarity between the Discogs tag *italo-disco* and the Lastfm tag *classicalbritishheavymetal*. Both indeed often co-occur in the data, but are ontologically unrelated.
- The target tag does not have a suitable equivalent in the source taxonomies. Some Latin and Caribbean music genres like *cumbia*, *fado*, *rocksteady* or *forró* are present in Discogs but are not in Lastfm or Tagtraum. Thus, the mapping to DBpedia, described in Section 3.3, fails.
- The considered tag is highly ambiguous. Take the example of the tag *classical*. Besides the identical counterparts, knowledge-based translation tables also indicates relatedness to some subgenres of *jazz*. However, the specific translation task on which we evaluate appears to be more biased towards an understanding of *classical* that relates to subgenres of *metal* and *electronic* music (*symphonicmetal*, *germanmetal*, *postmodernelectronicpop*).
- The existing genre representations are incomplete or noisy. For instance, *baroque* has a counterpart in each taxonomy, but no direct link with *classical* in DBpedia. Statistical models find high correlation in the data between those two tags and so achieve better AUC scores.

6. CONCLUSION

In this work, we investigated the translation of tags from various source tag systems to a common target tag system. We show that the availability of large amounts of data advantages statistical methods over the knowledge-based one in terms of multilabel classification metrics. Moreover, the proposed hybrid method consistently outperforms both other methods on the whole range of data availability.

Although we did not address multi-language tag systems, both the knowledge-based approach that uses a mapping through the multilingual DBpedia, and the data-informed approach that only takes advantages of parallel annotations and is then insensitive to language, should be able to handle it. As future work, we aim to gather multilingual music genre datasets in order to confirm this claim. We also aim to exploit more thoroughly the genre graph we created by adding more knowledge sources and generating genre representations as node embeddings. We also consider modelling the tag annotation noise, such as missing or spurious tags, or tag bombing, in order to filter it out.

GENERATING STRUCTURED DRUM PATTERN USING VARIATIONAL AUTOENCODER AND SELF-SIMILARITY MATRIX

ABSTRACT

Drum pattern generation is a task that focuses on the rhythmic aspect of music and aims at generating percussive sequences. With the advancement of machine learning techniques, several models have been proven useful in producing compelling results. However, one of the main challenges is to generate structurally cohesive sequences. In this study, a drum pattern generation model based on Variational Autoencoders (VAEs) is presented; Specifically, the proposed model is built to generate symbolic drum patterns given an accompaniment that consists of melodic sequences. A self-similarity matrix (SSM) is incorporated in the process for encapsulating structural information. Both the objective evaluation and the subjective listening test highlight the model's capability of creating musically meaningful transitions on structural boundaries.

1. INTRODUCTION

Music generation has become an increasingly popular research field as machine learning techniques continue to thrive [3]. Generating symbolic music sequences using variants of deep neural networks (DNNs) has shown promising results with various degrees of success [6, 9, 10, 19, 22]. In the meantime, drum pattern generation, a subtask that mainly concerns the creation of drum sequences, receives relatively less attention. While some models designed for melodic sequences could be applied to drums directly [6, 19], techniques developed specifically for drum patterns are still in need of further exploration.

In Western music genres such as rock, pop, and jazz, drums usually provide the rhythmic support to melodic instruments and reflect the structure of a song. For instance, drum patterns within the same section (e.g., verse) are typically derived from the same rhythmic motif, and new patterns such as drum fills would appear around the structural boundaries (e.g., from verse to chorus). In other words, drum patterns not only enhance the rhythmic progression, but also facilitate the structural segmentation. Additionally, in order to achieve the rhythmic coherence, drum patterns tend to correlate with other instruments (e.g., rhythmic guitar and bass guitar). These particularities suggest that the structural and rhythmic information from other instruments is crucial for designing reasonable drum patterns.

To build a model that accounts for the above considerations, we explore the idea of using a self-similarity matrix (SSM) as an intermediate structural representation for drum pattern generation. Particularly, we utilize a Variational Autoencoder Generative Adversarial Network (VAE-GAN) to predict the corresponding drum SSM given the SSM of polyphonic mixture of melodic instruments. Subsequently, another VAE-based model generates MIDI drum tracks based on the predicted drum SSM. The contributions of this work include:

(i) a new way of incorporating structural information in the context of drum pattern generation,

(ii) a novel bar selection mechanism that encourages self-repetition in similar sections, and

(iii) the insights into the model's capability of handling transitions between structural sections.

2. RELATED WORK

Drum pattern generation involves the creation of rhythmic patterns with all types of drums; it is an important subtask in conditional music generation problems such as multitrack and lead sheet generation [6, 14]. According to the input and output representation, drum pattern generation models can be roughly divided into (i) symbolic-domain and (ii) audio-domain models.

Systems operating in symbolic-domain work exclusively on discretized representations such as MIDI, a format that allows systems to concentrate on essential information at the semantic level. The majority of prior studies falls into this category. Some of the early systems adopt Genetic Algorithms (GA) to create variants of rhythmic patterns [2, 8, 11, 15] and explore new patterns through a simulated evolution process. However, designing an effective fitness function is non-trivial and relies heavily on the

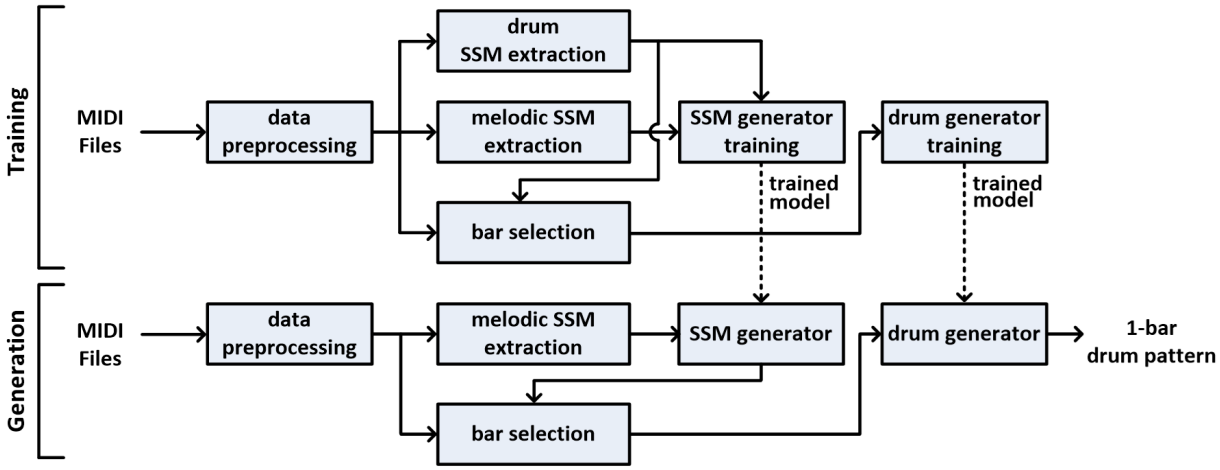

Figure 1. Block diagram of the proposed drum pattern generation system.

domain knowledge. In addition to GA, probabilistic models [16] and deep learning-based models [1,7,14] have also been proposed; these methods generally avoid predefined rules and learn from the data directly, but their performance and generality would vary depending on the data source.

Systems operating in the audio domain directly deal with continuous signals such as waveform. This type of systems usually has a higher degree of freedom in terms of the output. Training such systems requires a set of audio signals with manual annotations. To automate the annotation process, Automatic Drum Transcription (ADT) [21], another on-going research topic, would be a necessary intermediate step. As a result, prior studies in this category are relative scarce. Donahue *et al.* proposed to use generative adversarial network (GAN) for creating audio such as electronic drum beats [5], yet still, the current resulting pieces are short clips without long-term structure.

In this paper, we build our system in both audio and symbolic domains. By utilizing the audio data synthesized from the symbolic representation, we take advantage of a large collection of symbolic data and reserve the possibility of future extension to audio domain. To narrow down the scope of this task, we focus on generating drum patterns in Western music genres with a standard drum kit (e.g., Hihat, Snare Drum, Kick Drum, Toms, etc.). Inspired by previous studies on structural analysis [17] and self-similarity constraint for music generation [13], we use SSM to encapsulate the structural information and investigate its potential impacts on the generated sequences. More details are elaborated in the following sections.

3. METHOD

Figure 1 illustrates the flowchart of the proposed drum pattern generation system. We focus on generating drum patterns given a song as a conditional input. The goal of this conditional generation is to generate drum patterns that are both rhythmically and structurally compatible to the given song. To facilitate the preservation of global structure, we propose a system consisting of two generative models, namely, the SSM generator and the drum pattern generator. In the training phase, the MIDI file is separated into the drum track and the melodic track, followed by the calculation of their corresponding SSMs. The SSM generator is trained to predict drum SSM based on the given melodic SSM, and the drum generator is trained to predict drum patterns based on drum SSM and a bar selection mechanism. In the generation phase, two generators are used sequentially to predict the drum SSM and drum patterns given the melodic tracks.

3.1 Data preprocessing

The input of the proposed model is the audio rendered from all the melodic tracks in the MIDI dataset using a software synthesizer; [1] these audio signals are mono-channel sampled at 44.1 kHz. The advantage of using synthesized audio rather than symbolic data is to enable future adaptation to real-world audio. The tempo of each song is normalized to 120 BPM. Every spectrogram calculated from the audio is denoted as a tensor $\mathbf{Y}$ in shape of (b, f, t), where b is the number of bars, f is the number of frequency bins, and t are the number of time frames in a one-bar spectrogram, respectively. In this study, we set $b = 8$, $f = 84$, and $t = 96$.

For each synthesized audio clip, we first compute the constant-Q transform (CQT) spectrogram using `LibROSA` library. Subsequently, we divide the spectrogram into bars according to the beat and downbeat attributes in the MIDI data, and normalize the time step to 96 frames per bar through linear interpolation. The resulting size of each single-bar spectrogram is therefore 84×96.

The drum patterns are represented in a binary-valued matrix $\mathbf{B} \in \{0, 1\}^{i \times t}$, where i and t denote the activated instruments and the number of time steps respectively.

There are two types of SSM used in this work. The first one is melodic SSM and the second one is drum SSM. Both SSMs are 256×256 matrices computed using pairwise Euclidean distance between two sets of bar-level

[1] http://www.fluidsynth.org/, last access 2019/06/28

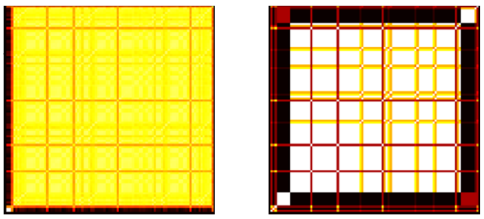

Figure 2. SSM examples of *Can't Buy Me Love* by Beatles. Left: melodic SSM. Right: drum SSM from original MIDI drum track. In the two figures, each pixel represents a Euclidean distance value between two bar-level spectrograms/symbolic drums and brighter color indicates a shorter distance (i.e., higher similarity).

spectorgrams. Since different songs vary in length, we zero-pad all the songs up to a uniform length of 256 bars. It should be noted that melodic SSM is computed using CQT spectrogram converted from synthesized audio domain data, whereas drum SSM is computed using symbolic drum track data directly.

3.2 Drum SSM generator

The motivation of generating a drum SSM from a melodic SSM is shown in Figure 2. It can be observed from Figure 2 that melodic and drum SSM are structurally correlated, and drum SSM seems to provide a relatively clearer view of structural boundaries. This difference could originate from the distinctive roles of percussive versus melodic instruments in Western music. For example, in pop or rock music, drum patterns tend to be homogeneous within a musical section. Sudden changes of drum patterns usually occur before transitioning into a new musical section. As a result, drum SSM could effectively reflect the global structure. Based on these observations, we assume that (i) it is possible to infer drum SSM given melodic SSM because they are highly correlated, and (ii) drum SSM provides more information about song structure information than the melodic SSM does.

To explicitly capture structural information of the entire song prior to drum pattern generation, a model that infers the drum SSM from a melodic SSM is needed. In this work, we propose a drum SSM generator based on the VAE-GAN model in [12]. The VAE-GAN model is a GAN consisting of a VAE-based Generator and a Discriminator. In the training stage, the VAE-based SSM generator is trained to infer the drum SSM based on the input melodic SSM, and the discriminator is trained to distinguish the VAE-generated drum SSM from the original one. The model is optimized by minimizing the total loss function $\mathcal{L}_{ssm}$ consisting of three loss terms, namely the reconstruction loss, KL-divergence loss, and the adversarial loss $\mathcal{L}_D$:

$$\begin{aligned}\mathcal{L}_{ssm} = &-\mathrm{E}_{v\sim q_s(z_s|s_m)}[\log p_s(s_d|z_s)] \\ &+ \mathrm{KL}(q_s(z_s|s_m)\|p(z_s)) + \mathcal{L}_D, \end{aligned} \quad (1)$$

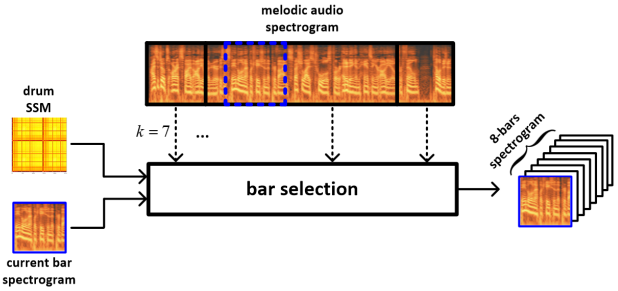

Figure 3. Bar selection mechanism to pick spectrogram data from the current and the other 7 relevant bars.

where s_d represents the generated drum SSM, s_m represents the input melodic SSM and z_s is the latent space representation of s_m.

In the generation stage, we feed the melodic SSM into the pre-trained generator and obtain the predicted drum SSM, which will be used in the following bar selection process.

3.3 Bar selection

To incorporate the structural information into drum pattern generation, the drum SSM is used in a bar selection mechanism. The proposed bar selection mechanism is based on an assumption that musical bars with higher similarities are more likely to provide relevant information for generating compatible drum patterns. To achieve this goal, we first find the k-nearest bars for every bar-level spectrogram according to the drum SSM. These bars are identified by finding the k smallest values in every column of the drum SSM. The process is illustrated in Figure 3. In our study, we set $k = 7$. The corresponding spectrograms of these eight bars are weighted and then stacked into an eight-channel feature representation, which will be used as the input to the subsequent drum pattern generator (see Section 3.4). The weighting coefficient of each channel is $1 - \mathrm{norm}(d(k, k_i))$, where k_i is the ith nearest bar, d is the Euclidean distance, and norm represents normalization over the column of the similarity matrix.

3.4 Drum pattern generator

Figure 4 illustrates the drum pattern generation model. The model is modified from the VAE proposed by Larsen et al. [12] The virtue of VAE is its capability of generating diverse output through simple manipulation in the latent space. For instance, drum patterns in-between two distinctive rhythmic styles can be generated by morphing the latent vector c and z.

To train this VAE model, we feed the encoder E with spectrogram and use symbolic drum track data as ground truth to minimizing the following loss function $\mathcal{L}_{drum}$:

$$\begin{aligned}\mathcal{L}_{drum} = &-\mathrm{E}_{z\sim q(z|y)}[\log p(x|z)] \\ &+ \mathrm{KL}(q(z|y)\|p(z)) + r(c, \hat{c}), \end{aligned} \quad (2)$$

where $r(c; \hat{c}) := |c - \hat{c}|$. x represents the generated drum

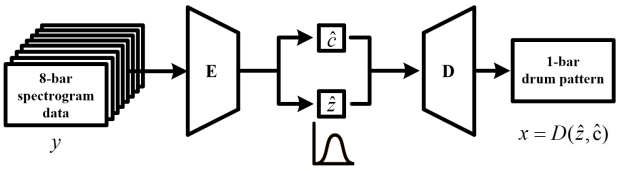

Figure 4. Illustration of the VAE-based drum pattern generator. The 8-bar spectrogram y is obtained from the bar selection mechanism. The encoder maps the spectrogram into two latent spaces, a Gaussian vector $\hat{z}$ and a note density value $\hat{c}$. The values sampled from these two latent spaces are fed to the decoder to generate drum patterns.

patterns, y is the input spectrogram, and c and $\hat{c}$ are the ground-truth and the estimated note density, respectively.

4. IMPLEMENTATION

4.1 Dataset

In this work, we use the Lakh pianoroll dataset (LPD-5) [6], a collection from cleaned MIDI data in the Lakh MIDI Dataset (LMD) [18]. LPD-5 contains 21,425 songs and each song has five tracks (piano, guitar, string, bass, and drums) extracted from the original MIDI data. The dimensionality of each bar in melodic tracks is 128 (pitch) $\times$ 96 (time step). For drum tracks, we process the data with following steps: (i) remove MIDI pitches (representing different percussive instruments) that are relatively inactive (e.g., less than 0.1% of all active drum notes); (ii) reduce time steps from 96 to 16 (see Section 4.2 for more details); (iii) apply binarization on each activated drum note, and (iv) calculate the note count in each single bar as a proxy for note density (rhythmic complexity). This procedure results in a down-sampled drum matrix with a dimensionality of 46$\times$16.

4.2 Data cleaning

Although the LPD-5 dataset has included a series of operations to clean up the original LPD [6], incomplete or noisy examples can still be found. To further improve the data integrity, we proceed with the following steps:

First, we remove songs with inconsistent duration after synthesis. Some tracks contain only a few notes throughout the entire file, and the empty bars are automatically removed during synthesis. By excluding these songs, we ensure the correctness of information regarding song progression (e.g., beat and downbeat locations).

Second, we remove songs with empty or noisy drum tracks. Specifically, we estimate the distribution of note count from drum tracks and exclude the ones that are outside of the two standard deviation range. This outlier removal process reduces the noise and avoids issues that might be induced by data sparsity.

Finally, we apply 16th beat quantization on drum tracks and remove the notes that are largely shifted during the quantization process. In LPD-5 dataset, 95% of activated drum notes are ether on the 16th beat grid or within a tolerance range of 96th beat. Our experiment shows that less than 5% of drum notes are affected by this data cleaning process. Therefore, we believe that 16th beat grid is applicable to provide a compact data representation while retaining a meaningful temporal resolution.

generation method	cosine similarity
OMD	1.0000
ODS	0.9208
PDS	0.9164
NB	0.9056

Table 1. Similarity measure of drum SSMs from different generation method, higher similarity value indicates less deviation from original song structure after generation.

4.3 Experimental setup

After the cleaning process, 9,907 songs remain in the dataset. We randomly split the dataset into 90% and 10% for training and testing, respectively. For each song, drum and melodic parts are extracted accordingly. The melodic tracks are rendered into wave format and transformed into per-bar CQT spectrogram. For drum tracks, we segment the data in bar-level and apply binarization. The training process is done by minimizing the loss function as defined in Section 3.3 and Section 3.4; the selected optimizer is ADAM with a batch size of 64. The models are implemented using Tensorflow.

A similar preprocessing procedure is applied to the data in testing phase. The major difference between the training and the testing is the source of drum SSM. During testing, only the melodic SSM is available, and the drum SSM is predicted using the pre-trained drum SSM generator.

4.4 Model parameters

Both the input and output dimensions of the drum SSM generator (as described in Section 3.2) are 256$\times$256. The encoder is composed of eight convolutional (CONV) layers followed by three fully-connected (FC) layers with skip connections. The FC layer is connected to a bottleneck layer that generates a 32 dimensional latent vector. Similarly, the decoder has the same layers in reverse order. The discriminator is a network similar to the encoder with a sigmoid output; this activation function is chosen for its potential probabilistic interpretation.

For drum pattern generation, the architecture of our VAE (i.e., no discriminator) is similar to the drum SSM generator. The input and output dimensions are changed to 84$\times$96$\times$8 and 46$\times$16$\times$1, respectively. The total numbers of parameters for the SSM generator and the drum pattern generator are around 17M and 62M, respectively. The total training time for the two models is 84 hours on a single 2080 Ti GPU. More implementation details can be found in our Github repository. [2]

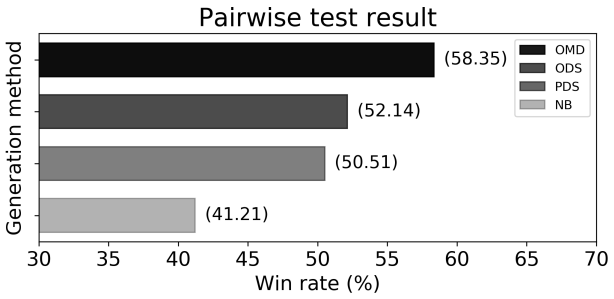

Figure 6. Global win rate of different models in pairwise listening test.

5. EVALUATION

5.1 Compared methods

To evaluate the quality of generated drum patterns of the proposed model, we conduct both objective and subjective tests on four different derived methods:

- **(OMD) Original MIDI Drums** are the drum patterns predefined in the MIDI files. These drum patterns are directly taken from the drum tracks and serve as the oracle samples among all methods.
- **(ODS) Original Drum SSM** is the model that generates the drum patterns with our pre-trained drum pattern generator. In this case, the drum SSM used for bar selection is computed from the oracle drum tracks (i.e., OMD).
- **(PDS) Predicted Drum SSM** is the model that generates the drum patterns with our pre-trained drum pattern generator. In this case, a drum SSM used for bar selection is predicted from melodic SSM using a pre-trained SSM generator (see Section 3)
- **(NB) Neighboring Bars** is the baseline model. Instead of applying bar selection mechanism, this model simply includes the neighboring bars (i.e., previous 4 bars, current bar, and subsequent 3 bars) to create the 8-bar feature representation; no information from SSM is used. This model ignores global structure and incorporates local structure naively.

5.2 Objective test

In our objective test, we compute the similarity between the oracle drum SSM (i.e., OMD) and the SSMs of the drum patterns generated by ODS, PDS, and NB. This evaluation examines the general quality of drum patterns. Ideally, the SSM with high similarity to oracle implies a better preservation of the structural information. For simplicity, we use a standard cosine similarity as our metric. We randomly collect 100 drum tracks generated from the LPD test set, and calculate the cosine similarity between the original and generated SSMs. The average of results are presented in Table 1. Both drum SSM informed methods (i.e., ODS and PDS) outperformed NB, which suggested the competence for drum SSM to preserve structural information. Interestingly, NB can achieve a relatively high similarity score without any additional information of the global structure. This result implies the need for a better and perceptually relevant evaluation.

5.3 Subjective evaluation - pairwise test

5.3.1 Experiment settings

In order to evaluate the perceptual quality of different models, we conducted a listening test to compare the above mentioned four methods. In the test, various samples generated by different methods were presented to participants. There are 10 trials per test; each trial consists of two different samples derived from the same melodic track. After listening, the participants were asked to select the sample with higher rhythmic compatibility. 10 different songs are included in the evaluation; 5 songs are randomly selected from LPD-5 test set, and another 5 songs are randomly collected online in order to test the generality of the methods. In order to examine the model's capability of handling transitions, each sample contains a structural boundary. Particularly, we select samples that include one transition from the verse to the chorus, and the duration is roughly 16 seconds. Listening examples are available online. [3]

5.3.2 Results

The evaluation for 1,350 listening pairs are provided by 135 respondents. 67.5% of the subjects have no music composition experience, and 92% of the subjects have never played drums. The listening test results are presented in Figure 6 and Figure 5. Based on the results, the following observations can be made:

First, OMD performs the best among all models. This result is expected since OMD has the most stable and compelling drum patterns compared to the others. However, the margin between OMD and ODS is relatively small. One possible explanation is that OMD tends to be highly

[3] https://sma1033.github.io/drum_generation_with_ssm/

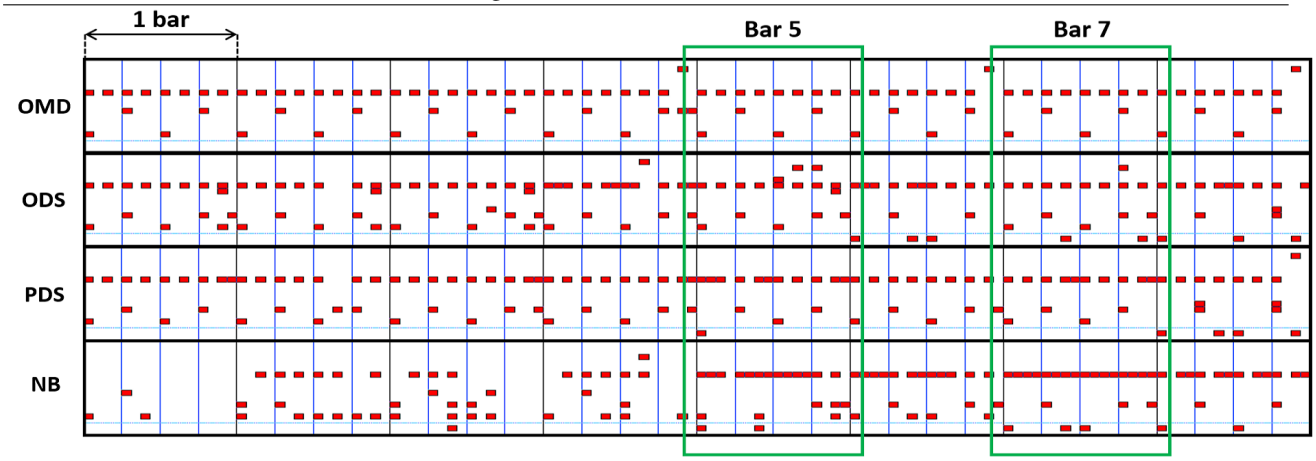

Figure 7. A 8-bar example of drum tracks from four different method in sec 5.1

consistent and predictable, and this can sometimes be regarded as conservative and even boring. On the contrary, the unexpected instrumentation or sequences in other models may accidental attract the audience's attention.

Second, it appears that both ODS and PDS outperform NB. To verify the significance of these comparisons, the t-tests of ODS/NB and PDS/NB pairs are conducted, which produce the p-values of **0.0087** and **0.001**. The results suggest that incorporating SSM in drum pattern generation models is a promising approach.

Third, the performance of PDS is comparable to ODS. The statistics from pairwise listening test suggest that the quality of drum patterns from PDS and ODS are similar for general public. This result not only indicates the effectiveness of the pre-trained SSM generator, but also shows the viability of generating meaningful drum patterns based on melodic SSM.

5.4 Subjective evaluation for professionals

Apart from the aforementioned pairwise test, we also conducted another listening test on professional musicians. The objective of this test is to collect descriptive feedback from subjects with extensive experiences in music composition and drum performance. Two professional drummers and one professional composer (with experience ranging from 3 to 14 years) participated in this test. Each participants was invited to listen to 5 selected songs; each song contains 3 different drum tracks (i.e., ODS, PDS, and NB) presented in random order, resulting in a total number of 15 clips. To further investigate the long-term structure of the generated drum patterns, the duration of each song is extended to 64 seconds. The participants were encouraged to provide detailed comments after each trial. The thematic analysis approach [4, 20] was applied to extract common themes from their comments in a bottom-up manner. The results of thematic analysis are described as follows.

The first theme regards the structural compatibility between the generated drum patterns and the melodic track. From this perspective, ODS seems to receive the best feedback among three competing models. In many occasions, the comments for ODS include "good distinction between sections", whereas PDS and NB are rarely mentioned. Moreover, for transition part between sections, ODS is reported as having active rhythmic changes (e.g., drum-fills). Overall, the professional listeners seem to prefer ODS in terms of its structure.

The second theme regards the stability and variability of the generation result. The comments from professional listeners indicate NB's ability of generating unstructured yet unexpected patterns. ODS and PDS, on the other hand, do not surprise the professional listeners. Figure 7 provides a visual example of all methods. According to Figure 7, ODS and PDS are visually more similar to OMD (e.g., bar 5 and bar 7). However, NB does provide unconventional patterns at several locations, which could be interpreted as "thinking outside of the box".

6. CONCLUSION

We have presented a conditional drum pattern generation model to generate drum patterns based on given melodic tracks. In particular, the model captures the global structure of melodic sequences using SSM and is capable of producing structurally coherent drum sequences. Results from both the objective and subjective evaluation are promising, and the comments from professional listeners also highlight the strength of the model to incorporate drum patterns with the melodic structure. Possible future directions include:

1. Design a user-friendly control interface for general public users. This could potentially encourage more interactions among users and facilitate the music creation process.

2. Generate genre-specific drum patterns according to the input condition. With genre-specific contents, users may customize the styles of outputs.

3. Develop a model that can ultimately perform drum pattern generation in audio domain. This would enable more potential applications in real-world scenarios and increase the expressivity of the model.

7. ACKNOWLEDGEMENT

We thank three professional musicians, Hsin-Ming Lin, Ying-Shu Kuo, and Jian-Hong Chen, for their qualitative assessment on generated drum patterns and our colleague, Yu-Fen Huang, for her generous assistance on the thematic analysis of the questionnaires. We would also like to express our gratitude to every participant of the subjective listening test for providing responses and constructive feedback.

RENDERING MUSIC PERFORMANCE WITH INTERPRETATION VARIATIONS USING CONDITIONAL VARIATIONAL RNN

Akira Maezawa Kazuhiko Yamamoto Takuya Fujishima
Yamaha Corporation

ABSTRACT

Capturing and generating a wide variety of musical expression is important in music performance rendering, but current methods fail to model such a variation. This paper presents a music performance rendering method that explicitly models the variability in interpretations for a given piece of music. Conditional variational recurrent neural network is used to jointly train, conditioned on the music score, an encoder from a music performance to a latent representation of interpretation and a decoder from the latent interpretation back to the music performance. Evaluation demonstrates the method is capable of predicting and generating an expressive performance, and that the decoder learns a latent space of musical interpretation that is consistent with human perception of interpretation.

1. INTRODUCTION

Music performance rendering is the task of generating a human-like performance data from a piano music score. That is, for each note in a given music score, it generates a set of expressive performance parameters such as the onset timing, the duration and the velocity. It is an important task in music production, allowing a composer to generate human-like piano part of a new composition, or a musician to listen to a convincing preview of a digital sheet music. It is not only important to generate a convincing performance, but also to allow humans to interact in the generation. For example, it is useful to be able to adjust expressive parameters, or, like how a musician might ask to another musician, feed a reference performance snippet, in expression of which the system should perform.

Capturing and generating a wide variety of musical expression are important in music performance rendering, but current methods are limited in such capabilities. For example, most methods permit control over concrete musical concepts like the average tempo and the average velocity [2], but cannot manipulate abstract musical concepts that cannot be labeled, such as liveliness within a performance. It is also not possible to feed a short reference performance snippet and ask the system to play with that particular musical musical interpretation.

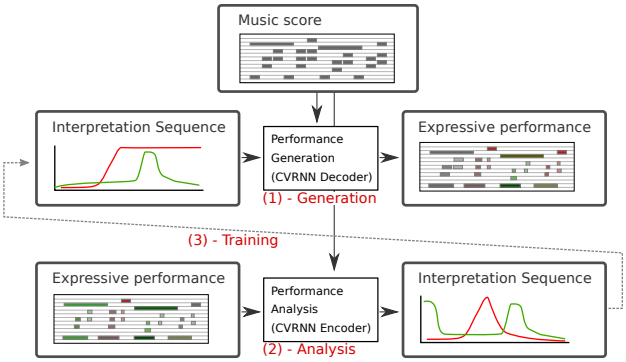

Figure 1. The overview of our method.

These limitations are rooted in the attempt to directly map between the music score and expressive performance [4]. Such a model entwines musical interpretation and its execution, but a human performer presumably decouples *musical intent* and its *execution* given the score. For example, when playing a piece multiple times, a musician might play lively the first time but calmly on the second. Given the intent, however, its execution is consistent based on musical contexts, such as whether a note is a melody or if a particular measure is a beginning of a new phrase. For example, a lively playing might be executed, almost second nature, as shorter chords and louder melody, or calm playing as softer and more broken chords.

To address this problem, we present a music performance rendering method that explicitly decouples intent and its execution based on a music score. We achieve this by jointly training a performance decoder (performance renderer) and a performance encoder (performance analyzer) that are conditioned on (1) a music score, and (2) an **interpretation sequence**, a latent low-dimensional sequence representation that expresses the underlying musical intent. It may be either generated automatically or manipulated coherently. Thus, it is possible to generate different interpretations to a score by either modifying the interpretation sequence or encoding a performance snippet as an initial value for generating the interpretation sequence.

The conceptual overview is shown in Figure 1. Our method, given a music score and an interpretation sequence, generates an expressive performance for the given music (denoted (1)). Conversely, it can encode an expressive performance into the interpretation sequence (denoted (2)). To achieve such a capability, the encoder and the de-

coder are jointly trained by encoding a human performance and trying to recover it with the decoder (denoted by path (3)).

Our contributions are as follows: (1) we propose a new machine learning model, CVRNN, which extends variational recurrent neural network (VRNN [6]) to accept position-dependent conditional inputs; (2) we apply convolutional recurrent network (CRNN) to extract features from the music score; (3) we apply these two models and present a first deep generative model that is simultaneously capable of analyzing and generating an expressive music performance for a given music score with adjustable musical interpretation.

We invite the readers to check out audio demonstrations at `https://sites.google.com/view/cvrnn-performance-render`.

2. RELATED WORK

Music performance rendering is the task of generating an expressive performance from a music score [4]. The research focuses mostly on generating a sequence of expressive onset timings, durations and velocities for a piano piece. Unlike the generation of improvisation [20], performance rendering needs to understand the musical contexts of the given music score, and generate a natural performance constrained by the score.

Previous studies formulate performance rendering as a prediction task of expressive parameters based on features extracted from the music score, such as melodic features [22], perceptual features [3], or neighboring contexts [9, 18]. Then, expressive performance to a new music score can be predicted using methods like a hidden Markov model [12], a decision tree [18], or a dynamic Bayesian network [8]. More recently, deep learning has been incorporated to better extract the features or predict the performance. For example, deep neural networks have been shown to be effective for dynamics prediction [21], tempo prediction [15], and piano performance generation [11, 17].

The capability to adjust the generated performance is important, but current methods cannot capture the abstract variations in playing. For example, the tempo or dynamics [1, 7] can be adjusted, but controlling a more abstract musical idea remains difficult. It is possible to manipulate the performance by mixing the parameters of performance renderers trained on multiple corpora [2], but it fundamentally cannot identify commonalities and differences among a set of corpora.

3. METHOD

Our method generates an expressive piano performance data to a given piano music score, and an interpretation sequence that is either automatically generated, manually adjusted, or initialized by a performance snippet. The score contains a sequence of notes (pitch, position and duration), the average tempo, the time signatures, and the key signatures. The interpretation sequence is a sequence of low-dimensional vectors, each element of which is associated with each note in the score. It is an abstract representation of playing style, each vector of which is called the **interpretation vector**. For each note, based on the interpretation vector and musical context inferred from the music score, our method estimates (1) the fine note onset timing, (2) the duration, (3) the note-on velocity, and (4) the tempo fluctuation of human performance.

To generate the performance, we use a deep generative model that has been trained to generate an expressive performance data, conditioned on the music score and the interpretation sequence. To acquire a temporally coherent manifold over the space of interpretation vector, we propose CVRNN, an extension of VRNN that accepts the music score as a conditioning input. Essentially, we jointly train three models: (1) a music score feature extractor that extracts, for each note, relevant features (**music score feature**) from the music score, (2) an encoder that maps a human performance to an interpretation sequence, and (3) a decoder that maps an interpretation sequence to an expressive performance.

Hereon, n indicates the index of a note encountered in the music score, lexicographically sorted by the onset beat position and the pitch. x_n indicates the expressive performance data, c_n indicates the music score feature that has been extracted from the nth note on the score, and z_n indicates the interpretation vector associated with x_n.

3.1 Representation of expressive performance

The generated expressive performance x_n comprises of the note velocity, the note duration, the micro-onset timing deviation and the tempo.

The **note velocity** is an integer between 1 and 127 indicating the MIDI velocity value, encoded as a 128-dimensional one-hot vector.

The **note duration** is an integer between 1 and 800, indicating the duration as $1/100$ths of a beat relative to the current tempo (*e.g.* duration of "42" means 0.42 beats). It is encoded as an 800-dimensional one-hot vector.

The **micro-onset timing** is an integer between -50 and 49, indicating the number of $1/100$ths of a beat elapsed after an ideal onset time. The ideal onset time is computed based on the generated tempo curve up to the current point in the score. It is represented as a 100-dimensional one-hot vector, ith element of which means that the onset is lagging by $(i - 50)/100$ beats.

The **tempo** is an integer indicating the the difference between the current tempo and the tempo written in the music score, in bpm. It is represented as a 100-dimensional one-hot vector, ith element of which means that the output should be faster than the written tempo by $i - 50$ bpm. It is computed by interpolating the music score position and the playback position of the performance using Gaussian regression with a squared exponential kernel with a FWHM of 2 beats.

3.2 Extraction of the music score feature

The music score contains a sequence of notes, average dynamics, average tempi, meters, and key signatures. From

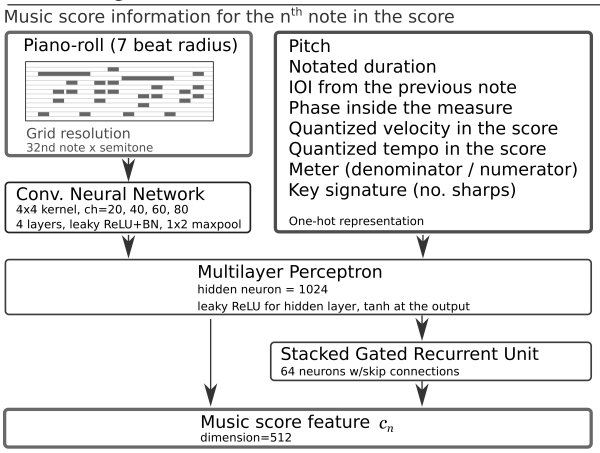

Figure 2. Overview of music score feature extractor for extracting the music score feature.

the music score, we extract the **music score feature** c_n, which represents the nth note and its surrounding context.

To extract the feature, we use the following information: the **key signature** as a 12 dimensional one-hot vector that indicates the number of accidentals; the **time signature** as a tuple of 12 dimensional one-hot vector, indicating the numerator and the denominator; the **pitch** as a 128 dimensional one-hot vector indicating the MIDI note number; the **inter-onset interval** from the previous note as a multiple of 96th note, represented as a 512 dimensional one-hot vector; the **duration** of the note as a multiple of 96th note, represented as a 192 dimensional one-hot vector; the written **tempo** quantized to a multiple of 30 bpm, represented as a 9 dimensional one-hot vector (30-300 bpm); the written **velocity** quantized to a multiple of 10, represented as a 12 dimensional one-hot vector; the **piano-roll** centered about the current position in the score, spanning a radius of 7 beats at a 32nd note resolution (224x128 dimension). The velocity and the tempo are quantized at a low resolution because different music notation software map the dynamics and tempo markings to similar velocity and bpm values, but the exact mapping differ.

Based on these inputs, we extract the feature using a CRNN as shown in Figure 2. First, the piano-roll passes through a CNN. It is comprised of four layers, whose kernel sizes are all (4×4), and channel sizes from the lower to the higher layers are [20, 40, 60, 80]. Each layer is followed by max-pooling with a kernel size of (2×1), batch normalization and leaky ReLU nonlinearity. The output the CNN is concatenated with the remaining one-hot vectors mentioned above. Then, the concatenated vector is passed through a multi-layer perceptron (MLP) with 1024 hidden units and leaky ReLU nonlinearity at the hidden layer. The MLP output passes through a tanh nonlinearity.

Second, the output of the perceptron is embedded to 64 dimensions using a linear layer. The embedded vector is then passed to a RNN consisting of 3 stacks of gated recurrent units (GRU) [5] with 64 neurons each.

Finally, the outputs of the MLP and the GRU stack are concatenated to create the music score feature c_n.

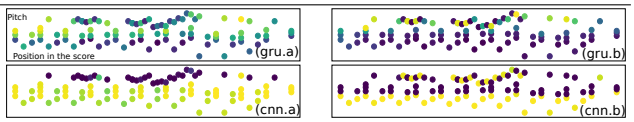

Figure 3. Activation of the most active components of GRU and CNN activations (dark=negative, yellow=positive).

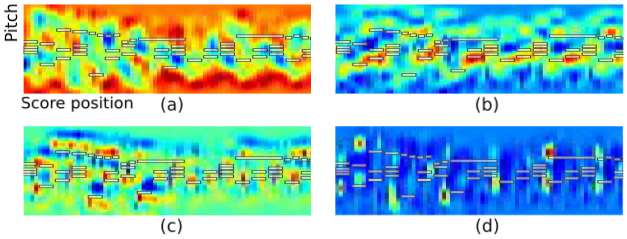

Figure 4. Some feature maps learned from the CNN, overlayed with the piano-roll (blue=negative, red=positive).

3.2.1 Analysis of the music score feature extractor

Here we illustrate some musically relevant concepts that are acquired by the music score feature extractor. We have trained our model using the same dataset used in Section 4, and extracted the music score feature from measures 5–6 of Chopin's Nocturne Op. 9-2 and extracted the GRU and the CNN activations. Some of the highest GRU and CNN activations are shown in Figure 3, showing, for each note, the value of the corresponding activation in different color, positioned at the beat position and the pitch written on the score, *a la* piano-roll. We can see that the GRU acquires concepts like the number of notes stacked below the current point in the score ("gru.a") or top notes ("gru.b"). The CNN extracts longer contextual information such as the melody ("cnn.a"), and the bottom notes ("cnn.b"). Neither the GRU nor the CNN becomes dead: the standard deviation of the activation of the CNN and the GRU are comparable (about 0.5 to 1.0), where about 90 GRU activations have standard deviation of above 0.1, and about 150 for the CNN.

To analyze how these concepts are acquired, we show in Figure 4 the feature maps of the final layers of the CNN, overlayed to the piano-roll. The tendency of the map suggests that the CNN expresses concepts like the register (Fig. 4a), rising arpeggio (b), top and bottom melodic contour (c), or melodic contour (d).

3.3 CVRNN for joint encoding and decoding of the interpretation sequence

We assume that an expressive performance depends on both (1) the musical context, expressed through the music score feature, and (2) a corresponding sequence of low-dimensional music interpretation vectors z_n, dimension of which is set to 5. It is necessary for z_n to learn (1) a manifold that z_n resides in, that explains interpretation reasonably well, and (2) a model of temporal evolution of z_n, so that the generated performance is temporally coher-

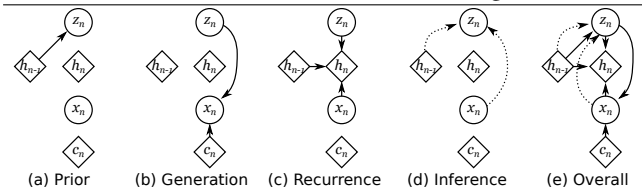

Figure 5. Dependency of the CVRNN model. Solid arrows indicate conditional dependence of the generative process, and dotted arrows indicate conditional dependence of the approximate posterior distribution.

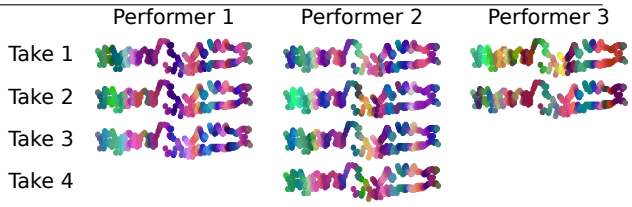

Figure 6. Visualization of the interpretation sequence, for different takes of three professional pianists. Horizontal axis indicates the music score position, vertical axis indicates the pitch, and the color indicates 3D projection of the temporally-smoothed interpretation vector.

ent. We achieve (1) by decoupling the music score and the generative model of z_n, such that z_n learns a repertoire-independent low-dimensional representation of variability of playing. We achieve (2) by basing the temporal evolution of z_n on the state of a RNN h_n.

To meet these requirements, we model the generation process with a CVRNN. There are three key components in a CVRNN, as shown in the dependency diagram in Figure 5: (1) generation of the interpretation sequence z_n given the underlying h_n (called the **prior** distribution), (2) generation of an expressive performance x_n given the interpretation sequence z_n and music score features c_n (called the **generation** distribution), and (3) generation of the interpretation vector z_n given a true human performance x_n (called the **inference** distribution). Finally, the true or the generated expressive performance x_n and the interpretation vector z_n are used to update the underlying h_n, used then to predict the next interpretation vector z_{n+1}.

3.3.1 Generation

We assume the following generative process:

$$p(x_{\leq N}, z_{\leq N}|c_{\leq N}) = \prod_{n=1}^{N} \underbrace{p(x_n|z_n, c_n)}_{\text{generation}} \underbrace{p(z_n|x_{<n}, z_{<n})}_{\text{prior}}. \tag{1}$$

Thus, the data is generated autoregressively by sampling z_n from the prior, generating x_n, and feeding it back to the prior to sample the z_{n+1} for the next note in the score.

For the prior distribution, the previous RNN state h_{n-1} passes through a three-layer densely-connected [10] fully-connected network with 250 units each with a leaky ReLU nonlinearity. By dense connection, we mean that the input to the current layer is a concatenation of the outputs of previous layers. It outputs the mean and log-variance of a Normal distribution $\mu(h_{n-1})$ and $\gamma(h_{n-1})$. Then z_n is sampled as follows:

$$z_n|h_{n-1} \sim \mathcal{N}(\mu(h_{n-1}), \exp(\gamma(h_{n-1}))). \tag{2}$$

From the interpretation vector z_n, we pass it through another feature extractor $\psi(z_n)$ to obtain a feature that describes the current musical interpretation. $\psi(\cdot)$ has the same three-layer architecture as mentioned above.

For the generation of x_n, we use the sampled interpretation vector z_n and the current music context c_n:

$$x_n|z_n, c_n \sim g(c_n, \psi(z_n)), \tag{3}$$

where $g(c, z)$ indicates a Cartesian product of categorical distributions over the one-hot representations of the velocity, the micro-onset timing, the duration and the tempo, parameterized by an output of a three-layer fully-connected network with leaky ReLU nonlinearity for the hidden layers and softmax for the output layer, applied separately for the four output variables.

To recurrently update h_n, we extract a feature vector from x_n by passing it through a network $\phi(\cdot)$ with a same architecture as ψ to obtain $\phi(x_n)$. Then, the underlying state h_n is updated as follows:

$$h_{n+1} = f(h_n, [c_n, \phi(x_n), \psi(z_n)]), \tag{4}$$

where $f(h, x)$ is state update equation of a stacked GRU of three layers, given h as the current state variable and x as the input that has been embedded to 64 dimensions by a fully-connected layer.

Let us elaborate on the modeling assumptions. First, the prior in Eq. 2 is independent of c_n. This forces z_n to express music interpretation abstractly, such that it is decoupled from the musical context, which provides strong hints on how to execute the performance given an interpretation. Second, x_n and h_n depends only indirectly via the bottleneck z_n. This is unlike the original formulation of VRNN where x_n and h_n are directly dependent. We found that such a bottleneck is vitally critical for learning a meaningful representation of z_n; if x_n depends on h_n, then the model simply learns to generate an auto-regressive model of x_n using h_t, almost completely bypassing z_n. Such an error mode occurs because it is much easier for a model to learn to simply predict the next note, instead of having to go through the hassle of trying to explain how it could have varied with a different interpretation.

3.3.2 Inference

In addition to the generative process, we also define an approximate posterior distribution, or the inference distribution, so that variational technique can be used to train the model [14].

We assume the following dependency for the inference distribution:

$$q(z_{\leq N}|x_{\leq N}) = \prod_{n=1}^{N} \underbrace{q(z_n|x_{\leq n}, z_{<n})}_{\text{inference}}. \tag{5}$$

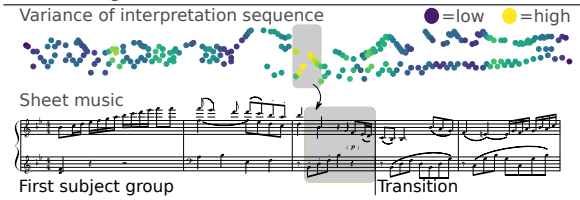

Figure 7. The variance of the interpretation vectors over different performers at each note.

If we assume that z_n is normally distributed and conditionally independent of $z_{<n}$ and $x_{<n}$ given h_{n-1}, it becomes:

$$q(z_n|x_{\leq n}, z_{<n}) = q(z_n|x_n, h_{n-1})$$
$$= \mathcal{N}(z_n|\eta(h_{n-1}, \phi(x_n)), \exp(\nu(h_{n-1}, \phi(x_n)))), \quad (6)$$

where $\eta(\cdot)$ and $\nu(\cdot)$ are the outputs of a neural network with the same architecture as $\psi(\cdot)$, that take $\phi(x_n)$ and h_{n-1} as the inputs. The inference is independent of the music score c_n, so that it learns a *repertoire-agnostic* model for inferring z_n given an expressive human playing.

3.3.3 Training

We train the model by minimizing the KL divergence from the approximate posterior to the true posterior. It amounts to the minimizing of the following note-level loss $l_n(\Theta)$ w.r.t. the set of model parameters Θ, accrued over every note in the training data:

$$l_n(\Theta) = \mathbb{E}_{z_n \sim q(z|x_n, h_{n-1})}[\log p(x_n|z_n, c_n)]$$
$$+ \mathrm{KL}(q(z|x_n, h_{n-1})||p(z|h_{n-1})). \quad (7)$$

The expectation is computed using the reparametrization trick [14]. We use truncated backpropagation with truncation length of 30 notes (longer truncation length of 50 notes yielded qualitatively similar outputs). We also augment the data by adding zero-reverting Wiener noise to the tempo curve and randomly transposing each piece by -7 to 7 semitones at every epoch. To minimize the loss, we use Adam [13], with gradient clipping for gradient values above 5.

3.4 Analysis of the learnt manifold of the interpretation vector

We briefly illustrate the essences of musical expression acquired by the interpretation sequence. Figure 6 shows the interpretation sequence of first 20 bars of Mozart's K333 piano sonata, mvt. 1 (from the top to the introduction of second subject group), played by three professional pianists for multiple takes. The figure shows that the interpretation sequence tends to remain similar within each performer, and different among different performers.

We can also show where in the music score has the highest variance of interpretation vector among the nine takes. Figure 7 shows the variance for each note, from which we can see that the maximum variance occurs at the structural boundary from the first subject group to the transition, supporting findings that music expression varies significantly at structural boundaries [19].

4. EVALUATION

We evaluate our method's capability to (1) create a natural expressive performance given the music score, and to encode an expressive performance into (2) perceptually relevant space that is (3) representative of the corresponding performance. For training, we used an in-house dataset comprising of 380 classical pieces, mostly Late romantic and Baroque. The piano performance comprised of 130 in-house performances and 250 performances obtained from the piano e-competition archive [1]. Some performances were different interpretations of the same piece. Furthermore, corresponding music scores were obtained. To generate a one-to-one mapping between the performance and the score, each performance was aligned to the music score using symbolic music alignment based on [16] with manual alignment correction. Then, the notes in the performance and the score were matched using maximum bipartite matching, using the pitch and the onset timing to determine the edge weights between notes in the score and the performance.

We have used 370 of 380 pieces for training. Of 370 pieces, all but 500 notes were used for training, and remaining notes for the optimization of the hyperparameters (validation). To test the decoder in experiment 1 and 2, we have sampled 10 piano music scores from the Mutopia project [2], and corrected the key signature, meter and downbeat positions. It contained a wide variety of pieces from Baroque to Ragtime. To test the encoder in experiment 3, we have used 10 pieces of 380 pieces that were not used for training.

4.1 Listening test

We evaluated the naturalness of the generated performance using different methods. For each of the ten pieces, we extracted a random 15-second segment, and generated performance using three methods: (1) method **Deadpan** directly played back the SMF data of the music score data that has been exported from MakeMusic's Finale Version 25; (2) method **Finale** used "Human Playback" function of Finale to create a natural performance, serving as a reproducible reference music performance method; and (3) the **proposed** method. Furthermore, we extracted seven 15-second excerpts from human playback in the training dataset, which serves as an **oracle** method. The selected pieces were different from the first three methods, because the human playing data to the first three were not always available. To make a fair comparison, we removed the sustain pedal data from the oracle, because the pedal is contained in none of the other methods.

Next, the MIDI data were synthesized using a high-quality piano synthesizer and presented in a random order to 11 participants. The participants were asked to evaluate the naturalness and expressiveness, on a rating from 1 to 5, 1 being unnatural or unexpressive, 3 being moderately natural or contains some expression, and 5 being the most

[1] www.piano-e-competition.com
[2] www.mutopiaproject.org

Table 1. Mean opinion scores of the performances

	Deadpan	Finale	Proposed	Oracle
Naturalness	3.02	3.08	**3.29**	3.23
Expressiveness	2.75	2.98	3.14	**3.62**

natural or expressive. The participants were between age 25 and late fifties, working on music technology.

The results are shown in Table 1. Kruskal-Wallis H-test was used for test of significance ($p < 0.01$), since Shapiro test showed non-normality. We found that the effects were significant for both expressiveness and naturalness, for all of the method pairs.

This shows that the system is capable of generating a performance that is as natural as human playing, but the expression has a room for improvement. One possible reason is that the system does not make use of music score markings like expression and phrase markings. The audio on our demo webpage suggests nonetheless that the system learns to "improvise" a noticeable evolution of musical expression over a timespan of multiple notes.

4.2 Test on the perception of the interpretation vector

Second, we analyzed the capability of the interpretation sequence to create a *perceptually distinguishable and consistent* space of musical interpretation.

First, a pair of non-identical and non-overlapping segments were sampled from a piece, which we call segments A and B. Second, a vector Δ was sampled from a 5-dimensional, zero-mean and unit-variance Normal distribution. Third, two interpretations are generated for each of A and B, where rendition A_1 and B_1 are generated with interpretation vector $\mu(h_{n-1}) + \Delta \otimes \exp(\gamma(h_{n-1}))$, and A_2 and B_2 with $\mu(h_{n-1}) - \Delta \otimes \exp(\gamma(h_{n-1}))$. Fourth, A_1, A_2, B_1 and B_2 were successively presented to the participants, randomly presenting B_2 before B_1. They were asked to identify whether the relationship of music expression between $A_1 \rightarrow A_2$ is the same as $B_1 \rightarrow B_2$ or $B_1 \leftarrow B_2$. The participants rated the perceived relationship with a confidence on a two-point scale 2 (0 means cannot tell, 2 means strongly confident about the response). We repeated this experiment on 9 other pairs of segments. After the experiment, we changed the signs of the responses, such that negative confidence indicates the wrong guess ($A_1 \rightarrow A_2$ is $B_1 \leftarrow B_2$), and positive indicates the right guess ($A_1 \rightarrow A_2$ is $B_1 \rightarrow B_2$).

The average rating was 0.34, meaning that there is an agreement between the change of interpretation vector and human perception of interpretation. To test the significance, Wilcoxon signed rank test was used under the null hypothesis that the median rating is zero, since Shapiro test showed non-normality. The effect was significant with $p < 0.01$.

This shows that the encoder does capture a perceptually coherent space of music interpretation, and its modification creates a perceptually consistent difference in the interpretation. Qualitatively, we found that by changing the interpretation vector, there are simultaneous and smooth changes not only in the dynamics and the tempo but also nontrivial aspects like breaking of the chords or the articulation of the accompaniment.

Table 2. Pearson's correlation coefficient between the generated performance and the true performance.

	Num. notes	$z_n = 0$	$z_n \sim$ prior
Velocity	10	0.61	0.72
	40	0.37	0.68
Onset deviation	10	0.02	0.07
	40	0.19	0.24
Duration	10	0.77	0.77
	40	0.82	0.82
BPM	10	0.07	0.21
	40	0.00	0.14

4.3 Test on the predictive capability of the encoder

Finally we evaluated the capability to encode a given performance, by priming h and z with an encoded true human performance, and comparing the true human and the generated performances. First, we primed the decoder by feeding to the encoder the first 20 notes to a performance to infer the initial value of z_n. Next, the remaining 10 or 40 notes were decoded using two different decoders: (1) use z_n sampled from the prior that has been primed in the first step, and (2) fix $z_n = 0$. We repeated this experiment on 100 different starting points, and evaluated the Pearson's correlation coefficient between the generated and human performance.

Table 2 shows the correlation coefficients. The result shows that the encoder is capable of encoding information pertinent to music performance. Significant improvements are seen for the velocity and the tempo, showing that the interpretation space is captures these aspects. At the same time, there are still rooms for improving the prediction of the onset deviation and the tempo.

This shows that we can indeed feed a reference performance snippet to the system, and the system would generate a performance in style of the snippet.

5. CONCLUSION

We have presented music performance rendering method that explicitly encodes underlying sources of expression variations. Our method opens door to wider possibilities for the co-creation of music performance between a machine and humans, by enabling an interpretable and adjustable performance rendering and analysis system. We also believe the capability to decouple musical intent and its execution given the intent opens door to a new abstraction layer for performance analysis.

Future work includes the inference of additional outputs like the pedals and note-off velocity, better expressiveness through incorporation of music score markings, disentanglement of the latent space and interfaces for interactive music performance rendering.

ABSTRACT

Automatic harmonic analysis is challenging: rule-based models cannot account for every possible edge case, and manual annotation is expensive and sometimes inconsistent, undermining the training and evaluation of machine learning models. We present an interactive workflow to address these problems, and test it on Bach chorales. First, a rule-based model was used to generate preliminary, consistent chord labels in order to pre-train three machine learning models. These four models were grouped into an ensemble that generated chord labels by voting, achieving 91.4% accuracy on a reserved test set. A domain expert then corrected only those chords that the ensemble did not agree on unanimously (20.9% of the generated labels). Finally, we used these corrected annotations to re-train the machine learning models, and the resulting ensemble attained an accuracy of 93.5% on the reserved test set, a 24.4% reduction in the number of errors. This versatile interactive workflow can either work in a fully automatic way, or can capitalize on relatively minimal human involvement to generate higher-quality chord labels. It combines the consistency of rule-based models with the nuance of manual analysis to generate relatively inexpensive high-quality ground truth for training effective machine learning models.

1. INTRODUCTION AND BASIC METHODOLOGY

In general, harmonic analysis refers to the identification of harmonies from the musical surface. As a key part of the foundation of modern Western music theory, harmonic analysis is inherently complex. It is based on low-level sensory distinctions (consonance vs dissonance), local constructs (counterpoint, voice-leading), and global musical structures (harmonic function, form, tonality, etc.). Learning it is thus a time-consuming process, requiring years of training. Furthermore, many prominent music theorists (e.g., Rameau, Riemann, Schenker) have proposed different approaches to harmonic analysis. This means it is often possible to analyze the same passage in numerous legitimate ways. For example, some analysts prefer interpretations with fewer chords, while others prefer interpretations with more frequent harmonic changes. We characterize these general strategies as "melodic" and "harmonic", respectively (Fig. 1 illustrates these interpretive strategies). Complicating matters further, analysts often disagree, and are not always internally consistent [12]. Given the complexity, subjectivity, and inconsistency of harmonic analysis, it is challenging to systemize it.

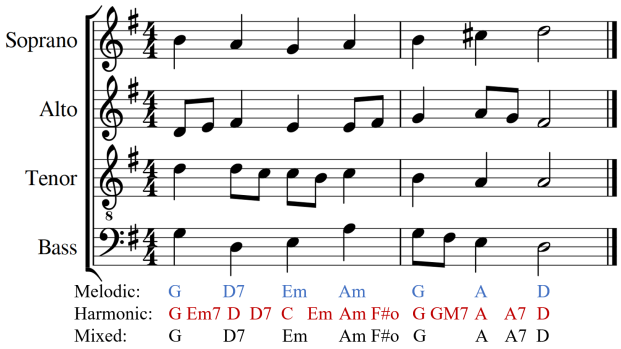

Figure 1. A passage with important differences between melody-oriented (blue) and harmony-oriented (red) analyses. The final analysis (black) mixes the two styles. Such inconsistencies are quite common, even between expert analyses.

In spite of these challenges, there have been various attempts to automate harmonic analysis. Data generated by automated approaches could be used to populate a large-scale, searchable database, which would serve as an invaluable resource for music research. For example, such a database could be used in corpus studies to answer re-

search questions about musical style or the development of modern harmonic practices. Automatic harmonic analysis can also be used in automatic composition and interactive accompaniment systems.

Some researchers have developed rule-based (RB) models for automatic harmonic analysis [4, 8, 10, 21–23]. Although these approaches generate chord labels that are internally consistent, they often fail to produce correct analyses for even moderately exceptional passages, as it is extremely complicated to define rules that are comprehensive enough to account for all possibilities.

Other researchers have made use of manual annotations by experts, who can better respond to exceptions [2,5,6,9,16,17]. Such ground truth can be used to train machine learning (ML) models for automatic harmonic analysis [3, 11, 14, 15, 18, 20, 24]. Although the annotations created by human analysts are more nuanced, manual harmonic annotations require an enormous amount of time and expertise, and can be inconsistent [12], which may undermine a ML model's effectiveness, especially when limited amounts of training data are available.

Due to these difficulties, few large high-quality datasets and automatic harmonic analysis models exist, a situation that has significantly limited the computational study of Western harmony.

In this paper, we combine the strengths of existing approaches to address the common problems of automatic harmonic analysis within a single interactive workflow, using a set of largely homorhythmic [1] Bach chorales. The proposed workflow is illustrated in Fig. 2 and described below:

1. To solve the problem of analytical inconsistency, we use an existing RB model [4] to generate preliminary, consistent chord labels according to a particular analytical style.

2. These analyses are used to pre-train three ML models, [2] which together with the RB model form an algorithm ensemble, where each model within the ensemble labels all the chords. The most-preferred chord labels [3] are then output as *Analysis 1*.

3. To improve the quality of the analyses, a human expert examines only those chords for which the ensemble did not agree unanimously, and corrects them as needed. We call this process "partial manual modification". Compared to annotating chorales from scratch, the amount of required work for the expert is significantly reduced. The first three steps of this workflow are shown in Part 1 of Fig. 2.

4. Once the expert's corrections are obtained (*Analysis 2*), we re-train the ML models. The most-preferred chord labels from the new ensemble are chosen as the final chord labels (*Analysis 3*), which is shown in Part 2 of Fig. 2. This paradigm of manually modifying the generated data and re-training the ML models is known as "interactive machine learning" [1,7].

This workflow is not limited to Bach chorales. With an adapted RB model (Model 4 in Fig. 2), it can easily be applied to other genres of music in a fully automatic way (ending with Analysis 1) or interactively if an expert analyst is available (ending with Analysis 3). The source code, data, and results from this project can be found at: https://bit.ly/2QUdGwH.

2. DETAILS OF METHODOLOGY

This section introduces additional details of the interactive workflow shown in Fig. 2 and described in Section 1.

2.1 Input Data Encoding and Processing

The workflow currently accepts music encoded in Humdrum's **kern symbolic representation. Any other formats that can be faithfully converted to **kern can also be used.

Each chord label consists of the letter-name of the root and the quality of the chord (e.g., C major). Triads can be major, minor, or diminished; and seventh chords can be major, minor, dominant, half-diminished, or fully diminished. Functional Roman numerals are not used, and chordal inversions are not specified.

Chord labels are appended to the original **kern file for each chorale and aligned with the music as "onset slices" [11,13], as shown in Fig. 4. An onset slice is formed whenever a new note onset occurs in *any* musical voice, and consists of a list of all pitch classes sounding at that moment.

Additionally, all chorales and corresponding chord labels were transposed to the same key to make the tonal relationships between pitch classes consistent across the dataset. [4]

2.2 Input Features

Each onset slice is mapped to a feature vector for processing by Model 1, Model 2, and Model 3 of the workflow. These features, [5] and the codes used to refer to them in Section 3, are as follows:

1. **PC12** : A 12-D binary vector of enharmonic pitch classes present in the slice.

2. **M**: A 3-D indication of the metrical context of the slice (down-beat, on-beat, off-beat).

3. **O**: A 12-D vector indicating which PC12 pitch classes are real onsets and which are artificial (see Fig. 4).

4. **Wn**: A variable size vector containing the (non-Wn) features from the n previous and following slices

[1] Homorhythm is a texture where all parts share a very similar rhythm, as in Fig. 1. It is commonly used in hymn and chorale settings.

[2] See the caption of Fig. 2 for the details of these models.

[3] If there is a tie, prefer the label for which the rule-based algorithm voted.

[4] The built-in key transposition function from music21 was used, with the Aarden-Essen key profile (https://bit.ly/2FSIwQY). Chorales were transposed to C major or A minor depending on their mode.

[5] A multi-label one-hot schema was used to encode the features as inputs for the ML algorithms.

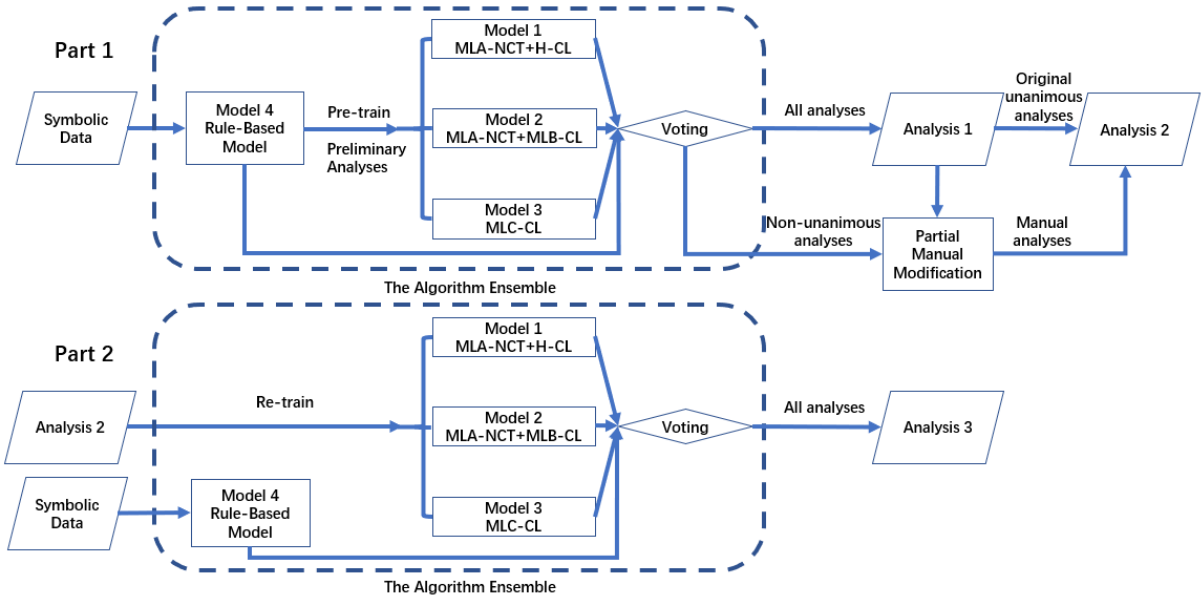

Figure 2. Interactive workflow for automatic harmonic analysis. There are four models within the algorithm ensemble, three of which are trainable. Models 1 and 2 both use a machine learning algorithm (MLA) to identify and remove non-chord tones (NCTs). After this, Model 1 (MLA-NCT+H-CL) uses a heuristic (H) algorithm and Model 2 (MLA-NCT+MLB-CL) uses a ML algorithm (MLB) to infer chord labels (CL) from the remaining chord tones. We term this process "NCT-first harmonic analysis", as shown on the right side of Fig. 3. Model 3 (MLC-CL) uses a single ML algorithm (MLC) to infer chord labels (CL) directly from the pitch-class collections, without removing NCTs. We term this process "direct harmonic analysis", as shown on the left side of Fig. 3.

(e.g., W1 indicates that features for the directly preceding and directly following slices are included in the features of the current slice). These surrounding slices are called "contextual windows".

The workflow allows for experimentation with different feature configurations. For example, a "PC12M" configuration indicates a 15-D vector, with O and Wn features omitted. This notation is adopted in Section 3.

2.3 Rule-Based Algorithms

We use an existing RB model [4] to generate preliminary chord labels (Model 4 in Fig. 2). This tool is publicly accessible online. [6] A "harmonic" rather than "melodic" style of analysis is used (see Fig. 1), which prefers more chord changes and fewer non-chord tones (NCTs) [19], and is better-suited to the typical chorale texture. An overview of the specific heuristics of this style can be found at: https://bit.ly/2XCmNVo. We also used a heuristic algorithm (H-CL from Fig. 2) in Model 1 to infer chord labels from remaining chord tones. The details of this algorithm can be found at: https://bit.ly/2MBL0dp.

2.4 Machine Learning Algorithms

As shown in Fig. 2, the workflow includes three ML algorithms (MLA, MLB, and MLC) to pre-train. MLA treats NCT identification as a multi-label problem; the output of MLA is a 12-dimensional vector specifying which pitch classes are both present and identified as NCTs; MLB and MLC treat chord labeling as a multi-class problem; they output similar vectors identifying the predicted chord label among all candidates.

We tested Support Vector Machines (SVMs) and Deep Neural Networks (DNNs) as MLA, MLB, and MLC classifiers. For DNN, we used three hidden layers, each with 300 hidden units. Adaptive Moment Estimation was used as an optimizer, with loss functions of binary cross-entropy for MLA and categorical cross-entropy for MLB and MLC. SVM used a linear kernel function.

3. EXPERIMENTS

3.1 Data

The experiments below were performed on a modified [7] dataset of Bach chorales originally produced by Craig Sapp. [8] This modified dataset consists of 369 chorales.

To evaluate the performance of our workflow, 39 chorales were randomly chosen before the experiments began and partitioned into a set reserved for final testing in Experiment 2. These reserved chorales had their chords hand-labelled in their entirety by a human expert.

The remaining 330 non-reserved chorales were used for training, validation (early-stopping) and internal testing.

[6] https://bit.ly/2Gh6IhA

[7] Available at: https://bit.ly/2VWHB8w. Some corrections were made to the music and Chorale 150 was added to the dataset. Chorales 130 and 316 were excluded, since the original **kern files and the music21-parsed results are different.

[8] https://bit.ly/2D4ju10

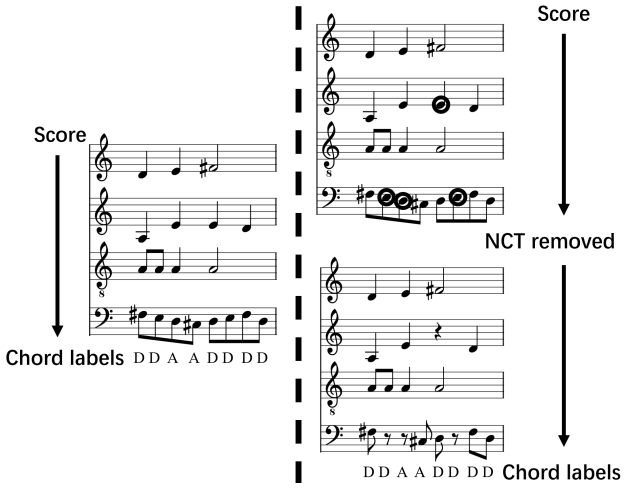

Figure 3. Comparison of "direct harmonic analysis" (left, used by Model 3 in Fig. 2) and "NCT-first harmonic analysis" (right, used by Model 1 and Model 2 in Fig. 2) approaches to automatic harmonic analysis. The former identifies chords directly from the score, while the latter first identifies and removes non-chord tones from the score, and then generates chord labels from the remaining chord tones.

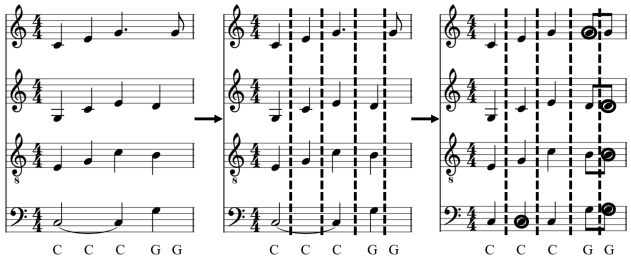

Figure 4. Illustration of note onset slices, aligned with chord labels. An onset slice is created whenever a new note onset occurs in *any* musical voice (middle). Any note sustained from a previous slice becomes an "artificial onset" in the new slice (right, circled).

The initial "ground truth" for these remaining 330 chorales consisted of the labels predicted by the RB model (Model 4), which was found to be quite effective, if not perfect [4]. This imperfect "ground truth" was used in Experiment 1 (see Section 3.2) to get a preliminary sense of how well the workflow's component classifiers performed. Final evaluation was performed in Experiment 2 (see Section 3.3) with the proper, hand-annotated 39-chorale reserved test set.

3.2 Experiment 1

Experiment 1 tested the effectiveness of several different workflow configurations by experimenting on varying input features and learning algorithms (see Section 2.4). The performance of Models 1, 2, and 3 from Fig. 2 were tested.

3.2.1 Experimental Setup

Ten-fold cross-validation was performed on the 330 non-reserved chorales described in Section 3.1. For the DNN experiments, we divided the non-reserved portion of the dataset (330 chorales) into training (80%), validation (10%) and internal testing (10%) folds. The SVM data was divided into training (90%, the union of the DNN training and validation sets) and internal testing (10%, matching the DNN internal test sets) folds. When the W features were included (see Section 2.2), n was set to 1 for MLA and MLC, and to 2 for MLB (represented as W1/2).

3.2.2 Results

The results of Experiment 1 are shown in Table 1. The highest classification value of 90.1% was achieved by Model 2 using PC12MOW1/2 input features. Results show that the addition of a small contextual window (feature Wn) improved the performances of Model 2 and Model 3 significantly.[9] This reflects the general music theoretical understanding that, in cases of ambiguous harmony (e.g., an incomplete chord), a chord's immediate context is essential to label it properly.

It is important to note that these Experiment 1 findings are based on imperfect ground truth (see Section 3.1), and so must be interpreted more as preliminary indications rather than as confirmed truth. Experiment 2 was performed in order to obtain more empirically meaningful results.

3.3 Experiment 2

Experiment 2 compared the performance of the classifier ensemble after fully automated training (Analysis 1 in Fig. 2) with that of the ensemble after human-assisted re-training (Analysis 3 in Fig. 2). This set of experiments involved evaluation on a reserved expert-labelled test set (see Section 3.1).

3.3.1 Experimental Setup

Classification models were pre-trained, had their outputs manually corrected, re-trained, and tested using the full workflow described in Section 1. Pre-training was done using the Model 4 output, just as in Experiment 1.

For the DNN training, we used 90% of the 330 non-reserved chorales as the training set and 10% as the validation set. A cross-validation-like training scheme was used: we conducted 10 experiments by training 10 models with rotated training and validation folds, while the testing fold (39 reserved chorales) remained the same. All 330 non-reserved chorales were used to train each of the SVM classifiers. Only the PC12MOW1/2 input features (see Section 2.2) were used in Experiment 2. For the W features, n was set to 1 for MLA and MLC, and to 2 for MLB (represented as W1/2).

Once Analysis 1 (see Fig. 2) was obtained, the human expert manually corrected only those chords that the ensemble did not agree on unanimously. The corrected labels (Analysis 2) were then used to re-train Models 1, 2, and 3. The 39 manually-labelled reserved test chorales were then used to test the original pre-trained models, and then the

Table 1. Experiment 1 cross-validation classification accuracies, averaged across folds. Uncertainty values indicate standard error across folds. Values indicate the percentage of onset slices "correctly" classified by Model 1 (CA1), Model 2 (CA2), and Model 3 (CA3), based on the Model 4 "ground truth". Columns indicate features (see Section 2.2) and rows indicate machine learning algorithms (see Section 2.4). The best performance in each column is highlighted in bold.

Model	Metric	PC12MOW1/2 Pre-trained	PC12MOW1/2 Re-trained
SVM	CA1	85.9%	87.0%
	CA2	88.6%	89.8%
	CA3	87.7%	89.3%
	CAVote	**91.4%**	92.7%
	PUA	79.1%	79.0%
DNN	CA1	85.4±0.2%	88.1±0.2%
	CA2	88.9±0.3%	91.3±0.4%
	CA3	87.9±0.7%	90.5±0.3%
	CAVote	90.9±0.2%	**93.5±0.2%**
	PUA	80.4±1.2%	79.7±0.4%
RB	CA4	90.7%	

Table 2. Experiment 2 classification accuracies on the reserved test set. DNN values are averaged across models trained using different training/validation sets, and uncertainty values indicate standard error across these folds. Values indicate how many onset slices were correctly classified by Model 1 (CA1), Model 2 (CA2), Model 3 (CA3), Model 4 (CA4), the ensemble as a whole (CAVote), and just those CAVote predictions that were unanimous (PUA). "PC12MOW1/2" indicates the input features (see Section 2.2. "Pre-trained" indicates performance before manual correction (i.e., Analysis 1 in Fig. 2), and "Re-trained" indicates performance after re-training on the corrected data (i.e., Analysis 3 in Fig. 2). The best performance in each column is highlighted in bold.

re-trained models. Performance on this reserved test set is shown in Table 2.

3.3.2 Results

One can see in Table 2 that the original RB algorithm (Model 4 in Fig. 2) attains a chord accuracy of 90.7%, which serves as our baseline. The highest accuracy obtained by the pre-trained ensemble is 91.4%, using PC12MOW1/2, SVM classifiers, and voting. This (pre-trained) performance is achieved without any expert human intervention. It is of interest that CAVote here is higher than CA4, even though the classifiers in CAVote were trained on the RB output; this is perhaps because the RB model is overfitting the theoretical model underlying it, and that the pre-trained ensemble trained on it may in fact be smoothing out some of this overfitting to result in a slightly more general model. A comparison of Table 1 and Table 2 indicates that the Table 1 performance with artificial ground truth is quite similar to the performance of Table 2 pre-trained classifiers on the proper test set; this encouragingly suggests that there is little or no overfitting.

Table 2 also shows that performance improved after re-training in most cases. [10] The best-performing [11] configuration attains an accuracy of 93.5%, using voting DNNs trained on PC12MOW1/2 features.

The partial manual modification workflow is also found to be relatively efficient, as the expert analyst is only required to provide manual analyses for about 20.9% [12] of all slices. Compared to examining and annotating every slice, the amount of required work is reduced substantially.

4. DISCUSSION

According to the results, our interactive workflow performed well on the Bach dataset using a "harmonic" style of analysis. It was found that quite good performance could be achieved with our rule-based model (90.7% on the reserved test data), that performance could be improved slightly using the RB model to self-train a classifier ensemble (91.4% on the test data), and that still greater improvements resulted from partial manual modification and re-training (93.5% on the test data). Although these improvements may seem small in absolute terms, they are statistically significant, and they represent meaningful fractional decreases in the error rate (drops of 7.5% comparing pre-trained CAVote to RB, 30.1% comparing re-trained CAVote to RB, and 24.4% comparing re-trained CAVote to pre-trained CAVote). Of particular importance, the first two approaches require no human intervention, and the third requires much less expert labor than full manual annotation.

Figure 5 provides an illustration of how this approach can be effective, using an excerpt from one of the test set chorales. Although some algorithms within the ensemble

[10] $p<0.05$ in Students' t-tests comparing results before and after re-training for CA1, CA2, CA3, and CAVote, but not PUA.

[11] $p<0.05$ in Students' t-tests comparing results of CAVote to CA1, CA2, CA3, and CA4.

[12] This value is inferred from Table 2: 100% - PUA.

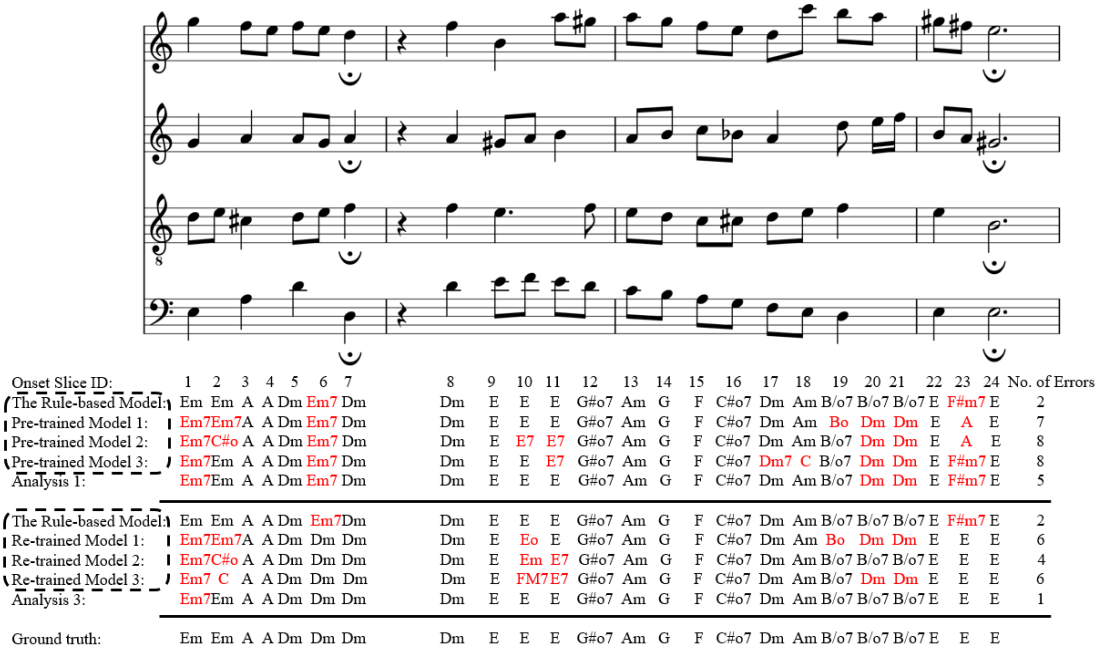

Figure 5. An illustration of how classifications evolve as processes proceed as outlined in Fig. 2, based on measures 9 through 12 of BWV 315 "Gib dich zufrieden und sei stille". Chord labels were generated by a DNN-based algorithm ensemble using PC12MOW1/2 features (see Section 2.2). The algorithm ensemble is made up of the four models within the dashed rectangle, which vote to generate Analyses 1 and 3. The labels above the first horizontal line were generated in a fully automatic way, without any human intervention. The labels between the two horizontal lines (other than the rule-based model) were generated automatically after re-training on partially corrected data. The chord labels highlighted in red are errors compared to the ground truth provided by an expert analyst.

make errors, the re-trained ensemble ultimately generates better answers in Analysis 3. Upon examining the errors, we find that some of them are reasonable alternative versions of the ground truth: chords with the same roots, but with or without an added seventh (slices 1, 11, 17, and 19); or chords that are subsets of the ground truth chords (slices 20 and 21). As a result, some of the "errors" that the ensemble makes in this particular excerpt are in fact theoretically acceptable answers. This is encouraging, as it suggests that at least some of the "mistakes" made by the classifiers may not in fact be mistakes at all. We still count them as mistakes, however, because consistency in analytical style is one of the goals of this work.

5. CONCLUSION AND FUTURE RESEARCH

We present a versatile interactive workflow for generating chord labels for homorhythmic music. It can be used in a fully automatic way or, with a relatively small amount of effort from an expert human analyst who corrects a small, automatically selected fraction of the generated analyses, a re-trained classifier ensemble can be produced that performs even better.

Results show that this workflow is quite compelling: it combines the consistency of rule-based models with the nuance of manual analysis to generate relatively inexpensive, high-quality ground truth for training effective machine learning models. The resulting classifier ensemble is able to automatically generate highly consistent and accurate chord labels, which can serve as invaluable resources for musicians, composers, and music researchers alike.

There are currently a few limitations to our research. First, music21's automatic key-finding might not be ideal for our dataset (early tonal music), and may have resulted in reduced performance due to faulty transpositions. Instead of transposing all chorales to the same key, a better, but more complicated solution would be to augment our data by transposing all chorales to all 12 possible keys. Second, the RB model can be improved to include chords of other qualities (e.g., augmented-sixth chords). Finally, the ground-truth annotations were prepared by a single expert annotator, and it would be better to repeat this process using annotations from multiple experts.

An important next step will be to test this workflow using other analytical styles (e.g., the "melodic" style), which can be done simply by specifying different heuristics in the RB model. We also plan to tackle the larger category of homophonic music, which includes any music with a primary melodic line accompanied by harmonic support. A greater variety of homophonic textures poses a challenge to our RB model because more individual onset slices are harmonically ambiguous, requiring larger contextual windows to correctly interpret the harmony. In light of this, we will modify our workflow to address homophonic music accordingly. Finally, we will investigate training and evaluation protocols that permit multiple valid chord labels per slice.

ACKNOWLEDGEMENT

We would like to thank the Social Sciences and Humanities Research Council of Canada (SSHRC) and the Fonds de recherche du Québec-Société et culture (FRQSC) for their generous funding. We would also like to acknowledge the contributions of our many collaborators on the Single Interface for Music Score Searching and Analysis (SIMSSA) project, especially Emily Hopkins and Gabriel Viglienson.

QUANTIFYING MUSICAL STYLE: RANKING SYMBOLIC MUSIC BASED ON SIMILARITY TO A STYLE

Jeff Ens

ABSTRACT

Modelling human perception of musical similarity is critical for the evaluation of generative music systems, musicological research, and many Music Information Retrieval tasks. Although human similarity judgments are the gold standard, computational analysis is often preferable, since results are often easier to reproduce, and computational methods are much more scalable. Moreover, computation based approaches can be calculated quickly and on demand, which is a prerequisite for use with an online system. We propose StyleRank, a method to measure the similarity between a MIDI file and an arbitrary musical style delineated by a collection of MIDI files. MIDI files are encoded using a novel set of features and an embedding is learned using Random Forests. Experimental evidence demonstrates that StyleRank is highly correlated with human perception of stylistic similarity, and that it is precise enough to rank generated samples based on their similarity to the style of a corpus. In addition, similarity can be measured with respect to a single feature, allowing specific discrepancies between generated samples and a particular musical style to be identified.

1. INTRODUCTION

Measuring musical similarity is a fundamental challenge, related to many tasks in Music Information Retrieval (MIR). In this paper, we focus on measuring the similarity between a MIDI file and an arbitrary musical style. In a musical context, the term style can refer to historical periods, composers, performers, sonic texture, emotion, and genre [8]. Here, we use the term style to denote the musical characteristics exhibited by a corpus $\mathcal{C} = \{C_1, ..., C_n\}$, as expressed by a feature set $\mathcal{F}$. Depending on the contents of $\mathcal{C}$, style may correspond to something as specific as a subset of a composer's work, as general as the entirety of Western Classical Music, or as personal as the musical preferences of an individual.

We propose StyleRank [1], a method for ranking MIDI files based on their similarity to a style delineated by $\mathcal{C}$. It can be used as a tool for musicological research, to evaluate Style Imitation (SI) systems, and to filter the output of an SI system. An SI system aims to generate music that exhibits the stylistic characteristics of $\mathcal{C}$ [27]. The primary contributions are as follows: a collection of novel features for symbolic music representation; an efficient MIDI feature extraction tool written in C++ with bindings in Python; a measure of similarity with respect to an arbitrary style delineated by $\mathcal{C}$; and two experiments demonstrating that this measure is robust, and highly correlated with human perception of stylistic similarity.

2. MOTIVATIONS

There are several motivating factors for this research. In general, modelling human perception of musical similarity is of particular interest within the areas of Musicology, Music Cognition, and Music Theory [42]. Moreover, robust measures of musical similarity are critical for many MIR tasks, including database querying, music recommendation, and genre recognition. Although human perception is the gold standard for measuring musical similarity, natural human limitations place restrictions on the quantity and speed at which judgments can be collected, directly motivating automated measures of musical similarity.

More specifically, there are inherent challenges in designing a robust and reproducible listening experiment to evaluate SI systems. There are many variables which directly effect the quality of an experimental result, such as the number of participants, the listening environment, the sound equipment, and the number of samples selected for comparison. Even controlling for those variables, there is significant variability in how music is perceived, based on one's level of training [5] and musical background [13, 16, 32], which can result in a limited inter-rater agreement [34]. This is a particular issue, as it may hamper reproducibility and comparison with previously published results.

In most cases, sampling from an SI system is a stochastic process, and as a result, generated samples vary in quality. Developing a filtering process for generated material is a high priority concern, as low quality samples are undesirable when using a generative model in a production setting. Although measuring the log-likelihood of a sample can be

[1] The code is available at https://github.com/jeffreyjohnens/style_rank

useful as a proxy for quality, there are cases where log-likelihood significantly diverges from human perception. Theis et al. provide examples of generated images with high log-likelihood and extremely low quality [37]. To the best of our knowledge, there are no pre-existing methods for ranking generated samples with respect to an arbitrary style.

3. RELATED WORK

A wide variety of similarity measures have been developed to measure melodic [41], harmonic [9,25,31] and rhythmic similarity [38]. Many of these algorithms measure similarity by comparing two symbolic sequences [43]. Stylistic similarity, however, is rarely exhibited through sequence similarity, but rather through the repeated use of particular musical devices (i.e. melodic phrases, voice leading, and chord voicing) interspersed throughout the material [43]. In order to address this concern, approaches based on compression or pattern extraction have been proposed to measure similarity [2, 6, 21]. Since we aim to measure similarity with respect to $\mathcal{C}$, a more suitable approach will leverage information about the discriminative aspects of the entire corpus $\mathcal{C}$, rather than only taking two MIDI files into consideration.

In the context of SI system evaluation, the Turing Test [40] and the Consensual Assessment Technique [3] have been used to measure the stylistic similarity between generated artifacts $\mathcal{G} = \{\mathcal{G}_1, ..., \mathcal{G}_m\}$ and a particular style $\mathcal{C}$ [20,28]. Objective measures have also been used to evaluate SI systems. Dong et al. measure the ratio of empty bars, pitch class diversity, note duration, rhythmic consistency, and tonal distance [10]. Trieu and Keller propose a variety of metrics ranging from rhythmic variety to harmonic consistency [39]. Since these metrics produce a single scalar value, it is easy to compare $\mathcal{C}$ and $\mathcal{G}$. However, these high-level metrics are likely only capable of measuring stylistic similarity in a very general sense. Sturm and Ben-Tal. plot distributions of meter, mode, number of tokens, pitch and pitch class for $\mathcal{C}$ and $\mathcal{G}$, but do not provide an automated method for analyzing discrepancies [36].

More comprehensive methodologies have been proposed, which involve computing all pairwise inter-set distances between samples in $\mathcal{C}$ and $\mathcal{G}$ ($D_{\mathcal{CG}} = [\texttt{dist}(c, g) : (c \in \mathcal{C}) \wedge (g \in \mathcal{G})]$), as well as all pairwise intra-set distances for samples within a set ($D_{\mathcal{GG}} = [\texttt{dist}(g_i, g_j) : (g_i \in \mathcal{G}) \wedge (g_j \in \mathcal{G}) \wedge (g_i \neq g_j)]$). [2] CAEMSI [14], a domain independent framework for the analysis of SI systems, provides a statistical method to test the null hypothesis $H_0 : (D_{\mathcal{GG}} \neq D_{\mathcal{CG}}) \vee (D_{\mathcal{CC}} \neq D_{\mathcal{CG}}) \vee (D_{\mathcal{CC}} \neq D_{\mathcal{GG}})$ against the alternative hypothesis $H_1 : D_{\mathcal{GG}} = D_{\mathcal{CC}} = D_{\mathcal{CG}}$. Yang and Lerch extract multi-dimensional features from each MIDI file [44]. For each feature, $D_{\mathcal{CG}}$ and $D_{\mathcal{CC}}$ are constructed using Euclidean distance and smoothed using kernel density estimation [26, 33]. The distance between $D_{\mathcal{CC}}$ and $D_{\mathcal{CG}}$ is measured using (1) the area of overlap and (2) the Kullback–Leibler Divergence [18]. In contrast to both of these approaches, which involve evaluating the similarity between $\mathcal{G}$ and $\mathcal{C}$, StyleRank is optimized to evaluate the similarity of a single sample $g \in \mathcal{G}$ to $\mathcal{C}$.

[2] Note that we adapt the set-builder notation to construct a list (e.g., $[i/2 : 0 \leqslant i < 4] = [0, 0, 1, 1]$), which unlike a set, may contain duplicate values.

4. FEATURES

Although the features extracted by jSymbolic2 [23] are quite comprehensive, many features are high-level, and thus, ill-suited for the fine-grained distinctions that are necessary to rank stylistically similar MIDI files. For example, the `Chord Type Histogram` feature contains only 11 categories. In order to capture the complexity of the musical material being analyzed, we extract a variety of high-dimensional categorical distributions from a single MIDI file. A categorical distribution is a discrete probability distribution describing a random variable that has k possible distinct states. In what follows we adopt the following notation. Given a set x, $||x||$ denotes the number of elements in the set x, $\min(x)$ and $\max(x)$ denote the minimum and maximum element in x respectively, and x_i denotes the i^{th} element in x. $x \backslash y$ is the set difference between x and y, and $x \times y$ is the Cartesian product of x and y. $\ll$ indicates a left bitwise shift and $\gg$ indicates a right bitwise shift. $\&$, $\vee$, and $|$ refer to the bitwise `AND`, `XOR`, and `OR` operations, respectively.

4.1 Pitch Class Set Representations

In order to reduce the number of chords, we discard octave information and represent chords as pitch class sets, using a 12-bit integer to denote the presence or absence of a particular pitch class ($\text{C} = 0, \text{C\#} = 1, ..., \text{B} = 11$). For example, the C-major chord $\{60, 64, 67\}$ corresponds to the pitch class set $x = \{0, 4, 7\}$, which corresponds to the integer $\sum_{i=1}^{||x||}(1 \ll x_i) = 2^0 + 2^4 + 2^7 = 145$. Since there are 12 pitch classes, there are $2^{12} = 4096$ pitch class sets, which greatly reduces the possible number of chords. However, it is possible to further reduce this space if we create an equivalence class for all transpositionally equivalent pitch class sets. For example, the pitch class sets $\{0, 4, 7\}$ and $\{2, 5, 10\}$ are transpositionally equivalent, as both are major chords, the only difference being their root. This results in 352 distinct pitch class sets (PCD). Using Eq. (1c) a PCD can be calculated, where x is an 12-bit integer. Notably, pitch class sets are considered equivalent under the reversal operation when calculating the Forte number of a pitch class set [15]. Consequently, the pitch class sets $\{0, 4, 7\}$ and $\{0, 3, 7\}$ have the same Forte number, but correspond to different PCD's.

$$\texttt{rot}(x, n, i) = (x \ll i) \mid (x \gg (n-i)) \;\&\; (2^n - 1) \quad \text{(1a)}$$

$$\texttt{reduce}(x, n) = \min(\{\texttt{rot}(x, n, i) : 0 \leqslant i < n\}) \quad \text{(1b)}$$

$$\texttt{pcd}(x) = \texttt{reduce}(x, 12) \quad \text{(1c)}$$

Alternatively, a pitch class set x can be represented as the set of scales which are supersets of x. Given a scale $\mathbb{S}$, let $\mathbb{S}_i = \{(s + i) \mod 12 : s \in \mathbb{S}\}$. The scale representation can be calculated with Eq. (2), where

$\mathbb{S}^{\text{M}} = \{0,2,4,5,7,9,11\}$ and $\mathbb{S}^{\text{H}} = \{0,2,3,5,7,8,11\}$ denote the major and harmonic minor scales respectively. $\phi(\cdot)$ returns 1 if the predicate $\cdot$ is true and 0 otherwise.

$$\texttt{sc}(x) = \Big(\sum_{i=1}^{12} \phi(x \subseteq \mathbb{S}_i^{\text{M}}) \ll i\Big) + \Big(\sum_{i=1}^{12} \phi(x \subseteq \mathbb{S}_i^{\text{H}}) \ll (12+i)\Big) \quad (2)$$

4.2 Feature Definitions

Given a MIDI file M, for each note $n \in M$, $\texttt{ons}(n)$ returns the onset time of n in ticks, $\texttt{dur}(n)$ returns the duration of n in ticks, and $\texttt{pitch}(n)$ returns the pitch. An ordered set containing the unique onsets $O = \{\texttt{ons}(n) : n \in M\}$ is constructed, and the i^{th} chord is the set of notes $\mathbb{C}^i = \{n : (\texttt{ons}(n) \leqslant O_i) \wedge (\texttt{ons}(n) + \texttt{dur}(n) > O_i)\}$. $\texttt{isOns}(\mathbb{C}, n)$ and $\texttt{isTie}(\mathbb{C}, n)$ are functions that return 1 if n is an onset or a tie respectively, and 0 otherwise. The function $\texttt{pc}_i(\mathbb{C}, n)$ returns 1 if n corresponds to the pitch class i and 0 otherwise. In order to simplify the feature definitions, we use Eq. (3d), which accepts a chord $\mathbb{C}$ and a set of functions F, and only returns 1 if there is an element in X for which each $f \in F$ evaluates to 1. As a result, $\mathbf{I}\big(\mathbb{C}, \{\texttt{isOns}, \texttt{pc}_i\}\big)$ is 1 if there is a note $n \in \mathbb{C}$ that is an onset and is equivalent to the pitch class i.

$$\texttt{pc}_i(\mathbb{C},n) = \begin{cases} 0, & \text{if } \texttt{pitch}(n) \mod 12 \equiv i \\ 1, & \text{otherwise} \end{cases} \quad (3a)$$

$$\texttt{isOns}(\mathbb{C},n) = \begin{cases} 0, & \text{if } \max(\{\texttt{ons}(n) : n \in \mathbb{C}\}) > \texttt{ons}(n) \\ 1, & \text{otherwise} \end{cases} \quad (3b)$$

$$\texttt{isTie}(\mathbb{C},n) = 1 - \texttt{isOns}(\mathbb{C},n) \quad (3c)$$

$$\mathbf{I}(\mathbb{C},F) = \begin{cases} 0, & \text{if } \max\big(\{\prod_{i=1}^{||F||} F_i(\mathbb{C},n) : n \in \mathbb{C}\}\big) < 1 \\ 1, & \text{otherwise} \end{cases} \quad (3d)$$

Table 1 provides formal definitions of all the features, where $\mathbb{C}^t$ denotes the t^{th} chord, $\mathbb{M}^t$ denotes the t^{th} melody pitch, $\mathbb{P}^t = \{\texttt{pitch}(n) : n \in \mathbb{C}^t\}$, $\mathbb{O}^t = \{\texttt{ons}(n) : n \in \mathbb{C}^t\}$, and $\mathbb{K}^t = \{\texttt{pitch}(n) : (n \in \mathbb{C}^t) \wedge \texttt{isOns}(n)\}$. $\texttt{popcount}(\cdot)$ is a function that counts the number of set bits in an integer, $\texttt{pc}(x) = x \mod 12$ and $\texttt{pcc}(x) = |(x \mod 12) - 6|$. Dissonance is calculated using Stolzenburg's periodicity function [35], which we refer to as $\texttt{stol}(\cdot)$. Let $\texttt{diss}(\mathbb{P}, \mathbb{T}) = \frac{1}{||\mathbb{T}||} \sum_{x \in \mathbb{T}} \texttt{stol}(\bar{\mathbb{P}}^x)$, where $\mathbb{P}$ and $\mathbb{T}$ are pitch sets, and $\bar{\mathbb{P}}^x = \{\mathbb{P}_i - x : \mathbb{P}_i \in \mathbb{P}\}$. $\texttt{voiceMotion}(\cdot)$ is a function that accepts two successive pitch sets $(\mathbb{P}^t, \mathbb{P}^{t+1})$ and returns an integer corresponding to the type of voice motion. $\texttt{tonnetzLength}(\cdot)$ is a function that accepts a pitch class set and returns the length of the shortest path through Tonnetz [24] vertices containing each pitch class.

Each function is calculated for all valid values of t, resulting in a categorical distribution with unsigned 64-bit integers as the categories. For example, given a standard 4-voice Bach chorale containing m chords, the function $\texttt{ChordSize}$ is calculated for $0 \leqslant t < m - 2$, producing a categorical distribution with the categories $\{0,1,2,3,4\}$. In some cases, we weight values by chord duration, denoted by a $\star$ in the table. In the case that a function returns a set of values ($\texttt{IntervalDist}$), we combine the returned sets to form the categorical distribution. Since the number of categories k grows exponentially large for some features (e.g., $\texttt{ChordShape}$), we restrict $k \leqslant 1000$ by ranking categories according to the number of samples they appear in, removing infrequently occurring categories.

4.3 Implementation

We implement the feature extraction tool in C++, using pybind11 [17] to create Python bindings. The Midifile library [3] is used to parse MIDI files.

5. SIMILARITY COMPUTATION

In the most general sense, we are interested in measuring the similarity between a single MIDI file $\mathcal{X}$ and a corpus $\mathcal{C} = \{\mathcal{C}_1, ..., \mathcal{C}_n\}$. We represent each MIDI file by applying a non-empty set of feature transformations $\mathcal{F} = \{f_1, ..., f_k\}$, producing a set of categorical distributions for each MIDI file. For each $f_i \in \mathcal{F}$, we aim to measure the similarity between a single categorical distribution $f_i(\mathcal{X})$ and a set of categorical distributions $f_i(\mathcal{C}) = \{f_i(\mathcal{C}_1), ..., f_i(\mathcal{C}_n)\}$. Using a distance metric $\mathscr{D}$, the average similarity could be calculated $\frac{1}{n}\sum_{i=1}^{n} 1 - \mathscr{D}(f_i(\mathcal{C}_i), f_i(\mathcal{X}))$. However, this approach does not leverage information about the discriminative aspects of the entire corpus. The results in Experiment 1 demonstrate the deficiencies of this approach. Instead, we use Random Forests [7] to construct an embedding space before measuring the average similarity. Although neural networks are often ideal for learning embeddings, the time required to train k neural networks is prohibitive for an online system.

Decision trees are commonly used to model complex data. When used to classify data, each terminal node represents a discrete class label, and an arbitrary input is classified based on the terminal node it reaches. Using a trained Random Forest, an input can be represented based on the terminal node it reaches in each decision tree. Given a Random Forest containing N decision trees each with L terminal nodes, an input can be represented as a vector $v \in \{0,1\}^{N \times L}$. To learn an embedding for a single feature transformation $f_i \in \mathcal{F}$, we train a Random Forest to discriminate between a collection of items $f_i(\mathcal{G}) = \{f_i(\mathcal{G}_1), .., f_i(\mathcal{G}_m)\}$ and a corpus $f_i(\mathcal{C}) = \{f_i(\mathcal{C}_1), ..., f_i(\mathcal{C}_n)\}$. Concretely, each $f_i(\mathcal{G}_i) \in f_i(\mathcal{G})$ is given the label 0, and each $f_i(\mathcal{C}_i) \in f_i(\mathcal{C})$ is given the label 1. We refer to the vector produced for a sample $\mathcal{X}$ as $\mathbf{R}_{\mathcal{X}}^{\mathcal{G},\mathcal{C},f_i}$. Breiman measures the similarity of two vectors using the dot product [7]. In order to weight each feature transformation ($f_i \in \mathcal{F}$) equally, we use cosine similarity (Eq. (4a)), which is simply the normalized dot product. The similarity between $\mathcal{X}$ and $\mathcal{C}$ with respect to a set of

6. EXPERIMENTS

In the following experiments, we train a Random Forest [7] using the scikit-learn python module [30]. We set the maximum tree depth at 5, the number of trees to 500, and measure the quality of the split using entropy. The class weight is balanced to be robust against size discrepancies between $\mathcal{C}$ and $\mathcal{G}$.

6.1 Experiment 1 : Analytic Testing

We test StyleRank with styles delineated by a single composer, and by an entire genre, using the Classical Archives MIDI dataset [4] . In total there are 75 composers, and 6 musical genres. More details on the composition of the dataset can be found in the Appendix [5] . We keep only one MIDI file per composition. Each MIDI file is represented as a list of pitches, sorted lexicographically according to onset and pitch. To compare two pieces, the Levenshtein distance [19] is measured twice, once for the first 100 pitches in each piece, and once for the last 100 pitches. We eliminate pieces which have a Levenshtein distance less than 0.75, after normalizing the distance on the range $[0, 1]$. We choose this conservative value to ensure all duplicates are removed.

Given two styles $A = \{a_1, ..., a_m\}$ and $B = \{b_1, ..., b_n\}$, where $m = 2n$, let $\mathcal{C} = \{a_i : 1 \leqslant i \leqslant n\}$,

[4] https://www.classicalarchives.com/midi.html

[5] https://github.com/jeffreyjohnens/style_rank/tree/master/appendix

$\mathcal{G}_A = \{a_i : n < i \leqslant 2n\}$, $\mathcal{G}_B = B$, and $\mathcal{G} = \mathcal{G}_A \cup \mathcal{G}_B$. By construction $\mathcal{G} \cap \mathcal{C} = \varnothing$. We train a Random Forest and compare two distributions $x = [S_g^{\mathcal{G},\mathcal{C},\mathcal{F}} : g \in \mathcal{G}_A]$ and $y = [S_g^{\mathcal{G},\mathcal{C},\mathcal{F}} : g \in \mathcal{G}_B]$, where $\mathcal{F}$ denotes the set of features described in Table 1. Ideally, each value in x should be larger than all values in y, since elements in $\mathcal{G}_A$ and $\mathcal{C}$ belong to the same style (A). However, depending on the specificity of the style, there may be some degree of overlap between A and B. In order to determine if there is a measurable difference between x and y we directly compare the means $(\bar{x} > \bar{y})$, and we calculate the p-value $(p^{\bar{x}>\bar{y}})$ for a One-Sided Mann-Whitney test [22] with the alternative hypothesis that $\bar{x} > \bar{y}$.

In cases where multiple statistical comparisons are performed, it is common practice to apply a correction to the raw p-values. The Bonferroni correction [11] is calculated by dividing the desired level of significance $(\alpha = 0.05)$ by the number of comparisons. The Benjamini–Yekutieli procedure [4] controls the false discovery rate under arbitrary dependence assumptions, and is less conservative than the Bonferroni correction. Given m null hypotheses and their corresponding p-values $P_1, ..., P_m$, the p-values are sorted in ascending order. For a given level of significance, in our case $\alpha = 0.05$, reject the null hypothesis for the first k values that satisfy $P_k \leqslant k\alpha/(m * c(m))$ where $c(m) = \sum_{i=1}^{m} 1/i$.

Table 2 shows the results of 1000 trials, reporting the percentage of trials where $\bar{x} > \bar{y}$, and the percentage of trials where $p^{\bar{x}>\bar{y}}$ is significant, applying no correction $(\alpha = 0.05)$, the Benjamini–Yekutieli procedure (FDR), and the Bonferroni correction (Bon). We compare StyleRank against three distance measures, Cosine, Manhattan and Euclidean, replacing $S_g^{\mathcal{G},\mathcal{C},\mathcal{F}}$ with $\frac{1}{||\mathcal{C}||||\mathcal{F}||} \sum_{c\in\mathcal{C}} \sum_{f\in\mathcal{F}} 1 - \mathscr{D}(f(c), f(g))$.

6.2 Experiment 2: Congruity with Human Perception

In order to evaluate how well StyleRank correlates with human perception, we use data from the BachBot [20] experiment. In total, there were 5,967 participants, including 1329 novices, 2786 intermediate, 1341 advanced and 511 experts. Liang et al. generated 36 samples $(\mathcal{G})$ from a neural network trained on a collection of Bach Chorales $(\mathcal{C})$. Participants were asked to discriminate between a generated musical excerpt and an actual Bach chorale. They were each asked to complete 5 comparisons.

For each $g \in \mathcal{G}$, we count the number of times it was mistakenly classified as a Bach chorale N_g^{miss}, and the number of times it was correctly identified as computer generated N_g^{corr}. The raw count data can be found in the Appendix. We take the relative frequency of missclassifications $T_g = N_g^{\text{miss}}/(N_g^{\text{miss}} + N_g^{\text{corr}})$ as an indication of how similar g is to the style of Bach's Chorales $(\mathcal{C})$. This results in $\binom{36}{2} = 630$ pairwise comparisons for which we have a ground truth ranking. Using a chi-square contingency test [29] we can measure the degree to which we are certain that there is a difference between two samples. We measure accuracy using Eq. (5b), where p_{ij} is the p-value for the chi-square contingency test comparing the counts for the i^{th} and j^{th} examples, $\phi(\cdot)$ is a function returning 1 if the predicate $\cdot$ is true and 0 otherwise, and α denotes the threshold for significance.

$$f(x,y) = \begin{cases} 1, & \text{if } \phi\big(S_x^{\mathcal{G},\mathcal{C},\mathcal{F}} < S_y^{\mathcal{G},\mathcal{C},\mathcal{F}}\big) = \phi\big(T_x < T_y\big) \\ 0, & \text{otherwise} \end{cases} \tag{5a}$$

$$\texttt{acc}(\mathcal{G},\mathcal{C},\alpha) = \frac{\sum_{i=1}^{||\mathcal{G}||} \sum_{j=i+1}^{||\mathcal{G}||} f(\mathcal{G}_i,\mathcal{G}_j)\phi(p_{ij} < \alpha)}{\sum_{i=1}^{||\mathcal{G}||} \sum_{j=i+1}^{||\mathcal{G}||} \phi(p_{ij} < \alpha)} \tag{5b}$$

The results for Experiment 2 are presented in Table 3. We report the accuracy, calculated using Eq. (5b), for a random ranking (Random), StyleRank with the jSymbolic [23] features (jSymbolic), Log-likelihood (Loglik), and StyleRank. All the default features are extracted using jSymbolic, and features with zero standard deviation are removed. This results in a single feature vector with dimension of 453, for which we train a single Random Forest. Using the Performance RNN [12], which was trained with the same representation and data as the original BachBot, we evaluate the negative log-likelihood $\mathscr{L}_g$ of each of the generated examples (loglik). To calculate the accuracy we simply replace the term $S_X^{\mathcal{G},\mathcal{C},\mathcal{F}} < S_Y^{\mathcal{G},\mathcal{C},\mathcal{F}}$ with $\mathscr{L}_X < \mathscr{L}_Y$ in Eq. (5a).

7. DISCUSSION

Collectively, the results of both experiments demonstrate that StyleRank is robust to corpora of varying sizes, and highly correlated with human perception of stylistic similarity. In the Appendix, we expand Experiment 1 to demonstrate that StyleRank's performance is robust, even when the number of distinct styles in $\mathcal{G}$ is increased. In Experiment 1, there is a large difference between raw distance measures and StyleRank. This highlights the limitations of the approach described by Yang and Lerch, which uses euclidean distance to measure the distance between feature vectors [44]. Although euclidean distance works well in low-dimensional settings, it does not scale well to high dimensions. In fact, it has been shown that Manhattan distance performs better than Euclidean distance in high dimensional settings [1], which we also see in our own experimental results. Understandably, there is a decrease in performance when analyzing styles delineated by genre, as these styles have more variance, and are less consistent than the work of a single composer. Overall, these results demonstrate that StyleRank can proficiently rank MIDI files with different styles.

The results for Experiment 2 demonstrate that StyleRank is capable of making fine-grained distinctions between MIDI files that correspond with human perception of stylistic similarity. It is worth noting that participants found it difficult to discriminate between generated and human-composed samples in the BachBot experiment, evidenced by the average classification accuracy of novice (0.57), intermediate (0.64), advanced (0.68), and expert

Table 3. The accuracy of each model, calculated using Eq. (5b), with standard error calculated over 10 trials.

(0.71) participants [20]. Based on our experimental results, the jSymbolic [23] feature set is no better at predicting rankings than a random model. This is likely due to the fact that high level features are not sufficiently discriminative for this task. In contrast to the jSymbolic feature set, our method involves full categorical distributions, which we believe are critical in measuring fine-grained differences. Importantly, there is a substantial difference between the accuracy of rankings based on log-likelihood and StyleRank. Interestingly, both log-likelihood and StyleRank best model high certainty ($\alpha = 0.005$) comparisons made by self identified novices. This may be an artifact of increased variance as the number of ground truth comparisons decreases as α increases.

It should be noted that participants in the BachBot experiment were not directly asked to rank samples according to their similarity to the style of Bach's chorales. We extrapolated a ranking from the number of times a sample was miss-classified, which is an indirect way of measuring stylistic similarity. However, since these rankings were based on a large sample size, we are confident that they are reflective of human perception.

8. APPLICATION

StyleRank can be used in a variety of settings. Importantly, we must note that there are no limitations on the composition of $\mathcal{G}$. For example, one could compare k different sets with $\mathcal{G} = \{\mathcal{G}_i^1, ..., \mathcal{G}_{n_1}^1, \mathcal{G}_1^2, ..., \mathcal{G}_{n_2}^2, ..., \mathcal{G}_1^k, ..., \mathcal{G}_{n_k}^k\}$. First of all, the method can be use to rank samples generated by an SI system, based on their similarity to $\mathcal{C}$. StyleRank can be used to filter highly dissimilar samples automatically. Filtering is as simple as taking the samples $g \in \mathcal{G}$ with a similarity $S_g^{\mathcal{G},\mathcal{C},\mathcal{F}}$ above some threshold, and discarding the rest. Secondly, StyleRank can be used to rank models. Given k models, let $\mathcal{G} = \{\mathcal{G}^1, ..., \mathcal{G}^k\} = \{\mathcal{G}_i^1, ..., \mathcal{G}_{n_1}^1, ..., \mathcal{G}_1^k, ..., \mathcal{G}_{n_k}^k\}$, where $\mathcal{G}^i$ denotes the set of samples generated by the i^{th} model. Then the distributions $x_i = [S_g^{\mathcal{G},\mathcal{C},\mathcal{F}} : g \in \mathcal{G}^i]$ can be compared using an appropriate statistical test. Third, the method can be used to isolate the specific features f that deviate from the style delineated by $\mathcal{C}$ by comparing the distributions $x_f = [S_g^{\mathcal{G},\mathcal{C},f} : g \in \mathcal{G}]$ for each f in a set of features $\mathcal{F}$. In addition, StyleRank can be used as a tool for musicologists to explore variations in style.

9. CONCLUSION

Quantifying musical stylistic similarity is a difficult task. We propose StyleRank, a method to rank individual MIDI files based on their similarity to an arbitrary style. Experimental evidence supports our approach, demonstrating that our method is robust, and is highly correlated with human perception of stylistic similarity. Future work involves applying this approach to other domains where SI systems are being developed. Additional features can be added to the current collection, in particular rhythm-based features, as the current collection is pitch-centric. Although we believe our experiments to be fairly comprehensive, continued validation of the proposed method on additional data is always beneficial.

ABSTRACT

In recent years, music source separation has been one of the most intensively studied research areas in music information retrieval. Improvements in deep learning lead to a big progress in music source separation performance. However, most of the previous studies are restricted to separating a few limited number of sources, such as vocals, drums, bass, and other. In this study, we propose a network for audio query-based music source separation that can explicitly encode the source information from a query signal regardless of the number and/or kind of target signals. The proposed method consists of a Query-net and a Separator: given a query and a mixture, the Query-net encodes the query into the latent space, and the Separator estimates masks conditioned by the latent vector, which is then applied to the mixture for separation. The Separator can also generate masks using the latent vector from the training samples, allowing separation in the absence of a query. We evaluate our method on the MUSDB18 dataset, and experimental results show that the proposed method can separate multiple sources with a single network. In addition, through further investigation of the latent space we demonstrate that our method can generate continuous outputs via latent vector interpolation.

1. INTRODUCTION

Music source separation, isolating the signals of certain instruments from a mixture, has been intensively studied in recent years. Due to the improvements in deep learning techniques, various approaches using deep learning for music source separation have been introduced. However, most of the previous studies are mainly focused on improving music source separation performances, not the range of separable sources. To tackle this problem, a few studies have tried to separate the fixed number of sources of interest by conditioning one-hot label in the deep learning network [14, 15].

*these authors contributed equally

While being the most straight-forward approach, we argue that such an approach is not a proper way to deal with the *outliers* when the generic and broadly defined class labels are the only available data at hand [7, 11]. To understand this situation more concretely, let us consider the mismatched situations where the target source is classified into a certain generic class but still somewhat far from the general characteristics of that broadly defined generic class. For example, consider the situation where we desire to separate 'distorted singing voice' or 'acoustic guitar' sources. In these cases, we can imagine that the performance can be boosted if we were to have more fine-grained labels such as 'distorted singing voice' or 'acoustic guitar' rather than generic classes such as 'vocals' or 'guitar'. One of the simplest ad-hoc solutions, therefore, can be manually annotating such *outliers* based on the music instrument ontology and conditioning those new classes into the deep learning network. Unfortunately, manually annotating an audio signal has limitation in many aspects. First, labeling an audio itself is costly. Second, given the same audio samples, the number of samples per class is reduced, hence it is likely that the separation performance degrades. Third, such a method is not scalable to new outlier samples, and is thus limited.

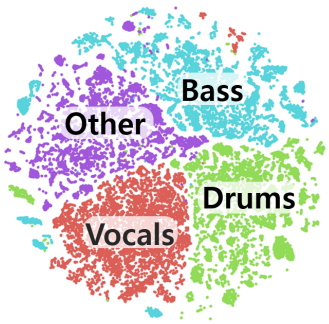

Figure 1. t-SNE visualization [8] of encoded latent vectors of the test dataset in MUSDB18. Without any classification loss, the Query-net is trained to output latent vectors that provide useful information about various instruments. It is observable that the latent vectors from the same class are clustered in the latent space while not being identical.

To deal with these problems, in this paper, a novel audio query-based music source separation framework is proposed. The main idea is to directly compress the diverse au-

dio samples into latent vectors – using the so-called *Query-net* – so that the audio samples can be mapped into non-identical points even when the samples are from the same class as illustrated in Fig. 1. The encoded latent vector is then fed into a separation network to output a source whose characteristics is similar to the audio sample taken into the Query-net. The proposed framework is scalable as the Query-net is able to encode an unseen singing voice or instrument sound into the continuous latent space. This property allows many useful utilities as follows. First, it is capable of separating various number of sources with a single network. Second, we can expect an increase in separation performance especially when the characteristics of the target source in the mixture is considered far from the given generic class since the user can manually select and encode the held-out sound sample that is deemed similar to the target signal. Third, it allows the natural control of the output of the separation network by interpolating the latent vectors in the continuous latent space.

To demonstrate the usefulness of the proposed method, we show various experiments using the MUSDB18 dataset [11]. The experiments show that the output of the separation network is highly dependent on the latent vector which allows smooth transition in signal level by controlling and interpolating the latent vectors. Also, we show that the proposed method becomes especially useful when the target source of interest is far from the general characteristic of coarsely defined sound class. Finally, we show that the proposed method can be even automated by iteratively encoding the separation output.

2. RELATED WORK

In this section, we first introduce previous music source separation studies that tried to separate mixture into multiple sound classes. One of the most basic ways is to estimate several separation masks with a single model. In [10], they tried to separate four sources with one stacked hourglass model [9]. While they showed a competitive results the method is not flexible as the model requires a fixed number of output. Next, [15] introduced a one-hot label conditioning approach and showed that their proposed method is capable of separating multiple sources. This method is more flexible than the aforementioned model but the model does not assume latent space, therefore, is not capable of manipulating output other than conditioning the one-hot label. Finally, [14] showed that they can embed each time-frequency bin of the mixture into a high-dimensional space using deep clustering [1] approach. However, this approach still has a limitation in that the model is not capable of encoding the audio signal directly into the latent space. Apart from the music source separation studies, [21] suggested a speaker-dependent speech separation method by incorporating a lstm-based anchor vector encoder which enables direct encoding of audio signal into a latent space. Using this technique, they showed that the proposed method can cluster the time-frequency bin embeddings that are close to the anchor vector in the latent space.

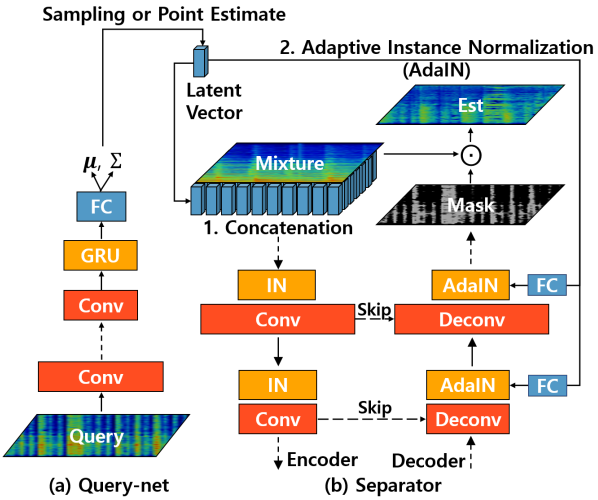

Figure 2. Illustration of the (a) Query-net and (b) Separator. The Query-net encodes the query into the latent vector and it is passed into the Separator by two methods. 1. Concatenation: The latent vector is concatenated with mixture spectrogram by tiling the latent vector along the spatial dimension. 2. AdaIN: Adaptive instance normalization is used in every layer of decoder part.

3. PROPOSED METHOD

3.1 Query-based Source Separation

The proposed framework is composed of two deep learning networks, Query-net $\mathbb{Q}(\cdot)$ and Separator $\mathbb{S}(\cdot)$. While most of the previous studies typically use $\mathbb{S}$ to extract a single class source from a mixture, we aim to separate the mixture by manipulating the additional input signal, a query. By doing so, we can expect to have a control over the mixture just by choosing a different query input which can be done either manually by the user or automatically by the system. Hence, the query signal is expected to be sampled from a similar sound class to the target signal within the mixture, but does not have to be identical. To achieve this, $\mathbb{Q}$ directly encodes the query audio signal into a latent vector so that we can control the output of $\mathbb{S}$ by manipulating the latent space.

$\mathbb{Q}$ is composed of 6 strided-convolutional layers followed by gated recurrent unit (GRU) layer. The stack of strided-convolutional layers are used to extract local features from the given query signal. Then, the extracted features are reshaped by stacking each feature map along the frequency axis. Finally, the reshaped tensor is passed into GRU and the last state of the GRU is used as a summary of the query signal. As we would like the encoded latent vector to have a meaningful high-level information, we designed $\mathbb{Q}$ to map the query into a small enough dimension compared to the dimension of the query signal. After the audio query has been encoded, the summarized information is passed into $\mathbb{S}$.

$\mathbb{S}$ is a U-Net [13] based network which has proven its effectiveness in many source separation studies [3, 10, 16, 18, 19]. It is a convolutional encoder and decoder with skip-

connections between the layers. $\mathbb{S}$ takes the mixture signal and estimate a sigmoid mask to separate the mixture into a source given the summarized information of query from $\mathbb{Q}$. To effectively pass the summary of the query signal to $\mathbb{S}$, we applied two methods. First, we simply concatenated the latent vector along the channel dimension of the input mixture spectrogram expecting the summarized information to be delivered from the start. Second, we used the adaptive instance normalization (AdaIN) technique in the decoding stage of $\mathbb{S}$, which is proven to be effective in many studies for conditioning latent vectors [2, 4]. AdaIN is simply done by applying two steps on each output $\mathbf{x}$ of the convolutional layer (before activation) of the decoder part of $\mathbb{S}$. First, each i-th feature map $\mathbf{x}_i$ is normalized using instance normalization technique [2]. Second, affine transformation is applied to the normalized feature map using learned scale and bias parameters which transforms encoded query vector $\mathbf{z}$ into $\mathbf{y}_s$ and $\mathbf{y}_i$ respectively as follows, $\mathbf{y}_s = W_s^T\mathbf{z}$, $\mathbf{y}_b = W_b^T\mathbf{z}$, where W_s and W_b denote the trainable parameters,

$$\text{AdaIN}(\mathbf{x}_i, \mathbf{y}) = \mathbf{y}_{s,i} \cdot (\frac{\mathbf{x}_i - \mu(\mathbf{x}_i)}{\sigma(\mathbf{x}_i)}) + \mathbf{y}_{b,i}. \quad (1)$$

The overall framework of the proposed method is illustrated in Fig. 2.

3.2 Training

3.2.1 Data Sampling

We first describe how the mixture and target source are selected throughout the training phase.

Let, v_i be the single source sampled from i-th source class, where $i \in \{1, 2, 3..., K\}$ and K denote the total number of source classes. We split the classes into two groups by randomly assigning each source class into group T (Target) and R (Rest) without replacement until every class is assigned to one of the two groups. Next, we multiply binary value α_i to the v_i, where α_i being sampled from the Bernoulli distribution, $\alpha_i \sim Bernoulli(0.5)$. This was done to make sure that there are not too many sources included in the mixture. After then, as a data augmentation strategy [20], we scale each source by multiplying a value β_i to source v_i, where β_i is sampled from the Uniform distribution, $\beta_i \sim \mathcal{U}$[0.25, 1.25]. Finally, the sources in each group is added to form two waveforms s_T and s_R and the mixture m is constructed as the linear sum of s_T and s_R as follows,

$$m = s_T + s_R = \sum_{i \in T}(\beta_i \cdot \alpha_i \cdot v_i) + \sum_{j \in R}(\beta_j \cdot \alpha_j \cdot v_j). \quad (2)$$

As we used magnitude spectrogram as input of the modules, m, s_T, and s_R are transformed into short-time-Fourier-transform (STFT) domain, which we denote in capital letter M, S_T and S_R, respectively. Note that, we do not assume any musicality of mixture signal, hence each class is sampled from arbitrary mixture tracks.

3.2.2 cVAE with Latent Regressor

To design the proposed framework, we borrow the formulation of conditional variational autoencoder (cVAE). While the latent vector $\mathbf{z}$ can be deterministically encoded into the latent space, in cVAE framework, $\mathbf{z}$ is instead sampled from the Gaussian distribution, where the parameters of the distribution (mean and variance) are estimated from $\mathbb{Q}$. Then, $\mathbb{S}$ is used to reconstruct S_T given M and $\mathbf{z} \sim \mathbb{Q}(S_T)$. This is ensured by one of the two objectives of cVAE, namely, reconstruction loss $\mathcal{L}_R$. The purpose of $\mathcal{L}_R$ is to guarantee that the output of $\mathbb{S}$ is dependent on the encoded latent vector as follows,

$$\mathcal{L}_R = \mathbb{E}_{S_T \sim p(S_T),\, M \sim p(M),\, \mathbf{z} \sim \mathbb{Q}(S_T)}[\|S_T - \mathbb{S}(M, \mathbf{z})\|]_1. \quad (3)$$

Note that, in training phase, the latent vector $\mathbf{z}$ is sampled using re-parameterization trick to allow backpropagation in training phase [5].

Next, KL-divergence loss is used to make the distribution of $\mathbf{z}$ be close to the Gaussian distribution $\mathcal{N}(\mathbf{0}, I)$ to guarantee a sampling at test time.

$$\mathcal{L}_{\text{KL}} = \mathbb{E}_{S_T \sim p(S_T)}\left[\mathcal{D}_{\mathbf{KL}}(\mathbb{Q}(S_T) \| \mathcal{N}(\mathbf{0}, I))\right] \quad (4)$$

Apart from cVAE framework, we also adopted latent regressor used in [24] to enforce the output of $\mathbb{S}$ to be more dependent on the latent vector. First, a random vector z is drawn from the prior Gaussian distribution $\mathcal{N}(\mathbf{0}, I)$ and passed to $\mathbb{S}$. Then, $\mathbb{S}$ produces a reasonable output reflecting the information in the random vector. Finally, $\mathbb{Q}$ is reused to restore the random vector from the output from $\mathbb{S}$. Note that, unlike Eq. 3 and 4, only the mean values (μ) are taken from $\mathbb{Q}$ as a point estimate of $\mathbf{z}$.

$$\mathcal{L}_{latent} = \mathbb{E}_{M \sim p(M),\, \mathbf{z} \sim p(\mathbf{z})}\|\mathbf{z} - \mathbb{Q}(\mathbb{S}(M, \mathbf{z}))\|_1 \quad (5)$$

Finally, the total loss can be written as follows,

$$\mathcal{L}_{Total} = \lambda_R\mathcal{L}_R + \lambda_{\text{KL}}\mathcal{L}_{\text{KL}} + \lambda_{latent}\mathcal{L}_{latent}. \quad (6)$$

3.3 Test

During the training phase, $\mathbb{S}$ was trained to separate the target source by using the target source as a query as in Eq. 3. In the test phase, however, the target source to be separated from the mixture is unknown. Hence, the target source and query can no longer be the same. Nevertheless, since we designed the output dimension of $\mathbb{Q}$ to be small enough, the latent vector $\mathbf{z}$ is trained to have a high-level information such as instrument class. In the test phase, therefore, we can utilize this property in many ways. For example, when the user wants to separate a specific source in the mixture, it is possible to collect a small amount of audio samples that have similar characteristics but not exactly the same to the source of interest. Then, the user can extract that specific source by feeding the collected audio samples into the Query-net and passing the summarized information to the Separator.

Apart from the query dependent approach, we can also take the average of latent vectors of each source class in the training set and use it as a representative latent vector that reflects the general characteristics of a single class.

4. EXPERIMENT

4.1 Dataset

We trained our network with the MUSDB18 dataset. The dataset consists of 100 tracks for training set and 50 tracks for test set and each track is recorded in 44.1kHz, stereo format. The dataset provides the mixture and coarsely defined labels for sources, namely, 'vocals', 'drums', 'bass' and 'other'. The class 'other' includes every instrument other than 'vocals', 'drums' and 'bass', providing the most coarsely defined class. We resampled the audio to 22050Hz and divided each track into 3-second segments. Magnitude spectrogram was obtained by applying STFT with a window size 1024 and 75% overlap. To restore the audio from the output, Inverse STFT is applied using the phase of the mixture. We evaluated our method on the test set of MUSDB18 using the official museval package [1] which computes signal-to-distortion ratio (SDR) as a quantitative measurement.

4.2 Experiment Details

The followings are the experimental details of our method. $\mathbb{Q}$ consists of 6 strided-convolutional layers with 4×4 filter size and the number of output channels for each layer is 32, 32, 64, 64, 128 and 128, respectively. Every strided-convolutional layer has the stride size of 2 along the frequency axis and only second, fourth and sixth layers have a stride size of 2 along the time axis. After every convolutional operation, we used instance normalization and relu. We used GRU with 128 units. The length of the query segment was fixed to 3-second in every experiment. For $\mathbb{S}$, the encoder part consists of 9 strided-convolutional layers and the decoder part consists of the same number of strided-deconvolutional layers, with a filter size of 4×4. The number of output channels for first, second, and third layer is 64, 128, 256, respectively, and 512 for the rest of the layers. Every layer has stride size of 2 along the frequency axis. And stride size along the time axis is set to 2 for every layer except the first layer of the encoder and the last layer of the decoder.

The dimension of the latent vector was set to 32 and the batch size was set to 5. The coefficients in Eq.6 were set to $\lambda_R = 10$, $\lambda_{\mathrm{KL}} = 0.01$, $\lambda_{latent} = 0.5$. The initial learning rate was set to 0.0002 and after 200000 iterations the rate was decreased to 5×10^{-6} for every 10000-iteration. We used Adam optimizer with $\beta_1 = 0.5$, $\beta_2 = 0.999$.

4.3 Manually Targeting a Specific Sound Source

To validate that our method captures the characteristics of the audio given in the query and separates them accordingly, we conducted an experiment of separating specific instruments. As shown in Fig. 3, an audio query of hi-hat and piano were given to the mixtures of (hi-hat + kick drum + bass) and (piano + electric guitar). Queries and mixtures were not from the train set, and both queries were not sampled from the mixture. We can observe in the hi-hat separation result that the kick drums and the bass which lie in the low-frequency band were mostly removed while broadband components of hi-hat remained. The result of piano separation is not as clear as in the case of hi-hat, but we can see the guitar was removed considerably.

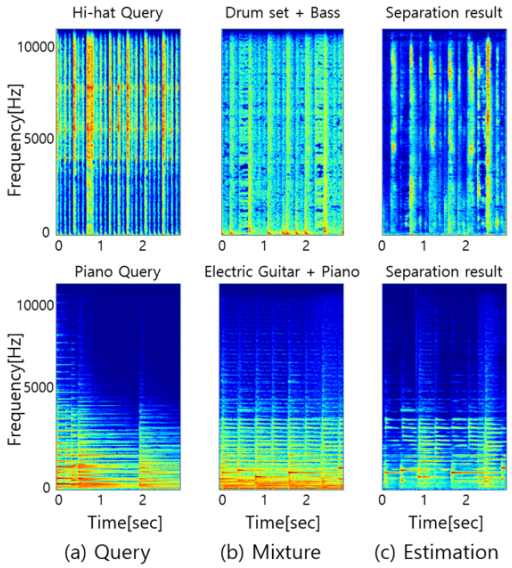

Figure 3. Results of manually targeting specific sound sources. The first row show the separation results of hi-hat from the mixture of hi-hat, kick drum and bass. The second row shows the separation results of piano from the mixture of electric guitar and piano. It is worth noting that the network was never trained to only separate a hi-hat component from 'drum' class nor piano from 'other' class.

The noticeable fact is that we trained our method only with the MUSDB18 dataset, which has no hierarchical class label information besides the coarsely defined labels of sources such as 'vocals', 'drums', 'bass' and 'other'. Under the definition of class in the dataset, hi-hat and kick drum are grouped into 'drums', and piano and electric guitar into 'other'. Although our method was never trained to separate the subclass from the mixture, it was able to separate hi-hat and piano from the mixture, which can be referred to as a zero-shot separation. These results indicate the proposed method can be well applied for audio query-based separation.

4.4 Latent Interpolation

Furthermore, we conducted a latent interpolation experiment using the mean vector of each source. The mean vector of each source was computed by averaging the latent vectors of each source in the training set, $\mathbf{z}_c = \frac{1}{N_c} \sum_i \mathbb{Q}(S_{c,i})$, where $S_{c,i}$ denotes i-th 3-second magnitude spectrogram in the sound class c and N_c denotes the number of segments in class c.

For the interpolation method, we used the spherical linear interpolation ($Slerp$) introduced in [23],

$$Slerp(\mathbf{z}_1, \mathbf{z}_2; \alpha) = \frac{\sin(1-\alpha)\theta}{\sin\theta}\mathbf{z}_1 + \frac{\sin\alpha\theta}{\sin\theta}\mathbf{z}_2, \quad (7)$$

[1] https://sigsep.github.io/sigsep-mus-eval

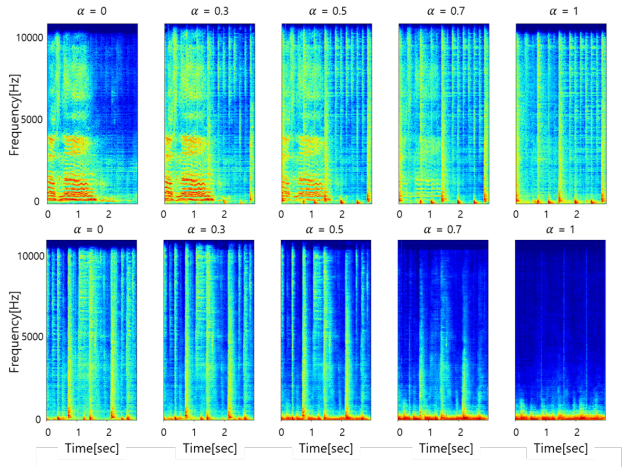

Figure 4. Results of the mean vector interpolation. The first row shows the interpolation results between vocals and drums. The second row shows the interpolation results between drums and bass.

where α denotes the weight of interpolation and θ denotes the angle between $\mathbf{z}_1$ and $\mathbf{z}_2$. As shown in Fig. 4, we interpolated between the mean vector of sound sources, drums ($\mathbf{z}_{drums}$) $\rightarrow$ bass ($\mathbf{z}_{bass}$) and vocals ($\mathbf{z}_{vocals}$) $\rightarrow$ drums ($\mathbf{z}_{drums}$). We can see the ratio of separated instruments changes as the weight α changes. These experimental results show that our method can generate continuous outputs just by manipulating a latent space.

4.5 Effects of Latent Vector on Performance

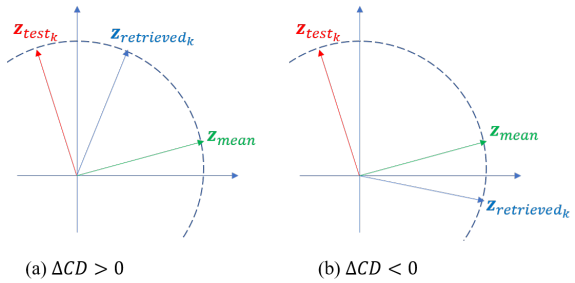

Figure 5. Illustration of two ΔCD cases. (a) shows the positive ΔCD case where we assume that the performance should be improved. (b) shows the negative ΔCD case where we assume that the performance should be worsened.

This subsection investigates the performance improvement varying the latent vector and see in which situation we can achieve a performance improvement. For the experiment, we first obtained the mean vector of each vocal track from the entire dataset as follows, $\mathbf{z}_i = \frac{1}{N_i}\sum_j \mathbb{Q}(S_{i,j})$, where i denotes a i-th vocal track, j denotes a j-th segment in i-th vocal track, and N_i denotes the number of segments in i-th vocal track. Then, we obtained the mean vector, $\mathbf{z}_{mean} = \frac{1}{100}\sum_{i \in training} \mathbf{z}_i$, of vocal tracks from training set. Finally, we retrieved the latent vector of certain vocal track $\mathbf{z}_{ret_k}$ from the training set which has the

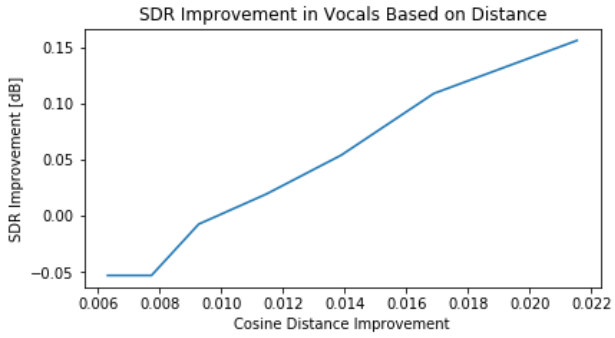

Figure 6. The relationship between SDR improvement (ΔSDR) and cosine distance difference (ΔCD) in vocal tracks.

closest cosine distance (CD) from k-th test vocal track $\mathbf{z}_{test_k} = \mathbf{z}_k$, $k \in test$ as follows,

$$\tilde{k} = \underset{i \in training}{\arg\min}\ CD(\mathbf{z}_i, \mathbf{z}_{test_k}),\ \ \mathbf{z}_{ret_k} = \mathbf{z}_{\tilde{k}}. \quad (8)$$

We compare the performance of two cases where the goal is to separate a k-th vocal track from test set. The first case is to use $\mathbf{z}_{mean}$ to separate a target source, $\hat{S}_{mean} = \mathbb{S}(M, \mathbf{z}_{mean})$. The second case is to use $\mathbf{z}_{ret_k}$ to separate a target source, $\hat{S}_{ret_k} = \mathbb{S}(M, \mathbf{z}_{ret_k})$. We defined performance improvement in terms of SDR as follows,

$$\Delta\text{SDR} = \text{SDR}(S_{GT_k}, \hat{S}_{ret_k}) - \text{SDR}(S_{GT_k}, \hat{S}_{mean}), \quad (9)$$

where S_{GT_k} denotes k-th ground truth vocal track from test set. To measure the distance between latent vectors we used cosine distance ($CD(\mathbf{z}_1, \mathbf{z}_2) = 1 - (\mathbf{z}_1 / \|\mathbf{z}_1\|_2) \cdot (\mathbf{z}_2 / \|\mathbf{z}_2\|_2)$) and defined cosine distance difference between ($\mathbf{z}_{test_k}, \mathbf{z}_{ret_k}$) and ($\mathbf{z}_{test_k}, \mathbf{z}_{mean}$) as follows,

$$\Delta CD = CD(\mathbf{z}_{test_k}, \mathbf{z}_{mean}) - CD(\mathbf{z}_{test_k}, \mathbf{z}_{ret_k}). \quad (10)$$

Fig. 5 illustrates two possible cases of using $\mathbf{z}_{ret_k}$. (a) shows the positive ΔCD case where we assume to induce positive effect on performance improvement ($\Delta\text{SDR} > 0$). In this case, we expect the performance to be improved since $\mathbf{z}_{ret_k}$ is expected to contain information close to $\mathbf{z}_{test_k}$ compared to $\mathbf{z}_{mean}$. (b) shows the negative ΔCD case where we assume to induce negative effect on performance improvement ($\Delta\text{SDR} < 0$). In this case, we expect the performance to be worsened as the system could not retrieve a $\mathbf{z}_{ret_k}$ that is close enough to $\mathbf{z}_{test_k}$. To empirically prove our assumption, we show the relationship between ΔSDR and ΔCD in Fig. 6. We can observe that the closer the vector gets to the targeted ground-truth vector, the larger the performance gain becomes, therefore reinforcing our assumption that better performances can be achieved if we can obtain closer latent vectors to the target latent vector.

4.6 Iterative Method

In this subsection, we seek a performance improvement by automating the query-based framework in an iterative

way, which we refer to as an iterative method. The iterative method is done as follows. First, we separate the target source using the mean vector of certain sound class $\mathbf{z}_{mean}$. Then, we re-encode the separated source into a latent space expecting the re-encoded latent vector to be closer to the target latent vector. Finally, we separate the target source using the re-encoded latent vector. We verify the effect of the proposed iterative method and show that it can be helpful under the harsh condition where the target sources are far from generic class. The results (Single step $\rightarrow$ Iterative) are as follows, 'vocals': $4.84 \rightarrow \mathbf{4.90}$, 'drums': $4.31 \rightarrow \mathbf{4.34}$, 'bass': $\mathbf{3.11} \rightarrow 3.09$, and 'other': $2.97 \rightarrow \mathbf{3.16}$. We can see the iterative method noticeably improves the performance in 'vocals' and 'other'. On the other hand, the differences are not significant in drums and bass.

We looked into the tracks which gained significant improvement in terms of SDR in vocals. 'Timboz - Pony' and 'Hollow Ground - Ill Fate' gained more than 0.5dB in SDR through the iterative method. We found the results intuitive as the vocals in the two songs feature a growling technique from heavy metal genres, which can be considered distant from the general characteristics of vocals.

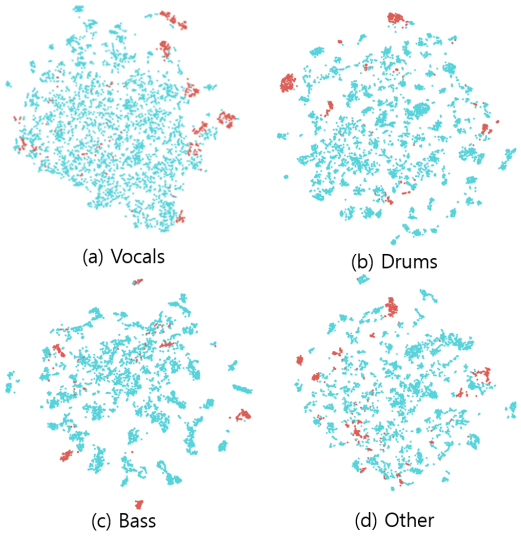

Figure 7. t-SNE visualization of encoded latent vectors from each source in the test dataset. Red points denote the vectors of the tracks which gained more than 0.4dB in terms of SDR by the iterative method.

To verify our assumptions, we divided each source of the test set into segments and converted them into latent vectors. We divided the encoded vectors into two groups, the ones which gained more than 0.4dB in terms of SDR by the iterative method and the ones did not. Then, we visualized the encoded vectors using t-SNE (results shown in Fig. 7). The red dots in Fig. 7 represent the latent vector from the group that showed significant SDR improvement more than 0.4dB. Although some vectors lie around the center, most of them are located far from the center. These vectors can be inferred as outliers and the results show that our iterative method is effective when it comes to separating the sources of distinctive characteristics.

	Vocals	Drums	Bass	Other
STL2 [16]	3.25	4.22	3.21	2.25
WK [22]	3.76	4.00	2.94	2.43
RGT1 [12]	3.85	3.44	2.70	2.63
JY3 [6]	5.74	4.66	3.67	3.40
UHL2 [20]	5.93	5.92	5.03	**4.19**
TAK1 [18]	**6.60**	**6.43**	**5.16**	4.15
Ours (mean)	4.90	4.34	3.09	3.16
Ours (GT)	5.48	4.59	3.45	3.26

Table 1. Median scores of SDR for the MUSDB18 dataset.

4.7 Algorithm Comparison

In this subsection, we compare our method to other methods with the evaluation result of the MUSDB18 dataset. As stated above, our method's output is dependent on the encoded latent vector from a query. For the comparison with other methods that do not require a query, therefore, we used the mean vector in the latent space encoded from the training samples for each source – *i.e.*, we ended up using four mean latent vectors for 'vocals', 'drums', 'bass', and 'other', respectively. Additionally, to show the upper bound of our proposed method, we used the encoded latent vector of the ground truth (GT) signal from test set. Note also that the separation is done with a single network.

Table 1 shows the median scores of SDR of methods reported in SiSEC2018 [17], including our method denoted as Ours. Although the proposed algorithm did not achieve the best performance, the results show that it is comparable to the other deep learning-based models that are dedicated to separating just four sources in the dataset. This means that our method is not limited to query-based separation, but also can be used for general music source separation just like as other conventional methods. Additionally, there is room for improvement: applying the multichannel Wiener filter and/or using other architecture for the separator besides U-net could be such an option.

5. CONCLUSION

In this study, we presented a novel framework, consisting of Query-net and Separator, for audio query-based music source separation. Experiment results showed that our method is scalable as the Query-net directly encodes audio query into a latent space. The latent space is interpretable as was shown by the t-SNE visualization and latent interpolation experiments. Furthermore, we have introduced various utilities of the proposed framework including manual and automated approach showing the promise of audio-query based source separation. As a future work, we plan to investigate more adequate conditioning method for audio and better neural architecture for performance improvement.

MOSAIC STYLE TRANSFER USING SPARSE AUTOCORRELOGRAMS

Dan MacKinlay and Zdravko Botev
School of Mathematics and Statistics, UNSW Sydney
dan@danmackinlay.name

ABSTRACT

We introduce a novel mosaic synthesis algorithm for musical style transfer using the autocorrelogram as a feature map. We decompose the autocorrelogram feature map sparsely in a decaying sinusoid basis, using that decomposition as an interpolation scheme in feature space. This efficiently provides gradient information in the mosaicing optimization, including gradients of the challenging time-scale parameters, which are usually computationally intractable for discretely sampled signals. The required calculations are straightforward to parallelize on vector-processing hardware. Our implementation of the method provides good quality output and novel musical effects in example tasks by itself and can also be integrated into alternative mosaicing methods.

1. INTRODUCTION

Mosaicing synthesis is a particular approach to the style transfer problem. As with all style transfer methods, the goal is combining two signals, a source, and a target, to produce a hybrid output signal with qualities of each, which we call a *mosaic*. A musical application of these methods would typically use the 'style' of one signal, the timbre, to express the 'content' of another, a melody. Concretely, if the target were a trumpet playing a melody, and the source a recording of a singing vocalist, the mosaic might aim to emulate the vocalist singing that melody.

There exist a variety of problem definitions of, and associated algorithms for, mosaicing synthesis; e.g. [8, 12, 13, 22, 23, 35, 41, 45], partially summarized in [32]. In mosaicing specifically, we accomplish style transfer using a dictionary-based granular synthesis method, which constructs its output by superposition of transformed short recordings, *grains*, from an audio dictionary, in the time or, more recently, spectral domains [1, 7, 16].

The granular synthesis methods in themselves are well understood and widely deployed in industrial applications. They comprise a significant proportion of the music industry market for software synthesizers, are integrated into every major Digital Audio Workstation package, and have been extensively researched – see e.g. [31] and references therein.

The extension of granular synthesis into a style-transfer problem as mosaicing is less well-understood. In this setting we choose the parameters of a granular synthesis so as to optimally approximate a desired target audio signal in the sense of optimising some measure of acoustic similarity. Typically, this implies approximating, in the sense of minimising some approximation loss, the power spectral density (PSD) of the target signal. Applications for this include musical accompaniment, creative musical effects, or user customization of speech synthesis [10].

Our sparse autocorrelogram method advances the capabilities of musical mosaicing applications, by leveraging a feature map that is related to, but more convenient than, classical PSD methods. This method is enabled by two major innovations.

Firstly, we define signal similarity through the *autocorrelogram*, a representation of the signal as covariance with delayed versions of itself. The autocorrelogram and its relationship to PSD is well-known (e.g. [44]) but our use in mosaicing synthesis appears novel. Although we use the autocorrelogram in a standalone procedure, it may be included in the feature vectors of loss functions of other mosaic techniques and is thus of independent interest.

Secondly, we decompose the high-dimensional empirical autocorrelogram into a sparse dictionary of decaying sinusoids. By interpolating discrete signals, this procedure calculates both error and gradients efficiently, enabling gradient-based optimization. The resulting technique is flexible and straightforward to parallelize on modern Single Instruction Multiple Data (SIMD) architectures such as Graphics Processing Units (GPUs).

We make our Python code [1] openly available for public use. We thereby aim to facilitate both the investigations of future researchers and the immediate application of these methods by musicians. Comparisons are made with benchmark mosaicing implementation, NiMFKS [7].

2. PRIOR WORK

Style transfer techniques, construed broadly, have a long history in signal processing research. Early work in this area begins with the channel vocoder [17], via various innovations to the modern repertoire of methods which includes innovations such as neural style transfer methods

Attribution: Dan MacKinlay and Zdravko Botev . "Mosaic style transfer using sparse autocorrelograms", 20th International Society for Music Information Retrieval Conference, Delft, The Netherlands, 2019.

[1] https://github.com/danmackinlay/mosaicing_omp_ismir_2019/

[19, 21, 43]. In the style transfer field, the mosaicing techniques form a sub field which fix a choice of synthesis to dictionary-based granular synthesis techniques.

We are concerned with the musical applications of style transfer. The archetypal task in this context is using the timbre of the 'style' signal to express the melodic 'content' of another. Concretely, if the target were a trumpet playing a melody, and the source a recording of a singing vocalist, the output should emulate the vocalist singing that melody.

In mosaicing synthesis, the task of choosing synthesis parameters to produce the desired output is non-trivial and subject of ongoing interest. Notable recent progress includes matrix factorization methods to decompose audio [1, 7, 16], various improvements in spectral matrix factorization [1, 7, 16] and optimization over features [8, 11, 36]. However, few methods can conveniently handle time-scaling of audio, so that time-scale parameters must be ignored, or selected by exhaustive search. One recent exception is Sound Retiler [1], which claims to handle time shifting via tensor decomposition. It is in this area that we make our main contribution, by the application of autocorrelogram features in this task.

While the autocorrelogram itself is not new in audio synthesis (e.g. [38]), our application to the mosaicing problem seems novel. The autocorrelogram-based analysis in combination with sparse coding induces a novel and analytically differentiable expression for the time scale parameter, and it is this we use to solve the mosaic problems.

3. PROBLEM DESCRIPTION

3.1 Audio signals and notation

We work with audio signals, a Hilbert space $\mathcal{H}$ of real L_2 functions $f : \mathbb{R} \to \mathbb{R}$ mapping time to instantaneous signal pressure level. Where the argument of the signal is clear, we abbreviate notation, writing for example, $t \mapsto f(at)$ as $f(at)$. We will handle transforms on signals $f(.)$ such as the autocorrelogram $\mathcal{A}$, and Fourier transform $\mathcal{F}$. Where not clear from context which argument of the signal with respect to which the transform is taken, we indicate it with a subscript to the transform. Thus $\mathcal{F}_t\{f(s,t)\}(\xi) := \int e^{-2\pi i t\xi} f(s,t)\mathrm{d}t$. Where we specify a weight v for the inner product or norm, we write it as a subscript, i.e. $\langle f, g\rangle_v := \int_{\mathbb{R}} v(t)f(t)g(t)\mathrm{d}t$.

In practice we do not observe continuous audio signals, but discretely sampled observations of signals. Sampling fidelity will be assumed, requiring signals are band-limited to some suitably low cutoff period Ω. We scale time so that the sample period $T = 1$ and $\Omega > 1/2$. The sampling process is a train of Dirac impulses, and inner products with a discrete signals are defined

$$\langle g, f\rangle_v := \sum_{t\in\mathbb{Z}} v(t)g(t)f(t). \tag{1}$$

We denote length-M vectors in bold, $\boldsymbol{x} = [x_1, x_2, \ldots, x_M]^\intercal$.

3.2 Mosaicing

Given a target signal f_0, we seek an approximant, the mosaic $\hat{f}_0$, as a sparse linear combination of scaled signals, called *codes*, from a source *dictionary* $\mathfrak{G} := \{g_1, \ldots, g_D\}$ subject to a maximum budget of J codes. In our earlier style transfer example, say, f_0 would be the recorded trumpet melody and $\mathfrak{G}$, recordings of the singing vocalist. For a fixed dictionary the mosaic is specified completely by the length-J parameter vectors $\boldsymbol{\alpha}, \boldsymbol{\gamma}, \boldsymbol{\rho}$ and written

$$\hat{f}_0(t; \boldsymbol{\alpha}, \boldsymbol{\gamma}, \boldsymbol{\rho}) = \sum_{j=1}^{J} \alpha_j g_{\gamma_j}(\rho_j t). \tag{2}$$

The problem requires selecting approximately optimal values for parameter vectors

$$\{\boldsymbol{\alpha}, \boldsymbol{\gamma}, \boldsymbol{\rho}\} \simeq \underset{\{\boldsymbol{\alpha},\boldsymbol{\gamma},\boldsymbol{\rho}\}}{\operatorname{argmin}} d\left(\hat{f}_0(t; \boldsymbol{\alpha}, \boldsymbol{\gamma}, \boldsymbol{\rho}),\ f_0(t)\right), \tag{3}$$

where $\rho_j \in \mathbb{R}^+, \alpha_j \in \mathbb{R}, \gamma_j \in \{1, \ldots, D\}$ and $d : \mathcal{H} \times \mathcal{H} \mapsto \mathbb{R}^+$ is a distance function quantifying the poorness of the approximation. In contrast to sparse coding for signal compression, $\hat{f}_0$ is an intentionally imperfect approximation of f_0, possessing qualities of both the source and target signals, hence the designation style *transfer*.

4. AUTOCORRELATION MOSAICING METHOD

The autocorrelogram mosaicing method has two stages.

1. In the pre-training stage, autocorrelogram features are computed from the source signals, and decomposed in a dictionary of decaying sinusoids.
2. In the inference stage, we search our dictionary of autocorrelogram decompositions for matches to the autocorrelogram of the target signal, and solve an inverse problem, synthesizing a corresponding mosaic from our result.

Both stages leverage convenient properties of autocorrelograms, and sparse dictionary decompositions, which we now introduce.

4.1 Properties of autocorrelograms

We now motivate the use of the autocorrelogram in our feature map. As with other style transfer methods we face the challenge that sample values of a time domain audio signal f are only indirectly indicative of how human listeners will perceive it. For audio analysis, one typically operates on a feature map $\mathcal{P}\{f\}$ which is in some sense closer to human perception of these signals. Specifically, we aim to find a feature map such that two signals are similar if some distance between their feature vectors is small, i.e. the similarity of f and $\hat{f}$ is high iff the distance $d_{\mathcal{P}}(f, \hat{f}) := \|\mathcal{P}\{f_0\} - \mathcal{P}\{\hat{f}\}\|$ is low, with some choice of norm $\|\cdot\|$. We would like $d_{\mathcal{P}}$ to approximate specifically *psychoacoustic* similarity, which is to say $d_{\mathcal{P}}(f, \hat{f})$ is small iff a typical human listener would perceive f and $\hat{f}$

as similar. Ideally the image of the feature map should also be of lower dimension than f, and $d_{\mathcal{F}}$ should be computationally efficient to manipulate.

True psychoacoustic similarity is not well-defined, so practical algorithms settle for feature maps compromising between convenience and psychoacoustic plausibility. Usually, feature maps are empirical PSDs [8, 23], or are derived from the PSD, as with the Mel-Frequency Cepstral Coefficient (MFCC) [27] or the Constant-Q transform [6]. These maps induce expensive mosaicing optimization problems [11, 12]. MFCCs for example, are suitable for low-dimensional indexing and search but are hard to invert. A raw empirical PSD is easier to invert, via, e.g. Griffin-Lim iteration, but of the same order of dimensionality as the original signal and thus difficult to search. One could ameliorate this difficulty if a computationally convenient feature map could be found which was well-behaved under operations of scaling and superposition, as in Eq. 2, so that one could conduct as much calculation as possible in the feature space.

These desiderata suggest the autocorrelogram map

$$\mathcal{A}\{f\} : \xi \mapsto (\xi \mapsto \langle f(t), f(t-\xi) \rangle) \,. \tag{4}$$

This is the deterministic covariance between $f(t)$ and $f(t-\xi)$. The autocorrelogram is an even function in ξ, so we work with one-sided autocorrelograms $\mathbb{R}^+ \to \mathbb{R}$. Autocorrelogram-like transforms are implicated in the neurological processing of harmonic audio by human listeners [3, 9, 25, 26]. For our purposes, the supposed neurological basis is a secondary consideration to the demonstrated empirical usefulness in psychoacoustic tasks, most notably in pitch-detection [30, 37, 40]. In this regard it resembles the cepstral analysis method [5], which also effectively identifies small numbers of periodic components by analysing a pointwise non-linear transformation of the power spectrogram , but unlike the cepstrum it is well-behaved under superposition.

Specifically, brief calculation shows the following useful properties: a) Multiplication by a constant $c \in \mathbb{R}$:

$$\mathcal{A}\{cf\}(\xi) = c^2 \mathcal{A}\{f\}(\xi). \tag{5}$$

b) Time scaling:

$$\mathcal{A}\{f(rt)\}(\xi) = \frac{1}{r} \mathcal{A}\{f\}\left(\frac{\xi}{r}\right) \tag{6}$$

c) Randomized addition:

$$\mathbb{E}\left[\mathcal{A}\{S_1 f + S_2 f'\}(\xi)\right] = \mathcal{A}\{f\}(\xi) + \mathcal{A}\{f'\}(\xi), \tag{7}$$

where $\{S_i\}$ are i.i.d. Rademacher variables, taking values in $\{+1, -1\}$ with equal probability.

We note two obstacles to the application of these formulae in the mosaicing problem. Firstly, Eq. 6 is not well-defined for the discrete signals that comprise the usual subject matter of digital signal processing. We will handle discrete signals by continuous interpolants, which turn out to be practically sufficient approximations. Secondly, the additive rule c) is valid only in expectation, via the contrivance of introducing Rademacher random variables. Solving for the deterministic case by accounting for phase cancellation is indeed possible, but considerably more involved, and constitutes an active area of research in its own right in, e.g. the Overlap-Add [15, 42], and phase retrieval [24, 34] literatures. As the randomised solution also turns out in practice to be already sufficient for many tasks, we defer such extensions to future work.

In order to construct these interpolants efficiently, we decompose discrete autocorrelograms using a matching pursuit, which we now introduce.

4.2 Orthogonal matching pursuit

In orthogonal matching pursuit (OMP) [14, 28], given a target signal f_0 and a dictionary of *code* signals $\mathfrak{D} = \{g_\theta\}_{\theta \in \Theta}$, one finds a decomposition $\hat{f}_0 = \mathrm{OMP}_{\mathfrak{D},K}(f_0)$ of form

$$f_0 \simeq \underset{\mathfrak{D},K}{\mathrm{OMP}}(f_0) := \sum_{i=1}^{K} \mu_i g_{\theta_i}. \tag{8}$$

A solution is a parameter vector $[\theta_1, \ldots, \theta_K] \in \Theta^k$ and code weights $[\mu_1, \ldots, \mu_K] \in \mathbb{R}^K$ which nearly minimize $\|f_0 - \hat{f}_0\|$. We require that f_0 and all codes g_θ are L_2 integrable and not null, i.e. possessing positive norm, $\|g_\theta\| > 0$.

The OMP algorithm is as follows.

1. Initialization. Let the first residual be $r_0 := f$. Set step counter $k \leftarrow 1$.
2. Find θ_k such that (possibly approximately)

$$\theta_k = \underset{\theta}{\mathrm{argmax}}\, A(r_k, g_\theta) \tag{9}$$

where A is the *normalized code product*

$$A(r_k, g_\theta) := \frac{\langle r_{k-1}, g_\theta \rangle}{\|g_\theta\|}. \tag{10}$$

3. Solve the least sum of squares problem

$$[\mu_1^k, \ldots \mu_k^k] = \underset{[\mu_1, \ldots, \mu_k]}{\mathrm{argmin}} \left\| \sum_{1 \le \ell \le k} \mu_\ell g_{\theta_\ell} - f_0 \right\| \tag{11}$$

giving kth decomposition $\hat{f}^k = \sum_{1 \le \ell \le k} \mu_\ell g_{\theta_\ell}$.

4. Update the residual $r_{k+1} = f_0 - \hat{f}^k$.
5. If $k = K$, stop, otherwise set $k \leftarrow k + 1$ and repeat from step (2).

We allow the components of θ to be either a) a discrete and finite, or b) a continuous parameter. For finitely enumerable components $\theta_{\text{finite}} \subseteq \theta$ we maximize normalized code product in Eq. 9 by enumeration. For continuous components $\theta_{\text{cts}} \subseteq \theta$ we assume that we can choose θ_{cts}

approximately by iterative optimization using the gradient $\nabla_{\theta_{\text{cts}}} A(r_k, g_\theta)$. As the objective may not attain a global maximum, we choose $I \geq 1$ different initial guesses, and select the best local optimum attained. A first order gradient ascent with fixed number of steps performs well in our examples and moreover requires no branching instructions, as suits our goal of a SIMD-compatible algorithm.

4.3 Sparse approximate autocorrelograms

In the pre-training stage, we find autocorrelograms for each of the empirical source autocorrelogram codes in $\mathfrak{G}$, decomposing them into a dictionary of sparse OMP matches, $\mathfrak{M}$. It is this dictionary which we search for mosaic matches, using matches here to identify approximately matching codes in the original space $\mathfrak{G}$.

In this section we use ξ as the free argument for signals, and restrict $\xi > 0$. For the interpolant dictionary we use decaying sinusoids

$$\mathfrak{S} := \{h(\xi; \omega, \tau, \phi) := \cos(\omega\xi + \phi)e^{-\tau\xi} : \phi, \tau, \omega \in \mathbb{R}\}. \tag{12}$$

The dictionary choice must ultimately be justified by empirical performance, which we demonstrate in the final section of the paper. It is notable that there are also *a priori* reasons for favouring this one for musical audio. Firstly, this basis will decompose an autocorrelogram into a global approximant, rather than a piecewise interpolant, as with for example polynomial splines. Evaluations of such an interpolant are tractable to parallelise without branching instructions, and therefore better suited to modern SIMD architectures.

Secondly, decaying sinusoid models are effective in compactly decomposing time-domain audio [20], and the nature of the autocorrelogram suggests that they could be similarly useful and even more compact in decomposing autocorrelograms. The space of superpositions of decaying sinusoids is, by inspection, closed under the autocorrelogram transform, so it is at just as plausible to represent autocorrelograms in a such a decaying sinusoid dictionary. The question remains how compact such a representation is. Analytic expansion of the superposition of many decaying sinusoids is a lengthy exercise in elementary calculus. However, we have reason to suspect that the amplitude coefficient of most terms in such expansions will negligible. Recall the Wiener-Khintchine theorem, which says that, for signals of finite energy, assuming all these terms are well-defined,

$$\mathcal{F}_\xi\{\mathcal{A}\{f\}(\xi)\}(s) = |\mathcal{F}_t\{f(t)\}(s)|^2$$

where $\mathcal{F}_\xi\{f(\xi)\}$ is the Fourier transform of signal $\xi \mapsto f(\xi)$. This tells us that the magnitude of sinusoidal components of the autocorrelogram are squared with respect to the magnitude of sinusoidal components of the PSD, and thus relatively sparser. This indicates that for autocorrelograms of musical signals, which are well approximated by a superposition of sinusoidal signals, the autocorrelogram could often be approximated with comparable relative error by a yet smaller number of sinusoidal signals, as can be seen in Fig. 1. Moreover, we know that the envelope of musical audio spectral content decays eventually super-exponentially with frequency [18] and thus high frequency content of an autocorrelogram will in general be proportionally even lower. This latter fact additionally implies that the autocorrelogram calculations might even be downsampled with little loss in information content, and some computational saving.

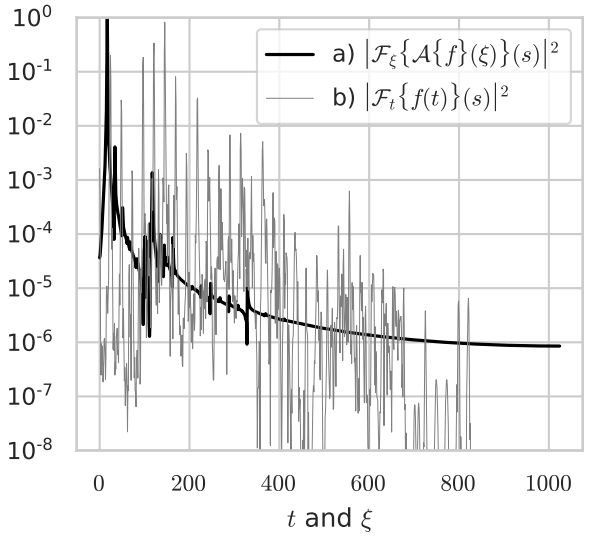

Figure 1. The relatively simple form of (a) the PSD of the autocorrelogram versus (b) the PSD of the signal itself. Signal is a length 2048 recording of a trumpet note onset. The scale of the vertical axis is arbitrary, and signals have been normalized for comparison. Sample period is $1/44100s$.

Implementing the decomposition is straightforward. For each code $g \in \mathfrak{G}$ we perform the following calculation: First, we find the empirical autocorrelogram $\mathcal{A}\{g\}$ at L points $\xi = 0, 1, \ldots, (L-1)$ with Eq. 4.

Next, we decompose each $\hat{G} = \text{OMP}_{\mathfrak{S},C}(\mathcal{A}\{g\})$ over the decaying sinusoid dictionary, as defined in Eq. 12. There are many methods of fitting decaying sinusoids to time series [2, 29, 33], but OMP is convenient in the current application [20] as we may re-use the same algorithm in the reconstruction stage of this algorithm. Autocorrelograms of musical audio in our experiments are highly sparse with respect to this decaying sinusoid dictionary, typically achieving negligible residual error with number of components $C \leq 4$.

We will apply the OMP with product $\langle \cdot, \cdot \rangle_v$ weighted by $v(\xi) := \mathbb{I}\{[0, L)\}(\xi)/L$, returning parameters $\{\tau_i, \omega_i, \phi_i\}$ and code weights μ_i. We first find the normalized code product (Eq. 10) in closed form. Substituting in Eq. 12 gives

$$A(r(\xi), h(\xi;\omega,\tau,\phi)\}) = \frac{\langle r_i(\xi), \cos(\omega\xi+\phi)e^{\tau\xi}\rangle_v}{\|\cos(\omega\xi+\phi)e^{\tau\xi}\|_v}. \tag{13}$$

The numerator is simply Eq. 1. Applying Euler identities gives the denominator

$$\begin{aligned}&\|\cos(\omega\xi+\phi)e^{-\tau\xi}\|_v^2\\ &= \frac{1}{2}\int_0^L (1+\cos(2\omega\xi+2\phi))e^{-2\tau\xi}\mathrm{d}\xi\\ &= \left.\frac{e^{-2\xi\tau}}{2}\frac{(\omega\sin(2\xi\omega+2\phi)-\tau\cos(2\xi\omega+2\phi))}{4\tau^2+4\omega^2}\right|_{\xi=0}^{\xi=L} + \frac{1-e^{-2L\tau}}{4\tau}\end{aligned} \tag{14}$$

Combining Eq. 1 and Eq. 14 gives a closed form normalized code product (Eq. 13), from which we can explicitly calculate gradients in τ, ω, ϕ as desired. Note that although the original signal is discrete, our decomposition is a continuous near-interpolant for it.

From these decompositions we construct the dictionary

$$\mathfrak{M} := \{\hat{G}_\gamma(\rho\xi) : \gamma \in (1,\ldots,D), \rho \in \mathbb{R}^+\}. \tag{15}$$

4.4 Synthesizing the mosaic

In the second, inference, stage we construct a mosaic $\hat{f}_0$ given a target f_0. Here we match the discrete autocorrelogram $F_0 := \mathcal{A}\{f_0\}$ by a second OMP decomposition $\hat{F}_0 := \mathrm{OMP}_{\mathfrak{M},J}(F_0)$, into

$$\hat{F}_0(\xi) := \sum_{j=1}^{J} \kappa_j \hat{G}_{\gamma_j}(\rho_j\xi) \tag{16}$$

for index parameters $\{\gamma_i, \rho_i\}$ and weights κ_i. The OMP has already been introduced, but we pause to verify that it may be applied to this new context. Since each $\hat{G}_{\gamma_j}$ is a linear combination of decaying sinusoids (Eq. 12), the normalizing denominator of the code product (Eq. 10) is again a linear combination of decaying sinusoids, so its integral has a (lengthy) closed form as a linear combination of integrals (Eq. 14), and we can find an explicit gradient $\nabla_\rho A(r_k, \rho)$. Thus we may find $\hat{F}_0$ as required.

Now we wish to construct $\hat{f}_0$ (Eq. 2) such that

$$\mathbb{E}[\mathcal{A}\{\hat{f}_0\}] = \hat{F}_0. \tag{17}$$

Choosing $\hat{f}_0 := \sum_j S_j\alpha_j g_{\gamma_j}(\rho_j t)$ by matching pursuit, simulating S_j independent Rademacher variates, and applying Eqns. 5, 6, 7 to Eq. 2, we find

$$\begin{aligned}\mathbb{E}[\mathcal{A}\{\hat{f}_0\}] &= \mathbb{E}\left[\mathcal{A}\left\{\sum_j S_j\alpha_j g_{\gamma_j}(\rho_j t)\right\}(\xi)\right]\\ &= \sum_j \frac{\alpha_j^2}{\rho_j}\mathcal{A}\left\{g_{\gamma_j}(t)\right\}(\rho_j\xi)\\ &\simeq \sum_j \frac{\alpha_j^2}{\rho_j}\hat{G}_{\gamma_j}(\rho_j\xi).\end{aligned} \tag{18}$$

By inspection,

$$\alpha_j = S_j\sqrt{|\rho_j||\kappa_j|} \tag{19}$$

satisfies Eq. 17. We resample the original discrete dictionary codes to target time scale ρ_i by band-limited sinc interpolation [39]. Finally, we substitute the resulting α_j into Eq. 2 and superpose grains to realize the desired mosaic.

4.5 Localized matching

So far we have discussed entire signals, implicitly assuming them to be brief. The autocorrelogram, taken globally over a long signal such as an entire musical piece, no longer estimates the local, stylistic characteristics. Just as one adapts the discrete Fourier transform for long signals into the Short-Time Fourier Transform (STFT) [4], so do we adapt the autocorrelogram mosaic method, applying it locally. A simple localization is to slice signals into short frames of fixed duration M, which are called *grains* by convention. As in the STFT, we multiply each frame point-wise with real window function w, supported on $[0, M]$ with $\|w\| = 1$. Hereafter, we assume a *sine window*, $w(t) := 2\sin(\pi t/M)\mathbb{I}[0, M]/M$. We fix hop length $H < M$. Next, we localize $\mathfrak{G}$ into a new dictionary whose codes are precisely these time-shifted grains (disallowing zero-energy grains).

$$\mathfrak{G}^{w,H} := \{w(t)g(t-\phi) : g \in \mathfrak{G}, \phi/H \in \mathbb{Z}, \|g'\| > 0\}. \tag{20}$$

In musical material a localized dictionary tends to high redundancy and marginal return on search effort decreases. Rather than proceeding exhaustively, we keep the search tractable by searching a pseudorandom subset of fixed size, where the size of this pseudorandom subset is a user selectable parameter.

In the synthesis stage, we localize the target signal, $f_0^w(t;\phi) := w(t)f_0(t-\phi)$, constructing a local mosaic $\hat{f}_0^w(t;\phi)$ from $\mathfrak{G}^{w,H}$ for $\phi = 0, H, 2H, \ldots$ Finally, we superpose the local mosaics into a global one,

$$\hat{f}_0(t) = \sum_{\ell\in\mathbb{Z}} \hat{f}_0^w(t + H\ell; H\ell). \tag{21}$$

5. EXPERIMENTS

As an initial example we transfer style with target f_0 trumpet solo [2] and source audio a vocal recording. [3] Audio is sampled with a period of $1/44100$s. We fix $M = 8192$, $H = M/2$, $L = 1024$, $C = 4$, $J = 1$, $I = 12$ and reasonable default parameters for the optimization routines. Examining the spectrogram Fig. 2 illustrates phenomena compatible with our claims: In the mosaic we observe local features of the source with the larger structure of the target, to wit, the pitch contours of the trumpet solo with a spectral distribution somewhat like the human voice.

[3] credit Emm Collins

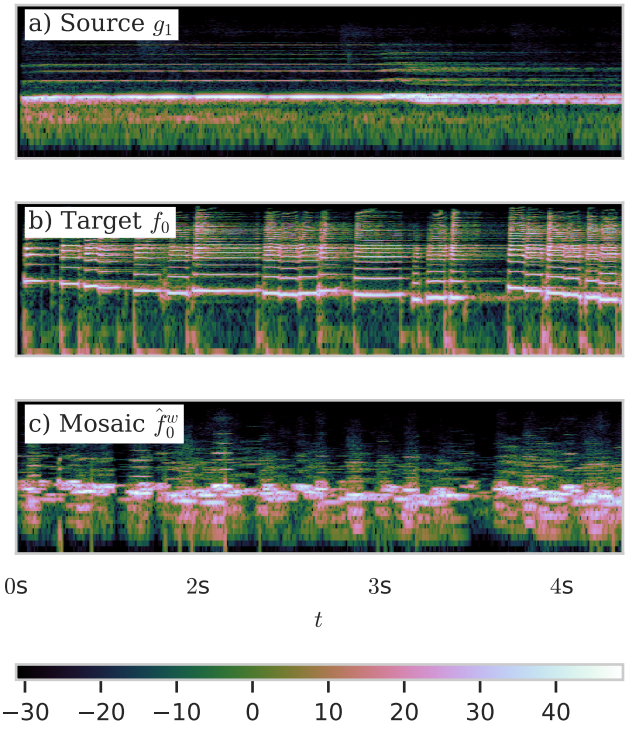

Figure 2. Power spectral density of signals a) source vocal recording b) target trumpet recording and c) resulting mosaic. Frequency increases up vertical axis, intensity in dB with arbitrary normalization.

We next apply the algorithm across a small corpus and compare our results against the mosaicing algorithm NiMFKS [7]. [4] NiMFKS is a useful benchmark for mosaicing synthesis, incorporating many different user-selectable loss functions and decompositions methods from elsewhere in the literature, and possessing openly available code. [5] Their method generalises classical mosaicing by using a non negative PSD factorization to further decompose grains into a sparse product of activations and responses. Unlike our method it does not infer optimal time scaling of audio.

Performance evaluation of mosaicing methods is subjective. In the following, we will nevertheless attempt to describe the behaviors of the two algorithms as objectively as we are able. In order to challenge the NiMFKS model, our corpus samples are tuned to a variety of different root notes, scales and audio ranges, including Indonesian, western and centerless tunings. Style transfer is applied to every pairing of samples. Parameters are left at default values in each algorithm. These may be heard in the supplemental material. Subjectively, neither method seems to produce naturalistic outputs for all pairs of source and target audio. NiMFKS seems ascendant where the source audio is polyphonic and the factorization succeeds at decomposing different notes where our method cannot. On the other hand, where the target tuning is not spanned by the source, the sparse autocorrelogram method is able to produce smoother and better related mosaics by transposing source grains to match the target. Occasionally the sparse autocorrelogram mosaics sound rough during rapid articulations; the method could possibly be improved in these cases by adaptive selection of grain size, or tuning of the free hyperparameters in the model, or extension with non-randomised reconstruction methods. Even in these cases, however, simultaneous playback of the target and the mosaic reveals that we maintain harmonic relationships with the target audio. As such, even this imperfect reconstruction can be regarded as an exotic musical effect. In summary, even at this early stage, our method succeeds in extending mosaic methods to previously intractable tasks, and produces musically interesting output.

[4] It would be instructive to compare against mosaicing method Music Retiler [1], which claims to handle time scaling of audio via a different method, should the source code become available.

6. CONCLUSION

By combining autocorrelogram feature maps and interpolating matching pursuit, we have extended the library of methods of audio mosaicing style transfer. Our method in isolation produces interesting results on the sample data with little tuning. Work remains to be done in analysing the robustness and generality of the method, and selecting optimal tradeoff of cost and quality of different style transfer tasks under different choices of user parameters. More work also remains to be done in integrating this method with existing ones. The flexible loss function of, for example, NiMFKS could be augmented to include autocorrelogram features, and the autocorrelogram approach can be applied to spectrally decomposed signals, which are still audio signals. However, the ease with which we produce good results suggests that further extensions and refinements are worthy of pursuit.

7. ACKNOWLEDGEMENTS

We are indebted to Graham Coleman, James Nichols, the Dadabots and MTF Stockholm for illuminating conversations that greatly improved this work.

AUTOMATIC CHOREOGRAPHY GENERATION WITH CONVOLUTIONAL ENCODER-DECODER NETWORK

Juheon Lee **Seohyun Kim** **Kyogu Lee**
Music & Audio Research Group, Seoul National University , Korea

ABSTRACT

Automatic choreography generation is a challenging task because it often requires an understanding of two abstract concepts - music and dance - which are realized in the two different modalities, namely audio and video, respectively. In this paper, we propose a music-driven choreography generation system using an auto-regressive encoder-decoder network. To this end, we first collected a set of multimedia clips that include both music and corresponding dance motion. We then extract the joint coordinates of the dancer from video and the mel-spectrogram of music from audio and train our network using music-choreography pairs as input. Finally, a novel dance motion is generated at the inference time when only music is given as an input. We performed a user study for a qualitative evaluation of the proposed method, and the results show that the proposed model is able to generate musically meaningful and natural dance movements given an unheard song. We also revealed through quantitative evaluation that the network has created a movement that correlates with the beat of music.

1. INTRODUCTION

Choreography is a kind of art that designs a series of movements. In particular, in performing art, choreography extends to the use of human bodies to express movements, and these are often performed with music. The choreography suitable for music has significance in that it is not only an artwork itself, but also maximizes the expression of music [4, 7]. For this reason, choreography has become an essential element in many pop music works in recent years. Therefore, the process of creating choreography for music is also considered to be important, and research on a system capable of automatically generating choreography is actively conducted. However, automatic choreography generation is a challenging task because both music and dance are abstract art concepts, and the clear relationship between the two concepts is also not defined by established rules.

In this paper, we proposed a music-driven choreography generation system. In order to model the relationship between music and movement, two concepts in different domains, we firstly designed an autoregressive sequence to sequence model based on neural network that has been actively studied recently. Sequence used as input is time series data with strong correlation between adjacent timestep. Therefore, we designed a network of causal-dilation convolutional layers to fully reflect the information in the adjacent frame. We also applied local conditioning methods to the network to ensure that information related to music is effectively conditioned in the process of creating choreography movements. To evaluate whether a trained network actually produces a dance motion that matches music, we conducted a user study that evaluated naturalness by comparing video that matched random choreography with music and video generated by the proposed network. We also proposed a comparison of the two sequences' auto-correlations to analyze whether the choreography actually reflects music. As a result, we confirmed that the proposed network produced choreography that better reflected music than randomly matched videos, and that the joint movements of the generated choreography had a periodicity similar to the tempo of the music.

The contribution of this paper is as follows: First, we designed a music driven choreography generation network trained by an end-to-end method. Second, to generate choreography reflecting music, we successfully applied a local conditioning method used in speech synthesis field. Third, for the task of creating a choreography that is relatively difficult to assess quantitatively, we proposed the evaluation method using auto-correlation and user evaluation.

The rest of the paper is organized as follows. Studies related to this paper are introduced in Section 2. In Section 3, we explain in detail our proposed method for choreography generation based on the encoder-decoder network. We describe the dataset for experiments and the training process in Section 4. The evaluation scheme and the results are presented in Section 5, followed by conclusions and directions for future work in Section 6.

2. RELATED WORK

Recent advances in machine learning and deep learning techniques have led to a variety of attempts to study the relationship between dance and music. Lee et al. proposed

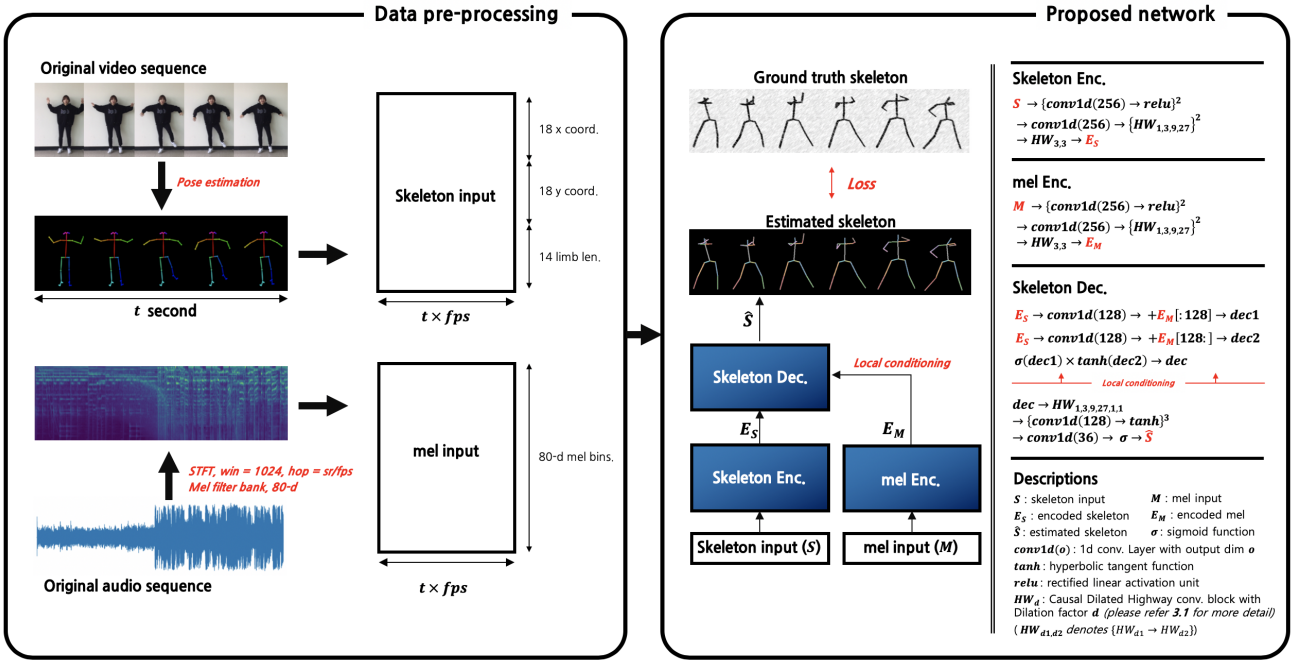

Figure 1. A schematic diagram of the proposed music-driven choreography generation system.

a choreography generation algorithm that retrieves the motions corresponding to the most similar pieces of music in the predefined motion-music-paired database for a given new music segment. [8]. This method selects dance motion from a predefined database, so choreography retrieved with high correlation with music is guaranteed. However, it has limitations in that it can not create novel dance movements that are not included in the database. Ofil et al. proposed a HMM-based model that categorizes the genre of music based on the Mel-Frequency Cepstrum Coefficients (MFCC) [10] feature and generates matching choreography based on the results [11]. But since the choreography is determined by the categorical value obtained through the genre classifier, there is a limit to generate a novel choreography. Omid et al. proposed a music-driven choreography model named Groovenet [1]. They used pairs of music and three-dimensional motion data to train the Factored Conditional Restricted Boltzmann Machines (FCRBM) [14]. They attempted to directly train the relationship between music and dance by using the mel-spectrogram in the training process. However, they reported that their model created awkward dance moves for unheard song, so they conclude that the model was overfitted and the dance moves according to music were not generalized enough.

Lee et al.'s and Ofil et al.'s studies have a limitation in that they can not create novel choreography because the former synthesizes motion by reusing the choreographic samples in a predefined database, and the latter creates choreography only for music input categorized by its genre. Omid et al. did succeed to create novel dance motions, but failed to yield good results mainly due to insufficient training data of merely 23 minutes.

In this study, we proposed a music-driven choreography generation system that can produce novel and natural choreography. [1] In order to secure the novelty of choreography, we used the method of creating choreography with frame by frame generation, not the method of retrieve in the pre-defined dataset. Also, to train the network with sufficient data, we also proposed a way to use the choreography-music data pairs that can be easily obtained from online video sharing community as training data. Finally, in order to conduct effective conditioning of music information, we have applied the methods used in other conditional sequence generation tasks effectively to our task.

3. PROPOSED APPROACH

In this chapter we explain the detailed structure of the proposed network. An overview of the proposed system is illustrated in Figure 1.

In order to learn the relationship between the time-series data of two different modalities, i.e., music and dance, we need a model that performs multi-modal sequence-to-sequence transformations. Also, since the choreographic movement at a certain time-step has a strong correlation with the information at the previous time-step, we should consider a system that provides sufficient reference to the information at the adjacent time-step. From this point of view, we have noted a text-to-speech system that shows reliable performance in a similar environment to these conditions, and then designed our system, inspired by the DCTTS [13] model, which is known to be capable of efficient text-to-speech training.

Our proposed model takes skeleton input S and mel input M as input, to predict skeleton $\hat{S}$ in the next time step:

[1] The generated result can be found at: listentodance.strikingly.com.

$$\hat{S}_{1:T} = CG(S_{0:T-1}, M_{1:T}) \quad (1)$$

where CG denotes our proposed model, choreography generator. For this purpose, each input is encoded via two encoder first. Then the encoded skeleton E_s passes through the decoder and predicts the next time step's skeleton $\hat{S}$, which utilizes the encoded E_M as conditioned information.

3.1 Causal Dilated Highway Conv. Block

In this section we explain the Causal Dilated Highway Convolution Block, one of the core structures of the proposed network. The choreography, which is basically the object that we should create, has a strong correlation with the information of the adjacent time-step. Therefore, in order to predict movement in the next time-step, information from previous time-steps should be fully consulted. Also, for choreography, a wide range of historical information should be referred to because it has relatively long-term dependency. To this end, we use the Causal Dilated Convolution. *Causal* means that only the input data from time 0 to $t-1$ can be referred to when calculating the output at time t. We used a causal convolution layer because our network must be an auto-regressive model to generate the next frame that is not yet known from the preceding frames. In addition, we used the *dilated convolution* proposed in the Wavenet [16] to ensure that the model has a wider receptive field. Finally, to enable efficient training even in deep model structures, we used a *highway network* architecture [12] where gated function could be trained. That is, the output of the CDHC block is calculated as:

$$\textbf{output} = tanh(\text{H1}) \cdot relu(\text{H2}) + (1 - tanh(\text{H1})) \cdot \textbf{input} \quad (2)$$

where [H1, H2] is the tensor calculated through the causal dilated convolution layer of the input tensor. The output channel of this convolution layer is twice the input channel, and the kernel size is 3.

3.2 Encoder & Decoder structure

To predict the next time-step skeleton information from the given input information, we used a method of effectively encoding input information and then combining them to decode. To this end, we designed two encoder and one decoder with CDHC block. Both the skeleton encoders and the audio encoders all consist of three convolution layers and 10 CDHC blocks. The first convolution layer of each encoder increases the input channel to 256 dimensions, and the other two layers perform 1x1 convolution. Thereafter, the output values from last convolutional layer are connected in sequence to 10 CDHC blocks with a dilation factor of (1,3,9,27,1,3,9,27,3,3), and the corresponding operations result in audio and skeleton data are encoded to have a sufficiently wide receptive field to reflect sufficient past information.

A decoder is a network that generates skeleton data for the next frame from an encoded skeleton and an encoded audio. To do this, the encoded skeleton input to the decoder is combined with the encoded audio in the following:

$$Dec1 = conv1d(E_S) + E_M[:128] \quad (3)$$

$$Dec2 = conv1d(E_S) + E_M[128:] \quad (4)$$

$$Dec = \sigma(Dec1) \times tanh(Dec2) \quad (5)$$

Where E_S and E_M refer to the encoded skeleton and encoded audio, respectively, and $conv1d$ means the convolution layer with an output channel of 128 and a kernel size of 1. The combined Dec tensor then goes through six CDHC blocks with a dilation factor of (1,3,9,27,3,3) and then through three 128-channel convolutional layers with a $tanh$ activation function. Finally, after passing through a convolution layer with the same output channel as the dimension of the target, the final decoder output is obtained via $sigmoid$ activation.

3.3 Proposed network

This network receives skeleton and music data from time 0 to $t-1$ as input. Both data are encoded via encoders and combined at the beginning of the decoder. The final output of the decoder is compared with the ground truth motion data at time 1 to t and we used it as a $L1$ loss. Since all convolution operations included in the network are with kernel size 1 or causal operations, the k-th value of output refers to only the 0 to $k-1$ time step of the input during the operation. Therefore, the model satisfies the causal condition.

4. EXPERIMENT

4.1 Data

We have collected 100 YouTube choreography videos and corresponding audios. The genre was selected mainly for K-pop dance, and the total length of collected data was 6.26 hours. We divided 85 songs into train sets, 5 songs into valid sets, and 10 other songs into test sets, to train and evaluate the proposed network.

4.1.1 Skeleton data

We extracted the x, y coordinates of 15 human body joints from each frame using the Openpose algorithm [3] from the collected video as shown in Fig. 2. Next, we min-max normalize the extracted coordinate values for each video, and use the linear-interpolation for the unrecognized coordinate values.

Since we can not measure the exact 3d angle between the human body limbs using the 2d joint coordinate, we used the absolute coordinates values of each point as the training target. However, in this case, the length of each limb in the projected skeleton can vary, and awkward motion can be generated if the model learns it incorrectly. So we additionally calculated the lengths of the 14 main limbs together and added a loss to compare with the limb length of the skeleton that the model generated. Therefore, the x, y coordinates of the total 15 joints, and the total of 14 main limb length are used as skeleton data.

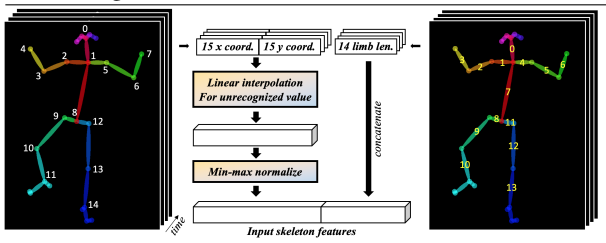

Figure 2. The process of extracting skeleton data from video frames.

4.1.2 Music data

We separated the audio contained in the collected video and used it as music data. The mel-spectrogram was extracted from the audio waveform with the window size of 1024 samples, and 80 mel-frequency bins. Because we need time-aligned audio-video pairs for training, we adjusted the hop size when extracting the mel-spectrogram so that audio and video data end up with the same frame rate.

4.2 Training

We have trained the proposed network that creates the next skeleton coordinate for a given previous skeleton sequence and music sequence. To do this, we first input skeleton data and music data from 0 to t-1 frames. Then, the output of the network is compared with the ground truth choreographic data corresponding to 1 to t frame by use L1 loss as a cost function. In addition, we calculated the length of each limb from the skeleton data of the generated frame, and compared with the actual ground truth length through the L1 loss.

We used the adam optimizer [6], with $\beta_1 = 0.5$, $\beta_2 = 0.9$, for training and set the learning rate to 0.0002. At every iteration, we used a video-audio pair that was cut in 500 frames for training, and it contains about 20 seconds of choreography and music information. The length of the input sample was set to 500 frame because we decided that the sequence of lengths, which fully reflected meaningful levels of behavior in the choreography, should be used for training. We set the batch size to 16, and then we finished the training after proceeding with a total of 30,000 iterations. We trained our network with one GEFORCE GTX 1080 ti GPU for three days.

4.3 Inference

The choreography inference process is performed in an auto-regressive manner different from training. That is, the initial position of each joint is given as an input skeleton frame, and at the same time, the first frame of mel-spectrogram is input to the trained model. When inference is performed once, estimated skeleton at $t = 1$ is output. Then we concatenate skeleton at $t = 0$ and $t = 1$, then input them back into the model with mel-spectrogram at $t = 0$ and $t = 1$. After than, we get estimated skeleton at $t = 1$ and $t = 2$. Therefore, we can generate the choreography by repeating the above process for the length of music input, and used it to evaluate the generated choreography.

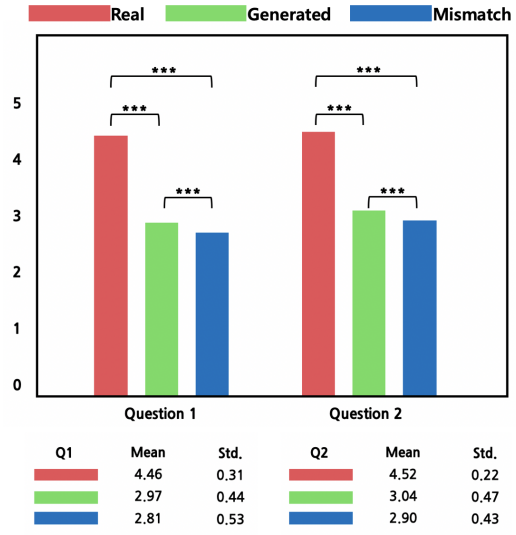

Figure 3. Average Likert-scale user scores on two questions (Q1: Is choreography natural? / Q2: Does choreography fit well with music?). The table below the graph indicates the mean and variance of responses by model for each question. The p-values for pairwise comparisons between the groups are also shown at the top. ***: $p < 0.001$; **: $p < 0.01$.

5. EVALUATION & RESULTS

5.1 User study

We conducted a user study to evaluate whether the generated choreography was natural and whether it was produced in accordance with the music. First, we generated 20 videos for each of the three groups: *Real*, *Generated*, and *Mismatch*. Group *Real* consists of music A_i and actual choreography for music A_i. Group *Generated* consists of music B_i and novel choreography generated by our model given music B_i. Finally, the group *Mismatch* consists of music C_i and novel choreography generated by our model but with randomly selected music rather than C_i. Music A_i, B_i, and C_i were randomly selected among the songs included in the validation dataset that was not used in training, and the length of each audio/video was 16 seconds.

After mixing the three groups of videos in a random order, we asked the participants whether each video's choreography is natural (Question 1) and whether it fits well with music (Question 2), and to give a score in a Likert scale [2]. After collecting the responses, we performed isoquantity and normality tests using data averaging 20 responses from each group, to see if there was a difference in the mean of the responses of the groups. After evaluating significance through repeated-measure ANOVA test , further post-hoc paired t-test analysis was performed to calculate the p-value, and the difference between the groups was examined [5].

A total of 33 participants answered the questionnaire

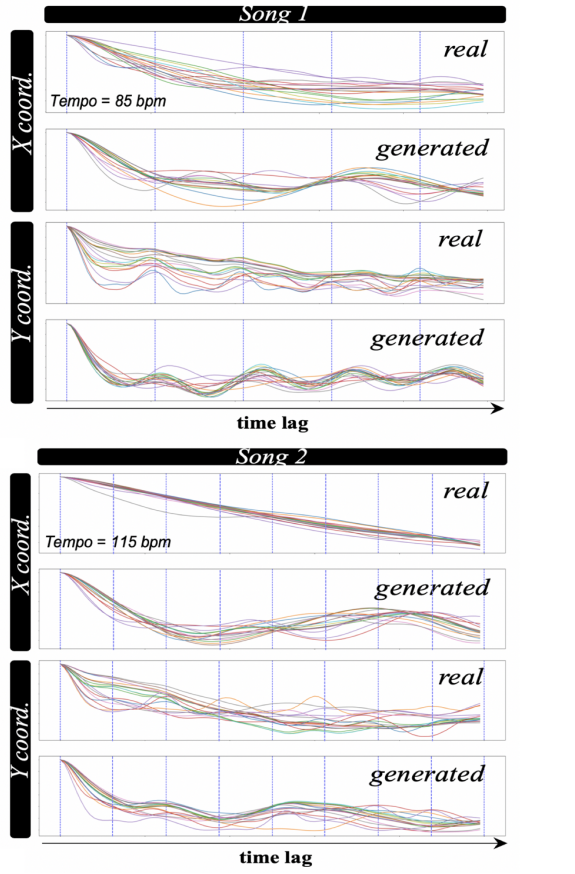

Figure 4. Autocorrelation of the x,y coordinates of each joint from real and generated choreography for two songs. The x-axis of each graph represents the time lag, y-axis of each graph represents the autocorrelation, and the blue vertical lines represent the beat positions of each song.

and the results are shown in the Figure 3. The results of the statistical tests confirmed that the mean scores between the three groups were significantly different for both questions. Average user score for both questions were highest in *Real* group and lowest in *Mismatch* group. It is clear that the *Real* group score is the highest, because it is made up of the choreography created by the human. The average score of the *Generated* group surpassed the *Mismatch* group in both questions. If the proposed model generates choreography that is not associated with music, participants will have a similar response, regardless of what music is played with the generated choreography. However, from the fact that the video received a significantly higher score when played with the music used in choreography generation, we judged that the proposed model produced choreography that listen and reflects the music.

5.2 Autocorrelation Analysis

We also performed an autocorrelation analysis to further investigate the differences between the generated choreography and the actual choreography. Autocorrelation is a correlation between a given sequence with itself, reflecting the periodic properties of the sequence. We can identify the periodic component of a given sequence through the location of the peaks observed in the autocorrelation results. Using this, we analyzed the motion by calculating the autocorrelation on the x, y coordinates of the choreography movement and compared it with the tempo of corresponding music. Our hypothesis was that if the model can produce dance by listening to the music, the autocorrelation peak position of the motion will appear at the same point as the beat of the music.

Fig. 4 shows the autocorrelation results of two choreography samples along with the tempo of corresponding music. In actual choreography, a clear peak is observed in y-direction movement, but not in x-direction movement. This tendency is also observed in the generated choreography. From this we can determine that the proposed network has learned the periodic tendency of the real choreography used in training. Also, In actual choreography, the first or second peak of the y-direction auto-correlation appears at the same position as the music beat. This means that music and choreography have similar periodic properties. This tendency can be confirmed also in the case of the generated sample. From this, it is judged that the proposed model has generated the choreography that listen the music and reflects its periodic nature.

6. CONCLUSION

In this study, we proposed an auto-regressive encoder-decoder network that generates matching choreography for a given music input. We used audio-video pairs data obtained from YouTube for training. As a result, it was found that motions matching with the music were generated through comparison of user study and autocorrelation analysis. This study has a significance in that it shows a significant performance in the area of learning-based choreography generation, in which sufficient performance has not been secured yet. Also, it is meaningful not only to learn the movement of dance but also to use the relationship with music together for generation.

Although we found in this study that the choreography generated compared to the mismatch group has a higher correlation with music at a significant level, we still have the limitation of having a large difference score from the real group. To overcome this, we will further model the correlation between movement and music more elaborately and carry out follow-up studies that reflect it in the network architecture. Also, this research has limitations that generated choreography reflects only the periodicity among various properties of music. Ultimately, it is necessary to create appropriate choreography according to various genres, moods, and contexts of music as well as periodicity. In order to do this, we plan to establish data sets that satisfy various conditions and carry out further research. In addition, we use 2-d skeleton position for training, and it is difficult to use this type of data in case of needing actual implementation such as a robot. Therefore, the extension of the model to 3-d choreography generation using the improved 3-d pose estimation algorithm [9, 15, 17] is also a future research topic.

ABSTRACT

Identifying the onset and offset time of a note is a challenging step in singing voice transcription, as the soft onset/offset, portamento, and vibrato phenomena are rich in singing voice signals. In this work, we utilize various types of signal representations with deep learning for onset and offset detection of monophonic singing voice. We consider onset and offset detection as a hierarchical classification problem, where every input segment is classified into one of all the possible states in monophonic singing, namely the silence, activation, and transition states,where the transition state is further classified into the onset and offset states. An objective function based on this hierarchical taxonomy nicely guides the model to capture complicated temporal dynamics of note sequences. Multiple input signal representations containing spectral differences and pitch saliency are employed to jointly enhance such temporal patterns. The proposed method implemented with residual networks provides improved performance over prior art in onset and offset detection. Moreover, by integrating with a pitch detection framework, the proposed method also outperforms previous singing voice transcription methods. This result emphasizes the importance of note segmentation in singing voice transcription.

1. INTRODUCTION

Note-level automatic music transcription (AMT) refers to converting a recorded music piece into its symbolic form containing the onset, offset, and pitch of every note [4, 22]. Note-level AMT is still a challenging problem, particularly in the case of singing voice transcription. The soft onset/offset and portamento patterns of singing voice hinder the positioning of onset and offset time in both the detection [8, 29] and the annotation process [10, 15, 19]. However, solving the onset and offset detection problem, or equivalently the *note segmentation* problem, [1] is mandatory in a note-level AMT system. How to improve a note segmentation model efficiently with limited scope of data, and how to incorporate the outcomes of detection into note-level AMT, are both important issues in developing a complete AMT system.

Previous note segmentation works on singing voice usually employ state-space machines such as the hidden Markov models (HMM), which consistently detect onset and offset by characterizing the temporal dynamics among the *states* (attack, sustain, and silence, etc.) of note events [16, 20, 24, 29]. Recently, deep neural networks with objective functions optimized for onset and offset detection have demonstrated excellent performance in note-level AMT [1, 12]. Some architectures such as the convolutional neural network (CNN) do achieve a great advance in modeling note transition by their compelling performance in pattern recognition on a local scale. One example is the CNN-based onset detection method in [25], where the local feature segments with CNN outperforms the temporal models based on the recurrent neural network (RNN) [9].

In this paper, we propose novel signal representations and objective functions in neural network-based singing voice segmentation. we regard onset and offset detection as a hierarchical classification problem that maps input segments/sequences onto our proposed state space, where a generalized hierarchical taxonomy of the states in a note sequence is specified to guide the learning process. Multiple data representations are also used to enhance signal-level expressivity of note transition events. Experiments using either the residual network (ResNet) [13] or the RNN with attention [2] demonstrate the effectiveness of hierarchical classification in note segmentation. Finally, a straightforward integration of the proposed note segmentation method and pitch detection provides improved note transcription performance over prior art.

2. RELATED WORK

The most challenging case of onset detection is arguably singing voice. According to the results from MIREX 2018 audio onset detection task, the best F1-score of singing voice onset detection among all submissions is 61.94%, lower than the best results of other instrument classes by at least 10%. [2] The state-of-the-art onset detection algorithms are based on either RNN [5, 11] or CNN [25]. In [25], the onset detection task is to classify whether the

[1] We refer to note segmentation as temporal segmentation of note objects, which is therefore equivalent to onset and offset detection [7].

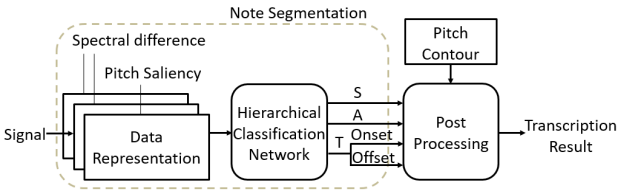

Figure 1: System overview of the proposed note segmentation and transcription framework.

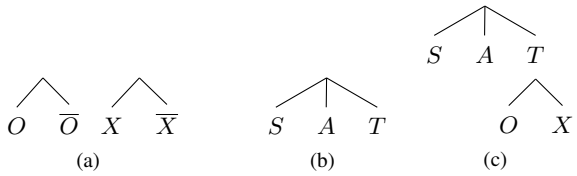

Figure 2: The taxonomy of the proposed models. Every tree represents an objective function, every siblings form a regularization term of the objective function, and every leaf of the tree represents a state label; S, A, O, $\overline{O}$, X, $\overline{X}$, and T represent silence, activation, onset, non-onset, offset, non-offset, and transition, respectively. Different trees therefore represent different optimization approaches: (a) On-Off model. (b) Tri-state model. (c) Hierarchical classification model. See Section 3.1 for more details.

middle of the input is at the onset time, where the inputs are short segments of spectrogram with various resolutions, each as one channel of the CNN. Besides spectrogram, other feature representations such as spectral difference, spectral flux and group-delay function are also widely-used in general-purpose onset detection [14].

Unlike onset detection, offset detection is seldom treated independently and is more often discussed in the context of note-level AMT [1, 3, 12]. The study carried out in [15] focuses on different playing styles of string instruments and summarizes several relevant features, including spectral difference, signal RMS energy, pitch confidence values, and pitch change, etc.

Previous methods in singing voice transcription widely adopt state-space machines to accomplish onset detection, pitch tracking, and offset detection in a single workflow. For example, the Tony software [16] uses an HMM containing three states, namely attack, stable, and silent, to characterize the temporal dynamics of a note sequence. The only allowed transition rules between these states are: 1) from attack to stable, 2) from stable to silent, and 3) from silent to attack of another note. However, these rules are oversimplified from real cases; for instance, an offset event is not always equivalent to a transition into the silent state. Rather, some offset events are followed immediately by the attack state of another consecutive note, which sometimes has the same pitch as the previous one. As a result, consecutive notes are merged and needs to be resolved by post-processing.

Recently developed note-level AMT methods utilizing deep learning has gained tremendous improvement, especially in offset detection. It is notable that in these methods, offset or onset detection sub-modules are optimized with more than one objective functions. Elowsson used two separate networks to learn 1) the offset curve, which outputs one at the instance of note offset, 2) the offset detection activation, which turns from zero to one when a note offset event turns into silence, and combined the results to describe offset events [1]. Hawthorne *et al.* used time-dependent object functions to infer the attack and decay of a musical note. These methods shed light on the note tracking of singing voice [12].

The above discussion inspires us two ways for improving singing voice segmentation. First, the objective functions can be designed to rely not merely on the onset and offset labels, but on an state space that describes all possible state transitions in a note sequence. Second, given the flexibility of neural network models, one may augment all the data representations related to onset/offset into the network to enhance the optimization process. The two ideas will be discussed in Section 3.1 and 3.2 respectively.

3. METHOD

Following previous discussion, we discuss the frame-wise onset and offset detection framework shown in Figure 1: for every time instance t, the hierarchical classifier predicts a set of labels y_t containing onset and offset information from a local feature representation $\mathbf{R}_t$. Note transcription is done by integrating pitch contour information.

3.1 Hierarchical classification for note segmentation

We consider the following states in a note sequence: silence (S), activation (A), and transition (T), where transition is further divided into two states, onset (O) and offset (X). When a transition (i.e. onset or offset) occurs, there are three possible *transition behaviors* of state evolution: $S \to T \to A$ where T represents an onset (O), $A \to T \to S$ where T represents an offset (X), and $A \to T \to A$ where T in this case contains an offset followed immediately by the onset of another note (XO). In other words, there is an important case that *an onset and an offset are presumably overlapped*. This fact motivates us to define such a state space that can encompass more general cases. As a result, there is a hierarchical taxonomy of these states, as shown in Figure 2 (c). See the caption of Figure 2 for more detailed information.

To investigate the behavior of this state space, we introduce several baselines and the proposed hierarchical classification model altogether to highlight the advantage of the proposed model in onset and offset classification.

1) First, we consider the note segmentation model consisting of two independent classifiers, one for onset detection and the other for offset detection. The 2-D onset label $y_{\text{on}} := [O, \overline{O}]$ is one-hot, where O represents the onset state while $\overline{O}$ represents the non-onset state. That means, $y_{\text{on}} = [1, 0]$ for onset and $y_{\text{on}} = [0, 1]$ for non-onset. Similarly, we have the offset label $y_{\text{off}} := [X, \overline{X}]$. Let the prediction of the two networks be $\hat{y}_{\text{on}}$ and $\hat{y}_{\text{off}}$, the model

is optimized by the following two objective functions:

$$L_{\text{on}}(y_{\text{on}}, \hat{y}_{\text{on}}) = \text{BCE}(y_{\text{on}}, \hat{y}_{\text{on}})\,, \quad (1)$$

$$L_{\text{off}}(y_{\text{off}}, \hat{y}_{\text{off}}) = \text{BCE}(y_{\text{off}}, \hat{y}_{\text{off}})\,. \quad (2)$$

where BCE is the binary crossentropy. This model is denoted as the on-off network (OON) model, and its taxonomy is illustrated in Figure 2 (a). Note that one tree represents one objective function, and every siblings form a regularization term in an objective function.

2) The onset and offset detection tasks share the same network, but with two task-specific layers, one for onset and the other for offset. The output label $y := [y_{\text{on}}, y_{\text{off}}]$ therefore has four dimensions. The total loss function is

$$L_{\text{M-OON}}(y, \hat{y}) := \text{BCE}(y_{\text{on}}, \hat{y}_{\text{on}}) + \text{BCE}(y_{\text{off}}, \hat{y}_{\text{off}}) \quad (3)$$

This model is denoted as the merged on-off network (M-OON) model hereafter.

3) The onset and offset are described implicitly by the three output states S, A, and T from a shared network. That means, the network outputs a multi-hot 3-D vector $y_{\text{tri}} := [S, A, T]$, where S, A and T are values between 0 and 1. The total loss function is

$$L_{\text{TSN}}(y, \hat{y}) := \text{BCE}(y_{\text{tri}}, \hat{y}_{\text{tri}}) \quad (4)$$

After obtaining the likelihood of S, T, A at every time instance t, we may follow the *transition behaviors* mentioned above to determine a T state to be an onset or an offset; the details can be found in Section 3.4. This model will be denoted as the tri-state notwork (TSN) model, and its taxonomy tree is constructed following Figure 2 (b).

Note that it is also possible to use categorical crossentropy rather than BCE in (4). However, using BCE allows possible overlapping of different states and therefore more flexibility for the model. Our pilot study also shows that using BCE achieves better performance.

4) We further consider the hierarchical structure that T can be onset, offset or an overlap of onset and offset. The output label is then a six-dimension space $y := [S, A, O, \overline{O}, X, \overline{X}]$, and the total objective function is:

$$L_{\text{HCN1}}(y, \hat{y}) := \text{BCE}(y_{\text{tri}}, \hat{y}_{\text{tri}}) + \text{BCE}(y_{\text{on}}, \hat{y}_{\text{on}}) + \text{BCE}(y_{\text{off}}, \hat{y}_{\text{off}}) \quad (5)$$

where we define the likelihood of the transition state as $T := \max(O, X)$. That means, if one of O or X is higher than a threshold (0.5 in the logistic regression case), then the state will be also predicted as T. The taxonomy tree of this case is illustrated in Figure 2 (c).

Finally, since T is in minority, optimizing the term $\text{BCE}(y_{\text{tri}}, \hat{y}_{\text{tri}})$ would suffer from data imbalance. To mitigate this issue, we enhance the *activity* classification between S and A by adding a new set of labels $y_{\text{act}} := [S, A]$, to enforce the output that only one of S and A would have high likelihood. The total objective function is then

$$L_{\text{HCN2}}(y, \hat{y}) := \text{BCE}(y_{\text{tri}}, \hat{y}_{\text{tri}}) + \text{BCE}(y_{\text{act}}, \hat{y}_{\text{act}}) + \text{BCE}(y_{\text{on}}, \hat{y}_{\text{on}}) + \text{BCE}(y_{\text{off}}, \hat{y}_{\text{off}}) \quad (6)$$

For clarity, (5) is denoted as the hierarchical classification network 1 (HCN1) model and (6) is denoted as the the hierarchical classification network 2 (HCN2) model.

3.2 Data representations

Based on the discussion in [15], we consider the spectral differences and the pitch salience representation in as the input of the proposed model. Given the input audio signal $\mathbf{x} := \mathbf{x}[n]$, where n is the time index. Let the amplitude part of the short-time Fourier transform (STFT) of $\mathbf{x}$ be $\mathbf{X}$. The forward spectral difference $\mathbf{S}^+$ and the backward spectral difference $\mathbf{S}^-$ are the time-forward and the time-backward differences of two neighbouring spectra in $\mathbf{X}$, as shown in the followings:

$$\mathbf{S}^+ = \text{ReLU}\left(\mathbf{X}[k, n+1] - \mathbf{X}[k, n-1]\right), \quad (7)$$

$$\mathbf{S}^- = \text{ReLU}\left(\mathbf{X}[k, n-1] - \mathbf{X}[k, n+1]\right), \quad (8)$$

where $\text{ReLU}(\cdot)$ represents the element-wise rectified linear unit: $\text{ReLU}(x) = x$ if $x > 0$, and 0 otherwise. That means, we split the first-order temporal difference of the spectrogram $\mathbf{X}$ into two channels, one is the part with positive temporal difference, and the other one is with negative temporal difference.

For the pitch saliency feature of $\mathbf{x}$, we adopt the one proposed in the combined frequency and periodicity (CFP) approach, which combines a frequency-domain feature indicating its fundamental frequency (f_0) and harmonics (nf_0), in a time-domain feature revealing its f_0 and sub-harmonics (f_0/n) to form a succinct, localized pitch feature with suppressed harmonic and sub-harmonic peaks [21, 28]. The feature is computed with the following process. Given a DFT matrix $\mathbf{F}$, high-pass filters $\mathbf{W}_f$ and $\mathbf{W}_t$, and activation functions σ_i, we consider three features, namely, spectrogram $\mathbf{Z}_0$, generalized cepstrum (GC) $\mathbf{Z}_1$, and generalized cepstrum of spectrum (GCoS) $\mathbf{Z}_2$:

$$\mathbf{Z}_0[k, n] := \sigma_0\left(\mathbf{W}_f \mathbf{X}\right), \quad (9)$$

$$\mathbf{Z}_1[q, n] := \sigma_1\left(\mathbf{W}_t \mathbf{F}^{-1} \mathbf{Z}_0\right), \quad (10)$$

$$\mathbf{Z}_2[k, n] := \sigma_2\left(\mathbf{W}_f \mathbf{F} \mathbf{Z}_1\right). \quad (11)$$

The index k in $\mathbf{Z}_0$ and $\mathbf{Z}_2$ is frequency, while the index q in $\mathbf{Z}_1$ is called *quefrency*, which has the same unit as time. The nonlinear activation function is defined as a rectified and root-power function $\sigma_i(\mathbf{Z}) = |\text{ReLU}(\mathbf{Z})|^{\gamma_i}$, where $i = 0, 1, 2\cdots$, $0 < \gamma_i \leq 1$, and $|\cdot|^{\gamma_0}$ is an element-wise root function. $\mathbf{W}_f$ and $\mathbf{W}_t$ are two high-pass filters designed as diagonal matrices used to remove slow-varying portions, where $\mathbf{W}_f$ applies cutoff frequency k_c and $\mathbf{W}_t$ applies cutoff quefrency q_c. In this paper we set $k_c = 80$ Hz and $q_c = 1/800$ sec. Based on the CFP approach, unwanted harmonics and sub-harmonics can be suppressed by merging $\mathbf{Z}_1$ and $\mathbf{Z}_2$ together. Note that $\mathbf{Z}_1$ should be mapped into the frequency domain because it is in the quefrency domain. Hence, we apply two sets of filter banks, both of which contain 174 triangular filters ranging from 80 Hz to 1000 Hz and with 48 bands per octave, respectively in the time and frequency domains. More specifically, the mth filter in frequency (or time) takes the weighted sum of the components whose frequency (or period) is between 0.25 semitones above and below the frequency at $f_m = 80 \times 2^{(m-1)/48}$ Hz (or the period at $1/f_m$

seconds). The filtered representations $\tilde{\mathbf{Z}}_1$ and $\tilde{\mathbf{Z}}_2$ are then both in the time-pitch scale. The CFP representation $\mathbf{Z}$ is

$$\mathbf{Z}[p,n] = \tilde{\mathbf{Z}}_1[p,n]\tilde{\mathbf{Z}}_2[p,n]\,, \tag{12}$$

where p is the pitch index. Details and source codes of computing the CFP representations can be found in [27].

In this work, the audio recordings are resampled to 16 kHz and are merged into mono-channel. Following [5], the input features are of multiple resolution.We compute $\mathbf{S}^+$, $\mathbf{S}^-$, and $\mathbf{Z}$ using the Hann window with 3 different sizes of 186, 372, and 743 samples (i.e. 11.61, 23.22, and 46.44 ms), resulting in nine data representation. The hop size is 320 samples (i.e. 20 ms). In CNN, $\mathbf{S}^+$, $\mathbf{S}^-$, and $\mathbf{Z}$ form the three input channels, and in each channel the data representations with three different window sizes are concatenated together. In RNN, all the nine data representations are concatenated as the input.

3.3 Model

We investigate two networks that stand for two strategies in modeling note sequences: ResNet for image classification [13] and RNN with attention for sequence classification [2]. Denote the frame-level feature at the time instance t as $\mathbf{r}_t$. For every t, we take the sequence $\mathbf{R}_t := [\mathbf{r}_{t-k}, \mathbf{r}_{t-k+1}, \cdots, \mathbf{r}_t \cdots, \mathbf{r}_{t+k}]$ as the input of the model to predict the presence of onset and offset at t. We set $k = 9$ according to the optimal loss on the validation set. That means, the dimension of every input $\mathbf{R}_t$ is $(c, 174, 19)$ (for ResNet) or $(c * 174, 19)$ (for RNN with attention mechanism), where c represents the number of channels: if $\mathbf{S}^+$, $\mathbf{S}^-$, and $\mathbf{Z}$ are stacked as the input, then $c = 3$.

Our implementation of the ResNet model basically follows the ResNet-18 architecture in [13]. The network is composed of eight sub-networks, each of which has two convolutional layers. The convolutional layers mostly have kernel of size $(3, 3)$. Batch normalization is used after each convolutional layer. The spatial pooling process is done by using convolutional layers with stride of two. Shortcut paths link the feature maps by skipping every two convolutional layers. After the convolution stages, the feature maps are pooled by averaging, and then are mapped to the output space through fully connected layers. See [13] for the implementation details. The output format and the objective functions follow the discussion in Section 3.1.

The RNN with attention is composed of a three bidirectional long-short-term memory (BLSTM) [26] layers, an attention layer, and two fully connected layers. For the three-layer BLSTM, the dimension of every hidden unit is 150. The outputs of the BLSTM are weighted and summed by the $2k + 1$ attention weights derived from the hidden units of the last BLSTM layer [2]. Layer normalization is used to stabilize training and inference processes. The results are then fed into the two-layer fully-connected network, each with a dimension of 150 and 6. The output format and the objective functions of the model also follows the discussion in Section 3.1.

Each data representation is normalized to zero mean before fed into the model. The manual labels in the dataset are not always exact since the exact time of an onset/offset event is hard to determine [5]. To solve this issue, we extend the labels to a *tolerance window* δ that can allow uncertainty in the onset/offset time labels: if a frame is within $\delta = \pm$50ms to the true label, the label is also set to 1. This δ value is chosen according to the evaluation convention of onset detection in MIREX. This can mitigate the issue of data imbalance. In this work, all the models are obtained after 80 epochs of training on an Nvidia TITAN Xp GPU, using the Adam optimizer with the learning rate of 0.001. The source code, supplementary materials, and listening examples are available at: `https://github.com/Itachi6912110/Hierarchical-Note-Segmentation`.

3.4 Post-processing and note segmentation

We employ a linear filter with impulse response $h(n) = [0.25, 0.5, 1, 0.5, 0.25]$ to smooth the predicted onset and offset sequences. Then we apply a threshold at 0.5 and a peak picking process on the sequences to determine possible onset and offset positions. At this stage, minor mismatches between the predicted onset and offset positions still remain. To ensure that every onset is followed by exactly one offset, additional procedures are used.

For the OON and the M-OON models, the procedure includes: 1) if there are two onsets having no offset between them, we insert an offset at the time when the second onset occurs; 2) if there are two offsets without any onset between them, we directly discard the second one.

For the TSN model, consistent segmentation results can be derived directly from the relationship among S, A and T, so there is no issue on onset/offset mismatching. Onsets and offsets are determined by the following steps: 1) obtain the peak positions of the predicted sequence of T; 2) sum over the likelihood values of S and A in every interval separated by those peaks obtained in 1). If the sum of S is higher than the sum of A, then the interval is determined to be S. Otherwise, the interval is determined to be A; 3) for every selected T in 1), if its left-side interval is S and its right-side interval is A, a $S{\rightarrow}T{\rightarrow}A$ pattern is detected and the transition is determined as an onset. Conversely, if we detect a $A{\rightarrow}T{\rightarrow}S$ pattern, the transition is determined as an offset; 4) if we detect an $A{\rightarrow}T{\rightarrow}A$ pattern, the transition is determined as an offset and an onset; 5) if we detect a S$\rightarrow$T$\rightarrow$S pattern, the transition is directly discarded.

For HCN1 and HCN2, the procedure is a combination of the two strategies above: 1) if there are two onsets having no offset between them, we insert an offset specified to the time when S firstly surpasses A at that interval; 2) similarly, if there are two offsets having no onset between them, the inserted onset is specified to the time when A firstly surpasses S at that interval; 3) any detection violating the rules of 1) and 2) is deleted.

3.5 Note-level transcription

We combine the note segmentation method with a simple pitch estimation process for note-level singing voice transcription. This is implemented by: 1) obtain the onset and

offset times of each note with the note segmentation model, and 2) use the vocal melody extraction method in [27] to obtain the pitch contour of every note, and 3) the final pitch value is simply determined by the median of the pitch contour of that note.

4. EXPERIMENTS

4.1 Data and evaluation metrics

To test the robustness of our model, we set a cross-dataset scenario for the experiments on note segmentation. We use TONAS [10, 19], a dataset of 71 flamenco a cappella sung melody, as our training dataset. In addition, we evaluate our proposed method on the ISMIR2014 sung melody dataset [17]. It contains singing data from 11 female adults, 13 male adults and 14 children.

Section 4.2 first compares the results using different input features. Section 4.3 further compares the results of training with five different objective functions mentioned in Section 3.1. Section 4.4 then compares the ResNet-18 model, the RNN model with attention and the onset detector in the `MADMOM` library [6]. The latter is known as the state of the art for general-purpose onset detection.

For the evaluation metrics, we report the F1-scores of onset detection, offset detection and note transcription and the average overlap ratio (AOR) by using the utilities in the `mir_eval` library with default parameters [23]. To quantify the mismatch between the detected onsets and offsets in note segmentation results, we further compare their *conflict ratio* (CFR), which is defined as the ratio between the number of unpaired detection and the number of all predicted transitions (i.e. onsets plus offsets):

$$\text{CFR} := \frac{\text{\# of unpaired transitions}}{\text{\# of predicted transitions}} \tag{13}$$

The unpaired transition is defined as the onset/offset that cannot be derived from, or that violates the relationship of the states used in the model. For example, in the OON model, if there are two consecutive onsets having no offset in between, the second offset violates the relationship between onset and offset and is accounted as an unpaired detection. On the other hand, the TSN model produces zero unpaired transition and therefore has zero CFR, as discussed in Section 3.4. CFR can be seen as a criterion of systematic consistency for a note segmentation model.

4.2 Comparison of input features

The first five rows of Table 1 lists the results of both onset and offset detection with various inputs: $\mathbf{X}$, $\mathbf{S}^+$, $[\mathbf{S}^+, \mathbf{S}^-]$, $[\mathbf{S}^+, \mathbf{Z}]$, and $[\mathbf{S}^+, \mathbf{S}^-, \mathbf{Z}]$. In comparison to others, using only the spectrogram ($\mathbf{X}$) with less feature engineering gives competitive result, which indicates the power of ResNet in pattern recognition. However, it should be emphasized that using a detailed set of features relevant to onset and offset such as $[\mathbf{S}^+, \mathbf{S}^-, \mathbf{Z}]$ achieves the best note transcription F1-score at 59.5%, which is better than the case using only $\mathbf{X}$ by 3.9%. Such improvement can be seen from other interesting comparisons. For example, adding either $\mathbf{S}^-$ or $\mathbf{Z}$ to $\mathbf{S}^+$ greatly improves the F1-scores of both the onset and offset. Adding $\mathbf{S}^-$ to $\mathbf{S}^+$ also results in 14.5% improvement on onset F1-score, meaning that the backward spectral difference may also be relevant to an onset event. These observations can all be explained by the fact that an onset event can be highly overlapped by an offset event of another notes, and the feature set revealing different aspects of the signal characteristics helps resolve such ambiguity. For simplicity, we adopt $[\mathbf{S}^+, \mathbf{S}^-, \mathbf{Z}]$ in the following experiments.

4.3 Comparison of objective functions

The lower part of Table 1 compares the results of models trained by four baseline objective functions, including OON, M-OON, TSN, and HCN1. Comparing the F1-scores of OON and M-OON, we observe that M-OON slightly degrades onset detection but greatly improves offset detection by 29.2%. This indicates the importance of joint training: incorporating onset information in a shared network can help offset detection.

Although the F1-score of TSN is worse than the one of M-OON, TSN achieves zero CFR as all onsets/offsets can be completely inferred from the rule mentioned in section 3.1 and 3.4. This shows that training on S, A, T and the temporal constraints make highly consistent prediction. However, the poor performance on onset and offset detection implies that using a single T state is not sufficient to describe the behavior of both onset and offset.

HCN1 and HCN2 therefore combine the advantage of both the M-OON model and TSN model. Result shows that the HCN1 model enhances the segmentation quality (reducing CFR to half) compared to the M-OON model and improves the onset and offset detection F1-score compared to the TSN model, then achieves the F1-score of 56.7% on note transcription. In addition, HCN2 model outperforms the HCN1 model in almost all evaluation metrics, where a 2.7% improvement on note transcription F1-score is obtained. Such advancement indicates the importance of regularizing activation/silence detection in note segmentation and transcription tasks.

4.4 Comparison of models

Table 1 also compares two implementations of HCN2 using different modules for the hierarchical classifier: ResNet-18, and the RNN with attention (denoted as RNN-attn) as a sequence classification network for comparison.

Results show that ResNet-18 outperforms RNN-attn in every performance metrics, probably because that an image-based classification network can extract more detailed features considering local information where sequential dependency is not that significant. These findings are partly in line with that in [25], where a CNN outperforms sequence models such as RNN.

4.5 Singing Voice Note Transcription

Table 2 shows the results of singing voice transcription compared with five previous methods: Ryynänen *et al.*

Objective	Classifier	Feature	F1 (onset)	F1 (offset)	CFR	AOR	P (note)	R (note)	F1 (note)
HCN2	ResNet-18	$\mathbf{S}^+$	0.599	0.409	0.078	0.862	0.430	0.394	0.409
		$\mathbf{X}$	0.757	0.740	0.050	0.873	0.576	0.538	0.555
		$[\mathbf{S}^+, \mathbf{S}^-]$	0.744	0.715	0.057	0.870	0.532	0.506	0.517
		$[\mathbf{S}^+, \mathbf{Z}]$	0.745	0.713	0.050	0.870	0.553	0.506	0.527

Table 2: Comparison of singing transcription results.

[24] , Gómez & Bonada [10], SiPTH [18], Yang *et al.* [29], and Tony [16]. The results for these five methods are reported in [29]. Our proposed method outperforms all the previous methods by more than 7.4% in terms of the F1-measure. It is important to note that although our model is trained on a dataset with the singing style (flamenco singing) quite different from the testing data, the model still outperforms the Tony software, which performance is actually based on a parametric grid search on the testing dataset [16]. This fact indicates that our method is potentially generalizable over various data modalities. Besides, since we do not directly deal with issues such as vibrato, unstable pitches and tuning shift [29], our model actually benefits more from a stable note segmentation method. This highlights the importance of note segmentation in note transcription.

Fig. 3 illustrates an example of the predicted silence, activation, onset, offset likelihood curves and note transcription results of a clip in the testing dataset. The transcription result from the Tony software is also provided for comparison. It can be shown that Tony tends to miss onsets for consecutive notes, while the proposed model successfully captures almost all the note transitions except the onset at 16.71 sec, which is a challenging case due to the bent pitch contour around the onset event and a relatively short note duration.

5. CONCLUSION

We have presented the effectiveness of the proposed hierarchical classification networks in note segmentation and transcription in singing voice. By unfolding the structure of the state evolution patterns in note sequences and by applying multi-channel data representations to modeling note transitions, the general, robust, and consistent note segmentation procedure plays a vital role in achieving state-of-the-art performance. One important aspect omitted in our discussion is using temporal modeling (e.g., HMM) over the hierarchical state space rather than using post-processing rules to complete the note transcription process. Based on the positive result of this study, this direction is with high potential and will be left as future work.

ABSTRACT

In this paper, we present our application of deep neural network to modeling piano performance, which imitates the expressive control of tempo, dynamics, articulations and pedaling from pianists. Our model consists of recurrent neural networks with hierarchical attention and conditional variational autoencoder. The model takes a sequence of note-level score features extracted from MusicXML as input and predicts piano performance features of the corresponding notes. To render musical expressions consistently over long-term sections, we first predict tempo and dynamics in measure-level and, based on the result, refine them in note-level. The evaluation through listening test shows that our model achieves a more human-like expressiveness compared to previous models. We also share the dataset we used for the experiment.

1. INTRODUCTION

Music performance is one of the most essential activities in music. Good performance requires not only translating notes in the score into physical actions with precise timing and right pitch on an instrument but also delivering emotions and messages through subtle controls of tempo, dynamics, articulations and other expressive elements.

There have been research interests in modeling expressive performance using a computational method. A recent review paper comprehensively summarized the history [4]. While some of previous work exploited computational modeling as a tool for understanding how humans perform [3], or listen to music [10], others focused on automatically generating expressive performances. The previous methods include rule-based approaches [2, 8], or probabilistic models [17, 29], and an artificial neural network [5, 11]. The instrument is mainly limited to piano because it is relatively easy to quantify the performances.

Recent approaches have attempted to apply deep learning to modeling expressive piano performance, such as rendering note velocity and deviation of note onset with vanilla recurrent neural network (RNN) [20], or predicting note velocity with a long short-term memory (LSTM) RNN [22]. Others introduced DNN models for generating polyphonic music with expressive timing and dynamics [13, 24]. While these models can generate performance MIDI notes, they are more like music composition models rather than expressive performance models that take music scores as input. Besides piano performance, a recent work presented DNN-based system for modeling expressive drum performance [9].

One of the bottlenecks in the DNN-based approach is the lack of dataset [4]. Since the task is rendering expressive performances from score inputs, the dataset should consist of music scores and their corresponding performances by human musicians. Furthermore, the pair of score and performance should be aligned in note-level to effectively train the model. Also, ideally, the list of music score and performance should cover various composers and performance styles.

In this paper, we present a hierarchical RNN-based model for expressive piano performance along with a dataset that we organized. The model takes MusicXML as input and generates performance MIDI with expressive tempo, dynamics, articulation and pedaling. The model consists of RNN with hierarchical attention network and conditional variational autoencoder (CVAE). In particular, the model predicts the performance features using a multi-scale approach; it first predicts tempo and dynamics in measure-level and, based on the result, fine-tunes them in note-level. A listening test with professional pianists shows that our model achieves a more human-like expressiveness compared to previous models.

2. DATASET

2.1 Performance and Score Data

As aforementioned, we need a dataset of human performances with their corresponding music scores to train a neural network model. A list of expressive performance datasets are summarized in [4]. Among others, Yamaha

Signature MIDI collection [1], which are recorded during Yamaha e-Competitions with computer-controlled pianos, is the largest public dataset that provides a substantial amount of expressive performance MIDI of professional pianists. Some of the pianists performed the same piece more than once in different rounds of the competition in different years. The Yamaha collection has been employed in automatic performance generation [24] and automatic music transcription and audio synthesis [12] as well.

While the Yamaha collection provides high-quality piano performance data in MIDI, it does not contain the corresponding music scores of the pieces. Thus, we collected the score files from another source. Specifically, we downloaded them from *MuseScore*, a community-based web platform of music score [2]. The scores were transcribed voluntarily by the community users and can be exported in MusicXML format. We also included our own transcriptions of scores to the dataset. While MIDI is suitable for representing performance, MusicXML aims to represent the Western music notation in its entirety. Therefore, MusicXML can contain various types of musical symbols such as rest, slur, beam, barline, key and time signature, articulation, ornament markings and so on, which are excluded in MIDI format.

2.2 Data Matching and Refinement

Since we collected the performance and score data from different sources, we had to match and refine them. In particular, transcription styles in the crowdsourced MusicXML files are not consistent. For example, some of the transcribers add extra expressions such as dynamics markings or tempo change to make the score sounds more expressive. They usually set them to "invisible objects" to make the transcribed score appear as the reference score. We deleted such extra markings added by transcribers. Also, we manually checked whether the performances followed the repetitions in the scores. If a performance skipped the repetition, we omitted the repetition from the score so that the performance and the score can be aligned.

To train a model with note-level score features and performance features, each note in the score should be matched to that in the performance. We employed a score-to-performance alignment algorithm proposed by Nakamura et al. [23]. The algorithm automatically handles asynchronously performed notes as well as missing and extra notes in the performance, and returns a list of note-to-note matches. Although the algorithm showed high accuracy in our test, a small amount of alignment errors can be critical in extracting performance features such as tempo or onset deviation. Since the dataset is too large to make manual corrections, we filtered out some erroneous matches based on simple rules and excluded them in training the performance model. For example, if a matched performance note is too close or even earlier than the previous note in the score, we regarded it as an alignment error. Also, if multiple notes have the same onset time in the score (e.g., chord notes) but one is too far from other notes in performance, we regarded it as an alignment error as well.

We found that this additional refinement made severe improvement on the training result, especially on onset deviation, or micro-timing, of individual notes. The standard deviation of onset deviation decreases from 7.369 to 0.053 after the refinement, where the unit is quarter-notes. Without the refinement, the prediction of onset deviation became too noisy that one could not perceive correct rhythm.

As a result, we collected music scores of 226 pieces by 16 composers in MusicXML and 1,052 piano performances in MIDI. After the matching and refinement, the score and performance data contain a total of 666,918 notes and 3,547,683 notes, respectively. Among the performance notes, 131,095 notes were failed to be aligned with score notes, and additional 114,914 notes were excluded by our refinement algorithm. The number of valid performance notes is ten times larger than the Magaloff corpus [7], which is the largest existing dataset for classical piano music [4].

3. SYSTEM ARCHITECTURE

3.1 Background

3.1.1 Input and Output Features

Designing input and output features is an important issue in performance modeling because it defines the characteristics of the computational task [4]. We followed the scheme we previously proposed in [15], which covers a wide range of score and performance features. The score features include pitch, duration, articulation marking, slur and beam status, tempo marking, dynamic markings, and so on. The performance features include absolute tempo, velocity, onset deviation, articulation and pedal usages. All the features are encoded in the note-level so that each note had the same dimension of score features and performance features.

3.1.2 Hierarchical Attention Network

Recent research has shown that a hierarchical approach can improve the performance of RNN model in modeling sequential data [6, 30]. It was also demonstrated that the hierarchical approach has advantages in generating symbolic music data [25]. In this paper, we employ a hierarchical attention network (HAN) to predict a sequence of performance features from a sequence of score features.

The HAN composes higher-level representations by summarizing lower-level representations in pre-defined hierarchical boundaries using a weighted sum. In our case, we set beat and measure as the hierarchical boundaries so that beat-level attention and measure-level attention summarize note-level and beat-level representations, respectively. Instead of directly implementing the HAN in [30], we combined it with the idea of multi-head attention [28] which splits the dimension into several heads and applies different weights of attention for each split.

Composing nodes through the attention layers can be described as follows. For each hierarchical boundary,

[1] `http://www.yamahaden.com/midi-files`
[2] `https://musescore.com`

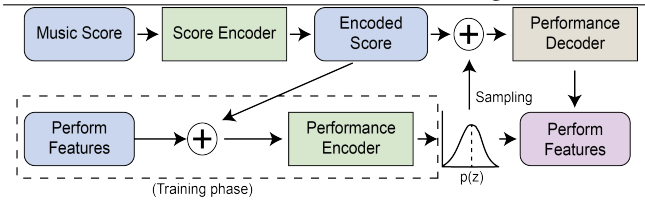

Figure 1. The overview of the proposed system.

which can be a beat or a measure in music score, the notes in the boundary can be indexed with $t \in [B_f, B_l]$, where B_f and B_l represent the index of the first and last notes in the selected boundary B. The lower-level hidden states $\mathbf{h}_t$ for t in the boundary B are summarized by context attention to compose a higher-level node $\mathbf{m}$. There are a total I number of attention heads indexed with i.

$$
\begin{aligned}
\mathbf{u}_t &= \tanh(\mathbf{W}_a \mathbf{h}_t + \mathbf{b}_a) \\
\mathbf{u}_t^i &= \mathbf{u}_{t,i:(i+1)d} \\
\mathbf{h}_t^i &= \mathbf{h}_{t,i:(i+1)d} \\
\boldsymbol{\alpha}_v^i &= \frac{\exp(\mathbf{u}_t^{i\intercal} \mathbf{u}_c^i)}{\sum_t \exp(\mathbf{u}_t^{i\intercal} \mathbf{u}_c^i)} \\
\mathbf{m}^i &= \sum_t \boldsymbol{\alpha}_t^i * \mathbf{h}_t^i \\
\mathbf{m} &= \text{Concat}(\mathbf{m}^0, ..., \mathbf{m}^I)
\end{aligned}
\tag{1}
$$

where $\mathbf{W}_a$ and $\mathbf{b}_a$ denote weight and bias parameters of attention, and $\mathbf{u}_c$ denotes a context vector representing query for importance, which are trainable parameters. The sequence of summarized nodes are fed into a new layer of LSTM.

3.1.3 Conditional VAE

A music score can be interpreted and performed in various styles, i.e. with a different tempo or phrasing. Therefore it is important to enable the performance modeling system to generate different types of performance. On the other hand, the variation of performance can be an obstacle for training the model, because it has to generate different outputs from the same input. To solve this problem we employed a conditional variational autoencoder (CVAE), which we proposed in our previous work [14].

VAE is a widely used generative models based on deep neural networks [19]. It is a type of autoencoder, which compresses input information into a lower dimensional latent vector and decodes the original information from the compressed latent vector. The main difference is that VAE constrains its latent vector to be sampled from a probability distribution. VAE consists of an encoder that models $q(z|x)$ and decoder to model $p(x|z)$. VAE also models the probability of latent vector $p(z)$, which usually has a normal distribution. The training loss of VAE can be define as follows:

$$
\mathcal{L}_{\text{VAE}} = \mathcal{L}_{\text{rec}} + \beta D_{KL}[(q(z|x)||p(z)] \tag{2}
$$

where $\mathcal{L}_{\text{rec}}$ is the reconstruction error from AE, D_{KL} is Kullback-Leibler divergence (KLD), and β is a weight for the KLD.

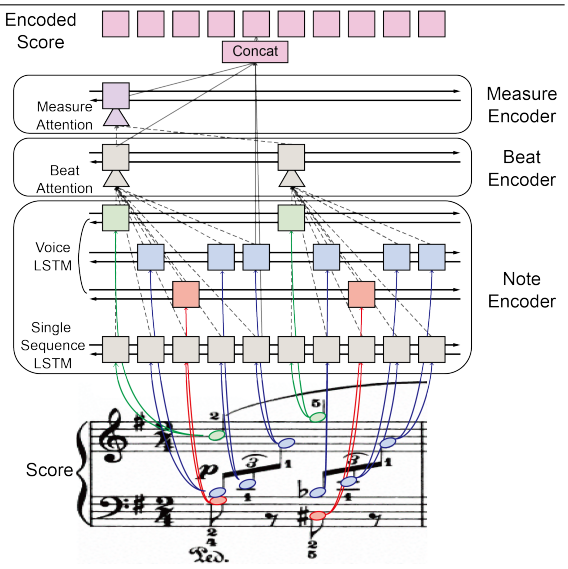

Figure 2. Diagram for Score Encoder with HAN and RNN

A conditional VAE (CVAE) provides an additional condition so that the output satisfies the given condition [27]. In our system, the condition is the learned score representation, and the target output are the performance features. The idea of employing CVAE for expressive performance modeling was first proposed in [21]. While the previous work encoded the latent vector in note-level, our idea is to encode the performance style in a longer-level, such as an entire piece.

3.2 Proposed System

Our proposed system consists of three parts: score encoder, performance encoder, and performance decoder as depicted in Figure 1.

The role of score encoder is to learn score representations C from an input sequence of notes. It consists of three hierarchical-levels: note, beat, and measure. Each level has a corresponding bidirectional LSTM unit with a different hidden size and number of layers. The note-level layer consists of two different LSTM units, one taking the input as a single sequence, and the other taking the input as voice-separated sequences. The "voice" means the voice index in MusicXML that represents an independent stream of music as depicted with different colors of notes in Figure 2. The hidden representations of the lower-level are summarized through the HAN to compose higher-level nodes. The output of the note-level LSTM is summarized to beat-level nodes and then they are fed into the beat-level LSTM. Similarly, we compose the measure-level LSTM. We concatenate the outputs of all the three layers in a note-level as depicted in Figure 2. The output of score encoder is a sequence with the same length as the input. Since we use multi-head attention instead of single-head attention, each attention head focuses on the different type of notes as illustrated in Figure 3.

We implemented the performance encoder using CVAE that models $q(z|C, y)$ to summarize the given performance y in score condition C to a probability distribution of the

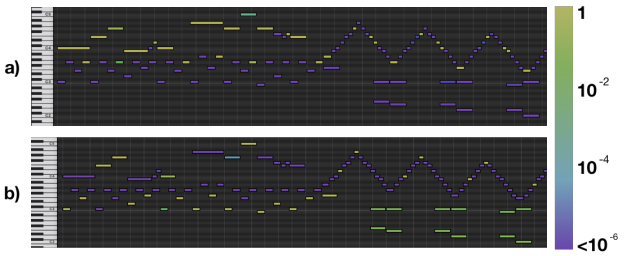

Figure 3. Visualization of attention weights from different attention heads. a) focuses more on the melody notes while b) focuses more on the bass or harmonic notes.

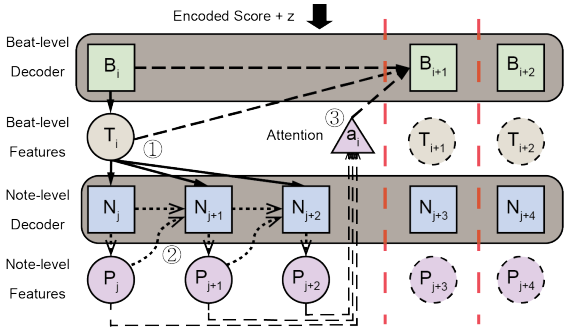

Figure 4. The figure shows how the beat-level decoder and the note-level decoder feed its results to the other. The dashed lines in red indicate the edge of beats.

latent vector z, which can be regarded as a performance style vector. C and y are concatenated and fed into a single dense layer that contracts the feature dimension. We use uni-directional note-level LSTM and measure-level HAN-LSTM to process the contracted input. The last output of the sequence from the measure-level LSTM is used to infer μ and σ of $q(z|C, y)$ by a dense layer.

During the actual performance generation from a given score, the performance encoding is bypassed, and the system randomly samples the style vector z from a normal distribution or exploits a pre-encoded z from other performances.

The performance decoder uses LSTMs to generate a sequence of performance features $\hat{y}$ for the given condition C and the style vector z. Since the tempo is always estimated in beat level, we have two different LSTM units, one in the beat-level and the other in the note-level. Both LSTMs are in auto-regressive, i.e., take their own output from the previous step as an input, and the outputs of the note-level decoder is fed into the beat-level decoder, and vice versa, as presented in Figure 4.

3.3 Measure-level Module

One of the main difficulties in expressive performance modeling is achieving long-term expression such as gradual change of tempo or contrast between loud and quiet sections. To solve this problem, we propose an optional measure-level module that predicts measure-level tempo and dynamics as presented in Figure 5. The main idea is to make our system predict overall progress of the performance in measure-level and then refine it in note-level. A similar idea achieved a successive result in image generation using GAN, which started training in a low resolution and progressively in higher resolutions [16].

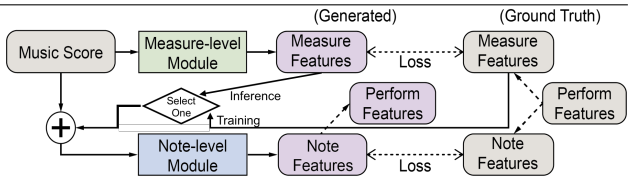

Figure 5. Diagram for Measure-level modules

To train the measure-level module, we have to define measure-level performance features. The measure-level tempo is defined by elapsed time to play the measure divided by the length of the measure in quarter-notes. We used average velocities of notes in the measure for a measure-level dynamics. The measure-level module has almost the same architecture with the note-level modules except that the output of the score encoder is the measure-level states instead of concatenated result of note, beat and measure hidden states. The performance encoder and decoder are also in measure level.

In this hierarchical approach, the note-level module takes not only the score data but also the output of the measure-level module as a concatenated input. It is possible to combine two modules as a single model or in a single training process, but we made two modules independent and trained them separately. Therefore, the note-level module is trained with ground-truth measure-level outputs.

4. EXPERIMENTS

4.1 Training

We split the dataset into training, validation, and test sets so that each set has a size of approximately 8:1:1 in the number of piece, performance, and notes, while considering the distribution of composers in each set. A single piece was included only in either of one of the splits. For the training set, we sliced the input sequences at the measure boundaries with the least size of 500 notes. When training the measure-level module, the sequence has at least 2000 notes or entire notes if the piece is short. The note is ordered by its appearance order and pitch. The features with continuous value was normalized to have zero mean and unit standard deviation.

We calculated the loss in mean square error (MSE) between each feature. The loss was calculated for each note and each output features, except the tempo, whose loss was calculated in beat level. During the training, the input sequences included all the notes that have non-matching performance notes, because missing notes in the input data can change the context of the other notes in the score. However, these notes were excluded in the loss calculation because we could not extract performance features for the notes. Since the articulation is largely affected by the sustain pedal, we reduced the weight for the articulation loss to 0.1 for notes with the sustain pedal pressed at the offset.

Model	Tempo	Vel	Dev	Artc	Pedal
Baseline	0.400	0.673	0.773	0.721	0.843
HAN-S	0.269	0.607	0.753	**0.688**	0.820
HAN-M	**0.220**	**0.532**	**0.747**	0.754	**0.810**

Table 1. Reconstruction loss of each model on the test set in MSE. Vel, Dev and Artc denote velocity, onset deviation and articulation, respectively.

We used the ADAM optimizer [18] with an initial learning rate of 0.0003 and dropout ratio of 0.1. To avoid that the system bypasses z during the decoding, we use the KLD weight annealing as proposed in [1], so that the KLD weight started from zero at the beginning of training, and increased to 0.02 gradually.

4.2 Model Configuration

The score encoder of our proposed system has three-layer dense network of size 128 with ReLU activation as an embedding layer, two-layer bidirectional(Bi)-LSTMs of size 128 for note-level and voice-level, two-layer Bi-LSTM of size 64 for beat-level, and one-layer Bi-LSTM of size 64 for measure-level. The performance encoder has two-layer unidirectional(Uni)-LSTM of size 16 for note-level and one-layer Uni-LSTM of size 16 for measure-level. The size of latent vector z in CVAE is 16. The performance decoder consists of one-layer Uni-LSTMs for beat-level and note-level both of size 64. The measure-level module has almost the same setting except that every hidden size of the network in the performance encoder is 8 including the latent vector z.

To compare our approach with HAN architecture and measure-level modules (HAN-M), we also trained two other models. The first model is a baseline model that uses only three-layers LSTM in note-level with hidden size of 256. The other model, which will be denoted as HAN-S, is a model that excludes the measure-level module. In HAN-S, the hidden size of beat-level layer in the score encoder and performance decoder was 128.

5. RESULTS

5.1 Reconstruction Error

Quantitative evaluation of modeling expressive performance is a not trivial issue. One of the frequently used quantitative evaluation method is calculating MSE of output features [4]. Comparing the predicted outputs with "target" performance can be arbitrary, because there can be various ways to perform the score. In our system, however, there is a performance encoder and a latent style vector z that, ideally, makes the output in a style of the target performance. Therefore, comparing output features with the target performances is more reasonable. Also, as a learning model, it is fair to check the test loss with the same criteria used for training.

Table 1 shows the reconstruction loss of each model on the test set which includes 21 pieces and 109 performances. The two HAN models achieved much less reconstruction error than the baseline model. This indicates that the hierarchical approach helps the model to generalize to unseen data. Between the two HAN models, HAN-M is slightly better than HAN-S. We have tested different parameter sizes for HAN-S so that HAN-S has a similar number of parameters with the sum of two modules in HAN-M, but the result was not much different.

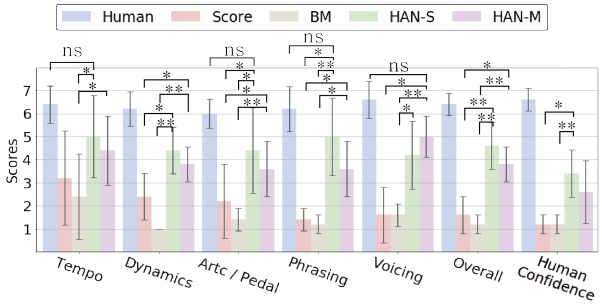

Figure 6. Average score of the listening test for Schubert Sonata in 7-point Likert scale. The t-test results between our models (HAN-S,M) and Human are marked with `ns` only if it is not significant. The results between our models and the others models are marked only if it is significant. "*" and "**" denote "p≤0.05" and "p≤0.01", respectively.

5.2 Listening Test

We also conducted a listening test to evaluate our model qualitatively. We asked five students, who are majoring piano at a college of music, to listen to the rendered performances and evaluate them with criteria presented in Figure 6 in 7-point Likert scale (1 - very bad, 7 - very good) with additional comments on the performance. We chose three pieces of different styles from our test set: the first movement from Beethoven's Piano Sonata No. 5 (cut before recapitulation), Chopin's Etude op. 10 No. 2 (entire piece), and the first movement from Schubert Piano Sonata D.664 (cut before development).

We prepared five different performances MIDI per piece: a human performance from Yamaha e-competition, a direct export from MusicXML score to MIDI by a notation program (MuseScore), each of rendered performances from HAN-S and HAN-M, and Basis Mixer (BM). The result exported from MuseScore had no tempo change but the velocities of notes were changed by a simple rule-based conversion of dynamic markings in the score. BM is the only publicly available model that does not require additional notation among previous expressive performance models [5]. It also achieved a highest score among other computational methods in previous research [26]. We included the BM model in the listening test and generated performances with the same MusicXML file we used for our model [3]. Since the recording and playback in audio systems can affect the quality of performance, we invited the participants to our studio and played the prepared MIDI files with a Yamaha Disklavier piano. Each performance was played once in a random order.

The result of evaluation on Schubert is presented in Figure 6 As expected, all participants gave highest scores in

[3] `https://basismixer.cp.jku.at/static/app.html`

every criteria for the human performance. Our proposed model, HAN-S and HAN-M, achieved higher scores in all seven criteria compared to other models. Two among five participants gave more than five out of seven points as the human confidence for the performance by HAN-S, and one gave five points to HAN-M. The t-test result showed that HAN-S and HAN-M showed statistically significant differences ($p \leq 0.05$) compared to the score and the BM model in overall ratings of the performance of Schubert.

The positive comments on our models were: *"the interpretation was interesting"* (Beethoven, HAN-M), *"felt that the flow of performance was humane"* (Beethoven, HAN-S), *"voicing was too good so that it felt like performed by multiple performers"* (Chopin, HAN-S), *"sounded like a performance by human with strong characteristics"* (Chopin, HAN-S), *"voicing was fine except some faults"* (Schubert, HAN-M), and *"sounded like machine-generated performance with fine pedaling"* (Schubert, HAN-S) .

There were also negative comments criticizing our models, such as *"used too much pedal"*, *"pedal points were unnatural"*, *"lack of color"*, *"too short articulation"*, *"some tempo or dynamic changes were unnatural"*, *"touch was too light"*, and *"it did not seem that the performer was listening to the performance"*. Although our models had predicted the pedal usage, the pedaling was often too deep and "dirty" or too shallow. The result showed that the note-level pedal embedding needs improvement.

The responses of our participants for performances by BM, which is a data-driven model based on RNN, were negative regardless of the piece. The comments from the participants said that *"although there was a clear intention to express phrasing, it was unnatural and sounded like a mechanical interpretation"* (Schubert), *"inaccurate and limping rhythm"* (Beethoven and Schubert),and *"the temporal gaps at measure boundary were unnatural"* (Chopin and Schubert). Unlike the Score MIDI, the performance by BM included clear change in tempo for phrasing. However, most of the participants gave almost the same level of negative response to its phrasing quality compared to the Score MIDI. This shows how difficult it is to model phrasing of the music.

The results were also largely differed by the characteristics of the piece. For example, Schubert's Sonata has a song-like melody with arpeggio accompaniments. Hence, it was important to model the natural phrasing, e.g., subtle change of tempo and velocity according to the melody. On the other hand, the fast chromatic scale in Chopin's Etude demands a stable tempo. Therefore, Score MIDI received six out of seven points for overall quality from three participants because the performance was in perfectly constant tempo with strict following of dynamic markings. The flexibility of tempo generated by our model was not favored by the participants in case of Chopin's Etude.

In summary, the results of listening test shows that our models have achieved more natural expressions compared to the other models, especially in a piece with song-like melodies. Modeling the pedal usage and a human-like stable tempo are issues to further investigate.

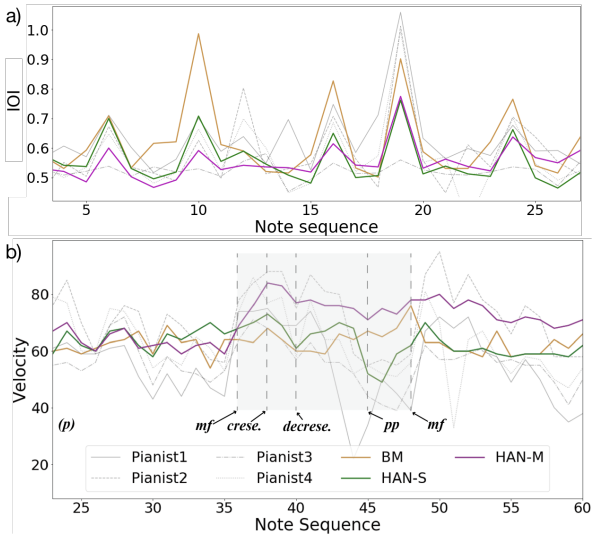

Figure 7. a) Local tempo changes and b) Dynamics change in different performances of Schubert's Piano Sonata

5.3 Case Study: Comparison in Tempo and Dynamics

The quality of phrasing can be also observed from examples. Figure 7-a) compares local tempo changes in difference performances of Schubert's Sonata. The local tempo is represented with inter-onset-interval (IOI) which is computed by dividing seconds into quarter-note. BM has an evident peak at around the 10th note, which was exaggerated than any other human pianists. In terms of Pearson correlation, HAN-S and HAN-M have a strong positive correlation with the pianists ($0.7<r<1.0$) while the BM model has a less positive correlation ($0.3<r<0.5$).

Figure 7-b) compares dynamics changes of melody notes in different performances of the same piece. The dynamics is represented with MIDI note velocity. Increasing and decreasing timings of HAN-M and HAN-S are generally similar to pianists. For example, *decrescendo* starts at note sequence 40 which follows *crescendo*, then *pp* starts at 45 and comes back to *mf* at 48. Both HAN-M and HAN-S show similar downward and upward curves with pianists while the BM model shows just slight upward curve. These trend can be proved by correlation coefficients among pianists and generated models. HAN-S and HAN-M have significant positive correlation with pianists ($0.3<r<0.7$) while BM has almost no correlation ($r<0.1$).

6. CONCLUSIONS

We introduced a hierarchical RNN-based system for modeling expressive piano performance and a dataset for training the model. Our listening test demonstrated that our model achieved more human-like musical expression compared to the previous model [5]. The source code and dataset are available in `https://github.com/jdasam/virtuosoNet`.

ABSTRACT

This paper investigates a cross-modal retrieval problem in which a user would like to retrieve a passage of music from a MIDI file by taking a cell phone picture of a physical page of sheet music. While audio–sheet music retrieval has been explored by a number of works, this scenario is novel in that the query is a cell phone picture rather than a digital scan. To solve this problem, we introduce a mid-level feature representation called a bootleg score which explicitly encodes the rules of Western musical notation. We convert both the MIDI and the sheet music into bootleg scores using deterministic rules of music and classical computer vision techniques for detecting simple geometric shapes. Once the MIDI and cell phone image have been converted into bootleg scores, we estimate the alignment using dynamic programming. The most notable characteristic of our system is that it does test-time adaptation and has no trainable weights at all—only a set of about 30 hyperparameters. On a dataset containing 1000 cell phone pictures taken of 100 scores of classical piano music, our system achieves an F measure score of .869 and outperforms baseline systems based on commercial optical music recognition software.

1. INTRODUCTION

Consider this scenario: A person is practicing at the piano, and would like to know what a particular passage of music sounds like. She takes a cell phone picture of a portion of the physical sheet music in front of her, and is immediately able to hear what those lines of music sound like.

In this paper, we explore the feasibility of such an application where we assume that the piece is known and a MIDI file of the piece is available. Our goal is to retrieve a passage of music from a MIDI file using a cell phone image as a query. This is a cross-modal retrieval scenario.

Several works have investigated the correspondence between audio and sheet music images. There are two general approaches to the problem. The first approach is to use an existing optical music recognition (OMR) system to convert the sheet music into a symbolic (MIDI-like) representation, to compute chroma-like features, and then to compare the resulting sequences to chroma features extracted from the audio. This approach has been applied to synchronizing audio and sheet music [4,5,15,16,21], identifying audio recordings that correspond to a given sheet music representation [14], and finding the audio segment corresponding to a fragment of sheet music [13]. A different approach has been explored in recent years: convolutional neural networks (CNNs). This approach attempts to learn a multimodal CNN that can embed a short segment of sheet music and a short segment of audio into the same feature space, where similarity can be computed directly. This approach has been explored in the context of online sheet music score following [7], sheet music retrieval given an audio query [8,9,11,12], and offline alignment of sheet music and audio [9]. Dorfer et al. [10] have also recently shown promising results formulating the score following problem as a reinforcement learning game. See [18] for a recent overview of work in this area.

The key novelty in our scenario is the fact that the queries are cell phone images. All of the works described above assume that the sheet music is either a synthetically rendered image or a digital scan of printed sheet music. In recent years, a few works have begun to explore optical music recognition (OMR) on camera-based musical scores [1–3,22,23]. Here, we explore the use of cell phone images of sheet music for *retrieval*. Cell phone images provide a natural and convenient way to retrieve music-related information, and this motivates our current study.

The main conceptual contribution of this paper is to introduce a mid-level feature representation called a bootleg score which explicitly encodes the conventions of Western musical notation. As we will show, it is possible to convert MIDI into a bootleg score using the rules of musical notation, and to convert the cell phone image into a bootleg score using classical computer vision techniques for detecting simple geometrical shapes. Once we have converted the MIDI and cell phone image into bootleg feature space, we can estimate the alignment using subsequence DTW. The most notable characteristic of our system is that it does test-time adaptation and *contains no trainable weights at all*—only a set of approximately 30 hyperparameters. In the remainder of this paper, we will describe the system and present our experimental results.

*The first two authors had equal contribution.

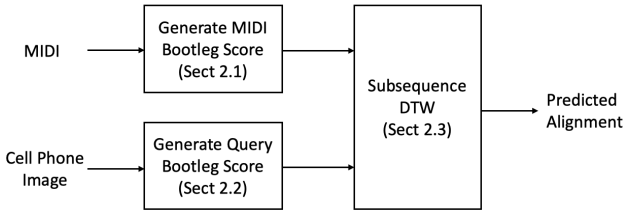

Figure 1. Block diagram of the proposed system.

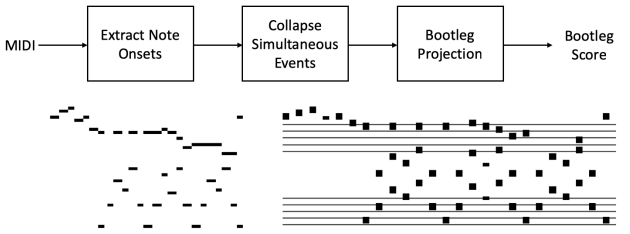

Figure 2. Overview of generating the MIDI bootleg score (Section 2.1). Below the block diagram, a short MIDI passage (left) and its corresponding bootleg score are shown.

2. SYSTEM DESCRIPTION

Our system takes two inputs: a cell phone picture of a page of sheet music and a MIDI file of the corresponding piece. The output of the system is a prediction of the time segment in the MIDI file that matches the lines of sheet music shown in the cell phone picture. Note that in this problem formulation, we assume that the piece is known, and that we are trying to identify the matching passage of music in the piece. In our study, we focus on piano music.

Our approach has three main components, which are shown in Figure 1. The first two components convert the MIDI and cell phone image into a representation which we call a bootleg score. A bootleg score is a very low-dimensional representation of music which is a hybrid between sheet music and MIDI. It is a manually designed feature space that explicitly encodes the rules of Western musical notation. The third component is to temporally align the two bootleg scores using subsequence DTW. These three components will be discussed in the next three subsections. [1]

2.1 Generating MIDI Bootleg Score

Generating the MIDI bootleg score consists of the three steps shown in Figure 2. The first step is to extract a list of all individual note onsets. The second step is to cluster the note onsets into groups of simultaneous note events. After this second step, we have a list of note events, where each note event consists of one or more simultaneous note onsets. The third step is to project this list of note events into the bootleg feature space.

The bootleg feature representation can be thought of as a very crude version of sheet music (thus the name "bootleg score"). It asks the question, "If I were to look at the sheet music corresponding to this MIDI file, where would the notehead for each note onset appear among the staff lines?" Note that there is ambiguity when mapping from a MIDI note value to a position in a staff line system. For example, a note onset with note value 60 (C4) could appear in the sheet music as a C natural or a B sharp, [2] and it could also appear in the right hand staff (i.e. one ledger line below a staff with treble clef) or the left hand staff (i.e. one ledger line above a staff with bass clef). The bootleg feature representation handles ambiguity by simply placing a notehead at all possible locations. The bootleg score is a binary image containing only these floating noteheads.

The bootleg score is a very low dimensional representation. Along the vertical dimension, it represents each staff line location as a single bootleg pixel (which we will refer to as a "bixel" to differentiate between high-dimensional raw image pixels and low-dimensional bootleg score pixels). For example, two adjacent staff lines would span three bixels: two bixels for the staff lines and one bixel for the position in between. The bootleg score contains both right hand and left hand staves, similar to printed piano sheet music. In total, the bootleg score is 62 bixels tall. Along the horizontal dimension, we represent each simultaneous note event as a single bixel column. We found through experimentation that a simple modification improves performance in the alignment stage (Section 2.3): we simply repeat each bixel column twice and insert an empty bixel column between each simultaneous note event. This gives the system more flexibility to deal with noisy bixel columns in the alignment stage.

The resulting MIDI bootleg score is a $62 \times 3N$ binary matrix, where N is the number of simultaneous note events in the MIDI file. [3] Figure 2 shows an example bootleg score. The staff lines are included as a visualization aid, but are not present in the bootleg feature representation.

2.2 Generating Query Bootleg Score

The second main component of our system (Figure 1) is to convert the cell phone image into a bootleg score representation. Unlike the MIDI representation, the image does not explicitly encode any information about the notes, so we will have to estimate this information from the raw image.

Our general approach rests on two key insights. The first key insight is that we can identify where we are in the piece if we can detect just three things: filled noteheads, staff lines, and bar lines. Because these objects are simple geometrical shapes, classical computer vision tools are sufficient to detect them (Section 2.2.2–2.2.4). The second key insight is that we know a priori that these three objects will occur many times in the image. This opens up the possibility of test-time adaptation, where we can use a very simple notehead detector to identify some of the noteheads in the image, and then use those detected instances to learn a more accurate notehead template at test time. This is

[1] Our code is available at `https://github.com/tjtsai/SheetMidiRetrieval`

[2] It could also appear as a D double flat, but we do not consider double sharps or double flats since they occur relatively infrequently.

[3] The factor of 3 comes from the filler and repetitions.

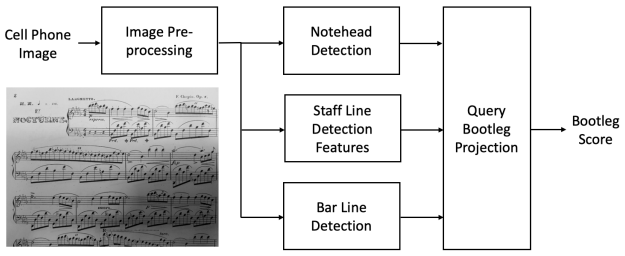

Figure 3. Overview of generating the query bootleg score (Sections 2.2.1–2.2.5). The cell phone image shown will serve as a running example throughout the paper.

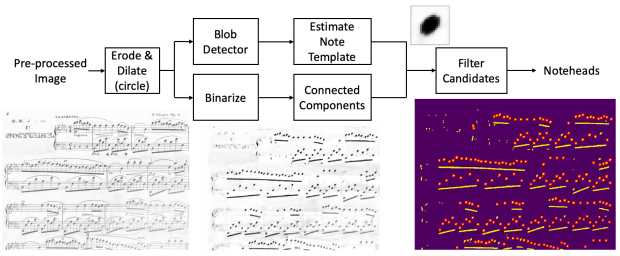

Figure 4. Overview of notehead detection (Section 2.2.2). The images at bottom show the pre-processed image before (left) and after (center) erosion & dilation, and the detected noteheads (right).

generally not possible with large object detection and classification scenarios like the ImageNet competition [6, 20].

Our method for generating the cell phone image bootleg score has five parts, which are shown in Figure 3. These will be described in the next five subsections.

2.2.1 Image Pre-processing

The preprocessing consists of three operations: (1) converting the image to grayscale, (2) resizing the image to a maximum dimension of 1000 pixels while retaining the same aspect ratio, and (3) removing background lighting by blurring the image and then subtracting the blurred image from the non-blurred image.

2.2.2 Notehead Detection

The goal of the notehead detection stage in Figure 3 is to predict a bounding box around every filled notehead in the cell phone image. Note that we do not attempt to detect non-filled noteheads (i.e. half-notes, dotted half notes, whole notes). The basic premise of our approach is that filled noteheads are much easier to detect, and they also generally occur much more frequently than half or whole notes. The notehead detection consists of the steps shown in Figure 4. We will explain these steps in the next four paragraphs.

The first step is to perform erosion and dilation of the pre-processed image with a circular morphological filter. The erosion replaces each pixel with the whitest pixel in a circular region centered around the pixel. This operation removes any objects that consist of thin lines, and it only passes through contiguous dense regions of black pixels. The dilation takes the resulting image and replaces each pixel with the blackest pixel in a circular region center around the pixel. This operation restores any objects that survived the erosion back to their original size. Figure 4 shows an example of an image after erosion and dilation (center image).

Next, we describe the processing in the upper path of Figure 4. We take the eroded and dilated image and apply simple blob detection. We use the simple blob detector in OpenCV with default parameter settings, except that we specify a minimum and maximum area in order to specify the rough size of object we expect. We then take crops of the (eroded and dilated) image around the detected keypoints, and we compute the average of the cropped regions. This average gives us an estimate of what a filled notehead looks like in this image. Figure 4 shows an example of an estimated template (upper right).

Now we describe the processing in the lower path of Figure 4. We take the eroded and dilated image and binarize it using Otsu binarization [19]. We then extract a list of connected component regions from the binary image, which gives us a list of candidate regions, some of which are noteheads.

The last step in notehead detection is to filter the list of candidates using our estimated notehead template. We filter the list of candidates to only contain those regions whose height, width, height-width ratio, and area all roughly match the notehead template (within some tolerance). We also filter the list of candidates to identify chord blocks, which often appear as a single connected component region. When a chord block is identified, we estimate the number of notes in the chord based on its area relative to the notehead template and then perform k-means clustering to estimate individual notehead locations.

At the end of these steps, we have a list of bounding boxes around the detected notes in the cell phone image. Figure 4 (bottom right) shows an example of the predicted notehead locations in an image.

2.2.3 Staff Line Detection Features

The goal of the staff line detection features stage in Figure 3 is to compute a tensor of features that can be used to predict staff line locations in the bootleg projection stage (Section 2.2.5). In a cell phone picture, staff lines may not be straight lines or have equal spacing throughout the image due to the camera angle or camera lens distortions. For these reasons, we estimate staff line locations locally rather than globally. In other words, for every detected notehead, we make a local estimate of the staff line location and spacing in its vicinity.

The staff line detection features are computed in three steps as shown in Figure 5. The first step is to perform erosion and dilation on the image with a short (1 pixel tall), fat morphological filter. This removes everything except for horizontal lines. In practice, we find that there are two types of objects that survive this operation: staff lines and horizontal note beams (e.g. the beam connecting a sequence of sixteenth notes). The second step is

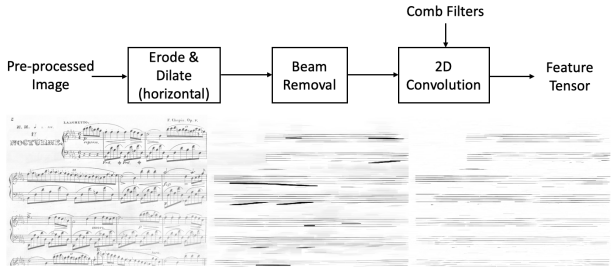

Figure 5. Overview of staff line features computation (Section 2.2.3). The images at bottom show the pre-processed image before (left) and after (middle) erosion & dilation, and the result after removing note beams (right). The actual feature tensor is not shown.

to remove the note beams, as they can throw off the staff line location estimates. Because the note beams are much thicker than staff lines, we can isolate the note beams based on their thickness and subtract them away from the image. The third step is to convolve the resulting image with a set of comb filters. We construct a set of tall, skinny (1 pixel wide) comb filters, where each comb filter corresponds to a particular staff line spacing. The set of comb filters is selected to span a range of possible staff line sizes. We then convolve the image (after beam removal) with each of the comb filters and stack the filtered images into a tensor. This feature tensor $\boldsymbol{T}_{global}$ has dimension $H_{image} \times W_{image} \times N_{comb}$, where H_{image} and W_{image} specify the dimensions of the image and N_{comb} is the number of comb filters. Note that the third dimension corresponds to different staff line spacings.

2.2.4 *Bar Line Detection*

The goal of the bar line detection stage (Figure 3) is to predict a bounding box around the barlines in the cell phone image. The bar lines are needed to correctly cluster staff lines into grand staff systems, where each grand staff consists of a right hand staff and a left hand staff.

The bar line detection consists of the five steps shown in Figure 6. The first step is to perform erosion and dilation of the image with a tall, skinny morphological filter. This filters out everything except vertical lines. In practice, we find that there are three types of objects that survive this operation: bar lines, note stems, and background pixels (e.g. music stand at edges of image). The second step is to binarize the eroded and dilated image using Otsu binarization. The third step is to extract a list of connected component regions from the binary image. The fourth step is to filter this list of candidates to identify bar lines. This can be done by first filtering out regions that are too wide (e.g. background pixel regions), and then distinguishing between note stems and bar lines by finding the threshold on height that minimizes intra-class variance (which is equivalent to Otsu binarization but applied to the heights). The fifth step is to cluster the detected bar lines into lines of music. We do this by simply clustering any bar lines that have any vertical overlap. Figure 6 shows this process for an example image.

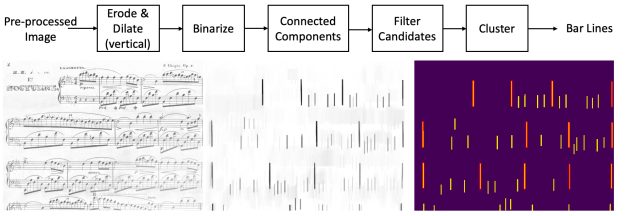

Figure 6. Overview of bar line detection (Section 2.2.4). The images at bottom show the pre-processed image before (left) and after (center) erosion & dilation, and the detected bar lines (right).

At the end of the bar line detection stage, we have a prediction of the number of lines of music in the cell phone image, along with the vertical pixel range associated with each line. Figure 6 shows an example of an image at the various stages of processing in the bar line detection.

2.2.5 *Query Bootleg Projection*

The last step in Figure 3 is to combine the notehead, staff line, and bar line information in order to synthesize a bootleg score for the cell phone image. This bootleg score synthesis consists of the three steps shown in Figure 7.

The first step is to locally estimate the staff line location and spacing for each notehead. We do this by selecting a subset $\boldsymbol{T}_{local}$ of the staff line feature tensor $\boldsymbol{T}_{global}$ which only contains a rectangular context region around the notehead's (x, y) location in the image. This gives us a three-dimensional feature tensor $\boldsymbol{T}_{local}$ with dimension $H_{context} \times W_{context} \times N_{comb}$, where $H_{context}$ and $W_{context}$ specify the size of the context region and N_{comb} specifies the number of comb filters. We calculate the sum of features across the rows of $\boldsymbol{T}_{local}$, and then identify the maximum element in the resulting $H_{context} \times N_{comb}$ matrix. The location of the maximum element specifies the vertical offset of the staff lines, along with the staff line size. Figure 8 shows a visualization of the estimated local staff line predictions for a line of music. Yellow dots correspond to estimated notehead locations, and the red and blue dots are predictions of the top and bottom staff lines.

The second step is to label and cluster detected noteheads. We estimate each notehead's discrete staff line location by applying simple linear regression on its local staff line coordinate system followed by quantization. This is necessary to determine where the notehead should be placed in the bootleg score. We also need to associate each notehead with an upper or lower staff in a specific line of music. To do this, we first check to see if the predicted staff line system is within the vertical range of a valid line of music (see Section 2.2.4) and, if so, if it falls in the upper or lower half of the region. If the predicted staff line system does not fall within a valid line of music, the notehead is ignored and will not appear in the bootleg score. The latter tends to happen with noteheads at the very top or bottom of the image, where a portion of a staff shows up but is cut off by the image boundaries.

The third step is to actually place the noteheads into

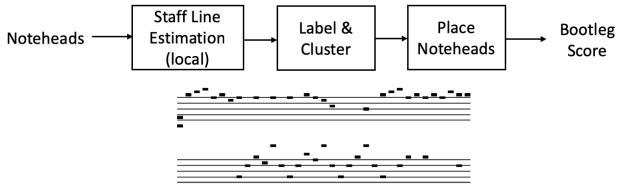

Figure 7. Overview of query bootleg projection (Section 2.2.5). The image at bottom shows part of the generated bootleg score for the cell phone image in Figure 3.

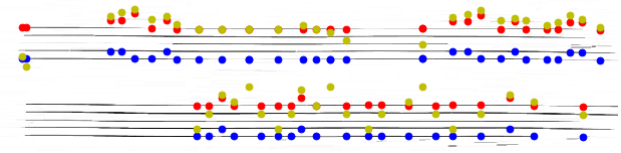

Figure 8. A visualization of local staff line estimation. Each yellow dot corresponds to a detected notehead, and the red and blue dots correspond to the predicted top and bottom staff lines.

the bootleg score. We collapse the noteheads within each valid bar line region into a sequence of simultaneous note events, and then construct the bootleg score as a sequence of simultaneous note events. Similar to the MIDI bootleg score, we repeat each simultaneous note event twice and insert a filler column between each simultaneous note event. Figure 7 shows part of the bootleg score generated from the cell phone image in Figure 3.

2.3 Subsequence DTW

The third main component of our system (Figure 1) is to align the two bootleg scores using subsequence dynamic time warping (DTW). DTW is a well-established dynamic programming technique for determining the alignment between two feature sequences. Subsequence DTW is a variant of DTW that finds the optimal match between a shorter query segment and a subsequence of a (longer) reference segment. For details on DTW and its variants, the reader is referred to [17]. Our cost metric computes the negative inner product between two bixel columns and then normalizes the result by the maximum of (a) the number of simultaneous noteheads in the sheet music and (b) the number of simultaneous note onsets in the MIDI. The inner product counts how many overlapping black bixels there are between the two columns, and the normalization factor ensures that the actual cost is not biased by the number of simultaneous notes. At the end of this stage, we have a prediction of the segment in the MIDI file that best matches the lines of sheet music shown in the cell phone image. This is the final output of our proposed system.

3. EXPERIMENTAL SETUP

The experimental setup will be described in three parts: the data, the annotations, and the evaluation metric.

The data was collected in the following manner. We first download 100 piano scores in PDF format from IMSLP. [4] These piano scores come from 25 well-known composers and span a range of eras and genres within the classical piano literature. To simplify the evaluation, we select scores that do not have any repeats or structural jumps. For each score, we then find a corresponding MIDI file from various online websites. This gives us a total of 100 MIDI-PDF matching pairs. Next, we printed out the PDF scores onto physical paper, placed the sheet music pages in various locations, and took 10 cell phone pictures of each score, spaced throughout the length of the piece. The pictures were taken in various ambient lighting conditions (some of which triggered the flash and some of which didn't), various perspectives, and varying levels of zoom. The pictures capture between 1 and 4 lines of music on a page. We collected the data with two cell phones (iPhone 8, Galaxy S10), and all pictures were taken in landscape orientation. As much as possible, we tried to emulate typical conditions of the application scenario. In total, the data contains 100 MIDI files, 100 scores, and 1000 cell phone images.

The data was manually annotated at the measure level. For the MIDI files, we used `pretty_midi` to programatically estimate the timestamps of the downbeats in each measure, which were then manually verified and corrected. For the cell phone images, we annotated which measures in the score were captured. Since the images would often capture a fragment of a line of music (at the top or bottom), we adopted the convention of only annotating measures on lines of music that are fully captured in the image. For each image, we can use these annotations to determine the matching time segment in the MIDI file.

The metric we use to evaluate our system performance is precision, recall, and F measure. Precision is the temporal duration of overlap between the hypotheses and ground truth segments divided by the total duration of hypothesis segments. Recall is the amount of overlap divided by the total duration of ground truth segments. F measure is then computed as the harmonic mean of precision and recall. In a few situations, the query perfectly matches two different sections in the score. In these situations, we consider any perfectly matching sections of the score to be correct.

4. RESULTS

We evaluate our system in the following manner. We first randomly select 10 out of the 100 scores and set apart their corresponding $10 \times 10 = 100$ cell phone images as the training set. The remaining 900 cell phone images are set apart for testing. Note that this train-test split has an unusually large emphasis on the test data. The reason that we do this is because our system has no trainable weights—only hyperparameters—so the training data is really only used to determine the hyperparameter settings. After doing iterative design on the training data and determining reasonable hyperparameter settings, we froze the system and evaluated it on the 900 test images coming from the 90 unseen music scores.

Bootleg	Test	.900	.840	.869
Bootleg	Train	.872	.869	.871

Table 1. Experimental results. The three rightmost columns show precision (P), recall (R), and F measure (F).

We compare our system to three baselines. The first two baseline systems are Photoscore and SharpEye, which are both commercially available OMR software. We use the software to convert the cell phone image to a (predicted) MIDI representation and then perform subsequence DTW with chroma features. Note that Photoscore and SharpEye were not designed to handle cell phone images, so they would sometimes fail to process the image (i.e. would throw an error). In these situations, we simply mapped errors to a predicted time interval with 0 duration. The third baseline is random (informed) guessing. We calculate the average number (N) of sheet music measures showing in the training images. At test time we randomly select a time interval in the reference MIDI file spanning N measures.

Table 1 shows the performance of our system and the three baseline systems. There are three things to notice about these results. First, the baseline systems all perform poorly. This is not a surprise, since Photoscore and SharpEye were designed to handle sheet music scans, not cell phone images. We would expect that other OMR-based approaches that are trained on scanned sheet music would likewise perform poorly on cell phone images. Second, the bootleg approach far outperforms the baselines. The proposed system achieves an F measure score of .869 on the test set, which is far better than the highest F measure score (.687) among the baseline systems. Third, the proposed system generalizes very well from the training data to the testing data. After iterating and optimizing the system on the training data, the F measure score only fell from .871 (on the training data) to .869 (on the test data). The reason that our system generalizes so well with such a small training data set is that our system has no trainable weights and only about 30 hyperparameters. Even then, many of these hyper parameters are dictated by conventions of Western musical notation for piano music. With such a small number of parameters, we don't expect the system to suffer severely from overfitting, and indeed this is what we observe in our experiments.

5. ANALYSIS

In this section we gain deeper insight into our system through two different analyses.

The first analysis is to manually investigate all of the test queries that were failures. Here, we define a failure as having no overlap at all between the predicted time interval and the ground truth time interval. These are instances where the system simply failed to find a reasonable match. There were two common causes of failure. The biggest cause of failure came from notehead detection mistakes. The notehead detector will obviously fail on half notes and whole notes, since we only try to detect filled noteheads. When the sheet music contains a high fraction of these notes, the system will perform poorly. Also, the system often failed to detect chord blocks where multiple noteheads were located in close proximity to one another. This problem is primarily due to poor hyperparameter settings, and could be mitigated by optimizing the hyperparameters over a larger, more diverse training data set. The second cause of failure were symbols that cause the noteheads to appear in a different place than expected. These include clef changes, octave markings, and trills. Clef changes and octave markings could be incorporated into the MIDI bootleg score by considering all possible clef and octave changes in both right and left hand staves, but there is no immediately obvious way to address the problem of trills.

The second analysis is to characterize run time. Because our application is an online search, the run time is an important consideration. Accordingly, we profiled our system to determine how long it takes to process each query, and to identify the parts of the system that are bottlenecks to improve runtime. Note that our entire system is implemented in python with OpenCV and a custom cython-accelerated subsequence DTW function. When each query is processed by a single 2.1 GHz Intel Xeon processor, the average runtime is 7.6 seconds. When we analyze the breakdown of runtime across the major components of the system, we find that the major bottleneck is the staff line detection features stage (92% of total runtime), which primarily consists of 2-D convolutions with the set of comb filters. This suggests one way to improve runtime: rather than using a large set of comb filters to handle a wide range of possible staff line spacings, we could explicitly estimate the staff line size and consider a much smaller set of comb filters. If we could reduce the set of comb filters by a factor of 10, the average time per query would be 1.3 seconds.

6. CONCLUSION

We explore an application in which a user would like to retrieve a passage of music from a MIDI file by taking a cell phone picture of a physical page of printed sheet music. We develop a proof-of-concept prototype and evaluate its performance on a dataset containing 1000 cell phone pictures of 100 different scores of classical piano music. Our system projects both the MIDI file and the cell phone images into a low-dimensional feature representation called a bootleg score, which explicitly encodes the rules of Western musical notation. We then align the two bootleg scores using subsequence DTW. The most notable characteristic of our system is that it has no trainable weights at all—only a small set of hyperparameters that can be easily tuned on a small training set. Our system generalizes very well from training to testing, and it achieves a test F measure score of .869. We hope that this work serves as an entry point to exploring new ways to retrieve various forms of music using cell phone images as a query.

ABSTRACT

In many musical traditions, the melody line is of primary significance in a piece. Human listeners can readily distinguish melodies from accompaniment; however, making this distinction given only the written score – i.e. without listening to the music performed – can be a difficult task. Solving this task is of great importance for both Music Information Retrieval and musicological applications. In this paper, we propose an automated approach to identifying the most salient melody line in a symbolic score. The backbone of the method consists of a convolutional neural network (CNN) estimating the probability that each note in the score (more precisely: each pixel in a piano roll encoding of the score) belongs to the melody line. We train and evaluate the method on various datasets, using manual annotations where available and solo instrument parts where not. We also propose a method to inspect the CNN and to analyze the influence exerted by notes on the prediction of other notes; this method can be applied whenever the output of a neural network has the same size as the input.

1. INTRODUCTION

Many musical traditions make use of melody-accompaniment structures. Generally, the melody line carries the most significant meaning, while the accompaniment provides harmonic and rhythmic support.

In Western art music – which, unlike music in some other traditions, is typically notated – special attention is paid to the construction of melodies during composition. Ideally, melodies in Western art music styles should involve an intervallic structure that is dependent on the specific tonal hierarchy defined by the piece [24, 26]. Musicians typically accentuate melody lines during performance as a way of clarifying the piece structure for listeners: for example, melody lines may be played louder and with more flexible timing than accompaniment [9, 10].

Most listeners readily distinguish melody lines from accompaniment. In contrast, identifying the melody line through visual inspection of a musical score – without hearing the piece – can be a difficult task, even for trained musicians [3]. In this paper, we propose a convolutional approach for identifying the melody line of a piece using a piano roll representation of the score. A solution for this task has potential implications for music information retrieval and musicology [27]. An effective algorithm could be applied to music retrieval tasks such as query-by-humming, searching a database of MIDI files for melodies, developing performance models that account for melody in predicting musical expression, etc. Our focus is on music of the common practice period that uses melody-dominated homophonic textures (i.e., a single melody line plus accompaniment lines), rather than equal-voice polyphony (i.e., multiple independent melody lines) or monophony (i.e., unison melody shared by all voices). However, we provide extensive tests of the proposed method in styles other than common practice era, such as pop, baroque and contemporary art music.

The rest of this paper is structured as follows: In Section 2, we discuss related work on voice separation and streaming. Section 3 briefly describes the baseline methods that we used for comparison against our model. Section 4 presents a description of the proposed method. Section 5 describes the three datasets used in this work. Section 6 describes the experimental evaluation of the proposed method. Section 7 discusses the results of the experimental evaluation. Finally, Section 8 concludes this paper and proposes some future research directions. A companion website was also created to show additional material for the sake of reproducibility. [1]

2. RELATED WORK

2.1 Voices and Streams

Music perception research has investigated listeners' abilities to distinguish between voices in homo- and poly-

[1] https://limunimi.github.io/Symbolic-Melody-Identification/

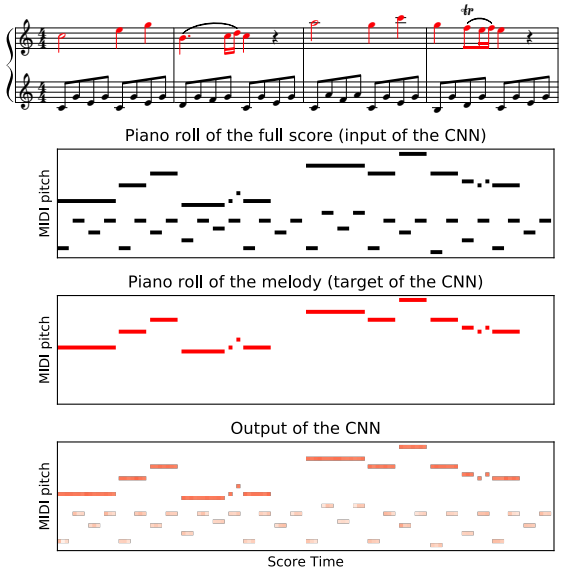

Figure 1. Top: Excerpt of Mozart's Sonata K. 545 (melody highlighted in red). Middle: Piano roll representation of the score (melody is highlighted in red). Bottom: Prediction of the CNN for this excerpt. In this piano roll, the intensity of the color of each pixel represents its probability of belonging to the melody.

phonic music, and has shown that the theoretical rules of voice leading are motivated by listeners' abilities to follow voices [15]. Cambouropoulos [4] proposed three ways of defining musical "voices": (1) for multi-instrument music, each instrument can be said to constitute a separate voice; this would allow for the possibility of non-monophonic voices in instruments that produce chords; (2) voices can be assigned to melodic streams as they are perceived and segmented by listeners, following cognitive grouping principles; and (3) in monophonic music, the harmonic content of the piece may imply a horizontal organization of polyphonic voices that unfold over time (i.e., implied polyphony), e.g., multiple temporally-overlapping voices could be assigned to passages of Bach's Cello Suites. In this work, we use the second definition, and we define the melody line as the most salient voice.

In the music information retrieval literature, three corresponding tasks have been addressed: 1) voice separation from symbolic scores [6, 11, 13, 21]; 2) main track identification (from MIDI files with multiple tracks) [8, 14, 19, 20]; and 3) main melody identification from audio [1, 2, 25]. The latter is a different problem than that addressed here: it deals with the complex task of identifying notes from an audio file, but can use performance cues (e.g., contrasts in timbre and dynamics, which are not present in MIDI data) to facilitate melody identification.

Most relevant to the current study is the task of voice separation from symbolic scores. Some of the proposed methods are computational implementations that attempt to capture perceptual rules of segmentation [4, 6, 11–13] – in particular those rules codified by Huron [15]. For a more in-depth discussion on voice separation algorithms from symbolic scores, we refer the reader to [7, 12, 17, 29].

3. BASELINE METHODS

3.1 Skyline Algorithm

The skyline algorithm is a heuristic that takes the highest note at each point in time [5, 28]. In Western art music, pop and many folk traditions from around the world, melodies are often carried by the highest voice. After the submission of this paper, we discovered that a new method was being submitted for this same task [18], confirming the relevance of this topic.

3.2 VoSA

Proposed by Chew and Wu [6], VoSA is a successful voice separation method. In this approach, a piece is split into segments based on voice entry and exit points, so that the number of sounding notes is constant within each segment. The segment with the highest number of sounding notes defines the number of voices in the piece. Notes are then connected into voices using connection weights, equal to the absolute size of the interval between one note and the next. Like most voice separation methods, VoSA was designed to work with polyphonic rather than homophonic music. In spite of its apparent simplicity, VoSA has been favorably compared against more sophisticated computational models of voice separation [12, 13, 21].

4. METHOD

4.1 Music Score Modeling Using CNNs

A schematic representation of our method is given in Figure 2. The backbone of the method consists of a fully convolutional neural network (shown in Figure 3), which takes as input segments of a music score, represented as a piano roll, and estimates the probability that each note in the score (more precisely: each pixel in the piano roll encoding) belongs to the melody line.

A piano roll can be described as a 2D representation of a musical score; the x-axis indicates score time and the y-axis indicates pitch. The piano rolls used in this study are constructed with a temporal resolution of 8 pixels/beat (i.e., a pixel represents a 32nd note in $\frac{4}{4}$). The piano roll of each piece is divided into overlapping fixed-length windows of 64 pixels (i.e., 8 beats). The length of the window was determined using hyper-parameter optimization, (see Section 6.2). The overlap between windows is 50% (i.e., 2 beats), and windows shorter than this size are padded with zeros. An output piano roll for each full piece is constructed by averaging probabilities for the pixels located in overlapping windows. Afterwards, we apply a mask on the output piano roll by multiplying it by the (binary) input piano roll, so that areas with no notes take values of zero, and non-zero probabilities only remain where there are notes. The probability of each note belonging to the melody is then calculated as the median across the output values of its pixels. In the following discussion, we will use *note*

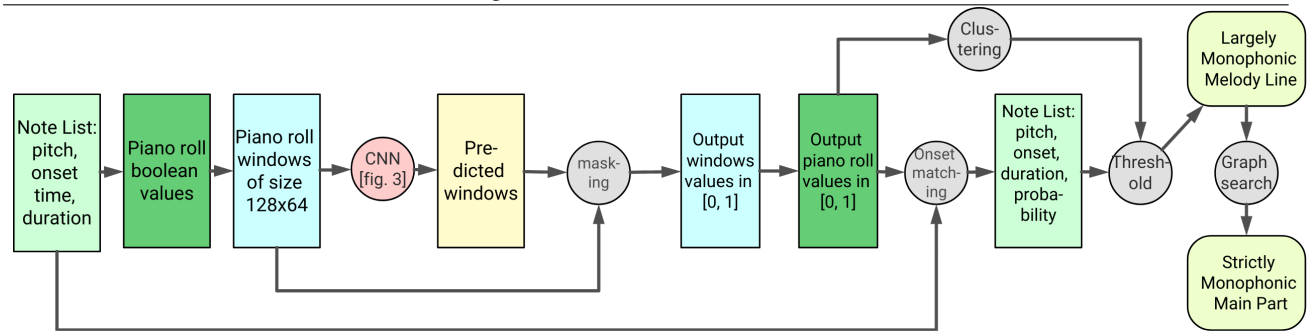

Figure 2. The pipeline of the proposed method (see Section 4).

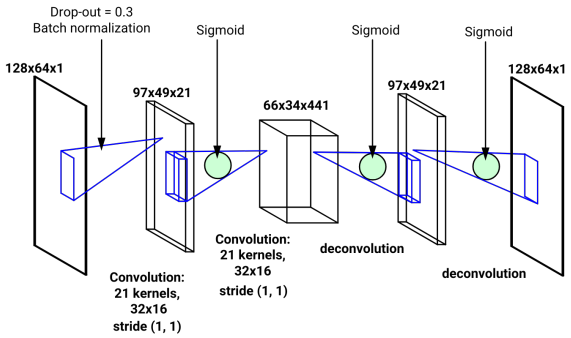

Figure 3. The architecture of the fully convolutional neural network used in the proposed method. The architecture of the network was determined using hyper-parameter optimization (see Section 6.2 for explanation).

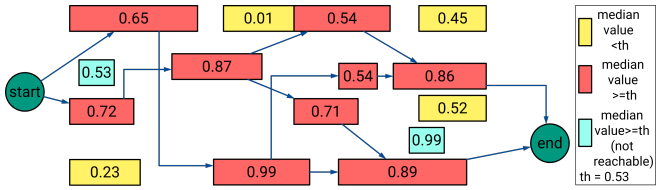

Figure 4. Example of graph built with Algorithm 1. Red notes are notes over threshold, yellow notes are under threshold, while blue notes are over threshold but are not reached by any path. The green circles are the starting and ending nodes. Numbers indicate note probabilities, which are computed as the median of their pixels.

probability as a shorthand to refer to the probability of a note to belong to the melody.

In Figure 1 we show an excerpt of Mozart's Piano Sonata K. 545 and three vertically aligned piano rolls corresponding to the excerpt. The second row of this figure is the input piano roll, while the third row gives the ground truth melody line that we aim to identify in the input. The bottom gives the piano roll that we obtain as output. The output is color-coded with the notes that were identified as melody highlighted in red.

A threshold is needed to determine which note probabilities should indicate melody notes. Distributions of probabilities differ between pieces, so a hard threshold (e.g. 0.5) would be inappropriate. Instead, we find a threshold for each piece using a statistical analysis of the values of the note probabilities. In the implementation of the proposed method we use hierarchical *single-linkage* clustering [23]: two clusters across the values of note probabilities are identified, and a piece-wise threshold is selected as the largest value of the lowest cluster. We then compare each note probability to this threshold and either retain the note as melody or filter it out as accompaniment. This produces largely (but not entirely) monophonic melody output – in some cases, multiple simultaneous notes pass the threshold. A graph-based method, explained next, was thus implemented to select a strictly monophonic melody line from this output.

4.2 Graph Search

Having identified notes that pass the threshold as defined above, we have to select a sequence of these notes that maximizes the probability of the sequence being monophonic. This is achieved using a graph-based approach. Algorithm 1 is used to build a *directed acyclic graph* (or digraph, see Figure 4). Such a graph consists of a set of nodes and a set of directed edges. Each of these edges specifies a connection from a node to another. In the graph defined by Algorithm 1, each note that passes the threshold is represented by a node, and the pitch, onset and duration information of this note are used to determine to which nodes is the note connected (in order to guarantee a strictly monophonic sequence). Note probabilities are used to determine the strength of the connection between nodes (similar to a "distance"; notes with high probabilities are considered "closer"). Additionally, we set a start and end node at the beginning and end of the piece, respectively. We can then use a single-source shortest path algorithm to find the main melody line as the shortest path from the start to the end nodes. In our current implementation, we use the negative note probabilities as connection weights and the Bellman-Ford algorithm [2] to find the shortest path through the graph. [3]

[2] `https://docs.scipy.org/doc/scipy-1.2.1/reference/generated/scipy.sparse.csgraph.bellman_ford.html`

[3] Depending on the choice of the connection weights, other shortest path algorithms (e.g., topological sorting, Dijkstra's, etc.) are possible.

Algorithm 1 Melo-digraph building

$L \leftarrow$ list of notes
$\alpha \leftarrow$ starting node (end time $= 0$)
$\omega \leftarrow$ ending node (onset $= \infty$, probability $= -0.5$)
Push α to the beginning of L
Push ω to the end of L

  $L' \leftarrow$ notes with onset $\geq$ end time of $note$
  $L' \leftarrow$ notes with onset $=$ minimum onset in L'
  for $note'$ in L' **do**
    if probability of $note' \geq$ threshold **then**
      $p =$ probability of $note'$
      add an edge $(note, note')$ with weight $-p$
    end if
  end for
end for

4.3 Training

The CNN is trained in a supervised fashion to filter out accompaniment parts. Inputs are provided in the form of piano roll segments and the targets are the corresponding piano rolls with only the melody notes. We also augmented the training dataset by 50% by creating copies of the original examples in the dataset with the melody transposed down for 2 octaves or up for 1 octave. Though the standard loss function for binary classification problems like this one is the binary cross entropy, during development of the model, we achieved more accurate models by minimizing mean squared error for the match between output and target piano rolls. The networks were trained using AdaDelta [30] with initial learning rate set to 1. In order to avoid overfitting, we use dropout with probability $p_{dropout} = 0.3$ and L_1-norm weight regularization. Additionally we use batch-normalization [16]. The training is stopped after 20 epochs without improvement in validation loss [22] .

5. DATASETS

We used three different datasets to evaluate the performances of our method. The first dataset ("Mozart") consists of 38 movements from (13) Mozart Piano Sonatas, for which the main melody line was annotated manually by a professional pianist. The second dataset ("Pop") consists of 83 popular songs (including pop and jazz). We used the vocal part of these songs as the melody line, and treated them as though they were compressed onto a single track (identifying the main track in multi-track music is a separate question, see [8, 14, 19, 20]).

These datasets were used for training and testing. A third dataset ("Web"), used only for testing, comprises MIDI files crawled from the web. This dataset includes 169 Western art music compositions from the late 16th to the early 20th centuries. All of these pieces included a solo instrument (typically voice, flute, violin or clarinet) and accompaniment (typically strings or piano).

The first and third of these datasets are publicly available for research purposes in the companion site – see footnote 1. We do not have distribution rights for the second dataset, which was professionally curated and annotated, but we provide the full list of pieces.

6. EXPERIMENTS

6.1 Evaluation Metrics and Baseline Methods

In all experiments, we evaluated the quality of the predictions using the F-measure. We experimented on the largely monophonic (which we denote *cnn* in the following discussion) and strictly monophonic (denoted as *cnn mono*) variants of the proposed model described in Sections 4.1 and 4.2, respectively. As a baseline comparison, we used the skyline algorithm and VoSA (both described in Section 3). Since VoSA does not directly output the melody line, we first separate the piece into individual voices (as identified by VoSA), then select the voice with the highest F-measure as the melody. These modifications allowed us to consider the best case scenario of VoSA.

6.2 Network Architecture

To determine the architecture of the network, we used hyper-parameter optimization. [4] The number of convolutional layers, kernel size and number, and window lengths were optimized. This hyper-parameter optimization was done on 100 pieces randomly selected from across the three datasets plus 65 MIDI files collected online using the same criteria as the Web dataset. To compare models, we constructed training, validation, and test sets from the 100 pieces. A model configuration was selected that performed most successfully on the test set. The selected network architecture is shown in Figure 3: 2 convolutional layers, each with 21 kernels of size 32×16 (i.e., over two and a half octaves in the pitch dimension and 2 beats in the time dimension).

6.3 Evaluation of the Proposed Method

To evaluate the quality of the predictions of the proposed method, we conducted two experiments. In the first experiment, we were interested in evaluating the predictive accuracy of the models trained on different datasets. In the second experiment we tested how well models generalize to different music styles. For the first experiment, we performed a 10-fold cross-validation on each of the Mozart and Pop datasets. In each of these cross-validations, the dataset was split into 10 folds. The model was trained on 9 of these folds and tested on the remaining one. We did this for all possible combinations so that each piece in each dataset appeared in the test set once. For the second experiment, we tested models trained on Mozart and models trained on Pop on the Web dataset.

[4] Using the "hyperopt" library in Python (`http://hyperopt.github.io/hyperopt/`).

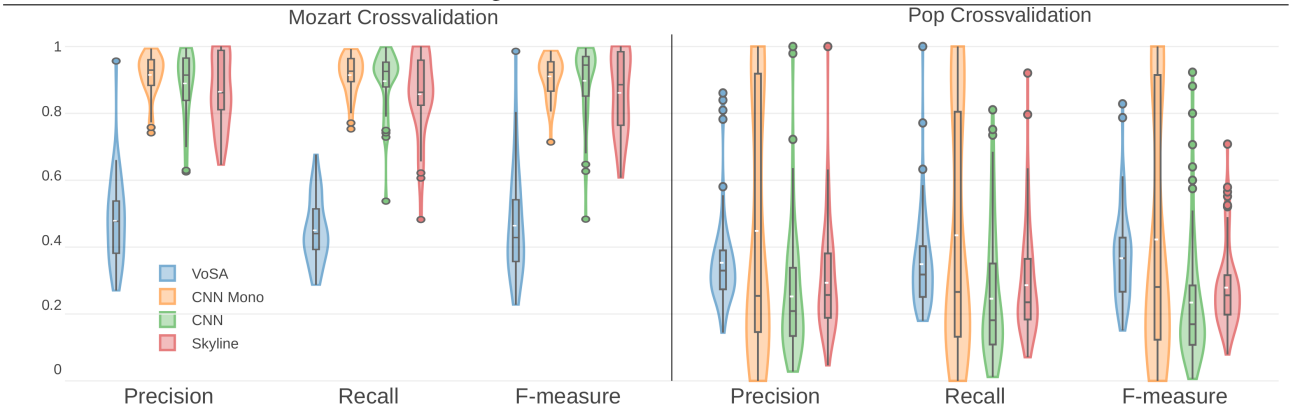

Figure 5. Cross-validation on Mozart and Pop datasets. With the Wilcoxon test applied to F-measure, we found a significant difference between *CNN Mono* and *VoSA* and between *CNN Mono* and *CNN*, but no significant difference was found between *CNN Mono* and *Skyline* in the Pop dataset (only in the Mozart dataset). The mean is marked with a white dash.

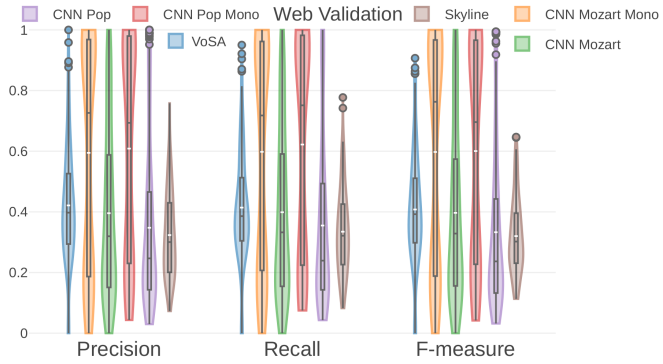

Figure 6. Validation on the Web music dataset. With the Wilcoxon test, we found a significant difference between *Mono* models and *Skyline*/*VoSA*, but there was not always a significant difference when comparing non-*Mono* models and *Skyline*/*VoSA*. The mean is marked with a white dash.

7. RESULTS AND DISCUSSION

7.1 Model Performance

The violin plots summarizing the results of these experiments are shown in Figures 5 and 6, while detailed plots are available in the companion website (see footnote 1).

Our first experiment tested how well models predicted melody lines given training and testing on the same genre of music. Wilcoxon signed-rank tests were run on F-measures to assess potential differences between models. Test results are described in the caption of Figure 5. Overall, our proposed method that identified strictly monophonic melody lines (*cnn mono*) performed better than the other models, but this difference was only significant for the Mozart dataset. The Mozart pieces are highly structured and their melody lines tend to occur in the uppermost voice. The Pop dataset, in contrast, contains pieces with variable structure, with longer breaks in the melody (e.g., there is sometimes an interlude in the accompaniment part). Furthermore, the accompaniment part often overlaps in register with the melody line. It seems that without additional timbral information, our model could not sufficiently distinguish between melody and accompaniment lines when they shared a similar texture.

Our second experiment tested how well trained models generalize to new types of data (i.e., Web dataset). We hypothesized that models trained on the Mozart dataset would outperform models trained on the Pop dataset, as the Mozart and Web datasets are more similar in style (though the Web dataset is more heterogeneous). However, no significant difference between models was found – both models performed well on the Web dataset.

Regarding the less-successful performance of the two baseline methods, the skyline method fails when the melody is not the highest voice; furthermore, this method cannot identify when pauses occur in the solo part. The VoSA method, which was developed for use with polyphonic music, tends to create too many voices and shows a bias towards connecting notes separated by small intervals – this is not surprising, as polyphonic music tends to assign voices to small pitch ranges. As a result, accompaniment notes are often wrongly included in the melody line that VoSA identifies.

7.2 Saliency Maps

To investigate what the CNNs are learning, we propose a method (similar to a sensitivity analysis) that evaluates the contribution of individual locations of the piano roll to predictions at other locations using saliency maps. [5] The method involves testing how the probability that a given note belongs to the melody changes (i.e., increases or decreases) when certain other notes are removed (i.e., by converting the pixels belonging to those notes to 0).

For example, take a rectangular input window I and its prediction P. A new input window I' with prediction P' is created by converting the pixels inside a given rectangle R to 0. The difference between the original and new predictions is denoted as $d(P, P')$ and can be interpreted as the contribution given by the notes inside R to the original

[5] Kernels, saliency maps and additional material are available on the companion website – see footnote 1.

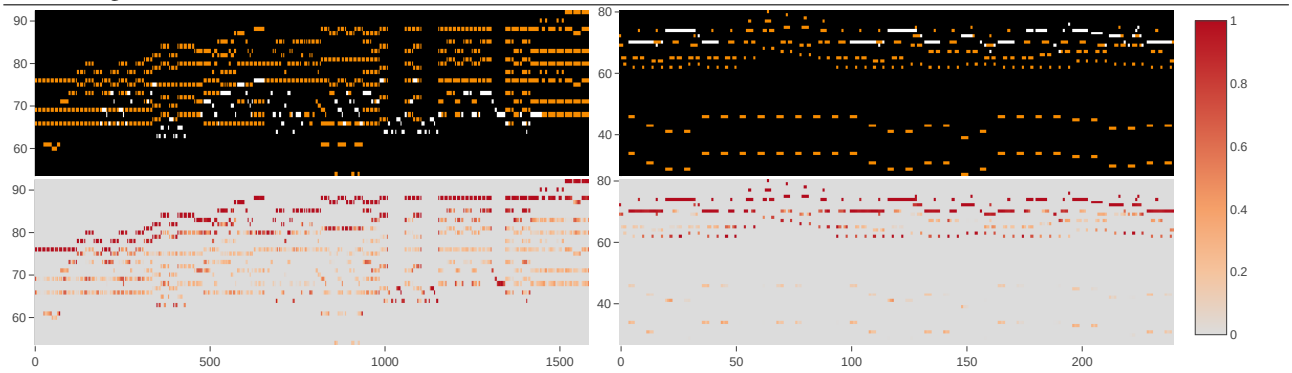

Figure 7. Liszt's *Ihr Glocken von Marling* (left) and an excerpt from Schubert's *Ave Maria* (right). Input piano roll (above), prediction of the CNN (middle). In Liszt, the model fails to identify the main part because the texture is rather different from the most common case and the melody is in the middle voices. In Schubert, instead, the texture changes but the model is not able to identify when the main part starts and stops because the accompaniment plays similar notes.

prediction. By testing different input windows across the piano roll, we can see how different elements of the music contribute to the predictions that are obtained for individual notes.

If we are interested in a particular note n, we can compute $d(P, P')$ specifically for the pixels belonging to n. For our analysis, for certain notes of interest, we define 5 randomly-positioned rectangles R and calculate $d(P, P')$. This difference is summed to the pixels of the notes inside each rectangle R. This procedure is repeated N times (where N is a trade-off between computational complexity and resolution of the saliency map; in our case $N = 30000$), and we select only the iterations in which the pixels of note n are not converted to 0. Each pixel is then normalized by the number of times it was converted to 0. As difference we use

$$d(P, P') = \frac{\sum_{i=n_{start}}^{i=n_{end}} P[i] - P'[i]}{Area(n_{start}, n_{end})} \quad (1)$$

where n_{start} and n_{end} identify the region occupied by the note n. In general, n_{start} and n_{end} indicate two opposite corners of any rectangle.

With this difference function, given a rectangle R, if $d(P, P') > 0$, then $P > P'$ in average across n and, thus, removing the notes inside R decreases the prediction values of n; conversely, if $d(P, P') < 0$, then $P < P'$ and removing the notes inside R increases the prediction.

For example, in the bottom piano roll in Figure 8, the blue high-pitched notes occurring around beats 20 and 35 have non-positive saliency values. Because they are higher pitched, these notes contribute negatively to the melody note highlighted with a green box, making it unlikely for this note to be identified as melody. In the companion website, we show the saliency of other regions highlighting that the prediction of some notes is influenced positively by some regions and negatively by others and that the CNN exploits the regular patterns in the accompaniment to identify the melody notes.

Overall, our model incorporates features of both the skyline algorithm and VoSA. Like the skyline algorithm it focuses on the highest notes of the piece; on the other hand, by allowing for different probabilities like VoSA, it is more successful at drawing coherent melody lines. Unlike VoSA, however, our model does not incorporate explicit perceptual constraints.

8. CONCLUSIONS

We implemented and analyzed a novel method to identify the melody line in a symbolic music score. Some of the functions of our model were found to be similar to functions of the skyline algorithm and VoSA (in particular, focusing on the upper-most pitch, and defining a melody line as finding the sequence of notes that minimizes the connection cost). However, our method does not take into account the long-term sequential nature of music; it can compute windows in any order. While such a property might have some practical benefits, it also makes the network unable to generalize to diverse textures, leading to poor results when musical texture is varied (e.g., Figure 7).

The next step for this line of research would be to develop a model that can take into account a larger temporal context. A promising approach would be to incorporate attention mechanisms into the network.

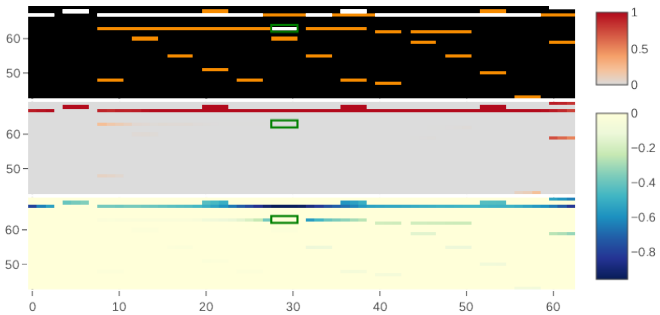

Figure 8. Input piano roll with ground truth in white (top), prediction of the CNN (middle) and proposed saliency computed with respect to the green rectangle (bottom).

9. ACKNOWLEDGEMENTS

This research has received funding from the European Research Council (ERC) under the European Union's Horizon 2020 research and innovation programme under grant agreement No. 670035 (project "Con Espressione"). We gratefully acknowledge the support of NVIDIA Corporation with the donation of the Titan V GPU used for this research. We thank Elaine Chew for sharing the code for VoSA. We thank Laura Bishop for proofreading an earlier version of this manuscript.
