Conference Organizing Committee

General Chairs
Cynthia C. S. Liem, Delft University of Technology, Delft, The Netherlands
Emilia Gómez, Universitat Pompeu Fabra, Barcelona, Spain / Joint Research Centre, European Commision, Seville, Spain

Program Chairs
Arthur Flexer, Austrian Research Institute for Artificial Intelligence, Vienna, Austria
Geoffroy Peeters, Telecom ParisTech, Paris, France
Julián Urbano, Delft University of Technology, Delft, The Netherlands
Anja Volk, Utrecht University, Utrecht, The Netherlands

Tutorial Chairs
Eva Zangerle, University of Innsbruck, Innsbruck, Austria
Masataka Goto, AIST, Tsukuba, Japan

Proceedings and Archival Chairs
Alastair Porter, Universitat Pompeu Fabra, Barcelona, Spain
Eric J. Humphrey, Spotify, Boston MA, USA
Stefan Balke, Institute of Computational Perception, Johannes Kepler University Linz, Austria

Publicity Chairs
Amélie Anglade, Arcona.ai, Berlin, Germany
Tejaswinee Kelkar, University of Oslo, Oslo, Norway

Fringe programming Chair
Andrew Demetriou, Delft University of Technology, Delft, The Netherlands

Music
Martin Gasser, Austrian Research Institute for Artificial Intelligence, Vienna, Austria
Christof Weiß, International Audio Laboratories Erlangen, Erlangen, Germany

Late Breaking News and Demos Chairs
Jaeyoung Choi, Delft University of Technology, Delft, The Netherlands / International Computer Science Institute, Berkley, CA, USA
Mohamed Sordo, Pandora Media, Inc. Oakland, CA, USA

Unconference
Peter van Kranenburg, Meertens Institute, Amsterdam, The Netherlands

Satellite Events Chair
Jaehun Kim, Delft University of Technology, Delft, The Netherlands

Newcomer Initiatives Chairs
Iris Yuping Ren, Utrecht University, Utrecht, The Netherlands
Sandy Manolios, Delft University of Technology, Delft, The Netherlands

Sponsorship Chairs
Steve Tjoa, Google, Inc. CA, USA
Stefan Sullivan, Smule, Inc. San Francisco, CA, USA

Web Chair
Bart Vastenhouw, Delft University of Technology, Delft, The Netherlands

Finances & local arrangements
TU Delft Event Solutions, Delft University of Technology, Delft, The Netherlands
Saskia Peters, Delft University of Technology, Delft, The Netherlands

Advisor
Blair Kaneshiro, Stanford University, Stanford, CA, USA
Meinard Müller, International Audio Laboratories Erlangen, Erlangen, Germany
Frans Wiering, Utrecht University, Utrecht, The Netherlands

Best Paper Awards Panel
Tom Collins, University of York; MAIA, Inc.
Zhiyao Duan, University of Rochester
Olivier Lartillot, RITMO, University of Oslo
Florence Levé, Université de Picardie Jules Verne - Lab. MIS - Algomus
Oriol Nieto, Pandora
Alexander Schindler, Austrian Institute of Technology
Peter Van Kranenburg, Meertens Insitute; Utrecht University

Preface

With great pleasure, we welcome you to ISMIR 2019, the 20th International Society for Music Information Retrieval Conference. ISMIR is the world's leading research forum on processing, searching, organizing and accessing music-related data. For the 20th anniversary of the conference, we are honored to welcome you to the beautiful city of Delft, The Netherlands, where the conference will take place from November 4-8, 2019.

The tagline for this year's conference is 'Across the Bridge'. Our community reflects a diversity of scientific disciplines, seniority levels, professional affiliations, and cultural backgrounds. It always has been explicitly interested in fostering and stimulating this diversity, leading to better science and better music services. For this anniversary edition of ISMIR, through various actions and program elements, we have tried to explicitly encourage the community to take this a step further, and actively connect across the bridges between our backgrounds.

Scientific program

We are excited to present this year's program. A total of 308 abstracts were registered, of which 246 finally turned into complete and well-formatted papers to enter the review process. The PC insisted on a strict adherence to ISMIR's submission policy, e.g. not accepting any paper simultaneously under review at another venue. Special care was taken to assemble an experienced and interdisciplinary review panel reflecting our community's diversity of scientific disciplines and cultural backgrounds in line with this year's conference tagline 'Across the Bridge'. As in previous years, reviews were double-blind (i.e., both the authors and the reviewers were anonymous) with a two-tier review model involving a pool of 212 reviewers, plus 66 meta-reviewers. Each paper was assigned to 1 meta-reviewer and 3 reviewers. The meta-reviewers' assignments were based on topic preferences and bids on papers. The reviewers' assignments were based on these criteria and meta-reviewer suggestions. Handling at most 4 submissions, each meta-reviewer was asked to provide a full review themselves and to adopt an active role in the discussion phase with the other reviewers, ultimately providing a final summarizing meta-review. Of the 246 reviewed papers, 110 were accepted, resulting in an acceptance rate of 44.7%. Among these 110 papers, 66 have a student as the first author.

Authors could assign one or more subject areas to their paper. The following table indicates the distribution (in percent of the total number of papers) of subject areas. We indicate this distribution over the submitted (246) and the accepted works (110).

Subject Area	% of accepted	% of submitted
Domain knowledge: machine learning/artificial intelligence for music	40.0	38.6
MIR data and fundamentals: symbolic music processing	23.6	15.9
Domain knowledge: representations of music	20.9	16.3
MIR data and fundamentals: music signal processing	19.1	16.7
Applications: music retrieval systems	18.2	16.3
Music processing: pattern matching and detection	16.4	13.0
Music processing: automatic classification	16.4	18.3
Music processing: similarity metrics	16.4	13.8
Domain knowledge: computational music theory and musicology	16.4	12.6

Music processing: music transcription and annotation	13.6	12.2
Applications: music composition, performance and production	13.6	12.6
Evaluation and Methodology: MIR tasks, datasets and annotation protocols	13.6	11.4
Musical features and properties: harmony, chords and tonality	13.6	10.6
Musical features and properties: rhythm, beat, tempo	11.8	8.9
Musical features and properties: expression and performative aspects of music	10.9	8.5
Musical features and properties: melody and motives	10.0	8.9
Musical features and properties: structure, segmentation and form	10.0	9.8
User-centered MIR: human-computer interaction and interfaces	10.0	8.5
Applications: digital libraries and archives	9.1	5.3

To commemorate the 20 year anniversary of the ISMIR conference, authors were also invited to submit a contribution to a "20th anniversary papers" track. Four papers (one of these having seven undergraduate student joint first authors) were chosen from 12 submissions. This took place in a separate process involving only meta-reviewers. Every anniversary paper was reviewed and discussed by 4 meta-reviewers and 1 senior meta-reviewer.

This year we introduced several changes to the submission and review processes, such as: 1) the use of Microsoft CMT as submission system, which offers more flexibility, more features, and can be used without cost; 2) the submission form was re-designed to let authors upload supplementary material (e.g., code, audio samples) and provide the takeaway message from their contribution; 3) the review form was also re-designed to reduce problematic borderline decisions and focus on the re-usable insights of the papers; 4) the review process was 100% anonymous, that is, no author, reviewer or meta-reviewer knew the identity of other author, reviewer or meta-reviewer; and 5) the attribution of best-paper awards, moving from the choice of a single best contribution to a set of best contributions.

Based on meta-reviewers' recommendations for best paper awards, a panel of 7 experts reread all 8 recommended papers and delivered a ranking of the papers plus verbatim explanations of their reasoning. With this information at hand, the Scientific Program Chairs made the final choice to award 4 best papers. Next to this, based on rating feedback given by meta-reviewers, the choice was made to award 4 best reviewers.

The table shown below summarizes the ISMIR publication statistics over the history of the conference. A very special thanks goes to our Scientific Program Chairs for their extensive efforts to ensure a fair and efficient paper selection.

Following the successful presentation format that was first piloted at ISMIR 2018 in Paris, all regular papers both have been assigned a short plenary oral presentation, as well as a poster presentation. With anniversary papers being more focused on community reflection, these papers are presented in longer oral slots, with plenary Q&A.

To further emphasize equality of all regular papers—regardless of their subject area—the presentation order of papers has been randomized. In doing this, authors of thematically related work also have lower odds of having to present their posters in parallel.

To allow for longer exchanges about the scientific work presented at ISMIR, and more public exposure of ISMIR's output (given various public outreach efforts, as mentioned below), the choice also was made to have all posters exhibited during the full conference.

Year	Location	Oral	Poster	Total Papers	Total Pages	Total Authors	Unique Authors	Pages/ Paper	Authors/ Paper	Unique Authors/ Paper
2000	Plymouth	19	16	35	155	68	63	4.4	1.9	1.8
2001	Indiana	25	16	41	222	100	86	5.4	2.4	2.1
2002	Paris	35	22	57	300	129	117	5.3	2.3	2.1
2003	Baltimore	26	24	50	209	132	111	4.2	2.6	2.2
2004	Barcelona	61	44	105	582	252	214	5.5	2.4	2
2005	London	57	57	114	697	316	233	6.1	2.8	2
2006	Victoria	59	36	95	397	246	198	4.2	2.6	2.1
2007	Vienna	62	65	127	486	361	267	3.8	2.8	2.1
2008	Philadelphia	24	105	105	630	296	253	6	2.8	2.4
2009	Kobe	38	85	123	729	375	292	5.9	3	2.4
2010	Utrecht	24	86	110	656	314	263	6	2	2.4
2011	Miami	36	97	133	792	395	322	6	3	2.4

2019	**Delft**	**114**		**114**	**889**	**390**	**315**	**7.8**	**3.4**	**2.8**

WiMIR

Women in MIR (WiMIR) is a group of people in the MIR community dedicated to promoting the role of, and increasing opportunities for, women in the field. We meet to network, share information, and discuss in an informal setting the goal of building a community that supports women—and more broadly, diversity—in the field of MIR. WiMIR has held annual meetings at the ISMIR conference since 2012, garnering a high turnout of both female and male attendees. Since 2016, WiMIR has also organized a mentoring program connecting female students, postdocs, and early-stage researchers to more senior females and male allies in the field.

In contrast to past ISMIRs, for ISMIR 2019, the choice was made to not designate dedicated WiMIR chairs to the conference, and to explictly not restrict topics of interest to WiMIR to a WiMIR reception and session only. Instead, efforts were taken to make WiMIR's themes of interest naturally integrated, central themes to the conference, as part of the tasks of the General Chairs.

This year, the WiMIR workshop, that offers an accessible entry and networking opportunity to people interested in ISMIR themes, was scheduled before the ISMIR main conference. This was done to encourage for newly made connections at this workshop to further be extended throughout the main conference.

The WiMIR bingo, that normally would be held at a dedicated WiMIR reception or cocktail, has this year been included as an element in the official Welcome Reception of the conference, still bearing the WiMIR brand. Again, this has been done to emphasize that networking and inclusion are important to ISMIR as a whole.

Finally, the scope of the WiMIR grants was broadened and formulated more inclusively. For the first time, the WiMIR grant management was also taken up by a male ally.

Diversity & Inclusion

Diversity and inclusion are key themes to ISMIR 2019. Beyond thematic/disciplinary diversity (reflected in the scientific program) and gender diversity (reflected through WiMIR actions), we have actively tried to also stimulate other forms of diversity, and explicitly strive for inclusion.

With regard to other forms of diversity: as for diversity regarding types of positions and affiliations, through our Meetup with Industry, we have offered an explicit platform to our industry partners to present their recent work to the local community, beyond traditional conference presentation forms.

As for diversity regarding seniority levels, this year's ISMIR also has strived to actively include and encourage newcomers, and to make ISMIR accessible for the young generation, as well as those who may not have natural support and opportunity to afford attendance of ISMIR.

To this end, dedicated newcomer inclusion and accessibility strategies were followed. Through multiple student author grants, also partially supported by the ISMIR board, student authors got financial support to be able to join the conference.

Besides this grant, partially out of the anniversary donation of the ISMIR board to the ISMIR 2019 organizers, a new type of grant was established for ISMIR 2019: the Community Grant. This grant was meant to support several individuals who would like to attend ISMIR, but who are not in the capacity to actively participate as contributors to the conference yet (or anymore). Existing ISMIR members were encouraged to suggest and champion Community Grant applicants. Thanks to this grant, we both have managed getting several past ISMIR members to re-engage with the community, but also have supported multiple young people, e.g. from different disciplines, and from labs that do not have strong MIR presence or priorities at this moment, to join our community.

Also in terms of registration pricing, priority was given to make rates as accessible as possible to students. Following all these actions, we indeed have seen a substantial share of participants to ISMIR 2019 being newcomers to the conference (as much as 40% of registered full conference participants). To explicitly include these newcomers in the community, a dedicated Newcomer Chair focuses throughout the conference on making our newest community members indeed feel welcomed.

Sustainability

When collecting community input for ISMIR 2019, one request coming up was finding ways to reduce the ecological footprint of ISMIR. To this end, this year, proceedings are only distributed in digital form, and not on USB drives. We further chose not to produce a formal hardcopy program booklet, but instead offer hardcopies of paper listings on demand only, while including hyperlinks to papers and supplementary material in the digital file bearing these listings. To further increase the attractiveness of a digital program, and make it more interactive, we have chosen to make use of Introwise, a digital event platform and networking tool, suggested to us by ISMIR community member Anna Aljanaki. We are curious to see in the conference whether this will indeed allow for a conference experience that is at least as good as former conference experiences have been.

In terms of digital sustainability, we further have worked hard to comply to the ISMIR society standards on digital archivability, now also including the LBD submissions as non-proceedings, yet ISMIR-archived contributions.

Public visibility

ISMIR 2019 takes place at a location that does not have a large, long-time established MIR lab; at the same time, Delft does have an engaged community of students and citizens interested in learning about recent scientific and technological advances in the field. Taking advantage of the Aula Conference Centre having sufficient physical capacity, while the town of Delft is relatively small, we have actively invested in furthering ISMIR's open culture, by sharing as much of ISMIR as possible with the public.

Therefore, ISMIR's evening keynotes, the Youth Music Challenge, as well as the Meetup with Industry have been made free-of-charge ISMIR elements, explicitly accessible to the general public.

Keynote speakers

For ISMIR 2019, we are very honored to host four esteemed keynote speakers:

- Henkjan Honing, Professor in Music Cognition, Faculty of Humanities and the Faculty of Science University of Amsterdam: "What makes us musical animals". Henkjan has been a major role model in performing interdisciplinary scientific research on music, and disseminating science to the general public. We are looking forward to an inspiring talk on musicality: a topic not central to the MIR field, but personally recognizable for many of us.
- Georgina Born, Professor of Music and Anthropology, Professorial Fellow, Mansfield College, University of Oxford: "MIR redux: Knowledge and real-world challenges, and new interdisciplinary futures". Linking to our 'Across the Bridge' tagline, we are grateful to have Georgina shedding light on our field, from disciplinary viewpoints that we would not naturally encounter at ISMIR at large.
- Jeremy Pickens, Principal Data Scientist, OpenText: "Music as Investigation". Jeremy was an active member of our community in the early years of ISMIR; while he now formally works in other domains, he has kept on following what happened in ISMIR, and we are delighted to have him back at this anniversary edition.
- Henriette Cramer, Principal Research Scientist & PM, Spotify: "Music and algorithmic responsibilities in practice". Henriette is the expert on fair and responsible recommendation in music. With this being a topic that has rapidly emerged as a critical focus point for ISMIR, we look very much forward to learning from her.

Three of the keynotes (Henkjan Honing, Georgina Born, Jeremy Pickens) have been scheduled in early evening slots, such that a broader audience can be reached. The fourth keynote (Henriette Cramer) is scheduled as part of the WiMIR session, to emphasize the relation between the keynote's theme and key interests of WiMIR.

Tutorials

Our tutorial chairs have selected six tutorials, based on relevance (i.e. being of interest to the whole community or only a segment thereof); suitability to generally knowledgeable students in MIR rather than specialists; quality; comprehensiveness / coverage; originality of topics with respect to previous ISMIR tutorials; novelty of authors with respect to previous ISMIR tutorials; expertise of authors; foster complementarity of tutorials; and foster open source and free software tools/data and reproducible research.

This has led to three tutorials in the morning, and three tutorials in the afternoon of Monday, November 4:

Morning

- [T1] Fundamentals of Music Processing: An Introduction using Python and Jupyter Notebooks by Meinard Müller and Frank Zalkow;
- [T2] Generating Music with GANs: An Overview and Case Studies by Hao-Wen Dong and Yi-Hsuan;
- [T3] Audiovisual Music Processing by Zhiyao Duan, Slim Essid, Bochen Li and Sanjeel Parekh.

Afternoon

- [T4] Computational Modeling of Musical Expression: Perspectives, Datasets, Analysis and Generation by Carlos Cancino-Chaćon, Katerina Kosta and Maarten Grachten;
- [T5] Waveform-based music processing with deep learning by Sander Dieleman, Jordi Pons and Jongpil Lee;
- [T6] Fairness, Accountability and Transparency in Music Information Research (FAT-MIR) by Emilia Gómez, Andre Holzapfel, Marius Miron and Bob L. Sturm.

Unconference

As in previous years, there will be an Unconference session during ISMIR 2019. This session will offer a platform to discuss MIR-related topics as proposed by the participants in a bottom-up fashion. With plenty of meeting rooms and a central hall, the conference venue provides an excellent infrastructure for the Unconference. We will start Friday 8th of November, 15:30 with a short plenary meeting in the Frans van Hasseltzaal, in which we will establish the topics. In principle, any topic that generates sufficient interest among the participants will be facilitated, limited by the amount of groups and time-slots available. To speed-up the topic selection process, the Introwise tool will be used to prepare topics and do the voting.

Late Breaking/Demo Session

The Late Breaking/Demo (LBD) Session features prototype systems, initial concepts, and early results which have not yet fully matured, but are of interest to the Music-IR community. Following the convention of past years, a light review was performed on submissions by our LBD chairs, and a maximum of 50 submissions has been admitted for presentation at the conference.

To further emphasize that LBD contributions are not part of the proceedings of ISMIR, but rather should be seen as non-refereed works, a new paper template has been used that makes this status more explicit. To allow for those in need of visas to apply in time, LBD acceptance was performed in two stages, with the first stage explicitly allowing for feasible timelines towards visa applications.

Youth Music Challenge

Many people, regardless of their backgrounds or interests, love music and consume it daily. These days, this consumption will mostly be focused on digital music, which users discover and access through online services. As such, many people in the world implicitly engage with MIR technology, and our research field has considerable potential for public outreach. As discussed during the WiMIR session of ISMIR 2018, this could be an opportunity to try engaging a more diverse young audience for STE(A)M topics.

On the occasion of ISMIR 2019, we have partnered with Roem, a Delft-based Campaign Agency for the Greater Good, to organize a Youth Music Challenge. In the months between ISMIR 2018 and ISMIR 2019, we visited various (platforms for) STEM teachers in Dutch secondary schools for advice, and developed workshops and a challenge for youngsters aged 12-18, asking for them to propose, prototype and present ideas for 'the music service of the future'.

The first edition of the Youth Music Challenge was run at the Christelijk Lyceum Delft, a 'Technasium' school which explicitly includes STEM design challenges in the curriculum. Five groups of middle and high school students (aged 12-13 and 15-16) have participated in the challenge, and will pitch their ideas on the night of November 5, 2019, at OPEN, the public library and music school of Delft. These outcomes will subsequently become part of a temporary public exhibit at OPEN, showcasing our youth's ideas to both the ISMIR community and the general public.

The students will receive feedback by a jury consisting of:

- Cynthia Liem, general co-chair of ISMIR 2019, assistant professor at Delft University of Technology and initiator of the Youth Music Challenge;
- Romain Hennequin, lead scientist at Deezer;
- Casper Karreman, senior developer at Muziekweb;
- Peter Sobot, staff software engineer at Spotify.

Our special thanks go to:

- Martijn Kirsten from Roem, for the production of the Youth Music Challenge;
- Alexander Ettema from Studio Alex, for creative and media support to the challenge;
- John Schmitz, dean of the Faculty of Electrical Engineering, Mathematics and Computer Science of Delft University of Technology, for having agreed to financially support the production of the Youth Music Challenge, as an effort to increase future diversity in our professional field;
- students and teachers from Christelijk Lyceum Delft, for having participated in the challenge.

The intention is to keep running the Youth Music Challenge in coming years, and expand its scope to a truly national one.

Meetup with Industry

Following an initiative first started at ISMIR 2018, after the main conference, a Meetup with Industry will take place on Friday, November 8 in the late afternoon and evening. With ISMIR being the world's leading R&D forum for music tech since 2000, and many colleagues having taken industry positions, the Meetup with Industry offers a networking platform and exposure opportunity in which participants can:

- Discover and shape the future of music technology;
- Connect with and recruit top talent from the MIR community and local universities;
- Meet world-class experts and explore the current state-of-the-art in music, creative and data science tech applications;
- Connect with and learn from leading music, creative and data science tech companies;
- Discover startups leveraging latest technologies in a variety of music, creative and data science applications;
- Exchange with other players and startups in the music, creative and data science industry;
- Showcase and market latest products and services.

We have strived to make the Meetup as accessible as possible, and to encourage the participation of interested parties who may not be in the ISMIR community, with special focus on students. Therefore, the choice was made to make access to the Meetup free of charge, including first drinks and bites, to explicitly campaign for it towards students at Delft University of Technology, and to organize it close to the campus, at the very end of the students' exam week.

Exhibitors present at the Meetup include Spotify, Tencent Music Entertainment, Pandora, Chordify, Google, Gracenote, Peachnote, AI Music, Universal Music Group and Dolby.

Social Events

ISMIR 2019 has two official social events.

Welcome reception

The ISMIR 2019 Welcome Reception will take place on Monday, November 4 at the Bierfabriek in Delft. In a building that was formerly the local discotheque of Delft, the Bierfabriek now hosts a large informal pub and restaurant, serving various types of home-brewed beer and comfort food.

Conference Banquet & Pandora Jam Session

The ISMIR 2019 Conference Banquet & Pandora Jam Session will take place on Thursday, November 7 at the Lijm & Cultuur complex in Delft. Formerly a glue factory, Lijm & Cultuur now is a multi-functional creative lab, mostly used as a cultural and festival location. Following dinner, the community will transition into its now-traditional jam session. We are grateful to our Gold Sponsor Pandora for having financially supported this jam, and look forward to seeing many ISMIR attendees playing.

Beyond these official social events, the city of Delft offers multiple opportunities for local social experiences in smaller groups. Several local cafes known for their live music agreed to allow ISMIR attendees to play during non-booked late nights, and we look forward to hearing them.

Music

To commemorate ISMIR's 20th anniversary, the Call for Music for ISMIR 2019 was targeted at creating a joint musical-technical performance, taking up the spirit of ISMIR conferences, jam sessions, late-breaking/demos, and hackathons.

To include as many people as possible, a video performance entitled "Variations on ISMIR" has been compiled with Mozart's famous Variations on the French song "Ah, vous dirai-je maman" (K. 265) as basis. The variation theme is also well-known as a children's or Christmas song ("Twinkle, twinkle little star"...). These variations have had significance to the first ISMIR in 2000, and a score excerpt of this piece has served as the first ISMIR logo for many years.

The ISMIR community was encouraged to contribute short variations on this theme (maximally 60 seconds), showing both ISMIR people and MIR technology in action. In response to the Call for Music, multiple contributions were sent in from across the world. The final result will be shown in a plenary music intermezzo, and also will be made available online.

Satellite Events

Surrounding the ISMIR 2019 conference, participants have the opportunity to attend several satellite events:

- **2nd International Workshop on Reading Music Systems (WoRMS)**, held on November 2 as a half-day workshop at the Aula Conference Centre of Delft University of Technology;
- **1st Workshop on Designing Human-Centric MIR Systems**, held on November 2 as a half-day workshop at the Aula Conference Centre of Delft University of Technology;
- **2nd Women in MIR Workshop**, held on November 3 as a full-day workshop at the Aula Conference Centre of Delft University of Technology;
- **6th International Conference on Digital Libraries for Musicology (DLfM)**, held on November 9 as a full-day conference at the National Library of The Netherlands, The Hague.

Host City

Delft is a compact, historic town between Rotterdam and The Hague in the province of South-Holland, The Netherlands. It forms part of the 'Randstad', the urban agglomeration in the western part of the Netherlands, and is one of the nation's main educational and research centers.

Delft is more than 900 years old. The city owes its name to the word 'delven' (digging). Around 1100 AD, a local river was widened by hand to enable better drainage of the surrounding farmland, leading to the oldest (and still existing) canal called the Oude Delft (Old Delft). In 1246, Delft received its city franchise from the Dutch Earl Willem II. Delft flourished and new neighborhoods were added. As early as 1355, the city reached the size it would remain until the 19th century.

During the country's war of independence against Spain in the 16th and 17th centuries, Delft played an important role as the residence of William of Orange, known as the Father of the Nation who initiated the establishment of the state of The Netherlands. Upon his assassination at his Prinsenhof residence, he was buried in the New Church of Delft. His descendants formed the House of Orange-Nassau, which ultimately would become the Dutch Royal Family. The Royal Family still holds a special connection to Delft, and the New Church has now become the Royal Crypt in which former kings and queens are buried.

Many world-renowned painters like Johannes Vermeer, Jan Steen and Karel Fabritius lived and worked in Delft. Delft was also the hometown of scientist Antoni van Leeuwenhoek, inventor of the microscope. Furthermore, the city became famous for its Delft Blue pottery.

The establishment of the Royal Academy for the Training of Civil Engineers in 1842 (which later would become Delft University of Technology) was a strong stimulus to the revival of the industry (and thus the importance of Delft) in the 19th century. New neighborhoods were built, and university buildings and faculties were relocated from the historic center of the city to a new quarter dedicated to the university.

Despite wars and rapid population growth, the historic center of Delft has remained almost completely intact. Today, Delft is a beloved tourist location, an important high-tech hub, and a pleasant home to almost 100,000 inhabitants, many of whom are affiliated to the university.

Acknowledgements

We are very proud to present to you the proceedings of ISMIR 2019. The conference program was made possible thanks to the hard work of many people, including the members of the organizing committee, and the many reviewers and meta-reviewers from the program committee.

We would like to thank our sponsors, whose contributions have been indispensable for us to be able to support the multiple grants of ISMIR 2019:

Platinum sponsors

- Spotify
- Tencent Music Entertainment

Gold sponsors

- Pandora
- Deezer
- Chordify
- Google
- Gracenote

Silver sponsors

- ACRCloud
- Steinberg
- Adobe
- iZotope
- Kobalt Music Group
- Sony

Bronze sponsors

- Peachnote
- Cochlear.ai
- Antescofo
- Facebook

Besides, we would like to thank the sponsors that explicitly chose to sponsor WiMIR, its grants and its initiatives:

WiMIR Benefactor

- Spotify

WiMIR Contributor

- Smule

WiMIR Supporter

- iZotope
- Peachnote
- Native Instruments
- Steinberg
- Kobalt Music Group

We thank the ISMIR board, for having both financially and morally supported the Student Author and Community Grants of ISMIR 2019. We also are very grateful for the board

having given us both trust and freedom to pro-actively innovate many elements in ISMIR 2019, striving to make ISMIR's conferences even better than they already are.

We thank both the leadership and support staff of Delft University of Technology for having enabled this ISMIR. Implicitly, when counting in-kind support as contributions too, TU Delft has by far been the largest sponsor to this conference. We are extremely grateful we could make use of many in-house facilities, thus keeping this ISMIR financially manageable, despite us having taken greater financial risks when giving out grants and lowering our student rates.

We especially want to thank:

- Ginny Ruiter and Natascha Voskuijl from TU Delft Event Solutions, for having supported the logistics of ISMIR 2019;
- The event managers & tech supporters of the Aula Conference Centre, for making our conference experience comfortable, smooth and stable;
- TU Delft Media Solutions, in particular Saskia de Been and Debby van Vondelen, for having made the visual designs for ISMIR 2019;
- Saskia Peters, Management Assistant at the Multimedia Computing Group of Delft University of Technology, for having supported a considerable share of contractual and financial administrative work surrounding ISMIR 2019;
- Andrew Demetriou, Jaehun Kim and Sandy Manolios, PhD students at the Multimedia Computing Group of Delft University of Technology, for having taken important middle-management tasks throughout ISMIR;
- Francesca Lucas, for further practical and last-minute assistance on ISMIR matters;
- The many student volunteers, who have helped us in making ISMIR 2019 run smoothly.

We also thank you, the community: authors, reviewers, researchers, and participants of this conference. Thanks so much for making and being ISMIR. Let's make this a productive, memorable, and inspiring conference together. Let's consciously foster the welcoming and open culture of ISMIR, and proudly share it with those around us, within and beyond the ISMIR community. And here's to another 20 years of ISMIR, and beyond.

Keynote Talks

Keynote Talk 1

What makes us musical animals

Henkjan Honing

Professor in Music Cognition
Faculty of Humanities and the Faculty of Science
University of Amsterdam

Abstract

We are all born with a predisposition for music, a predisposition that develops spontaneously and is refined by listening to music. Nearly everyone possesses the musical skills essential to experiencing and appreciating music. Think of "relative pitch," recognizing a melody separately from the exact pitch or tempo at which it is sung, and "beat perception," hearing regularity in a varying rhythm. Research shows that all humans possess the trait of musicality. We are a musical species—but are we the only musical species? Can there be musical machines? In his presentation, Henkjan Honing embarks upon the quest to discover the cognitive and biological mechanisms that underpin musicality.

Biography

Henkjan Honing is a professor of Music Cognition at both the Faculty of Humanities and the Faculty of Science of the University of Amsterdam (UvA). He studies what musicality is or can be and to what extent human beings share musicality with other animals. His aim is to define the cognitive and biological mechanisms that underpin musicality. In addition to a research agenda (The Origins of Musicality, 2018, MIT Press), Honing has published several books for the general public, including the English-language publications Musical Cognition and The Evolving Animal Orchestra. Honing's books and lectures are popular with a broad audience and are appreciated both inside and outside the scientific world.

Keynote Talk 2

MIR redux: Knowledge and real-world challenges, and new interdisciplinary futures

Georgina Born
Professor of Music and Anthropology
Professorial Fellow, Mansfield College
University of Oxford

Abstract

How can MIR refresh itself and its endeavors, scholarly and real world? I speak as an outsider, and it is foolhardy to advise scientist colleagues whose methodologies one would be hard pressed to follow! Nonetheless, my question points in two directions: first, to two areas of auto-critique that have emerged within the MIR community – to do with the status of the knowledge produced, and ethical and social concerns. One theme that unites them is interdisciplinarity: how MIR would gain from closer dialogues with musicology, ethnomusicology, music sociology, and science and technology studies in music. Second, the 'refresh' might address MIR's pursuit of scientific research oriented to technological innovation, itself invariably tied to the drive for economic growth. The burgeoning criticisms of the FAANG corporations and attendant concerns about sustainable economies remind us of the urgent need for other values to guide science and engineering. We might ask: what would computational genre recognition or music recommendation look like if, under public-cultural or non-profit imperatives, the incentives driving them aimed to optimise imaginative and cultural self- and/or group development, adhering not to a logic of 'similarity' but diversity, or explored the socio-musical potentials of music discovery, linked to goals of human flourishing (Nussbaum 2003, Hesmondhalgh 2013)? The time is ripe for intensive and sustained interdisciplinary engagements in ways previously unseen. My keynote ends by inviting action: a think tank to take this forward.

Biography

Georgina Born OBE FBA is Professor of Music and Anthropology at the University of Oxford, was the bass player with Henry Cow in the late 70s, played improvised cello in the 80s, wrote an ethnography of IRCAM in the 90s and an ethnography of the BBC in the 2000s, and is a leading interdisciplinary scholar writing on the mediation of music, especially its social forms. She ran an ERC-funded research group (2010-15) studying ethnographically how digitization and the internet have affected music worldwide.

Keynote Talk 3

Music as Investigation

Jeremy Pickens
Principal Data Scientist
OpenText

Abstract

The music information retrieval landscape has changed dramatically in the past two decades since ISMIR's inception. Music and user data exist at web scale and systems and algorithms have evolved to take advantage of it. Yet there remain classes of problems and information needs for which scale data will never be available. The early ISMIR community, perhaps if only out of necessity, responded to such challenges by adopting various mindsets: exploratory, investigatory, niche. The benefits of these mindsets extend far beyond music into other individual-scale, task-oriented domains such as law, where popularity and prevalence do not provide easily-distillable answers. Do the benefits run both ways?

Biography

Jeremy Pickens is a Principal Data Scientist at OpenText (né Catalyst Repository Systems), a leader in enterprise software and legal technology. His research in information retrieval has spanned a number of domains from music to images and video to various legal applications. The common thread among these disparate areas has been an emphasis on recall-oriented, comprehensive, and holistic views of relevance. Jeremy is a pioneer in the field of collaborative exploratory search, a form of information seeking in which a group of people who share a complex information need actively collaborate to achieve it. His ongoing research focuses on methods for continuous learning. Jeremy holds a PhD in Computer Science from the University of Massachusetts, Amherst, Center for Intelligent Information Retrieval. He conducted his post-doctoral work at King's College, London. Before joining Catalyst and OpenText, he spent five years as a research scientist at FX Palo Alto Lab, Inc. He was also a member of many of the early (2000-2005) ISMIR organizing committees.

WiMIR Keynote

Music and algorithmic responsibilities in practice

Henriette Cramer
Principal Research Scientist & PM
Spotify

Abstract

Music is deeply personal, and influences our moods and motivation. Music creates communities, shapes subcultures, and powers an enormous industry. What music is available, what can be found, what is recommended, matters. Who gets to learn, to play, to record, matters.
And, crucially, how the music recommendation and retrieval community defines success determines who gets amplified.

We're at a moment in tech where, alongside its successes, machine learning's failures and biases have gained much attention. There is an overwhelming number of calls-to-action but still relatively few standard practices for industry practitioners. This means we have a responsibility, especially as an ISMIR community. But what does that mean, practically?

This talk will outline challenges encountered in practice and at scale, specific to music streaming. We'll briefly travel through time, and take you from early 1900's magic lantern slides' music promotion to the current zeitgeist where new guidelines for algorithmic accountability are clamoring for attention themselves. We'll discuss how new UIs (like voice) can make certain creators inaccessible, female creators' representation in streaming, and optimizing for more than just engagement. We'll share technical and organizational lessons learned, pitfalls, and tensions in assessing decisions' potential impact.

Biography

Henriette Cramer is a principal researcher at Spotify Research, and product manages Spotify's Algorithmic Responsibility effort. She is particularly interested in the impact that teams' design, data and organizational decisions have on algorithmic outcomes. Prior, she set up Spotify's 'human side of Machine Learning' Hai lab, and led data research for Spotify's voice platform. She has worked on recommendations, ad quality, and conversational interactions at Yahoo, and on location-based data, perceptions of place, and human-robot interaction at the Swedish Institute of Computer Science. She holds a PhD from the University of Amsterdam focused on people's responses to autonomous systems. More at: `http://henriettecramer.com`

Tutorials

Tutorial 1

Fundamentals of Music Processing: An Introduction using Python and Jupyter Notebooks

Meinard Müller and Frank Zalkow

Abstract

This tutorial will give an easy-to-understand introduction to music processing with a particular focus on audio-related analysis and retrieval tasks. In particular, the tutorial is aimed at non-experts and researchers who are new to the field. Based on well-established topics in Music Information Retrieval (MIR) as motivating application scenarios, we present fundamental techniques and algorithms that apply to a wide range of analysis and retrieval problems. We intend to explain the main ideas and techniques in an intuitive fashion using various figures and sound examples. Besides the theory, we also show how these techniques can be implemented going through specific Python code examples. All material, including the introduction of MIR scenarios, illustrations, sound examples, technical concepts, mathematical details, and code examples, are integrated into a comprehensive framework based on Jupyter notebooks. The notebooks are organized along with the eight chapters of the textbook on Fundamentals of Music Processing (FMP) (Springer 2015, `http://www.music-processing.de`). Another important goal of this tutorial is to show how the notebooks can be used to generate educational material for lectures and presentations. The notebooks (as well as HTML exports and multimedia examples) can be accessed via `https://www.audiolabs-erlangen.de/FMP`.

Reference

Meinard Müller
Fundamentals of Music Processing — Audio, Analysis, Algorithms, Applications
Springer Verlag, ISBN: 978-3-319-21944-8, 2015.

Meinard Müller studied mathematics (Diplom) and computer science (Ph.D.) at the University of Bonn, Germany. In 2002/2003, he conducted postdoctoral research in combinatorics at the Mathematical Department of Keio University, Japan. In 2007, he finished his Habilitation at Bonn University in the field of multimedia retrieval. From 2007 to 2012, he was a member of the Saarland University and the Max-Planck Institut für Informatik. Since September 2012, Meinard Müller holds a professorship for Semantic Audio Processing at the International Audio Laboratories Erlangen, which is a joint institution of the Friedrich-Alexander-Universität Erlangen-Nürnberg (FAU) and the Fraunhofer-Institut für Integrierte Schaltungen IIS. His recent research interests include music processing, music information retrieval, audio signal processing, and motion processing. Meinard Müller has been a member of the IEEE Audio and Acoustic Signal Processing Technical Committee from 2010 to 2015 and is a member of the Board of Directors of the International Society for Music Information Retrieval (ISMIR) since 2009. He wrote a monograph titled "Information Retrieval for Music and Motion" (Springer, 2007) as well as a textbook titled "Fundamentals of Music Processing" (Springer, 2015, `http://www.music-processing.de`).

Frank Zalkow studied Music Informatics and Musicology (Bachelor) and Music Informatics (Master) at the University of Music Karlsruhe, Germany. Since 2016, he has been working towards his Ph.D. degree in the Semantic Audio Processing Group headed by Meinard Müller at the International Audio Laboratories Erlangen. Previously, he worked for the Max-Reger-Institute Karlsruhe (2008–15) as well as Institute for Musicology at Saarland University (2015–16). His research interests include music retrieval, machine learning, as well as cross-connections between musicology and music information retrieval.

Tutorial 2

Generating Music with GANs: An Overview and Case Studies

Hao-Wen Dong and Yi-Hsuan Yang

Abstract

This tutorial aims to provide an overview of generative adversarial networks (GANs) and their use in generating music. The format of the tutorial will include lectures, demonstration of sample systems and technical results with illustrative musical examples.

- We will start by discussing the scope of music generation and introduce various tasks that can broadly be regarded as music generation. For each task, we will then discuss its challenges, commonly used approaches and some notable systems proposed in the literature.
- In the second part, we will explain the machine learning fundamentals for GANs. We will also present some interesting applications of GANs in other fields to showcase their potentials.
- The following section will contain the case studies of four different tasks---symbolic melody generation, symbolic arrangement generation, symbolic musical style transfer and musical audio generation. In each part, we will first provide an overview of the task and then introduce several models proposed in the literature as examples.
- We will conclude the tutorial by discussing the current limitations of GAN-based models and suggesting some possible future research directions.

In addition to lectures, we will go through some demo projects using Google Colab. These demo projects are designed to provide participants with hands-on experience and deeper understanding of the training of GANs. We will also cover topics such as data representation, processing, I/O, visualization and evaluation.

The tutorial is targeted to students and newcomers who are interested in or working on music generation research, and also machine learning specialists who want to see how GANs can be applied to music generation.

Tutorial website: `https://salu133445.github.io/ismir2019tutorial/`

Hao-Wen Dong is currently a research internship in the Research and Development Division at Yamaha Corporation. He will be starting a Ph.D. this fall in Electrical and Computer Engineering at University of California, San Diego. Previously, he was a research assistant under the supervision of Dr. Yi-Hsuan Yang in the Music and AI Lab at Academia Sinica. He received his bachelor's degree in Electrical Engineering at National Taiwan University. His research interests lie at the intersection of machine learning and music.

Yi-Hsuan Yang is an Associate Research Fellow with Academia Sinica, where he leads a research lab called the Music and AI Lab. He received his Ph.D. degree in communication engineering from National Taiwan University in 2010. He is also a Joint-Appointment Associate Professor with the National Cheng Kung University. His research interests include

music information retrieval, affective computing, and machine learning. Dr. Yang was a recipient of the 2011 IEEE Signal Processing Society Young Author Best Paper Award, the 2012 ACM Multimedia Grand Challenge First Prize, and the 2015 Best Conference Paper Award of the IEEE Multimedia Communications Technical Committee. In 2014, he served as a Technical Program Chair of the International Society for Music Information Retrieval Conference (ISMIR). He gave a tutorial on “Music Affect Recognition: The State-of-the-art and Lessons Learned” in ISMIR 2012. He was an Associate Editor for the IEEE Transactions on Affective Computing and the IEEE Transactions on Multimedia in 2016-2019. He is currently on a sabbatical leave to work with a privately funded research organization in Taipei called the Taiwan AI Labs.

Tutorial 3

Audiovisual Music Processing

Zhiyao Duan, Slim Essid, Bochen Li, and Sanjeel Parekh

Abstract

Music is a multimodal art form. While sound plays a key role, other modalities, especially visual, are also critical to enhancing the musical experience. Recently, the MIR field has witnessed a rapid growth of interest in audiovisual processing of music.

This tutorial is intended to introduce this emerging research direction to the broader MIR community. It extends a recently published overview article on audiovisual analysis of music performances [1] into general audiovisual music processing. Specifically, it provides a comprehensive overview of state-of-the-art research in different aspects of audiovisual music processing, including music performance analysis, content-based retrieval, and music creation. It summarizes datasets, tools and other resources in this field, and articulates challenges and opportunities for future research. An interesting aspect of this tutorial is that it contains two hands-on case studies (30 min each) for the audience to personally experience audiovisual research. Instructions of software environments and starter code will be provided prior to the tutorial for preparation.

To our best knowledge, this is the very first tutorial on audiovisual processing at ISMIR. This tutorial is designed for students and researchers who have general knowledge of music information retrieval and who are interested in learning the state of the art and gaining hands-on experience of audiovisual music processing research. The comprehensive overview and categorization of different aspects of this field will help the audience gain a global view of the research problems, methods, tools, challenges, and opportunities. The hands-on case studies will provide the audience a first-hand experience of the research, helping them quickly arrive at the research frontier. We especially look forward to ideas and inspirations that the MIR community has to offer through this interactive and hands-on tutorial.

[1] Zhiyao Duan*, Slim Essid*, Cynthia C. S. Liem*, Gaël Richard*, and Gaurav Sharma*, “Audiovisual analysis of music performances: overview of an emerging field,” IEEE Signal Processing Magazine, vol. 36, no. 1, pp. 63-73, 2019. (* authors in alphabetical order)

Zhiyao Duan is an assistant professor in Electrical and Computer Engineering, Computer Science and Data Science at the University of Rochester. He received his B.S. in Automation and M.S. in Control Science and Engineering from Tsinghua University, China, in 2004 and 2008, respectively, and received his Ph.D. in Computer Science from Northwestern University in 2013. His research interest is in the broad area of computer audition, i.e., designing computational systems that are capable of understanding sounds, including music, speech, and environmental sounds. He is also interested in the connections between computer audition and computer vision, natural language processing, and augmented and virtual reality. He co-presented a tutorial on Automatic Music Transcription at ISMIR 2015. He received a best paper award at the 2017 Sound and Music Computing (SMC) conference, a best paper

nomination at the 2017 International Society for Music Information Retrieval (ISMIR) conference, and a CAREER award from the National Science Foundation.

Slim Essid received his state engineering degree from the École Nationale d'Ingénieurs de Tunis, Tunisia, in 2001, his M.Sc. (D.E.A.) degree in digital communication systems from the École Nationale Supérieure des Télécommunications, Paris, France, in 2002, his Ph.D. degree from the Université Pierre et Marie Curie (UPMC), Paris, France, in 2005, and his Habilitation à Diriger des Recherches degree from UPMC in 2015. He is a professor in Telecom ParisTech's Department of Images, Data, and Signals and the head of the Audio Data Analysis and Signal Processing team. His research interests are machine learning for audio and multimodal data analysis. He has been involved in various collaborative French and European research projects, among them Quaero, Networks of Excellence FP6-Kspace, FP7-3DLife, FP7-REVERIE, and FP-7 LASIE. He has published over 100 peer-reviewed conference and journal papers, with more than 100 distinct coauthors. On a regular basis, he serves as a reviewer for various machine-learning, signal processing, audio, and multimedia conferences and journals, e.g., a number of IEEE transactions, and as an expert for research funding agencies.

Bochen Li received his B.S. from University of Science and Technology of China in 2014. He is currently pursuing a Ph.D. degree in the Department of Electrical and Computer Engineering at the University of Rochester in the USA, under the supervision of Professor Zhiyao Duan. His research interests lie primarily in the inter-disciplinary area of audio signal processing, machine learning, and computer vision towards multimodal analysis of music performances, such as video-informed multipitch estimation and streaming, source separation and association, and expressive performance modeling and generation.

Sanjeel Parekh received B. Tech (hons.) degree in Electronics and Communication engineering from LNM Institute of Information Technology, India in 2014 and M.S. in Sound and Music Computing from Universitat Pompeu Fabra (UPF), Spain in 2015. His Ph.D. thesis titled 'Learning representations for robust audio-visual scene analysis' was completed in collaboration with Technicolor R&D and Telecom ParisTech, France between 2016-19. His research focusses on developing and applying machine learning techniques to problems in audio and visual domains. Currently, he is with LTCI lab at Telecom ParisTech, France.

Tutorial 4

Computational Modeling of Musical Expression: Perspectives, Datasets, Analysis and Generation

Carlos Cancino-Chacón, Katerina Kosta, and Maarten Grachten

Abstract

The aim of this tutorial is to introduce the theory and practice of music performance research to a broad MIR audience. A music performance—an acoustic or audio-visual rendering of it—provides a much richer musical experience than the symbolic or notated representation of the performed music. This richness is arguably an important aspect of our engagement with music and is shaped by the musician's interpretation of the intentions of the music, as conveyed through their performance. The means of expressing these intentions vary from one instrument to another, and can include tempo, timing, dynamics, articulation, timbre, and intonation, among others.

In this tutorial we will give a brief overview of the music performance literature and highlight how expressive dimensions affect the perception and the creation of music. Furthermore we will showcase some state-of-the-art computational methods for both analysis and synthesis of expressive piano performances. We include a hands-on part in which we share easily operated and adaptable code written in Python using Jupyter iPython notebook for demonstrating how to get started with computational analysis and synthesis of musical expression.

This work is partially supported by the European Research Council (ERC) under the European Union's Horizon 2020 Research and Innovation Programme under grant agreement No 670035 (project "Con Espressione").

Carlos Cancino-Chacón is a postdoctoral researcher at the Austrian Research Institute for Artificial Intelligence (OFAI), Vienna, Austria. His research focuses on studying expressive music performance, music cognition and music theory with machine learning methods. He pursued a doctoral degree on computational models of expressive performance at the Institute of Computational Perception of the Johannes Kepler University Linz, Austria. He received an M.Sc. degree in Electrical Engineering and Audio Engineering from the Graz University of Technology, a degree in Physics from the National Autonomous University of Mexico and a degree in Piano Performance from the National Conservatory of Music of Mexico.

Katerina Kosta is a senior machine learning researcher at ByteDance AI lab. She pursued her Ph.D. from the Centre for Digital Music at the Computer Science and Electronic Engineering department of Queen Mary University of London, conducting research on computational modelling and quantitative analysis of expressive changes of dynamics in performed music. Research interests during her studies included time series analysis, custom data structures, pattern recognition, audio processing, and machine learning for music synthesis and analysis of perceived emotion in music audio. She received degrees from University of Athens (Mathematics) and Filippos Nakas Conservatory, Athens (Piano), and a

Sound and Music Computing Masters from the Music Technology Group at Universitat Pompeu Fabra, Barcelona.

Maarten Grachten is a senior researcher in machine learning for music and sound technology, currently active as an independent machine learning consultant. He holds an M.Sc. in Artificial Intelligence from University of Groningen (The Netherlands, 2001), and a Ph.D. in Computer Science and Digital Communication from Pompeu Fabra University (Spain, 2007). He has worked on computational modeling of musical expression in jazz and classical music since 2001. His work has been funded by European and national research grants at research institutions including the Austrian Research Institute for Artificial Intelligence (OFAI) and Johannes Kepler University (Austria), and has been published in international peer-reviewed conferences and journals.

Tutorial 5

Waveform-based music processing with deep learning

Jongpil Lee, Jordi Pons, and Sander Dieleman

Abstract

A common practice when processing music signals with deep learning is to transform the raw waveform input into a time-frequency representation. This pre-processing step allows having less variable and more interpretable input signals. However, along that process, one can limit the model's learning capabilities since potentially useful information (like the phase or high frequencies) is discarded. In order to overcome the potential limitations associated with such pre-processing, researchers have been exploring waveform-level music processing techniques, and many advances have been made with the recent advent of deep learning.

In this tutorial, we introduce three main research areas where waveform-based music processing can have a substantial impact:

1) Classification: waveform-based music classifiers have the potential to simplify production and research pipelines.

2) Source separation: making possible waveform-based music source separation would allow overcoming some historical challenges associated with discarding the phase.

3) Generation: waveform-level music generation would enable, e.g., to directly synthesize expressive music.

Jongpil Lee received the B.S. degree in electrical engineering from Hanyang University, Seoul, South Korea, in 2015, the M.S. degree, in 2017, from the Graduate School of Culture Technology, Korea Advanced Institute of Science and Technology, Daejeon, South Korea, where he is currently working toward the Ph.D. degree. He interned at Naver Clova Artificial Intelligence Research in the summer of 2017 and at Adobe Audio Research Group in the summer of 2019. His current research interests include machine learning and signal processing applied to audio and music applications.

Jordi Pons is a researcher at Dolby Laboratories. He is finishing a PhD in music technology, large-scale audio collections, and deep learning at the Music Technology Group (Universitat Pompeu Fabra, Barcelona). Previously, he received a MSc in sound and music computing (Universitat Pompeu Fabra, Barcelona), and his BSc was in telecommunications engineering (Universitat Politècnica de Catalunya, Barcelona). He also interned at IRCAM (Paris), at the German Hearing Center (Hannover), at Pandora Radio (USA, Bay Area), and at Telefónica Research (Barcelona).

Sander Dieleman is a Research Scientist at DeepMind in London, UK, where he has worked on the development of AlphaGo and WaveNet. His current research interest is large-scale generative modeling of perceptual signals (images, audio, video). He was previously a PhD student at Ghent University, where he conducted research on feature learning and deep learning techniques for learning hierarchical representations of musical audio signals. In the summer of 2014, he interned at Spotify in New York, where he worked on implementing audio-based music recommendation using deep learning on an industrial scale.

Tutorial 6

Fairness, Accountability and Transparency in Music Information Research (FAT-MIR)

Andre Holzapfel, Marius Miron, Bob L. Sturm, Emilia Gómez

Abstract

This tutorial focuses on the timely issues of ethics, fairness, accountability and transparency, with particular attention paid to research in applications in music information research. These topics arise from a broader consideration of ethics in the field – related work of which was recently published in TISMIR: https://transactions.ismir.net/articles/10.5334/tismir.13. These topics are also receiving attention in the broader domain of machine learning and data science, e.g., the FAT-Machine Learning (ML) conference 2014-2018, Explainable AI workshops 2017-2018, Interpretable Machine Learning workshops, and in the context of the HUMAINT project and winter school on ethical, legal, social and economic impact of Artificial Intelligence (https://ec.europa.eu/jrc/communities/en/community/humaint). This tutorial is suitable for researchers and students in MIR working in any domain, as these issues are relevant for all MIR tasks, from low- to high-level, from system to user-centered research. There are no prerequisites for taking this tutorial.

Andre Holzapfel received M.Sc. and Ph.D. degrees in computer science from the University of Crete, Greece, and a second Ph.D. degree in music from the Centre of Advanced Music Studies (MIAM) in Istanbul, Turkey. He worked at several leading institutes in computer engineering as postdoctoral researcher, with a focus on rhythm analysis in music information retrieval. His field work in ethnomusicology was mainly conducted in Greece, with Cretan dance being the subject of his second dissertation. In 2016, he became Assistant Professor in Media Technology at the KTH Royal Institute of Technology in Stockholm, Sweden. Since then, his research subjects incorporate the computational analysis of human rhythmic behavior by means of sensor technology, and the investigation of ethical aspects of computational approaches to music.

Marius Miron is a Postdoctoral researcher for European Commission's Joint Research Centre within the project HUMAINT, working on fairness and interpretable machine learning and on assessing the influence of artificial intelligence on humans. He has a PhD (2018) in Computer Science (Audio Signal Processing and Machine Learning) from Pompeu Fabra University, Barcelona. His PhD thesis concerned separating the audio corresponding to the instruments in an orchestral music mixture. He has completed internships at Computational Perception Group, Johannes Kepler University, Linz where he worked on deep learning for source separation, and at Telefonica Research, Barcelona, where he worked on catastrophic forgetting in machine learning. During 2011-2013 he was a research engineer for the research institute INESC in Porto for a project aiming at modelling groove in music.

Bob L. Sturm received the B.A. degree in physics from University of Colorado, Boulder in 1998, the M.A. degree in Music, Science, and Technology, at Stanford University, in 1999, the M.S. degree in multimedia engineering in the Media Arts and Technology program at University of California, Santa Barbara (UCSB), in 2004, and the M.S. and Ph.D. degrees in Electrical and Computer Engineering at UCSB, in 2007 and 2009. In Dec. 2014, he became a

Lecturer at the Centre for Digital Music at Queen Mary University of London. In July 2018 he became an associate professor of computer science at the Royal Institute of Technology KTH in Stockholm Sweden.

Emilia Gómez leads the HUMAINT (HUman and MAchine INTelligence) team at the Centre for Advanced Studies, Joint Research Centre (European Commission) and the MIR (Music Information Research) lab of the Music Technology Group, Universitat Pompeu Fabra in Barcelona. Her research background is in music information retrieval, where she has particularly focused on pitch, melody and tonal processing of music audio signals. She also researches more widely on the impact of artificial intelligence technologies on human behaviour. She is a Telecommunication Engineer (Universidad de Sevilla, Spain), DEA in Acoustics, Signal Processing and Computer Science applied to Music (IRCAM, Paris) and Ph.D. in Computer Science (Universitat Pompeu Fabra). Emilia Gómez has co-authored more than 130 scientific publications in peer-reviewed scientific journals and conferences, and contributed to several open datasets and software libraries. She is currently president of the International Society for Music Information Retrieval (ISMIR), and particularly interested in promoting diversity in the MIR field.

ABSTRACT

The MIR community faces unique challenges in terms of data access, due in large part to country-specific copyright laws. As a result, there is an emerging divide in the MIR research community between labs that have access to music through large companies with abundant funds, and independent labs at smaller institutions who do not have such expansive access. This paper explores how independent researchers have worked to overcome limitations of access to music data without contributing to the crisis of reproducibility. Acknowledging that there is no single solution for every data access problem that smaller labs face, we propose a number of possibilities for how the MIR community can bridge the gap between advancements from large companies and those within academia. As MIR looks towards the next 20 years, democratizing and expanding access to MIR research and music data is critical. Future solutions could include a distributed MIREX system, an API designed for MIR researchers, and community-led advocacy to stakeholders.

1. INTRODUCTION

Since its very conception, the field of Music Information Retrieval (MIR) has struggled with data accessibility, due in part to the nature of music copyright. To deal with this, MIR researchers have developed methods for avoiding or circumventing copyright infringement. Said methods include relying upon public domain and/or Creative Commons music, attainment of certain licenses and/or permissions, use of private in-house data sets, and the access of music data without specifically accessing the audio itself. Each of these methods, however, possess inherent drawbacks such as cost, lack of diverse data, or challenges associated with acquiring required licenses. Public domain and Creative Commons music is often constrained to Western classical pieces; in-house data sets require financial investment; and music data without audio often fail to give a full picture. These drawbacks contribute to an overall disparity of access to data in the MIR community and add to the crisis of reproducibility. In an attempt to strengthen both MIR research and the MIR community as a whole, this paper will propose a number of potential solutions to the drawbacks in existing methods in the hopes that they may serve as a guiding future direction.

The paper is organized as follows. In Section 2, we report on the current concerns and constrictions to data access for MIR researchers. In Section 3, we discuss how datasets from the first ISMIR in 2000 differ from the 10th ISMIR in 2009, and how both compare to the most recent ISMIR in 2018. In Section 4, we outline three proposals for expanding and enhancing access to music data for researchers. Finally, in Section 5, we challenge the community to think urgently about the future and how we can support efforts to improve access to music data.

2. MOTIVATION AND BACKGROUND

Over the last 20 years, society's access to music has evolved. At the first ISMIR conference in 2000, we could only dream of a world with smartphones complete with numerous personalized music streaming applications that make music readily available. Platforms like Spotify and SoundCloud – that now allow for artists to directly share music with the world – had yet to be a pervasive reality.

While the rise of these technologies allows end users to enjoy music more easily and expands MIR research greatly in scope, data commonly used MIR research has not necessarily become more accessible. As with any rapidly growing field, careful attention needs to be paid to legal and scientific concerns with regards to data. In this section, we provide a historical overview of copyright in the United States as it relates to MIR research (though similar statements could be said for other countries). We also discuss the importance of reproducibility for MIR studies.

2.1 History of US Copyright and MIR research

As every MIR researcher is keenly aware, musical recordings are closely protected by copyright laws, which vary by country. In this paper, we treat copyright law in the

† Joint first authors with equal contribution

United States as a case study. The Copyright Act of 1790 marks the beginning of copyright in the US [26]. In 1998, just before the first ISMIR conference, one of the most extensive laws passed was the Digital Millennium Copyright Act (DMCA). This law dealt with issues that arose due to the advent of computers, including allowing data to be copied temporarily during computer maintenance and the ease of broadcast data over the Internet. It also facilitated the implementation of World Intellectual Property Organization (WIPO) Internet treaties, a set of international norms aimed at preventing unauthorized access to and use of creative works on the internet [26]. [1]

As technology has continued to evolve, so too have US laws. In 2018, the Music Modernization Act (MMA) was passed to establish a system of music licensing for digitally distributed music of today [4]. The MMA designates a mechanical licensing collective to oversee a database of musical works that is made publicly available, as well as ensure that artists are paid for their work through the administration of a blanket license. MMA also specifies what songs are in the public domain. With a clearer regulation on music copyright and establishment of a centralized database to track down songwriters, MMA helps reduce unnecessary US copyright related lawsuits while protecting the interests of the music creators. However, given the global nature of the MIR community, being compliant with US laws alone is not enough. As a result, researchers tend to opt for international open source licenses such as Creative Commons (see Section 3.2).

2.2 Reproducibility and Validity of Research

Two vital aspects of scientific research are reproducibility (which encodes reliability) and validity (which often is a proxy for generalizability). These concepts determine how "good" research is – a study that cannot be generalized or trusted is not worth doing.

As MIR tasks grow increasingly complex, it is urgent that the community address the crisis of reproducibility and how it affects the reliability of research. At ISMIR 2014, Raffel et. al. reported that differing evaluation implementations can produce deviations of 9-11% in commonly used metrics across diverse tasks including beat tracking, structural segmentation, and melody extraction [29]. The ability of researchers to verify each other's work is an integral step in the scientific process; without it, consensus on new findings is difficult to reach. That process, however, has been hindered by the use of copyright-protected data in MIR research. Privatized data cannot be legally shared between authors, thus preventing proper re-evaluation for reproducibility [24].

In addition, private and copyright-protected data can be expensive to procure, thus incentivizing and often limiting MIR researchers to using relatively small datasets. This is unfavorable when considering the external validity of a study. It is a general consensus, as Sturm puts eloquently, that "experimental power increases with the number of observations" [35]. Using larger datasets helps control for confounding variables and can sometimes reveal subtle patterns that smaller collections would not pick up on [6]. Smaller datasets carry none of these benefits in addition to having weaker experimental power, greater susceptibility to variation, and revealing only the more obvious patterns. Moreover, limited access to material leads to "restricted and biased subsets," which are difficult to generalize to larger music populations and thus bring into question the external validity of such studies [37].

3. DATA USAGE & EVOLUTION

In this section, we explore data usage and data evolution as well as features of datasets commonly used today. We investigate different classifications of data explored in papers in three different ISMIR conferences. We then discuss the evolution of data creation and examine the limitations of popular datasets.

3.1 Dataset Classification

To illustrate how data usage has evolved over the last 20 years, this paper analyzes datasets used in published papers from ISMIR 2000 [1], 2009 [2], and 2018 [3]. This is done in order to answer three key questions. First, are these datasets diverse enough? Second, how were these datasets created and did the process get easier or harder over time? Third, how were these datasets released and what was their impact?

3.1.1 Genre Classification

To address the first question, we investigate how different music genres have been represented at ISMIR. To do so, we examined the published submissions from the first (in 2000), 10^{th} (in 2009), and most recent (in 2018) ISMIR conferences. Each paper in the respective proceedings was analyzed by three of the authors of this paper, and all music data used for analysis, training, or testing was classified by genre. Although most papers explicitly stated what type of music was used, any disagreements regarding dataset classification were discussed until there was consensus. The results of this survey are displayed in Figure 1. Datasets that used four or fewer genres were classified with each of the genres, those with five or more were given the genre label "various". [2] As many datasets contained multiple genres and many papers referenced multiple datasets, there may be more than one genre representing each paper. Any genre only used once in a given year was categorized as "Other," such as the analysis of opera singing in ISMIR 2018 by Parada-Cabaleiro et.al. [28].

We find that the proceedings in ISMIR 2018 [3] and ISMIR 2009 [2] used data from more music genres, and have a more equal distribution among these genres than those in 2000 [1]. The proportion of pop and rock songs used decreased over time as other genres were included. The proportion of papers that did not use music data or did not

[2] Datasets with at least one non-Western genre were labeled both "various" and "non-Western." Datasets with only Western genres were given no other genre labels

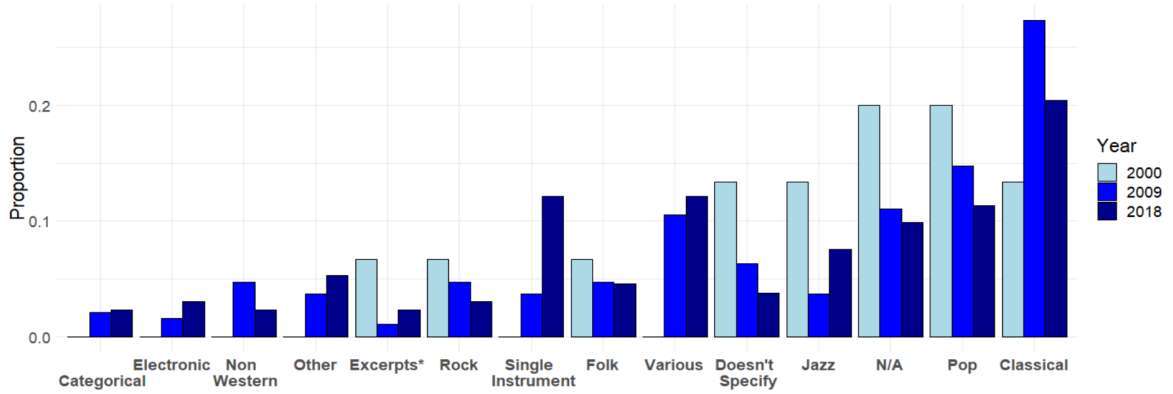

Figure 1: Proportion [3] of the number of papers that use different genres of data from first ISMIR conference in 2000 [1] to the 10th ISMIR in 2009 [2], to the 19th ISMIR in 2018 [3]. "Excerpts*" refers to music excerpts under 3 seconds, and "categorical" refers to music selected for a non-genre category such as mood. The "non-Western" category does not include genres such as J-pop and K-pop, which were classified as solely "pop".

specify the type of music they used have also decreased over time. The latter may be due to an increasing emphasis on reproducibility in MIR, researchers becoming more diligent in documenting their data sources so that others may accurately reproduce their work.

The diversity of MIR research has increased over time. For example, "electronic", "categorical", "non-Western", and "single instrument" music were studied in both 2009 and 2018, even though they had not been in 2000. There has been a substantial increase in papers that consider five or more different genres. However, non-Western genres remain comparatively under-studied, and "classical" continues to be one of the most-studied genres in MIR.

3.1.2 Dataset Collection and Release

To address the second and the third questions, four authors of this work determined the data classifications for datasets used in ISMIR 2018. The categories can be applied to both the dataset creation process and the dataset release process and are summarized in Table 1. [4]

- Creative Commons – CC – includes all datasets released under a Creative Commons license, such as MedleyDB [7]. [5]
- Public Domain – PD – includes all freely available, downloadable, open source datasets that are not licensed under Creative Commons, including datasets released on GitHub; for example, The Million Song Dataset (MSD) [6]. [6]
- Commercial datasets – COM – include those that are owned by for-profit companies such as Spotify and Deezer, and are therefore either not available for public use or available only for purchase.
- In-house datasets – IH – refers to unshareable datasets that are privately owned or contributed via personal connections. For example, some of MedleyDB's data are in-house, though the database is released under CC.
- Library held datasets – LIB – refer to all datasets that are owned and maintained by libraries, or research institutions, including archives dedicated to preserving historical audio records; for example, the University of Iowa Musical Instrument Samples. [7]
- Meta library – MET – refers to aggregates of several existing datasets; for example, the MuMu dataset combines info from MSD and Amazon Reviews [27].
- Permission needed category – PER – refers to any dataset that needs explicit permission to access, but are available for free or at a minimal cost so as to distinguish from the commercial category. An example would be the RWC database [18]. [8]
- Short clips category – SHO – consists of datasets that are made up of short audio samples (usually less than 30 seconds) or recordings of single notes and chords. The NSynth dataset is one example [16]. [9]

3.2 Evolution of dataset creation process: Creative Commons and open source practices

Creative Commons [34] is an international system that creators can use to offer certain usage rights to the public while reserving other rights. This licensing allows content to be distributed within the boundaries of copyright laws, ensuring that creators get credit for their work while allowing for non-commercial distribution and use of the

[3] Proportion out of all genres labels generated for music data used for each paper in that year's ISMIR. The authors found 15 instances of genre usage in ISMIR 2000, 190 in ISMIR 2009, and 132 in 2018.
[4] Note that one dataset can be put into multiple categories.

Category	Creation Count	Release Count
CC	10	22
PD	16	32
COM	9	5
IH	18	5
LIB	9	9
MET	9	0
PER	4	9
SHO	12	12
unclear	17	12

Table 1: Classifications of datasets in ISMIR 2018 [3]. Creation count is the number of datasets in each form as gathered by dataset creator, while release count refers to the number of datasets in each form as released for use. There were a number of papers that were not clear on the dataset that they used.

copyrighted material [9, 19]. There are six types of Creative Commons licenses, all applicable worldwide [9, 19].

Before the emergence of Creative Commons in 2002 [8], early MIR research used small and idealized data sets [24]. This is evident in the proceedings of the first ISMIR conference held in 2000, which suffered from a lack of data. Out of the ten papers published in the proceedings, only six described the datasets used. Out of these six, just two papers – [21, 30] – used existing databases, while the other four had to gather data on their own. In comparison with ISMIR 2000, ISMIR 2018 has expanded not just in the scope and complexity of MIR research, but also in the number of datasets referenced, leveraging the resources licensed under Creative Commons or in the public domain.

3.3 Popular Databases Today

Some of the most influential datasets are *Million Song Dataset* (*MSD*), *RWC* and *MedleyDB*. As of June 2019, according to Semantic Scholar, these sets were cited 560, 364, and 124 times respectively. [10] Some CC and OPS datasets such as *Jamendo* are popular, but their influence is difficult to quantify because citations are often not explicitly required. [11] Both *MedleyDB* and *Jamendo* rely on Creative Commons for copyright-free distribution of music files [7, 20].

In ISMIR 2018 alone, the *MSD* was used in 11 different papers, making it one of the most frequently cited datasets in that conference. Released in 2011, the *MSD* is a freely available collection of derived Echo Nest features and metadata of one million contemporary Western commercial songs [6]. The dataset can be used along with `7digital` to fetch short samples of songs within certain limitations for free [6].

This lack of audio is not unusual; our investigations (described in Section 3.1) found that about one-fifth of all datasets used in ISMIR 2018 do not contain any audio files. Research on this kind of data is limited to the provided features (by Echo Nest in the case of *MSD*), and does not allow for the kind of in-depth investigation that audio data provides. However, the model of collaborating with free, community-driven datasets as well as commercial companies has served as a good solution for expanding the scale of MIR datasets without violating copyright law.

Due to copyright limitations, many MIR researchers also choose to use music databases that consist exclusively of public domain works, Creative Commons works, or those with limited features of the raw audio. The *Classical Music Archive*, for instance, is a large repository of classical music with each track existing in public domain [5]. The pervasiveness of classical music (and dirth of other genres) in the public domain leads to research being greatly skewed towards the classical genre with other genres being explored much less. Although this research remains important, it is worth pointing out that the vast majority of music produced today is not classical, and is not encompassed by these studies.

Other datasets avoid copyright infringement by omitting material subject to copyright. For instance, *AcousticBrainz* is a publicly available database that is entirely composed of features extracted from songs, rather than the songs themselves [5]. *AcousticBrainz* extracts features on the song level, accumulating the values researchers might want to use and associating them with songs without storing any audio [5]. Similarly, in 2006, *OMEN* was proposed as a system of feature extraction that would take place in libraries [22]. The proposal indicates a method of communication between researchers and libraries that would allow researchers to request specific features from a specific song that would then be extracted by librarians. Frameworks such as *OMEN* would help researchers circumvent copyright and the cost of in-house datasets while protecting content created by artists through the separation of music from its features to create more available music data.

3.4 Many Datasets; Yet Limited Data & Data Access

Despite the numerous cited datasets, an issue repeatedly raised within MIR is the existence of bias [12] in data commonly used in the field. Bias is frequently inevitable due to lack of resources. For example, the structural segmentation task in MIREX 2010 used two datasets with 397 songs in total almost exclusively biased towards Western popular music [15]. This was partially because the data were donated by a few universities and were therefore limited in quantity and diversity. A new annotated dataset with over 1,300 songs covering pop, jazz, classical and world music then became available in 2011 [15], and has been used since in the structural segmentation task of MIREX.

Community and partnership-driven data initiatives have provided working data access to further MIR research. However each member of the MIR community faces

[10] Accessed on June 23, 2019

[11] https://www.jamendo.com/

[12] Bias can exist in terms of geographic location, musical instruments, music genres, musical styles and musical fundamentals such as key, harmony, tempo and rhythm.

unique hindrances to accessing data. *MSD* and Creative Commons currently help researchers bypass these challenges with innovative solutions, but do not support a data access framework for the MIR community as a whole.

4. PROPOSALS

As concerns about access and reproducibilty mount, we offer proposals to increase data access that draw upon resources existing within the MIR community. These suggestions seek to address the crisis of reproducibility while working within current copyright law.

The three proposals below tackle these issues from three different parts of the MIR community. The first calls upon our academic partners to build a distributed MIREX. The second asks our industrial partners to leverage their existing infrastructures. The third asks the whole community to expand our support for dataset creators. Noting that MIR researchers around the world fall under different copyright laws given their location, some of these proposals focus on actions that could be taken in the United States (to the benefit of the worldwide community), while others provide potential global solutions.

4.1 Academic Proposal: Distributed MIREX

Our first proposal is a new, decentralized, distributed Music Information Retrieval Exchange (MIREX) system that would build on the success of the existing MIREX infrastructure, while leveraging previously untapped resources to support the development of such a system. Drawing on the strengths of the proposals in [11–13], this distributed MIREX seeks to be a middle ground between small, in-house datasets and large industrial ones – allowing researchers to test algorithms without violating copyright or relying solely on non-copyrighted music.

This proposed system would distribute the responsibilities and challenges associated with running MIREX among three institutions, by creating two new MIREX sites in addition to the current one run by IMIRSEL at University of Illinois Urbana-Champaign (UIUC). Though the startup cost of a new MIREX site is substantial (data, servers, and other infrastructure needs), creating several MIREX locations is a long-term investment in MIR research and future researchers. More MIREX locations will increase the community's opportunities to access music datasets and allow for additional comparisons between algorithms.

4.1.1 Current MIREX

MIREX was created by IMIRSEL as a method to make comparisons between algorithms. The system's process of submitting, running, and returning results ensures that the music data being used is in accordance with US copyright laws [10]. Though MIREX has been a successful tool for MIR research, it presents challenges of accessibility and efficiency. In response to these challenges, several MIR papers have called on the community for help and have proposed a distribution of MIREX responsibilities including: a web service system to give some algorithm execution responsibility to the user [13], a distributed task management [11], a breakdown of the MIR process across labs participating in the NEMA framework with inter-lab communication [12], and a proposal for a distributed computation model that leverages open source methods [23].

4.1.2 Logistics of Distributed MIREX

The first step in creating a distributed MIREX is to identify the additional two sites. We propose that the three sites would not operate in a coordinated fashion, as suggested in [11, 12], other than ensuring that the timings of the runs do not overlap. Undergraduate-focused institutions – common in the US – are ideal for selection as new MIREX locations, as these schools tend to have existing systems for supporting undergraduate student research and student work-study programs.

Within the MIR community, MegsRadio, under the direction of Douglas Turbull, is an example of an undergraduate student driven MIR project that thrived at Ithaca College [36]. MegsRadio ran throughout the year with students addressing technical issues as well as working on user-facing elements of their work [36]. Student involvement similar to that in MegsRadio is what we envision for the proposed distributed MIREX. Additionally, research has suggested that students who do undergraduate research in STEM may be more likely to pursue a graduate/professional degree in a STEM field [14]. It stands to reason that these findings could be extended to MIR, especially the field's technical aspects. As such, intentionally involving more undergraduates in MIR research will help broaden the field and provide some of the labor required to maintain a distributed MIREX system.

In addition to the potential of undergraduate workers, our distributed MIREX's ability to run algorithms on different datasets multiple times per year could allow researchers the the chance to test their work more than once a year. Furthermore, this system could lessen the individual infrastructure-related responsibility of handling the "interim data explosion" problem [12] caused by specific algorithms. More locations could allow for more storage of features created and generated by algorithms, which the current MIREX discards due to storage limitations [12]. The task of maintaining not only the data itself, but any features created by algorithms, would be distributed to various MIREX sites – thus addressing the infrastructure capacity issues in the current model. The current system entails engaging in several hours of intensive back and forth communication with participants about their algorithms as described in [11]. Instead, this distributed MIREX could increase access to more diverse and quality datasets over time as well as foster growth in the MIR community. Additionally, the creation of the distributed MIREX would compliment open source systems like those proposed in [23] at ISMIR 2016.

4.2 Industrial Proposal: Researcher API License

As the MIR field has grown, so have industrial research groups and public-facing technologies. To complement

our academic proposal, we advocate developing a researcher API license that leverages existing industrial infrastructure. This proposed new license would be designed with the workflow of MIR research practices in mind and would allow for actions that are completely disjointed from current developer licenses.

Developer licenses are designed with software developers in mind and possess inherent restrictions that make them unsuited for MIR research. For example, a streaming phone app that allows for streaming from a different platform would be created under a developer license. But actions such as feature extraction, harmonic-percussive separation, and sampling are in violation of most developer licenses (for example, see Section IV.1.a of [33]). These guidelines leave very little room for MIR research of any kind, and similar language exists on other APIs' terms of use, including Soundcloud's API terms of use that prohibits the using of any data from their platform (see [32]).

We propose that companies with existing developer licenses and API infrastructure (such as Spotify and SoundCloud) create a new license that explicitly allows for common MIR practices such as feature extraction and explicitly prohibits using algorithm outputs for commercial or listening purposes, but limits casual listening. To create appropriately narrow language, companies could consult with IMIRSEL who forged similar agreements to build the MIREX [10]. Such a license addresses concerns about data biased towards popular music, as smaller artists can directly share their work on these streaming platforms.

An immediate and real concern with such a license is the potential for abuse. To help address this concern, we propose the creation of an ethics training module similar to those taken by researchers conducting work using human and animal subjects (colloquially referred to as IRB courses). In this ethics training module, MIR researchers would be educated on the ethical, cultural, and financial issues at play in using and misusing music data. MIR researchers would also have to complete various assessments that certify their understanding of these nuanced issues.

This proposal has the potential for global reach as many companies already operate in several countries, and seeks to provide access to more diverse data.

4.3 Community Proposal: Usage and Advocacy

In addition to creating a decentralized MIREX system and an academic API license, the MIR community must also continue to support the current creators and maintainers of research datasets, not only through their use but through advocacy of laws that make them possible in the first place. The passing of laws such as the Music Modernization Act in the US (Section 2.1) affect the MIR community, but the community had no influence on the creation or implementation of this policy.

Since ISMIR is affected by these policy changes, it is important for the society to know about the current policies. It would be beneficial to be involved in the politics behind these laws to ensure that the voices of researchers are heard. Many research societies have created frameworks for government communication. The American Association for the Advancement of Science (AAAS) has the Center for Science Diplomacy, which connects science to policy and allows the strengthening of connections between diplomatic and science communities [17]. The American Mathematical Society (AMS) is a part of the Coalition for National Science Funding and the Task Force on American Innovation, both of which are alliances of professional, academic, and scientific organizations that advocate for issues that affect the members and their communities [31]. These alliances and committees ensure that these fields of research are not negatively affected by policy changes and that the voices of the societies are heard.

As stated on the ISMIR website, one of the purposes of the ISMIR Organization is "to cooperate with representatives of other organizations and disciplines toward the furtherance of music information retrieval" [25]. To achieve this goal, it is necessary to cooperate not only with other research societies but also with the government bodies that create the infrastructures that MIR researchers work under. The creation of an ad-hoc committee or some other system focused on current music policy changes and advocating for music research in policy would benefit the MIR community. Allying with other music research organizations such as the American Musicological Society or the International Musicological Society could also help facilitate change in music policy for the betterment of research. These systems would benefit both the society and the growth of the MIR field as a whole.

5. CONCLUSION: TOWARDS A STRONGER MIR COMMUNITY

We have proposed three possibilities for expanding researcher access to music data. While progress on any of these three proposals will better the field, simultaneous efforts will lead to a collective impact that is greater than the sum of each proposal's individual impacts. For example, as new MIREX locations begin, industrial researchers can consult on how to design and build appropriate infrastructure given the school's constraint. Similarly, in the US model, undergraduate students working in MIR research groups would make excellent testers for early versions of companys' researcher API licenses. Finally, with the creation of an ad-hoc committee (supported by the ISMIR board) representing the interests of MIR researchers to policy-makers and vice versa, the whole MIR community will be better informed about current laws concerning music. This increased awareness will help to continually improve both academic and industrial research efforts.

Unequal access to music data has led to field-wide issues including a crisis of reproducibility and concerns about access. Despite this, future directions and solutions do exist. By implementing the multi-pronged approach outlined in this paper, MIR research can adapt to overcome these obstacles and avoid the looming schism between corporate and independent labs. Moreover, the methods we have proposed will foster cooperation within the field and could lead to greater diversity within MIR.

ABSTRACT

Music Information Retrieval (MIR) tends to focus on the analysis of audio signals. Often, a single music recording is used as representative of a "song" even though different performances of the same song may reveal different properties. A performance is distinct in many ways from a (arguably more abstract) representation of a "song," "piece," or musical score. The characteristics of the (recorded) performance —as opposed to the score or musical idea— can have a major impact on how a listener perceives music. The analysis of music performance, however, has been traditionally only a peripheral topic for the MIR research community. This paper surveys the field of Music Performance Analysis (MPA) from various perspectives, discusses its significance to the field of MIR, and points out opportunities for future research in this field.

1. INTRODUCTION

Music, as a performing art, requires a performer or group of performers to render a musical score into an acoustic realization [38]. This is also true for non-classical music: for example, the 'score' might be a lead sheet or only a structured sequence of musical ideas, a 'performer' could also be a computer rendering audio, and the acoustic realization might be represented by a recording. The performance plays a major role in how listeners perceive a piece of music: even if the score content is identical for different renditions, as is the case in western classical music, listeners may prefer one performance over another and appreciate different 'interpretations' of the same piece of music. These differences are the result of the performers actively or subconsciously interpreting, modifying, adding to, and dismissing score information.

Although the distinction between score and performance parameters is less obvious for other genres of western music, especially ones without clear separation between the composer and the performer, the concept of interpreting an underlying score is still very much present, be it as a live interpretation of a studio recording or a cover version of another artist's song. In these cases, the freedom of the performers' in modifying the score information is often much higher than it is for classical music — reinterpreting a jazz standard can, e.g., include the modification of content related to pitch, harmony, and rhythm.

Performance parameters can have a major impact on a listener's perception of the music [13]. Formally, performance parameters can be structured in the same basic categories that we use to describe audio in general: tempo and timing, dynamics, pitch, timbre [51]. While the importance of different parameters might vary from genre to genre, the following list introduces some mostly genre-agnostic examples to clarify the performance parameter categories:

- *Tempo and Timing* — the score specifies the general rhythmic content, just as it often contains a tempo indicator. While the rhythm is often only slightly modified by performers in terms of micro-timing, the tempo (both in terms of overall tempo as well as expressive tempo variation) is frequently seen only as a suggestion to the performer.
- *Dynamics* — in most cases, score information on dynamics is missing or only roughly defined. The performers will vary loudness based on their plan for phrasing, tension, importance of certain parts of the score, and highlight specific events with accents.
- *Pitch* — the score usually defines the general pitches to play, but pitch-based performance parameters include expressive techniques such as vibrato as well as conscious or unconscious choices for intonation.
- *Timbre* — as the least specific category of musical sound, scores encode timbre parameters often only implicitly (e.g., instrumentation) while performers can, e.g., change playing techniques or the choice of specific instrument configurations (such as the choice of organ registers).

Note that usually the performance to be analyzed is a *recording* and not a live performance; every recording contains processing choices and interventions by sound engineer and editor with potential impact on expressivity — these modifications cannot be separated from the musicians' creation and are thus an integral part of what is investigated [58].

The most intuitive form of Music Performance Analysis (MPA) —discussing, criticizing, and assessing a performance after a concert— has arguably taken place since music was first performed. Early attempts at systematic and empirical MPA can be traced back to the 1930s with vibrato and singing analysis by Seashore [90] and the examination of piano rolls by Hartmann [37]. In the past two decades, MPA has greatly benefited from the advances in audio analysis made by members of the Music Infor-

mation Retrieval (MIR) community, significantly extending the volume of empirical data by simplifying access to a continuously growing heritage of commercial audio recordings. However, while advances in audio content analysis have had clear impact on MPA, the opposite is less true. While there have been publications on performance analysis at ISMIR, the major MIR conference, their absolute number remains comparably small (compare [3, 10, 18, 41, 53, 54, 73, 84, 85, 98, 104, 105] with a title referring to music performance out of approximately 1800 ISMIR papers overall).

Historically, MIR researchers often do not distinguish between score-like information and performance information even if the research deals with audio recordings of performances. For instance, the goal of music transcription, a very popular MIR task, is usually to transcribe all pitches with their onset times [5]; that means that a successful transcription system transcribes two renditions of the same piece of music differently, although the ultimate goal is to detect the same score (note that this is not necessarily true for all genres). Therefore, we can identify a disconnect between MIR research and performance researchers that impedes both the evolution of MPA approaches and robust MIR algorithms, slows gaining new insights into music aesthetics, and hampers the development of practical applications such as new educational tools for music practice and assessment.

The remainder of this paper is structured as follows. The next Sect. 2 presents research on the objective description and visualization of the performance itself, identifying commonalities and differences between performances. The subsequent sections focus on studies taking these objective performance parameters and relating them to either the performer (Sect. 3) or the listener (Sects. 4 and 5). We conclude our overview with a summary on applications of MPA and final remarks in Sect. 6. Note that while performance research has been inclusive of various musical genres, such as the Jingju music of the Beijing opera [33, 118], traditional Indian music [15, 34, 65] and jazz music [1], the vast majority of studies have been concerned with Western classical music. Therefore, the remainder of the paper focuses primarily on Western music.

2. PERFORMANCE MEASUREMENT

A large body of work focuses on a descriptive approach to analyzing performance recordings. Such studies typically extract characteristics such as the tempo curve [69, 75, 77] or loudness curve [82, 90] from the audio and aim at either gaining general knowledge on performances or comparing attributes between different performances/performers based on trends observed in the extracted data.

Several researchers observed a close relationship between musical phrase structure and deviations in tempo and timing [71, 75, 91]. For example, tempo changes in the form of *ritardandi* tend to occur at phrase boundaries [50, 69]. A similar co-occurrence was observed between dynamic patterns and timing [50, 81]. Additionally, Dalla Bella found the overall tempo influences the overall loudness of a performance [16]. There are also indications that loudness can be linked to pitch height [81]. While the close relation of tempo and dynamics to structure has been repeatedly verified, Lerch did not succeed in finding similar relationships between structure and timbre properties in the case of string quartet recordings [50].

Pitch-based performance parameters have been analyzed mostly in the context of single-voiced instruments. Vibrato and its rate has, e.g., been studied for vocalists [17, 90] and violinists [22, 57]. Regarding intonation, Devaney et al. found significant differences between professional and non-professional vocalists in terms of the size of the interval between semi-tones [17].

Other studies use a multitude of performance parameters and aim to identify trends over time. For example, Ornoy and Cohen investigated violin performances of 19th century repertoire recorded in the past two decades [68]. They found a blend of stylistic approaches among violinists which questions the traditional distinction made between a historically informed and a mainstream performance.

The challenges in accessibility and interpretability of the extracted performance parameters have also led researchers to work on more intuitive or condensed forms of visualization that allow describing and comparing different performances beyond the traditional forms of visualization such as tempo curves [69, 75, 77] and scatter plots [50]. The "performance worm," for example, is a pseudo-3D visualization of the tempo-loudness space that allows the identification of specific gestures in that space [23, 48]. Sapp proposed so-called "Timescapes" and "Dynascapes" to visualize subsequence similarities of performance parameters [84, 85].

While most of the studies mentioned above make use of statistical methods to extract, visualize, and investigate patterns in the performance data, few studies make use of Machine Learning (ML) for MPA and performance modeling. However, ML-based approaches are useful for tasks such as composer classification, discovery of performance rules, or modeling performance characteristics. Widmer conducted studies that utilized ML to model expression in musical performance [109, 111, 112] and to learn simple rules from performance data with inductive learning [110]. He also applied ML to identify performers, showing that performer characteristics can be modeled by ML algorithms [112].

The studies presented in this section often follow an exploratory approach; extracting various parameters in order to identify commonalities or differences between performances. While this is, of course, of considerable interest, one of the main challenges is the interpretability of these results. Just because there is a timing difference between two performances does not necessarily mean that this difference is perceptually meaningful. Without this link, however, results can only provide limited insights into which parameters and parameter variations are ultimately important. Another typical challenge in such studies is the reliability of MIR algorithms for automatic annotations. While the accuracy of such algorithms has steadily improved over time, the fact that the majority of studies surveyed here continue to rely on manually-annotated data implies that the state-of-the-art algorithms for automatic annotation still

lack the required degree of accuracy for most tasks.As a result, most analyses are performed on small sample sizes possibly leading to poor generalizability of the studies.

3. PERFORMER

While most studies focus on the extraction of performance parameters or the mapping of these parameters to the listeners' reception (see Sects. 4 and 5), some investigate the capabilities, goals, and strategies of performers. A performance is usually based on an explicit or implicit performance plan with clear intentions [14]. There is, as Palmer verified, a clear relation between reported intentions and objective parameters related to phrasing and timing of the performance [69]. Similar relations between the intended emotionality and loudness and timing measures were reported by Juslin [42] and Dillon [19–21]. For example, projected emotions such as anger and sadness show significant correlations with high and low tempo and high and low overall sound level, respectively. Moreover, a performer's control of expressive variation has been shown to significantly improve the conveyance of emotion. For instance, a study by Vieillard et al. found that listeners were better able to perceive the presence of specific emotions in music when the performer played an expressive (versus mechanical) rendition of the composition [107]. This suggests that the performer plays a fairly large role in communicating an emotional "message" above and beyond what is communicated through the score alone [44]. In addition to the performance plan itself, there are other influences shaping the performance. Acoustic parameters of concert halls such as the early decay time have been shown to impact performance parameters such as tempo [55, 86, 87]. Another interesting area of research is performer error. Repp analyzed performers' mistakes and found that errors were concentrated in mostly unimportant parts of the score (e.g., middle voices) where they are harder to recognize [40], suggesting that performers consciously or unconsciously avoid salient mistakes [80].

There is a wealth of information about performances that can be learned from performers. The main challenge of this direction of inquiry is that such studies have to involve the performers themselves. This limits the amount of available data and possibly excludes well-known and famous artists, resulting in a possible lack of generalizability. Depending on the experimental design, the separation of possible confounding variables (e.g., motor skills, random variations, and the influence of common performance rules) from the scrutinized performance data can be a challenge.

4. LISTENER

Every performance will ultimately be received and processed by a listener. The listener's meaningful interpretation of the incoming musical information relies on a sophisticated network of parameters. These include not only external, or semi-objective parameters such as score or performance-based features, but also "internal" ones such as those shaped by the culture, training, and history of the listener. For this reason, listener-focused MPA remains one of the most challenging and elusive areas of research. However, to the extent that MPA research depends on purely perceptual information (e.g., expressiveness) or intends to deliver perceptually-relevant output (e.g., performance evaluation or reception, similarity), it is imperative to achieve a fuller understanding of the perceptual relevance of the manipulation and interaction of performance characteristics (e.g., tempo, dynamics, articulation).

4.1 Musical expression

When it comes to listener judgments of a performance, it remains poorly understood which aspects are most important, salient, or pertinent for the listener's sense of satisfaction. According to Schubert and Fabian [89], listeners are very concerned with the notion of "expressiveness" which is a complex, multifaceted construct. Discovering which performance characteristics contribute to an expressive performance thus requires dissecting what listeners deem "expressive" as well as understanding the relation and potential differences between measured and perceived performance features. For instance, expressiveness is style-dependent, meaning that the perceived *appropriate* level of expression in a Baroque piece will be different from that of a Romantic piece — something that has been referred to as "stylishness" [25, 45]. In addition, there is the perceived *amount* of expressiveness, which is considered independent of stylishness [88]. Finally, Schubert and Fabian distinguish a third "layer" of expressiveness which arises from a performer's manipulation of various features specifically to alter or enhance emotion [89]. This is distinct from *musical* expressiveness which more generally refers to the manipulation of compositional elements by the performer in order to be "expressive" without necessarily needing to express a specific emotion. Practically speaking, however, it may be difficult for listeners to separate these varieties of expressiveness [89, p.293]), and research has demonstrated that there are interactions between them (e.g., [107]).

4.2 Expressive variation

Several scholars have made significant advances in our understanding of the role of timing, tempo, and dynamics on listeners' perception of music. As noted in Sect. 2, the subtle variations in tempo and dynamics executed by a performer have been shown to play a large role in highlighting and segmenting musical structure. For instance, changes in timing and articulation within small structural units such as the measure, beat, or sub-beat appear to aid in the communication and emphasis of the metrical structure (e.g., [4, 29, 70, 93]), whereas changes across larger segments such as phrases, aid in the communication of formal structure. In fact, the communication of musical structure has been suggested as one of the primary roles or functions of a successful performer (see [43, 83]). For instance, an experiment by Sloboda found that listeners were better able to identify the meter of an ambiguous passage when performed by a more experienced performer [93]. Through measuring the differences in the performers' expressive

variations, Sloboda identified dynamics and articulation — in particular, a *tenuto* articulation— as the most important features for communicating which notes were accented.

The extent to which a performer's expressive variations align with a listener's musical expectations appears an important consideration. For example, because of the predictable relation between timing and structural segmentation, it has been demonstrated that listeners find it difficult to detect timing (and duration) deviations from a "metronomic" performance when the pattern and placement of those deviations are stylistically typical [66, 77, 78]. Likewise, Clarke [11] found pianists able to more accurately reproduce a performance when the timing profile was "normative" with regards to the musical structure, and also found listeners' aesthetic judgments to be highest for those performances with the original timing profiles compared with those that were inverted or altered.

In addition to communicating structural information to the listener, the role of performance features such as timing and dynamics have also been studied extensively for their role in shaping "expressive" performance (see [12, 30]). For instance, a factor analysis in [89] examined the features and qualities that may be related to perceived expressiveness, finding that dynamics had the highest impact on the factor labeled "emotional expressiveness." Gingras et al. studied the relation between musical structure, expressive variation, and listeners' ratings of musical tension. They found that variations in expressive timing were most predictive of listeners' tension ratings [31]. While the role of expressive variation in timbre and intonation have generally been less studied, there has been substantial attention given to the expressive qualities of the singing voice where these parameters are especially relevant (see [96]). For instance, Sundberg found that a sharpened intonation at a phrase climax contributed to increased expressiveness and perceived excitement [97], and Siegwart and Scherer found that listener preferences were correlated with certain spectral components such as the relative strength of the fundamental and higher spectral centroid [92].

The reason why expressive variation is so enjoyable for listeners remains largely an open research question. As mentioned above, its role appears to go beyond bolstering the communication of musical structure. As pointed out by Repp, even a computerized or metronomic performance will contain grouping cues [83]. However, one prominent theory suggests that systematic performance deviations (such as tempo) may generate aesthetically pleasing expressive performances in part due to their exhibiting characteristics that mimic "natural motion" in the physical world [32, 49, 79, 102, 103] or human movements or gestures [8, 66]. For instance, Friberg and Sundberg suggested that the shape of final ritardandi matched the the velocity of runners coming to a stop [27], and Juslin includes "motion principles" in his model of performance expression [43].

4.3 Mapping and Predicting Listener Judgments

In order to isolate listeners' perception of features that are strictly performance-related, several scholars have investigated listeners' judgments across multiple performances of the same excerpt of music (e.g., [24, 77]). A less-common technique relies on synthesized constructions or manipulations of performances, typically using some kind of rule-based system to manipulate certain musical parameters (e.g., [11, 76, 83, 95]), and frequently making use of continuous data collection measures (e.g., [89]).

From these studies, it appears that listeners (especially "trained" listeners) are capable not only of identifying performance characteristics such as phrasing, articulation, and vibrato, but that they are frequently able to identify them in a manner that is aligned with the performer's intentions (e.g., [26, 63]). However, while listeners may be able to identify performers' intentions, they may not have the perceptual acuity to identify certain features with the same precision allowed by acoustic measures. For instance, a study by Howes [39] showed there was no correlation between measured and perceived vibrato onset times. This suggests that there are some measurable performance parameters that may not map well to human perception. For example, an objectively measurable difference between a "deadpan" and "expressive" performance does not necessarily translate to a *perceived* "expressive" performance, especially if the changes in measured performance parameters are structurally normative, as discussed in Sect. 4.2.

Given a weak relation between a measured parameter and listeners' perception of that parameter, an important question arises: is the parameter itself not useful in modeling human perception, or is the metric simply inappropriate? For example, there are many aspects of music perception that are known to be categorical (e.g., pitch) in which case a continuous metric would not work well in a model designed to predict human ratings. Similarly, there is the consideration of the role of the *representation* and transformation of a measured parameter for predicting perceptual ratings. This question was raised by Timmers, who examined the representation of tempo and dynamics that best predicted listener judgments of musical similarity [101]. This study found that, while most existing models rely on normalized variations of tempo and dynamics, the absolute tempo and the interaction of tempo and loudness were better predictors.

Clearly, the execution of several performance parameters are important for the perception of both fine-grained and large-grained musical structures, and appear to have a large influence over listeners' perception and experience of the emotional and expressive aspects of a performance. Since the latter appears to carry great significance for both MPA and music perception research, it suggests that future work ought to focus on disentangling the relative weighting of the various features controlled by performers that contribute to an expressive performance. Since it is frequently alluded to that a performer's manipulation of musical tension is one of the strongest contributors to an expressive performance, further empirical research must attempt to break down this high-level feature into meaningful collections of well-defined features that would be useful for MPA.

The research surveyed in this section highlights the importance of human perception in MPA research, especially

as it pertains to the communication of emotion, musical structure, and creating an aesthetically pleasing performance. In fact, the successful modeling of perceptually-relevant performance attributes, such as those that mark "expressiveness," could have a large impact not only for MPA but for many other areas of MIR research, such as computer-generated composition and performance, automatic accompaniment, virtual instrument design and control, or robotic instruments and HCI (see, e.g., the range of topics discussed in [46]). A major obstacle impeding research in this area is the inability to successfully isolate (and therefore understand) the various performance characteristics that contribute to a so-called "expressive" performance from a listener's perspective. Existing literature reviews on the topic of MPA have not been able to shed much light on this problem, in part because researchers frequently disagree (or conflate) the various definitions of "expressive." Careful experimental design and/or meta-analyses across both MPA and cognition research, as well as cross-collaboration between MIR and music cognition researchers, may therefore prove fruitful areas for future research.

5. PERFORMANCE ASSESSMENT

Assessment-focused MPA deals with modeling how we as humans assess a musical performance. While this is technically a subset of listener-focused MPA, its importance to MPA research and music education warrants a tailored review of research in this area. Performance assessment is a critical and ubiquitous aspect of music pedagogy: students rely on regular feedback from teachers to learn and improve skills, recitals are used to monitor progress, and selection into ensembles is managed through competitive auditions. The performance parameters on which these assessments are based are not only subjective but also ill-defined, leading to large differences in subjective opinion among music educators [100, 108]. Work within Assessment-focused MPA seeks to increase the objectivity of performance assessments [62], and build accessible and reliable tools for automatic assessment.

Over the last decade, several researchers have worked towards developing tools capable of automatic music performance assessment which can be categorized based on: (i) the parameters of the performance that are assessed, and (ii) the technique/method used to design these systems.

Tools for performance assessment typically assess one or more performance parameters which are usually related to the accuracy of the performance in terms of pitch and timing [56, 72, 106, 113], or quality of sound (timbre) [47, 74]. In building an assessment tool, the choice of parameters may depend on the proficiency level of the performer being assessed. For example, beginners will benefit more from feedback in terms of low-level parameters such as pitch or rhythmic accuracy as opposed to feedback on higher-level parameters such as articulation or expression.

Assessment tools can also vary based on the granularity of assessments. Tools may simply classify a performance as 'good' or 'bad' [47, 64], or grade it on a scale, say from 1 to 10 [72]. Systems may provide fine-grained note-by-note assessments [74] or analyze entire performances and report a single assessment score [64, 72].

While different methods have been used to create performance assessment tools, the common approach has been to use descriptive features extracted from the audio recording of a performance based on which a cognitive model predicts the assessment. This approach requires availability of performance data (recordings) along-with human (expert) assessments for the rated parameters.

The level of sophistication of cognitive models was limited especially for early attempts; e.g., simple classifiers such as Support Vector Machines were used to predict human ratings. In this case, descriptive features became an important aspect of the system design. In some approaches, standard spectral and temporal features such as Spectral Centroid, Spectral Flux, and Zero-Crossing Rate were used [47]. In others, features aimed at capturing cognitive aspects of music perception were hand-designed using either musical intuition or expert knowledge [2, 52, 64, 74]. For instance, Nakano et al. used features measuring pitch stability and vibrato as inputs to a simple classifier to rate the quality of vocal performances [64]. Several studies also attempted to combine low-level audio features with hand-designed feature sets [56, 106, 113], as well as incorporating information from the musical score into feature computation [6, 7, 18, 106].

Recent methods, however, have transitioned towards using advanced ML techniques such as Sparse Coding [36, 114, 116] and Deep Learning [72] as a proxy to sophisticated cognitive models. Contrary to earlier methods which focused on extracting cognitively intuitive or important features, these techniques input raw data (usually in the form of pitch contours or spectrograms) and train the models to automatically learn meaningful features so as to accurately predict the assessment ratings.

In some ways, this evolution in methodology has mirrored that of other MIR tasks: there has been a gradual transition from feature design to feature learning. Feature design and feature learning have an inherent trade-off. Learned features extract relevant information from data which might not be represented in the hand-crafted feature set. This is evident from their superior performance at assessment modeling tasks [72, 114]. However, this superior performance comes at the cost of low interpretability. Learned features tend to be abstract and cannot be easily understood. Custom-designed features, on the other hand, typically either measure a simple low-level characteristic of the audio signal or link to high-level semantic concepts such as pitch or rhythm which are intuitively interpretable. Thus, such models allow analysis that can aid in the interpretation of semantic concepts for music performance assessment. For instance, Gururani et al. analyzed the impact of different features on an assessment prediction task and found that features measuring tempo variations were particularly critical, and that score-aligned features performed better than score-independent features [35].

In spite of several attempts across varied performance parameters using different methods, the important features

for assessing music performances remain unclear. This is evident from the average performance of these tools in modeling human judgments. Most of the presented systems either work well only for very select data [47] or have comparably low prediction accuracies [106, 113], rendering them unusable in most practical scenarios. While this may be partially attributed to the subjective nature of the task itself, there are several other factors which have limited the improvement of these tools. First, most of the models are trained on small task-specific or instrument-specific datasets that might not reflect noisy real-world data. This reduces the generalizability of these models. The problem becomes more serious for data-hungry methods such as Deep Learning which require large amounts of data for training. Second, the distribution of ground-truth (expert) ratings given by human judges is in many datasets skewed towards a particular class or value [35]. This makes it challenging to train unbiased models. Finally, the number of parameters required to adequately model a performance results in high dimensional data. While the typical approach is to train different models for different parameters, this approach necessitates availability of performance data along-with expert assessments for all these parameters. In many occasions, such assessments are either not available or are costly to obtain.

Given these data-related challenges, an interesting direction for future research might consider leveraging models which are successful at assessing a few parameters (and/or instruments) to improve the performance of models for other parameters (and/or instruments). This approach, usually referred to as transfer learning, has been found to be successful in other MIR tasks [9]. In addition, the ability to interpret and understand the features learned by end-to-end models will play an important role in improving assessment tools. Interpretability of neural networks is still an active area of research in MIR, and performance assessment is an excellent test-bed for developing such methods.

6. CONCLUSION

The previous sections outlined insights gained by MPA at the intersection of audio content analysis, empirical musicology, and music perception research. These insights are of importance for better understanding the process of making music as well as affective user reactions to music. Furthermore, they enable a considerable range of applications spanning a multitude of different areas including systematic musicology, music education, MIR, and computational creativity, leading to a new generation of music discovery and recommendation systems, and generative music systems. The most obvious application example connecting MPA and MIR is music tutoring software. Such software aims at supplementing teachers by providing students with insights and interactive feedback by analyzing and assessing the audio of practice sessions. The ultimate goals of an interactive music tutor are to highlight problematic parts of the students' performance, provide a concise yet easily understandable analysis, give specific and understandable feedback on how to improve, and individualize the curriculum depending on the students' mistakes and general progress. Various (commercial) solutions are already available, exhibiting a similar set of goals. These systems adopt different approaches, ranging from traditional music classroom settings to games targeting a playful learning experience. Examples for tutoring applications are SmartMusic [59], Yousician [117], Music Prodigy [99], and SingStar [94].

Performance parameters have a long history being either explicitly or implicitly part of MIR systems. For instance, core MIR tasks such as music genre classification and music recommendation systems have been utilizing tempo and dynamics features successfully [28]. Generative models often require performance data to allow for the rendition of a convincing output. This obviously includes performance rendition systems that take a score and attempt to render a human-like output [60, 67], but it is also important for models of improvisation such as jazz solos as pitch information is part of the performance.

Despite such practical applications, there are still many open topics and challenges that need to be addressed. The main challenges of MPA have been summarized at the end of the sections above. The related challenges to the MIR community, however, are multi-faceted as well. First, the fact that the majority of the presented studies use manual annotations instead of automated methods should encourage the MIR community to re-evaluate the measures of success of their proposed systems if, as it appears to be, the outputs lack the robustness or accuracy required for a detailed analysis even for tasks considered to be 'solved.' Second, the missing separation of score and performance parameters when framing research questions or problem definitions can impact not only interpretability and reusability of insights but might also reduce algorithm performance. If, e.g., a music emotion recognition system does not differentiate between the impact of core musical ideas and performance characteristics, it will have a harder time differentiating relevant and irrelevant information. Thus, it is essential for MIR systems to not only differentiate between score and performance parameters in the system design phase but also analyze their respective contributions during evaluation. Third, lack of data continues to be a challenge for both, MIR core tasks and MPA; a focus on approaches for limited data [61], weakly labeled data, and unlabeled data [115] could help address this problem..

In conclusion, the fields of MIR and MPA each depend on the advances in the other field. In addition, music perception and cognition, while not a traditional topic within MIR, can be seen as an important linchpin for the advancement of MIR systems that depend on reliable and diverse perceptual data. Cross-disciplinary approaches to MPA bridging methodologies and data from music cognition and MIR are likely to be most influential for future research. Empirical, descriptive research driven by advanced audio analysis is necessary to extend our understanding of music and its perception, which in turn will allow us to create better systems for music analysis, music understanding, and music creation.

ABSTRACT

Providing means to assist the user in finding music is one of the original motivations underlying the research field known as Music Information Retrieval (MIR). Therefore, already the first edition of ISMIR in the year 2000 called for papers addressing the topic of "User interfaces for music IR". Since then, the way humans interact with technology to access and listen to music has substantially changed, not least driven by the advances of MIR and related research fields such as machine learning and recommender systems.

In this paper, we reflect on the evolution of MIR-driven user interfaces for music browsing and discovery over the past two decades. We argue that three major developments have transformed and shaped user interfaces during this period, each connected to a phase of new listening practices: first, connected to personal music collections, intelligent audio processing and content description algorithms that facilitate the automatic organization of repositories and finding music according to sound qualities; second, connected to collective web platforms, the exploitation of user-generated metadata pertaining to semantic descriptions; and third, connected to streaming services, the collection of online music interaction traces on a large scale and their exploitation in recommender systems.

We review and contextualize work from ISMIR and related venues from all three phases and extrapolate current developments to outline possible scenarios of music recommendation and listening interfaces of the future.

1. INTRODUCTION

With a history of five years of ISMIR conferences, in 2004, Downie [11] attempts to define the research field of Music Information Retrieval (MIR) as "a multidisciplinary research endeavor that strives to develop innovative content-based searching schemes, novel interfaces, and evolving networked delivery mechanisms in an effort to make the world's vast store of music accessible to all". Given the music industry landscape and how people listen to music 15 years later, this definition has not only stood the test of time, but also proven to be visionary.

With its origins in Information Retrieval research (cf. [5]), one of the original motivations underlying MIR was indeed to develop technology and provide means to assist the user in finding music. As the way humans interact with technology to access and listen to music has substantially changed since then, user interfaces for music discovery remain to be a pivotal element in MIR research. [1]

In this paper, we reflect on the evolution of MIR-driven user interfaces for music browsing and discovery over the past two decades—from organizing personal music collections to streaming a personalized selection from "the world's vast store of music". Therefore, we connect major developments that have transformed and shaped MIR research in general and user interfaces in particular to prevalent and emerging listening practices at the time. We identify three main phases that have each laid the foundation for the next and review work that focuses on the specific aspects of these phases.

First, we investigate the phase of growing digital personal music collections and interfaces built upon intelligent audio processing and content description algorithms in section 2. These algorithms facilitate the automatic organization of repositories and finding music in personal collections, as well as commercial repositories according to sound qualities. Second, in section 3, we investigate the emergence of collective web platforms and their exploitation for listening interfaces. The extracted user-generated metadata often pertains to semantic descriptions and complements the content-based methods that facilitated the developments of the preceding phase. This phase also constitutes an intermediate step towards exploitation of collective listening data, which is the driving force behind the third, and ongoing phase, which is connected to streaming services (section 4). Here, the collection of online music interaction traces on a large scale and their exploitation in recommender systems are defining elements.

[1] So do interfaces for "active listening," aiming at increasingly engaging the listener through augmented experiences and allowing also musically untrained listeners to gain deeper insights into aspects of the music they are consuming [20]. However, in this work we will not emphasize these interfaces.

Extrapolating these and other ongoing developments, we outline possible scenarios of music recommendation and listening interfaces of the future in section 5.

2. PHASE 1: CONTENT-BASED MUSIC RETRIEVAL INTERFACES

Based on the technological advancements in encoding and compression of audio signals (most notably mp3) together with the establishment of the Internet as mainstream communication medium and distribution channel, and, in rapid succession, the development of high capacity portable music players in the late 1990s, digital music has not only stirred up the IT industry, but also initiated a profound change in the way people "use" music.

At the time, the most popular and conventional interfaces for such music access display the list of bibliographic information (metadata) such as titles and artist names. When the number of musical pieces in a personal music collection was not large, music interfaces with the title list and mere text searches based on bibliographic information were useful enough to browse the whole collection to choose pieces to listen to. However, as the accessible collection grows, such simple interfaces become insufficient, and new research approaches targeting the retrieval, classification, and organization of music emerge.

"Intelligent" interfaces for music retrieval became a research field of interest with the developments in content-based music retrieval [6]. A landmark in this regard was the development of query by humming systems [31] and search engines indexing sound properties of loudness, pitch, and timbre [77] that initiated the emancipation of music search systems from traditional text- and metadata-based indexing and query interfaces. While interfaces were still very much targeted at presenting results in sequential order according to relevance to a query, in the early 2000s, MIR research proposed several alternatives to facilitate music discovery.

2.1 Map-based music browsing and discovery

Interfaces that allow content-based searches for music retrieval are useful when people can formulate good queries and especially when users are looking for a particular work, but sometimes it is difficult to come up with an appropriate query when faced with a huge music collection and vague search criteria. Interfaces for music browsing and discovery are therefore proposed to let users encounter unexpected but interesting musical pieces or artists. Visualization of a music collection is one way to provide users with various bird's-eye views and comprehensive interactions. The most popular visualization is to project musical pieces or artists onto a 2D or 3D space by using music similarity. 2D visualizations also lend themselves to being applied on tabletop interfaces for intuitive access and interaction, e.g. [30]. The trend of spatially arranging collections for exploration can be seen throughout the past 20 years and is still unbroken.

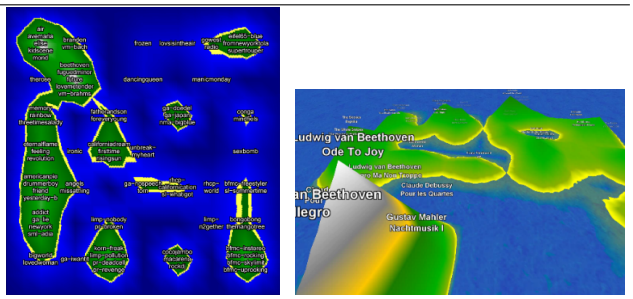

Figure 1. Islands of Music (left) and nepTune (right): music browsing interfaces that let a user explore a music collection by using a metaphor of "islands" visualizing self-organized clusters.

One of the earliest interfaces is *GenreSpace* [69] that visualizes musical pieces with genre-specific colors in a 3D space. Coloring of each piece is determined by automatic genre classification. The layout of pieces is determined by principal component analysis (PCA), which projects high-dimensional audio feature vectors into 3D positions. This idea is frequently used in other more recent interfaces.

Another early interface called *Islands of Music* [48] visualizes musical pieces on a 2D space representing an artificial landscape. It uses a self-organizing map (SOM) to arrange musical pieces so that similar pieces are located near each other. As shown on the left side in Figure 1, it uses a metaphor of "islands" that represent self-organized clusters of similar pieces. The denser the regions (more items in the same cluster), the higher the landscape (up to "mountains" for very dense regions). Sparse regions are represented by the ocean. This interface provides three different views corresponding to similarities based on three aspects: (1) timbre analysis, (2) rhythm analysis, and (3) metadata like artist and genre. A user can smoothly change focus from one view to another while exploring how the organization changes. Several extensions of the Islands of Music idea were proposed in following years. An aligned SOM is used by Pampalk et al. in [48] to enable a seamless shift of focus between clusterings created for different musical aspects, for instance, between a SOM created only on rhythm features and one created only on timbre features. The *nepTune* interface presented by Knees et al. in [36], as shown on the right side in Figure 1, enables exploration of music collections by navigating through a three-dimensional artificial landscape. Variants include a mobile version [27] and a larger-scale version using a growing hierarchical self-organizing map (GHSOM) [10] that automatically structures the map into hierarchically linked individual SOMs [57]. Neumayer et al. propose a method to automatically generate playlists by drawing a curve on the SOM visualization [47]. Lübbers and Jarke [42] present a browser employing multi-dimensional scaling (MDS) and SOM to create 3-dimensional landscapes. In contrast to the *Islands of Music* metaphor, they use an inverse height map, meaning that agglomerations of songs are visualized as valleys, while clusters are separated by mountains. Their interface further enables the user to adapt

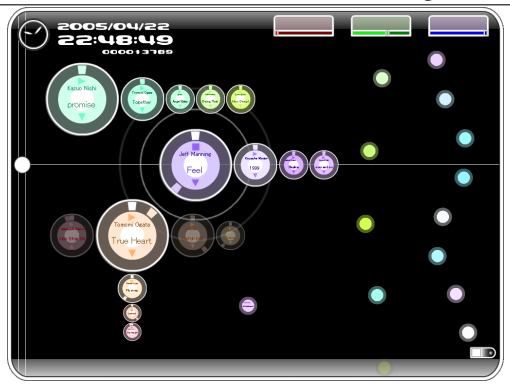

Figure 2. Musicream: A music playback interface that lets a user unexpectedly come across various musical pieces similar to those liked by the user.

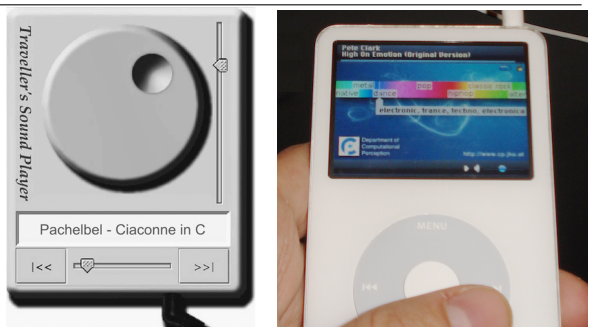

Figure 3. "Reinventing the Wheel" (left) and its application on an iPod using the dial for browsing the collection (right).

the landscape by building or removing mountains, which triggers an adaptation of the underlying similarity measure.

Another SOM-based browsing interface is *Globe of Music* [40], which maps songs to a sphere instead of a plane by means of a GeoSOM [78]. Mörchen et al. [46] employ an emergent SOM and the U-map visualization technique [70] to color-code similarities between neighboring clusters. Vembu and Baumann incorporate a dictionary of musically related terms to describe similar artists [74].

In the *Search Inside the Music* application [38], Lamere and Eck use a three-dimensional MDS projection. Their interface provides different views that arrange images of album covers according to the output of the MDS, either in a cloud, a grid, or a spiral. Vad et al. [71] apply t-SNE [72] to mood- and emotion-related descriptors, which they infer from low-level acoustic features. The result of the data projection is visualized on a two-dimensional map, around which the authors build an interface to support the creation of playlists by drawing a path and by area selection.

While the above interfaces focus on musical pieces, interfaces focusing on artists have also been investigated. For example, *Artist Map* [73] is an interface that enables users to explore and discover artists. This interface projects artists onto a 2D space and visualizes them as small dots with genre-specific, tempo-specific, or year-specific colors. This visualization can also be used to create playlists by drawing paths and specifying regions.

Other examples use, e.g., metaphors of a "galaxy" or "cosmos," or extend visualizations with additional information. *MusicGalaxy* [65], for example, is an exploration interface that uses a similarity-preserving projection of musical pieces onto a 2D galaxy space. It takes timbre, rhythm, dynamics, and lyrics into account in computing the similarity and uses an adaptive non-linear multi-focus zoom lens that can simultaneously zoom multiple regions of interest while most interfaces support only a single region zooming. As a similar metaphor, "planetarium" has been used in *Songrium*, [2] a public web service for interactive visualization and exploration of *web-native music* on video sharing services [23]. It uses similarity-preserving projection of pieces onto both 2D and 3D galaxy spaces and provides various functions: analysis and visualization of derivative works, and interactive chronological visualization and playback of musical pieces. *Instrudive* [66] enables users to browse and listen to musical pieces by focusing on instrumentation detected automatically. It visualizes each musical piece as a multicolored pie chart in which different colors denote different instruments. The ratios of the colors indicate relative duration in which the corresponding instruments appear in the piece.

[2] `https://songrium.jp`

2.2 Content-based filtering and sequential play

When a collection of music becomes huge, it is not feasible to visualize all pieces in the collection. Other types of interfaces that visualize a part of the music collection instead of the whole have also been proposed. An example is *Musicream* [21], a user interface that focuses on inducing active user interactions to discover and manage music in a huge collection. The idea behind Musicream is to see if people can break free from stereotyped thinking that music playback interfaces must be based on lists of song titles and artist names. To satisfy the desire "I want to hear something," it allows a user to unexpectedly come across various pieces similar to ones that the user likes. As shown on the right side in Figure 2, disk icons representing pieces flow one after another from top to bottom, and a user can select a disk and listen to it. By dragging a favorite disk in the flow, which serves as the query, the user can easily pick out other pieces similar to the query disk (attach similar disks) by using content-based similarity. In addition, to satisfy a desire like "I want to hear something my way," Musicream gives a user greater freedom of editing playlists by generating a playlist of playlists. Since all operations are automatically recorded, the user can also visit and retrieve a past state as if using a time machine.

The *FM4 Soundpark Player* makes content-based suggestions by showing up to five similar tracks in a graph-like manner [17] and constructing "mixtapes" from given start and end tracks [15]. *VocalFinder* [16] enables content-based retrieval of songs with vocals that have similar vocal timbre to the query song.

Visualization of a music collection is not always necessary to develop music interfaces. Stewart et al. [64] present

an interface that uses only sound auralization and haptic feedback to explore a large music collection in a two or three-dimensional space.

The article *"Reinventing the Wheel"* [51] revealed that a single-dial browsing device can be a useful interface for musical pieces stored on mobile music players. The whole collection is ordered in a circular locally-consistent playlist by using the Traveling Salesman algorithm so that similar pieces can be arranged adjacently. The user may simply turn the wheel to access different pieces. This interface also has the advantage of combining two different similarity measures, one based on timbre analysis and the other based on community metadata analysis. Figure 3 shows the conceptual prototype as well as an extended implementation on an Apple iPod [60], the most popular mobile listening device at the time.

3. PHASE 2: COLLABORATIVE AND AUTOMATIC SEMANTIC DESCRIPTION

While content-based analysis allowed for unprecedented views on music collections based on sound, interfaces built solely upon the extracted information were not able to "explain" the music contained or give semantically meaningful support for orientation within the collections. That is, while they are able to capture qualities of the sound of the contained music, they largely neglect human concepts of music organization, such as (sub-)genres or listening purposes, e.g., during activities like workouts. This information is however typically found on the web and ranges from user-generated tags to unstructured bits of expressed opinions (e.g., forum posts or comments in social media) to more detailed reviews and encyclopedic articles (containing, e.g., biographies and discography release histories). In MIR, this type of data is often referred to as community metadata or music context data [35]. These online "collaborative efforts" of describing music are resulting in a rich vocabulary of semantic labels and have shaped music retrieval interfaces towards music information systems. In parallel, platforms like *Last.fm* [3] (in this context better: *AudioScrobbler*), take advantage of users being increasingly always connected to the Internet and tracking listening events for the sake of identifying listening patterns and making recommendations, leading to the phase of automatic playlisting and music recommendation (cf. section 4). In this section, we focus on tags as a main driver of MIR research and music interfaces.

3.1 Collaborative platforms and music information systems

With music related information being ubiquitous on the web, dedicated web platforms that provide background knowledge on artists emerge, e.g., the AllMusic Guide, depending on editorial content. Using new technologies, such music information systems can, however, also be built by aggregating information extracted from various sources using text mining methods [59] or by taking advantage of

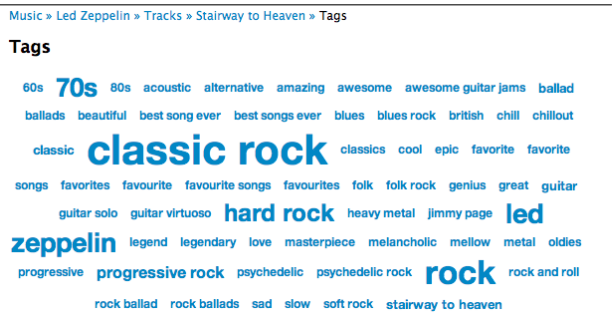

Figure 4. Last.fm tags of Led Zeppelin (source: `https://musicmachinery.com/tag/lastfm/`)

the "wisdom of the crowd" and building collaborative platform like the above mentioned Last.fm.

A central feature of Last.fm is to allow users to tag their music, ideally resulting in a democratic ground truth of what could be considered the semantic dimensions of the corresponding tracks, cf. Figure 4. However, typical problems arising with this type of information are noisy and non-trustworthy information as well as data sparsity and cold start issues mostly due to popularity biases, cf. [37].

MIR research during this phase has therefore dealt extensively with auto-tagging, i.e., automatically inferring semantic labels from the audio signal of a music piece (or related data), to overcome this shortcoming, e.g., [3, 12, 33, 44, 63, 68, 76].

Alternative approaches to generate semantic labels include human workforce. *TagATune* [39] is a game that pairs players across the Internet who try to determine whether they are listening to the same song by typing tags. In return for entertaining users, TagATune has collected interesting tags for a database of songs. Other examples of interfaces that were designed to collect useful information while engaging with music are *MajorMiner* [43], *HerdIt* [2], and *Moodswings* [34] (cf. section 4.1).

A more traditional way to obtain musically informed labels is to have human experts, e.g. trained musicians, manually label music tracks according to predefined musical categories. This approach is followed by the Music Genome Project, [4] and serves as the foundation of *Pandora's* automatic radio stations (cf. section 4).

As a consequence of these efforts, during this phase, the question of how to present and integrate this information into interfaces was secondary to the question of how to obtain it, as will become obvious next.

3.2 Visual interfaces

With the trend towards web-based interfaces, visualization and map based interfaces integrating semantic information have been proposed.

MusicRainbow [49] is a user interface for discovering unknown artists, which follows the above idea of a single-dial browsing device but features informative visualization. As shown in Figure 5, artists are mapped on a circular rainbow where colors represent different styles of music.

[3] `https://last.fm`

[4] `https://www.pandora.com/about/mgp`

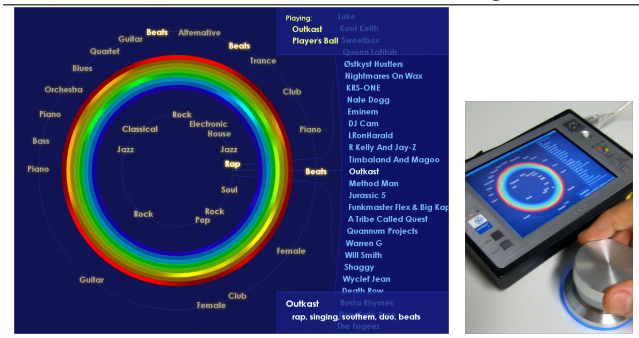

Figure 5. MusicRainbow: An artist discovery interface that enables a user to actively browse a music collection by using audio-based similarity and web-based labeling.

Similar artists are automatically mapped near each other by using the Traveling Salesman algorithm and summarized with word labels extracted from artist-related web pages. A user can rotate the rainbow by turning a knob and find an interesting artist by referring to the word labels.

The *nepTune* interface shown in Figure 1 also provides a mode that integrates text-based information extracted from artist web pages for supporting navigation in the 3D environment. To this end, labels referring to genres, instruments, origins, and eras serve as landmarks.

Other approaches explore music context data to visualize music over real geographical maps, rather than computing a clustering based on audio descriptors. For instance, Govaerts and Duval extract geographical information from biographies and integrate it into a visualization of radio station playlists [22]. Hauger and Schedl extract listening events and location information from microblogs and visualize both on a world map [25].

Lyrics are also important elements of music. By using semantic topics automatically estimated from lyrics, new types of visual interfaces for lyrics retrieval can be achieved. *LyricsRadar* [55] is a lyrics retrieval interface that uses latent Dirichlet allocation (LDA) to analyze topics of lyrics and visualizes the topic ratio for each song by using the topic radar chart. It then enables a user to find her favorite lyrics interactively. *Lyric Jumper* [67] is a lyrics-based music exploratory web service that enables a user to choose an artist based on topics of lyrics and find unfamiliar artists who have similar profile to her favorite artist. It uses an advanced topic model that incorporates an artist's profile of lyrics topics and provides various functions such as topic tendency visualization, artist ranking, artist recommendation, and lyric phrase recommendation.

4. PHASE 3: RECOMMENDER INTERFACES AND CONTINUOUS STREAMING

With ubiquitous Internet connection and a development of computer and entertainment systems to be always online, personal music collections have lost relevance to many people, as virtually all music content is available at all times. In essence, such subscription streaming services like Spotify, Pandora, Deezer, Amazon Music, or Apple Music have transformed the music business and music listening alike.

Central element to these services is the aspect of personalization, i.e., providing foremost a user-tailored view onto the available collections of allegedly tens of millions of songs. Discovery of music is therefore performed by the system, based on the user profile of past interactions, rather than by the user herself.

Interfaces for music recommendation can support music listening in more personalized ways. Music recommendation typically models personal preferences of users by using their listening histories or explicit user feedback, e.g. [7, 62]. It then generates a set of recommended musical pieces or artists for each user. This recommendation can be implemented by using collaborative filtering based on users' past behaviors and exhibits patterns of music similarity not captured by content-based approaches [61]. When the playback order of recommended pieces is important, automatic playlist generation is also used, e.g. [4, 24, 45].

The main challenges of this type of algorithms are, as in all other domains of recommender systems, cold start problems. The approach taken to remedy these are again to integrate additional information on the music items to recommend, i.e. facets of content and metadata as applied in the earlier phases, by building hybrid recommenders on top of pure collaborative filtering. Additionally, context-awareness plays an important role, for instance to recommend music for daily activities [75].

An overview over aspects, techniques, and challenges of music recommender systems can be found in [58]. Therefore, in this section, we do not elaborate on the basics of music recommender systems but highlight again interfaces that focus on personalization and user-centric aspects, as we consider these to be the bridge to future intelligent music listening interfaces.

4.1 Recommender interfaces

Although most related studies have focused on methods and algorithms of music recommendation and playlist generation, some studies focus on interfaces.

MusicSun [50] is a user interface for artist recommendation. A user first puts favorite artist names into a "sun" metaphor, a circle in the center of the screen, and then obtains a ranked list of recommended artists. The sun is visualized with some surrounding "rays" that are labeled with words to summarize the query artists in the sun. By interactively selecting a ray, the user can look at and listen to the corresponding recommended artists.

Moodplay [1] is an interactive music recommender system that uses a hybrid recommendation algorithm based on mood metadata and audio content. A user first constructs a profile by entering favorite artist names and then obtains a ranked list of recommended artists. It highlights those artist positions in a latent mood space visualization, showing various mood labels. The centroid of profile artist positions is used to recommend nearby artists. The change of a user's preference is interactively modeled by moving

in this space and its trail is used to recommend artists.

In *MoodSwings* [34], users try to match each other while tracing the trajectory of music through a 2D emotion space. The users' input provides metadata on the emotional impression of songs as it changes over time.

Recent studies deal with the design of recommender user interfaces regarding complexity and user control [28] and the implications of recommender techniques on the discovery of music in playlist building [32].

4.2 Psychologically-inspired music recommendation

Recently, music recommender research is experiencing a boost on topics related to psychology-informed recommendation. In particular the psychological concepts of personality and affect (mood and emotion) are increasingly integrated into prototypes. The motivation for this is that while listening to music both personality traits and affective states have been shown to strongly influence music preferences [14, 52, 56].

Lu and Tintarev [41] propose a system that re-ranks results of a collaborative filtering approach according to the degree of diversity each song contributes to the recommendation list. Since previous studies showed that personality is most strongly correlated with music key, genre, and number of artists, the authors implement diversity through these features and adjust results depending on the listener's personality. Fernández-Tobías et al. [13] propose a personality-aware matrix factorization approach that integrates a latent user factor describing users' personality in terms of the Big Five/OCEAN model (openness, conscientiousness, extraversion, agreeableness, and neuroticism) [29]. Deng et al. [9] propose an emotion-aware recommender for which they extract music listening information and emotions from posts in Sina Weibo, [5] a popular Chinese microblogging service, adopting a lexicon-based approach (Chinese dictionaries and emoticons). *FocusMusicRecommender* [79] recommends and plays back musical pieces suitable to the user's current concentration level estimated from the user's behavior history.

5. THE NEXT PHASE: THE FUTURE OF INTELLIGENT MUSIC USER INTERFACES

In terms of interfaces, we observe strong trends towards context-awareness and personalization, also on the level of individual user and personality traits that should guide the recommendation process when other sufficient interaction data is unavailable. The central challenge behind these facets is to accurately infer the user's intent in an action (listening, skipping, etc.), i.e., to uncover the reasons why humans indulge in music, from the comparatively limited signal that is received.

On the other hand, we see the development in the realm of music generation and variation algorithms, which permit to create content based on large repositories of examples (cf. recent work by *Google Magenta* [6] [26, 53, 54]) and/or with the help of informed rules and templates, e.g., for automatic video soundtrack creation or adaptive music generation in video games marketed by companies such as *Jukedeck* [7] or *Melodrive*, [8] respectively.

In the long run, we expect the border of these domains to blur, i.e., there will be no difference in accessing existing, recorded music and music automatically created by the system tailored to the listener's needs. More concretely, as discussed as one of grand challenges in MIR in [19], we envision music streaming systems that deliver preferred content based on the user's current state and situational context, automatically change existing music content to fit the context of the user, e.g., by varying instruments, arrangements, or tempo of the track, [9] and even create new music based on the given setting.

With the current knowledge of streaming platforms about a user's preferences, context sensing devices running the music apps, and first algorithms to variate and generate content, the necessary ingredients for such a development seem to be available already.

6. CONCLUSIONS

We identified three phases of listening culture and discussed corresponding intelligent interfaces. Interfaces pertaining to the first phase focus on structuring and visualizing smaller scale music collections, such as personal collections or early digital sales repositories. In terms of research prototypes, this phase is most driven by content-based MIR algorithms. The second phase deals with web-based interfaces and information systems, with a strong focus on textual descriptions in the form of collaborative tags. MIR research during this phase therefore deals with automatic tagging of music and utilization of tag information in interfaces. Finally, the third and current phase is shaped by lean back experiences driven by automatic playlist algorithms and personalized recommendation systems. MIR research is therefore shifting towards exploitation of user interaction data, however always with a focus on integration of content-based methods, community metadata, user information, and contextual information of the user. While the former three strategies are typically applied to remedy cold start problems, integrating context-awareness is often an additional source thereof.

The trend of personalizing listening experiences leads us to belief that, in the not too distant future, music listening will not only be a matter of delivering the right music at the right time, but also of generating and "shaping" the right music for the situation the user is in. We will therefore see a confluence of music retrieval and (interactive) music generation – with ample challenges for MIR research ahead.

ABSTRACT

In 1999, Fujishima published *Realtime Chord Recognition of Musical Sound: a System using Common Lisp Music*. This paper kickstarted an active research topic that has been popular in and around the ISMIR community. The field of Automatic Chord Recognition (ACR) has evolved considerably from early knowledge-based systems towards data-driven methods, with neural network approaches arguably being central to current ACR research. Nonetheless, many of its core issues were already addressed or referred to in the Fujishima paper. In this paper, we review those twenty years of ACR according to these issues. We furthermore attempt to frame current directions in the field in order to establish some perspective for future research.

1. INTRODUCTION

This year marks the twentieth anniversary of Fujishima's [17] seminal ACR system. In this work the author proposed the calculation of a 12-D chroma feature which gets compared to a dictionary of binary chord templates. The label of the most similar chord template is then considered to be the chord output. Fujishima also proposed exploiting the temporal continuity of chords by smoothing the chromas across time to produce less noisy labels, and suggested that musical information could be exploited. This system outline created the framework within which much of the early research on ACR would happen.

Perhaps the most striking evolution in ACR has been the move from knowledge-driven to data-driven systems. Initially, data-driven elements were used as one-for-one replacements, or additions, of elements to the framework set by Fujishima. Examples are more sophisticated chroma features, learnt Gaussian chord models or HMM-based temporal models. More recently ACR research has been dominated by Deep Learning (DL). In DL-ACR the relationship of tasks and elements becomes blurred as systems have become more integrated. This is perhaps most evident in the system of McFee and Bello [40], which appears superficially to be a singular unit, although closer inspection reveals convolutional filters providing short-term context, recurrent elements modelling musical language, chroma, and auxiliary targets for extra musical context. We therefore consider that the system outline provided by Fujishima is still valid in a discussion of ACR.

ACR systems have developed considerably in these twenty years and commercial products providing such functionality have recently been developed. However, there is still room for improvement. For instance, while ACR results have continually progressed, complex chords are still recognised less well than major and minor triads. Nonetheless, ACR results have improved to the point where the ambiguity in chord labels is now becoming a topic of research. Such ambiguity can be introduced by the chord labels themselves, or may result from different interpretations of chord and melody. An interesting aspect of modern ACR research derived from user research in commercial products is the prediction of user interpretations in the presence of ambiguity.

In the rest of this paper we review previous and current research in ACR. Based on such review, we propose several areas that have potential for improvement in ACR. We first consider the related features and chord models, before discussing temporal and musical context. We furthermore consider ambiguity and subjectivity in ACR, and problems associated with chord vocabularies before concluding.

2. PROBLEM 1: FINDING AN APPROPRIATE FEATURE REPRESENTATION

The chroma feature has been perhaps the most influential idea in ACR, and much early ACR research focused on producing chroma variants. Typically the chroma feature is calculated by summing the energy of elements of the same pitch class in a preliminary pitch spectrum feature. In Fujishima's paper, and subsequent others, the pitch feature was calculated by gathering the energy under windows of a spectrogram that are positioned logarithmically in frequency. Later approaches used a constant-Q transform (CQT) [4] which places windows on a multi-scale spectrogram, affording higher resolution of low frequencies, at the cost of lower temporal resolution. Such pitch-based spectra are more compact than linear spectrograms and afford simple summation in the chroma calculation, a process referred to as pitch folding. Indeed, pitch folding of logarithmic spectra into chroma features is perhaps the most important technical aspect of Fujishima's paper, as it

affords a low-dimensional semantically meaningful feature that is easily derived. However, the log-frequency spectrum may result in corruption of harmonic structure as e.g. the second overtone of a root note is located in a pitch bin labelled with the class of its perfect fifth. Such windowing also results in bins of higher pitch being of large frequency width, and possibly containing energy from several pitch class sources. However, even in the presence of such potential sources of error the pitch folded chroma feature has endured as a staple of ACR.

Many chroma variants have been designed to attempt to counter the negative effects of pitch folding. In the simplest case, a spectral weighting is employed that lowers the effect given to higher pitches, which are more likely to contain misassigned harmonics. Other researchers have applied extra weight based upon the harmonic structure in the spectrogram, for instance the harmonic product spectrum is windowed and folded in the Enhanced Pitch Class Profile [34] and in [41]. Alternatively note spectral templates are employed through convolution [18] and for spectral decomposition [38] although the log-frequency windowed spectrogram has generally prevailed. Other chroma refinements through pitch feature manipulation have been proposed. Placing less effect on the relative coefficients in the pitch feature, thereby inducing a level of timbre-invariance, is encouraged by regularisation using e.g. log compression [42] which is seen to be useful for ACR [10].

Researchers have attempted to create chroma with sharper definition. High-resolution spectral methods such as parabolic interpretation [18] and spectral reassignment [27, 46] have been used in order to sharpen a spectrogram before windowing. Likewise, sharpness of features can be diminished when a piece is not tuned to the standard 440Hz, and tuning estimation is often performed to counter this problem [18, 21]. Alternatively, higher dimensional chroma have been employed to avoid these pitfalls [18,59].

In DL-ACR systems, the network is expected to learn any necessary weightings or transforms from training on data. DNNs are often employed as direct classifiers, and for ACR can be trained with one-hot chord class vectors [3,14,15,61,68]. Using chroma feature targets has become a popular design choice in ACR [30,31]. As in more traditional ACR methods, CQT and other log-frequency spectra are seen to predominate as input features [24, 30, 40, 61]. Different inputs have occasionally been employed, e.g. the Harmonic CQT is employed in [64]. Dimensionality reduction of input data has been explored with principal component analysis (PCA) applied to a spectrogram [3] and to a CQT [68]. It is unclear whether PCA was useful other than for dimensionality reduction, and its related decrease in computational expense. Tuning is often ignored, possibly with the assumption that the data-driven systems have the capability to learn to deal with tuning errors. Some exceptions to this are the inputs used in [14,15], while training data of a CNN-based ACR system is augmented using detuning in [31].

So far there is a lack of comparative evaluation of the effects of the input feature in DL-ACR, with most papers instead focussing on the effects of later steps in the processing chain. In the particular case where chroma targets are employed in DL-ACR, the DNN can be seen simply as a replacement for e.g. tuning, compression, weighting and pitch folding. It is no surprise that fast convergence is observed in such DNNs, although rarely reported. Few alternatives to logarithmic spectra have been considered, unlike other music processing tasks where raw audio input observed has been examined [56]. We propose that the use of linear spectra for DL-ACR should be explored. Linear spectrograms do come with the caveat that invariance to pitch-shift is lost, a property that is attractive for use with CNNs. However, overtones of a given root frequency can be expected to be found approximately equidistant from each other in a linear spectrogram, a structure that should also be extractable. In the log-frequency spectrogram, such overtone structure is not so simply presented because harmonics of orders that do not possess an integer base-2 logarithm are misassigned in pitch class. One can consider this a form of information loss that may be detrimental to ACR, particularly when a large vocabulary of chords is employed and some exploration of spectrogram-based training should be undertaken. Alternatively, a multiple input DNN system could be employed using both CQT and Fourier spectrograms.

3. PROBLEM 2: DEFINING WHAT A CHORD LOOKS LIKE IN FEATURE SPACE

Chord classification requires models of chords that can be compared to a given feature such as chroma. Originally, the use of binary chroma templates for classification was proposed in tandem with the pitch-folded chroma [17]. In such a binary chroma template each pitch expected to be active in a chord is set to one. Comparison of a chroma vector with a dictionary of binary templates affords a simple classification approach to chord recognition, with each chroma vector labelled according to the most similar template. Most ACR research has similarly focussed on the comparison of chroma-based features and chord models. The most notable early alternative chord feature is the tonal centroid, or tonnetz, feature [20] which is actually a partial Fourier Transform of a chroma feature. Binary templates formed the basis of much early ACR research [21] and many chroma estimation methods [33, 38] implicitly targeted outputting chroma vectors similar to binary vectors, a goal that can still be seen in DNNs when chroma targets are employed [30, 64]. Binary templates possess the ability to model a chord when there is no representative data available, and despite their simplicity are often effective [10]. However, binary templates may be unrealistic as the effects of misasssignment of harmonics in chroma features are ignored.

An alternative perspective is to place less emphasis on manipulating chroma vectors, and create templates that are more similar to the expected data. A template can be synthesised as in [48, 50], where chord templates are formed by summing spectra of several note templates, parameterised by a number of harmonics and a roll-off factor

determining the energy in each harmonic [19]. This approach has largely been overlooked as data-driven methods that naturally learn models akin to the data became popular. Early data-driven models learnt chord models from labelled chroma features, with several different model types explored. Perhaps the most common of these have been multivariate Gaussian (mixture) models, a generative approach learnt from data, which have been applied in the context of chroma features [10, 59] and tonal centroid features [35], and also in the context of DNN features [24] Other chroma based classifiers have included support vector machines [41, 57], which have also been applied to DNN chroma outputs [68], and random forests [25].

Other research has looked beyond chroma, considering chord classification on the full pitch spectrum. A linear full spectrum classifier is applied in [8] while logistic regression is used in [30] where it is seen to improve on a similar classification applied to chroma features. Such results indicate some limitations for ACR of the chroma feature, which may lose useful information in the pitch folding process. The chroma representation is compact and octave-invariant, qualities that have allowed templates and simple Gaussians to be effective in ACR. Such approaches may be less viable in the context of extra spectral information, with data-driven methods more likely to be able to deal with the extra information coming from the increased dimensionality. The octave-invariance also prevents the chroma feature from distinguishing between different inversions of a given chord. A bass chroma calculated from a window on the lower octaves of the pitch feature was introduced in [39] in order to capture inversions. Extending this, a three windowed chroma with Gaussian models was proposed in [9] approximating full-spectrum analysis.

In DL-ACR there are different options for training and classification. Aside from chroma target outputs, DNNs can also employ more standard black-box classification vectors where each element denotes the likelihood of a different chord [14, 15, 68] or can even be trained using both chroma and label targets [3]. Furthermore, chord classification with DNNs may be performed using activations of the penultimate layer of the network as a feature, which may be passed to a subsequent network [3, 31, 61].

A new perspective is seen in the most recent DL-ACR methods, which are being trained to learn extra information encoded through the use of auxiliary targets. This can be clearly seen in the works [40] and [64] where alongside the chroma feature, one-hot feature targets representing the bass note [40, 64], root note [40], highest pitch note [64] alongside a distinctive no-chord target [40] have been introduced to network training. Such approaches, which we call *target label engineering* should be of benefit in ACR. More possibilities for auxilary targets may exist. This target label engineering displays a turnaround in ACR feature research; where traditionally the focus has been on manipulating features close to the input, it seems that more attention may now be given to the target labels, and the sorts of information that ACR researchers might like to extract.

4. PROBLEM 3: THE MISMATCH BETWEEN PROCESSING RATE AND CHORD RATE

To locate chords in time, feature representations consist of multiple time-localised frames. The simplest way is to create features at a constant, but arbitrary rate, which determines the processing rate of the entire system. This approach was taken by Fujishima, whose features had a rate of 3.906 Hz. In this case, it is important to make the rate high enough, because it effectively imposes a time grid onto which all chord labels are projected, and making this grid too coarse leads to misalignment at the chord boundaries. Therefore later approaches generally increased this feature rate to the order of tens of Hz.

The rate of chord changes is typically an order of magnitude higher than the frame rate. Although the exact number depends on the music piece, the Isophonics dataset used for MIREX has an average chord change rate of 0.46 Hz for example [52]. Especially in the traditional methods where the features are processed frame-wise, the high frame rate compared to the chord rate leads to a high risk of fragmented chord output. A number of techniques have therefore been tried to enforce temporal continuity between frames, starting with a simple smoothing filter. Fujishima himself used a mean filter, but median [47] filters have also been used. These smoothing filters can be applied either to chord probabilities [48] or to the features themselves [2] to remove noise such as percussive sounds and non-harmonic melody notes. In the latter case, a chord model then works on a smoother feature representation, which indirectly also leads to a less fragmented chord output.

The drawback of blindly applying a smoothing filter is that chord transitions may be smeared, leading to inaccuracy in boundary estimation and will cause short chords to be smoothed out even if they are very apparent in the signal. A better method is therefore to consider the chord matching outputs as the observations of an HMM and smooth them with the Viterbi algorithm [2, 5, 59]. The strength of each of the chord candidates is then taken into account and the diagonal elements of the transition matrix control the probability of a chord change [2]. The Viterbi smoothing has been shown to outperform filtering of the chroma output, and filtering of the feature representation does not bring any additional benefits [10].

A consequence of using a HMM for smoothing is that the imposed duration distribution takes the shape of a geometric distribution, meaning that the shorter a chord, the more likely it becomes. Since this obviously is not a realistic distribution, the usage of duration-explicit HMMs has been explored, which allow arbitrary duration distributions. The shape of the distribution was not found to have a major influence on the results, however [8].

An advantage of modern, recurrent neural network (RNN) based approaches is that the chord duration distribution is learnt automatically as part of the chord modelling, without further intervention. RNNs [3] or, more recently, long short-term memory (LSTM) units [16, 61, 64] are fed the feature frames one by one, but remember previ-

ous input which can be used in the prediction of the current frame. With the advent of bidirectional LSTMs [16, 64], future frames can now also be taken into account.

Feedforward networks do not learn a chord duration distribution, as they have no memory elements, but achieve temporal stability by processing multiple time frames at once instead of isolated frames [22]. The entire local environment can then be used to learn the label of the middle frame, which includes learning to integrate over time and to avoid short disturbances. A context window of 1.5 s was found to be optimal in [30]. Of course, convolutional-recurrent models [40] combine the benefits of both.

Following sporadic usage of conditional random fields (CRFs) in traditional systems [5], the combination of CRFs and deep learning is gaining popularity [31, 64]. In this case, a CRF is stacked onto a neural network as the last layer to smooth the output, where one advantage is that they can be trained together for maximum discriminability.

Another way of handling the difference between feature and chord rates is to reduce the discrepancy from the start. This can be accomplished by segmenting the time axis of the feature representation in a musically meaningful way. A first option is to use the output of a beat-tracker to resample the feature representation onto a beat-synchronous grid [2, 36, 60]. The underlying assumption is that chords only change at beat times. The features can then be smoothed over the inter-beat interval without risk of blurring the chord boundaries. It has been shown, however, that beat-synchronous processing may not be advantageous compared to smoothing the chord output with an HMM [10]. A potential reason is the reliance of this method on a correct beat estimation, which was not as common at the time these experiments were performed as it is today. A certain benefit of beat-synchronous features is that the processing rate of systems built around them is lower (0.33–1 Hz for 60–180 BPM), so they run faster.

A final possibility is to explicitly determine chord boundaries before attempting to identify the chords they delineate [13, 20]. This way, the features or chord output can be maximally smoothed without drawbacks, but determining a good chord segmentation function is hardly an easier problem. A recent deep learning approach consists of two stages [64], the first determines the chord segmentation and triad using a small vocabulary, while the second stage picks the final chord type from a larger vocabulary.

Going forwards, we note that blind feature segmentation has been amply used by neural network approaches, but musically meaningful segmentation has not. Although one of the advantages of deep learning is that a network can come up with the most optimal feature representation itself, making the input to the network more musically explicit would be worth investigating. Feeding beat-synchronous features into a network would allow it to learn chord duration distributions expressed in terms of beats instead of frames, which could be more expressive. Such an approach would accumulate the errors of the beat tracking though, so multi-task learning [65] where a single network jointly learns to predict multiple outputs might be better. Beat-tracking could be learnt together with chord recognition. In case intermediate features are desired, chroma could be calculated together with chord segmentation.

5. PROBLEM 4: ACHIEVING LONG-TERM CONSISTENCY IN CHORD SEQUENCES

Multiple chords in a sequence do not follow each other randomly, but exhibit strong temporal links. Typical chord patterns have emerged throughout history, which have been studied by scholars such that expert knowledge about them is available [58]. ACR systems have been trying to incorporate this knowledge, initially with expert-based approaches, nowadays driven by data.

Implementation-wise, chord sequence consistency is mostly dealt with together with duration modelling of a single chord, as discussed in Section 4. In HMM-based approaches, the off-diagonal elements of the transition matrix determine where a chord change will lead to, whereas the diagonal elements influence when it takes place. The sources of knowledge for chord change information are different from the ones used for duration though. The doubly nested circle of fifths has been used frequently [2, 49] (or abused, as it is a model for key similarity) as well as other expert theories [39, 54].

The chord change probabilities of those probabilistic models have also been determined through corpus analysis [43, 54], before deep learning approaches became popular [31, 40, 61, 64, 68]. Typical for deep learning is that chord changes can be handled together with chord duration and models (problems 2, 3 and 4) by a single network [40, 64] to maximally exploit their mutual information. Nonetheless, some of the proposed approaches find it beneficial to handle the problems separately [32], in a way reminiscent of earlier knowledge-based systems.

Taking into account chords beyond the directly adjacent ones remains a challenge. A standard HMM can only model preceding chords indirectly, through chaining bigrams, so increasing the Markov order to trigrams and 4-grams has been tried [26], but their overall improvement remained small. As for deep learning techniques, the typical receptive field of feedforward neural networks is too small (1.5 s for [30]) to contain multiple chord changes and learn long-term dependencies. Recurrent neural networks have the theoretical advantage that all previous and/or future frames can be remembered, but vanishing gradient problems restrict their long-term memory in practice [1]. Attention mechanisms, which are used in machine translating to remember the context of long phrases, are potential solutions to this problem. The Transformer architecture [63] is one candidate for future exploration.

Since long-term chord dependencies are so hard to take into account with the aforementioned techniques, a couple of alternatives have been proposed that rely on musical structure. Feature representations of a repeated section have been averaged in order to make them more stable [11, 37] and that average has then been used for all instances of that section. A more probabilistic version of this idea has been explored in a statistical-relational frame-

work [51]. While these techniques do not exactly use long term dependencies to improve chord recognition, at least they ensure that repeated sections are consistent.

6. PROBLEM 5: EXPLOITING RELATIONSHIPS WITH RELATED MUSICAL CONCEPTS

Chords are just one way of describing musical content. Other musical concepts such as key, genre, bass or melody describe different aspects of the same piece of music. Several research efforts have incorporated ACR in systems that recognise multiple musical concepts, jointly or in sequence, to exploit the mutual information between them. We've already discussed the use of beat information to address Problem 3, so this section focusses on other concepts.

Practically, we see that probabilistic graphical models such as HMMs [35, 54] or dynamic Bayesian networks (DBNs) [39] have been the dominant approach so far to integrate related concepts into ACR. Their inherent modularity is exploited to decompose the probabilistic relations between concepts into more comprehensive factors.

Arguably the musical concept most related to chords is the musical key, as the latter also describes the harmony in a music piece, albeit on a longer temporal scale, i.e. a key spans multiple chords in sequence. Assigning different probabilities to all combinations of keys and chords is therefore a way to exploit their relationship. These probabilities can be derived from musical knowledge [39, 54] or data-driven [26, 35, 54]. One advantage of extracting keys with chords is that the chord sequence can be expressed relative to the key, in a representation close to functional harmony analysis, which has been shown to have a higher information density [58]. The required keys to make this possible can be derived prior to [26] or jointly with chord recognition [35, 54]. However, it has not been proven that using key-independent relative chord representations lead to improvements in actual chord recognition.

Downbeat is also related to chords in the sense that chords are more likely to change on downbeats than on other beats. This link has been exploited by making chord transition probabilities depend on the metric position of a beat in a measure. One example is a joint downbeat-chord system [50] that can deal with different time signatures and added or deleted beats. Another approach included beat-dependent chord transitions as part of a larger system that involves chord inversion and key as well [39], but which is limited to the 4/4 time signature. In both cases, the probabilities were determined by expert knowledge.

Other relationships between musical concepts can be exploited in a similar way. Bass notes, for instance, can be strongly indicative of the chord being played. They have the advantage of being comparatively easy to identify in a spectrum and are used as such to inform ACR [62, 67]. A joint key-chord-structure system has been proposed [53] based on the hypothesis that certain chord sequences are more likely at the start or end of high-level structures such as chorus or verse. Finally, different genres have different idiomatic chord sequences, so genre-dependent context modelling has also been examined [34, 44].

None of the recent deep-learning approaches have involved other musical concepts so far. In theory, it would be possible to identify the key segments of a piece beforehand and then transpose all segments of all pieces into one single key, instead of augmenting the feature representation as in [22, 40]. However, just like feeding beat-synchronous representations into a network, this would suffer from errors in the preceding key recognition step. Most likely a better solution would be to create specific networks that recognise chords together with any of the discussed concepts in a multi-task learning process such as [65]. Unfortunately, data annotated with multiple concepts is even less available than data that is annotated with just chords.

7. PROBLEM 6: HANDLING AMBIGUITY AND SUBJECTIVITY

Fujishima's system was tested using a strongly controlled setup. His dataset consisted mostly of clean, well-defined chords produced by an electronic keyboard using three different presets. He furthermore tailored his settings to these specific sonorities, but noticed that these settings didn't translate well to real music. Indeed, when we want to apply chord recognition to real music, the situation is very different from a controlled environment.

An enormous variety of music exists that may not even contain chords. Music can be monophonic, from a musical tradition that doesn't know the concept, or polyphonic without containing chords (e.g. a fugue). Even if chords are present in a music signal, it can also contain many sources – such as untuned percussion – that disturb the perception of a chord in a listener, human or mechanical. Furthermore, what exactly contributes to a chord is also ill-defined. The distinction between chord sequence and melodic line is not clear cut and can be a matter of opinion. Also the granularity of a chord sequence, for instance whether fast approach chords or anacrusis (pickup) chords are transcribed, depends on the user or use-case. A final cause of ambivalence is when chords are only implied, not audible as such, as with arpeggiated chords for instance.

Because all of these reasons human annotators aren't in total agreement when it comes to transcribing chords. The reported agreement on the root of a chord lies between 76% [29] (4 annotators) and 94% [12] (2 annotators) on average, but large outliers towards the bottom can appear in individual files [23, 45]. When comparing algorithmic output to a single human reference output, it is therefore hard to tell if any disagreements are valid alternative interpretations or outright errors. Although this phenomenon has been diagnosed and quantified [23, 45] multiple times already, final solutions are yet to emerge. The availability of chord datasets with multiple annotations, such as [45] (20 songs annotated by 5 persons) and [29] (50 songs annotated by 4 persons) is certainly a first step on the way. That former dataset has been used to learn the idiosyncrasies of different annotators and create personalised algorithmic output tailored to their preferences [28]. While it does provide a means of personalisation, it requires example transcriptions for each user, which might not be avail-

able. Furthermore multiple viewpoint annotations do not answer the question of whether an algorithmic output differing from all N viewpoints is plain wrong or the $N+1$th valid viewpoint. A different way of evaluating will be necessary for this, but it will probably be hard to scale. Asking human experts whether an automatic transcription is a good chord analysis (even if not exactly their own) would work, but would also mean that every different setting of an algorithm needs to be evaluated manually. Even by crowdsourcing the process, it would be impossible to test multiple parameterisations of a system.

8. PROBLEM 7: CHORD VOCABULARY AND ASSOCIATED BALANCE PROBLEMS

Fujishima's system was able to distinguish no less than 27 different chord types, but subsequent systems quickly reduced this number to two [2] or four [21] types of triad. Apart from [39], small vocabulary sizes remained the defacto standard until the last few years, with an upward trend that seems more definitive this time [14, 40].

The necessity of imposing an algorithmic chord vocabulary stems directly from the choice of treating chord recognition as a classification problem. This design choice is extremely wide-spread, but is not inherently part of the task. Chord class-free approaches can be envisaged, such as labelling sets of active chromas, where the complexity is then shifted towards determining when a chroma is active (itself potentially a classification problem). A vocabulary-free model of chords such as proposed in [66] can be used to label the chroma sets, but only the model in isolation has been tested so far, not as part of a full ACR system.

A particularity to increasing the classes in ACR is that the distinction between them becomes smaller the more classes are added. Especially when triads and tetrads (4-chroma chords) are mixed, because the set of chromas in tetrads are a superset of the chromas in their associated triad. Commonly used flat classification approaches assume disjoint categories, and therefore aren't an optimal match for the problem [23]. A form of hierarchical or alternatively multi-stage classification [64] is one way to address this problem, but these need to be explored further in the future. Different ways of representing target labels to make classes more orthogonal [7, 40, 64] constitute another type of solution, one in which standard flat classification algorithms can continue being used. Multiple auxiliary labels are introduced in this approach, which we called *target label engineering* in Section 3. Alternatively, multiple distances between chords have been used as targets [7]. These chord label representations constitute a modern take on introducing musical knowledge into deep learning. Where feature engineering tried to shape the audio input into features that were maximally discriminative, target label engineering aims to do the same working back from the label output.

A further complication when considering chord labels as separate classes is that their frequency of occurrence is strongly unbalanced. For instance, the five most common chord types account for over 80% of popular music datasets [6, 64]. This imbalance in chord distribution affects both training data-driven ACR systems and evaluation. For training, new strategies need to be developed to avoid overemphasising the most frequent classes [16]. In evaluation, improvements on rare chords are barely visible when using a metric that reports the percentage of time the correct chord is found. Discussing performance on multiple levels, with rarer chords separated, is necessary to get more insight into algorithm performance [55].

Finally, the chord imbalance itself differs from dataset to dataset. Genre, instrumentation, cultural origin, key and chord distributions are all linked, and are manifested as a skew towards certain roots and chord types, as well as variance in timbre. Since the majority of available annotated data consists of anglophonic pop music, its representativeness is questionable. Until current algorithms are cross-checked with new datasets containing e.g. Latin, jazz and metal, their general applicability remains unproven.

9. CONCLUSIONS

In this paper, we discussed 20 years of research on automatic chord recognition, starting with Fujishima's paper [17]. Even though modern ACR systems differ strongly in their proposed technical solutions, we find that his initial system was very effective at identifying the problems that arise during the creation of ACR systems. We therefore compared past and recent solutions thematically according to these problems, with the intention of inspiring future work on this topic.

We note a tendency towards tackling the different problems in ACR as a single integrated approach, in contrast to the compartmentalised strategies of the early years. This evolution follows the move from knowledge-driven to data-driven approaches. The lack of available training data in the early years called for knowledge-based systems, which in turn required systems to be broken down into smaller components for them to remain comprehensible. Each component usually dealt with one sub-problem in isolation. Early data-driven approaches replaced these knowledge-based components with learnt ones, while retaining the modular structure. The arrival of deep learning permitted to replace all these components by a single system that is better at exploiting the interactions between the ACR problems. Nonetheless, some researchers choose to keep the modularised approach, to increase interpretability or to employ specific training data or procedures.

A consequence of moving towards integrated systems, is that the comparison between them becomes harder. No general blueprint of a DL-ACR system can be given, as many approaches compete, and therefore it is difficult to translate findings of one system to the other or to combine parts of two systems into one. Without a doubt, more innovations in deep learning will make their way to ACR, which will keep the field moving fast for the foreseeable future. It is encouraging to see that the specific characteristics of music are starting to show up in the deep learning approaches, with musical knowledge guiding the training procedure and architecture.

ABSTRACT

Audio-based music classification and tagging is typically based on categorical supervised learning with a fixed set of labels. This intrinsically cannot handle unseen labels such as newly added music genres or semantic words that users arbitrarily choose for music retrieval. Zero-shot learning can address this problem by leveraging an additional semantic space of labels where side information about the labels is used to unveil the relationship between each other. In this work, we investigate the zero-shot learning in the music domain and organize two different setups of side information. One is using human-labeled attribute information based on Free Music Archive and OpenMIC-2018 datasets. The other is using general word semantic information based on Million Song Dataset and Last.fm tag annotations. Considering a music track is usually multi-labeled in music classification and tagging datasets, we also propose a data split scheme and associated evaluation settings for the multi-label zero-shot learning. Finally, we report experimental results and discuss the effectiveness and new possibilities of zero-shot learning in the music domain.

1. INTRODUCTION

Audio-based music classification and tagging is a task that predicts musical categories or attributes such as genre, mood, instruments and other song quality from music tracks. Current state-of-the-arts algorithms are based on supervised learning of deep convolutional neural networks that directly predict the labels in the output layer [18]. That is, the neural networks are trained to minimize the prediction errors with regards to the labels. The prediction results can be used to automatically annotate music tracks or retrieve music tracks using the labels as a query word [32]. By the nature of the setting in the supervised learning, however, the approach allows only a fixed set of word labels in the annotation and retrieval.

Zero-shot learning is a learning paradigm that can overcome this limitation and enables the trained model to predict unseen labels [12, 20]. For example, it allows the model to predict newly added music genres after the training or retrieve songs using a query word that users arbitrarily choose. This is possible by utilizing side information that derives a separate semantic space from labels. For example, the side information can be musical instrument annotation vectors of music genres or word embedding learned from sentences. The zero-shot learning approach conducts supervised learning between the semantic space and audio feature space. Once the mapping between two embedding spaces is learned, the model can predict unseen labels. Figure 1 illustrates the concept of zero-shot learning applied to music classification and tagging.

The zero-shot learning approach was previously applied to music data [28]. However, they focused on evaluating a specific semantic embedding method that works for general multimedia data rather than delving into zero-shot learning in the music domain. In this work, we carefully investigate how the concept of zero-shot learning can be properly applied to audio-based music classification and tagging. Specifically, we designed two settings of side information. One is using human-labeled attribute information and the other is using general word semantic information. Also, considering a music track is usually multi-labeled in music classification and tagging datasets, we propose a data split scheme that yields a comprehensive list of combinations for seen or unseen audio and labels, and evaluate them in the various settings. Through the experiments, we show the effectiveness and new possibilities of zero-shot learning in the music domain.

2. BACKGROUND: ZERO-SHOT LEARNING

Zero-shot learning has been studied mainly for object recognition in the field of computer vision [34]. They have attempted to build a model that can recognize novel visual categories without any associated training samples by employing a joint embedding space of both images and their class labels [34]. It was originally inspired by human's ability to recognize objects without seeing training examples or even create new categories dynamically based on semantic analysis [9]. What enables this semantic exploitation of unseen images is "information transfer" that

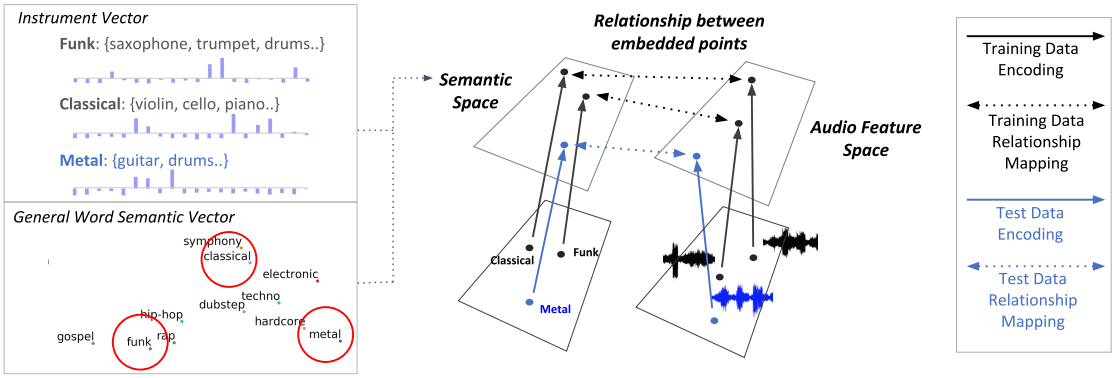

Figure 1. Overview of zero-shot learning concept applied to music classification and tagging.

applies the knowledge learned in an auxiliary domain to the main targeted task. Thus, it aims to explore how seen and unseen images are semantically related based on the side information.

The types of side information can be largely divided into two categories [9, 34, 37]. One is human-annotated attributes of the labels. In the computer vision community, there are publicly available human-annotated attribute datasets such as AWA (Animals With Attributes) [12] and CUB (Caltech-UCSD Birds-200) [35]. For example, AWA offers images of 50 animals annotated on 85 attributes associated with animals characteristics such as "furry" or "has tail". These examples may be equivalent to music genre classification where corresponding attributes are musical instruments. These attributes can be used as binary output to train a classifier and infer unseen class based on similarity measure [2, 12] or to learn their relative strength [21, 30]. When such explicit attributes data are not available, the semantic attributes can be learned with hierarchy of classes or other relationships [14,25,27]. In general, this attribute-based approach has advantages in interpretability but requires well-defined attributes and annotation data.

The other type of side information is a general word semantic space learned from different resources. A commonly used choice is neural language models such as Word2Vec [1, 8, 15, 16, 19, 36] and GloVe [1, 23, 36]. Another choice is learning relational semantic embeddings using pre-defined lexical hierarchy such as WordNet [17,27]. These general semantic spaces have an advantage in that they have a large set of words in the vocabulary to predict unseen labels. However, if the target labels have a specific context, the general semantic space may fail to capture it [28].

3. DATA SPLIT SCHEME FOR MULTI-LABEL ZERO-SHOT LEARNING

Many of music classification and tagging datasets have multiple labels to annotate music tracks. However, zero-shot learning in the image domain has been treated primarily as a single-label problem, although a few studies have attempted to address it in multi-label classification [10,14]. An important difference between single-label and multi-label zero-shot learning is data split scheme for training and test. In general, in zero-shot learning, both data and labels are split into seen and unseen sets. In the single-label setup, the label split can automatically divide the dataset into training and test sets (Figure 2 (a)). In the multi-label setup, however, specifying reasonable instance or label splits is not straightforward.

3.1 Previous Approaches

Most of previous works on multi-label zero-shot learning are conducted the instance-first split [26]. They first split instances into train and test, and only used seen labels for training as shown in the left of Figure 2 (b). In this case, some of the instances in the train set can have positive annotations for unseen labels. As an alternative, the label-first split was proposed in [33]. They first split labels into seen and unseen groups, and select training instances to have no positive annotation for unseen labels and select test instances to have at least positive annotation on unseen labels as shown in the right of Figure 2 (b). However, in this case, due to the nature of multi-label data, too many instances can be assigned to the test set.

Meanwhile, it is an important issue to determine which split in instance (train and test) or label (seen and unseen) should be evaluated in measuring zero-shot learning performance. A generalized zero-shot learning evaluation setting is proposed in [37]. It includes both seen and unseen labels at test time to examine more natural annotation performance compared to use only unseen labels at test time. In multi-label zero-shot learning, however, the data split and evaluation settings are still not clear and there is no agreed consensus yet.

3.2 Proposed Data Split Scheme

We propose a data split scheme and evaluation settings for multi-label zero-shot learning to measure the performance in more refined and various settings. The proposed data split is shown in Figure 2 (c). We first divide labels into seen (X) and unseen (Y) groups and then split instances into three groups. The first subset (A) of instances are labeled with at least one from seen labels and not labeled with any of unseen labels. The second subset (B) of in-

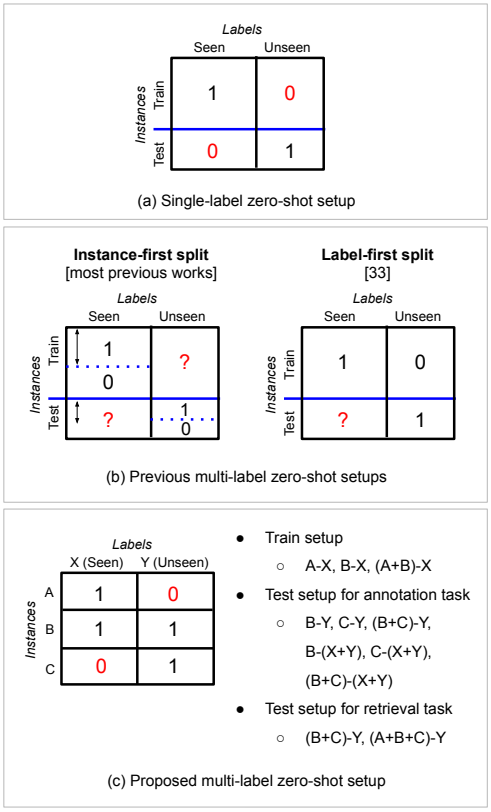

Figure 2. Data split for zero-shot learning

stances are labeled with at least one from each of seen and unseen labels. Lastly, the third subset (C) of instances are only labeled with at least one from unseen labels. Then we create the three setups (including train setup, test setup for annotation task, and test setup for retrieval task) with a combination of instance subsets (A, B, and C) and label subsets (X and Y) as described in Figure 2 (c).

In this configuration, the label-first split can be obtained when the training set is A-X (a subset where instances are from A and labels are from X) and the test set is (B+C)-Y (a subset where instances are from (B+C) and labels are from Y). Also, the generalized zero-shot learning evaluation setting can be expressed to include not only the Y area but also the (X+Y) area at test time. We therefore extend the split and evaluation settings more comprehensively, allowing for many aspects of multi-label zero-shot learning to be considered.

We take the train setup from A-X, B-X, and (A+B)-X. The instances in A-X only contain annotations on seen labels and the instances in B-X contain annotations on both seen and unseen labels. By distinguishing these two areas, we expect to see the difference in model learning by using instances with and without annotations in the unseen labels in multi-label zero-shot learning.

The test setup for the annotation task is made up of combinations of B, C, or (B+C) with Y. In addition, combinations of B, C, or (B+C) with (X+Y) can be also considered to measure generalized zero-shot learning performance on the annotation task as explained in the Section 3. The test setup for retrieval task is composed of (B+C)-Y and (A+B+C)-Y. We can regard (A+B+C)-Y as a case of generalized zero-shot learning evaluation setting because the retrieval is performed not only on the instances of unseen labels ((B+C) split) but also on instances of seen labels (A split). The C-Y area cannot be formed in the retrieval evaluation. The reason for this is that once we split labels into seen and unseen and then assign overlapping instances to the B area, we may not guarantee that all the unseen labels have at least one positive activation on the instances in the C area.

4. MODEL

4.1 Deep Embedding Model

Zero-shot learning is primarily performed by a compatibility function that maps multimedia embedding and semantic embedding. The joint embedding methods can be categorized into learning linear compatibility, nonlinear compatibility, intermediate attribute classifier, and their hybrid [37]. In this work, we focus on learning nonlinear compatibility. The model takes audio mel-spectrogram as input rather than audio embedding extracted from pre-trained model. A convolutional neural network (CNN) module for audio is learned directly with semantic embedding from ground truth annotations. Figure 3 illustrates the model architecture. The model takes audio from one module and randomly selected a positive word and a negative word from the ground truth annotations of the audio via the semantic vector lookup table. Following the previous works [8, 22], the loss function is chosen as a max-margin hinge loss as below:

$$\mathrm{L}(A, W) = \max\left[0, \Delta - Rel\left(A, W^{+}\right) + Rel\left(A, W^{-}\right)\right]$$

where Δ is the margin, W^{+} denotes the label with positive annotation for the audio input, and W^{-} denotes the label with negative annotation. The cosine similarity of the last hidden layer of the audio module and semantic module is used as a relevance score [22]:

$$Rel(A, W) = Similarity_{cosine}\left(y_A, y_W\right) = \frac{y_A^T y_W}{|y_A||y_W|}$$

where y_A and y_W denote the output of the last hidden layer for the audio module and the semantic module, respectively.

The mel-spectrogram based audio CNN module is constructed with four 1D convolutional layers with a 2D filter [5, 7, 13, 24]. Each layer is followed by a rectified linear unit (ReLU) activation and a max pooling layer. We added a convolutional layer and an average pooling layer on top of them to construct a fixed-size audio embedding vector compatible to the semantic module. The semantic module is constructed by adding a fully connected layer over a semantic embedding (the output of semantic vector lookup table). In this case, the semantic embedding (or semantic vector lookup table) can be composed with both human-annotated attributes data or general word semantic space.

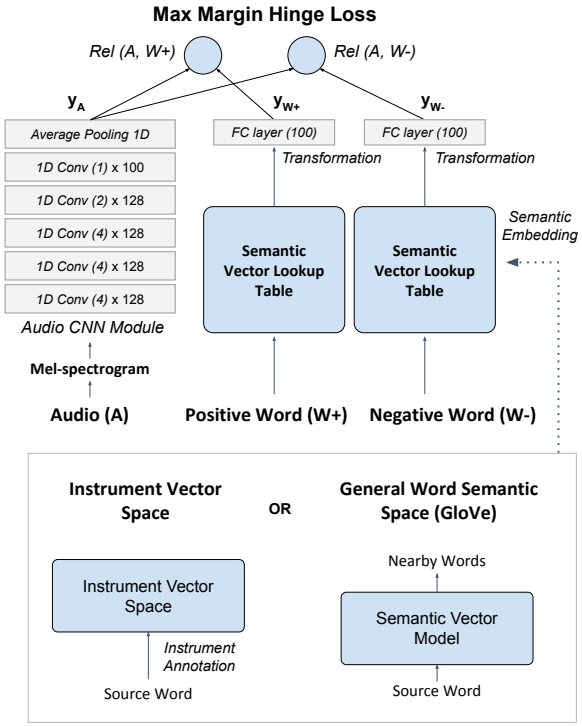

Figure 3. Deep embedding model for zero-shot learning using instrument vector space or general word semantic space.

4.2 Classification Model

The deep embedding model can be used for not only the zero-shot learning setting but also the conventional multi-label classification and tagging problem where we train and evaluate the model with only seen labels. Therefore, we construct a classification model and compare it with the deep embedding model to evaluate the learning capability of the deep embedding model. The classification model is basically the same as the audio module of the deep embedding model but the output is the binary representation of the labels. To this end, we added a fully-connected output layer with the size of seen labels on top of the average pooling layer of the audio module. We used the sigmoid activation and binary cross-entropy loss for the multi-label classification.

4.3 Training Details

We extract mel-spectrogram from audio with 128 mel bins, 1024 size FFT (Hanning window), and 512 size hop in 22,050 Hz sampling rate. We standardized the mel-spectrogram across all training data to have zero mean and unit variance. We randomly selected three seconds of audio chunk (130 frames) as an input size to the CNN module. We optimized the model using stochastic gradient descent with 0.9 Nesterov momentum, 0.001 learning rate, and $1e^{-6}$ learning rate decay for all models and datasets. Our system is implemented in Python 3.5.2, Keras 2.2.2, and Tensorflow-gpu 1.6.0 for the back-end of Keras. [1]

Table 1. Data split statistics.

In the test phase, we took the average of the fixed-size audio embedding vectors over a single music track to obtain a track-level embedding, and made the predictions by the distance between track-level audio embedding and tag embedding.

5. EXPERIMENTAL SETTINGS

We apply the proposed data split scheme and the deep embedding model to publicly available music classification and tagging datasets. We experiment with this in two settings of side information that we discussed in Section 2. For all the splits, we reserve 10% instances of train set as a validation set randomly. [2]

5.1 Experiment 1: Genre with Instrument Attributes

Musical instrument is one of the most important elements that determine music genre. Thus, recognizing instruments in a music track can be a strong cue to predict an unseen (or unheard) genre (assuming that the predictor learned the genre from some literature). For this experiment, we use Free Music Archive (FMA) [6] and OpenMIC-2018 datasets [11]. FMA contains audio files and genre annotations. OpenMIC-2018, which was originally designed for multiple instrument recognition, has 20 different instrument annotations to the audio files in FMA. We filtered the audio files to have both genre and instrument annotations. As a result, 19,466 audio with 157 genre labels and 20 instrument annotations are left. Following the proposed data split scheme, we randomly split 157 labels into 125 seen and 32 unseen ones. Then, three groups of audio instances (A, B, C) are created naturally. The statistics of audio and labels is described in Table 1.

The annotations on 20 different instruments in the OpenMIC-2018 dataset are labeled as a likelihood measure summarized from crowd-sourced annotations. They are regarded as positive if the likelihood value of an instrument annotation is larger than 0.5 and, otherwise, negative. The exact value of 0.5 means that it's unannotated. So, we treated positive and negative information independently and created 40 dimensional instrument vectors that can represent both positive and negative information. The genre to instrument attribute relationship is then constructed by accumulating 40 dimensional instrument vectors of the songs according to the genre labels. Finally, we standardized the instrument vectors to have zero mean and unit variance. This was used as the semantic vector lookup table in the learning model.

[2] All the data splits are available along with the source code.

Table 2. Zero-Shot learning results for annotation task.

5.2 Experiment 2: General Word Semantic Space

The other type of side information is word embedding learned from a large-scale text dataset separately from music datasets. It can represent words as vectors in a semantic space. We adopted GloVe as a word embedding model [23]. Instead training it from scratch, we used a publicly available pre-trained GloVe model [3]. It consists of 300-dimensional vectors of 19 million vocabularies trained from documents in Common Crawl data. Since this can cover a large vocabulary of words, we used a music dataset with rich annotations, which is Million Song Dataset (MSD) with the Last.fm tag annotations [3]. From the full set of 498,035 tags in the Last.fm annotations, we filtered the tags that correspond to 2,000 genre/sub-genre classes contained in Tagtraum genre ontology [29]. We filtered the result (1800 tags) again into 1,126 tags after eliminating missing words in the dictionary of the pre-trained GloVe model. We used 406,409 audio instances annotated with the refined 1,126 tags. Following the proposed data split scheme, we randomly split 1,126 tags into 900 seen and 226 unseen ones, and organized three groups of audio instances (A, B and C). They are summarized in Table 1.

5.3 Evaluation Metrics

We used the area under the ROC curve averaged over instance (AUC-i), mean average precision over instance (MAP-i), and precision at K (P@K) as evaluation metrics for the annotation task. The retrieval task is evaluated using the area under the ROC curve averaged over label (AUC-l) and mean average precision over label (MAP-l).

6. RESULTS

6.1 Multi-label Zero-Shot Annotation

We compare the results of the combination of the proposed multi-label zero-shot learning split in the annotation task.

[3] The Common Crawl model was trained with 42B tokens containing 1.9M vocabulary. https://nlp.stanford.edu/projects/glove/

Data Split		FMA		MSD

	(A+B+C)-Y	0.7377	0.0518	0.6789	0.0172

Table 3. Zero-Shot learning results for retrieval task.

From Table 2, we can find that training with (A+B) or B instance set shows better performance than that with A in general. This indicates that the instances in B give better supervision over the entire tag set. In the case of test on C-(X+Y), the MAP-i and P@K scores are very low. This is because the case is generalized zero-shot learning evaluation setting [37] which makes predictions of seen label even when the ground truth of seen labels have only negatives.

We also see that some results have different trends between the two datasets. For example, test on B gives better results than C on FMA, but the results are opposite to those on MSD. We suspect that this may be due to difference in label cardinality, the average number of labels per instance [31], which can significantly affect performance in multi-label classification [4]. Specifically, FMA tracks have cardinality of 1.18 for B-Y and 1.15 for C-Y, whereas MSD tracks have cardinality of 2.04 in B-Y and only 1.11 in C-Y. This lower cardinality may cause better performance in C-Y than B-Y for MSD. However, we need further investigation considering differences in datasets and side information.

6.2 Multi-label Zero-Shot Retrieval

The results of the retrieval task are reported in Table 3. As in the annotation task, the overall performance is high when training with (A+B)-X. Also, the test results on

Table 4. Results on retrieval task that compares deep embedding model to classification model. The detail of classification model is described in Section 4.2.

Query	Top 5 Retrieved Tracks (Title / Artist)	Original Last.fm Annotation
guitar	Iron Acton / Beak	psychedelic, experimental, krautrock, english, bass
	Drink Whiskey And Shut up / Brian Setzer	rock
	Thar She Blows / The Halibuts	party, surf, surfrock
	All Quiet On 34th Street / Eric Burdon And The New Animals	rock, rocknroll, hardrock, screamo, 00s
	Gimme Some Lovin' / Traffic	60s, british, classicrock, rock
lovely	Eddie My Love / The Chordettes	50s, doowop, oldies, pop, vocal
	Vaya Con Dios / Les Paul & Mary Ford	50s, jazz, oldies
	(I Can't Help You) I'm Falling Too / Skeeter Davis	country, oldies
	Mr. Blue / The Fleetwoods	oldies, 50s, pop, doowop, ballad
	I'm Blue Again / Patsy Cline	blue, country

Table 5. Top 5 retrieved tracks for a query word from unseen tag subset ('guitar') and an arbitrary word ('lovely').

(A+B+C)-Y are lower than that on (B+C)-Y. We can regard the test on (A+B+C)-Y as a generalized zero-shot learning evaluation setting for the retrieval task. This means that even for instances that do not have a positive annotation on unseen label according to the split (instances that were denoted as A), the evaluation is performed including this instances so to consider whether the model actually make a negative prediction on them. Thus, this is a more strict evaluation setting.

6.3 Deep Embedding Model vs. Classification Model

We also conducted an additional experiment to verify the performance of the deep embedding model in the conventional multi-label classification and tagging task [4]. Table 4 shows results in the retrieval scenario following previous work [5, 7, 13, 24]. We can see that the deep embedding model outperforms the classification model on both datasets. This indicates that associating audio with labels via the side information is a powerful approach even in the conventional multi-label classification and tagging task.

[4] In this evaluation, some labels were excluded because there are some labels that have negative annotations for all instances according to the split.

Smells like teen spirit Nirvana	Superstition Stevie Wonder	Theme to Grace / Lament George Winston
classicrock (unseen)	funk (unseen)	folk
punk	soul	instrumental
rock (unseen)	pop (unseen)	jazz
80s (unseen)	jazz	piano (unseen)
alternative	80s (unseen)	singersongwriter
punkrock	blues (unseen)	chillout
90s	classicrock	acoustic
metal	90s (unseen)	blues
vintage	disco	mellow
alternativerock	dance	chill

Table 6. Top 10 auto-tagging results for examples of well-known songs including unseen tags during training.

Query	General Semantic Space	Zero-shot Embedding Space
guitar	bass, acoustic, piano, vocals, violin, percussion, strings, vocal, music, jazz	instrumental, minimal, rock, acidrock, progressiverock, alternative, psychedelic, folkrock, classicrock, band
lovely	awesome, love, cool, romantic, relaxing, summer, christmas, holiday, vintage, soft	relaxing, relax, lovesongs, easylistening, baby, country, romantic, easy, americana, ballad

Table 7. Comparison of top 10 nearest word vectors (out of 1,126 tags) on general semantic space and the trained zero-shot embedding space.

6.4 Case Study

We conducted case studies to better understand the performance of the zero-shot learning model. Table 6 shows the results of annotation on several famous music tracks. They show that the predictions are reasonable for both seen or unseen tags. Table 5 lists retrieved tracks given a query word and their original labels. We can see that the results are reasonable even if we did not use seen tags. Furthermore, we compared the general semantic space of GloVe model to our trained deep embedding space in Table 7. The examples show the deep embedding space learns the relationship between words in a more musically meaningful way.

7. CONCLUSIONS

In this paper, we showed that zero-shot learning is capable of associating music audio with unseen labels using side information. This allow to use a rich vocabulary of words to describe music, thereby enhancing the experience of music retrieval or recommendation in a more human-friendly way. There is a large room to explore for future work. For example, lyrics can be used as side information which can be obtained without manual human annotation. The neural language models can be also trained to contain more musical context, for example, using text descriptions of playlists or music articles.

ABSTRACT

Optical Music Recognition (OMR) promises great benefits to Music Information Retrieval by reducing the costs of making sheet music available in a symbolic format. Recent advances in deep learning have turned typical OMR obstacles into clearly solvable problems, especially the stages that visually process the input image, such as staff line removal or detection of music-notation objects. However, merely detecting objects is not enough for retrieving the actual content, as music notation is a configurational writing system where the semantic of a primitive is defined by its relationship to other primitives. Thus, OMR systems must employ a notation assembly stage to infer such relationships among the detected objects. So far, this stage has been addressed by devising a set of predefined rules or grammars, which hardly generalize well. In this work, we formulate the notation assembly stage from a set of detected primitives as a machine learning problem. Our notation assembly is modeled as a graph that stores syntactic relationships among primitives, which allows us to capture the configuration of symbols in a music-notation document. Our results over the handwritten sheet music corpus MUSCIMA++ show 95.2% precision, 96.0% recall, and an F-score of 95.6% in establishing the correct syntactic relationships. When inferring relationships on data from a music object detector, the model achieves 93.2% precision, 91.5% recall and an F-score of 92.3%.

1. INTRODUCTION

Optical Music Recognition is the field of research that investigates how to read music notation in documents computationally. This technology enables many computational tasks that, otherwise, could not be performed directly on the music sources themselves [17]. One interesting application of OMR is concerned with reconstructing the notes encoded in the music-notation document, also referred to as *replayability* [22]. In particular, the objective of the replayability application is to recover the pitches, onsets, durations, and velocities of notes from a document and export them into a symbolic representation. This symbolic representation—e.g., a MIDI file—is already a very useful abstraction of the music itself and allows for plugging in a wide range of music information retrieval tools. However, despite prolonged efforts, the replayability application is still under research [4, 7, 16, 36].

Given the wealth of information that is contained in a music score, the task of decoding its content is usually addressed by dividing the process into smaller stages that represent limited challenges. The general pipeline, proposed first by Bainbridge and Bell [3] and later refined by Rebelo et al. [29], is considered a de-facto standard, which organizes the process into four main blocks: i) preprocessing, which works over the input image to ease further steps and make the system more robust; ii) music object detection, which is in charge of retrieving and classifying all objects and glyphs of the image; iii) notation assembly, which must infer the relationships among the detected objects to reconstruct the music notation itself; and iv) encoding, which exports the symbolic reconstruction into the desired format, typically MIDI for replayability or an XML-based encoding such as MusicXML [15] or MEI [19] for further computational processing.

As our starting point towards completing the OMR pipeline, we assume that the music object detection stage can be solved reliably, which allows us to investigate how to deal with the later stages. In this paper, we want to focus in particular on the third stage, which is responsible for the notation assembly. Although previous work exists, most approaches are based on predefined rules that hardly generalize, and that only work for a limited set of scenarios. In contrast, we propose a well-principled machine learning approach, which addresses the problem in a generalizable way, provided there is convenient training data.

2. RELATED WORK

Most literature on OMR focuses on the first stages of the pipeline. This comes as no surprise because if one struggles with detecting music objects in an image reliably, it is understandable that subsequent stages that build on top of that are often neglected. With the appearance of deep

learning in OMR, however, many steps that traditionally produced suboptimal results, such as the staff-line removal or symbol classification, have seen drastic improvements [14, 26] and are no longer considered obstacles for OMR development.

Deep learning also caused some steps to become obsolete or collapse into a single (bigger) stage. For instance, the music object detection stage, which was traditionally separated into segmentation plus classification stages, is currently addressed in a single step. Convolutional neural networks have been shown to be able to deal with the music object detection stage holistically, without having to remove staff lines at all [25]. A compelling advantage is the capability of these models to be trained in a single step by merely providing pairs of images and positions of the music objects to be found, eliminating the preprocessing step altogether [24, 35]. This issue has been the subject of intense recent research. A comparison of existing approaches to holistic music object detection is presented in the work of Pacha et al. [27].

Since the beginning of the OMR research, there have been attempts to complete the full pipeline, including the notation assembly stage. Below, we introduce some particular proposals to perform this stage that can be found in the existing literature. They can be broadly divided into grammar-based approaches, and approaches that rely on heuristics and pre-defined rules.

2.1 Grammar-based approaches

Formal grammars represent the most widely used description of music notation. This feels natural, given that music notation has syntactic rules and hierarchical structures that invite such a formalization. These grammars are manually built to describe the expected relationships among music-notation objects and then used to reconstruct the music notation from the detected primitives [1–3, 5, 6, 30, 33]. The 2D nature of music notation also inspired graph grammars, as in the work of Fahmy and Blostein [12]. A prominent example of this approach is the DMOS system, proposed by Coüasnon et al. [8,9], which uses a definite clause grammar for describing the relations between graphical objects on two levels: a graphical one that assists the recognition of symbols and a syntactic one, which introduces the musical semantics into the process.

2.2 Heuristical approaches

The other set of approaches relies on *ad hoc* rules for the music notation at hand. This includes assumptions about the configuration and position of the occurring primitives to reconstruct composite symbols and the notation graph [10, 23, 28, 34]. Rossant et al. [31] additionally considered fuzzy modeling, which allows for self-correction during the recognition [32]. Their system evaluated different hypotheses of recognized symbols to verify the compatibility between them.

3. NOTATION ASSEMBLY

The related works clearly show a lack of machine learning approaches. This work aims to fill that gap, by proposing a formulation of the notation assembly stage based on machine learning models. The advantage of such models is that they provide greater flexibility since they can vary their behavior by just changing the provided training set. This is especially interesting for OMR, where there is a great diversity of scenarios depending on the epoch or type of composition of the music scores.

The conventional OMR pipeline foresees that the notation assembly stage infers the relationships among previously detected music objects to retrieve the necessary information to infer the sequence of notes and rests.

Our approach understands that music notation can be modeled as a directed graph $G = (V, T)$, hereafter referred to as Music Notation Graph (MuNG). V represents the set of vertices, where $\zeta(v), v \in V$ is the label associated with a vertex. T represents the set of directed edges, such that $t_i = (v_1, v_2), t_i \in T, v_1, v_2 \in V$ denotes an edge from vertex v_1 to vertex v_2. The primitives that make up the music notation, such as noteheads or stems, are modeled as vertices of this graph, while the relationships between these symbols are modeled by the edges. In our MuNG, the edges are not labeled, but there are two types of relationships:

- Syntactic edges that relate elements syntactically. This includes relationships between primitives that make up a composite symbol, such as an eighth note, which consist of a notehead, a stem, and a flag or beam as well as general relationships, e.g., between an accidental and the notehead that is affected by it.

- Precedence edges that specify the temporal order between notes. In most cases, the position on the horizontal axis is sufficient to infer this kind of relationship; however, for polyphonic music, a more sophisticated mechanism is needed to handle ambiguous situations.

We can, therefore, define the set of edges as $T = S \cup P$, where S is the set of edges that define the syntactic relationships and P is the set of edges that define the precedence relationships. A graphical representation of MuNG is shown in Fig. 1. The primary goal of our work is to train a machine learning model to construct such a MuNG G from a music score image.

4. LEARNING MUSIC NOTATION GRAPH ASSEMBLY

There are existing algorithms that are capable of dealing with the input image and retrieving a set of detected music-notation primitives. In other words, these algorithms process the input and provide the set of vertices V, along with its associated labels and bounding-boxes. In order to complete the OMR pipeline for replayability, we also need to recover the set of edges T.

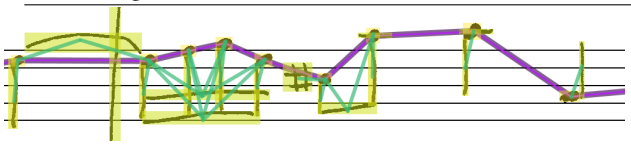

Figure 1: Graphical representation of a Music Notation Graph in a selected excerpt of music notation: vertices are highlighted with transparent yellow bounding boxes around the music-notation primitives, syntactic edges are shown as transparent cyan lines, and precedence edges are shown as transparent purple lines connecting the noteheads.

We propose a principled way of inferring T without resorting to a set of fixed rules but using machine learning. Our system learns to establish these relationships from a conveniently annotated training set so that the rules are implicitly modeled by the machine learning model.

The edges that relate vertices of the set T have an unlabeled binary nature; i.e. for each pair of vertices, a relationship either exists or not. Formally speaking, the inference of these relationships can be formulated as a function $f : V \times V \rightarrow \{0, 1\}$. However, given their different nature, the set of edges S and P are inferred by independent models. To learn the functions f_S and f_P, for the edges of S and P, respectively, we propose to train binary classifiers that receive two vertices and predict whether such relationship must be established or not. To do so, one would have to estimate the potential relationship between each pair of symbols, which entails high computational costs. However, it is obvious that most of these relationships are unfeasible. Since the music object detection stage also retrieves some associated information, such as the label $\zeta(v)$ associated to each vertex and the bounding box of that object in the input score image, we can use this information to filter edges by two criteria:

1. An edge is only feasible if the distance between the bounding boxes of their vertices falls below a certain threshold t. In other words, two vertices that are too far apart cannot be related.

2. An edge is only feasible if the labels of its associated vertices are "compatible", e.g., a notehead with a stem. This eliminates a large number of incompatible combinations, such as an edge between an accidental and a rest. The compatibility map is a fixed list of vertex pairs that, according to the syntax of modern music notation, can hold a relationship to each other.

Then, given two vertices v_1 and v_2, for which their edge is declared feasible, we train a deep convolutional neural network to predict whether there must be an edge from v_1 to v_2 or not. We generate a multi-channel image with a fixed size that serves as input features for the neural network, which consists of:

- Channel 1: the patch of the input score image that is centered at the objects represented by v_1 and v_2.
- Channel 2: the binary mask of the object v_1
- Channel 3: the binary mask of the object v_2

The required information to generate these multi-channel images can be obtained from the bounding boxes of v_1 and v_2, which are expected to be generated during the preceding music object detection stage. Note, that the masks for channel 2 and 3 are obtained from the bounding boxes and the underlying image, which means that the masks can (partially) include other objects as well unless the exact masks are provided via pixelwise segmentation [16, 35].

The network is then fed with this 3-channel image and trained to predict 1 if there should be a relationship between the vertices, and 0 otherwise. Visualizations of the input images are given in Fig. 2.

4.1 Dataset

To carry out our experiments we need a corpus, which has annotations for both the individual symbols as well as their relationships. Currently, the only publicly available dataset which fulfills this requirement is the MUSCIMA++ dataset [18] of handwritten music notation. It provides symbol-level annotations as well as relationship annotations for 140 out of 1 000 images from the CVC-MUSCIMA dataset [13]. The MUSCIMA++ dataset contains 91 254 annotated symbols, consisting of both notation primitives and higher-level notation objects, such as key signatures or time signatures as well as 82 247 explicitly marked relationships between symbol pairs.

Unfortunately, the precedence relationships between notes are not included in the MUSCIMA++ dataset, so our experiments consider only the syntactic edges. However, the formulation and the proposed approach are very similar and should work for both kinds of edges.

4.2 Relationship Reconstruction

For learning the relationships, we train a convolutional neural network in PyTorch with five consecutive blocks, each consisting of a convolution, batch normalization, a non-linearity (ReLU), and max-pooling, before going into a fully connected layer with a single output neuron followed by a sigmoid activation function that produces the final estimation. The network has 28 865 parameters in total. We use the Binary Cross-Entropy loss and train with the Adam optimizer [20] until the validation performance has not improved for ten epochs, upon which we stop.

The data-loading routine presents the biggest challenge because it has to construct the multi-channel images as described in Sect. 4. To efficiently generate the set of vertex-pairs, we compute the pairwise distance between all objects in an image but filter them considerably afterward by the distance and compatibility criteria (see Sec. 4). The distance threshold was set to $t = 200$ pixels for including most valid edges from the MUSCIMA++ dataset. Valid relationships between objects that are further apart than 200 pixels are extremely rare and were neglected in favor of

(a) A positive example of two objects that are related.

(b) A negative example of two objects that are unrelated.

(c) A hard negative example of a dot that could be related to the notehead, but is not.

Figure 2: Three samples of images that are used during training. The mask given in channel 2 is shown as bright green overlay and the mask from channel 3 as cyan overlay.

computational efficiency. Our compatibility map contains 225 valid combinations of primitives. To improve the performance even further and simplify the classification task, the input image for the neural network is cropped to a sub-image of 512×256 pixels (width $\times$ height), containing the two objects of interest at its center. Both the distance threshold and the sub-image dimensions are hyperparameters that are dataset-dependent but can be obtained by running a statistical analysis on the used dataset.

We split the 140 images of the dataset into 60 % training data, 20 % validation data, and 20% test data. In each epoch, the network is trained on approximately 250 000 images of candidate pairs. Approximately 25 percent of the candidates contain positive examples. The best results were obtained after just 12 epochs before the network started to overfit and the validation performance declined. The source-code is publicly available on Github. [1]

4.3 Music Object Detection

Since the notation assembly stage begins after the music objects have been detected in the score image, we also wanted to evaluate, how well our approach works on actual detection results. For obtaining such results, we resort to a state-of-the-art music object detector as proposed by Pacha et al. [25] with a minor modification: While we do divide the full page into sub-images containing one stave each, we do not see the need for cutting the images any further. The model selection and training procedure remains unchanged. We split the dataset into 100 images for training, 20 images for validation and 20 images for testing, as proposed by the authors of the MUSCIMA++ dataset. The improved implementation is publicly available. [2]

We evaluate the trained model on the test set for the stave-wise individual images and report the Mean Average Precision (mAP) as defined for the COCO challenge [21] which is a unified metric, commonly used for object detection tasks. The trained model achieves 69.5 % mAP. For comparison, we also report a mAP of 93.3 % when using the mAP as defined for the PASCAL VOC challenge [11], which was used in the original paper. Finally, the images are merged into the full-page results upon we achieve: 34.5 % mAP / 45.2 % w-mAP [3] (COCO) and 53.8 % mAP / 80.9 % w-mAP (PASCAL). As our main focus is on learning relationships and not music object detection, we do not go into further details on these numbers. However, we want to point out that the COCO metric is very strict and probably underestimating the performance of the music object detector (see Fig. 3 for an example output).

4.4 Evaluation Protocol

Once the music objects have been detected, and their relationships established, the system can produce a complete MuNG that can be compared with the reference MuNG, provided as ground truth. However, it is necessary to first establish the correspondences between vertices from the prediction and the ground-truth. To do so, we assume that a detected object v_1 corresponds to a ground-truth object v_2 if they depict the same class $\zeta(v_1) = \zeta(v_2)$ and their Intersection over Union exceeds 50 %.

Once the vertices of the ground-truth are matched with the detected objects, it is possible to compute the statistics. If an established relationship is correct, it is considered a true positive (TP); if an established relationship is incorrect, it is considered a false positive (FP); and, if an expected relationship is not predicted, it is considered a false negative (FN). Then, we can compute precision (P), recall (R), and F-score (F_1) metrics:

$$P = \frac{\text{TP}}{\text{TP} + \text{FP}}, \quad R = \frac{\text{TP}}{\text{TP} + \text{FN}}, \quad F_1 = 2\frac{P \times R}{P + R}$$

P measures how reliable the established relationships are, whereas R measures the ability of the model to retrieve as many relationships as possible. F_1 summarizes both metrics with a single value.

Note that, although our evaluation is primarily focused on the relationships between objects, the used metrics are affected by the performance of the music object detector. Errors from earlier stages of the OMR process propagate to later stages. So if musical objects were missed, their relationships are counted as false negatives. To account for this, we evaluate our model in two ways:

[2] https://github.com/apacha/MusicObjectDetector-TF

[3] Weighted Mean Average Precision is the Mean Average Precision, weighted by the frequency of the occurring classes, which is higher because frequent classes yielded better results than rare ones.

Figure 3: Sample output of the improved music object detector. Each detected object v has a box around it, with the color representing the class $\zeta(v)$ of the particular object, e.g., light green for full-noteheads.

- over a hypothetical set of perfect detections, which we can extract from the ground-truth of the corpus, and
- over the result of an actual music object detector, specifically using the state-of-the-art model, described in Sect. 4.3.

These settings allow us to answer the two questions: Does the proposed approach for reconstructing the MuNG with a machine learning model work at all? If yes, how well does the system perform in a real-world scenario, when confronted with (imperfect) object detector results instead of the perfect ground-truth bounding boxes?

4.5 Results

The main objective of our work is to demonstrate that the notation assembly stage can be formulated as a machine learning task. The main results of our experiments are given in Table 1. It can be observed that the proposed approach is highly effective: in all cases, values above 90 % are reported.

When starting from ground-truth music object detection, our model yields $P = 95.2\,\%$, $R = 96.0\,\%$, and $F_1 = 95.2\,\%$, which indicates a successful approach to completing the OMR pipeline. In case of starting from actual results of a state-of-the-art detector, performance decreases slightly to $P = 93.2\,\%$, $R = 91.5\,\%$, and $F_1 = 92.3\,\%$. We think this is because the location of the objects is not always exact (leading to a lower P) and missing symbols cause relationships to be irrecoverable (leading to a lower R).

	Graph Edges / Relationships		
	Precision	**Recall**	**F-Score**
Perfect Detection	95.2%	96.0%	95.6%
Real Detector	93.2%	91.5%	92.3%

Table 1: Overall performance of the proposed machine learning model to reconstruct syntactic edges of the Music Notation Graph (MuNG), given hypothetically perfect detection results (top row), and given results from a state-of-the-art detector (bottom row).

In order to provide more experimental insights, Table 2 reports 10 out of the 225 compatible combinations of relationships that are most common in the MUSCIMA++ dataset. As might be expected, the *notehead* primitives are involved in all of these frequent combinations. In this regard, our model obtains nearly optimal results for these over-represented cases. Note that these relationships are of particular relevance to be able to decode the notes that appear in the score. When comparing the individual results to the overall results in Table 1, the discrepancy can be explained by looking at the remaining 215 combinations that are not shown. Many of these have a much lower F_1, probably because they are under-represented in the dataset.

From	To	Number of candidate pairs in the dataset	F-Score on the test set
notehead-full	stem	158064	99.5%
notehead-full	beam	61253	98.7%
notehead-full	leger_line	47503	98.1%
notehead-full	slur	24738	96.4%
notehead-full	8th_flag	12877	97.7%
notehead-full	sharp	12563	97.5%
notehead-full	duration-dot	12305	96.7%
notehead-empty	stem	9488	100.0%
notehead-full	staccato-dot	8628	96.8%
notehead-full	natural	7160	98.7%

Table 2: Overview of the ten most common combinations of object-pairs, along with the number of generated candidate pairs in the dataset, as seen by the network. The last column contains the F-scores that were reported for the individual combinations when evaluating the trained model on the test set, containing the ground truth of music primitives v.

5. CONCLUSION AND OUTLOOK

In this work, we study how to complete the OMR pipeline from the previous efforts to detect the music objects within the input image. Our approach seeks the construction of a music notation graph that stores the information of the notation primitives as well as their syntactic and precedence relationships. We propose a machine learning model that can predict whether two primitives are related to each other or not.

Results over the set of syntactic relationships from the handwritten sheet music dataset MUSCIMA++ show that our approach is very effective. We obtain success rates close to the optimum when establishing the correct relationships from the ground-truth primitives ($F_1 = 95.6\%$). When re-evaluating the results starting from the primitives detected by a state-of-the-art music object detector, a slightly lower performance can be observed ($F_1 = 92.3\%$). These figures indicate that the notation assembly stage of the OMR pipeline can be solved reliably with a machine learning model, given a curated set of annotated scores. Comparing our approach to existing methods is extremely difficult, if not impossible, because:

- most existing solutions are black boxes with closed source-code, or there is no available implementation at all,
- only a few systems are capable of handling handwritten modern notation, and
- it is unclear how to compare the music notation assembly stage between two different systems, especially given that the notation graph is only an intermediate representation.

So, although the results are promising, we still see many interesting avenues for further research. For instance, by adding data augmentation during training to make the notation assembly model more robust against variations in the bounding box retrieval of the first stage. Also, we plan to look into providing other meaningful features to the network, such as the class labels $\zeta(v)$ of the involved primitives $v \in V$. Furthermore, we observed that the fixed-sized input patch given to the network is often covering a much larger area than required to contain the objects of interest, especially when they are very close (see Fig. 2c). This could be handled by using size-independent neural network layers such as *Global Pooling*, instead of flattening the features and feeding them into a fully-connected layer, allowing us to adjust the input patch for each sample.

We also believe that the notation assembly stage could benefit from having a broader set of hypotheses about the objects detected in the previous stage, instead of a fixed set of proposals. State-of-the-art music object detectors are based on statistical neural models that are able to provide a probability distribution over the whole set of possible detection hypotheses. When it comes to recognizing, we are typically interested in the most likely hypothesis—the one that is proposed as an answer—forgetting the other ones. However, it is certainly interesting to exploit this statistical modeling: the notation assembly algorithm could establish relationships that are more logical a priori, although the objects involved have a lower probability according to the object detector. These types of approaches have yet to be explored in the field of OMR.

And finally, for completing the OMR pipeline, the encoding stage is still missing. However, we see two benefits of the notation graph representation: the encoding can be implemented by experts in music encoding that are proficient in a particular format and given a complete graph representation, there is no restriction on the actual output format because the graph contains all the information that is present in the image.

ABSTRACT

While the automatic recognition of musical instruments has seen significant progress, the task is still considered hard for music featuring multiple instruments as opposed to single instrument recordings. Datasets for polyphonic instrument recognition can be categorized into roughly two categories. Some, such as MedleyDB, have strong per-frame instrument activity annotations but are usually small in size. Other, larger datasets such as OpenMIC only have weak labels, i.e., instrument presence or absence is annotated only for long snippets of a song. We explore an attention mechanism for handling weakly labeled data for multi-label instrument recognition. Attention has been found to perform well for other tasks with weakly labeled data. We compare the proposed attention model to multiple models which include a baseline binary relevance random forest, recurrent neural network, and fully connected neural networks. Our results show that incorporating attention leads to an overall improvement in classification accuracy metrics across all 20 instruments in the OpenMIC dataset. We find that attention enables models to focus on (or 'attend to') specific time segments in the audio relevant to each instrument label leading to interpretable results.

1. INTRODUCTION

Musical instruments, both acoustic and electronic, are necessary tools to create music. Most musical pieces comprise of a combination of multiple musical instruments resulting in a mixture with unique timbre characteristics. Humans are fairly adept at recognizing musical instruments in the music they hear. Recognizing instruments automatically, however, is still an active area of research in the field of Music Information Retrieval (MIR). Instrument recognition in isolated note or single instrument recordings has achieved a fair amount of success [14, 26]. Recognizing instruments in music with multiple simultaneously playing instruments, however, is still a hard problem. The task is difficult because of (i) the superposition (in both time and frequency) of multiple sources/instruments, (ii) the large variation of timbre within one instrument, and (iii) the lack of annotated data for supervised learning algorithms.

Identifying music in audio recordings is helpful for general retrieval systems by allowing users to search for music with specific instrumentation [32]. Instrument recognition can also be helpful for other MIR tasks. For example, instrument tags may be vital for music recommendation systems to model users' affinity towards certain instruments, genre recognition systems could also improve with genre-dependent instrument information. Building models conditioned on a reliable detection of instrumentation could also lead to improvements for tasks such as automatic music transcription, source separation, and playing technique detection.

As mentioned above, one of the challenges in MIR in general, and in instrument recognition in particular, is the lack of large-scale annotated or labeled data for supervised machine learning algorithms [17, 36]. Datasets for instrument recognition in polyphonic music can broadly be divided into strongly and weakly labeled. A weakly labeled dataset (WLD) contains clips that may be several seconds long and have labels for one or more instruments for their entirety without annotating the exact onset and offset times of the instruments. A strongly labeled dataset (SLD), however, contains audio with fine-grained labels of instrument activity. WLDs are easier to annotate compared to SLDs and therefore scale better. Even though SLDs enable strong supervision of learning algorithms, the smaller size may lead to poor performance of deep learning methods. WLDs, however, have the disadvantage that an instrument may be marked positive even if the instrument is active for a very short duration of the entire clip. This makes it challenging to train models with WLDs.

Models for recognition in weakly labeled data may benefit from inferring the specific location in time of the instrument to be recognized. We formulate the polyphonic instrument recognition task as a multi-instance multi-label (MIML) problem, where each weakly labeled example is a collection of short-time instances, each with a contribution towards the labels assigned to the example. Toward that end, we apply an attention mechanism to aggregate the predictions for each short-time instance and compare this approach to other models which include binary-relevance

random forests, fully connected networks, and recurrent neural networks. We hypothesize that the ability of the attention model to weigh relevant and suppress irrelevant predictions for each instrument leads to better classification accuracy. We visualize the attention weights and find that the model is able to mostly localize the instruments, thereby enhancing the interpretability of the classifier.

The next section reviews literature in instrument recognition and audio tagging or classification. Sect. 3 discusses various datasets for instrument recognition and the challenges associated. Next, Sect. 4 formulates the problem and describes the model. Sect. 5 specifies the various experiments and the evaluation metrics to measure performance. We report the results of the experiments and discuss them in Sect. 6. Finally, in Sect. 7 we conclude the paper suggesting future directions for research.

2. RELATED WORK

2.1 Musical Instrument Recognition

Instrument recognition in audio containing a single instrument can refer to both recognition from isolated notes or recognition from solo recordings of pieces. We refer to [15, 26] for a review of literature in single instrument and monophonic instrument recognition.

Current research has focused on instrument recognition in polyphonic and multi-instrument recordings. While traditional approaches extract features followed by classification algorithms were previously prevalent [9, 21], deep neural networks have dominated recent work in this field. Han et al. [13] applied Convolutional Neural Networks (CNNs) to the task of predominant instrument recognition on the IRMAS dataset [5] and outperformed various feature-based techniques. Li et al. [25] proposed to learn features from raw audio using CNNs for instrument recognition using the MedleyDB dataset [4]. Gururani et al. [12] compared various neural network architectures for instrument activity detection using two multi-track datasets containing fine-grained instrument activity annotations: MedleyDB and Mixing Secrets [11] . They found significant improvement of CNNs and Convolutional Recurrent Neural Networks (CRNNs) over fully connected networks and proposed a method for visualizing model confusion in a multi-label setting. Hung et al. [19] utilized the fine-grained instrument activity as well as pitch annotations in the MusicNet dataset [33] and showed the benefits of pitch-conditioning on instrument recognition performance. In follow-up research, Hung et al. [18] proposed a multi-task learning approach for instrument recognition involving the prediction of pitch in addition to instrumentation. They released a synthetic, large-scale, and strongly-labeled dataset generated from MIDI files for evaluation and found that multi-task learning outperforms their previous approach of using pitch features as additional inputs.

2.2 Audio event detection, tagging and classification

The task of audio or sound event classification shares many commonalities with instrument recognition. Both tasks aim to identify a time-variant sound source in a mixture of multiple sound sources. A few key differences are that research in sound event classification typically focuses on uncorrelated sounds such as motor noise, car horns, baby cries, or dog barks, while musical audio is highly correlated. Additionally, music has a rich harmonic and temporal structure usually absent in audio captured from real world acoustic scenes.

For a historic review of work in sound event and audio classification, we refer readers to the survey article by Stowell et al. [31]. We focus on more recent literature involving deep neural network architectures —which are now the standard approach— as well as on methods that focus on addressing weak labels.

Hershey et al. [16] adapted deep CNN architectures from computer vision and found that they are effective for large-scale audio classification. Cakir et al. [6] researched the benefits of CRNNs for sound event detection over models comprising of only CNNs. They found that the ability of RNNs to capture long-term temporal context helps improve performance against models only comprising CNNs. Adavanne et al. [1] proposed to use spatial features extracted from multi-channel audio as inputs for CRNN architectures. They found that presenting these features as separate layers to the model outperforms concatenation of these features at the input stage.

Learning from weakly labeled data has also been a focus in audio classification. Most works utilize the Multiple-Instance Learning (MIL) framework for the task, where each example is a labeled bag containing multiple instances whose labels are unknown. Kumar and Raj [24] utilized support vector machines and neural networks for solving the MIL problem. They train bag-level classifiers capable of predicting instances and are hence also useful for localization of sound events. Similarly, Kong et al. [22] proposed decision-level attention to solve the MIL problem for Audio Set [10] classification. Attention is applied to instance predictions to enable weighted aggregation for bag-level prediction. Kong et al. [23] extended this and propose feature-level attention where instead of applying attention to the instance predictions, it is applied to the hidden layers of a neural network to construct a fixed-size embedding for the bag. Finally a fully connected network predicts the labels for the bag using the embedding vector. McFee et al. [27] compared various methods for aggregating or pooling instance-level predictions. They developed an adaptive pooling operation capable of interpolating between common pooling operations such as mean-, max- or min-pooling.

3. DATA CHALLENGE

In Sec. 2.1, we introduced research on instrument recognition in polyphonic, multi-timbral music. One theme that emerges is that with almost every new publication, a new dataset is released by the authors in an effort to address issues with previous ones. While releasing new datasets is highly encouraged and vital for research in MIR in general, an uncoordinated effort leads to lack of uniformity in the

datasets used. In this section we briefly describe the common datasets for instrument recognition and identify the challenges associated with them.

The IRMAS dataset [5] is a frequently used dataset for predominant instrument recognition. It consists of a separate training and testing set, each containing annotations for 11 predominant instruments. The dataset consists of short excerpts —3 s for training and variable length for testing— of weakly labeled data. One fundamental problem of the IRMAS annotations is that the training set lacks multi-label annotation; this can be problematic for a general use case as instrument co-occurrence is ignored.

The MedleyDB [4] and Mixing Secrets [11] datasets are both multi-track datasets. Due to the availability of instrument-specific stems, strong annotations of instrument activity are available. Thus, these two multi-track datasets provide all the necessary detailed annotations for instrument activity detection and have been used in [12, 25]. These datasets have two disadvantages when training models. First, with a few hundred distinct songs models trained with the data are hardly generalizable. Second, the datasets are not well balanced in terms of either musical genre or instrumentation. However, this may not be a problem if the datasets were larger and the distribution represented the real-world.

Most of these problems were addressed with the release of the OpenMIC dataset [17]. This dataset contains 20,000 10 s clips of audio from different songs across various genres. Each clip is annotated with the presence or absence of one or more of 20 instrument labels. OpenMIC presents a larger sample size as well as a uniform distribution across instruments. It is, however, weakly labeled, i.e., each 10 s clip has instrument presence or absence tags without specific onset and offset times. Due to the nature of weak labels, models cannot be trained using fine-grained instrument activity annotation as done, e.g., in [12, 19]. Additionally, not all clips are labeled with all 20 instruments, i.e., there are missing labels. This complicates the training procedure if models are to predict the presence/absence for all 20 instruments for an input audio clip. Despite their drawbacks, creation of WLDs scales better since weak labels are cheaper to obtain; models capable of exploiting WLDs may thus be vital for the future development of instrument recognition.

4. METHOD

Before describing the model details, we provide a formalization of our approach to the instrument recognition problem in weakly labeled data.

4.1 Pre-Processing

As mentioned in Sect. 3, the OpenMIC dataset consists of 10 s audio clips, each labeled with the presence or absence of one or more of 20 instrument labels. For each audio file in the dataset, the dataset creators also release features extracted from a pre-trained CNN, known as "VGGish" [16]. The VGGish model, based on the VGG architectures for object recognition [30], is trained for audio classification. The model produces a 128-dimensional feature vector for 0.96 s windows of audio with no overlap. The features are ZCA-whitened and quantized to 8-bits. For a 10 s audio file, we obtain a 10×128-dimensional matrix. We also normalize the 8-bit integers to a quantized range of $[0, 1]$.

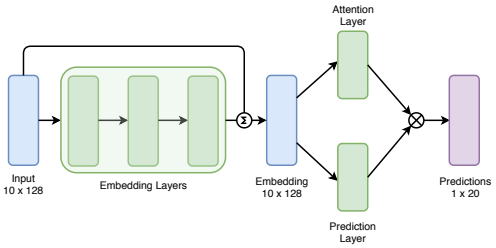

Figure 1: Model Architecture

4.2 Formulation

4.2.1 Multi-Instance Multi-Label Problem

In the most general setting, instrument recognition can be framed as Multi-Instance Multi-Label (MIML) classification [38, 42, 43]. Under this setting, we are given a training dataset $\{(\mathbf{X}_1, \mathbf{Y}_1), \dots (\mathbf{X}_m, \mathbf{Y}_m)\}$ where $\mathbf{X}_i$ is a bag containing r instances $X_i = \{\boldsymbol{x}_{i,1}, \dots \boldsymbol{x}_{i,r}\}$ and $\mathbf{Y}_i = [\boldsymbol{y}_{i,1}, \dots, \boldsymbol{y}_{i,L}] \in \{0, 1\}^L$ is a label vector with L labels with $\boldsymbol{y}_{i,j} = 1$ if any of the instances in $\mathbf{X}_i$ contains label j. In the remainder of this section, we will drop the indices used to reference a specific data point and simply represent a sample from the dataset as $(\mathbf{X}, \mathbf{Y})$. In our case, a bag $\mathbf{X}$ refers to the 10×128-dimensional feature matrix representing one audio clip and each bag contains 10 instances. Our problem is also a Missing Label problem since for a sample $(\mathbf{X}, \mathbf{Y})$, not all $\boldsymbol{y}_j$ are known or annotated (compare Sect. 3).

In our experiments, we assume that all labels can be independently predicted for each instance. Under this assumption, the MIML problem decomposes into L (20 for OpenMIC dataset) instantiations of Multi-Instance Learning (MIL) [8,41] problems, one for each label in the dataset.

Note that exploiting label-correlation in multi-label classification has shown to significantly improve the classification performance [28, 28, 34, 40]. However, exploring ways to incorporate label-correlation for instrument recognition in the OpenMIC dataset has the additional challenge of missing and sparse labels [3]. Also, as is prevalent in most MIL approaches [8], we assume independence among different instances in a bag. Neighboring instances in a bag representing a polyphonic music snippet will, however, likely have high correlation. Relaxing the aforementioned assumptions about independence among labels, and instances in a bag is left for future work since in our current work, we focus on the impact of attention for aggregating instance-level predictions.

4.2.2 Multi-Instance Learning

In the MIL setting, a bag label is produced through a score function $S(\mathbf{X})$. Under the assumption of independence

among instances, $S(\mathbf{X})$ admits a parametrization of the form

$$S(\mathbf{X}) = \mu\Big(f(\boldsymbol{x}) \Big) \tag{1}$$

where $f(.)$ is a score function for an instance $\boldsymbol{x}$, and $\mu(.)$ is a permutation-invariant aggregation operation for instance scores $f(\boldsymbol{x})$ [37]. This parameterization induces a natural approach to classify a bag of instances: (i) to produce scores for each instance in the bag using an instance-level scoring function $f(\boldsymbol{x})$, and (ii) to aggregate the scores across different instances in the bag using the aggregation function $\mu(.)$. In our approach, we use a classification function to produce instance-level scores $f(\boldsymbol{x})$, which are essentially the probabilities of a label being present for each instance. The max and avg functions are two commonly used permutation-invariant operations to aggregate instance-level scores to bag-level scores. McFee et al. found that *learning* an aggregation operation, however, significantly improved performance over fixed predefined operations like max and avg. We choose to represent our aggregation operation $\mu(.)$ as a weighted sum of instance-level scores, i.e.,

$$S(\mathbf{X}) = \sum_{\boldsymbol{x} \in \mathbf{X}} w_{\boldsymbol{x}}\ f(\boldsymbol{x}) \tag{2}$$

where $w_{\boldsymbol{x}}$ is a learnable weight for instance $\boldsymbol{x}$. Our choice of $f(.)$ and $\mu(.)$ has the two advantages that (i) the resulting $S(.)$ is the probability of a label being present in the bag and can be directly used to make a prediction and (ii) the learned weights for each instance add interpretability to the MIL models by encoding beliefs placed by the MIL model on the score of each instance.

4.2.3 Attention Mechanism

The learnable aggregation operation is equivalent to attention. Given a bag $\mathbf{X} = \{\boldsymbol{x}_1, \ldots, \boldsymbol{x}_r\}$ of r instances, the instance level scoring function $f(.)$ produces a bag $\{f(\boldsymbol{x}_1), \ldots, f(\boldsymbol{x}_r)\}$ of instance scores. The bag-level score $S(\mathbf{X})$ is then computed using Eq. (2).

We further impose the restriction that instance weights w_x should sum to 1, i.e., $\sum_{\boldsymbol{x} \in \mathbf{X}} w_{\boldsymbol{x}} = 1$. This ensures that the aggregation operation is invariant to the size of the bag, thus allowing the model to work with sound clips of arbitrary length. Furthermore, this normalization leads to a probabilistic interpretation of the instance weights which can then be used to infer the relative contribution of each instance towards $S(\mathbf{X})$. For an instance $\boldsymbol{x} \in \mathbf{X}$, the weight $w_{\boldsymbol{x}}$ is thus parametrized as

$$w_{\boldsymbol{x}} = \frac{\sigma(\boldsymbol{v}^\top h(\boldsymbol{x}))}{\sum_{\boldsymbol{x}' \in \mathbf{X}} \sigma(\boldsymbol{v}^\top h(\boldsymbol{x}'))} \tag{3}$$

where $h(\boldsymbol{x})$ is a learned embedding of the instance $\boldsymbol{x}$, $\boldsymbol{v}$ are the learned parameters of the attention layer, and $\sigma(.)$ is the *sigmoid* non-linearity.

This corresponds to the attention mechanism traditionally used in sequence modeling [2, 35]. For example, Raffel and Ellis [29] produced attention weights in a manner similar to Eq. (3) with the only difference being the use of *softmax* operation to perform normalization of weights across the instances.

4.3 Model Architecture

Computing bag-level scores $S(.)$ involves computing instance-level scores $f(.)$ and aggregating the scores across instances using a learned set-operator $\mu(.)$ which performs weighted averaging with the weights computed with Eq. (3). For our experiments, we represent the scores, both instance level $f(.)$ and bag-level $S(.)$, as the probability estimate of the instance or bag being a positive sample for a given label. We first pass each instance $\boldsymbol{x}$ through an embedding network of three fully connected layers to project each instance to a suitable embedding space. Next, instance-level scores $f(.)$ are computed from the output of embedding network with another fully connected layer. Similarly, attention weights are computed by normalizing the outputs of a fully connected layer, the weights of which correspond to parameters $\boldsymbol{v}$ in Eq. (3). Note that the output dimension of these two parallel fully connected layers is equal to the number of labels, i.e., 20. Figure 1 illustrates the model architecture. In the embedding layer, the number of hidden units is 128. We also found that adding a skip connection from the input to the final embedding stabilized the training across different random seeds. We use batch normalization, ReLU activations, and a dropout of 0.6 after each embedding layer. The model has 55336 learnable parameters.

4.4 Loss Function and Training Procedure

Our model performs a multi-label classification over 20 labels given an input. However, as we point out earlier, the OpenMIC dataset does not contain all labels for each instance. This leads to missing ground truth labels for training with loss functions such as binary cross-entropy (BCE). To account for this, we utilize the partial binary cross-entropy (BCE_p) loss function introduced for handling missing labels [7]:

$$\begin{aligned} \mathrm{BCE}_p(\boldsymbol{y}, \boldsymbol{q}) &= \frac{g(p_y)}{L} \sum_{l \in L^o} \boldsymbol{y}_l \log \boldsymbol{q} + (1 - \boldsymbol{y}_l) \log(1 - \boldsymbol{q}) \\ g(p_y) &= \alpha p_y^\gamma + \beta \end{aligned} \tag{4}$$

Here $g(p_y)$ is a normalization function, p_y is the proportion of observed labels for the current data point, L is the total number of labels, L^o is the list of observed labels for the input data, $\boldsymbol{y}_l \in \{0, 1\}$ is the ground truth (absent or present) for label l, and $\boldsymbol{q}$ is the model's probability output for the label l being present in the input data $\mathbf{X}$. The hyperparameters in Eq. (4) are α, β, and γ. Note that in the absence of $g(p_y)$, data points with few observed labels will have a lower contribution in loss computation than those with several observed labels. This is undesirable behavior and the inclusion of a normalization factor, dependent on the proportion of observed labels, is important. Therefore, we set α, β, and γ to 1, 0, and -1, respectively. This normalizes the loss for a data point by the number of observed labels and is equivalent to only computing the loss for observed labels.

Finally, the Adam optimization algorithm [20] is used for training with a batch size of 128 and learning rate of $5e^{-4}$ for 250 epochs. We checkpoint the model at the epoch with the best validation loss.

5. EVALUATION

In this section we describe the experimental setup including the dataset, the baseline methods, and evaluation metrics.

5.1 Dataset

We use the OpenMIC dataset for the experiments in this paper. In addition to the audio and label annotations, the data repository contains pre-computed features extracted from the publicly available VGG-ish model for audio classification. We utilize those features in our experiments to strictly focus on handling the weak labels and avoid further complexity by having to learn features from the raw data or spectrogram representations. Pilot experiments for feature learning showed that CNN architectures based on state-of-the-art instrument recognition models were unable to outperform the baseline model of 20 instrument-wise random forest classifiers trained using the pre-computed features. For reproducibility and comparability, we utilize the training and testing split released with the dataset. Additionally, we randomly sample and separate 15% data from the training split to create a validation set.

5.2 Experiments

We compare the attention model (ATT) with the following models:

1. RF_BR: This model is the baseline random forest model in [17]. A binary-relevance transformation is applied to convert the multi-label classification task into 20 independent binary classification tasks [39].
2. FC: A 3-layer fully connected network trained to predict the presence or absence of all instruments for a given data instance. Here, the input features of dimension 10×128 are flattened into a single feature vector for classification. Dropout is used for regularization and the Leaky ReLU (0.01 slope) is used. The model has 986772 parameters.
3. FC_T: This model serves as an ablation study to observe the benefits of the attention mechanism. FC_T uses the same embedding layer as ATT. However, the aggregation of predictions in time is simply performed with average-pooling. The model has 52116 parameters.
4. RNN: A 3-layer bi-directional gated recurrent unit model with 64 hidden units per direction. The model processes the input features and produces a single embedding which is then fed to a classifier for all 20 instruments. The model has 226068 parameters.

Source code for the Pytorch implementation of the neural network models is publicly available. [1] For each model, we train 10 randomly initialized instances with different random seeds and compute the classification metrics for each.

[1] https://github.com/SiddGururani/AttentionMIC

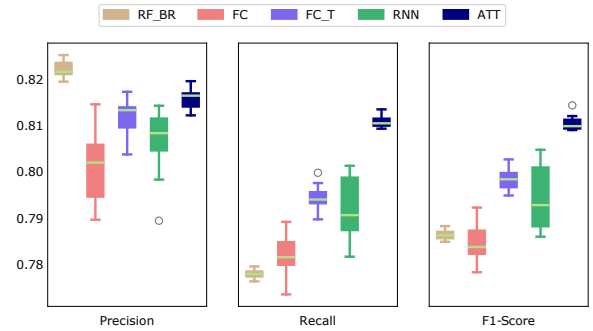

Figure 2: Precision, recall, and F1-score for different models

This gives us a distribution of each model's performance. One benefit of ATT over the FC and RNN models is its small size. Both the ATT and FC_T utilize weight-sharing for embedding instances from the bags. This leads to significantly fewer learnable parameters compared to FC and RNN while performing better than both of these models.

5.3 Metrics

While the total number of clips per instrument label in the OpenMIC dataset is balanced, the number of positive and negative examples is not well balanced for each instrument label. Therefore, we separately compute the precision, recall and F1-score for the positive and negative class. Thereafter, we compute the macro-average of these metrics to report the final instrument-wise metrics, meaning that positive and negative examples are weighted equally. We call these the instrument-wise precision, recall, and F1-score. Additionally, to measure the overall performance of a classifier, we macro-average the instrument-wise precision, recall and F1-score. We use a fixed threshold of 0.5 to convert the outputs into binary predictions for computing the classification metrics.

6. RESULTS AND DISCUSSION

Figure 2 shows the overall performance of ATT compared to the baseline models with box plots for the macro-averaged precision, recall, and F1-score. Additionally, we compare the instrument-wise F1-score for each model in Figure 3. Note that we only show the mean instrument-wise F1-score across 10 seeds in Figure 3 for improved visibility.

We observe that while the attention mechanism does not lead to an improvement in precision compared to the other models, the recall is improved significantly and consequently the F1-score is also improved. We also observe that ATT performs better than RF_BR in almost every instrument label, especially for the labels with high positive-negative class imbalance, such as clarinet, flute, and organ. This ties to the observation made about improved recall, as ATT is able to overcome this imbalance possibly due to the ability to localize the relevant instances for the minority class. In the case of an imbalanced instrument label, the recall for the minority class greatly suffers for RF_BR.

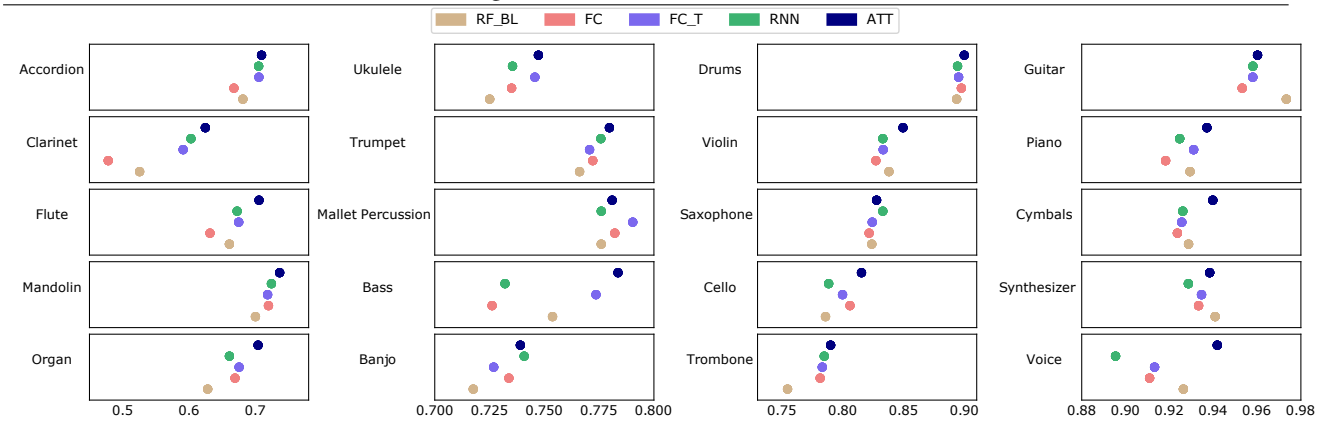

Figure 3: Instrument-wise F1-scores

While this problem is easily mitigated in standard multi-class problems by using balanced sampling, it is difficult to address with multi-label data. Comparing to FC_T, we can attribute the better performance of ATT to better aggregation of instance-level predictions. FC_T is essentially the same model as ATT using mean pooling instead of attention, and ATT outperforms it for most instrument classes, especially the generally more difficult to classify instruments. The RNN model also beats the RF_BR baseline. In polyphonic music, the instances in a bag are structured and highly correlated and hence using a recurrent network to model the temporal structure in the instance sequence leads to a powerful embedding of the bag, incorporating useful information from each instance.

We visualize the attention weights for two example clips in Figure 4. The left clip is from the test set and starts with the vocals fading out until 2 seconds. From 5 second onwards, the vocals grow in loudness until the end of the clip. The violin plays throughout but is the pre-dominant instrument only for a few seconds between 3 and 6 seconds, as visualized in the corresponding attention weights as well. The right clip is from the training set and contains vocals starting from 6 second onwards. The attention weights for vocals directly coincides with that. It is interesting to note that the annotation for vocals was missing for this clip.

7. CONCLUSION

Weakly labeled datasets for instrument recognition in polyphonic music are easier to develop or annotate than strongly labeled datasets. This calls for a paradigm shift in the approaches towards supervised learning approaches better suited for weakly labeled data. We formulate the instrument recognition task as a MIML problem and introduce an attention-based model, evaluated on the OpenMIC dataset for 20 instruments, and compared against several other baseline models including: (i) binary-relevance random forest, (ii) fully connected networks, and (iii) recurrent neural networks, We find that the attention mechanism improves the overall performance as well as the instrument-wise performance of the model while keeping the model light-weight. The example visualizations show that the model indeed is

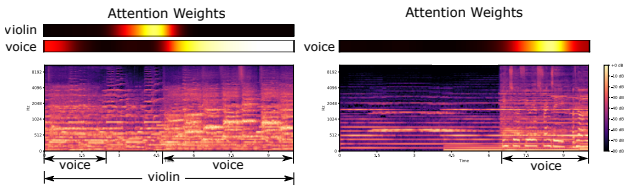

Figure 4: Attention Weight Visualization: The horizontal bars above the mel-spectrogram represent the attention weights across the instances of the clip for the respective instruments.

able to attend to relevant sections on a clip.

Some of the assumptions made in the formulation of the MIML problem are strong and may be worth relaxing due to the nature of musical data. We plan to further explore the task of instance-level embeddings using recurrent networks or using self-attention mechanisms as used in Transformer networks [35]. Additionally, we plan to address the problem of missing labels or label sparsity in the OpenMIC dataset using the curriculum learning-based methods proposed in [7]. Our concern is that the dataset is not large enough with enough labels for strictly supervised learning approaches to significantly improve the results much further than what we achieve with the attention mechanism, and we therefore plan to tackle the problem from other angles, such as handling missing labels or data augmentation.

8. ACKNOWLEDGEMENTS

This research is partially funded by Gracenote, Inc. We thank them for their generous support and meaningful discussions. We also thank Nvidia Corporation for their donation of a Titan V awarded as part of the GPU grant program.

ABSTRACT

MIDI–sheet music alignment is the task of finding correspondences between a MIDI representation of a piece and its corresponding sheet music images. Rather than using optical music recognition to bridge the gap between sheet music and MIDI, we explore an alternative approach: projecting the MIDI data into pixel space and performing alignment in the image domain. Our method converts the MIDI data into a crude representation of the score that only contains rectangular floating notehead blobs, a process we call bootleg score synthesis. Furthermore, we project sheet music images into the same bootleg space by applying a deep watershed notehead detector and filling in the bounding boxes around each detected notehead. Finally, we align the bootleg representations using a simple variant of dynamic time warping. On a dataset of 68 real scanned piano scores from IMSLP and corresponding MIDI performances, our method achieves a 97.3% accuracy at an error tolerance of one second, outperforming several baseline systems that employ optical music recognition.

1. INTRODUCTION

This paper tackles the problem of MIDI–sheet music synchronization. Given a symbolic music representation and its scanned sheet music, the goal is to determine the alignment between each time instant in the symbolic representation and its corresponding pixel location in the sheet music.

Many tools for alignment have been developed in the context of audio synchronization. The goal of audio synchronization is to find the temporal alignment between two different audio recordings of the same musical piece. The main technique used to solve this alignment problem is called dynamic time warping (DTW) [3] [10] [15]. DTW consists of four steps: (1) extracting a sequence of features from both audio recordings, (2) computing a cost matrix C, where C_{ij} indicates the dissimilarity between the i^{th} frame of recording 1 and the j^{th} frame of recording 2, (3) using dynamic programming to calculate a cumulative cost matrix D and backtrace matrix B, where D_{ij} indicates the optimal path score from $(0, 0)$ to (i, j) given a set of allowable transitions and transition weights, and where B_{ij} indicates the penultimate element in the optimal path, and (4) backtracing through B to determine the lowest cost path through the entire matrix. Many works have proposed ways to extend or improve upon this basic method, including doing the time warping in an online fashion [4] [18], estimating the alignment at multiple granularities [22] [26], handling repeats and jumps [12], handling subsequences or partial alignments [20] [28], dealing with fixed memory constraints [23], and utilizing multiple recordings [1] [31].

Several previous works have studied the problem of finding correspondences between audio and sheet music. There are two general approaches to the problem. The first approach is to use an existing optical music recognition (OMR) system to convert the sheet music into a symbolic (MIDI-like) representation, to collapse the pitch information across octaves to get a chroma representation, and then to compare this representation to chroma features extracted from the audio. This approach has been applied to synchronizing audio and sheet music [2] [16] [27], identifying audio recordings that correspond to a given sheet music representation [13], and finding the audio segment corresponding to a fragment of sheet music [11]. A different approach has been explored in recent years: convolutional neural networks (CNNs). This approach attempts to learn a multimodal CNN that can embed a short segment of sheet music and a short segment of audio into the same feature space, where similarity can be computed directly. This approach has been explored in the context of online sheet music score following [5], sheet music retrieval given an audio query [6] [7], and offline alignment of sheet music and audio [7]. Dorfer et al. [8] have also recently shown promising results formulating the score following problem as a reinforcement learning game.

In this paper, we consider the task of MIDI–sheet music synchronization, which can be seen as a variant of the audio–sheet music synchronization scenario. As symbolic (MIDI-like) representations often serve as a bridge between audio and sheet music, MIDI–sheet music synchronization can be regarded as an important intermediate step for more general cross-modal alignment. As men-

[*] The first two authors had equal contribution.

tioned above, traditional approaches typically apply OMR to bridge the modality gap—a step that often introduces severe errors. On the other side, deep learning approaches that try to extract shared feature representations directly from waveforms (audio) and images (sheet music) are promising, but are still in their infancy [21]. As the main contribution of this paper, we introduce an approach that avoids an explicit OMR step by working with an explicitly known sparse, binary representation in the image domain. As we will demonstrate, we can convert both sheet image data and MIDI data into this representation using simple logic coupled with a notehead detector. Based on this common binary representation, we show how the alignment problem can then be solved using a simple variant of DTW. In a sense, our approach mimics a deep learning approach, but explicitly introduces a mid-level representation. We hope that our contribution not only sheds a new light into cross-modal alignment, but may also serve as a non-trivial baseline approach for future fully automated procedures.

The paper is organized as follows. Section 2 describes the proposed algorithm. Section 3 explains the experimental results. Section 4 provides an analysis of system performance. Section 5 concludes the work.

2. SYSTEM DESCRIPTION

There are two inputs to our system: a MIDI file and its corresponding sheet music. Similar to recent work [6–8], we assume that the sheet music is presented as a sequence of image strips, where each image strip contains a single line of music. We focus exclusively on piano music in this work, so each line of music consists of a single grand staff containing an upper staff (treble clef) and a lower staff (bass clef). The image strips may be different sizes, and the staff lines may appear at a different location on each strip.

Our proposed method has three main steps. The first step is to convert each image strip into a sparse, binary representation in pixel space (A_i in Figure 1). We perform this conversion by applying a notehead detector and filling in the predicted bounding boxes around each detected notehead. This representation is a very crude representation of the score that only contains rectangular floating notehead blobs. Accordingly, we call this a bootleg representation. The second step is to project the MIDI data into the same bootleg space (B_i in Figure 1). We perform this projection by converting MIDI note onsets into floating notehead blobs that are appropriately placed in pixel space. The third step is to align the bootleg representations using a variant of DTW (Figure 3). These three steps are described in detail in the next three subsections. [1]

2.1 Notehead Detection

The first step is to convert each image strip into a bootleg representation. As shown in Figure 1 (left side), we accomplish this by applying a notehead detector and filling in the predicted bounding boxes around each detected notehead. The remainder of this subsection describes our notehead detection.

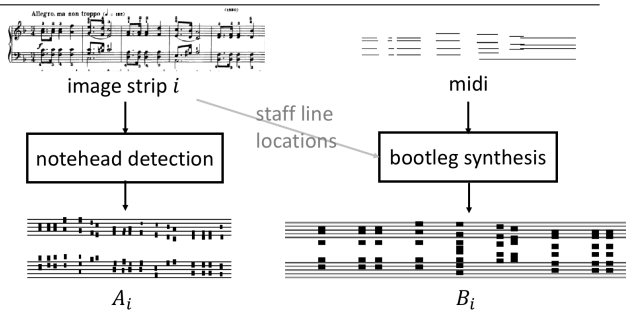

Figure 1. Projecting data to bootleg space. We convert the image strips and MIDI data into a very crude approximation of the sheet music that only contains floating notehead blobs. The staff lines in A_i and B_i are shown as a visual aid, but are not included in the bootleg representation.

Our notehead detector is based on the deep watershed detector recently proposed by Tuggener et al. [30] for musical object detection in sheet music. The deep watershed detector is a fully convolutional network [17] modified to predict three outputs: (a) a quantized energy output map which indicates the likelihood of having an object at each pixel location, (b) a class output map which predicts which type of object is present at each pixel location (e.g. filled notehead, staff line, treble clef, sharp, quarter rest, etc.), and (c) a bounding box output map which indicates the width and height of an object at that pixel location. Figure 2 illustrates the overall architecture of the deep notehead detection network. The reader is referred to [30] for more details. In [29] and [30], Tuggener et al. show that fully convolutional networks are more suitable for semantic segmentation and detection of tiny objects in sheet music, tasks where (large) object detection methods like Fast R-CNN [14], Faster R-CNN [25], and YOLO [24] fail miserably.

We trained our network on the DeepScores dataset [29]. This dataset contains approximately 300,000 full pages of synthetically generated musical scores and pixel-level ground truth labels for 124 different symbol classes. The inputs to the network are 500x500 grayscale image patches that are randomly sampled from the full page images. The loss function is a linear combination of the losses from the quantized energy output map (cross entropy loss), class output map (cross entropy loss), and bounding box output map (mean squared error).

After training on DeepScores, we fine-tune the network on real scanned sheet music. For fine-tuning, we manually annotated the location and type of approximately 2200 noteheads in 30 different pages of piano music downloaded from IMSLP. [2] These 30 pages of music were selected to maximize diversity across composers and music publishers, and they are a completely separate set from the data used to evaluate alignment. Because we only care about detecting noteheads, we disregard all other musical objects

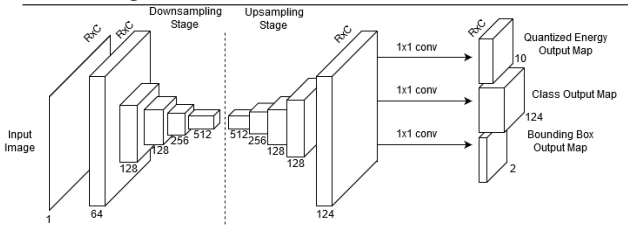

Figure 2. Architecture of the deep watershed notehead detector. The number below each layer indicates the number of feature maps. In the downsampling and upsampling stages, the length and width of the feature maps change by a factor of two in each successive layer. We train on the DeepScores dataset [29] and fine-tune on a small set of manually labeled noteheads in real scanned music.

in the fine-tuning process. Because the real scanned music contains a variety of font sizes, we scale each input image to match the staff line spacing in the DeepScores data. After fine-tuning, the notehead detector achieves a training mean average precision (mAP) of 0.4201 for all notehead types (black notehead, half notehead, and whole notehead). For reference, in normal object detection tasks (not tiny objects), the state-of-the-art mAP is around 0.4 to 0.6. [3] Figure 5 (top half) shows an example of the notehead detector predictions on a section of Brahms Intermezzo Op. 117 No. 2.

2.2 Bootleg Synthesis

The second step is to convert the MIDI data into a bootleg representation. As shown in Figure 1 (right side), we accomplish this by converting note onsets into appropriately placed floating notehead blobs. This process consists of three key parts.

The first part is determining the staff line coordinate system. For each image strip, we would like to determine the location of the staff lines in the upper staff and lower staff. We can accomplish this by computing the row sum of image pixels, convolving the result with comb filters of various sizes (each containing 5 regularly spaced impulses), and identifying the comb filter that yields the strongest response at two non-overlapping staff locations. This gives us the staff line coordinate system for the upper and lower staves.

The second part is synthesizing and placing noteheads. Given the coordinate system from an image strip, we convert each MIDI note onset into one or more floating rectangular noteheads. Note that there is ambiguity when converting from a MIDI note number to a location on a staff. For example, a MIDI note number of 68 might appear as a G-sharp or an A-flat, which correspond to two different staff locations. To handle this ambiguity, we can place a larger-than-normal rectangular notehead which overlaps both possible locations. Furthermore, since notes in the middle register could appear in the right hand or left hand staves, we can simply place two different floating noteheads at both possible locations. In the visualization of B_i in Figure 1, for example, you can see that the first chord contains a C4, which produces a notehead in both the upper and lower staves.

[3] http://cocodataset.org/#detection-leaderboard

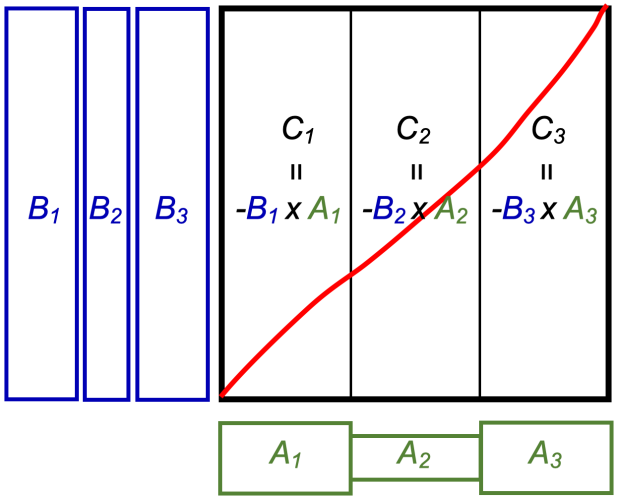

Figure 3. Aligning MIDI-generated bootleg scores with the sheet image-generated bootleg strips. Each bootleg strip A_i is compared to its corresponding bootleg score B_i to yield a cost matrix block C_i. Note that each B_i is a MIDI-generated bootleg score of the *entire* piece projected onto the staff line coordinate system of strip A_i. The red line indicates an alignment path.

The third part is handling timing issues. One issue is the choice of sampling rate. When converting the MIDI data into the bootleg representation, we must choose how much time corresponds to a single pixel column. To avoid extreme time warping, we select this parameter to ensure that the bootleg representation is approximately the same length as the image strips concatenated end-to-end. Another issue is shortening long pauses. When there is a fermata in the score, for example, the MIDI performance may slow down in tempo by a factor of three or four. The sheet music, however, does not reflect this, i.e., the length of the measure in pixels is not elongated by a factor of three or four. To mitigate this issue, we simply shorten long gaps greater than a fixed threshold to the length of the threshold. In experiments, we find that system performance is relatively insensitive to this threshold (across an order of magnitude).

Because each sheet image strip A_i has a different size and a different staff line coordinate system, we generate one bootleg score B_i of the *entire* MIDI performance for each image strip A_i. In other words, B_i is the bootleg score representation of the entire MIDI performance projected onto the staff line coordinate system of image strip A_i. A schematic illustration of this process is shown in Figure 3 for the case of three image strips A_1, A_2, and A_3. Note that the duration of each B_i ($i \in \{1, 2, 3\}$) semantically corresponds to the total duration of the concatenation $A_1 A_2 A_3$, while the pixel height of each B_i matches the height of image strip A_i.

2.3 Block DTW

The third step is to determine the alignment between the bootleg representations. Figure 3 shows a graphical depiction of this process. In this example, the sheet music contains three image strips A_1, A_2, and A_3. The alignment is carried out in two substeps.

The first substep is to calculate the cost matrix (C_i) between each bootleg image strip (A_i) and its corresponding MIDI-generated bootleg score (B_i). In choosing a suitable cost metric, we must consider the nature of the bootleg representations. The MIDI-generated bootleg score will have many redundant notes, where (for example) a C4 will appear in both the left and right hand staff systems in order to handle both possibilities. For this reason, we do not want to penalize the two bootleg representations when they disagree—we only want to reward them when they agree. One simple cost metric that meets this criteria is a negative inner product, i.e. the $(k, \ell)^{\text{th}}$ element of C_i indicates (-1 times) the number of overlapping black pixels in the k^{th} pixel column of B_i and the ℓ^{th} pixel column of A_i. When black ink shows up in the same vertical pixel position in two pixel columns, it will make the cost more negative.

The second substep is to perform global DTW. We assemble the constituent cost matrices C_i into a single global cost matrix (represented as a bold black rectangle in Figure 3). We then apply DTW with step transitions $\{(1,1),(1,2),(2,1)\}$ and corresponding weights $\{2,3,3\}$. This set of step transitions and weights is a robust, common choice in alignment tasks (e.g. see [19]). The lowest cost path through the global cost matrix is the estimated alignment between the MIDI performance and the sheet music. The estimated alignment is shown as a red line in Figure 3.

3. EXPERIMENTS

We now summarize our experiments, where we evaluate and compare our bootleg alignment approach with several baseline approaches. In Section 3.1, we describe our experimental setup introducing the dataset, the manually generated reference annotations, and the evaluation measure. In Section 3.2, we then present and discuss our quantitative results.

3.1 Experimental Setup

The data consists of sheet music scans and MIDI representations for 22 compositions from 8 different composers. The pieces are all for solo piano, contain no repeats or structural jumps, and span a variety of eras, styles, and lengths. The sheet music is downloaded from IMSLP and contains digital scans of printed sheet music editions in the public domain. Note that the choice of using scans of real printed sheet music is a significant departure from other works that focus on synthetically rendered sheet music representations (e.g. [7, 8]). In total, there are 68 sheet music scores. For each composition, we also collected one MIDI performance from online websites. [4] The MIDI performances are symbolic score representations that have been modified to sound like expressive, realistic human performances. Table 1 summarizes the dataset.

Table 1. Summary of dataset. For each piece, the table indicates the number of sheet music versions (Sh), the number of measures (Meas), and the minimum & maximum number of image strips (i.e. lines of music) across the different sheet music versions.

The ground truth consists of beat-level annotations. For the sheet music, we annotate the horizontal pixel location of a subset of beats in each piece, along with the measure number and image strip number. Because pixel-level annotation of beat locations is very time-consuming, we annotate the beats in $N = 40$ measures equally spaced throughout each piece. For the MIDI performances, we estimate the ground truth beat locations using `pretty-midi` [5] and manually correct any errors.

To evaluate the system performance, we compare the predicted alignment to the ground truth annotations. At the ground truth beat locations in the sheet music, we compare the predicted corresponding times in the MIDI to the ground truth timestamps. Given a fixed error tolerance, we define the error rate to be the percentage of predictions that fall outside of the allowable error tolerance. By considering a range of error tolerances, we can characterize the tradeoff between error rate and error tolerance.

In total, we have 68 MIDI-score pairings, and the resulting alignments are evaluated at $10,913$ ground truth beat locations. Our choice to use scans of real published musical scores has a tradeoff: it places a constraint on the size of the dataset due to the time-consuming nature of annotation, but it is more representative of performance "in the wild" compared to large synthetic datasets like the Multimodal Sheet Music Dataset (MSMD) [9]. We also evaluate

our system on MSMD as a point of comparison.

3.2 Results

We compare our bootleg method (with and without fine-tuning the notehead detector) to five baseline systems. The first baseline system ('globlin') simply assumes a global linear correspondence between the concatenated sheet image strips and the MIDI performance. The second and third baseline systems use two different commercial OMR systems (Photoscore [6] and SharpEye [7]) to convert the sheet music to MIDI, synthesize the MIDI to audio, and then perform audio–audio alignment using DTW on chroma features with 25 ms hop size. [8] These baselines are abbreviated as 'ps-audio' and 'se-audio' in Figure 4. The fourth and fifth baseline systems use the same two OMR systems to convert the sheet music to MIDI, estimate the beat locations using `pretty-midi`, and then assume a 1-to-1 correspondence between beat locations in both MIDI files. Note that the OMR system can have many recognition errors but still have perfect alignment if it can simply interpret barlines and beats correctly. These two baselines are abbreviated as 'ps-midi' and 'se-midi' in Figure 4. [9]

There is one important issue to mention about evaluating the OMR baseline systems. Because PhotoScore and SharpEye do not retain the connection between sheet music pixel location and corresponding MIDI time, there is no reliable way to automatically infer ground truth beat locations in the OMR-generated MIDI. Thus, it was necessary to manually annotate the ground truth beat locations in the OMR-generated MIDI on every sheet music score, so that the predicted alignment can be evaluated. This is a very time-consuming process, and clearly not sustainable for large-scale evaluations. However, the benefit of these results is a fair comparison to commercial OMR systems over a reasonably diverse data set.

Figure 4 compares the performance of our proposed bootleg approach (with and without fine-tuning) against the five baseline systems. There are three things to notice about Figure 4.

First, the bootleg method ('bootleg') outperforms the baselines by a wide margin. For example, at 500 ms error tolerance the bootleg systems achieve error rates around 10%, whereas the best performing baseline system achieves an error rate of 47%. Similarly, at 1000 ms error tolerance the bootleg systems achieve $3-4\%$ error rate, whereas the best baseline system has a 27% error rate.

Second, fine-tuning the notehead detector on sheet music scans ('bootleg-ft') shows demonstrable improvement. For example, at 1000 ms error tolerance the fine-tuning improves the error rate from 4.0% to 2.7%, and at 100 ms error tolerance the fine-tuning improves the error rate from 48.8% to 42.8%. We already know that fine-tuning will always improve results. The key observation here is that we can significantly improve results even with an extremely small dataset (2200 noteheads).

Third, the bootleg systems achieve very low asymptotic error rates. Whereas the best-performing baseline system achieves an error rate of 24.7% at a 2000 ms error tolerance, the fine-tuned bootleg system achieves a 0.4% error rate. So, the bootleg alignments are reliable, at least on the data in our experiments.

4. FURTHER ANALYSIS

In this section, we further investigate the proposed system through three different types of analyses.

4.1 Visualization of Alignments

The first method of analysis is to create a visualization that shows the predicted alignment between the bootleg repre-

[6] `https://www.neuratron.com/photoscore.htm`
[7] `http://www.visiv.co.uk`
[8] We also experimented with doing DTW directly on a piano roll representation of the MIDI data, but found that the results were always worse than synthesizing to audio and aligning chroma features.
[9] Note that the stairstep shape of the 'se-midi' system comes from the fact that SharpEye always renders its OMR-generated MIDI at 120 BPM, so that missing or extra beats correspond to errors at integer multiples of 500 ms.

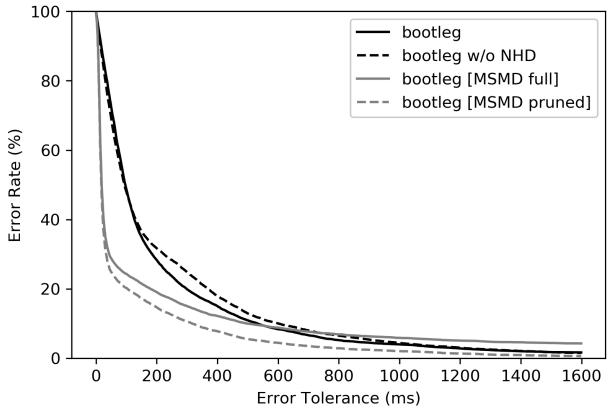

Figure 6. This figure shows two comparisons: (a) The performance of the bootleg system on real scanned sheet music vs. synthetically generated sheet music (see Section 4.2). (b) The performance of the bootleg system with and without notehead detection (see Section 4.3).

sentations. Figure 5 shows an example from a section of Brahms Intermezzo Op. 117 No. 2. In the upper half, the detected notehead regions are overlaid on top of the original score for ease of visualization. The bottom half contains the aligned MIDI-generated bootleg score. We can see that most noteheads are correctly detected, and the two bootleg representations match well.

By looking at example visualizations, we discovered two weaknesses in our system. The first weakness is that the notehead detector performs poorly on half noteheads and whole noteheads. This is due to the fact that the training data was highly imbalanced towards filled noteheads. The second weakness is that the staff line detection occasionally fails, which leads to poor alignments on the entire strip. Interestingly, the system is fairly robust to clef changes, mainly because clef changes usually only occur in one staff but not in both staffs simultaneously.

4.2 Synthetic vs. Real Data

The second analysis investigates the question: “How well does the proposed system work on synthetic data vs. real data?" As mentioned before, we chose to evaluate the baseline systems on real data (i.e. scans of music from IMSLP) rather than synthetically rendered data so that we can assess performance “in the wild." The primary drawback of using real data is that it needs to be manually annotated, which is very costly and limits the practical size of the evaluation dataset. To see how well our system performs on synthetic data, we also ran a large-scale evaluation on the Multimodal Sheet Music Dataset (MSMD) [9].

Figure 6 compares the performance of the bootleg system on the real dataset (black solid line) and the test set from MSMD (gray solid line). We can see that the synthetic data is “easier" to align, especially at lower error tolerances. However, the performance on MSMD leveled off at a much higher error rate for large error tolerances (e.g. 4.4% error at 1500 ms tolerance vs. 1.8% error on the real dataset). Upon further investigation, we found that these errors came from a small set of six pieces that all had one of two peculiar characteristics: (a) they consisted of almost all half or whole notes throughout the entire piece (e.g. Erik Satie’s *Gymnopedies*), or (b) they had very frequent time signature changes (on average every 1.4 measures for the two relevant pieces). The first characteristic will cause the bootleg system to fail because of the imbalance in notehead detection training data, and the second will cause extreme time warping in the alignment stage. While these pieces might be considered extreme or unusual in this regard, they nonetheless provide additional insight into failure modes of the bootleg approach. When we removed this set of six pieces from evaluation, the error curve falls significantly (dotted gray line in Figure 6). We can interpret the gap between the dotted gray curve and the solid black curve as the performance loss when transitioning from synthetic data to real scanned sheet music.

4.3 Importance of Notehead Detection

The third analysis investigates the question: “How much does system performance depend on notehead detection?" To answer this question, we simply removed the notehead detection from our system and directly aligned the MIDI-generated bootleg scores to the raw image strips. We expect the performance to be worse without notehead detection because the raw sheet music will contain many symbols that the MIDI-generated bootleg score does not have: note stems, rests, accidentals, etc. These additional symbols introduce noise that can lead to poor alignments.

Figure 6 compares the performance of the bootleg system with (solid black line) and without (dotted black line) notehead detection on the real dataset. Surprisingly, the system without notehead detection performs only marginally worse, and it approaches approximately the same error rate at high error tolerances. This suggests a way to significantly reduce the complexity of the system without sacrificing much performance.

5. CONCLUSION

We investigate the MIDI–sheet music synchronization problem as an important intermediate step for cross-modal alignment. Because OMR is a difficult task and may not be needed for music alignment, we avoid the need for OMR by introducing a mid-level representation called a bootleg score. We project the MIDI data into bootleg space using the rules of Western musical notation, and we project the sheet music into bootleg space by applying a deep watershed notehead detector. Once the MIDI and sheet music have been projected to this bootleg representation, the alignment can be performed using a simple variant of DTW. We evaluate the proposed system on scans of real published piano scores. Our results indicate that the proposed approach works well for piano music, and it outperforms several baseline systems based on optical music recognition. Our approach may serve as a non-trivial baseline approach for future end-to-end learning approaches.

ABSTRACT

There are a number of efforts in the MIR community towards increased reproducibility, such as creating more open datasets, publishing code, and the use of common software libraries, e.g. for evaluation. However, when it comes to datasets, there is usually little guarantee that researchers are using the exact same data in the same way, which among other issues, makes comparisons of different methods on the "same" datasets problematic. In this paper, we first show how (often unknown) differences in datasets can lead to significantly different experimental results. We propose a solution to these problems in the form of an open source library, `mirdata`, which handles datasets in their current distribution modes, but controls for possible variability. In particular, it contains tools which: (1) validate if the user's data (e.g. audio, annotations) is consistent with a canonical version of the dataset; (2) load annotations in a consistent manner; (3) download or give instructions for obtaining data; and (4) make it easy to perform track metadata-specific analysis.

1. INTRODUCTION

Music Information Retrieval (MIR) systems are often software or algorithms which are evaluated and compared based on their performance according to appropriate metrics on chosen datasets. These systems are becoming increasingly complex; reproducing systems presented in academic publications requires access to the software and data [23]. As outlined in [23], some of the common elements of an MIR system are (1) Data (Audio and Annotations) (2) Codecs and Parsing (3) Modeling and (4) Evaluation. The reproducibility of each of these elements poses challenges, but efforts are being made to reduce potential inconsistencies.

For evaluation, different implementations of evaluation metrics can result in substantially different results, motivating the need for `mir_eval` - a common and transparent evaluation software [29]. For modeling, slightly different implementations of the same algorithm can result in very different results [23]. Recently, this has been mitigated by the availability of software with tools for popular MIR tasks. Some examples are `librosa` [25] and `essentia` [6] - tools for MIR related signal processing, simple models and commonly used algorithms; Scikit-Learn [28] - tools for training simple machine learning algorithms; and `madmom` [5] - deep learning and machine learning models for common MIR tasks such as chord recognition, beat and downbeat tracking.

It is very difficult to get licenses to distribute music recordings openly. As a result, the majority of datasets available do not have freely available audio files; the exchange of this data is often done manually, which can result in varying data versions. When working with pairs of audio and annotation files, it is important that the audio files used are the same files that were used to create the annotations. When audio files are released separately from annotations, unknown differences between the original and other versions of the audio can create reproducibility issues. Websites such as Zenodo [1] and Figshare [2] provide permanent hosting and versioning of datasets, increasing reproducibility, but many datasets used in MIR are not available on such websites, and (often unknown) differences in data can adversely affect downstream performance.

Additionally, the annotations that come with each of these datasets exist in a huge variety of formats. Among these formats, some provide very complete information e.g. in the form of a JAMS file [17, 22], while others lack crucial information needed to accurately use the data, such as the time stamps associated with different observations. Most of the time, researchers write their own code for parsing the specific annotation files they use for a particular dataset. This is both inefficient and error-prone; what was found for evaluation and modeling is also true for data parsing: small differences in annotation loading code can result in huge differences in results downstream. Finally, the pairing of audio and annotation files is often done manually each time, usually by matching on filename substrings. In addition to being cumbersome, this can also lead to mismatched audio and annotation files.

To summarize, obtaining datasets and writing code to

[1] `https://zenodo.org`
[2] `https://figshare.org`

process them is both time consuming and error-prone. As a result, researchers are less inclined to use multiple datasets for their task, and instead develop or test their models on single datasets, reducing the reliability of their results [33]. We believe that the two current biggest blockers of reproducibility in the MIR community are (1) the lack of open datasets, resulting in a lack of transparency as to the consistency of data across publications and (2) the lack of an open library for consistently loading annotations in various formats in common datasets.

In this paper, we introduce an open source library, `mirdata`, which provides tools for using common MIR datasets. We aim to create a useful tool for researchers, which will increase reproducibility, and facilitate and encourage the use of several datasets for evaluation. In particular, it contains tools for loading dataset-specific annotations in a consistent manner, validating if a dataset copy the user has is consistent with a canonical version of the dataset, downloading datasets, and linking audio and annotation files along with track level metadata. We demonstrate the need for this tool by highlighting inconsistencies in common practices when loading annotations and in the data itself (annotations and audio) for three popular MIR datasets, namely iKala, Salami, and the Beatles dataset.

The library is publicly available on Github at `github.com/mir-dataset-loaders/mirdata`.

2. RELATED WORK

Data utility libraries exist for other fields such as text, video and image analysis [1, 10, 27, 28] which allow a user to download a dataset and load it into memory for ease of use in experimentation and consistent results. TensorFlow [1], a deep learning framework, includes a variety of datasets covering images, text, language translation and video [3]. In order to ensure the integrity of the data, TensorFlow hard codes expected file sizes and SHA256 checksums of each file in their library, as well as paths of the data included with the dataset. If the expected values do not match what is downloaded, the local dataset is not considered valid and is not available for usage in the library.

Scikit-Learn [28], a popular machine learning library for Python, includes their own set of dataset loading utilities [4]. Some small datasets, known as "toy datasets", are included directly in the library. Larger datasets, known as "real-world datasets" are downloaded and stored in a "data home" directory on the local machine. Like TensorFlow, Scikit-Learn checks for dataset integrity based on a SHA256 checksum, but only checks the downloaded zip or tar file itself. This approach requires that users download the entirety of the Scikit-Learn library in order to use the dataset loaders.

MLDatasets [5] acts as a specification for how datasets should be managed. DataDeps [36] specifies dataset metadata that conforms to a management system. This method allows for multiple people to maintain their own dataset repositories or for a single organization to set up multiple, independent libraries, each for one dataset.

There are few examples of dataset utility libraries for music. However, the python library Nussl [19] for source separation contains some dataset utilities. Unlike the other libraries previously mentioned, `Nussl` does not include any utilities for dataset retrieval and expects the user to have the datasets locally on the machine before use. However, it includes expected checksums for the dataset audio and logic to check for validity and existence of the dataset as well as simple utilities for loading the data.

Software also exists for loading particular types of (music-centric) annotations, including `pretti_midi` [6] for MIDI data, JAMS [17] for data released in JAMS format, and Music21 [7] for MIDI and MusicXML data. When annotations are released in these formats, custom loading code is less necessary. However, many annotations are released in other formats and require custom loading code.

3. AUDIO FILES IN MIR DATASETS

Datasets in MIR suffer from a unique constraint: most music is protected under copyright. Datasets which are built on copyrighted materials are not typically available for open download. There are several common levels of access for the audio files for different MIR datasets:

1. Open Access
2. Restricted Access (e.g. password protected)
3. "Do it yourself" Access (e.g. YouTube links)
4. No Access

We surveyed 128 MIR datasets from the "Audio Content Analysis" website [8] in April 2019 and determined their access levels. By our estimate, 80 were "open access", 19 were "restricted access", 15 were "DIY" Access, 14 were "no access", meaning that 22.8% of the total list is not openly available. These limited access datasets include historically popular datasets such as RWC [13], AudioSet [12], CAL10k [32], the Beatles dataset [16], iKala [8], the Million Song Dataset [2], and Salami [31].

The more restrictive the access level, the more room there is for "dataset telephone"; when it is difficult to access a particular dataset from a common repository, researchers may share their personal copies with each other, which may contain perturbations from when they first received it. Additionally, since the audio and annotations are sometimes released separately, if the audio is incorrect, the annotations will not correspond to the audio files, resulting in inconsistencies during model development and evaluation. As a result, researchers are performing experiments and computing metrics on datasets they believe are the same as others versions, but may be quite different in reality.

[7] `http://web.mit.edu/music21/doc/index.html`
[8] `https://www.audiocontentanalysis.org/data-sets/`

In an ideal case, the audio files used for a dataset should be the same as those used to create the annotation files. There are a number of popular datasets for which the audio is difficult to obtain. For example, the 7-digital preview clips of the million song dataset [2] have often been used for music classification tasks. While the clips were previously available through an API, it has since been shut down and the clips are no longer available. In the Beatles dataset [16], audio is not released, but instead, catalog numbers and release years of the albums used are provided to prevent differences in audio versions used. Regardless, we found that different versions of the dataset have been used by researchers (see Section 4.1). In the case of AudioSet [12], audio is provided in the form of YouTube video identifiers, adding a new challenge in data reproducibility. However, the availability of the linked YouTube videos changes over time, and accessibility varies by country.

4. EXPERIMENTS - WHY A COMMON TOOL IS NEEDED

Differences in audio or annotations, or in the code used to load data into memory can have a huge impact on downstream results. In this section, we examine the effect of real differences we found on evaluation metrics in instances of three popular MIR datasets.

4.1 The Beatles Dataset

The Beatles dataset [16] contains annotations for beats, downbeats, sections, and chords for the nearly entire Beatles' collection. However, as the audio is copyrighted, only the annotations are released as part of the dataset. The researchers are asked to use their personal copy of the Beatles' catalog and match the audio files with the annotations.

The annotations were created using a particular version of the audio, and they may not correspond well with other versions. For this dataset in particular, it is quite easy to end up with different versions of the same Beatles track, since there are several releases of every album, including remastered versions.

To evaluate these potential differences, we first compared checksums across four different researcher's copies of the audio files corresponding to the Beatles dataset. Out of the four versions, three had identical checksums, while one had invalid checksums on every single audio file, indicating that the audio is completely different between the two versions. Upon further examination of the differences, we found inconsistencies in the number of channels, the duration, and the average RMS of the audio files between the two versions.

The differences go even further than channels, duration and volume. In Figure 1, we first normalize a pair of audio files to have the same peak level and compute the absolute difference in their spectrograms. In the low frequencies, in particular, there are major differences between the frequency content of the two versions, despite sounding similar.

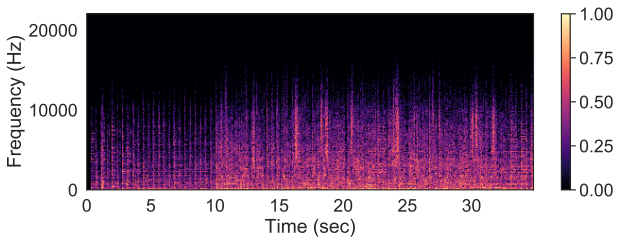

Figure 1. Normalized absolute difference between two spectrograms of the first 30 seconds of "Across the Universe" computed on audio files from two versions of the Beatles dataset audio.

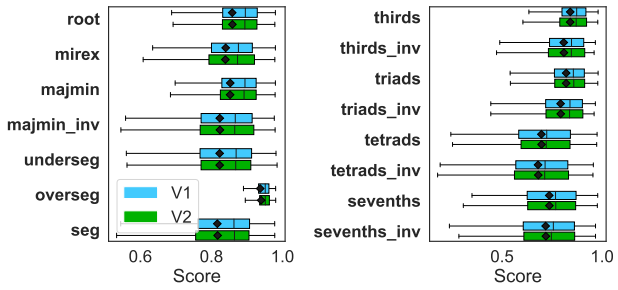

Figure 2. Chord metrics for chord estimates computed on two different versions of the Beatles audio, compared with the Beatles dataset reference chord annotations.

Next, we ran a chord recognition algorithm [21] on the two different versions of the audio collection, and computed the standard chord recognition metrics as implemented in `mir_eval` using the dataset's (public) reference chord annotations. The differences in the metrics are shown in Figure 2. While only one of these metrics had statistically significantly different results ("overseg", according to a paired t-test), we see that the same chord recognition algorithm produces results which are different enough to affect the metrics.

4.2 The iKala Dataset

The iKala dataset [8] is commonly used for melody estimation, vocal activity detection, and source separation. It contains isolated vocals and instruments (provided as left and right channels of a stereo audio file), along with vocal f_0 annotations and lyrics.

We performed the same checksum experiment as for the Beatles dataset and compared checksums for four different researcher's copies of the iKala dataset. We found that all four versions (audio and annotations) were identical.

One challenge with the iKala dataset is that the vocal f_0 annotations are provided as newline-separated files with the pitch, but without timestamps, which must be inferred upon load. On the dataset's website, they state that the hop size is 0.032 seconds, but it does not state the alignment of the first time frame (left aligned or center aligned). The dataset's website also provides code for loading the annotation files, which uses a different hop size of 0.03125 seconds and center aligned frames (with the first time stamp

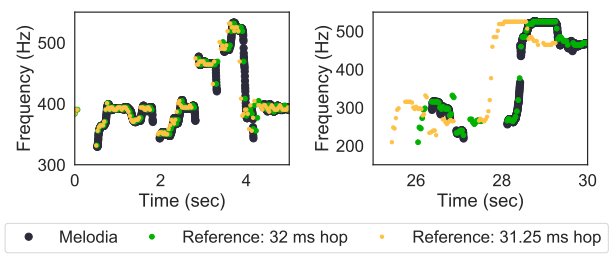

Figure 3. iKala reference annotations loaded using two different hop sizes (32 ms and 31.25 ms) versus the output of Melodia. (Left) the first 5 seconds of the track. (Right) the last 5 seconds of the track.

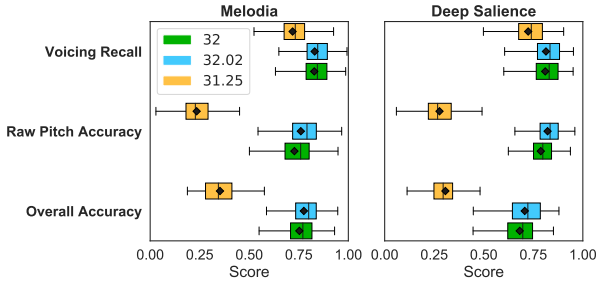

Figure 4. Melodia and Deep Salience melody metrics when evaluated against iKala's reference data loaded with 3 different hop sizes.

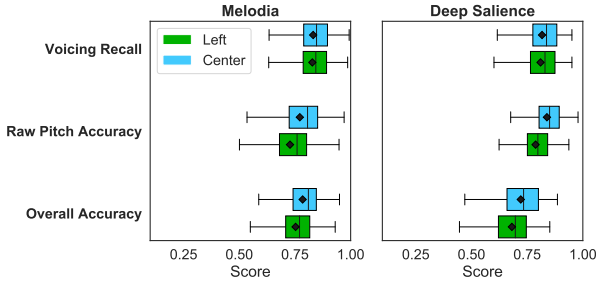

Figure 5. Melodia and Deep Salience melody metrics when evaluated against iKala's reference data loaded with left and center-aligned time stamps.

at 0.5 * hop seconds).

To see how users infer the iKala time stamps, we performed a search of public code on Github.com for code which loads the iKala pitch annotations. We found 5 unique ways of loading the time stamps, consisting of 3 different hop sizes (0.032 s and 0.03125 as listed on the dataset website, and 0.032017, inferred from the duration of the audio files), and two different alignments (left and center). By far, the most common combination was using a hop size of 0.032 s and left aligned frames.

The differences in hop size have a major effect on the alignment of the audio and the annotation, especially over time. Figure 3 shows an example of the annotations loaded with two of the hop sizes, and the estimate of a melody extraction algorithm (Melodia [30]) for comparison. In the first 5 seconds, the differences are small, but in the last 5 seconds, we see a visible misalignment between the loaded annotations and the audio.

To investigate the severity of these differences, we ran two melody extraction algorithms, Melodia [30] and Deep Salience [3], on the iKala audio. We then compute melody evaluation metrics using `mir_eval` with reference times computed using the three different hop sizes, $h = 32$ ms, $h = 32.017$ ms and $h = 31.25$ ms, using *left* aligned frames. In Figure 4, we show boxplots of the results across tracks in the dataset for each of these reference hop sizes. The results for different hop sizes are quite different, and drastically so for the smallest hop size, 0.03125 s. Even the difference between $h = 32$ and $h = 32.017$ in Overall Accuracy is substantial for both datasets - a difference that is historically enough to claim state of the art over another algorithm. A paired T-test shows statistically significant differences for all pairs of hop sizes for each metric, with the exception of Voicing Recall for $h = 32$ and $h = 32.017$

Next, we compute the melody metrics for the same melody extraction algorithms using a hop size of $h = 32$ ms and compare left vs center aligned frames in the reference. Figure 5 shows the results per track of the two different reference alignments. The difference in metrics is smaller than for the hop size differences, but left alignment is statistically significantly worse than right alignment for Overall Accuracy and Raw Pitch Accuracy under a paired T-test.

This begs the question: which is the correct way to load the timestamps? Since it is quite unlikely that an incorrectly time aligned reference would produce higher scores than a correct alignment, it is likely that, despite the norm of using left-aligned frames, the annotations are intended to have center aligned timestamps. Indeed, if we look at a specific example of left vs. center aligned timestamps for a short excerpt compared with two different algorithm estimates, as in Figure 6, we see that the reference is better aligned with both estimates when using center aligned time frames. Note that in Figure 4, the reference hop of 32.02 ms resulted in higher metrics than the hop of 32 ms (both with left aligned frames), and a 32 ms hop with center aligned frames has higher metrics than all of the left-aligned hops. The data loaded with a hop size of 32.02 ms starts off misaligned but over time, approaches a center alignment, explaining the "better" score with this incorrect hop size.

The shocking result of this set of experiments is that every single example we found publicly – including the code found on the dataset's website – appears to be loading the f_0 data incorrectly, either with an incorrect hop size or an incorrect alignment - no example we found had both a hop size of 32 ms and center alignment.

4.3 Salami Dataset

The Salami dataset [31] is a popular dataset used for music structural segmentation. It consists of 1359 tracks across

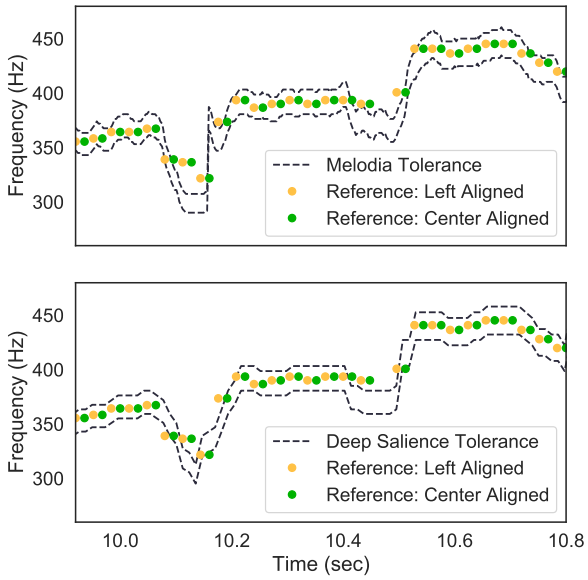

Figure 6. Left and center aligned time stamps for a track in iKala versus algorithm estimates from Melodia and Deep Salience. The dashed lines show the distance from the estimate where the algorithm would be considered correct in the standard melody extraction metrics.

a wide variety of genres, namely classical, jazz, popular, world, among others. Each track has annotations of 'coarse' and 'fine' segments, and among the annotated files, a subset of 884 tracks was annotated by two distinct annotators. The complete set of annotations was released in version 2.0 of the dataset, increasing the volume of the dataset with respect to previous versions. For instance, from version 1.9 to 2.0 additional annotations related to 539 tracks were added, 390 with multiple annotations and 189 with single annotations. Both versions are available in the dataset's main repository. However, as in other cases when a dataset is updated, there is no centralized version control that is transparent and ensures the awareness of the community to these changes.

Data-driven models are increasingly popular for addressing MIR tasks, including the task of boundary detection using the Salami dataset [15, 35]. One of the main reproducibility-related issues about data-driven models is their training, in particular, the amount of annotated data is crucial. When using Salami, it is important to avoid using an old version of the annotations, which could have a negative impact in a model's performance in comparison with the same model trained on the newest version of the dataset. In particular, if different data is used for training two different models with the aim of comparing their performance afterward, it is difficult to isolate possible causes of performance differences. An example of this situation is shown in [11], where the authors use a different subset of Salami than previous works, obtaining substantially different results when intending to re-implement other authors' model (e.g. 0.246 instead of the previously reported 0.523 F-measure with a ± 0.5 s tolerance window).

Another possible source of inconsistency with the use of this dataset relates to contributions from people other than the dataset creators. The authors in [24] manually edited 171 of the annotations in version 2.0, to correct formatting errors and enforce consistency with the annotation guide proposed by the dataset creators. However, this "corrected" version of the annotations was not included in the dataset's main repository. This third version of annotations is used in recent works [24, 34]; comparison of systems without awareness of the difference with the version 2.0 released annotations may lead to differences in performance that are beyond models' design.

5. MIR DATASET LOADERS

In this section, we describe the `mirdata` python library, our proposed solution to the current reproducibility issues with dataset versions and loaders. A driving philosophy of this library is to work with the imperfect situation we are faced with, with regards to the limited openness of MIR data. In an ideal scenario, all data would be freely sharable and version controlled; since this is not the case, we do our best to create tools to maximize reproducibility given the current constraints. Most importantly, we aimed to create a clean, transparent and easy to use interface to encourage reuse and contributions. The first release of the library will include loaders for Orchset [7], iKala [8], MedleyDB Melody and Pitch subsets [4], the Beatles dataset [16], Salami [31], the Million Song Dataset [2], Medley Solos-DB [18], RWC [9, 13, 14, 20], DALI [26], and GuitarSet [37].

5.1 Dataset Indexes and Checksums

Datasets, by their definition, are collections of data. In the case of MIR datasets, the data is often a collection of separate files, some of which correspond to e.g. a particular audio file. For example, the Beatles dataset contains four separate text files containing chord, beat, section, and key annotations for each audio file. Since each of these four annotation files are related to the same audio file, it is desirable to have a common way of linking them. In `mirdata`, we use a *dataset index* to link related files, in the form of a JSON file. This index contains a unique identifier for each group (for example, the name of the audio file), which is mapped to its corresponding file paths and their expected *checksums*, for example:

```
{
    "track1": {
        "audio": [
            "example/audio/track1.wav",
            "912ec803b2ce49e4a541068d495ab570"
        ],
        "annotation": [
            "example/annotations/track1.csv",
            "2cf33591c3b28b382668952e236cccd5"
        ]
    },
    ...
}
```

The use of an index for each dataset is advantageous for a number of reasons. First, it groups related data files in

a transparent way, avoiding audio-annotation pairing mistakes, and removing the need for custom filename substring matching per dataset. Second, it gives a version-controlled record of all expected files in the dataset, preventing inconsistencies due to missing or extra files; we can check if all the expected files are present in a local copy of a dataset, and we load data to memory based on the index, ignoring files not included in it. Finally, it provides a way to verify if a local copy of a dataset is consistent with a canonical version on a file-by-file basis.

For each dataset, we also provide a `validate()` function, which checks for the existence of files locally and compares the expected checksums with checksums of the local copy. A checksum is a representation of a digital file similar to a fingerprint and usually computed by taking a hash of the bits in a file. The smaller (in size) representation created allows for efficient file comparisons at the bit level. If two files have the same checksum then a user can assume that the two files are exactly the same with high confidence. If the checksums between two files differ or the computed checksum is different from an expected checksum, then the user is at a minimum aware of discrepancies and can take appropriate action. In the `mirdata` use case, checksums allow users who have a local copy of a dataset to know whether or not they are using the same data as others, simply by running the validation function.

Note that there is not always one "correct" version of a dataset, so it is difficult to decide which version of a dataset should be used to create the reference checksums. For this library, we compute checksums on the version that is as close to the "original" as possible, for example by obtaining a version from dataset creators.

5.2 Dataset Downloading

It can often be difficult or unclear how to get access to a particular dataset, and same data often exists in multiple places and may not be identical. In `mirdata`, we provide a `download()` function for each dataset. When data is openly available online, the function automatically downloads the data, and this version of the data is same the version used to create the checksums. When the data has been downloaded, we run validation to ensure it matches and warn the user if not (e.g. in the case of an incomplete download). When data is not openly available online, we provide instructions for how to obtain the data (e.g. by requesting access on a particular website). Once the data has been obtained, the user can then run validation to ensure the data is consistent.

5.3 Annotation Loaders

As highlighted previously, differences in implementations for loading annotation data to memory can have big effects on the resulting data. In `mirdata`, we remove the need for users to manually write loaders per dataset and annotation type by providing functions for loading all annotations for each dataset. These implementations are shared and transparent, allowing users to permanently correct mistakes in the way data is loaded.

As an example, for some of the beat annotations in the Salami dataset, the beat position is missing for only a few observations. These missing positions can be inferred from the neighboring information (e.g. beats 1 and 3 have labels, and the one in between is absent), and in `mirdata`'s implementation we fill in this information on load.

5.4 Track Metadata

More often than not, in addition to data files containing e.g. time varying annotations, datasets provide track-level metadata. When loading annotations, we also link any available track level metadata with each track id group. This can be particularly useful when splitting data, such as for creating unbiased train-validation-test splits [23], or for analyzing evaluation metrics over different splits of a dataset.

6. CONCLUSIONS

Although data distribution challenges remain, we believe that the use of `mirdata` will result in reproducible usage of datasets in research moving forward. Future iterations of `mirdata` will include support for large (out of memory) datasets and an increased number of supported datasets. As datasets become more open and annotation formats standardize, the scientific need for this library will lessen, but it will remain a useful tool for ease of working with datasets.

Importantly, we designed `mirdata` to have a low barrier to entry for contributions. New datasets can be easily included independently with minimal interfacing with the rest of the library. With active community participation, we believe that `mirdata` can help ensure that MIR datasets are used in a consistent, reproducible manner moving forward.

ABSTRACT

Automatic cover detection – the task of finding in an audio database all the covers of one or several query tracks – has long been seen as a challenging theoretical problem in the MIR community and as an acute practical problem for authors and composers societies. Original algorithms proposed for this task have proven their accuracy on small datasets, but are unable to scale up to modern real-life audio corpora. On the other hand, faster approaches designed to process thousands of pairwise comparisons resulted in lower accuracy, making them unsuitable for practical use.

In this work, we propose a neural network architecture that is trained to represent each track as a single embedding vector. The computation burden is therefore left to the embedding extraction – that can be conducted offline and stored, while the pairwise comparison task reduces to a simple Euclidean distance computation. We further propose to extract each track's embedding out of its dominant melody representation, obtained by another neural network trained for this task. We then show that this architecture improves state-of-the-art accuracy both on small and large datasets, and is able to scale to query databases of thousands of tracks in a few seconds.

1. INTRODUCTION

Covers are different interpretations of the same original musical work. They usually share a similar melodic line, but typically differ greatly in one or several other dimensions, such as their structure, tempo, key, instrumentation, genre, etc. Automatic cover detection – the task of finding in an audio database all the covers of one or several query tracks – has long been seen as a challenging theoretical problem in MIR. It is also now an acute practical problem for copyright owners facing continuous expansion of user-generated online content.

Cover detection is not *stricto sensu* a classification problem: due to the ever growing amount of musical works (the classes) and the relatively small number of covers per work, the actual question is not so much "to which work this track belongs to ?" as "to which other tracks this track is the most similar ?".

Formally, cover detection therefore requires to establish a similarity relationship S_{ij} between a query track A_i and a reference track B_j. It implies the composite of a feature extraction function f followed by a pairwise comparison function g, expressed as $S_{ij} = g(f(A_i), f(B_j))$. If f and g are independent, the feature extraction of the reference tracks B_j can be done offline and stored. The online feature extraction cost is then linear in the number of queries, while pairwise comparisons cost without optimisation scales quadratically in the number of tracks [16].

Efficient cover detection algorithms thus require a fast pairwise comparison function g. Comparing pairs of entire sequences, as DTW does, scales quadratically in the length of the sequences and becomes quickly prohibitive. At the opposite, reducing g to a simple Euclidean distance computation between tracks embeddings is independent of the length of the sequences. In this case, the accuracy of the detection entirely relies on the ability of f to extract the common musical facets between different covers.

In this work, we describe a neural network architecture mapping each track to a single embedding vector, and trained to minimize cover pairs Euclidean distance in the embeddings space, while maximizing it for non-cover pairs. We leverage on recent breakthroughs in dominant melody extraction, and show that the use of dominant melody embeddings yield promising performances both in term of accuracy and scalability.

The rest of the paper is organized as follow: we review in §2 the main concepts used in this work. We detail our method in §3, and describe and discuss in §4 and §5 the different experiments conducted and their results. We finally present a comparison with existing methods in §6. We conclude with future improvements to bring to our method.

2. RELATED WORK

We review here the main concepts used in this study.

2.1 Cover detection

Successful approaches in cover detection used an input representation preserving common musical facets between different versions, in particular dominant melody [19, 27, 40], tonal progression – typically a sequence of chromas [10, 12, 33, 39] or chords [2], or a fusion of both [11, 29]. Most of these approaches then computed a similarity score between pairs of melodic and/or harmonic sequences, typically a cross-correlation [10], a variant of the DTW algorithm [12, 20, 33, 39], or a combination of both [25].

These approaches lead to good results when evaluated on small datasets – at most a few hundreds of tracks, but are not scalable beyond due to their expensive comparison function. Faster methods have recently been proposed, based on efficient comparison of all possible subsequences pairs between chroma representations [34], or similarity search between 2D-DFT sequences derived from CQTs overlapping windows [31], but remain too costly to be scalable to query large modern audio databases.

Another type of method has been proposed to alleviate the cost of the comparison function and to shift the burden to the audio features extraction function – which can be done offline and stored. The general principle is to encode each audio track as a single scalar or vector – its embedding – and to reduce the similarity computation to a simple Euclidean distance between embeddings. Originally, embeddings were for instance computed as a single hash encoding a succession of pitch landmarks [3], or as a vector obtained by PCA dimensionality reduction of a chromagram's 2D-DFT [4] or with locality-sensitive hashing of melodic excerpts [19].

As for many other MIR applications, ad-hoc – and somewhat arbitrary – hand-crafted features extraction was progressively replaced with data-driven automatic feature learning [15]. Different attempts to learn common features between covers have since been proposed: in particular, training a k-means algorithm to learn to extract an embedding out of chromagram's 2D-DFT lead to significant results improvements on large datasets [16]. Similar approaches, commonly referred to as *metric learning* approaches, have been used in different MIR contexts, such as music recommendation [21, 41], live song identification [38], music similarity search [24], and recently cover detection [23].

2.2 Metric learning

Although the concept can be traced back to earlier works [1, 8], the term of metric learning was probably coined first in [43] to address this type of clustering tasks where the objective is merely to assess whether different samples are similar or dissimilar. It has since been extensively used in the image recognition field in particular [14, 36, 37].

The principle is to learn a mapping between the input space and a latent manifold where a simple distance measure (such as Euclidean distance) should approximate the neighborhood relationships in the input space. There is however a trivial solution to the problem, where the function ends up mapping all the examples to the same point. Contrastive Loss was introduced to circumvent this problem, aiming at simultaneously *pulling* similar pairs together and *pushing* dissimilar pairs apart [13].

However, when the amount of labels becomes larger, the number of dissimilar pairs becomes quickly intractable. It was moreover observed in practice that once the network has become reasonably good, negative pairs become relatively easy to discern, which stalls the training of the discriminative model. *Pair mining* is the strategy of training the model only with hard pairs, i.e. positive (resp. negative) pairs with large (resp. small) distances [35]. Further improvement was introduced with the triplet loss, which is used to train a model to map each sample to an embedding that is closer to all of its positive counterparts than it is to all of its negative counterparts [30]. Formally, for all triplets $\{a,\ p,\ n\}$ where a is an anchor, and p or n is one of its positive or negative example, respectively, the loss to minimize is expressed as $\ell = \max(0, d_{\mathrm{ap}} + \alpha - d_{\mathrm{an}})$, where α is a margin and d_{ap} and d_{an} are the distances between each anchor a and p or n, respectively.

2.3 Dominant melody extraction

Dominant melody extraction has long been another challenging problem in the MIR community [18, 28, 42]. A major breakthrough was brought recently with the introduction of a convolutional network that learns to extract the dominant melody out of the audio Harmonic CQT [7]. The HCQT is an elegant and astute representation of the audio signal in 3 dimensions (time, frequency, harmonic), stacking along the third dimension several standard CQTs computed at different minimal multiple frequencies. Harmonic components of audio signal will thus be represented along the third dimension and be localized at the same location along the first and second dimensions. This representation is particularly suitable for melody detection, as it can be directly processed by convolutional networks, whose 3-D filters can be trained to localize in the time and frequency plan the harmonic components.

In a recent work [9], we suggested in an analogy with image processing that dominant melody extraction can be seen as a type of image segmentation, where contours of the melody have to be isolated from the surrounding background. We have thus proposed for dominant melody estimation an adaptation of U-Net [26] – a model originally designed for medical image segmentation – which slightly improves over [7].

3. PROPOSED METHOD

We present here the input data used to train our network, the network architecture itself and its training loss.

3.1 Input data

We have used as input data the dominant melody 2D representation (F0-CQT) obtained by the network we proposed in [9]. The frequency and time resolutions required for melody extraction (60 bins per octave and 11 ms per time frame) are not needed for cover detection. Moreover, efficient triplet loss training requires large training batches, as we will see later, so we reduced data dimensionality as depicted on Figure 2.

The F0-CQT is **a)** trimmed to keep only 3 octaves around its mean pitch (180 bins along the frequency axis), and only the first 3 minutes of the track (15500 time frames) – if shorter, the duration is not changed. The resulting matrix is then **b)** downsampled via bilinear 2D interpolation with a factor 5. On the frequency axis, the semi-tone resolution is thus reduced from five to one bin,

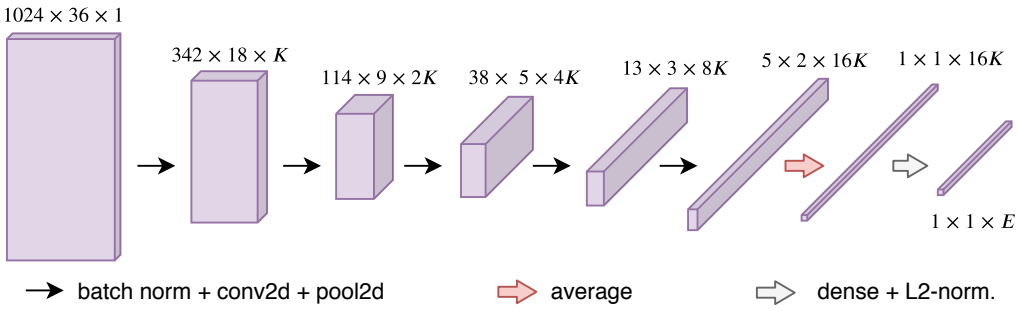

Figure 1: Convolutional model (time on the first dimension, frequency on the second dimension).

which we considered adequate for cover detection. On the time axis, it is equivalent to a regular downsampling.

Finally, as the representation of different tracks with possibly different durations shall be batched together during training, the downsampled F0-CQT is **c)** shrunk or stretched along the time axis by another bilinear interpolation to a fixed amount of bins (1024). This operation is equivalent to a tempo change: for the 3 minutes trimmed, shrinking is equivalent to multiply the tempo by a factor 3. We argue here that accelerated or decelerated version of a cover is still a cover of the original track.

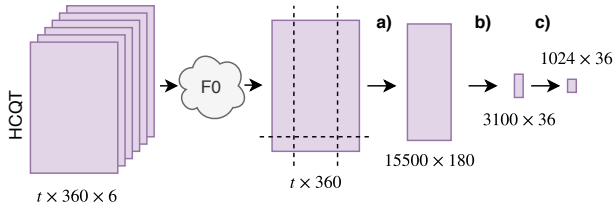

Figure 2: Input data pre-processing: dominant melody is extracted from HCQT, then a) F0 output is trimmed, b) downsampled by a factor 5 and c) resized time-wise to 1024 bins (time bins on first dimension, frequency bins on second dimension).

3.2 Model

The proposed model is a simple convolutional network pictured in Figure 1. As we are constrained by the input data shape, whose time dimension is much larger than its frequency dimension, only five layers blocks are needed. Each layer block consists of a batch normalization layer, a convolution layer with 3×3 kernels and a mean-pooling layer with a 3×2 kernel and 3×2 stride in order to reduce time dimensionality faster than frequency dimensionality. A dropout rate of $0.1, 0.1, 0.2$ and 0.3 is applied to the blocks 2, 3, 4 and 5, respectively.

The first convolutional layer has K kernels, and this number is doubled at each level (i.e. the deeper layer outputs 2^4K-depth tensors). The penultimate layer averages along frequency and time axes to obtain a vector. A last dense layer outputs and L2-normalizes the final embedding vector of size E.

Our assumption behind the choice of this convolutional architecture is that we expect it to learn similar patterns in the dominant melody, at different scales (tempo invariance) and locations (key and structure invariance).

3.3 Objective loss

We use a triplet loss with online semi-hard negative pairs mining as in [30]. In practice, triplet mining is done within each training batch: instead of using all possible triplets, each track in the batch is successively considered as the anchor, and compared with all its covers in the batch. For each of these positives pairs, if there are negatives such as $d_{\text{an}} < d_{\text{ap}}$, then only the one with the highest d_{an} is kept. If no such negative exist, then only the one with the lowest d_{an} is kept. Other negatives are not considered.

Model is fit with Adam optimizer [17], with initial learning rate at $1e^{-4}$, divided by 2 each time the loss on the evaluation set does not decrease after 5k training steps. Training is stopped after 100k steps, or if the learning rate falls below $1e^{-7}$. The triplet loss was computed using squared Euclidean distances (i.e. distances are within the $[0, 4]$ range), and the margin was set to $\alpha = 1$.

3.4 Dataset

As metric learning typically requires large amount of data, we fetched from internet the audio of cover tracks provided by the SecondHandSongs website API [1]. Only works with 5 to 15 covers, and only tracks lasting between 60 and 300 seconds where considered, for a total of $W = 7460$ works and $T = 62310$ tracks.

The HCQT was computed for those 62310 tracks as detailed in [7], i.e. with f_{min} = 32.7 Hz and 6 harmonics. Each CQT spans 6 octaves with a resolution of 5 bins per semi-tone, and a frame duration of ~11 ms. The implementation was done with the Librosa library [22].

The dominant melody was extracted for these 62310 HCQT with the network we described in [9], and the output was trimmed, downsampled and resized as described in §3.1.

4. PRELIMINARY EXPERIMENTS

We present here some experiments conducted to develop the system. The 7460 works were split into disjoint train and evaluation sets, with respectively 6216 and 1244 works and five covers per work. The evaluation set represents ~20% of the training set, which we considered fair enough given the total amount of covers. The same split has been used for all preliminary experiments.

[1] https://secondhandsongs.com/

4.1 Metrics

Ideally, we expect the model to produce embeddings such that cover pair distances are low and non-cover pair distances are high, with a large gap between the two distributions. In the preliminary experiments, we have thus evaluated the separation of the cover pairs distance distribution $p_c(d)$ from the non-cover pairs distance distribution $p_{nc}(d)$ with two metrics:

- the ROC curve plots the true positives rate (covers, TPR) versus the false positive rate (non-covers, FPR) for different distance d thresholds. We report the area under the ROC curve (AuC), which gives a good indication about the distributions separation. We also report the TPR corresponding to an FPR of 5% (TPR@5%), as it gives an operational indication about the model's discriminative power.

- we also report the Bhattacharyya coefficient (BC), expressed as $\sum_d \sqrt{p_c(d)p_{nc}(d)}$, as it directly measures the separation between the distributions (smaller is better) [6].

4.2 Influence of input data

We first compared the results obtained for different inputs data: chromas and CQT computed using Librosa [22], and the dominant melody computed as described in 3.1. As shown on Figure 3 (left), dominant melody yields the best results. It does not imply that melody features are more suited than tonal features for cover detection, but shows that convolutional kernels are better at learning similar patterns at different scales and locations across different tracks when the input data is sparse, which is not the case for chromas and CQT.

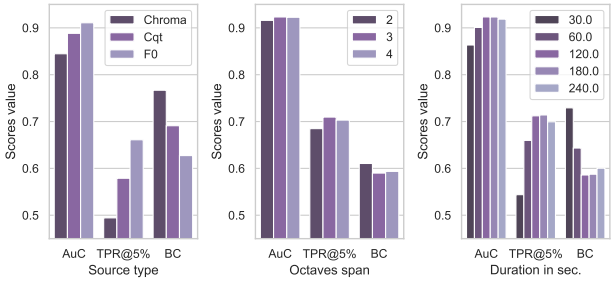

Figure 3: Scores obtained on evaluation set for a model trained - with chromas, CQT or F0 (left). - on the F0 with various octaves spans (middle). - on the F0 with various durations (right).

Results obtained when trimming the F0-CQT with various octaves and time spans are also shown Figure 3. It appears that keeping 3 octaves around the mean pitch of the dominant melody and a duration of 2 to 3 minutes yields the best results. Smaller spans do not include enough information, while larger spans generate confusion.

All other results presented below are thus obtained with the dominant melody 2D representation as input data, and a span of 3 octaves and 180 seconds for each track.

4.3 Influence of model and training parameters

We then compared the results obtained for different numbers of kernels in the first layer (K) and the corresponding sizes of the embeddings (E). As shown on Figure 4 (left), results improve for greater K, which was expected. However, increasing K above a certain point does not improve the results further, as the model has probably already enough freedom to encode common musical facets.

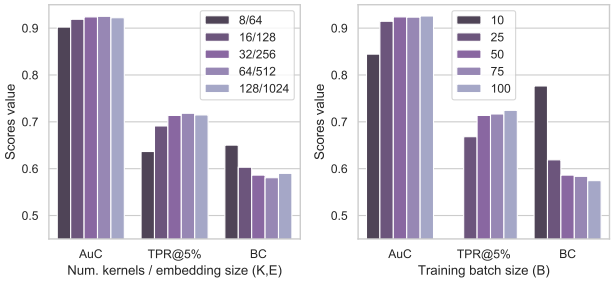

Figure 4: Scores obtained on evaluation set for a model trained - with various K/E (left) - with various B (right).

We have then compared the results obtained for different sizes of training batches (B). As shown on Figure 4 (right), results improve with larger B: within larger batches, each track will be compared with a greater number of non-covers, improving the separation between clusters of works. A closer look at the distances shows indeed that the negative pairs distance distribution $p_{nc}(d)$ gets narrower for larger batches (not showed here). Due to GPU memory constraints, we have not investigated values above B=100.

All other results presented below are obtained with K=64, E=512 and B=100.

5. LARGE SCALE LOOKUP EXPERIMENTS

We now present experiments investigating the realistic use case, i.e. large audio collections lookup. When querying an audio collection, each query track can be of three kinds: **a)** it is already present in the database, **b)** it is a cover of some other track(s) already in the database, or **c)** it is a track that has no cover in the database. The case **a)** corresponds to the trivial case, where the query will produce a distance equal to zero when compared with itself, while case **c)** corresponds to the hard case where neither the query or any cover of the query have been seen during training. We investigate here the case **b)**, where the query track itself has never been seen during training, but of which at least one cover has been seen during training.

5.1 Metrics

In these experiments, we are interested in measuring our method's ability to find covers in the reference set when queried with various unknown tracks. This is commonly addressed with the metrics proposed by MIREX [2] for the cover song identification task: the mean rank of first correct result (MR1), the mean number of true positives in the top ten positions (MT10) and the Mean Average Precision (MAP). We refer the reader to [32] for a detailed review of these standard metrics. We also report here the TPR@5%, already used in the premilinary experiments.

[2] https://www.music-ir.org/mirex/wiki/2019

5.2 Structuring the embeddings space

We study here the role of the training set in structuring the embeddings space, and in particular the role of the number of covers of each work. More precisely, we tried to show evidence of the *pushing* effect (when a query is pushed away from all its non-covers clusters) and the *pulling* effect (when a query is pulled towards its unique covers cluster).

To this aim, we built out of our dataset a query and a reference set. The query set includes 1244 works with five covers each. The reference set includes P of the remaining covers for each of the 1244 query works, and N covers for each other work not included in the query set (Figure 5).

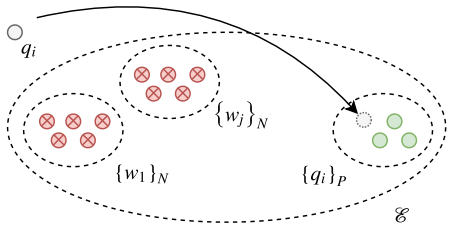

Figure 5: Big dotted oval represents the embeddings space $\mathcal{E}$. Smaller dotted ovals represent work clusters of covers. Red crossed circles represent the positions in the manifold of the reference tracks w_j that *are not* covers of query track q_i (N per cluster). Green circles represent the positions of the tracks that *are* covers of query track q_i (P per cluster).

Pushing covers We first train our model on the reference set with fixed P=5. We compute query tracks embeddings with the trained model, compute pairwise distances between query and reference embeddings, as well as the different metrics. We repeat this operation for different values of $N \in [2, ..., 10]$, and report results on Figure 6 (left). We report MR1's percentile (defined here as MR1 divided by the total of reference tracks, in percent) instead of MR1, because the number of reference tracks varies with N.

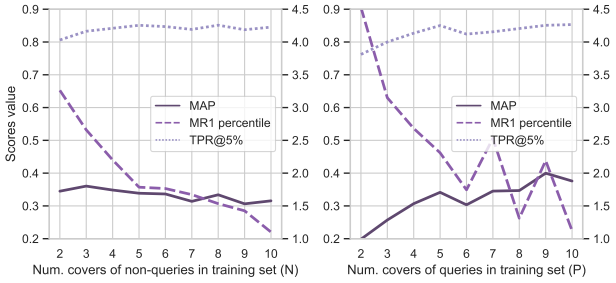

Figure 6: Query scores for different training/reference sets. Left: increasing N, number of covers of non-queries, P fixed. Right: increasing P, number of covers of queries, N fixed. (Y-axes scale MAP and TPR on the left, and the MR1 percentile on the right).

The MAP only slightly decreases as N increases, which indicates that the precision remains stable, even though the number of examples to sort and to rank is increasing. Moreover, the MR1 percentile and the TPR@5% clearly improve as N increases. As P is fixed, it means that the ranking and the separation between covers and non-covers clusters is improving as the non-queries clusters are consolidated, which illustrates the expected *pushing* effect.

Pulling covers We reproduce the same protocol again, but now with N=5 fixed and for different values of $P \in [2, ..., 10]$. We report results on Figure 6 (right). It appears clearly that all metrics improve steadily as P increases, even though the actual query itself has never been seen during training. As N is fixed, this confirms the intuition that the model will get better in locating unseen tracks closer to their work's cluster if trained with higher number of covers of this work, which illustrates the expected *pulling* effect.

5.3 Operational meaning of $p_c(d)$ and $p_{nc}(d)$

We now investigate further the distance distributions of cover and non-cover pairs. To this aim, we randomly split our entire dataset into a query and a reference set with a 1:5 ratio (resp. 10385 and 51925 tracks). Query tracks are thus not seen during training, but might have zero or more covers in the reference set.

Covers probability Computing queries vs. references pairwise distances gives the distributions $p_c(d)$ and $p_{nc}(d)$ shown on Figure 7 (left). Using Bayes' theorem, it is straightforward to derive from $p_c(d)$ and $p_{nc}(d)$ the probability for a pair of tracks to be covers given their distance d (Figure 7, right). This curve has an operational meaning, as it maps a pair's distance with a probability of being covers without having to rank it among the entire dataset.

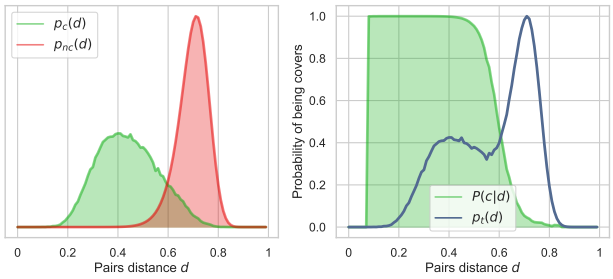

Figure 7: Left: separation of $p_c(d)$ (green) and $p_{nc}(d)$ (red). Right: probability of being a covers pair given the distance d (green) and total pairs distance distribution $p_c(d)+p_{nc}(d)$ (blue).

Easy and hard covers We repeat the previous test five times with random splits, and report metrics in Table 1. At first sight, MR1 and MT@10 could seem inconsistent, but a closer look at the results gives an explanation. To illustrate what happens, imagine a set of five queries where the first query ranks ten covers correctly in the first ten positions, e.g. because they are all very similar, while all other four queries have their first correct answer at rank 100. This would yield to MT@10=2.0, and MR1=80.2. This kind of discrepancy between MR1 and MT@10 reflects the fact that some works in our dataset have similar covers that are easily clustered, while other are much more difficult to discriminate. This can be observed on the positive pairs distribution $p_c(d)$ on Figure 7 (left), which is spread over a large range of distances.

	MAP	MT@10	MR1	BC	AuC	TPR@5%
Proposed	0.39 (<0.01)	2.90 (0.03)	581 (59)	0.40 (<0.01)	0.97 (<0.01)	0.88 (<0.01)

Table 1: Results of query set lookup in reference set.

6. COMPARISON WITH OTHER METHODS

6.1 Comparison on small dataset

We first compared with two recent methods [31, 34], who reported results for a small dataset of 50 works with 7 covers each. The query set includes five covers of each work (250 tracks), while the reference set includes each work's remaining two covers (100 tracks). As this dataset is not publicly available anymore, we have mimicked it extracting randomly 350 tracks out of own dataset [3] .

Our data-driven model can however not be trained with only 100 tracks of the reference set, as it would overfit immediately. We have thus trained our model on our full dataset, with two different setups: **a)** excluding the 350 tracks reserved for the query and reference sets. **b)** excluding the 250 tracks of the query set, but including the 100 tracks of the reference set. We repeated this operation ten times for each setup, and report the mean and standard deviation on Table 2 for the same metrics used in [31, 34], as well as the p-value obtained by a statistical significance t-test carried out on results series.

	MAP	P@10	MR1
[34]	0.591	0.140	7.910
[31]	0.648	0.145	8.270
Proposed **a)**	**0.675**	**0.165**	**3.439**
	(0.04), p=.29	(0.005), p<.001	(1.062), p<.001
Proposed **b)**	**0.782**	**0.179**	**2.618**
	(0.104), p<.01	(0.014), p<.001	(1.351), p<.001

Table 2: Comparison between recent method [31, 34] and our proposed method on a small dataset (precision at 10 P@10 is reported instead of MT@10. As there are only two covers per work in the reference set, P@10 maximum value is 0.2).

Our method significantly improve previous results: for the hardest case **a)** where the model has not seen any queries work during training, embeddings space has been sufficiently structured to discriminate the unseen works from the other training clusters (*pushing* effect). For the easier case **b)**, the *pulling* effect from the known queries covers provides further improvement.

6.2 Comparison on large dataset

We also compared with [16], who is to our knowledge the last attempt to report results for thousands of queries and references – a more realistic use case. This paper reported results on the SecondHandSong (SHS) subset of the MillionSong dataset (MSD) [5] for two experiments: **a)** only the training set of 12960 covers of 4128 works was used both as the query and reference sets. **b)** the SHS MSD test set of 5236 covers of 1726 works was used to query the entire MSD used as reference.

The SHS MSD is not available anymore. However, as our dataset has also been built from the SHS covers list, we consider that results can be compared [3] . We have therefore randomly generated out of our dataset a training and a test set mimicking the original ones. We trained our model on the training set, and perform the pairwise distances computation between the query and reference sets (as the query set is included in the reference set, we excluded for comparison the pairs of the same track). For experiment **b)**, we have used our entire dataset as reference set as we do not have one million songs. We have repeated this operation five times and report in Table 3 the mean and standard deviations for the same metrics used in [16], as well as MR1, MT@10 and the p-value of the t-test carried out.

		MAP	MR	MT@10	MR1
a)	[16]	0.285	1844	-	-
	Proposed	**0.936**	**78**	2.010	33
		(0.001), p<.001	(6), p<.001	(<0.001)	(3)
b)	[16]	0.134	173117	-	-
	Proposed	**0.220**	**3865**	1.622	430
		(0.007), p<.001	(81), p<.001	(0.003)	(19)

Table 3: Comparison between method [16] and our proposed method on a large dataset (MR=Mean rank). For **b)**, the MR percentile should be compared, as our reference set does not have 1M tracks (6^{th} vs. 17^{th} percentile for [16]).

Our method significantly improve previous results. For case **a)**, results are notably good, which is not surprising as the model has already seen all the queries during the training. Case **b)** is on the other hand the hardest possible configuration, where the model has not seen any covers of the queries works during training, and clusterisation of unseen tracks entirely relies on the *pushing* effect.

As to our method's computation times, we observed on a single Nvidia GPU Titan XP for a ~3 mn audio track: ~10 sec for F0 extraction, ~1 sec for embeddings computation, and less than 0.2 sec for distances computation with the full dataset embeddings (previously computed offline).

7. CONCLUSION

In this work, we presented a method for cover detection, using a convolutional network which encodes each track as a single vector, and is trained to minimize cover pairs Euclidean distance in the embeddings space, while maximizing it for non-covers. We show that extracting embeddings out of the dominant melody 2D representation drastically yields better results compared to other spectral representations: the convolutional model learns to identify similar patterns in the dominant melody at different scales and locations (tempo, key and structure invariance).

We have also shown that our method scales to audio databases of thousands of tracks. Once trained for a given database, it can be used to assess the probability for an unseen track to be a cover of any known track without having to be compared to the entire database. We have finally shown that our method improves previous methods both on small and large datasets.

In the future, we plan to grow our training dataset to address the realistic use case where collections of millions of tracks should be queried: as for many other data-driven problems, will the cover detection problem be solved if the embeddings space is sufficiently structured?

[3] We acknowledge that, strictly speaking, results can not be directly compared to rank methods, as original datasets of [34], [31] and [16] are not available any longer. They however reflect the level of performance of the proposed method.

Acknowledgements.

The dominant melody representations of tracks used as training dataset in this work is available upon request.

We are grateful to Xavier Costaz at Sacem for his suggestions and support, and to Philippe Esling at Ircam for fruitful discussions.

ABSTRACT

Existing kinematic research on orchestral conducting movement contributes to beat-tracking and the delivery of performance dynamics. Methodologically, such movement cues have been treated as distinct, isolated events. Yet as practicing musicians and music pedagogues know, conductors' expressive instructions are highly flexible and dependent on the musical context. We seek to demonstrate an approach to search for effective descriptors to express musical features in conducting movement in a valid music context, and to extract complex expressive semantics from elementary conducting kinematic variations. This study therefore proposes a multi-task learning model to jointly identify dynamic, articulation, and phrasing cues from conducting kinematics. A professional conducting movement dataset is compiled using a high-resolution motion capture system. The ReliefF algorithm is applied to select significant features from conducting movement, and recurrent neural network (RNN) is implemented to identify multiple movement cues. The experimental results disclose key elements in conducting movement which communicate musical expressiveness; the results also highlight the advantage of multi-task learning in the complete musical context over single-task learning. To the best of our knowledge, this is the first attempt to use recurrent neural network to explore multiple semantic expressive cuing in conducting movement kinematics.

1. INTRODUCTION

During orchestral conducting, conductors use their body movements to guide musicians' expressions of various features such as the tempo, dynamics, and articulation in music. Through these delicate nuances in their body movement, conductors are able to communicate their refined interpretations and expressive intentions of the musical work in question. As documented in pedagogical literature, 'conducting semantics' - a codified repertoire of movements bearing specific musical instructions - are broadly accepted as core knowledge, fundamental to conducting practice. [11,15,21,31]. However, in the scenario of actual conducting performances, conductors' movement styles are remarkably diverse. Moreover, while it is conventional common sense for experienced musicians to identify distinct musical features (e.g. phrasing, dynamics, articulation), these features associate with one another in the complex musical context, and conductors tend to communicate similar musical features using diverse strategies depending on the musical context, e.g., dynamic and phrase cuing may vary when conducted with different articulation patterns. As a result, existing music-movement coupling models are limited in some aspects [16, 28, 33]. The straightforward association which presumes that certain movement features can communicate specific musical traits, as stated in conducting pedagogy, has not been observed in such models.

The major challenges to overcome for current conducting movement research are: 1) to identify interpretable quantitative descriptors to represent movement features; 2) to construct a generalisable model, which is robust in identifying features such as phrase, dynamic, and articulation cuing in complex musical context, and which is tolerant to the flexibility of conducting performance and the differences between individual conductors. In this study, we approach both of the challenges by adopting machine learning algorithms. More specifically, to determine potential movement descriptors relevant to expressive musical features, we first applied a supervised feature selection technique, ReliefF [17–19], to three-dimensional body movement data. Based on such selected features, we then sought to jointly identify different types of expressive cuing in conducting movement, and thus trained a recurrent neural network (RNN) on the body movement data from various conductors to perform multi-task learning (MTL).

This study identifies the effective descriptors in conducting movement which are used to communicate musical features. As the pioneering attempt to apply RNN to music-movement coupling in conducting, we also verify the advantage for RNN framework with MTL to probe potential complex connections between various movement and musical elements, especially compared to previous works using other models. In the subsequent section, re-

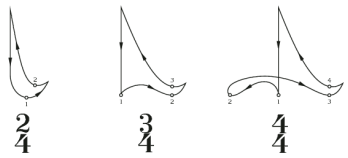

Figure 1. Basic metrical patterns in musical conducting. (reproduced from http://www.purposeful primarymusic.com).

lated research in musical conducting movement will be reviewed. Our dataset and model will be introduced in section 3 and 4 respectively. The experimental designs will be reported and the results will be discussed in section 5, followed by the conclusion in section 6.

2. RELATED WORK

For orchestral performance, a fundamental function of conducting is to coordinate musicians' playing. Conductors regulate the musical timing using basic beat patterns (e.g. two-beat, three-beat, or four-beat cycles etc., see Figure 1), and such beating movements communicate both the tempo arrangement and the metrical structure of the performed musical piece [11, 15, 21, 31]. The beating pattern in conducting has been substantially investigated, and it is found that the vertical action is the major component to lead the beat timing [4, 22, 24, 34, 35]. The tracking of beat is the most efficient under the constraint of movement bounding box area [35] and using dynamic time warping technique [34]. Based on these findings, interactive systems such as Pinocchio, vMaestro, and Personal Orchestra has built, in which the tempo of recorded orchestral audio is manipulated by the user's body movement, and the music automatically aligns with the beat timing identified in the movement [4, 22, 24].

Yet conducting movement is far more complicated than simple beating. Built on these basic metrical patterns, conductors take a step further to communicate their musical interpretations via refined variations in their movement. Pedagogical sources present a stock of movements frequently used by conductors to instruct their expressive intentions regarding articulation, dynamics, and phrasing [11, 15, 21, 31]. As summarised by the authors' previous work, specific conducting movements carrying expressive intentions, i.e. conducting semantics, are understood to comprise distinct combinations of hand position (high/ low/ away from the body/ close to the body), movement size (large/ small), speed (quick/ slow), acceleration (sudden/ gradual change of movement), smoothness (smooth/ jerky), trajectory shape (straight/ curved), and palm direction (upward/ downward/ facing musicians/ facing the conductor) [13, 14]. These qualitative, subjective descriptions of movement features match with quantitative, empirical analysis of conducting kinematics, in which the palm directions, movement size, hand positions and velocity reflect the dynamic change in music [8, 33, 35].

That conductors use their body movement to communicate musical expressiveness is self-evident, and is a truth demonstrated by both musical pedagogy and empirical analysis of conducting movement. However, existing music-movement coupling models generate only low to moderate correlations between musical and movement features [16, 33], and the computational approach which automatically classifies conductors' expressive intentions based on their movement has also produced unsatisfactory results [28]. These findings demonstrate that the expressive semantics in conducting are highly context-dependent. Different aspects of musical expression, such as dynamics, articulation, and phrasing are entangled in actual instances of musical performance, and their study would benefit from the ecologically-valid, intact musical contexts.

In music information retrieval (MIR) research, vast efforts have been devoted to extracting semantic representations such as pitch, beat, and harmony from audio signals. The machine learning approach has gained great success in modelling the semantics from music audio recordings [7]. During performance, musical sound is usually generated by the execution of body movement. There is a pressing need, therefore, for an equivalent effort to explore the expressive semantics carried by musical movement. The recurrent neural network (RNN) is widely used to analyse music semantics in a sequential way [25, 30, 32, 38]. RNN also allows the multi-task learning (MTL) setting, which has been proven successful in music information retrieval [12, 39]. We therefore propose a RNN framework with MTL approach in this study, and test the model on our conducting movement corpus.

3. DATA

This study is based on a professional conducting movement dataset collected by the authors, which contains conductors' upper body movement recorded by a high-resolution motion capture system, together with annotations of beat timing, phrase, dynamic, and articulation.

3.1 Collection of motion capture data

The motion capture data were recorded in the Biomechanical Laboratory at the Institute for Sport, Physical Education and Health Sciences (ISPEHS), University of Edinburgh, UK. Conductors' movement were collected using a nine-camera optical motion capture system (Qualisys, Pro-Reflex, Sweden) at a sampling frequency of 120 frames per second. The captured area was calibrated using the Qualisys 300 mm wand kit with the average residual being lower than 2 mm. Twenty-seven 12 mm optical markers were attached to the conductor's upper body and baton following the Golem Upper Body Model in Visual3D documentation [6]. The locations of 27 markers were illustrated in Figure 2 and listed in Table 1.

Six conductors (3 professional conductors and 3 advanced conducting students) participating the collection were all right-handed males, with an average conducting experience for 10.6 years (SD = 9.37), and conducted for 4.4 hours per week on average (SD = 2.38) at the time of participation. Five string musicians accustomed to musi-

Table 1. The locations for 27 optical markers placed on the conductor's upper body

cal conductors' directions were recruited from University ensembles; the average number of years' instrumental experience was 15.6 (SD = 2.30) and average experience of playing in orchestra was 12.2 (SD = 3.11).

Each conductor rehearsed with musicians for 30 minutes. In the subsequent recording session, the conductor's movements were collected in a repeated measures design. The 6 conductors performed 3 different excerpts of Western classical orchestral repertoire: 1) W. A. Mozart, *Serenade in G major, K.525* (first movement, bars 1-55), 2) A. Dvořák, *Serenade in E Major, Op.22* (first movement, bars 1-53), and 3) B. Bartók, *Divertimento for String Orchestra, Sz. 133* (third movement, bars 1-183). The excerpts represent different compositional styles [5], yet share aspects of metrical structure, which lends them to comparison. Each excerpt is roughly 1 minute long according to constraints of the motion capture equipment. Individual conductors recorded 3 instances of each excerpt, with excerpt performance order counterbalanced across the 6 individuals. As a result, 54 conducting performances were collected in the corpus in total (3 performances x 3 musical excerpts x 6 conductors). The complete dataset was uploaded as the C3D file format for motion capture analysis to the DataShare open access data repository at the University of Edinburgh: https://datashare.is.ed.ac.uk/handle/10283/2906.

3.2 Data pre-processing and labelling

3.2.1 Pre-processing of motion capture data

The collected motion capture data were exported from Qualisys Tracker Manager (version 2.7, Pro-Reflex, Sweden) and imported to Visual3D (standard version 4.93, C-motion, USA) and Python (version 3.6.8) for further analysis. The original movement data containing the position on x-, y-, and z- axes of 27 markers were smoothed by the fourth-order low-pass Butterworth filter with a cut-off frequency of 10 Hz. The speed on x-, y-, z- axes of each marker was defined as the first derivative of x-, y-, z- position respectively, divided by the sampling interval (1/120 s). Speed was considered to carry important information in previous studies on musical conducting movement [13, 14, 26, 27], and thus was chosen as the variable to be investigated. The speed data were normalised based on the mean and standard deviation in each performance trial, and were converted to the z-scores of speed.

The z-scores of speed were then imported in the subsequent feature selection procedure ReliefF. Moreover, a generalisable element is preferable for RNN model. Considering that the minor fluctuations within 1/10 beats (roughly 5 frames) has only trivial effect on our target musical features – which are phrase, dynamic, and articula-

tion structure in bar level, and such minor fluctuations may, on the contrary, have negative effect on generalisation, the simple moving averages of speed data for per 5 frames were thus taken before being imported in RNN model.

In order to align motion capture data with expressive labels extracted from musical scores, the timing of beats and bars in conducting movement was assessed. The beat timing in movement was estimated using the motion capture analysis software Visual3D, and was defined as the time when the lowest position of baton tip on the z-axis (vertical axis) occurred within a beat period according to previous studies [13, 14, 26, 27]. The initiation of a musical bar is then defined as the onset of the first beat in the given bar.

3.2.2 Annotation of expressive labels

The label for dynamics, articulation, and phrasing were annotated by three experienced music theorists (with an average experience for music analysis = 20.7 years, SD = 2.89) based on designated edition of musical scores [2, 9, 29]. Where the annotators disagreed with each other, the opinion of the majority was taken. The dynamic and articulation labels were appointed to each musical bar. Phrasing labels, on the other hand, indicate the initiation timing of phrases, which is dissimilar to dynamic and articulation status that prolongs for a period of time. The phrase initiation was thus determined as the timing of the first beat in each phrase, and then entered the model with a window size of +/- 60 frames, which is equivalent to +/- 0.5 seconds of the phrase initiation in the given sample frequency 120 fps, and roughly +/- 1 beat of the phrase initiation according to 120 bpm instructed in musical scores. The labels are illustrated in Figure 3. The annotation process complied with the following principles:

1) Dynamics: The dynamic annotation contains 6 classes including: *pp, p, mp, mf, f, ff* in the 3 music excerpts. Dynamic levels were labelled according to the expressive terminology in the scores. Where there is no dynamic instruction specified in the given bar, the dynamic level in the previous bar was taken. Where the dynamic level changes within a bar, the dynamic level for the majority of beats was taken. Where different dynamic levels exist in equal number of beats within a bar, the first dynamic level occurring in the given bar was taken. Where crescendo or diminuendo is marked, the gradual change of dynamics was divided into equal levels and was designated to the bars in the crescendo or diminuendo process.

2) Articulation: The articulation annotation contains 3 classes including: *legato, neutral, staccato*. The legato label was assigned to where the slur is printed; the staccato label was assigned to where the staccato mark is printed in the score, or where a note equals to or shorter than a quaver is followed by a rest; the neutral label was assigned to bars where no specific legato or staccato marks was printed. Where there are more than one type of articulation terms printed within a bar, the articulation type for the majority of beats was taken. Where different articulation types exist in equal number of beats within a bar, the first articulation type occurring in the given bar was taken.

3) Phrasing: The phrasing annotation specifies the initiation of phrases, and it contains 2 classes including: *the phrase onset, none*. The phrase structure was determined according to conventional music analysis techniques [3]. Where different melodies interlocked, the phrase in the main melody is taken.

4. DATA ANALYSIS AND MODEL

The aforementioned data set was analysed in two steps: 1) the supervised feature selection technique ReliefF was applied to identify effective descriptors in conducting movement to communicate musical expressiveness; 2) the RNN architecture with MTL setting were constructed to model generalisable rules to associate multiple movement and musical features.

4.1 Data representation

The input data is represented as the z-score of speed on x-, y-, z- axes of 27 markers (3 x 27 = 81 features) with the sample frequency of 120 fps. As shown in Figure 4, each segment fed into the bidirectional long-short-term memory (BLSTM) network contains 81 features with 121 frames (which is equivalent to roughly 1 second or 2 beats); the hop size for consecutive segments is 30 frames (0.25 seconds or 0.5 beats); each input clip contains 64 segments (16.75 seconds or roughly 32 beats; 8 bars in Mozart and Dvořák; 32 bars in Bartók). In addition, we also imported the top 15 movement elements selected by ReliefF (15 features x 121 frames per segment) into RNN, to examine if our recognition model is capable of identifying musical expressions from a small assemble of crucial features.

4.2 Feature selection for movement data

Orchestral conducting consists of movements from different body parts. Conducting pedagogy mainly describes the expressive guidance instructed by hand movements, yet no evidence has been provided by previous motion capture studies to verify such emphasis on hands. To this end, it is essential to know which parts of the body and what kinds of movements are relevant to the expressive intentions in music. The process of finding such relevance can be regarded as a feature selection problem. The ReliefF algorithm, one of the most commonly used supervised feature selection algorithms for music related movement [23], is applied here as an exploratory study. ReliefF is an extension from the original Relief [17–19] with higher reliability and is applicable to multi-class datasets. The algorithm searches every class of features x_i for their k-nearest neighbours from the same class (nearest hit) and from a different class (nearest miss) to score how well such feature to distinguish data from different classes [19]: $\text{Score}_i \sim -\sum_k d(x_i, x_{\text{NearHit}}) + \sum_k d(x_i, x_{\text{NearMiss}})$, where $d(\cdot,\cdot)$ is a distance measure. The exact form of ReliefF can be found in [23]. In this research, we set $k = 20$ as suggested by Urbanowicz *et al.* [37].

Figure 3. The example of musical scores, 3 types of expression label (phrase onset, dynamic level, articulation), and the movement data from right finger marker.

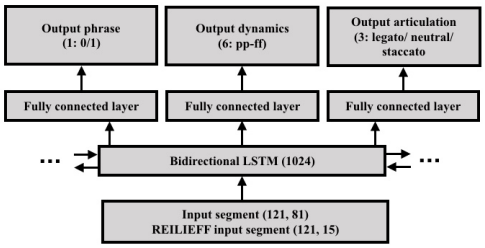

Figure 4. The multi-task model built on the RNN

4.3 Recognition model for music expression

We applied a recurrent neural network (RNN) with bidirectional long-short-term memory (BLSTM) cells to carry out multi-task learning (MTL) for expressive cuing in conducting movement. Such architecture is advantageous to determine sequential features in musical signals [7, 30, 32, 38], yet to the best of our knowledge, this approach has not been applied to musical movement in any existing study.

As shown in Figure 4, the model has a shared BLSTM layer with 1024 hidden units, and a task-specific fully-connected layer. The outputs from forward and backward LSTMs are concatenated as a 2-by-1024 matrix in the segment level, which is then flattened to link the fully-connected layer. The output layer is a 10-D vector containing the classes for the three tasks. Sigmoid is applied to output phrase initiation (1D); Softmax is applied to output the dynamic level (6D) and the articulation type (3D).

To examine the advantage of MTL, we also constructed single-task learning (STL) models, where the same RNN framework and BLSTM cells are applied to phrase, dynamics, and articulation tasks respectively.

5. EXPERIMENT

5.1 Experimental settings

The 54 conducting performance trials (810 input clips) are divided into training set (48 trials, 720-722 clips) and testing set (6 trials, 88-90 clips). The 9-fold cross-validation is performed in a way that per 6 trials are in turns assigned to the testing set in 9 experiments. Each clip fed into the BLSTM network contains 64 segments (# of feature x 121 frames per segment); the hop size for consecutive clips are 32 segments. To prevent the problem of over-fitting, data augmentation is performed in a way that random Gaussian noise is added to the original data with the level of 0.1 standard deviation of the input data.

All networks are implemented using TensorFlow [1], and are trained using stochastic gradient descent with Adam optimiser. The cross-entropy between output and labels are computed for training purpose. To avoid over-fitting, L2 regularisation is applied. The dropout rate for both the input and output of BLSTM cells is 0.7. The learning rate is 0.0001 with 4800 training steps. This procedure is performed on 4 models: the MTL model, STL models for phrase, dynamics, and articulation tasks respectively.

5.2 Evaluation metrics

For the phrase recognition task, The Precision, Recall, and F1 measures (the balanced harmonic mean of Precision and Recall) [10] are computed in segment level (hop size = 30 frames; 0.25 seconds; roughly 0.5 beats). A detected phrase cuing event is considered as a true positive if it lies within a tolerance window +/- 60 frames (0.5 second and roughly 1 beat) from the ground truth annotation. If there are two or more phrase cuing detected within this tolerance window, one of the detections is considered as a true positive, and others are considered as false positives. For dynamic and articulation recognition tasks, the accuracies (acc) are computed in segment level: acc = (# of true posi-

tive segments/ # of total segments).

5.3 Result

5.3.1 Results of movement feature selection

The top 15 relevant movement features selected by ReliefF algorithm to fit 3 types of musical features (phrase, dynamics, articulation) are illustrated in Figure 2. It appears that the elements from right and left fingers, and right and left wrists are prominent in communicating all three types of musical expressions. These top 15 elements are inputted in the subsequent RNN model.

It is an unexpected outcome that the elements from the baton end are not included in the top list. As suggested in conducting pedagogy, the baton end has been considered as an important reference to communicate expressive information in conducting [11, 15, 21, 31]. In the ReliefF analysis, the elements from baton end are ranked as no 31-33 within 81 elements. It could be the effect that our target musical features are in bar level rather than in beat level. According to eigenvalue and eigenvector analysis in previous research on musical movement, the movements in extremity usually correspond to lower-level musical elements with a shorter period (such as per beat), whereas movements in torso tend to associate with higher-level musical features with a longer period (such as per bar or longer) [36]. The right finger and wrist are in the intermediate location between the body and baton tip, and are the key body part for conductors to manipulate the baton, which could be the reason that why they contribute the most to our expressive targets.

5.3.2 Results of music expression recognition

The results of using RNN framework to perform MTL and STL are reported in Table 2. It is manifest that the accuracy produced by all models is higher than the random incidence (0.166 for 6-class dynamics; 0.333 for 3-class articulation). All the t-tests comparing the models with the feature selection procedure (# of feature = 15) and with full feature sets (# of feature = 81) do not reach the significant p-value of 0.05, which suggests that the top 15 features selected by ReliefF are effective descriptors regarding the expressiveness in conducting movement. It is evident from t-tests that the MTL model shows its advantage over STL models. It appears that these three musical features are intertwined in the musical context. Identifying phrase cuing can be the most challenging one among the three tasks. Considering the characteristics of movement kinematic signal, the phrase cuing can be easily confused with local-level beat cuing. Yet in the multi-task model, the dynamic and articulation information can help the recognition of phrase in one way or another.

The majority of previous research on conducting movement focuses on the beating pattern in basic level [24, 34, 35], and in this study, we make effort to explore the higher-level expressive semantics in conducting. There are several previous attempts to tackle the semantic-level in conducting, but exclusively target on the dynamic instructions, and tend to consider such gestures as isolated events regardless

Model	#	Phrase			Dync.	Artc.

Table 2. Recognition results (in %) using RNN with multi-task setting (MTL) and single-task setting (STL): The precision (P), recall (R), F1 (F) measures for the phrase task, and the accuracy (acc) for dynamics (dync.) and articulation (artc.) tasks, comparing all movement features (# = 81) and the top 15 features selected by ReliefF (# = 15). Asterisks indicate the p-value of t-test of MTL and STL counterparts: * for $p < 0.05$; ** for $p < 0.01$; *** for $p < 0.001$.

the musical context [4, 8]. Previous studies examined the correlations of movement-music dynamic feature pairs and yield moderate r^2 ranging from 0.4 - 0.5 [33]. Our model takes another approach and is competent to investigate the complex inter-connections among multiple factors, and is able to produce further and solid results. As we expect from previous MIR research using MTL settings [12, 39], our MTL model demonstrates the advantage to consider multiple musical and movement elements together to investigate the complex inter-connections in the communication process during conducting performance. Moreover, as suggested by the previous research, musicians may perform the dynamics and articulation differently from the notated scores [20], the connection between the conducting movement and the performed sound can be further investigated using a similar approach presented in this study.

6. CONCLUSION AND FUTURE WORK

In this paper, we describe results from our investigation into the expressive semantics in conductors' movement used to communicate the phrase, dynamics, and articulation in music. The supervised feature selection technique ReliefF provides insights into effective descriptors in elementary kinematic signals of conducting movement. The movement elements from the right and left hand, and right and left wrists appear to carry important information regarding the conductor's expressive intentions. These selected descriptors are further investigated using recurrent neural network with multi-task learning. The RNN architecture yields improved results compared to previous works using other analysis techniques. Particularly, the multi-task learning model demonstrates a promising approach to examine the complex interactions among multiple musical and movement elements.

As the pioneering investigation on conducting movement using RNN, we highlight the potential for this framework to be applied to further explore other issues in music conducting, such as the connection between the conducting movement and the performance sound. The findings of such studies can enlighten the musical education for both conductors and orchestral musicians.

THE ROMANTEXT FORMAT: A FLEXIBLE AND STANDARD METHOD FOR REPRESENTING ROMAN NUMERAL ANALYSES

Dmitri Tymoczko[1] **Mark Gotham**[2] **Michael Scott Cuthbert**[3] **Christopher Ariza**[4]

ABSTRACT

Roman numeral analysis has been central to the Western musician's toolkit since its emergence in the early nineteenth century: it is an extremely popular method for recording subjective analytical decisions about the chords and keys implied by a passage of music. Disagreements about these judgments have led to extensive theoretical debates and ongoing controversies. Such debates are exacerbated by the absence of a public corpus of expert Roman numeral analyses, and by the more fundamental lack of an agreed-upon, computer-readable syntax in which those analyses might be expressed. This paper specifies such a standard, along with an associated code library in `music21`, and a preliminary set of example corpora. To frame the project, we review some of the motivations for doing harmonic analysis, some reasons why it resists automation, and some prospective uses for our tools.

1. INTRODUCTION AND MOTIVATION

Roman numeral analysis represents tertian chords by their triad type (major, minor, diminished, augmented), their position relative to the tonic (specified by the scale degree of their root), their bass note or inversion, and the presence of sevenths or other added or altered notes. The practice emerged in the early nineteenth century, with Gottfried Weber's *Versuch einer geordneten Theorie der Tonsetzkunst* [19] drawing on Rameau's earlier concept of the fundamental bass. Weber's method was so immediately popular that he complained other theorists were stealing his methods, and it has remained common to the present day. It is useful to contrast Roman numerals with alternatives, notably:

- Absolute labels for chords such as 'C', as often found in lead sheets;
- Function-theoretic labels such as 'T[onic]';
- Inversional symbols accompanying bass notes as used in figured-bass notation.

Absolute chord labels are performer-oriented in the sense that they specify which notes should be played, but do not provide any information about their function or meaning: thus one and the same symbol can represent a tonic, dominant, or subdominant chord. Accordingly, these labels obscure a good deal of musical structure: a dominant-functioned G major chord (i.e. G major in the local key of C) is considerably more likely to descend by perfect fifth than a subdominant-functioned G major (i.e. G major in the key of D major). This sort of contextual information is readily available to both trained and untrained listeners, who are typically more sensitive to relative scale degrees than absolute pitches.

Roman numerals include contextual information at the cost of increased subjectivity: by labelling chords relative to a local tonic, they require the analyst to make a potentially difficult decision about what the tonic is. However, these decisions can be undone: given a Roman numeral and a key, one can algorithmically derive an absolute chord label. Thus Roman numerals can be used even in contexts where absolute labels are needed (for instance, exploring the frequency of "open" chords in guitar-based music). This makes it a good choice for the construction of analytical corpora, as one can translate from Roman numerals to absolute labels but not vice versa.

Function theoretical labels go one step further toward abstraction: here chords are identified not by their note content but by their perceived harmonic role. (Usually, the three Riemannian functions T, S, D are employed, though other writers have suggested additional harmonic categories.) Thus in C major, a term like "D[ominant]" could mean B-D-F, G-B-D-[F], or some other chord entirely; just as "S[ubdominant]" could mean either D-F-A-[C] or F-A-C. Because many distinct harmonies map to a single functional term, these labels cannot be translated into Roman numerals or absolute chord labels. However, function labels can often be recovered from Roman numerals: in ordinary musical contexts, vii and V are Dominants, while ii and IV are Subdominants [17]. Once again the asymmetry gives us reason to prefer Roman numerals for analytical corpora.

The inversional symbols of figured-bass notation are in many ways analogous to absolute chord labels, but with an important difference: they are often used to label "non-harmonic" sonorities containing dissonances that do not belong to the underlying harmony. For this reason, many recent theorists have favored them, [5, 10] be-

lieving that Roman numerals impose too strong a distinction between the harmonic and non-harmonic realm. (Ironically, Riemann himself made the converse complaint against figured-bass notation, believing that it did not draw a sharp enough distinction between harmonic and non-harmonic [13]). When we restrict our attention to tertian sonorities, however, figured-bass symbols are largely equivalent to absolute chord labels, telling performers what notes to play but not what they mean.

Each of these methods has its benefits and shortcomings; we have chosen Roman numerals for their widespread popularity, their translatability to the other formats, and their proven utility.

1.1 Motivation for Roman Numeral Analysis Corpora

Roman numeral analysis involves several different layers of subjective judgment:

- which notes are harmonic / non-harmonic;
- what complete harmony, if any, an incomplete or otherwise ambiguous chord might represent; and
- the underlying keys and when they change.

Thus Roman numeral analysis is not an automatic process, and humans may legitimately disagree about the best analysis of a given passage [14, 15, 18]. Instrumental textures present a particular challenge because it is not always clear where harmonies change, and even a single, monophonic passage such as an Alberti bass can imply multiple voices. Even in rhythmically simpler genres, such as the Bach chorales, there are significant challenges to automatic Roman numeral parsing.

One of us has written a rule-based Roman numeral analyzer that reproduces human analyses of the Bach chorales with roughly 82% accuracy (DT forthcoming work; code available on request). That figure represents something like the state of the art, and while 82% accuracy is sufficient for some applications, it falls far short of what is needed in serious analytical and pedagogical contexts. Furthermore, extending the method to instrumental textures poses a range of considerable challenges.

Such challenges motivate the construction of human-made corpora, which can serve as the "ground truth" for evaluating computational analyses. Human-made corpora can also allow us to study the degree of alignment among expert analysts, as well as providing important first-order information about harmonic practices in different historical eras. Finally, the combination of automatic analyses with machine-readable scores facilitates a host of analytical projects including the automatic identification of non-harmonic tones.

2. THE .RNTXT SPECIFICATION STANDARD

We now outline our proposed standard. Previous work to define standards and create corpora include [1, 3, 4, 7, 8, 11, 12, 16]. Our goal is to create a format that is not just parsable by a computer, but also easy for human beings to read and write. Previous work tends to neglect this latter consideration, and thus limits corpus creation to dedicated coders and researchers prepared to learn formats divergent from textbook models. The Clercq-Temperley and DCMLab's tabular representation are user-friendly exceptions; we provide converters as part of the `music21` code to connect with those format (as discussed below in Section 3.1) [2]. Additionally, [4] reports that TAVERN has plans for a forthcoming `music21` converter which would further extend the connections and interoperability between these corpora. We provide extensive online examples (cf. Section 3.2) below and include one extract in the text as Figure 1.

```
Composer: J. S. Bach
Piece: Chorale BWV269
Analyst: Dmitri Tymoczko

```

Figure 1. An example of the new standard as used to represent an analysis of the Bach chorale BWV269.

2.1 Metadata

Documents may begin with the following optional lines:

- Composer: e.g. 'Mozart'
- Piece: Name and/or catalogue number, e.g. 'K550'

- Analyst: The name of the original analyst / originator of this document, e.g. 'Jo Blogs'.
- Proofreader: The name(s) of the anyone involved in checking and correcting this work, e.g. 'Jo Vlogs'.

After the metadata, may include movement and time signature information on separate lines.

Movement. Use Arabic numbering to label the movement of a multi-movement piece.

```
Movement: 1
```

Each movement is typically contained in its own file.

Time Signature. Specify time signatures on a separate line in the form of a simple string, such as:

```
Time Signature: 6/8
```

Changes of time signature are notated with a new specification immediately preceding the change. If no time signature is specified 4/4 is assumed.

Key Signature. The format supports the (optional) specification of the notated key signature as a number of sharps (or negative number for flats) in the key signature. So the specification:

```
Key Signature: -1
```

stands for a key signature of one flat (F major or d minor).

Minor Sixth / Minor Seventh. Specifies how scale degrees 6 and 7 are to be interpreted in minor mode. Supported values are 'quality' (major chords are on flattened degrees, minor or diminished on raised degrees), 'cautionary' (default: same as quality, but # and b can used to leave off ambiguity), 'sharp' (raised degrees are standard; lowered degrees require b), and 'flat' (lowered degrees are standard). See github.com/MarkGotham/When-in-Rome for a tabular comparison of these options.

2.2 General syntax of Chords

After the metadata, the document proceeds to itemize each chord with one line per measure. Each line of analysis starts with the symbol 'm' followed immediately by a measure number with no space; it then proceeds with pairs of beat numbers (preceded by 'b') and their corresponding Roman numerals. For instance, the line:

```
m5 b1 IV6 b2 V
```

indicates that in measure 5, a IV^6 chord falls on beat 1, followed by a V chord on beat 2.

Chord Inversions. The format supports all standard representations of triad and seventh inversions, as itemized in Section 2.3. Slashes are optional for separating subscript from superscript numbers, so I^6_4 may be `I6/4` or `I64`.

Missing beats. If no beat is specified at the start of a line, beat 1 is assumed. For any further beats that are missing, the existing chord remains in effect. So the line:

```
m14 IV6 b2 V b4 V2
```

indicates that measure 14 starts with IV^6 chord on beat 1, followed by a V chord on beat 2 which remains in effect across beat 3, and becomes V^2 on beat 4.

No chord. 'NC' indicates a passage with no chord – where one chord terminates prior to the onset of the next.

Measure numbers. Each line begins with a measure number and each movement should be numbered separately. This means that every movement will start with measure 1, except in the case of an initial anacrustic measure which is numbered 0. (The `music21` parser interprets the length of the anacrusis based on the first notated beat: thus in 4/4, `m0 b4 C: V` indicates a quarter-note pickup, while `m0 b4.5 C: V` indicates an eighth-note pickup.) Thus measure 1 is always the first full measure. For multiple alternative measure numbers, such as first / second time repeats or endings, use lower-case Latin script, so '216a', '217a', '218a' for the first, and '216b', '217b', '218b' for the second. See 'Repeats' in Section 2.5 below for details of how to handle measures that repeat the harmonic context of other measures.

Beats. Beat numbering follows the conventions for the given meter, so 4/4 has 4 beats in total, while 6/8 and 2/2 have two. Thus a succession of eighth notes will be assigned different beat positions depending on that context, for instance:

- in 4/4: 1, 1.5, 2, 2.5, 3, 3.5, 4, 4.5.
- in 2/2: 1, 1.25, 1.5, 1.75, 2, 2.25, 2.5, 2.75.
- in 6/8: 1, 1.33, 1.66, 2, 2.33, 2.66 (or 2.67).

The X.33 and X.66 format is also used for the second and third units in a triplet division of a duple meter. For further division of ternary beats, analysts can either use more precision or multiple decimal points, so that '1.833' and '1.66.5' indicate the point halfway through the second eighth of the first beat of a 6/8 measure.

Keys. Indicate key changes with the name of the key in the correct (upper or lower) case, followed by a colon. `C:` indicates the key of C major; while `c:` is c minor. Sharps are notated with '#' and flats with either 'b' or '-'. Key changes occur between beat and chord, so

```
m112 IV6 b4 C: ii
```

indicates a key change to C major on beat 4 of measure 112. A single chord can be notated as a pivot chord belonging to two keys like so:

```
m112 IV6 b4 vi C: ii
```

Here, one and the same (D minor) chord is recorded both as 'ii' in the new key of C major and 'vi' in the old key (F major). (Note the lack of a beat between the Roman numerals in the two keys.) There is no need to change keys for modally-inflected chords:

```
m112 IV6 b3 iv6
```

indicates a major triad $\hat{6}$-$\hat{1}$-$\hat{4}$ followed by the minor triad $\flat\hat{6}$-$\hat{1}$-$\hat{4}$ with the same root.

A key with a semicolon preceding the colon, such as `C;:` indicates that the new key should also be indicated with a change of key signature in any generated score.

In cases of key ambiguity, a secondary key may be preceded by a question mark and an open parentheses such as `?(Bb:` which indicates that the analyst believes that B-flat major is also a valid key but that the prevailing key (such as g-minor) is the one to which subsequent Roman numerals will refer. These optional keys can be concluded by reversing the direction of the parenthesis as in `?)Bb:`.

Chromatic Alteration. For altered chords, simply use the appropriate triadic symbol: lowercase with the suffix

'o' for diminished, lowercase for minor, uppercase for major, uppercase with the suffix '+' for augmented. Roots can be raised or lowered with a preceding '#' and 'b'(e.g. `iv`). Thus `bIII+` indicates an augmented triad on a lowered scale-degree 3, or Eb-G-B in C major.

Altered, added, and omitted tones. These may be indicated by an operation and chord step in brackets. Thus `V4/3[b5]` indicates a V_3^4 chord with whose bass is lowered. Note the potentially confusing (but standard) combination of figured-bass and root-functional symbols: in `V4/3[b5]` the '43' refers to intervals above the bass, while [b5] refers to an interval above the root. The symbol 'no' can be used to specify chord tones that are to be removed. Each alteration should appear in its own set of brackets. Thus, as a non-sensical demonstration of multiple possible features, `V65[no5][add#6][b3]` indicates Bb-E#-F-G in C major.

Minor mode. In minor, scale degrees 6 and 7 are variable depending on whether the melodic or natural minor collection is used. For the purpose of legibility the expectation is that common chords conform to one of the standard minor scales. Thus `a: VII` refers to G-B-D while `a: viio` refers to G#-B-D. Similarly, `a: VI` is F-A-C while `a: vio` is F#-A-C. Augmented chords are treated as altered major chords (i.e. based on natural-minor scale degrees), while diminished chords are treated as altered minor triads (raised degrees). These interpretations can be changed through the 'Sixth minor' and 'Seventh minor' metadata tag described above.

Applied Chords. 'Applied', or 'secondary', chords are notated using '/'. For instance, `V/V` indicates the dominant chord of the dominant key of the prevailing tonic, so D major (V of G major) in the key of C major. Applied chords are typically used for local tonicisations (including the purely diatonic V/III in minor), reserving 'full' key changes like `C:` for longer modulations. Chained applied chords such as `V7/V/V` are allowed.

Augmented and Neapolitan sixth chords. These are sufficiently canonical to be afforded their own abbreviation. Thus 'Ger*' is shorthand for `#ivo*[b3]` where * labels the appropriate inversion (7, 6/5, 4/3, or 2), 'It*' for `#ivo*[b3]` (with possible inversions being 5/3 or blank, 6/3 or 6, or 6/4), and 'Fr*' for `II*[bV]`. For the Neapolitan, 'N' and 'N6' are both accepted abbreviations for `bII6`. Use `bII` for the Neapolitan in root position.

Cadential 6/4. For computational simplicity, the parser expects any of `I64`, `I6/4` or `Cad64` for the cadential 6/4 chord (`V64` is not treated as equivalent here since its meaning depends on context).

2.3 Chord Symbol Summary

The following list summarises the possible symbols available for use in describing chords.

- Sharps and flats: b = flat, # = sharp, bb = double-flat, ## = double sharp, etc.
- Major Triads: I, II, III, IV, V, VI, VII (upper case)
- Minor Triads: i, ii, iii, iv, v, vi, vii (lower case)
- Triad suffixes: add '+' to major for an augmented triad; 'o' to minor for a diminished triad (note, this is the letter 'o' not the numeral '0'); '/o' indicates a half-diminished seventh chord.
- Abbreviations: 'It', 'Ger', 'Fr', 'N', 'Cad'.
- Triad inversions: no symbol or '5/3' for root position; '6' or '6/3' for first inversion; '6/4' for second inversion (with or without the optional '/').
- Seventh inversions: '7' for root position, '6/5' for first inversion, '4/3' for second inversion and '2' for third inversion. '9', '11', and '13' are also supported in root position.
- Altered/added/omitted notes: use square brackets and Arabic numerals, e.g. '[no5]' for no fifth.

Together, these elements are sufficient to describe any standard tonal chord. Roman numerals may involve more or less complicated combinations of these symbols. Formally, the triad type is the only required element, so 'I' and 'V' (and their minor-mode equivalents) are the simplest possible syntatical entries. A maximally-complex chord description involves all of the available elements, which will be parsed in the following order:

1. Triad type (with quality indicated by case);
2. Triad suffix for diminished / augmented;
3. Accidental for raising/lowering the root (sometimes computed, in minor, from triad type);
4. Accidental for modifying a seventh and/or inversion that follows;
5. Seventh, ninth, etc. and/or inversion;
6. Accidental for modifying an ...
7. Altered/added/omitted note;
8. Relative key (in the case of applied chords)

Steps 6 and 7 also may be repeated.

See Section 3.1 for details of how the code processes this, and github.com/MarkGotham/When-in-Rome for full reference lists of all possible Roman numerals along with the pitches they entail in C major and a minor.

2.4 Form, Phrase, and Pedals

Pedal points. With pedal points, analysts face a choice between integrating the pedal into the Roman numerals – for instance, `I IV6/4 I` and `V I6/4 V` each has the same tones in the bass throughout – or to indicate that the pedal has harmonically separated from the passage and should no longer be represented in this way [9, p.113]. This format supports both notations. To notate a pedal separately, use a line of the kind:

`Pedal: G m14 b3 m19 b1`

Here a G pedal begins in measure 14 beat 3 and lasts until (but not through) measure 19 beat 1.

Large-scale formal labels. Formal sections can be identified using the prefix `Form:`. Examples include the major sections of Sonata Form ('Exposition', 'Second Theme', 'Development', 'Recapitulation' and 'Recapitulation Second Theme'); numbered variations in variations form ('Variation N'); and the large-scale divisions of a Rondo ('Rondo A', 'Rondo B'). These should be positioned on a separate line before the measure in which the section begins.

Phrase boundary. Phrase boundaries can be identified with '||'. This provides data useful for many lines of enquiry. From the strictly harmonic perspective, this can help to contextualise unusual progressions. For instance, in

```
m33 V || b2 IV
```

the oddity of an apparent V-IV progression is contextualised by the fact that it occurs across a phrase break: the music stops on V before resuming on IV.

2.5 Repeated Progressions and Variants

Repeats. For different passages with the same harmonies, the format supports the following abbreviation:

```
m3-4 = m1-2
```

This indicates that measure 3 is the same as measure 1 and measure 4 is the same as measure 2. This shorthand works for exact repeats of chords progressions, with the same chords, in the same order, in the same part of the measure. For near variants, judicious copy-and-paste is required, taking care to make the necessary changes. One of the authors (DT) has written a simple python program to renumber measures and shift chords into a new key, available on request.

Variant readings. For multiple readings of the same passages, use the 'var' tag. For instance,

```
m1 viio6
m1var1 ii
```

indicates that the chord in measure 1 is ambiguous: it may be viio6 or ii. Multiple variants may be indicated with var1, var2.

Notes. The 'Note' tag affords an opportunity to record any other noteworthy elements, such as a pattern not evident from the Roman numerals alone. Include notes on separate line, before the moment of interest. This subsidiary feature is for the analyst's reference only and not processed as part of the harmonic analysis.

3. CODE AND CORPUS

Apart from the .rntxt standard specification, this paper also presents a code library in `music21` for handling Roman numeral analyses, as well as a set of initial corpora.

3.1 Code

The code focusses on translation routines for the .rntxt representation defined above, the related Clercq-Temperley standard defined by Trevor de Clercq and David Temperley for rock harmony ('.tdc' extension), and the DCMLab's tabular representation format ('.tsv' extension). [1]

Figure 2. An example of `music21`'s default musical-notation rendering, with chords in close position and the numeral itself included as a 'lyric'. This example is from the start of BWV269, corresponding to Figure 1.

Like the .rntxt representation format, the code also provides a neutral conduit for processing Roman numeral analyses in various ways: converting between representation formats, rendering the analyses in musical notation, and engaging in computational analysis using the wider `music21` code base. Again, that neutrality means supporting any in-principle approach to Roman numeral analysis as long as the representation meets the syntactical criteria of the format.

Exceptions are raised in the case of divergence from the syntax, and the parsers are fully integrated into `music21`, so both `corpus.parse()` and `converter.parse()` read directly from the file types listed (.rntxt, .tdc, and .tsv). Files with other extensions can be parsed by passing in a format parameter: `.parse('file.txt', format='romantext')`.

All features of RomanText described in this paper are supported by the most recent release of music21 (v.5.7), except [addX] tones and settings for alternative parsing of vi/VI and vii/VII included in v.6.0alpha, and variant readings which are not currently supported.

From these RomanText analyses, the code creates a `music21` Score with a single Part object containing all the RomanNumeral objects within the relevant measures. Figure 2 shows an example of how `music21` renders Roman numerals: unless specified otherwise, the tonic is placed in octave 4 (the octave above middle C inclusive), the root (or imagined root if in inversion) is placed above that tonic, and the real bass of each chord is placed in the octave above that pitch. Where the corresponding score exists in an encoded format, this analysis part can be inserted as an additional 'part' in order to view the relationship between score and analysis in musical notation. Future work may see an option for matching the analysis up with the original piece in order to render chords in their original spacing.

The `RomanNumeral()` class extends the `Chord` class, inheriting mutually useful variables like `.root`,

[1] For more information on the deClercq-Temperley format, see the scholarly reports in [3] and [16]. For the DCML lab's standard, see [12] and the code base at `github.com/DCMLab/ABC/` For music21's provision, see the code base at: `github.com/cuthbertLab/music21/tree/master/music21/romanText` or for documentation: `web.mit.edu/music21/doc/moduleReference/moduleRoman.html` for the code and Chapter 23 of the User's Guide: `web.mit.edu/music21/doc/usersGuide/`

and introducing new read/write attributes. Thus anything one can do to or with a `Chord` is also possible with a `RomanNumeral`. A Roman numeral pairs a `.figure` (such as `I6`) with a `.key` (such as `C`), but the class supports a range of additional attributes, some settable, others read-only.

Additional methods support the creation of RomanNumeral object ab initio, such as the `.romanNumeralFromChord()` method which processes any chord (which in turn can be made from a list of pitches) into a `RomanNumeral` object when paired with a specific key.

As discussed in Section 2, the RomanText format supports additional elements that are more textual than harmonic: 'large scale formal labels', 'pedals', and 'notes'. music21 processes these as text with a dedicated subclass of TextExpression.

3.2 Corpus

Finally, we present a set of example corpora approximately representing the start, middle and end of common-practice tonality as follows (with the total analyses in brackets):

1. Monteverdi madrigals, Books 3–5 (48 works);
2. Bach chorales (a sample, 20 analyses);
3. Preludes from the first book of Bach's Well Tempered Clavier (complete, 24 preludes);
4. Beethoven string quartets, converted from the DCMLab's ABC corpus and with manual error-correction (complete, 16 quartets, 70 movements);
5. 19th-century French and German songs from the 'Scores of Scores' corpus [6], (sample, 50 songs).

See github.com/MarkGotham/When-in-Rome for directions to these corpora: the first two are included in the latest version of music21; more will be added after error checking. We offer them in order to illustrate how the format works in a range of repertoire contexts, and to provide an initial dataset for experimenting with the format. An additional corpus of approximately 1,000 scores, ranging from Dufay to Brahms, will be released within a year.

As we have been at pains to point out, the .rntxt format accommodates any kind of Roman numeral analysis, as long it is adopts the basic syntax as outlined above. That said, any particular corpus will have to make 'policy' decisions about its approach, if it is to be consistent. In these corpora, we have elected to prefer:

1. harmony changes on metrically strong positions and at regular intervals;
2. to analyse similar material in similar ways;
3. to identify as 'harmonic' notes that do not belong to any common species of non-harmonic tone (e.g. notes that are both leapt-to and leapt-from); and
4. harmonic analyses that are more consistent with standard harmonic theory.

No.1 and No.2 are intuitive enough, though No.2's reliance on 'similar' leaves ample room for ambiguity; furthermore there are cases where harmonic considerations lead to different analyses of parallel passages. Rule No. 3 requires harmonic analyses to conform to the precepts of traditional contrapuntal theory, which is mostly appropriate for our chosen repertoires (though some allowances need to be made in the case of Monteverdi).

No.4 is arguably more interesting. The preference may appear circular, but it is not: standard harmonic theory asserts that the majority of tonal chord progressions can be understood as conforming to a small number of harmonic and contrapuntal patterns; it does not assert that all passages are unambiguous, nor that composers tried to avoid analytical ambiguity when composing. Thus analysts commonly rely on their harmonic expectations when identifying chords. For instance, given a D-F dyad between I and I^6 in a common-practice C major context, preference No.4 helps lead us to identify the most promising candidates for completion as ii, V^4_3, and $viio^6$ and to choose either of the latter two, since the progressions I $viio^6$ I6 and I V^4_3 I^6 are significantly more common than I ii I^6. (The former is more common in Bach; the latter in Beethoven, so detailed stylistic information is needed in this case.) The sense of 'commonness', furthermore, can be justified by looking only at those cases where a complete triad intervenes between I and I^6. In this way, we use our sense of what happens in the non-ambiguous cases to guide our interpretation of the ambiguous ones.

A more thorough-going discussion of the philosophical options available to Roman numeral analysts will be published by author DT soon.

4. SUMMARY AND OUTLOOK

This paper presents a specification for Roman numeral analysis, code for working with those analyses, and a set of example corpora. The format thus supports a range of data-driven approaches to harmonic analysis, as well as other applications including pedagogical (e.g. visualisation and the selection of pertinent teaching examples) to compositional (setting harmonic constraints for stochastic composition). We hope that these offerings will contribute positively to ISMIR's 20th anniversary call for 'reusable' material to 'build up consistent knowledge across the community.'

5. ACKNOWLEDGEMENTS

The development of music21's RomanText processing module was generously supported by a grant from the Seaver Institute. Author MG's work was supported by a grant from Cornell University's Active Learning Initiative.

20 YEARS OF PLAYLISTS: A STATISTICAL ANALYSIS ON POPULARITY AND DIVERSITY

Lorenzo Porcaro[1], Emilia Gomez[1,2]

[2]Joint Research Centre, European Commission, Seville
{lorenzo.porcaro,emilia.gomez}@upf.edu

ABSTRACT

Grouping songs together, according to music preferences, mood or other characteristics, is an activity which reflects personal listening behaviours and tastes. In the last two decades, due to the increasing size of music catalogue accessible and to improvements of recommendation algorithms, people have been exposed to new ways for creating playlists. In this work, through the statistical analysis of more than 400K playlists from four datasets, created in different temporal and technological contexts, we aim to understand if it is possible to extract information about the evolution of humans strategies for playlist creation. We focus our analysis on two driving concepts of the Music Information Retrieval literature: popularity and diversity.

1. INTRODUCTION

The advent of the streaming era has transformed the role of music playlists, which have become central to the listening experience. The current interest by both academia and private company is illustrated by the ACM RecSys Challenge 2018 for Automatic Music Playlist Continuation, where almost 2K people registered for participating [4]. However, the interest in algorithmic-enhanced methods for playlist generation started much before, when large catalogues of digital music became available, around the beginning of this century [1, 13, 17].

In the last 20 years, Music Information Retrieval (MIR) literature has addressed several aspects of playlists, both from a user and an algorithmic perspective [8]. In this work, we focus on the analysis at scale of large playlist datasets in order to understand how humans create a playlist in different contexts. The main hypothesis of our work is that technological innovations occurring in the last two decades have affected how people are experiencing music, and thus how music pieces are grouped together.

We center our attention on two main facets considered important in the design of playlist generation systems, according to the literature. On one hand, we address the characterization of playlists in terms of popularity, which has been a focus of several studies and related to the so-called long-tail effect [3]. On the other hand, we address the semantic diversity of a playlist, considered as the contrary to the semantic similarity concept. The trade-off between similarity and diversity has been already object of analysis [6, 7], so following a similar direction we study the diversity of semantic information in playlists.

In detail, we measure the popularity of a playlist, starting from the popularity of its component tracks. The advantage of this measure relies in the possibility to compute it without looking at the content. Furthermore, using tags retrieved from *Last.fm* [1] , we define a playlist diversity index based on the semantic distance between its tracks. The distance is computed using tag embeddings, a compact and meaningful representation of user-generated annotations.

This work has three main contributions. First, we propose and implement two distinct indexes for playlist dataset characterization: one related to the concept of popularity and another one to the concept of diversity. Second, we apply, study and discuss the statistical distribution of these measures to four datasets, containing more than 400K playlists created in the last 20 years. Third, we release the data and software used for the analysis in order to foster reproducible research and future work in the topic.

The paper is structured as follows. Section 2 provides an overview of previous works related to the analysis of the playlist creation processes. We then propose an analysis methodology in Section 3, which includes a description of the model, the considered datasets and the proposed statistical measures. Section 4 provides the obtained results, which are discussed in Section 5.

2. RELATED WORK

A playlist is usually described in a very broad way as "*an ordered sequence of songs meant to be listened to as a group*", a noteworthy definition in the literature [9]. Several approaches have been proposed to build computational models of the mechanisms behind playlist creation such as Combinatorial Pattern Generation [13], Gaussian Process Regression [17], Markov Chains [5], or Hypergraph Random Walks [12] among the others. Recent studies for analyzing playlists proposed context-aware algorithms, which

takes into account characteristics such as the playlist title [16], and also sequence-aware algorithms, which analyze the order of songs in a playlist [20]. For an extensive review of manual, automatic and assisted techniques for playlist creation, we refer to [8].

Understanding how people create playlist is fundamental for creating computational models capable of emulating this human generation process (automatic playlist generation) [5], or predicting the most likely song to add in a given playlist (automatic playlist continuation) [4]. In addition, the intrinsic value that individuals give to a set of songs cannot be always fully explained by the analysis of the acoustic features, as tempo or tonality, emotional state or contextual information [6], and the sentence "*Making a playlist is more of an art than a science*" partly summarizes this hindrance [7]. Finally, interactive tools for supporting users during the decision-making process of playlist creation have been shown effective, but at the same time affecting human decisions. Indeed, in [11] the authors show how these kinds of tools can bias humans towards adding

tracks more popular or more recent, in comparison to what they would independently add to the playlist. It can be considered as a consequence of the difficulty of creating models which effectively reflect human behaviors.

3. METHODOLOGY

3.1 Dataset

This study considers a total of 409K playlists (2.3M songs) from four different playlist datasets (see summary in Table 1), three of them already proposed in the literature:

1. Art of the Mix [2] (AOTM): Playlists submitted by users to the Art of the Mix website [2].
2. Yes.com [5] (CORN): Playlists from radio stations in the United States.
3. Spotify [16] (SPOT): Playlists from Twitter's users tweeting via Spotify.
4. Deezer (DEEZ): Playlist from Deezer's users, crawled in-house.

The datasets were considered because of the heterogeneity of their nature. Indeed, they have been created using playlists from different periods, with different usage and purpose. CORN [3] provides playlists from radio stations in the United States, without restrictions on musical genres. This is the only dataset where playlists are not generated by users. AOTM [4] is the dataset containing the oldest playlists, covering a 13 years period from 1998 to 2011. It is formed by playlists submitted by users to Art of the Mix, a website where a community of playlist passionates share their creations. SPOT [5] has been composed tracking Spotify's users active in Twitter between 2012 and 2015. Similarly, DEEZ has been created using the Deezer API, selecting users playlists created between 2013 and 2018.

There are two main differences between AOTM and the other two user-generated datasets. First, SPOT and DEEZ

Table 3. Example of tracks and relative tags of a playlist with low diversity ($pDI = 0.12$, *top*), and a playlist with high diversity ($pDI = 0.98$, *bottom*)

playlist creation process is embedded on particular streaming platform, while this does not apply to AOTM. Second, playlists in AOTM have been created before streaming services became intensively used worldwide [6], while DEEZ and SPOT dataset are representative of a period in which streaming technologies were already consolidated.

As pre-processing step, we filtered out playlists with less than 4 unique tracks. In addition, we excluded extremely long playlists by computing, for each dataset separately, the interquartile range (IQR) of the playlist lengths and excluding all playlists that are longer than $Q_3 + 1.5\,IQR$, where Q_3 is the 3rd quartile. Table 1 shows a summary of the dataset characteristics.

3.2 Playlist Popularity Analysis

We address the characterization of popularity by defining a popularity index for both tracks and playlists based on a set of metrics proposed in the literature.

We estimate the *Track Popularity Index* (tPI) as the track frequency within a dataset, i.e. the number of playlists in a dataset in which it occurs, as proposed in [20]. This index is normalized between 0 and 1, using min-max normalization. In order to understand how track popularity is distributed, we uniformly split each dataset into 10 different groups, according to tPI. The first one contains tracks with $tPI \in [0, 0.1)$, the second one with $tPI \in [0.1, 0.2)$, etc. We then analyze the statistical distribution of track popularity per group, using two qualitative measures proposed in the literature: *Shannon* index [18] and *Simpson* index [19]. For both indexes, 0 indicates that there is no variation in terms of popularity, while 1 indicate that popularity varies significantly within the dataset.

In addition, we define the *Playlist Popularity Index* (pPI) for a playlist p as the average of tPI for the playlist tracks t_i

$$pPI(p) = \frac{1}{len(p)} \sum_{i=1}^{len(p)} tPI(t_i) \qquad (1)$$

We compute pPI for each playlist and we then compute the $Gini$ coefficient [10] to estimate the degree of imbalance of the playlist popularity distribution for each dataset, i.e. we obtain a measure of the statistical dispersion of playlist popularity. $Gini$ coefficient is comprised between 0 and 1, where 0 express the maximum balance, which means that pPI is almost equally distributed between playlists in the dataset, while 1 represents an unbalanced situation, which means that few playlists have high pPI, while several playlists have low pPI.

In the case of playlist popularity, the choice of using *Gini* coefficient is motivated by the idea of having a value representing the influence of every playlist on the overall dataset distribution. Differently, when tracks are grouped together according to their popularity, thanks to *Shannon* and *Simpson* indexes we have an estimation of how tracks are distributed within groups.

3.3 Playlist Semantic Diversity Analysis

In order to characterize the diversity of tracks on a given playlist, we consider a semantic distance measure based on user-generated tags. For every track, we queried *Last.fm* website to retrieve its top 5 related tags. We then proceed as follows. First, we create a tag-vector representation to estimate tag distances. Second, we use a linear combination of tags-embedding distances, weighted with a tag popularity count, to obtain the distance between every two tracks of a playlist. Third, we average the distances between tracks to yield a final diversity estimation for a playlist, according to the retrieved tags.

Finally, we obtain two metrics: 1) a distance between tracks, based on tag-similarity; 2) a playlist diversity index, based on the distance variations between tracks. We provide more details on the process in the next sections.

3.3.1 Tag-embeddings

Recent developments of NLP techniques have shown how particular types of words vector representation can bring with them valuable semantic information. In our study, we select the *GloVe* [15] learning algorithm [7], an architecture that exploits the ratio of word-word co-occurrences probabilities within a corpora for generating tag embeddings.

[6] `https://www.ifpi.org/downloads/GMR2016.pdf`

[7] `https://nlp.stanford.edu/projects/glove`

We choose this representation because of its compact form, the low computation cost needed for training the model with new corpora, and the facility to compute a distance metric between embeddings. For training the model, we combine the retrieved tags from *Last.fm* to create a corpus of track tags, and we use it to generate a vector representation for each tag.

In Table 2, we report the most frequent tags for the four datasets. Most of them are shared between datasets, so we study the few not shared tags to better understand their peculiarities. As an example, *"French"* only appear in DEEZ, having Deezer been founded in France. Furthermore, we observe how *"Electr."* and *"Hip Hop"* tags only appear in SPOT and DEEZ. The rise of commercial music in these these two genres in the last decade may be reflected in their extended presence.

Figure 1 shows an example of similar tags, where the distance has been computed using the trained tag-embeddings. *"rock"* and *"pop"* clusters are quite near, as *"jazz"* and *"classical"*. Within *"electronic"* similar tags, *"dance"* is the nearest one to *"pop"*. Within the *"jazz"* cluster, there are *"trumpet"* and *"saxophone"*, two instruments often related to this genre. These are some examples of observations that can be derived, and which reflect semantic information contained in the computed vector representation.

3.3.2 Playlist Track-Tag diversity index

We define a track *tr* as linear combination of its T weighted tags:

$$tr = \sum_{i=1}^{T} w_i \, tag_i \tag{2}$$

where in our settings $T = 5$. Basing on (2), we define a distance measure between tracks, named *Track-Tag distance* (d_{TT}), as follow

$$d_{TT}(tr^{(1)}, tr^{(2)}) = \frac{1}{T} \sum_{i=1}^{T} W_i^{(1,2)} \, d_{tag}(tag_i^{(1)}, tag_i^{(2)}) \tag{3}$$

where the weight term is

$$W_i^{(1,2)} = \frac{w_i^{(1)} + w_i^{(2)}}{2\, max(w_i^{(1)}, w_i^{(2)})} \tag{4}$$

and the distance between two tags is defined as

$$d_{tag}(tag_1, tag_2) = \sqrt{2(1 - cos(tag_1, tag_2))} \tag{5}$$

$cos(tag_1, tag_2)$ represents the cosine similarity between tag-embeddings. The computation of the tag distances has been carried out with the Annoy Python library [8], which makes use of the approximate nearest neighbor technique for an efficient computation of the euclidean distance of normalized vectors. In the d_{TT} formula, $W_i = 1$ if $w_i^{(1)} = w_i^{(2)}$, so weights do not impact the distance. Otherwise, $W_i \in (0.5, 1)$, hence final distance decreases when multiplying the weight term with the tag distance. In detail, d_{TT} is near to 0 when two tracks have a high similarity, while it is around 1 when they are very different, according to their combination of user-generated tags.

For understanding a playlist diversity in terms of semantic annotations, we first compute the d_{TT} distance for every combination of two tracks in the playlist. Summing the distances and dividing by the number of total possible combinations, we obtain the *Playlist Track-Tag diversity index* (pDI):

$$pDI(playlist) = \frac{2}{M(M-1)} \sum_{i,j} d_{TT}(tr_i, tr_j),$$
$$\forall tr_i, tr_j \in playlist, j > i$$

where M is the length of the playlist. pDI is near to 0 when there is a low diversity between tracks within the playlist, and almost 1 when tracks are extremely diverse, according to the d_{TT} distance. Table 3 provides two examples of playlists with different pDI values. The playlist with low pDI is formed by tracks mainly tagged as *"punk"*, *"rock"* or *"indie"*, while the playlist with high pDI has tracks with tags more diverse, passing from *"punk"* to *"downtempo"*, to *"hip hop"*.

4. RESULTS

4.1 Playlist Popularity Analysis

Results of the popularity analysis are shown in Table 4. We first observe the great differences between radio playlists from the CORN dataset and user-generated playlists from the other datasets. Tracks' popularity tPI in CORN varies significantly more than in the other cases, according to the *Shannon* and *Simpson* indexes, and the percentage of tracks with $tPI \in [0.0, 0.1)$ is smaller, indicating a large presence of popular tracks within the dataset. The mean of playlist popularity pPI is not extremely high, but it is more balanced than for DEEZ, SPOT and AOTM according to the *Gini* coefficient. Results can be interpreted as a consequence of the nature of radio playlists. Indeed, tracks rotation in radios is often constrained by commercial policies, because artists, or someone in their behalf, have to pay for broadcasting their tracks. This clearly makes difficult for artists with few resources to be on air in a radio. This phenomena is reflected in having few tracks from the long-tail, i.e. less popular, inserted in radio playlists. The balanced playlist popularity level also derives from the policy of alternating popular tracks with less know ones [9] .

Regarding user-generated playlists, we observe how track popularity in DEEZ and SPOT are quite similarly distributed. On the contrary, in AOTM the presence of 99.99% of track with $tPI \in [0.0, 0.1)$ influences both the *Shannon* index, the *Simpson* index and the *Gini* coefficient, creating an unbalanced situation with no diversity in terms of track popularity. However, results of playlist popularity analysis give similar values among the three user-

generated datasets, where only the DEEZ stands out for having a high average value of pPI.

In general, the popularity of a playlist, intended as average of the frequency of its tracks within a dataset, can be influenced by several factors. As example, AOTM dataset has been created with playlists from 1998 to 2011, when music was consumed by means of different services than the ones which lead the market today. We suppose that playlists in AOTM do not often come from the interaction with a large music catalogues, or with algorithms for facilitating music search and discovery for playlist generation, and this can be related to a major presence of less popular tracks. Furthermore, current streaming services employ several tools to facilitate playlist sharing, to make this a collaborative process, and to incorporate tracks of a playlist into new playlists [14]. In terms of popularity, the possibility to share a playlist can have a positive impact, increasing the accessibility to much more content and then reducing the number of less popular tracks.

4.2 Playlist Semantic Diversity Analysis

We faced two limitations when retrieving tags from *Last.fm*: 1) we did not find tags for all queried tracks; 2) for part of the tracks, the associated tags were small, less than five. As a consequence, we follow a conservative approach when computing the Playlist Track-Tag diversity index: 1) we only consider playlists for which all tracks have associated tags (*complete information*); 2) tracks are only compared with other tracks with the same number of tags (*balanced information*).

After obtaining the semantic index for each playlist, we compute descriptive statistics for understanding how the computed descriptor characterizes these datasets. In addition, for every case we also extract the same statistics on playlists of average size, created with random tracks from the original playlists. In Table 5, we observe part of the differences between datasets.

As in the previous sections, the analysis on CORN radio playlists provides values of different order of magnitude than user-generated playlists. Indeed, the mean and the minimum value of the diversity index pDI are higher for this dataset. This can be related to the fact that radio playlists are rarely composed by tracks from the same artist, as it is the case for low diversity playlists according to our analysis. Moreover, we observe that CORN playlists are more balanced in terms of tag-similarity, as they are in terms of track popularity, as represented by a low *Gini* coefficient and low quartile coefficient of dispersion.

In order to better understand how the diversity index represents playlists' characteristics, we have carried out a qualitative analysis of the 10% of playlists with higher, and 10% with lower diversity. For every groups of playlists, we compute the following values, reported in Table 6: 1) average of Playlist Track-Tag index (Avg pDI); 2) average of unique tags for playlist (Avg tag count); 3) number of playlists with at least one tag in common between all the tracks (Common tags); 4) average of unique tags over tracks (Avg Tag/Tracks); 5) average of unique artists for playlist (Avg artist count); 6) playlist with tracks from the same artist (Single-Artist); 7) average of unique tracks for playlist (Avg track count) ; 8) average of unique tracks over artist (Avg Tracks/Artist).

From the analysis of these values, we confirm previous observations on the pronounced difference between CORN and the other datasets. Looking at the percentage difference of each parameter, we see how CORN playlists span

	AOTM			CORN			SPOT			DEEZ		
	Low	High	PD	Low	High	PD	Low	High	PD	Low	High	PD
Avg pDI	0.43	0.85	64	0.65	0.98	40	0.19	0.87	128	0.28	0.93	108
Avg Tag Count	20	44	75	25	25	0	15	30	67	11	22	67
Common Tags (%)	34	0	34	0	0	0	23	1	22	44	1	43
Avg Tag/Tracks	1	3	100	3	4	29	1	3	100	2	3	40
Avg Artist Count	6	15	86	9	7	25	2	7	111	2	5	86
Single-Artist (%)	55	2	53	0	0	0	83	22	61	69	7	62
Avg Track Count	17	16	6	10	7	35	12	11	9	8	7	13
Avg Tracks/Artist	11	1	167	1	1	0	11	4	93	6	2	100

Table 6. Qualitative analysis results of low/high 10% playlists, ranked by their pDI. Column "PD" reports the percentage difference (in %) between low and high cases values, calculated as $PD(a,b) = 100\ \frac{|a-b|}{(a+b)/2}$

a small range of diversity, in comparison to user-generated playlist datasets. SPOT and DEEZ present more variation in terms of diversity, reflecting the values obtained for the quartile coefficient of dispersion, presented in Table 5.

In general, these parameters are coherent with the analysis carried out before: playlists with a low pDI, hence with less diversity, present in average a smaller number of unique tags, more tags in common between tracks, few artists for playlist and a higher percentage of single artist playlists. Playlists with a high index present the inverse characteristics.

5. CONCLUSIONS

We have presented a statistical analysis of more than 400K playlists (2.3M songs) from four different datasets, three composed by user-generated playlists, while one, CORN, composed by radio playlists. Two of the user-generated datasets, SPOT and DEEZ, have playlists created between 2012 and 2018, while AOTM playlists between 1998 and 2011. We develop our analysis using descriptive statistics, and in addition we make use of indexes from the information retrieval literature for evaluating the distribution of the analyzed features within the sets. In particular, we focused on two aspects: popularity and diversity.

From the proposed metrics, we observe how differences between datasets emerge, reflecting the distinct context in which playlists have been created. On one side, radio playlists analysis shows clear different results from the ones obtained from user-generated playlist. On the user-generated side, we observe how the study of AOTM playlists reveals different characteristics than for SPOT and DEEZ datasets. Behind this fact, we identify as possible cause the change of music listening behaviours, shifting from the idea of personal music repositories in the beginning of the digital era, to the dominance of streaming services of today. We hypothesize that this paradigm change has also impacted the way users create playlists, and our results partially reflect this shift.

In our analysis, we have found a more balanced situation in SPOT and DEEZ datasets in terms of popularity, although they contain playlists with a high level of diversity in terms of semantic tags. Even if different explanations can be at the root of the different values, e.g. the larger song search space of streaming services, the lower cost to create and share a new playlist online, or the recommendation algorithms that support playlist creation, we cannot identify a specific cause with our analysis.

The proposed methodology can be applied to characterize playlists in terms of popularity and semantic diversity, allowing the comparative analysis of human-generated and algorithm-generated playlists in different contexts such as historical periods, platforms and musical genres. We find extremely valuable to compare different playlist datasets, as it allows to understand how changes in the listening experience are affecting playlist creation strategies.

We hypothesize that if we extend this analysis to a larger number of datasets, we would achieve a better understanding of these changes. For instance, one of the limitations of the considered datasets is that they provide a Western-centric view. Adding playlist creators country information could enrich our study. Similarly, a yearly-based temporal analysis would help to better understand temporal variations. Moreover, adding other content- and context-based features from playlists can help to explore factors that are hidden in the presented analysis. Finally, it has already been shown that considering the tracks ordering is helpful for extracting playlist characteristics [20], so we plan to include this information in future research.

To facilitate the reproducibility and transparency of our study, the data and the software used are made publicly available [10] .

ABSTRACT

In the course of editing musical works, musicologists regularly compare multiple sources of the same musical piece, such as composers' autographs, handwritten copies, and various prints. For efficient comparison, cross-source navigation is essential, enabling to quickly jump back and forth between multiple sources without losing the current musical position. In practice, measures are first annotated by hand in the individual source images and then related to each other. Our approach automates this time-consuming and error-prone process with the help of deep learning. For this purpose, we train a neural network that automatically finds bounding boxes of all measures in images. A second network is trained to compute the similarity between two measures to determine if they have the same musical content and should, therefore, be linked for navigation. Sequences of outputs from the second network are matched using Dynamic Time Warping to provide the final proposal of measure relationships, so-called *concordances*. In addition to cross-source navigation, the results can be used to spot structural differences across the sources which are essential for editorial work, so that musicologists can focus more on analytical tasks.

1. INTRODUCTION

Modern musical editions are the result of a long musicological process. From the composer's manuscript to the printed music book, a musical work usually undergoes a large number of iterations and minor corrections, occasionally even substantial changes, such as striking or reworking complete parts [1]. Many of these changes are either unintentional—e.g., errors in handwritten copies, typographical errors by publishers—or generally not documented in a transparent manner. Musicologists, therefore, work on this genesis when editing a work and try to record the chronological order and causalities in their edition creation process.

The first step in this process is, therefore, the screening of the source material to identify differences between the various sources of a work. To facilitate this process, links are created between the sources so that editors can quickly switch back and forth between them. Adequate granularity of these links are usually musical measures, a feasible compromise between annotation effort and accuracy [29]. Currently, the measures of all sources are manually annotated with bounding boxes and related to each other in a very time-consuming and error-prone way.

We have automated this multi-stage process by first recognizing and sorting measures in score images (both handwritten and typeset) and then linking them according to their musical content. For this purpose, deep learning was used to develop a distance metric in an end-to-end fashion without an intermediate representation. The results can be further processed using classic alignment algorithms from the MIR community such as *Dynamic Time Warping* (DTW). While DTW-based approaches have achieved sufficient quality for practical use, audio-to-score alignment is still an active field of research [31]. Promising approaches for the synchronization of scans and sound recordings [5,6] are currently limited to monophonic and piano music and have not yet achieved sufficient accuracy for most real-world scenarios. With the contribution of this paper, we decrease a potential gap in the "audio – symbolic score – image" triangle and offer a new way for measure-accurate alignment across modal boundaries.

2. RELATED WORK

Detecting measures can be seen as a preprocessing step in Optical Music Recognition (OMR). Therefore, it was rarely singled out as a dedicated task. While Pedersoli and Tzanetakis perform document segmentation, they only distinguish between music scores and text blocks [22]. The only research we know of, that specifically addresses the automatic extraction of measures is by Vigliensoni et al. [30]. In their work, they attempt to extract measures with a traditional computer vision approach by heuristically finding all bar lines and then joining them into measures. Their approach requires human intervention for each page and straight bar lines to work well.

For retrieval of sixteenth-century musical texts, Crawford et al. [4] have recently proposed a two-step procedure. They run an OMR algorithm to obtain an intermedi-

ate format, followed by a second step that uses n-grams and minimal absent words (MAWs) to find duplicates, related texts, or parts that have the same musical material. Neural networks make such intermediate formats partly obsolete and allow for learning bimodal embeddings end-to-end as shown by Dorfer et al. [5, 6], who correlate the scanned music score with a sound recording. For this purpose, synchronization was considered either a reinforcement learning problem [6] or a metric learning problem [5]. In the metric learning approach, Dorfer et al. use the *pairwise ranking loss*—also known as *triplet loss* [26]—that draws triplets from a dataset consisting of an anchor, a positive example (picture fits the audio) and a negative example (picture does not fit the audio). This loss function creates an embedding, where images and audio with the same content are appear close together, while non-matching images and audio are placed relatively far apart. Their approach has successfully been used before in other application domains, such as facial recognition [26]. We resort to a similar cost function for metric learning (see section 4.2).

As the basis for our detection, we use a convolutional neural network (CNN). While CNNs are currently an active field of research for OMR, the most influential approaches come from the research area of computer vision. They are used for many tasks, including image recognition, semantic segmentation, object detection, and instance segmentation. R-CNN [9] performs object detection by analyzing a large number of heuristically generated region proposals that are classified into background or one of the classes of interest. Additionally, the bounding box is refined with regression. R-CNN uses a CNN that extracts features for object detection. These features are used in a downstream SVM for classification and regression. Faster R-CNN [23] improves the process by incorporating both the region proposal step as well as the classification and regression into the architecture of the neural network.

CNN-based computer vision approaches are largely transferable to OMR and actively used for Music Information Retrieval: Gallego and Calvo-Zaragoza are using auto-encoders to remove staff lines [8]. Pacha et al. compare various CNN-based approaches for detecting music symbols in scores [21]. CNNs can also be used for semantic segmentation for staff-line removal, music and text separation as well as for layout analysis as shown by Calvo-Zaragoza et al. [3]. Using U-Nets [25], Hajic et al. do semantical segmentation of handwritten music [10]. Pacha and Calvo-Zaragoza recognize musical objects in mensural notation using region-based CNNs [20]. By learning energy levels that are used as inputs to a watershed algorithm, Tuggener et al. recognize music symbols [28]. In addition to the energy levels, the network also predicts class labels and bounding boxes. And finally, Calvo-Zaragoza and Rizo use convolutional recurrent neural networks trained with a Connectionist Temporal Classification (CTC) loss to recognize musical symbols in monophonic music scores [2]. To simulate non-ideal image conditions, they artificially distort the images.

3. DATA & ANNOTATIONS

The success of Deep Learning approaches largely depends on the amount and diversity of data used during training. Since no dataset of sufficient size was available for measure recognition or the concordance task, we created a large dataset ourselves in cooperation with musicologists and professional musicians.

Our dataset contains measure annotations that were created manually by musicologists for digital music editions. In most cases, the image sources are high-resolution scans of facsimiles, occasionally supplemented by early music prints and PDFs exported directly from music engraving software. Due to an imbalance between handwritten and typeset scores, we additionally obtained scores from the *IMSLP/Petrucci Music Library* while paying attention to varying image quality, the used engraving mechanism as well as diverse musical content. We complemented our collection with 140 pages from the MUSCIMA++ dataset [1] [7, 11].

Our data collection has a total of 8 251 pages with 81 124 annotated measures. The distribution according to engraving type and the number of systems per page is given in Table 1. One category is particularly overrepresented: handwritten music scores with just one system per page because of a large quantity of full orchestral scores from operas by Carl Maria von Weber. Book covers, text pages, and empty pages have zero systems.

Systems per page	**Pages per engraving type**	
	Handwritten	Typeset
0	413	113
1	5627	932
2	175	553
3	122	175
4 or more	102	39
Total pages	6439	1812

Table 1. Overall distribution of the dataset used.

The accuracy of the measure annotations varies. Since the exact boundaries are not relevant for musicologists, they were recorded only roughly. That is why many bounding boxes contain small overlaps with adjacent measures as shown in Figure 1.

To annotate the measures in the individual pictures, the Android app *Vertaktoid* [2] [18] was used. It allows to conveniently draw bounding boxes for all measures with a pen directly on the tablet screen. The results can then be exported to the MEI format [24] and used as ground truth training data.

Data coming from digital music editions are partly provided with concordance annotations between the measures.

[1] The measure annotations are published as separate dataset at `https://apacha.github.io/OMR-Datasets/#muscima`

[2] `https://github.com/cemfi/vertaktoid`

Figure 1. Examples of cropped measures originating from different sources of the same work. All measures represent the same musical position, i.e. the same measure, within the work, but are in part extremely diverse in terms of instrumentation, graphic representation and also image resolution.

4. ALIGNING MEASURE SEQUENCES

Our proposed solution for the given task can be split into three individual parts. First, we have to find the bounding boxes of all measure in the score images. Then we need a metric in order to compute the similarity between two given measure in terms of musical content. And finally, we have to compute actual concordances for multiple sources of the same music.

4.1 Optical Measure Recognition

For automatically detecting measures in complete music scores, we propose a machine-learning approach with deep convolutional neural networks and a Faster R-CNN detector [23]. Faster R-CNN has been shown to work well in a range of situations, including detecting music objects [21]. In this case, there is just one class of objects that needs to be detected, and the objects typically cover large portions of the entire image with little overlap. Our implementation is based on the TensorFlow Object Detection API framework [14] and freely available online [3] .

We split the dataset randomly into 80% for training, 10% for validation, and 10% for testing. To avoid a bias toward scores with just one system, we sample the images equally from the ten categories depicted in table 1. The only exception are images without systems which are sampled only half as often as the other categories.

We tested the three different backbones, ResNet50, ResNet101 [13], and Inception-ResNet-V2 [27] and restricted ourselves to these to enable transfer-learning by initializing the networks with weights trained on ImageNet which generally improves the learning process, especially at the beginning. Input images are resized to be no longer than 1024 pixel on the longest edge. The Intersection over

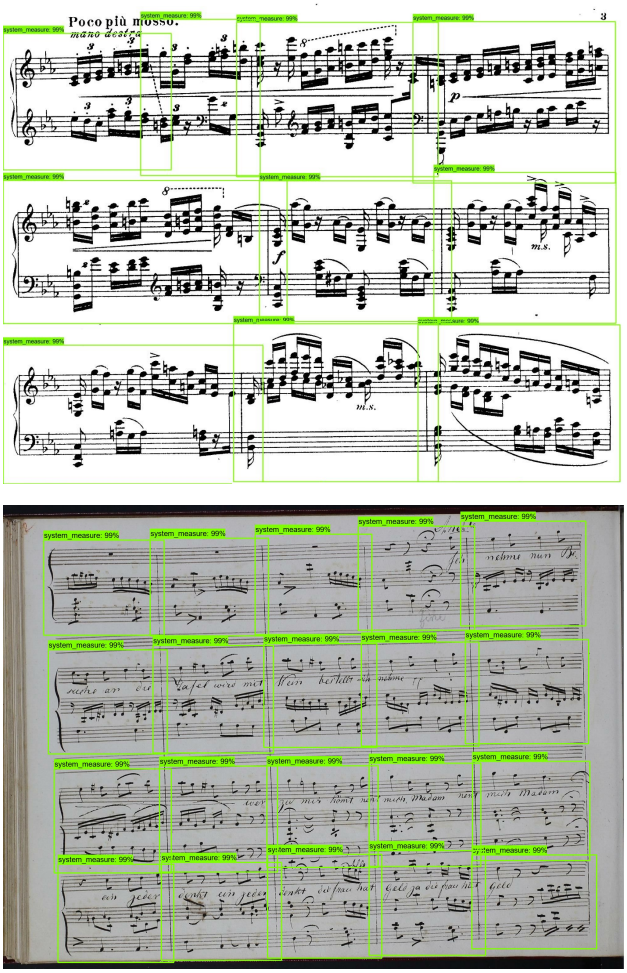

Figure 2. Two samples of the detection results. Measures are detected robustly in typeset and handwritten scores without the need for preprocessing the images.

[3] https://github.com/OMR-Research/MeasureDetector

Union (IoU) measures how well two bounding boxes overlap. If two predictions are very close, non-maximum suppression filters the box with the lower score. The IoU threshold is set to 0.6 and a maximum of 600 objects are detected per image. These parameters are derived from statistical analysis of the entire data set and cover $> 99.99\%$ of the dataset.

We evaluated the optical measure detection with the commonly used average precision (AP) metric, as defined for the COCO detection challenge [15]. It produces a single number that measures how well objects were detected. A detection is considered a match with the underlying ground truth if the IoU is above a certain threshold. The trained models achieve very good results with 78.7% AP (IoU=0.5:0.95) on the test set for the top-performing model with Inception-ResNet-V2 [27] backbone. A few samples of the detection output are depicted in Figure 2.

Given that the measure recognition step does not necessarily return the measures of a page in the musically correct order, we sort them according to the measure numbering rules outlined by Mexin et al. in [18].

4.2 Metric Learning

Now that the scans of all scores are divided into individual measures, they have to be compared with each other to identify equivalent measures. Again, a deep learning approach is used to learn such a musical similarity metric between two measures directly from the images. The neural network is trained to compute an embedding for measure images so that similar measures are placed in the proximity of one another in the embedding space. This allows for convenient comparison of two measures by computing their distance, e.g., using the L^2 norm.

The idea is based on *triplet loss* [26]: A pair of equivalent measure images from two different sources is drawn from the list of concordances. We will call them the *anchor* image and the *positive* image. Additionally, a *negative* measure image is drawn from the same source as the positive image, serving as a counterexample, i.e. having no musical relation to the anchor or the positive measure image. Each of these three images is fed separately into the same neural network, resulting in three k-dimensional vectors. The loss function is defined as

$$\mathcal{L} = max(d(f^a, f^p) - d(f^a, f^n) + \alpha, 0) \qquad (1)$$

with f^a, f^p, and f^n being the resulting vectors from the network f for the three images and a distance measure d. Training with this loss function minimizes the distance from the anchor to the positive image while maximizing the distance between the anchor and the negative image. The additional margin α defines how far away the least dissimilarity should be. Finally, the surrounding $max(...)$ function ensures that the loss never gets negative.

We chose ResNet50 as the base network and replaced the usual final average pooling and classification layers by a fully connected layer with k-dimensional output. (Other CNN-based networks used for computer vision would most likely work comparably well.) All measure images are resized to 512×512 pixels but the original width and height information is also passed to the network as additional input.

The success of the used loss function depends heavily on the sampling strategy for the image triplets as discussed by Wojke and Bewley in [32]. In our context, there are three specific problems in the dataset:

1. A randomly sampled negative image might accidentally have the same musical content as the two other images. Those cases are not covered in the concordance dataset since not all measures with equal content have to be linked together.
2. Intuitively, it seems beneficial to take the previous or subsequent measure of the positive sample as the negative measure with the goal of enhancing the contrast between them in terms of increased distance in the embedding space. This would make adjacent measures more distinguishable. But again, the chance of these measures having the same content is higher compared to random sampling.
3. Especially handwritten sources sometimes exhibit excessive use of measure repeats and other abbreviations as can be seen in the left part of Figure 1. Such symbols are meaningless if their immediate context is not given.

The first two problems could be solved by manually adding all measures with the same content to the list of concordances. Given the amount of images, we decided against doing so and rely on rare collisions thanks to the large number of data. We also discarded the (perfectly valid) idea of looking at adjacent measures to form the triplets.

The third problem—presence of measure repeats and abbreviations—has a direct impact on the appropriate choice of the distance metric d in our loss function; When using triplet loss, it is common practice to normalize the embedding vectors. This constraint puts all embeddings on a k-dimensional hypersphere, leading to some advantages for further processing (see [26]). Furthermore, *cosine distance* is often used to calculate the distances. Both decisions make it impossible to get an embedding vector that is equally distant to all other possible vectors. This very property, however, characterizes the meaning of measure repeats if no context is given. We, therefore, opted for no vector normalization and chose the L^2 norm as our distance metric, resulting in

$$\mathcal{L} = \sum_{i=1}^{N} \left[\|f_i^a - f_i^p\|_2 - \|f_i^a - f_i^n\|_2 + \alpha \right]_+ \qquad (2)$$

for a training batch with size N. To speed up training and ensure fast convergence we select triplets that violate the following constraint:

$$\|f_i^a - f_i^p\|_2 + \alpha < \|f_i^a - f_i^n\|_2 . \qquad (3)$$

This filter step is performed for each batch during training and makes sure that only those triplets are used that significantly contribute to the learning process. It also prevents the network from overfitting.

4.3 Concordance Computation & Manual Adjustments

Given the embedding vectors for all measures of each source of a musical work, we can compare two sources by computing the distances between all measures from one source to the other. The resulting similarity matrices can then be used for *dynamic time warping* (DTW) as described by Müller in [19] to get an alignment path between the sources as shown in Figure 3.

We implemented the canonical DTW algorithm without any noteworthy modifications to the core. Allowed step sizes inside the similarity matrix during path computation are $(0, 1)$, $(1, 0)$, and $(1, 1)$. It rarely happens that a measure gets divided into two parts at system or page breaks, so we penalized steps along a single axis by a factor of 2 to slightly enforce one-to-one mappings of the measures.

The quality of the alignment was evaluated using a dataset with two sources and given ground truth concordances as outlined in Table 2. We have decided in favor of this particular dataset because it offers several challenges that occur only rarely in other works:

Split measures: Some measures are split into two parts at page breaks. Therefore, one measure of source A maps to two other measures of source B.

Completely different sections: An entire part of the piece was replaced in source B. Finding the "correct" concordance is impossible.

Additional parts: Source B contains a 16-measure Aria that is not present in the other source.

Missing measure annotations: We also intentionally removed measures from source A to simulate annotation errors.

	Pages	Measures
Source A (typeset)	250	3098
Source B (handwritten)	532	3176
Total	782	6274

Table 2. Structure of the evaluation dataset.

In the MIR community, DTW is often used to synchronize audio and/or symbolic score sources with each other [12]. The time resolution of the features in such scenarios is usually in the range of several dozen milliseconds. Deviations in the alignment path are therefore undesirable, but can often be neglected as long as they do not exceed certain limits. In our context, however, any deviation from the ground truth marks a significant error. We took this into account and defined a very simple score for the overall performance:

$$score = 1 - \frac{\text{Number of } (x, y) \text{ pairs from alignment not in ground truth}}{\text{Total number of concordances in ground truth}} \quad (4)$$

Our evaluation showed 14 errors in relation to 3079 concordance pairs, resulting in a score of **99.545%**.

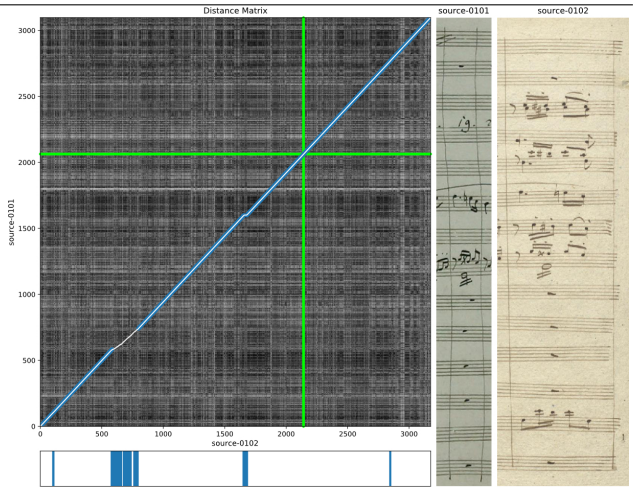

Figure 3. Interface for inspecting the computed measure concordances. The alignment (white) and ground truth (blue, only available in evaluation dataset) are plotted over the currently visible part of the similarity matrix. Measures of both sources (right) can be compared by moving a cursor within the matrix (green crosshair). A plot at the bottom indicates potentially interesting positions.

As pointed out, the remaining 0.455% error rate still present a non-negligible problem. Therefore, we developed an interface for manual adjustments to the alignment. Apart from being able to quickly compare the measures from two sources as shown in Figure 3, users can define points in the similarity matrix that have to be part of the alignment path. Each of these points splits the matrix into two parts and computes the warping path for each part individually, ensuring that either the beginning or end of the path matches the desired point. An event plot at the bottom of the matrix helps to identify regions with potential errors by showing where the alignment path is not diagonal, i.e. taking a step in $(0, 1)$ or $(1, 0)$ direction.

The mentioned obstacles for correct alignment have been handled successfully by either resulting in a correct alignment or—in case of substantial structural differences—indicating a problem that cannot be solved without human intervention by marking these parts in the plot below the similarity matrix.

This alignment and adjustment step has to be repeated for each source in regard to a *master source* of choice. The corrected alignment data can then finally be imported into the tools used by musicologists for their editorial work.

5. CONCLUSIONS AND FUTURE WORK

In this paper we proposed an approach to automate the tedious task of annotating and linking measures in heterogeneous score images, thereby allowing for cross-source navigation between measures without losing the current musical position. We used deep learning to find bounding boxes of measures in score images, learned a distance metric for measures, and used that to align measures from various sources, effectively linking equivalent musical po-

sitions across sources. The evaluation showed that our approach is feasible and solves a real-world problem while still retaining complete flexibility in case editors need to make manual adjustments, thanks to an interactive correction tool.

The presented solution still does not cover all possible situations that might occur in the editorial process. If the measure sequences to be compared have a different order, the alignment fails for these parts if not completely. We will address this specific problem in the future by identifying such passages and proposing reasonable re-ordering.

Having a musically meaningful distance metric for measures also allows closing the gap between score images and symbolic scores. The latter can be rendered with suitable engraving software and divided into individual measures, followed by the steps of our alignment pipeline. Since audio can also be rendered from symbolic scores, alignments between all three modalities are possible.

Another interesting application of our distance metric is the ability to visualize datasets in image fields as shown in Figure 4. Using dimensionality reduction algorithms such as T-SNE [16] or UMAP [17], the measures are positioned such that musically similar measures appear proximate to one another, giving new insight into a musical piece but also into the inner workings of the distance metric. For example, the visualization shows that measure repeats are placed almost in the center, indicating that their learned embedding retains the musical property of being close to basically every other measure in the embedding space.

Figure 4. 46 344 measure images from 15 different sources of the same piece are projected into a two-dimensional manifold with the UMAP algorithm. The map is interactively zoomable.

QUERY-BY-BLENDING: A MUSIC EXPLORATION SYSTEM BLENDING LATENT VECTOR REPRESENTATIONS OF LYRIC WORD, SONG AUDIO, AND ARTIST

Kento Watanabe **Masataka Goto**
National Institute of Advanced Industrial Science and Technology (AIST), Japan

ABSTRACT

This paper presents *Query-by-Blending*, a novel music exploration system that enables users to find unfamiliar music content by flexibly combining three musical aspects: lyric word, song audio, and artist. Although there are various systems for music retrieval based on the similarity between songs or artists and for music browsing based on visualized songs, it is still difficult to explore unfamiliar content by flexibly combining multiple musical aspects. Query-by-Blending overcomes this difficulty by representing each of the aspects as a latent vector representation (called a "flavor" in this paper) that is a distinctive quality felt to be characteristic of a given word/song/artist. By giving a lyric word as a query, for example, a user can find songs and artists whose flavors are similar to the flavor of the query word. Moreover, by giving a query combining (blending) lyric-word and song-audio flavors, the user can interactively explore unfamiliar content containing the blended flavor. This multi-aspect blending was achieved by constructing a novel vector space model into which all of the lyric words, song audio tracks, and artist IDs of a collection can be embedded. In our experiments, we embedded 14,505 lyric words, 433,936 songs, and 44,696 artists into the same shared vector space and found that the system can appropriately calculate similarities between different aspects and blend flavors to find related lyric words, songs, and artists.

1. INTRODUCTION

Given a huge collection of musical pieces such as those provided by online music services, conventional music access based on bibliographic metadata like song titles and artist names has not been sufficient. The Music Information Retrieval (MIR) community, therefore, has covered various types of music retrieval and exploration. When a listener wants to listen to familiar musical pieces, a popular approach is content-based music retrieval [4, 15, 26, 31] based on music similarity. When a query is entered by humming [5, 8, 12, 24, 29, 33], for example, similarities between the query and melody lines in a database are computed to show its title. When a query is given by a musical piece [7, 17, 19, 25, 28], a ranked list of similar musical pieces is shown. Music retrieval based on various kinds of metadata [3, 6, 14, 27] is also proposed. Although music would have multiple aspects, previous approaches typically assume a single aspect as a query. Moreover, it is necessary for users to conceive appropriate queries, which is sometimes not easy.

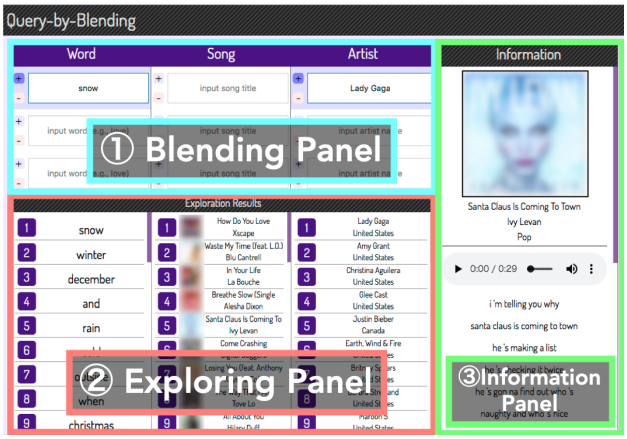

Figure 1. Query-by-Blending interface that consists of blending, exploring, and information panels.

When a user wants to discover unfamiliar musical pieces, an approach of music exploration is important. Music exploration systems typically provide interfaces that visualize a music collection by embedding musical pieces or artists into a 2D or 3D space and let users explore the collection to find favorite pieces [11, 21, 25, 30] or artists [1, 25, 27, 32]. However, it is difficult for previous music exploration systems to take different aspects of music into account. Another approach is to help users flexibly conceive a variety of queries for music discovery [9]. Such assistance, however, has not been investigated much in the MIR community.

We therefore propose a novel music exploration system, *Query-by-Blending*, that can embed three musical aspects – lyric word (word in lyrics), song audio (audio signal of a song), and artist (represented as artist ID) – into a unified high-dimensional latent vector space and enable users to find unfamiliar but interesting music content by flexibly combining those aspects (Figure 1). Query-by-Blending

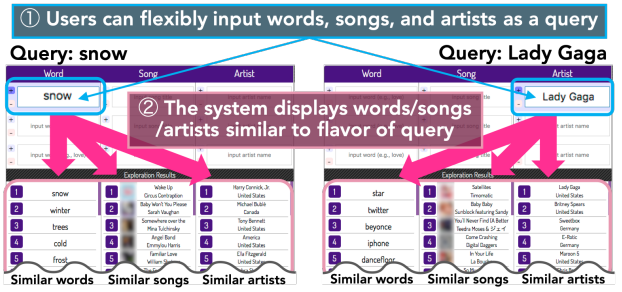

Figure 2. Query-by-Blending enables the exploration of three musical aspects: lyric word, song audio, and artist.

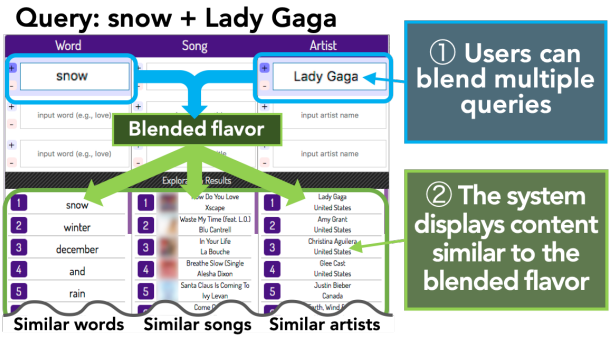

Figure 3. By blending multiple flavors, Query-by-Blending can display music content similar to the blended flavor. The blended flavor "snow + Lady Gaga" is similar to Christmas, Pop, and Soul songs/artists.

uses a "flavor" and "blending flavors" metaphor to help users combine different aspects to flexibly conceive a variety of queries. The terms "lyric-word flavor", "song-audio flavor", and "artist flavor" denote latent vector representations that are distinctive qualities felt to be characteristic of a given word, song, and artist. Each of the three kinds of flavors can be used as a query to retrieve and display three kinds of ranked lists: related lyric words, titles of songs having related song audio, and related artist names.

By giving a favorite artist as a query, for example, a user can not only listen to various songs containing its artist flavor but also see lists of lyric words and artists containing its artist flavor. Since the retrieved songs are not necessarily songs by the query artist, a user can explore a variety of unfamiliar music content. Since all three of the musical aspects are embedded into the same latent vector space as flavors, a user can add another flavor to "blend flavors" (i.e., give a query combining multiple musical aspects). Adding a lyric-word flavor, for example, causes the displayed lists to be interactively updated to give every musical content containing that flavor as well as the previous flavor a higher rank. Query-by-Blending can thus provide novel interactive, incremental, and iterative exploration experiences based on multiple musical aspects.

In implementing Query-by-Blending, it is difficult to calculate similarities among the three musical aspects because there are no large-scale annotations for supervised learning of such similarities. To overcome this difficulty, we propose a method of constructing a latent vector space model that can be trained with unsupervised learning under the assumption that a lyric word, song audio, and artist sampled from the same song tend to have similar meanings and are mapped to positions close to each other in the unified vector space. This method is based on multi-task learning, which has been used successfully across various applications of neural networks, and uses a vector model that can learn shared representations of music content by separately training each aspect of a large music collection (one including 14,505 words, 433,936 songs, and 44,696 artists).

2. QUERY-BY-BLENDING

Query-by-Blending enables a user to iteratively issue a query of any combination of lyric words, song titles, and artist names and obtain ranked lists of lyric words, song titles, and artist names that are similar to the query. The interface of Query-by-Blending is shown in Figure 1 and consists of (1) a blending panel for issuing the query, (2) an exploring panel displaying the retrieved ranked lists and allowing the user to select a song, and (3) an information panel displaying the title, artist name, and lyrics of the selected song and allowing the user to play back a short excerpt of the song for trial listening.

2.1 Exploring Three Musical Aspects

When a user enters a lyric word, song title, or artist name as a query on the blending panel, the exploring panel displays the retrieved lists of lyric words, song audio tracks, and artists whose flavors (latent vector representations) are similar to the flavor of the query. The lists are sorted in the order of the similarity. Figure 2 shows two screenshots of the interface. As shown in the left side of Figure 2, for example, when a user types "snow" into the lyric word text field on the blending panel, the exploring panel displays the lyric word "winter", "Angel Band" (the title of a song containing the word "snow"), and "Harry Connick, Jr." (who released the Christmas song album "When My Heart Finds Christmas", which can be considered to be related to "snow"). On the other hand, as shown in the right side of Figure 2, when the user types "Lady Gaga" into the artist text field on the blending panel, the exploring panel displays music content with "Lady Gaga" flavor – lyric words "star" and "dance floor", songs of Pop and Dance music sung by female singers, and an American female singer "Britney Spears". The user can then click one of the displayed songs to listen to its excerpt. These results and their music excerpts are available at a web page (`https://kentow.github.io/qbb/`). Query-by-Blending thus enables the user to flexibly issue a query to explore music content that is similar to the query.

2.2 Blending and Subtracting Flavors

Although issuing a single-flavor query with one of the three aspects (flavors) has already been useful, the blending panel further enables a user to issue a query blending multiple flavors. As shown in Figure 3, for example, when the user

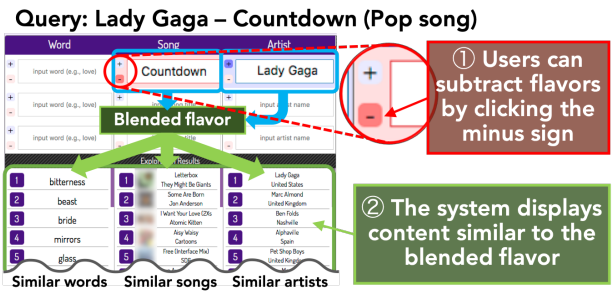

Figure 4. Query-by-Blending allows the user to subtract flavors from others. The flavor "Lady Gaga − Countdown (Pop song)" is similar to Alternative and Rock songs/artists.

types both "snow" and "Lady Gaga" into the two text fields on the blending panel, the retrieved ranked lists are updated to be more similar to the blended flavor of both of them. The exploring panel displays a Christmas song sung by the female Soul singer "Ivy Levan". Then the user can feel free to iteratively add more flavors.

Moreover, when a user issues a query and finds some of the listed songs or artists unappealing, the blending panel enables the user to subtract a flavor related to them from the current query. As shown in Figure 4, when the user subtracts a Pop song "Countdown" having a "Pop song" flavor from the original query of "Lady Gaga" (by clicking the minus sign (−) located beside the text field of the song "Countdown"), the exploring panel updates the lists to include Alternative and Rock music songs (e.g., "Letterbox") and artists (e.g., "Ben Folds") that are similar to the flavor "Lady Gaga − Countdown". The user can also subtract some flavors after blending multiple flavors.

When a user issues a query and finds unfamiliar songs or artists interesting after trial listening on the information panel, the user can add (blend) some of them to the current query to update the retrieved lists. Query-by-Blending thus provides novel exploration experiences, such as being able to incrementally conceive a variety of queries including both familiar and unfamiliar songs and artists. It enables users to flexibly update their queries by blending and subtracting various flavors to explore unfamiliar but interesting music content interactively in a trial-and-error manner.

3. IMPLEMENTATION

We implemented Query-by-Blending by developing a novel unsupervised method of constructing the unified latent vector space in which similar aspects are located nearby. Since similarities related to the three musical aspects are not annotated in a typical music collection, we leveraged the *Distributional Hypothesis* [10] that is well-known in the field of Natural Language Processing and has successfully been used in *word2vec* [23].

To explain the mechanism of capturing similarities, we first focus on the similarity between two lyric words without using audio and artist aspects. According to the Distributional Hypothesis, we assume that *words that occur in similar contexts tend to have similar topics*. As an example,

		Context word				Context audio		
		cold	white	devil	…	Relaxed audio	Tense audio	Sad audio
Target word	snow	41911	32910	33	…	50192	288	101
	winter	52202	22291	52	…	48381	210	134
	dark	18	213	43982	…	104	32017	89
	shadow	31	114	50928	…	251	22015	72
Target song audio	Jazz song A	12	9	0	…	33	10	3
	Jazz song B	10	11	0	…	43	9	7
	Metal song	0	0	20	…	4	20	1
Target artist	Jazz artist	330	221	19	…	513	45	25
	Metal artist	80	20	531	…	32	384	16

Figure 5. The Distributional Hypothesis for multiple aspects.

consider the following two lyrics:

*"***Snow** *white side street of cold NewYork City."*

"But here in the white of a cold **winter** *night, ..."*

Since "snow" and "winter" each co-occur with "cold" and "white" (i.e., the same context), we can assume that "snow" and "winter" have a similar topic. In this paper, we define a *context word* (e.g., "cold" or "white") to be a word co-occurring with a *target word* (e.g., "snow" or "winter") in the same song. This mechanism is expressed by a *co-occurrence matrix* where each row corresponds to a target word and columns give the context words (the red frame in Figure 5). In this matrix, each cell contains the frequency of co-occurrence of the target word and the context word in all the songs. In Figure 5, the target words "snow" and "winter" have high co-occurrence with the context words "cold" and "white" but low co-occurrence with "devil". Other target words "dark" and "shadow" frequently co-occur with the context word "devil". By calculating the co-occurrence matrix, we can estimate that "snow" and "winter" have similar topics and that "dark" and "shadow" have similar topics. We call each row of this matrix a *target word vector* and calculate the similarity between target words as the distance between their target word vectors.

We then extend this co-occurrence matrix to *context audio tracks* so that we can utilize audio signals for capturing the similarity between target words. Each context audio is a short fragment of song audio and is represented as an *audio-word* defined in Section 3.2. In the green frame of Figure 5, the target words "snow" and "winter" tend to co-occur with some short fragments of song audio and are considered similar, but other target words "dark" and "shadow" do not co-occur with those short fragments. Both the context words and context audio tracks can thus be used to capture the similarity and are included in each *target word vector*. As with the similarity between target words, we assume that *songs that occur in similar contexts tend to have similar topics*. In the blue frame of Figure 5, we call each row of a target song audio in the co-occurrence matrix a *target audio vector*. Each cell of a target audio vector contains the number of occurrences of a context word in lyrics of the song corresponding to the target song audio, or contains the number of occurrences of a context audio in the target song audio. In Figure 5, the target vectors of "snow", "Jazz song audio", and "Jazz artist" are close to context vectors

of "cold" and "white"; thus these multiple aspects can be located near each other. Moreover, we can also naturally calculate the similarity between any target word vector and any target audio vector as the distance between them since those vectors are represented in the same matrix.

Finally, in the same way, we can extend the co-occurrence matrix to *target artists*. In the bottom part of Figure 5, we call each row of a target artist in the co-occurrence matrix a *target artist vector*. Each cell of a target artist vector contains the number of occurrences of a context word in lyrics of all songs by its artist, or contains the number of occurrences of a context audio in all song audio tracks by its artist. By extending the Distributional Hypothesis, we can calculate similarities related to the three aspects.

3.1 Dataset

To calculate the above similarities, we made a dataset containing 433,936 songs by 44,696 artists. The dataset item for each song consists of a text file of English lyrics provided by a lyrics distribution company, an audio file of a short music excerpt (30 sec, 44.1kHz) available for trial listening on a music service, and an artist ID. Here, each text file contains all sentences of the lyrics of a song. We extracted 14,505 frequent lyric words from all the text files and did not use words that appeared less than 100 times.

3.2 Creating Audio-word Representation

To represent a short fragment of song audio for a context audio, we use a discrete symbol called an *audio-word*. The audio-word can be obtained by a *bag of audio-words* (BoAW) model [18] as follows. (1) Each music excerpt is downsampled to 22,050 Hz. (2) We use *LibROSA*, a python package for music and audio analysis, to extract 20-dimensional mel-frequency cepstral coefficients (MFCCs) with the FFT size of 2048 samples and the hop size of 512 samples. This result is represented as an MFCC matrix (20×1280). (3) The MFCC matrix is divided into 128 submatrices (20×10) without overlap. (4) Each submatrix including 10 frames of MFCCs is flattened into a 200-dimensional vector that represents local temporal dynamics of MFCCs. (5) We use the k-$means$++ algorithm [2] to group all 200-dimensional vectors of all 433,936 songs into 3,000 clusters. (6) Each cluster is regarded as a discrete audio-word. We thus obtained 3,000 audio-words.

3.3 Vector Space Model for Multiple Musical Aspects

Since the co-occurrence matrix is huge and extremely sparse, it is too computationally expensive to deal with. To overcome this problem, our latent vector space model uses a neural network to reduce the huge matrix to a dense matrix as *word2vec* [23] also does.

The structure of the model is illustrated in Figure 6. Let w_t denote the target word, let aw_m denote the audio-word, let a denote the artist ID, and let c denote the context consisting of the context word and context audio-word. To obtain a D-dimensional latent vector space/representation

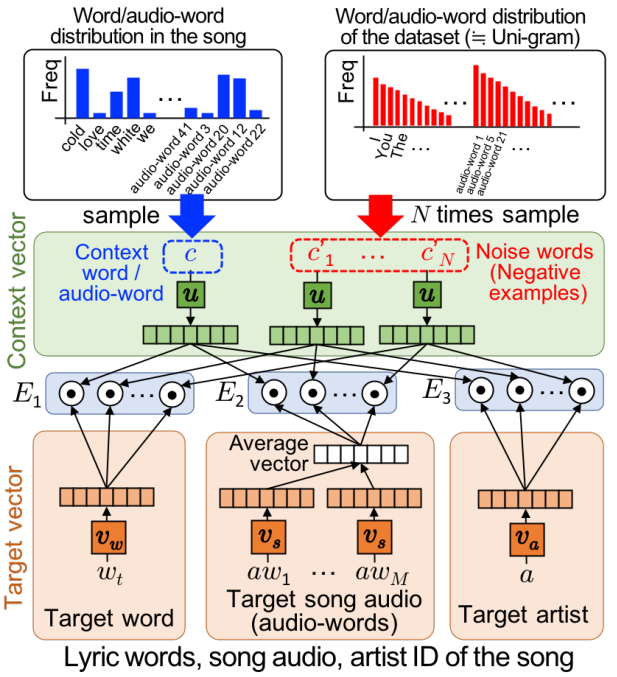

Figure 6. Multiple musical aspect vector space model.

after dimension reduction, we define an embedding function $\boldsymbol{v_w}(\cdot)$ that maps the target word to a D-dimensional vector and define an embedding function $\boldsymbol{u}(\cdot)$ that maps the context word/audio-word to a D-dimensional vector.

We formulate this as an optimization problem that minimizes the distance between $\boldsymbol{v_w}(w_t)$, the target vector of a target word w_t in a song, and $\boldsymbol{u}(c)$, the context vector of another context word or a context audio-word c randomly sampled from the same song. By iterating this sampling and minimization for every target word, the model captures the similarity between target words. In Figure 5, for example, "snow" and "winter" are frequently sampled for the target words, and "cold" and "white" are frequently sampled for the context words. In other words, the vectors of the target words "snow" and "winter" are close to both of the vectors of context words "cold" and "white" in the embedded vector space. Thus, these target word vectors can be located near each other. In the training phase to minimize the above distance, we maximize $\boldsymbol{u}(c)^{\mathsf{T}} \cdot \boldsymbol{v_w}(w_t)$, the dot product of the context word/audio-word vector $\boldsymbol{u}(c)$ and the target word vector $\boldsymbol{v}(w_t)$ in the lyrics of a song. This maximization can be done by optimizing parameters of $\boldsymbol{u}(\cdot)$ and $\boldsymbol{v_w}(\cdot)$.

To accelerate training, we not only maximize the dot product of co-occurring w and c but also minimize the dot product of w and c', where c' is a noise word. This technique is called *Negative Sampling* and is known to be useful in training word2vec [23]. We define and minimize the objective function E_1 to maximize $\boldsymbol{u}(c)^{\mathsf{T}} \cdot \boldsymbol{v_w}(w_t)$ and minimize $\boldsymbol{u}(c')^{\mathsf{T}} \cdot \boldsymbol{v_w}(w_t)$:

$$E_1 = -\log\sigma\Big(\boldsymbol{u}(c)^{\mathsf{T}} \cdot \boldsymbol{v_w}(w_t)\Big) - \sum_{n=1}^{N} \log\sigma\Big(-\boldsymbol{u}(c'_n)^{\mathsf{T}} \cdot \boldsymbol{v_w}(w_t)\Big), \quad (1)$$

where $\sigma(\cdot)$ is a sigmoid function. N is the number of negative words/audio-words $c'_n (1 \le n \le N)$ sampled from

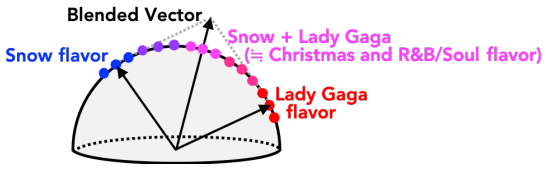

Figure 7. Normalized multiple aspect vector on hypersphere. Each circle denotes an embedded aspect. The cosine similarity between similar aspects is large.

the following noise distribution:

$$P(c'_n) = \#(c'_n)^{0.75} / \textstyle\sum_{c' \in V} (\#(c')^{0.75}), \quad (2)$$

where V is the word and audio-word vocabulary and $\#(c')$ is the global frequency of a word and audio-word c' in the whole dataset. This is for maximizing the distance between the target word and common words, such as "I" and "You", that occur frequently in the dataset.

In our current implementation, we set the vector dimension D to 400, the number of samplings for context words and context audio-words in each song to 400, and the number of negative samplings to 10. The objective function E_1 is optimized using stochastic gradient descent with a learning rate of 0.025, and training was run for 5 epochs.

We can also use the same idea to handle the similarities related to song audio tracks and artists. For song audio tracks, we define and minimize the loss function E_2:

$$E_2 = -\log\sigma\Big(\boldsymbol{u}(c)^\top \cdot \tfrac{1}{M}\textstyle\sum_{m=1}^{M} \boldsymbol{v_s}(aw_m)\Big) - \textstyle\sum_{n=1}^{N} \log\sigma\Big(-\boldsymbol{u}(c'_n)^\top \cdot \tfrac{1}{M}\textstyle\sum_{m=1}^{M} \boldsymbol{v_s}(aw_m)\Big), \quad (3)$$

where M is the number of audio-words in the song, $\boldsymbol{v_s}(\cdot)$ is an embedding function that maps the one-hot representation of every audio-word in the song to a D-dimensional vector, and the vector of the target song audio is represented by averaging all the audio-word vectors $\boldsymbol{v_s}(aw_m)$ in the song. For artists, we define and minimize the loss function E_3:

$$E_3 = -\log\sigma\Big(\boldsymbol{u}(c)^\top \cdot \boldsymbol{v_a}(a)\Big) - \sum_{n=1}^{N} \log\sigma\Big(-\boldsymbol{u}(c'_n)^\top \cdot \boldsymbol{v_a}(a)\Big). \quad (4)$$

where $\boldsymbol{v_a}(\cdot)$ is an embedding function that maps the one-hot representation of the artist ID to a D-dimensional vector. In the training phase, these objective functions E_2 and E_3 are optimized with the same settings as E_1.

The proposed model can capture similarities between the *same aspects* by minimizing E_1, E_2, and E_3. In addition, iterative optimization of the three objective functions enables training of the similarity between *multiple aspects* because these three objective functions share the embedding function for the context vector $\boldsymbol{u}(\cdot)$. In Figure 5, the target vectors of "snow", "Jazz song audio", and "Jazz artist" get closer to the context vectors such as $\boldsymbol{u}$(white); thus these multiple aspects can be located near each other.

3.4 Similarity Calculation

When calculating similarity, we use vectors obtained using $\boldsymbol{v_w}(\cdot)$, $\boldsymbol{v_s}(\cdot)$, and $\boldsymbol{v_a}(\cdot)$ without $\boldsymbol{u}(\cdot)$. We can use the cosine similarity as a measure of the similarity of two vectors. According to Levy et al. [16], multiple aspect vectors are normalized to unit length before they are used for similarity calculation, making cosine similarity and dot product equivalent. By this constraint, all the words, songs, and artists are located on a hypersphere and the system finds music content considering two flavors by calculating the content close to the blended vector on the hypersphere (Figure 7).

4. QUALITATIVE ANALYSIS

We investigated whether the trained vector space model appropriately captures the similarity between multiple musical aspects. Table 1 shows the five most similar lyric words, song audio tracks [1] , and artists – as well as their cosine similarities – that were obtained when we issued three different queries written at the top.

We can see in Table 1 that the query word "death" is similar to the words "blood" and "dead", which is reasonable since those words are often used in metal songs. Moreover, "death" is similar to song audio tracks having aggressive sounds using electric guitars and to Heavy Metal artists such as "Savatage". Metal songs like "Neuro Osmosis" were found even though their lyrics do not include the word "death".

Table 1 also shows that the query song "Amazing Grace" is similar to clean words such as "meadow" and "lullaby" and to relaxation songs such as New Age and Holiday music. Interestingly, the query artist "Michael Jackson" is similar to the artist "Janet Jackson" who is his sister even though the model does not know that they are siblings. This query is also similar to rhythmic songs by other artists.

These results indicate that the multi-aspect vector space model makes it possible to find related lyric words, songs, and artists that are hard to find otherwise. Furthermore, we tried to issue various queries by blending and subtracting flavors of multiple aspects and confirmed the usefulness of this blending and subtracting. Some results were illustrated in Section 2.2. Another interesting result is that the blended flavor "Stevie Wonder" + "snow" − "spring" is similar to "California Christmas".

5. QUANTITATIVE EVALUATION

Since ground-truth annotations of similarities between different aspects do not exist, it is not easy to quantitatively evaluate the model in general, but we tried to evaluate the effectiveness of blending latent vector representations by comparing content-based distributions of retrieved results. In Table 1, for example, the results retrieved for the word "death" and the song "Amazing Grace" are contrasting and have different impressions, which means that the distance between their distributions is large. If we issue a query blending them and it works effectively, we expect to see somewhat intermediate results between them, which means that the distance between one of the above distributions and the new distribution after blending becomes smaller.

[1] The song audio tracks used in this table can be listened to at our demo page (`https://kentow.github.io/qbb/`).

	Input word: death		Input song: Amazing Grace		Input artist: Michael Jackson	
Similar words	blood	0.70	may	0.37	hypnotized	0.41
	dead	0.65	sadly	0.35	maurice	0.40
	flesh	0.65	gentle	0.34	babygirl	0.39
	reborn	0.63	meadow	0.34	confused	0.39
	mortal	0.62	lullaby	0.34	emotions	0.39
Similar songs	Burning Sermon (Rock)	0.49	I Wish I Was In England (World)	0.85	It's a Man's Man's Man's World (Pop)	0.50
	Neuro Osmosis (Metal)	0.48	North Country Maid (Pop)	0.84	Tight (Gospel)	0.49
	Scraping the Barrel (Metal)	0.48	Mary, Did You Know (Holiday)	0.83	Play with Bootsy (Rock)	0.48
	Coins Upon the Eyes (Metal)	0.47	No Turning Back (Alternative)	0.83	Unspeakable (Pop)	0.48
	The Harlot Ov the Saints (Rock)	0.47	Beloved (NewAge)	0.83	Dead Heat (Pop)	0.48
Similar artists	Gary Numan	0.40	Barbra Streisand	0.40	Janet Jackson	0.61
	L'Âme Immortelle	0.39	Ella Fitzgerald	0.39	Sarah Connor	0.52
	Cowboy Junkies	0.38	Linda Ronstadt	0.38	Luther Vandross	0.52
	Don Moen	0.38	Debby Boone	0.37	Kylie Minogue	0.52
	Savatage	0.37	Nana Mouskouri	0.35	Faith Evans	0.51

Table 1. The most similar words, songs, and artists obtained by Query-by-Blending. The genre tags are shown in parentheses.

We therefore quantitatively examined how much this distance decreases after blending as follows. (1) A word query w and a song query s for evaluation are sampled from the dataset. (2) We get the 100 most similar songs retrieved by the word query w and compute ψ_w that denotes a content-based distribution of all lyric words and audio-words (i.e., a histogram of them) appearing in those 100 songs. (3) We get the 100 most similar songs retrieved for the song query s and compute ψ_s that denotes a content-based distribution obtained from those 100 songs in the same way. (4) We then get the 100 most similar songs retrieved for the query blending w and s and compute ψ_{w+s} that denotes a content-based distribution obtained from those 100 songs in the same way. (5) We calculate the Jensen-Shannon (JS) divergence between every pair of distributions: (ψ_w, ψ_s), (ψ_w, ψ_{w+s}), and (ψ_s, ψ_{w+s}). If the JS divergences of (ψ_w, ψ_{w+s}) and (ψ_s, ψ_{w+s}) are smaller than that of (ψ_w, ψ_s), we can confirm that our query blending lyric word and song audio works effectively. In addition, we replace the song s with the artist a and repeat the above procedure.

[Experimental Setup] For the above step (1), we used 1,000 word queries (most frequent nouns, verbs, adjectives, and adverbs), 1,000 song queries, and 1,000 artist queries. For the step (4), we made one million word-song pairs and one million word-artist pairs for the blended queries.

[Results] Table 2 shows JS divergences that are averaged over pairs. We can see that, as expected, the JS divergences of (ψ_w, ψ_{w+s}) and (ψ_s, ψ_{w+s}) are smaller than the JS divergence of (ψ_w, ψ_s). The same applies to (ψ_w, ψ_a). We thus confirmed that our blended queries work effectively with regard to content-based distributions of retrieved results.

Distributions		JS divergence	Distributions		JS divergence
ψ_w	ψ_s	0.261	ψ_w	ψ_a	0.224
ψ_w	ψ_{w+s}	**0.057**	ψ_w	ψ_{w+a}	**0.147**
ψ_s	ψ_{w+s}	**0.227**	ψ_a	ψ_{w+a}	**0.119**

6. RELATED WORK

Several studies have dealt with the similarity between different aspects of music. McFee and Lanckriet [22], for example, developed a hypergraph of song nodes whose edges capture multi-aspect relationships. Although it can be used to calculate similarities between songs while considering multiple aspects, it does not deal with similarities between the multiple musical aspects.

Some studies embedded musical aspects into a high-dimensional vector space in an unsupervised manner. Weston et al. [35] proposed a model by which musical audio signals and artist tags are embedded assuming that songs created by the same artist are correlated. Wang et al. [34] modeled the relationships between songs by using the same architecture as word2vec under the assumption that songs played by the same listener are similar. There are also studies that embedded vectorized audio-words and social tags by using the singular value decomposition (SVD) [13, 20]. All these studies shared with ours the motivation of embedding multiple aspects into a vector space but dealt only with audio signals and metadata without lyrics even though lyrics are an important element that conveys messages and emotions of music. To the best of our knowledge, there is no study in which lyric word, song audio, and artist ID are embedded into the same vector space.

7. CONCLUSION

In this paper we proposed a novel interface, Query-by-Blending, that enables users to find unfamiliar but interesting music content by flexibly combining (blending) three musical aspects: lyric word, song audio, and artist. Our contributions are summarized as follows: (1) Query-by-Blending is the first interface that lets users iteratively issue various queries by blending and subtracting multiple musical aspects. (2) We developed the novel embedding method of constructing the unified latent multi-aspect vector space by using unsupervised learning. (3) We demonstrated that our vector space model captures the similarities between multiple aspects. We plan to conduct a user study evaluating the Query-by-Blending interface. We also plan to extend our model to blend other aspects, such as genre tags and album cover images.

ABSTRACT

Structural segmentation is the task of partitioning a recording into non-overlapping time intervals, and labeling each segment with an identifying marker such as A, B, or *verse*. Hierarchical structure annotation expands this idea to allow an annotator to segment a song with multiple levels of granularity. While there has been recent progress in developing evaluation criteria for comparing two hierarchical annotations of the same recording, the existing methods have known deficiencies when dealing with inexact label matchings and sequential label repetition.

In this article, we investigate methods for automatically enhancing structural annotations by inferring (and expanding) hierarchical information from the segment labels. The proposed method complements existing techniques for comparing hierarchical structural annotations by coarsening or refining labels with variation markers to either collapse similarly labeled segments together, or separate identically labeled segments from each other. Using the multi-level structure annotations provided in the SALAMI dataset, we demonstrate that automatic hierarchy expansion allows structure comparison methods to more accurately assess similarity between annotations.

1. INTRODUCTION

In the music information retrieval (MIR) literature, the problem of *musical structure analysis* broadly concerns methods for automatically inferring relationships between moments in time within a piece [1, 10]. Substantial effort has been expended to develop computational techniques to infer various structures in recorded music, and the existence of reliable reference data and evaluation methodology is critical to accurately assess the efficacy of these methods. More broadly, reliable methods for comparing interpretations of musical structure can be informative for understanding human perception of music [13, 14].

Musical structure can be represented in a variety of ways, depending on the intended use case, ranging from (symbolic) staff notation, to chord annotations, lead sheets, *etc*. MIR research typically focuses on the *segmentation* problem, where the time extent of a recording is partitioned, and each partition is labeled with a descriptor that can be used to indicate repetitions, such as A, B, A, C or *verse, chorus, verse, bridge*. Much of the computational work in this area models musical structure as *flat*, meaning that there is exactly one partitioning of the piece, and the elements of the partition (*segments*) cannot be merged or subdivided to form larger or smaller structures.

In contrast, there is a long tradition in music theory of modeling music with *hierarchies* that simultaneously represent structure at multiple levels of granularity [2, 3]. Indeed, even when instructed to produce a flat segmentation of a piece, expert annotators will often encode latent hierarchical information by using variation markers in their segment labels, *e.g.*, $A, \ldots, A'$ or *verse, ..., verse_(instrumental)* [9, 12]. Although an annotator's choice of segment label may clearly be informative in these cases, this information is ignored by standard segmentation comparison methods. This owes, primarily, to an inability to directly support multi-level segmentations, which could be used to simultaneously represent both the original and simplified annotation as a coherent structure.

In recent years, there has been increasing interest and progress in developing datasets [8, 12], computational methods [16], representations [7], and evaluation criteria [6] for hierarchically structured music segmentations. However, little attention has been paid to exposing *latent* hierarchical structure encoded by segment labels for use in conjunction with these methods.

1.1 Our contributions

In this work, we develop a method for automatically exposing latent multi-level structure encoded by label similarity in music segmentations. The proposed *automatic hierarchy expansion* method operates by simultaneously contracting similar (but distinct) segment labels, and refining identically labeled (but distinct) segments. The contraction and refinement are combined with the original annotation into a hierarchical annotation, which can then be compared to other hierarchies using existing techniques.

Using the SALAMI dataset as a test case, we demonstrate that the proposed method is effective at identifying similarities across annotations that are not captured by previous methods. Finally, we leverage insights gained in developing the method to explore issues of internal consistency within multi-level structure annotations.

1.2 Preliminaries

For a signal of duration T, we define a (flat) *segmentation* as a function $S : [0, T] \rightarrow V$ where V denotes a set of segment labels, e.g., $V = \{A, B, \ldots\}$. We define a *multi-level segmentation* (or *hierarchy*) as a sequence of segmentations $H = (S_0, S_1, \ldots)$, where S_0 maps to a single label, and subsequent segmentations S_i are ordered from *coarse* to *fine*. We assume that each segmentation S_i maps to a distinct vocabulary. Finally, we say that a hierarchy H is *monotonic* if for every level k, we have that

$$S_k(u) = S_k(v) \quad \Rightarrow \quad S_{k-1}(u) = S_{k-1}(v). \quad (1)$$

2. RELATED WORK

Methods for evaluating musical structure analysis algorithms, or more generally comparing two different (flat) structural annotations, broadly fall into two categories: boundary detection and label agreement. Boundary detection metrics capture the agreement between annotations in localizing moments of time when the piece transitions from one coherent segment to another [15]. Segment boundaries are entirely local phenomena, and the metrics do not attempt to encode any sense of long-term structure in the annotations.

Label agreement metrics, on the other hand, are globally informed, and derive from comparisons between the segment labels applied to short samples, typically 0.1s in duration. The *pairwise* precision metric [4] is defined by determining which time points i and j are both given the same label in the reference annotation, and checking to see if the estimate annotation also gives both time points the same label; the fraction of such pairs of time points determines a precision score. Exchanging the roles of the reference and estimate annotations yields definitions for recall and F_1-score. Similarly, the *normalized conditional entropy* measures [5] quantify agreement in terms of the mutual information between the two annotations.

Although label agreement metrics account for global structure, they have three notable shortcomings. First, they are sensitive to alignment errors: if two annotators are operating at different levels of granularity, this information can be obscured by the evaluation. Hierarchical structure evaluation measures address this by integrating multiple segmentations at different levels of granularity into a single hierarchy, and comparing hierarchies to one another [6].

Second, since they depend on frames in isolation from their surrounding context, label agreement metrics cannot distinguish a long segment A from two short segments aa that cover the same time extent. Typically, practitioners circumvent this issue by reporting boundary detection metrics as well as label agreement metrics, but the interactions between the two types of score are rarely easy to interpret.

Finally, label agreement metrics have no mechanism to exploit similarity encoded within segment *labels*: labels A and A' are considered equally distinct as A and B, even though the annotator is clearly implying some high-level similarity in the first case that is absent in the second. While one could modify such annotations directly and use a flat segment evaluation metric, doing so discards information that could still be useful for comparison purposes.

In this work, we address these three issues by deriving segment hierarchies which are informed by label similarity. Discarding variation markers ($A' \rightarrow A$) allows the evaluation to recover from superficially distinct segment labels, while adding counters ($aa \rightarrow a_0 a_1$) provides a way to distinguish a long segment from sequential repetitions of a short segment. By integrating these two modifications into a hierarchy, along with the original annotation, we preserve all of the information present in the annotation.

2.1 Hierarchical evaluation

The approach taken in this work is based on the L-measure method for multi-level segmentation comparison [6], summarized here for completeness. Given a hierarchy H, a *meet matrix* M is defined by the maximum level at which every pair of time instants (u, v) receive the same label:

$$M[u, v] := \max \{k \mid S_k(u) = S_k(v)\}. \quad (2)$$

The meet matrix induces a partial ordering over pairs of time instants, which is summarized by a set of triplets:

$$A(H) := \{(t, u, v) \mid M[t, u] > M[t, v]\}. \quad (3)$$

Finally, given two hierarchies H^R (the reference) and H^E (the estimate), a precision score is defined by comparing the two triplet sets:

$$\text{L-Precision}\left(H^R, H^E\right) := \frac{\left|A\left(H^R\right) \cap A\left(H^E\right)\right|}{\left|A\left(H^E\right)\right|}. \quad (4)$$

Recall is defined analogously by reversing the roles of reference and estimate, and an F_1-score (hereafter denoted as L-Measure) can be computed by the harmonic mean of precision and recall. The terms *reference* and *estimate* to distinguish between annotations derive from the method's use in comparing algorithm outputs to manual annotations. However, the method can generally compare between different annotations of equal status, *e.g.*, produced by two different human annotators. In this case, the terms *reference* and *estimate* are merely intended to identify the annotators, but not to confer privileged status to either.

Although defined for multi-level segmentations, the L-measure can also be applied to compare flat segmentations by including a vacuous segment S_0 which produces a single segment spanning the entire duration. This results in an evaluation which is similar to the pairwise frame similarity metric [4], differing only in that it compares triples rather than pairs. For consistency across experiments, we will employ this method (with the S_0 segment) when comparing flat segmentations in the remainder of this article.

3. METHODS

This work proposes a method for expanding flat annotations to include both more nuanced and coarser structural information. Such expansions seek to address the three shortcomings of label agreement metrics detailed in Section 2. We also explore the concept of *monotonicity* within the hierarchy resulting from applying our methods to several levels of flat annotations.

3.1 Automatic Hierarchy Expansion

Here, we propose an automatic hierarchical expansion for any 'flat' annotations. Our method expands a flat annotation into a hierarchy with three levels. The first level is a *contraction* of the variation markers. The second level is the original annotation. The third level is a *refinement* of the labels by making each instance of a label unique by adding counters to the label.

For a concrete example, consider Figure 1. The left part of the image shows the flat annotation which is repeated on the right side of the image as the middle level of the hierarchy. The contraction level, shown in green, removed the variation markers of the A repetition. The result is that the contraction part of the hierarchy has two kinds of repetitions instead of three.

The refined level of the hierarchy, shown in blue, has at most one block per line. For clarity, the refinement level is created directly from the contraction level of the hierarchy. For each instance of a label in the contraction level, we append a counter (starting with 0) to form a new label. If instead we had conducted this refinement starting at the middle level, we would have ended up with the annotation labels $\{A0, A'0, B0, B1, B2\}$ instead of $\{A0, A1, B0, B1, B2\}$. Both methods produce equivalent results, but the latter is easier to interpret.

Although the expansion described above is most easily understood when applied to flat inputs, it can also be applied to hierarchical inputs by expanding each level independently and combining the results. An example of this multi-level hierarchy expansion is given in Figure 2. We also note that whenever a contraction (or refinement) leaves the segmentation unchanged, the redundant level is omitted from the expanded hierarchy as it produces no additional content. Note that the expansions of the upper and lower annotations in Figure 2 only have two levels each; this is due to the lack of variation markers within the original annotations, meaning that there is nothing to contract.

3.2 Monotonicity

The L-measure described in section 2.1 hinges upon the definition of the meet matrix M (see eq. (2)), which can be interpreted as measuring the similarity between two time points by the depth in the hierarchy at which they receive the same label. When expanding a flat segmentation S, the result is guaranteed to be a monotonic hierarchy. If $S(u) \neq S(v)$, then the contraction level *may* assign u and v the same label, but the refinement level will not. Conversely,

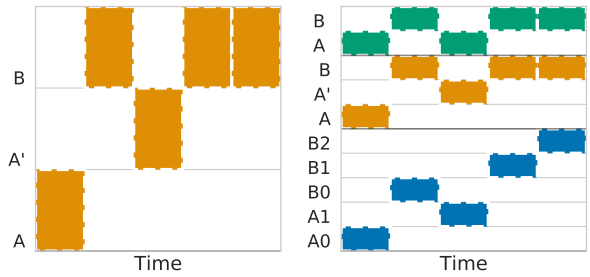

Figure 1. An example of automatic hierarchy expansion. A flat segmentation (left) with segments (A, B, A', B, B) is expanded into a three-level hierarchy (right). The contraction level (green, top) removes variation markers, while the refinement level (blue, bottom) adds counters to each instance of a segment label. The center level (orange) preserves the original annotation.

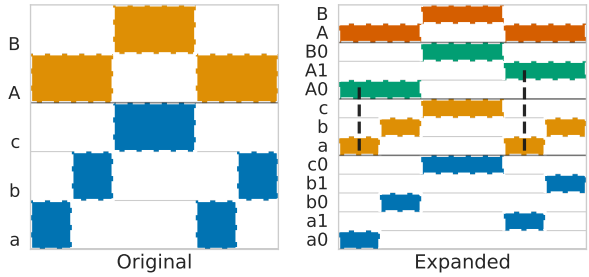

Figure 2. Automatic hierarchy expansion is not guaranteed to preserve monotonicity when applied independently to each level of a hierarchy (left). The dashed lines indicate two instants which receive the same label a in one level, but different labels ($A0$ and $A1$) in a preceding level.

if $S(u) = S(v)$, then the contraction level *must* preserve this equivalence, while the refinement level may not.

However, when applying automatic expansion independently to each level of a hierarchical annotation, the result may not be monotonic. Figure 2 illustrates this effect, where the refinement of the upper level (orange, left plot) results in violations of monotonicity, indicated by the dashed lines in the right plot.

While one could preserve monotonicity by only contracting at the highest level and refining at the lowest level, this is undesirable for three reasons. First, there may be informative structure encoded by variation markers in the intermediate levels which would be missed. Second, annotators may not be internally consistent (*i.e.*, monotonic) from upper to lower-level, so monotonicity would be violated from the start. And finally, because the L-measure depends only on the maximum level of agreement, it does not strictly *require* monotonicity to operate, though the results may be somewhat counter-intuitive. Still, the L-measure definition is most intuitive when the underlying annotations are monotonic, so it is worth investigating the effects of hierarchy expansion on monotonicity.

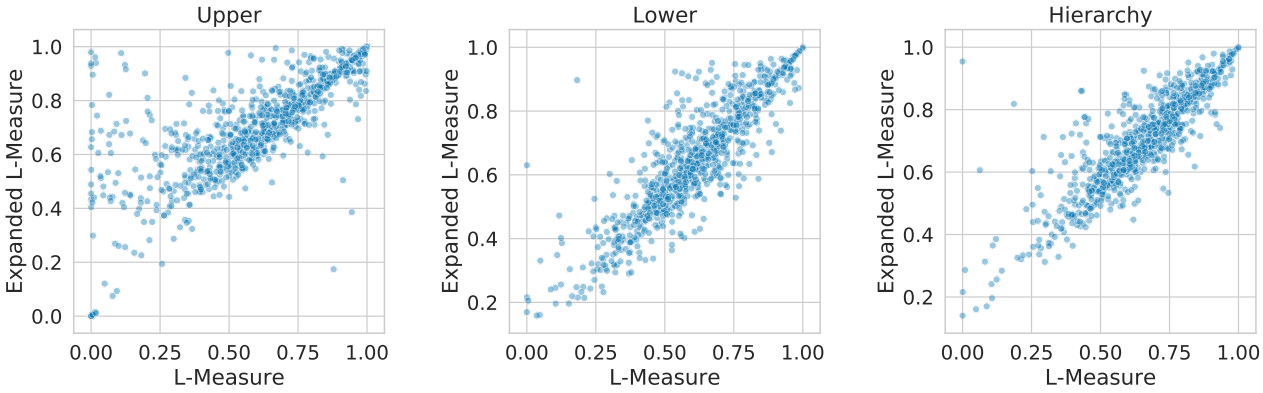

Figure 3. L-measure applied to pairs of annotations in the SALAMI dataset before and after automatic expansion. Left: upper-level annotations; middle: lower-level annotations; right: hierarchical annotations.

4. EXPERIMENTS

We evaluated the effect of automatic hierarchy expansion on flat annotations in the SALAMI dataset [12]. This dataset was selected for two reasons. First, it contains multiple reference annotations (by different annotators). Second, each annotation includes segmentations at different levels of granularity (*upper* and *lower*), which can be treated separately or combined into one hierarchy. All experiments were conducted using the L-measure implementation included in `mir_eval` version 0.5 [11].

4.1 Expansion on flat annotations

For each SALAMI track with two annotators, we first computed the L-measure between the two *upper* annotations. Because neither annotator has a privileged status as reference, we computed the "L-measure" as the harmonic mean of L-precision and L-recall. We then applied the hierarchy expansion procedure to each annotation, and the recomputed the L-measure on the expansions. Comparing the L-measure before and after expansion of a single level allows us to quantify the amount of structural similarity implicitly coded in the segment labels. This process was then repeated for the *lower*-level annotations.

Figure 3 (left and middle plots) summarizes the results of this experiment. As a general trend, expansion has substantial impact on the *upper* level, and less impact on the *lower* level. More specifically, expansion of the upper level produces a change in L-measure of 0.107 ± 0.168 (mean $\pm$ standard deviation), while expansion of the lower-level produces a change of 0.038 ± 0.09. The trend is generally positive at the upper level (with a few exceptions), while the lower-level changes are more symmetric.

Figure 4 illustrates two extreme cases where automatic hierarchy expansion dramatically changes the L-measure between *upper* annotations. [1] In the first case, track 242 improves from 0 to 0.979, because the refinement of the second annotation ($AA \rightarrow A_0A_1$) agrees with the first annotation (AA'), and the contraction of the first annotation

[1] Qualitatively similar examples can be observed for the *lower* annotations, which are omitted here for brevity.

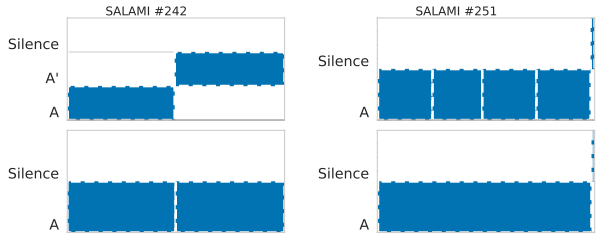

Figure 4. Two extreme examples where hierarchy expansion changes the L-measure from flat (upper) annotations. Left: track 242 increases by $+0.979$; right: track 251 decreases by -0.705.

($AA' \rightarrow AA$) matches with the second annotation. These annotations effectively encode the same information, differing only in the use of variation markers. The second case, track 251, decreased from 0.879 to 0.174 after expansion. This is explained by the first annotation explicitly marking repeated A sections, which are refined into unique sections $(A0, A1, A2, A3)$ by expansion. This structure is absent from the second annotation, which covers the entire duration by a single A segment. Prior to expansion, label-agreement metrics over-estimate the similarity between these annotations. Hierarchy expansion exposes this oversight, resulting in a more accurate comparison.

4.2 Expansion on hierarchical annotations

Extending the analysis of the previous section, we combined each annotator's upper and lower segmentations into a hierarchical annotation H. We then applied hierarchy expansion to each level of the hierarchy, resulting in a new hierarchy H^*. Finally, we computed the L-measure between pairs of hierarchies before and after expansion, which provides a more holistic view of how expansion affects measured agreement between annotators.

The results of expansion comparison for hierarchies are summarized in Figure 3 (right). Overall, the differences are qualitatively similar to the *lower*-level comparison, producing differences in L-measure of 0.048 ± 0.090. While

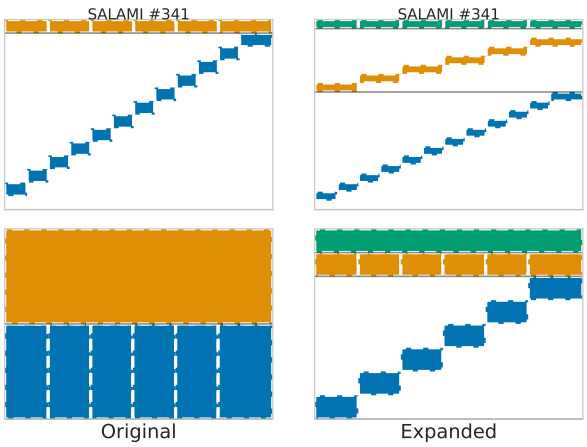

Figure 5. Automatic expansion significantly improves L-measure agreement between two hierarchical annotations of track 341 (increase of $+0.954$). Left: the original hierarchies; right: the expanded hierarchies. Segment labels are suppressed to enhance legibility.

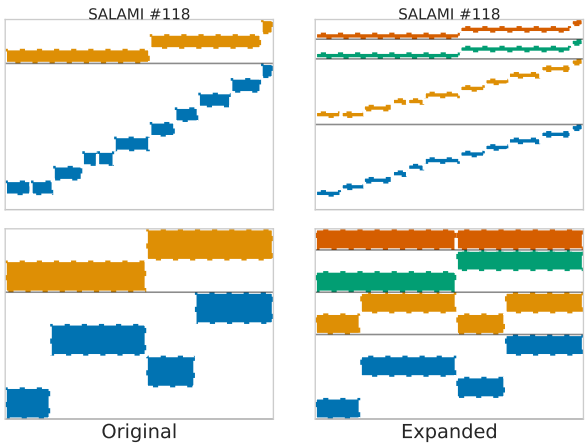

Figure 6. An example where automatic expansion significantly reduces L-measure agreement between two hierarchical annotations (decrease of -0.223). Left: the original hierarchies; right: the expanded hierarchies.

less dramatic than the *upper*-level comparison, the trend is still generally positive, with over 77% of comparisons increasing in value after applying hierarchy expansion. This indicates that even when evaluating with hierarchical annotations, there is still some latent structure encoded in the segment labels which current methods do not account for.

Figure 5 illustrates an example where expansion increases L-measure between two hierarchies, from 0 to 0.954. The second hierarchy (bottom left) assigns the same label to each segment, though the lower level is divided in to repetitions. Expansion separates these repeated segments in both annotations, exposing the common structure shared by both hierarchies (right two subplots).

Figure 6 illustrates the opposite case, where expansion exposes disagreement, decreasing score from 0.841 to 0.618. In this case, looking only at the upper level of the two annotations (left plots, orange level) would indicate considerable agreement between the two annotations, though the lower levels (blue) diverge significantly.

These selected examples are the extreme cases where L-measures deviated the most after hierarchy expansion. In both cases, we find that the divergence can be easily explained by visual inspection, which validates that hierarchy expansion behaves as expected. Note that these cases are relatively unusual, and most changes in scores are much smaller in magnitude. We therefore conclude that hierarchy expansion is effective at recovering from exceptional cases while not detrimentally affecting the common cases.

4.3 Quantifying monotonicity

The experiment described in Section 4.1 started with flat segmentations, and is therefore guaranteed to produce monotonic hierarchies. As noted in Section 3.2, this is not generally true when expanding hierarchies. This raises the question of the importance of monotonicity on hierarchical segmentation evaluation, and whether a given annotator is

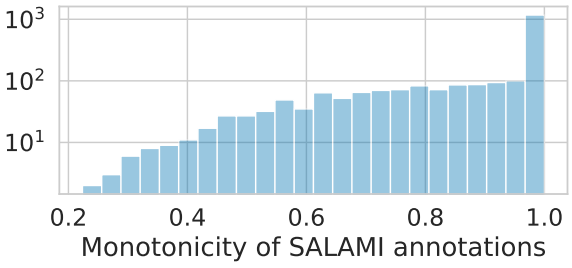

Figure 7. The distribution of monotonicity scores across all segment hierarchies in SALAMI (median: 0.98).

internally consistent between upper and lower levels.

The definition of monotonicity given in eq. (1) is binary, but it can be relaxed by instead measuring the *proportion* of time instants u and v where agreement at level k implies agreement at level $k-1$. This is calculated exactly by the pairwise recall measure [4], when S_k is treated as the reference and S_{k-1} is the estimate. We thus computed pairwise recall between lower and upper segmentations for each annotation: measures close to 1 are highly monotonic, and lower values indicate violations of monotonicity. The results are summarized by the distribution plot in Figure 7. Overall, the median monotonicity score across all annotations was 0.98, though there appears to be a heavy tail of non-monotonic annotations.

Looking more carefully into the data, we observed that a significant portion of monotonicity violations could be explained by the use of variation markers in the upper-level segmentation. These annotations are specifically problematic because the lower segment a may correspond to distinct upper labels A and A'. More than 60% of hierarchies that do not use variation markers in the upper level are perfectly monotonic, while only 27% of hierarchies with upper variations are monotonic.

Figure 8 illustrates the distribution of monotonicity

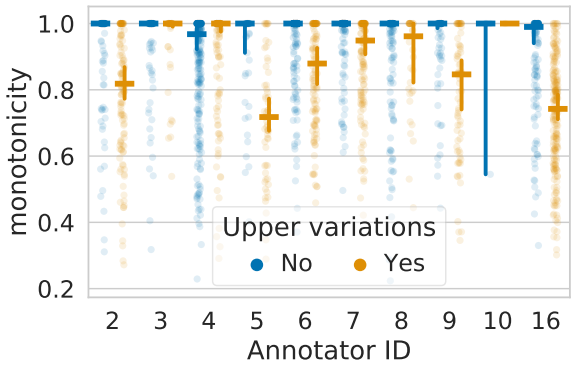

Figure 8. Monotonicity measurements for each SALAMI annotation, grouped by annotator. Median values and 95% bootstrap confidence intervals are indicated by bars.

scores for each individual annotator, sub-divided according to the presence or absence of variation markers in the upper level. Figure 8 shows that use of upper variation markers consistently coincide with lower monotonicity score.

In these experiments, we identified that variation markers can introduce unnecessary differences between sections. What is more, our investigations suggest that the use of variation markers coincides with reduction in monotonicity. The contraction level in the automatic hierarchy expansion seeks to address this issue. However, expanding multiple levels can introduce monotonicity violations. Combining the investigations in this section with the results from Section 4.2, we conclude any new violations created by the contraction of the lower level and the refinement of the upper levels are not substantially detrimental compared to the overall improvements conferred by automatic hierarchy expansion.

4.4 Permutation stability

It is natural to ask whether the previous results are due to introducing multiple hierarchical levels (independent of labels), or if the specific manner in which the contraction and refinement levels are constructed matters. If the effects of hierarchy expansion on L-measure are primarily due to additional levels, but not their specific label structure, we expect that expanding the segmentation with randomly permuted labels should produce comparable results.

To test this idea, we took inspiration from statistical permutation testing, and conducted the following experiment on each level of flat segmentations.

- For each annotation S, construct its hierarchy expansion H and compute the L-recall from S to H.
- (Repeat): randomly permute the labels of S to produce new flat segmentation P, and expand P to new hierarchy H^P. Compute L-recall from S to H^P.

We then compared the distribution of recall scores arising from the (S, H) comparisons to distribution arising from (S, H^P) comparisons. Since the expansion H contains S, the recall score will be identically 1.[2] Note that the expansion H^P will have equivalent refinement level to that of H because each segment is uniquely labeled, so the differences induced by permutation are confined to the middle and upper (contraction) levels.

Level	Mean (original)	Mean (permutation)	KS
Upper	0.992	0.603	0.940
Lower	0.996	0.468	0.977

Table 1. Results of the permutation-expansion test on upper- and lower-level segmentations. *KS* reports the 2-sample Kolmogorov-Smirnov test statistic between expansion and permuted expansion comparisons.

For each annotation, 20 independent permutations were generated. For each level, we report the mean L-recall over original expansions and permuted expansions. We then calculated the 2-sample Kolmogorov-Smirnov test statistic (KS) to determine if the two samples could plausibly be generated from the same underlying distribution. Table 1 summarizes the results of the experiment. In both cases, this null hypothesis was rejected with p-value numerically indistinguishable from 0, indicating that the effects of the hierarchy expansion on the L-measure depend on both the additional hierarchical information and its specific label structure.

5. CONCLUSION

The automatic hierarchy expansion method proposed in this article provides a flexible framework for retaining subtle differences in annotations, while simultaneously exposing coarse similarity. By leveraging ideas from hierarchical structure evaluation, the proposed method is able to illuminate detailed structure latent in the annotations, and recover from problematic edge cases not handled by previous methods. Moreover, the segment refinement technique provides a way to simultaneously evaluate segment boundaries and repetitions, which has been problematic for previous, frame-based evaluations.

Although our focus of the experiments in this work relies on structural segmentation labels in the SALAMI dataset, the general ideas may be applied more broadly, *e.g.*, to the functional section labels used in the Isophonics and TUT annotations [9]. Alternatively, this automatic hierarchy expansion could be applied to other musical concepts where hierarchies naturally occur, such as chord labels (*root, quality, extensions*) or instrumentation (*family, instrument, register*). This could provide a robust alternative evaluation technique for classification problems where adhering to a flat vocabulary is problematic, but where modeling full taxonomies might also be intractable.

[2] When S consists of a single segment spanning the entire duration, it will produce an L-recall of 0. However, we note that the permutation procedure on such annotations will have no effect.

ABSTRACT

Data-driven models for audio source separation such as U-Net or Wave-U-Net are usually models dedicated to and specifically trained for a single task, e.g. a particular instrument isolation. Training them for various tasks at once commonly results in worse performances than training them for a single specialized task. In this work, we introduce the Conditioned-U-Net (C-U-Net) which adds a control mechanism to the standard U-Net. The control mechanism allows us to train a unique and generic U-Net to perform the separation of various instruments. The C-U-Net decides the instrument to isolate according to a one-hot-encoding input vector. The input vector is embedded to obtain the parameters that control Feature-wise Linear Modulation (FiLM) layers. FiLM layers modify the U-Net feature maps in order to separate the desired instrument via affine transformations. The C-U-Net performs different instrument separations, all with a single model achieving the same performances as the dedicated ones at a lower cost.

1. INTRODUCTION

Generally, in Music Information Retrieval (MIR) we develop dedicated systems for specific tasks. Facing new (but similar) tasks require the development of new (but similar) specific systems. This is the case of data-driven music source separation systems. Source separation aims to isolate the different instruments that appear in an audio mixture (a mixed music track) i.e., reversing the mixing process. Data-driven methods use supervised learning where the mixture signals and the isolated instruments are available for training. The usual approach is to build dedicated models for each task to isolate [1, 19]. This has been proved to show great results. However, since isolating an instrument requires a specific system, we can easily run into problems such as scaling issues (100 instruments = 100 systems). Besides, these models do not use the commonalities between instruments. If we modify them to do various tasks at once i.e., adding more filters for the last layers and having fix numbers of outputs, they reduce their performance [19].

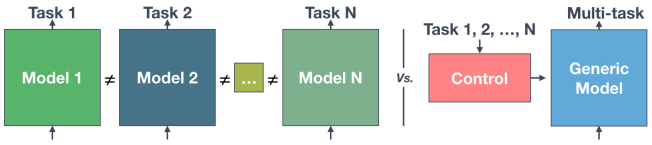

Figure 1: [Left part] Traditional approach: a dedicated U-Net is trained to separate a specific source. [Right part] Our proposition based on conditioning learning. The problem is divided in two: a standard U-Net (which provides generic source separation filters) and a control mechanism. This division allows the same model to deal with different tasks using the commonalities between them.

Conditioning learning has appeared as a solution to problems that need the integration of multiple resources of information. Concretely, when we want to process one in the context of another i.e., modulating a system computation by the presence of external data. Conditioning learning divides problems into two elements: a **generic system** and a **control mechanism** that governs it according to external data. Although there is a large diversity of domains that use it, it has been developed mainly in the image processing field for tasks such as visual reasoning or style transfer. There, it has been proved very effective, improving the state of the art results [3, 13, 20]. This paradigm can be integrated into source separation creating a generic model that adapts to isolate a particular instrument via a control mechanism. We also believe that this paradigm can benefit to a great diversity of MIR tasks such as multi-pitch estimation, music transcription or music generation.

In this work, we propose the application of conditioning learning for music source separation. Our system relies on a **standard U-Net system** not specialized in a specific task but rather in finding a set of generic source separation filters, that we **control** differently for isolating a particular instrument, as illustrated in Figure 1. Our system takes as input the spectrogram of the mixed audio signal and the control vector. It gives as output (only one) the separated instrument defined by the control vector. The main advantages of our approach are - direct use of commonalities between different instruments, - a constant number of parameters no matter how many instruments the system is dealing with - and scalable architecture, in the sense that

new instruments can be potentially added without training from scratch a new system. Our key contributions are:

1. the Conditioned-U-Net (C-U-Net), a joint model that changes its behavior depending on external data and performs for any task as good as a dedicated model trained for it. C-U-Net has a fixed number of parameters no matter the number of output sources.

2. The C-U-Net proves that conditioning learning (via Feature-wise Linear Modulation (FiLM) layers) is an efficient way of inserting external information to MIR problems.

3. A new FiLM layer that works as good as the original one but with a lower cost (fewer parameters).

2. RELATED WORK

We review only works related to conditioning in audio and to data-driven source separation methods.

Conditioning in audio. It has been mainly explored in **speech generation**. In the WaveNet approach [22, 23] the speaker identity is fed to a conditional distribution adding a learnable bias to the gated activation units. A WaveNet modified version is presented in [18]. The time-domain waveform generation is conditioned by a sequence of Mel spectrogram computed from an input character sequence (using a recurrent sequence-to-sequence network with attention). In **speech recognition** conditions are used in [10], applying conditional normalisation to a deep bidirectional LSTM (Long Short Term Memory) for dynamically generating the parameters in the normalisation layer. This model adapts itself to different acoustic scenarios. In [10], the conditions do not come from any external source but rather from utterance information of the model itself. They have been also used in **music generation** for accompaniments conditioned on melodies [6] or incorporating history information (melody and chords) from previous measures in a generative adversarial network (GAN) [25]. Finally, it has been also proved to be very efficient for **piano transcription** [5]: the pitch onset detection is internally concatenated to the frame-wise pitch prediction controlling if a new pitch starts or not. Both, onset detection and frame-wise prediction are trained together.

Source separation based on supervised learning. We refer the reader to [15] for an extensive overview of the different source separation techniques. We review only the data-driven approaches. Here, the neural networks have taken the lead. Although architectures such as RNN [7] or CNN [2] have been studied, the most successful one use a deep U-Net architecture (also called U-Net). In [1], the U-Net is applied to a spectrogram to separate the vocal and accompaniment components, training a specific model for each task. Since the output is the spectrogram, they need to reconstruct the audio signal which potentially leads to artifacts. For this reason, Wave-U-Net proposes to apply the U-Net to the audio-waveform [19]. They also adapt their model for isolating different sources at once by adding to their dedicated version as many outputs as sources to separate. However, this multi-instruments version performs worse than the dedicated one (for vocal isolation) and has to be retrained to different source combinations.

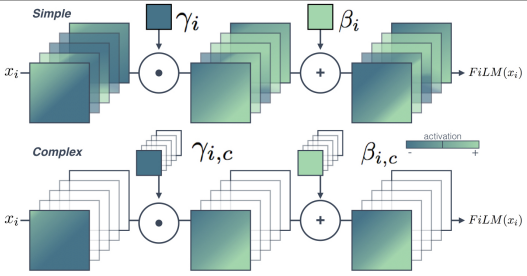

Figure 2: [Top part] *FiLM simple* layer applies the same affine transformation to all the input feature maps x. [Bottom part] In the *FiLM complex* layer, independent affine transformations are applied to each feature map c.

The closest work to ours is [9]. In there, they propose to use multi-channel audio as input to a Variational Auto-Encoder (VAE) to separate 4 different speakers. The VAE is conditioned on the ID of the speaker to be separated. The proposed method outperforms its baseline.

3. CONDITIONING LEARNING METHODOLOGY

3.1 Conditioning mechanism.

There are many ways to condition a network (see [4] for a wide overview) but most of them can be formalized as affine transformations denoted by the acronym FiLM (Feature-wise Linear Modulation) [13]. FiLM permits to modulate any neural network architecture inserting one or several FiLM layers at any depth of the original model. A FiLM layer conditions the network computation by applying an affine transformation to intermediate features:

$$FiLM(x) = \gamma(z) \cdot x + \beta(z) \quad (1)$$

where x is the input of the FiLM layer (i.e., the intermediate feature we want to modify), γ and β are parameters to be learned. They scale and shift x based on the external information, z. The output of a FiLM layer has the same dimension as the intermediate feature input x. FiLM layers can be inserted at any depth i in the controlled network.

As described in Figure 2, the original FiLM layer applies an independent affine transformation to each feature map c [1]: $\gamma_{i,c}$ and $\beta_{i,c}$ [13]. We call this a *FiLM complex* layer (**Co**). We propose a simpler version that applies the same γ_i and β_i to all the feature maps (therefore γ and β do not depend on c). We call it a *FiLM simple* layer (**Si**). The *FiLM simple* layer decreases the degrees of freedom of the transformations to be carried out forcing them to be generic and less specialized. It also reduces drastically the number of parameters to be trained. As FiLM layers do not change the shape of x, FiLM is transparent and can be used in any particular architecture providing flexibility to the network by adding a control mechanism.

[1] Or element-wise.

3.2 Conditioning architecture.

A conditioning architecture has two components:

The conditioned network. It is the network that carries out the core computation and obtains the final output. It is usually a generic network that we want to behave differently according to external data. Its behavior is altered by the condition parameters, $\gamma_{i,(c)}$ and $\beta_{i,(c)}$ via FiLM layers.

The control mechanism - condition generator. It is the system that produces the parameters (γ's and β's) for the FiLM layers with respect to the external information z: the input conditions. It codifies the task at hand and provides the instructions to control the conditioned network. The condition generator can be trained jointly [13, 20] or separately with the conditioned network [3].

This paradigm clearly separates the tasks description and control instructions from the main core computation.

4. CONDITIONED-U-NET FOR MULTITASK SOURCE SEPARATION

We formalize source separation as a multi-tasks problem where one task corresponds to the isolation of one instrument. We assume that while the tasks are different they share many similarities, hence they will benefit from a conditioned architecture. We name our approach the **Conditioned-U-Net** (C-U-net). It differs from the previous works where a dedicated model is trained for a single task [1] or where it has a fixed number of outputs [19].

As in [1, 19], our **conditioned network** is a standard U-Net that computes a set of generic source separation filters that we use to separate the various instruments. It adapts itself through the control mechanism (the condition generator) with FiLM layers inserted at different depths. Our external data is a condition vector $\overline{z}$ (a one-hot-encoding) which specify the instrument to be separated. For example, $\overline{z} = [0, 1, 0, 0]$ corresponds to the drums. The vector $\overline{z}$ is the input to the control mechanism/condition generator that has to learn the best $\gamma_{i,c}$ and $\beta_{i,c}$ values such that, when they modify the feature maps (in the FiLM layers) the C-U-Net separates the indicated instrument i.e., it decides which features maps information is useful to get each instrument. The control mechanism/condition generator is itself a neural network that embeds $\overline{z}$ into the best $\gamma_{i,c}$ and $\beta_{i,c}$. The conditioned network and the condition generator are trained jointly. A diagram is shown in Figure3.

Our C-U-Net can perform different instrument source separations as it alters its behavior depending on the value of the external condition vector $\overline{z}$. The inputs of our system are the mixture and the vector $\overline{z}$. There is only one output, which corresponds to the isolated instrument defined by $\overline{z}$. While training, the output corresponds to the desired isolated instrument that matches the $\overline{z}$ activation.

4.1 Conditioned network: U-Net architecture

We used the U-Net architecture proposed for vocal separation [1], which is an adaptation of the microscopic images

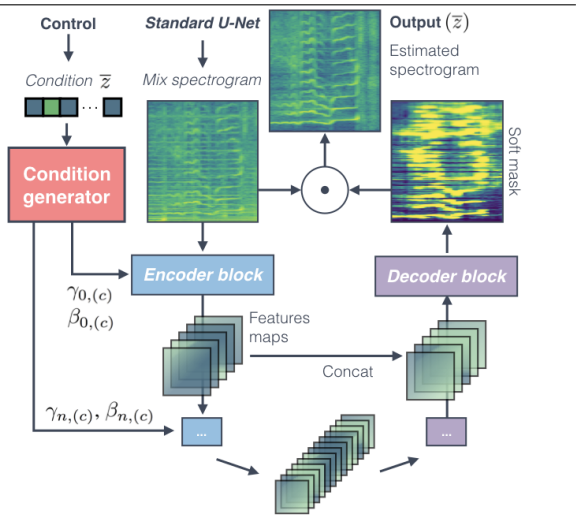

Figure 3: The C-U-Net has two distinct parts: the condition generator and a standard U-Net. The former codifies the input the condition vector, $\overline{z}$ (with the instrument to isolate) for getting the needed $\gamma_{i,(c)}$ and $\beta_{i,(c)}$. The generic U-Net has as input the magnitude spectrum. It adapts its conduct via FiLM layers inserted in the encoder part. The system outputs the desired instrument defined by $\overline{z}$.

U-Net [17]. The input and output are magnitude spectrograms of the monophonic mixture and the instrument to isolate. The U-Net follows an encoder-decoder architecture and adds a skip connection to it.

Encoder. It creates a compressed and deep representation of the input by reducing its dimensionality while preserving the relevant information for the separation. It consists of a stack of convolutional layers, where each layer halves the size of the input but doubles the number of channels.

Decoder. It reconstructs and interprets the deep features and transforms it into the final spectrogram. It consists of a stack of deconvolutional layers.

Skip-connections. As the encoder and decoder are symmetric i.e., feature maps at the same depth have the same shape, the U-Net adds skip-connections between layers of the encoder and decoder of the same depth. This refines the reconstruction by progressively providing finer-grained information from the encoder to the decoder. Namely, feature maps of a layer in the encoder are concatenated to the equivalent ones in the decoder.

The final layer is **a soft mask** (sigmoid function $\in [0, 1]$) $f(X, \theta)$ which is applied to the input X to get the isolated source Y. The loss of the U-Net is defined as:

$$\mathcal{L}(X, Y; \theta) = \|f(X, \theta) \odot X - Y\|_{1,1} \qquad (2)$$

where θ are the parameters of the system.

Architecture details. Our implementation mimics the original one [1]. The **encoder** consists in 6 encoder blocks. Each one is made of a 2D convolution with 5x5 filters, stride 2, batch normalisation, and leaky rectified linear

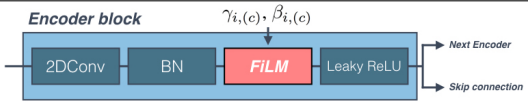

Figure 4: FiLM layers are placed after the batch normalisation. The output of a encoding block is connected to both, the next encoding block and the equivalent layer in the decoder via the skip connections.

units (ReLU) with leakiness 0.2. The first layer has 16 filters and we double them for each new block. The **decoder** maps the encoder, with 6 decoders blocks with stride deconvolution, stride 2 and a 5x5 kernel, batch normalisation, plain ReLU, and a 50% dropout in the first three. The final one, the soft mask, uses a sigmoid activation. The model is trained using the ADAM optimiser [11] and a 0.001 learning rate. As in [1], we downsample to 8192 Hz, compute the Short Time Fourier Transform with a window size of 1024 and hop length of 768 frames. The input is a patch of 128 frames (roughly 11 seconds) from the normalised (per song to [0, 1]) magnitude spectrogram for both the mixture spectrogram and the isolated instrument.

Inserting FiLM. The U-Net has two well differentiated stages: the **encoder** and **decoder**. The **enconder** is the part that transforms the mixture magnitude input into a deep representation capturing the key elements to isolate an instrument. The **decoder** interprets this representation for reconstructing the final audio. We hypothesise that, if we can have a different way of encoding each instrument i.e., obtaining different deep representations, we can use a common 'universal' decoder to interpret all of them. Following this reasoning, we decided to condition only the U-Net encoder part. In the C-U-Net, a FiLM layer is inserted inside each encoding block after the batch normalisation and before the Leaky ReLU, as described in Figure 4. This decision relies on previous works where feature are modified after the normalisation [3,10,13]. Batch normalisation normalises each feature map so that it has zero mean and unit variance [8]. Applying FiLM after batch normalisation re-scale and re-shift feature maps after the activations. This allows the net to specialise itself to different tasks. As the output of our encoding blocks is transformed by the FiLM layer the data that flows through the skip connections carries on also the transformations. If we use the *FiLM complex* layer, the control mechanism/condition generator needs to generate 2016 parameters (1008 $\gamma_{i,c}$ and 1008 $\beta_{i,c}$). On the other hand, *FiLM simple* layers imply 12 parameters: one γ_i and one β_i for each of the 6 different encoding blocks, which means 2002 parameters less than for *FiLM complex* layers.

4.2 Condition generator: Embedding nets

The control mechanism/condition generator computes the $\gamma_{i,(c)}(\overline{z})$ and $\beta_{i,(c)}(\overline{z})$ that modify our standard U-net behavior. Its architecture has to be flexible and robust to generate the best possible parameters. It has also to be able to find relationships between instruments. That is to say, we want it to produce similar $\gamma_{i,(c)}$ and $\beta_{i,(c)}$ for instruments that have similar spectrogram characteristics. Hence, we explore two different embeddings: a fully connected version and a convolutional one (CNN). Each one is adapted for the *FiLM complex* layer as well as for the *FiLM simple* layer. In every control mechanism/condition generator configuration, the last layer is always two concatenated fully connected layers. Each one has as many parameters (γ's or β's) as needed. With this distinction we can control $\gamma_{i,(c)}$ and $\beta_{i,(c)}$ individually (different activations).

Table 1: Params number in millions. With dedicated U-Nets, each task needs a model with 10M params. C-U-Nets are multi-task and the number of params remains constant.

MODEL	Non-conditioned	SiF	CoF	SiC	CoC
PARAM	39,30 (4 tasks x 9,825)	9,85	12	9,84	10,42

Fully-Connected embedding (F): it is formed of a first dense layer of 16 neurons and two fully connected blocks (dense layer, a 50% dropout and batch normalised) with 64 and 256 neurons for the *FiLM simple* version and 256 and 1024 for the *FiLM complex* one. All the neurons have relu activations. The last fully connected block is connected with the final control mechanism/condition generator layer i.e., the two fully connected ones. We call the C-U-Net that uses these architectures *C-U-Net-SiF* and *C-U-Net-CoF*.

CNN embedding (C): similarly to the previous one and inspired by [18], this embedding consists in a 1D convolution with $lenght(\overline{z})$ filters followed by two convolution blocks (1d convolutional with also $lenght(\overline{z})$ filters, 50% dropout and batch normalized). The first two convolutions have 'same' padding and the last one, 'valid'. Activations are also relu. The number of filters are 16, 32 and 64 for the *FiLM simple* version and 32, 64, 252 for the *FiLM complex* one. Again, the last CNN block is connected with the two fully connected ones. The C-U-Net that uses these architectures are called *C-U-Net-SiC* and *C-U-Net-CoC*. This embedding is specially designed for dealing with several instruments because it seems more appropriated to find common $\gamma_{i,(c)}$ and $\beta_{i,(c)}$ values for similar instruments.

The various control mechanisms only introduce a reduced number of parameters to the standard U-Net architecture remaining constant regardless of the instruments to separate, Table 1. Additionally, they make direct use of the commonalities between instruments.

5. EVALUATION

Our objective is to prove that conditioned learning via FiLM (generic model+control) allows us to transform the U-Net into a multi-task system without losing performances. In Section 5.1 we review our experiment design aspects and we detail the experiment to validate the multi-task capability of the C-U-Net in Section 5.2.

5.1 Evaluation protocol

Dataset. We use the Musdb18 dataset [16]. It consists of 150 tracks with a defined split of 100 tracks for training

Table 2: Overall performance (mean ± std) for the 4 tasks. *Si*= simple FiLM, *Co*= complex FiLM, *F*= Fully-embed and *C*= CNN-embed, *p*= progressive train or *np*= not.

MODEL	Total		
	SIR	SAR	SDR
Fix-U-Net(x4)	7.31 ± 4.04	5.70 ± 3.10	2.36 ± 3.96
C-U-Net-SiC-np	7.35 ± 4.13	5.74 ± 3.18	2.34 ± 3.69
C-U-Net-SiC-p	**8.00** ± 4.37	**5.74** ± 3.63	**2.54** ± 4.07
C-U-Net-CoC-np	7.27 ± 4.24	5.60 ± 2.88	2.36 ± 3.81
C-U-Net-CoC-p	7.49 ± 4.54	5.67 ± 3.03	2.42 ± 4.21
C-U-Net-SiF-np	7.23 ± 3.97	5.59 ± 3.01	2.22 ± 3.67
C-U-Net-SiF-p	7.64 ± 4.05	5.73 ± 2.88	2.46 ± 3.88
C-U-Net-CoF-np	7.42 ± 4.20	5.59 ± 3.07	2.32 ± 3.85
C-U-Net-CoF-p	7.52 ± 4.04	5.71 ± 2.99	2.42 ± 3.97

and 50 for testing. From the 100 tracks, we use 95 (randomly assigned) for training, and the remaining 5 for the validation set, which is used for early stopping. The performance is evaluated on the 50 test tracks. In Musdb18, mixtures are divided into four different sources: **Vocals**, **Bass**, **Drums** and **Rest** of instruments. The 'Rest' task mixes every instrument that it is not vocal, bass or drums. Consequently, the C-U-Net is trained for four tasks (one task per instrument) and $\overline{z}$ has four elements.

Evaluation metrics. We evaluate the performances of the separation using the mir evaltoolbox [14]. We compute three metrics: Source-to-Interference Ratios (SIR), Source-to-Artifact Ratios (SAR) and Source-to-Distortion Ratios (SDR) [24]. To compute the three measure we also need the predicted 'accompaniment' (the mixture part that does not correspond to the target source). Each task has a different accompaniment e.g., for the drums the accompaniment is rest+vocals+bass. We create the accompaniments by adding the audio signal of the needed sources.

Audio Reconstruction method. The system works exclusively on the magnitude of audio spectrograms. The output magnitude is obtained by applying the mask to the mixture magnitude. As in [1], the final predicted source (the isolated audio signal) is reconstructed concatenating temporally (without overlap) the output magnitude spectrums and using the original mix phase unaltered. We compute the predicted accompaniment subtracting the predicted isolated signal to the original mixture. Despite there are better phase reconstruction techniques such as [12], errors due to this step are common to both methods (U-Net and C-U-Net) and do not affect our main goal: to validate conditioning learning for source separation.

Activation function for γ and β. One of the most important design choices is the activation function for $\gamma_{i,(c)}$ and $\beta_{i,(c)}$. We tested all the possible combinations of three activation functions (linear, sigmoid and tanh) in the *C-U-Net-SiF* configuration. As in [13], the C-U-Net works better when $\gamma_{i,(c)}$ and $\beta_{i,(c)}$ are linear. Hence, our γ's and β's have always linear activations.

Training flexibility. The conditioning mechanism gives the flexibility to have continuous values in the input $\overline{z} \in [0, 1]$,

Table 3: Task comparison between the *dedicated U-Nets* and the *C-U-Net-CoF*. Results indicate that they perform similarly for all the tasks. We also add the multi-instrument Wave-U-Net (M) results (median in parenthesis) and when possible the dedicated version (D). For vocals isolation the Wave-U-Net-M performs worse than the Wave-U-Net-D.

	Model	SIR	SAR	SDR
Vocals	*Fix-U-Net(x4)*	10.70 ± 4.26	5.39 ± 3.58	3.52 ± 4.88 (4.72)
	C-U-Net-CoF	10.76 ± 4.39	5.32 ± 3.27	3.50 ± 4.37 (4.65)
	Wave-U-Net-D	-	-	0.55 ± 13.67 (4.58)
	Wave-U-Net-M	-	-	-2.10 ± 15.41 (3.0)
Drums	*Fix-U-Net(x4)*	10.08 ± 4.28	6.42 ± 3.28	4.28 ± 3.65 (4.13)
	C-U-Net-CoF	10.03 ± 4.34	6.80 ± 3.25	4.30 ± 3.81 (4.38)
	Wave-U-Net-M	-	-	2.88 ± 7.68 (4.15)
Bass	*Fix-U-Net(x4)*	4.64 ± 4.76	6.51 ± 2.68	1.46 ± 4.31 (2.48)
	C-U-Net-CoF	5.30 ± 4.73	6.29 ± 2.39	1.65 ± 4.07 (2.60)
	Wave-U-Net-M	-	-	-0.30 ± 13.50 (2.91)
Rest	*Fix-U-Net(x4)*	3.83 ± 2.84	4.47 ± 2.85	0.19 ± 3.00 (0.97)
	C-U-Net-CoF	4.00 ± 2.70	4.37 ± 3.06	0.24 ± 3.64 (1.71)
	Wave-U-Net-M	-	-	1.68 ± 6.14 (2.03)

which weights the target output Y by the same value. We call this training method **progressive**. In practice, while training, we randomly weight $\overline{z}$ and Y by a value between 0 and 1 every 5 instances. This is a way of dealing with ablations by making the control mechanism robust to noise. As shown in Table 2, this training procedure *(p)* improves the models. Thus, we adopt it in our training. Moreover, preliminary results (not reported) show that the C-U-Net can be trained for complex tasks like bass+drums or voice+drums. These complex tasks could benefit from 'in between-class learning' method [21] where $\overline{z}$ will have different intermediate instrument combinations.

5.2 Multitask experiment

We want to prove that a given C-U-Net can isolate the **Vocals**, **Drums**, **Bass**, and **Rest** as good as four dedicated U-Net trained specifically for each task [2] We call this set of dedicated U-Nets, *Fix-U-Nets*. Each C-U-Nets version (one model) is compared with the Fix-U-Nets set (four models). We review the results at Table 2 and show a comparison per task in Table 3.

Results in Table 2 for all 4 instruments highlight that *FiLM simple* layers work as good as the complex ones. This is quite interesting because it means that applying 6 affine transformations with just 12 scalars (6 γ_i and 6 β_i) at a precise point allows the C-U-Net to do several source separations. With *FiLM complex* layers it is intuitive to think that treating each feature map individually let the C-U-Net learn several deep representations in the encoder. However, we have no intuitive explanation for *FiLM simple* layers. We did the Tukey test with no significant differences between the *Fix-U-Nets* and the *C-U-Nets* for any task and metric. Another remark is that the four C-U-Nets benefit from the *progressive* training. Nevertheless, it impacts more the simple layers than in the complex ones. We think that the restriction of the former (fewer parameters) helps them to find an optimal state.

[2] with the same learning rate and optimizer as the C-U-Nets.

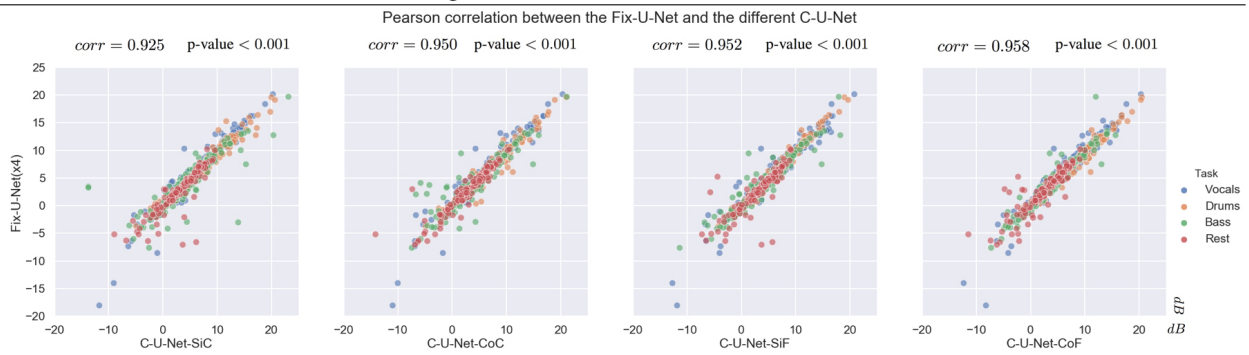

Figure 5: Each graph correlates the performance of two models. On top of it, we show the correlation and p-value. The 'y' axis represents the fixed version (the four dedicated U-Nets) and the 'x' one a different C-U-Net version (with progressive train). The coordinates of each dots correspond to the models' performance i.e., 'y' position for the Fix-U-Net performance and 'x' for C-U-Net. There are three dots per song one per metric (SIR, SAR, and SDR) which does a total of 600 (50 songs x 3 metrics x 4 instruments). The dots alignment in the diagonal implies a strong correlation between models: if one works well, the others too and vice versa. Each color highlights the points of each source separation task.

However, these results do not prove nor discard the significant similarity between systems. For demonstrating that we have carried out a Pearson correlation experiment. The results are detailed in Figure 5. The Pearson coefficient measures the linear relationship between two sets of results (+1 implies an exact linear relationship). It also computes the p-value that indicates the probability that uncorrelated systems have produces them. Our distinct C-U-Net configurations have a global $corr > .9$ and p-value < 0.001. Which means that there is always more than 90% correlation between the performance of the four dedicated *U-Nets* and the (various) conditional version(s). Additionally, there is almost no probability that a C-U-Net version is not correlated with the dedicated ones. We have also computed the Pearson coefficient and p-value per task and per metric with the same results. In Figure 5 shows a strong correlation between the *Fix-U-Net* results and the distinct *C-U-Nets* (independently of the task or metric). Thus, if one works well, the others too and vice versa.

In Table 3 we detail the results per task and metric for the *Fix-U-Net* and the *C-U-Net-CoF* which is not the best C-U-Net but the one with the highest correlation with the dedicated ones. There we can see how their performances are almost identical. Nevertheless, our vocal isolation (in any case) is not as good as the one reported in [1], we believe that this is mainly due to the lack of data. These results can only be compared with the Wave-U-Net [19]. Although they report the results (only the SDR) for the four tasks in the multi-instrument version (multiple outputs layers) they only have a dedicated version for vocals. For vocal separation, the performance of the multi-instrument version decreases more than 2.5 dB in mean, 1.5 dB in the median and the std increase in almost 2 dB. Furthermore, the C-U-Net performs better than the multi-instrument in three out of four tasks (vocals, bass, and drums) [3] . For the 'Rest' task, the multi-instrument wave-u-net outperforms our C-U-Nets. This is normal because the dedicated U-Net has already problems with this class and the C-U-Nets inherits the same issues. We believe that they come from the vague definition of this class with many different instruments combinations at once.

This proves that the various C-U-Nets behave in the same way as the dedicated U-Nets for each task and metric. It also demonstrates that conditioned learning via FiLM is robust to diverse control mechanisms/condition generators and FiLM layers. Moreover, it does not introduce any limitations which are due to other factors.

6. CONCLUSIONS AND FUTURE WORK

We have applied conditioning learning to the problem of instrument source separations by adding a control mechanism to the U-Net architecture. The C-U-Nets can do several source separation tasks without losing performance as it does not introduce any limitation and makes use of the commonalities of the distinct instruments. It has a fixed number of parameters (much lower than the dedicated approach) independently of the number of instruments to separate. Finally, we showed that *progressive training* improves the C-U-Nets and introduced the *FiLM simple*, a new conditioning layer that works as good as the original one but requires less γ's and β's.

Conditioning learning faces problems providing a generic model and a control mechanism. This gives flexibility to the systems but introduces new challenges. We plan to extend the C-U-Net to more instruments to find its restrictions and to explore the performance for complex tasks i.e., separating two or more instruments combinations (e.g., vocals+drums). Likewise, we are exploring ways of adding new conditions (namely new instrument isolation) to a trained C-U-Net and how to detach the joint training. Additionally, we intend to integrate it other source separation architectures such as Wave-U-Net.

Lastly, we believe that conditioning learning via FiLM will benefit many MIR problems because it defines a transparent and direct way of inserting external data to modify the behavior of a network.

[3] Our experiment conditions are different in training data size (95 Vs 75) and in sampling rate (8192 Hz Vs 22050 Hz) than Wave-U-Net.

ABSTRACT

Musical schemata theory entails the classification of subphrase-length progressions in melodic, harmonic and metric feature-sets as named entities (e.g., 'Romanesca', 'Meyer', 'Cadence', etc.), where a musical schema is characterized by factors such as music content and form, position and tonal function within phrase structure, and interrelation with other schemata. To examine and automate the task of musical schemata classification, we developed a novel musical schemata classifier. First, we tested methods for exact and approximate matching of user-defined schemata prototypes, to establish the notions of identity and similarity between composite music patterns. Next, we examined methods for schemata prototype extraction from collections of same-labelled annotated examples, performing training and testing sessions similar to supervised learning approaches. The performance of the above tasks was verified using the same annotated dataset of 40 keyboard sonata excerpts from pre-Classical and Classical periods. Our evaluation of the classifier sheds light on: (a) ability to parse and interpret music information, (b) similarity methods for composite music patterns, (c) categorization methods for polyphonic music.

1. INTRODUCTION

Schemata have been characterised by psychologists as 'the building blocks of cognition' [17], enabling an understanding of the world in packages of knowledge. Similarly, musical schemata can be thought of as 'minimal meaningful' entities, enabling coherent interpretations of Classical phrases. Musical schemata theory is studied and developed by musicologists as a means of classifying short passages in musical works, mainly from the Classical period [2, 10].

Aiming to model musical schemata theory, we consider the development of computational systems that create and update definitions for prototypes of schemata categories from annotated music examples. This work builds on a relatively small amount of existing research in computational modeling of musical schemata theory [8, 9, 18].

The novel system will enable the study of higher-level operations and reasoning in content-based music information retrieval than has been possible to date, and facilitate further research with machine learning approaches in music pattern extraction [15, 19, 20].

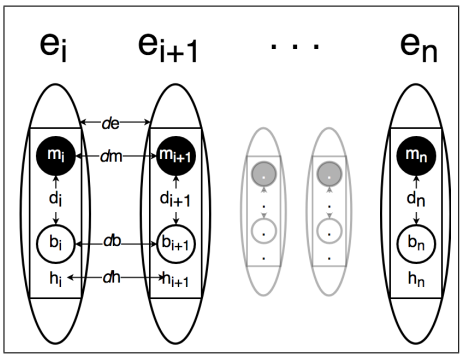

Figure 1. Musical schemata are considered as sequences of schema-events.

2. TASK DESCRIPTION AND BACKGROUND

2.1 Musical schemata in Classical keyboard works

A musical schema is defined as a stereotypical progression of *schema-event* elements (Figure 1): a feature-set consisting of notes from two melodic movements (melody and bass) and harmonic and metric information [7, 10]. A schema is characterized by its content, that is, the number and type of its constituent schema-events, but also as part of phrases and even greater morphological entities such as paragraphs, periods, etc., as well as its position, tonal function, and any interrelations with other schemata.

An interesting aspect of the theory is the notion of a prototype for a set of similar progressions. The extraction of schemata prototypes is a learning process and musical schemata theory is an example-based approach, meaning that knowledge about a schema prototype is obtained and updated from examples and not by rules.

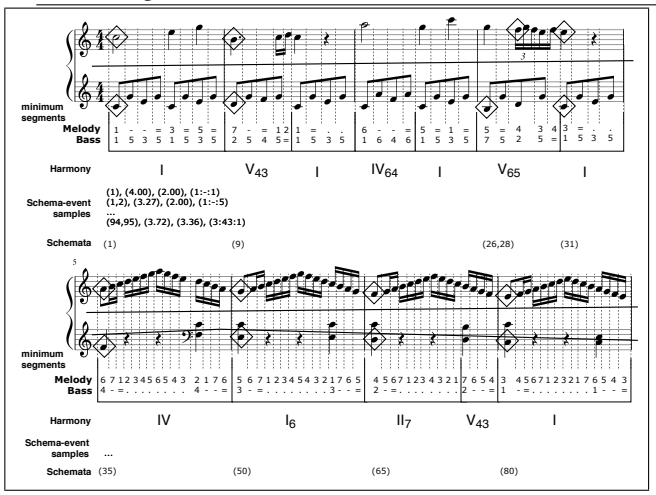

Figure 2. Annotated example with melodic movement separation (horizontal lines), harmonic regions, and schemata notes (diamonds). The first line of the score has a 'Meyer' instance and the second, a 'Prinner'. Excerpt from Wolfgang Amadeus Mozart, Piano Sonata no.16 in C major K545 1st movement Allegro mm.1-8.

2.2 Modeling musical schemata theory

We implemented example-based machine learning with the development of a musical schemata classifier. The classifier works in three steps: making observations of the music data, comparing these observations to stored schema prototypes, and identifying schema-class similarity.

2.2.1 Observations

To classify music patterns such as musical schemata, the input needs to be processed so that only relevant, 'schematic' material is considered. As described previously, musical schemata are viewed as progressions of schema-events, and for that reason we consider two types of 'observations': a) schema-states, and, b) schema-state combinations/progressions. We will refer to these elements as 'low-' and 'high-observations' respectively. The schema-states are schema-voice and schema-event samples, a kind of low-level form of music understanding for small feature-sets. Combining these schema-state elements, we can create schemata instances/samples that are comparable to musical schemata prototypes and thus, perform similarity and classification tasks.

Creating the schema-state observations is a preprocessing step, independent from the tasks of recognition and learning, but the observation process can utilize information from stored prototypes to select only known (stored) schema-states and, thus, reduce the number of schema-event state observations.

2.2.2 Similarity

A fundamental task of the classifier is to perform comparisons of same-class information (e.g. states or schemata) from different sources (e.g. observations, prototypes). The matching of observations from a source score and a stored schema prototype is the recognition process. To evaluate our musical schemata classifier, these recognition results are compared/validated against schemata annotations, a 'ground-truth', giving measures of recall and precision.

To perform comparisons, the idea is to define a similarity metric for multi-feature elements and sequences, such as schema-states and complete schemata, and utilize it to identify and categorize them according to their content.

2.2.3 Class similarity

In addition to recognition and evaluation similarity, class similarity is another type of similarity whereby common relations amongst schema states and schemata observations of the same schema type are identified, hence, describing the properties of a schema family type. In this study, a schema class is defined by a set of examples, an example-base of high-level observations, and a class (similarity) function that validates all its existing examples, acting as the identity validator for all of them.

An interesting aspect of our classification method for schemata is that, contrary to matching methods that create a search-space for specific targets, our approach can go beyond merely finding matches to existing schemata prototypes to automatically identifying potential schemata.

3. METHODOLOGY

3.1 Method overview

The musical schemata classifier was developed by application to incrementally more complex scenarios:

- Identification (labelled I hereafter). Initially, the classifier performed musical schemata identification with pattern matching techniques, identifying the exact positioning of user-defined schema-family prototypes in complete music parts;
- Recognition (labelled R and F). Next, we examined the task of multiple and approximate recognition of user-defined schema-family prototypes, to study similarity-approximation methods for both single-family prototypes (R) and collections of multiple variants for a single schema class (F);
- Learning (labelled L). Finally, we tested the schemata classifier on learning of schemata prototypes from schema-annotated music examples.

The annotations were of a dataset of 40 keyboard sonata parts (10 from Haydn, 10 from Mozart, and 20 from Beethoven), containing annotations for 3 schemata types ('Meyer', 'Prinner', and, 'Cadence'). In total the number of unique annotations are: 17 generic and 23 'Meyer' variations, 22 generic and 8 'Prinner' variations, and, 40 generic and 15 'Cadence' variations.

3.2 Model overview

The details of the model's implementation are beyond the scope of this paper and therefore the following provides

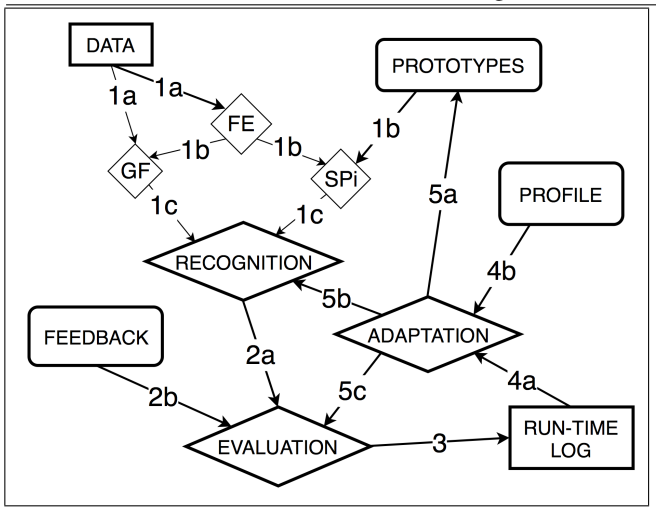

Figure 3. Top view of the schemata classifier model.

only a high-level overview of the approach. [1] The classifier runs in sessions where information from up to five sources is processed and combined (please see Figure 3). The *music-data* source (Figure 3, DATA) supplies complete sonata parts in MusicXML format sequentially, and each input file follows the same information processing path, where the input file is first converted into operational representations to perform score analysis and feature extraction, and then extract state samples (schema-events and -voices). The *memory-data* source (Figure 3, PROTOTYPES) is where schemata prototypes reside and are being recalled for recognition. The *feedback* source (Figure 3, FEEDBACK) inputs non-musical information to the model and is utilized to pass annotations, such as schemata labels for measure ranges. The run-time information of a session is written to a *session log* (Figure 3, RUN-TIME LOG). The learning operations are governed by a system *profile* (Figure 3, PROFILE).

In general, the classifier creates and compares two classes of information: a) *schematic states*, either schema-events or schema-voices, and b) combinations and/or progressions of (a). The three basic operations that connect these information sources all relate to similarity and are: i) recognition, during which states and schemata from memory and data are compared, ii) evaluations, where the results from (i) are compared with annotations, and, iii) adaptation, where the class similarity function of a schema type is updated to include new entries to the example base (the inclusion of a training observation).

The model also employs a number of task-specific functions with smaller scope that aid the similarity functions described above. For example, the results of feature extraction (Figure 3, FE) are sent to both grouping functions (Figure 3, GF, to extract schema-state and progression samples) and a schemata prototype instantiation function (Figure 3, SPi, to create comparable instances from schemata prototypes).

[1] See `https://tinyurl.com/y5x2d99j` for code and data.

3.3 Making music observations

The processing path for each music input element (a complete sonata part) starts with the conversion of the MusicXML file into operational encodings (datapoints and 'minimal segments' [16]) to perform tonal and harmonic score analysis and feature extraction, utilizing formalisms in symbolic music processing from [14] and [4]. Next, stylistic reduction, a combination of the aforementioned analyses for the extraction of schematic information, selects material from the score for the sampling of schema-states (schema-voice and -event feature sets).

In addition to notated information available from the MusicXML encoding, information about metric, tonal, and harmonic properties is extracted utilizing task-specific algorithms. Rhythm is extracted from the notated time signature of the input file and is embedded to operational representations in the form of *metric strength* using [5]. Tonality is extracted from notation using 'key' and 'mode' attributes from MusicXML, but also using probe-tone profiles [12]. Harmony is extracted in segments using the *HarmAn* algorithm [16]. Complex voice separation is not undertaken – rather, the outer notes, based on absolute pitch, are considered to comprise melodic and bass movements.

3.3.1 Sampling schematic-states

After score analysis and feature extraction, the system has enough information to extract schema-state samples. A schema-voice is considered a monophonic sequence of datapoints whose adjacent temporal interval is constrained by extracted features that relate with metric information. The extraction of schema-voices, often termed as music n-grams, is in compliance with voice-leading rules [11]. The schema-event sampling algorithm starts with score analysis information and 'minimal segments', and generates *schema-events*, a type of temporal reduction with similarities to *time-span* reduction described in [13]. First, each 'minimal segment' is assigned positional and (adjacent) transitional 'significance' from two algorithms that weight parameters from the 'minimal segment' properties and harmony. Then, a 'minimal segment' merger creates samples from pairs of 'minimal segment' elements by combining and selecting values for the schema-event characteristics.

The positional 'significance' of each 'minimal segment' is found using (1) and the weights in Table 1:

$$poSig = \tfrac{1}{3}(dpQ + bStr + card) + outVp \qquad (1)$$

where *poSig* is the significance of the 'minimal segment', *dpQ* is the overall quality of datapoints in the 'minimal segment', *bStr* is the beat-strength value, *card* is the cardinality, and *outVp* is the bonus from movement in outer voices.

Transitional 'significance' is calculated in a similar manner but also considering the changes between the adjacent 'minimal segment' elements, mainly in harmony.

A schema-event sample has ontime and duration and all the properties of a prototype schema-event but most importantly, each schema-event sample is rated with the

Feature	Factor
beat strength	2
harmony	2
cardinality	1.5
outer voices	2
complete datapoint in 'minimal segment'	1
starting datapoint in 'minimal segment'	1
ending datapoint in 'minimal segment'	0.25
middle datapoint in 'minimal segment'	0.125

Table 1. The manual weights for *positional* 'significance' (poSig) of single 'minimal segment' elements.

combined 'significance' ratings of its 'minimal segment' elements, allowing further thresholding and selection.

For example, the total number of datapoints and 'minimal segment' elements for the excerpt in Figure 2 is 124 and 95, respectively. Thresholding 'minimal segment' elements using above-average positional 'significance' ratings, event-sampling returns a total of 107 schema-event samples in the following form: ((measure, time signature, beat), (pitch-value of each voice's datapoints: [melody, bass]), (positional 'significance'), (transitional 'significance'), (melody:harmony:bass, in scale-degrees)). For example, the first sample of the excerpt in Figure 2 is:

$$((1, 4/4, 1.0), [C5*, C4], (4.00), (2.00), (1 : - : 1))$$

At a later stage, the type of schemata and the position in which they appear in prototypes are also added to each sample.

With the extraction of schematic material, in the form of schema-voices and schema-events, we have extracted low-level observations, i.e. schema-states. These elements are utilized later for the creation of complete schemata-instances (high-level observations).

3.4 The memory module

The *memory module* stores the schemata prototypes and handles creation, update and instantiation operations of each prototype. It is the knowledge-base, a repository of generic prototypes starting with definitions from [10], where each schema prototype is represented as a sequence of schema-events (please see Figure 1).

3.5 Recognition

A core task of the schemata classifier is to assign/identify prototype schema-states in low-level observations and complete schemata prototypes in high-level observations, with the latter consisting of pairs of schema-voices and progressions of schema-events.

From the data part, post-stylistic analysis (please refer to the data processing path in 3.3), the information of input elements is converted into a set of state samples for voices and events. From the memory part, a target space consisting of schema-states and prototype schemata instances is created according to extracted features (Figure 3, SPi).

3.5.1 Creating and thresholding schemata search space

After the extraction of schema-states, the classifier applies an observation method to select and group state-samples in schema-instances that are comparable to schemata prototypes. Initially, schema-state samples are thresholded based on their 'significance' ratings and, optionally, according to their similarity with prototype states. When forming schemata samples, state-groups are filtered by number of events (minimum/maximum), a minimum/maximum duration, and temporal regularity [6, 18].

3.5.2 Similarity between prototypes and constructs

When comparing extracted and prototype states and schemata, these can either be exact or different, with the latter case being comparable with a similarity metric.

3.5.3 Proto-state similarity

A schema-voice has a single melodic movement and is characterized by the number of notes it contains. Matching a schema-voice sample with a prototype schema-voice is a sequence-similarity task and two voice-states are the same, if their content is the same, regardless of the temporal relations of the datapoints that comprise them. Considering the order of appearance, the position of a datapoint in each voice-state, the difference between schema-voice samples and prototype schema-voices is measured as the sum of differences of same position datapoints, also known as the Hamming distance. For example, the distance d_H between schema-voices (in scale-degrees): a) 1,7,5,3, b) 1,7,4,3, and c) 6,5,4,3, is: $d_H(a, b) = 1$, $d_H(a, c) = 3$, and, $d_H(b, c) = 2$.

The similarity between event-states is hierarchical, considering two layers of similarity for harmonic and melodic information, and Boolean, meaning that differences are not quantified. The harmonic information of two schema-events can differ in type of harmony, expressed within the tonal context (e.g., I, II, etc.) and in the arrangement of the notes within the chord, the type of chord inversions (e.g., 53, 63, etc.). To get a single numeric value from the multi-feature comparisons of schema-events and maintain the types of difference, we consider different decimal powers for each type of difference. Thus, difference in harmonic type equals to 10^3, in chord type, to 10^2, in melody, 10^1, and in bass, 10^0. Therefore, the possible values from a schema-event state comparison are equal to 2^4 (0, 1, 10, 11,. . ., 1110, and 1111). For example, the comparison between schema-events c_{SE} with values (bass, bass-intervals, melody) a) (1, 53, 5), b) (1, 63, 3), and c) (3, 63, 1), is $c_{SE}(a, b) = 1110$, $c_{SE}(a, c) = 111$, and $c_{SE}(b, c) = 1011$. Temporal and metric information is not considered for single event-states comparisons.

After the comparison with prototypical schema-states, each schema-state sample can be tagged with the schema-label and index it appears in prototypes.

3.5.4 Musical schemata similarity

Musical schemata similarity is handled as a sequence similarity problem, similarly to voice-state similarity, but in-

stead of counting the number of pitch-differences in same order datapoints, schema-event differences are counted instead. Thus, similarity between two schemata structures can be expressed as the overall percentage of common schema-events.

Approximation in schemata recognition is similar to the methods presented in [3], using local, γ-, and global, δ- variability thresholds, for schema-events and progressions respectively. Thus, when comparing schema-event progressions, there are two approximation thresholds, one limiting the number and type of differences between schema-events of the same position, and another limiting the number of differences in the complete schema-event progression.

3.5.5 Recognition workflow

The recognition process begins with the comparisons between prototypes and extracted state-samples. First, each schema-state sample is tagged with the id and index of their matching prototypes. Then schema-sampling occurs, creating high-observations – progressions of schema-event samples based on regularity and 'significance' rating thresholds.

3.5.6 Schemata recognition output

The recognition process returns schema-labelled segments of the score and a set of high-observations, rated with the degrees of matching (percentage) with stored prototypes.

3.6 Learning prototypes

Learning musical schemata prototypes is about the extraction and update of schema-event progressions from annotated observations. To achieve this goal, we consider an example-base for each schema prototype class – a repository of observations within a music excerpt. After the recognition process, if the input from feedback suggests a label for a temporal region, then all observations of that segment become training observations and are added to the example-base for that particular schema-label. Maintaining an example-base for each schema-type, we retain access to all the information therein. Processing the elements of the example-base, we examine a class function that extracts relations that are common to all observations that are stored in the example-base repository of a schema. The class function validates all the example-base and is also used for recognition of unlabelled observations.

3.6.1 Class similarity function

To extract prototypes from an example-base of a schema class, we need to identify the harmonic and melodic relations that are common in all exemplars. The algorithm first generates schema-samples and returns variable-length progressions of schema-events that are then converted into harmonic and melodic progressions within the tonal context of the segment (in chord and scale degrees). These contextualized progressions are then sorted by number of schema-events, and the progressions with the highest frequency of appearance and maximum number of events are selected for prototypes.

3.7 Evaluation

The tasks of recognition and learning are evaluated in terms of recall and precision with schemata annotations in measure-level detail. The comparison of the recognition results is Boolean, meaning that the temporal range and label of a recognized schema must match exactly; otherwise they will be considered false-positives.

4. COMPUTATIONAL EXPERIMENTS

We tested four configurations of the musical schemata classifier to gradually achieve the goal of prototype extraction. First, we tested a pattern matching configuration aiming for maximum accuracy in identifying a single schema-type (label I). The second scenario examined approximate matching of a single-schema (label R). The third configuration tests approximate matching of a schema-family, including variations (label F). The last scenario tests the learning algorithm and the extraction of a prototype for annotated examples (label L).

4.1 Maximum accuracy for a user-defined schema

The first model configuration for the schemata classifier examined methods for the extraction of schema-voice states and exact schemata matching for two schemata types, namely 'Meyer' and 'Prinner' (please see Figure 2 for their generic types). The configuration uses datapoints, extracted tonalities, and no harmonic information. The algorithm creates a search-space of schema-voice samples and filters them in pairs, with temporal regularity, to compare them with schemata prototypes. There is no variation in matching and no information preservation after each input element. A recognition example of the algorithm and its configuration is shown in Figure 4.

4.2 Approximate recognition for multiple user-defined schemata targets

The task of approximate recognition of multiple schemata prototypes is examined with two model configurations, matching 'Meyer', 'Prinner', and 'Cadence' schemata. The first case searches for generic approximations (omissions and thresholds in similarity metrics) of each schema family prototype, by first tagging all the extracted schema-states with labels and positions of similar corresponding elements in prototypes and then recognizes complete schemata by combining elements with the same schema class tag under temporal limitations. The second case recognizes approximations of schema families (collections of variants), performing comparisons between schema-samples and class functions that validate all the variants of a schema class. The type of matching approximation of the second case includes those of the first case, but also hierarchical comparisons, considering harmonic similarity first, as a prerequisite, and voice similarity second.

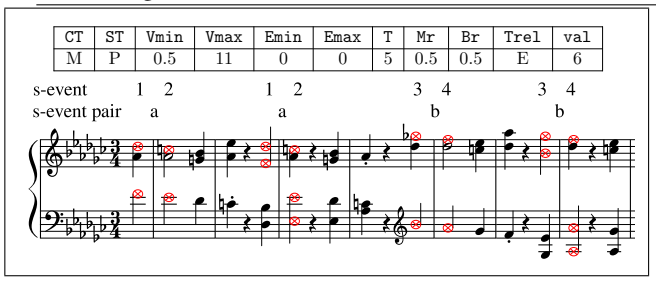

Figure 4. Identification of a generic 'Meyer' instance. The parameters from left to right: Manual search configuration for generic 'Meyer' prototype with temporal distance between events in a range between 0.5 and 11 beats, and 0 for schema-event durations, for a single tonality (5) and 0.5 regularity threshold for temporal intervals in each melodic movement, and maximum (6) thresholding in inter-event temporal regularity. From Ludwig van Beethoven, Piano Sonata in C-sharp minor op.27 no.2 2nd mvt mm.1-7.

4.3 Approximate recognition of extracted schema family type from examples

This computational experiment examines prototype extraction and classification. The algorithm maintains repositories of exemplars for each schema-type separately, from which prototype forms of schemata are extracted utilizing a class function. The validity of the extracted prototypes is examined by evaluating the recognition performance with the extracted prototypes on previously unseen examples.

5. RESULTS

The identification task (Figure 5, $I_{<SCHEMA>}$) achieved high recall and precision for both schemata types, indicating that basic music information processing of the classifier is working as it should.

The recognition models, due to approximate matching, have increased recall but lower precision (Figure 5, (Figure 5, $R_{<SCHEMA>}$, $F_{<SCHEMA>}$). The first configuration that tests family-prototype generic approximation (Figure 5, $R_{<SCHEMA>}$) can be very imprecise, as approximating the prototypical form can yield completely unrelated patterns. The second configuration (Figure 5, $F_{<SCHEMA>}$) has slightly lower recall from the first but increased precision, due to more targeted approximations with the use of a class function.

The learning model (Figure 5, $L_{<SCHEMA>}$) achieved low recall, due to occasional erroneous prototype extractions and even lower precision, because of the highly-generalised extractions of prototypes.

6. FINDINGS AND DISCUSSION

This paper presented a prototype model architecture for musical schemata classification. It is among a small handful of computational models for extracting instances of such high-level music-theoretic concepts from input staff notation.

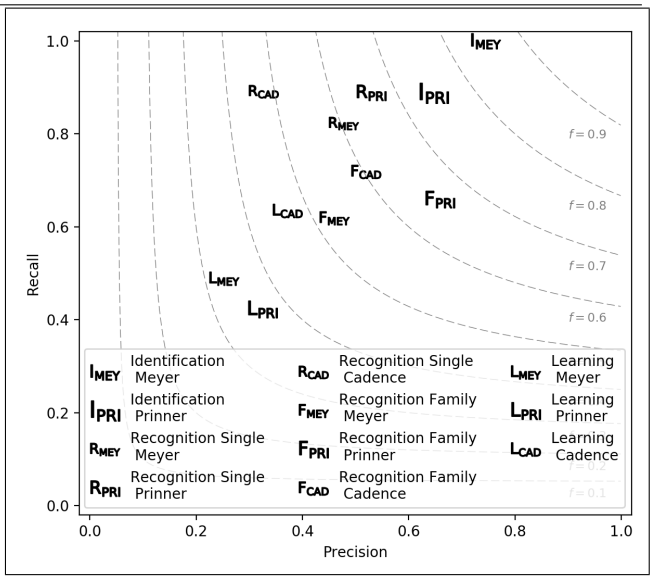

Figure 5. The F_1 score of all musical schemata identification models.

The computational model that was developed for a musical schemata classifier was tested under different tasks and configurations, and proves to be a reliable framework that can facilitate classification operations regarding musical patterns. The use of structured music information (i.e. the 'low' and 'high' observations) enabled high-level operations such as comparisons of abstract patterns, and the methods that were developed to produce them can be further fine-tuned. Moreover, the maintenance of an example-base proved very helpful in prototype extraction, as it provides transparency of operations. Furthermore, the repository of a learning session can be reused in other sessions, transferring learned knowledge.

The model was tested on a small dataset and its expansion both in number and types of schemata annotations is a natural future task. There are numerous improvements that can be applied in this prototype model by fine-tuning individual functions. For example, the sampling mechanisms for schema-states and progressions can become adaptive to local context, instead of global, part-wise features, and thus become more accurate. Another interesting and informative development would be the comparison of this model's performance with popular classifiers for sequential data, such as convolutional and recurrent neural networks. In addition, extending the classification capabilities of the model to include information concerning the position and function of schemata within phrases could be useful for both learning and discovery of schemata. Lastly, even the current abilities of the schema classifier can be utilized to support content-based retrieval on digital score libraries. The sampling method is independent from the model and, thus, large databases of digital scores can be represented as samples, or even symbolic fingerprints [1]. In addition, on top of a database representation for music scores, a query language for music patterns (as musical schemata) would provide a flexible interface for a user-defined content-based music information retrieval.

Session B

EVOLUTION OF THE INFORMATIONAL COMPLEXITY OF CONTEMPORARY WESTERN MUSIC

Thomas Parmer, Yong-Yeol Ahn
School of Informatics, Computing, and Engineering
Indiana University, Bloomington, IN, USA
tjparmer@indiana.edu, yyahn@iu.edu

ABSTRACT

We measure the complexity of songs in the Million Song Dataset (MSD) in terms of pitch, timbre, loudness, and rhythm to investigate their evolution from 1960 to 2010. By comparing the Billboard Hot 100 with random samples, we find that the complexity of popular songs tends to be more narrowly distributed around the mean, supporting the idea of an inverted U-shaped relationship between complexity and hedonistic value. We then examine the temporal evolution of complexity, reporting consistent changes across decades, such as a decrease in average loudness complexity since the 1960s, and an increase in timbre complexity overall but not for popular songs. We also show, in contrast to claims that popular songs sound more alike over time, that they are not more similar than they were 50 years ago in terms of pitch or rhythm, although similarity in timbre shows distinctive patterns across eras and similarity in loudness has been increasing. Finally, we show that musical genres can be differentiated by their distinctive complexity profiles.

1. INTRODUCTION

Our everyday life is surrounded by cultural products; we wake up to a song, read a book on the subway, watch a movie with friends, or even travel far to admire a piece of art. Despite such pervasiveness, we cannot fully explain why we like a particular song over others or what makes something a great piece of art. Although the perceived quality of a piece is affected by numerous contextual factors, including one's cultural, social, and emotional background, theories suggest that preference, or 'hedonistic value', may also be affected by innate properties of the products, such as *novelty* and *complexity* [1, 18, 28]. In particular, a popular theory suggests there is a *Goldilocks principle* — that just the right amount of novelty or complexity elicits the largest amount of pleasure, whereas pieces with too little or too much complexity are less interesting and enjoyable [3]. On the other hand, cultural products are also *fashionable* — what is popular now may be completely out of fashion next month. Such seemingly contrasting observations prompt us to ask the following questions: *as fads come and go, is there still a consistent preference towards the optimal amount of complexity in cultural products? How has the complexity of contemporary cultural products changed over time?*

This question may apply to any type of cultural product, but we focus here on the complexity of contemporary Western songs. Although various studies have already reported evidence of the 'inverted U-shaped' relationship between perceived complexity and the pleasantness of music in terms of individual-level preference [1, 11, 32], evidence of this preference at the population-level is unclear [7, 22, 30], and many past studies have been limited by the size or extent of the data, in terms of genres or temporal range.

Recently, datasets such as the Million Song Dataset (MSD) began to allow researchers to systematically analyze patterns in music at a massive scale [6, 8, 26]. For example, Serra *et al.* used musical 'codewords' based on song segments in the MSD to identify changes in pitch, timbre, and loudness over time, finding that newer songs restrict pitch transitions, homogenize timbre, and increase loudness (without increasing the variability in loudness) [26]. Mauch *et al.* used a corpus of 17,000 songs from the Billboard Hot 100 to analyze how popular music has evolved between 1960 and 2010 in the United States; using timbral and harmonic features derived from songs on the Hot 100, they identified three stylistic revolutions that occurred in 1964, 1983, and 1991 [15].

In this paper, we analyze the large-scale evolution of complexity in contemporary music in terms of pitch, loudness, timbre, and rhythm, during the period from 1960 to 2010 using the Million Song Dataset (MSD) [4]. We find that complexity does seem to constrain popularity, as evidenced by the most popular songs (those on the Billboard Hot 100) clustering around average values and exhibiting smaller variance compared to a random sample. However, complexity values do fluctuate over time, as long-term trends are seen in loudness, timbre, and rhythm complexity and in the similarity between songs on the Billboard Hot 100. Finally, we compare the complexity of different genres and find that genres have characteristic complexity profiles, leading us to hypothesize that complexity may be a factor in an individual's musical selection.

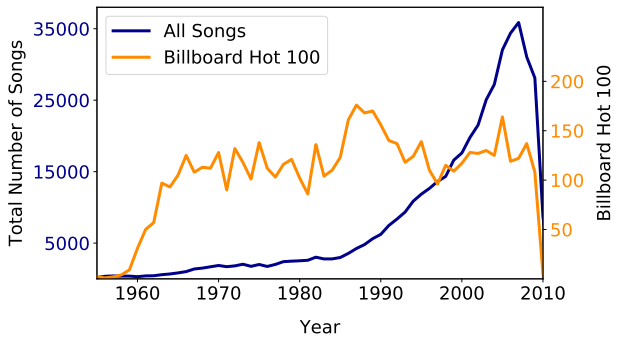

Figure 1. The number of songs per year. 'All Songs' refers to the filtered MSD dataset, while 'Billboard Hot 100' refers to those songs whose title and artist we matched with songs on the Hot 100 as identified in [15].

2. METHODS

2.1 Data

The MSD is a dataset of one million songs created by Columbia University's LabROSA in collaboration with The Echo Nest [4]. Each song in the dataset is divided into small temporal segments (based on note onsets) with detailed data derived from the song's audio signal, and includes metadata such as title, artist, year, duration, and genre terms.

Prior to analysis, we filtered the MSD to remove duplicates, songs with missing genre or duration metadata, and songs likely to be commentary pieces (whose title included the tokens 'interview', 'commentary', 'introduction', 'discuss', 'conference', or 'intro'), resulting in a dataset of 905,896 songs. Some songs also did not have all data types — pitch, loudness, timbre, rhythm, or year — that we examine here and were thus left out of the corresponding calculations. Due to a limited amount of data from the early years, we restricted our analysis to the period from 1960 to 2010. The genre of each song was determined by the term (Echo Nest tag) with the strongest weight, although we note that terms are assigned at the artist level so all songs by the same artist are grouped into the same genre.

To discover the most popular musical pieces in our dataset, we found 6,661 songs which charted on the Billboard Hot 100 as identified in a previous study [15]. The number of songs per year in our final dataset is shown in Figure 1.

2.2 Codewords

To estimate complexity, we defined "codewords" for each song across four dimensions (pitch, loudness, timbre, and rhythm), similar to a previous study [26]. Each codeword is based on a segment of the song. Pitch and timbre codewords are vectors containing the pitches (based on the binary presence of each of 12 pitches in the chromatic scale) and timbres (based on analysis of the audio signal, with 11 components thresholded into three bins) present in the segment. Loudness codewords are equal to the binned maximum decibel value of the segment. Similarly, rhythm codewords are defined as the number of average sixteenth notes between segments, where the average sixteenth note is based on the time signature. We then defined a measure of complexity for each feature per song based on the conditional entropy of each type of codeword. [1]

2.3 Measuring Complexity

Although many studies have examined the relationship between the complexity of a piece and the derived pleasure from it [1, 19–21, 31, 32], there is no universally adopted way to measure the complexity of a song. Existing definitions of complexity include hierarchical complexity, dynamic complexity, information-theoretic complexity, and cognitive complexity [10,23,27,34]. Information-theoretic measures are attractive because they capture the surprise inherent in a pattern, such as the notes played in a musical piece. Theories propose that music can be understood as the kinetics of expectation and surprise, and that composers seek to elicit emotions by fulfilling or denying these expectations [1, 17, 35]. In particular, Implication-realization (IR) theory posits that open intervals evoke expectations in a listener and the surprises of these expectations may be related to complexity [18, 32, 35].

Information-theoretic measures include Shannon entropy, joint entropy, conditional entropy, compression or algorithmic complexity [10, 16, 27, 29], and more complicated techniques such as pairwise predictability between time series, Hidden Markov Models, Normalized Compression Distance, and predictive information rate [1, 8, 9]. Previous studies have used information-theoretic quantities to estimate perceived complexity, identify piece similarity, derive psycho-acoustic features, and classify genres [5, 10, 13, 25, 27, 30].

We use conditional entropy as our measure of complexity, dependent on the immediately preceding symbol, as it is known that events during even short preceding intervals are enough to evoke strong expectations in the listener [1, 12, 35]. Other information-theoretic measures are either more complicated (e.g. predictive information measures), can only be approximated in practice (e.g. Kolmogorov or algorithmic complexity), or do not take past information into account (e.g. Shannon entropy).

Each song was assigned a complexity value for pitch, loudness, timbre, and rhythm, which is equal to the conditional entropy of the feature codewords:

$$H(Y|X) = \sum_{x \epsilon X} p(x) H(Y|X = x) = \\ - \sum_{x \epsilon X} p(x) \sum_{y \epsilon Y} p(y|x) \log_2 p(y|x) \quad (1)$$

where X and Y are possible codewords, $p(x)$ is the probability of observing codeword x and $p(y|x)$ is the probability of observing codeword y given the previous codeword x.

[1] Code is available at https://github.com/tjparmer/music-complexity.

3. RESULTS

3.1 Complexity and Popularity

The complexity distribution of songs is approximately bell-shaped, although timbre is skewed towards zero complexity — unlike the other features, timbre becomes easily predictable after only one previous codeword. The distributions of the Hot 100 songs are similar, although the Hot 100 tends to exhibit statistically lower complexity in pitch and timbre and higher loudness complexity, compared to 95% confidence intervals of 1,000 bootstrap random samples of the same size (see Fig. 2). Furthermore, we found that the variances of the Hot 100 complexity values are smaller than for other songs (based on 95% confidence intervals of 1,000 bootstrap samples from the Hot 100 compared to 1,000 bootstrap samples from the overall distribution); thus, the popular songs tend to be located in a narrower range near the mean across pitch, loudness, and rhythm complexity. This result supports the theory for an inverted U-shaped curve where global popularity is maximized by medium complexity.

3.2 Complexity Across Time

To examine the evolution of song complexity, we calculate the mean complexity values for each year (for all songs and the Hot 100 songs separately) in Fig. 3, which shows several long-term trends. Later years mark the appearance of songs with low loudness and rhythm complexity and songs with high timbre complexity, but they were not reflected strongly in the Hot 100 songs. The low loudness complexity may be due to the trend often called the "loudness war" [26], which describes the tendency to produce the entire song to be as loud as possible. Another possible reason may be the emergence of low complexity genres in recent years. For instance, terms associated with low loudness complexity outliers include 'grindcore', 'hip hop', and 'black metal', all of which are relatively newer genres in the dataset. Low rhythm and high timbre complexity may be due to pop or electronic music that contain modern production techniques with many different synthesized textures and strong dance beats. Terms associated with low rhythm outliers include 'tech house', 'techno', and 'hard trance', while terms associated with high timbre complexity outliers include 'tech house', 'techno', and 'deep house'.

Previous research has indicated that the evolution of Western popular music experienced significant changes during three musical 'revolutions' in 1964, 1983, and 1991 [15]. The first was associated with rock and soul music, the second with disco, new wave, and hard rock, and the third with the emerging popularity of rap music over rock music. These three revolutions split our period of analysis into three 'epochs': 1964-1983, 1983-1991, and 1991-2010. With this reference frame, we examine our measures of complexity.

If we consider the entire dataset, each aspect of complexity shows a different pattern. The pitch complexity has been more or less stable across the whole period; the loudness complexity has been decreasing overall, although the period from 1983 to 1991 shows a slight increase; the timbre complexity has been steadily increasing and reached a plateau after the 1990s; finally, the rhythm complexity was decreasing through the period from 1964 to 1983, and then stabilized.

Meanwhile, we find that the temporal evolution of the Hot 100 songs does not follow the overall pattern. The largest difference can be observed in the timbre complexity. While the timbre complexity of the entire dataset has been steadily increasing, it has been almost completely flat for the most popular songs, diverging from the overall trend. This may indicate that the emergence of new genres with high timbre complexity primarily happened for more niche musical tastes. Pitch and loudness complexity, by contrast, have been higher for popular songs in recent years, while rhythm complexity was lower until the 2000s.

3.3 Popular Song Similarity

The analysis of complexity over time suggests that modern day popular songs (at least from the 2000s) are more likely to have higher pitch, loudness, and rhythm complexity (and lower timbre complexity) than their less popular contemporaries. However, while this suggests that popular songs are not simpler than the average song, it does not necessarily indicate whether they sound more or less similar to their popular contemporaries (that is, other Hot 100 songs that are released in the same year). A recent report suggests that popular songs are sounding more and more similar to other songs on the charts [33]. In contrast, other research finds that songs that perform well on the charts do not sound too similar to their contemporaries but often have an optimal level of differentiation [2]. To analyze whether popular songs become more similar to their contemporaries over time, we measure the Kullback-Leibler (KL) divergence [14] from each song in the Hot 100 to other popular songs that were released in the same year. KL divergence captures the unexpectedness of a song's codewords given the codewords present in other popular songs and thus indicates the spread of codeword usage per year.

In Fig. 4, we show the KL divergence per year for each feature, with each epoch marked. Larger KL divergence in the figure suggests that the songs in that year are more different from their contemporaries as compared to other years. Our measurement shows that the 1964-1983 and 1991-2010 period are similar to each other while 1983-1991 shows a reversing trend. Across features, the KL divergence was either decreasing (songs are more similar to each other) or stable during 1964-1983 and 1991-2010, while 1983-1991 marked either a positive trend reversal or a slow-down of the decreasing trend. These changing trends suggest that musical revolutions are not born equal; some may have spurred diversity among popular songs while some may have homogenized the field.

Despite these fluctuations, the divergence trend is roughly stable over time for pitch and rhythm, while timbre rebounds after similarity decreases; thus, our findings are consistent with research that songs that perform well

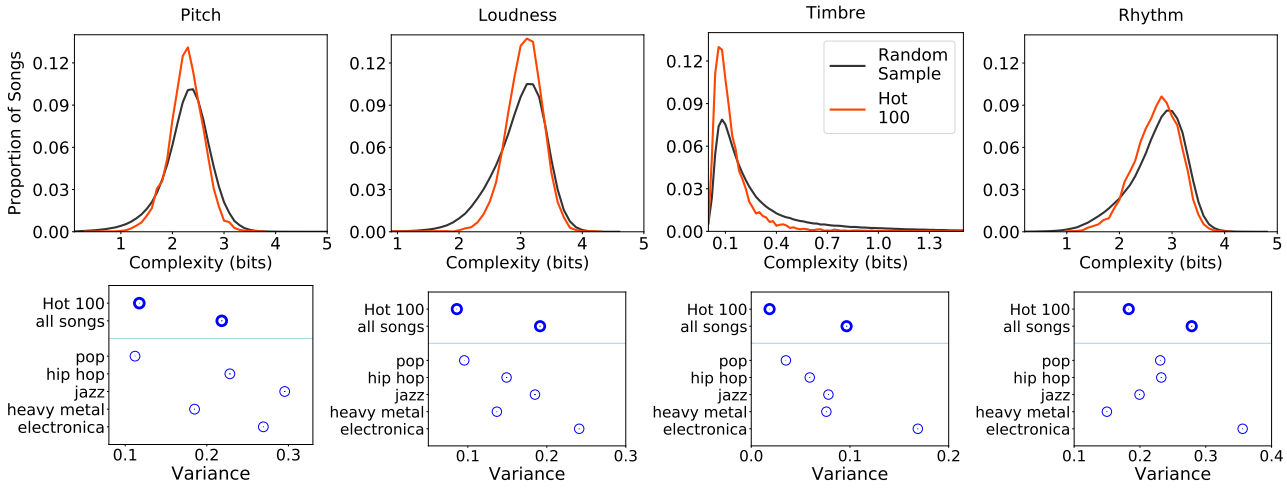

Figure 2. Feature complexities and variances. Complexity distributions are shown (in bins of 0.1 bits, except for timbre which is in bins of 0.02 bits). The variance plots include 95% confidence intervals in black (although confidence intervals are smaller than the symbol and not visible), based on 1000 bootstrap samples of 1000 songs from the respective genre.

on the charts do not sound too similar to their contemporaries but rather maintain a degree of uniqueness which is statistically consistent over time.

3.4 Complexity Across Genres

Let us turn our attention to musical genres and their complexity. As some genres may be characterized by complex harmonic structures or simple, repeated patterns, we expect to see differences across different genres in terms of complexity. For example, jazz is often considered to have complex patterns whereas dance music may be assumed to use simpler rhythmic patterns. Our measurement concurs with such speculation, but finds that different subsets of genres may be relatively complex across one or two features but not others. For instance, electronic and dance styles tend to have high pitch complexity values, whereas jazz and blues have high loudness complexity values. The highest timbre complexity values belong to electronic genres, although metal also scores highly, but electronic genres have reduced rhythmic complexity which is instead maximal in jazz, progressive and vocal genres.

We found that a variety of common genres were significantly different from a random sample drawn from the overall distribution in terms of each feature complexity (based on a two-sample Kolmogorov-Smirnoff nonparametric test as well as 95% confidence intervals of the means of each feature), with the exception that pop was not rhythmically distinct. Thus each genre seems to have distinctive complexity features that describe its songs: jazz is relatively complex (except in terms of timbre), hip hop has higher than average pitch and loudness complexity, heavy metal has high rhythm complexity but low pitch and loudness complexity, and electronica has high timbre complexity but low rhythm complexity (Fig. 6).

This pattern may be indicative of some trade-offs that listeners make. If they prefer timbre at the expense of rhythmic complexity, they may prefer electronic genres. If they prefer pitch and loudness complexity, they may prefer hip hop or jazz. If they care about timbre and rhythm over pitch and loudness, they may prefer heavy metal. There is a positive correlation between pitch and loudness complexity (Pearson's r=0.77) across all songs, suggesting that genres tend to have high pitch and loudness complexity (e.g. hip hop, jazz) or low pitch and loudness complexity (e.g. heavy metal). There is also a negative correlation seen between timbre and rhythm complexity (Pearson's r=-0.55), suggesting that rhythmic complexity decreases with higher timbre complexity (although this is not true for metal genres).

Interestingly, the Hot 100 is similar to the pop genre in feature means and variances (although statistically different). Both pop music (whose songs are given no genre-specific term with higher weight than 'pop') and the Hot 100 (whose songs are primarily classified as genres other than 'pop') have near average values of pitch, loudness, and rhythm complexity, and lower than average values of timbre complexity, while also having smaller variance than the other selected genres (refer to Figures 2 and 6). This may suggest that listeners expect the same from listening to the Hot 100 as they do when listening to music labeled as 'pop': mildly surprising songs that do not vary too much in complexity and which are sonically predictable.

One may also expect similar genres to share similar complexity scores. We used agglomerative clustering on genres represented with over 5000 songs in the dataset (a total of 41 genres), using Euclidean distance between the genre mean complexity scores of each feature, and then used the silhouette coefficient [24, 28] to find nine optimal communities. The result matches intuitive expectations, such that rock genres are grouped together as are electronic genres; interestingly jazz is grouped with hip hop and rap, due to these genres having similar complexity scores. These results suggest that a genre may be defined, to some degree, by its pitch, loudness, timbre, and rhythmic complexity.

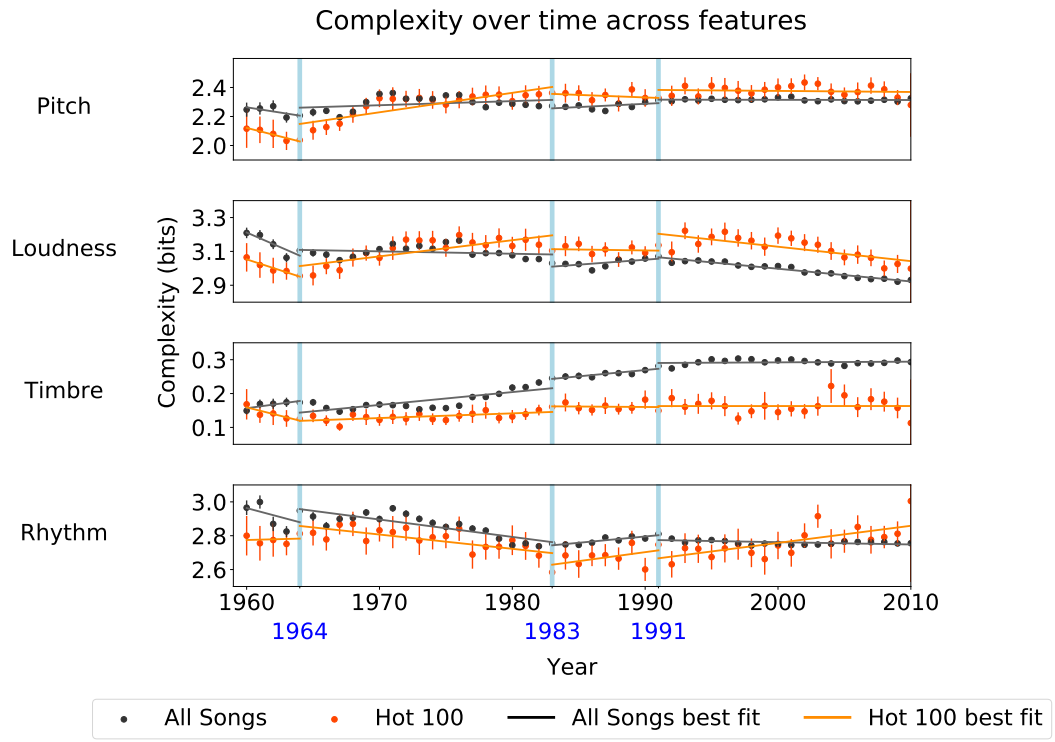

Figure 3. Average complexity over time across features. Linear trend lines (obtained using OLS linear regression) are shown for each epoch, along with 95% confidence intervals of the mean. Light blue lines indicate the musical revolutions found in [15].

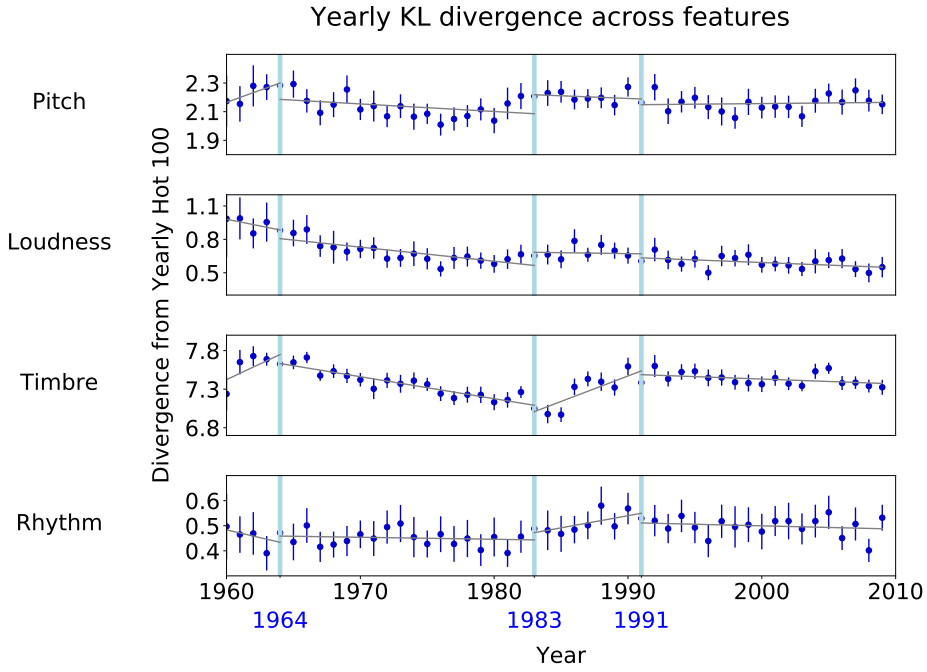

Figure 4. Yearly KL divergence of Hot 100 songs across features. Complexity variance, as measured by KL divergence between a song's codewords and codewords from other songs released in that year, shows changing trends at the time of certain musical 'revolutions' in 1964, 1983, and 1991 (indicated by light blue lines). Linear trend lines (obtained using OLS linear regression) are shown for each epoch, along with 95% confidence intervals of the mean.

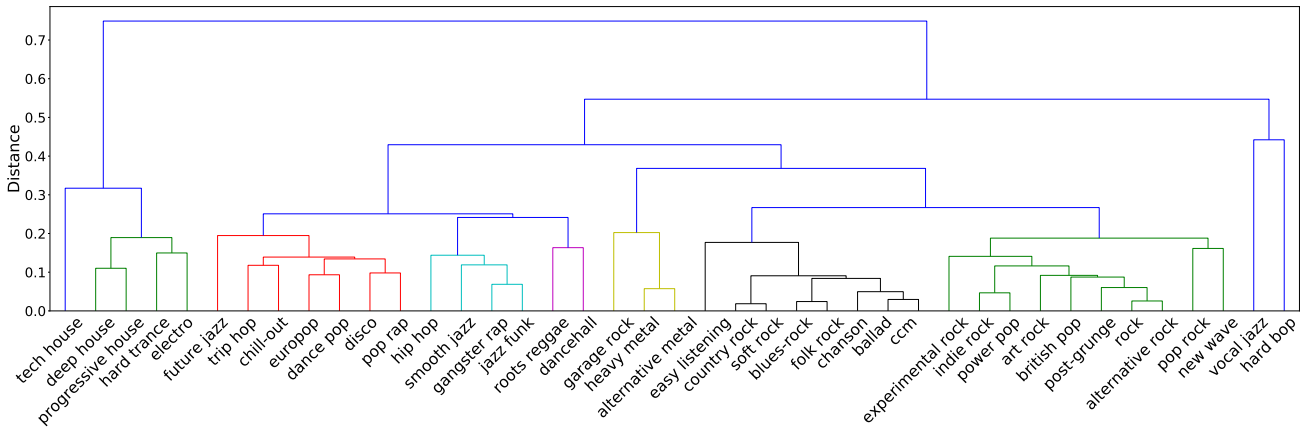

Figure 5. Dendrogram of top genres. Clustering is based on the Euclidean distance between complexity features. Colors indicate different communities.

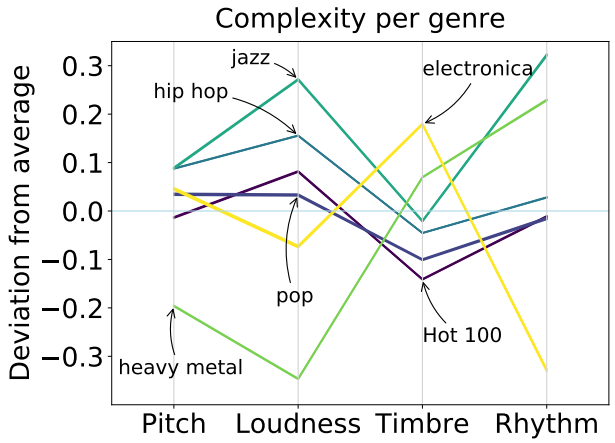

Figure 6. Complexity of select genres across features. For each feature, the deviation of the genre complexity mean from the mean of 100 bootstrapped samples of the same size as the genre is shown. Note the similarity between the Hot 100 and the pop genre.

4. DISCUSSION

Understanding and characterizing the complexity of music is an important area of study with both cultural and economic significance. Although music may seem complicated, songs quickly become predictable as you take previous knowledge into account. This suggests that conditional entropy may be a useful way to characterize musical complexity, although our approach here assumes that the uniform distribution of codewords is the state of maximum uncertainty and expectations are made based on only one previous symbol, which cannot distinguish counts of repeating patterns or phrasing [1]. Our approach is thus intrinsic to the song itself and ignores any *a priori* contextual information.

Using this measure, we find that pitch complexity has been generally stable over the period from 1960 to 2010, while loudness and rhythm complexity have decreased and timbre complexity has increased. Complexity norms seem to constrain the most popular songs, as those on the Hot 100 are distributed around the overall feature means with small variance in complexity, the exception being timbre which is lower than average. Indeed, the Hot 100 is similar to songs labeled as 'pop', in that pop also has average pitch, loudness, and rhythm complexity and low variance.

This result provides evidence of a global, inverted U-shaped relationship between popularity and complexity, where popular songs are, on average, the most pleasant to the population. Listeners may expect popular songs to be mildly complex, but not to deviate far from expected timbre or complexity norms. Complexity of the Hot 100 has in fact been consistent over fifty years in pitch and timbre, while increasing recently in rhythm and decreasing in loudness. Similarly, popular songs continue to maintain a consistent level of differentiation from their contemporaries in terms of pitch, timbre, and rhythm.

Certain genres do differ significantly across complexity features, suggesting that they have specific complexity profiles that help define them. We hypothesize that certain genres may 'make up' for lack of complexity in one area by increased complexity in another. Perhaps fans of electronic genres prioritize complexity in timbre but rhythmically simple dance beats, or metal fans prioritize rhythmic complexity and high volume at the expense of loudness complexity.

More research needs to be done to fully elucidate the relationship between complexity and musical appreciation. For example, future research can relate musical complexity to the listening habits of people on a large scale to determine a more fine-grained measure of song popularity. The consistency of popular songs over time suggests that, collectively, people tend towards songs that are a certain optimal level of complexity rather than being too simple or complicated. However, it remains an open question to what degree complexity plays a role in people's cognitive appreciation of music.

ABSTRACT

We introduce DrummerNet, a drum transcription system that is trained in an unsupervised manner. DrummerNet does not require any ground-truth transcription and, with the data-scalability of deep neural networks, learns from a large unlabeled dataset. In DrummerNet, the target drum signal is first passed to a (trainable) transcriber, then reconstructed in a (fixed) synthesizer according to the transcription estimate. By training the system to minimize the distance between the input and the output audio signals, the transcriber learns to transcribe without ground truth transcription. Our experiment shows that DrummerNet performs favorably compared to many other recent drum transcription systems, both supervised and unsupervised.

1. INTRODUCTION

Transcription is a music information retrieval task with the goal of estimating the score y when input audio x is given. The majority of the recent transcription systems is based on supervised learning, where the transcriber is an *analysis* system $\hat{y} = F_a(x)$ that is trained with annotated pairs $\{(x_m, y_m)\}_{m=1}^M$ to minimize the distance between y and $\hat{y}$ [6, 7, 27, 31, 33, 34, 37, 38].

The trend is similar in drum transcription on which we focus in this paper. Supervised learning approaches may incorporate models based on frame-based feature extraction and classification [15], non-negative matrix factorization (NMF) for pattern matching [10], or hidden-Markov model [25]. More attention has been given recently to deep learning based models such as convolutional neural networks (CNNs, [13, 34]) and recurrent neural networks (RNNs, [33, 37, 38]), all of which have greatly improved transcription systems.

However, the lack of a large-scale annotated dataset is one of the most frequently mentioned obstacles that hinder further improvement. In practice, this limits the generalizeability of supervised learning systems, as will be discussed in Section 4, and using synthetic data is one way to address this issue [7, 39]. Although there have been proposals to use unlabeled data [42, 43], the issue remains as they still rely on supervised learning combined with teacher-student learning [16]. Parallel to those approaches, an annotation-free and, therefore, a more scalable and generalizable alternative would be unsupervised learning.

Unsurprisingly, one of the humans' music learning procedures, self-taught by trial-and-error, is very similar to unsupervised learning. For example, musicians learn to transcribe by (a) listening, (b) playing an instrument, (c) identifying differences, and (d) making adjustments. *Can this be done without any supervision? Yes*, if the person can spot the pitch difference (e.g., the pitch should be higher or lower). Consistent with this logic, developing a transcription system based on unsupervised learning would be feasible if the system can test the estimation, measure the error, and correct itself accordingly.

To implement such an unsupervised transcription system, we need a *synthesis* system, $\hat{x} = F_s(\hat{y})$, making the overall system $\hat{x} = F_s(F_a(x))$. During its training, the system is given $\{x\}_{m=1}^M$ and trained to minimize the distance between x and $\hat{x}$. There have been few systems relying on unsupervised learning as explained above. In MIR, the system in [1] utilized sparse coding to learn a dictionary of time-frequency templates of piano and harpsicord, assuming a (matrix-)multiplication model with additive noise, $F_s(\mathbf{y}) = \mathbf{A}\mathbf{y}+\mathbf{e}$. Yoshii et al. proposed to use sparse coding in a jointly-learned chord recognition and transcription system [44]. Berg et al. designed a probabilistic graphical model that parameterizes the spectral and temporal envelopes, note events, and note activations, in order to transcribe piano by inferring their parameters [2]. In drum transcription, many systems have used NMF to decompose a drum track spectrum into spectral templates and their temporal activations (or transcription) [26, 41]. Several variants of NMF were proposed to address the limits of the fixed spectrum template of NMF [19, 20, 29]. Lastly, a similar system can be found in computer vision, where the parameters of input images are estimated by reconstruction using an image renderer [18].

In this paper, we introduce DrummerNet, a deep neural network based drum transcription system that is trained by unsupervised learning. With a more end-to-end approach, DrummerNet is distinguished from previous research [1, 2, 44], which has strong priors on the target sounds. In §2, we present the system design principle behind DrummerNet, followed by its details in §3. In §4, the evaluation results are discussed along with the ablation study. We present our conclusion, the problems of our system, and the future direction towards fully unsupervised learning in transcription/MIR in §5.

Name	Description	Note
n, N	The temporal index/length of audio input	
k, K	The index/total number of drum components	K=11
x, y	Mixture and transcription	$\in \mathbb{R}^N$
$\hat{x}, \hat{y}$	Estimations of mixture/transcription	$\in \mathbb{R}^N$

Table 1: Symbols used in this paper

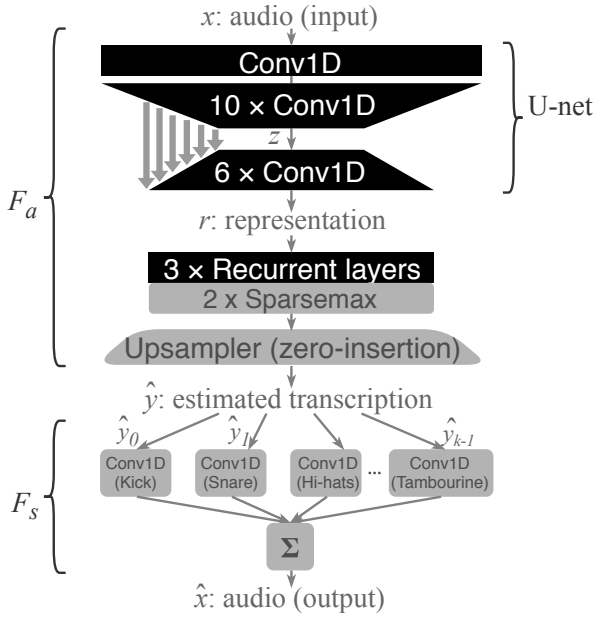

Figure 1: Block diagrams of DrummerNet structure. Trainable modules are illustrated as black boxes and fixed modules as rounded grey boxes.

2. SYSTEM DESIGN PRINCIPLES

Training the proposed DrummerNet is similar to the previous unsupervised learning approaches in music [1, 2, 44], as they all train a system to output $\hat{x}$ that reconstructs the original signal x. The difference between $\hat{x}$ and x works as a proxy of the difference between $\hat{y}$ to y.

There are three conditions under which unsupervised learning of a transcriber can be achieved successfully. First, the output of the analysis module F_a must be in the form of transcription – a set of discrete events representing the timing and intensity of the notes. Second, the synthesis module F_s must synthesize the audio signal given the transcription input $\hat{y}$. Third, all the components in the network must be differentiable as we rely on backpropagation to train it.

3. DRUMMERNET

In this section, we introduce the proposed system structure. We specify the number of channels, kernel size, and stride as `(channel, kernel, stride)`. All the convolutional and recurrent layers use an exponential linear unit as an activation function [9]. [1]

[1] The implementation of DrummerNet is available on `https://github.com/keunwoochoi/DrummerNet`

3.1 Analysis module F_a

The analysis module F_a, as illustrated in the top half of Figure 1, takes the audio signal x as an input and processes it through a series of U-net variant [30], recurrent layers, and gated Sparsemax activation [21]. After training, this module is used as a transcriber (with peak-picking).

U-net The U-net consists of 1D convolutional layers, max-pooling layers, and concatenations between the encoder and the decoder. The encoder consists of a convolutional layer `(128, 3, 1)` followed by 10 convolutional layers `(50, 3, 1)` interleaved with max-pooling of size 2. As a result, it outputs $z \in \mathbb{R}^{N/1024}$ which has a receptive field size of 3,072 time steps.

The decoder has only 6 convolutional layers `(50, 3, 1)` interleaved with a concatenation with the feature map at the same depth as in the encoder and a $\times 2$ bi-linear interpolation. We call the output of decoder $r \in \mathbb{R}^{N/16}$, the representation based on which the transcription is estimated. The asymmetry between the encoder and the decoder makes the length r to be shorter by a factor of $4^2 = 16$ compared to that of input x. Assuming the input audio is sampled at 16 kHz, [2] r would have a sampling rate of 1,000 Hz.

Recurrent layers We use three recurrent layers: (GRUs [8]) {along time-axis, bi-directional, 100-channel}, {along time-axis, uni-directional, 50-channel}, and {along channel-axis, uni-directional, K-channel}. These three recurrent layers have properties of i) being bi-directional so that the onset at n can be determined by the vicinity of n (both the past and the future), ii) enforcing temporal dependency, and iii) enforcing component-wise dependency, respectively. The width (or the hidden vector size) of the third recurrent layer is equal to K, the number of drum components in the synthesizer, to map each channel to each drum component.

Sparsemax In an ideal case of transcription, there would be local sparsity along both the time and channel-axes because the drum events would not repeat with a rate of 1,000 Hz (which is faster than 16-beat on 240 BPM), nor would all the K drum components be activated simultaneously. Although sparsity is one of the properties that *can* be achieved by the autoregressive nature of the recurrent layers, we add Sparsemax [21] activation to encourage it explicitly. The output of Sparsemax has two important properties: i) it always sums to 1 (same as Softmax) and ii) it is highly likely to be sparse with actual zeros (unlike Softmax). In DrummerNet, two Sparsemax layers are applied in parallel, one along channel-axis (=instrument-axis) and the other time-axis within a non-overlapping window size of 64. This design choice is based on the assumption that there are only a few onsets among notes (channel-axis sparsity) and within 64 samples at $\hat{y}$, or 64 ms (temporal sparsity). The outputs from these two Sparsemax layers are then multiplied element-wise.

[2] This is the sampling rate of input audio in our experiment.

Class	Subclass	Description
KD	KD	Kick drum
SD	SD	Snare drum
HH	CHH, PHH	Closed/pedalled hi-hat
	OHH	Open hi-hat
TT	HIT, MHT,	High/high-mid/
	HFT, LFT*	high-floor/low-floor tom
CY	RDC, RDB*	Ride cymbal, ride cymbal bell
	CRC, CHC*,	Crash/china cymbal
	SPC*	splash cymbal
OT	SST*, TMB	side stick, tambourine

Table 2: A drum component hierarchy [36]. The synthesizer F_s consists of 11 classes, following Subclass of the table with omitting ones marked with asterisks *.

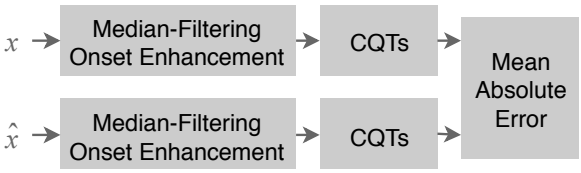

Figure 2: The block diagrams of loss calculation

Upsampler Finally, the low temporal resolution of the Sparsemax output is addressed by zero-insertion upsampling by the factor of 16. According to this, we modify the temporal quantization rate of events, unlike the upsampling of a digital signal.

3.2 Synthesis module F_s

The synthesis module F_s consists of K parallel 1D convolutional layers and a channel-wise summing operator. The kernel of each layer is not trained but fixed to the known waveform of each drum component to convert a transcription of a component $\hat{y}_k$ into a track $\hat{x}_k$. The tracks are summed to generate the final output $\hat{x}$ ($= \sum_{k=1}^{K} \hat{x}_k$), the synthesized audio signal. This module is only used during training.

In the implementation, we use $K = 11$, using Subclass in Table 2, following [36]. Ones marked with asterisks were excluded due to their scarcities in our source of isolated drum recordings, which consisted of 12 virtual drum instruments provided by Logic Pro X. Multiple drum kits, including rock, pop, funk, and soul [3] , were used to prevent the network from overfitting to a specific drum kit. During training, a drum kit was randomly assigned for every batch.

3.3 Learning

Unable to directly compute the transcription loss during unsupervised learning, we carefully designed a loss function at the audio level, $L_x(x, \hat{x})$, as minimizing it would also minimize the transcription loss, $L_y(y, \hat{y})$. To do so,

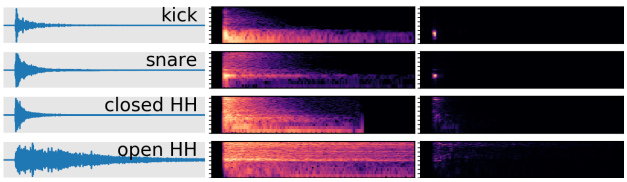

Figure 3: The effect of drum extraction for kick, snare, close hi-hat, and open hi-hat, from top to bottom. Columns are from left to right: original waveform, original spectrum, and onset-enhanced spectrum

L_x should be able to differentiate the drum components – kick drum (KD), snare drum (SD), and hi-hat (HH) – while being invariant to the varying drum kits. Perceptually, there are clear differences between KD, SD, and HH. Although both impulsive, KD is in the low-frequency band while SD is in the mid-frequency band. SD is also relatively tonal and has a longer envelope. HH is more complicated to describe due to its variation from its playing technique. For example, closed and pedalled-HH's are in the high-frequency band, impulsive, and with relatively low energy, while open-HH's are similar except louder with a longer noisy envelope.

We thus define and use *onset spectrum similarity*, which is designed to represent the similarity based on the onset part of sounds in the spectrum domain. As illustrated in 2, it is measured by i) applying median-filtering based drum extraction [12] which enhances onsets (with a FFT size of 1024 and median filter length of 31 on both axes), ii) converting to multi-resolution CQTs (constant-Q transform) for both x and $\hat{x}$, and then iii) calculating the mean absolute difference between them.

Among many spectral magnitude representations, we use (log-magnitude) CQT since the logarithmic frequency scale is known to match well to human auditory perception [23]. We followed the implementation of Pseudo-CQT [4] which multiplies linear-to-octave filterbanks to an STFT. As a result, the CQT covered nearly 8-octave bands

[4] `http://librosa.github.io/librosa/`

from 32.07 Hz (C1) to 8 kHz (the Nyquist frequency of our experiment) with a 12-band/octave resolution. This implementation is differentiable.

Figure 3 shows the effect of onset enhancement. It preserves the characteristics of the drum components in the transient part while removing the after-onset components. This process makes L_x and L_y more similar, as the non-transient parts vary more among drum kits due to their random and noisy nature. In a preliminary experiment, for example, the network tried to reconstruct all the non-transient components of SD using tom-toms and HHs, resulting in non-sparse and severe false-positive detection of onsets.

4. EXPERIMENTS AND ANALYSIS

4.1 Setup

For the training of DrummerNet, we used an in-house dataset of drum stems that are crawled from many websites. The dataset consisted of 3,940 unique tracks averaging 225 seconds each for a total of 249 hours. Since the dataset was crawled from various websites, some details, such as the distribution of drum components, are hard to identify. The tracks were mostly popular western rock/pop music. Alternatives to this in-house dataset can be found in [7] (3,758 drum sample recordings ($\times$8 second = over 8 hours) or 60,000 synthesized drum loops ($\times$8 second = over 133 hours)) and [39] (4,197 drum tracks (259 hours)). We opted for the in-house dataset because it provided more diversity as it was not synthesized.

Each audio file was resampled to 16 kHz and down-mixed to mono. The training batch size was 16, and for each audio file, we randomly selected a 2-second segment. On average, there were 112.5 segments in a track, and therefore training with 443,250 (=3,940 $\times$ 112.5) items would be approximately one epoch. With a Nvidia Tesla P100 and a batch size of 32, it took about 9 hours to train a single epoch. We implemented DrummerNet using Pytorch 1.0 [24] and used Librosa 0.6.3 [22] and Madmom 0.16 [4] for audio processing and peak-picking.

We used a heuristic peak-picking method introduced in [5]. This method selects a peak $\hat{y}[n]$ at n if it satisfies the three conditions in Eq. (1),

$$\begin{aligned} \hat{y}[n] &= \max(x[n-w_m], ..., x[n+w_m]) \\ \hat{y}[n] &\geq \text{average}(x[n-w_a], ..., x[n+w_a]) + \delta \\ n &> n_{lp} + w_w, \end{aligned} \quad (1)$$

where the max window w_m=50 ms, average window w_a=100 ms, threshold δ=0.2, waiting window w_w=50 ms, and n_{lp} is the last detected peak. We mainly use F1 score along with Precision and Recall using mir_eval [28]. The tolerance window is 50 ms.

After training, we test the system on three public datasets: IDMT-SMT-Drums (SMT, 104 drum tracks, total 130 minutes [10]), Medley-DB Drums (MDB, 23 tracks, total 20 minutes [36]), and ENST-drums (ENST, 61 minutes [14], drum-only tracks known as 'wet-mix' of 'minus-one' subset). According to [40], a task is DTD [5] if tracks are drum-only, more precisely KD/SD/HH-only, and the system annotates KD/SD/HH events. This is the case for the SMT dataset. A task with the system annotating KD/SD/HH but with drum tracks consisting of more than those three components, e.g., tom-toms and cymbals, is named DTP [6] in [40]. Following this convention, we evaluate DTD with SMT (Section 4.3), and DTP with MDB/ENST. We did not fine-tune for any dataset in any experiment and used the whole datasets for evaluation only.

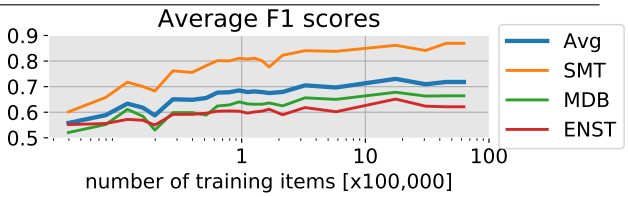

Figure 4: The F1 scores of DrummerNet over training items on each dataset (SMT, MDB, ENST), averaged over KD, SD, and HH. AVG indicates the overall average F1 scores of three datasets.

4.2 Trend of Performance over Training

We did not employ a stopping strategy but trained the network for 6×10^6 items (about 13 epochs). As illustrated in Figure 4, the overall performance gradually increases as the training proceeds and approaches converging towards the end of training. This indicates that the proposed loss function is a good proxy of transcription loss. After the initial phase of training, the performance differences among datasets remain consistent, probably due to the different characteristics of drum tracks in each dataset, as will be discussed in Section 4.4.

4.3 Relative Performance against Baselines

In this experiment, we trained our system on the in-house training set without any annotation and evaluated it on a separate test set (also known as 'eval-cross (trained on DTP)', [40]), which is a stronger condition than a usual train/test split scenario in supervised learning ('eval-subset', [40]). This setup allows us to measure the generalization capabilities across the datasets. Specifically, our experiment is equivalent to DTD, 'eval-cross (trained on DTP)' experiment in [40]. [7], which is only available on SMT. Therefore, only the performances on SMT are compared in this Section. Overall, the performance of DrummerNet is favorable to that of recent drum transcription systems. With an average F1 score of 0.869 on SMT, the proposed unsupervised DrummerNet outperformed 9 out of 10 systems. The nine systems include ones with deep neural networks and supervised approach (ReLUts, RNN, lstmpB, tanhB, and GRUts [33,34,37,38]), as well as ones with NMF and unsupervised approach (AM1, AM2,

[7] Numbers are omitted in the paper but are available online: https://www.audiolabs-erlangen.de/resources/MIR/2017-DrumTranscription-Survey.

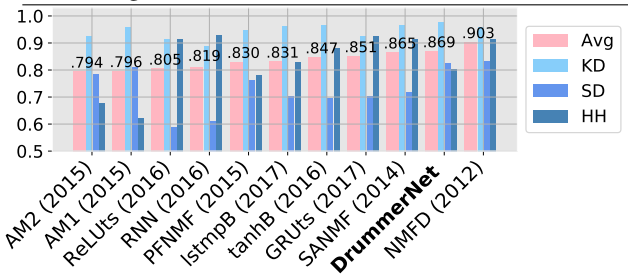

Figure 5: The F1 scores of DrummerNet and other systems on SMT with 'eval-cross' setup, sorted by the ascending order of the overall average. The system names follow [40].

PFNMF, and SANMF [10, 41]). It did not outperform NMFD [20], a system based on the convolutive NMF.

The comparison between DrummerNet and the NMF/unsupervised learning-based systems [10, 41] implies that the proposed deep neural network structure effectively learns relevant representations. Furthermore, DrummerNet allows constant-time inference, unlike NMF and other factorization-based approaches which require iterative optimization in the test time.

What is more interesting is its *generalizability*. All the deep learning based systems [8] present deteriorating performance in the transfer learning scenario (eval-cross) compared to the dataset split scenario (eval-subset). [9] However, less data-driven approaches [10] present similar or even increased performances in eval-cross. This implies that the distributions within datasets are fairly different and biased to certain types of drum tracks and therefore, a transcription system trained with those datasets will be also biased accordingly. This limitation may be attributed to the small sizes of those datasets. Theoretically, supervised deep learning systems may generalize better if trained on a very large dataset, which lacks practicality due to the high annotation cost. In contrast, it is relatively easy to *unbias* DrummerNet. One only needs to control the distribution of drum tracks by their style/genre/sounds without annotating every note.

4.4 Qualitative Analysis

In this section, we will analyze the performance and the behavior of DrummerNet by components, datasets, and metrics, as illustrated in Figure 6. Here, we notice two clear trends. First, across all of the three datasets and the metrics, detecting KD was the easiest, followed by SD and HH (except the precision on SMT). Second, SMT seems to be the easiest, followed by MDB and ENST. *What could be the reasons?*

The first trend is strongly related the proposed loss function. KD has the least within-class variability while being the most distinguishable component (the largest mutual-class variability) due to its solitary frequency range. SD and HH share both the mid and high-frequency ranges

[8] RNN, tanhB, ReLUts, lstmpB, GRUts - RNN-based systems

[9] See Figure 10 (b) of [40]. Note that most of the reported scores in papers also follow eval-subset setup.

[10] SANMF, NMF, PFNMF, AM1, AM2 - NMF-based systems

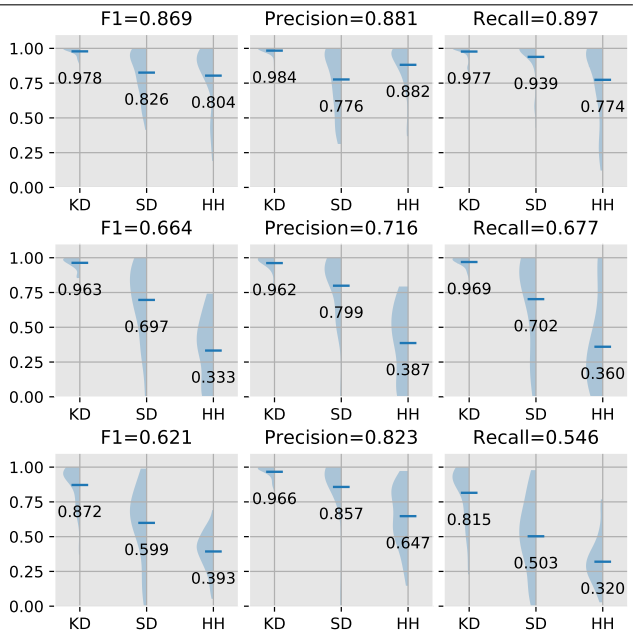

Figure 6: Evaluation of DrummerNet on SMT (top), MDB (middle), and ENST (bottom) datasets.

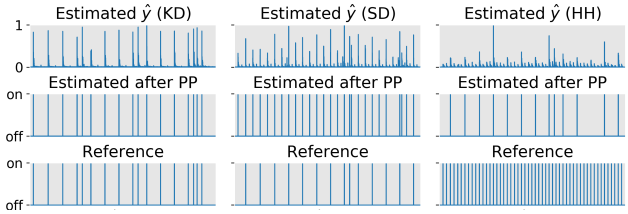

Figure 7: A transcription example of DrummerNet, 'Real Drum 01-12' in SMT - the output of analysis module (top), after peak-picking (middle), and ground truth (bottom); KD, SD, HH (left to right).

and their sounds can vary significantly across drum kits – i.e., larger within-class variability and smaller mutual-class variability. A common pattern, consequently, is the false positive of HH due to SD and vice versa. This is presented in Figure 7, where SD has many false positives due to HH.

The second trend is caused by the mixed use of the probability and the onset velocity in the DrummerNet. Although transcription $\hat{y}$ *is* the estimated amplitude of drum components, the peak-picking method treats $\hat{y}$ as if it was a probability. This discrepancy becomes problematic when the velocities of drum events in a track vary drastically as in the case of MDB and ENST. A failure case is demonstrated in Figure 7, where the HH with strong accents on several occasion caused DrummerNet to miss many of the other HH peaks.

4.5 Ablation Study

We conducted an ablation study where the performance of DrummerNet is compared with that of its variants. Figure 8 shows the reported F1 scores averaged over datasets and components. Please refer to the caption in Figure 8 for the definitions of the system names.

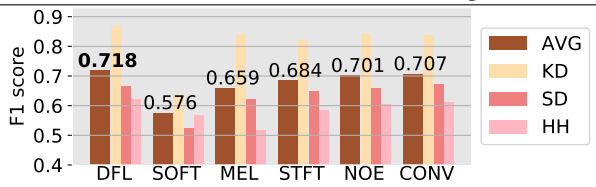

Figure 8: The ablation study results, F1 scores averaged over three datasets per component (KD, SD, HH) and their overall average (AVG). The label indicates as follow: DFL (default DrummerNet as introduced), SOFT (two Softmax layers instead of Sparsemax), MEL (use 128-band melspectrogram instead of CQTs), STFT (use 1024-point STFT instead of CQTs), NOE (not onset enhancement in loss), CONV (3-layer convolutional layers instead of recurrent layers).

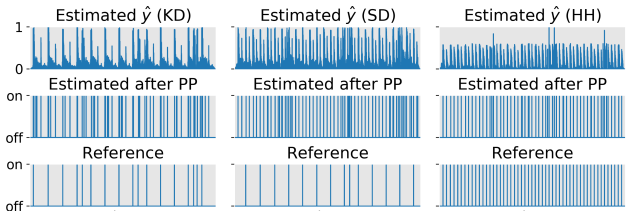

Figure 9: A transcription example of SOFT (DrummerNet with Softmax) , 'Real Drum 01-12' in SMT - the output of analysis module (top), after peak-picking (middle), and ground truth (bottom); KD, SD, HH (left to right).

Sparsemax (DFL vs. SOFT) Among all the variants in this experiment, we observe the most dramatic change in the performance when we replaced Sparsemax with Softmax (SOFT), mostly in a negative way. In SOFT, the two Softmax layers were applied in sequence instead of in-parallel and multiplied, which we tested, but the training was unstable. The transcription $\hat{y}$ of SOFT tends to be much noisier with many false positives, as presented in Figure 9. We conclude that the sparsity induced by Sparsemax is a crucial factor behind the success of the proposed unsupervised transcription.

Figure 9 provides a good example of the performance degradation pattern for each component. As in Figure 8, although the scores of all the three components decrease in SOFT, the degradation is not as critical for HH as in the case of KD/SD. This observation reflects the underlying properties of the different components. KD and SD are sparser than HH, and thus may benefit more from the introduction of Sparsemax.

CQT (DFL vs. MEL vs. STFT) Replacing CQTs with either melspectrograms (MEL) or short-time Fourier transform magnitudes (STFT) results in decreased performance. Unlike CQTs, where different numbers of FFT are used for each octave range, melspectrograms are computed based on single-resolution STFT. This implies that DrummerNet benefits from CQTs which consider multiple temporal and spectral resolutions.

Comparing MEL and STFT, the melfrequency compression helps with the better detection of KD but not SD nor HH. This is explained by the different frequency band weighting of STFT and melspectrogram. Since melfrequency is linear below 1 kHz and logarithmic above 1 kHz [32], melspectrogram allocates relatively more bins below 1 kHz. This means that the loss function in MEL is biased towards the low-frequency range, resulting in training that favors KD over the others.

Onset Enhancement (DFL vs. NOE) The onset enhancement is shown to be boosting the performance, but not significantly (0.017). In the learning curve, we observe that removing the onset enhancement from the loss function results in a large performance degradation during the initial phase of training. This is mainly due to false-positives in the non-transient part.

Recurrent layers (DFL vs. CONV) Overall, replacing three recurrent layers with three convolutional layers does not make significant differences (0.011). This may means i) a long-term relationship may not provide additional information, probably because the transcription largely depends on local information, and ii) the mutual conditioning in the last recurrent layer is not effective in our experiment. In an informal analysis, we observed that with recurrent layers, $\hat{y}$ still has some local temporal correlation, e.g., the activations are smeared over time, probably because that is better to reconstruct the input audio.

5. CONCLUSION

We introduced DrummerNet, a deep neural network that is trained to transcribe drum tracks without a labeled dataset. In the experiment, DrummerNet achieved strong performance compared to existing systems trained with supervised learning, showing its generalizability towards a real-world drum transcription scenario. Our ablation study showed that Sparsemax and CQT played a crucial role in the successful training of DrummerNet.

The experiment also revealed room for further improvements. Considering the discreteness of the musical notes, a reinforcement learning approach may be more suitable [35], making the prediction more sparse and replacing the peak-picking with trainable action. The onset-enhancement on audio similarity is a function carefully-chosen in order to approximate L_y when x and $\hat{x}$ are given. Unfortunately, the approximation is limited because the exact drum sounds in x are not given, and therefore a perfect reconstruct of (onsets of) the input audio ($L_x(x, \hat{x}) = 0$) does not lead to a perfect transcription ($L_y(y, \hat{y}) = 0$). An alternative way would be measuring a similarity on a (perceptual) representation domain instead of the audio, for example, by learning a loss using forward-backward consistency (also known as a cyclic loss [17]) or known audio features. Lastly, the current synthesizer module is limited to drums as it does not handle the duration of notes. A trainable synthesizer can be used to expand DrummerNet to other instruments [3, 11], eventually leading to an unsupervised universal transcription system combined with instrument recognition.

6. ACKNOWLEDGEMENT

We thank Tristan Jehan and Sebastian Ewert for their valuable comments and discussions. We would also like to express our sincere gratitude to Chih-Wei Wu for sharing his insight with us.

ABSTRACT

Target-based assisted orchestration can be thought of as the process of searching for optimal combinations of sounds to match a target sound, given a database of samples, a similarity metric, and a set of constraints. A typical solution to this problem is a proposed orchestral score where candidates are ranked by similarity in some feature space between the target sound and the mixture of audio samples in the database corresponding to the notes in the score; in the orchestral setting, valid scores may contain dozens of instruments sounding simultaneously.

Generally, target-based assisted orchestration systems consist of a combinatorial optimization algorithm and a constraint solver that are jointly optimized to find valid solutions. A key step in the optimization involves generating a large number of combinations of sounds from the database and then comparing the features of each mixture of sounds with the target sound. Because of the high computational cost required to synthesize a new audio file and then compute features for every combination of sounds, in practice, existing systems instead estimate the features of each new mixture using precomputed features of the individual source files making up the combination. Currently, state-of-the-art systems use a simple linear combination to make these predictions, even if the features in use are not themselves linear.

In this work, we explore neural models for estimating the features of a mixture of sounds from the features of the component sounds, finding that standard features can be estimated with accuracy significantly better than that of the methods currently used in assisted orchestration systems. We present quantitative comparisons and discuss the implications of our findings for target-based orchestration problems.

1. INTRODUCTION

In many music information retrieval and signal processing contexts, we are required to reason about signals that are themselves the sum of multiple sources. Whether the summing comes from instruments in a multi-track recording, voices in a group conversation, or simply from noise in the signal, we generally need to consider the full set of sources that make up an audio signal.

Much work in MIR deals with pulling apart the sources in a signal, either in the most straightforward sense via source separation [3,4], or through any of a number of classification tasks such as tagging [11, 31], instrument recognition [14, 18], or automatic transcription [16, 26]. A separate body of work deals with the inverse problem, that of putting sources together: work in applications like assisted orchestration [8] and automatic mixing [13, 25] aims to guide people through the task of combining signals together with the help of a machine in the loop.

In the cases of both separation and combination, tasks can be solved presumably because the source components and the summed signal are sufficiently correlated; the more correlated a source is with the mixture, the easier it is to identify, and as more signals are summed together, correlations between the combination and any single source tend to diminish. In a computational setting, these correlations are of course measured through a set of features of the signals, whether they be hand-engineered features like FFT and MFCC, or modern features learned by neural networks.

There are some cases, however, in which we can observe the source signals of a mixture, but it is impractical or impossible to actually compute the features of the signal in question; these are the cases that we investigate in this work. Broadly speaking, there are two primary settings in which we may be unable to observe the features of audio signals:

1. We do not have access to the signals.
2. Computing the features for *all* relevant signals is computationally expensive.

The first setting is commonly encountered in MIR, in which, as with many fields centered around media that may be under copyright or other protections, it is quite common

for researchers to have access to pre-computed features but not to raw data itself. For example, the audio files of the million songs that comprise the Million Song Dataset [5], which serves as a benchmark for many common MIR tasks, cannot be legally distributed. Instead the data contains common audio features like MFCC, chroma, note onsets, and spectral centroids. [1] Though this dataset and others like it are attractive because of their size and scope, they have been of limited use as source material for constructing additional audio mixtures. As semi-supervised and self-supervised approaches to machine learning have become more competitive with fully supervised systems, large datasets even of weakly labeled source material are becoming more useful for research in areas like source separation [15, 24]; estimating the features of mixtures might be one path towards making use of this data in new contexts.

The second setting in which we cannot observe audio features, which is the focus of this work, is the case where the computational cost of calculating an exponential number of audio mixtures is prohibitively high. This computational bottleneck often arises in the aforementioned body of work that attempts to automatically combine signals together during the course of tasks like target-based orchestration. In this context, learning algorithms need to explore a combinatorial space of potential solution sets, making it infeasible to compute the real features of all possible mixtures of signals. Moreover, methods for narrowing down this set of possible solutions, such as reinforcement learning algorithms, are generally iterative, requiring online evaluation of a reward function before the next set of candidates can be explored. Because these methods both have a large solution space and need to be evaluated iteratively, features must be computed *on the fly*, making fast feature computation, or accurate estimation, a necessity.

In this work, we take steps to explore the potential of machine learning models for predicting audio features of a mixture of sounds that we are unable to observe, focusing on the task of target-based assisted orchestration [2, 6, 8]. Concretely, we consider models of the following form: given a feature function f and M individual signals $S_1, \ldots, S_M$, we learn mappings from input features $f(S_1), \ldots, f(S_M)$ to the true feature of the mixture $f(S_1 + \ldots + S_M)$.

In experiments, we examine one standard feature that is known to typically behave linearly when summed (FFT magnitude spectra) and one feature that is less well suited to linear approximation (MFFC coefficients), investigate the ability of different models to predict each feature across a varying number of mixtures ranging from 2 notes to 30, and discuss the implications of our findings for target-based assisted orchestration as well as for the broader range of scenarios in which real audio features cannot be observed.

Code to reproduce our results can be found at `https://github.com/jrgillick/audio-feature-forecasting`.

2. TARGET-BASED ASSISTED ORCHESTRATION

Musical orchestration, and in many cases, music production, consists largely of choosing combinations of sounds, instruments, and timbres that support the narrative of a piece of music. Strong orchestration can bring a composition to life by emphasizing, clarifying, or perhaps questioning the elements of the music, and through this process, orchestration can often be a difference-maker to critical or commercial success [20, 21].

Different musical styles and composition environments have different constraints (for example, scores for live performance should only require the sounds of the instruments in the group, whereas the sounds available for use on a recording are only limited by their stylistic relevance), but fundamentally, finding the right set of sounds is important regardless of the context. For composers and producers, employing MIR systems during the orchestration process holds the potential to help spark inspiration, solve challenging problems, or save time.

Though the orchestral setting has been explored extensively in previous work, assisted orchestration methods hold the potential for application in other styles. For example, *layering* drum samples is common practice in music production, and MIR-based tools for drum sample search are beginning to make their way into professional toolkits [2]; existing methods for query-based drum sample retrieval [23] could be extended to consider mixtures of drum samples.

3. RELATED WORK

Existing systems for target-based assisted orchestration compute spectral similarities using standard spectral features [8] or perceptual descriptors [2], along with evolution-based methods for exploring the solution space.

Most relevant to our experimental setting is the implementation of the publicly available state-of-the art Orchidea system [10], which is based in part on a study conducted in [9] on predicting timbral features of combined sounds. This study found that for 3 features (Spectral Centroid, Spectral Spread, and Main Resolved Partials), and for mixtures of up to 4 sounds, predicting the features of the mixture by a linear combination of the source features both achieved a low error and did not vary as a function of the number of mixture components.

Since computing a linear combination has very low computational cost, this finding enables real-time estimation of thousands of candidate mixtures for use in online reinforcement learning, making tools like Orchidea practical for real-world use. The effects on the features of mixing many more components, along with the behavior of higher-dimensional and richer features, however, have not yet been investigated.

4. EXPERIMENTS

4.1 Data

For our experiments, we use the OrchDB dataset of individually recorded musical notes from a variety of orchestral instruments. OrchDB is a streamlined subset of the Studio Online (SOL), dataset that has been optimized for assisted orchestration [30]. Collected as part of the Studio Online project at IRCAM, the full SOL data set contains over 117,000 instrument samples, including extended techniques and contemporary playing styles. OrchDB, which contains a curated subset of these samples, has been used for assisted orchestration since 2008 [7]; the contents of the data are summarized below:

- OrchDB contains about 20,000 notes with lengths ranging from about 1 second to 30 seconds.
- Instruments include bassoon, clarinet, flute, horn, oboe, saxophones, strings, trombone, trumpet, and tuba.
- Approximately 30 different playing styles are represented in OrchDB, such as ordinario, pizzicato, pizzicato Bartók, aeolian, Flatterzung, col legno battuto; brass instrument samples include a variety of different types of mutes.
- Notes across the pitch range are included, along with a range of dynamics from *ppp* to *fff*, including sforzato and crescendo.

4.2 Mixtures of Notes

To train and evaluate models for feature estimation, we partition the dataset into nonoverlapping subsets for training, development, and testing, choose 6 different numbers of mixture components M between 2 and 30, and then for each M, we synthesize a dataset of new audio files by adding together the raw waveforms of M randomly chosen notes. Finally, we divide the summed signals by M to keep the amplitudes of the mixture in the same range as those of the source files.

For each value of M, we synthesize 7500 new audio mixtures for training, 2000 for development, and 2000 for testing, creating these new mixtures after partitioning our data so that no source file that appears in the training set can be chosen as part of a mixture in the test set. After synthesizing the mixtures, we compute and store the real FFT and MFCC features for every mixture for use in training and evaluating our models.

4.3 Predicting Unobserved Features

With this data in hand, we explore several models for predicting the features of a mixture of audio signals given the features of the individual signals. In all experiments, given a feature function f and M individual signals $S_1, \ldots, S_M$, each model is trained to learn a mapping from input features $f(S_1), \ldots, f(S_M)$ to the true feature of the mixture $f(S_1 + \ldots + S_M)$.

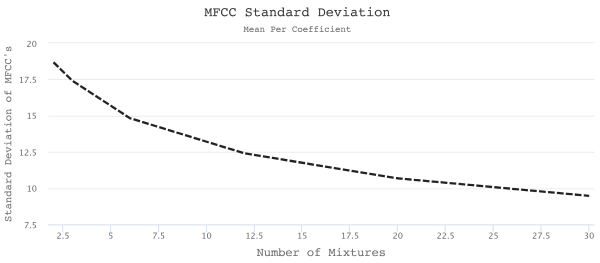

Figure 1. Standard Deviations (averaged across all 19 coefficients) of the real MFCC coefficients of mixtures of audio files. As M increases, the variance in the MFCC coefficients goes down.

5. MODELS

5.1 Features

For our modeling experiments, we choose two standard features: 1024-dimensional FFT magnitude spectra and 19-dimensional MFCC coefficients (we discard the first of 20 MFCC coefficients). Our choice of features is meant to capture the most common MIR settings, so we use the default FFT and MFCC dimensions specified in the Librosa library [22] and compute the features on audio files sampled at 22050 Hz using the default window size (2048 samples) and hop size (512 samples) of the Librosa implementations. We then follow [8] in flattening both the FFT and MFCC features from 2-dimensional time-frequency representations into 1-dimensional feature vectors by taking a linear combination of the features at each frame, weighted by the RMS energy at the corresponding frame.

This method of averaging over time allows us to summarize the spectral characteristics of signals with different lengths using a single feature feature vector, while at the same time ignoring the quieter parts of the signal. In addition, we preserve the interpretability of the FFT and MFCC features through this process, which is particularly useful for inspecting and analyzing our model outputs. Of course, the downside of this preprocessing step is that we discard all time-domain information, so we are unable to predict anything about the envelope or movement of the sound. Depending on the source material and the downstream application, different preprocessing choices might be more appropriate than averaging over time; for example, unpitched percussive sounds require different modeling choices from pitched material. Since our data consists of mostly pitched notes from orchestral instruments, however, we follow the convention of the assisted orchestration literature by focusing on timbre independent of time.

Finally, before training or evaluating models, in order to best align our quantitative results to the expected perceptual results with regards to timbre, we normalize the FFT feature vectors such that the maximum value is 1. Although in the FFT case, relative magnitudes are known to be more correlated with perception of timbre than the raw amplitudes are, magnitudes of MFCC coefficients are important descriptors of timbre, so we do not normalize the

MFCC's, instead predicting the real values.

5.2 Baseline

As a baseline, we compute the element-wise mean of the feature vectors over the entire training set. This vector is computed once for each value of the number of mixture components M. Models that perform better than this baseline can be said to be capturing some useful information about how the features sum together. One important factor to take into account when evaluating results it that as we increase M, mixing more and more notes together, the variance in the features of the mixtures decreases, making the predictive task appear easier. The MFCC features, because they are much lower dimensional than the FFT's, are especially effected by this change in variance; the higher dimensional FFT features exhibit the same trend but to a smaller extent, as they can capture a wider range of combinations of signals. For this reason, in Section 6, we report error metrics as a percentage relative to the error metric of this baseline at the corresponding value of M. Concretely, an error of 0.5 would mean that, averaged over the test set, the sum of squared errors of our predictions was equal to half of the sum of squared errors obtained by always predicting the mean of the data set.

5.3 Linear Combination

The first model we examine is the linear combination of features proposed in [9], which is currently used in state-of-the-art assisted orchestration systems [10]. This model implicitly assumes that for a feature f, the feature of the sum is approximately equal to the sum of the features:

$$w_1 f(S_1) + \ldots + w_M f(S_M) \approx f(w_1 S_1 + \ldots w_M S_M) \quad (1)$$

When features are linear or can be well approximated linearly, this method can be a strong baseline. Especially with high dimensional features like our 1024 FFT magnitudes, subtle details that might be difficult to summarize in an intermediate representation can be easily preserved with a linear model.

For this model, we combine source features in two ways, first by taking the element-wise mean of the M feature vectors as shown in Equation (2) and second by weighting the features by the corresponding RMS energies $a_1 \ldots a_M$ of the component signals as in Equation (3):

$$\bar{f} = \frac{1}{M} \sum_{f_i} \quad (2)$$

$$\tilde{f} = \frac{\sum f_i a_i}{\sum a_i} \quad (3)$$

5.4 MLP

Particularly for nonlinear features, it is reasonable to expect that nonlinear models have the potential to make better estimates. We train multilayer perceptron (MLP) neural networks to predict both FFT and MFCC features. For these models, we use a single hidden layer, and we minimize the mean squared error (MSE) between the predictions and the targets. For the FFT models, in order to constrain the network to output magnitudes between 0 and 1, we use a ReLU activation followed by a L_∞ normalization layer as the last stage in our network. Although we found empirically that sigmoid activations gave similar accuracies, these choices match better with the intuition of normalization performed in preprocessing. We train all our neural network models with Tensorflow [1] and Keras [12], Dropout [27], and the Adam optimizer [19].

Because we are interested in testing our methods on a variable number of audio mixtures M, we train separate MLP models for each value of M. As M increases, the input size and number of parameters in the network increases accordingly; with a feature of dimension D and a hidden layer of size H, the first layer of these networks has $D \times M \times H$ trainable parameters.

5.5 LSTM

As we increase the number of mixtures M, a recurrent network architecture is a natural choice to reduce the number of parameters needed. Intuitively, if a network can learn to estimate the sum of two signals, the same network should be able to process M signals in sequence over M steps by estimating the sum of one signal with the sum of all the signals processed so far.

5.5.1 Ordered Sets

Because the true sum of M signals is independent of the order in which they are combined, we experiment with two approaches inspired by the literature on sequence models for sets. First, even when no true ordering exists, previous results demonstrate that the ordering of inputs to factorized probabilistic models still affects the ability of models to learn [29]. In the case where two semantically valid orderings exist, empirical results from machine translation show that simple changes to the ordering, such as reversing the words in a sentence, can significantly affect model performance [28]. Based on these results, for this variant of the model, we sort the signals by their L_2 norm before passing them to LSTM model, such that the source signal with the highest energy is observed at the final timestep before outputting a final prediction.

5.5.2 Unordered Sets

Although previous work points to the benefits of ordering the signals in a consistent way, fixing an ordering prevents us from implementing a simple but potentially powerful form of data augmentation - randomly shuffling the order of mixtures during training. We empirically test the relative benefits of these two options, reporting results for both ordered and unordered inputs with the same LSTM archicture.

5.5.3 Residual Connections

Finally, we experiment with one more variation of our LSTM model, in which we add a residual connection [17]

between the model inputs at each timestep and the outputs of the LSTM layer, which allows information to pass directly from the input to the final layer without having to be mediated by the nonlinear structure of the LSTM. Intuitively, to the degree to which features are linear, this connection should provide the model with the option to directly sum up the features as part of its computation.

6. RESULTS

We train and evaluate all of the models across 6 different numbers of mixtures M ranging from 2 to 30, summarizing the results in Tables 1 and 2 and displaying the trends across values of M in Figures 2 and 3.

6.1 Predicting FFT Features

As demonstrated in Figure 2, the linear combination outperform the neural methods for values of M between 2 and 12, but the LSTM models make up ground and ultimately begin to overtake the linear combinations at $M = 20$ mixtures. All of the models in the FFT setting trend up in error towards the baseline as the number of mixtures increases; with $M = 30$, all models except for the residual LSTM cross the threshold of the baseline. These results indicate several findings:

- While the ordering in which the mixtures are passed to the LSTM model does not appear to make a significant difference here, the residual LSTM model outperforms the rest of the neural methods at all values of M, demonstrating increasingly large gains as the number of mixtures goes up. This suggests that the residual connection may be enabling the model to exploit the linearity of features when it is advantageous to do so, while maintaining flexibility to make better estimations once the signal from the linearity of the feature fades.
- In confirmation with previous findings [9], these results suggest that linear approximations of FFT features can be quite accurate. As the number of mixtures increases, however, these estimates worsen; by $M = 30$, the linear approximations are no better than random.
- Although estimating a high dimensional feature like the FFT is clearly a challenging task as many streams of audio are mixed together, these results show that neural models do possess the potential to estimate these features to some degree even in settings with many different sources.

6.2 Predicting MFCC Features

Unlike in the case of the FFT features, all of the neural models outperform the linear combination for both small and large numbers of mixtures, and as shown in Figure 3, with more than 6 mixtures, linear combinations of MFCC features no longer contain a useful signal. We detail our findings from the MFCC experiments below:

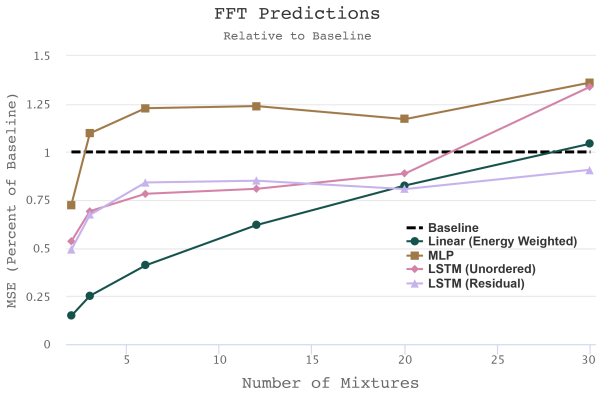

Figure 2. The linear models work well for predicting FFT features of small numbers of mixtures, but at around $M = 20$ mixtures, the best performing LSTM model overtakes the linear combination.

- Because MFCC features are nonlinear, it is not surprising that nonlinear models are able to predict them better than the linear combination. Relative to the baseline, however, we can see that for mixtures of 2, 3, and even 6 different sources, a linear combination of MFFC's can still be reasonably accurate. This suggests that in some cases, MFFC features do behave approximately linearly when summed.
- In contrast to the FFT setting, the residual LSTM does not appear to offer any gains in comparison with the other LSTM models. Perhaps because of the much smaller dimension of the features, the Unordered LSTM model, which we train with data augmentation by randomizing the order in which mixtures of processed, performs best.
- As M continues to increase, the accuracies of the LSTM models flatten out rather than continuing to approach the baseline. This trend suggests that even when dozens of notes are mixed together, we may be still able to estimate certain features of these mixtures based only on the features of the source files.

6.3 Computation Time

While the exact computation time of FFT or MFFC features depends on the implementation, the length of the audio files, and the availability of parallel processing, estimating features with the networks we explore is, in practice, significantly faster than computing the real features. Though it is beyond the scope of this paper to report results on a comprehensive list of hardware and software configurations, as a point of reference, Table 3 displays running times for parallel computation on our research server containing 20 CPU's and one Tesla K40 GPU.

7. CONCLUSIONS

In this work, we experiment with neural models for predicting unobserved audio features based on precomputed

Model	2 Mixtures	3 Mixtures	6 Mixtures	12 Mixtures	20 Mixtures	30 Mixtures

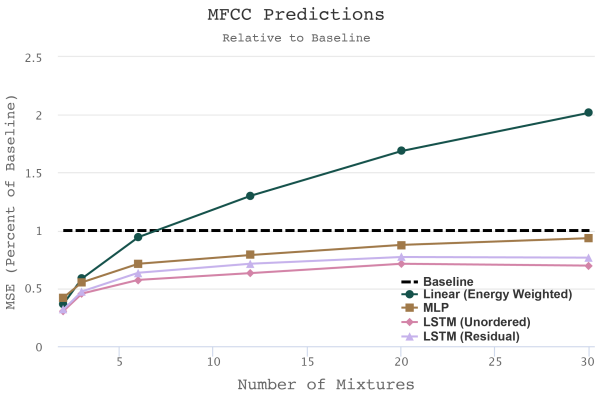

Figure 3. The neural models outperform the linear combinations significantly, widening the gap as M increases.

Feature	**Real** (CPU x 20)	**LSTM** (CPU x 20)	**LSTM** (GPU x 1)
FFT (Mix 2)	14.71	0.32	0.07
FFT (Mix 30)	14.71	4.75	1.10
MFCC (Mix 2)	73.50	0.03	0.01
MFCC (Mix 30)	73.50	0.34	0.15

Table 3. Time in seconds to compute or estimate energy-weighted FFT or MFCC features for the 2000 audio files in the test set using parallel processing. FFT (Mix 30) refers to the FFT feature of a mixture of 30 audio files, which requires 30 autoregressive LSTM steps. LSTM refers to the Residual LSTM model.

features of source files in a mixture, examining the cases of FFT features, which should behave linearly when summed, as well as MFCC's, which are known to be nonlinear. We find that in the case of nonlinear features, LSTM models significantly outperform the methods currently in use for feature estimation, and further, that while the linear predictors perform well for small numbers of mixtures, as we mix more and more signals together, the neural models begin to outperform the linear methods as well.

Our results suggest that we may be able to improve current assisted orchestration systems [10] by replacing feature estimation components with LSTM-based nonlinear predictors. As with any real-world problem that involves perceptual similarity rather than comparisons in a feature space, however, more work is needed to understand how these models may interact with other components of systems they may be embedded in. Deep neural network models can and do adapt to any correlations present in the data, so understanding how these models are making there estimates may be important.

Beyond tasks like assisted orchestration in which we cannot always observe the features of an audio file because of computational limitations, we hope that future work may be able to take advantage of the methods for feature estimation explored here in order to make creative use of data like the Million Song Dataset, for which precomputed features are available but raw data cannot be distributed.

ABSTRACT

A common method to create beat annotations for music recordings is to let a human annotator tap along with them. However, this method is problematic due to the limited human ability to temporally align taps with audio cues for beats accurately. In order to create accurate beat annotations, it is therefore typically necessary to manually correct the recorded taps in a subsequent step, which is a cumbersome task. In this work we aim to automate this correction step by "snapping" the taps to close-by audio cues—a strategy that is often used by beat tracking algorithms to refine their beat estimates. The main contributions of this paper can be summarized as follows. First, we formalize the automated correction procedure mathematically. Second, we introduce a novel visualization method that serves as a tool to analyze the results of the correction procedure for potential errors. Third, we present a new dataset consisting of beat annotations for 101 music recordings. Fourth, we use this dataset to perform a listening experiment as well as a quantitative study to show the effectiveness of our snapping procedure.

1. INTRODUCTION

Identifying the time positions of beats in music recordings has been a core task in the Music Information Retrieval (MIR) community for a long time. Irrespectively of whether the goal is to evaluate beat tracking algorithms or to train new data-driven models for beat detection, it is necessary to have accurate annotations that describe the temporal locations of beats in music recordings. The beat positions of a music recording are often loosely defined as the time instances where a human would tap along when listening to it [6]. A straightforward approach to create beat annotations is therefore to record these taps—for example by using a specialized audio player software like *Sonic Visualizer* [5], which allows annotators to tap on a key of the keyboard. This method was used, for example, in [20, 21, 25, 26]. However, this procedure is problematic due to the limited ability of humans to accurately align their taps with acoustic cues that are associated with beats such as instrument onsets, percussive sound events, or chord changes [29, 30]. Perception literature indicates that, depending on the complexity of a recording, the onset times of two tones must differ by less than 40 milliseconds such that they may be perceived as being temporally aligned [19]. This means that when sonifying human-made taps with a click track, a click and an audio cue for a beat have to both fall into an interval of at most 40 milliseconds such that the click could be perceived as accurately representing the beat position. [1] This is often not the case as is illustrated in Figure 1. In Figure 1a, we see a short spectrogram excerpt of the song "T'envoler" by Paul Daraiche (item 006 in our dataset, see Table 1 for the YouTube link). One can observe the vertical spectral structures originating from the piano onsets in the song's intro. The human-made taps are visualized in Figure 1b. They roughly coincide with the audio cues, but precede them by about 80 milliseconds most of the time. To obtain more accurate beat annotations, several approaches have been used in the past. One way is to manually correct the taps of a human annotator in a subsequent step [20,21]. However, manual corrections are cumbersome to perform since often every single tap has to be corrected individually—usually in a drag&drop fashion using tools like Sonic Visualizer. Another approach, which has been used in [15, 24], is to compute an initial

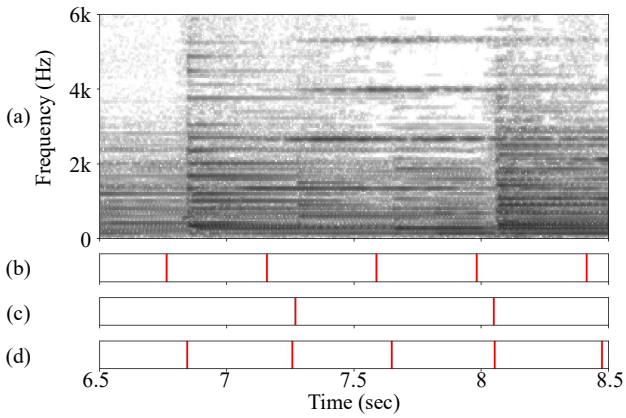

Figure 1. **(a)** Excerpt of the spectrogram for item 006 from our dataset, **(b)** taps by the annotator, **(c)** beat positions as estimated by [4], **(d)** automatically corrected taps.

[1] Note that the 40 milliseconds constitute an upper bound. Depending on the quality of the audio cue this threshold may be significantly lower.

estimate of the beat positions using a beat tracking algorithm. Beat trackers such as [3, 14] actively aim to "snap" potential beat candidates to close-by audio cues in order to create accurate results. In Figure 1c, we see the beat positions as estimated by *madmom*, a Python library featuring a state-of-the-art beat tracker [3, 4]. The estimated beats are well aligned with the audio cues visible in the spectrogram. However, we also see that only every other beat has been captured. Correcting these kinds of errors made by beat tracking algorithms can be just as cumbersome as manually correcting the taps of a human annotator.

In this paper, we propose a new way of creating beat annotations. Our idea is to mostly automate the manual correction of human-made taps by using the concept of snapping beat candidates to audio cues. The intuition is that the taps made by an annotator constitute good beat candidates that are located in close proximity to the actual beat positions. Therefore, snapping them to nearby audio cues should accurately correct the vast majority of taps. This is visualized in Figure 1d, where the automatically corrected taps are aligned with the audio cues in the spectrogram. In this paper, we explore this simple idea in a systematic fashion. First, in Section 2, we model the automatic correction procedure mathematically. Then, in Section 3, we propose a novel visualization that can serve as a tool to reveal rhythmically challenging sections in music recordings as well as potential errors made by the snapping procedure. Section 4 is dedicated to experiments. In Section 4.1, we apply our proposed annotation strategy to create a dataset of beat annotations for 101 music recordings from YouTube. In Section 4.2, we then discuss the results of a listening experiment that shows that human listeners perceive the corrected taps as more accurate than the original taps. In Sections 4.3, we finally conduct a small study that investigates the effect of using either the original or the corrected taps as ground truth for the quantitative evaluation of different beat tracking algorithms. For the purpose of reproducibility, we made our Python implementations (snapping procedure and visualizations) as well as the dataset of beat annotations along with YouTube identifiers publicly available at [13].

2. PROPOSED PROCEDURE

In this section, we formalize our procedure for the automatic correction of human-made taps. We start by explaining the core ideas in Section 2.1 and discuss choices of specific processing steps in Section 2.2.

2.1 Basic Principle

The goal of our proposed procedure is to correct the human-made taps by snapping them to nearby audio cues in the music recording. Our fundamental assumption is that each of the taps indicates the rough position of a beat such that the "real" beat position can be found in close temporal proximity. Given the music recording $x : \mathbb{Z} \to \mathbb{R}$ (Figure 2a), we first derive an *activation curve* $a : \mathbb{Z} \to \mathbb{R}$ (Figure 2b) that is sampled at a sampling rate of $f_s \in \mathbb{R}^+$

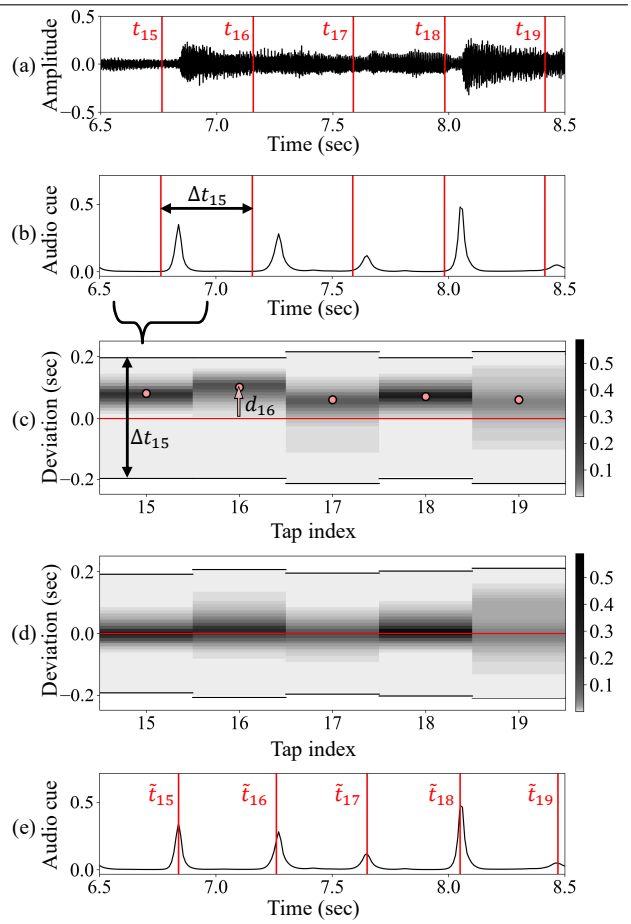

Figure 2. Proposed tap correction procedure. **(a)** Music recording x with taps t. **(b)** Activation curve a. **(c)** Deviation function $\mathcal{D}_t$ with envelope reflecting the inter-tap-intervals, tap positions indicated by red line, and deviation sequence d indicated by light-red dots. **(d)** Deviation function $\mathcal{D}_{\tilde{t}}$ with corrected taps $\tilde{t}$ indicated by red line. **(e)** Activation curve a with corrected taps $\tilde{t}$ indicated in red.

(we use f_s=100 Hertz as suggested in [4, 12, 17]). An activation curve a can be seen as a function whose values $a(n)$ reflect how likely it is that there is a beat present in the music recording x at time n/f_s. We discuss different choices for activation curves in Section 2.2. Along with x and a, we are also given the *sequence of taps* $t = [t_0, \ldots, t_{M-1}]$ with $t_m \in \mathbb{Z}$. Each tap t_m indicates that the human annotator tapped at time t_m/f_s. In our example in Figure 2b one can see that the taps are not well aligned with the peaks in the activation curve a.

With the activation curve and the taps, we now compute the *deviation function* $\mathcal{D}_t : \mathbb{Z} \times [0 : M-1] \to \mathbb{R}$ by

$$\mathcal{D}_t(n, m) := w_m(n)\ a(t_m + n)$$

for $n \in \mathbb{Z}, m \in [0 : M-1]$. Here, $w_m : \mathbb{Z} \to \mathbb{R}$ is a Hann window centered around zero, whose length is defined by the *inter-tap-interval*

$$\Delta t_m := t_{m+1} - t_m$$

for $m \in [0 : M-2]$ and we define $\Delta t_{M-1} := \Delta t_{M-2}$ (such that Δt_m is defined for all taps). The reason for using a

window function is to effectively implement our assumption that the taps are located in close temporal proximity to the actual beat positions. The more temporal distance between a tap and a high activation value, the less likely it is that the activation value reflects the actual beat the tap was meant to represent. In the visualization of $\mathcal{D}_t$ seen in Figure 2c, the length of w_m is indicated with two additional black lines in each column of $\mathcal{D}_t$. This "envelope" of $\mathcal{D}_t$ serves as a visual representation of the individual inter-tap-intervals. In our example, the envelope does not exhibit any significant variation across the shown taps which indicates that the annotator tapped with an almost constant tempo. However, when looking at the individual activation maxima in each column of $\mathcal{D}_t$—which can be found at deviations between 70 and 110 milliseconds—it becomes obvious that the inaccuracy of the human-made taps is not just a constant offset but varies over time.

In the next step we compute the *deviation sequence* $d = [d_0, \ldots, d_{M-1}]$, $d_m \in \mathbb{Z}$, that indicates the individual corrections we will apply to each tap t_m (Figure 2c). There are several options of how to derive d from $\mathcal{D}_t$ which we discuss in Section 2.2. From t and d we finally compute the *automatically corrected taps* $\tilde{t} = [\tilde{t}_0, \ldots, \tilde{t}_{M-1}]$ by

$$\tilde{t}_m := t_m + d_m \ .$$

Based on $\tilde{t}$ we now can also compute the deviation function $\mathcal{D}_{\tilde{t}}$ (Figure 2d). Note that in this visualization, all high activation values are now centered around a deviation of zero. Furthermore, the envelope of $\mathcal{D}_{\tilde{t}}$ does not differ significantly from the envelope of $\mathcal{D}_t$ which indicates that the inter-tap-intervals in $\tilde{t}$ are similar to those in the original tap sequence t. This can be verified when plotting $\tilde{t}$ on top of the activation curve a where the taps now accurately align with the peaks (Figure 2e).

2.2 Technical Realization

In traditional music signal processing, a common choice for activation curves are *novelty curves*, see for example [2, 7, 27]. These functions are designed to reflect sudden temporal changes in a music recording's spectrogram, which are typically caused by percussive sound events such as instrument onsets. As beats often go along with these kinds of sound events it is reasonable to use a novelty curve as activation curve in our tap correction procedure. We denote this activation curve by a^{nov} and the resulting deviation function for taps t by $\mathcal{D}_t^{\text{nov}}$.

Another option is using activation curves based on data-driven models. Recently, models that were trained to transform spectrogram representations of music recordings into activation curves have significantly improved the quality of state-of-the-art beat tracking algorithms [16]. For example in [4], a *deep neural network* (DNN) using a bidirectional long-short-term memory architecture is trained on a large collection of beat-annotated music recordings for that task. It was shown in [4] that the peaks in activation curves derived using this model align well with beats in the underlying music recordings. Using it in our procedure is therefore

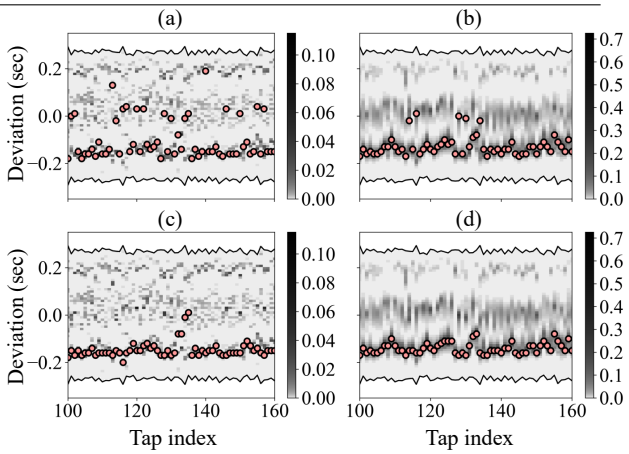

Figure 3. Excerpts of different deviation functions and deviation sequences for item `011`. **(a)** $\mathcal{D}_t^{\text{nov}}$ with $d^{\max}$ derived from it. **(b)** $\mathcal{D}_t^{\text{DNN}}$ with $d^{\max}$ derived from it. **(c)** $\mathcal{D}_t^{\text{nov}}$ with d^{con} derived from it. **(d)** $\mathcal{D}_t^{\text{DNN}}$ with d^{con} derived from it.

reasonable as well (we use the implementation freely available in [3]). We denote the resulting activation curves by a^{DNN} and the deviation function by $\mathcal{D}_t^{\text{DNN}}$, respectively.

We also have several choices concerning the derivation of the deviation sequence d from $\mathcal{D}_t$. A straight-forward way is to simply pick the deviation that yields the highest activation value in each column of $\mathcal{D}_t$ as

$$d_m^{\max} := \operatorname*{argmax}_n \mathcal{D}_t(n, m) \ .$$

While this method considers every tap individually, it is also possible to incorporate some contextual information into the derivation by defining

$$d^{\text{con}} := \operatorname*{argmax}_{[d_0,\ldots,d_{M-1}]} \mathcal{D}_t(d_0, 0) \prod_{m=1}^{M-1} \mathcal{D}_t(d_m, m)\, \mathcal{T}(d_{m-1}, d_m),$$

with $\mathcal{T} : \mathbb{Z} \times \mathbb{Z}$ being a transition function defined by

$$\mathcal{T}(i, j) := e^{-\lambda|i-j|}$$

with $i, j \in \mathbb{Z}$. The sequence d^{con} can be derived using dynamic programming. The idea, inspired by [14, 22], is that subsequent human taps are unlikely to drastically vary in their deviation from the actual beat. To reflect this, the use of the transition function $\mathcal{T}$ makes it unlikely to have large deviation jumps from one tap to the next (we use λ=0.1 in our experiments). Furthermore, this method also allows us to correct *non-event beats* [18], meaning taps for which no cue in the music recording exists. In this case, the activation curve shows no salient values around the tap and $\mathcal{T}$ favors a constant deviation until there are clear cues in the activation curve again.

Figure 3 shows the two types of deviation functions $\mathcal{D}_t^{\text{nov}}$ and $\mathcal{D}_t^{\text{DNN}}$ in combination with the two methods for deriving the deviation sequences $d^{\max}$ and d^{con}. We use item `011` in our dataset as an example (see Table 1). It is a rather old recording featuring singing voice, acoustic guitar, mouth-organ, and piano. Comparing $\mathcal{D}_t^{\text{nov}}$ in Figure 3a/c to $\mathcal{D}_t^{\text{DNN}}$ as seen in Figure 3b/d, we can observe

item	YouTubeID	artist	song title
006	I3gHugP6bPE	Paul Daraiche	T'envoler
009	hRFLv29K__o	La Sonora Dinamita	Escandalo
011	M7u5SdjDSQQ	The Lovin' Spoonful	Daydream
025	8jsFGdeWNPo	Nicky Jam	Juegos Prohibidos
040	1zrxnqejwCk	Los Tigres Del Norte	Mañanitas Tapatias
046	ebZZpVFUQDY	Green Valley	Relaja
048	B_e7QbWc5mI	Orthodox Celts	Rocky Road To Dublin

Table 1. List of dataset items used throughout this paper. The YouTube videos can be found by using the URL `www.youtube.com/watch?v=[YouTubeID]`.

that $\mathcal{D}_t^{\text{nov}}$ is noisier while the structures seen in $\mathcal{D}_t^{\text{DNN}}$ are smoother and more salient. This becomes obvious when comparing the two $d^{\max}$ in Figure 3a and b. While the $d^{\max}$ based on $\mathcal{D}_t^{\text{nov}}$ jumps back and forth between deviations of about -0.2 and $+0.2$ seconds, $d^{\max}$ for $\mathcal{D}_t^{\text{DNN}}$ is more stable, showing only a few jumps between tap indices 115 and 135. The strength of using contextual information in the computation of the deviation sequence is visible in Figure 3c, where we see d^{con} based on $\mathcal{D}_t^{\text{nov}}$. Here, similar as in Figure 3b, most deviation values cluster around -0.2 seconds, except for a short passage of deviation 0 around tap index 135. This is caused by a single very strong activation value which does not coincide with a beat position in the recording. In the deviation function $\mathcal{D}_t^{\text{DNN}}$ this spurious activation is not present and the deviation sequence d^{con} in Figure 3d does not show prominent jumps. When listening to the sonified automatically corrected taps based on this deviation sequence, one can hear that they are in fact very accurate. Overall, we made similar observations for the vast majority of songs in our dataset. For this reason, we chose the combination of $\mathcal{D}_t^{\text{DNN}}$ with d^{con} in our subsequent experiments and also refer to them by just $\mathcal{D}_t$ and d for the sake of simplicity.

3. ANALYSIS OF AUTOMATED CORRECTIONS

Although the method introduced in the previous section is capable of automatically correcting the vast majority of taps, there is still potential for error. To find these errors efficiently, visualizing the deviation functions $\mathcal{D}_t$ and $\mathcal{D}_{\tilde{t}}$ can give helpful insights into the automatic correction process, point to problematic sections in music recordings, and reveal anomalies in the human-made taps. In Figure 4, we show several examples.

Figure 4a depicts the deviation functions of the original and automatically corrected taps for item `009`. This latin american song features strong and steady rhythmic pulses, which is reflected in the activation values visible in $\mathcal{D}_t$. In each column of $\mathcal{D}_t$, there is basically only one high activation value. The deviation sequence d nicely captures this train of high activations, which leads to a very clean deviation function $\mathcal{D}_{\tilde{t}}$. Note that the inter-tap-intervals in $\mathcal{D}_{\tilde{t}}$ are more regular than in $\mathcal{D}_t$, which can be seen by the envelope of $\mathcal{D}_{\tilde{t}}$ being less noisy than the one of $\mathcal{D}_t$. Based on this visualization, it is rather safe to assume that the corrected taps are accurate with virtually no errors. One thing noteworthy about this example is that d has a fairly constant offset of about -90 milliseconds, meaning that almost all original taps were about 90 milliseconds behind the beat. This was caused by technical problems in the process of recording the taps of the human annotator, which caused delays between the physical taps and the registered times.

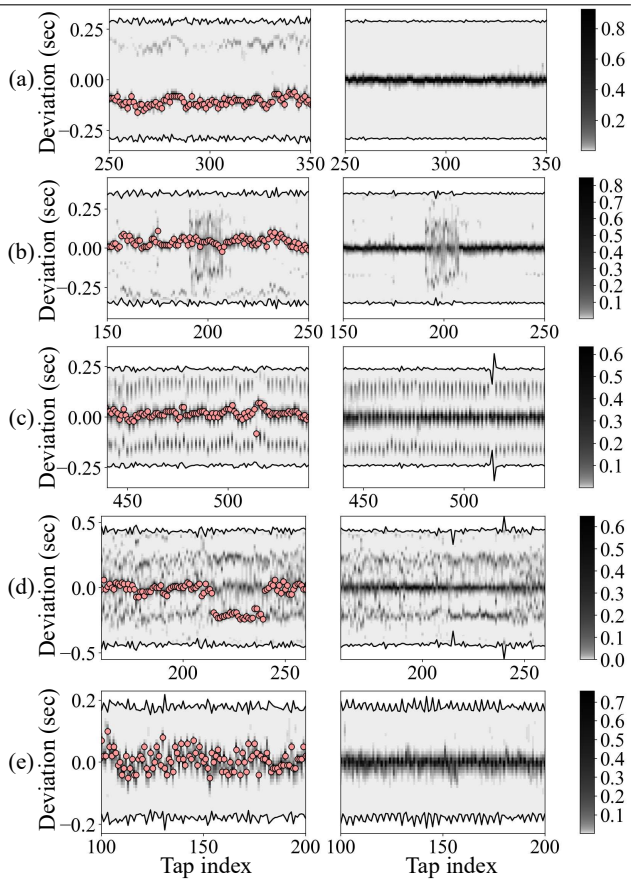

Figure 4. Deviation functions $\mathcal{D}_t$ (left) and $\mathcal{D}_{\tilde{t}}$ (right) for excerpts of different items from our proposed dataset. **(a)** Item `009` (2:25 to 3:23), **(b)** item `025` (2:12 to 3:22), **(c)** item `048` (3:30 to 4:18), **(d)** item `046` (2:21 to 3:49), **(d)** item `040` (0:37 to 1:13).

In Figure 4b, we see the deviation functions for item `025`. This hip hop song again has a very clear and prominent beat, which is reflected in the activations in $\mathcal{D}_t$. However, around the 200$^{\text{th}}$ beat, the song has a short part without any percussions. This manifests in $\mathcal{D}_t$ as a blurry section, which is caused by low and diffuse activation values. Since this indicates that there are fewer audio cues that the procedure can utilize to correct the original taps, such sections should be manually inspected after the automatic correction step. In this particular example the inspection showed that no manual corrections were necessary.

As a third example, we see the deviation functions for item `048` in Figure 4c. In the last part of this Irish folk song the bass drum plays a swing-like rhythm. This pattern causes the activation structures as seen in $\mathcal{D}_t$ with strong activations around deviation zero and weaker ones at about ± 200 milliseconds for every other tap. In the computation of the deviation sequence d, this lead to an error at tap in-

dex 510, where the tap was incorrectly snapped to one of the activations caused by the rhythmic ornaments. This single tap, misplaced by the correction procedure, can be easily detected in our visualization, since it caused a distinct structure in the envelope of $\mathcal{D}_{\tilde{t}}$, where it manifested in a "lightning" pattern.

A similar error can be seen in Figure 4d, which shows the deviation functions of an excerpt from item 046. This acoustic song featuring vocals, guitar, and keyboard is pretty challenging for beat tracking due to the lack of strong audio cues for beats, as can be seen by the rather noisy activations in $\mathcal{D}_t$. As in the previous example, the used rhythmic pattern, this time played by the guitar, causes strong activations at non-beat positions. In the computation of the deviation sequence d, these lead to a section of about 30 taps that were incorrectly snapped to these off-beat guitar accents rather than the actual beats. This can be seen by d being shifted to a deviation of about -0.2 seconds from tap index 210 to 240. The visualization of d allowed us to easily locate and understand this problematic passage, which could then be corrected manually in a post-processing step.

As a final example, Figure 4e shows the deviation functions of an excerpt from item 040. This Polka-like song has a $3/4$ time signature, but the third beat in each bar is consistently played late. [2] The human annotator tapped through the song in a rather straight fashion, not explicitly reflecting this rhythmic pattern. The automatic correction procedure then aligned each tap with the closest instrument onset, resulting in unevenly spaced corrected taps. This is visible as regular spike pattern in the envelope of $\mathcal{D}_{\tilde{t}}$. Whether the corrected taps reflect the "true" beat positions is dependent on whether one sees the delayed note onsets as part of the rhythm or mere ornamentation. Either way, this interesting example was easily revealed by our visualization of the deviation functions.

4. EXPERIMENTS

In this section, we evaluate our proposed procedure. We first introduce in Section 4.1 a dataset of beat annotations which we created using our correction procedure. Then, in Section 4.2, we discuss the results of a listening experiment to show that the corrected taps are actually perceived as being more accurate than the original taps. Finally, in Section 4.3, we show how the choice of annotation used as ground truth influences the evaluation of beat tracking algorithms.

4.1 The Dataset

In order to show the usefulness of our proposed tap correction procedure in a real-world annotation scenario, we applied it to create a new dataset of beat annotations. To this end, we selected 101 different music recordings available on YouTube. [3] This collection, which consists of about 7.25 hours of music in total, comprises a variety of different genres, recording conditions and instrumentations. Similar to [1, 23], we decided to use music recordings from YouTube to ensure reproducibility of our results. For each of these recordings, a musically experienced annotator tapped along to create the tap sequences t using Sonic Visualizer, adding up to 41.011 individual taps. The sequences of automatically corrected taps $\tilde{t}$ were then computed for each recording using the method described in Section 2. Each sequence $\tilde{t}$ was then manually inspected by the first author using Sonic Visualizer. In this step, a total of 331 incorrect taps were identified across 54 of the 101 sequences and corrected manually. We denote the resulting *fully corrected tap sequences* by $\tilde{t}'$.

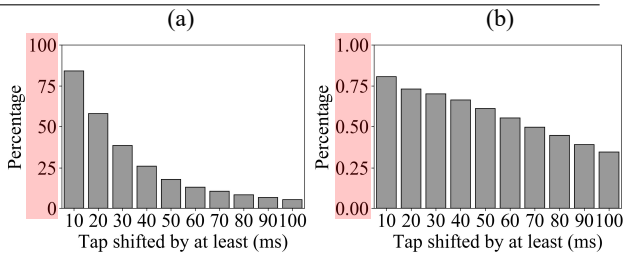

Figure 5. Percentage of the 41.011 original taps that were shifted in the two consecutive automatic and manual correction steps. Note the different scales of the vertical axes. **(a)** Creating $\tilde{t}$ from t, **(b)** creating $\tilde{t}'$ from $\tilde{t}$.

Figure 5 summarizes the distribution of shifts applied to the individual taps in the two consecutive correction steps. In Figure 5a we can see that about 25% of the original taps were shifted by 40 milliseconds or more by the automatic correction procedure. This means that in case these corrections would have been done manually, about one in four taps, would have been shifted—even when assuming that smaller inaccuracies where taps were misaligned with audio cues by less than 40 milliseconds would not have been considered. To create the fully corrected taps on the other hand, less than 1% of the 41.011 original taps were shifted at all, see Figure 5b. The shifts applied in the manual correction step were equally distributed between very small and larger shifts which can be seen by the rather constant slope of the graph.

The dataset containing all three annotations t, $\tilde{t}$, and $\tilde{t}'$ for each recording as well as metadata and the respective YouTube links is available at [13].

4.2 Listening Experiment

With the creation of the fully corrected taps $\tilde{t}'$, the main question is whether the applied corrections actually make the beat annotations perceptually more accurate—and therefore better. To answer this, we conducted a listening experiment. For each of the 101 recordings in our dataset, we created two new recordings by sonifying the taps t as well as the fully corrected taps $\tilde{t}'$ as a click track and superimposed each of them on the original mu-

[2] This observed rhythmic pattern is rather unusual for the style of the song but commonly found in Viennese Waltz.

[3] The dataset is part of a Chordify project that assesses the quality of automatically generated annotations in a large scale industry setting. The selected recordings reflect a random sample of songs used on Chordify, weighted by their popularity on the service.

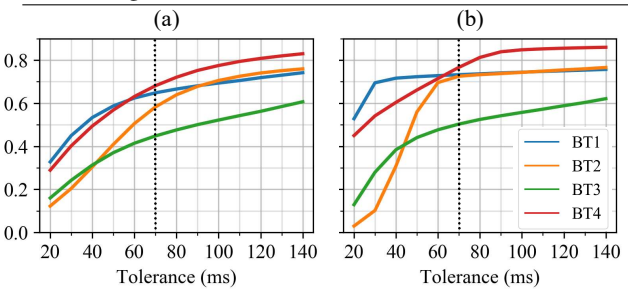

Figure 6. Average beat F-measures on our dataset for four different beat tracking algorithms when using different ground truth annotations. **(a)** Original taps t, **(b)** fully corrected taps $\tilde{t}'$.

sic recording. Note that we chose to use the fully corrected taps $\tilde{t}'$ rather than the automatically corrected taps $\tilde{t}$ because the difference between $\tilde{t}$ and $\tilde{t}'$ is very small and we did not want the participants to focus on the few noticeable mistakes made by the automatic correction procedure. Three musically trained people took part in the experiment, none of them being one of the authors. Each participant was presented with the 101 pairs of recordings and asked to pick the recording with the more accurate click track from each pair. The order in which the two recordings of a pair were presented was random and the participants did not know whether the clicks they heard were the original taps t or the fully corrected taps $\tilde{t}'$. They were able to listen to each recording for as long and as often as they liked before making their decision. Additionally, they had the opportunity to give comments. The complete set of answers and comments can be found at [13]. Looking at all 303 given answers individually (three participants times 101 pairs), 89% of the time the participants found the fully corrected taps $\tilde{t}'$ to be more accurate than the original taps t. For 72% of the 101 pairs, all three participants even consistently perceived $\tilde{t}'$ to be more accurate than t. Having a closer look at the participants' answers and comments, it turned out that in many instances where a participant chose the original taps to be more accurate than the fully corrected taps, the two click tracks were perceived as being very similar (*"Both are about the same quality, IMO."*). Furthermore, some of the comments also indicate that sometimes there was also a degree of personal preference involved in the decision (*"...[the click track] lags like a proper gospel drummer."*). Overall, the results show that the fully corrected taps $\tilde{t}'$ are commonly perceived as more accurate than the original taps t.

4.3 Quantitative Study

As a final experiment, we were interested in the effects of using either the original taps t or the fully corrected taps $\tilde{t}'$ as ground truth for a quantitative evaluation of beat tracking algorithms. We investigated four different algorithms: The *Queen Mary beat tracker* (BT1) [10], the *librosa beat tracker* (BT2) [14], the *Aubio beat tracker* (BT3) [8, 9], and our own implementation of [4] (BT4). Note that the madmom beat tracker [3,4], which would have an intrinsic advantage since our tap correction procedure is built upon the same activation curve, is not among them. For each of the four beat tracking algorithms, we computed the *beat F-measure* [11], a popular beat tracking evaluation measure, for all recordings in our dataset. We did this two times, once taking the original taps t as ground truth and once the fully corrected taps $\tilde{t}'$, see Figure 6a and 6b, respectively. An important parameter in the computation of the beat F-measure is the tolerance, which determines the maximal temporal distance between an estimated beat and a ground truth beat such that the estimate can be considered correct. In Figure 6, we see that for a very large tolerance (140 milliseconds and above) it basically makes no difference whether we use t or $\tilde{t}'$ as ground truth. This makes sense when recalling that most of the corrections applied were smaller than 100 milliseconds (see Section 4.1). However, this changes when considering a smaller, and hence more realistic tolerance. The default tolerance as implemented in *mir_eval* [28], the Python library we used for this evaluation, is 70 milliseconds, indicated by dotted black lines in Figure 6. At this tolerance, the computed beat F-measures differ noticeably depending on the ground truth. For example, BT4 achieves an average beat F-measure of 0.68 when the original taps t are used as ground truth, but 0.77 when the fully corrected taps $\tilde{t}'$ are used. The difference is even more prominent when comparing BT1 and BT2. Here, BT1 scores much better (0.65) than BT2 (0.58) when comparing the two algorithms based on the original taps. However, when using the fully corrected taps as ground truth, the algorithms perform nearly identically (both 0.73). For smaller tolerances, the differences between the individual algorithms become even more salient. For example, at a tolerance of 30 milliseconds and using the original taps as ground truth, BT1 and BT2 differ in beat F-measure by 0.25 (scoring 0.45 and 0.20, respectively), while differing by 0.59 (scoring 0.69 and 0.10, respectively) on the fully corrected taps. This shows that it can make a substantial difference for quantitative evaluations of beat tracking algorithms whether the underlying ground truth annotations are "only" human-made taps or corrected ones.

5. CONCLUSIONS

In this paper we proposed and formalized a simple procedure for correcting tapped beat annotations by automatically "snapping" the tap positions to cues in the underlying music recording. Furthermore, we proposed a visualization that can help identifying errors made by the correction procedure as well as rhythmically interesting passages in music recordings. Finally, we created a new dataset for which we showed that beat annotations corrected with our procedure are perceived as being more accurate and that using them for the quantitative evaluation of beat tracking algorithms may significantly impact the evaluation results. The last observation motivates us to apply our proposed correction procedure to beat annotated datasets commonly used in the MIR community. We believe that our proposed visualization could help in identifying incorrectly annotated recordings and therefore getting a more realistic view on the performance of beat tracking algorithms.

6. ACKNOWLEDGMENTS

We would like to thank Leigh Smith and Sebastian Böck for our discussions at ISMIR 2018 that sparked the ideas for this contribution. Furthermore, we thank Jeroen Bransen for the discussions about the algorithmic details of the procedure, Jeffrey van Rossum for creating the original taps for the recordings in the dataset, as well our listening experiment participants Tijmen Ruizendaal, Matúš Tejiščák, and Bart Laan. Hendrik Schreiber and Meinard Müller are supported by the German Research Foundation (DFG MU 2686/10-1). The International Audio Laboratories Erlangen are a joint institution of the Friedrich-Alexander-Universität Erlangen-Nürnberg (FAU) and Fraunhofer Institut für Integrierte Schaltungen IIS.

ABSTRACT

Music prediction and generation have been of recurring interest in the field of music informatics: many models that emulate listeners' musical expectancies, or that produce novel musical content have been introduced over the past few decades. So far, these models have mostly been evaluated in isolation, following diverse evaluation strategies. Our paper provides an overview of the new MIREX task *Patterns for Prediction*. We introduce a dataset, which contains monophonic and polyphonic data, both in symbolic and audio representations. We suggest a standardized evaluation procedure to compare algorithmic musical predictions. We compare two neural network models to a baseline model and show that algorithmic approaches can correctly predict about a third of a monophonic segment, and around half of a polyphonic segment, with one of the neural network models achieving best results. However, other approaches to algorithmic music prediction are needed to achieve a more rounded picture of the potential of state-of-the-art methods of music prediction.

1. INTRODUCTION

Prediction of future events is fundamental to human and artificial intelligence, and has therefore been discussed as a core research interest bridging cognitive psychology and machine learning [5]. Music, with its complex event sequences extending over time, provides an excellent setting for the study of prediction.

In music cognition, human prediction of future events, or *expectation*, is studied from theoretic, behavioral, imaging, and modeling perspectives. Some theoretical work [2, 15] distinguishes between *veridical*, *schematic*, and *dynamic* expectations: veridical expectations occur due to familiarity with a musical piece, schematic expectations are elicited by familiarity with a genre, and dynamic expectations manifest in-the-moment predictions, when, consciously or subconsciously, a listener becomes attuned to a pattern in a novel piece. It has been claimed that the pleasure we derive from music resides in the tension between these three forms of expectation [15].

While the full complexity of expectation in music may still be hard to capture in computational models, the goal of this paper is to give an overview of how computational models may emulate human expectations through prediction of future musical events, and how we should evaluate such models.

Our main contributions are as follows: first, we review different approaches to modelling expectation in music. Second, we introduce a dataset on which such models can be trained and evaluated. Third, we propose two evaluation tasks and associated evaluation measures. [1] Fourth, we provide the results of a baseline and two more complex models on the tasks. Finally, we discuss findings and recommendations for future model development and evaluation.

2. RELATED WORK

2.1 Approaches to music prediction

2.1.1 Markov models

Markov models have been influential in music prediction: statistics on transitions between musical events may be used to generate predictions for unseen musical events. Musical events may be represented in various ways, such as pitch, duration, onset, metric weight, and so on. Therefore, it has been suggested to build distinct models for different combinations of music representations [11]. Markov models trained on music corpora may very well serve to model schematic expectation, such as a leading tone to be followed by an octave. Dynamic (i.e., work-specific) expectations may also be modelled through a Markovian approach through training on a musical piece itself, where the model is incrementally updated as the piece progresses. The question of how to combine models of various music representations, or how to combine models trained on corpora ("long-term models") and models trained incremen-

[1] The corresponding MIREX task description, datasets, and evaluation code can be found at https://tinyurl.com/y455cf97

tally on a piece ("short-term models") has been experimentally investigated [26], but on specific styles, which might not generalize to other musical genres.

Even though some models can theoretically extend over very long contexts, the question remains whether Markovian models, which are by nature "forgetful", will capture longer structure that may facilitate precise predictions, such as repetition of themes in a Classical piece of music, or the return of the theme in a jazz performance. [36]

2.1.2 Neural networks

Over the last two decades, interest in neural network models for music prediction has been increasing. The first attempts in this direction made use of recurrent neural networks (RNNs) [23], with an input, hidden and output layer, which predict future states of sequential input data. Variants of RNNs, such as long short-term memory models (LSTM), have also been applied to music [13]. Various extensions of such models have been presented since [4, 14].

Another class of neural networks, convolutional neural networks (CNN), is usually used for image data. A musical composition may also be thought of as an image rendered in time-pitch or time-amplitude space. Some authors therefore applied CNNs to piano roll representations of symbolic music [12], or to audio [34] for music prediction.

While these and other neural network architectures have resulted in generation and prediction of music, the output of the models in itself is often not easy to predict. One of the challenges for neural network models, as for Markovian models, is the degree to which they can capture large-scale structure in a musical piece, and recreate dynamic expectations that may arise within a piece in itself.

2.1.3 Pattern discovery

Yet another approach to predicting the musical future is to search for repeating patterns within the piece. This approach emulates dynamic expectations of a listener (patterns occur in earlier parts of a piece, leading to predictions based on later, partially complete occurrences of the same patterns [6, 26]), but less so schematic expectations.

Various algorithms have been proposed to discover repeated patterns within a piece [7, 18, 22, 28, 30, 35], which differ in the kinds of patterns they aim to discover, in the way music is represented, and in the algorithms used to find repetitions [16]. These algorithms have been tested on benchmarks of annotated patterns, while evaluation by prediction is suggested but yet-to-be implemented [21].

2.2 Evaluating music prediction

To ascertain how models compare to human expectations, various approaches have been used: some of them fall in the domain of music generation, while others fall in the domain of information theoretic measures.

2.2.1 Information-theoretic measures

In order to investigate musical predictions of a model with information theoretic measures, the model is trained on a corpus or a corpus subset, then exposed to a novel musical piece. For each musical event, the likelihood of that event according to the model is measured. Alternatively, the uncertainty of the model after each note in predicting the following melody note may be recorded. Ratings of likelihood or uncertainty may then be compared to human ratings from experimental research.

To compare likelihood as rated by a model to human ratings, priming experiments may serve as an evaluation ground: in such experiments, participants had to give an indication as to how well, given a melodic context, a note fitted their expectations [17, 31]. There were also experiments on uncertainty, in which participants were asked to indicate how uncertain they were of what might follow each note in a Bach chorale [19]. As phrase boundaries often coincide with points of greater uncertainty, human segmentations have also been occasionally used as a ground truth for evaluating model predictions [27].

2.2.2 Music generation

A very common way to evaluate predictions from a model is the demonstration of music generated by a given model (e.g., [11]). While this is informative, it is not self-evident how to judge the quality of such an output. Music practitioners of a given genre may be asked as judges [32], but aesthetic judgments alone may not reveal much about a model's shortcomings [1].

Another approach to evaluating music generation is through comparing generated music with human-composed melodies. Human compositions can then be used as the touchstone of how well a model captures structure and style [20]. We choose this approach by providing models with a short piece of music, or prime, and instruct the models to generate a continuation, which we evaluate against the true continuation. Moreover, we test how successfully a model distinguishes between the true continuation and an artificial, foil continuation.

3. A DATASET FOR MUSIC PREDICTIONS

3.1 Dataset construction

We provide small, medium, and large development datasets (100, 1,000, and 10,000 pieces, respectively). This caters to different approaches to designing models for the task, some of which are more data-intensive than others. Each dataset has audio/symbolic and monophonic/polyphonic variants.

Pieces were selected at random from the Lakh MIDI Dataset (LMD) [29] with the aim of creating primes lasting $\approx 35\,\mathrm{sec}$ according to tempo information. True continuations were selected – and foil continuations generated – such that onsets (note start times) occurred in a 10 quarter-note-beat window.

We also constructed a test dataset from another corpus of MIDI files, which is similar in nature to LMD. The test dataset also contains audio/symbolic and monophonic/polyphonic variants, and provides primes, true and foil continuations. In keeping with the MIREX guidelines,

Figure 1. Item from the large, polyphonic variant of the development dataset. Musical provenance unknown.

we will not reveal details about the provenance of the test dataset. What we can say is that the source for the test dataset contains approximately $30,000$ files, and that both this source and LMD are gathered from sites that represent musical interests and tastes, broadly construed. The number of items in the test source tagged as "pop", for instance, is $9,165$. Other items have similar tags, however, such as "latin pop". To our knowledge, no such analysis of genres exists for the LMD, so remarks about the overlap of genres and content between our training and test datasets are necessarily speculative.

MIDI files were selected at random, imported using midi-convert, [2] quantized, and then the following criteria were applied when generating monophonic primes and continuations:

1. A prime had to contain at least 20 notes;
2. The maximum inter-onset interval in a prime could not exceed 8 quarter-note beats;
3. A continuation had to contain at least 10 notes;
4. The channel from which material was selected had to be suitably monophonic prior to *skylining* (see below), meaning at least 80% of minimal segments [25] had to be single notes or rests.

Skylining means to select the highest-sounding notes at each onset and return only those notes, perhaps with modified durations, so that the output is truly monophonic. The rationale for only skylining material that was already 80% or more monophonic is that skylining inherently polyphonic material often results in odd-sounding or implied-polyphonic output. For polyphonic dataset generation, criteria (1)-(3) were the same, but a replacement for (4) was needed because parsed MIDI files sometimes contain erroneously long notes. In place of criterion (4), polyphonic dataset generation involved clipping any notes longer than 8 quarter-note beats.

If a prime or continuation did not satisfy one or more of the above criteria, generation proceeded to the next randomly selected piece (rather than, say, selecting a different excerpt from the same piece). Approximately $1/6$ random selections passed the criteria, meaning we had to process $6N$ pieces to produce a dataset of size N.

Our baseline for generating foil continuations is the Racchman-Jun2015 model [9] described in section 4. Since previous work has emphasized the need to progress from Markovian approaches to modeling music [36], this seemed to be the most appropriate baseline. Examples of a prime, true and foil continuations are shown in Figure 1. This excerpt came from an LMD song called "Dirtyluv". We were unable to identify further title or artist information – an issue when working with this source.

Returning to the discussion of pattern discovery for prediction, the example is annotated with pattern occurrences $A_1, A_2, B_1, B_2, \ldots, B_5$ to indicate how such an approach would be fruitful in this case. The annotating lines are placed above and below the stave for clarity, but encompass notes from both staves that begin in the indicated time spans. The prime ends by repeating the first 3 notes of A_1.

[2] `https://www.npmjs.com/package/@pioug/MidiConvert`

Therefore, one reasonable prediction for the continuation is that it will proceed to restate the remainder of A_1. Comparing such a prediction to the true continuation, we see that it would be quite successful – some extra notes in the left hand in measure 16 are the only difference between A_1 and A_2. In an analogous fashion, the regularity of occurrences of B_1, B_2, B_3 could be used to make a prediction about B_4 and B_5 appearing in the true continuation.

3.2 Dataset characteristics

Figure 2 contains three violin plots showing basic distributional characteristics of the symbolic, monophonic, medium-size development ("dev") dataset and the symbolic, monophonic test dataset. Inspection of these plots suggests that the development and test datasets share similar characteristics. A slightly more marked peak can be seen around inter-onset 0.5 in the primes and true continuations of the test compared to the development datasets (Figure 2A), and the test dataset has a slightly lower mean MIDI note number than that of the development dataset (Figure 2C). While the test dataset is separate from the development dataset (LMD) and it would be inappropriate to report the extent to which they overlap in terms of content, evidently their distributional characteristics are similar. It is worth noting that there is healthy representation of "bass lines" in monophonic – but not polyphonic – variants of the datasets (see the modal concentration around MIDI note 35 in Figure 2C), as a result of the selection criteria outlined above.

4. COMPARED MODELS FOR MUSIC PREDICTION

We compare the output of foil continuations by the first-order Markov model (see section 3.1), in the following referred to as *baseline* model, with two recurrent neural network models, *BachProb* [10] and *Seq2SeqP4P* [24].

BachProb is a deep-gated, recurrent neural network with three consecutive layers. Notes are represented as triplets of pitch, duration and inter-onset interval with respect to the previous note. Durations and inter-onset intervals are rounded to durations commonly found in musical scores. *BachProb* is trained on the development dataset using truncated back propagation, with separate models for the monophonic and the polyphonic parts of the dataset.

Seq2SeqP4P is a long short-term memory network with two layers. Music was represented as the MIDI commands *note-on*, *note-off*, which define when a given pitch starts or ends, and time shifts between those commands, quantized to 12 subdivisions per beat. Such a sequence of MIDI commands and time shifts was used as the input to training the model on the development dataset. By virtue of design, Seq2SeqP4P was trained only on the monophonic part of the dataset.

The baseline model consists of a first-order Markovian generator nested in other processes intended to ensure the output has long-term repetitive and phrasal structure [9]. The state space consists of beat of the mea-

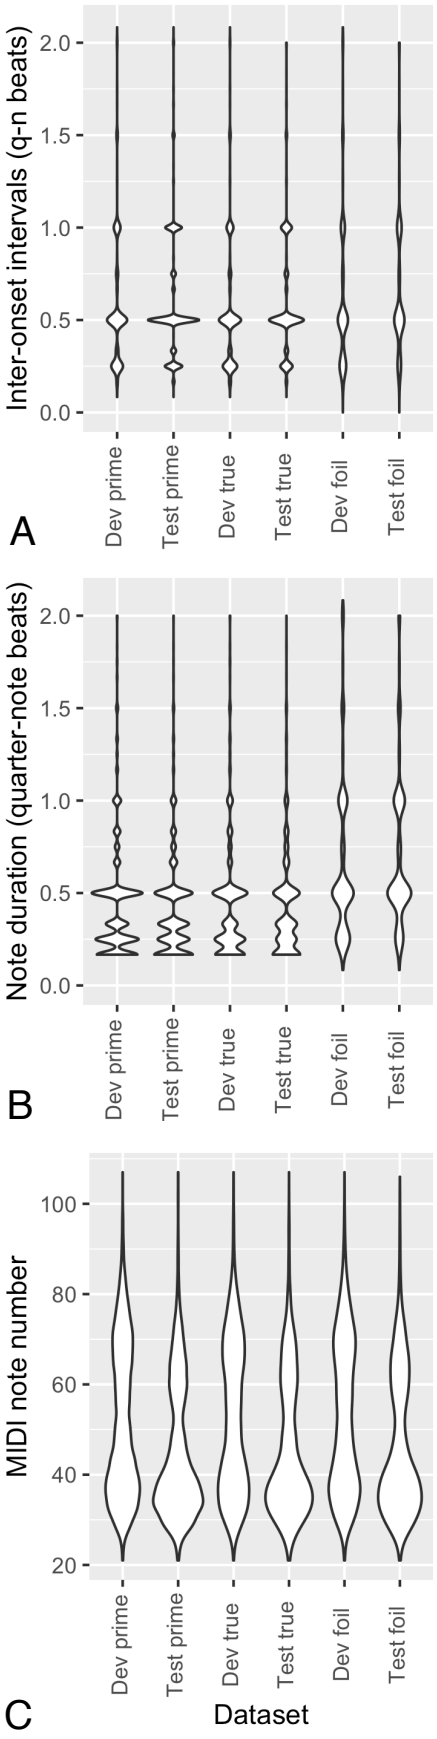

Figure 2. Characteristics of the symbolic, monophonic, medium-size dataset: (A) Inter-onset interval distributions of development and test datasets; (B) Duration distributions; (C) MIDI note number distributions.

sure on which notes occur, and MIDI note numbers relative to tonal center. The Markov generator alone, called Racchman-Jun2015, is a useful benchmark, because any longer structures that emerge here do so by chance.

5. EVALUATION

We evaluate music prediction in two ways:

- Explicit task. Models are provided with a prime, from which they generate continuations. The output of the models is then judged according to how many events of the true continuation they correctly predicted (metric definitions below).
- Implicit task. Models are provided with correct and foil continuations after a prime, from which they have to select the correct continuation.

5.1 Explicit task

For the explicit task, the evaluation proceeds as follows: within a time interval of ten quarter notes, we step through the time line by small time increments. We choose a time increment of $t = 0.5$ quarter notes, i.e., an eighth note.

We represent each note in the true and algorithmic continuation as a point in a two-dimensional space of onset and pitch, giving the point-set $\mathbf{P}$ for the true continuation, and $\mathbf{Q}$ for the algorithmic continuation. We calculate differences between all points p_i in $\mathbf{P}$ and q_j in $\mathbf{Q}$, which represent the translation vectors $\mathbf{T}$ to transform a given algorithmically generated note into a note from the true continuation [8, 33].

We then search for the largest set match achievable through translation with any vector, leading us to the number of correctly predicted notes cp:

$$\text{cp}(\mathbf{P}, \mathbf{Q}) = \max_{\mathbf{T}} |\{q_j | q_j \in \mathbf{Q} \wedge q_j + \mathbf{T} \in \mathbf{P}\}| \quad (1)$$

We define recall as the number of correctly predicted notes, divided by the cardinality of the true continuation point set $\mathbf{P}$. Since there exists at least one point in $\mathbf{Q}$ which can be translated by any vector to a point in $\mathbf{P}$, we subtract 1 from numerator and denominator to scale to $[0, 1]$.

$$\text{Rec} = (\text{cp}(\mathbf{P}, \mathbf{Q}) - 1)/(|\mathbf{P}| - 1) \quad (2)$$

Precision is the number of correctly predicted notes, divided by the cardinality of the point set of the algorithmic continuation $\mathbf{Q}$, scaled in the same way:

$$\text{Prec} = (\text{cp}(\mathbf{P}, \mathbf{Q}) - 1)/(|\mathbf{Q}| - 1) \quad (3)$$

The F_1-score is the harmonic mean of precision and recall. As the measures we propose are not defined for cases in which either the true or the algorithmic continuation contain fewer than two events, we start evaluation from onset 2.0, i.e, two quarter notes after the end of the prime, which ensures long enough sequences.

5.2 Implicit task

In the implicit task, a prediction model has to judge which of two continuations after a given prime is the true continuation. The foil is generated by the baseline model (see Section 4).

To evaluate the implicit task, we measure the success rate, i.e., the number of cases in which the model correctly picks the true continuations, divided by the total amount of decisions undertaken by the model.

6. RESULTS

Our evaluation and results focus on the symbolic variants of our test dataset. For the monophonic part of the dataset, we compare all three models, whereas for the polyphonic part, we only compare *BachProb* against the baseline, as *Seq2SeqP4P* has not been trained on polyphonic data yet.

6.1 Explicit task

For the monophonic dataset, the various models predict around a third of the events correctly, with *BachProb* outperforming the baseline and *Seq2SeqP4P* slightly, especially at the start of the predicted continuation (see Figure 3B).

Seq2SeqP4P predicts more of the notes in the true continuation correctly than the baseline, but at the cost of precision (Figure 3A), which means that its F_1 score is also lower overall than the baseline (Figure 3C).

For the polyphonic dataset, *BachProb* achieves a much higher recall than the baseline Markov model (Figure 3E). In precision, it performs close to the baseline, which results in very similar F1-scores, too (Figure 3D, F).

In general, the recall, precision, and F_1 score of the models decrease as the onset of the generated continuation increases, even though the baseline model has fairly stable performance over the evaluated time interval for the monophonic dataset, and *Seq2SeqP4P* increases in performance at the start of the continuation.

6.2 Implicit task

BachProb achieves a success rate of 0.85 for the monophonic continuations, i.e., 85% of the true continuations were identified correctly. For the polyphonic continuations, *BachProb* scores a success rate of 0.90. According to the binomial distribution, a success rate of 0.54 or higher constitutes above-chance performance on this task. At present, *Seq2SeqP4P* has not been implemented for the implicit task, so there are no results for it at this stage.

7. DISCUSSION

How events in the recent or more distant past may be appraised – consciously or otherwise – so as to be better adapted for what lies ahead is a phenomenon that has intrigued researchers from diverse disciplines such as cognitive psychology, philosophy, computer science, and music. In this paper, we focussed on music as a vehicle for studying the ability of computational models to predict continuations of given primes, and described datasets, evaluation procedures, and results to this end.

BachProb, utilizing a gated recurring neural network, outperforms the other two models. *Seq2SeqP4P*, based

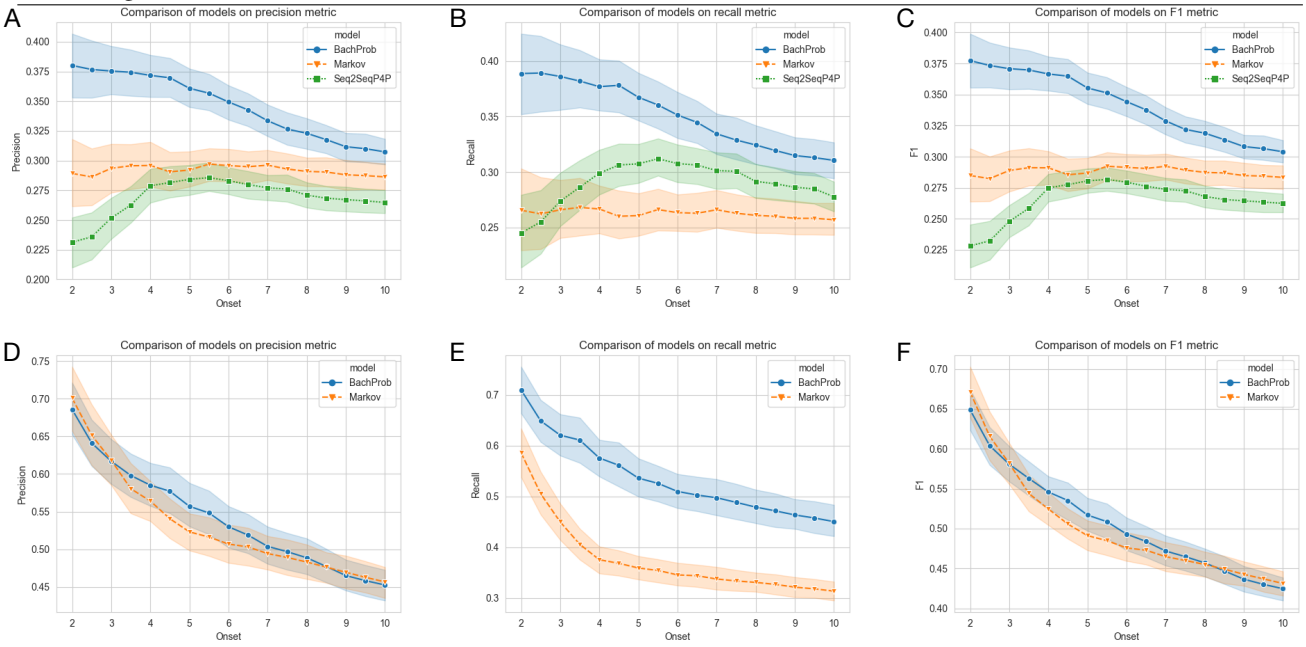

Figure 3. (A) Precision, (B) recall, and (C) F_1-measure of the three monophonic prediction models; (D) precision, (E) recall, and (F) F_1-measure of the two polyphonic prediction models. Evaluation measures are not defined for very short sequences, so evaluation starts at onset 2.0. Shading around the curves indicates one standard error from the mean.

on a long-short term memory model, predicts less musical material correctly. Arguably, music representation may be a larger factor in this than network architecture: as the model reportedly produces repeated pitches in some cases, and tends to always assign the same durations between the note-on and note-off events [24], the sequences of decoupled pitch and duration related information may not be suitable for the model to learn musical structure. Repeated short durations in the output may also explain the high recall and low precision of the model.

The overall higher recall, precision and F1-score of *BachProb* and the baseline on the polyphonic dataset, as compared to the monophonic results, is surprising. A possible explanation may be that repetitive chords, for instance in a piano or guitar part, are frequently present in the dataset and may be relatively easy to predict. The comparatively lower precision of *BachProb* suggests that while many notes from the true continuation are generated, there are also many spuriously generated notes.

For the implicit task, it is remarkable that *BachProb* distinguishes between true and foil continuations highly above chance. While the explicit task shows that the Markovian continuation reproduces a modest percentage of notes in the true continuations, the implicit task shows that *BachProb* learned details of the musical structure which could not be emulated by the Markovian foil.

We hope to evaluate more models for music prediction in the future, which might give us more insights into what constitutes successful prediction. As such, our proposal of a dataset and evaluation measures opens up the ground to discussion of how comparison of music prediction models may be improved.

First, we need to consider improved, or additional evaluation measures for the explicit task: our current approach to evaluating the explicit task entails that algorithmic continuations will be evaluated as correct continuations even if they are shifted in onset or pitch. The proposed measures may also penalize deviations from a true continuation that might be almost imperceptible to a human listener, such as an added chord note, or the reordering of chord tones.

Second, the evaluation of the implicit task also needs to be reconsidered: it depends heavily on the quality of the foil continuation. Perhaps the Markov baseline generates material which is too easily distinguishable from the true continuation. Moreover, we measure success rate, which has the advantage of easy interpretation, but does not take into account a model's confidence in its distinction between the true and foil continuation. Alternative foil continuations, or more fine-grained measures of the models' distinctions, would certainly give additional insights on model performance.

Third, additional tasks and datasets may be needed. We envision bringing together outcomes of music prediction models with evidence on human expectations in music. The continued systematic comparison of various models for music prediction can teach us much about the successes and shortcomings of prediction models in relation to each other, as well as about the influence of music representation and model parameters. Studies which measure human responses on their levels of surprise when hearing the continuation of a musical prime [19], or studies which ask humans to improvise a continuation [3] may inform improved tasks and evaluation strategies, and underpin models to predict the musical future.

ABSTRACT

Connecting large libraries of digitized audio recordings to their corresponding sheet music images has long been a motivation for researchers to develop new cross-modal retrieval systems. In recent years, retrieval systems based on embedding space learning with deep neural networks got a step closer to fulfilling this vision. However, global and local tempo deviations in the music recordings still require careful tuning of the amount of temporal context given to the system. In this paper, we address this problem by introducing an additional soft-attention mechanism on the audio input. Quantitative and qualitative results on synthesized piano data indicate that this attention increases the robustness of the retrieval system by focusing on different parts of the input representation based on the tempo of the audio. Encouraged by these results, we argue for the potential of attention models as a very general tool for many MIR tasks.

1. INTRODUCTION

Algorithms for content-based search and retrieval play an important role in many applications that are based on large collections of music data. In this paper, we re-visit a challenging cross-modal retrieval problem, namely audio–sheet music retrieval: given a short audio excerpt, we are trying to retrieve the corresponding score from a database of sheet music (stored as images).

Traditional methods for audio–sheet retrieval are based on common mid-level representations that allow for an easy comparison of time points in the audio and positions in the sheet music, see for instance [2, 14, 17, 21]. Typical examples are spectral features like pitch class profiles (chroma-features) or symbolic representations. Unfortunately, deriving such mid-level representations is an error-prone process, as this may involve preprocessing steps such as music transcription [6, 9, 16, 18, 19, 26], Optical Music Recognition [7, 15, 24, 25, 28], and sometimes both. For a recent overview of different cross-modal retrieval approaches, see [22].

In [11], an alternative approach has been proposed that circumvents these problematic preprocessing steps by learning embeddings directly from the multi-modal data (see Figure 1 for a schematic overview). Given short snippets of audio and their respective excerpts of sheet music images, a cross-modal neural network is trained to learn an embedding space in which both modalities are represented as 32-dimensional vectors (Figure 1a). The vectors can then be easily compared in the embedding space by means of a distance function, e. g., the cosine distance (Figure 1b). The retrieval results are then selected by sorting the candidates by the obtained distances (Figure 1c). A conceptually similar retrieval approach for videos was presented in [1].

In essence, the neural network replaces the step of extracting mid-level features by directly learning a transformation from the audio and from the sheet music image data to a common vector space. A limitation of this approach is that the temporal context (or field of view) of the data in both modalities is of fixed size. For audio data, this implies that the actual musical content of the window depends on the tempo a piece is played in. If it is played in a fast tempo, the audio excerpt will contain a larger amount of musical content (i. e., more notes) than if the same piece is played slowly. Obviously, this can lead to large discrepancies between what the model has seen during training, and the data it will see during test time.

A possible solution to this problem is to let the network decide the appropriate temporal context for a given audio query by using a separate attention mechanism [3,8,23,27]. In a recent workshop paper [12], the concept of using a soft-attention mechanism in a cross-modal retrieval scenario was presented. This allowed the network to deal with a much larger temporal context at the input than without attention. In this paper, we substantially extend this idea with systematic and quantitative experiments with respect to tempo robustness, as well as giving further details about the used architecture and the training data. The remainder of this paper is structured as follows. In Section 2, we introduce the retrieval task and explain the necessary steps to approach it with end-to-end cross-modal embedding learning. Section 3 reports on systematic experiments that show the benefits of using a dedicated attention network on audio spectrograms, to improve retrieval results compared to

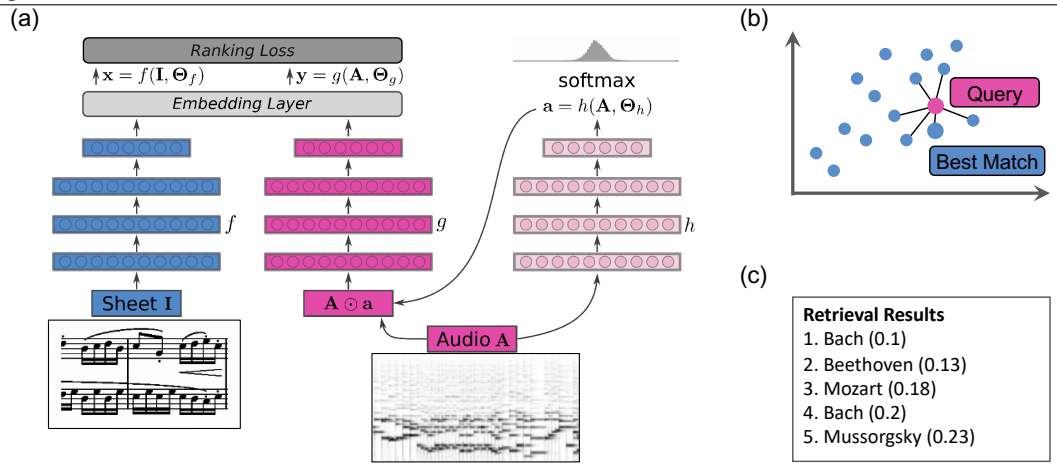

Figure 1: Illustration of the cross-modal retrieval application. (a) Audio snippet serves as input query to the embedding network. (c) Ranked list of candidates sorted by their distances to the query embedding.

the current state of the art. Furthermore, we present qualitative examples to highlight the intuitive behavior of the attention network and conclude the paper in Section 4.

2. AUDIO–SHEET RETRIEVAL

We consider a cross-modal retrieval scenario (Figure 1): given an audio excerpt as a search query, we wish to retrieve the corresponding snippet of sheet music of the respective piece. We approach this retrieval problem by learning a low-dimensional multimodal embedding space (32 dimensions) for both snippets of sheet music and excerpts of music audio (Figure 1a). We desire for each modality a projection into a shared space where semantically similar items of the two modalities are projected close together, and dissimilar items far apart (Figure 1b). Once the inputs are embedded in such a space, cross-modal retrieval is performed using simple distance measures and nearest-neighbor search. Finally, the retrieval results are obtained by means of a ranked list through sorting the distances in an ascending order (Figure 1c).

The embedding space is trained with convolutional neural networks (CNN). Figure 1a sketches the network architecture. The baseline model (without attention) consists of two convolutional pathways: one is responsible for embedding the sheet music, and the other for embedding the audio excerpt. The key part of the network is the canonically correlated (CCA) embedding layer [13]. This layer forces the two pathways to learn representations that can be projected into a shared space. The desired properties of this multimodal embedding space are enforced by training with pairwise ranking loss (also known as contrastive loss) [20]. This is the basic structure of the model recently described and evaluated in [11]. This attention-less model serves as a baseline in our experiments, i. e., the input audio (or sheet music) has to be sliced into excerpts of a given size (e. g., 2 s). However, when processing performed music, the temporal context captured by the fixed-size input excerpts varies, based on the current tempo of the piece.

Table 1: Overview of the network architecture. The upper part describes the attention network, the lower part the embedding part. Conv(3, pad-1)-24: 3×3 convolution, 24 feature maps and zero-padding of 1. We use ELU activation functions on all layers if not stated otherwise [10].

This attention-less model trains and operates on fixed-size input windows from both modalities. In other words, the musical content provided to the CNN may contain significantly less or more information—especially note onsets—than excerpts it has been trained on. One may of course compensate this with data augmentation, but a more general solution is to simply let the model decide how much information is needed from the audio.

For this purpose, we explore a soft-attention mecha-

nism. First, we substantially increase the audio field of view (number of spectrogram frames), up to a factor of four. Next, we add to the model the attention pathway h, which should learn to restrict the audio input again by focusing only at those parts that appear relevant for an efficient search query. As detailed in Table 1, this attention mechanism is implemented as a separate CNN. The output of this CNN is a probability density function a which has the same number of frames as the audio spectrogram. Before feeding the spectrogram to the audio embedding network g, we multiply each frame with its attention weight. This enables the model to cancel out irrelevant parts of the query and focus on the important information. In the following experiments, we show that adding this attention network in combination with the longer temporal context, substantially improves the results in the considered audio–sheet retrieval task.

3. EXPERIMENTS

This section reports on the conducted retrieval experiments. We start by describing the data used for training and testing the models, and the data augmentation steps applied during training. Afterwards, we present the results for the two main experiments, both dealing with audio–sheet retrieval: given an audio excerpt, retrieve the corresponding snippet of sheet music of the respective piece. Finally, we look at the attention-layer's behavior for five examples and discuss benefits and limitations of the approach.

3.1 Data Description and Training

We use a dataset of synthesized classical piano music, called *MSMD* [11]. In version 1.1, MSMD comprises 467 pieces by 53 composers, including Bach, Mozart, Beethoven and Chopin, totalling in over a thousand pages of sheet music and 15+ hours of audio, with fine-grained cross-modal alignment between note onsets and noteheads. The main changes from version 1.0 (as used in [11]) to version 1.1 are that we cleaned the test set from broken pieces and set all note velocities to a value of 64. The scores and audio are both synthesized using the score engraving software LilyPond [1] and FluidSynth. [2]

During training, we augment the sheet music by resizing and shifting the image. For augmenting the audio, we vary the tempo between 95 and 110 % and sample from a pool of three different piano soundfonts. For details of these augmentation steps, we kindly refer the reader to the explanation given in [11]. After training convergence, we refine the used CCA embedding layer on the whole training set. The reason for this is that during training, the covariance estimates used in the CCA projection are only based on the number of samples contained in the mini-batch.

For testing, we select 10,000 audio–sheet music pairs from an unseen testset, where the synthesized audio is rendered with a separate, hold-out piano soundfont. The rendering procedure for the sheet music remains the same.

(b) Refined CCA layer.

Table 2: Overview of the experimental results. (a) Lists the results without and (b) with a refinement of the CCA layer. All experiments used 10,000 candidates and were conducted on MSMD-v1.1 (R@k = Recall@k, MRR = Mean Reciprocal Rank, MR = Median Rank).

The above described augmentation steps are disabled during testing. In terms of performance, the refinement step of the CCA layer yields an increase in performance of around 0.07 up to 0.15 in terms of mean reciprocal rank (MRR) on the test set (see Table 2 for details). The used dataset , [3] as well as the implementation along with trained models , [4] are publicly available.

3.2 Experiment 1: Attention

In the first experiment, we investigate the influence of the additional attention network. We systematically increase the temporal context of the audio representation from a short context (SC, 42 frames = 2.1 s), over a medium (MC, 84 frames = 4.2 s), to a long context (LC, 168 frames = 8.4 s). The results are summarized in Table 2. As evaluation metrics we use different Recalls (R@1, R@5, R@25 $\in [0, 100]$, higher is better), the mean reciprocal rank (MRR $\in [0, 1]$, higher is better), as well as the median rank (MR $\in [1, 10000]$, lower is better). In the following discussion, we focus on the results of the refined CCA layer, as given in Table 2b.

As a baseline (BL1-SC), we use the network architecture as described in [11], which uses the short context (SC). For this model, approximately 20% of the queries are on rank 1 (R@1 = 19.12) and in almost 70% of the audio

[4] https://github.com/CPJKU/audio_sheet_retrieval/tree/ismir-2019

Model	$\rho = 0.5$	$\rho = 0.66$	$\rho = 1$	$\rho = 1.33$	$\rho = 2$
BL1-SC [11]	0.20	0.27	0.31	0.30	0.22
BL2-SC	0.44	0.52	0.57	0.56	0.46
BL2-MC	0.46	0.53	0.57	0.55	0.43
BL2-LC	0.44	0.50	0.55	0.51	0.35
BL2-SC + AT	0.55	0.63	0.63	0.64	0.56
BL2-MC + AT	0.54	0.61	0.67	0.67	0.62
BL2-LC + AT	0.64	0.69	0.75	0.73	0.64

Table 3: Mean Reciprocal Rank (MRR) for different models and different tempo ratios $\rho \in \{0.5, 0.66, 1, 1.33, 2\}$. For example, $\rho = 0.5$ stands for half of the original tempo and $\rho = 2$ for doubling the tempo. The listed models correspond to the refined CCA models as listed in Table 2b with the same test set size of 10,000 candidates.

queries, the relevant sheet image is within the first 25 ranks (R@25 = 66.63). As a second baseline (BL2-SC), we slightly adapt the original architecture by exchanging the global average pooling layer (before the embedding layer) by a dense layer for each modality (see the non-attention part of Table 1 for details). With this adaptation, the results improve significantly to R@1 = 48.91, R@25 = 78.27, and a median rank MR = 2, instead of MR = 8 for BL1.

By increasing the temporal context on BL2 to medium sized context (BL2-MC), mean reciprocal rank (MRR = 0.57) and median rank (MR = 2) stay unchanged. When increasing the temporal context to the long context (BL2-LC), the model degrades in performance, e. g., R@1 drops from 48.91% for SC to 43.46% for LC and the MRR from 0.57 to 0.55. Adding the attention network to the audio input (BL2-SC + AT) improves the results by 7, 5, and 3% for the recalls, as well as 0.05 for the MRR compared to BL2-SC. The more context is given to the network, the better the performance metrics get, e. g., R@1 improves from 58.14 (BL2-MC + AT) to 66.71 (BL2-LC + AT). The MRR, improves from 0.63 (BL2-SC + AT), over 0.67 (BL2-MC + AT), up to 0.75 (BL2-LC + AT).

We derive two main observations from these results. First, optimizing the network architecture is important; dropping the global average pooling in favour of a fully-connected dense layer lifted the results to another level. The reason could be that the fully-connected layer better retains the structure of the input spectrogram than the average pooling and in addition can be more selective on relevant input parts, e. g., by setting weights to zero. Second, the attention network enables the network to deal with larger temporal context sizes. From a signal processing perspective, one would expect that more context (and thus longer queries) would always help since it increases the specificity of the query. However, since we squash this information into a 32-dimensional embedding vector, it seems that too much information (e. g., too many onsets in the audio), actually harms the retrieval quality when not using attention.

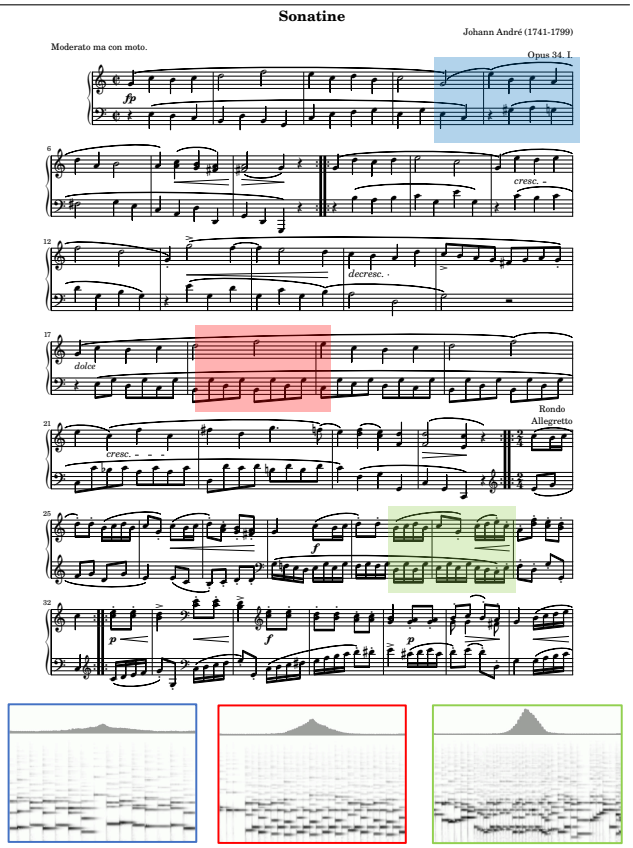

Figure 2: Example of tempo variations within a piece by Johann André - Sonatine (Op. 34, I.). The three boxes below the sheet music show the attention output, and the corresponding audio spectrogram for the respective excerpt.

3.3 Experiment 2: Tempo Robustness

In a second experiment, we explicitly test the system's robustness to global tempo changes. For this purpose, we re-rendered the MSMD test dataset with various tempo ratios $\rho \in \{0.5, 0.66, 1, 1.33, 2\}$, where $\rho = 0.5$ stands for halving and $\rho = 2$ for doubling the original tempo. The results are given in Table 3. For the sake of brevity, we only show the mean reciprocal rank (MRR) for the refined CCA models.

In general, we observe a similar trend as in the first experiment. While the original baseline approach (BL1-SC) performs rather poorly (0.20 to 0.31), exchanging the global average pooling layer (BL2-SC) helps to improve the performance (0.44 to 0.57). The best attention model (BL2-LC + AT) yields values ranging from 0.64 to 0.75. In this experiment, we would have expected that the improvement holds true for all testsets rendered at different global tempi. However, the numbers tell a slightly different story. To understand this, we had to go back to the generation of the MSMD dataset. Recall that the dataset is generated from LilyPond files obtained from the Mutopia Project. [5] These files contain tempo specifications which are retained in the synthesis pipeline. The specified tempi vary in a range between 30 and 182 bpm (mean tempo = 106 bpm,

[5] https://www.mutopiaproject.org

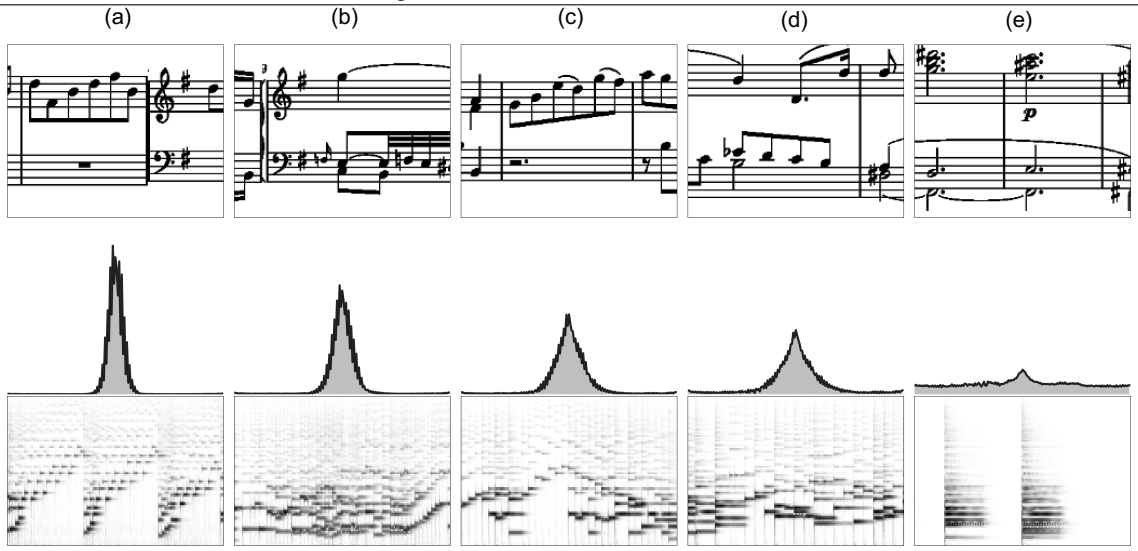

Figure 3: Illustration of the sheet music, input attention (normalized), and spectrogram for five examples from the MSMD test set. (a) L. v. Beethoven - Piano Sonata (Op. 79, 1st Mvt.), (b) J. S. Bach - Goldberg Variations: Variatio 12 (BWV 988), (c) J. S. Bach - French Suite VI: Menuet (BWV 817), (d) R. Schumann - Album for the Youth: Untitled (Op. 68, Nr. 26), and (e) M. Mussorgsky - Pictures at an Exhibition VIII: Catacombae.

std. dev. = 25 bpm). This distribution of tempi implies that all experiments we perform on the original MSMD testset ($\rho = 1$) already test for a variety of tempi. Synthesizing this dataset with different tempo factors—as done in our second experiment—shifts and stretches this distribution. In the edge cases ($\rho = 0.5$ and $\rho = 2$), this leads to unrealistic tempi, e. g., 15 bpm or 364 bpm, producing input audio windows with absurdly low or high onset density.

In summary, all of the tested models have in common that they work best for the original testset tempo ($\rho = 1$) and have similar relative performance drops for the tempo variations. However, the attention model is able to keep the retrieval results at a much higher level than all the other models. In the following section, we take a closer look at some examples from the MSMD test set to get a better intuition of the soft-attention mechanism and how it reacts to tempo deviations.

3.4 Examples

In the experiments above, we have seen that the attention models improve the retrieval results by a considerable margin. Another positive aspect of the soft-attention mechanism is that its behavior is directly interpretable—a rare case in the deep learning landscape. For all the presented examples, we provide further videos with audio on an accompanying website, along with detailed instructions for reproduction. [6]

Figure 2 shows the sheet music for Johann André's Sonatine, Op.34. The piece starts with a calm part with mainly legato quarter notes at 103 bpm. The first (blue) box shows the corresponding attention output and the audio spectrogram for measure five. The attention output is relatively flat with a small peak in the middle of the audio excerpt. In bar 17, the note density changes, with eighth notes in the left hand entering the scene. As shown by the second (red) box, the attention layer reacts to this by building up a more distinct focus around the center, placing less weight on the outer parts of the spectrogram. In the third part beginning with measure 24, the "tempo" (more precisely: the perceived "speed", in terms of events per time unit) essentially doubles, which is reflected in a high peak and narrow distribution in the attention output (green right box). From these three examples, it also becomes clear that tempo and note density are essentially two sides of the same coin for the attention network.

In Figure 3, we show examples from the testset with different global performance tempi, along with the sheet music excerpt, the attention weights, and the spectrogram. The fastest piece, with around 250 bpm, is shown in Figure 3a. The corresponding attention output is very focused on the middle part of the audio spectrogram, trying to concentrate the attention to the notes that actually appear in the sheet music snippet. The second example (b) is rather slow with 95 bpm. However, through the use of 16th and 32th notes, the main melody gets a double-time feel, thus the actual tempo is perceived at around 190 bpm. In Figure 3c, the tempo is at 115 bpm. The attention output starts to widen up, allowing more temporal context to reach the actual embedding network. This trend goes in Figure 3d when the tempo 78 bpm. Figure 3e shows an extreme example where the piece mainly consists of chords with long, dotted half notes. Here, the attention has to use the complete temporal context of the audio spectrogram to match the score information with the audio.

The examples demonstrate that depending on the spec-

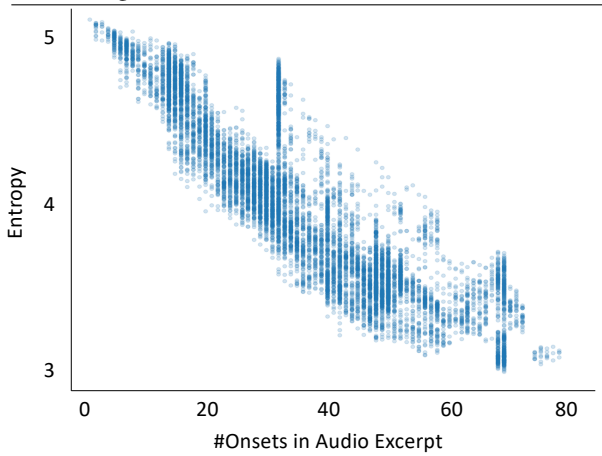

Figure 4: Entropy of the input attention vs. the number of onsets in the respective audio frame.

trogram content, the model indeed attends to whatever it believes is a representative counterpart of the target sheet music snippet. Since the fixed-size sheet snippets contain roughly similar numbers of notes, as the density of note heads on the printed page tends to be independent of the tempo of the piece, attention is sharply peaked when the density of onsets in the audio is high, and conversely is distributed more evenly when there are fewer notes in the audio excerpt.

4. SUMMARY

In this paper, we have described a soft-attention mechanism that helps to overcome the fixed window sizes uses in Convolutional Neural Networks. In our end-to-end audio–sheet music retrieval application, the results improved substantially compared to the state of the art. By looking at a number of examples from the retrieval results, the soft-attention mechanism showed an intuitive and interpretable behavior.

This appealing and intuitive behavior is summarized in Figure 4, which shows the entropy of the attention distribution in relation to the number of onsets contained in the audio excerpt, for all 10,000 test samples. The entropy is a measure of flatness of the attention output: a flat function gives high entropy, a very narrow function low entropy. The downward trend in the figure confirms our observations from above: the more onsets in the respective audio spectrogram, the narrower the attention distribution.

Given the improved retrieval performance and the intuitive behavior of the attention model, we think this is a promising line of research for reducing the sensitivity of cross-modal music retrieval models to the audio input window size. To this end, our experiments were conducted on synthesized piano recordings. However, results in [11] indicate that the embedding models trained on this data generalize to real scores and performances. A possible next step would be to investigate whether the attention mechanism reacts to local tempo changes as occuring frequently in real performances (e. g., ritardandi and accelerandi). Furthermore, it would be interesting to leave the piano music domain and extend the model to cope with differences in timbre, (e. g., orchestral music) as done in [4] for the challenging Barlow–Morgenstern scenario [5].

ABSTRACT

Arab-Andalusian music was formed in the medieval Islamic territories of the Iberian Peninsula, drawing on local traditions and assuming Arabic influences. The expert performer and researcher of the Moroccan tradition of this music, Amin Chaachoo, is developing a theory whose last formulation was recently published in *La Musique Hispano-Arabe, al-Ala* (2016), which argues that centonization, a melodic composition technique used in Gregorian chant, was also utilized for the creation of this repertoire.

In this paper we aim to contribute to Chaachoo's theory by means of tf-idf analysis. A high-order n-gram model is applied to a corpus of 149 prescriptive transcriptions of heterophonic recordings, representing each as an unordered multiset of patterns. Computing the tf-idf statistic of each pattern in this corpus provides a means by which we can rank and compare motivic content across *nawabāt*, distinct musical forms of the tradition. For each *nawba*, an empirical comparison is made between patterns identified as significant via our approach and those proposed by Chaachoo. Ultimately we observe considerable agreement between the two pattern sets and go further in proposing new, unique and as yet undocumented patterns that occur at least as frequently and with at least as much importance as those in Chaachoo's proposals.

1. INTRODUCTION

The rich culture developed in the medieval Islamic territories of the Iberian Peninsula known as Al-Andalus gave birth to a refined musical and literary tradition that combines local musical practices with Middle Eastern Arabic poetry and sensibilities. The core of this tradition is the singing of *ṣanā'i'* (plural of *ṣan'a*) or poems either by a choir accompanied by an instrumental ensemble or by a soloist. These *ṣanā'i'* are performed in suites known as *nawabāt* (plural of *nawba*), which also include orchestral pieces and both instrumental and vocal solo improvisations [6, 13]. The migration of Andalusian population to North Africa brought this tradition to this region, were it survived to this date after the disappearance of Al-Andalus in the 15th century. Nowadays, it is considered the classical musical repertoire in countries such as Morocco, Algeria, and Tunisia, in each of which it developed local characteristics, and is commonly known (among other names [22]) as Arab-Andalusian music. In this paper, we focus on the Moroccan repertoire of this tradition, which is known as *al-Āla* [6].

1.1 Music Theory and Centonization

Nawba is the essential form of Arab-Andalusian music. All the *ṣanā'i'* and other pieces in one *nawba* are composed in one single mode, known in this tradition as *ṭāb'* (plural *ṭūbu'*). In the specific case of the Moroccan *al-Āla* repertoire, pieces from certain *nawabāt* were lost during the process of oral transmission, so that the surviving ones where attached to other *nawabāt* according to modal similarity. In the 18th century, the scholar al-Haiek fixed the number of *nawabāt* in the *al-Āla* tradition to eleven (Table 1) [6].

The scholar and expert performer of *al-Āla* Amin Chaachoo is researching and developing a theoretical framework for this tradition. Chaachoo argues that regarding its musical aspect, Arab-Andalusian music heavily draws on local Iberian practices, and especially on plainchant in terms of compositional principles. A main argument for this proposal is the nature of Arab-Andalusian *ṭūbu'*, which lack the microtonalities and nuances of Arabic *maqam*. Chaachoo, in his publication *La música andalusí al-Ála* [5] characterizes each *ṭāb'* with a particular ascending and descending scale, a fundamental degree similar to the *finalis* of Gregorian modes, and one or two dominant degrees. In his more recent *La Musique Hispano-Arabe, al-Ala* [6], he also proposes the concept of a "persistent degree," inspired in the reciting tone from plainchant.

One of the most original proposals by Chaachoo is the use of centonization as the basic technique for melodic creation in Arab-Andalusian music. Centonization, from latin *cento* meaning patchwork, is defined by Paolo Ferretti as

melodic composition by synthesis of pre-existing musical units known as *centos* [11], and is generally associated to melodic creation in Gregorian chant [1, 7]. Chaachoo argues that the melodic material in Arab-Andalusian music is also created by combination of *centos*, thus strengthening the connection between this tradition and Iberian local practices. The author associates these melodic units or *centos* to specific *ṭūbu'* (See Fig.1), so that one particular *ṭāb'* is characterized by a set of *centos*. To the best of our knowledge, Chaachoo's is the first attempt to explain melodic creation of Arab-Andalusian music through the concept of centonization.

Figure 1: Score example with the characteristic *centos* of the piece *Btayhi Rasd Dayl* of Nawba 4

1.2 Motivation

The use of centonization as composition technique in Arab-Andalusian music is still being developed by Chaachoo. Already published in two recent works [5,6], the list of *centos* per *ṭāb'* slightly varies from its first formulation to the second, as the theory is being consolidated. Chaachoo draws on his lifetime experience as performer and instructor of this music, as well as in his analytic work as a musicologist, for the definition of each *ṭāb'* list of characteristic *centos* [1] . Therefore, our main goal is to contribute to the development of Chaachoo's theoretical work with findings from computational analysis of melodic patterns in a dataset of machine readable music scores.

Preliminary experiments with this dataset shows that, if we were to try and identify the *nawba* to which a specific score belongs by simply counting the occurrences of *centos* unique to the *ṭūbu'* that constitute it as specified by Chaachoo, we would be unsuccessful. In fact, attempting to do so on the corpus used in this study results in a misclassification rate of 80%. This is due to certain *nawabāt* relying heavily on very general melodic sequences located around the tonic and the dominant of the modes, these general sequences can be found in many of the *centos* documented by Chaachoo as being specific to a certain *ṭāb'* (and therefore *nawba*).

Our aim is to quantify the importance of particular melodic patterns with respect to *nawabāt* and provide an empirical ranking of melodic content for each. We must therefore rely on an approach that considers more than just frequency of occurrence, one that normalises for generality, putting forward new proposals, as to the melodic constitution of each *nawba* [6].

[1] Personal communication

2. RELATED WORK

There exists many studies into melodic pattern recognition, summaries of which have been made by Jansen et al. [15] and more recently Ren et al. [24]. Lack of agreement on the current state-of-the-art stems from the difficulty in evaluating approaches, with expertly annotated ground truth often required for performance measurement, more often than not on a study-by-study basis.

In no deviation from this trend we draw on the work of Chaachoo [6] for validation of our results and go further in suggesting/supplementing his studies with unique insights of our own. Accordingly, we aim to approach this investigation with interpretability in mind, seeking to build upon the string-based, frequency approaches found in [8,14,16], where patterns are represented by counting the number of instances of re-occurring sub-sections of notes in a musical sequence and their significance computed by comparing these counts, ignoring potential *interaction* between non-consecutive notes. The appeal of this method is that the theory is intuitive to a non-specialist and aligns with what a musician might consider important when characterising a musical piece melodically, an important consideration when wishing to contribute to and communicate with Chaachoo and his works.

The choice to consider only consecutive notes as belonging to the same pattern is supported by the nature of the music scores in our dataset (see section 3.1). These scores are manual transcriptions by Chaachoo himself from a collection of representative recordings. Due to the heterophonic nature of this music tradition, and the analytical purpose of the music scores, they contain only the common melodic line underlying the actual rendition of the choir and instruments in the orchestra. This rather prescriptive character of the transcriptions results in a representation of the music more theoretical than fine detailed, thus permitting the assumption that *centos* are literally repeated in the score, without the modifications of the ornamentation in actual performance.

As mentioned in the previous section however, simple frequency alone is not sufficiently powerful in characterising *nawba*. A more desirable attitude would be probabilistic, as found with Conklin in [9]. Conklin puts forth a novel method of computing pattern significance by comparing the probability of occurrence in a corpus with the probability of occurrence in an anti-corpus, patterns overrepresented in the former are said to be distinct to that. Our tf-idf approach is very similar, the probability of occurrence of each pattern in a score is normalised by how likely it is to occur across all other scores.

Nawba number	*Nawba* transliterated name	Number of Scores
1	*raml al-māya*	19
2	*al-isbahān*	13

10	*ʻirāq al-ʻaǰam*	7
11	*al-ʻušš*āq	7

Table 1: Distribution of Scores across *nawabāt*

3. METHODOLOGY

Our analysis is implemented in Python, the code for which is available on Github [2] should the reader wish to reproduce this work. We use the music21 library [10] for processing scores and adopt the same convention for accidental notes in our reporting as in this toolkit, that is '#' for a sharp and '-' for a flat.

It is worth noting that we do not take into account any note/rest duration in this analysis, this decision is based on Chaachoo's theory which proposes the set of centos with no variation in their durations. Furthermore, we omit all octave information from our data, observing that melodic lines in our corpus very rarely jump between octaves and that same omission is made by Chaachoo in his work.

3.1 Dataset

Our dataset is a subset of 149 scores across all 11 Moroccan *nawabāt* from the CompMusic Arab-Andalusian corpus [25] of Dunya [23]. It has been selected such that each score is accompanied with the relevant *ṭāb'* metadata (and hence allows us to identify the *nawba* to which they belong). Each score is represented as an ordered list of consecutive notes (all scores are monophonic) with rests included. Table 1 shows the number of scores for each *nawba*.

3.2 Pre-processing

In analogy to a bag-of-words representation of a document, we represent each score as a bag-of-patterns. That is, we extract from each every possible n-gram up to a specified length, N. Any n-gram (or pattern as they will from here on be referred to as) that contains a rest, R, is discarded. For example, the bag-of-patterns for a score of [G, E, F, F, R, E, G, E] is:

$N = 2$: [GE, EF, FF, EG, GE];
$N = 3$: [GE, GEF, EF, EFF, FF, EG, EGE, GE];
$N \geq 4$: [GE, GEF, GEFF, EF, EFF, FF, EG, EGE, GE]

This method of motivic representation - where every possible sub-pattern is included alongside its parent patterns down to minimum length - is said to satisfy the *Sub-motif Existence Axiom* (SEA), first proposed in [18] and realised by Buteau in [2–4, 12].

3.3 TF-IDF Algorithm

Pattern importance is computed using the tf-idf statistic. Tf-idf, short for term frequency–inverse document frequency, is a numerical statistic that is intended to reflect how important a word is to a document in a collection or corpus [26]. With each of our 149 scores in bag-of-patterns form, we compute the tf-idf for each pattern on a score by score basis, using sub-linear term frequency so as to down-weight very popular or very rare terms.

Averaging our tf-idf values for each pattern for each *nawba* provides a metric for pattern importance per *nawba*.

3.4 Post-processing

A common problem in melodic pattern recognition by computational means is in dealing with the large quantity of results. As is typical of such methods, a set of selection rules is required. After applying the tf-idf algorithm to identify significant patterns, they are filtered according to the following:

1. We consider a pattern having occurred less than 50 times per score per nawba as being insufficiently frequent given our data size, this choice is informed by inspecting the frequency of patterns identified by Chaachoo as characteristic.

2. We do not consider strings that contain less than three notes or more than ten notes a pattern, these are discarded. This decision is informed by referring to existing literature on melodic composition of Arab-Andalusian music [6, 20, 25] and is somewhat justifiable intuitively, the same lower bound can be found in [9, 21] for example.

3. Any pattern that is a substring of another pattern in our selection of significant patterns (subject to previous selection rules) is discarded in favour of the longer pattern. A similar approach is adopted in [9, 14, 17, 19].

4. RESULTS AND EVALUATION

For each *nawba* we rank its pattern content by our averaged tf-idf, cross-referencing our findings with the patterns identified as characteristic of the *nawba* from Chaachoo.

4.1 Visualising Patterns Importance

Fig.2 and Fig.3 show the top ranked patterns for *nawba* 1 and 2 respectively. Each bar is coloured such that patterns identified as characteristic of the *nawba* by Chaachoo are black, patterns that themselves contain patterns identified

[2] https://github.com/MTG/quantifyingcentones

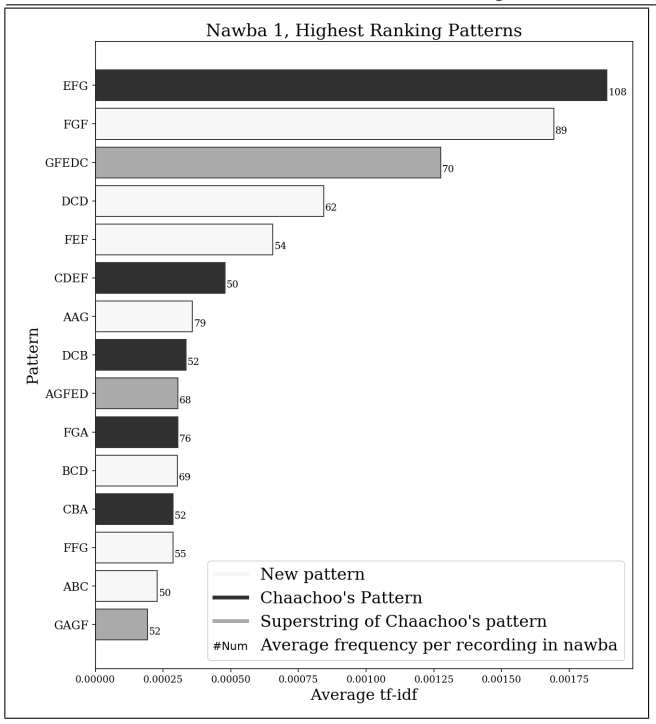

Figure 2: Ranked pattern importance for Nawba 1

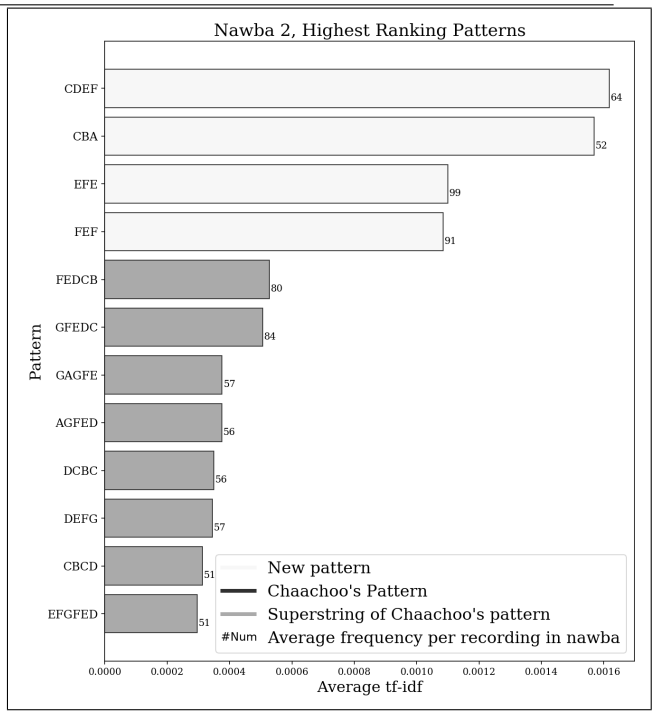

Figure 3: Ranked pattern importance for Nawba 2

by Chaachoo as characteristic of the *nawba* are grey and hitherto undocumented patterns white. Each bar is annotated with the average frequency of occurrence of that pattern in that *nawba*; that is the total number of occurrences in the corpus as a proportion of how many scores we have for that *nawba* (Table 1). These two examples are representative cases in which the most relevant patterns are a mix of Chachoo's patterns and new ones. Fig.4 displays the same score excerpt as in Fig.1 but with the new recognized relevant patterns for the *nawba*.

Table 3 presents the top 10 (where 10 exist) patterns determined by our analysis to be most characteristic of each *nawba*. The patterns identified by Chaachoo as characteristic of the *nawba* are bolded, those that themselves contain patterns identified by Chaachoo as characteristic of the *nawba* are italicized.

4.2 Evaluation

As a method of evaluating which patterns are most characteristic of each *nawba*, we compare the classification power of the patterns identified in this study to those documented by Chaachoo in [6] through a simple classifier.

4.2.1 Simple Classifier

An l2 regularised logistic regression model is applied to our corpus of 149 scores, we use a 60/40 train/test split and the frequency of occurrence of each pattern as features. In total, there are 184 patterns from Chaachoo's literature and 182 from our own.

We bootstrap our accuracy score on test 100 times. The results are displayed in Table 2.

Pattern Set	μ	σ
Chaachoo	70.8	4.9
Ours (Table 3)	72.2	5.0

Table 2: Bootstrapped accuracy when classifying nawba using two pattern sets (n=100)

5. DISCUSSION

The patterns discovered by this analysis are found to be as predictive as those of Chaachoo for classifying *nawabāt* and 44% of our top 109 patterns match the *centos* outlined in his works. Furthermore, we have demonstrated that in Arab-Andalusian music of the Moroccan tradition there exists at least 61 unique melodic patterns that occur as frequently (and in many cases more frequently) as those identified and documented to date and with at least as much significance as measured via our normalised frequency approach.

From a musical perspective it is clear that our patterns share some similarities; they constitute very simple cells, based on the relevant degrees of the *ṭāb'* (tonic and dominant). Since Arab-Andalusian music has uniform melodic contour and intervals rarely larger than a third, some of these new patterns could probably be clustered into other more generic groups. This could mean that we are not discovering new important material rather than variations of the known *centos* proposed previously by Chaachoo.

6. CONCLUSIONS

Our methodology is not without its limitations. The variability of our results is conditioned by factors such as whether we include rests in our patterns (and if so to what

length), the minimum frequency of occurrence for a pattern to be considered significant and maximum/minimum pattern length. The alteration of these and others like them would likely have marked consequences for our results. The justification for our decision was driven by necessity and intuition but would indeed benefit from further collaboration with experts of the tradition.

A further limitation exists in our inability to compare the significances computed here with other methods given that the tf-idf statistic is proportional to corpus size and hence only comparable within our training corpus.

However, as one of the first computational analysis on Arab- Andalusian music, we hope to have contributed to the musicological theory around centonization and hope that our approach may serve as a first reference for pattern recognition in Arab-Andalusian music, establishing the principles and basis for future and helpful study for musicological theories that can contribute to a better understanding and preservation of the musical tradition.

7. ACKNOWLEDGMENTS

The authors would like to acknowledge Mr. Amin Chaachoo, expert musicologist and experienced musician of this tradition, main curator of the Arab-Andalusian corpus and author of the music transcriptions and for his help with musicological explanations. This work was carried out with the support of the Musical Bridges project, funded by ObraSocialLaCaixa.

ABSTRACT

The task of speech and music detection aims at the automatic annotation of potentially overlapping speech and music segments in audio recordings. This metadata extraction process finds important applications in royalty collection for broadcast audio. This study focuses on deep neural network architectures made to process sequential data, and a series of recent architectures that have not yet been applied for this task are evaluated, extended and compared with a state-of-the-art architecture. Moreover, different training strategies are evaluated, and we demonstrate the advantages of a pre-training procedure with low-quality data that facilitates the combination of heterogeneous datasets. The study shows that Temporal Convolution Network (TCN) architectures can outperform state-of-the-art architectures. In specific, the novel non-causal TCN extension introduced in this paper leads to a significant improvement of the accuracy.

1. INTRODUCTION

The location of speech and music segments in large amounts of audio recordings is an important metadata information especially in the context of royalty collection in broadcasting. The task of speech and music detection is a multi-label problem, each frame can be labeled as music, speech, both, or neither of both. Assuming potential overlaps between the classes makes speech and music detection a complex and unsolved task, as opposed to a simple discrimination of segments into either speech or music [12]. Apart from royalty collection, a speech and music detection system can be useful to extract the relevant parts of the audio on which to apply other meta-data extraction such as speech-to-text, genre classification or music fingerprinting.

The first approaches to speech/music detection – discussed in the work of Carrey et al. [5] – focused on manually designed features and subsequent classification. More recently, features are automatically learned from spectrogram images using deep neural networks for various audio tasks [4, 7, 14, 22, 27, 33, 37]. End-to-end learning systems with waveform-audio input have been compared with spectrogram-based learning, with better results of the latter approach [16]. This may however be due to the lack of sufficient data in the particular case, as discussed by Pons et al. [24].

Recently, the Temporal Convolutional Network (TCN) [2] showed promising results on tasks involving sequential data. No study to date has compared the TCN architecture with other deep learning architectures such as Recurrent Neural Networks (RNN) for the task of speech and music detection. A key contribution of this paper is the investigation of a novel non-causal TCN architecture. This is of special interest to various applications where real-time analysis is not a constraint. The results of this study demonstrate that TCN architectures can outperform RNN. The final system is compared with the state of the art on the MIREX dataset [1] with results that further document the high performance of the non-causal TCN.

Another contribution of this paper is the use of an efficient pre-training procedure with low-quality data that facilitates the combination of heterogeneous datasets. We compiled the most extensive data resource available until now for the task of speech and music detection, and trained and tested networks using this heterogeneous data resource. Our results document the advantage of the pre-training procedure, and we provide the code of this study as a toolbox for the systematic comparison of system architectures for the speech and music detection task.

The following section is a review of existing work with neural networks on speech and music detection and tasks that employ similar methods. Section 3 explains the method that will be applied in this study. Section 4 presents the results that are discussed in Section 5. Finally, Section 6 draws various conclusions about this work.

2. BACKGROUND

The speech and music detection problem is a sound event detection problem. It applies to an audio stream containing temporal segments of speech and/music in arbitrary positions. Segments of speech and audio may overlap. Furthermore, some parts of the audio might contain neither music nor speech, but task-irrelevant content such as environmental sounds, footsteps or keyboard typing sounds.

Figure 1 shows an overview of the processing chain typically applied in speech/music detection and other related tasks, such as acoustic event detection. The following subsections provide an overview of examples of these steps from the literature.

Figure 1: Overview of the processing chain

2.1 Pre-Processing & Spectrogram Extraction

The most commonly used features in the literature are the Mel-scaled log-magnitude spectrograms [14,18,22,27,33]. To obtain them, a Short-Time Fourier Transform (STFT) is computed from the audio sample containing the discrete-time signal. Only the magnitudes are kept and a Mel-scaled Filterbank is applied. Finally, the obtained coefficients are put on a log magnitude scale and normalized.

Data augmentation is a pre-processing solution that artificially creates new data based on the available ones by applying various manipulations either in the time-domain [27] or on the spectrograms [29].

2.2 Network Architectures

In the context of deep neural networks, there are two different ways described in the literature to handle the speech and music detection task (or related tasks). The first possibility is to treat the audio as non-sequential data by working on small excerpts independently which is mainly used for classification tasks. The state-of-the-art architectures are based on the Convolutional Neural Networks (CNN) [14, 19, 27, 33].

The second possibility is to use a sequence model for the audio. An audio sample is injected into the network and each frame will be classified as music, speech, both music and speech or neither of both. The state-of-the-art architectures are mainly based on the Bidirectional Long Short-Term Memory (B-LSTM) [18, 22], which are a type of RNN.

Since the systems have been evaluated on differing test sets, no conclusion regarding the best performing architecture can be obtained from the above cited work. Moreover, music and speech have different temporal and spectral properties than environmental sounds, and it is therefore not clear if results from other tasks apply to speech and music detection.

2.2.1 Convolutional, Long Short-Term Memory, Fully Connected Deep Neural Networks (CLDNN)

Information from the long-term context in past and future can be very relevant for the classification and especially for borderline cases. It motivates the use of sequential models for the detection tasks. However, CNNs have obtained state-of-the-art results in image and audio feature extraction, which motivated the combination of RNN and CNN in the CLDNN architecture [26] to use the strength of both. CLDNN are divided into three sections: first, the input goes through several convolutional layers. Then, the result goes through a classic LSTM network and finally, several fully connected (FC) layers are applied. This architecture was shown to outperform CNN, RNN or DNN based approaches on various datasets [26]. This architecture has also been reused in several subsequent audio and music related studies [4, 7, 10], but has so far not been applied to speech and music detection.

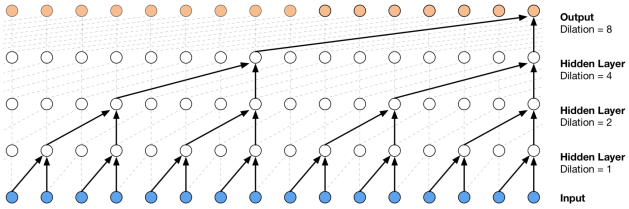

Figure 2: Visualization of a stack of dilated causal convolutional layers. Source: [35]

2.2.2 Temporal Convolutional Network (TCN)

Recently, the Temporal Convolution Network (TCN) was introduced [2] as a simple and flexible architecture using CNN for sequential learning. This architecture is based on the previous work trying to use only CNNs for sequential learning [13, 35] but it remains much simpler. A TCN cell is based on causal and dilated convolutions, and on residual blocks [15]. Figure 2 illustrates a dilated causal convolutional layer. Dilated convolutions permit to retrieve information from far in the past without extensive computation.

TCN architectures have not been used for speech and music detection yet. Therefore, within this paper, we compare four architectures: the standard TCN, a novel non-causal extension of the TCN, the BLSTM and the CLDNN architectures. This non-causal TCN architecture is designed to combine the strengths of both BLSTM and CNN architectures: the bidirectional long-term memory of the BLSTM architecture and the performance and parallelizability of the CNN architecture.

2.3 Post-processing and Evaluation

The network output vector contains two coefficients between 0 and 1, one for speech and one for music, and commonly 0.5 is used as a threshold for the labeling decision [18, 30]. A probabilistic model has been used by [11] to smooth the output and reduce the noise.

Two evaluation methods for speech and music detection – segment-level evaluation and event-level evaluation [21] – are applied within MIREX [1] and in most related studies. Segment-level evaluation compares the labels of segments of fixed size given by the algorithm with the ground-truth labels. Event-based evaluation takes the whole ground-truth events into account and a time-window tolerance is allowed. This evaluation is either made on the on-set of the events or on both the on-set and the off-set.

3. METHODOLOGY

3.1 Datasets

A larger amount of previously compiled datasets have been obtained and combined for this study (*MUSAN Corpus* [31] (MUSAN), *GTZAN Speech and Music Dataset* [34] (GTZAN), *Scheirer & Slaney Music Speech Corpus* [28] (SSMSC), *MuSpeak Speech and Music Detection Dataset* [2] (MuSpeak), *OFAI Speech and Music Detection Dataset* [30] (OFAI), *ESC-50: Dataset for Environmental Sound Classification* [23] (ESC)). In addition, a newly compiled dataset (Sveriges Radio dataset) was included as well, which is composed of songs from different genres that are played on the radio (42h 57mn) and of speech files (17h 24mn) that are extracted from radio programs.

Table 1: Categorization of the datasets according to the precision of their labels.

Low-quality datasets (LQ)	High-quality datasets (HQ)
MUSAN, GTZAN	OFAI
SSMSC, ESC	MuSpeak
Sveriges Radio dataset	

The datasets can be separated into two families regarding the precision of their labels, "low-quality datasets" (LQ) and "high-quality datasets" (HQ) as presented in Table 1. The HQ datasets are labeled at the frame-level, which precisely corresponds to the goal of the speech and music detection task to classify each frame of the audio. On the other hand, the LQ datasets are labeled at the file-level, which assumes that all the frames in the audio recording have the same label. It corresponds to a low-precision version of the targeted system (*e.g.* pauses in speech are not annotated).

The datasets were split into training, validation, and test set (if not already done in the source material). HQ datasets were split into 70% training set, 20% validation set and 10% test set, and LQ datasets into 80% training set and 20% validation set, because labels are not precise enough to be used for testing. The resulting data collection contains about 78h15mn / 86h54mn / 15mn / 8h49mn of speech, music, both speech and music, and task-irrelevant data in the LQ data, and 47h12mn of audio combining all the previous categories in the HQ data, making it the most extended data resource compiled so far for the task of speech and music detection.

3.2 Architectures

Three previous sequential architectures and one novel extension will be compared in this paper. All four architectures are followed by a dense layer that reduces the number of coefficients to 2, one for music and one for speech, and by a sigmoid activation to have coefficients between 0 and 1. The range of allowed values for hyper-parameter were chosen to cover the ranges previously presented in literature, and are listed in the following tables for each architecture. In each case, a dropout randomly selected from 0.05 and 0.5 was added.

[2] `http://mirg.city.ac.uk` - visited 09/11/2018

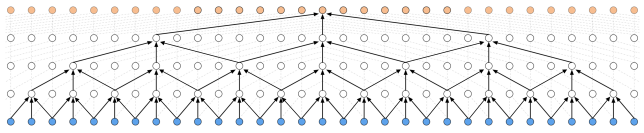

Figure 3: Visualization of a stack of dilated non-causal convolutional layers. The architecture presented in Figure 2 was made non-causal to take both past and future into account for the prediction. The kernel size had to be increased by 1.

The TCN architecture as introduced in [2] is causal. In this paper, we propose a novel extension of the TCN that takes future data into account, the non-causal TCN (ncTCN). To this end, the dilated convolutions were made non-causal, as shown in Figure 3. The use of non-causal dilated convolutions was previously shown to be successful for image processing with the Dilated Temporal Fully-Convolutional Neural Network (DTFCN) architecture [6].

Table 2: Hyperparameters for the four architectures.

Architecture 1: B-LSTM	
Num. of layers	1, 2, 3, 4
Units by layer	25, 50, 75, ... 250
Architecture 2: CLDNN	
Num. of layers	1, 2, 3
Kernel size (conv. layers)	3, 5 or 9
Number of LSTM layers	1, 2, 3
Units per LSTM layer	25, 50, 75, ... 150
Num. of fully-connected layers	1, 2, 3
Units per fully-connected layer	25, 50, 75, ... 150
Architectures 3 & 4: TCN & non-causal TCN (ncTCN)	
Num. of layers	1, 2, 3, 4
Num. of stacks	3, 4, 5, ... 10
Kernel size	3, 5, 7, ... 19
Skip some connections	true/false
Dilatations	$[2^0, 2^1, ..., 2^{N_D}]$ $N_D = 3, 4, ..., 8$
Num. of filters by layer	8, 16, 32

3.3 Comparison methodology

The study in this paper is composed of two phases: The first phase conducts a comparison of four sequential neural network architectures (B-LSTM, CLDNN, TCN, ncTCN) for the speech and music detection task. In order to facilitate the comparison in a reasonable time, two assumptions were made. First, the neural network architecture achieving the best performances on a sub-training set is likely to achieve the best performances on the total training set. And, second, the neural network architecture achieving the best performance with a restricted number of pa-

rameters is likely to perform best without this restriction. Therefore, the comparison was done with a limited number of parameters and on a sub-dataset. A Bayesian hyper-parameter optimization with a Tree of Parzen Estimators (TPE) surrogate [3] was performed for each architecture on the *OFAI* and the *MuSpeak* datasets, with the number of hyper-parameters restricted to 1 million. The best set of hyper-parameters was then used to train each architecture over more epochs to get a final validation loss, and the architecture achieving the lowest validation loss was kept for the second phase.

In the second phase, the best-performing architecture from the first phase is further optimized without limiting the number of hyper-parameters. This hyper-parameter optimization was done on *OFAI*, *MuSpeak*, and *ESC* to have a more balanced dataset between music, speech, and task-irrelevant content. Then the architecture was trained on more training data and evaluated on the test set. However, due to the heterogeneity in the quality of the labels, explained in Section 3.1, only the high-quality datasets represent the target of the network. Therefore, four strategies to take advantage of both HQ and LQ data were compared. The four strategies were to (1) train the network on the high-quality datasets, (2) to train the network on the low-quality datasets, (3) to train the network on both the low and the high-quality datasets at the same time, and (4) to pre-train the network on the low-quality datasets and then train on the high-quality datasets to fine-tune the parameters.

The final system was evaluated on two different test sets. The first test set is the in-house test set described in subsection 3.1 and it shows the generalization of the system on similar data. In order to compare the system with several state-of-the-art algorithms, and to assess the generalization of the system on data different than the one used for the training, the dataset number 2 of the 2018 MIREX Competition [1] [11] was used as a second test set.

The evaluation methods and parameters from MIREX 2018 were applied for comparisons, using the implementation of sed_eval [21]. The segment-level evaluation was conducted with segments of 10ms. The event-level evaluation was performed with a tolerance time-window size of 500ms on on-set only and both on-set and off-set. Precision, Recall, and F-measure were computed for segment level (P_s, R_s, F_s), and event-level (P_e, R_e, F_e).

3.4 Pre-processing

Before the training, the audio samples were re-sampled to 22.05 kHz mono audio samples split into files of 90 s. Then a Short Time Fourier Transform (STFT) with a Hann window, a frame length of 1024 and a hop size of 512 samples was computed. Only the squared magnitude (the power spectrum) was kept and saved for the training. During the training, data augmentation was applied to the saved spectrograms and then, a Mel-filterbank with 80 triangular filters between 27.5 Hz and 8 kHz was applied. Finally, the data were put on a logarithmic scale and normalized to a zero mean and unit variance over the training set.

The data augmentation pipeline applied to each spectrogram used the implementation and paramatrisation of [29], applying time stretching, pitch shifting, Gaussian filtering, loudness manipulation, and block mixing. Data from the HQ datasets and LQ data labeled as task-irrelevant content was augmented without block mixing. Otherwise, couples of speech and of music spectrograms were created, passed individually in the data augmentation pipeline and then each couple was mixed together with random overlap. It helps to have a more balanced dataset by artificially creating overlaps between speech and music.

Broadcast audio is characterized by overlaps between speech and music, for instance in jingles, commercial ads, and transitions between pieces of music. Data augmentation helps to obtain larger overlaps that resemble this characteristics of broadcast audio.

3.5 Training

To allow parallel computation and to speed up the backward pass, mini-batches are used with a sequence length of 270 and a batch size of 32. Binary cross-entropy was minimized during training, and stochastic gradient descent with momentum $m = 0.9$ [25] was used. When the validation loss did not improve after three epochs, the learning rate was divided by 10. Dropout [32] was used and the training was stopped whenever the validation loss had not improved in 5 consecutive epochs.

3.6 Post-processing

A threshold of 0.5 was applied to the output of the networks. A simple strategy was applied to smooth the output and delete spurious breaks or events. To this end, thresholds for the minimal duration of speech (Dur_{sp}) and music (Dur_{mus}) events were defined, respectively. Furthermore, thresholds for the minimal duration of a break in speech (Brk_{sp}) and music (Brk_{mus}) were defined. In order to specify values for these four duration thresholds, the training set was analyzed to obtain statistics on the lengths of the events and the breaks. To choose the best values between the relevant values found with the analysis, each set of values was evaluated on the validation set and the set achieving the best performances was selected. The effect of post-processing will be analyzed separately in the results.

3.7 Implementation

The implementation is done with *Keras* [9] using TensorFlow as a backend [1] and the library *keras-tcn* [3] is used for the TCN implementation. The code is provided as a new framework for speech and music detection that allows comparison between configurations with different architectures, datasets and hyper-parameters. The implementation has been made available on GitHub. [4]

[3] https://github.com/philipperemy/keras-tcn
[4] https://bit.ly/2XcuzsJ

4. RESULTS

4.1 Comparison

After each hyper-parameter optimization, the best configuration has been trained until the early-stopping. Figure 4 shows the micro-averaged [36] ROC curve of the 4 different architectures. The architecture that achieved the best performances under the constraints of the experiment is the non-causal TCN. All three architectures that have not yet been applied to this task (ncTCN, TCN, CLDNN) outperform the BLSTM architecture.

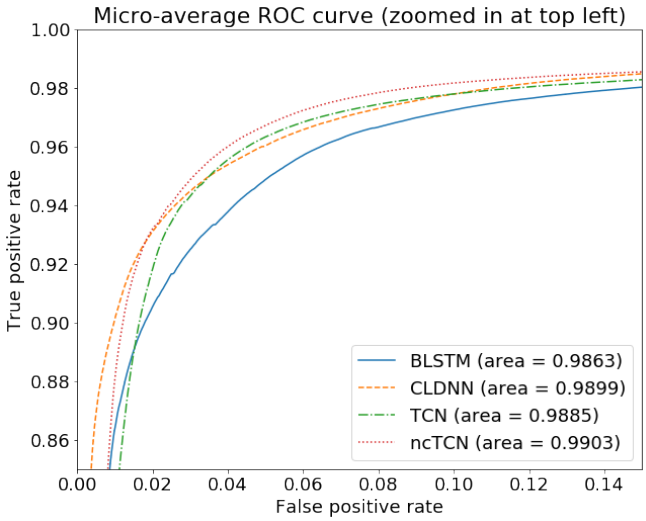

Figure 4: ROC curve micro-averaged over speech and music.

4.2 Dataset strategies

A new hyper-parameter optimization allowing for a bigger range of hyper-parameters was performed for the best-performing architecture (ncTCN). The batch size was reduced to 16 to allow the GPU to work with bigger architectures. The resulting architecture was trained with the four different strategies explained in Section 3.3. The strategy that achieved the lowest validation loss (Table 3) on the targeted high-quality dataset (HQ loss) is pre-training on the low-quality dataset, and subsequent training on the high-quality dataset (Strategy 4).

Table 3: Validation loss of the different strategies to use on high and low quality datasets.

Strategy	LQ loss	LQ/HQ loss	HQ loss
(1) LQ	**0.097**	0.125	0.232
(2) HQ	0.365	0.323	0.096
(3) LQ/HQ	0.098	**0.101**	0.136
(4) Pre-train	0.222	0.181	**0.070**

4.3 Post-processing (PP)

The high-quality training set was analyzed to set the four duration thresholds for the post-processing (see Section 3.6). The 1st, 5th and 10th percentiles were considered to obtain threshold values. For instance, in the case of the 5th percentile for the music event duration, it means that 95 % of the music events in the training set have a length exceeding the threshold. Table 4 presents the evaluation of the system with several post-processing methods based on the values from the different percentiles.

Table 4: F-measures for segment-level evaluation (F_s) and event-level evaluation (F_e) on the high-quality validation set by percentile. Underlined values denote statistically significant differences to the value one row above (paired-sample t-test, $p < 0.05$).

PP	F_s (segment)			F_e (event)		
	All	Mus.	Sp.	All	Mus.	Sp.
None	**0.973**	**0.982**	**0.951**	0.182	0.247	0.129
1st	**0.973**	**0.982**	0.950	0.510	0.589	0.417
5th	**0.973**	**0.982**	0.950	0.544	0.615	0.454
10th	0.971	0.981	0.949	**0.547**	**0.617**	**0.459**

The different impact of the post-processing on the segment and on the event-level evaluation is caused by the fact that a small modification at the frame level has a limited impact on the segment-level evaluation, but it can have a significant impact on the event-level evaluation. The set of values from the 5th percentile was selected for the rest of the evaluation since it represents a good compromise between a decrease in the segment-level evaluation and an increase in the event-level evaluation.

4.4 Evaluation of the ncTCN

Table 5: Segment-level evaluation of the final system

	All	Music	Speech
F_s	0.968	0.971	0.957
P_s	0.963	0.969	0.944
R_s	0.973	0.973	0.971

The results of the segment-level and event-level evaluations on the test set 1 are presented in Table 5 and Table 6, respectively. For the segment-level evaluation, the proposed non-causal TCN system obtains an F-measure of 0.971 for the music and of 0.957 for the speech. Due to the marginal effect of post-processing on the segment level, only results with post-processing are depicted. For the event-level evaluation, the system obtains clearly superior results with the post-processing. For example, the overall F-measure on both onset and offset increases from 0.151 without post-processing to 0.417 with post-processing.

Finally, the non-causal TCN was evaluated on the dataset 2 of the 2018 MIREX competition. The results are presented in Table 7 and Table 8 and the results of the other systems are taken from the MIREX website [1]. For the segment-level evaluation, the system obtains the best F-measure (0.946) on speech. On music, the system obtains an F-measure of 0.879 and the best system of the

Table 6: Event-level evaluation of the final system. Underlined values denote statistically significant difference to the value without pre-processing (paired-sample t-test, $p < 0.05$).

5. DISCUSSION

Based on the curves from Figure 4, our experiments suggest that the TCN-based architectures are outperforming the RNN-based architectures. Moreover, the TCN-based architectures train faster than the RNN-based architectures at similar sizes (around 80s/epoch for the TCN-based architectures and 340s/epoch for the RNN-bases architectures), results that corroborate conclusions [2] in different task contexts. The proposed non-causal TCN achieves better results than the causal TCN.

We also demonstrated that pre-training the neural network on a low-quality dataset prior to training it on the high-quality dataset improves the validation loss. Table 3 highlights the difference between the different strategies and it shows that the HQ loss function goes down from 0.096 to 0.070 by pre-training the network on low-quality datasets, it represents a relative improvement of 27 %. The analysis of the training set provides relevant thresholds for the post-processing method. Those values allow an improvement for the event-level evaluation on the validation set without harming the segment-level evaluation. Results on the test set (Table 5 and 6) confirm this analysis made on the validation set. Instead of applying some thresholds, more sophisticated probabilistic models may further improve the post-processing.

For the event-level evaluation, the overall results of all algorithms are much lower compared to the segment-level results. It shows one of the limits of the event-level evaluation: it is difficult to standardize precise boundaries for the events and especially the speech events. The results of the event-level evaluation highly depend on the rules that have been chosen during the annotation of the training set. Therefore, the segment-level evaluation might be more relevant to compare different algorithms on a test set with unknown annotation rules.

End-to-end learning may be considered an important area for future research. Pre-training an end-to-end learning solution on low-quality datasets and fine-tuning it on high-quality datasets might be a viable solution to overcome the expensive price of labeling data. This method was shown to be successful in this study and it might be suitable for other tasks.

6. CONCLUSION

In this paper, various architectures have been compared in a speech and music detection task. The findings are consistent with previous studies, demonstrating that convolutional architectures can yield better performance and are faster to train than RNN-based architectures for sequence modeling. Furthermore, the novel non-causal TCN can improve performance when real-time computation is not a constraint. Low-quality data was successfully used to improve the system performance on high-quality data. It provided a better starting point for the learning phase and it converged faster towards a lower minimum. Through the MIREX evaluation, the final system has demonstrated to perform well in relation to the state of the art. This encourages further exploration of TCN and non-causal TCN architectures for sequence modeling tasks.

7. ACKNOWLEDGEMENTS

This work was supported by the NordForsk's Nordic University Hub "Nordic Sound and Music Computing Network - NordicSMC" (proj. nr. 86892), and conducted in collaboration with Swedish Radio.

Special thanks to Christofer Bustad, Paul Nygren, and Ragnar Schön from Sveriges Radio for their help and advice during this project.

TOWARDS EXPLAINABLE MUSIC EMOTION RECOGNITION: THE ROUTE VIA MID-LEVEL FEATURES

Shreyan Chowdhury Andreu Vall Verena Haunschmid Gerhard Widmer
Institute of Computational Perception, Johannes Kepler University Linz, Austria
firstname.lastname@jku.at

ABSTRACT

Emotional aspects play an important part in our interaction with music. However, modelling these aspects in MIR systems have been notoriously challenging since emotion is an inherently abstract and subjective experience, thus making it difficult to quantify or predict in the first place, and to make sense of the predictions in the next. In an attempt to create a model that can give a musically meaningful and intuitive explanation for its predictions, we propose a VGG-style deep neural network that learns to predict emotional characteristics of a musical piece together with (and based on) human-interpretable, mid-level perceptual features. We compare this to predicting emotion directly with an identical network that does not take into account the mid-level features and observe that the loss in predictive performance of going through the mid-level features is surprisingly low, on average. The design of our network allows us to visualize the effects of perceptual features on individual emotion predictions, and we argue that the small loss in performance in going through the mid-level features is justified by the gain in explainability of the predictions.

1. INTRODUCTION

Emotions – portrayed, perceived, or induced – are an important aspect of music. MIR systems can benefit from leveraging this aspect because of its direct impact on human perception of music, but doing so has been challenging due to the inherently abstract and subjective quality of this feature. Moreover, it is difficult to interpret emotional predictions in terms of musical content. In our quest for computer systems that can give musically or perceptually meaningful justifications for their predictions [17], we turn to the notion of *'mid-level perceptual features'* as recently described and advocated by several researchers [1, 5]. These are musical qualities (such as rhythmic complexity, or perceived major/minor harmonic character) that are supposed to be musically meaningful and intuitively recognizable by most listeners, without requiring music-theoretic knowledge. It has been shown previously that there is considerable consistency in human perception of these features; that they can be predicted relatively well from audio recordings; and that they also relate to the perceived emotional qualities of the music [1].

That is the motivation for the work to be reported here. Our goal is to use mid-level features as a basis for providing explanations of (and thus get further insights into, or handles on) a model's emotion predictions, by training it to recognize mid-level qualities from audio, and predict emotion ratings from the mid-level predictions. Further, we wish to quantify the cost – in terms of loss of predictive performance – incurred by this detour. We will call this the 'cost of explainability'.

Focusing our study on a specific benchmark dataset labelled with both perceived emotional qualities and mid-level perceptual features, we first establish our basic VGG-style model architecture [16], showing that it can learn the two individual prediction tasks (mid-level from audio, emotion from mid-level) from appropriate ground-truth data, with accuracies that are at least on par with previously published models. We then present a network with nearly identical architecture that learns to predict emotional characteristics of a piece by explicitly going through a mid-level feature prediction layer. We compare this to predicting emotion directly, using an identical network with the exception of the mid-level layer, and find that the cost of going through the mid-level features is surprisingly low, on average. Finally, we show that by training the network to learn to predict mid-level and emotions jointly, the results can be further improved. A graphical overview of the general scenario is shown in Figure 1.

The fact that in our model, emotions are predicted from the mid-level by a single fully-connected layer, allows us to measure the effects of each of the features on each emotion prediction, providing the basis for interpretability and simple explanations. There are a number of application scenarios in which we believe this could be useful; some of these will be briefly discussed in the final section.

The remainder of this paper is structured as follows: Section 2 briefly discusses related work on which this research is based. In Section 4 the datasets that provide us with emotion and mid-level annotations are described. The three different approaches to modelling emotion are summarized in Section 5. Experimental results and a demonstration of interpretability are given in Sections 6 and 7.

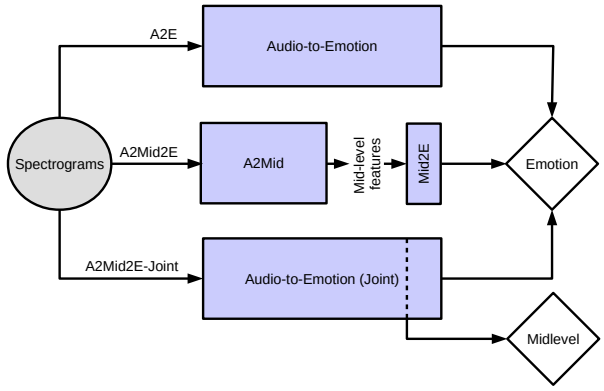

Figure 1: Three different architectures are compared for predicting emotion from audio.

We discuss our findings and conclude in Section 8.

2. RELATED WORK

In the MIR field, audio-based music emotion recognition (MER) has traditionally been done by extracting selected features from the audio and predicting emotion based on subsequent processing of these features [7]. Methods such as linear regression, regression trees, support vector regression, and variants have been used for prediction as mentioned in the systematic evaluation study by Huq et al [6]. Techniques using regression-like algorithms have generally focused on predicting arousal and valence as per the well-known Russell's *circumplex model* of emotion [15]. Deep learning methods have also been employed for predicting arousal and valence, for example [18], that investigated BLSTM-RNNs in tandem with other methods, and [3], that used LSTM-RNNs. Others such as [12] and [9] use support vector classification to predict the emotion class. Aljanaki et al. [2] provide a summary of entries to the MediaEval emotion characterization challenge and quote results for arousal and valence prediction.

Deep neural networks are preferable for many tasks due to their high performance but can be considered black boxes due to their non-linear and nested structure. While in some fields such as healthcare or criminal justice the use of predictive analytics can have life-affecting consequences [14], the decisions of MIR models are generally not as severe. Nevertheless, also in MIR it would be desirable to be able to obtain explanations for the decisions of a music recommendation or search system, for various reasons (see also Section 8). Many current methods for obtaining insights into deep network-based audio classification systems do not explain the predictions in a human understandable way but rather design special filters that can be visualized [13], or analyze neuron activations [8]. To the best of our knowledge, [19] is the only attempt to build an interpretable model for MER. They performed the task of feature extraction and selection and built models from different model classes on top of them. The only interpretation offered is the reporting of coefficients from their logistic regression models, without further explanation.

3. MID-LEVEL PERCEPTUAL FEATURES

The notion of *('mid-level') perceptual features* for characterizing music recordings has been put forward by several authors, as an alternative to purely sound-based or statistical low-level features (e.g., MFCCs, ZCR, spectral centroid) or more abstract music-theoretic concepts (e.g., meter, harmony). The idea is that they should represent musical characteristics that are easily perceived and recognized by most listeners, without any music-theoretical training. Research on such features has quite a history in the fields of music cognition and psychology (see [5] for a compact discussion). Such features are attractive for our purposes because they could provide the basis for intuitive explanations of a MIR system's decisions, relating as they do to the musical experience of most listeners.

Various sets of such perceptual features have been proposed in the literature. For instance, Friberg et al.'s set [5] contains such concepts as speed, rhythmic clarity/complexity, articulation, dynamics, modality, overall pitch hight, etc. In our study, we will be using the seven mid-level features defined by Aljanaki & Soleymani [1], because they come with an openly available set of annotated audios (see below). We recapitulate the features and their definitions in Table 1, for convenience.

4. DATASETS

For our experiments, we need music recordings annotated both with mid-level perceptual features, and with human ratings along some well-defined emotion categories. Our starting point is Aljanaki & Soleymani's *Mid-level Perceptual Features* dataset [1], which provides mid-level feature annotations. For the actual emotion prediction experiments, we then use the *Soundtracks* dataset, which is contained in the Aljanaki collection as a subset, and comes with numeric emotion ratings along 8 dimensions.

4.1 Mid-level Perceptual Features Dataset

The *Mid-level Perceptual Features Dataset* [1] consists of 5000 song snippets of around 15 seconds each annotated according to the seven mid-level descriptors listed in Table 1. The annotators were required to have some musical education and were selected based on passing a musical test. The ratings range from 1 to 10 and were scaled by a factor of 0.1 before being used for our experiments.

4.2 Emotion Ratings: The Soundtracks Dataset

The *Soundtracks (Stimulus Set 1)* [1] dataset, published by Eerola and Vuoskoski [4], consists of 360 excerpts from 110 movie soundtracks. The excerpts come with expert ratings for five categories following the discrete emotion model (happy, sad, tender, fearful, angry) and three categories following the dimensional model (valence, energy,

[1] https://www.jyu.fi/hytk/fi/laitokset/mutku/en/research/projects2/past-projects/coe/materials/emotion/soundtracks

Perceptual Feature	Question asked to human raters
Melodiousness	To which excerpt do you feel like singing along?
Articulation	Which has more sounds with staccato articulation?
Rhythmic Stability	Imagine marching along with the music. Which is easier to march along with?
Rhythmic Complexity	Is it difficult to repeat by tapping? Is it difficult to find the meter? Does the rhythm have many layers?
Dissonance	Which excerpt has noisier timbre? Has more dissonant intervals (tritones, seconds, etc.)?
Tonal Stability	Where is it easier to determine the tonic and key? In which excerpt are there more modulations?
Modality ('Minorness')	Imagine accompanying this song with chords. Which song would have more minor chords?

Table 1: Perceptual mid-level features as defined in [1], along with questions that were provided to human raters to help them interpret the concepts. (The ratings were collected in a pairwise comparison scenario.) In the following, we will refer to the last one (*Modality*) as *'Minorness'*, to make the core of the concept clearer.

tension). This makes it a suitable dataset for musically conveyed emotions [4]. The ratings in the dataset range from 1 to 7.83 and were scaled by a factor of 0.1 before being used for our experiments. As stated above, all the songs in this set are also contained in the Mid-level Features Dataset, so that both kinds of ground truth are available.

5. AUDIO-TO-EMOTION MODELS

In the following, we describe three different approaches to modeling emotion from audio, all based on VGG-style convolutional neural networks (CNNs). The architectures are summarized in Figure 2. For all models, we use an Adam optimizer with a learning rate of 0.0005 and a batch size of 8, and employ early stopping with a patience of 50 epochs to prevent overfitting.

In terms of preprocessing, the audio samples are first converted into 149-point spectrograms calculated on randomly selected 10-second sections of the original snippets. The audio is resampled at 22.05 kHz, with a frame size of 2048 samples and a frame rate of 31.25 frames per second, and amplitude-normalized before computing the logarithmic-scaled spectrogram. This results in input vectors of size 313×149. These spectrograms are used as inputs for the following model architectures.

5.1 A2E Scheme

The first model, which we term "A2E", is the most straightforward one. The spectrograms are fed into a VGG-style CNN to directly predict emotion values from audio. This is the leftmost path in Figure 2. This model is not interpretable due to its black box architecture and is used as a baseline and for computing the *cost of explainability* when comparing to more interpretable but possibly worse performing models.

5.2 A2Mid2E Scheme

In order to obtain a more interpretable model, an intermediate step is introduced. First, a VGG-style network is used to predict mid-level features from audio. This model is trained on the mid-level features dataset described in Section 4.1 above. Next, a linear regression model is trained to predict the 8 emotion ratings in the Soundtracks dataset from the 7 mid-level feature values that we get as an output from the mid-level predictor network. This corresponds to a fully connected layer with 7 input units and 8 outputs and linear (identity) activation function – see the middle path in Figure 2. We call this scheme "A2Mid2E". A linear model is chosen because its weights can easily be interpreted to understand the importance of each mid-level feature in predicting the emotion ratings.

5.3 A2Mid2E-Joint Scheme

In an attempt to replace the step-wise training of two separate models with a single model that, ideally, could learn an internal representation useful for both prediction tasks, while keeping the interpretability of the linear weights, we propose a third architechture, called "A2Mid2E-Joint" (rightmost path in Figure 2). This network learns to predict mid-level features and emotion ratings jointly, but still predicts the emotions directly from the mid-level via a linear layer. This is achieved by the second last layer having exactly the same number of units as there are mid-level features (7), followed by a linear output layer with 8 outputs. From this network, we extract two outputs – one from the second last layer ("mid-level layer"), and one from the last layer ("emotion layer"). We compute losses for both the outputs and optimize the combined loss (summation of both the losses).

6. EXPERIMENTS

The audio clips are preprocessed as described in Section 5 to obtain the input spectrograms. During training, one ran-

	Valence	Energy	Tension	Anger	Fear	Happy	Sad	Tender	Avg.
Mid2E (Aljanaki)	0.88	0.79	0.84	0.65	0.82	0.81	0.73	0.72	0.78
Mid2E (Ours)	0.88	0.80	0.84	0.65	0.82	0.81	0.74	0.73	0.79
A2E	0.81	0.79	0.84	0.82	0.81	0.66	0.60	0.75	0.76
A2Mid2E	0.79	0.74	0.78	0.72	0.77	0.64	0.58	0.67	0.71
A2Mid2E-Joint	0.82	0.78	0.82	0.76	0.79	0.65	0.64	0.72	0.75
$CoE_{A2Mid2E}$	0.02	0.05	0.06	0.10	0.03	0.02	0.02	0.08	0.05
$CoE_{A2Mid2E\text{-}Joint}$	-0.02	0.01	0.02	0.06	0.02	0.01	-0.04	0.03	0.01

Table 2: Summaries of the different model performances on predicting emotion. The last two rows show the "cost of explainability" (CoE), as the difference between our baseline (A2E) and the newly proposed models (A2Mid2E, A2Mid2E-Joint). A positive cost indicates a loss in performance.

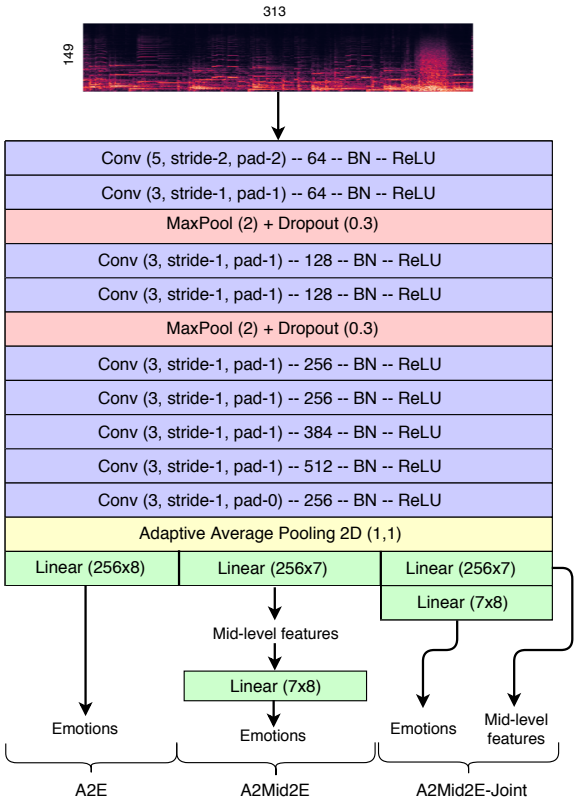

Figure 2: The same architecture from the first layer up to the 'Adaptive Average Pooling 2D' layer is shared by all networks.

dom 10-second snippet from each spectrogram is taken as input. We optimize the mean squared error, and use Pearson's correlation coefficient as the evaluation metric for emotion rating prediction. Each of the paths (A2E, A2Mid2E, A2Mid2E-Joint) is run ten times and the average correlation values are reported. Each run has a different seed which reshuffles the train-test split.

6.1 Verifying our Basic Architecture

Before going any further, we first want to verify that our VGG-style network model performs on par with comparable methods on the basic component tasks of predicting mid-level features from audio (A2Mid) and emotions from (given) mid-level features (Mid2E).

For the A2Mid scenario (Table 3), we train in two ways: first on the entire Mid-level features dataset with 8% test set selected as described in [1]. We call this A2Mid+. This is the result that should be directly compared to column 1. Second, we train only on the songs from the Soundtracks dataset with 20% test set, and call this A2Mid. The column 'Joint' in Table 3 gives the mid-level predictions produced by our A2Mid2E-Joint model. As can be seen, our models are broadly comparable to the results reported in [1], with A2Mid+ and *Joint* performing slightly better, on average.

Regarding the prediction of emotions from given mid-level feature annotations (Table 2, first two rows), there is not much space for deviation, as the models used by Aljanaki [1] and us are very simple.

Mid-level feature	Aljanaki	A2Mid+	A2Mid	Joint
Melodiousness	0.70	0.70	0.69	0.72
Articulation	0.76	0.83	0.84	0.79
R. Stability	0.46	0.39	0.39	0.34
R. Complexity	0.59	0.66	0.45	0.46
Dissonance	0.74	0.74	0.73	0.74
Tonal Stability	0.45	0.56	0.61	0.63
Minorness	0.48	0.55	0.51	0.57

Table 3: Correlation values for mid-level features predictions using our models, compared with those reported by Aljanaki et al. [1].

6.2 Quantifying the Cost of Explainability

We now compare our three model architectures (A2E, A2Mid2E, A2Mid2E-Joint) on the full task of predicting emotion from audio, We train on the Soundtracks dataset as described above, with 10 runs with randomly selected train-test 80:20 splits. The A2E model serves as reference for the subsequent models with explainable linear layers. The results can be found in Table 2.

In the case of direct emotion prediction (A2E), the final layer is connected to 256 input nodes. However, in the A2Mid2E scheme, due to the fact that we introduce a bottleneck (viz. the 7 mid-level predictions) as inputs to the subsequent linear layer predicting emotions, our hypothesis is that doing so should result in a decrease in the perfor-

mance of emotion prediction. We calculate this cost as the difference in correlation coefficients between the two models for each emotion. The results (rows A2E and A2Mid2E in Table 2) reflect the expected trend, but as can be seen, the decrease in performance is quite small (less than 7% of the original correlation coefficient on average).

6.3 Joint Learning of Mid-level and Emotions

Further improvements in the performance of the mid-level-based network can be obtained by training jointly on the mid-level and emotion annotations (as described in Section 5.3). This model reduces the cost even further, as can be seen in Table 2, row A2Mid2E-Joint. The decrease in performance is now less than 1.5% of the correlation coefficients for the A2E case on average. We believe this is acceptable in view of the possibility of obtaining explanations from this network (see below).

7. OBTAINING EXPLANATIONS

Since the mapping between mid-level features and emotions is linear in both proposed schemes (A2Mid2E, A2Mid2E-Joint), it is now straightforward to create human-understandable explanations. Linear models can be interpreted by analyzing their weights: increasing a numerical feature by one unit changes the prediction by its weight. A more meaningful analysis is to look at the *effects*, which are the weights multiplied by the actual feature values [10]. An effects plot shows the distribution, over a set of examples, of the effects of each feature on each target. Each dot in an effects plot can be seen as the amount this feature contributes (in combination with its weight) to the prediction, for a specific instance. Instances with effect values closer to 0 get a prediction closer to the intercept (bias term). Figure 3 shows the effects of the model A2Mid2E-Joint.

First we will show how this can be used to provide model-level explanations and then we will explain a specific example at the song level.

7.1 Model-level Explanation

Before a model is trained, the relationship between features and response variables can be analyzed using correlation analysis. The pairwise correlations between mid-level and emotion annotations in our data are shown in Figure 4. When we compare this to the effect plots in Figure 3, or the actual weights learned for the final linear layer (Figure 5) it can be seen that for some combinations (e.g., valence and melodiousness, happy and minorness) positive correlations go along with positive effect values and negative correlations with negative effect values, respectively. This is not a general rule, however, and there are several examples (e.g., tension and dissonance, energy and melody) where it is the other way around. The explanation for this is simple: correlations only consider one feature in isolation, while learned feature weights (and thus effects) also depend on the other features and must hence be interpreted in the overall context. Therefore it is not sufficient to look at the data in order to understand what a model has learned.

	predicted		annotated	
	#153	#322	#153	#322
valence	0.28	0.39	0.38	0.46
energy	0.37	0.50	0.37	0.54
tension	0.40	0.46	0.50	0.56
anger	0.28	0.23	0.15	0.22
fear	0.41	0.27	0.18	0.28
happy	0.17	0.21	0.17	0.17
sad	0.20	0.23	0.27	0.28
tender	0.18	0.23	0.10	0.10

Table 4: Emotion prediction profiles for the two example songs #153 and #322.

To get a better understanding, we will look at each emotion separately, using the effects plot given in Figure 3. In addition to the direction of the effect – which we can also read from the learned weights in Figure 5 (but only because all of our features are positive) – we can also see the spread of the effect which tells us more about the actual contribution the feature can have on the prediction, or how different combinations of features may produce a certain prediction.

7.2 Song-level Explanations

Effect plots also permit us to create simple example-based explanations that can be understood by a human. The feature effects of single examples can be highlighted in the effects plot in order to analyze them in more detail, and in the context of all the other predictions. To show an interesting case we picked two songs with similar emotional but different midlevel profiles. To do so we computed the pairwise euclidean distances between all songs in emotion (d_{E}) and midlevel space (d_{Mid}) separately, scaled both to the range $[0, 1]$ and combined them as $d_{\mathrm{comb}} = d_{\mathrm{E}} - (1 - d_{\mathrm{Mid}})$. We then selected the two songs from the Soundtracks dataset that maximised d_{comb}. The samples are shown in Figure 3 as a red square (song #153) and a blue dot (song #322). The reader can listen to the songs/snippets by downloading them from the Soundtracks dataset page [1] .

As can be seen from Figure 3 and from the emotion prediction profile of the two songs (see Table 4), both songs have relatively high predicted values for *tension* and *energy*, but apparently for different reasons: song #322 more strongly relies on “minorness" and “articulation" for achieving its “tense" character; on the other hand, its rhythmic stability counteracts this more strongly than in the case of song #153. The higher score on the “energy" emotion scale for #322 seems to be primarily due to its much more articulated character (which can clearly be heard: 153 is a saxophone playing a chromatic, harmonically complex line, 322 is an orchestra playing a strict, *staccato* passage).

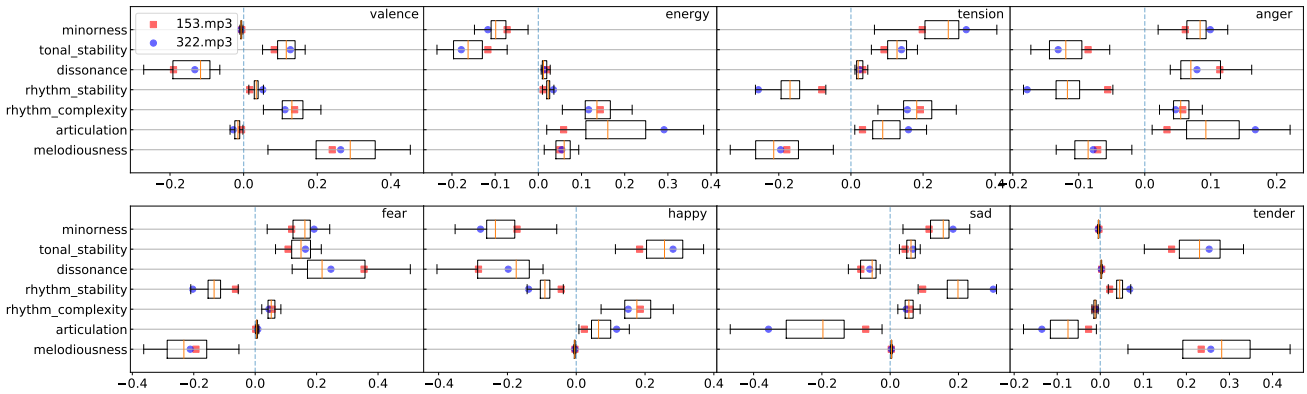

Figure 3: Effects of each mid-level feature on prediction of emotion. The boxplots show the distribution of feature effects of the model 'A2Mid2E-Joint' helping us to understand the model globally. Additionally, two example songs (blue dots, red squares) are shown to provide song-level explanations (see Section 7.2 for a discussion).

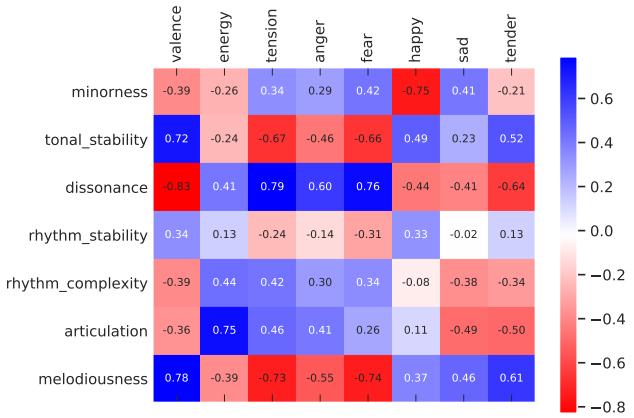

Figure 4: Pairwise correlation between mid-level and emotion annotations.

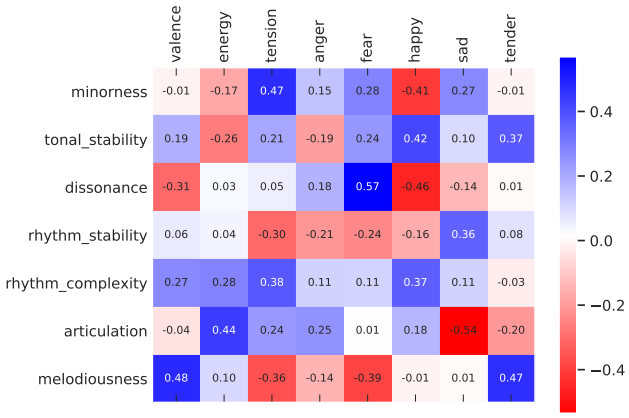

Figure 5: Weights from the linear layer of the 'A2Mid2E-Joint' model.

8. DISCUSSION AND CONCLUSION

Model interpretability and the possibility to obtain explanations for a given prediction are not ends in themselves. There are many scenarios where one may need to understand why a piece of music was recommended or placed in a certain category. Concise explanations in terms of mid-level features would be attractive, for example, in recommender systems or search engines for 'program music' for professional media producers, where mid-level qualities could also be used as additional search or preference filters [2] . As another example, think of scenarios where we want a music playlist generator to produce a music program with a certain prevalent mood, but still maintain musical variety within these limits. This could be achieved by using the mid-level features underlying the mood/emotion classifications to enforce a certain variability, by sorting or selecting the songs accordingly.

There are several obvious next steps that need to be taken in the research. The first is to extend this analysis to a larger set of diverse datasets and emotion-related dimensions. [3]

Second, we plan to extend the models and sets of perceptual features. One rather obvious (and obviously relevant) perceptual dimension that is conspicuously missing from our (Aljanaki & Soleymani's) set of mid-level features is *perceived speed* (which is not the same as tempo). Adding this intuitive musical dimension is an obvious next step towards improving our model. Of course, this will require an appropriate ground truth for training.

Generally, the relation between the space of musical qualities (such as our mid-level features) and the space of musically communicated emotions and affects deserves more detailed study. A deeper understanding of this might even give us means to control or modify emotional qualities in music by manipulating mid-level musical properties.

[2] A demonstration of mid-level explanations of emotional variability in multiple versions of songs can be found in `https://shreyanc.github.io/ismir_example.html`

[3] In fact, we do have preliminary results on a second dataset – the *MIREX-like Mood Dataset)* of [11], which is also covered by the Mid-level Perceptual Features Dataset of [1] and differs from *Soundtracks* in that is comes with discrete mood labels. The results confirm the general trends reported in the present paper, but because of the different emotion/mood encoding scheme, further optimisations on our models may still improve the results further.

ABSTRACT

Audio-based cover song detection has received much attention in the MIR community in the recent years. To date, the most popular formulation of the problem has been to compare the audio signals of two tracks and to make a binary decision based on this information only. However, leveraging additional signals might be key if one wants to solve the problem at an industrial scale. In this paper, we introduce an ensemble-based method that approaches the problem from a many-to-many perspective. Instead of considering pairs of tracks in isolation, we consider larger sets of potential versions for a given composition, and create and exploit the graph of relationships between these tracks. We show that this can result in a significant improvement in performance, in particular when the number of existing versions of a given composition is large.

1. INTRODUCTION

With the rise of online streaming services, it is becoming easier for artists to share their music with the rest of the world. With catalogs that can reach up to tens of millions of tracks, one of the rising challenges faced by music streaming companies is to assimilate ever-better knowledge of their content – a key requirement for enhancing user and artist experience. From a musical perspective, one highly interesting aspect is the detection of composition similarities between tracks, often known as the *cover song* detection problem. This is, however, a very challenging problem from a content analysis point of view, as artists can make their own version of a composition by modifying any number of ingredients – instruments, harmonies, melody, rhythm, structure, timbre, vocals, lyrics, among others.

Over the years, it has become customary in the Music Information Retrieval (MIR) literature to address the cover song detection problem in what is arguably the most challenging setting. Indeed, most papers attempt to detect composition relationships between pairs of tracks based on their two audio signals only – in other words, completely out of context and without using any metadata information. While this well-defined task makes sense from an academic perspective, it might not be the optimal approach for solving the problem at an industrial scale [4].

The second starting point of our work is the fact, often mentioned in cognitive science, that commonly observed patterns are represented and stored in a redundant fashion in the human brain, which makes them more likely to be retrieved, recognised and identified than patterns that are observed less frequently [14]. If true, this would apply to our assessment of composition similarities as well. The main idea behind our work is that the corpus of existing versions of a composition can be precisely a substitute for these multiple representations.

Following these guiding intuitions, we turn to a new use case, where we do not just have pairs but a pool of *candidates* that are likely to be instances of some given musical work (according *e.g.* to some first metadata analysis). We then compare these candidates not only to *one* reference version (*e.g.* the original track, if it exists) but also to other candidate versions. We then build a graph of all these versions to identify composition clusters. Sometimes, when hundreds or thousands of versions of a given work exist (which is quite common in the catalogue of a streaming company), this ensemble-based approach can result in substantial improvements on the cover detection task.

In Section 2 we present a review of the literature on cover identification. In Section 3, we present the 1-vs-1 cover identification algorithm that we use throughout the paper, which is heavily based on [23]. The main contribution of this paper lies in Section 4, in which we present the new use case for cover identification described in the previous paragraph.We then showcase our method with examples in Section 5 and discuss some challenges in Section 6.

2. RELATED WORK

A number of possible approaches to cover song identification [12, 15] have been developed in the last decade. The authors of [9] introduced a first solution to this problem which has been used as a starting point for many subsequent studies. The main idea is to extract a list of beat-synchronous [6] chroma features from two input tracks and quantify their similarity by applying dynamic programming algorithms to a cross-similarity matrix derived from these features. This algorithm has been refined in [8] by adding a few modifications such as tempo biasing. Harmonic Pitch Class Profile (HPCP) features (chroma features) have proven very useful in cover identification [9, 18–20] as they capture meaningful musical information for composition. Other features have subsequently been introduced, such as self-similarity matrices of MFCC features [23, 24]. To take advantage

of the complementary properties of different types of features, [23] further introduced a method to combine several audio features by fusing the associated cross-similarity matrices, which resulted in a significant increase in performance compared to single-feature approaches. Having extracted audio features from two tracks to be compared, most methods use dynamic programming (either Dynamic Time Warping or the Smith-Waterman algorithm [22]) to assign a score to the pair [9, 23, 24]. One drawback of these methods is that they are computationally expensive and cannot be run at scale. Scalable solutions have been developed by mapping audio features to smaller latent spaces. For instance, [1, 13] use Principal Component Analysis (PCA) to compute a condensed representation of audio features which they use to perform a large-scale similarity search (*e.g.* a nearest neighbor search). In the same vein, [10, 17] use deep neural networks to learn low-dimensional representations of chroma features.A smaller number of papers take an ensemble-based approach and report increases in performance. In particular, [3, 23] leverage the network of songs using Similarity Network Fusion thereby fusing scores obtained via different methods, while [21] investigate several clustering methods and report in particular that the original song tends to be central within their communities.

3. PAIRWISE MATCHING

As mentioned above, our ensemble-based cover identification method consists of two steps. For a given work, we proceed to: ***(i)*** a pairwise (1-vs-1) comparison of all the tracks in a pool of potential candidates, ***(ii)*** a clustering of these candidates based on the results of step (i). In this section we present the 1-vs-1 cover song identification algorithm (i) which will be used as a starting point for our ensemble-based approach, and evaluate its performance on two distinct cover datasets.

3.1 The algorithm

For the purposes of this work, any 1-vs-1 similarity measure could be used for step (i), as we are mainly interested in quantifying the impact of step (ii) on the overall performance. We have chosen to rely on an implementation of the algorithm introduced in [23], as the algorithm achieves the best results to date on the *Covers80* [7] and *MSD* (*Covers1000*) datasets [2]. For a high-level overview of the pipeline, please refer to Figure 2 in [23]. As with most algorithms presented in Section 2, it can be decomposed into two stages: first, it extracts a list of meaningful audio features from the two tracks to be compared, then it computes a similarity score based on these. The details of this method are not directly relevant to our work, so we will focus here on a quantitative assessment of its performance, to give the reader a quantitative idea of our starting point. More details on the algorithm can be found in [23].

3.2 Quantitative evaluation of the 1-vs-1 method

We evaluate our implementation of [23] on two different datasets, and compare it with the numbers reported in the original paper as well as with a publicly available implementation of [23] by its author. [1] To make the comparison more interpretable, we evaluate two versions of our implementation with two sets of parameters: *Params1* mimics the parameters used in [23], and should therefore produce numbers that very similar to those described in the original paper, while *Params2* uses shorter 8-beats-long blocks.

We first compare the algorithms on the widely used *Covers80* dataset [7] to enable comparison with other published methods. The dataset is composed of 160 tracks that are divided into two sets (A and B) of 80 tracks each, with every track in set A matching one (and only one) track in set B. For each of the 160 tracks, we compute its score with all the other 159 tracks and report the rank of its true match. Table 1 reports the Mean Rank (MR) of the true match (1 is best), the Mean Reciprocal Rank (MRR) [5], as well as the Recall@1 (R@1) and Recall@10 (R@10). We also compute the so-called *Covers80 scores* by querying each track in set A against all the tracks in set B and reporting the number of matches found with rank 1. [2] Overall, our results are close to the ones reported in [23] – even though we could not quite reach the numbers given in their paper.

	Covers80					**Internal Dataset**	
	MR	MRR	R@1	R@10	*Covers80* score	Recall	Recall (no Jazz)
[23] paper	**7.8**	**0.85**	**82.4%**	89.9%	**68/80**	-	-
[23] code	8.6	0.77	71.7%	**91.2%**	62/80	73.2%	81.8%
Params1	10.5	0.81	78.6%	85.5%	64/80	79.2%	87.8%
Params2	13.2	0.75	73.0%	80.5%	60/80	**85.8%**	**95.1%**

Table 1: Comparison of our implementations (*Params1* and *Params2*) against the implementations of [23], on the *Covers80* dataset and on our internal dataset. The recall rates for the internal dataset correspond to a false positive rate of 0.5%. For each column, the best performance is printed in bold.

To complement this baseline, we have created an internal dataset of 452 pairs of covers grouped into several categories, obtained by metadata filtering based on the keywords *Acoustic Cover, Instrumental Cover, Karaoke, Live, Remix, Tribute* as well as some *Classical* and *Jazz* covers. Such granularity allows us to compare the performance of our algorithm across genres and cover types, providing a new perspective on the problem, as shown in Table 2. We have tested the two versions of our algorithm on the 452 positive pairs and 10,000 negative pairs selected uniformly at random. We selected the classification threshold to ensure a very low false positive rate below 0.5%. Results are presented in Table 1. Our algorithm reaches 85.8% recall, versus 73.2% for the publicly available implementation of [23] [3] . Note that jazz is the most challenging genre to

[1] https://github.com/ctralie/GeometricCoverSongs

[2] Each track from set A is now queried against the 80 tracks from set B, instead of all other 159 tracks.

[3] As the computational time is much higher for this algorithm, we only computed the false positive rate using 500 negative pairs.

detect, as jazz covers include a lot of improvisation that can be structurally different from their parent track (see Table 2). If we remove jazz covers from the dataset, the recall increases to 95.1% with the *Params2* implementation.

Type	Acoustic	Instr.	Karaoke	Live	Remix	Tribute	Classical	Jazz
# of pairs	57	63	46	57	31	53	77	68
Recall	94%	84 %	97%	100%	93 %	96 %	100 %	35 %

Table 2: Recall rates for each genre in our internal dataset, with a $< 0.5\%$ false positive rate.

In view of these results, we will use our own implementation with *Params2* throughout the rest of this paper, as it is faster and performs best on our internal dataset, which is larger and more diverse than *Cover80*.

3.3 Distributions of scores

Figure 1 presents the histogram of pairwise scores for all the positive and negative pairs in our internal dataset. The distribution of scores for the negative pairs is short-tailed and tightly concentrated around $s = 2$. This means that above $s \simeq 5$, all the pairs can be matched with high confidence. The distribution of scores for the positive pairs is much wider. As we can see from the histogram, a non-negligible fraction of these pairs lies below the classification threshold (dashed vertical line) and thus cannot be detected with this 1-vs-1 method. The purpose of the next section will be to apply an ensemble method to a pool of candidate versions of a given work, to bring these undetected candidates above the threshold by exploiting the many-to-many relationships between the candidates.

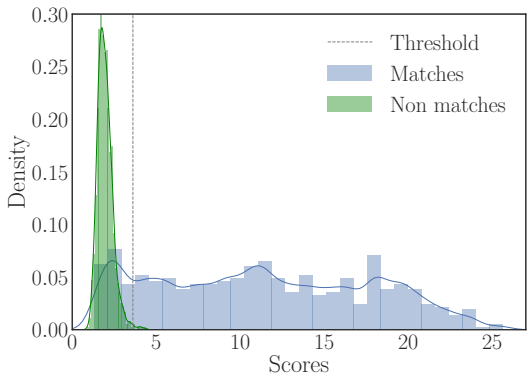

Figure 1: Histogram of the scores for positive *(blue)* and negative *(green)* pairs on our internal dataset. The threshold corresponds to the threshold used for Table 2.

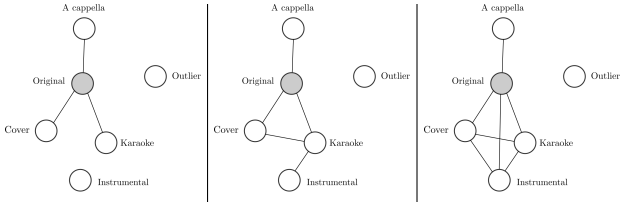
4. ENSEMBLE ANALYSIS

While the 1-vs-1 algorithm we presented in Section 3 gives satisfying results overall, it still struggles on covers that are significantly different from their original track. Here we show how analyzing a large pool of candidate covers for one given reference track can improve the quality of the matching. The intuition behind this idea is that a cover version can match the reference track poorly, but match another intermediate version which is closer to the reference. For instance, an acoustic cover can be difficult to detect on a 1-vs-1 basis, but might match a karaoke version which itself strongly matches the reference track. We therefore turn to a new use case, where we not only compare single pairs (*e.g.* one reference track against one possible cover), but instead start from a pool of candidates that are all likely to be instances of some given composition (or *work*). Usually, this pool corresponds to candidates that have been pre-filtered according to some non-audio related signal, *e.g.* their title, and might comprise up to a few thousands candidates, depending on the popularity of the work and the specificity of the pre-filtering step.



(a) Computing scores versus the reference track

(b) Computing all pairwise scores

(c) Final graph

Figure 2: Direct (a) vs. ensemble-based approach (b)-(c).

4.1 Computing all pairwise scores

Given a set of N candidate versions of a work, we first compare all possible pairs of candidates within the set, resulting in $\frac{N(N-1)}{2}$ distinct scores $\{s_{ij}\}_{1 \leq i < j \leq N}$. As mentioned above, if the candidates have been pre-filtered using some metadata-matching algorithm, N typically varies from a few dozen to a few thousand candidates.

4.2 Scores to distances

Figure 1 shows that almost all negative pairs have scores between 0 and 4 while scores above 8 always correspond to positives. Scores above 8 should thus indicate a high probability of a true match regardless of the score, while a variation in score around 4 should have a significant impact on that probability. To account for this fact, we convert our scores into more meaningful distances using a logistic function: $d_{ij} = \left(1 + e^{-\frac{s_{ij}-m}{\sigma}}\right)^{-1}$, where s_{ij} is the score associated to pair (i, j) and d_{ij} is the resulting distance. We have found that the values $\sigma = 0.5$ and $m = 4.3$ work well with the distance-collapsing algorithm introduced in the next section.

4.3 Collapsing the distances

Let $D = \{d_{ij}\}$ denote the pairwise distance matrix between all pairs of candidates (see Figure 3, top left). The idea behind the ensemble-based approach is to exploit the geometry of the data to enhance the accuracy of the classification – for example, the fact that a track can match the reference track better through intermediate tracks than

directly. We use a loose version of the Floyd-Warshall algorithm [11] to update the distances in D, such that the new distances satisfy the triangular inequality most of the time [4]. The method is presented in Algorithm 1.

Algorithm 1 Loose Floyd-Warshall

procedure COLLAPSEDISTANCES(distance matrix D)
  while D still updates **do**
    for i, j in $1..N$ **do**
      $\widetilde{D}(i,j) \leftarrow \mathbf{min}^{(2)}_{k \neq i,j} D(i,k) + D(k,j) + \eta$
      $D(i,j) \leftarrow \mathbf{min}\Big(D(i,j),\ \widetilde{D}(i,j)\Big)$

Here $\min^{(k)}(x)$ denotes the k^{th} smallest value of a vector x. Using $k > 0$ allows to gain robustness as several short paths are required to merge clusters. We have found that the algorithm is slightly more robust when imposing a penalty $\eta > 0$ for using an intermediate node, which we have set to $\eta = 0.01$ after performing a grid-search optimization.

Figure 3 shows the distance matrix before (top left) and after (top right) updating the distances using Algorithm 1, for a set of candidates versions of *Get Lucky* by Daft Punk. We can see that the updated distance matrix has a more neatly defined division between clusters of tracks. The figure shows one large cluster in which all tracks are extremely close to each other (the white area), a few smaller clusters (white blocks on the first diagonal) and a number of isolated tracks that match only themselves.

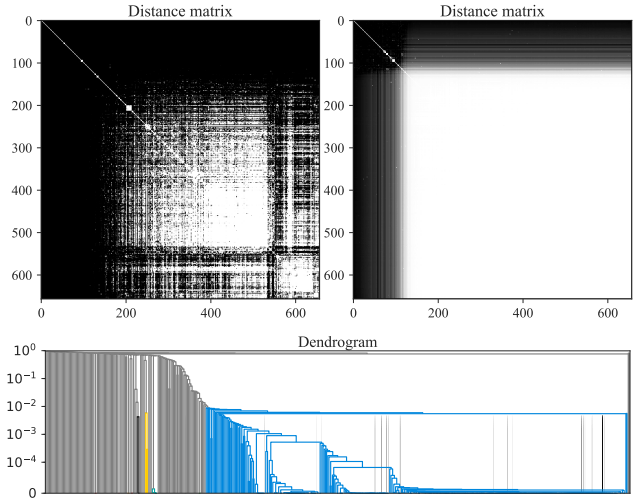


Figure 3: Top: The Floyd-Warshall algorithm applied to the distance matrix of *Get Lucky*, with (left) original distance matrix and (right) the distance matrix after applying the Floyd-Warshall algorithm. For better visual interpretation, tracks are reordered along the axes according to proximity. Darker shades correspond to larger distances. Bottom: dendrogram representation of the hierarchical clustering on the Floyd-Warshall distance matrix.

[4] The distances that would be obtained by applying the original Floyd-Washall algorithm to D would always satisfy the triangular inequality, but the resulting configuration would be very sensitive to outliers. Our method is more robust to outliers, as it requires to find more than one better path to update the distance between two points.

4.4 Hierarchical clustering

We then proceed to a clustering of the tracks using the updated distance matrix defined in 4.3, denoted D'. We use hierarchical clustering with centroid linkage [16] as we have no prior knowledge on the number of clusters in the graph. Figure 3 (bottom) shows a dendrogram representation of the hierarchical clustering applied to D'. In this example, if we apply a relatively selective threshold, we find one major cluster (colored in blue in Figure 3) that contains 97% of the true positives and no false positives. Most other clusters contain a single element, which are all the negative tracks and the remaining 3% of the positives. If we set the clustering threshold lower, then we can get more granular clusters within a same work.

4.5 Final score

In order to assign each track a final score that measures its similarity to the reference track, we use the *cophenetic distance* to the reference track that is produced by the hierarchical clustering (*i.e.* the minimum distance threshold for which they would find themselves in the same cluster as the reference track). Each track is thus assigned a final score in $0 - 100$, simply taken equal to $100 \times$ (1 - cophenetic distance), such that exact matches have a score of 100.

5. ANALYSIS OF REAL WORLD EXAMPLES

5.1 Data

We now apply the above to real world data. Our dataset consists of 10 sets of candidates that correspond to 10 works that we want to find the versions of. These 10 works span multiple genres and musical styles, including Hip Hop, R&B, Rap, Pop and Jazz. For a given work, we create the set of candidates by performing a metadata search of the given work's title on the whole Spotify catalogue, which we then annotate manually. Across the given works that we study, this produces sets of candidates whose sizes vary from a few hundred to a few thousand candidate tracks. Each set includes a reference track, which will be the anchor point for that composition. More details on the dataset can be found in Table 3.

Work	# tracks	% positives	Reference artist
Airplane	811	19%	B.o.B
Believer	2552	5%	Imagine Dragons
Blurred Lines	386	71%	Robin Thicke
Bodak Yellow	110	78%	Cardi B
Brown Sugar	721	5.8%	D'Angelo
Embraceable You	1319	94%	Sarah Vaughan
Get Lucky	657	83%	Daft Punk
Halo	2995	7.9%	Beyoncé
Heartless	1747	5.3%	Kayne West
Imagine	2044	50%	John Lennon

Table 3: The "10 works" dataset. For each work, we have selected a reference track that will be our anchor point for that composition. *Click on a work to play the reference track in the browser.*

5.2 Outline of the analysis

For each of these works, we analyze the set of candidates following the steps outlined in the previous two sections, providing us with two sets of outputs for each work: ***(a)*** the *direct score*, defined as the output of the 1-vs-1 algorithm between each candidate and the reference track, as described in Section 3 (rescaled between 0 and 100); ***(b)*** the *ensemble-based score*, produced by the method described in Section 4 (also between 0 and 100).

In the next section we start by quantitatively evaluating our ensemble-based approach (b) against the direct approach (a), before turning to some qualitative examples.

5.3 Quantitative results

We define two different metrics to evaluate the direct and the ensemble-based methods:

Ranking metric: For each work, we pick the value of the threshold that minimizes the number of classification errors, and report the number of errors. We call this a *ranking metric* as the number of errors is minimized when positives and negatives are perfectly ranked, regardless of their scores. We also report the corresponding recall and false positive rates for this threshold.

Classification metric: We fix a universal classification threshold and compute the corresponding number of classification errors.

Work	Best thr.	Ranking errors - direct					
		False negatives		False positives		Both	
		Abs.	Rel.	Abs.	Rel.	Abs.	Rel.
Airplane	12.1	33	21.9%	1	0.2%	34	4.2%
Believer	18.2	6	5.2%	0	0.0%	6	0.2%
Blurred Lines	10.1	19	7.0%	9	8.3%	28	7.3%
Bodak Yellow	6.1	6	7.0 %	6	33.3%	12	10.9%
Brown Sugar	12.1	2	4.8%	1	0.1%	3	0.4%
Embraceable You	4	0	0%	74	98.7 %	74	5.6 %
Get Lucky	10.1	17	3.1%	3	2.6%	20	3.0%
Halo	11.1	8	3.4%	8	0.3%	16	0.5%
Heartless	12.2	15	16.3%	2	0.1%	17	1.0%
Imagine	15.2	72	7.1%	17	1.7%	89	4.4%

(a) Direct approach.

Work	Best thr.	Ranking errors - ensemble-based					
		False negatives		False positives		Both	
		Abs.	Rel.	Abs.	Rel.	Abs.	Rel.
Airplane	70.7	4	2.6%	3	0.5%	7	0.9%
Believer	85.9	0	0.0%	0	0.0%	0	0.0%
Blurred Lines	52.5	0	0.0%	0	0.0%	0	0.0%
Bodak Yellow	29.3	9	10.5%	0	0.0%	9	8.2%
Brown Sugar	70.7	0	0.0%	1	0.1%	1	0.1%
Embraceable You	40.4	22	1.8 %	19	25.3 %	41	3.1 %
Get Lucky	78.8	5	0.9%	2	1.7%	7	1.1%
Halo	98.0	4	1.7 %	20	0.7%	24	0.8%
Heartless	83.8	8	8.7%	1	0.1%	9	0.5%
Imagine	96.0	1	0.1%	5	0.5%	6	0.3%

(b) Ensemble-based approach.

Table 4: Optimal thresholds and corresponding results for the ranking metric.

Table 4 shows the results for the ranking metric for each work in our dataset. For the optimal thresholds, we report the number of false negatives, false positives and the sum of both (*i.e.* the total number of classification errors). We also compute the corresponding false negative rate, false positive rate and total error rate.

Table 4a shows the ranking results for the direct approach. Interestingly, the number of false negatives tends to be higher than the number of false positives. [5] This is in line with the histogram in Figure 1, which shows a short-tailed distribution for the negatives and a wider distribution for the positives. Overall, the error rate lies between $0 - 10\%$, corresponding to a recall rate between 80% and 97% and a false positive rate below 10% (except for *Bodak Yellow* and *Embraceable You* which have a very small number of negatives to begin with – the latter case is in fact degenerate as nearly all tracks are classified as matching).

Table 4b shows the ranking results for our ensemble-based approach. The number of ranking errors is substantially lower than for the direct approach, including both the number of false positives and false negatives, as the total error rate goes down below 1% in most cases. Again, the main exception is *Bodak Yellow*, which has the smallest number of candidates. [6] *Embraceable You* is the second most challenging work, but remarkably its threshold is no longer degenerate, meaning that the method has now found a way to separate the candidates. Notably, the number of false negatives no longer outnumbers the number of false positives: the ensemble-based approach has successfully caught most of the difficult tracks that poorly matched the reference track. Among the few tracks that are still missed, several are actually very close to the threshold, and only a handful are still completely undetected (cf Table 7).

Table 5 shows the results for the classification metric. The universal threshold for each approach is defined as the median of the optimal thresholds obtained in the ranking experiment above. Again, we report the number of false negatives, the number of false positives and the sum of both. We also compute the corresponding false negative rate, false positive rate and total error rate. Here again, the results of the ensemble-based approach are overall superior to the direct approach, mostly due to an increase in recall. Although Table 5a is quite similar to Table 4a, which is a sign that the threshold on direct scores can be chosen in a nearly universal way, Table 5b differs considerably from Table 4b for some specific works (namely *Halo*, *Imagine* and *Believer*). This happens as the optimal threshold is significantly higher on these works (often $> 95\%$), letting a large number of false positives above the 78.8% threshold.

5.4 Examples

For each work, we can identify the cases where the ensemble-based approach has allowed us to detect previously undetected tracks, and trace back the optimal path that joined the reference track and the newly found track. Table 6 shows a few examples of such paths for various works. For each example, the reference track is shown at

[5] *Embraceable You* is an exception, as its threshold is degenerate and all tracks are classified as matching.

[6] It was also a genuinely difficult example and we struggled to annotate it.

Work	Thr.	Classification errors - direct					
		False negatives		False positives		Both	
		Abs.	Rel.	Abs.	Rel.	Abs.	Rel.
Airplane	12.1	33	21.9%	1	0.2%	34	4.2%
Believer	12.1	4	3.5%	91	3.7%	95	3.7%
Blurred Lines	12.1	28	10.3%	0	0%	28	7.3%
Bodak Yellow	12.1	49	57 %	0	0%	49	44.5%
Brown Sugar	12.1	2	4.8%	1	0.1%	3	0.4%
Embraceable You	12.1	753	60.5 %	3	4 %	756	57.3 %
Get Lucky	12.1	23	4.2%	1	0.9%	24	3.7%
Halo	12.1	12	5.1%	4	0.1%	16	0.5%
Heartless	12.1	15	16.3%	2	0.1%	17	1.0%
Imagine	12.1	49	4.8%	94	9.3%	143	7%

(a) Direct approach.

Work	Thr.	Classification errors - ensemble-based					
		False negatives		False positives		Both	
		Abs.	Rel.	Abs.	Rel.	Abs.	Rel.
Airplane	78.8	9	6.0%	1	0.2%	10	1.2%
Believer	78.8	0	0.0%	27	1.1%	27	1.1%
Blurred Lines	78.8	2	0.7%	0	0.0%	2	0.5%
Bodak Yellow	78.8	19	22.1%	0	0.0%	19	17.3%

	1	Karaoke Universe	**20.5**	**99.96**
Halo Halo	2	Fajters	7.45	**99.35**

Table 6: Some examples of tracks that are undetected by the direct approach and captured by the ensemble-based approach, in the ranking experiment. The scores that are above the detection thresholds for each method are displayed in bold (the corresponding detection thresholds can be found in Table 4). *Click on an artist to play in the browser.*

the top of the cell (depth 0), and the newly found track at the bottom of the cell (depth > 1), with the intermediate tracks that allowed to bridge the gap in between. All the examples are true positives, except for the last example (*Halo Halo* by Fajters), which has been erroneously matched to a karaoke version of the reference track.

What about the tracks that are still undetected? Table 7 shows examples of tracks that are still undetected by our ensemble-based approach for a couple of works. No clear pattern emerges – apart from the fact that they are often in a very different musical style from the original.

Work	Main artist - Title	Direct score	Ensemble -based score
Get Lucky	The Getup - *Get Lucky*	6.4	24.9
Halo	Amanda Sense - *Halo*	12.4	94.3
Imagine	Dena De Rose - *Imagine*	10.4	86.2
Embraceable You	Earl Hines - *Embraceable You*	9.6	36.3

6. DISCUSSION

One main challenge associated with our ensemble-based approach is how to correctly handle transitivity. This issue emerges from the fact that compositions are not mutually exclusive. For example, a medley might constitute a bridge between two distinct composition groups, which our algorithm would then merge together (which is undesirable). There are probably at least two ways around this issue: one is metadata-based (*i.e.* identify these potential outliers from the metadata and exclude them from the graph computation), while another is to detect them directly from the graph structure (identify bridges between otherwise unrelated clusters).

7. CONCLUSION

In this paper, we consider the following formulation of the cover song identification problem: among a pool of candidates that are likely to match one given reference track, find the actual positives. We have introduced a two-step approach, with a first step that computes pairwise similarities between every pair of tracks in the pool of candidates (for which any known 1-vs-1 approach can be used), and a second ensemble-based step that exploits the relationships between all the candidates to output final results. We have shown that this second step can significantly improve the performance compared to a pure 1-vs-1 approach, in particular on the ranking task, where the error rate is down from a few percents to less than 1% in general. The classification task is naturally more challenging as the optimal threshold might vary from work to work, suggesting that the method would be best exploited as a complement to human annotations – where the human's task would mainly be to find the optimal threshold for the classification. Automating this last step turned out to be non-trivial and is left for future work.

ABSTRACT

Events in music frequently exhibit small-scale temporal deviations (microtiming), with respect to the underlying regular metrical grid. In some cases, as in music from the Afro-Latin American tradition, such deviations appear systematically, disclosing their structural importance in rhythmic and stylistic configuration. In this work we explore the idea of automatically and jointly tracking beats and microtiming in timekeeper instruments of Afro-Latin American music, in particular Brazilian *samba* and Uruguayan *candombe*. To that end, we propose a language model based on conditional random fields that integrates beat and onset likelihoods as observations. We derive those activations using deep neural networks and evaluate its performance on manually annotated data using a scheme adapted to this task. We assess our approach in controlled conditions suitable for these timekeeper instruments, and study the microtiming profiles' dependency on genre and performer, illustrating promising aspects of this technique towards a more comprehensive understanding of these music traditions.

1. INTRODUCTION

Across many different cultures, music is meter-based, i.e., it has a structured and hierarchical organization of pulsations. Within this metrical structure, the different pulsations interact with one another and produce the sensation of rhythm, inducing responses in the listeners such as foot tapping or hand clapping. In the so-called "Western" music tradition, that hierarchical structure often includes the beat and downbeat levels, where the former corresponds to the predominant perceived pulsation, and the latter has a longer time-span that groups several beats into bars. In some cases, the events in music present small-scale temporal deviations with respect to the underlying regular metrical grid, a phenomenon here referred to as microtiming. The interaction between microtiming deviations and other rhythmic dimensions contribute to what has been described as the sense of 'swing' or 'groove' [8, 9, 30]. The systematic use of these deviations is of structural importance in the rhythmic and stylistic configuration of many musical genres. This is the case of jazz [9, 10, 20, 38], Cuban *rumba* [2], Brazilian *samba* [32, 39] and Uruguayan *candombe* [22], among others. Consequently, the analysis of these music genres without considering microtiming leads to a limited understanding of their rhythm.

Samba and *candombe* are musical traditions from Brazil and Uruguay, respectively, that play a huge role in those countries' popular cultures. Both genres have deep African roots, partly evidenced by the fact that their rhythms result from the interaction of several rhythmic patterns played by large ensembles of characteristic percussive instruments. *Candombe* rhythm is structured in 4/4 meter, and is played on three types of drums of different sizes and pitches—*chico*, *repique* and *piano*—, each with a distinctive rhythmic pattern, the *chico* drum being the timekeeper. [1] *Samba* rhythm is structured in 2/4 meter, and comprises several types of instruments—*tamborim*, *pandeiro*, *chocalho*, *reco-reco*, *agogô*, and *surdo*, among others. Each instrument has a handful of distinct patterns [16], and more than one instrument may act as the timekeeper. Because of this combination of several timbres and pitches, the texture of a *samba* performance can become more complex than that of a *candombe* performance, where only three types of drums are present. Nevertheless, both rhythms have in common that they exhibit microtiming deviations at the sixteenth note level [22, 28, 32], with no deviations in the beat positions. [2] This is illustrated in Figure 1 for the recording of a *tamborim* playing in the *samba de enredo* style.

[1] In this musical context, the role of timekeeper is assigned to an instrument that plays an invariable rhythmic pattern (i.e., an *ostinato*) usually at a high rate, thus defining the subdivision of the beat.

[2] In other musical forms, such as waltz, microtiming may be mostly on beats.

1.1 Related Work

Microtiming has been studied in the context of Music Information Retrieval (MIR) for many years [2, 8, 17]. Besides the interest in characterizing microtiming for musicological studies, it is important for music synthesis applications, since it is a central component for "humanizing" computer generated performances [18]. Depending on the musical context, microtiming can take the form of tempo variations, like *rubato* or *accelerando*, or small-scale deviations of events with respect to an underlying regular metrical grid [22]. Therefore, in order to study microtiming deviations one has to know the expected position of the events within the metrical grid and the actual articulated positions—which can be inferred from information related to the onset positions, the tempo and/or the beats.

Most of the proposed methods for microtiming analysis are based on manually annotated data. Laroche et al. [27] proposed a method for the joint estimation of tempo, beat positions and swing in an ad-hoc fashion. The proposal exploits some simplifications: assuming constant tempo and swing ratio, and propagating beat positions based on the most likely position of the first beat. More recent works perform semi-automatic analysis still relying on informed tempo [9, 10], or using an external algorithm for its estimation [30]. Within the context of *candombe* and *samba*, microtiming characterization has also been addressed using either semi-automatic or heuristic methods [17, 22, 32].

In other rhythm-related MIR tasks such as beat and downbeat tracking, graphical models (GM) such as hidden Markov models or dynamic Bayesian networks are widely used [4, 19, 25, 36]. GMs are capable of encoding musical knowledge in a flexible and unified manner, providing structure to the estimations and usually a gain in performance for different models across genres [14]. In particular, Conditional Random Fields (CRFs) are discriminative undirected GMs for structured data prediction [37]. CRFs relax some conditional independence assumptions of Bayesian Networks, which allows for modeling complex and more general dependency structures, thus making them appealing for music modeling. CRFs have been applied in MIR tasks such as beat tracking [13] or audio-to-score alignment [21], and have been successfully combined with deep neural networks (DNNs) [11, 15, 24].

1.2 Our Contributions

This work takes a first step towards fully-automatic tracking of beats and microtiming deviations in a single formalism, applied to the analysis of two (usually underrepresented) Afro-Latin American music genres, namely Brazilian *samba* and Uruguayan *candombe*. More precisely, we introduce a CRF model that uses beat and onset activations derived from deep learning models as observations, and combines them to jointly track beats and microtiming profiles within rhythmic patterns at the sixteenth note level. To the best of our knowledge, this is the first work that explores the use of CRFs for tracking microtiming and beats jointly. This temporal granularity is in accordance with the type of microtiming deviations present in the music traditions under study. Following previous works [9], we derive microtiming labels from annotated onsets and use them to evaluate the proposed system, attaining promising results towards more holistic and descriptive models for rhythm analysis. We also study the usefulness of this approach in controlled conditions, as a first assessment of its capabilities. We explore our microtiming representation in some applications, namely the extraction of microtiming profiles of certain instruments, and the study of differences between musical genres based on their microtiming traits.

2. PROPOSED METHOD

2.1 Language Model

The proposed language model consists of a linear-chain CRF [26, 37]. Formally, the conditional probability of a label sequence $\mathbf{y} = (y_1, ..., y_T)$ of length T given an input sequence of observations $\mathbf{x} = (x_1, ..., x_T)$ is given by:

$$p(\mathbf{y}|\mathbf{x}) = \frac{1}{Z(\mathbf{x})} \prod_{t=1}^{T} \psi(y_t, y_{t-1})\, \phi(y_t, x_t), \qquad (1)$$

where ψ is the transition potential and ϕ is the observation potential. They play a role similar to transition and observation probabilities in dynamic Bayesian networks or hidden Markov models, with the difference that the potentials in a CRF do not need to be proper probabilities, hence the need for the normalization factor $Z(\mathbf{x})$.

In our model, depicted in Figure 2, the output labels $\mathbf{y}$ are a function of three variables that describe the position inside the beat, the length of the beat interval in frames, and the microtiming within the beat-length pattern at the sixteenth note level. Formally,

$$y_t := (f_t, l_t, m_t), \qquad (2)$$

where f_t is the frame counter with $f_t \in \mathcal{F} = \{1, ..., l_t\}$, $l_t \in \mathcal{L} = \{l_{\min}, ..., l_{\max}\}$ is the number of frames per beat, which relates to the tempo of the piece; and the microtiming $\mathbf{m}_t \in \mathcal{M} = \{\mathbf{m}_1, ..., \mathbf{m}_N\}$. The observations $\mathbf{x}$ are based on estimated beat and onset likelihoods, as detailed later. The problem of obtaining the beat positions and microtiming profiles is then formulated as finding the sequence of labels $\mathbf{y}^*$ such that $\mathbf{y}^* = \arg\max_{\mathbf{y}} p(\mathbf{y}|\mathbf{x})$.

2.1.1 Microtiming Tracking

Both in *samba* and *candombe*, timekeeper instruments usually play a beat-length rhythmic pattern that articulates several sixteenth notes [16], as shown in Figures 1 and 3 for the *tamborim*. In order to provide a common framework for comparing both music genres, we focus our study on the microtiming deviations of beat-length rhythmic patterns articulated by timekeeper instruments in groups of four sixteenth notes. [3] To that end, we consider the following hypothesis, which we explain further below:

- The tempo is constant within a beat.

[3] Note that minor adjustments to the proposed model allow for the tracking of microtiming deviations in other kinds of rhythmic patterns.

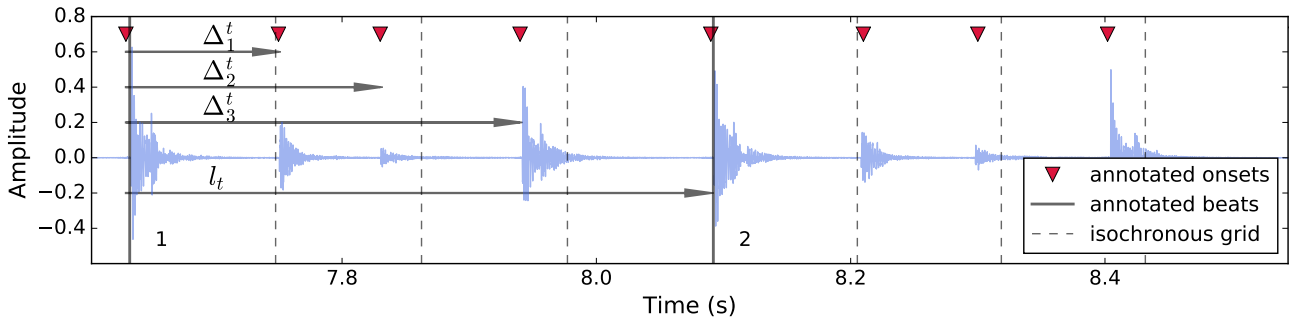

Figure 1. Example of microtiming deviations at the sixteenth note level for a beat-length rhythmic pattern from the *tamborim* in *samba de enredo*.

- The microtiming profile changes smoothly only at beat transitions.
- The tempo is between 120 and 135 BPM, to ensure an appropriate temporal resolution.

We define the microtiming descriptor $\mathbf{m}$ at frame t as:

$$\mathbf{m}_t := (m_t^1, m_t^2, m_t^3)$$

where $m_t^i := \frac{\Delta_t^i}{l_t} \in [\frac{i}{4}+\delta_L^i, \frac{i}{4}+\delta_U^i]$, and Δ_t^i is the distance in frames between an articulated sixteenth note and the beginning of the beat interval, as shown in Figure 1. Thus, each m_t^i models the position of the i-th sixteenth note with respect to the beginning of the beat, relative to the total beat length. For instance, the value of the microtiming descriptor for a rhythmic pattern of four isochronous sixteenth notes, i.e., located exactly on an equally-spaced metrical grid, is $\mathbf{m} = (0.25, 0.50, 0.75)$, indicating the articulation of events at $1/4, 1/2$ and $3/4$ of the beat interval respectively. To account for different microtiming profiles, the value of m_t^i is estimated within an interval determined by lower and upper deviations bounds, δ_L^i and δ_U^i, modeled as positive or negative percentages of the beat interval length. The proposed microtiming descriptor provides an intuitive idea of how the articulated sixteenth notes deviate within the rhythmic pattern from their isochronous expected positions. It is independent of tempo changes, since it is normalized by the estimated beat interval length, allowing for studies on microtiming–tempo dependencies.

The definition of the microtiming descriptor $\mathbf{m}_t$ can be related to the *swing-ratio*, s, proposed in previous work [9,30], though the two differ in various aspects. The *swing-ratio* is defined in terms of the inter-onset intervals (IOIs) of a long–short rhythmic pattern, such that $s \geq 1$ is the ratio between the *onbeat* IOI (longer interval) and the off-beat IOI (shorter interval). In contrast, the $\mathbf{m}_t$ descriptor is composed by three *microtiming–ratios*, m_t^i, whose IOIs are defined with respect to the beginning of the beat instead of the previous onset as in [9, 30]. However, it is possible to convert the model proposed here into the *swing-ratio* by redefining $\mathbf{m}$ as $m_s := m_t^1$, and then, from the estimated m_s, computing $s = \frac{m_t^1}{1-m_t^1}$. With such modifications, the model could be applied to the studies presented in [9, 30].

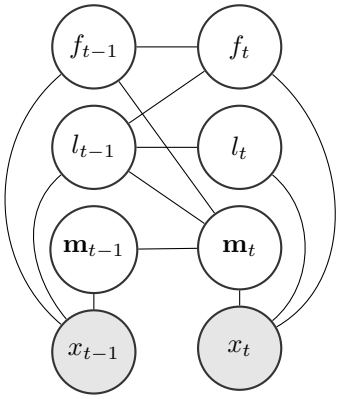

Figure 2. CRF graph. Observations and labels are indicated as gray and white nodes respectively.

2.1.2 *Transition Potential* ψ

The transition potential is given in terms of f_t, l_t, and m_t (see Equation 2) by:

$$\psi(y_t, y_{t-1}) := \psi_f(f_t, f_{t-1}, l_t, l_{t-1})\psi_m(\mathbf{m}_t, \mathbf{m}_{t-1}, f_{t-1}, l_{t-1})$$

Similar to [13,25], we force frame counter f_t to increase by one, at each step, up to the maximum beat length considered, and to switch to one at the end of the beat. Beat duration changes are unlikely (i.e., tempo changes are rare) and only allowed at the end of the beat. We constrain these changes to be smooth, giving inertia to tempo transitions. Those rules are formally expressed by:

$$\psi_f(f_t, f_{t-1}, l_t, l_{t-1}) := \begin{cases} 1 & \text{if } f_t = (f_{t-1} \bmod l_{t-1}) + 1, \\ & \quad f_{t-1} \neq l_{t-1} \\ 1 - p_f & \text{if } l_t = l_{t-1}, \\ & \quad f_t = 1,\ f_{t-1} = l_{t-1} \\ \frac{p_f}{2} & \text{if } l_t = l_{t-1} \pm 1,\ f_t = 1 \\ 0 & \text{otherwise} \end{cases}$$

The microtiming descriptor m_t changes smoothly and only at the end of the beat, that is:

$$\psi_m(\mathbf{m}_t, \mathbf{m}_{t-1}, f_{t-1}, l_{t-1}) := \begin{cases} 1 & \text{if } \mathbf{m}_t = \mathbf{m}_{t-1}, \\ & \quad f_{t-1} \neq l_{t-1} \\ 1 - p_m & \text{if } \mathbf{m}_t = \mathbf{m}_{t-1}, \\ & \quad f_{t-1} = l_{t-1} \\ \frac{p_m}{2} & \text{if } m_i^t = m_i^{t-1} \pm 0.02\ \forall i, \\ & \quad f_{t-1} = l_{t-1} \\ 0 & \text{otherwise} \end{cases}$$

In the transition potential, p_f and p_m represent the probability of changing the beat interval length (i.e., tempo) and the probability of changing the microtiming profile at the end of the beat, respectively. The values of $1-p_f$ and $p_f/2$ were chosen following previous works, whereas $1-p_m$ and $p_m/2$ were similarly set in order to make the possible microtiming transitions equally likely.

Since m_t^i is given in percentage with respect to the inter-beat-interval (IBI), the resolution with which microtiming can be estimated in the model is also percentual, and it is given by the relation between the sampling rate SR of the features and the BPM: $\mathrm{res} = \frac{\mathrm{BPM}}{60\mathrm{SR}}$. It has been shown in the literature that a resolution of 0.02 of the IBI is sufficient for representing microtiming deviations [17, 32]. To keep computational complexity low but at the same time guaranteeing a resolution $\mathrm{res} = 0.02$, we use observation features sampled at 110 Hz and we study pieces whose tempo is within range of 120 to 135 BPM. Note that these assumptions are valid in the music under study, and they could be adapted to a different music genre, e.g. increasing sampling rate to increase the BPM interval.

2.1.3 Observation Potential ϕ

The observation potential depends on the beat and onset likelihoods, the frame counter f_t and the microtiming m_t:

$$\phi(f_t, \mathbf{m}_t, x_t) := \begin{cases} b_t & \text{if } f_t = 1 \\ o_t - b_t & \text{if } \frac{f_t}{l_t} \in \mathbf{m}_t \\ 1 - o_t & \text{otherwise} \end{cases}$$

where b_t and o_t are beat and onset likelihoods, respectively. The onset likelihood was estimated using the ensemble of recurrent neural networks for onset activation estimation from *madmom* [3]—we refer the interested reader to [5, 12] for further information. We designed a simple DNN for the beat likelihood estimation and trained it on *candombe* and *samba*.[4] It consists of 6 layers, namely: batch normalization, dropout of 0.4, bidirectional gated recurrent unit (Bi-GRU) [6] with 128 units, batch normalization, another identical Bi-GRU layer, and a dense layer with two units and a softmax activation.

We use a mel-spectrogram as input feature for the DNN. The short–time Fourier transform is computed using a window length of 2048 samples and a hop of 401 samples, to ensure a sampling rate of 110 Hz with audio sampled at 44.1 kHz. We use 80 mel filters, comprising a frequency range from 30 Hz to 17 kHz.

3. DATASETS

In our experiments we use a subset of the *candombe* dataset [35] and the BRID dataset [29] of Brazilian *samba*.

candombe dataset: it comprises audio recordings of Uruguayan *candombe* drumming performances in which ensembles of three to five musicians play the three different *candombe* drums: *chico*, *piano* and *repique*. It has separated stems of the different drums, which facilitates the microtiming analysis. We focus our study on the *chico* drum, which is the timekeeper of the ensemble. We select a subset of the recordings in the dataset, in which the *chico* drum plays a beat-length pattern of four sixteenth notes, for a total of 1788 beats and 7152 onsets.

BRID dataset: it consists of both solo and ensemble performances of Brazilian *samba*, comprising ten different instrument classes: *agogô*, *caixa* (snare drum), *cuíca*, *pandeiro* (frame drum), *reco-reco*, *repique*, *shaker*, *surdo*, *tamborim* and *tantã*. We focus our study on the *tamborim*, which is one of the timekeepers of the ensemble. We select a subset of the solo tracks, in which the *tamborim* plays a beat–length rhythmic pattern of four sixteenth notes (shown in music notation[5] in Figure 3), for a total of 396 beats and 1584 onsets.

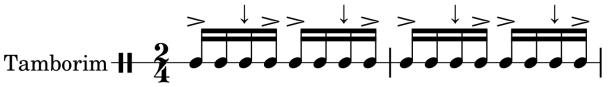

Figure 3. Example of the beat-length rhythmic pattern of the *tamborim* from the *samba* dataset in music notation.

3.1 Ground-Truth Generation

The microtiming ground-truth is inferred following the approach of [9], in which the onsets are used to derive the swing-ratio annotations. Analogously, we compute the microtiming ground-truth using the annotated onsets, obtaining one value of $\mathbf{m} = (m_1, m_2, m_3)$ for each beat. In order to mitigate the effect of onset annotation errors and sensori-motor noise, we use a moving-median filter to smooth the microtiming ground-truth, with a centered rectangular window of length 21 beats, as shown in Figure 4.

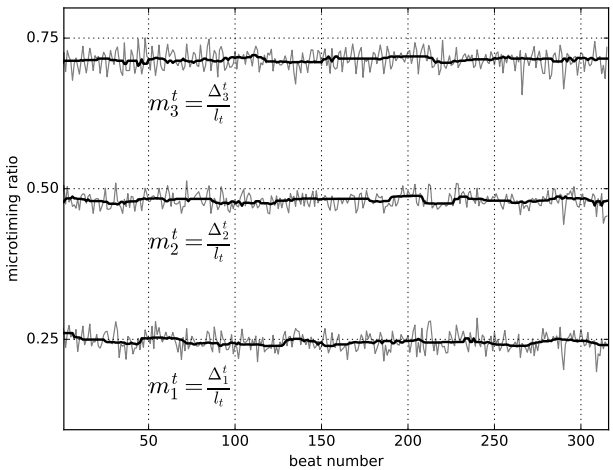

Figure 4. Example of the microtiming values for a *chico* drum recording in the *candombe* dataset. Dark and light lines represent the ground-truth with and without median filtering, respectively.

[4] The training proved necessary because the timekeeper pattern of *candombe* rhythm has a distinctive accent displaced with respect to the beat that misleads beat–tracking models trained on "Western" music [34].

[5] The symbol '>' refers to an accent, and '↓' implies to turn the *tamborim* upside down and execute the strike backwards.

4. EXPERIMENTS

4.1 Experimental Setup

We investigate the performance of the model and whether the microtiming descriptor is useful for analyzing the music at hand. To that end, we scale the *candombe* dataset to match the size of the *samba* dataset at test time by selecting excerpts in each track. We assess the model's performance using manually annotated onsets and beats, from which we derive our ground-truth as explained in Section 3.1. To evaluate if the microtiming estimation affects the beat tracking, we compare the model's performance with a simplified version of it that only tracks beats. This version has only variables f_t and l_t (see Figure 2); the same potential ψ_f is used, and the observation potential is simply b_t (the beat likelihood) at beat positions and $1 - b_t$ otherwise. We assess the microtiming estimation by: varying the p_m microtiming transition parameter—allowing smooth changes within the piece or no changes at all; and varying the tolerance used on the F-measure (F1) score. Finally, we discuss our main findings on the potential of jointly tracking beats and microtiming.

4.1.1 Implementation, Training and Evaluation Metrics

The DNN beat likelihood model is implemented in *Keras* 2.2.4 and *Tensorflow* 1.13.1 [1, 7]. We use the *Adam* optimizer [23] with default parameters. Training is stopped after 10 epochs without improvement in the validation loss, to a maximum of 100 epochs. We train the network with patches of 500 frames and a batch size of 64, leaving one track out and training with the rest, which we split in 30% and 70% for validation and training respectively, among the same genre. The onset activation was obtained with *madmom* version 0.16.1 [3], and the mel-spectra was computed using *librosa* 0.6.3 [31].

We evaluate the model using the F1 score for beat tracking with a tolerance window of 70 ms, as implemented in *mir_eval* 0.5 [33]. To evaluate the microtiming estimation, we first select the correctly estimated beats, then compute F1 for each estimated m_t^i with tolerance windows of different lengths, and the overall score as the mean F1 ($\text{F1}_{\mathbf{m}_t} = \sum_i \text{F1}_{m_t^i}/3$).

4.2 Results and Discussion

The results on the microtiming tracking are depicted in Figure 5, which shows the F1 scores as a function of the tolerance. The different colors represent the different p_m values. We evaluate the model for the set of values $p_m = \{0, 0.001, 0.06\}$, that is no, very unlikely and more likely microtiming changes respectively. Those values were obtained from statistics on the data in preliminary experiments. We searched for microtiming ratios within the interval $[0.25, 0.29] \times [0.42, 0.5] \times [0.67, 0.75]$, for microtiming dimensions $i = 1, 2, 3$ respectively. This corresponds to $\boldsymbol{\delta}_L = (0, -0.03, -0.08)$ and $\boldsymbol{\delta}_U = (0.04, 0, 0)$.[6] As illustrated in Figure 5, we found that the restriction of a constant microtiming profile ($p_m = 0$) along the piece relates to a worse performance, specially with small tolerances. We hypothesize that this occurs because in some *samba* excerpts the microtiming ratio changes are percentually bigger than those tolerances, leading to an inaccurate estimation. From considering the dependency of the F1 score with respect to the tolerance, we observe that is possible to achieve a reasonable F1 score from 0.025 on. The results with the best compromise in terms of variance and median are achieved with $p_m = 0.001$, which aligns with the hypothesis that microtiming profiles change very smoothly over time. We explored different tolerances since we are working with frames which are noisy, and the comparison with the smoothed ground truth still makes sense with large tolerances.

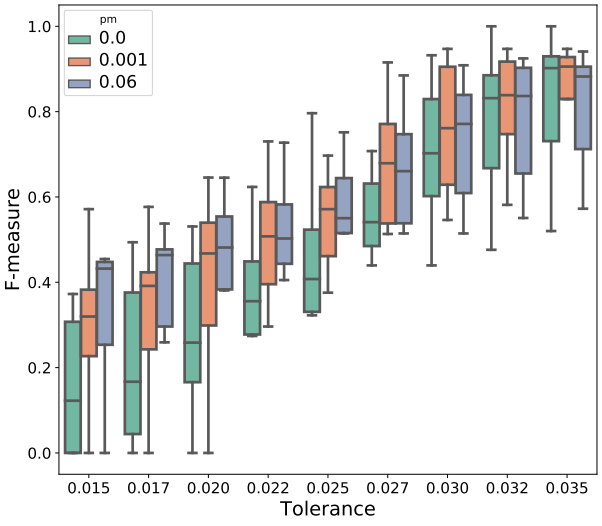

Figure 5. Mean microtiming F-measure score on the two datasets.

We found that the beat tracking performance of the model reaches a 95.7% F1 score, being equivalent to the beat tracking only version. The high F1 score in beat tracking is not surprising given that the DNN was trained using data of the same nature (acoustic conditions and genre) and the sets are homogeneous. As mentioned before, state-of-the-art beat tracking systems based on DNNs fail dramatically in this specific scenario [34], particularly tracking the beats in time-keeper instruments in *candombe*, because the data is too different from what was used in their training. We do not consider this as a challenging beat tracking case, but a training stage was needed to perform adequately.

During our experiments we observed that the microtiming descriptor $\mathbf{m}_t$ could be used to help beat tracking in some cases. Informing the microtiming profile a priori, by setting δ_L^i and δ_U^i, can disambiguate beat positions by helping the joint inference. This could allow to apply non pre-trained beat tracking models to *candombe* recordings, which usually fail in estimating the beat location by displacing it one sixteenth note (due to an accent in the rhythmic pattern). Aligned to that idea, the model could be use-

[6] Symmetric windows around the isochronus sixteenth note positions were used for the microtiming ratios in preliminary experiments with no gain in tracking performance and a higher computational burden.

ful in scenarios where onsets from other instruments are present. Besides, when the beat tracking is incorrect, the obtained microtiming profile can be descriptive of the type of mistake that occurs by contrasting the obtained profile with the expected one. The same case mentioned before—a lag of a sixteenth note in the beat estimation—shows in the microtiming estimation as unexpected forward positions in the second and third sixteenth notes, with a synchronous fourth one, which is the *candombe* microtiming profile lagged by a sixteenth note position.

Microtiming description and insights: Figure 4 illustrates an example of microtiming profile for an excerpt of the *candombe* dataset. This example shows the microtiming variations per beat interval along the complete recording. In the performance of the example, the rhythmic pattern is played with the same microtiming profile in the whole track. This microtiming template is characteristic of some patterns of *candombe* drumming [34], and it is present in several recordings of the dataset. We noticed that microtiming profiles do not present significant variations within tempo changes in the *candombe* dataset. However, the presented method can be used to characterize curves of microtiming vs. tempo that could be informative of musical phenomena for other music genres or datasets.

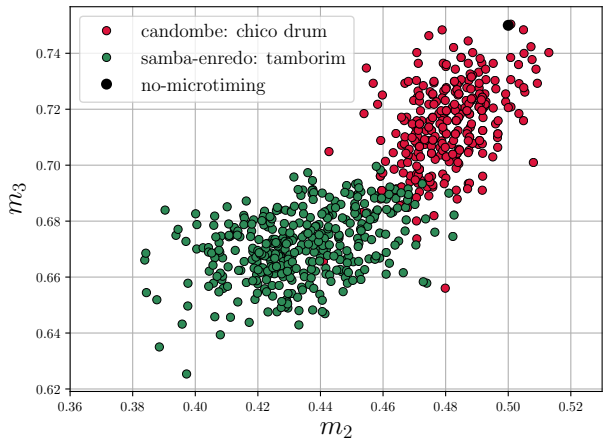

Figure 6. Microtiming distribution depending on style, view of the plane $m_t^2 m_t^3$, denoted as $m_2 m_3$ for simplicity. A dot at $(0.50, 0.75)$ indicates the expected position of a beat that shows no microtiming, that is, where all onsets are evenly spaced.

As shown in Figures 6 and 7, the microtiming descriptor $\mathbf{m}_t$ encodes musical features that are informative about the music genre, instrument type or performer. These two figures show the microtiming profile for all beats from *tamborim* and *chico* recordings, using the annotations for better visualization. Firstly, by observing the 'no-microtiming' reference in the figures that corresponds to $\mathbf{m}_t = (0.25, 0.50, 0.75)$, it becomes clear that both *samba* and *candombe* present considerable microtiming deviations in their time-keeper instruments. Even though the rhythmic patterns from both instruments present deviations that tend to compress the IOI in a similar manner, the microtiming profile differs for each music style, being more drastic in the case of the *tamborim*. This analysis should be extended to other *samba* instruments in order to determine if differences are due to the rhythmic pattern of a particular instrument; or if different patterns within the same genre tend to follow the same microtiming profile (characteristic of the genre). Figure 7 shows the microtiming profiles of each performer. It is quite clear that performers tend to be consistent with their microtiming, opening the perspective of studying microtiming profiles for performer characterization, as was done for jazz [9].

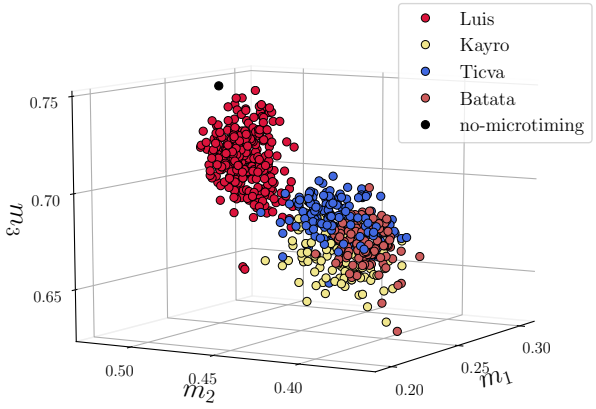

Figure 7. Microtiming distribution depending on performer (top musician plays *candombe* and the others play *samba*). A dot at $(0.25, 0.50, 0.75)$ indicates the point of no microtiming.

5. CONCLUSIONS AND FUTURE WORK

In this work, we introduced a language model that performs automatic tracking of beats and microtiming deviations in a single formalism. We applied this model to Afro-Latin American music, particularly Brazilian *samba* and Uruguayan *candombe*, and we focused our study on beat–length rhythmic patterns of timekeeper instruments, with four articulated sixteenth notes. The promising results we obtained with our method using a ground-truth derived from annotated onsets indicate it can facilitate automatic studies of these rhythms. This work intends to take a further step towards holistic systems that produce consistent and coherent estimations of music content.

As future work, we plan to extend our model to describe the microtiming profile depending on the nature of the rhythmic pattern being played, i.e., whether they articulate 2, 3, 4 or more notes, and to explore the usefulness of our model in challenging scenarios in comparison to heuristic methods.

6. ACKNOWLEDGEMENTS

This work was partially funded by CAPES, CNPq, ANII, CNRS, and STIC-AmSud program project 18-STIC-08. The authors would like to thank the reviewers for their valuable feedback.

HARMONY TRANSFORMER: INCORPORATING CHORD SEGMENTATION INTO HARMONY RECOGNITION

Tsung-Ping Chen and Li Su
Institute of Information Science, Academia Sinica, Taiwan
{tearfulcanon, lisu}@iis.sinica.edu.tw

ABSTRACT

Musical harmony analysis is usually a process of unfolding and interpreting the hierarchical structure of music. Computational approaches to such structural analysis are still challenging, owing to the fact that the boundary between different harmonic states (such as chord functions) is not explicitly defined in the audio or symbolic music data. It is a novel approach to improve chord recognition by jointly identifying chord change using end-to-end sequence learning. In this paper, we propose the Harmony Transformer, a multi-task music harmony analysis model aiming to improve chord recognition through incorporating chord segmentation into the recognition process. The integration of chord segmentation and chord recognition is implemented with the Transformer, a deep sequential learning model yielding fruitful results in the field of natural language processing. A non-autoregressive decoding framework is also adopted here in aid of concatenating the two highly correlated tasks. Experiments of both chord symbol recognition and functional harmony recognition on audio and symbolic datasets demonstrate that explicitly learning the hierarchical structural information of musical data can facilitate and improve the harmony recognition.

1. INTRODUCTION

Automatic chord recognition is a hallmark research topic in the field of music information retrieval (MIR) and has been widely studied. In the past decade, this problem has been dealt with by using a variety of deep learning methods ranging from multi-layer perceptrons (MLPs) [1] to more complex models such as convolutional neural networks (CNNs) [2–6] and recurrent neural networks (RNNs) [7–11]. Hybrid systems such as convolutional recurrent neural network (CRNN) are also introduced to the chord recognition task for taking advantage of different neural networks [12–15].

In spite of the significant achievements for deep learning models to advance the state of the art, further improvement in the chord recognition task appears to be limited and has reached a glass ceiling [4]. Such limitations may result from the incompetence for deep learning methods to infer the hierarchical structure of music based on frame-level data. An overlooked tendency in many previous studies is that the majority of chord recognition models regard a music piece as a concatenation of semantically incomplete segments, and therefore are ineffective to capture complex musical grammar such as chord transition [13]. Figure 2 (see Section 4.4) depicts an example where an RNN model cannot segment chord boundaries adequately when arpeggios or key modulation exists. This problem was dealt with by integrating temporal knowledge such as the metric and beat information [16, 17], by adding post-processing such as hidden Markov models (HMM) [18, 19], or by feature engineering such as the harmonic change detection function (HCDF) [20] and beat-synchronous audio features [21]. One recent study attempted to solve this problem by incorporating models which recognize chords at different levels, i.e., the frame level and the chord level, and the cooperative models gained improved chord recognition results [14].

In this paper, we propose the Harmony Transformer, which jointly integrates chord recognition and chord segmentation into an end-to-end chord recognition system. The Harmony Transformer is based on the Transformer, a deep neural network nowadays applied to a wide variety of sequence modeling problems such as machine translation [22], natural language understanding [23], music generation [24], and so forth. For the encoder-decoder architecture of the Transformer, we assign the chord segmentation task to the encoder, and the chord recognition task to the decoder. This division allows the chord recognition network to benefit from the prediction of the chord segmentation. In comparison to other designs using RNN, which is considerably time-consuming owing to heavy sequential computations, the Transformer is more effective in speed, as it enforces parallelization to process sequential data. The Harmony Transformer is also capable of a complex analytic scenario—harmonic function [1] recognition [25]. Our experiment results highlight the advantage of the proposed model to improve both the chord symbol recognition and the harmonic function recognition. To the best of our knowledge, this is the first work that connects the chord segmentation task with the chord recognition task through the Transformer framework. We hope

[1] 'Harmonic function' refers to the diatonic function in music which denotes the relationship of a chord to a tonal center.

that our contribution facilitates more developments in automatic chord recognition.

2. HIERARCHICAL STRUCTURES AND CHORD RECOGNITION

The chord recognition can be formulated as a *sequence labeling* task [26] that assigns a categorical label (e.g., chord name) to each element of a given sequence (e.g., musical sequence). Considering the sequential and structural nature of music, chord recognition task resembles many natural language processing (NLP) problems, in such a way that both the sequential arrangements of chords in music and words in language are dominated by higher-level rules—the function of harmony and the grammar in language. A compelling recognition model for music or language is, therefore, expected to unfold the intrinsic hierarchical structure of the sequences. A typical example is the part-of-speech (POS) tagging task in NLP, which assigns a specific part of speech to each word in a sentence. Albeit many words can represent more than one part of speech at different times, deep learning models have shown their ability to regulate local-level assignments with a given context, and demonstrated satisfactory performance. [2]

On the other hand, the chord recognition results in recent years still could not be satisfactory [1,8,13–15]. A primary difference between language and music is that each word in the input sentence of the POS tagging task represents a semantically meaningful unit, whereas the musical segments to be labeled in the chord recognition task are not necessary harmonically completed. It can be argued that the unsatisfying achievements in the chord recognition task can be associated with the deficiency of explicit knowledge of the harmonic boundaries within a musical sequence. Since the sequential property and the hierarchical structure are shared characteristics between language and the harmonic progression, it would be advantageous to introduce the segmentation information of harmony in higher-level musical hierarchy into deep learning models of chord recognition.

Recent research tackled the hierarchical issue of frame-wise chord recognition using two RNN-based models to separately predict the duration and the transition of each chord in a *parallel* fashion [14]. Concretely, frame-wise chord predictions are first generated through a CNN-based *acoustic model*, which are then simultaneously fed into the two RNN-based models—the *chord duration model* and the *harmonic language model* to predict the time points of chord change at the frame level and the chord progression at the chord level respectively. The two RNN-based models are trained separately from the acoustic model, and are utilized as *language model* which computes the probability distribution of each token sequentially.

It has been demonstrated that incorporating musical hierarchy is promising to improve chord recognition. Nevertheless, the local assignment of chord labels in practice is dependent *successively* on the knowledge from different hierarchical levels. We hence argue that 1) the chord change and the chord progression should be modeled in a vertical rather than a horizontal manner; in other words, we suppose that the chord recognition problem belongs to a higher level in the musical hierarchy than the chord segmentation problem, and the recognition of chords should base on the result of segmentation. 2) The models processing higher-level information such as the two RNN-based language models should be trained *jointly* with the lower-level ones. In this study, we propose a new framework that predicts chord progression for a given sequence according to the chord segmentation result, and is trained in an end-to-end manner.

[2] The per-token accuracy of the POS tagging task had surpassed 96% in 2000. For an overview of the state of the art of the POS tagging task, see: `https://aclweb.org/aclwiki/POS_Tagging_(State_of_the_art)`.

3. THE HARMONY TRANSFORMER

The proposed model, as shown in Figure 1, follows the encoder-decoder architecture of the Transformer [22], while adopting a non-autoregressive framework for treating segmentation as the intermediate before the recognition process [27]. The encoder of the Harmonic Transformer performs the chord segmentation task from the input data sequence (e.g., chroma), and the decoder performs the chord recognition task from the input data sequence along with the segmentation result from the encoder.

3.1 Basic units

The Harmony Transformer model is built on two computational units, that is, *multihead-head attention* (MHA) and *feed-forward network* (FFN). The MHA unit takes three inputs $\mathbf{Q}$, $\mathbf{K}$, and $\mathbf{V}$, which stand for *queries*, *keys*, and *values*, respectively. The three inputs are matrices with the first dimension representing the number of time steps and the second dimension being the number of feature; the feature sizes of the three inputs are usually the same, while their number of time steps may be different.

In general, the MHA unit computes a weighted sum of $\mathbf{V}$ based on the similarity between $\mathbf{Q}$ and $\mathbf{K}$. To be more exact, the inputs are first 'transformed' through an *attention* mechanism which outputs a *head* (denoted as $\mathbf{D}$). The MHA unit is then constructed by concatenating multiple heads out of several attention mechanisms:

$$\mathrm{Attention}(\mathbf{Q},\mathbf{K},\mathbf{V}) = \mathrm{softmax}\left(\frac{\mathbf{Q}\mathbf{K}^{\mathrm{T}}}{\sqrt{d}}\right)\mathbf{V}\,, \quad (1)$$

$$\mathbf{D}_i = \mathrm{Attention}(\mathbf{Q}\mathbf{W}_i^{\mathrm{Q}}, \mathbf{K}\mathbf{W}_i^{\mathrm{K}}, \mathbf{V}\mathbf{W}_i^{\mathrm{V}})\,, \quad (2)$$

$$\mathrm{MHA}(\mathbf{Q},\mathbf{K},\mathbf{V}) = \mathrm{Concat}(\mathbf{D}_1,\cdots,\mathbf{D}_h)\mathbf{W}^{\mathrm{D}}\,, \quad (3)$$

where h is the number of heads, $\mathbf{D}_i$ is the ith head, and d is the dimension of feature. $\mathbf{W}^{\mathrm{D}} \in \mathbb{R}^{d\times d}$, and $\mathbf{W}^{\mathrm{Q}}$, $\mathbf{W}^{\mathrm{K}}$, $\mathbf{W}^{\mathrm{V}} \in \mathbb{R}^{d\times \frac{d}{h}}$ are all learnable parameter matrices. Note that if $\mathbf{Q} = \mathbf{K} = \mathbf{V}$, such attention mechanism is called *self-attention* as the three inputs stand for the same sequence; if $\mathbf{Q} \neq \mathbf{K} = \mathbf{V}$, such attention mechanism is called *encoder-decoder attention* in the case when $\mathbf{K}$ and $\mathbf{V}$ come from the encoder and $\mathbf{Q}$ comes from the decoder.

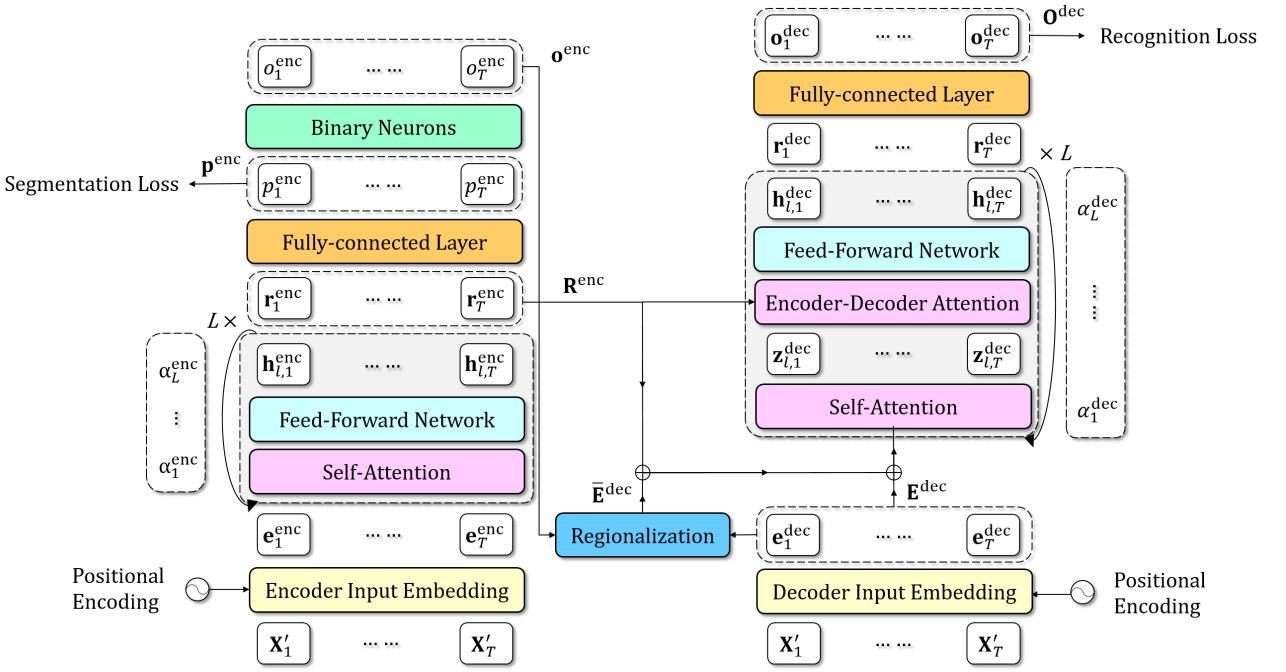

Figure 1. The architecture of the Harmony Transformer. During training, the chord change prediction $\mathbf{p}^{\text{enc}}$ from the encoder is used to calculate the segmentation loss, while the decoder output $\mathbf{O}^{\text{dec}}$ is used to calculate the recognition loss.

On the other hand, the FFN unit is constructed by two fully-connected layers parameterized by weighted matrices and bias vectors $(\mathbf{W}_1, \mathbf{W}_2, \mathbf{b}_1, \mathbf{b}_2)$ and one activation function in between the two layers:

$$\text{FFN}(\mathbf{X}) = \text{ReLU}(\mathbf{X}\mathbf{W}_1 + \mathbf{b}_1)\mathbf{W}_2 + \mathbf{b}_2\,, \qquad (4)^{3}$$

where $\mathbf{X}$ is also a matrix like $\mathbf{Q}$, $\mathbf{K}$, or $\mathbf{V}$, and $\text{ReLU}(\mathbf{X}) := \max(0, \mathbf{X})$ is the element-wise rectified linear unit activation. In practice, both the MHA and the FFN computations include residual connections [28] and layer normalization [29]:

$$\text{MHA}^*(\mathbf{Q}, \mathbf{K}, \mathbf{V}) = \text{LayerNorm}(\text{MHA}(\mathbf{Q}, \mathbf{K}, \mathbf{V}) + \mathbf{Q})\,,$$
$$\text{FFN}^*(\mathbf{X}) = \text{LayerNorm}(\text{FFN}(\mathbf{X}) + \mathbf{X})\,.$$

In the rest of the paper, we omit the $*$ symbol for simplicity. More detailed descriptions of MHA and FFN can be found in Section 3.2 and Section 3.3 of [22].

3.2 Input embedding

We denote the sequence of frame-level features (e.g., piano roll or chromagram) with T time steps as $\mathbf{X} := [\mathbf{x}_1, \ldots, \mathbf{x}_T]^{\text{T}}$,[4] in which $\mathbf{x}_t$ is a feature vector of $\mathbf{X}$ at time t. The data representation entering the Harmony Transformer at time t, as denoted by $\mathbf{X}'_t$ here, is a segment of $\mathbf{X}$ around t: $\mathbf{X}'_t := [\mathbf{x}_{t-\tau}, \cdots, \mathbf{x}_{t+\tau}]^{\text{T}}$, where the length of the segment is $2\tau+1$. For the embedding process, the encoder (or decoder) maps each $\mathbf{X}'_t$ into an encoder (or decoder) embedding through MHA and FFN units, then flattens it into a vector $\mathbf{e}_t^{\text{enc}}$ (or $\mathbf{e}_t^{\text{dec}}$). More specifically, the embedding vector $\mathbf{e}_t$ which is to be fed into time step t of either the encoder or the decoder is:

$$\mathbf{e}_t = \text{Flatten}(\text{FFN}(\text{MHA}(\mathbf{X}'_t, \mathbf{X}'_t, \mathbf{X}'_t))\mathbf{W}^{\text{e}}), \qquad (5)$$

where $\mathbf{W}^{\text{e}}$ is the parameter matrix to be learned, and the encoder and the decoder use different set of parameters. The embedding sequences for the encoder and the decoder are then $\mathbf{E}^{\text{enc}} = [\mathbf{e}_1^{\text{enc}}, \cdots, \mathbf{e}_T^{\text{enc}}]^{\text{T}}$ and $\mathbf{E}^{\text{dec}} = [\mathbf{e}_1^{\text{dec}}, \cdots, \mathbf{e}_T^{\text{dec}}]^{\text{T}}$, respectively.

Moreover, since the computational units mentioned in Section 3.1 are intrinsically unaware of the sequential order of their inputs, the positional information is added to the feature embeddings. In this work, we adopt the absolute positional encoding composed of sinusoidal functions, as used in [22]:

$$\text{PE}_{t,i} = \begin{cases} \sin(t/10000^{\frac{i}{d}}) \text{ if } i \text{ is even,} \\ \cos(t/10000^{\frac{i}{d}}) \text{ if } i \text{ is odd,} \end{cases} \qquad (6)$$

where $t = 1, \ldots, T$ is the time step, d is the embedding size, and $i = 1, \ldots, d$ is the index of the embedding dimension. And $\text{PE}_{t,i}$ is added into the ith element of $\mathbf{e}_t$.

3.3 Encoder: chord segmentation

The encoder is composed of L layers, each of which comprises a self-attention MHA unit and a FFN unit. Inspired by [30], L softmax-normalized parameters are introduced to the encoder for weighting the hidden states of each layer. Formally, for the embedded sequence of the encoder, $\mathbf{E}^{\text{enc}}$, the encoder computes hidden states

[3] Note that the two additions in the equation are element-wise additions which will 'broadcast' the bias vectors to the same dimensions as the matrices to be added.

[4] In our notation, the normal T means the transpose of a matrix, while the italic T indicates the number of time steps.

$\mathbf{H}_l^{\text{enc}} := [\mathbf{h}_{l,1}^{\text{enc}}, \cdots, \mathbf{h}_{l,T}^{\text{enc}}]^{\text{T}}$ at layer l, where $\mathbf{h}_{l,t}$ denotes the output at time t in the lth layer:

$$\begin{aligned} \mathbf{H}_l^{\text{enc}} &= \text{FFN}(\text{MHA}(\mathbf{H}_{l-1}^{\text{enc}}, \mathbf{H}_{l-1}^{\text{enc}}, \mathbf{H}_{l-1}^{\text{enc}}))\,, \\ \mathbf{H}_0^{\text{enc}} &= \mathbf{E}^{\text{enc}}\,. \end{aligned} \tag{7}$$

The hidden states of all layers are then weighted by the softmax-normalized parameters $\boldsymbol{\alpha}^{\text{enc}} := \{\alpha_l^{\text{enc}}\}_{l=1}^{L}$ to produce a weighted-sum representation $\mathbf{R}^{\text{enc}} := [\mathbf{r}_1^{\text{enc}}, \cdots, \mathbf{r}_T^{\text{enc}}]^{\text{T}}$ with $\mathbf{r}_t^{\text{enc}} = \sum_{l=1}^{L} \alpha_l^{\text{enc}} \mathbf{h}_{l,t}^{\text{enc}}$, which is later taken as one of the inputs of the decoder. The purpose of using the weighted sum of hidden states from all layers instead of using the output of the last layer is that different layers tend to encode specific information which individual tasks may rely on to different extents [30–33].

To predict chord change, $\mathbf{R}^{\text{enc}}$ is then fed into a fully-connected layer followed by a sigmoid activation. That is, the likelihood of chord change at time t is estimated by the equation: $p_t^{\text{enc}} = \text{sigmoid}(\mathbf{w}^{\text{T}}\mathbf{r}_t^{\text{enc}})$, where $\mathbf{w}$ are the parameters to be learned for mapping each $\mathbf{r}_t^{\text{enc}}$ in $\mathbf{R}^{\text{enc}}$ into a real number. And the *segmentation loss* is calculated with $\mathbf{p}^{\text{enc}} := \{p_t^{\text{enc}}\}_{t=1}^{T}$ during training, as depicted in Figure 1. In order to make use of the chord change prediction for the later part of the chord recognition task, we utilize deterministic binary neurons (DBNs) [34, 35] to binarize the real-valued chord change probabilities with hard thresholding. Accordingly, the final output of the encoder $\mathbf{o}^{\text{enc}} := \{o_t^{\text{enc}}\}_{t=1}^{T}$ is a sequence of binary chord segmentation prediction, which is 1 at the point of chord change, or 0 otherwise: $o_t^{\text{enc}} = 1$ if $p_t^{\text{enc}} > 0.5$ and $o_t^{\text{enc}} = 0$ if $p_t^{\text{enc}} \leq 0.5$. That means, when $o_t^{\text{enc}} = 1$, there is a chord change at time t. For example, for a source sequence of 6 segments, $\mathbf{o}^{\text{enc}} = [1, 0, 0, 1, 1, 0,]$ means that there are three *chord regions* with the first region containing three segments, the second containing one segment, and the final containing two segments.

3.4 Decoder: segmentation-informed chord recognition

Similar to the encoder, the decoder also consists of L layers, while in each layer, there is an additional encoder-decoder attention module besides the MHA and the FNN modules to imitates the classical attention mechanism in sequence-to-sequence models [36, 37]. Different from the encoder, the input of the decoder is derived from three sources: $\mathbf{E}^{\text{dec}}$, $\mathbf{o}^{\text{enc}}$, and $\mathbf{R}^{\text{enc}}$. First of all, the embedded sequence of the decoder $\mathbf{E}^{\text{dec}}$ is *regionalized* in line with $\mathbf{o}^{\text{enc}}$ to generate $\bar{\mathbf{E}}^{\text{dec}}$. Precisely, let $\mathbf{c} := \{c_k\}_{k=1}^{K}$ be the K time steps where chord changes, i.e., $o_{c_k}^{\text{enc}} = 1$, then the regionalization unit in Figure 1 replaces each member $\mathbf{e}_t^{\text{dec}}$ in $\mathbf{E}^{\text{dec}}$ with average pooling:

$$\bar{\mathbf{e}}_t^{\text{dec}} := \frac{1}{c_{k+1} - c_k} \sum_{i=c_k}^{c_{k+1}-1} \mathbf{e}_i^{\text{dec}} \quad \text{for } t \in [c_k, c_{k+1})\,, \tag{8}$$

and the resulting embedding is $\bar{\mathbf{E}}^{\text{dec}} := [\bar{\mathbf{e}}_1^{\text{dec}}, \cdots, \bar{\mathbf{e}}_T^{\text{dec}}]^{\text{T}}$. Next, the decoder takes the original embedding $\mathbf{E}^{\text{dec}}$, the regionalized embedding $\bar{\mathbf{E}}^{\text{dec}}$, and the weighted-sum representation $\mathbf{R}^{\text{enc}}$ to compute hidden states of the decoder $\mathbf{H}_l^{\text{dec}} = [\mathbf{h}_{l,1}^{\text{dec}}, \cdots, \mathbf{h}_{l,T}^{\text{dec}}]^{\text{T}}$ at layer l with the three modules in the layer:

$$\mathbf{H}_l^{\text{dec}} = \text{FFN}(\text{MHA}(\mathbf{Z}_l^{\text{dec}}, \mathbf{R}^{\text{enc}}, \mathbf{R}^{\text{enc}}))\,, \tag{9}$$

$$\mathbf{Z}_l^{\text{dec}} = \text{MHA}(\mathbf{H}_{l-1}^{\text{dec}}, \mathbf{H}_{l-1}^{\text{dec}}, \mathbf{H}_{l-1}^{\text{dec}})\,, \tag{10}$$

$$\mathbf{H}_0^{\text{dec}} = \mathbf{E}^{\text{dec}} + \bar{\mathbf{E}}^{\text{dec}} + \mathbf{R}^{\text{enc}}\,. \tag{11}$$

The intuition of adding the regionalized embeddings $\bar{\mathbf{E}}^{\text{dec}}$ to the decoder inputs is to guide the model to recognize the sequence with the segmentation-level, or chord-level information; and using $\mathbf{R}^{\text{enc}}$ is to take the advantage of the explicit alignment information of the sequence labeling problem for the encoder-decoder architecture [38].

Then, the decoder weighs the hidden states of all layers, as does in the encoder, with the softmax-normalized parameters $\boldsymbol{\alpha}^{\text{dec}} := \{\alpha_l^{\text{dec}}\}_{l=1}^{L}$ to produce the final presentation $\mathbf{R}^{\text{dec}}$ of the decoder inputs:

$$\mathbf{R}^{\text{dec}} = [\mathbf{r}_1^{\text{dec}}, \cdots, \mathbf{r}_T^{\text{dec}}]^{\text{T}} = \sum_{l=1}^{L} \alpha_l^{\text{dec}} \mathbf{H}_l^{\text{dec}}\,. \tag{12}$$

Finally, the representation $\mathbf{R}^{\text{dec}}$ is fed into a fully-connected layer followed by a softmax activation to predict the probability distribution over the chord vocabulary for each time step t in the source sequence:

$$\mathbf{O}^{\text{dec}} = [\mathbf{o}_1^{\text{dec}}, \cdots, \mathbf{o}_T^{\text{dec}}]^{\text{T}} = \text{softmax}(\mathbf{R}^{\text{dec}}\mathbf{W}^{\text{O}}), \tag{13}$$

where $\mathbf{W}^{\text{O}}$ is the parameter matrix of the fully-connected network which maps each $\mathbf{r}_t^{\text{dec}}$ in $\mathbf{R}^{\text{dec}}$ into a vector of the chord vocabulary size. And the *recognition loss* is calculated with $\mathbf{O}^{\text{dec}}$.

We denote the ground truth labels of chord change and chord symbol as $\hat{\mathbf{o}}^{\text{enc}}$ and $\hat{\mathbf{O}}^{\text{dec}}$ respectively. The total loss function L_{total} in the Harmony Transformer is:

$$L_{\text{total}} := \lambda_1 \text{BCE}(\mathbf{p}^{\text{enc}}, \hat{\mathbf{o}}^{\text{enc}}) + \lambda_2 \text{CCE}(\mathbf{O}^{\text{dec}}, \hat{\mathbf{O}}^{\text{dec}})\,, \tag{14}$$

where BCE is the binary crossentropy, CCE is the categorical crossentropy, and λ_1 and λ_2 are coefficients used for balancing the two cross entropies. The two terms in (14) correspond to the segmentation loss and the recognition loss in Figure 1, respectively. [5]

4. EXPERIMENTS

4.1 Data

The proposed model is evaluated on both audio and symbolic datasets. For the audio part, we use the **McGill Billboard** dataset, which consists of 890 musical pieces sampled from the Billboard chart slots [39]. [6] For the symbolic data, we use the **BPS-FH** dataset, in which the first movements of Beethoven's 32 piano sonatas are included [25]. The chord annotations are available in the two datasets; chord segmentation labels are further derived from the chord annotations for the supervised training of the chord segmentation task.

[5] The implementation can be found at `https://github.com/Tsung-Ping/Harmony-Transformer`.

[6] The dataset can be found at `http://ddmal.music.mcgill.ca/research/billboard`.

Dataset	BLSTM	FK	HT	HT*	F1 (Seg.)
Billboard	77.03	78.90	82.68	**83.00**	57.15
BPS-FH	78.87	-	83.96	**84.18**	66.65

Table 1. The chord symbol recognition results in term of WCSR score. BLSTM stands for the 1-layer bidirectional RNN using LSTM cells; both HT and HT* denote the proposed model, except the tonal centroid vector is added into the input feature of the latter. The F1 scores of the chord segmentation of HT are shown in the rightmost column.

Function	BLSTM	HT
Key	72.62	**78.35**
Degree	47.75	**65.06**
Secondary	48.23	**68.15**
Quality	53.31	**74.60**
Inversion	61.59	**62.13**
F1 (Seg.)	-	67.34

Table 2. The accuracy (in %) of harmonic function recognition. Note that *Degree* stands for the accuracy of correctly predicting both the primary and secondary degrees, and *Secondary* indicates the accuracy of correctly predicting the degrees of secondary chords. The segmentation result (with F1 measure) is shown in the bottom row.

4.1.1 Audio data

For each piece in the McGill Billboard dataset, the non-negative-least-squares (NNLS) chromagram is computed with the Chordino VAMP plugin, [40] in which the default settings of the plugin are adopted. Combining the 12-D treble chroma and the 12-D bass chroma, for each track we obtain a 24-by-T-dimensional chromagram, where T represents the length of the track. [7] Each input sequence for the Harmony Transformer contains 100 segments (around 23 sec), and is generated through a sliding window of frame size 21 with hop size 5. Following [13] (see Section 2.2), pieces with id numbers smaller than 1000 are used for training, and the remaining for testing; also, identical pieces are filtered out. As a result, there are 5,647 sequences for training and 1,628 sequences for testing.

4.1.2 Symbolic data

We represent the piano sonatas in the BPS-FH dataset as pianorolls with the pitch ranging from A0 to G$^{\#}$7 (middle C = C4), where the duration of each note is measured in term of crotchet beats, and is quantized to 32th note. The length of each sequence is 64, and each element in the sequence is a pianoroll segmented with window size of 33 and hop size of 2. As the input element for the Harmony Transformer, each pianoroll segment is flattened into a vector whose length is 84×33. We use 4-fold cross-validation for evaluation; the number of sequences of each fold varies from 368 to 585.

4.1.3 Data augmentation

All the training data are augmented with key modulation and thus expanded to 12 times.

4.2 Experimental trials

For the Harmony Transformer (denoted as HT), we use the embedding size $d = 512$, the number of heads $h = 8$, and the number of layers of both the encoder and the decoder $L = 2$. The two coefficients λ_1 and λ_2 in the loss function are set to be 3 and 1 respectively. The chord symbol recognition task is conducted for both audio and symbolic data, and the harmonic function recognition task, as defined in [25], is further applied to the symbolic dataset. Besides, we employ the *tonal centroid* vector [20], which models the relationship between chords in a 6-D tonal space, as the additional input feature of the HT for better representing the input data.

4.2.1 Chord symbol recognition

The chord symbol recognition model has a 26-dimensional output, in which 24 of them represent major and minor triads, 1 represents 'others' for chords other than major or minor triads, and the remaining one represents the 'no-chord' case. The weighted chord symbol recall (WCSR) is used as the evaluation metric. We employ a 1-layer bidirectional RNN using LSTM cells of 512 hidden units (abbreviated as BLSTM) as the baseline for the evaluations of the two datasets. Additionally, we include the best evaluation result achieved by the ConvNet-HMM model (denoted as FK here) in [13] (see Section 3) for the comparison of the evaluation on audio data. The FK model is similar to the Madmom audio chord recognition framework, [8] which achieves many state-of-the-art scores in the MIREX Audio Chord Estimation (ACE) campaign. [9]

4.2.2 Harmonic function recognition

We formulate the harmonic function recognition task as a multi-task learning problem, in which the model outputs segment-wise predictions of the 5 chord functions: *local key* of 24 classes, *primary degree* of 21 classes, *secondary degree* of 21 classes, *chord quality* of 10 classes, and *chord inversion* of 4 classes. We use the classification accuracy to measure the performance of the proposed model. The BLSTM, as mentioned in Section 4.2.1, is also employed for comparison. For more information about the terminology of harmonic function, please refer to [25].

[7] For more information of the Chordino VAMP plugin and the NNLS chromagram, please refer to `http://www.isophonics.net/nnls-chroma`.

[8] `https://madmom.readthedocs.io/en/latest/modules/features/chords.html`.

[9] See `https://www.music-ir.org/mirex/wiki/2018:Audio_Chord_Estimation_Results`. The algorithm denoted as FK2 in the website is part of the Madmom audio processing framework.

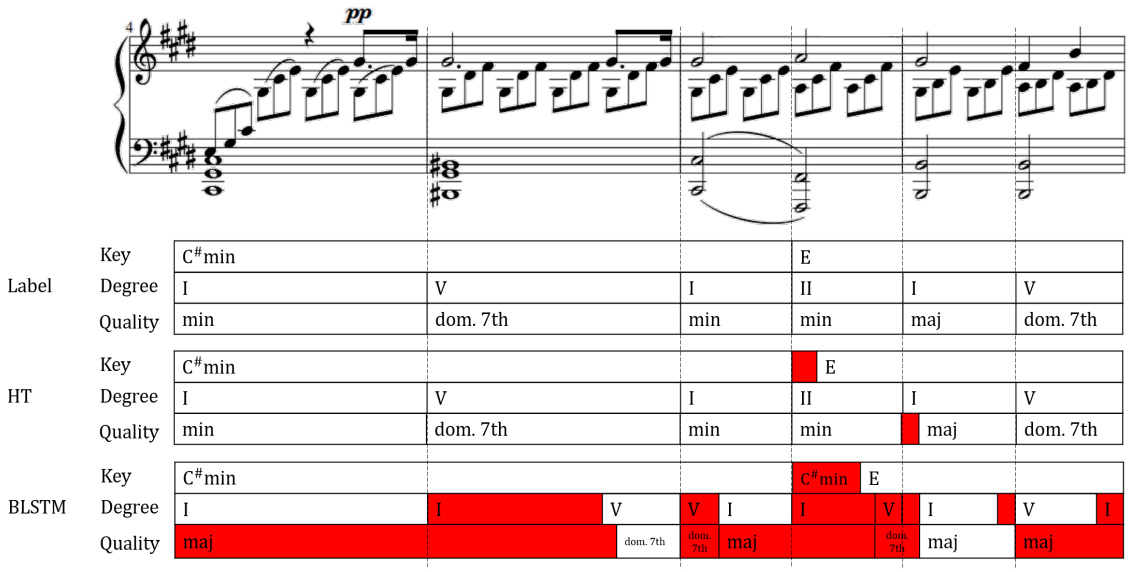

Figure 2. The predictions of harmonic function by the proposed model HT and the BLSTM, where *maj*, *min*, and *dom. 7th* stand for major, minor, and dominant seventh, respectively. Wrong predictions are marked in red. The example here is an excerpt from Beethoven's piano sonata No. 14, Op. 27-2, Mvt. 1, MM. 4-7.

4.3 Hyperparameters and training

The model is trained with the Adam optimization method of the learning rate $= 10^{-4}$, $\beta_1 = 0.9$, $\beta_2 = 0.98$, $\epsilon = 10^{-9}$. To avoid overfitting, we employ dropout [41] of rate $= 0.6$ and label smoothing [42] of the value $\epsilon_{ls} = 0.1$. In addition, because the encoder output contains discrete variables, i.e., the binary chord segmentation predictions $\mathbf{o}^{\text{enc}}$, we utilize a straight-through estimator along with the slope annealing trick [43] to estimate the derivative gradient during backpropagation.

4.4 Evaluation results

Table 1 shows the evaluation results of the chord symbol recognition task. For the Billboard dataset, the performance of the Harmony Transformer outperforms the BLSTM and the FK by 5.65% and 3.78% respectively. For the BPS-FH dataset, our model also surpasses the BLSTM by 5.09%. When we employ the tonal centroid vector for the input feature, the proposed model further boosts the recognition results. This indicates that the explicit information of harmonic change is useful for chord recognition. The fact that the proposed model outperforms the BLSTM in both audio and symbolic data exhibits our model's capability of sequence learning even though the model consists of no temporally recurrent computation. In addition, based on the same training and evaluation data, the proposed model performs better than the FK and therefore may compete with the ACE framework of Madmom. Nevertheless, the F1 scores for the segmentation task are not satisfied due to the low recall rates (57.10% and 58.69% for Billboard and BPS-FH). This indicates the challenge to identify the exact time when chord changes.

For the harmonic function recognition task, the HT outperforms the BLSTM in all of the five chord functions, as shown in Table 2. In particular, for local key, chord degree, secondary chord degree, and chord quality, the HT outperforms the BLSTM greatly by 5.73%, 17.31%, 19.92%, and 21.29%, respectively. This indicates that our model is able to deal with challenging cases such as the key modulation, and chords with special harmonic function. Figure 2 gives an example of such instances. The HT correctly predicts the chord progression in terms of local key, chord degree, and chord quality, except that the timing of modulating to E major is slightly later than the ground truth. Notably, the F minor triad at the second half of measure 6, functioned as a pivot chord in a common chord modulation, is precisely identified by our model in spite of the key change. In contrast, the BLSTM not only fails to recognize the degree of some chords in this example, but also mistakes the minor triads as major ones, such as in measure 4.

5. CONCLUSION AND FUTURE WORK

We have demonstrated that the Harmony Transformer is competent in harmony analysis. Built upon the commonality of musical chord recognition and natural language processing, we emphasize the importance of modeling segmental and hierarchical structures in music. The encoder-decoder architecture and the non-autoregressive decoding in the Harmony Transformer enhance the flexibility in modeling chord sequences. Specifically, the end-to-end combination of chord segmentation and chord recognition contributes great benefits to the chord symbol recognition, as well as to the joint recognition of five harmony functions, a challenging task that relies heavily on the contextual and structural information in music. Our model has the potential to be further improved by using the segmentation results to learn the *word-level* embedding, which has also witnessed success in natural language processing.

ABSTRACT

This paper describes a music structure analysis method that splits music audio signals into meaningful segments such as musical sections and clusters them. In this task, how to model the four fundamental aspects of musical sections, *i.e.*, homogeneity, repetitiveness, novelty, and regularity, in a unified way is still an open problem. Here we propose a solid statistical approach based on a homogeneity-, repetitiveness-, and regularity-aware hierarchical hidden semi-Markov model. The higher-level semi-Markov chain represents a sequence of sections that tend to have *regularly* spaced boundaries. The timbral features in each section are assumed to follow emission distributions that are *homogeneous* over time. The lower-level left-to-right Markov chain in each section represents a chord sequence whose sequential order is constrained to be a *repetition* of a chord sequence in another section of the same cluster. The whole model can be trained unsupervisedly based on Bayesian sparse learning where unnecessary sections automatically degenerate. The proposed method outperformed representative methods in segmentation and clustering accuracies with estimated sections having similar statistical properties as the ground truth data.

1. INTRODUCTION

Music structure analysis is a long-standing research topic [1] because detection of meaningful segments called musical sections (*e.g.*, intro, verse, bridge, and chorus sections in popular music) from music audio signals forms a basis of music information retrieval (MIR). In general, music structure analysis involves a *segmentation* step that splits music signals into sections [2–9], a *clustering* step that categorizes such sections into several classes [10–18], and a *labeling* step that gives each section a concrete label such as "verse A", "verse B", or "chorus" [19–21]. We here tackle the segmentation and clustering for popular music.

In previous studies, sections of popular music have been characterized in three aspects, *i.e.*, *homogeneity* referring to the intra-section characteristics and *repetitiveness* and *novelty* referring to the inter-section relationships [1]. More specifically, homogeneity means that musical characteristics (*e.g.*, timbral features such as mel-frequency cepstrum coefficients (MFCCs)) are consistent within a section. Repetitiveness means that the same sequence of some musical elements (*e.g.*, chroma features and chord progressions) of a section is repeated in sections of the same class. Novelty means that musical characteristics change abruptly at a boundary between sections. In addition, *regularity* of section durations has often been focused on [8–10] because there are typical lengths such as four or eight measures in popular music.

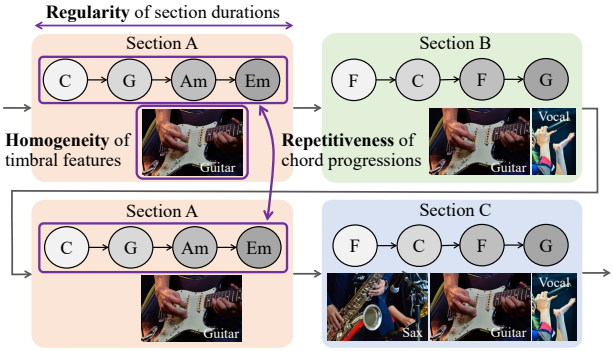

Figure 1. Music structure analysis based on homogeneity of timbral features, repetitiveness of chord progressions, and regularity of section durations.

Most studies on music structure analysis, however, have focused on only one of the above aspects or consider some of them in a separate and/or ad-hoc manner, as reviewed in Section 2. Joint computational modeling of these four aspects is thus the central issue in music structure analysis. Instead of manually designing segmentation and clustering criteria based on these aspects, we pursue a statistical approach to *data-driven* music structure analysis.

In this study, we propose a statistical music structure analysis method that simultaneously deals with the homogeneity, repetitiveness, and regularity of musical sections in a probabilistic framework (Fig. 1). We formulate a unified probabilistic model called a hierarchical hidden semi-Markov model (HHSMM) that represents the hierarchical generative process of musical sections, chord sequences, and music audio signals (timbral features and chroma features). This model has two sequences of latent states in a hierarchical manner. The upper-level sequence

represents a series of section classes following a semi-Markov model with explicit regularity (duration) modeling and the lower-level sequence represents chords following a section-conditioned left-to-right Markov model. To represent the intra-section homogeneity of timbral features, the MFCCs of a section are assumed to be generated from an upper-level state corresponding to the section. To represent the inter-section repetitiveness of chord progressions, the chroma features of a section are assumed to be sequentially generated from lower-level states. Given a music audio signal as observed data, the whole model can be trained unsupervisedly using Gibbs sampling and Viterbi training, where unnecessary sections are automatically degenerated during the Bayesian sparse learning.

The main contribution of this study is to propose a solid Bayesian approach to music signal analysis based on a fully *generative* model that can deal with the homogeneity, repetitiveness, and regularity of sections in a unified way. This enables *unsupervised* learning unlike another statistical approach based on deep *discriminative* models [6–8] that require section annotations for supervised training. Since these two approaches have a mutually complementary relationship, our results open up a door to deep Bayesian integration of discriminative and generative models in a variational autoencoding framework (audio signal $\rightarrow$ sections $\rightarrow$ audio signal) [22] for further improvement.

Another important contribution is to investigate the statistical characteristics of musical sections estimated by the proposed method in comparison with representative methods. Our method is shown to be able to yield distributions of section durations, of the numbers of section classes used for representing music audio signals, and of the metrical positions of section boundaries much more similar to those of the ground-truth data than the other methods.

2. RELATED WORK

Homogeneity, repetitiveness, novelty, and regularity have been considered to be important for music structure analysis. The most standard approach to music structure analysis is to use the self-similarity matrix (SSM) of acoustic features such as chroma features and MFCCs, whose element represents the acoustic similarity between two time frames (Fig. 2). In an SSM, the homogeneity, repetitiveness, novelty, and regularity are observed as block-diagonal structure, short stripes parallel to the diagonal line, grid patterns, and grid intervals, respectively. One or some of these four aspects have been used for segmentation and clustering tasks in music structure analysis.

2.1 Segmentation

Foote [2] proposed a novelty-based method that detects peaks from a time-varying novelty curve obtained by shifting and convoluting a checkerboard kernel along the diagonal elements of an SSM. Jensen [3] attempted to find section boundaries that minimize a homogeneity- and novelty-based cost function. While Goto [19] originally proposed a lag SSM in which repetitions appear not as stripes but as vertical lines and calculated a novelty curve over

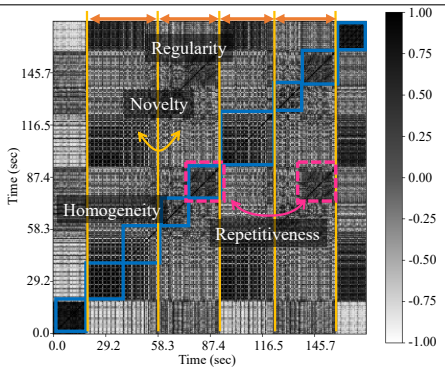

Figure 2. Self-similarity matrix (SSM) of MFCC features (part of RWC-MDB-P-2001 No. 25).

time lags, Serrà [4] proposed another novelty curve over time frames. Peeters and Bisot [5] successfully integrated these two methods [4, 19] for better segmentation. Ullrich *et al.* [6] pioneered a supervised approach based on a convolutional neural network (CNN), which was extended to deal with both coarse- and fine-level boundary annotations [7]. Sargent *et al.* [9] pointed out the effectiveness of focusing on the regularity to favor structural segments of comparable size. Maezawa [8] developed a long short-term memory (LSTM) network with homogeneity-, repetitiveness-, novelty-, and regularity-based cost functions. In this study we take an *unsupervised* approach based on a homogeneity-, repetitiveness-, and regularity-based *generative* model. To keep the model simple, incorporation the aspect of novelty is left for future work.

2.2 Clustering

Cooper *et al.* [12] sequentially performed music segmentation [2] and section clustering based on intra- and inter-section statistical characteristics. Goodwin *et al.* [13] attempted to efficiently detect off-diagonal stripes in an SSM as repetitions using dynamic programming. To deal with repetitiveness and homogeneity, Grohganz *et al.* [14] converted a repetitiveness-dominant SSM with off-diagonal stripes into a homogeneity-dominant SSM with block-diagonal structure. Nieto *et al.* [15] used a convex variant of non-negative matrix factorization for section segmentation and clustering. McFee *et al.* [16] proposed a method that encodes repetitive structures into a graph and performs spectral clustering for graph partitioning.

Several studies took a statistical approach based on generative models for joint segmentation and clustering. Aucouturier *et al.* [11] used a standard hidden Markov model (HMM). Ren *et al.* [17] proposed a nonparametric Bayesian extension of an HMM that can estimate an appropriate number of sections. Barrington *et al.* [18] proposed a nonparametric Bayesian extension of a switching linear dynamical system (LDS) that also has the ability of automatic model complexity control. While these methods mainly focused on the homogeneity, our method simultaneously considers the homogeneity, repetitiveness, and regularity and can incorporate prior knowledge about the statistical characteristics of sections (*e.g.*, durations and metrical positions) in a data-driven manner.

3. PROPOSED METHOD

This section describes the proposed statistical method for music structure analysis.

3.1 Problem Specification

Our problem is formulated as follows:

Input: A chroma feature sequence $\mathbf{X}^c = \mathbf{x}^c_{1:B} \in \mathbb{R}^{B\times 12}$ and an MFCC sequence $\mathbf{X}^m = \mathbf{x}^m_{1:B} \in \mathbb{R}^{B\times 12}$ obtained from a given music audio signal. They are computed in units of beats estimated by a beat tracking method [23].
Output: Boundaries and classes of sections.

Here, B is the number of beats (quarter notes) and a subscript $\bigcirc_{a:b}$ represents the sequence $(\bigcirc_a, \ldots, \bigcirc_b)$.

We use 12-dimensional chroma features obtained by aggregating all spectral information of each pitch class into a single element. We also use 12-dimensional MFCCs as timbral features.

3.2 Model Formulation

The proposed model consists of two-level hierarchical Markov chains and an acoustic model as shown in Fig. 3. The upper-level Markov chain describes the section-level structure (*i.e.*, section classes and durations) and the lower-level Markov chain describes the internal structure of each section. The states of these Markov chains are latent variables that represent abstract musical structure. The acoustic model connects the abstract structure with the observed musical features (chroma vectors and MFCCs).

3.2.1 Upper-Level Markov Chain

The upper-level Markov chain is an ergodic semi-Markov model. The sequence of section classes $\mathbf{Z} = z_{1:T}$ ($z_\tau \in \{1, \ldots, N_Z\}$) and their durations $\mathbf{D} = d_{1:T}$ ($d_\tau \in \{1, \ldots, N_D\}$) are generated by the model, where T is the number of sections, N_Z is the number of distinct section classes, and N_D is the maximum duration of a section. The generative process is described as follows:

$$p(z_1, d_1) = \rho_{z_1}\psi_{d_1}, \tag{1}$$

$$p(z_\tau, d_\tau | z_{\tau-1}, d_{\tau-1}) = \pi_{z_{\tau-1}z_\tau}\psi_{d_\tau}, \tag{2}$$

where ρ_z and $\pi_{zz'}$ are the initial and transition probabilities of section classes and ψ_d is the duration probability.

3.2.2 Lower-Level Markov Chain

The lower-level Markov chain is a left-to-right Markov model with N_K states. The state sequence of this model describes the internal structure of a section corresponding to the chord progression, where each state is expected to correspond to a chord. We consider such a Markov chain for each section class. The model continues state transitions for each beat from the start time of a section until its duration passes. The state sequence $\mathbf{K}_\tau = k_{\tau,1:d_\tau}$ ($k_{\tau,t} \in \{1, \ldots, N_K\}$) is generated as follows:

$$p(k_{\tau,t} | z_\tau, k_{\tau,t-1}) = \phi^{(z_\tau)}_{k_{\tau,t-1}k_{\tau,t}}, \tag{3}$$

where z_τ and d_τ are the corresponding section class and duration, and $\phi^{(z_\tau)}_{kk'}$ is the transition probability from state k to state k'.

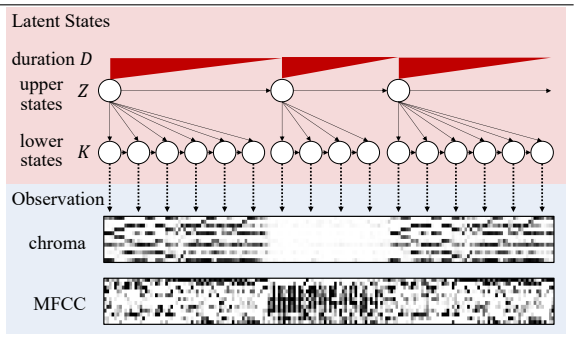

Figure 3. The proposed generative model.

The left-to-right Markov model meets a condition that the initial state has $k_{\tau,1} = 1$ and $k_{\tau,t_1} \le k_{\tau,t_2}$ for $t_1 < t_2$. We introduce a hyperparameter σ that describes the maximum number of states that may be skipped in a transition; a transition from state k to state $k+\sigma$ is possible but a larger skip is forbidden. In this way, the model can describe repetitions with some variations, which is another important aspect of musical structure. $\mathbf{K}$ denotes $\mathbf{K}_{1:T}$.

3.2.3 Acoustic Model

The acoustic model describes the generative processes of the chroma features $\mathbf{x}^c_b \in \mathbb{R}^{12}$ and MFCCs $\mathbf{x}^m_b \in \mathbb{R}^{12}$ by using output probabilities that are defined conditionally on the section classes $\mathbf{Z}$ and their internal states $\mathbf{K}$. The repetitiveness is represented by applying the same set of output probabilities to all sections of the same class. The output probabilities of chroma features $\chi^c_{z,k}$ depend on both $\mathbf{Z}$ and $\mathbf{K}$ to represent the sequential structure of chord progressions. To capture the homogeneity of timbre characteristics of each section, the output probabilities of MFCCs χ^m_z are assumed to depend only on $\mathbf{Z}$. Thus we have

$$p(\mathbf{x}^c_b, \mathbf{x}^m_b) = \chi^c_{z_b,k_b}(\mathbf{x}^c_b)\chi^m_{z_b}(\mathbf{x}^m_b), \tag{4}$$

where z_b and k_b are the section class and the internal state at beat b, respectively. The output probabilities are described as multivariate Gaussian distributions:

$$\chi^c_{z,k}(\mathbf{x}^c_b) = \mathcal{N}(\mathbf{x}^c_b | \boldsymbol{\mu}^c_{z,k}, (\boldsymbol{\Lambda}^c_{z,k})^{-1}), \tag{5}$$

$$\chi^m_z(\mathbf{x}^m_b) = \mathcal{N}(\mathbf{x}^m_b | \boldsymbol{\mu}^m_z, (\boldsymbol{\Lambda}^m_z)^{-1}), \tag{6}$$

where $\boldsymbol{\mu}^c_{z,k}$ and $\boldsymbol{\Lambda}^c_{z,k}$ are the mean and precision for the chroma features, and $\boldsymbol{\mu}^m_z$ and $\boldsymbol{\Lambda}^m_z$ are defined similarly.

3.2.4 Prior Distributions

To find an effective number of distinct section classes, we formulate a Bayesian HHSMM by putting conjugate prior distributions. We put Dirichlet prior distributions for the categorical distributions as follows:

$$\boldsymbol{\rho} \sim \text{Dirichlet}(\mathbf{a}^{\boldsymbol{\rho}}), \tag{7}$$

$$\boldsymbol{\psi} \sim \text{Dirichlet}(\mathbf{a}^{\boldsymbol{\psi}}), \tag{8}$$

$$\boldsymbol{\pi}_z \sim \text{Dirichlet}(\mathbf{a}^{\boldsymbol{\pi}}), \tag{9}$$

$$\boldsymbol{\phi}^{(z)}_k \sim \text{Dirichlet}(\mathbf{a}^{\boldsymbol{\phi}}), \tag{10}$$

where $\boldsymbol{\rho} = \rho_{1:N_Z}$, $\boldsymbol{\psi} = \psi_{1:N_D}$, $\boldsymbol{\pi}_z = \pi_{z(1:N_Z)}$, $\boldsymbol{\phi}^{(z)}_k = \phi^{(z)}_{k(1:N_K)}$, and $\mathbf{a}^{\boldsymbol{\rho}}$, $\mathbf{a}^{\boldsymbol{\psi}}$, $\mathbf{a}^{\boldsymbol{\pi}}$, and $\mathbf{a}^{\boldsymbol{\phi}}$ are Dirichlet parameters. When these parameters are small, the transition probabilities of section classes become sparse. The model can

thus capture repetitions regardless of small acoustic variations and remove unnecessary section classes.

Since section durations tend to be the integer multiples of four measures in popular music (see Fig. 4), such a statistical tendency can be incorporated in the prior distribution. Specifically, we use as $\mathbf{a}^{\boldsymbol{\psi}}$ the empirical distribution of section durations $\mathbf{a}^{\boldsymbol{\psi}}_{\mathrm{emp}}$ multiplied by a constant factor. Since the structure of section classes is quite different over individual musical pieces, we put uniform Dirichlet prior distributions for their transition probabilities.

Finally, we put Gaussian-Wishart prior distributions on multivariate normal distributions as follows:

$$\boldsymbol{\mu}^c_{z,k}, \boldsymbol{\Lambda}^c_{z,k} \sim \mathcal{N}(\boldsymbol{\mu}^c_{z,k}|\mathbf{m}^c_0, (\beta^c_0\boldsymbol{\Lambda}^c_{z,k})^{-1})\, \mathcal{W}(\boldsymbol{\Lambda}^c_{z,k}|\mathbf{W}^c_0, \nu^c_0),$$
$$\boldsymbol{\mu}^m_z, \boldsymbol{\Lambda}^m_z \sim \mathcal{N}(\boldsymbol{\mu}^m_z|\mathbf{m}^m_0, (\beta^m_0\boldsymbol{\Lambda}^m_z)^{-1})\, \mathcal{W}(\boldsymbol{\Lambda}^m_z|\mathbf{W}^m_0, \nu^m_0),$$

where $\mathbf{m}^c_0$, β^c_0, $\mathbf{W}^c_0$, ν^c_0, $\mathbf{m}^m_0$, β^m_0, $\mathbf{W}^m_0$, and ν^m_0 are hyperparameters.

3.3 Bayesian Learning

Letting $\boldsymbol{\Theta} = \{\boldsymbol{\rho}, \boldsymbol{\psi}, \boldsymbol{\pi}, \boldsymbol{\phi}, \boldsymbol{\mu}, \boldsymbol{\Lambda}\}$, we aim to calculate the posterior distribution $p(\mathbf{Z}, \mathbf{D}, \mathbf{K}, \boldsymbol{\Theta}|\mathbf{X}^c, \mathbf{X}^m)$. Since this is analytically intractable, we use the Gibbs sampling method. We first sample the latent variables $\mathbf{Z}$, $\mathbf{D}$, and $\mathbf{K}$ from the distribution $p(\mathbf{Z}, \mathbf{D}, \mathbf{K}|\boldsymbol{\Theta}, \mathbf{X}^c, \mathbf{X}^m)$ and we then sample the model parameters $\boldsymbol{\Theta}$ from the distribution $p(\boldsymbol{\Theta}|\mathbf{Z}, \mathbf{D}, \mathbf{K}, \mathbf{X}^c, \mathbf{X}^m)$. Iterating this process, we obtain samples from the true posterior distribution.

3.3.1 Sampling Latent Variables

We use the forward filtering-backward sampling algorithm for sampling the upper- and lower-level latent variables $\mathbf{Z}$, $\mathbf{D}$, and $\mathbf{K}$. We introduce variables z_b and d_b that denote the class and duration of a section starting at beat $b-d_b+1$ and ending at beat b. We also define the marginalized output probabilities for this section $\omega_{z_b}(\mathbf{x}^c_{b-d_b+1:b}, \mathbf{x}^m_{b-d_b+1:b})$, which can be calculated by the forward algorithm for the lower-level Markov chain.

In the forward filtering step for the upper-level model, we initialize and update the forward variables $\alpha_b(z_b, d_b) = p(z_b, d_b, \mathbf{x}^c_{1:b}, \mathbf{x}^m_{1:b})$ as follows:

$$\alpha_b(z_b, d_b = b) = \rho_{z_b}\psi_{d_b}\omega_{z_b}(\mathbf{x}^c_{1:b}, \mathbf{x}^m_{1:b}), \tag{11}$$

$$\alpha_b(z_b, d_b) \tag{12}$$
$$= \sum_{z', d'} \alpha_{b-d_b}(z', d')\pi_{z'z_b}\psi_{d_b}\omega_{z_b}(\mathbf{x}^c_{b-d_b+1:b}, \mathbf{x}^m_{b-d_b+1:b}).$$

In the backward sampling step, the latent variables $\mathbf{Z}$ and $\mathbf{D}$ are sequentially sampled in the reverse order:

$$p(z_B, d_B|\mathbf{X}^c, \mathbf{X}^m) \propto \alpha_B(z_B, d_B). \tag{13}$$

When variables z_b and d_b are already sampled, the variables $z_{b'}$ and $d_{b'}$ at beat $b' = b - d_b$ are sampled according to the probability

$$p(z_{b'}, d_{b'}|z_{b:B}, d_{b:B}, \mathbf{X}^c, \mathbf{X}^m) \propto \alpha_{b'}(z_{b'}, d_{b'})\pi_{z_{b'}z_b}. \tag{14}$$

Next, the latent variables $\mathbf{K}$ are sampled using the sampled $\mathbf{Z}$ and $\mathbf{D}$. Each set of variables $\mathbf{K}_\tau$ is sampled by forward filtering-backward sampling for the lower-level model of section class z_τ. Here we use a beat index $t \in \{1, \ldots, d_\tau\}$ considered in relative to the section boundary. In the forward filtering step, we calculate the probabilities $\zeta_{\tau,k_{\tau,t}}$ recursively as follows:

$$\zeta_{\tau,k_{\tau,1}} = p(k_{\tau,1}, \mathbf{x}^c_1, \mathbf{x}^m_1|z_\tau, d_\tau)$$
$$= \delta_{k_{\tau,1}1}\chi^c_{z_\tau,1}(\mathbf{x}^c_1)\chi^m_{z_\tau}(\mathbf{x}^m_1), \tag{15}$$

$$\zeta_{\tau,k_{\tau,t}} = p(k_{\tau,t}, \mathbf{x}^c_{1:t}, \mathbf{x}^m_{1:t}|z_\tau, d_\tau) \tag{16}$$
$$= \left(\sum_{k_{\tau,t-1}} \zeta_{\tau,k_{\tau,t-1}}\phi^{(z_\tau)}_{k_{\tau,t-1}k_{\tau,t}}\right)\chi^c_{z_\tau,k_{\tau,t}}(\mathbf{x}^c_t)\chi^m_{z_\tau}(\mathbf{x}^m_t).$$

In the backward sampling step, the latent variables $\mathbf{K}$ are sequentially sampled in the reverse order as follows:

$$p(k_{\tau,d_\tau}|z_\tau, d_\tau, \mathbf{x}^c_{1:d_\tau}, \mathbf{x}^m_{1:d_\tau}) \propto \zeta_{\tau,k_{\tau,d_\tau}}, \tag{17}$$

$$p(k_{\tau,t}|z_\tau, d_\tau, k_{\tau,t+1:d_\tau}, \mathbf{x}^c_{1:d_\tau}, \mathbf{x}^m_{1:d_\tau}) \propto \zeta_{\tau,k_{\tau,t}}\phi^{(z_\tau)}_{k_{\tau,t}k_{\tau,t+1}}. \tag{18}$$

3.3.2 Sampling Model Parameters

We use the Gibbs sampling method for updating the model parameters as follows:

$$\boldsymbol{\rho} \sim \mathrm{Dirichlet}(\mathbf{a}^{\boldsymbol{\rho}} + \mathbf{b}^{\boldsymbol{\rho}}), \tag{19}$$
$$\boldsymbol{\pi}_z \sim \mathrm{Dirichlet}(\mathbf{a}^{\boldsymbol{\pi}} + \mathbf{b}^{\boldsymbol{\pi}_z}), \tag{20}$$
$$\boldsymbol{\psi} \sim \mathrm{Dirichlet}(\mathbf{a}^{\boldsymbol{\psi}} + \mathbf{b}^{\boldsymbol{\psi}}), \tag{21}$$
$$\boldsymbol{\phi}^{(z)}_k \sim \mathrm{Dirichlet}(\mathbf{a}^{\boldsymbol{\phi}} + \mathbf{b}^{\boldsymbol{\phi}^{(z)}_k}), \tag{22}$$
$$\boldsymbol{\Lambda}^c_{z,k} \sim \mathcal{W}(\mathbf{W}^c_{z,k}, \nu^c_{z,k}), \tag{23}$$
$$\boldsymbol{\mu}^c_{z,k}|\boldsymbol{\Lambda}^c_{z,k} \sim \mathcal{N}(\mathbf{m}^c_{z,k}, (\beta^c_{z,k}\boldsymbol{\Lambda}^c_{z,k})^{-1}), \tag{24}$$
$$\boldsymbol{\Lambda}^m_z \sim \mathcal{W}(\mathbf{W}^m_z, \nu^m_z), \tag{25}$$
$$\boldsymbol{\mu}^m_z|\boldsymbol{\Lambda}^m_z \sim \mathcal{N}(\mathbf{m}^m_z, (\beta^m_z\boldsymbol{\Lambda}^m_z)^{-1}), \tag{26}$$

where $\mathbf{b}^{\boldsymbol{\rho}} \in \mathbb{R}^{N_Z}$, $\mathbf{b}^{\boldsymbol{\pi}_z} \in \mathbb{R}^{N_Z}$, $\mathbf{b}^{\boldsymbol{\psi}} \in \mathbb{R}^{N_D}$, and $\mathbf{b}^{\boldsymbol{\phi}^{(z)}_k} \in \mathbb{R}^{N_K}$ are vectors counting the sampled data. $b^{\boldsymbol{\rho}}_z$ is 1 if $z = z_1$ and 0 otherwise, $b^{\boldsymbol{\pi}_z}_{z'}$ counts the number of transitions from state z to state z', $b^{\boldsymbol{\psi}}_d$ counts the number of times that sampled sections have a duration of d, and $b^{\boldsymbol{\phi}^{(z)}_k}_{k'}$ counts the number of transitions from state k to state k' in the lower-level model of section class z. The parameters $\mathbf{m}^c_{z,k}$, $\beta^c_{z,k}$, $\mathbf{W}^c_{z,k}$, and $\nu^c_{z,k}$ are calculated as follows:

$$\beta^c_{z,k} = \beta^c_0 + N_{z,k}, \quad \nu^c_{z,k} = \nu^c_0 + N_{z,k}, \tag{27}$$

$$\mathbf{m}^c_{z,k} = \frac{1}{\beta^c_{z,k}}(\beta^c_0\mathbf{m}^c_0 + N_{z,k}\overline{\mathbf{x}}^c_{z,k}), \tag{28}$$

$$(\mathbf{W}^c_{z,k})^{-1} = (\mathbf{W}^c_0)^{-1} + N_{z,k}\mathbf{S}^c_{z,k} + \frac{\beta^c_0 N_{z,k}}{\beta^c_0 + N_{z,k}}(\overline{\mathbf{x}}^c_{z,k} - \mathbf{m}^c_0)(\overline{\mathbf{x}}^c_{z,k} - \mathbf{m}^c_0)^{\mathrm{T}}, \tag{29}$$

where we have defined

$$N_{z,k} = \sum_{b=1}^{B} \delta_{z_b z}\delta_{k_b k}, \tag{30}$$

$$\overline{\mathbf{x}}^c_{z,k} = \frac{1}{N_{z,k}}\sum_{b=1}^{B} \delta_{z_b z}\delta_{k_b k}\mathbf{x}^c_b, \tag{31}$$

$$\mathbf{S}^c_{z,k} = \frac{1}{N_{z,k}}\sum_{b=1}^{B} \delta_{z_b z}\delta_{k_b k}(\mathbf{x}^c_b - \overline{\mathbf{x}}^c_{z,k})(\mathbf{x}^c_b - \overline{\mathbf{x}}^c_{z,k})^{\mathrm{T}}. \tag{32}$$

The parameters $\mathbf{m}^m_z$, β^m_z, $\mathbf{W}^m_z$, and ν^m_z can be calculated similarly.

3.3.3 Refinements

We introduce two refinements to facilitate the learning process. First, since the samples from the Gibbs sampler are not necessarily local optimums of the posterior distribution, we apply Viterbi training in the last step of the parameter estimation. Specifically, we apply the Viterbi algorithm (instead of the forward filtering-backward sampling algorithm) to estimate the latent variables and update the model parameters to the expectation values of the posterior probabilities (instead of samples from those probabilities). It is known that Viterbi training is generally efficient for finding an approximate local minimum [24].

Second, we introduce a weighting factor $w_{\mathrm{dur}}(\geq 1)$ for the duration probability to enhance its effect. Specifically, we replace the probability factor ψ_{d_b} in the forward algorithm (11) and (12) with $(\psi_{d_b})^{w_{\mathrm{dur}}}$. Similar replacements are applied to the Viterbi training step as well as to the final estimation step of latent states explained in Section 3.4. Increasing the weighting factor has the effect of lowering the temperature and putting more focus on more frequent section durations.

3.4 Estimation of Musical Sections

After training the model parameters, we compute the maximum a posteriori (MAP) estimate of the latent variables (musical sections). Specifically, we maximize the posterior probability $p(\mathbf{Z}, \mathbf{D}|\mathbf{\Theta}, \mathbf{X}^c, \mathbf{X}^m)$ with respect to latent variables $\mathbf{Z}$ and $\mathbf{D}$. This can be solved by integrating out the lower-level states $\mathbf{K}$ and applying the Viterbi algorithm for hidden semi-Markov models [25] to the upper-level model.

4. EVALUATION

4.1 Experimental Conditions

We used the RWC popular music database [26] with structure annotations [27] for evaluation. Out of the 100 pieces in the data, we used 85 musical pieces in consistent 4/4 time for simplicity. For running the proposed method, we obtained chroma features using the deep feature extractor [28] and MFCCs using the librosa library [29]. Beat information was obtained using the madmom library [23]. The empirical distribution $\mathbf{a}^{\boldsymbol{\psi}}_{\mathrm{emp}}$ of section durations was trained using the piece-wise cross validation among the 85 pieces. For parameter estimation, we iterated the Gibbs sampling 15 times and the Viterbi training 3 times, which took roughly around 5 times the duration of an input signal with a standard CPU.

The hyperparameters of the proposed models were set as follows: $N_Z = 12$, $N_D = 40$, $N_K = 16$, $\sigma = 1$, $w_{\mathrm{dur}} = 4$, $\mathbf{a}^{\boldsymbol{\rho}} = 0.1 \cdot \mathbb{I}$, $\mathbf{a}^{\boldsymbol{\pi}} = \mathbb{I}$, $\mathbf{a}^{\boldsymbol{\psi}} = 50 \cdot \mathbf{a}^{\boldsymbol{\psi}}_{\mathrm{emp}}$, $\mathbf{a}^{\boldsymbol{\phi}} = \mathbb{I}$, $\mathbf{m}^c_0 = \mathbb{E}[\mathbf{X}^c]$, $\beta^c_0 = 8$, $\mathbf{W}^c_0 = (\nu^c_0 \operatorname{cov}[\mathbf{X}^c])^{-1}$ with $\nu^c_0 = 96$, $\mathbf{m}^m_0 = \mathbb{E}[\mathbf{X}^m]$, $\beta^m_0 = 4$, and $\mathbf{W}^m_0 = (\nu^m_0 \operatorname{cov}[\mathbf{X}^m])^{-1}$ with $\nu^m_0 = 80$, where $\mathbb{I}$ denotes a vector with all entries equal to 1. The first three parameters N_Z, N_D, and N_K were determined by consulting the statistics of the annotated data (see Fig. 4). According to the data, most songs have 12 or less sections and most sections have a length of 40 beats or less. If we expect a section length of 32 beats (8 measures) and a chord duration of 2 beats, the expected number of chords in each section is 16. The value of σ is set to 1 for simplicity. The other parameters were determined by a coarse optimization w.r.t. the two evaluation measures explained below. Each parameter was optimized by a grid search, fixing the other parameters. Further optimization of the parameters is left for future work.

Method	$F_{0.5}$ (%) (segmentation)	F_{pair} (%) (clustering)
VMO [30]	8.72	28.5
CNMF [15]	17.4	41.7
SCluster [16]	23.4	45.5
Proposed	**33.0**	**54.3**

Table 1. Evaluation results.

For comparison, we ran variable Markov oracle (VMO) [30], convex non-negative matrix factorization (CNMF) [15], and spectral clustering (SCluster) [16], which were available in the music structure analysis framework (MSAF) [31]. We used the default settings in the MSAF.

We evaluated the quality of segmentation and clustering in the same way as MIREX [32]. The quality of segmentation is evaluated by the F-measure $F_{0.5}$ of section boundaries [33] defined as follows. An estimated boundary is accepted as correct if there is a boundary in the ground truth data within the range of ± 0.5 seconds. The precision rate is the percentage of correct estimates. The recall rate is the percentage of true boundaries that are correctly estimated. The F-measure $F_{0.5}$ is defined as the harmonic mean of the precision and recall.

The quality of clustering is evaluated by the pairwise F-measure F_{pair} [34] defined as follows. We compare pairs of frames (with a length of 100 ms) that are labeled with the same class in an estimation result with those in the ground truth. The precision, recall, and F-measure are defined as

$$P_{\mathrm{pair}} = \frac{|P_E \cap P_A|}{|P_E|}, \quad R_{\mathrm{pair}} = \frac{|P_E \cap P_A|}{|P_A|}, \tag{33}$$

$$F_{\mathrm{pair}} = \frac{2P_{\mathrm{pair}}R_{\mathrm{pair}}}{P_{\mathrm{pair}} + R_{\mathrm{pair}}}, \tag{34}$$

where P_E denotes the set of similarly labeled frame pairs in the estimation and P_A denotes that in the ground truth. These values are calculated by the `mir_eval` library [35].

4.2 Experimental Results

The results in Table 1 show that SCluster had the best $F_{0.5}$ and F_{pair} among the three conventional methods. The F-measures obtained by VMO were very low and the estimated results included many unnatural short segments (see Fig. 4). This was presumably caused by the implementation in the MASF. In both $F_{0.5}$ and F_{pair}, the proposed method significantly outperformed the three compared methods.

Next, let us examine the estimated results more closely (Fig. 4). The distribution of section durations for the proposed model was similar to that of the ground truth. In particular, both distributions have peaks at the 32 beats (eight measures) and 16 beats (four measures). In contrast, the distributions for the results of the other three methods were

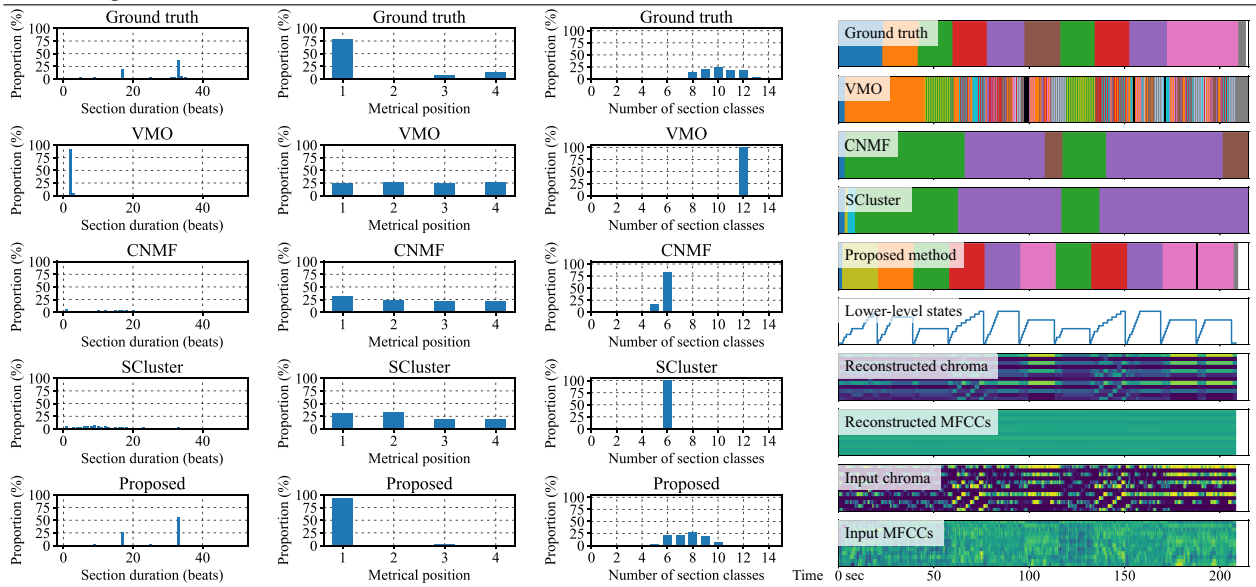

Figure 4. The left panels show the distributions of section durations, those of metrical positions of section boundaries, and those of the numbers of section classes in the estimated results and ground truth data. The right figure shows example results by the proposed and the three existing methods (RWC-MDB-P-2001 No. 29). The lower-level states are obtained by the Viterbi algorithm and the reconstructed features indicate the mean values of the corresponding output probabilities.

significantly different from that of the ground truth. This result clearly demonstrates the effect of explicitly modelling the section durations to capture their regularity. We also found that the distribution of metrical positions of section boundaries for the ground truth data was similar to that for the proposed method, but significantly different from those for the conventional methods.

The numbers of section classes in the ground truth data were roughly distributed in the range from eight to twelve. The distribution for the proposed model had a similar shape, though it is slightly shifted to the lower side. This result demonstrates the nontrivial ability of the proposed method to automatically find the appropriate number of section classes, even though it often finds the number smaller than the actual value. On the other hand, the distributions for the other methods were much more sparse; they found more or less the same number of section classes for all the tested pieces. In particular, CNMF and SCluster estimated too few section classes.

From these analyses, we find that the results of music structure analysis by the proposed method have much more similarity with the human annotated results than the compared existing methods. It is also important to point out that these results could not be made clear only by looking at the F-measures. The F-measures are not sufficient for evaluating results of music structure analysis.

We can observe these tendencies in the example results (Fig. 4). Particularly, CNMF and SCluster estimated too few section classes and irregular section durations. For the proposed method, we see that sections of the same class had similar lower-level sequences of latent states. This suggests that the model successfully captured repeated chord progressions in the sections of the same class. We can also observe that the proposed model often used only a part of lower-level states, which might be improved by imposing more constraints on the lower-level Markov chain.

For a fair comparison, we remark that parameters of the three existing methods were not optimized using our training data. Since we used limited data containing only J-pop pieces, adapting the parameters of these methods to this particular musical style may improve their performance to some extent. In addition, using the state-of-the-art beat tracker [23] to obtain reliable beat information and using that as input to those three methods may also improve their accuracy. However, it is unlikely that these methods can be refined to reproduce the aforementioned statistics of sections simply by re-training the parameters.

5. CONCLUSION

We have presented a statistical method for music structure analysis based on a Bayesian HHSMM that describes intra- and inter-section structures in a unified way. Three of the most important aspects of musical sections, homogeneity, repetitiveness, and regularity are incorporated into the model. Music segmentation and section clustering are performed jointly by unsupervised Bayesian learning of the model, and musically important characteristics such as the repetitive structure and the distribution of section durations are incorporated by the Bayesian extension. The experimental results showed that the proposed method achieved segmentation and clustering accuracies significantly better than the representative existing methods.

For future work, we plan to refine the model to incorporate the aspect of novelty and to deal with more hierarchies [16] because music has a hierarchical structure, from motive and phrase to section and section group [36]. Our unsupervised learning approach is complementary to another approach based on deep discriminative models [6–8]. A promising direction is to integrate these models into a variational autoencoding framework [22].

TOWARDS MEASURING INTONATION QUALITY OF CHOIR RECORDINGS: A CASE STUDY ON BRUCKNER'S LOCUS ISTE

Christof Weiß, Sebastian J. Schlecht, Sebastian Rosenzweig, Meinard Müller

ABSTRACT

Unaccompanied vocal music is a central part of Western art music, yet it requires excellent skills for singers to achieve proper intonation. In this paper, we analyze intonation deficiencies by introducing an intonation cost measure that can be computed from choir recordings and may help to assess the singers' intonation quality. With our approach, we measure the deviation between the recording's local salient frequency content and an adaptive reference grid based on the equal-tempered scale. The adaptivity introduces invariance of the local intonation measure to global intonation drifts. In our experiments, we compute this measure for several recordings of Anton Bruckner's choir piece *Locus Iste*. We demonstrate the robustness of the proposed measure by comparing scenarios of different complexity regarding the availability of aligned scores and multi-track recordings, as well as the number of singers per part. Even without using score information, our cost measure shows interesting trends, thus indicating the potential of our method for real-world applications.

1. INTRODUCTION

Unaccompanied vocal music constitutes the nucleus of Western art music and the starting point of polyphony's evolution. Despite an increasing number of studies [1, 4, 5, 8–11, 16, 17, 21] dating back to the 1930s [29], many facets of polyphonic a cappella singing are yet to be explored and understood. A central challenge of a cappella singing is the adjustment of pitch in order to stay in tune relative to the fellow singers. Even if choirs achieve locally good intonation, they may suffer from intonation drifts slowly evolving over time [8–10, 15–17, 21, 23]. Thus, one has to deal with different intonation issues that refer to harmonic (or *vertical*) and melodic (or *horizontal*) intonation. In Fig. 1, we show how these different aspects of intonation quality may be visualized separately. Our schematic example illustrates the assessment of note-wise pitch deviations (color-coded) in the presence of a global pitch drift. Fig. 1a shows the idealized situation, where each note-wise pitch lies on a fixed reference grid. In Fig. 1b, all pitches are sharp (too high) compared to the same reference grid. The intonation quality, however, should be considered equivalent in both cases. Fig. 1c illustrates a different situation with downward intonation drift. Using a fixed reference grid, the deviations gradually accumulate. To compensate for this, one can use an adaptive reference grid [12, 15, 31] so that the vertical intonation quality is separated from the horizontal intonation drift. The residual pitch deviations—relative to the adaptive grid—only refer to vertical intonation problems (Fig. 1d), which are in the focus of our analysis.

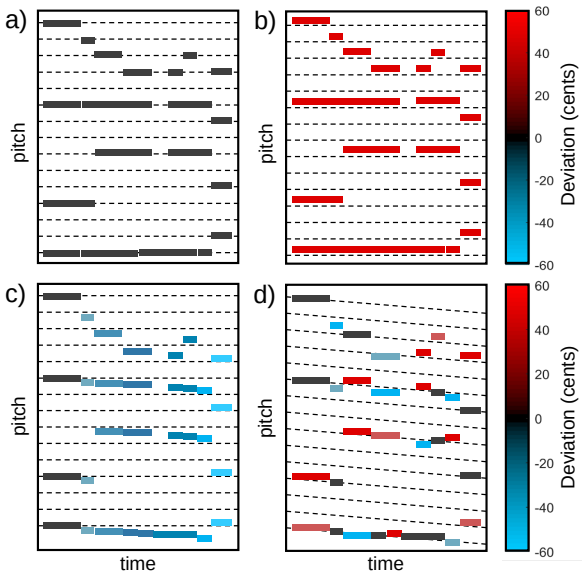

Figure 1. Note-wise analysis for polyphonic music. (a) Global intonation matching a fixed reference grid. (b) Global intonation higher than a fixed reference grid. (c) Intonation drift shown against a fixed reference grid. (d) Intonation drift with deviations from an adaptive grid.

In this paper, we propose an intonation cost measure that can be computed from choir recordings and may help to assess the singers' intonation quality. Developing such a measure encompasses two central challenges: (i) accurate estimation of the local salient frequency content from a choir recording, and, (ii) reliable measurement of intonation quality corresponding to human perception on the one hand and to music theory on the other hand.

Concerning the estimation of the local salient frequency content (i), recordings of polyphonic choir pieces constitute extremely difficult scenarios. Often, the different

parts of a musical composition are highly correlated both in rhythm (joint on- and offsets) and harmony (overlap of partials). In the case of a *mix* recording (single-track), this leads to overlaps in time–frequency representations, which makes the estimation of fundamental frequencies (F0s) [3] or partial tracking [25] hard. On the other hand, capturing intonation at the sub-semitone level requires high frequency resolutions. One can leverage these problems using dedicated recording scenarios where singers are isolated acoustically [5] or recorded sequentially [4]. Alternatively, special devices such as Larynx microphones [6, 16, 28] or additional score information [9] can help to simplify the F0-estimation problem [18, 27]. In Section 3.2, we detail the strategy used for this paper's experiments.

For assessing intonation quality (ii), we aim towards developing a robust intonation cost measure. Ideally, a high value of this measure indicates passages of low intonation quality. Hereby, intonation quality may relate to human perception such as the measure proposed in [30] based on psychometric curves [26]. On the other hand, intonation quality may be guided by music theory or historical performance practice [9]. In particular, choirs often aim for just intonation, which involves complex adjustment strategies according to the harmonic context [10]. In contrast to such ideas, we follow a simplified approach based on 12-tone equal temperament (12-TET). Even though 12-TET is not considered to be the ideal intonation practice for Western choir performance, it is a first approximation and can provide useful feedback [15]. As a major advantage, our strategy estimates the sub-semitone intonation quality for *any* type of notated chord irrespective of its *harmonic* consonance—in contrast to other methods [30] that measure a mixture of harmonic consonance and intonation.

As our main contribution, we propose a 12-TET-based intonation cost measure (Section 2). Inspired by prior work [15, 24], we accumulate the overall deviation of frequency components from an adaptive 12-TET grid weighted by their corresponding amplitudes. For testing this measure, we compiled a small but diverse dataset of Anton Bruckner's Graduale *Locus Iste* using different performances (Section 3). We evaluate the robustness of our method by comparing scenarios of varying complexity regarding the availability of aligned scores and multi-track recordings (Section 4.1). Finally, we apply our method to different performances and show its benefit for assessing the overall intonation quality of a recording (Section 4.2). Section 5 concludes the paper and gives an outlook on future work and practical applications.

2. MEASURING INTONATION QUALITY

In the following, we describe the computation of an intonation cost measure based on frequency deviations from a 12-tone equal-temperament (12-TET) grid.

2.1 Intonation Cost Measure

The proposed measure operates on a set of N frequency components $\mathcal{P} := \{(f_1, a_1), \ldots, (f_N, a_N)\}$, where each tuple $(f_n, a_n) \in \mathcal{P}$ denotes the frequency f_n and amplitude a_n of an individual component.

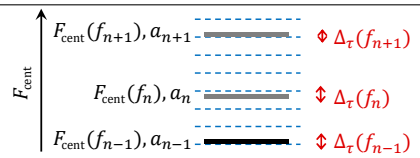

Figure 2. Grid deviations $\Delta_\tau(f_n)$ in cents of frequency components f_n (solid gray lines) from a 12-TET grid (dashed blue lines) shifted by τ. The corresponding amplitudes a_n are indicated by the grayscale colors.

First, we convert a given frequency f in Hertz (Hz) to cents by

$$F_{\text{cent}}(f) := 1200 \cdot \log_2\left(\frac{f}{f_0}\right), \tag{1}$$

where $f_0 := 55\,\text{Hz}$ is an arbitrary but fixed reference frequency. We compute the deviation of the frequency component f from a 12-TET grid

$$\Delta_\tau(f) := \min_{i \in \mathbb{Z}} |F_{\text{cent}}(f) - \tau - 100i|, \tag{2}$$

where $\tau \in [-50, 50[$ specifies the overall grid shift in cents, see Fig. 2. Applying a Gaussian-like function to the grid deviation $\Delta_\tau(f)$, we define the intonation cost (IC) Θ_τ as

$$\Theta_\tau(\mathcal{P}) := \frac{\sum_{(f,a)\in\mathcal{P}} a\left(1 - \exp\left(-\frac{\Delta_\tau^2(f)}{2\sigma^2}\right)\right)}{\sum_{(f,a)\in\mathcal{P}} a}, \tag{3}$$

where the deviations are weighted and then normalized by the corresponding amplitudes. Due to the normalization, we obtain $\Theta_\tau(\mathcal{P}) \in [0, 1]$ where $\Theta_\tau(\mathcal{P}) = 1$ indicates the maximal IC. The parameter σ adjusts the cost for deviating from the grid. As suggested by [24], we choose a value of $\sigma = 16$ cents. To obtain invariance to pitch drifts, i.e., variation of the reference frequency, we choose the grid shift τ in an adaptive way so that the IC is minimized:

$$\tau^* := \operatorname*{arg\,min}_{\tau \in [-50, 50[} \Theta_\tau(\mathcal{P}). \tag{4}$$

We then define the intonation cost Θ as

$$\Theta(\mathcal{P}) := \Theta_{\tau^*}(\mathcal{P}). \tag{5}$$

For instance, in a scenario where a choir performs with good local intonation but is affected by a pitch drift, τ^* slowly changes over time while Θ is constantly small.

2.2 Example with Synthetic Signals

In the following, we illustrate the properties of the IC measure $\Theta(\mathcal{P})$ by means of synthetic examples. To this end, we define a harmonic tone $x_f : \mathbb{R} \to \mathbb{R}$ with K partials and fundamental frequency f as

$$x_f(t) := \sum_{k=1}^{K} a_k \cdot \sin(2\pi k f t), \tag{6}$$

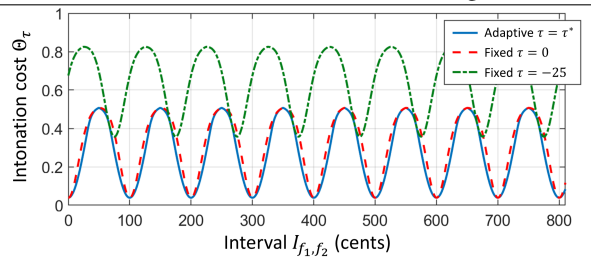

Figure 3. ICs Θ_τ for two harmonic tones x_{duad} with an interval of size I_{f_1,f_2} in cents and three grid shifts: adaptive grid τ^*, fixed grid $\tau = 0$, and, fixed grid $\tau = -25$. The F0 of the lower tone is fixed at $f_1 = 220$ Hz.

where t denotes time and

$$a_k := s^{k-1} \tag{7}$$

denotes the geometrically decaying partial amplitudes for some $s \in [0, 1]$ and $k = 1, \ldots, K$. Thus, the set of frequency components of signal x_f is

$$\mathcal{P}[x_f] := \{(f, a_1), (2f, a_2), \ldots, (Kf, a_K)\}. \tag{8}$$

Let $x_{\text{duad}} := x_{f_1} + x_{f_2}$ be the sum of two harmonic tones whose fundamental frequencies differ by the interval

$$I_{f_1,f_2} := |F_{\text{cent}}(f_2) - F_{\text{cent}}(f_1)| \tag{9}$$

given in cents. Consequently, $\mathcal{P}[x_{\text{duad}}] = \mathcal{P}[x_{f_1}] \cup \mathcal{P}[x_{f_2}]$.

Fig. 3 shows $\Theta(\mathcal{P}[x_{\text{duad}}])$ for two harmonic tones with $K = 16$ and $s = 0.6$ for different interval sizes I_{f_1,f_2}. The lower fundamental frequency is set to $f_1 = 220$ Hz such that $\Delta_0(f_1) = 0$. $\Theta(\mathcal{P}[x_{\text{duad}}],)$ is minimal for I_{f_1,f_2} being an integer multiple of 100 cents. However, $\Theta(\mathcal{P}[x_{\text{duad}}])$ does not reach zero as some partial frequencies $k \cdot f$ of a harmonic tone do not lie on the 12-TET grid even if the fundamental frequency f does. For example, the third partial $3f_1 = 660$ Hz leads to $\Delta_0(3f_1) \approx 2$ cents and the fifth partial $5f_1 = 1100$ Hz leads to $\Delta_0(5f_1) \approx 14$ cents. Since the minimal values are close to zero, this effect is small for a partial decay of $s = 0.6$. On the other hand, even a quarter tone interval $I_{f_1,f_2} = 50$ cents does not lead to the maximal IC of 1, since the grid deviation $\Delta_{\tau^*}(k \cdot f_1) \approx \Delta_{\tau^*}(k \cdot f_2) \approx 25$ cents for $\tau^* = 25$ cents. Fig. 3 further shows that the IC of a fixed grid shift $\tau = 0$ is similar to the adaptive grid τ^*, while a fixed shift $\tau = -25$ significantly increases the overall IC. It is important to note that the IC with adaptive grid shift τ^* is invariant to the choice of f_1 while a fixed grid shift is not. Further, the minimal and maximal values depend on the amplitude decay s and on the Gaussian width σ. Since the IC measure relates to a 12-TET grid, the IC curve is periodic in interval size with a period of 100 cents. As a consequence, each musical interval is only evaluated by its deviation from the 12-TET scale—regardless of its harmonic consonance quality.

In Fig. 4, we expand the previous example to three harmonic tones $x_{\text{triad}} := x_{f_1} + x_{f_2} + x_{f_3}$ with $f_1 \leq f_2 \leq f_3$. For instance, the intervals $I_{f_1,f_2} = 400$ cents, $I_{f_2,f_3} = 300$ cents describe an equal-tempered major triad. The colors in Fig. 4 indicate $\Theta(\mathcal{P}[x_{\text{triad}}])$ with respect to the

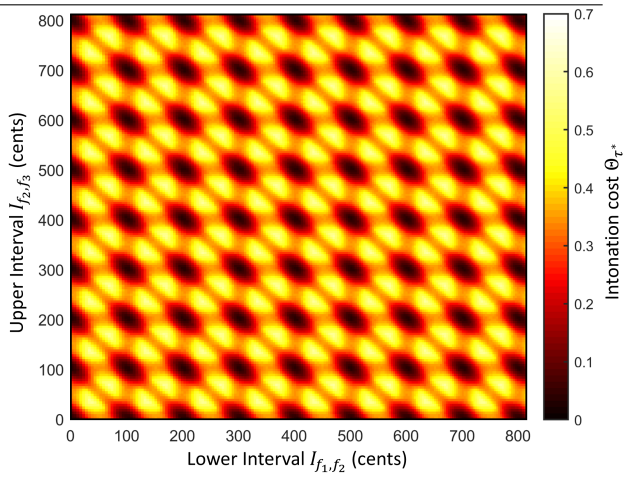

Figure 4. IC Θ for three harmonic tones x_{triad}. The plot axes indicate the size of the lower and upper interval in cents, I_{f_1,f_2} and I_{f_2,f_3} respectively.

lower and upper intervals, I_{f_1,f_2} and I_{f_2,f_3}, respectively. Similar to Fig. 3, we observe a periodic structure with period 100 cents as the IC is invariant to the musical intervals. Thus, the measure is equally suited for estimating the intonation quality of both consonant and dissonant triads.

3. EXPERIMENTAL SCENARIO

This section describes the experimental scenario for applying our intonation cost measure to choir recordings.

3.1 Dataset

We compiled a small but diverse dataset of performances of Anton Bruckner's Gradual *Locus iste* WAB 23 (see Fig. 5). This choir piece is in Latin and lasts approximately three minutes. It is musically interesting, contains several melodic and harmonic challenges—such as the highly chromatic middle part—but also harmonically clear passages, and covers a large part of each voice's tessitura.

Central to this dataset is a publicly available [1] multitrack recording from the Choral Singing Dataset (CSD) [4]. The performance of 16 singers from the semi-professional Anton Bruckner choir (Barcelona) was recorded in a studio setting. The four musical parts—soprano, alto, tenor, and bass—were recorded sequentially using directional hand-held microphones. Rhythmic and harmonic synchronization was ensured by a conducting video and an acoustic reference (MIDI version of the piece). Due to this recording scenario, the individual singers' tracks exhibit a small amount of bleeding from other singers of the same part (e. g., soprano 2, 3, and, 4 slightly bleed into soprano 1 track). Interactive intonation or adaptation across musical parts was not possible since the parts were recorded in isolation and each singer listened to the reference MIDI signal while singing—this also prevented substantial pitch drifts. The restricted interaction limits the usability of the data to study intonation and

[1] https://zenodo.org/record/1319597#.XJor8ShKhaR

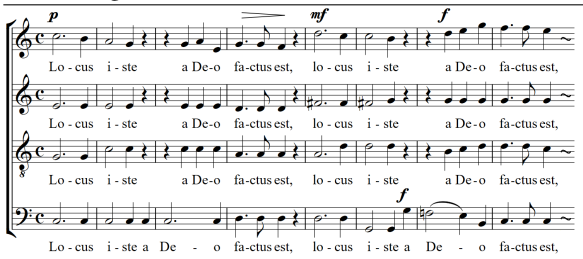

Figure 5. Anton Bruckner, *Locus iste* WAB 23, beginning.

adaptation phenomena in choir performances. Nevertheless, since this paper focuses on measurement strategies, the multi-track data provides an excellent resource. To address subsets of the multi-track recording, we refer to the signals of the four soprano voices as x_{S1}, x_{S2}, x_{S3}, and x_{S4}, and to the first voices of the alto, tenor, and bass as x_{A1}, x_{T1}, and x_{B1}, respectively. We denote the mixed signal of the first voices of each part as x_{SATB1} and the mixed signal of all 16 voices as x_{SATB}. We further manipulated the original tracks x^{orig} with the digital audio correction software Melodyne [2] to augment the dataset: x^{note} is generated by quantizing the median pitch of each note event onto a 12-TET grid with reference frequency $f_0 = 55$ Hz. x^{fine} is generated by quantizing the complete F0-trajectory onto the 12-TET grid. To assist our analysis, we use additional score information from the aligned MIDI file.

In addition to this multi-track recording, we collected several commercial [3] and freely available [4] performances of the piece. As a reference for the real audio measurements, we sonified the piece with harmonic tones (Section 2.2) using random pitch deviations sampled from Gaussian distributions with different standard deviations.

3.2 Measuring Frequency Content

As discussed in Section 1, the extraction of salient frequency content from choir recordings is challenging. In the case of a mix recording, we have to blindly estimate all partial frequencies using a partial tracking algorithm such as [25]. For choir music, partial tracking can be simplified as the singing voice's partial frequencies are located quite precisely at integer multiples of an estimated F0. To estimate F0-trajectories for the CSD, we can use the individual tracks of the multi-track recording. Due to the bleeding of other voices from the same part, traditional F0-estimation techniques [7, 20] may have problems. Therefore, we use a salience-based method similar to Melodia [27]. We compute a log-frequency representation using instantaneous frequency estimation [2, 14, 27] and binning with a resolution of $1\,\mathrm{cent}$. Subsequently, we estimate F0-trajectories using dynamic programming [22]. As post-processing, we apply median filtering with a filter length of 101 frames and downsample by a factor of 50 obtaining trajectories with a time resolution of $290\,\mathrm{ms}$.

[4] Internet Archive, `https://archive.org/details/LocusIste`

In the case of the CSD, we can exploit additional score information from the aligned MIDI file [13]. We restrict the F0-estimation to rectangular time–frequency regions ("constraint regions") derived from onsets, durations and center frequencies of the aligned MIDI notes, including a frequency tolerance of $\pm 60\,\mathrm{cents}$ around the center frequencies (according to 12-TET with reference 440 Hz). Such additional information is particularly helpful when estimating F0-trajectories from a mix recording. [5] Especially, the constraint regions prevent the common confusion of the F0 with higher partials.

4. RESULTS

In our experiments, we investigate the robustness of the proposed intonation measure for different scenarios of the CSD where either score information or multi-track recordings are not used (Section 4.1). Furthermore, we compare the measure's behaviour for different synthetic and real performances of *Locus Iste* (Section 4.2).

4.1 Local Analysis and Visualization

As a visual orientation, we show in Fig. 6a a piano roll representation of the entire piece, generated from the aligned MIDI file. Considering the subset of each part's first voice x_{S1}, x_{A1}, x_{T1}, and x_{B1}, we estimate F0-trajectories as described in Section 3.2 and compute the local, sub-semitone deviation of the F0-estimate from the corresponding MIDI reference. The deviations are color-coded with a range of $\pm 60\,\mathrm{cents}$. While there seems to be no significant global drift (which is not surprising because of the CSD's recording scenario, see Section 3.1), we observe a slight dominance of notes sung flat (negative deviation) except for the alto part, which is sharp more often.

The main results are shown in Figures 6b–g, which indicate IC values throughout each performance. We compute the IC measure $\Theta(\mathcal{P})$ of the set $\mathcal{P}$ comprising the frequencies (F0 and higher partials) and amplitudes from all parts that are, according to the aligned score, active in a frame. Assuming that the human voice's partials are harmonic, we calculate the first 16 partial frequencies from the measured F0-trajectories and extract the corresponding amplitudes from the log-frequency spectrogram. For computing Θ, we use the adaptive grid shift proposed in Section 2.1. To remove local outliers, we post-process the IC curves using a moving median filter with a length of 21 frames.

The blue, solid line in Fig. 6b shows the resulting IC curve for x^{orig}, computed from the individual tracks for the first voice of each part x_{S1}, x_{A1}, x_{T1}, and x_{B1} using score constraints. For silent regions (e. g., after 160 sec), the IC is zero since no constraint region is active. Due to the adaptive grid shift, the IC is small for monophonic passages where only one singer is active (see, e. g., the passage at 80 sec). For some of the consonant chords (e. g., at 110 sec), we observe low IC values of about 0.2. During the highly chromatic three-part passage (80–110 sec), the

[5] We do not use harmonic summation as in [27] to avoid smearing of other parts' partials into the constraint regions for mix recordings.

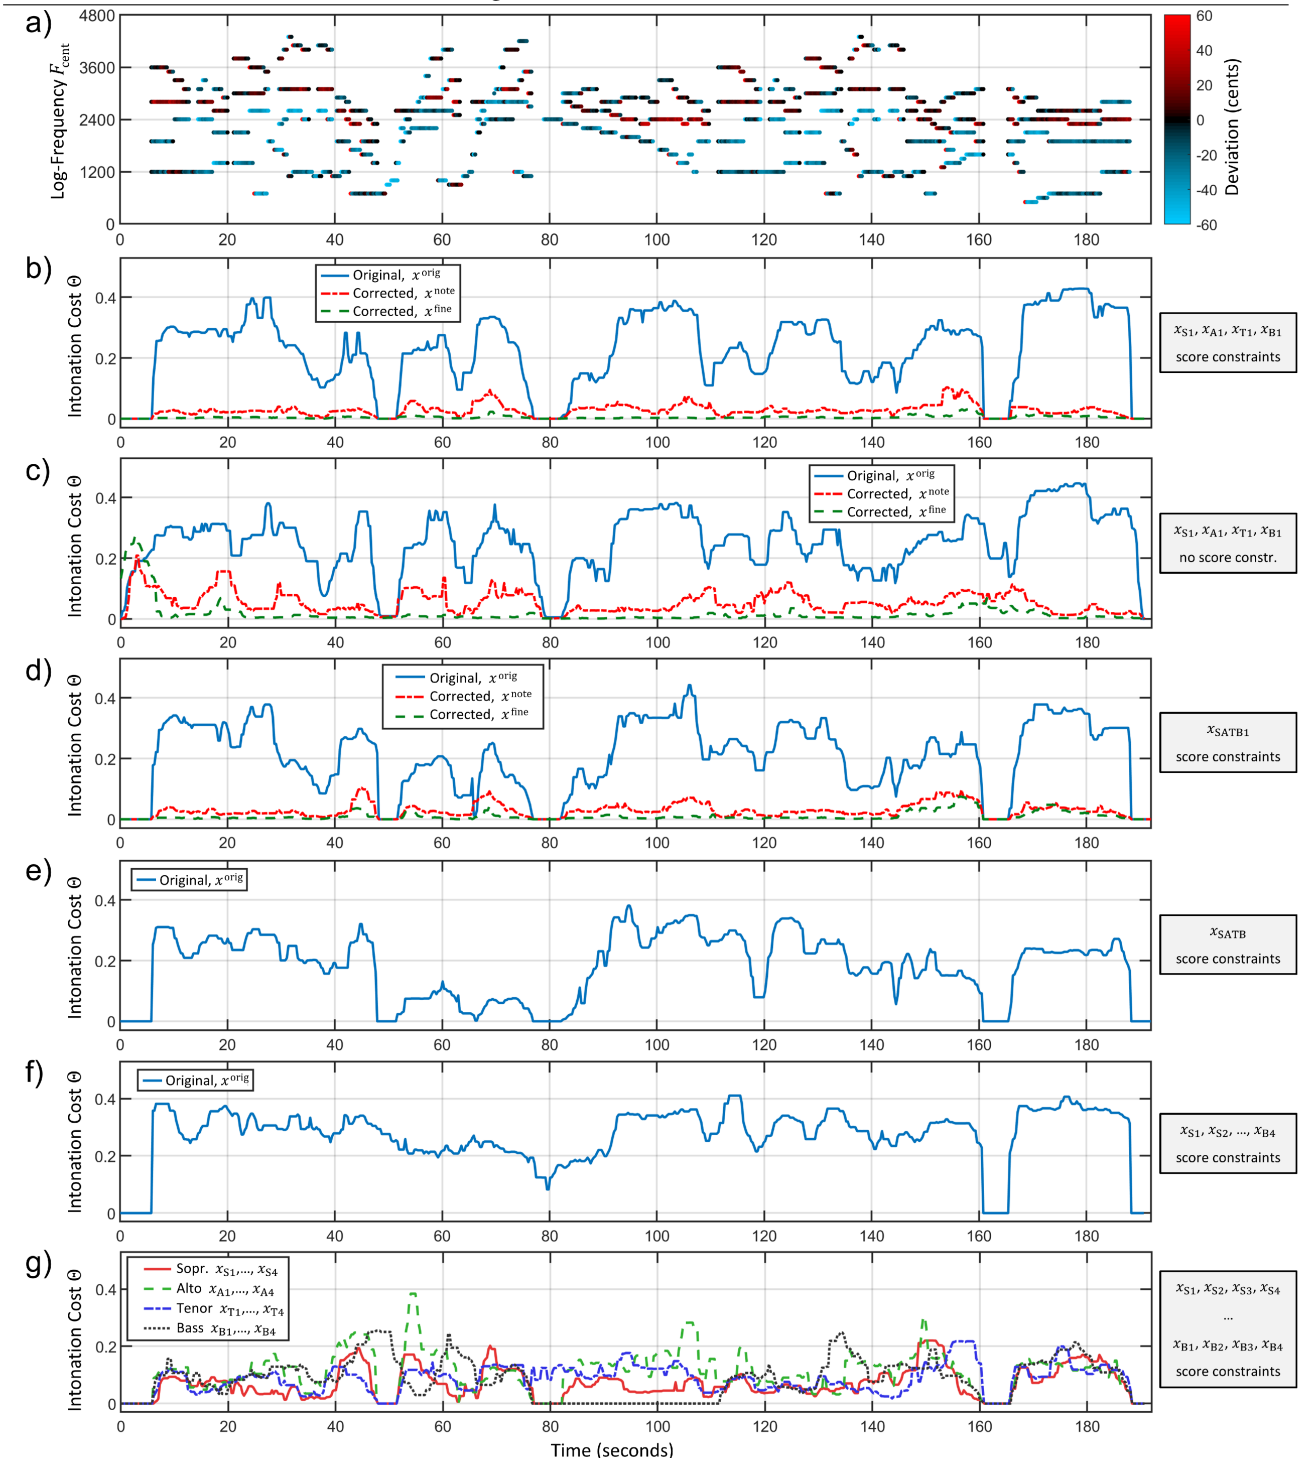

Figure 6. Intonation cost (IC) curves for different CSD versions of *Locus Iste*. (a) Piano roll representation with a log-frequency axis where C2 corresponds to 1200 cents, C3 to 2400 cents etc. The colors encode the deviation of the first voice of each part (x_{S1}, x_{A1}, x_{T1}, x_{B1}) from the MIDI reference. (b) IC curves for x_{S1}, x_{A1}, x_{T1}, x_{B1} with score constraints from four individual tracks. The blue curve corresponds to x^{orig}, the red curve to x^{note}, and the green dashed curve to x^{fine}. (c) IC curves as in (b) without score constraints. (d) IC curves for mixed signal x_{SATB1} with score constraints. (e) IC curve for mixed signal of all voices x_{SATB} with score constraints. (f) IC curve computed from all 16 individual tracks x_{S1}, x_{S2}, ..., x_{B4} with score constraints. (g) Individual IC curves for the four tracks of each part with score constraints.

IC increases, thus indicating that the singers have difficulties to stay in tune in this passage.

As a sanity check, we compare the results for x^{orig} to the the pitch-corrected versions x^{note} and x^{fine}. As we expected, the note-wise corrections x^{note} (red curve) obtain lower values than x^{orig}—with only minor peaks that may be caused by pitch fluctuations during a note event. If we correct such local fluctuations as in x^{fine} (green, dashed curve), the IC is almost constantly zero.

In Fig. 6c, we repeat the experiment of Fig. 6b without using score constraints. In this case, F0-estimation is less reliable and, in particular, confusions between F0 and higher partials may occur. However, since many partials lie on the same 12-TET grid as the F0 (octave-related partials) or very close to that (2 cents for fifth-related partials), the IC measure is largely invariant to such confusions. The high similarity between Fig. 6b and Fig. 6c confirms the IC measure's robustness to F0-extraction errors. Only for silent passages (e. g., after 160 sec or at the beginning), we obtain higher IC values due to erroneously extracted frequency components. [6] We conclude that our strategy is, in principle, applicable for any multi-track recording and does not necessarily require score information.

To test the applicability in absence of multi-track recordings, we compute the IC curve from the mix signal x_{SATB1} using score constraints (Fig. 6d). Due to the constraints, confusions with higher partials cannot occur, but partials of other parts may leak into the same constraint regions, thus affecting the estimated F0s and partials' amplitudes. The comparison of Fig. 6b and Fig. 6d indicates that such phenomena only slightly affect the IC measure.

Next, we measure the IC from the CSD's full recording x_{SATB} (all 16 voices). F0-estimation is more challenging since the four singers of each part contribute to the same constraint regions. The resulting ICs (Fig. 6e) exhibit slightly lower values than in previous cases. We assume that having several voices per part stabilizes the F0-estimation to some degree. Overall, we see a similar trend between Fig. 6d and Fig. 6e. This might be an effect of mutual influence between the singers of each part. To further investigate the multiple-singer effect, we show in Fig. 6f the IC curves computed from all 16 individual tracks $x_{\mathrm{S1}}, x_{\mathrm{S2}}, \ldots, x_{\mathrm{B4}}$. We obtain higher IC values than in Fig. 6e, especially for the monophonic passages (e. g., at 48 sec). Due to the score constraints, this must be caused by deviations between the singers of a part, sometimes denoted as *dispersion* [4]. To analyze this, we repeat the experiment for each part separately (Fig. 6g). The resulting curve supports our hypothesis since. For instance, the high value at around 48 sec (Fig. 6f) is mainly caused by the basses' dispersion (dotted curve in Fig. 6g).

4.2 Global Analysis of Different Performances

Since our experiments on the CSD have shown the robustness of our method even for mix recordings, we finally compare the global IC values of multiple synthetic and real performances of *Locus Iste*. We align the MIDI file to all performances [13], use the resulting constraint regions for extracting F0-trajectories [27], and compute the IC curves. In Fig. 7, we show the statistics of the entire curves over time (median, mean, and standard deviation). First, we report values for sonifications using harmonic tones as defined in Eq. (6). To simulate detuning, we shifted each note's fundamental frequency by a random value sampled from a Gaussian distribution with variance

[6] This problem could be leveraged using a suitable algorithm for voice activity detection [19] or on-/offset detection in vocal music [6].

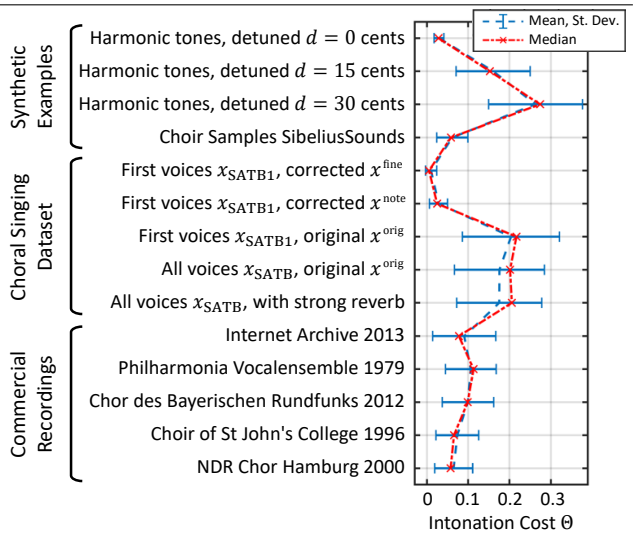

Figure 7. Statistics of the intonation cost measure Θ over full recordings of different type.

d^2. For $d = 0$ cents, the mean IC is almost zero. For $d = 15$ cents and $d = 30$ cents, the IC gradually increases as expected. The average IC of a sample-based sonification [7] is moderately higher than the rendition with ideal harmonic tones, which suggests that some choir effects such as dispersion are also synthesized. Both corrected versions of the CSD show very low IC values, with x^{fine} even lower than x^{note}. In contrast, the versions based on the original recording x^{orig} have high IC values, where the difference between first voices only (x_{SATB1}) and the full mix (x_{SATB}) as well as the effect of adding artificial reverberation is marginal. All commercial recordings performed by professional choirs obtain lower IC than the CSD recording. Several effects might contribute to this observation. Besides the singers' level of training, commercial recordings often feature larger choirs (60 singers or more) and long natural reverberation (recorded in churches). In line with the authors' subjective judgment, the recording by NDR Chor Hamburg exhibits the best intonation quality according to the IC measure. [8] Overall, this experiment indicates that the proposed IC measure may serve as a first indicator for a choir recording's global intonation quality.

5. CONCLUSIONS

In this paper, we proposed a strategy for measuring the intonation quality of choir recordings. Although robust extraction of salient frequencies is challenging, the measure produced meaningful and reliable results once multi-track recordings are available or score information can be utilized. Even though the insights from such a measure are limited, it might be a first indicator for the overall intonation quality and, thus, could be useful for choir singers or choir directors in performances and rehearsals.

GUITAR TABLATURE ESTIMATION WITH A CONVOLUTIONAL NEURAL NETWORK

Andrew Wiggins, Youngmoo Kim
Drexel University, Dept. of Electrical and Computer Engineering
{awiggins, ykim}@drexel.edu

ABSTRACT

Guitar tablature is a popular notation guitarists use to learn and share music. As it stands, most tablatures are created by an experienced guitarist taking the time and effort to annotate a song. As the process is time consuming and requires expertise, we are interested in automating this task. Previous approaches to automatic tablature transcription break the problem into two steps: 1) polyphonic pitch estimation, followed by 2) tablature fingering arrangement. Using a convolutional neural network (CNN) model, we can jointly solve both steps by learning a mapping directly from audio data to tablature. The model can simultaneously leverage physical playability constraints and differences in string timbres implicit in the data to determine the actual fingerings being used by the guitarist. We propose TabCNN, a CNN for estimating guitar tablature from audio of a solo acoustic guitar performance. We train and test our network using microphone recordings from the GuitarSet dataset [24], and TabCNN outperforms a state-of-the-art multipitch estimation algorithm. We also introduce a set of metrics to evaluate guitar tablature estimation.

1. INTRODUCTION

Given the popularity of the guitar as an instrument for both professional musicians and amateur hobbyists, there have been numerous previous works addressing the problem of automatic guitar transcription. Automatic guitar transcription is a task which aims to generate a symbolic transcription instructing a guitarist how to perform, given an audio recording of a guitar performance. In general, the task of polyphonic transcription is challenging, due to the fact that when multiple different pitches sound at once, their overtones may overlap in the frequency domain, making it hard to tell which pitches are sounding. Despite the narrowed focus on a single instrument, transcription of solo guitar audio remains challenging. Since it has six strings, the guitar can produce up to six pitches at a given time. The guitar is also capable of producing a wide variety of timbres, stemming from differences in guitar models, guitar strings, audio effects, and strumming, plucking, and picking styles.

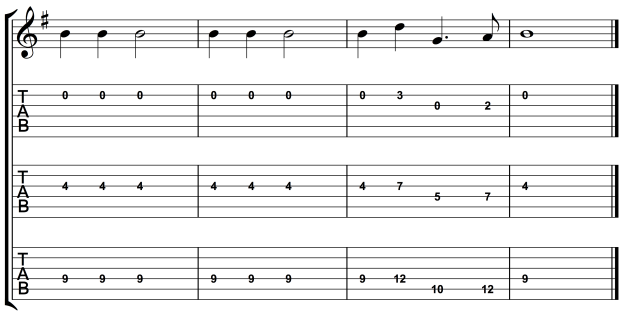

Figure 1. Multiple fingerings (3 bottom staves) can be used to play a given score (top staff) on guitar. These are just 3 of many possible fingerings. In each tablature staff, the horizontal lines represent the 6 guitar strings, and numbers on them indicate the fret on that string to be activated.

Perhaps the greatest challenge in automatic guitar transcription, however, arises from the symbolic representation of guitar music. Rather than using score notation, guitarists commonly use tablature notation to compose, share, and learn music. While music scores display the arrangements of pitches in time, tablature notation additionally indicates which guitar strings and positions along the fretboard were activated to produce the sounding pitches. On guitar, most notes can be played in numerous locations along the fretboard. Figure 1 provides an example of this. These identical pitches played in different locations differ in timbre and can give different characteristics to an overall performance. In order to effectively transcribe a guitar performance from audio, a system needs to estimate both the pitches and fingerings changing over the course of the performance.

Previous works have approached automatic tablature transcription by splitting the problem into two separate steps [5, 6, 25, 26]. First, the systems perform a multipitch estimation on the audio, which determines the set of pitches sounding over the course of the audio. Then, using the estimated pitches, a tablature is arranged, usually by choosing a fingering that maximizes physical ease of play. These methods are designed to output a valid tablature given the detected pitches, but not necessarily the true fingering used by the guitarist during the performance.

In this paper we propose TabCNN [1], a guitar tablature estimation system which outputs the actual fingerings used

[1] Source code: https://github.com/andywiggins/tab-cnn

by the guitarist at the frame-level from audio of a solo performance on a standard 6-string acoustic guitar. The proposed system uses a convolutional neural network (CNN) to learn a direct mapping from audio signal to guitar tablature.

The next section provides background on some related work in automatic guitar transcription and the use of CNNs in music information retrieval. In Section 3 we outline our methodology, including the dataset, preprocessing, and proposed system architecture. In Section 4, we evaluate the proposed system for multipitch estimation and tablature estimation. We further discuss the system performance in Section 5. Finally, in Section 6 we give our conclusions and suggest future work.

2. RELATED WORK

2.1 Automatic Tablature Transcription

Several previous works have addressed the problem of automatic tablature transcription by performing multipitch estimation and then arranging tablature by optimizing the physical ease of play. Burlet and Fujinaga outlined a framework for a guitar transcription web application [5]. Their framework combines a preexisting polyphonic transcription algorithm proposed by Zhou and Reiss [28] with a novel guitar tablature arrangement algorithm that creates a directed acyclic weighted graph of string-fret combinations and finds an optimal path using the A* search algorithm. In [6], Burlet and Hindle utilized the aforementioned tablature arrangement algorithm in conjunction with a novel multipitch estimation algorithm, using deep belief networks to learn framewise pitch estimates from the short-time Fourier transform. Yazawa et al. used latent harmonic allocation (LHA) for multipitch estimation and arranged tablature by filtering the LHA results based on a set of spatial and temporal playability constraints [26]. In [25], the authors applied knowledge of each guitarist's proficiency to further filter the pitches estimated from LHA and generate a sensible tablature arrangement.

Few previous approaches to automatic tablature transcription that we found seek to learn the true fingering used by the guitarist. In [3], Barbancho et al. used peak-picking from the magnitude spectrum to determine fundamentals and partials for candidate pitches and then analyzed the inharmonicity of the partials to determine the most likely string each pitch was played on. The system's performance on "free chords" – i.e., not recognition of predetermined chords, or strictly monophonic playing – is respectable, but is limited to a maximum of 4 pitches sounding simultaneously. In [13], Kehling et al. proposed a system that applies the Blind Harmonic Adaptive Decomposition algorithm proposed in [7] for multipitch estimation. After aggregating framewise pitch estimates into note estimates, their system applies Support Vector Machines to classify various performance parameters, including the guitar string each note was played on. The authors show good performance for this system for notewise multipitch estimation and guitar string estimation, but they do not evaluate the system directly for framewise tablature estimation.

2.2 Related Tasks

There have been a number of works that tackle different problems related to automatic guitar transcription. For guitar chord recognition, Barbancho et al. used a hidden Markov model (HMM) to transcribe guitar chords and fingerings from acoustic features [2]. In [12], Humphrey and Bello approached chord recognition using a convolutional neural network model to output tablature, and this model was trained using a pop music dataset, rather than audio of isolated guitar performances. Hrybyk and Kim used video data in conjunction with audio of solo guitar performances to recognize guitar chords [11].

Regarding the problem of tablature arrangement from symbolic data (not audio), Tuohy and Potter combined a neural network model with a local heuristic-climber to take pieces composed for other instruments and arrange them for guitar [23]. In [18], Mistler used deep neural networks to arrange guitar tablature from sheet music by predicting a fretting cost function and predicting string-fret activations directly.

The problem of arranging solo guitar covers of pop songs was addressed by Ariga et al., who proposed a system which processes pop music audio and generates tablature arrangements that can scale in difficulty [1]. Finally, in the area of automatic music generation, McVicar et al. built an algorithmic composition system to compose tablatures for rhythm and lead guitar parts from an input chord progression [17].

2.3 CNNs for Automatic Music Transcription

While, to our knowledge, the task of guitar tablature estimation has not been approached using convolutional neural networks, CNNs have shown promise for the similar task of automatic piano transcription. In [21], Stigita et al. proposed a hybrid neural network model for piano transcription that combines a CNN for framewise acoustic modelling and a recurrent neural network (RNN)-based music language model. Kelz et al. provided a comparison of various network-based approaches to framewise transcription of piano audio, and the authors argued that the high accuracy and low parameter amount offered by CNNs, compared to other classes of deep neural networks, gives them a "distinct advantage" for piano transcription [14].

The use of CNNs has also been explored for various other tasks within music information retrieval such as musical tempo estimation [20], key classification [15], singing voice detection [19], and instrument classification [9, 10].

3. METHODOLOGY

3.1 Dataset

Since we are interested in learning tablatures for the exact fingerings used by the guitarist, it is important that the dataset contains audio of an actual guitar performance. Previous approaches to guitar transcription utilize audio

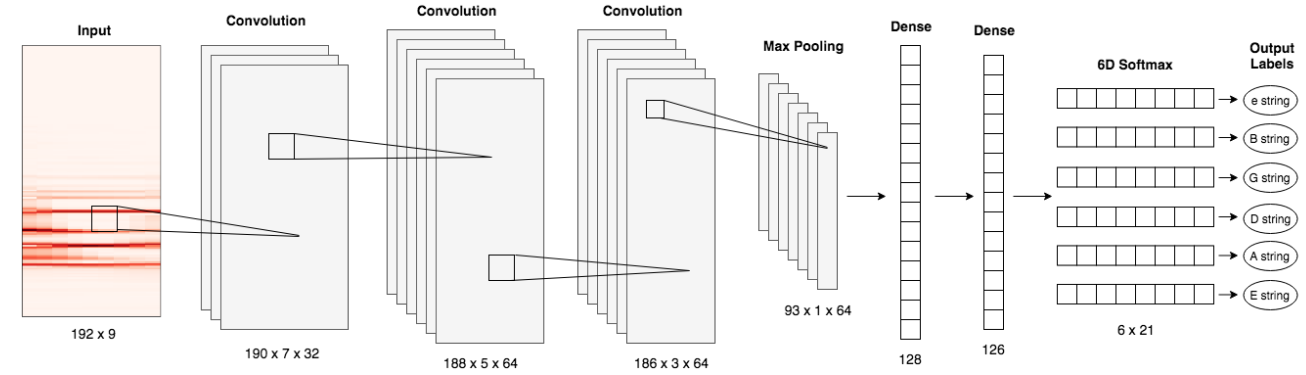

Figure 2. The proposed TabCNN network architecture. The input is a constant-Q spectrogram image of solo acoustic guitar audio. There are a series of 2D convolutional layers followed by a max pooling layer, which learn to extract spatial features relevant for guitar tablature estimation. The dense layers and final softmax function aim to use the learned representation to predict fret-number labels for each of the 6 guitar strings.

data that was automatically generated using MIDI to playback audio samples [5, 6, 25, 26]. As a result, the audio does not represent a performance of specific guitar fingerings. This is problematic for our purposes since there is no ground truth tablature.

We employ the GuitarSet dataset [24], which consists of audio recordings of solo acoustic guitar performances. This dataset was created using a guitar equipped with a hexaphonic pickup. The signals from each individual guitar string were processed separately to produce a frame-level pitch annotation for each of the 6 guitar strings. This dataset enables the ground truth fretting used by the guitarist to be easily accessible. Since the guitar used remained in standard tuning, we can use these pitch estimations to determine the corresponding frets being fingered over the course of the performance. While the hexaphonic signals were used by the GuitarSet authors to create the ground truth annotations, our system uses only the monophonic microphone signal of each song to estimate the tablature.

The GuitarSet contains audio recordings of 360 solo guitar performances, each approximately 30 seconds in length. These performances span every key and cover a variety of styles including bossa nova, rock, and funk. The guitarists were instructed to play two different versions of each song: soloing, which contains mostly single notes, and comping, which means playing chords. Six different guitarists contributed to the dataset, each performing to a provided chord progression, but interpreting it in their own way.

3.2 Audio Preprocessing

During the preprocessing stage, we first downsample the audio from 44100 Hz to 22050 Hz, making the assumption that there is not too much relevant information above 11025 Hz, in order to reduce the dimensionality of the input signals. We normalize each audio clip by its maximum value, to account for any major amplitude differences between clips.

As CNNs are useful in learning spatial features from images, we are interested in transforming the raw audio data into an image representation. The Short-Time Fourier Transform (STFT), commonly used to represent a signal changing over time and frequency, is not a desirable choice for CNNs because of its high dimensionality. Additionally, since the task at hand involves recognizing musical pitches, it would be advantageous to use a representation with a frequency axis that is linearly spaced with respect to pitch. This allows pitch-invariant features to be learned by the network. For these reasons we employ the constant-Q transform (CQT), which greatly reduces the dimension of the frequency axis by linearly spacing the frequency bins with respect to musical pitch.

Motivated by previous work [12], we use a CQT with 192 bins, spanning 8 octaves. This equates to 24 bins per octave, or 2 bins per semitone. We use a hopsize of 512 samples, which corresponds to a frame rate of about 43 frames per second, a rate sufficient for framewise analysis [10]. Using a sliding context window, we generate input images centered around each frame. In our experiments, we observed the best results using a context window of 9 frames. We pad either side of the CQT with zeros so that the beginning and ending frames of each clip can have a full 9-frame-long context window. Thus, input samples are of size 192×9 at each frame.

3.3 Label Preprocessing

To obtain annotations for each individual frame of audio, we sample the stringwise pitch annotations at the same frame rate of approximately 43 frames per second. For each sampled MIDI pitch value, we round it to the nearest integer, which corresponds to finding the nearest musical pitch. Depending on which string the pitch was played on, we subtract the corresponding string's open pitch value. The resulting integers correspond to the frets that were activated to produce the sounding pitches. A value of zero indicates that the string was plucked open (while no frets were being pressed). Since there are 19 frets used on the acoustic guitar, and a string may at times be closed (not produce any sound), this results in 21 different fret classes

that each string may be in during any given frame: open, closed, or any one of the 19 frets. We convert each string's label to a one-hot representation, resulting in label size of 6×21 at each frame.

3.4 Network Architecture

The structure of our neural network model is generally inspired by popular models in computer vision, such as AlexNet [16] and VGGNet [22], which both contain series of convolutions followed by a sub-sampling operation. These architectures terminate in dense layer connections. When using this type of CNN architecture, the expectation is that the early convolutional layers act as a hierarchy of feature extractors, learning spatial filter coefficients that result in feature maps useful for the given classification task. We interpret the final dense layers and output connection to act as a classifier that processes the features to output a final decision or prediction.

The proposed network structure for TabCNN is shown in Figure 2. First, there is a series of three convolutional layers, each with a filter size of 3×3. The first convolutional layer has 32 filters, and the latter two each have 64. These parameters were determined empirically, based on experiments with the validation data. Each convolution is immediately followed by a Rectified Linear Unit (ReLU) activation. Activation functions, in general, allow for complicated, nonlinear mappings to be learned, and the ReLU activation has been shown to train faster [16] and produce better results [8] than alternatives.

The resulting feature maps are subsampled by a 2×2 max pooling layer, which introduces a slight translation invariance in both time and frequency. The structure is then flattened and followed by a dense layer of dimension 128, this size determined empirically in our experiments. After this dense layer, a ReLU activation is applied. This is connected to a second dense layer of dimension 126, which is reshaped to 6×21. The output shape comes from the 6 guitar strings and the 21 different fret classes a string can be assigned. Finally, a softmax activation is applied to each of the 6 rows. As a result, similar to the network described in [12], our model learns to output an estimation of six probability mass functions, which represent the probability of each fret class for each string.

3.5 Training Procedure

For training the model, we design a loss function by viewing the problem as 6 simultaneous multiclass classification problems. For multiclass classification, a common practice is to optimize the categorical cross-entropy between the predictions and the targets [10]. For our loss function, we compute the categorical cross-entropy for each string and sum these values. The loss function is computed as in Eqn (1). We use z_{ij} to denote an activation at frame i on string j that belongs to fret class $C_{z_{ij}}$. The term $p[z_{ij} \in C_{z_{ij}}]$ is the probability output by the network of z_{ij} belonging to class $C_{z_{ij}}$. N is the total number of frames in the mini batch.

$$Loss = -\frac{1}{N} \sum_{j=1}^{6} \sum_{i=1}^{N} \log p[z_{ij} \in C_{z_{ij}}] \tag{1}$$

We train using the ADADELTA optimization algorithm [27], which adapts learning rates for parameters based on a window of previous gradient values. We use an initial learning rate of 1.0 and a mini batch size of 128 training samples. We train for 8 epochs, as we noticed overfitting when training for longer. We also employ dropout regularization to combat overfitting, with a dropout rate of 0.25 applied immediately after the max pooling layer, and a second dropout rate of 0.5 applied after the first dense layer.

4. EVALUATION

To evaluate the proposed system, we first review multipitch estimation metrics from the literature [6] and assess the quality of the system as a polyphonic pitch detector. Then, since there are no standards for evaluating the performance of a tablature estimation system, we introduce a set of metrics to measure performance in estimating tablature for the actual fingering used during the performance. In our evaluations we use 6-fold cross validation, holding out one of the 6 guitarists to test on, while training on the remaining 5. We average our numerical results over the 6 folds of data, testing with a total number of 472,560 frames.

4.1 Multipitch Estimation Metrics

In the following equations, we use Y to denote a binary matrix of size $N \times 44$, where N is the total number of testing frames, and the matrix represents the presence or absence of each pitch for each frame of audio. (The guitar can produce a total of 44 distinct pitches.) Y_{gt} contains the ground truth pitch detections for the testing set, while Y_{pred} contains the predicted pitch detections during testing. We use e to denote a vector of all ones, and $\odot$ to denote element-wise multiplication.

4.1.1 Multipitch Precision

We compute multipitch precision using Eqn (2), which calculates the number of correctly identified pitches divided by the total number of predicted pitches. This metric measures how frequently the pitches that are detected are in fact correct.

$$p_{\text{pitch}} = \frac{e^T (Y_{\text{gt}} \odot Y_{\text{pred}}) e}{e^T Y_{\text{pred}} e} \tag{2}$$

4.1.2 Multipitch Recall

We also compute multipitch recall using Eqn (3), which calculates the number of correctly identified pitches divided by the the total number of ground truth pitches. This metric measures how frequently pitches existent in the signal are are detected by the system.

$$r_{\text{pitch}} = \frac{e^T (Y_{\text{gt}} \odot Y_{\text{pred}}) e}{e^T Y_{\text{gt}} e} \tag{3}$$

System	p_{pitch}		r_{pitch}		f_{pitch}	
TabCNN	**0.900**	±	**0.764**	±	**0.826**	±
	0.016		0.043		0.025	
Deep	0.778	±	0.562	±	0.646	±
Salience	0.092		0.099		0.078	

Table 1. Multipitch estimation metrics for our system, TabCNN, compared against a baseline, the Deep Salience f0-estimation algorithm introduced in [4], from experiments carried out in [24]. For all metrics, we report the mean and standard deviation over the entire dataset.

4.1.3 Multipitch F-measure

Finally, we compute multipitch F-measure using Eqn (4), which is the harmonic mean of multipitch precision and recall. This metric summarizes the system's overall performance for multipitch estimation.

$$f_{\text{pitch}} = \frac{2p_{\text{pitch}}r_{\text{pitch}}}{p_{\text{pitch}} + r_{\text{pitch}}} \tag{4}$$

4.2 Multipitch Estimation Results

The evaluation results of TabCNN for multipitch estimation, alongside a baseline algorithm, are shown in Table 1. For a benchmark, we look to the GuitarSet paper [24], in which the authors employ the Deep Salience multiple-f0 estimation algorithm in [4] to transcribe framewise pitch estimations for the GuitarSet data. [2] Deep Salience, although not designed specifically for guitar transcription, achieves a multipitch F-measure of 0.646. The proposed system TabCNN outperforms these baseline results, achieving a multipitch F-measure of 0.826.

Looking at a recent multipitch system designed specifically to operate on guitar signals, in [6] Burlet and Hindle report a multipitch F-measure of 0.71 before frame smoothing with a Hidden Markov Model (HMM), and an F-measure of 0.77 afterward. Our system's multipitch F-measure of 0.826 without any temporal smoothing is promising. However, these results cannot be compared too closely since the authors were evaluating on a different dataset.

Our results reveal that the proposed system behaves conservatively for multipitch estimation. The multipitch precision being significantly larger than the multipitch recall indicates that the system will more often make an error by missing a detection, rather than reporting a pitch not actually present in the signal. This is a common behavior for multipitch estimation systems, as a pitch can be easily missed if it is able to blend in to the overtones of another pitch present at the same time. We noticed that this often occurs with pitches an octave apart; the higher pitch will often be missed, as it may appear to just be overtones of the lower pitch.

[2] We acknowledge and thank the authors of [24] who have granted us access to the full numerical results from the experiments conducted in the work.

4.3 Tablature Estimation Metrics

We use Z to denote a binary matrix of size $N \times 120$, N being the total number of testing frames. The dimension of 120 arises from all possible sounding string-fret combinations on guitar (6×20). This matrix represents the presence or absence of each string-fret combination for each frame of audio. Z_{gt} contains the ground truth tablature detections for the testing set, while Z_{pred} contains the predicted tablature detections during testing. Again, we use e to denote a vector of all ones and $\odot$ to denote element-wise multiplication.

4.3.1 Tablature Precision

We define tablature precision, which calculates the number of correctly identified string-fret combinations divided by the total number of predicted string-fret combinations. This metric measures how frequently the tablature detected is in fact correct.

$$p_{\text{tab}} = \frac{e^T(Z_{\text{gt}} \odot Z_{\text{pred}})e}{e^T Z_{\text{pred}} e} \tag{5}$$

4.3.2 Tablature Recall

We also introduce tablature recall, which calculates the number of correctly identified string-fret combinations divided by the the total number of ground truth string-fret combinations. This metric measures how frequently tablature existent in the signal is detected by the system.

$$r_{\text{tab}} = \frac{e^T(Z_{\text{gt}} \odot Z_{\text{pred}})e}{e^T Z_{\text{gt}} e} \tag{6}$$

4.3.3 Tablature F-measure

We define multipitch F-measure, which is the harmonic mean of tablature precision and recall. This metric summarizes the system's overall performance for tablature estimation.

$$f_{\text{tab}} = \frac{2p_{\text{tab}}r_{\text{tab}}}{p_{\text{tab}} + r_{\text{tab}}} \tag{7}$$

4.3.4 Tablature Disambiguation Rate

Finally, we introduce a tablature disambiguation rate (TDR) which is computed by dividing the total number of correctly identified string-fret combinations by the total number of of correctly identified pitches. This metric measures how frequently pitches that are correctly identified are assigned the correct tablature.

$$TDR = \frac{e^T(Z_{\text{gt}} \odot Z_{\text{pred}})e}{e^T(Y_{\text{gt}} \odot Y_{\text{pred}})e} \tag{8}$$

4.4 Tablature Estimation Results

The tablature estimation evaluation results for TabCNN are shown in Table 2. While, to our knowledge, there are no prior approaches to directly compare these metrics to, the results are respectable, as each tablature metric is not too far below its multipitch counterpart. As in multipitch estimation, the proposed system achieves a higher tablature

System	p_{tab}	r_{tab}	f_{tab}	TDR
TabCNN	**0.809** $\pm$ 0.029	**0.696** $\pm$ 0.061	**0.748** $\pm$ 0.047	**0.899** $\pm$ 0.033

Table 2. Tablature estimation results for the proposed system, TabCNN, using the metrics we introduce to measure performance in fingering prediction. For all metrics, we report the mean and standard deviation over the entire dataset.

precision than tablature recall. This implies that errors made by the system are more often due to missed string-fret combinations than predicting fingerings not present in the signal. The TDR of 0.899 indicates that over 89% of correctly identified pitches are assigned the correct fingering. This value is promising given that the majority of pitches playable on guitar can be played in multiple locations.

5. DISCUSSION

Viewing the predicted tablature alongside the ground truth [3] , the system appears to output correct string-fret activations a good amount of the time, with the occasional error. To better understand these results, Figure 3 contains examples of 3 common types of errors made by the proposed system.

False alarms occur when a string-fret combination that is predicted is not actually present in the input signal. This type of error negatively impacts the tablature precision metric. In Figure 3 (a), a false alarm occurs when an F3 pitch is mistakenly detected on the 3rd fret of the D-string. This specific error likely happened because the overtones of the F2 pitch, which is present, could be mistaken for the presence of the F3 pitch an octave up. Also, the predicted fingering is a chord shape commonly used by guitarists called a "power chord."

Missed detections occur when the system fails to detect a string-fret combination that is present in the input signal. These errors hurt the tablature recall score. In Figure 3 (b), the presence of the A♭4 pitch on the 4th fret of the e-string is missed by the system. This type of error could be due to the note having been played quietly or having mostly faded out by the current frame, but still technically being active according to the ground truth. Also, this specific error can be attributed to octave confusion, since the A♭4 could easily be mistaken for overtones of A♭3 note, which was activated on the 6th fret of the D-string.

Finally, miss-frettings occur when a pitch is correctly detected, but it is assigned the incorrect string-fret combination. This is essentially a simultaneous false alarm and missed detection, so both the tablature precision and tablature recall are negatively affected. However, the TDR metric most directly represents how often this third type of error is avoided. In Figure 3 (c), the A♭4 pitch is detected as an activation on the 4th fret of the e-string. However, the pitch was actually played on the 9th fret of the B-string. In this is specific case, there were no other pitches simultaneously present to cause confusion. Instead, this error is likely due to the system's failure to predict the correct guitar string based on timbre.

[3] As supplementary materials, video demonstrations showing predicted and ground truth tablature synced with input audio are available at: https://github.com/andywiggins/tab-cnn

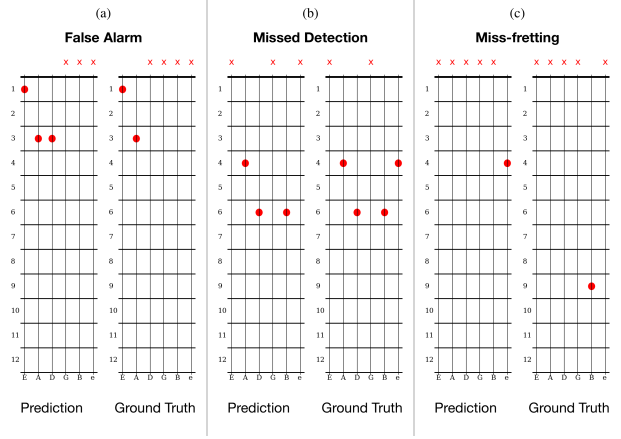

Figure 3. Fretboard diagrams showing examples of 3 common error types made by TabCNN. In each diagram, the vertical lines are guitar strings, and the horizontal lines are the frets. The circles indicate positions of the guitarist's fingers on the fretboard. An "X" over a string means that string is not sounding.

Overall, we observed that errors often occur at the beginning or end of a note. A strategy for improving estimation performance could be the incorporation of a temporal smoothing algorithm.

6. CONCLUSIONS AND FUTURE WORK

In this paper, we have proposed TabCNN, a convolutional neural network (CNN) approach to tablature estimation from audio of a solo acoustic guitar performance. Our system performs competitively in guitar multipitch estimation, while providing the advantage of additionally predicting the true fingering used by the guitarist. The guitar community, which frequently shares music in tablature form, can benefit from a system that automates the arduous task of transcribing tablature, while retaining nuance from the original performance, in the form of the exact fretboard positions being used.

Looking ahead to future work, the approach in this paper could be integrated into an end-to-end tablature transcription system. A temporal smoothing method could be added to aggregate these framewise tablature estimations into a note-level transcription. Additionally, we hope that the tablature estimation metrics introduced in this paper can serve to evaluate future guitar transcription approaches that aim to predict the guitarist fingering.

Session C

LEARNING A JOINT EMBEDDING SPACE OF MONOPHONIC AND MIXED MUSIC SIGNALS FOR SINGING VOICE

Kyungyun Lee **Juhan Nam**
Graduate School of Culture Technology, KAIST
{kyungyun.lee, juhannam}@kaist.ac.kr

ABSTRACT

Previous approaches in singer identification have used one of monophonic vocal tracks or mixed tracks containing multiple instruments, leaving a semantic gap between these two domains of audio. In this paper, we present a system to learn a joint embedding space of monophonic and mixed tracks for singing voice. We use a metric learning method, which ensures that tracks from both domains of the same singer are mapped closer to each other than those of different singers. We train the system on a large synthetic dataset generated by music mashup to reflect real-world music recordings. Our approach opens up new possibilities for cross-domain tasks, e.g., given a monophonic track of a singer as a query, retrieving mixed tracks sung by the same singer from the database. Also, it requires no additional vocal enhancement steps such as source separation. We show the effectiveness of our system for singer identification and query-by-singer in both the in-domain and cross-domain tasks.

1. INTRODUCTION

Singing voice is often at the center of attention in popular music. We can easily observe large public interest in singing voice and singers through the popularity of karaoke industry and singing-oriented television shows. A recent study also showed that some of the most salient components of music are singers (vocals, voice) and lyrics [5]. Therefore, extracting information relevant to singing voice, i.e., to singers, from music signals, is an important area of research in music information retrieval (MIR) [9, 11]. The relevant tasks include singing voice detection [16], singing melody extraction [14, 28], singer identification [12, 21], and similarity-based music retrieval [8, 22].

Modern singer information processing systems have been designed to work with only one of monophonic or mixed music signals [15, 21, 34]. Then, given both types of signals for analysis, we question whether the system can extract information relevant to singing voice that is transferable between between monophonic and mixed tracks. In our experiment, we observe that systems trained with only one type of signals do not perform well, when tested with another type. To address this limitation, we introduce a new problem of *cross-domain* singer identification (singer-ID) and similarity-based retrieval, in which we regard monophonic and mixed music signals as two different audio domains. Cross-domain problems have been explored in computer vision and recommender systems, for example, image retrieval from user sketches to real images [29] and user preference modeling from movies to books [6]. In MIR, information transfer between monophonic and mixed tracks can open up new possibilities for singer-based retrieval systems. Some examples are: 1) given a user's vocal recording in a karaoke application, finding popular singers who sound similar to the user, and 2) given a studio vocal track of a singer, retrieving all tracks (monophonic and mixed) relevant to the singer from a large music database.

To learn a joint feature representation of data from both monophonic and mixed tracks, we adopt a metric learning method, which forces tracks from the same singer to be mapped closer to each other than those from others (Section 3.2). To acquire sufficient training data, we create a synthetic dataset by performing a simple music mashup on two public datasets: vocal recordings from DAMP [30] and background tracks from musdb18 [25] (Section 3.1.1). We present experiments to demonstrate that our system is able to extract singer-relevant information from both monophonic and mixed music signals, and share the information between the two domains (Section 4). Source code, trained models, example audios and detailed information about the dataset are available [1] .

2. RELATED WORK

Cross-domain systems have not yet been examined regarding singing voice analysis. Nonetheless, a common challenge in singer information processing systems is to extract singing voice characteristics from music signals in the presence of background accompaniment music. The most direct way to obtain vocal information is to use monophonic vocal tracks. Recently, Wang et al. [34] trained a siamese neural network on monophonic recordings from a subset of the DAMP dataset. Their model scored higher on singer classification but lower on song classification compared to a baseline model. This implies that the model was able to learn singing voice characteristics, rather than the

[1] http://github.com/kyungyunlee/mono2mixed-singer

content of a music piece, such as its melody or lyrics. However, since music of our interest is often mixed tracks, this approach has limitations.

Several works have handled mixed audio signals by enhancing vocal signals through source separation or melody enhancement [8, 15, 21]. Given recent advances in source separation [32], this approach may bring improved results for most singing voice analysis systems. Another common choice is using audio features that represent human voice or singing voice, such as mel-frequency cepstral coefficients (MFCCs) [2, 15]. With the success of deep neural networks, it is even possible to learn appropriate features from more general audio representations, i.e., short-time Fourier transform (STFT) or even raw audio. We take this last approach and train our model to be a feature extractor for a given input audio represented by a mel-spectrogram.

Depending on the target task, background music can be helpful. An example is singer recognition in popular music [19]. This is because singing style is often dependent on the genre or mood of the music, and singers tend to perform in similar genres throughout their careers. However, our work focuses on learning the actual characteristics of singing voice, independent from background music.

3. METHODS

In this section, we describe the data generation pipeline, model configuration and training strategy for learning a joint representation of monophonic and mixed tracks for singing voice.

3.1 Data generation

For training cross-domain singer-ID and retrieval systems, a sufficiently large number of monophonic and mixed track pairs per singer is needed. Existing singing voice datasets, such as MIR-1K [10], iKala [3] and Kara1K [1], provide the monophonic and mixed track pairs, but they have a small number of singers or only a few tracks per singer. An alternative option may be to perform singing voice detection (SVD) and vocal source separation on a large dataset, but the audio quality can be degraded.

In this work, we choose to utilize the DAMP dataset, which contains vocal-only recordings from mobile phones of around 3,500 users from the Smule karaoke app (there are 10 full-length songs per user). This serves as the main ingredient to generate our synthetic singer dataset. As a preprocessing step, we perform a simple energy-based SVD to remove silent segments. Then, 1000 singers are chosen for training stage and additional 300 singers are put aside for testing. The original DAMP dataset processed with SVD, *DAMP-Vocal*, is used as the monophonic dataset; the synthesized mixed track dataset, *DAMP-Mash* (detailed in section 3.1.1), is used as the mixed track dataset in this work.

3.1.1 Mashup: DAMP and musdb18

A music mashup is a way of creating music by carefully mixing two or more tracks from several different pre-recorded songs. Inspired by such work, we automatically generate a synthetic singer dataset, called DAMP-Mash, by combining vocal recordings from the DAMP dataset with background tracks from the musdb18 dataset. Instead of random mixing, we build a pipeline (Figure 1) to identify the "mashability" [4] between tracks. Our mashability criteria requires 3-second long vocal and background tracks to have the same tempo and key. Once the two segments pass the mashability test, they are mixed at their nearest beat location. Before mixing, we adjust the loudness by balancing the root-mean-square energy between both segments.

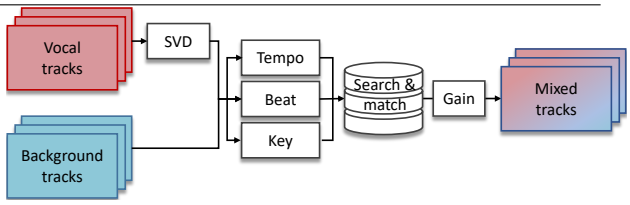

Figure 1: Mashup pipeline to generate synthetic dataset, *DAMP-Mash*.

Tempo detection and beat tracking are performed at track-level using librosa 0.6.2 [20]. On the other hand, key is determined locally at 3-second long segments by using the Krumhansl-Schmuckler key finding algorithm [13] on chromagrams. As a result, vocal segments within the same song end up being mixed with multiple different background tracks. Thus, we view our synthetic dataset as being genre-independent. This mashup pipeline can be also regarded as a data augmentation technique.

3.2 Model

3.2.1 Skeleton model

A 5-layer 1-D convolutional neural network (CNN) is the skeleton of larger networks used in this paper. First four convolutional layers have 128 filters of size 3, each followed by a maxpooling layer of size 3. The last convolutional layer consists of 256 filters of size 1 to output a final embedding vector of 256 dimensions. All convolution operations are done on the temporal dimension only. The final embedding vector will be used to represent input audio and to perform tasks described in Section 4. Batch normalization and Leaky ReLU [17] are applied to all convolutional layers, and dropout of 50% is applied after the last convolutional layer to prevent overfitting.

The input is a 3-second long audio of at least 70% singing voice frames. The sample rate of audio is 22050 Hz and we compute an STFT using a 1024-sample long Hanning window with 50% overlap. We then convert it to a mel-spectrogram with 128 bins and apply logarithmic compression on the magnitude. As a result, the input shape is 129 frames by 128 bins.

3.2.2 Embedding model

The outcome of metric learning is a mapping function from inputs to output vectors in an embedding space, where inputs of the same class are closer to each other than those

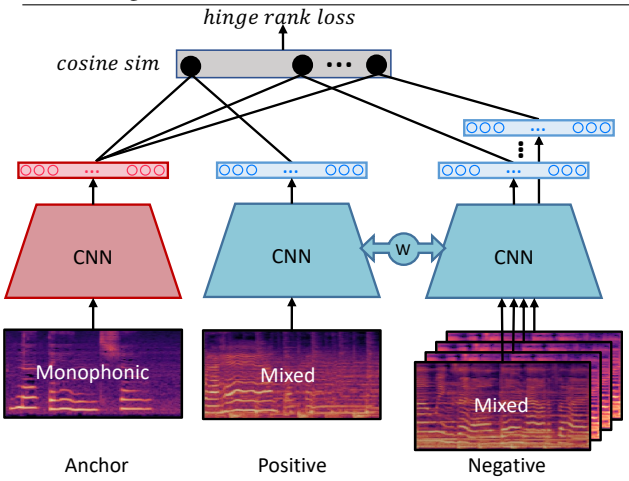

Figure 2: Configuration of `CROSS` model. The anchor network (left) is for modeling monophonic tracks; the rest is for modeling mixed tracks.

from different classes. Specifically, we build our model upon a triplet network, which consists of three potentially weight-sharing networks that takes three inputs: anchor, positive (same class as the anchor) and negative (different class as the anchor) items. This architecture can be extended to take multiple negative items [31] to overcome the limitation of learning from only one negative example. For model configuration, we closely follow the work of [24], using 4 negative items. We also use a type of margin-based ranking loss, called hinge rank loss, with cosine similarity as our metric [7].

Thus, the loss function for a given set of anchor (p_i), positive (p_+) and negative (p_-) feature vectors is:

$$loss(p_i, p) = \sum_{p_-} max[0, \alpha - S(p_i, p_+) + S(p_i, p_-)] \quad (1)$$

where S is a similarity score:

$$S(p_i, p_j) = cos(p_i, p_j) = \frac{p_i \cdot p_j}{||p_i|| \cdot ||p_j||} \quad (2)$$

and α indicates the margin, which is fixed to 0.1 after performing a grid search on values between 0.01 and 1.0. Negative tracks are selected through negative sampling among tracks that do not belong to the singer of the anchor item. We tested a more difficult negative sampling strategy of selecting the four highest scoring items among twenty randomly chosen negative samples, but the model showed minor improvement with an increase in computation time. Investigation on negative sampling is left as our future work.

We choose metric learning for three main reasons. First, by giving a higher similarity score to any pair of tracks performed by the same singer, the model can learn to identify the singer from a track regardless of it being monophonic or mixed. Thus, it is especially suitable for training cross-domain systems. Second, using singer identity as the only ground truth to measure similarity between two tracks will force the model to focus only on singing voice. Since DAMP-Mash is genre-invariant, the only common component in two tracks is going to be related to singing voice. Thus, we may expect the model to perform a feature-level source separation on mixed tracks. Lastly, the model can be trained on a larger number of singers without increasing the number of parameters. On the other hand, a classification model that uses a softmax layer will need to increase the output layer size to match the number of training singers [24].

We explore our ideas with three models, which differ in the type of data used for training:

- `MONO`: all inputs are monophonic tracks
- `MIXED`: all inputs are mixed tracks
- `CROSS`: anchors are monophonic, while positive and negative items are mixed tracks (Figure 2)

Our main idea in this work is reflected in the `CROSS` model, for which the hinge rank loss ensures that the cosine similarity between monophonic and mixed tracks from the same singer is scored higher than that from different singers. `MONO` and `MIXED` models are reference models for comparison.

While networks within `MONO` and `MIXED` model share weights, in `CROSS` model, the anchor network and the rest do not share weights. Thus, it yields two separate feed-forward networks, each designed specifically for its corresponding domain (Figure 2). As a result, depending on the domain of an input audio, one of the two networks is used as the feature extractor. Each network is configured with the skeleton model described in Section 3.2.1.

3.2.3 Pre-training via classification

Metric learning is known for its difficulty in optimization [35, 36]. To alleviate this problem, we train a classification model and use it to initiate the learning of the embedding models. The classification model has one linear layer added to the skeleton model (Section 3.2.1) and predicts the correct singer with a softmax probability. Instead of fully training it, we remove the last output layer after 30 epochs and use it to continue the training in a metric learning style. We do not freeze any layers.

4. EXPERIMENTS & EVALUATION

4.1 Test scenarios

Two main tasks for evaluation are singer identification and query-by-singer. In both tasks, a music signal to be analyzed (source) is queried to a collection of data (target) to retrieve desired information. Depending on the domain of source and target data, we design three test scenarios:

- *Mono2Mono*: both source and target data are *monophonic* (in-domain)
- *Mix2Mix*: both source and target data are *mixed* (in-domain)
- *Mono2Mix*: source data is *monophonic*, but the target data is *mixed* (cross-domain)

Each task is evaluated on all three test scenarios.

4.2 Task 1: Singer identification

Dataset : We select 300 singers unseen from the training stage for evaluation. For each singer, we use 6 tracks for building singer models and set aside 4 tracks as query tracks, resulting in 1200 queries. Depending on the domain of source and target data, DAMP-Vocal (monophonic) and DAMP-Mash (mixed) dataset are used accordingly.

Description : As in [23, 27], singer identification is to determine the correct singer of the query track among the 300 candidate singer models. All queries and singer models are represented as 256 dimensional feature vectors; a track vector is an average of 20 feature vectors computed from 3-second long segment of the same track and a singer model is an average of 6 track vectors from the same singer. We made predictions by computing cosine similarity (2) between the query track and all the singer models. Then, the singer with the highest score is chosen.

For our baseline, we train a Gaussian Mixture Model-Universal Background Model (GMM-UBM), which is commonly used in speaker recognition systems [26]. Each singer model is adapted through maximum a posteriori (MAP) estimation from a single singer-independent background model. All models are composed of 256 components with MFCCs of dimension 13 as input. We train 2 GMM-UBMs, one with monophonic tracks for *Mono2Mono* and the other with mixed tracks for *Mix2Mix*.

We report both top-1 and top-5 classification accuracy. They represent the proportion of correct guesses out of 1200 queries in total. Top-5 accuracy is calculated by considering a prediction as being correct if the ground truth singer appears within the top 5 highest scoring singers.

4.3 Task 2: Query-by-singer

Dataset : As in the singer recognition task (Section 4.2), same 300 singers are used for evaluation. 6 tracks from each singer are selected to build a collection of 1800 tracks to represent a search database and 4 tracks are used as test queries.

Description : Given a query track, the task is to retrieve tracks that are performed by the same singer among the track database. We compute the similarity (Equation (2)) between the query track and all the tracks in the database, and rank them based on their similarity scores. This can be applied to singer-based music recommender systems to discover singers with similar singing voice characteristics.

We report *precision* and *recall-at-k* as well as mean average precision (mAP) score, where k is set to 5 to resemble music retrieval systems. Given a query track performed by singer A, *precision-at-k* (Pr@k) refers to the proportion of tracks that are performed by A and are recommended among k items; *recall-at-k* (R@k) refers to the proportion of tracks that are performed by A and are recommended out of all the tracks performed by A (6 tracks in total) in the database. Unlike Pr@k and R@k, mAP takes into account the actual order of the recommended tracks. Thus, it

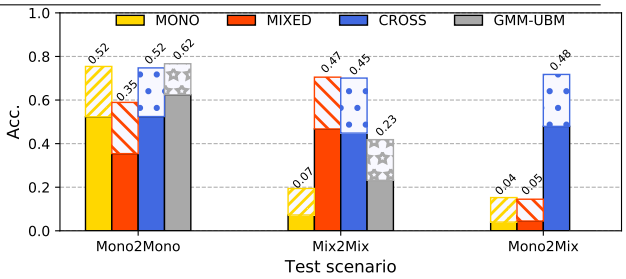

Figure 3: Singer identification results for `MONO`, `MIXED` and `CROSS` on different test scenarios. The solid section points to the top-1 accuracy (also written above each bar) and the hatched section points to the top-5 accuracy.

is useful for music recommender systems, where it is important that relevant items are not only retrieved, but also with higher confidence than false positive items.

4.4 Results

In Figure 3 and Figure 4, we observe a large performance variation for `MONO` and `MIXED` models across different test scenarios. Both models perform well in *Mono2Mono* and *Mix2Mix*, respectively. However, their performances drop significantly in other scenarios, especially for *Mono2Mix*. This is expected, because these models have not been trained to handle cross-domain scenarios.

On the other hand, `CROSS` model performs well on all three test scenarios, benefiting from two jointly trained networks that can each handle monophonic and mixed tracks. We see that it is the only model that is able to match and compare the singer identity between tracks from different domains. Also, its performances on *Mono2Mono* and *Mix2Mix* are on par with the `MONO` and `MIXED` models. This is a useful observation, since training only the `CROSS` model can still give good performance on all three test scenarios, avoiding the effort of training separate models for each scenario. Note that the baseline model, GMM-UBM, shows the best performance in *Mono2Mono*, but not so well in *Mix2Mix*. Result for *Mono2Mix* is omitted, since it is close to random prediction. When there is no background music, GMM-UBM with MFCCs are efficient in characterizing singing voice.

As mentioned in Section 3.2.3, we show the effect of using a pre-trained network on singer identification task (Figure 5). `CROSS` model (blue stars) shows the largest performance improvement compared to the other two models. We assume that comparing the singer identity between monophonic and mixed track is more difficult than comparing between tracks of the same domain. Therefore, a pre-trained model, which learned to somewhat identify singers from an input audio, serves as a hint to focus on signals relevant to singing voice. Using a pre-trained model not only improved the accuracy, but also accelerated the learning process.

Regarding background music as noise and singing voice as the signal, signal-to-noise ratio (SNR) has a large impact on the performance of singing voice analysis systems [16]. We change the SNR of the test data and show

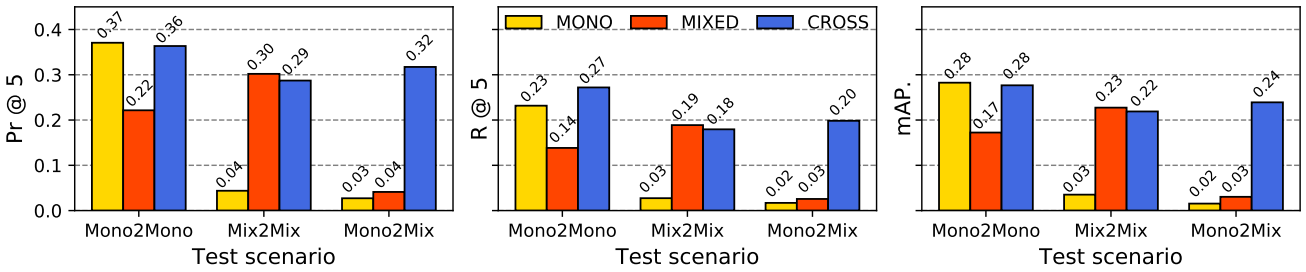

Figure 4: Query-by-singer result for MONO, MIXED and CROSS models. *precision-at-k* (left), *recall-at-k* (center) and mean average precision score(right) are shown. Each number above the bar refers to corresponding model's score.

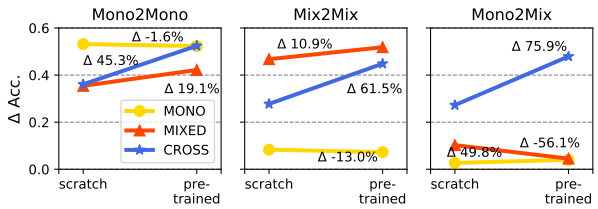

Figure 5: Top-1 accuracy improvement on singer identification when using a pre-trained network. The numbers on the line indicates the percentage of improvement.

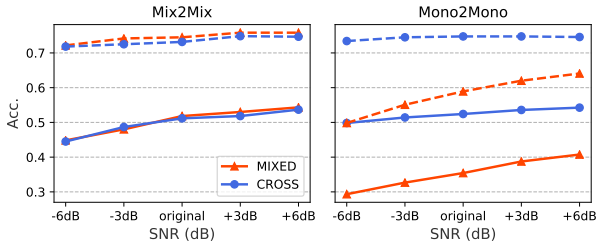

Figure 6: Result of MIXED and CROSS model for singer recognition on varying SNR. Solid line indicates top-1 and dotted line indicates top-5 accuracy.

results on singer recognition task for MIXED and CROSS models in Figure 6. Since *Mono2Mono* deals with only monophonic tracks, the change in performance exhibited in *Mono2Mono* (right) is due to the overall loudness of the track, not SNR. Therefore, as the performance change on *Mix2Mix* (left) shows a similar trend across different SNR, it implies that models trained on DAMP-Mash dataset is able to identify singing voice in more difficult conditions. This is a great benefit for singing voice analysis systems.

4.5 Evaluation on Popular Music Recordings

As our system is trained with a synthetic dataset, we evaluate it on popular music recordings to ensure that the trained system can also generalize to real-world data.

Dataset : Million Song Datatset (MSD) contains 1,000,000 tracks and 44,745 artists from popular music recordings. As done in [23], we filter the dataset to select artists with substantial vocal tracks using singing voice detection (SVD). This dataset is referred to as *MSD-Singer* [2] . For comparison, we train a model, named POP, on 1000 artists from MSD-Singer dataset. We used 17 30-second long tracks for each artist for training. 500 singers, unseen from the training stage, are used for evaluation. 15 tracks of each singer are used for building singer models and 5 tracks are used as query tracks.

	MIXED	CROSS	POP	Random
Acc.	0.291	0.282	0.393	0.002
Top-5 Acc.	0.511	0.491	0.664	0.01

Table 1: Accuracy result on singer recognition on dataset of popular music recording, MSD-Singerdataset

Description : The task is equivalent to singer identification in Section 4.2, only with a different dataset. The result from the POP model is the upper bound, as it is trained and tested on MSD-Singer dataset; meanwhile, MIXED and CROSS models are trained on DAMP-Mash and DAMP-Vocal dataset.

Result: The result shown in Table 1 compares MIXED and CROSS models with POP model and a random classifier. It shows that even though our models are trained only with the synthetic dataset, they are also able to identify singing voice in popular music. Therefore, we can confirm that DAMP-Mash dataset is able to represent the popular music to some degree and that our models are able to generalize to real-world recordings. We believe that the results will improve with a better automatic mashup pipeline. Training the CROSS model on source separated MSD-Singer dataset is also left as a future work.

5. EMBEDDING SPACE VISUALIZATION

We visualize the embedding space learned by the MIXED and CROSS models to understand how they each process monophonic and mixed tracks. From DAMP-Voice and DAMP-Mash dataset, we select 25 singers unseen from the training stage and highlight 10 with colors for better visualization. 20 tracks are plotted for each singer: 10 monophonic vocal tracks and their corresponding mixed tracks. After feature extraction, we reduce the dimension of each

[2] Details provided at http://github.com/kyungyunlee/MSD-singer

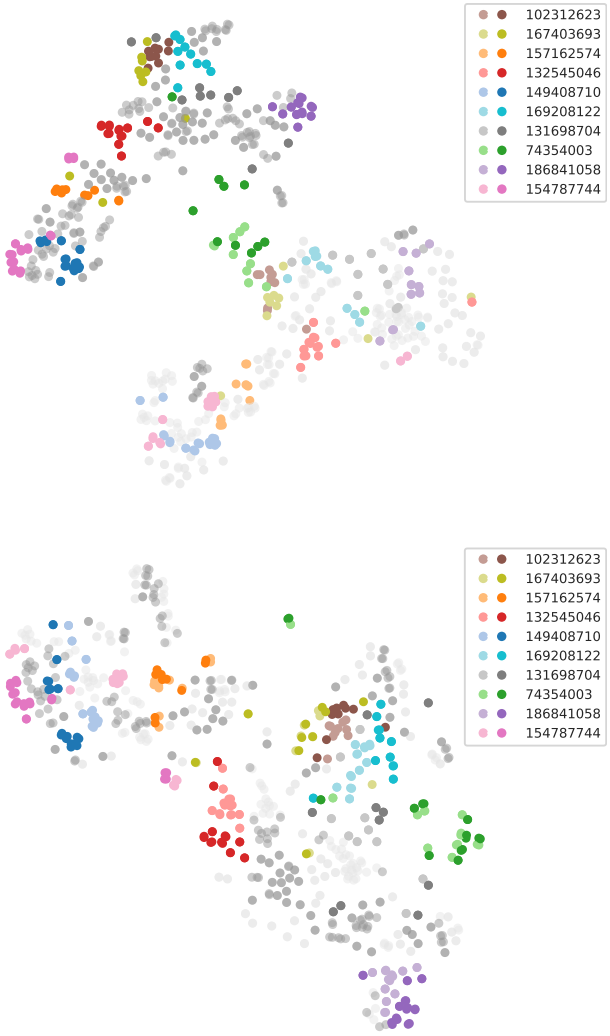

Figure 7: Singer embedding space from `MIXED` model (top) and `CROSS` model (bottom). The label numbers are player IDs from the DAMP dataset. The colors on the left column refers to monophonic vocal tracks; the right column refers to mixed tracks. Best viewed in color.

feature vector from 256 to 2 dimensions using t-distributed stochastic neighbor embedding (t-SNE) [18]. Each dot on the embedding space represents a track. For visualization, we use a paired color palette and assign lighter color to monophonic tracks. Since both monophonic and mixed tracks are from the same singer, an ideal embedding space will show clusters of 20 tracks for each singer.

Figure 7 shows the embedding space learned from the `MIXED` model. There is a noticeable gap between the features of monophonic tracks and that of mixed tracks, which means that the model differentiates monophonic and mixed tracks, rather than finding similar singing voice. Still, we can see that the model is able to cluster tracks from the same singer within the same domain. However, in Figure 7, the monophonic and mixed track features of the same singer are mapped close to each other. This explains why the `CROSS` model shows good performance on cross-domain tasks. We can observe that it is able to transfer singer information across two domains.

6. MOTIVATION FOR FUTURE WORK

Improvement on music mashup: Our mashup pipeline has a large room for improvement. Besides errors produced from existing algorithms, such as key detection, more efforts can be put towards mixing two tracks with a good balance as in real-world recordings. A good automatic mashup system can benefit many areas of research in MIR. The creativity and limitless choices of techniques that can be applied to generate a mashup imply that a large amount of multitrack dataset can be generated for many tasks of interest.

From track to singer modeling: In this work, we use an average of several track-level feature vectors to build singer models. However, in case of singers with highly varying vocal characteristic between different tracks and taking into account the "album effect", averaging may not always be the best choice. Exploring GMMs with multiple mixtures or principal component analysis (PCA) can be an interesting future direction.

Going beyond singing voice: Although we have focused on singing voice, our methods can be tested with tasks involving other instruments, such as multiple instrument recognition. The same mashup technique can be applied to create a dataset, by replacing the monophonic vocal tracks with any instrument of interest. Data generation with mashup may yield better results for instrument recognition in real-world recordings compared to the method proposed in [33], where only two monophonic instrument tracks are used to create a random mix.

7. CONCLUSION

In this paper, we introduced a new problem of cross-domain singer identification and singer-based music retrieval to allow information transfer between monophonic and mixed tracks. Through data generation using music mashup, we were able to train an embedding model to output a joint representation for singing voice from tracks regardless of their domain. We evaluated on three different test scenarios, which include both in-domain and cross-domain cases. A huge advantage of `CROSS` model is that it performs well not only on the cross-domain scenario, but also on commonly observed in-domain scenarios. Therefore, by training only the `CROSS` model, it yields two models, one for each domain. Additional evaluation on varying SNR and on popular music dataset demonstrated that the model is robust to background music and can also be generalized beyond our synthetic dataset.

To conclude, we believe that cross-domain systems can enable many interesting applications related to singing voice, as well as in MIR. Specifically, our future interests include improving the quality of the mashup dataset and performing comparisons between singing voices of karaoke users and that of popular singers.

AUGMENTING MUSIC LISTENING EXPERIENCES ON VOICE ASSISTANTS

ABSTRACT

Voice interfaces have rapidly gained popularity, introducing the opportunity for new ways to explore new interaction paradigms for music. However, most interactions with music in current consumer voice devices are still relatively transactional; primarily allowing for keyword-based commands and basic content playback controls. They are less likely to contextualize content or support content discovery beyond what users think to ask for. We present an approach to dynamically augment the voice-based music experience with background information using story generation techniques. Our findings indicate that augmentation can have positive effects on voice-based music experiences, given the right user context and mindset.

1. INTRODUCTION

Voice-enabled devices, such as "smart speakers" like Amazon's Echo, Apple's HomePod, Google Home, or Sonos One, have reached the mainstream. In particular, listening to music is a popular use case for such devices [23, 25]. Finding music to listen to and discovering music on these devices can be a challenge as the interactions supported by voice-enabled speakers are relatively limited by current interaction models.

Prior research suggests listeners employ music search to learn and explore about new content to consume. Listeners seek background information to stay informed about their favorite artists, genres, and songs, and use it as a relationship builder with others [19]. This exploratory mindset, however, is relatively rare on music streaming apps because catalog-based entity search does not support this user need well [13]. Augmenting listening experiences and conversational interactions have the potential to support these exploratory user goals but leveraging them for a good user experience remains a challenge.

Learning about background information is sometimes a part of the listening experience itself. Often, such information is presented together with the music playback to contextualize the content. For example, user interfaces of several music streaming services, such as Apple Music, Pandora, and Spotify, include a section for additional information beyond basic track metadata for artists, albums, and playlists. Sometimes, songs are contextualized further by displaying the lyrics, stories, or background information associated with certain parts of the songs (e.g., "Behind the Lyrics" feature on Spotify [27]).

In this paper, we provide a method for how voice-based content consumption can be automatically augmented with background information and present the development and study of a prototype inspired by story generation methods.

We make the following contributions:

- Introduction of a type of content augmentation to contextualize voice-based content consumption with background information in Section 3.
- Detailed design of an approach taking playlists as input and utilizing weighted graphs to generate textual music augmentations, inspired by story generation in Section 3.
- Identification of best practices for using augmentation and conversation in voice-based music consumption in Section 5.

2. RELATED WORK

2.1 Listener Information Needs and Music Search

When listeners search for music, they have multiple information needs that they may be trying to fulfill. These user needs help to shape how listeners approach their music search goals. For instance, listeners may be in the mindset of looking for something specific or they may be in the mindset where they are open to multiple types of music-related information. Prior research has suggested that users of a streaming music service have distinct mindsets when they are searching for music [13]. In a focused mindset, users have one particular item in mind. Catalog, entity-based search interfaces favor this particular mindset and queries that align with the structure of available metadata. In an analysis of Google Answers queries, Bainbridge et al. [3] found that users typically (81.3% of the

time) expressed needs through bibliographic queries, using performer, title of work, or date of recording. Li et al. [17] also observed that typed searches on a streaming music platform are typically focused, suggesting that the modality and design of the current feature supported this type of mindset.

Listeners also have broader information needs that are not met by catalog-based entity searches commonly supported in online music services. Lee et al. [15] observed that people use cloud music services that store listeners' music libraries to listen to music that they were unfamiliar with, suggesting that music discovery and exploration is an important user need. In addition, listeners indicated they search for information about the artists and music for learning purposes [14]. Users of a streaming music platform, however, tended not to use the search feature to deeply learn about a specific type of music and left the platform to fulfill that need [13].

2.2 Voice Assistants and Music Consumption

Voice-enabled speakers currently allow music listeners to search for content (e.g., by saying "play Jazz" or "play Time by Pink Floyd") and control the music playback (e.g., play/pause/skip and volume controls). In fact, these basic playback controls form the most common category of user commands [25]. While many of these speakers can be used in conjunction with a secondary device that has a graphical user interface (GUI), voice interaction is increasingly becoming a primary modality for consuming music [25], which increases the importance of evolving and improving the music experience through voice. Notably though, the voice-only smart speaker experience does not offer much in the way of discovery or background information, and such lack of contextualization and grounding can reduce music discovery and listener's emotional investment [26].

Our work focuses on contextualizing the voice-based music experience with relevant background information. This idea shares similarities to music radio shows, where the hosts provide relevant information about the content they play and add other talking points in between songs. In [4], radio's interaction of speech and content is framed as a special kind of narrative, in which the DJ or radio host is the narrator. One of the main challenges in creating an experience like radio shows is maintaining the "flow" of the music, and balancing the spoken words and songs, as this is one of the main skills of the radio hosts [2]. Our user study seeks to learn more about how to achieve a balance between this flow and providing background information.

2.3 Story Generation

Story generation is the problem of automatically selecting a sequence of events that meet a certain criteria and can be narrated as a story [18]. Story generation and our approach to augment the music listening experience share the goal to generate sequences of textual content given specific constraints. While there are many different approaches to generate stories [12, 20, 28], ours is similar to planning-based approaches which also commonly use graph representations to map the space of story events and the possible constraints of a valid or optimal progression of the storyline. In [18] such constraints are reflected by logical precedence rules, while our method utilizes edge weights and pathfinding to extract a preferred storyline. Similar to PlotShot [9] we apply this a graph-based approach to generate a sequence of text for a given form of input media. Inspired by these different approaches, we take playlists as input and utilize graphs with edge weights that denote content preferences to generate textual music augmentations.

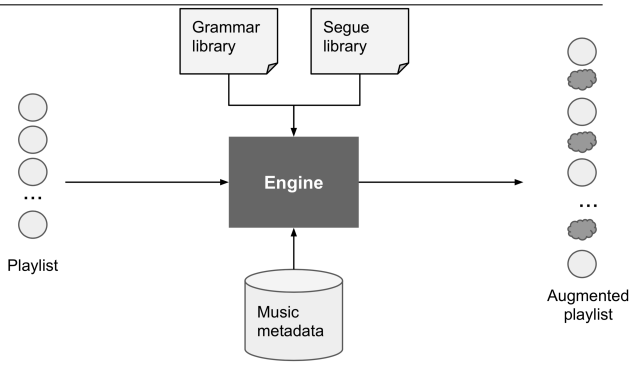

Figure 1. The system architecture of our prototype.

3. APPROACH AND PROTOTYPE

Our prototype takes ordered playlists as input, finds relevant background information and relationships for the songs it contains, and chooses a subset of that information for being used in the output (illustrated in Fig. 1). We call every piece of information that comes in between two consecutive songs a *segue*. Every segue describes a predefined property, such as some information or characteristic, of the next song or a relationship between the current and the next song.

While our approach is not limited to playlists as input, we decided to use them as a starting point given that songs in a playlist typically contain more variety in the metadata as opposed to an individual artist's album. Moreover, songs in a playlist often have an implicit reason for having been grouped together (e.g., being of the same genre, suiting a specific mood or situation [21], artist similarity, etc.) We kept the original order of playlist songs to preserve possible semantic reasons behind curation by playlist creators.

3.0.1 Music Metadata

Our prototype uses a set of metadata and background information about songs, artists, and albums. Table 1 shows some sample entries of qualitative facts about songs and artists consisting of short extractions from publicly available sources of background information (e.g., Wikipedia).

3.0.2 Segue Library and Grammar Library

Table 2 contains a few examples for segues. Each segue has a natural language generation (NLG) template resulting in a "segue text" when realized. Our segue library contains 21 segues. The authoring effort for creating new

Table 1. Songs' metadata examples.

Property	Applicable Entities	Example
Name	Artist, Album, Song	Drake, Scorpion, Wild Thoughts
Genre	Album, Song	Hip Hop
Qualitative fact	Artist, Song	Rihanna's real name is Robyn Rihanna Fenty.

segues simply depends on the complexity of the segue logic.

Inspired by the story generation concept of grammars [7], we defined a simple construct in our system to allow prioritizing authored sequences of segues that are presumed to be interesting. For instance, by preferring a sequence of `ArtistFact`, `ArtistOriginJump`, and `ArtistFact`, an augmentation can focus on the background of songs and their artists. Grammars are an instrument for professional authorship and editorial opinion to be reflected in the system.

3.1 Generating a Sequence of Segues

First, our prototype accesses available metadata about songs, artists, and albums appearing in the playlist. Then it finds all the matching segues for every two consecutive songs which results in a list of segue options for each such position. For the entire playlist, we get a list of these lists, which we call the *story possibility space*. Given that the choice of a segue at each position in this space is independent of other positions, the story possibility space forms a graph and the search problem for finding a sequence of augmentations becomes a problem of finding the best path in this graph. To do so, we use a set of heuristics and preferences which are reflected in a *weighting function*. These scores are assigned as weights to the edges that represent those transitions in our graph.

$$\begin{aligned} weight(s_1, s_2) = {} & diff(s_1, s_2) \\ & + s_1^{pref} + s_2^{pref} \\ & - lengthiness + silence\_reward \\ & + playlist\_reward \\ & + positional\_preference \end{aligned}$$

Several variables enable weighting absolute and relative preferences. $diff(s_1, s_2)$ enables avoiding repetition between consecutive segues. Static "segue preference scores" s_i^{pref} give specific segues authored preference. For example, pointing out a change of genre between two consecutive songs might be more interesting than simply stating title and artist of the next song. Terse responses are often preferred in conversational interactions [10], hence $lengthiness$ punishes a segue if it has a long text and $silence\_reward$ rewards a graph edge if the previous segue is long but the next segue is `NullSegue`. $playlist\_reward$ represents that some segues fit better to a specific type of playlist, such as ArtistQualFact in artist-focused playlists. $positional\_preference$ is used for segues that make only sense at a specific part of a playlist. For example, a playlist introduction with a short authored description only makes sense at the beginning.

Given a weighted graph, we first look for and choose any possible grammar matches. A grammar is a match if there exists a path in a sub-graph of the story possibility space, where the sequence of nodes in that path matches the grammar's sequence of segue types. Edge weights do not have a role in finding a grammar match. If two grammars overlap, we choose the path representing one of them at random.

For the portions of the story possibility space where no grammar match is found, we use the edge weights to find the best path, one with the heaviest sum of weights. If a given portion of the overall graph that needs pathfinding is larger than 5 playlist positions, we find the path step by steps in windows of size 5. In doing so, we ensure that each such window does not contain any segue types that exist in the previous window, and hence avoiding local repetition of segue types.

To exemplify conversational interactions, we identify possible interaction points in which we could trigger a short dialog and let the user response determine which segue option comes next. We do so by checking against simple logic definitions, e.g., if there are specific types of segues in the next list of segue options (see Table 3.)

After the full graph path is determined, we use the realized segue text of the segues in the chosen path, and insert these segue texts in between the songs. An example excerpt of an augmented playlist is shown in Table 4. Our prototype can generate augmentations for any given playlist as long as it has access to the metadata for the songs in that playlist. For our evaluation, we decided to focus on three popular types of playlists to start with those based on an artist, a genre, or listener popularity.

4. EVALUATION

To better understand how our method of adding contextual information to smart speaker experiences affects music listening, we conducted a two-phased study within Spotify.

In phase 1, we gathered feedback from two professional writers who are familiar with the music domain to elicit expert feedback on the content of the segues. They received the written output of our prototype generated for one representative example of each playlist type: artist, genre, and listener popularity. While we invited them to provide any type of feedback, we specifically asked them to share their views on the contents of individual segues and describe how they would approach writing similar content from a professional perspective as writers. After they returned their comments, we conducted a semi-structured interview with both of the writers which took about 45 minutes.

In phase 2, we conducted an internal evaluation with nine Spotify employees (four female, five male) from various parts of the organization to identify potential future improvements and establish a first understanding of user needs. Participants were in their early 20s to late 40s from non-technical functions (such as design, marketing, or operations) and located in various locations across the United

Table 2. Examples for segues, their logic description, and samples for their realized text.

Segue Type	Logic Description	NLG template	Realized text
`NullSegue`	Always a match regardless of the songs.	N/A	N/A
`MundaneSegue`	Always a match regardless of the songs.	Next song is `next_song_name` by `next_song_artist_name`.	Next song is Time by Pink Floyd.
`ArtistOriginJump`	Musical origin of the previous song's artist is different than the next one's.	From `prev_city` where `prev_artist_name`'s musical origins are, to `next_city` where `next_artist_name`'s are.	From Los Angeles where Tupac's musical origins are, to New York City, where Biggie's are.
`SameYearSameArtist`	Previous and next song share the same artist and release year.	Just like the last song, the next song is from `next_song_release_year` by `next_song_artist_name`.	Just like the last song, the next song is from 2007 by Rihanna.

Table 3. Examples for conversational augmentations.

Voice Prompt	User Response	Voice Response
From when do you think this last song was?	Correct	That's right. But the next song, called Shook Ones, Pt. II takes us into a different era. All the way to 1995. (`DifferentEraSegue`)
	Wrong	Actually, it's from 2007. The next song called Shook Ones, Pt. II and [...]. (`DifferentEraSegue`)
Question! Are you more interested in the artist's background or the genre?	Genre	The genre of the upcoming song is called "Latin Trap". (`NextGenreSegue`)
	Artist	Next song is by Cardi B. Here's a fun fact about their biography... (`ArtistQualFact`)

States. Each session included a semi-structured interview in which we asked participants about their previous experience with voice assistants and whether or how they look for additional content around music. Each participant was asked to listen to a demo audio file for one of our three playlist types. After answering a short questionnaire, they also interacted with our envisioned conversational experience in a short Wizard-of-Oz (WoZ) demo where an experimenter controlled which content to play. Each playlist type was presented to three users who were randomly assigned to a condition.

The demo consisted of ten shortened songs (first and last 15 seconds) and ten segues (one intro segue, nine transition segues) which were generated using our proposed method and then read by a text-to-speech (TTS) engine. Overall, they had a duration of 5:30-5:50 minutes. The short WoZ section to convey the conversational experience covered three songs only, but between the songs the TTS voice prompted the participant with a potential question such as *"Question! Are you more interested in the artist's background or the genre?"*. Depending on the answer the experimenter chose the next audio file to play to continue the experience. Table 3 shows two examples.

We recorded and transcribed all sessions. Two of the co-authors went independently through the transcripts, first categorizing them for their relevance to the stated research questions and then doing an affinity analysis [5] moving relevant quotes between the high-level categories to derive our findings.

5. FINDINGS

We identified various factors that influence the perception and usefulness of including contextual information in music listening experiences.

5.1 Addressing Listener Needs and Contexts

Music is consumed in vastly different situations, playing a different role for listener's needs in each one. We found that listeners' perceived usefulness of the voice-based augmentations heavily depends on the situation and its unique needs.

Augmentations enable music discovery and education. Augmentations are well received when listeners are in an exploratory mindset. Our participants expressed special interest in voice augmentations to learn about content that is new to them. P4 said: *"[Talking about a playlist containing new songs] I'm like 'Wait, what band is this?' [...] 'What other songs can I listen to from them.' "* P6 described their interest in being able to learn about (niche) genres through such augmentations: *"I feel like metal would work really well for this because a lot of bands have a lot of history behind them [...] it's the opposite of trendy [...] people are still listening to music that was written and performed 20 years ago consistently."*

Similarly, editor 2 saw them as a way of discovering less-known artists by providing information about them: *"[When choosing music automatically] you might end up*

skewing the information toward [...] the top-selling artists of all time; yet obviously there are hugely influential artists that have not sold a lot of records but have impacted other artists and bands." Lastly, P1 brought up the need to identify the right occasions for adding information: *"I like that it's just another way to get to know an artist that you already like and I would potentially like if it was getting to know an artist that you don't know. What I wouldn't like is if it's in between."* This highlights a potential for leveraging listener's level of affinity for an artist they already know, or the predicted level of affinity for a new artist, in determining the quantity or focus of the augmentations.

Activities determine needs for and appropriateness of augmentations. Music often supports a specific listener activity. We found that activities with low cognitive load, such as doing chores or cooking, were commonly mentioned as appropriate contexts for voice-based augmentations. P8 said: *"The perfect experience [is] if I'm at home doing something fun like cooking or something not fun like cleaning."* Activities that require a higher level of focus but that listeners consciously choose to support with background music were perceived to be less suitable. Participants mentioned several examples where the music is serving such an activity-supporting focus like working out, studying, or relaxing and felt that any addition to the music could get into the way of that primary activity. *"I need [the music] to keep the motivation going, keep the music going."* (P8)

5.2 Selection of Appropriate Content for Augmentations

The next category of our findings relates to the content of the augmentation and what it focuses on.

Personalizing augmentations improves the experience. The level of affinity with an artist or genre varies significantly across listeners, and the same is true for the level of familiarity with background information. For example, using a sub-genre to describe a song might be very interesting to someone familiar with the general genre, but vague and uninteresting to someone who is only a casual listener of that type of content. P3 said: *"[...] a high, medium, low, [or] novice/expert setting [would be good], because I'm not an expert on this, so I don't understand [some of the segues]."* Similarly, P1 saw an opportunity to point out to them if they are listening to an artist for the first time: *"Say it's the first time I've listened to an artist, I think it would be cool to learn more about that artist."*

Another frequently mentioned interest for personalization was to allow the listener to adjust the topics that the augmentations focus on (e.g., artist life or genre information). P9 said: *"If I could somehow customize like what's being said by the voice to choose like facts or historical whatever, I think that'd be cool."* Editors had similar views. Editor 2 said: *"we've got one end of the spectrum there is music nerds. They've already put their hands in the air and said, 'Please give me more as much as you can."'* The same editor then drew a parallel between customization of content and augmentation: *"can I add another layer of personalization to this which is, please make [the augmentation] minimal [or] please tell me as much as you can about this artist or this genre."*

Augmentations could explain recommendations or present relevant news. Our study subjects mentioned other types of information that would be useful for them to hear. Music listeners increasingly delegate their choice of music content to streaming services, which use various algorithmic and machine learning methods to choose songs that they believe the listener might enjoy. However, listeners usually do not get any explanation for why a particular set of content is chosen for them. P4 said: *"It kind of guides you to know how they're piecing together this playlist for you. It's like, 'this is why we're playing this song for you',"* and P3 mentioned: *"A lot of times for [automatically generated playlists], I'm like why do I have this song, it would be great if [the voice] could tell me."* Alluding to the same point, Editor 1 noted: *"With just the bare information the name, the title, and to give more information and background obviously [one can] provide a much deeper experience for users and give users the reason why they should continue listening."*

Contextual needs of music listeners often extend to their awareness of the current happenings in the music world. Most prominently, our participants expressed interest in hearing about tours and relevant news headlines. P1 said: *"If they were on tour in my area, that's something I'd want to know,"* and P5 mentioned: *"There's a lot of news always with musicians, whether it's a controversy or other things [...] if you had some of that, like why is this song popular right now or what's going on with this song."* Editor 1 brought up the same point, and discussed the following as an example: *"Let's say [an artist] passes away [...], and you insert a little nugget of information to inform people about that. And then the next song is [by the same artist]. I mean [...] that might make it even more important for maybe someone to listen."*

5.3 Appropriate Presentation of Augmentations

Our last category of findings offers insights about the delivery and presentation of the augmentation content.

TTS voice needs to be trustworthy, high quality and fitting. The synthesized voice in which the segues are presented to the listener was one of the most common topics brought up by our participants; most prominently, the quality of the TTS voice as described by P5: *"With the DJ kind of idea, I think the sound of the thing makes a big difference; so [...] that computery voice takes me out of the moment"*. Despite the quality of the TTS, participants seemed to establish a connection with the agent behind the voice, and explicitly expressed a preference for knowing or at least being able to trust the agent. For instance, P2 said: *"Using someone's voice who is an authority on the genre*

or playlist [is better] [...] there's a difference between that voice telling me little tidbits and somebody like [reference to a Jazz musician]."

Participants mentioned they would like specific properties of the voice, such as gender and accent, to be personalized, either based on the current content or their general preferences. For instance, P4 said: *"I like [it] when people have the Google or Waze, the driving apps, and you can change the accent."* P5 noted: *"I think it would be cool if it was kind of genre-based [...] yea if it's tied to genre or playlist type of thing."* Editor 1 pointed out to voice's gender as well, saying: *"It'd be really jarring to hear like a very male voice [on] Ani DiFranco or Riot grrrl playlists or a very feminist playlist"*.

Augmentations should not be frequent. Participants expressed a preference for segues that connect the previous and the next songs (e.g., by highlighting similarities or differences) over segues that focus solely on the next song. For example, P3 said: *"I like this [...] it tells me a little bit about what I just listened to [...] and then it sets me up into what the next song is going to be,"* and P5 mentioned: *"I [liked] that some of them attempt to link the previous song to the next song."* While semantic continuity is valuable, the frequency of augmentations should not be too high, and segues should not come in between every two songs. We included a representation of an intentional skip (`NullSegue` in Table 2), but it formed either zero or just one out of the 10 generated segues that each participant experienced. Five of our participants (P1, P2, P4, P5, and P8) believed the augmentation was too frequent. P1, for instance, said: *"I definitely in no scenario want [to hear the segues] after every single song"*. Lee et al. [16] found that different user personas have a varying desire for engagement when interacting with music information retrieval systems, which needs to be taken into additional consideration when designing such augmented listening experiences.

Participants enjoyed the conversational augmentations. Our conversational augmentations showcased the ability to ask about the music that is being played, and this was well received by our participants. Most of them (seven out of nine) counted the conversational demo as more fun and interesting than the non-conversational case. When probed on the reasons, participants frequently pointed out the ability to interact. P4, for instance, said: *"You kind of feel like there's this other entity that you're having a conversation with."* In another example, P7 said: *"I think I like this better [than the non-conversational demo]. It was more fun [because of] the interaction aspect of it."* However, two of the participants (P1 and P3) could not imagine themselves using the conversational experience in any situation and generally disliked it. Both participants attributed this dislike to usually preferring a "leaned-back" music consumption mindset, as P3 said: *"I don't want it asking me questions. I actually hated it. It wasn't lean back and was trying to get me to interact..."*

6. LIMITATIONS AND FUTURE WORK

Our results indicate that augmenting voice-based music consumption with background information addresses some of the listener needs that are commonly ignored in current experiences [1, 6]. But similar to how different listening situations affect musical preferences [22], we need to investigate situation-specific preferences for augmentations to understand when music listening is a passive [8], flow-like [11] experience which should not be interrupted.

Our augmentations did not have a "narrative coherence" [24], i.e., a coherent story about a particular topic. In the music context, such narratives could be based on a variety of topics, such as recent events, genres, or artists, all of which were mentioned by our study participants as well. For instance, a dynamically generated augmentation about the history of a genre could focus on songs that represent the turning points of it or have other musical significance. Access to more metadata and large semantic models that capture music-related relationships between various entities can help a story generator in achieving this goal.

In terms of presentation, our evaluation suggests that the quality of the TTS engine seems to be particularly important for music listening experiences. We suspect that the imperfections of the TTS might be more apparent due to a general focus on the audio quality, both for music and voice output. In other use cases for voice assistants, the focus is often more on retrieving the requested information; however, this hypothesis requires further research. Changing the voice's accent or gender, based on explicit listener preference, was stated as an interest by several participants; doing so automatically, such as based on a listener model or audio content, is not only very difficult, but also poses the risk of reinforcing stereotypes of societal and cultural associations for certain types of music.

To minimize negative effects of breaking the audio flow of the music experience, a smoother transition between augmentations and music content is needed. For example, by matching audio properties of the augmentation with those of the surrounding music content, similarly to the techniques used by radio show hosts to match the nearby songs in their ending and beginning [2].

7. CONCLUSIONS

Consuming music via voice assistants is currently a limited experience. While enabling transactional requests for catalog search and basic playback controls, listeners may miss out on context or history of the consumed content. To better support an exploratory mindset for discovering music, we introduce a method that uses story generation techniques to augment the voice-based music experience with relevant background information in between the songs. Our results indicate that adding contextual information to voice-based music interactions can improve smart speaker experience and meet listener needs for music discovery and background information. However, there are also limitations to when the augmentations are desirable based on playback context and listener's mindset and activities.

8. ACKNOWLEDGEMENTS

We thank Keunwoo Choi and Aparna Kumar for their valuable feedback on this paper. Dedicated to Mila Kim, a constant presence during this project.

ABSTRACT

This paper introduces a novel recurrent model for music composition that is tailored to the structure of polyphonic music. We propose an efficient new conditional probabilistic factorization of musical scores, viewing a score as a collection of concurrent, coupled sequences: i.e. voices. To model the conditional distributions, we borrow ideas from both convolutional and recurrent neural models; we argue that these ideas are natural for capturing music's pitch invariances, temporal structure, and polyphony. We train models for single-voice and multi-voice composition on 2,300 scores from the KernScores dataset.

1. INTRODUCTION

In this work we will think of a musical score as a sample from an unknown probability distribution. Our aim is to learn an approximation of this distribution, and to compose new scores by sampling from this approximation. For a broad survey of approaches to automatic music composition, see [9]; for a more targeted survey of classical probabilistic approaches, see [3]. We note the success of parameterized, probabilistic generative models in domains where problem structure can be exploited by models: convolutions in image generation, or autoregressive models in language modeling. This work examines autoregressive models of scores (Section 3): how to evaluate these models, how to build the structure of music into parameterized models, and the effectiveness of these modeling choices.

We study the impact of structural modeling assumptions via a cross-entropy measure (Section 4). It is reasonable to question whether cross-entropy is a good surrogate measure for the subjective quality of sampled compositions. In theory, a sufficiently low cross-entropy indicates a good approximation of the target distribution and therefore must correspond to high-quality samples. In practice, we observe of other generative modeling tasks that learned models do achieve sufficiently low cross-entropy to produce qualitatively good samples [4, 19, 29]. Studying the cross-entropy allows us to explore many models with various structural assumptions (Section 5). Finally, we provide a qualitative evaluation of samples from our best model to demonstrate that these models have sufficiently small cross-entropy for samples to exhibit a degree of subjective quality (Section 6). Supplementary material including appendices, compositional samples, and code for the experiments is available online. [1]

2. RELATED WORKS

In this work, we consider both single-voice models and multi-voice, polyphonic models. Early probabilistic models of music focused on single-voice, monophonic melodies. The first application of neural networks to melody composition was proposed by [28]. This work prompted followup [18] using an alternative data representation inspired by pitch geometry ideas [25]; the relative pitch and note-embedding schemes considered in the present work can be seen as a data-driven approach to capturing some of these geometric concepts. For recent work on monophonic composition, see [12, 23, 26].

Work on polyphonic music composition is considerably more recent. Early precurors include [15], which considers two-voice composition, and [5], which proposes an expert system to harmonize 4-voice Bach chorales. The harmonization task became popular, along with the Bach chorales dataset [1]. Multiple voice polyphony is directly addressed in [16], albeit using a simplified preprocessed encoding of scores that throws away duration information.

Maybe the first work with a fair claim to consider polyphonic music in full generality is [2]. This paper proposes a coarse discrete temporal factorization of musical scores (for a discussion of this raster factorization and others, see Section 3) and examines the cross-entropy of a variety of neural models on several music datasets (including the Bach chorales). Many subsequent works on polyphonic models use the dataset, encoding, and quantitative metrics introduced in [2], notably [30] and [13]. We also note recent, impressive work on the closely related problem of modeling expressive musical performances [11, 20].

Many recent works focus exclusively on the Bach

[1] http://homes.cs.washington.edu/~thickstn/ismir2019composition/

chorales dataset [7, 10, 17]. The works [7, 17] evaluate their models using qualitative large-scale user studies. The system proposed in [7] optimizes a pseudo-likelihood, so its quantitative losses cannot be directly compared to generative cross-entropies. The generative model proposed in [17] could in principle report cross entropies, but this work also focuses on a qualitative study. Quantitative cross-entropy metrics on the chorales are analyzed in [10]. Both [7] and [10] propose non-sequential Gibbs-sampling schemes for generation, in contrast to the ancestral samplers used in [17] and in the present work.

3. FACTORING THE DISTRIBUTION OVER SCORES

Polyphonic scores consist of notes and other features of variable length that overlap each other in quasi-continuous time. Scores contain a vast heterogenous collection of information, much of which we will not attempt to model: time signatures, tempi, dynamics, etc. We will therefore give a working definition of a score that captures the pitch, rhythmic, and voicing information we plan to model. We define a score of length T beats as a continuous-time, matrix-valued sequence $\mathbf{x}$, where $\mathbf{x}_t \in \{0,1\}^{V\times 2P}$ for each time $t \in [0,T]$. Specifically, for each voice $v \in \{1,\dots,V\}$ and each pitch $p \in \{1,\dots,P\}$ we set

$$\mathbf{x}_{t,v,p} = 1 \quad \text{iff pitch } p \text{ is on at time } t \text{ in voice } v, \quad (1)$$

$$\mathbf{x}_{t,v,P+p} = 1 \quad \text{iff pitch } p \text{ begins at time } t \text{ in voice } v. \quad (2)$$

Both "note" bits (1) and "onset" bits (2) are required to represent a score, expressing the distinction between a sequence of repeated notes of the same pitch and a single sustained note; see Appendix C for further discussion.

Let q denote the (unknown) probability distribution over scores $\mathbf{x}$. Score are high dimensional objects, of which we have limited samples (2,300 – see Section 4). Rather than directly model q, we will serialize $\mathbf{x}$, factor q according to this serialization, and model the resulting conditional distributions $q(\cdot|\text{history})$. There are many possible ways to factor q; in the remainder of this section we review the popular raster factorization, and propose a new sequential factorization based on voices.

Raster score factorization. Many previous works factor a score via rasterization. If we sample a score $\mathbf{x}$ at constant intervals Δ and impose an order on parts and notes, we can factor the distribution q over scores as $q(\mathbf{x}) =$

$$\prod_{k=1}^{T/\Delta}\prod_{v=1}^{V}\prod_{p=1}^{2P} q(\mathbf{x}_{k\Delta,v,p}|\mathbf{x}_{1:k\Delta},\mathbf{x}_{k\Delta,1:v},\mathbf{x}_{k\Delta,v,1:p}). \quad (3)$$

Throughout this work, a slice $1\!:\!i$ is inclusive of the first index 1 but does not include the final index i.

This factorization generates music in sequential Δ-slices of time. Some prior works directly model the (high-dimensional) distribution $\mathbf{x}_{k\Delta}$; this approach was pioneered by [2], using NADE to model the conditional distributions $q(\mathbf{x}_{k\Delta}|\mathbf{x}_{1:k\Delta})$. Others impose further order on notes (and voicings, if they choose to model them) and factor the distribution into binary conditionals as in (3). Notes are typically ordered based on pitch, either low-to-high [7] or high-to-low [17].

Sequential voice factorization. Putting full scores aside for now, consider factoring a single voice v, i.e. a slice $\mathbf{x}_{1:T,v,1:2P}$ of a score. By definition, a Kern-Scores voice is homophonic in the sense that its rhythms proceed in lock-step: a voice consists of a sequence of notes, chords, or rests, and no notes are sustained across a change point.[2] Instead of generating raster time slices, suppose we run-length encode the durations between change points in v. We denote these change points by $c_0^v,\dots,c_{L_v}^v$ where L_v is the number of change points in voice v. Let D be the number of unique distance between change points, and define a run-length encoded voice $\mathbf{r} \in \left(\{0,1\}^D \oplus \{0,1\}^N\right)^{L_v}$. At each index $k \in \{1,\dots,L_v\}$, $\mathbf{r}_k = (\mathbf{r}_{k,0},\mathbf{r}_{k,1})$ with $\mathbf{r}_{k,0} \in \{0,1\}^D$ and $\mathbf{r}_{k,1} \in \{0,1\}^N$ such that

$$\mathbf{r}_{k,0} = \mathbf{1}_{d_k} \quad \text{where } d_k = \frac{c_{k+1}^v - c_k^v}{\Delta} \in \mathbb{N},$$

$$\mathbf{r}_{k,1,p} = 1 \quad \text{iff pitch } p \text{ begins at time } c_k^v \text{ in voice } v.$$

The durations d_k correspond to note-values (quarter-note, eighth-note, dotted-half, etc.). We proceed to factor the voice sequentially as $p(\mathbf{r}) =$

$$\prod_{k=1}^{L_v} q(\mathbf{r}_{k,0}|\mathbf{r}_{1:k}) \prod_{p=1}^{P} q(\mathbf{r}_{k,1,p}|\mathbf{r}_{1:k},\mathbf{r}_{k,0},\mathbf{r}_{k,1,1:p}). \quad (4)$$

Sequential score factorization. We now consider a sequential factorization that interlaces predictions in the score's constituent voices. The idea is to predict voices sequentially as we did in the previous section, but we must now choose the order across voices in which we make predictions. The rule we choose is to make a prediction in the voice that has advanced least far in time, breaking ties by the arbitrary numerical order assigned to voices (ties happen quite frequently: for example, at the beginning of a score when all parts have advanced 0 beats). This ensures that all voices are generated in near lock-step; generation in any particular voice never advances more than one note-value ahead of any other voice.

Mathematically, we can describe this factorization as follows. First, we impose a total order on change points c_k^v across voices by the rule $c_k^v < c_{k'}^u$ for all v,u if $k<k'$ and $c_k^v < c_k^u$ if $v<u$. Define $L \equiv \sum_{v=1}^{V} L_v$. For index $i \in \{1,\dots,L\}$ let α_i and β_i denote the index and voice of the corresponding change point according the the total ordering on change points. We define a sequentially encoded score $\mathbf{s} \in (\{0,1\}^D \oplus \{0,1\}^N)^L$ by

$$\mathbf{s}_{k,0} = \mathbf{1}_{d_k} \quad \text{where } d_k = \frac{c_{\alpha_k+1}^{\beta_k} - c_{\alpha_k}^{\beta_k}}{\Delta} \in \mathbb{N},$$

$$\mathbf{s}_{k,1,p} = 1 \quad \text{iff pitch } p \text{ begins in voice } \beta_k \text{ at time } c_{\alpha_k}^{\beta_k}.$$

And we factor the distribution sequentially by $q(\mathbf{s}) =$

$$\prod_{k=1}^{L} q(\mathbf{s}_{k,0}|\mathbf{s}_{1:k}) \prod_{p=1}^{P} q(\mathbf{s}_{k,1,p}|\mathbf{s}_{1:k},\mathbf{s}_{k,0},\mathbf{s}_{k,1,1:p}). \quad (5)$$

[2] For polyphonic instruments like the piano, we must adopt a more refined definition of a voice than "notes assigned to a particular instrument;" see Appendix B for details.

4. DATASET AND EVALUATION

Dataset. The models presented in this paper are trained on KernScores data [24], a collection of early modern, classical, and romantic era digital scores assembled by musicologists and researchers associated with Stanford's CCARH. [3] The dataset consists of over 2,300 scores containing approximately 2.8 million note labels. Tables 1 and 2 give a sense of the contents of the dataset.

We contrast this dataset's Humdrum encoding with the MIDI encoded datasets used by most works discussed in this paper. [4] MIDI was designed as a protocol for communicating digital performances, rather than digital scores. This is exemplified by the MAPS [6] and MAESTRO [8] datasets, which consist of symbolic MIDI data aligned to expressive performances. While this data is symbolic, it cannot be interpreted as scores because it is unaligned to a grid of beats and does not encode note-values (quarter-note, eighth-note, etc). Some MIDI datasets are aligned to a grid of beats, for example MusicNet [27]. But heuristics are still necessary to interpret this data as visual scores. For example, many MIDI files encode "staccatto" articulations by shortening the length of notes, thwarting simple rules that identify note-values based on length.

Evaluation. Let $\hat{q}$ be an estimate of the unknown probability distribution over scores q. We want to measure the quality of $\hat{q}$ by its cross-entropy to q. Because the entropy of a score grows with its length T, we will consider a cross-entropy rate. By convention, we measure time in units of beats, so the cross-entropy rate has units of bits per beat.

Defining cross-entropy for a continuous-time process generally requires some care. But for music, defining the cross-entropy on an appropriate discretization will suffice. Musical notes begin and end at rational fractions of the beat, and therefore we can find a common denominator d of all change points in the support of the distribution q (for our dataset $d = 48$). For a score of length T beats, we partition the interval $[0, T]$ into constant subintervals of length $\Delta \equiv 1/d$ and define a rate-adjusted, discretized cross-entropy

$$H_{\mathcal{P}}(q||\hat{q}) \equiv \mathop{\mathbb{E}}_{\mathbf{x}\sim q}\left[-\frac{1}{T\Delta}\log \hat{q}(\mathbf{x}_0, \mathbf{x}_\Delta, \mathbf{x}_{2\Delta}, \ldots, \mathbf{x}_T)\right]. \tag{6}$$

Proposition 1 in Appendix F shows that we can think of Δ as the resolution of the score process, in the sense that any further refinement of the discretization d yields no further contributions to the cross entropy.

Definition 6 is independent of any choice about how we factor q: it is a cross entropy measure of the joint distribution over a full score. As we discussed in Section 3, there are many ways to factor a generative model of scores. These choices lend themselves to different natural cross-entropies, each with their own units. By measuring in units of bits per beat at the process resolution Δ as defined by Definition 6, we can compare results under different factorizations.

[3] http://kern.ccarh.org/

[4] A notable exception is [16], which uses data derived from the KernScores collection considered here.

Computational cost. Raster models are expensive to train and evaluate on rhythmically diverse music. A raster model must be discretized at the process resolution Δ to generate a score with precise rhythmic detail. The process resolution Δ of a corpus containing both triplets and sixty-fourth notes is $\Delta = 3 \times 16 = 48$ positions per beat. Corpora with quintuplet patterns require a further factor of 5, resulting in $\Delta = 240$. To generate a score from a raster factorization requires Δ predictions per beat; to ease the computational burden of prediction, when the raster approach is taken scores are typically discretizing at either 1 or 2 positions per beat [2]. Unfortunately, this discretization well above the process resolution leads to dramatic rhythmically simplification of scores (see Appendix C).

In contrast, a sequential factorization such as (4) or (5) requires predictions proportional to the average number of notes per beat, while maintaining the rhythmic detail of a score. The KernScores single-voice corpus averages ≈ 1.25 notes per beat, requiring 1.25 predictions per beat for sequential factorization versus Δ predictions per beat for raster factorization. The KernScores multi-voice corpus averages ≈ 5 notes per beat, requiring 5 predictions per beat for sequential factorization, an order of magnitude less than the $\Delta \approx 50$ predictions per beat required for raster prediction.

5. MODELS AND WEIGHT-SHARING

Modeling voices allows us to think of the polyphonic composition problem as a collection of correlated single-voice composition problems. Learning the marginal distribution over a single voice v is similar in spirit to classical monophonic tasks. Learning the distribution over KernScores voices generalizes this classical task to allow for chords: formally, a monophonic sequence would require the vector $\mathbf{r}_{k,1} \in \{0, 1\}^N$ described in Section 3 to be one-hot, whereas our our dataset includes voices where this vector is multi-hot, expressing intervals and chords (e.g. chords in the left hand of a piano, or double-stops for a violin).

We will explore two modeling tasks. First we consider a single-voice prediction task: learn the marginal distribution over a voice v, estimating the conditionals that appear in the factorization (4). Results on this task are summarized in Table 3. Second we consider a multi-voice prediction task: learn the joint distribution over scores, estimating the conditionals that appear in the factorization (5). Results on this task are summarized in Table 4.

5.1 Representation

Like our choice of factorization, we are faced with many options for encoding the history of a score for prediction. Some of the same computational and modeling considerations apply to both the choice of a factorization and the choice of a history encoding, but these are not inherently connected decisions. For the single-voice task, we use the encoding $\mathbf{r}$ introduced to define the sequential voice factorization in Section 3.

For the polyphonic task, we also encode history using a run-length encoding. Let $c_1, \ldots, c_K$ denote change points in the full score $\mathbf{x}$, let $d_j^v \equiv (c_{j+1}^v - c_j^v)/\Delta \in \mathbb{N}$, and define

Bach	Beethoven	Chopin	Scarlatti	Early	Joplin	Mozart	Hummel	Haydn
191,374	476,989	57,096	58,222	1,325,660	43,707	269,513	3,389	392,998

Table 1. Notes in the KernScores dataset, partitioned by composer. The "Early" collection consists of Renaissance vocal music; a plurality of the Early music is composed by Josquin.

Vocal	String Quartet	Piano
1,412,552	820,152	586,244

Table 2. Notes in the KernScores dataset, partitioned by ensemble type.

a sequence $\mathbf{e} \in (\{0,1\}^{D+1} \oplus \{0,1\}^{P})^{K \times V}$ where

$\mathbf{e}_{k,v,0,0:D} = \mathbf{1}_{d_j^p}$ iff $c_k = c_j^v$ for some c_j^v in voice v,

$\mathbf{e}_{k,v,0,D} = 1$ iff c_k is not a change point in voice v,

$\mathbf{e}_{k,v,1,p} = 1$ iff pitch p begins in voice v at time c_k.

This is not the fully serialized encoding **s** used to define a score factorization (for discussion of a fully sequential representation, see [20]). At each time step k for which any voice exhibits a change point, we make an entry in **e** for every voice; we refer to $\mathbf{e}_k$ as a frame. This requires us to augment our alphabet of duration symbols D with a special continuation symbol that indicates no change (comparable to the onset bits in the encoding **x**). An advantage of this representation over sequential or raster representations is that more history can be encoded with shorter sequences.

For a fixed voice v, let $\tilde{\mathbf{r}} \equiv \mathbf{e}_{:,v}$ be a single-voice slice of the score history. Observe that $\tilde{\mathbf{r}} \neq \mathbf{r}$, where **r** is the run-length encoding used for the single-voice task. The slices $\tilde{\mathbf{r}}$ are spaced out with aforementioned continuation symbols where there are change points in other voices. With the single-voice encoding **r**, simple linear filters can be learned that are sensitive to particular rhythmic sequences: e.g. groups of four eighth notes, or three triplet-quarter notes. This is not the case for $\tilde{\mathbf{r}}$; rhythmic patterns can be somewhat-arbitrarily broken up by continuation symbols.

These observations might lead us to consider raster encodings for multi-voice history, which restore the effectiveness of simple linear filters at the cost of increasing the dimensionality of the history encoding. We find that recurrent networks for the single-voice task are unhampered when retrained on $\tilde{\mathbf{r}}$: compare experiments 21 and 22 in Table 3. Performance falls slightly when learning on $\tilde{\mathbf{r}}$, but this is to be expected because history interspersed with continuations is effectively a shorter-length history.

For both the single-voice and multi-voice tasks, we truncate the history at a fixed number of frames prior to the prediction time. We explore several history lengths in the experiments and observe diminishing improvement in quantitative results for windows beyond the range of 10-20 frames of **e**: see experiment group (1,2,6,7) in Table 4.

5.2 Single-voice models

Using factorization (4), we explore fully connected, convolutional, and recurrent models for learning the conditional distributions $q(\mathbf{r}_{k,0}|\mathbf{r}_{1:k})$ over note-values and $q(\mathbf{r}_{k,1,n}|\mathbf{r}_{1:k}, \mathbf{r}_{k,0}, \mathbf{r}_{k,1,1:p})$ over pitches. We build separate models to estimate $\mathbf{r}_{k,0}$ and $\mathbf{r}_{k,1,p}$, with respective losses Loss_t and Loss_n. In the remainder of this section, we consider opportunities to exploit structure in music by sharing weights in our models. Quantitative results for single-voice models are summarized in Table 3, with additional details available in Appendix A.

Autoregressive modeling. To build a generative model over conditionally stationary sequential data, it often makes sense to make the autoregressive assumption $q(\mathbf{r}_k|\mathbf{r}_{1:k}) = q(\mathbf{r}_{k'}|\mathbf{r}_{1:k'})$ for all $k, k' \in \mathbb{N}$. We can then learn a single conditional approximation $\hat{q}(\mathbf{r}_k|\mathbf{r}_{1:k})$ and share model parameters across all time translations.

Scores are not quite conditionally stationary; the distribution of notes and rhythms varies substantially depending on the sub-position within a beat. To address this, we follow the lead of [13] and [7] and augment our history tensor with a one-hot location feature vector ℓ that indicates the subdivision of the beat for which we are presently making predictions. [5] Compare the loss of duration models (Loss_t) with and without these features in experiment pairs (3,4), (6,7), (10,11), (12,13), and (15,16).

Relative pitch. We can perform a similar weight-sharing scheme with pitches as we did with time. Instead of building an individual predictor for each pitch conditioned on the notes in the history tensor, we adopt an idea proposed in [13]: build a single predictor that conditions on a shifted version of the history tensor centered around the note we want to predict. Convolving this predictor over the pitch axis of the history tensor lets us make a prediction at each note location, as visualized by Figure 1.

As with time, the distribution over notes is not quite conditionally stationary. For example, a truly relative predictor would generate notes uniformly across the note-class axis, whereas the actual distribution of notes concentrates around middle C. Therefore we augment our history tensor with a one-hot feature vector $\mathbf{1}_p$ that indicates the pitch p for which we are making a prediction. This allows us to take full advantage of all available information when making a prediction, while borrowing strength from shared harmonic patterns in different keys or octaves. We compare absolute pitch-indexed classifiers ($\mathbf{lin}_p$) to a single, relative pitch classifier (**lin**) in Table 3: compare the loss of pitch models (Loss_p) in experiment groups (2,3,4), (5,6,7), (8,9,10), (11,12,13), and (15,16).

Relative pitch models serve a similar purpose to key-signature normalization [17] or data augmentation via transposition [7]. Building this invariance into the model

[5] Location can always be computed from a full history. But we truncate the history, so this information is lost unless it is explicitly reintroduced.

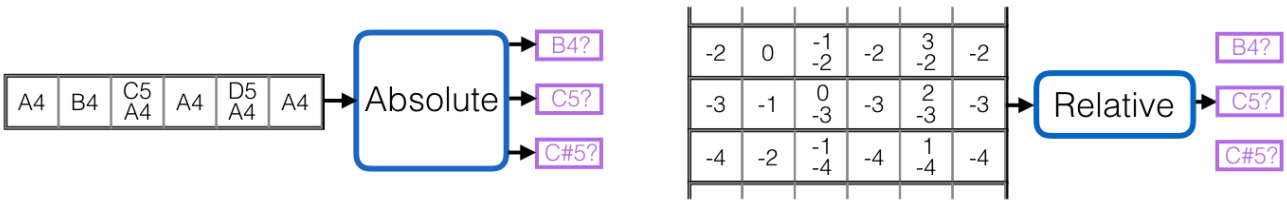

Figure 1. Left: an absolute pitch predictor learns individual classifiers for each pitch-class. Right: a relative pitch predictor learns a single classifier and translates the data along the frequency axis to center it around the pitch to be predicted. Whereas the absolute predictor decides whether C5 is on given the previous note was A4, the relative predictor decides whether the note under consideration is on given the previous note was 3 steps below it.

offers an alternative approach, avoiding data preprocessing or the introduction of hyper-parameters. We find that training with transpositions in the range ± 5 semi-tones yields no performance increase for relative pitch models.

Pitch embeddings. Borrowing the concept of a word embedding from natural language processing, we consider learned embeddings $\mathbf{c}$ of the pitch vectors $\mathbf{r}_{k,1}$ ($\mathbf{e}_{k,v,1}$ for the multi-voice models). For recurrent models, we do not see performance benefits to learning these embeddings: compare experiments 20 and 21 in Table 3. However, we do find that we can learn compact embeddings (16 dimensions for the experiments presented in this paper) without sacrificing performance, and using these embeddings reduces computational cost. We also find that using a 12 dimensional fixed embedding of pitches $\mathbf{f}$, in which we quotient each pitch class by octave, reduces overfitting for the rhythmic model while preserving predictive accuracy.

5.3 Multi-voice models

Using the factorization (5), we now explore ways to capture correlations between the voices and model the conditional distributions $q(\mathbf{s}_{k,0}|\mathbf{s}_{1:k})$ over note-values and $q(\mathbf{s}_{k,1,p}|\mathbf{s}_{1:k}, \mathbf{s}_{k,0}, \mathbf{s}_{k,1,1:p})$ over notes. We build separate models to estimate $\mathbf{r}_{k,0}$ and $\mathbf{r}_{k,1,p}$, with losses Loss_t and Loss_p in Table 4 respectively. The same structural observations that we made about scores for the single-voice models apply to multi-voice modeling; all multi-voice models considered in this paper use the three weight-sharing schemes considered for single-voice models. We explore an additional weight-sharing opportunity below for the multi-voice task: voice decomposition.

The effectiveness of recurrent models for the single-voice modeling task, and the representational considerations in Section 5.1, motivate us to consider extensions of the recurrent architecture to capture structure in the multi-voice setting. One natural extension of the standard recurrent neural network to model multiple, concurrent voices is a hierarchical architecture, illustrated in Figure 2:

$$
\begin{aligned}
h_{k,v}(\mathbf{e}) &\equiv \mathbf{a}\left(W_v^\top h_{k-1,v}(\mathbf{e}) + W_e^\top \mathbf{c}\left(\mathbf{e}_{k,v}\right)\right), \\
g_k(\mathbf{e}) &\equiv \mathbf{a}\left(W_g^\top g_{k-1}(\mathbf{e}) + W_{hv}^\top \sum_u h_{k,u}(\mathbf{e})\right).
\end{aligned} \tag{7}
$$

The first equation is a standard recurrent network that builds a state estimate $h_{k,v}$ of a voice v at time index k based on transition weights W_v, an input embedding $\mathbf{c}$, input weights W_e, and non-linear activation $\mathbf{a}$ (we use a ReLU activation). We integrate the state of each voice (weights W_{hv}) into a global state g_k given the previous global state g_{k-1} (weights W_g). Because voice order is arbitrary in our dataset, we sum (i.e. pool) over their states before feeding them into the global network. At each time k, we use the learned state of each voice together with the global state to make a note-value prediction: $\hat{\mathbf{s}}_{k,0} = \mathbf{lin}(h_{k,\beta_k}(\mathbf{e}), g_k(\mathbf{e}))$, where $\mathbf{lin}$ is a log-linear classifier. We make pitch predictions $\mathbf{s}_{k,1,p} \in \{0, 1\}$ using the same architecture. We learn a single, relative-pitch classifier for $\mathbf{s}_{k,1,p} \in \{0, 1\}$ in all multi-voice experiments

#	History	Arch	Loc?	Relative?	Pitch?	Embed?	Loss
1	$\mathbf{r}_{(1)}$	bias	no	no	no	no	10.07
2	$\mathbf{r}_{(1)}$	linear	no	no	no	no	8.05
3	$\mathbf{r}_{(1)}$	linear	no	yes	no	no	6.29
4	$\mathbf{r}_{(1)}$	linear	yes	yes	yes	no	6.12
5	$\mathbf{r}_{(1)}$	fc	no	no	no	no	5.92
6	$\mathbf{r}_{(1)}$	fc	no	yes	no	no	6.05
7	$\mathbf{r}_{(1)}$	fc	yes	yes	yes	no	5.70
8	$\mathbf{r}_{(5)}$	linear	no	no	no	no	7.91
9	$\mathbf{r}_{(5)}$	linear	no	yes	no	no	5.76
10	$\mathbf{r}_{(5)}$	linear	yes	yes	yes	no	5.63
11	$\mathbf{r}_{(5)}$	fc	no	no	no	no	4.90
12	$\mathbf{r}_{(5)}$	fc	no	yes	no	no	4.80
13	$\mathbf{r}_{(5)}$	fc	yes	yes	yes	no	4.69
14	$\mathbf{r}_{(5)}$	fc	yes	yes	yes	yes	4.63
15	$\mathbf{r}_{(10)}$	linear	no	yes	no	no	7.88
16	$\mathbf{r}_{(10)}$	linear	yes	yes	yes	no	5.53
17	$\mathbf{r}_{(10)}$	fc	yes	yes	yes	yes	4.55
19	$\mathbf{r}_{(10)}$	cnn	yes	yes	yes	yes	4.42
20	$\mathbf{r}_{(10)}$	rnn	yes	yes	yes	no	4.37
21	$\mathbf{r}_{(10)}$	rnn	yes	yes	yes	yes	4.36
22	$\tilde{\mathbf{r}}_{(10)}$	rnn	yes	yes	yes	yes	4.52

Table 3. Single-voice results. We define $\mathbf{r}_{(m)} \equiv \mathbf{r}_{k-m:k}$ (a truncated history of length m); $\tilde{\mathbf{r}}_{(m)}$ is defined likewise, based on the alternate encoding $\tilde{\mathbf{r}}$ discussed in Section 5.1, Representation. The Relative flag indicates the use of a relative-pitch classifier, and the Loc, Pitch, and Embed flags indicate the use of location features, pitch features, and pitch embeddings, discussed in Section 5.2. For additional details of these experiments, see Appendix A.

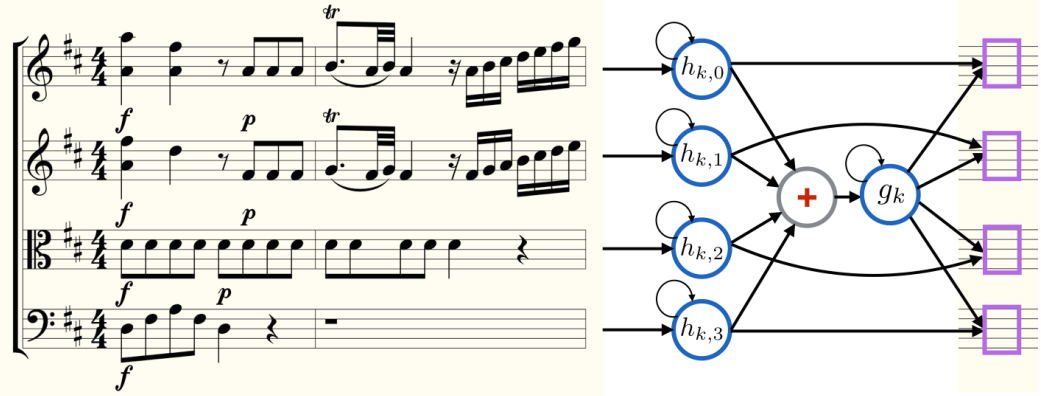

Figure 2. Coupled state estimation of Mozart's string quartet number 2 in D Major, K155, movement 1, from measure 1, rendered by the Verovio Humdrum Viewer. A recurrent network models the state $h_{k,v}$ of each voice v at step k, based on the previous state $h_{k-1,v}$ and the current content of the voice. Another recurrent network models of the global state g_k of the score at step k based on the previous global state g_{k-1} and a sum of the current states of each voice. Subsequent notes (purple) in each voice are predicted using features of the global state and the state of the relevant voice. See Equations 7 for a precise mathematical description of this model.

(section 5.2, Relative pitch). We do not share weights between the note-value and pitch models.

Voice decomposition. Decomposing a score into multiple voices presents us with an opportunity to share weights between voice models by learning a single set of weights W_v in equation (7), rather than learning unique voice-indexed weights W_{v_i} for each voice v_i. Indeed, because voice indices are arbitrary, the weights W_{v_i} will converge to the same values for all i; sharing a single set of weights W_v accelerates learning by enforcing this property. All score models presented in Table 4 share these weights.

#	History (voice/global)	Architecture	Loss (total)	Loss_t (time)	Loss_n (notes)
1	3 / 3	hierarchical	14.05	5.65	8.40
2	5 / 5	hierarchical	13.40	5.35	8.04
6	10 / 10	hierarchical	12.87	5.12	7.75
7	20 / 20	hierarchical	12.78	5.01	7.76
8	10	independent	18.63	6.56	12.08

Table 4. Multi-voice results. The "hierarchical" architecture is defined by equations (7). Voice and global history refer to the number of time steps used to construct the states $h_{k,v}$ and g_k respectively. Experiment 8 is a baseline where the voice models are completely decoupled (equivalent to single-voice Experiment 22 in Table 5; the average number of voices per score is 4.12). Results are reported on non-piano test set data (see Appendix B for discussion of piano data). For additional experiments and ablations, see Appendix A.

6. CONCLUSION

To gain insight into the quality of samples from our models, we recruited twenty study participants to listen to a variety of audio clips, each synthesized from either a real composition or from sampled output of Experiment 6 in Table 4. For each clip, participants were asked to judge whether the clip was written by a computer or by a human composer, following a procedure comparable to [21]. The clips varied in length, from 10 frames of a sample **e** (2-4 seconds; the length of history conditioned on by the model) to 50 frames (10-20 seconds). Participants become more confident in their judgements of the longer clips, but even among the longest clips (around 20 seconds) participants often identified an artificial clip as a human composition. Results are presented in Table 5; see Appendix E for further study details.

Clip Length	10	20	30	40	50
Average	5.3	5.7	6.6	6.7	6.8

Table 5. Qualitative evaluation of the 10-frame hierarchical model: Experiment 6 in Table 4. Twenty participant were asked to judge 50 audio clips each, with lengths varying from 10 to 50 frames. The scores indicate participants' average correct discriminations out of 10: 5.0 would indicate random guessing; 10.0 would indicate perfect discrimination.

These results superficially suggest that we have done well in modeling the short-term structure of the dataset (we make no claims to have captured long-term structure; indeed, the truncated history input to our models precludes this). But it is not clear that humans are good–or should be good–at recognizing plausible local structures in music without context. See [14, 22] for criticism of musical Turing tests like the one presented here. It is also unclear how to use such studies to make fine-grained comparisons between models (as we have done quantitatively throughout this paper). It is not even clear how to prompt a user to discriminate between such models. Therefore we re-emphasize the interpretation of this qualitative evaluation, proposed in Section 1, as a perceptual grounding of the quantitative evaluation considered throughout this work.

7. ACKNOWLEDGEMENTS

We thank Lydia Hamessley and Sreeram Kannan for sharing valuable insights. ABSTRACT

Assessing the potential success of a given song based on its acoustic characteristics is an important task in the music industry. This task has mostly been approached from an internal perspective, utilizing audio descriptors to predict the success of a given song, where either low- or high-level audio features have been utilized separately. In this work, we aim to jointly exploit low- and high-level audio features and model the prediction as a regression task. Particularly, we make use of a wide and deep neural network architecture that allows for jointly exploiting low- and high-level features. Furthermore, we enrich the set of features with information about the release year of tracks. We evaluate our approach based on the Million Song Dataset and characterize a song as a hit if it is contained in the Billboard Hot 100 at any point in time. Our findings suggest that the proposed approach is able to outperform baseline approaches as well as approaches utilizing low- or high-level features individually. Furthermore, we find that incorporating the release year as well as features describing the mood and vocals of a song improve prediction results.

1. INTRODUCTION

The task of predicting hit songs aims to infer the potential (commercial) success of a given song, possibly before the release of the song [18]. This is particularly interesting for the music industry as it allows to find potentially successful songs, promising songwriters and composers, to allocate budget for promotion, and to identify key elements that are pivotal for the success of a song. A natural next step would be the automatic generation of musical pieces which actually exhibit these features that have been shown to be crucial for success. To this end, the hit song prediction task has been tackled from two perspectives [12, 23]: an *internal* perspective, which relies solely on (musical) features extracted from the audio, and an *external* perspective, which models aspects of the musical ecosystem, for instance by incorporating social media or market data.

In this work, we take on the internal perspective, focusing on audio descriptors of a song to predict its success. While this might not capture all the aspects that are relevant for the musical success of songs (e.g., social media trends and events [25], psychological issues [18] or social influence [9, 20]), we believe that it is still an important problem that can be approached on its own and possibly enriched with external information at a later stage.

Approaches focusing on internal factors have mostly modeled hit prediction as a classification or regression problem solved by traditional approaches or, more recently, deep learning [23, 24]. The features used to characterize songs range from low-level Mel-Frequency Cepstral Coefficients (MFCC) [6], melodic features [8], temporal features [10], lyrics features [21] to high-level audio features describing e.g., the danceability of songs [7, 17]. While both of these feature types have been individually shown to contribute to hit prediction, they have yet to be exploited jointly for this task.

Recently, Demetriou *et al*. [5] have investigated the most influential features when it comes to users liking or disliking a song in a user study. They have shown that the most significant features of a song are its ability to evoke emotions, vocals of the singer, beat and rhythm and the lyrics. Along these lines, we are particularly interested in investigating whether these features are also influential in the task of hit song prediction. Interiano *et al*. [12] have shown that audio descriptors relevant for the success of a song change over time and that musical fashion is rather short-lived, rendering it hard to exploit past data to predict future trends. Despite approaches to predict the release year of songs based on acoustic features [2] and the use of temporally weighted regression methods to account for changing features over time [7], this fact has not yet been explicitly explored for hit song prediction. Incorporating release year information into our hit song prediction approach to reflect the dynamics of success on the music market is another distinguishing feature of this work.

Consequently, we shed light on the following two research questions (RQ) in this study:

RQ1: How can we predict hit songs based on acoustic features extracted from the song's audio in a deep learning scenario?

RQ2: Which role do individual features (or groups of features) and the release year of a song play in this task?

To answer these research questions, we model the prediction of hit songs as a regression task. We extract low-

and high-level features from the audio of each track and feed these into a deep neural network architecture, where low-level features are fed into the deep part of the network to distill dense representations thereof, whereas high-level features are fed into the wide part of the network to be utilized directly. This also allows feeding the release year of a song into the network as a high-level feature. Utilizing the dense computed dense representations of low-level features in combination with high-level features, we subsequently compute a regression task to predict a track's peak ranking position.

The contribution of this paper lies in the following aspects: (i) we present a novel regression approach towards hit song prediction using neural networks which combines wide (high-level) and deep (low-level) acoustic features; (ii) we show that mood and vocals (the features identified as being crucial when it comes to liking and disliking a song [5]) are also of high relevance for the hit prediction task; (iii) we show that adding the release year as a high-level feature allows for further improvements, implying that contextualizing the song temporally is important due to the short-lived trends in music [12]; (iv) this is the first work that utilizes solely data from the public domain for this task. For reproducibility and to encourage follow-up research along this line, we also make public the data underlying our experiments [1] .

The remainder of this paper is structured as follows. Section 2 provides information about the dataset underlying our analyses. Section 3 details our proposed approach towards the prediction of hit songs. Section 4 presents the experiments we conducted and the results obtained. Section 6 concludes this paper and discusses future work.

2. DATASET

We base our experiments on the widely used and freely available Million Song Dataset (MSD) [2], which contains one million songs that are representative for western commercial music released between 1922 and 2011. The dataset contains release year information for 515,576 of the MSD songs [2]. As we are interested in the impact of the release year information on hit song prediction quality, we constrain our dataset to those songs that we can obtain the release year information for. In contrast to previous studies on hit song prediction, our dataset fully stems from the public domain. Please refer to Table 1 for an overview of the datasets utilized in existing work and their availability.

To extract low- and high-level audio features for every song, we rely on representative 30 seconds samples for each of the songs in the Million Song Dataset. We make use of the Essentia framework [3] to extract low- and high-level features from the audio (cf. Section 3.1 for details) and dropped all songs in the MSD where we could not determine all those features.

Moreover, our approach requires distinguishing between hits and non-hits of musical success [15]. Along the lines of previous research [13, 21], we define a song as successful if it is featured in the weekly Billboard Hot 100 [2] at least once. Therefore, we crawl the Billboard Hot 100 from the according website for the years 1954 until 2018. To find songs in the Billboard Hot 100 matching the songs contained in the Million Song Dataset, we compare both the artist name and track title for each song pair in the two sets and only consider exact matches as hit songs. After that, we dropped duplicates (determined based on artist name and track title). This provides us with a set of 5,832 hit songs and hence, positive samples for which we extract their highest rank in the charts. For negative samples (and hence, non-hits) sampled from the MSD, it is important to ensure that they are not accidentally hits. Hence, we used to following procedure based on the set of songs for which we have release year information and Essentia features. Firstly, we compute a fuzzy matching ratio [3] between all MSD songs and the set of hit songs by concatenating the artist name and track title with a delimiter and selecting the best matching pairs thereof. Based on this matching procedure, we gather a pool of non-hits where the title fuzzy matching ratio is less or equal than 40. We determined this threshold by preliminary experiments and manually inspecting results. We only consider the title ratio here as it is possible that an artist has multiple further songs, that we nevertheless aim to include in our set of possible non-hits and hence, we do not include artist similarity in this computation. The resulting dataset contains a substantially higher number of non-hits (89,235) than hits (5,832), hence it is highly imbalanced (6.1% positive vs. 93.9% negative instances). To overcome this imbalance, we decided to randomly draw 5,832 samples from the pool of non-hits to get a balanced dataset for our experiments.

Paper	Data	PD	AV

3. HIT SONG PREDICTION

In this section, we detail our approach on hit-song prediction. We first present the features utilized to characterize songs and then detail the neural network-based approach.

3.1 Song Features

Previous research in the field of hit song prediction has relied on utilizing either low- or high-level features of songs.

[1] https://doi.org/10.5281/zenodo.3258042

[2] https://www.billboard.com/charts/hot-100

[3] The ratio of matching tokens between the two strings is based on Levenshtein distance as implemented by Python's fuzzywuzzy library.

Category	Features
mood	acoustic, aggressive, electronic, happy, party, relaxed, sad [14]; Hu and Downie's 5 clusters of mood [11]
genre	blues, classic, country, disco, hip-hop, jazz, metal, pop, reggae, rock [22]
voice	voice, instrumental, female voice, male voice
rhythm/beat	bpm, beats count, bpm histogram, beats loudness, beats loudness band ratio, onset rate, danceability
chords	chords strength, chords change rate, chords number rate, chords key, chords scale, harmonic pitch class profile, tuning strength and frequency

Table 2. Feature categories and the Essentia features each category contains.

Low-level features allow capturing acoustic descriptors like loudness, dynamics, and spectral shape of a signal, rhythm descriptors or tonal information [19]. In contrast, high-level features are computed from low-level feature models and capture abstract concepts such as mood, genres, vocals or music type [19]. In this work, we aim to combine those two types of features. The intuition here is that while low-level features allow for a detailed description of the acoustic characteristics of a song, high-level features complement this detailed view with abstract concepts such as mood or danceability, resulting in a more holistic description of a song.

Based on the dataset presented in Section 2, we propose to extract low- and high-level features based on a given MP3 file of a song containing a 30 seconds preview. Particularly, we make use of the Essentia toolkit [19], a well-established and widely used extraction library for audio descriptors. For the extraction of low-level features, we rely on Essentia's pre-compiled extractors [4], which provide a variety of spectral, time-domain, rhythm, and tonal descriptors. This provides us with 40 basic features (e.g., MFCCs, dissonance or silence rate), 11 rhythm features (e.g., beats per minute or onset-rate) and 13 tonal features (e.g., key or harmonic pitch class profiles) that serve as low-level input for our task.

For high-level features, we again rely on Essentia and utilize the provided pre-trained high-level classification models [5] to compute high-level features based on the low-level features previously extracted. These features include musical genre, mood, timbre, vocals/voice, or danceability.

In this work, we hypothesize that features identified as salient in users liking/disliking a song [5] are also relevant for the task of hit song prediction. To assess the relative importance of these different features, we rely on the categories of features proposed by Demetriou *et al*. [5] and perform a matching between Demetriou's categories of features and our dataset's features. As our approach is based on internal features only, we are not able to match all of Demetriou's categories (e.g., lyrics). We argue that this is still a valid approach as this work is focused on internal aspects of a song. We hence make use of the following feature categories: mood, genre, voice, rhythm/beat, and chords. The first three contain solely high-level features computed by Essentia, whereas the latter two stem from both Essentia's low- and high-level features. Table 2 shows the assignment of individual low- and high-level features to those categories. As previous research has shown that musical fashion and trends are highly dynamic and short-lived [12], we are also interested in the impact of information about the release year of a song. The idea here is that providing temporal context in terms of the release year of a song can contribute to improved prediction performance as the characterization and embedding of the song is improved. Hence, we extract the release year information for each song from the Million Song Dataset and treat it as a high-level feature.

3.2 Regression Wide and Deep Network

The core idea of our approach is to combine low- and high-level acoustic features to characterize tracks as those two types of features capture different aspects and characteristics of a track (on different levels of abstraction). Given the differences between these two feature types in terms of the amount of features, complexity, and diversity, we aim to reflect this in the architecture of the neural network used for hit prediction. Therefore, we utilize a network architecture inspired by the structural concept of the Wide and Deep network architecture by Cheng *et al*. [4]. While our proposed solution is in fact quite different from the original model [6], we believe that the distinction and notion of deep and wide features describes our scenario well. Hence, we will nevertheless use this notion of wide and deep features and the corresponding network parts.

Figure 1 presents an overview of the proposed network architecture. This architecture allows training a wide linear model alongside a deep neural network while distinguishing two types of features: wide features can be regarded as abstract, high-level features that can directly be used for further computation, whereas deep features in the deep part of the network are used to learn dense, lower-dimensional representations of input features. In our scenario, low-level features can be considered deep features, whereas high-level features are wide features. Based on the wide features and the computed dense representations of the deep features, we aim to perform a regression task for predicting the peak position a song will reach in the charts. This can also be used to distinguish hits and non-hits by using any position larger than 100 as a threshold value. As for the implementation of the deep part of the network, the goal here

[6] The original wide and deep approach was designed for a recommendation scenario, where the wide part is used to model user-item co-occurrences and the deep part is used to learn low-dimensional latent descriptors of queries and items.

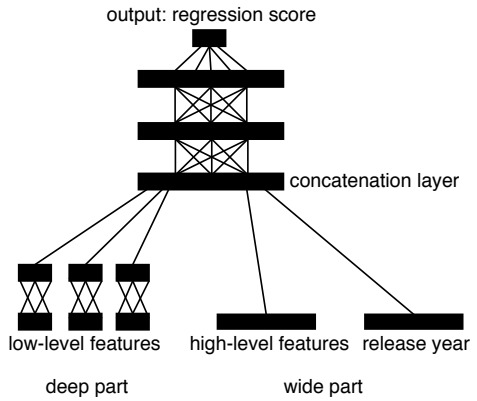

Figure 1. The wide and deep network architecture employed for hit song prediction.

is to use the sparse low-level features as input and to compute meaningful dense representations of audio descriptors to be processed further.

Low-level features comprise a variety of different feature formats: e.g., aggregations of frame-based features across the song or per-frame values for a set of frequency bands—rendering a sparse, complex set of feature representations, where also the computed individual values stem from a broad range. Practically speaking, our approach has to be able to cope with nested input features of varying size, complexity and value ranges. We chose to flatten these input arrays into one-dimensional arrays that can be fed into the deep part of the network.

The purpose of the deep part of the network is to aggregate feature vectors to a one-dimensional representation of the original input features, which are subsequently fed into the regression part of the network. We create multiple groups of low-level features corresponding to the feature categories and their components presented in Table 2. Each group is then fed into a single feature aggregation block (FAB) in the deep part of the network. We chose to model each FAB as a dense layer utilizing a sigmoid activation function as this has been shown to be effective for feature selection in deep neural networks [16]. The input size is chosen to fit the number of values in the feature group and the output size is one. This results in a single value per feature group which is the newly computed higher-level representation of this group. The resulting features computed by the FABs in the deep part of the network are subsequently merged with the features that we feed into the wide part of the network. This concatenation (merge) layer is followed by two dense layers with batch normalization and a ReLU activation function. These two dense layers have the same size as the concatenation layer. To ultimately compute the final result of the regression task, we add another dense layer with output size one and no activation function to ensure that the computed result is in the desired range of possible ranking positions (1–150).

Each high-level feature is represented by classes, where each class is assigned a probability value (range $[0, 1]$). In the special case of two complementing classes such as danceable and not danceable, we chose to only use one of these two probabilities (in the above example, the probability of a song being danceable) to model this feature. We use the resulting values as input for the wide part of the neural network. Feeding categorical values such as the tonal key into the network is realized by previously converting them to a one-hot encoded vector representation. Further, it should be mentioned that we normalized all input (feature) values to the range $[0, 1]$ using a min-max-scaler. Feeding the release year into the neural network is realized by adding another high-level feature (normalized to $[0, 1]$).

4. EXPERIMENTS AND RESULTS

Here, we first present the experimental setup used and secondly, we present and discuss the results obtained.

4.1 Experimental Setup

We base our experiments on the dataset presented in Section 2 and experiment with two different regression tasks: predicting the highest rank of a song in the Billboard Hot 100. For non-hits, we set the highest rank achieved to 150. We chose to use a ranking of 150 to describe non-hits to make the difference between hits and non-hits in terms of ranking more explicit based on preliminary experiments. Due to the high imbalance of hit and non-hit instances in the dataset, we chose to randomly downsample the negative class to achieve balanced classes [7]. Subsequently, we applied five fold cross validation on the remaining instances.

We trained the proposed network architectures with mean squared error (MSE) as loss function and a batch size of 32. The neural network was implemented based on Tensorflow [1], utilizing Keras. As optimizer, we used the adaptive learning rate optimization algorithm, Adam. As for the number of epochs used for training the network, we experimented with values between 10 and 200. All input data is scaled to $[0, 1]$. As we experimented with a wide variety of different setups, training epochs, etc., we utilized a grid search approach to determine the best configuration and present the best obtained results in Section 4.2. Naturally, the underlying network was trained and optimized individually for each input feature set. For the evaluation and comparison of the proposed regression approaches, we use root mean squared error (RMSE) and the mean absolute error (MAE). To also derive a measure of how well these approaches perform when it comes to actually predicting hit songs, we also present the accuracy values for each approach. These were computed based on the results of the regression computation and classifying all tracks with a predicted ranking of less than 100 as hits and a predicted ranking larger than 100 as non-hits. However, we consider this two-class classification an easier task than the regression task based on the actual ranking. Here, we argue that the accuracy evaluation allows us to get an intuition on how

[7] Manual inspection showed that the release year distribution of the test- and training datasets are comparable.

well the regression results may be used to generally distinguish hits from non-hits.

To assess the relative importance of feature classes, we base our evaluation on the following classes, combinations thereof and the combination of individual features stemming from those classes:

- **LL**: basic low-level acoustic features as presented in Section 3.1.
- **LL-filtered**: a subset of the low-level feature set that we have identified as highly relevant in our preliminary feature selection experiments [8]. We argue that pre-selecting a smaller feature set contributes to both runtime and performance (cf. Section 4.2 for results).
- **chords**: chords features as presented in Table 2, extracted from low-level Essentia features.
- **rhythm**: rhythm and beat features as presented in Table 2, extracted from low-level Essentia features.
- **HL**: all high-level acoustic features, information about the release year of the track, including the following sub-categories: **voice**, **mood**, **genre** and **release year** (cf. Table 2 for details on the contained features).

Please note that depending on the feature set utilized, we adapt the way we utilize the neural network accordingly—i.e., for the low-level feature set, we utilize the deep part of the proposed neural network only, whereas, for the high-level feature set, we utilize the wide part of the network only and for any combination of high- and low-level features, we exploit both parts of the full wide and deep network.

We propose to conduct two experiments to answer our research questions: Experiment 1 aims to assess the performance of the proposed wide and deep network architecture. Therefore, we utilize the proposed low-level features in the deep part of the network and the proposed high-level features in the wide part of the network aiming to show that the proposed architecture achieves superior results than (i) a linear regression baseline as well as (ii) utilizing the two parts of the network individually, relying solely on either low- or high-level features. Based on the results of Experiment 1, Experiment 2 aims to investigate the relative importance of individual feature subsets in the wide and deep neural network. To do so, we experiment with different feature sets (low- and high-level) and compare their prediction performance.

As baselines to compare our approach to, we chose to utilize traditional linear regression [9], which we apply to the same feature sets.

[8] Feature set comprises: dissonance, spectral features (centroid, spread, skewness, kurtosis, flatness db, flux, rolloff, decrease, energy), low energy ratio, avg. loudness, barkbands, erbbands, melbands, MFCCs and HFCs.

[9] We experimented with a number of linear regression algorithms (e.g., ridge, lasso or elastic net regularization), where linear regression obtained the best results.

Approach	RMSE	MAE	Acc.
HL (wide)	57.11	48.50	72.08%
LL-filtered+chords+rhythm (deep)	63.94	54.15	65.50%
LL, chords, rhythm (deep)	60.82	52.09	66.94%
HL+LL-filtered+chords+rhythm (wide + deep)	56.05	45.12	74.23%
HL+LL+chords+rhythm (wide + deep)	**55.45**	**43.84**	**75.04%**
HL (baseline)	58.10	50.38	71.01%
LL-filtered+chords+rhythm (baseline)	223.20	57.68	65.97%
LL+chords+rhythm (baseline)	8.54×10^{9}	7.92×10^{6}	68.47%
HL+LL-filtered+chords+rhythm (baseline)	504.90	52.98	72.56%
HL+LL+chords+rhythm (baseline)	6.4110^{9}	5.95×7^{9}	73.91%

Table 3. Results for highest rank prediction on full feature sets. Both the values of RMSE and MAE are the lower the better; the best results are printed in bold font.

4.2 Results and Discussion

In the following, we discuss the findings of the two experiments conducted.

Experiment 1 aimed to investigate the performance of the wide and deep parts of the network individually but also combined in a full wide and deep architecture. Here, we deliberately include all low- and high-level feature sets proposed. Table 3 depicts the results of this experiment. As can be seen, the proposed wide and deep network approach outperforms the baseline approaches across all evaluation measures. This approach achieves the lowest RMSE and MAE values of 55.45 and 43.84 when relying on all low-level features. Using the filtered set of low-level features reaches an RMSE of 56.05 and an MAE of 45.21. When inspecting the results of the network-based approaches that utilize solely either low- or high-level features (which we also consider as representative baseline methods), we observe that utilizing solely high-level features provides us with reasonable results, suggesting that high-level features indeed capture the abstract characteristics of songs well. In contrast, utilizing only low-level features achieves higher RMSE and MAE values. These observations our initial hypothesis as we find that the combination of low- and high-level features is indeed able to substantially outperform approaches utilizing these feature sets individually. The linear regression baseline approaches in the bottom half of the table achieve the best results when utilizing solely high-level features (MAE of 50.38).

When inspecting the accuracy evaluation, we can observe that the highest accuracy value of 75.04% is achieved by the proposed network approach, again utilizing both high- and low-level features. Interestingly, for the linear regression baselines, while RMSE and MAE values are substantially higher than our proposed approach, we can observe that accuracy values are within a reasonable margin, albeit still lower than the proposed wide and deep approach. We lead this discrepancy back to the fact that we assign non-hits a rank of 150. The observed error measures suggest that the predicted ranks computed by linear regression are very high, leading to such high error margins. This is particularly the case when utilizing the full set of low-level features, holding a substantially higher set of features and hence, posing a more complex regression task. However, given the reasonable accuracy results and

the fact that the regression model indeed seems to capture the distinction between hit- and non-hit songs well (with a wide margin between predicted rankings for hits and non-hits) and hence, can be considered a reasonable baseline. To conclude and to answer RQ1, our experiments show the proposed wide and deep neural network-based approach combining low- and high-level features is a suitable approach towards hit song prediction.

Experiment 2 aimed to analyze the relative importance of individual features and classes thereof. Therefore, we evaluated different feature sets in the proposed wide and deep network. As the LL basic features have shown to outperform the filtered set of basic low-level features, we restrain the results presented here to the full low-level feature set. Please note that due to space constraints, we only list the best performing and informative configurations and their obtained results.

For low-level features (including chords and rhythm features), we hardly find differences in their performance (across all combinations with high-level features). Differences in RMSE and MAE between different feature variations are very subtle and do not show a clear pattern regarding best performing features. We conclude that neither chords nor rhythm features are particularly pivotal for hit song prediction. Hence, in the following, we restrain the presented results to the full set of low-level features (LL-filtered, chords, rhythm). Table 4 depicts the results of these analyses.

For high-level features, we can observe that year information profoundly contributes to the prediction performance, improving every experiment by 12–13%, when added to set of high-level features. This confirms our hypothesis that due to short-lived fashion and trends in the music industry, embedding songs in their temporal context by adding release year information allows modeling these dynamics efficiently for hit song prediction. Furthermore, we can observe that—along the lines of Demetriou *et al*. [5]—voice, mood, and genre features are also important for this task. Our experiments show that the combination of high-level features improves RMSE and MAE; the best results are obtained when utilizing low-level, rhythm, and chords features in combination with release year, voice, mood and genre features (hence, the full feature set). Inspecting the performance of single HL features (such as e.g., mood) in combination with low-level features shows that year has the highest impact on the evaluation measures, with genre, mood and voice leading to higher error measures. Combining those high-level features, however, allows to substantially increase performance in all evaluated measures. While the differences between these different feature sets are partly subtle, the patterns detected are stable across all our experiments. To answer RQ2, we find that the release year information is the most important high-level feature. Our experiments also show that voice and mood descriptors contribute to the hit prediction task, which is in line with previous findings regarding salient features in regards to whether people like or dislike a song.

Features LL	Features HL	RMSE	MAE	Acc.
LL, rhythm, chords	year, voice, mood, genre	**55.45**	**43.84**	**75.04%**
LL, rhythm, chords	year, genre	55.93	45.80	73.84%
LL, rhythm, chords	year, mood	57.12	45.66	73.55%
LL, rhythm, chords	year, voice	56.63	46.04	72.04%
LL, rhythm, chords	genre	64.14	52.84	65.11%
LL, rhythm, chords	mood	61.77	52.82	67.92%
LL, rhythm, chords	voice	61.18	52.50	68.00%
LL, rhythm, chords	year	57.51	46.35	72.29%
LL, rhythm, chords	year, mood, voice	56.22	45.53	74.46%
LL, rhythm, chords	year, genre, mood	57.35	45.38	73.63%
LL, rhythm, chords	year, genre, voice	56.06	45.66	73.60%

Table 4. Results for highest rank prediction on feature sets (best results are printed in bold font).

5. LIMITATIONS

We acknowledge that our dataset and our definition of a successful song are biased towards western, commercial music. While we believe that this approach is legitimate, it remains to be shown that our approach can be extended to other types of music and possibly other characterizations of success. However, we believe that due to using audio features, the approach taken is generalizable. Another limitation is the prevalent problem of class imbalance among hits and non-hits as the current setting does not reflect the real distribution of classes. We aim to experiment with unbalanced distributions between hits and non-hits as part of our future work to perform the evaluation in scenario that captures the real-world distribution better. Furthermore, our approach takes an internal perspective based on the audio signal to characterize the track and to predict its success. Here, we have to acknowledge that this model naturally does not include any external factors such as information about the artist (e.g., whether he/she has been on the charts before), marketing strategies of music labels or the relation with special events (e.g., songs being played at Super Bowl).

6. CONCLUSION

In this paper, we have presented a novel approach for the task of hit song prediction. Particularly, we propose to combine low- and high-level audio features of songs in a deep neural network that distinguishes low- and high-level features to account for their particularities. Our experiments on the Million Song Dataset suggest that the combination of these two types of features in the proposed network architecture can indeed improve the prediction performance. Furthermore, we find that incorporating the release year of songs into the wide part of the network allows for temporally contextualizing songs and hence, reflecting musical trends and fashions. In addition, we can show that mood and voice are salient features for this task. Future work includes experimenting with more complex network architectures to allow for improved feature selection and the computation of latent features within the network as well as analyzing and utilizing those features that distinguish hits from non-hits.

ABSTRACT

This paper focuses on Cover Song Identification (CSI), an important research challenge in content-based Music Information Retrieval (MIR). Although the task itself is interesting and challenging for both academia and industry scenarios, there are a number of limitations for the advancement of current approaches. We specifically address two of them in the present study. First, the number of publicly available datasets for this task is limited, and there is no publicly available benchmark set that is widely used among researchers for comparative algorithm evaluation. Second, most of the algorithms are not publicly shared and reproducible, limiting the comparison of approaches. To overcome these limitations we propose Da-TACOS, a DaTAset for COver Song Identification and Understanding, and two frameworks for feature extraction and benchmarking to facilitate reproducibility. Da-TACOS contains 25K songs represented by unique editorial metadata plus 9 low- and mid-level features pre-computed with open source libraries, and is divided into two subsets. The Cover Analysis subset contains audio features (e.g. key, tempo) that can serve to study how musical characteristics vary for cover songs. The Benchmark subset contains the set of features that have been frequently used in CSI research, e.g. chroma, MFCC, beat onsets etc. Moreover, we provide initial benchmarking results of a selected number of state-of-the-art CSI algorithms using our dataset, and for reproducibility, we share a GitHub repository containing the feature extraction and benchmarking frameworks.

1. INTRODUCTION

Cover songs play an important role in the history of recorded music. Weinstein [42] argues that cover songs are peculiar to rock music, and some iconic early rock bands, like The Beatles, The Rolling Stones and Led Zeppelin, recorded cover songs at the beginning of their careers. Artists from other genres eventually followed this trend of reinterpreting recorded musical works. More recently, audio and video online streaming platforms have given rise to a great volume of fan versions of numerous original songs, including so-called "Youtube covers". Cataloguing and tracking cover versions of songs are important both from a historical and a legal standpoint, since there is sometimes a fine line between creative license and plagiarism [22]. However, this task often requires automation via content-based MIR strategies due to the explosion of recordings across many repositories.

Automatic Cover Song Identification (CSI) systems must contend with the myriad changes of musical facets that can occur among versions. While cover songs may share some musical characteristics, such as melody, harmony or chord progression, they are not identical musical works. According to Serrà [28], one can categorize musical transformations between cover versions into 8 main groups: timbre (due to production techniques and/or due to instrumentation), tempo, timing, structure, key, harmonization, lyrics and noise. Given this, the vast majority of CSI systems focus solely on the tonal content [3, 8, 31, 33, 35], a characteristic thought to be least altered between a song and its cover versions. Such systems work on top of features which are invariant to these transformations, incorporating techniques such as beat-synchronous features [12] to control for changes in tempo, or Optimal Transposition Index (OTI) [29] to control for changes in key.

In spite of Serrà's taxonomy and intuition about what makes a cover, to our knowledge, there are no large-scale studies quantifying the extent to which the aforementioned musical attributes change among cover versions. Furthermore, a variety of CSI algorithms have been designed under different assumptions about what makes a cover, each with different goals and trade-offs in mind, but the community lacks a large-scale open source dataset to compare their performance; the largest benchmark set to date is the SecondHandSongs dataset (SHS), a subset of the Million

Song Dataset [4], with 18,196 songs but this contains proprietary features. Motivated by both of these problems, we propose a new dataset, which we call "Da-TACOS"; a DaTAset for COver Song Identification and Understanding (Section 3). This dataset consists of 25,000 songs with a variety of audio descriptors, including low level features such as frame level HPCPs/MFCCs, beat onsets, and higher level information such as key, tempo, and audio tags. We then split our collection of songs into two subsets. The *Cover Analysis subset* is used to quantify what makes a cover by looking at changes in key, local onset deviation, tempo, rhythm, and audio tag descriptions (Section 4). In our analyses, we also introduce some tools not previously seen in the MIR community, such as ShapeDNA [25] and topological time series analysis [26]. The *Benchmark subset* is used for detailed benchmarking of a set of representative CSI algorithms selected across years of work on this topic (Section 5). After we set the stage with our preliminary experiments, we expect this dataset will enable researchers to continue to explore both the *what is a cover* question and *benchmarking* in more detail.

2. RELATED WORK

Most CSI systems have 3 main building blocks [23]: feature extraction, feature post-processing, and similarity estimation. An extensive review of the traditional cover song identification systems can be found in Serrà et al. [30]. In this section, we present a brief overview of these building blocks, the datasets for this task, and the observed limitations of current approaches.

Traditional CSI systems begin with low level feature extraction from the audio. The most common audio descriptors used in those systems are Pitch Class Profiles (PCP), or Chroma features, which represent the tonal content of songs via the octave-folded energies for each of the 12 pitch classes used in Western music theory. The task at hand informs which strategy is chosen, and to improve robustness, different variants of Chroma features [31, 34] were used in the CSI literature for this task. Moreover, many audio descriptors such as pitch salience [27], chord profiles [16], self-similarity MFCC [39], cognition-inspired descriptors [2] were also utilized; however, they suffer from lower performance scores in isolation compared to PCPs.

After the feature extraction, several feature post-processing steps can be applied to achieve invariances in several musical facets such as key, tempo and structure. Key invariance can be obtained using OTI [29] or the 2D Fourier Transform Magnitude (2DFTM) coefficients of the tonal features [14]. Beat-synchronous features are used to achieve tempo invariances [12, 38]. Similarity Matrix Profile (SiMPle) [35], which is a "representation of the similarity join between subsequences", can be useful to control for structural invariance or to obtain audio thumbnails of songs which can be later used to estimate the similarity of two songs [34].

The final step of this general CSI system framework is the similarity estimation. For certain representations, e.g. 2DFTM, this step may consist of only a simple distance function such as Euclidean or Cosine distances. However, for more accurate smaller scale algorithms, a quadratic alignment algorithm is often used to obtain tempo or structural invariance. Since global alignments between versions don't often exist in practice, CSI researchers put more emphasis on the Local Alignment methods such as Smith-Waterman algorithm [36] that is designed to detect alignments among all possible subsequences by incorporating local constraints. Depending on these constraints, many versions of this algorithm were proposed, e.g. *Qmax* [31] and *Dmax* [8]. The longest alignment is taken as the cover similarity measure/distance generally after normalizing it to the length of the reference track.

A number of previous works also explored combining different features and similarity measures to improve their systems. Salamon et al. [27] combine the distance values obtained with *Qmax* for melody, accompaniment and bass line. Chen et al. [8] use a technique called Similarity Network Fusion (SNF) [41] to integrate the similarity matrices obtained with *Qmax* and *Dmax* for the final similarity estimation. Tralie [38] uses SNF to combine cross-similarity matrices obtained with using HPCP and MFCC features to get a final similarity score.

Over the years, new methods were proposed by the MIR community to solve specific problems of the CSI task; however, due to the O(N^2) complexity of local alignment algorithms, some have focused on alternative algorithms that scale better. With the introduction of the SHS dataset [4], techniques such as audio fingerprinting [3], database pruning strategies [24] and multi-modal approaches [10] were also explored in the literature. But the performance scores of these scalable approaches obtained for SHS were not satisfactory. Thus, a trade-off between efficiency and robustness exists in the CSI task as well as in many other MIR tasks, and the "Holy Grail" algorithm for CSI that is both scalable and robust is still missing.

Although a large amount of previous works exist for CSI task, there are only a few public datasets available for benchmarking. Covers80, released by Ellis [13], contains 80 cliques, or cover groups, with 2 songs per clique. Although small in terms of size, this dataset includes audio files of the songs, which provides an opportunity for developing new features or fine-tuning the existing feature extraction algorithms. The YoutubeCovers dataset [33] contains 50 cliques with 7 songs per clique, and instead of audio files, pre-computed Chroma, CENS and Chroma DCT-Reduced log Pitch (CRP) features are included in this dataset. SHS is a subset of Million Song Dataset, and it contains pre-computed features extracted with EchoNest API [1] for 12960 songs in 4128 cliques for the training subset and 5236 songs in 726 cliques for the test subset [4]. Although comparatively larger in size, SHS comes with features pre-computed with proprietary algorithms which makes it impossible to reproduce or even use other audio descriptors for the CSI task.

Based on the limitations of current CSI systems and dif-

[1] http://the.echonest.com/

ficulty in comparing them, we propose a new dataset, and public frameworks for feature extraction and benchmarking to give CSI research a uniform direction. Our contributions can be summarized as follows:

- The largest benchmark set with 15,000 songs including state-of-the-art audio features for CSI
- The Cover Analysis subset with 10,000 songs for musicological studies
- First large-scale quantitative analysis on modified musical characteristics
- Open Source frameworks for feature extraction and benchmarking specifically created for the CSI task
- Open Source implementations of seven state-of-the-art systems and their initial benchmarking results

3. DA-TACOS: DATASET FOR COVER SONG IDENTIFICATION

For facilitating benchmarking and providing a set of analyses regarding links among cover songs, here, we propose a new dataset for CSI research. Da-TACOS, a DaTAset for COver Song Identification and Understanding, contains commercial or live recordings of 25,000 songs that are distributed into 2 subsets: the *Cover Analysis subset* and the *Benchmark subset* with 10,000 and 15,000 songs, respectively. The song annotations are collected from SecondHandSongs.com [2], and are licenced under Creative Commons BY-NC 3.0 [3]. Metadata for each song includes song title, name of the performer, original song title, name of the original writer and release year.

We have also matched the original metadata with MusicBrainz [4] [37] to obtain the MusicBrainz ID (MBID), length and genre tags. Most songs belong to rock, pop, metal and jazz genres. The average length of songs in the dataset is 3.59 minutes.

Along with the metadata, we share low- and mid-level features pre-computed with open source feature extraction libraries from MIR community; a comprehensive list can be found in Table 1. To increase the reliability of our results and assist future works, we share a common feature extraction framework, with which we obtained the feature values, in our GitHub repository.

In particular, Da-TACOS addresses two needs of the current state of CSI research. First, in Section 2, we mentioned the difficulty of benchmarking CSI systems, and with this dataset, we take a step toward tackling this challenge. We provide a large set of pre-computed features that have been constantly used in CSI research, and we provide initial benchmarking results of a selected number of state-of-the-art CSI systems. Second, to our knowledge, our benchmark subset is the largest dataset to date for comparing the performances of CSI systems. We see this as an opportunity to scale up CSI research to discover methods that are more likely to be used in real world scenarios. We believe that having a large dataset for benchmarking will have a positive effect on the direction of future research for this task.

Table 1. List of features provided in each subsets of Da-TACOS and the related feature extraction libraries used.

3.1 The Cover Analysis subset

Our first subset is dedicated to a series of analyses to understand the changes in musical characteristics when a new version of a song is created. This subset includes 10,000 songs in 5,000 cliques, a pair of cover songs for each clique. Out of all songs, we were able to match 6,821 songs with a MBID. The information regarding feature extraction and results of our analyses can be found in Section 4.

3.2 The Benchmark subset

The second subset of Da-TACOS is designed for benchmarking purposes. This subset includes total of 15,000 songs: 13,000 songs in 1000 cliques with 13 songs each, and 2,000 songs that do not belong to any clique, acting as noise in the data. For this subset 10,027 songs have MBIDs, and an initial benchmark of a selected set of CSI systems can be found in Section 5.

4. WHAT IS A COVER?

In this section, we exploit the features to explore the frequency and intensity of a subset of Serrà's [28] posited changes between cover versions. The analyses below are performed on the Cover Analysis subset of Da-TACOS. While key and tempo are straightforward to compare, we devise custom distance measures to compare timing, structure, and semantic aspects, e.g. instrumentation, genre. In these latter cases, we compare distributions of the corresponding distances between true cover pairs in this subset to all other non-cover pairs in the subset. To quantify the extent to which the true cover and non-cover distributions differ in these cases, we report the 2-sample Kolmogorov-Smirinov (KS) score, with its associated p-value, which indicates the statistical significance of the difference between two distributions.

4.1 Results

4.1.1 Key

Using a key estimation algorithm [15], we considered all pairs with both songs exceeding a confidence of 0.75,

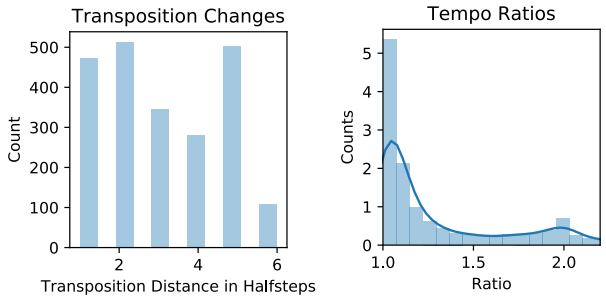

Figure 1. (Left) Distribution of halfsteps between key estimates for cover pairs with a reported key change. (Right) Distribution of tempo ratios between cover pairs.

which was 4288/5000 pairs. Among these, 69.3%, were reportedly in a different key. The distribution of said halfstep shifts is shown in Figure 1. Thus, the use of OTI in many CSI algorithms is justified. One caveat is that the key estimation algorithms report a single estimate which is either major or minor. Under this scheme, the key estimation algorithm reported that 17.5% of the pairs shifted from major to minor. However, upon spot checking, it was clear that many of these examples either switched keys at different times, or they were in modes beyond major and minor. In the absence of more sophisticated algorithms, expert ear trained individuals would be needed to determine how often changes beyond simple transpositions occur.

4.1.2 Tempo

We now examine tempo ratios between cover pairs by picking out the tempo with the maximum confidence from a state-of-the-art tempo estimator [6]. The right of Figure 1 shows the results. There is a slight peak around 2 which is likely due to "octave errors" from pieces which can be subdivided into 4/4. Beyond that, at the first quartile is a 1.03x change in tempo, in the second quartile is a 1.11x change in tempo, and in the third quartile is a 1.53x change in tempo. Thus, half of the songs are quite stable, but in the 50-75% quartile, we have a fair number of songs with a significant tempo change which can't easily be explained by a direct tempo doubling mistake, and which are likely "real." Hence, tempo is often a factor which needs to be controlled for when analyzing cover versions.

4.1.3 Structure

One particularly successful approach to multiscale music structure analysis uses eigenvectors of the Graph Laplacian, or "spectral clustering" [19]. While one can compare agreement of this technique to that of human annotators on the same piece of music [18], this representation does not immediately extend across versions of songs. We instead use the eigen*values* of the Graph Laplacian, which we stack up into a Euclidean vector which can be compared across songs. This has been referred to as "Shape DNA" in the context of 3D shape analysis of triangle meshes [25]. In our case, we use feature fused SSMs [40] downsampled to a common dimension of 256×256, followed by 30 eigenvalues of a random walk Laplacian.

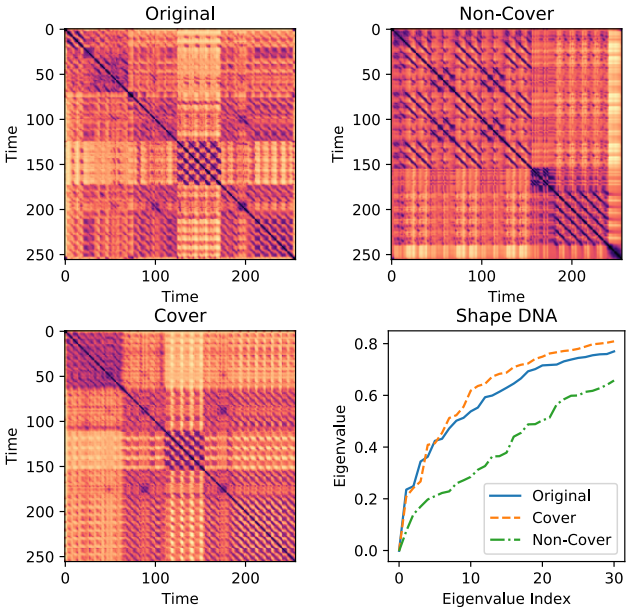

Figure 2. An example of fused similarity matrices of "The Wizard" by Uriah Heep (upper left), a cover by Blind Guardian (lower left), and "Million Pieces" by The Piano Tribute Players (upper right), which is unrelated. The corresponding Shape DNAs are shown in the lower right.

Figure 2 shows an example of Shape DNA between a pair of covers and a third, unrelated song. Even though the cover pairs' similarity matrices do not align perfectly and contain other variations, their shape DNAs are close, while they are both different from an unrelated song with a different structure. Figure 3 shows the distributions of shape DNA differences between true cover and non-cover pairs. The KS score between the two distributions is 0.22 ($p \ll 0.001$), indicating that while large structural changes do occur between cover versions (e.g. added/deleted sections), it is overall more likely for cover songs to share structure than random pairs of songs.

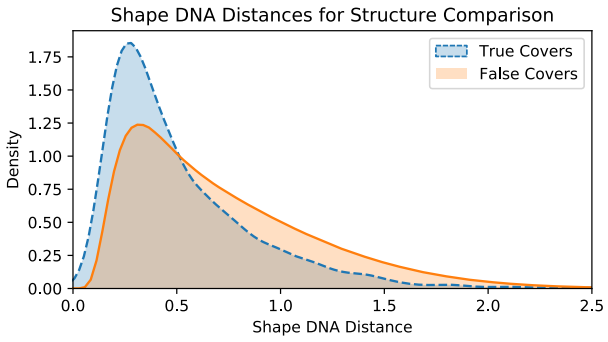

Figure 3. Distributions of shape DNA differences between pairs of songs as a means of assessing structural changes.

4.1.4 Timing

We now turn to timing, which we define as local changes in tempo over time. We first extract N beat onset estima-

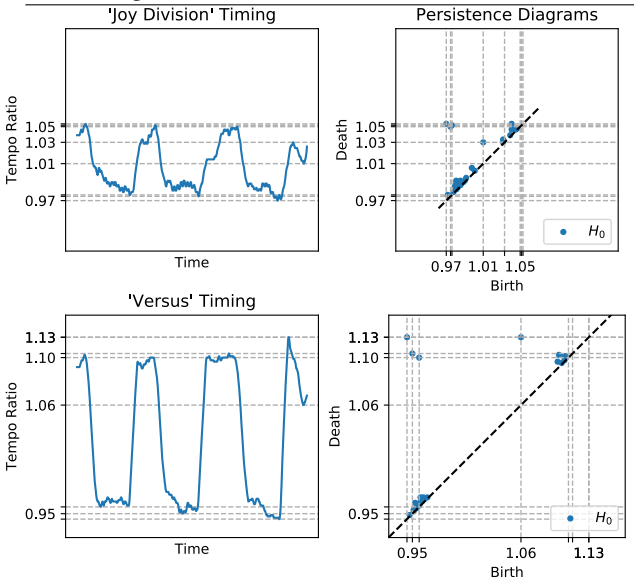

Figure 4. An example of $r[t]$ functions and their associated persistence diagrams for the song "24 Hours" by Joy Division and Versus. Both songs speed up in the chorus and slow down in the verse, so they each contain several local mins with high persistence which are born during the verses. They each also contain some low amplitude wobbling which shows up as dots near the diagonal.

tion times $b[t], t = 1, 2, \ldots N$ using the technique of Krebs [17], down to a resolution of 10 milliseconds. We then extract unit-less local tempo estimates by convolving $b[t]$ with a Gaussian derivative $b'[t] = b[t] * (-te^{-t^2/2})$, followed by a sliding window average of width 20 to smooth out noise. Finally, we divide $b'[t]$ by its median to obtain a relative, tempo-normalized local tempo deviation $r[t]$; $r[t] > 1$ if a song has sped up locally, and $r[t] < 1$ if it has slowed down locally.

The left column of Figure 4 shows $r[t]$ for two different versions of the same song. Note the multi-scale features of $r[t]$, from small wobbles in tempo to large changes that persist over a section. To capture all scales in one distance measure which can tolerate missing beats and added/deleted sections, we turn to the "lower star filtration," a watershed method from topological data analysis [11]. This summarizes a time series in a "persistence diagram"[5] (PD). This has been used, for instance, on speed time series of drivers to quantify driving behavior [26].

The right column of Figure 4 shows PDs for the $r[t]$ functions for an example cover pair, with the birth and death values of the points with 4 largest "persistence" (death-birth) marked. To compare PDs between two different songs, we use persistence images [1], which transform a diagram into birth-persistence space and place a Gaussian over each point, whose magnitude is proportional to the persistence. Figure 5 shows the distributions of Euclidean distances between peristence images for true cover

[5] A multiset of points whose x-coordinates correspond to local mins where pools of water form as water rises from bottom to top ("birth events"), and and whose y-coordinates correspond to local maxes paired to these mins where two pools merge together ("death events")

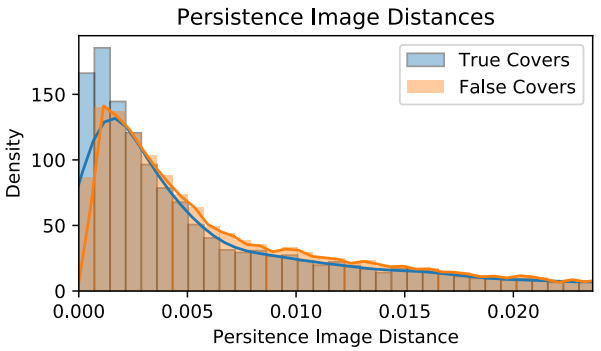

Figure 5. Distribution of persistence image distances of lower star filtrations relative tempo functions between pairs of songs.

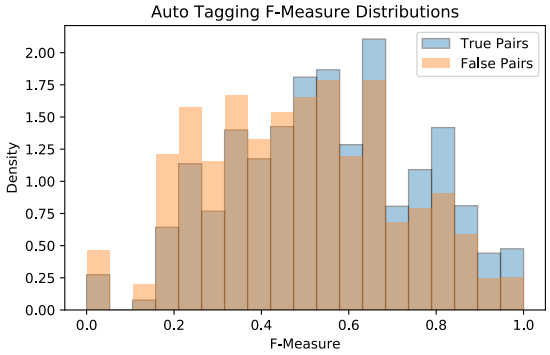

Figure 6. Distributions of f-measures for auto tagging for true cover pairs and non-cover pairs.

pairs and non-cover pairs. Though the distributions are quite similar, the KS score is 0.095 ($p \ll 0.001$), indicating that though relative timing can be different (as evidenced by Figure 4 where one song speeds up more in the chorus relative to the other), the difference is less for covers than for random pairs.

4.1.5 Semantic Aspects

To analyze semantic aspects of the songs such as mood, instrumentation and "genre" without explicitly defining them, we turn to auto tagging techniques of Choi et al. [9] which use log-mel spectrograms as input to return a set of tags which qualitatively describe the songs. Since the auto tagger returns many tags with low confidence, we only take tags which are in the 90$^{\text{th}}$ percentile over all confidences, which is a confidence value of 0.062. If p is the fraction of tags in song A contained in the set of tags for song B, and r is the fraction of tags in song B contained in the tags for song A, then the *f-measure* between two songs is defined as $2pr/(p + r)$, which is 1 if they are in complete agreement and 0 if they have nothing in common. Figure 6 shows the distribution of f-measures between true cover and non-cover pairs. While the distributions are overall quite similar, the f-measures are skewed slightly lower for non covers. The KS score between the two distributions is 0.118 ($p \ll 0.001$), indicating these two distributions are

different by more than chance; thus, we can conclude that although less frequent than between two random songs, stylistic changes occur between cover pairs.

5. BENCHMARKING

As mentioned in Section 3, Da-TACOS contains a benchmark subset of 15,000 songs for comparative algorithm evaluation. In this section, we present the results on seven different state-of-the-art algorithms on this data. To the best of our knowledge, this is the first work comparing these algorithms for CSI on a publicly available, large-scale dataset with features obtained with open source algorithms.

5.1 Methodology

One of the main limitations of current CSI research is the lack of a public framework to compare the performance of different systems. We acknowledge that the audio cover song identification task in the Music Information Retrieval Evaluation eXchange (MIREX) [6] addresses this. However, MIREX data is not publicly available, and it restricts the evaluation to a limited time window per year. According to the results from previous MIREX, [32] is still an algorithm which may be considered in the state-of-the-art CSI system. We chose to benchmark six other unsupervised algorithms which more recently presented good results on CSI for comparison in this competition [8, 14, 31, 35, 38, 39]. In their original implementations, these algorithms differ with the features used, a large scale or small scale design goal, their ability to combine distance measures or fusing more than one feature set [8, 38], exploitation of network structure of songs [8, 38], the application of beat-synchronous features [14, 38, 39], or a combination of these properties. In our work, we have the opportunity to control for implementation details that can greatly impact performance [20] both by sharing features across all algorithms, and by using common implementations of some sub-algorithms, including OTI, Similarity Network Fusion (SNF) [41] (for [38] and [8]), and QMax alignment [31].

5.2 Results

The empirical evaluation of CSI algorithms is another point in which published papers differ greatly. Commonly, different authors use different subsets of evaluation measures. For this reason, we used a large number of evaluation measures assessing the results, namely Mean Rank (MR), Mean Reciprocal Rank (MRR), Median Rank (MDR), Mean Average Precision (MAP), and the counting of correctly identified versions in top 1 and top 10.

In addition to using HPCPs as Chroma features for all the algorithms, we also use CREMA chord model features [18], sampled at the same rate, as a drop-in replacement for Chroma on all algorithms.

Table 2 presents the results obtained by all the algorithms considered in our evaluation, with a simplified version of Tralie's early fusion [38] which uses a weighted average in the early fusion stage instead of SNF for speed.

		MR	MRR	MDR	MAP	Top 1	Top 10
FTM2D [14]	H	207	0.314	15	0.126	3954	6131
	C	155	0.523	1	0.275	7185	9072
Simple [35]	H	358	0.362	13	0.165	4916	6361
	C	142	0.555	1	0.332	7739	9391
Dmax [8]	H	155	0.562	1	0.292	7939	9320
	C	134	0.571	1	0.322	7981	9611
LateFusion [8]	H	210	0.604	1	0.410	8761	9880
	C	177	0.621	1	**0.454**	8897	10223
Qmax [31]	H	119	0.606	1	0.333	8630	9931
	C	113	0.611	1	0.365	8625	10212
Qmax* [32]	C	**104**	0.619	1	0.373	8766	10246
SSM [39]	M	434	0.273	39	0.096	3540	5139
EarlyFusion [38]	H	116	**0.680**	1	0.426	**9843**	**10861**
	C	120	0.672	1	0.416	9667	10829

Table 2. Performance statistics of all algorithms. H stands for HPCP, C for CREMA and M for MFCC.

Overall, we find the CREMA improves results over HPCP, which suggests an adoption of CREMA for future research. We are particularly surprised at how well the large-scale FTM2D algorithm performs with CREMA.

6. CONCLUSION

In this work, we have presented a new public dataset, Da-TACOS, for analyzing how a number of musical facets vary among cover songs and benchmarking CSI systems. Our "what is a cover" analysis takes Serrà's [28] categories of modifiable musical characteristics as a basis, and the results demonstrate large variations between cover pairs across all of the aspects we examined, which supports Serrà's claims on the subject. However, the same analyses among non-cover pairs show a larger variation than cover pairs, and this can be interpreted as there are some links remaining among cover songs.

Moreover, we created a framework that includes open source implementations of seven state-of-the-art unsupervised CSI algorithms to facilitate the future work in this line of research. Using this framework, researchers can easily compare existing algorithms on different datasets, and we encourage all CSI researchers to incorporate their algorithms into this framework in order to support Open Science principles. Our feature extraction and benchmarking frameworks as well as instructions to can be found in our GitHub repository [7].

Our future work includes constructing several other subsets based on various characteristics of songs (e.g. subsets based on genre and release year), as well as training sets for supervised algorithms, to identify the further needs of CSI research. We believe that a better understanding of the relationships among cover songs is valuable both for musicological aspect of this line of research and for advancing the state of the art in CSI research.

HARMONIC SYNTAX IN TIME RHYTHM IMPROVES GRAMMATICAL MODELS OF HARMONY

ABSTRACT

Music is hierarchically structured, both in how it is perceived by listeners and how it is composed. Such structure can be elegantly captured using probabilistic grammatical models similar to those used to study natural language. They address the complexity of the structure using abstract categories in a recursive formalism. Most existing grammatical models of musical structure focus on one single dimension of music–such as melody, harmony, or rhythm. While these grammar models often work well on short musical excerpts, accurate analysis of longer pieces requires taking into account the constraints from multiple domains of structure. The present paper proposes abstract product grammars–a formalism which integrates multiple dimensions of musical structure into a single grammatical model–along with efficient parsing and inference algorithms for this formalism. We use this model to study the combination of hierarchically-structured harmonic syntax and hierarchically-structured rhythmic information. The latter is modeled by a novel grammar of rhythm that is capable of expressing temporal regularities in musical phrases. It integrates grouping structure and meter. The combined model of harmony and rhythm outperforms both single-dimension models in computational experiments. All models are trained and evaluated on a treebank of hand-annotated Jazz standards.

1. INTRODUCTION

Music is hierarchically organized, which is probably most evident in the structure of harmonic sequences. Grammatical models of music describe both local and non-local relations between musical objects such as notes or chords by assuming a latent hierarchical structure. Originally inspired by Schenkerian analysis and generative linguistics [9], grammatical models have been used in music theory [14, 19, 24, 25], computational musicology [1, 5, 6, 13, 16, 27], music information retrieval [3, 4, 12, 18, 26], and increasingly also music psychology [7, 20]. Consider for example the Jazz chord sequence C^6 D^7 Dm^7 G^7 C^6 of the A-part of the Jazz standard *Take the A-Train*. A hierarchical analysis of this sequence is shown in Figure 1a. The progression D^7 Dm^7 G^7 forms a *dominant phrase* inside the *tonic phrase* C^6 D^7 Dm^7 G^7 C^6, exhibiting a non-local harmonic relationship between the chords D^7 and G^7. The nesting of the phrases moreover illustrates the idea of how pieces can be decomposed into hierarchically-structured constituents (subtrees) which stand in part-whole relationship with one another [6]. Figure 2 displays a typical case of a non-local harmonic relation in Jazz harmony.

To analyze hierarchical harmonic structures, music theorists make use of many additional structural features such as melody, rhythm, voice-leading, and form, for disambiguation. From this perspective, the latent harmonic structure of a piece cannot be fully inferred from sequences of chord symbols alone. Most existing grammatical models of harmony, however, do not take these other domains of musical structure in account. In this paper, we propose a novel formalism that combines models of different musical features. The mathematical idea is similar to Coupled-context-free Grammars [17]. We extend that approach by a probabilistic model and apply the general construction to improve models of harmonic syntax by incorporating harmonic rhythm.

1.1 Problem Setting

Existing grammatical models of harmony typically do not capture how harmonic structure is laid out in time [21], as shown in Figure 1a. This analysis captures information such as the dependencies between different kinds of musical phrase (tonic, dominant, subdominant), ordering, and hierarchical constituency, but contains no information on the duration of chords. This paper extends models of harmonic syntax to include rhythmic structure illustrated in Figure 1b. This figure shows how the musical phrases in Figure 1a are laid out in time by progressively assigning constituents to a metrical grid consisting of eight measures. The inclusion of the metrical domain reveals previously hidden structure. In the first step, the root of the harmonic tree is assigned to the entire eight bars. In the second step, the tonic phrase is split into equal halves which are assigned to bars 1-4 and bars 5-8 of the metrical grid. In the third step, the second half of the piece is split into equal halves, introducing a V in the first part of the split

and limiting the tonic scale degree to the second part. The fourth step, in contrast, splits the first half (measures 1–4) into two and assigns the second half of this split to the second half of the progression (measures 5–8). Measures 3 and 4 are said to be a *harmonic upbeat* to measures 5 and 6. In the following, we present an integrated model of harmony and phrase rhythm [22] that accounts for the structural differences of the steps three and four. Note that we therefore assume the existence of hypermeter, the extension of metrical structures within a single measure to relations between measures [11].

We propose an approach that models the upbeat and the downbeat of harmonic constituents separately. Figure 1c shows a hierarchical analysis integrating harmonic syntax and harmonic rhythm. In this notation, the durations of upbeats are separated from the durations of downbeats by the symbol $\oplus$. The symbol $\ominus$ is used to indicate the "time stealing" from generation step 3 in Figure 1b.

2. GRAMMATICAL MODELS

2.1 Abstract Context-Free Grammars

The following two definitions are adopted from [6], where further explanation and examples can be found.

A *(non-probabilistic) Abstract Context-free Grammar* $G = (T, C, C_0, \Gamma)$ consists of a set T of *terminal symbols*, a set C of *constituent categories*, a set of *start categories* $C_0 \subseteq C$, and a set of partial functions

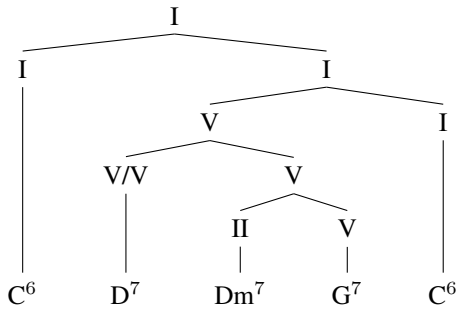
$$\Gamma := \{\, r \mid r : C \nrightarrow (T \cup C)^* \,\}, \tag{1}$$

called *rewrite rules* or *rewrite functions*. The arrow $\nrightarrow$ is used throughout the paper to denote partial functions and $\mathrm{dom}(r)$ denotes the set of arguments for which a partial function r is defined. A sequence $\beta \in (T \cup C)^*$ can be generated from a sequence $\alpha \in (T \cup C)^*$ by one *rule application* of a rewrite function $r \in \Gamma$, denoted by $\alpha \longrightarrow_r \beta$, if there exist $\alpha_1, \alpha_2 \in (T \cup C)^*$ and $A \in C$ such that $\alpha = \alpha_1 A \alpha_2$ and $\beta = \alpha_1 r(A) \alpha_2$. A sequence of rewrite rules $r_1 \dots r_n$ is called a *derivation* of a sequence of terminals $\alpha \in T^*$ if there exists a start category $\alpha_1 \in C_0$, and $\alpha_2, \dots, \alpha_n \in (C \cup T)^*$ such that

$$\alpha_1 \longrightarrow_{r_1} \alpha_2 \longrightarrow_{r_2} \cdots \longrightarrow_{r_n} \alpha, \tag{2}$$

where r_i is always applied to the leftmost category of α_i for $i \in \{1, \dots, n-1\}$. The set of derivations of α is denoted by $D(\alpha)$. The language of the grammar G is the set of terminal sequences that have a derivation in G.

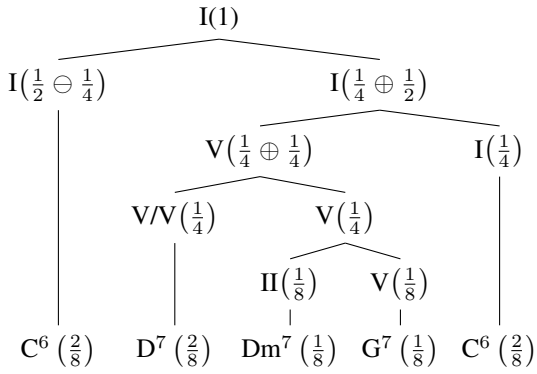
A *Probabilistic Abstract Context-free Grammar* is an Abstract Context-free Grammar where each category $A \in C$ is associated with a random variable X_A over rewrite functions r such that the probability $\mathbb{P}(X_A = r)$ is positive if and only if $r(A)$ is defined, that is $A \in \mathrm{dom}(r)$. In the following, we also use the notation $p(r \mid A) = \mathbb{P}(X_A = r)$ and $p(A \longrightarrow_r \alpha) = \mathbb{P}(X_A = r)\ \mathbb{1}(r(A) = \alpha)$. The probability $p(d)$ of a derivation $d = r_1 \dots r_n$ of a sequence of terminal symbols $\alpha \in T^*$ is defined as the product $\prod_{i=1}^{n} \mathbb{P}(r_i \mid A_i)$ where in each step r_i is applied to a category $A_i \in C$. The probability of α is then defined as $p(\alpha) = \sum_{d \in D(\alpha)} p(d)$.



(a) Generative syntax tree of the harmonic structure. The leafs of the tree are the chord symbols of the A-part. The internal nodes show scale degrees with respect to C major as latent categories. Subtrees form harmonic constituents. The nested structure of the subtrees shows how complex constituents are build from simpler constituents [6].

1:	I							
2:	I				I			
3:	I				V		I	
4:	I		V/V		V		I	
5:	I		V/V		II	V	I	
6:	C^6		D^7		Dm^7	G^7	C^6	

(b) Schematic generation of the chord sequence including their metrical positions. Each row consists of 8 measures and shows one step in the generation process. Chords are tied over following "empty" measures. The third and the fourth step show the two basic kinds of harmonic preparation with respect to their metrical placement. In step three, the preparation of the I by the V pushed the I back by two measures while in step four, the preparation of V by V/V protrudes into the time domain of the preceding I.



(c) Generative syntax tree of the harmonic structure with integrated rhythmic information. The numbers in parentheses denote the duration of the constituents relative to the whole progression. The branch I(1) $\longrightarrow$ I($\frac{1}{2} \ominus \frac{1}{4}$) I($\frac{1}{4} \oplus \frac{1}{2}$) is an instance of a split that anticipates the upbeat preparation of G^7 by D^7. Because of a 2 measures long upbeat, the left child is 2 measures shorter and the right child is 2 measures longer than in a preparation without an upbeat.

Figure 1: Hierarchical analysis of the A-part of the Jazz standard *Take the A-Train* in C major, considering the structural domains of harmony and rhythm.

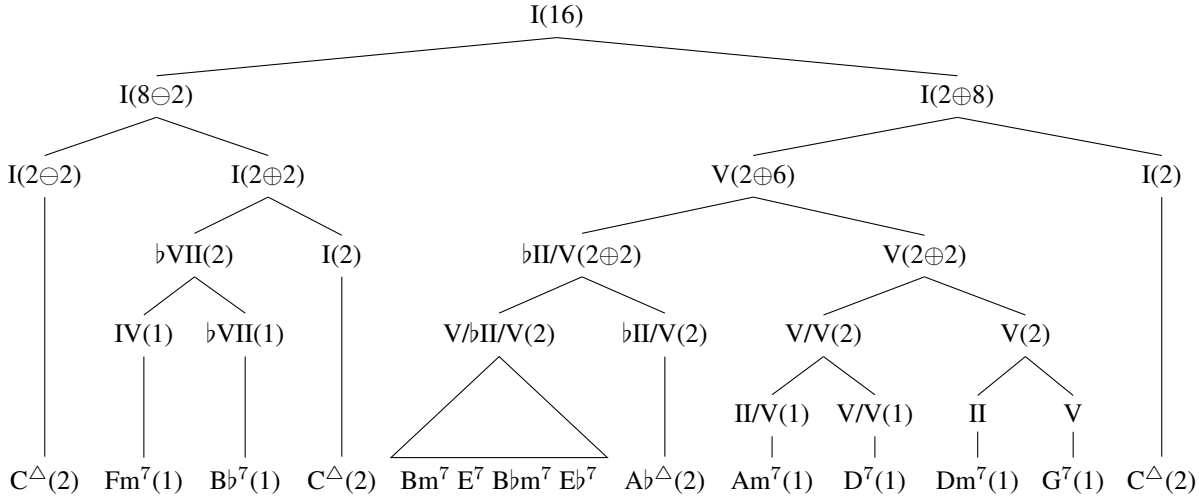


Figure 2: Hierarchical analysis of the Jazz standard *Half Nelson*, integrating harmonic and rhythmic structure. In this tree, a duration of 1 corresponds to one measure for the sake of readability (the whole tune spans 16 measures). The non-local dependency between the chords $A\flat^{\triangle}$ and G^7 constitutes a characteristic harmonic relation of the tune.

2.2 Product Grammars

This paper proposes to improve generative grammar models of harmony by forming a product of a harmony grammar and a rhythm grammar.

Let $G = (T, C, C_0, \Gamma)$ and $G' = (T', C', C'_0, \Gamma')$ be two PACFGs and let $\mathrm{ar}(r)$ denote the *arity* of a rule r, which is defined as the length of its right-hand side. The *product grammar*

$$G \bowtie G' = (T \times T', C \times C', C_0 \times C'_0, \Gamma \bowtie \Gamma') \quad (3)$$

is constructed from the Cartesian products of the sets of terminals, categories, and start categories. The rewrite functions of $G \bowtie G'$ are all pairs of functions of equal arity,

$$\Gamma \bowtie \Gamma' = \{\, (r, r') \in \Gamma \times \Gamma' \mid \mathrm{ar}(r) = \mathrm{ar}(r') \,\}. \quad (4)$$

For a product category $(A, A') \in C \times C'$ and rewrite functions $r \in \Gamma$ and $r' \in \Gamma'$ of equal arity, the application of (r, r') to (A, A') is defined component-wise,

$$(r, r')(A, A') = (r(A), r'(A')). \quad (5)$$

By abuse of notation, the right-hand side of this equation does not stand for a pair of sequences, but a sequence of pairs. The probability of a product rule application is defined as the product of the probabilities of the rule application components,

$$p((r, r') \mid (A, A')) = p(r \mid A)\, p(r' \mid A'). \quad (6)$$

That is, the choice of rule r is set to be independent of A' and r', and the choice of r' is independent of A and r in the generative process.

A helpful intuition of product grammars is that they compute the intersection of two sets of derivation trees for a sequence. The derivation trees of the grammar $G \bowtie G'$ are exactly those which are derivations in both G and G' if the labels of the trees (terminals and categories) are ignored. The probability of a derivation in $G \bowtie G'$ is then also equal to the product of its corresponding derivations in G and G'.

2.3 Rhythm Grammar

2.3.1 Full Rhythm Grammar

A *rhythmic category* $a \oplus b$ consists of two rational numbers $a \in \mathbb{Q}$ and $b \in \mathbb{Q}$ such that $0 \leq a$, $0 < b$, and $a + b \leq 1$. The first number a is called the *upbeat* and the second number b is called the *downbeat* of the category. The intuition behind the symbol $\oplus$ is that the total length of a rhythmic category equals the sum of its two components, $\lambda(a \oplus b) := a + b$, where λ is the function that denotes the length of the rhythmic constituent as a proportion of the overall piece, which is fixed to be the unit $1 \in \mathbb{Q}$. The condition $0 \leq a$ forbids negative upbeat parts, $0 < b$ ensures positive category lengths, and $a + b \leq 1$ ensures that no category is longer than the whole piece. For convenience, we use two additional short-hand notations: a category with no upbeat is denoted by the length of its downbeat, $b = 0 \oplus b$. The category of a rhythmic constituent that loses a portion c of its downbeat (formerly with length b) to the upbeat of the following rhythmic constituent is denoted by $b \ominus c := 0 \oplus (b - c)$. In this case $\lambda(b \ominus c) = b - c$, too.

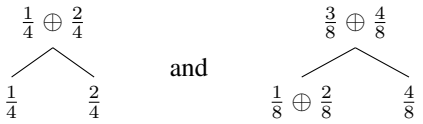
The start category of the rhythmic grammar is 1, the length of the piece, and any category with zero upbeat is allowed to be a terminal (leaf node). The essential grammar rules are given by two families of rewrite functions, one family of partial functions for splitting the upbeat components of categories $\texttt{usplit}_v : C \nrightarrow C^*$ and one family of total functions for splitting the downbeats $\texttt{dsplit}^u_v : C \to C^*$,

$$\begin{aligned} \texttt{usplit}_u(a \oplus b) &:= ((1-u)a \oplus ua) && (0 \oplus b) \\ \texttt{dsplit}^v_w(a \oplus b) &:= (a \oplus (1 - v - vw)b) && (vwb \oplus wb), \end{aligned} \quad (7)$$

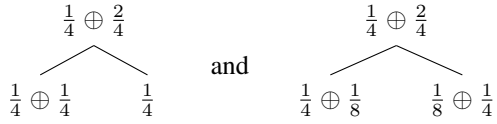
where $u, v, w \in \mathbb{Q}$ such that $\frac{1}{2} < u \leq 1$ and $a > 0$ in the first equation, and $0 \leq v < 1$ and $0 < w < 1$ in the second equation. The parameter u represents the downbeat

proportion of the upbeat, v is the upbeat proportion of the second category of a downbeat split, and w is the downbeat proportion of the second category of a downbeat split.

In other words: The upbeat split rule $\texttt{usplit}_u$ separates the upbeat from the downbeat and optionally splits the upbeat again into a new upbeat and downbeat. For example for $u = 1$ and $u = \frac{2}{3}$:



In contrast, the downbeat split $\texttt{dsplit}_w^v$ ignores the upbeat and splits the downbeat. It optionally introduces a new upbeat preparation. For example for $v, w = 0, \frac{1}{2}$ and $v, w = \frac{1}{2}, \frac{1}{2}$:



One rule $\texttt{unary}(a \oplus b) := a \oplus b$ is added to the grammar to ensure compatability with grammars that use rewrite rules of arity one.

The probability of a rhythmic rewrite functions does not depend on the particular rhythmic category that it rewrites, but only on whether or not the category has an upbeat of length zero. This enables a maximal sharing of probability mass by preserving consistency with the constraints of the rewrite rules. More precisely,

$$\begin{aligned} 1 = \; & p(\texttt{unary} \mid a \oplus b) \\ & + \sum_{\frac{1}{2} < u \leq 1} p(\texttt{usplit}_u \mid a \oplus b) \\ & + \sum_{0 \leq v < 1} \sum_{0 < w < 1} p(\texttt{dsplit}_w^v \mid a \oplus b) \end{aligned} \tag{8}$$

for $a > 0$ and

$$\begin{aligned} 1 = \; & p(\texttt{unary} \mid 0 \oplus b) \\ & + \sum_{0 \leq v < 1} \sum_{0 < w < 1} p(\texttt{dsplit}_w^v \mid 0 \oplus b). \end{aligned} \tag{9}$$

For practical applications, the parameters u, v, and w are limited to a finite set of rational numbers to put a proper normalized prior on the rule distributions.

2.3.2 Simplified Rhythm Grammar

For comparison, we additionally consider a simplified version of the rhythm grammar presented above which does not explicitly model upbeats. The rhythmic categories and the terminals of this grammar are rational numbers $0 < a \leq 1$ representing constituent durations relative to the full piece. Apart from the technical unary rule, the rules of the grammar form a family of total rewrite functions

$$\texttt{split}_s(a) := (sa) \qquad (a - sa). \tag{10}$$

The parameter $0 < s < 1$ is called the *temporal split ratio* of the rule. The probabilities of the rewrite rules are set to be independent from the category they rewrite. Therefore,

$$1 = p(\texttt{unary}) + \sum_{a \in \mathbb{Q}} p(\texttt{split}_a). \tag{11}$$

2.4 Harmony Grammar

The harmony grammar used in this paper is a standard probabilistic context-free grammar (Σ, N, S, R) in Chomsky normal form. It consists of a set Σ of chord symbols as terminal symbols, a set of copies of chord symbols N as non-terminal symbols, a distinguished start symbol $S \in N$, and a set of standard rewrite rules

$$R \subseteq \{\, A \longrightarrow B_1 \; B_2 \mid B_k \in N, A = B_1 \text{ or } A = B_2 \,\}.$$

In particular, rules of the form $A \longrightarrow A \; A$ are included by this definition. Each non-terminal symbol A is also associated with a random variable X_A over rewrite rules that have A as their left-hand side. The symbols, rules, and parameters of the grammar are read from dataset of tree annotations described in the next section.

Note that since every rewrite rule of a standard context-free grammar can be interpreted as a partial function with a singleton domain,

$$\text{dom}(A \longrightarrow \alpha) = \{\, A \,\} \quad \text{for all } \alpha \in (\Sigma \cup N)^*, \tag{12}$$

every standard context-free grammar is also an Abstract Context-free Grammar and can be used in the product grammar construction.

3. DATASET

This study uses a dataset of 75 hand-annotated tree analyses of Jazz chord sequences from the iRealPro dataset [23]. The tree annotations were performed by the authors and a student assistant. Each chord sequence is annotated with a single binary tree that spans the whole piece. In contrast to the introductory examples of this paper, the internal nodes of each tree in the data are not labeled by scale degrees but chord symbols. depth one subtrees corresponds to a rule of the grammar described in the previous section. Figure 3 shows the absolute frequencies of the 20 most frequent harmonic rewrite rules from the dataset, after each sequence was transposed to the root of C. Rules of the form $A \longrightarrow A \;\; A$, called *prolongation rules*, and rules of the form $A \longrightarrow B \;\; A$ for $A \neq B$, called *preparation rules*, are the most used rule schemes.

The dataset additionally includes the length of each chord in quarter notes. The chord durations of each piece are divided by the total duration of the piece. From the chord durations and the harmonic tree annotations, the duration of each constituent (subtree) can be calculated automatically as shown in Figure 4. The temporal split ratios of the rule applications–as introduced in Equation 10–are then in turn calculated from the durations of the constituents. Consider for example the rule application $\text{G}^7(\frac{5}{32}) \longrightarrow \text{F}^{\triangle}(\frac{2}{32}) \;\; \text{G}^7(\frac{3}{32})$ from Figure 4. Its temporal split ratio is $\frac{2}{5}$.

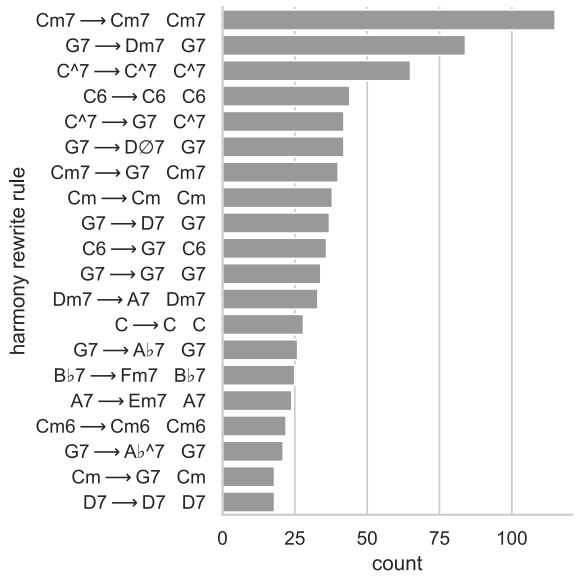


Figure 3: Absolute frequencies of the 20 most frequent harmonic rewrite rules of the tree annotations. All sequences are transposed to the common root C. Major-seventh chords are denotes as `C^7` and `A♭^7`.

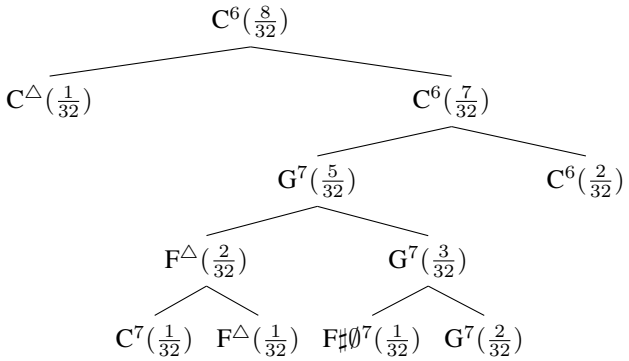

Figure 4: Tree annotation of the last chords of *St. Thomas*. Chord durations are shown relative to the total duration of the tune, $\frac{2}{32}$ corresponds to one measure. The durations of the inner nodes are calculated automatically.

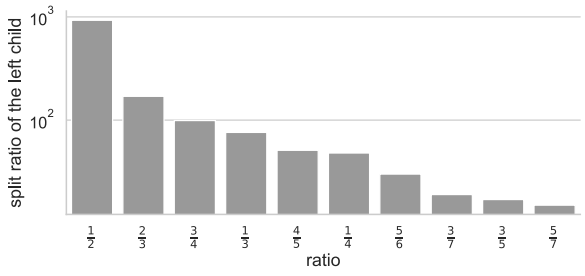

Figure 5: Absolute frequencies of the 10 most frequent split ratios of annotated tree constituents. The split ratio of a binary rewrite rule is defined as the time proportion of the left child. The y-axis is plotted using a logarithmic scale.

The 10 most frequent temporal split ratios are shown in Figure 5. The split ratio $\frac{1}{2}$ is by far the most frequent one. Most of the remaining ratios can be expressed either as $\frac{n-1}{n}$ or as $\frac{1}{n}$ for some $n \in \mathbb{N}$. The former arise for example from chains of descending fifths or applied dominants that accumulate time step by step in the temporal order of the piece. The latter arise from upbeat preparations that can be understood using the rhythmic categories described in Section 2.3.1. Two rhythmic rewrite rules that explain a split ratio of $\frac{1}{n}$ are $\left(\frac{n}{m}\right) \longrightarrow \left(\frac{\frac{n}{2}}{m} \ominus \frac{\frac{n}{2}-1}{m}\right) \quad \left(\frac{\frac{n}{2}-1}{m} \oplus \frac{\frac{n}{2}}{m}\right)$ and $\left(\frac{1}{m} \oplus \frac{n-1}{m}\right) \longrightarrow \left(\frac{1}{m}\right) \quad \left(\frac{n-1}{m}\right)$, where $m \in \mathbb{N}$. The former results from a downbeat split with $w = \frac{1}{2}$ and the latter results from an upbeat split with $u = 1$.

4. PARSING WITH PRODUCT GRAMMARS

A naive approach to parsing against a product grammar would enumerate all product categories and memoize the inverted rewrite rules on these categories. In this section, we show how the inefficient blow-up of the number of categories can be avoided using the independence assumption of Equation 6.

Consider an Abstract Context-Free Grammar in Chomsky normal form. The standard CYK algorithm–here used to calculate the probability of a sequence of terminals $w \in T^*$ of length n, indexed from 0 to $n-1$–can be formulated recursively by the equations

$$p(A, i, i) = \sum_{r \in \Gamma} p(A \longrightarrow_r w_i) \tag{13}$$

and

$$p(A, i, j) \tag{14}$$
$$= \sum_{k=i}^{j-1} \sum_{r \in \Gamma} p(A \longrightarrow_r B_1\ B_2) p(B_1, i, k)\ p(B_2, k+1, j)$$

where $A, B_1, B_2 \in C$ and $i, j \in \mathbb{N}$ such that $0 \leq i < j \leq n-1$. The probability of the sequence is then given by $p(w) = \sum_{A \in C_0} p(A, 0, n-1)$.

Given a product grammar $G \bowtie G'$, a sequence of product terminals can be parsed utilizing Equation 6,

$$p((A, A'), i, i) = \sum_{(r, r') \in \Gamma \bowtie \Gamma'} p(A \longrightarrow_r w_i)\ p(A' \longrightarrow_{r'} w'_i) \tag{15}$$

and

$$p((A, A'), i, j) = \sum_{k=i}^{j-1} \sum_{(r, r') \in \Gamma \bowtie \Gamma'} p(A \longrightarrow_r B_1\ B_2) \tag{16}$$
$$p(A' \longrightarrow_{r'} B'_1\ B'_2) p((B_1, B'_1), i, k)\ p((B_2, B'_2), k+1, j)$$

It is therefore sufficient to parse the component grammars individually at each step. In other words, the combined grammar is computed on-the-fly to achieve efficiency.

5. EXPERIMENTS

We compare four product grammars that integrate harmonic and rhythmic structure. Additionally, we report the performances of their single-domain components and of a random baseline. As first component, we consider the harmony grammar presented in Section 2.4, trained either on the annotations in the original keys of the tunes or on the annotations after each tune was transposed to C major. As second component, we consider the full rhythm grammar presented in Section 2.3.1 that distinguishes upbeats and downbeats of constituents, and its simplification that uses the total length of the constituents, presented in Section 2.3.2. All models are trained and evaluated on the dataset described in Section 3. Apart from the full rhythm grammar, all models are trained by counting the harmonic rewrite rules or the temporal split ratios present in the dataset. The full rhythm grammar is trained using variational Bayesian inference [8]. Every model predicts the latent tree structure of a given sequence using the maximum a posteriori tree. One-fold cross validation was applied to avoid overfitting to the data: 75 times the model was trained on 74 sequences and evaluated on the remaining sequence.

5.1 Evaluation Metric and Baseline

The similarity of two trees is calculated as the unlabeled tree accuracy, defined as follows. Let α be a sequence of n terminals, left-to-right indexed from 0 to $n-1$, let t be a tree with α as leafs, and let s be a subtree of t. The *span* of s is defined as the pair of the index of its left-most child and the index of its right-most child. The set of spans of t consists of the spans of all subtrees of t that are not leafs. The unlabeled tree accuracy of a tree prediction t to the respective Goldstandard tree t^* is then defined as the cardinality of the correctly predicted spans, divided by the total amount of spans of t^*.

Given a chord sequence of length n, the random baseline uniformly samples one tree from the set of all binary trees with n leafs.

5.2 Results and Discussion

The results of the computational experiments are shown in Figure 6. All combined models of harmony and rhythm perform significantly better than the single-domain harmony grammars and all models perform significantly better than the random baseline ($p < 0.01$ using 2-sample bootstrap tests). There is no statistical difference observable between the not transposed and the transposed harmony models. Surprisingly, the single-domain rhythm grammars perform much better than the single-domain harmony grammars. This is, however, only possible because we consider the unlabeled tree accuracy. Other measures such as perplexity would reveal the obvious incapability of the rhythm grammars to predict chord sequences.

Both rhythm grammars improve the harmony models similarly. As discussed in Section 3, the simplified version of the proposed rhythm grammar is also able to capture some complex rhythmical structures. The music-theoretically more sophisticated formalism, however, facilitates the interpretation and explanation of the observed split ratios.

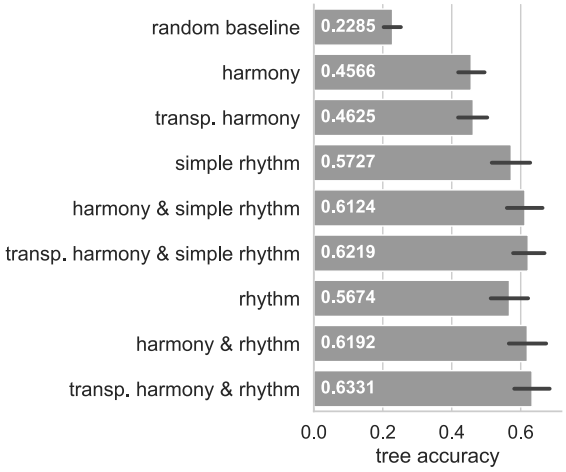

Figure 6: One-fold cross-validated tree accuracies of the tested models and the random baseline. The error bars show 95% bootstrap confidence intervals. The combined models of harmony and rhythm perform significantly better than the plain harmony grammars.

6. CONCLUSION

The usage of rhythmical information is shown to significantly improve the performance of harmonic syntax models. The empirical comparison between a music-theoretical motivated model and its simplified version shows that both models improve the harmony grammar equally well. The simplified model can therefore be used as an algorithmic proxy of the more expressive model. This might, however, only be true for rhythmically regular structures such as the harmonic rhythm of chord sequences from Jazz standards. It is, moreover, surprising how much information is already contained in the rhythm of the sequences, which underpins the importance of the rhythmic dimension of music [10]. In these sequences, both the harmonic syntax and the phrase rhythm work together to strengthen the intentionality of the music.

The here proposed model of interaction between harmony and rhythm is also capable to describe the interaction of pitch and rhythm in melodies. A rewrite function for syncopation could be added for future applications, since syncopation is an essential part of melodic rhythm.

The general product grammar construction presented in this paper integrates multiple domains of structure using strong independence assumptions. Future research can extent the formalism, explicitly modeling inter-domain dependencies. We hope that the presented approach will prove to be useful for applications such as rhythm quantization [2], the definition of similarity metrics [5], and computational composition assistance [15].

7. ACKNOWLEDGEMENTS

This project has received funding from the European Research Council (ERC) under the European Union's Horizon 2020 research and innovation programme under grant agreement No 760081 – PMSB and from the Natural Sciences and Engineering Research Council of Canada (NSERC). We thank Claude Latour for supporting this research through the Latour Chair in Digital Musicology. The authors additionally thank the anonymous referees for their valuable comments.

ABSTRACT

Music Inpainting is the task of filling in missing or lost information in a piece of music. We investigate this task from an interactive music creation perspective. To this end, a novel deep learning-based approach for musical score inpainting is proposed. The designed model takes both past and future musical context into account and is capable of suggesting ways to connect them in a musically meaningful manner. To achieve this, we leverage the representational power of the latent space of a Variational Auto-Encoder and train a Recurrent Neural Network which learns to traverse this latent space conditioned on the past and future musical contexts. Consequently, the designed model is capable of generating several measures of music to connect two musical excerpts. The capabilities and performance of the model are showcased by comparison with competitive baselines using several objective and subjective evaluation methods. The results show that the model generates meaningful inpaintings and can be used in interactive music creation applications. Overall, the method demonstrates the merit of learning complex trajectories in the latent spaces of deep generative models.

1. INTRODUCTION

Over the last decade, machine learning techniques have emerged as the tool of choice for the design of symbolic music generation models [1] with deep learning being the most widely used [2]. Deep generative models have been successfully applied to several different music generation tasks, e.g., monophonic music generation [3–5], polyphonic music generation [6, 7] and creating musical renditions with expressive timing and dynamics [8, 9]. However, most of these models assume sequential generation of music, i.e, the generated music depends only on the music that has preceded it. In other words, the models rely only on the past musical context. This approach does not align with typical human compositional practices which are often iterative and non-sequential in nature. In addition, the sequential generation paradigm places severe limitations on the degree of interactivity allowed by these models [10, 11]. Once generated, there is no way to tweak specific parts of the generation so as to conform to users' aesthetic sensibilities or compositional requirements.

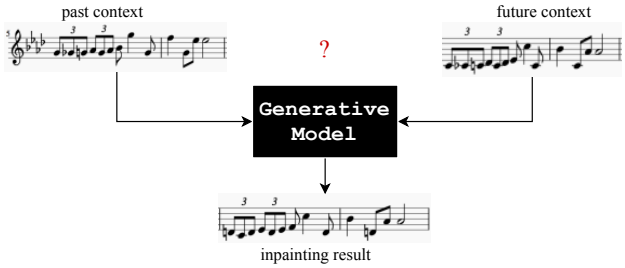

Figure 1: *Musical Score Inpainting* task schematic. A generative model needs to take past and future musical contexts into account to generate a sequence that can connect them in a musically meaningful manner.

In this paper, we seek to address these problems by incorporating future musical context into the generation process. Specifically, the task is to train models to fill in missing information in musical scores, duly taking into account the complete musical context — both past and future. In essence, this is similar to *inpainting* where the objective is to reconstruct missing or degraded parts of any kind of media [12]. For music, inpainting has been traditionally used for restoration purposes [13] or to remove unwanted artifacts such as clipping [14, 15] and packet loss [16]. However, we investigate models for *Musical Score Inpainting* (see Figure 1 and Section 3.1) as tools for music creation which can aid people in (i) getting new musical ideas based on specific styles, (ii) joining different musical sections together, and (iii) modifying or extending solos. In addition, such models can allow interactive music generation by enabling users to change the musical context and get new suggestions based on the updated context.

Our main technical contribution is a novel approach for musical score inpainting which relies on *latent* representation-based deep generative models. These models are trained to compress information from high-dimensional spaces, e.g., the space of all 1-bar melodies, to low-dimensional *latent* spaces. While these latent spaces have been shown to be able to encode hidden attributes of musical data (see Section 2.3), the primary form of interaction

with latent spaces has been using simple operations such as attribute vectors [17, 18] or linear interpolations [19, 20]. Using the proposed method (see Section 3), we demonstrate that Recurrent Neural Networks (RNNs) can be trained using latent embeddings to learn complex trajectories in the latent space. This, in turn, is used to predict how to fill in missing measures in a piece of symbolic music. Our secondary contributions are: (i) a stochastic training scheme which helps model training and generalization (see Section 3.4), and (ii) a novel data encoding scheme using uneven tick durations that allows encoding triplets without substantial increase in sequence length (see Section 3.5). The effectiveness of the proposed method is demonstrated using several objective and subjective evaluation methods in Section 4.

2. RELATED WORK

2.1 Audio & Music Inpainting

The first applications of audio inpainting methods were restoration-oriented [13, 14, 16, 21, 22] using different methods such as matrix factorization [14], non-local similarity measures [22] and audio similarity graphs [16]. While these techniques have been useful for audio-based tasks, they are not easily extendable to symbolic music.

For inpainting in the symbolic domain, the early attempts were based on Markov Chain Monte Carlo (MCMC) methods which allowed users to specify certain constraints, e.g., which notes to generate and which to retain [23, 24]. Another approach, proposed by Lattner et al., used iterative gradient descent to force the output of a deep generative model to conform to a specified structural plan [25]. However, methods based on MCMC (which rely on repeated sampling), and those using iterative gradient descent are slow during inference time and hence unsuitable for interactive applications. More recently, Hadjeres et al. proposed the AnticipationRNN framework [10] which used a pair of stacked RNNs to enforce user-defined constraints during inference. This allowed selective regeneration of specific parts of the music (generated or otherwise) using only two forward passes through the RNN-pair and enabled real-time generations.

2.2 Variational Auto-Encoders

The Variational Auto-Encoder (VAE) [26] is a type of generative model which uses an auto-encoding [27] framework; during training, the model is forced to reconstruct its input. The architecture comprises an encoder and a decoder. The encoder learns to map real data-points $\mathbf{x}$ from a high-dimensional data-space X to points in a low-dimensional space Z which is referred to as the *latent* space. The decoder learns to map the latent vectors back to the data-space. VAEs treat the latent vector as a random variable and model the generative process as a sequence of sampling operations: $\mathbf{z} \sim p(\mathbf{z})$, and $\mathbf{x} \sim p(\mathbf{x}|\mathbf{z})$, where $p(\mathbf{z})$ is a prior distribution over the latent space, and $p(\mathbf{x}|\mathbf{z})$ is the conditional pdf. Variational inference [28] is used to approximate the posterior by minimizing the KL-divergence [29] between the approximate posterior $q(\mathbf{z}|\mathbf{x})$ and the true posterior $p(\mathbf{z}|\mathbf{x})$ by maximizing the evidence lower bound (ELBO) [26]. The training ensures that the reconstruction accuracy is maximized and realistic samples are generated when latent vectors are sampled using the prior $p(\mathbf{z})$.

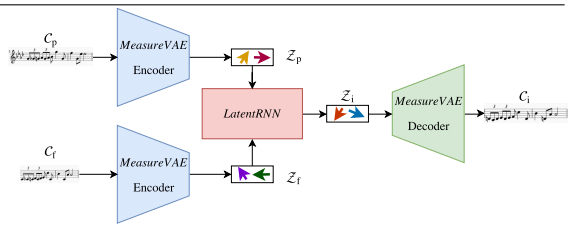

Figure 2: Schematic of the proposed approach. The pre-trained MeasureVAE encoder is used to convert the past and future context sequences ($\mathcal{C}_\mathrm{p}$ and $\mathcal{C}_\mathrm{f}$) into their respective latent vector sequences ($\mathcal{Z}_\mathrm{p}$ and $\mathcal{Z}_\mathrm{f}$). The LatentRNN learns to traverse the latent space of MeasureVAE to output a latent vector sequence $\mathcal{Z}_\mathrm{i}$ which is passed through the pre-trained decoder to output the inpainted musical sequence $\mathcal{C}_\mathrm{i}$.

2.3 Leveraging Latent Spaces for Music Generation

Latent representation-based models such as VAEs have been found to be quite useful for several music generation tasks. Bretan et al. used the latent representation of an auto-encoder-based model to generate musical phrases [30]. Lattner et al. forced the latent space of a gated auto-encoder to learn pitch interval-based representations which improved the performance of predictive models of music [31, 32]. Latent spaces of music generation models have also been used to explicitly encode and control musical attributes [3, 20, 33, 34], inter-track dependencies [35] and musical genre [36]. These studies show that trained latent spaces are able to encode hidden attributes of musical data which can be leveraged for different music generation tasks. However, latent space traversals have been relying on simpler methods such as attribute vectors [17, 18] or linear interpolations [19, 20].

3. METHOD

3.1 Problem Statement

We define the score inpainting problem as follows: given a past musical context $\mathcal{C}_\mathrm{p}$ and a future musical context $\mathcal{C}_\mathrm{f}$, the modeling task is to generate an inpainted sequence $\mathcal{C}_\mathrm{i}$ which can connect $\mathcal{C}_\mathrm{p}$ and $\mathcal{C}_\mathrm{f}$ in a musically meaningful manner. In other words, the model should be trained to maximize the likelihood $p(\mathcal{C}_\mathrm{i} \mid \mathcal{C}_\mathrm{p}, \mathcal{C}_\mathrm{f})$. Without much loss of generality, we assume that $\mathcal{C}_\mathrm{p}$, $\mathcal{C}_\mathrm{f}$, and $\mathcal{C}_\mathrm{i}$ comprise of n_p, n_f, and n_i measures of music, respectively.

3.2 Approach

The key motivation behind the proposed method is that the latent embeddings of deep generative models of music encode hidden attributes of music which can be leveraged to perform inpainting. Firstly, we train a VAE-model, referred to as *MeasureVAE*, to reconstruct single measures of music,

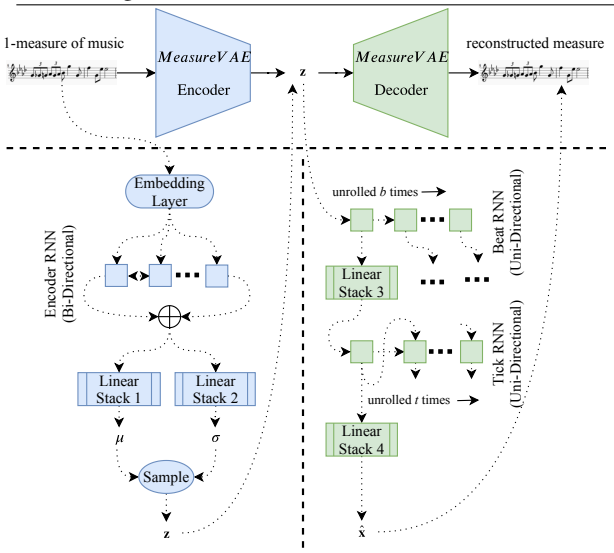

Figure 3: MeasureVAE schematic. Individual components of the encoder and decoder are shown below the main blocks (dotted arrows indicate data flow within the individual components). $\mathbf{z}$ denotes the latent vector and $\hat{\mathbf{x}}$ denotes the reconstructed measure.

i.e., the latent vectors of this model $\mathbf{z} \in Z$ map to individual measures of music. Once trained, the encoder of this model can be used to process sequences $\mathcal{C}_\mathrm{p}$ and $\mathcal{C}_\mathrm{f}$ and output corresponding latent vector sequences $\mathcal{Z}_\mathrm{p}$ and $\mathcal{Z}_\mathrm{f}$. Secondly, we train an RNN-based model, referred to as *LatentRNN*, to take as input the past and future latent vector sequences ($\mathcal{Z}_p$ and $\mathcal{Z}_\mathrm{f}$) and output a third latent vector sequence $\mathcal{Z}_\mathrm{i}$ which can be passed through the decoder of MeasureVAE to obtain $\mathcal{C}_\mathrm{i}$.

Effectively, the LatentRNN model learns to traverse the latent space of the MeasureVAE model so as to connect the provided contexts in a musically meaningful manner. The inference is fast since it only requires forward passes through the two models. This overall approach is shown in Figure 2. We call this joint architecture *InpaintNet*. While we restrict ourselves to $4/4$ monophonic melodic sequences in this paper, the approach can be extended to other time signatures and polyphonic sequences as well. The individual model architectures are discussed next.

3.3 Model Architectures

3.3.1 MeasureVAE

The MeasureVAE architecture (see Figure 3) is loosely based on the hierarchical recurrent MusicVAE architecture [3] which proved successful in modeling individual measures of music.

The encoder consists of a learnable embedding layer (operating on tick-level) followed by a bi-directional RNN [37]. The concatenated hidden state from both directions of the RNN is then passed through two identical parallel linear stacks to obtain the mean μ and variance σ which are used to sample the latent vector $\mathbf{z}$ via $\mathbf{z} \sim \mathcal{N}(\mu, \sigma^2)$.

The decoder follows a hierarchical structure where the

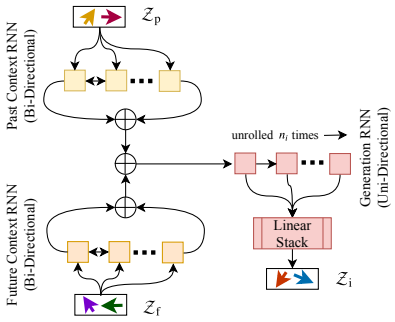

Figure 4: LatentRNN schematic. The Past-Context and Future-Context-RNNs encode $\mathcal{Z}_\mathrm{p}$ and $\mathcal{Z}_\mathrm{f}$, respectively. The Generation-RNN initialized using a concatenation of context-RNNs embeddings is unrolled n_i times to get $\mathcal{Z}_\mathrm{i}$.

sampled latent vector $\mathbf{z}$ is used to initialize the hidden state of a beat-RNN which is unrolled b times (where b is the number of beats in a measure). The output at each step of the beat-RNN is passed through a linear stack before being used to initialize the hidden state of a tick-RNN which is unrolled t times (where t is the number of events/ticks in a beat). The outputs of the tick-RNN are individually passed through a second linear stack which maps them back to the data-space. The hierarchical architecture mitigates the auto-regressive nature of the RNN and forces the decoder to use the latent vector more efficiently (as advocated in [3]).

3.3.2 LatentRNN

The LatentRNN model (see Figure 4) consists of 3 sub-components. There are 2 identical bi-directional RNNs, referred to as Past-Context-RNN and Future-Context-RNN, which process the latent vector sequences for the past and future contexts ($\mathcal{Z}_\mathrm{p}$ and $\mathcal{Z}_\mathrm{f}$), respectively. These are unrolled for n_p and n_f times in order to encode the context sequences, respectively. The final hidden states of the two context-RNNs are concatenated and then used to initialize the hidden state of a third RNN, referred to as the Generation-RNN, which is unrolled n_i times. The outputs of the Generation-RNN are passed through a linear stack to obtain n_i latent vectors corresponding to the inpainted measures.

The hyper-parameters for the model configurations are chosen based on initial experiments and are provided in Table 1. For the RNN layers in both models, Gated Recurrent Units (GRU) [38] are used.

3.4 Stochastic Training Scheme

We propose a novel stochastic training scheme for training the model. For each training batch, the number of measures to be inpainted n_i and the number of measures in the past context n_p are randomly sampled from a uniform distribution. Thus, the number of measures in the future context becomes $n_\mathrm{f} = N - n_\mathrm{i} - n_\mathrm{p}$, where N is the total number of measures in each sequence of the training batch. Using these, the input sequences are split into past, future and target sequences and the model is trained to predict

the target sequence given the past and future context sequences. This stochastic training scheme ensures that the model learns to deal with variable length contexts and can perform inpaintings at arbitrary locations.

3.5 Data Encoding Scheme

We use a variant of the encoding scheme proposed by Hadjeres et al. [24] for our data representation. The original encoding scheme quantizes time uniformly using the sixteenth note as the smallest sub-division. For each sub-division or tick, the note which starts on that tick is represented by a token corresponding to the note name. If no note starts on a tick, a special continuation symbol '__' is used to denote that the previous note is held. Rest is considered as a note and has a special token. The main advantages of this encoding scheme are (i) it uses only a single sequence of tokens, and (ii) uses real note names (e.g., separate tokens for A# and Bb) which allows generation of readable sheet music.

However, a limitation of using the sixteenth note as the smallest sub-division is that it cannot encode triplets. The naive approach of evenly subdividing the sixteenth note divisions to encode triplets increases the sequence length a factor of 3 which can make the sequence modeling task harder. To mitigate this limitation, we propose a novel uneven subdivision scheme. Each beat is divided into 6 uneven ticks (shown in Figure 5). This allows encoding triplets while only increasing the sequence length by a factor of 1.5. Consequently, each $4/4$ time signature measure is a sequence of 24 tokens.

4. EXPERIMENTS

The proposed method is compared with two baseline methods (see Section 4.1) using a dataset of monophonic folk melodies in the Scottish and Irish style taken from the Session website [5]. For the purposes of this work, only

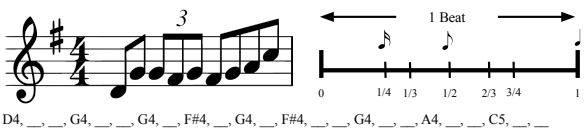

Figure 5: Figure showing the data representation. The token string on the bottom demonstrates the encoding scheme for the measure displayed on the top-left. Top-right shows the proposed uneven tick-duration scheme for each beat.

melodies with $4/4$ time signature in which the shortest note is greater than or equal to the sixteenth note are considered resulting in approx. 21000 melodies. Implementation details and source code are available online. [1]

4.1 Baseline

The performance of the proposed method is compared with the AnticipationRNN model proposed by Hadjeres et al. [10]. This model, referred to as *Base-ARNN*, uses a stack of 2 LSTM-based [40] RNN layers. Each of the 2 RNNs comprises of 2 layers with a hidden size of 256. In addition to the note-sequence tokens, this model also uses additional metadata information, i.e., tokens to indicate beat and downbeat locations as part of the user-defined constraints. For more details, the readers are directed to [10].

The original model operates on tick-level sequences and inpainting locations are specified in terms of individual tick locations. Hence, the inpainting locations may or may not be contiguous. In order to make a fair comparison, a second variant of the AnticipationRNN model is considered, referred to as *Reg-ARNN*, where the stochastic training scheme from Section 3.4 is used instead.

4.2 Training Configuration

The MeasureVAE model was pre-trained using single measures following the standard VAE optimization equation [26] with the β-weighting scheme [41, 42]. In order to prioritize high reconstruction accuracy, a low value of $\beta = 1\text{e}{-3}$ was used. Pre-training was done for 30 epochs resulting in a reconstruction accuracy of approx. 99%. While this seems to be better than results in [3], we attribute this to the shorter duration of generation (single measures) and the differences in datasets and data encoding. MeasureVAE parameters were frozen after pre-training and no gradient-based updates were performed on these parameters during the InpaintNet model training.

The Adam algorithm [43] was used for model training, with a learning rate of $1\text{e}{-3}$, $\beta_1 = 0.9$, $\beta_2 = 0.999$, and $\epsilon = 1\text{e}{-8}$. To ensure consistency, all models were trained for 100 epochs (with early-stopping) with the same batch-size using a sub-sequence length of 16 measures (384 ticks). For the InpaintNet and Reg-ARNN models, the number of measures to be inpainted and the number of past measures were randomly selected: $n_\text{i} \in [2, 6]$, $n_\text{p} \in [1, 16 - 1 - n_\text{i}]$. This ensured that past and future contexts each contain at

least 1 measure. For the baseline models, teacher-forcing was used with a probability of 0.5.

4.3 Predictions on Test Data

Two experiments were conducted to evaluate the predictive power of the models.

The first experiment considered the average token-wise negative log-likelihood (NLL) on a held-out test set. The results (see first 3 rows of Table 2) indicate that our proposed model outperforms both baselines, showing an improvement of approx. 25% in the NLL over the Reg-ARNN model and approx. 55% over the Base-ARNN model.

The next experiment compared the models by varying the number of measures to be inpainted. Figure 6 shows the average token-wise NLL when n_{i} was increased from 2 to 8. Again, our proposed model outperforms both baselines. It should be noted that since the sub-sequence length is constant at 16 measures, increasing n_{i} means that the available context is reduced. Thus, there is an expected drop in the performance with increasing n_{i} as the models are forced to make longer predictions with less contextual information. However, the InpaintNet model performs better even when forced to predict beyond the training limit of 6 measures.

4.4 Ablations Studies

In order to further ascertain the efficiency of the proposed approach, ablation studies were conducted to evaluate the benefit of adding past and future context information. Specifically, we trained two variants of the InpaintNet model which relied on only one type of contextual information. The first model, referred to as PastInpaintNet only considered the past context $\mathcal{C}_{\mathrm{p}}$ as input whereas the second model, referred to as FutureInpaintNet considered only the future context $\mathcal{C}_{\mathrm{f}}$. The last two rows of Table 2 summarize the performance of these ablation models. It is clear that both past and future contexts are important for the modeling process. In addition, we also tried training a variant of the InpaintNet model with an untrained (randomly initialized) MeasureVAE model. This model failed to train properly achieving an NLL of approx. 1.33. This indicates that a structured latent space where latent vectors are trained to encode hidden data attributes is important for training the LatentRNN model.

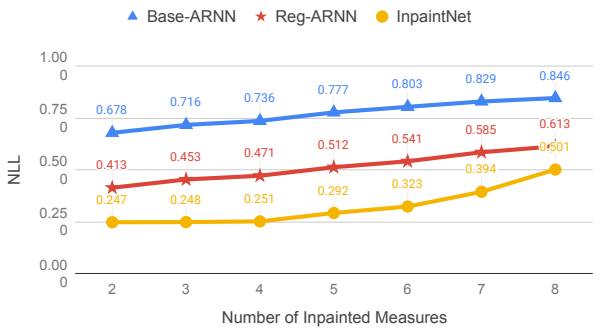

Figure 6: Figure showing token-wise NLL (nats/token) for different number of inpainted measures on the held-out test set (lower is better). InpaintNet outperforms both baselines. Models were trained to predict only 2 to 6 measures.

4.5 Qualitative Analysis

Considering that we are primarily interested in the aesthetic quality of the inpaintings, we encourage the readers to browse through the inpainting examples provided in the supplementary material. [2] We consider some of those examples in the analysis below.

Figure 7 shows sample inpaintings by the models for one of the melodies in the test set. While the Base-ARNN model collapses to produce long half notes which do not effectively reflect the surrounding context, the other two models do better. Both the Reg-ARNN and InpaintNet model generate rhythmically consistent inpaintings. The InpaintNet, in particular, mimics the rhythmic properties of the context better. For instance, measures 7 and 10 of the inpainted measures match the rhythm of measures 6, 14, and 15. Also, measure 8 matches measure 16. However, the use of G (subdominant scale degree in D-major) in the half-note to end measure 8 is unusual. We observed that in other examples also, the InpaintNet model occasionally produces pitches which are anomalous — either out-of-key or not fitting in the context. The Reg-ARNN model, on the other hand, tends to stay in key. Additional examples are provided in the supplementary material.

One advantage of working with the latent space is that the sampling operation, inherent in the VAE inference process, ensures that for the same context we can get different inpainting results. Figure 8 shows three such generations for the context of Figure 7. It is interesting to note that the base rhythm is retained across all three inpaintings. This feature is particularly interesting from an interactive music generation perspective, as this model can be used to quickly provide users with multiple ideas and will be investigated further in future work.

4.6 Subjective Listening Study

To evaluate the perceived quality of the inpainted measures, a listening test was conducted to compare our proposed model against the two baselines. A set of 30 melodies from the held-out test set were randomly selected and their first

Figure 8: Figure showing different inpaintings (using the InpaintNet model) for the same context as Figure 7.

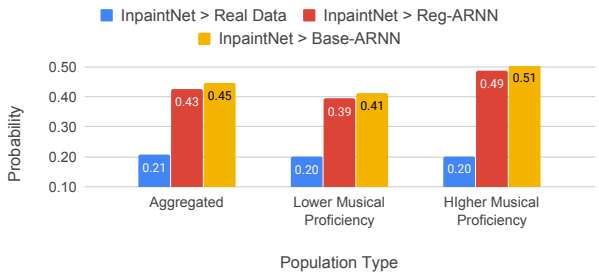

Figure 9: Figure based on the subjective listening study showing the probability that the InpaintNet model is rated higher. Analysis is based on the Bradley-Terry model [44, 45]. The proposed model loses against the real data but performs at par with the baseline models.

16 measures were extracted. The models were then used to inpaint 4 measures (measure number 7 to 10) in these melodic excerpts. Participants were presented with pairs of melodic excerpts and asked to select the one in which they thought the inpainted measures fit better within the surrounding context. In some of the pairs, one melodic excerpt was the real data (without any inpainting). Each participant was presented with 10 such pairs. A total of 72 individuals participated in the study (720 comparisons). The location of the inpainted measures was kept consistent across all examples so as to prevent confusion among participants and allow them to focus better on the inpainted measures.

The Bradley-Terry model [44,45] for paired comparisons was used to get an estimate of how the proposed model performs against the baselines and the real data (see Figure 9). While the proposed model expectedly has a very low probability of winning against the real data (wins approx. 1 out of 5 times), it performs only at par with the baseline models (with probability approx. 0.5). Significance tests using the Wilcoxon signed rank test were further conducted which validated that differences between the proposed model and the baselines were not statistically significant (p-value > 0.01). This was unexpected since the proposed model showed significant improvement over the baselines in the NLL metric. Further dividing the study population into two groups differing in musical proficiency (based on the Ollen index [46]) showed that, comparatively, the group with greater musical proficiency favored the generations from the InpaintNet model more than the group with less musical proficiency.

Additional analysis revealed that cases where the InpaintNet model performed the worst (maximum losses against the baselines), had anomalies in the predicted pitch similar to those discussed in Section 4.5. Specifically, they either had a single out-of-key note (e.g., F note in G-Major scale) or used a pitch or interval not used in the provided contexts. We conjecture that it is these anomalous pitch predictions which lead to poor perceptual ratings in spite of the model performing better in terms of modeling rhythmic features. This will be analyzed further in future studies.

5. CONCLUSION

This paper investigates the problem of musical score inpainting and proposes a novel approach to generate multiple measures of music to connect two musical excerpts by using a conditional RNN which learns to traverse the latent space of a VAE. We also improve upon the data encoding and introduce a stochastic training process which facilitate model training and improve generalization. The proposed model shows good performance across different objective and subjective evaluation experiments. The architecture also enables multiple generations with the same contexts, thereby, making it suitable for interactive applications [47]. We think the idea of learning to traverse latent spaces could be useful for other music generation tasks also. For instance, the architecture of the LatentRNN model can be changed to add contextual information from other voices/instruments to perform multi-instrument music generation. Future work will include a more thorough investigation of the anomalies in pitch prediction. A possible way to address that would be to add the context embedding as input at each step of unrolling the LatentRNN or use additional regularizers. Another promising avenue for future work is substituting RNNs with attention-based models [48] which have had success in sequential music generation tasks [9].

ABSTRACT

While Georgia has a long history of orally transmitted polyphonic singing, there is still an ongoing controversial discussion among ethnomusicologists on the tuning system underlying this type of music. First attempts have been made to analyze tonal properties (e. g., harmonic and melodic intervals) based on fundamental frequency (F0) trajectories. One major challenge in F0-based tonal analysis is introduced by unstable regions in the trajectories due to pitch slides and other frequency fluctuations. In this paper, we describe two approaches for detecting stable regions in frequency trajectories: the first algorithm uses morphological operations inspired by image processing, and the second one is based on suitably defined binary time–frequency masks. To avoid undesired distortions in subsequent analysis steps, both approaches keep the original F0-values unmodified, while only removing F0-values in unstable trajectory regions. We evaluate both approaches against manually annotated stable regions and discuss their potential in the context of interval analysis for traditional three-part Georgian singing.

1. INTRODUCTION

Polyphonic singing plays a vital role in many musical cultures. One of the oldest forms of polyphonic singing can be found in Georgia, a country located in the Caucasus region of Eurasia. The traditional three-part songs, which are typically passed down orally from one generation to the next, are acknowledged as Intangible Cultural Heritage by the UNESCO. Although being a long-studied subject, the non-tempered nature of traditional Georgian vocal music is still discussed controversially among musicologists [7,33]. So far, musicological studies on traditional Georgian music have mostly been conducted on the basis of manually transcribed field recordings. Such approaches are problematic, since important tonal cues (as well as many other performance aspects) are likely to get lost in the transcription process. The importance of field recordings in research on Georgian vocal music has raised the demand for computer-based methods to assist ethnomusicologists in analyzing the audio material.

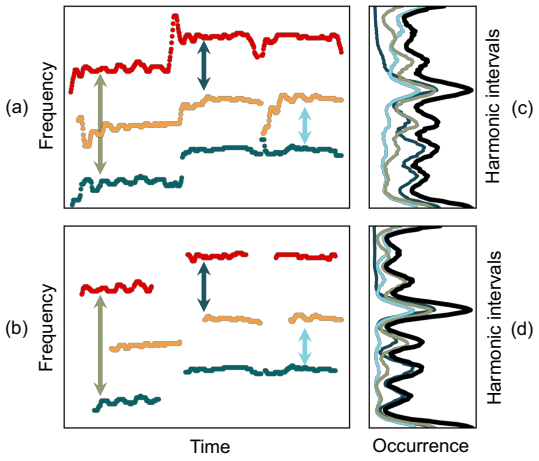

Figure 1. Detection of stable regions in F0-trajectories for a three-part singing recording. **(a)** Original F0-trajectories. **(b)** F0-trajectories restricted to stable regions. **(c)** Harmonic interval histogram based on (a). **(d)** Sharpened harmonic interval histogram based on (b). The histograms in (c) and (d) were computed considering the entire Erkomaishvili dataset.

One source of central importance for ethnomusicological research is a collection of audio recordings of the former master chanter Artem Erkomaishvili (1887–1967). The collection, which was created at the Tbilisi State Conservatory in 1966, comprises 101 three-part songs. Each chant was recorded in a three-stage "dubbing" process using tape recorders, where Erkomaishvili successively sung the individual voices with previously recorded voices being played back. In the study [20], a semi-automatic salience-based approach was applied to determine fundamental frequency (F0) trajectories of all three voices. The extracted F0-annotations are publicly available. [1] In a follow-up study [31], the authors determined from these trajectories harmonic (vertical) as well as melodic (horizontal) intervals, which give cues on the tonal organization [21, 22] of Georgian vocal music.

[1] https://www.audiolabs-erlangen.de/resources/MIR/2017-GeorgianMusic-Erkomaishvili

In general, studies on tonal analysis (see, e. g., [14, 15, 17, 31]) have shown that the usage of previously extracted F0-trajectories leads to various challenges. For example, as a stylistic element of traditional Georgian music, sung notes often start, end, or are continuously connected using pitch slides, see Figure 1a. Furthermore, automated F0-estimation procedures typically introduce inaccuracies such as extraction errors, outliers, or smoothing artifacts. Consequently, tonal analysis of Georgian vocal music based on highly fluctuating and error-prone F0-trajectories is problematic. For example, when computing harmonic interval statistics (as illustrated by Figure 1c), such artifacts may lead to an increased noise level and a less salient peak structure in the computed histograms. When analyzing melodic intervals, the presence of frequency variations (such as pitch slides) have a strong negative impact on subsequent analysis results. To alleviate such issues, contributions such as [17, 31] apply (semi-automatic) post-processing procedures to remove unstable regions in the trajectories and derive note-like events with a stable pitch. Note that for other scenarios (e. g. the tonal analysis of Hindustani Raga [29]), non-stable regions may contain musically important information.

Motivated by such tonal analysis applications, we present in this paper two automatic approaches that aim at identifying stable regions in frequency trajectories. Technically speaking, such regions correspond to horizontal structures (up to some tolerance) of trajectories. In acoustical and musical terms, such regions relate to pitched sounds where a singer has tuned into a harmonically stable pitch synchronized to other singers. In this context, our goal is to remove all frequency values in unstable regions, while keeping the original frequency values unmodified in the stable ones (see Figure 1b). For accomplishing this task, we introduce two conceptually different approaches—one based on morphological operations and the other one based on binary masking. Furthermore, we evaluate both approaches against manually annotated stable regions and indicate their potential for interval analysis using the Erkomaishvili recordings as example.

The remainder of this paper is organized as follows. We discuss related work in Section 2, then give a technical description of our approaches in Section 3, and summarize our experiments in Section 4.

2. RELATED WORK

In the following, we give an overview on work that is related to detecting stable regions in F0-trajectories. First, we want to note that stable region detection is not equivalent to F0-based transcription. In general, automated music transcription (AMT) aims at converting a music recording into some form of music notation [1, 2, 13]. In this process, many AMT systems apply temporal and spectral quantization of previously extracted F0-trajectories to derive pitches, onsets, and offsets of note events [3, 4, 6, 10, 15, 16, 18, 23, 30]. Rather than using quantized or modified F0-trajectories for our analysis, we aim at using trajectories restricted to stable regions (that may or may not correspond to note events) while leaving the original F0-values unmodified.

Detecting stable, transitional, and fluctuating patterns in F0-trajectories plays an important role for various tasks such as vibrato detection [5, 26, 37], singing style classification [24, 27], and motif detection [12, 25]. For example, in [35–37], the authors address the problem of detecting portamento (note transition) regions in Chinese string music. In [15], the authors identify stable regions as an important step towards transcribing recordings of Flamenco singing. In [19], the authors propose a vocal trajectory segmentation algorithm based on hysteresis defined on pitch–time curves. However, the underlying octave equivalence assumption may not be fulfilled in traditional Georgian vocal music. For a recent overview article of singing voice analysis, we refer to [11].

Furthermore, there are various studies on Indian Raga music, which are related to our work. In [9], a global pitch histogram ("pitch inventory") of the whole recording is computed. Then, informed by the histogram's peaks, stable regions are derived using empirically chosen thresholds for duration and fluctuation tolerance. In [14], the authors compute the local slope of the F0-trajectory and obtain stable regions by thresholding and quantization. However, due to the underlying scale assumptions, such approaches can not be directly applied to analyzing traditional Georgian singing, where pitch drifts may occur over the course of the song.

3. STABLE REGION DETECTION

In this section, we formalize the notion of a frequency trajectory as used in this work (Section 3.1). Then, to motivate the subsequent procedures, we introduce a simple median-based filtering approach (Section 3.2). As our main technical contributions, we introduce two conceptually different approaches for determining stable regions in frequency trajectories—one based on morphological operations (Section 3.3) and the other one based on binary masking (Section 3.4).

3.1 Frequency Trajectories

To account for the logarithmic nature of human pitch perception, we convert frequency values into the log-frequency domain. To this end, we fix a reference frequency ω_{ref} given in Hertz (Hz). In the following, we set $\omega_{\mathrm{ref}} = 55$ Hz. Then, an arbitrary frequency value ω is converted into the logarithmic domain by defining

$$F_{\mathrm{cents}}(\omega) := 1200 \cdot \log_2 \left(\frac{\omega}{\omega_{\mathrm{ref}}} \right), \tag{1}$$

which measures the distance between ω and ω_{ref} in cents. In this paper, we model a frequency trajectory as a function

$$\gamma : \mathbb{Z} \to \mathbb{R} \cup \{*\}, \tag{2}$$

which assigns to a given time index $n \in \mathbb{Z}$ either a real-valued frequency value $\gamma(n) \in \mathbb{R}$ (given in cents) or the symbol $\gamma(n) = *$ (when the frequency value is left to be

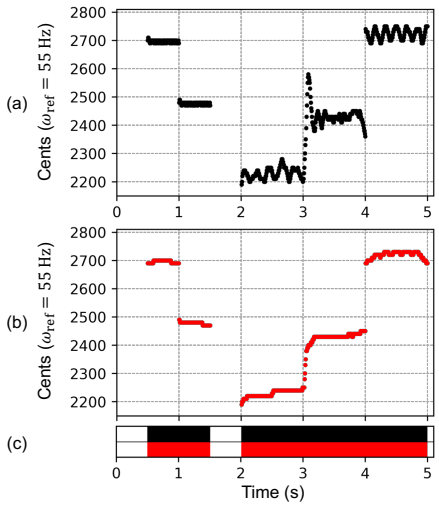

Figure 2. Effect of median filtering. **(a)** Original trajectory γ. **(b)** Median-filtered trajectory γ^{Median}. **(c)** Activation regions of γ (black) and γ^{Median} (red).

unspecified). In our implementation, we use a time resolution of 5.8 ms per time index and a frequency resolution of 10 cents. Figure 2a shows a frequency trajectory, which will serve as our running example in the remainder of this section. In the first two seconds, two notes are played on a piano without interruption. Subsequently, in the next two seconds, there are two sung notes smoothly connected by a pitch slide. Finally, the recording contains a note sung with vibrato.

3.2 Median Filtering

For tonal analysis based on frequency trajectories, one often applies some kind of filtering to remove outliers and other undesired pitch fluctuations [17, 32]. For example, by applying a median filter of odd length $L \in \mathbb{N}$, one obtains a smoothed trajectory γ^{Median} defined by

$$\gamma^{\text{Median}}(n) := \text{median}\big\{\gamma(n - \tfrac{L-1}{2} : n + \tfrac{L-1}{2})\big\} \quad (3)$$

for $n \in \mathbb{Z}$. In this definition, the symbol $*$ is handled as $-\infty$. Figure 2b shows γ^{Median} of our running example using $L = 69$ (corresponding to 0.4 sec). This example shows how median filtering introduces smoothing while removing outliers (such as the peak around the third second). However, the non-stable transition between the two sung notes remains after filtering. This is not what we aim at. First, we do not want to change frequency values in stable regions (with the goal not to introduce smoothing effects in subsequent tonal analysis steps). Second, we aim at explicitly detecting unstable regions, which can then be removed from the frequency trajectory. In the following, we present two conceptually different approaches that fulfill these requirements.

3.3 Morphological Approach

The first approach, which is inspired by work of Vávra et al. [34], uses morphological operations as known in image processing. Applying these operators to frequency trajectories, dilation corresponds to max filtering, and erosion to min filtering. Given a trajectory γ, this results in a dilated trajectory $\gamma^L_{\max}$ and an eroded trajectory $\gamma^L_{\min}$ defined by

$$\gamma^L_{\max}(n) := \max\big\{\gamma(n - \tfrac{L-1}{2} : n + \tfrac{L-1}{2})\big\}, \quad (4a)$$

$$\gamma^L_{\min}(n) := \min\big\{\gamma(n - \tfrac{L-1}{2} : n + \tfrac{L-1}{2})\big\}, \quad (4b)$$

for $n \in \mathbb{Z}$, where $L \in \mathbb{N}$ is assumed to be an odd integer. In max filtering, the symbol $*$ is handled as $-\infty$, whereas in min filtering it is handled as $+\infty$. Figure 3a shows the resulting trajectories $\gamma^L_{\max}$ and $\gamma^L_{\min}$ for our running example using $L = 43$ (corresponding to 0.25 sec). In a next step, we define the difference Δ^L between the dilated and eroded trajectories, also termed morphological gradient [28]:

$$\Delta^L(n) := \gamma^L_{\max}(n) - \gamma^L_{\min}(n) \quad (5)$$

for $n \in \mathbb{Z}$, where we set $\Delta^L(n) = *$ whenever $\gamma^L_{\max}(n)$ or $\gamma^L_{\min}(n)$ are not defined. As shown in Figure 3b, the difference Δ^L is large in non-stable parts (e. g., around the third second), whereas it is small in stable parts (e. g., within each of the piano notes). Fixing a suitable threshold $\tau > 0$ (given in cents), we define the trajectory γ^{Morph} by setting

$$\gamma^{\text{Morph}}(n) := \begin{cases} \gamma(n), & \text{for } |\Delta^L(n)| \leq \tau, \\ *, & \text{otherwise.} \end{cases} \quad (6)$$

The threshold τ can be seen as a tolerance parameter that specifies the maximally allowed fluctuation under which a

Masking approach for detecting stable regions. **(a)** Binary representation Γ_R. **(b)** Max-filtered representation Γ_R^β. **(c)** Median-filtered binary mask $\Gamma_R^{\beta,L}$. **(d)** Trajectory γ^{Mask} restricted to stable regions. **(e)** Activation regions for γ (black) and γ^{Mask} (red).

trajectory is still considered to be stable. The resulting trajectory γ^{Morph} for our running example is depicted in Figure 3c using a threshold of $\tau = 90$ cents. As shown in Figure 3d, the morphological approach succeeds in identifying stable regions. However, it also introduces a truncation at both sides of sudden jumps (e. g., around the first and fourth second) by half the filter length $(L-1)/2$. In the next section, we show how this truncation effect can be reduced by applying a 2D-masking approach involving some median filtering. Finally, we want to note that considering the morphological gradient is conceptionally similar to the approach based on Gaussian derivate filtering as described in [15]. In our approach, the threshold parameter τ can be adjusted dynamically to account for characteristics of individual trajectories, e. g. by considering the p-quantile of the morphological gradient Δ^L.

3.4 Masking Approach

We now introduce an alternative approach for detecting stable trajectory regions, which works in the 2D-domain. In a first step, we encode a trajectory γ as a binary 2D-representation $\Gamma_R : \mathbb{Z} \times \mathbb{Z} \to \{0, 1\}$. Given a frequency resolution of $R \in \mathbb{R}$ (given in cents), Γ_R is defined by

$$\Gamma_R(n, b) := \begin{cases} 1, & \text{for } \left\lfloor \frac{\gamma(n)}{R} + 0.5 \right\rfloor = b, \\ 0, & \text{otherwise,} \end{cases} \tag{7}$$

with time index $n \in \mathbb{Z}$ and frequency bin index $b \in \mathbb{Z}$ (corresponding to a logarithmic frequency axis). Figure 4a shows the binary representation Γ_R using $R = 10$ cents for our running example. In the second step, we introduce some tolerance in frequency direction by vertically applying a max-filtering using a filter length parameter $\beta \in \mathbb{N}_0$ (specified in bins). This results in the representation Γ_R^β defined by

$$\Gamma_R^\beta(n, b) := \max\{\Gamma_R(n, b - \beta : b + \beta)\}. \tag{8}$$

This operation is illustrated by Figure 4b using $\beta = 5$ (leading to a frequency width of $2\beta + 1 = 11$ bins corresponding to 110 cents). In a third step, inspired by an algorithm for Harmonic–Percussive Source Separation [8], a median filter of odd length $L \in \mathbb{N}$ is applied in horizontal direction yielding a representation $\Gamma_R^{\beta,L}$:

$$\Gamma_R^{\beta,L}(n, b) := \text{median}\big\{\Gamma_R^\beta(n - \tfrac{L-1}{2} : n + \tfrac{L-1}{2}, b)\big\}. \tag{9}$$

Applying horizontal median filtering suppresses vertical structures (e. g., pitch slides), while enhancing horizontal structures (corresponding to stable regions), see Figure 4c for an illustration when using $L = 43$ (corresponding to 0.25 sec). In the fourth step, the output trajectory γ^{Mask} is obtained by setting

$$\gamma^{\text{Mask}}(n) := \begin{cases} \gamma(n), & \text{if } \Gamma_R^{\beta,L}(n, b) = 1, \\ *, & \text{otherwise,} \end{cases} \tag{10}$$

with $b = \left\lfloor \frac{\gamma(n)}{R} + 0.5 \right\rfloor$. This last step can be thought of as "masking" the input trajectory γ using the binary mask $\Gamma_R^{\beta,L}$. Figure 4d shows the resulting trajectory γ^{Mask} for our running example. Note that, even though the masking procedure involves some quantization parameter R, the final trajectory γ^{Mask} coincides with the original trajectory γ in stable regions. Similar to the parameter τ for computing γ^{Morph}, the parameter β controls the frequency tolerance within stable regions for γ^{Mask}. As also indicated by our running example, the truncation effects at sudden jumps introduced by the morphological approach have been eliminated by our masking approach (compare γ^{Morph} and γ^{Mask} around the first and fourth second). While the 2D-masking approach is computationally more expensive than the 1D-morphological approach, it allows for processing multiple (non-overlapping) trajectories at the same time. Furthermore, one may account for weighted trajectories (e. g., trajectories with assigned amplitude or confidence values) by using real-valued instead of binary masks. Note that both algorithms do not enforce continuity of output trajectories. In particular, strict parameter settings (e. g. small τ and small β) may result in fluctuating sound events (e. g. a note sung with strong vibrato) being split up into several disconnected regions.

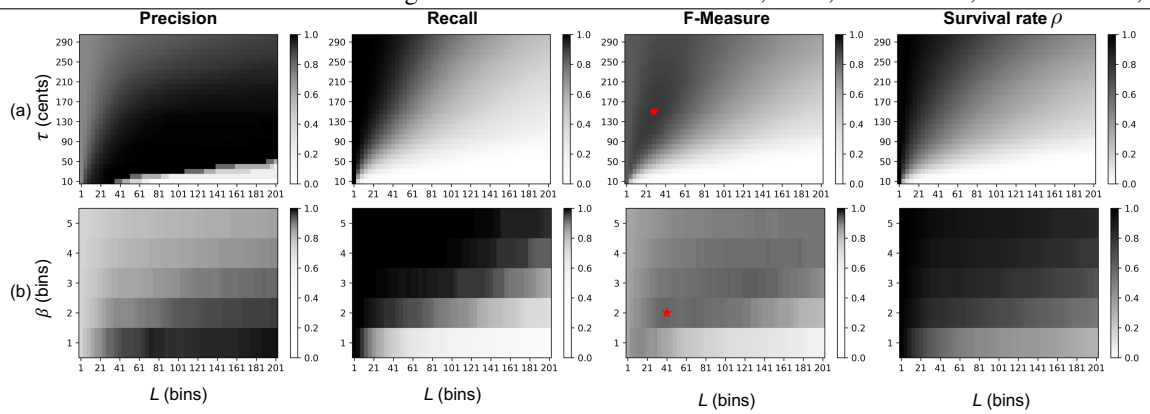

Figure 5. Precision, recall, F-Measure, and survival rate ρ of parameter sweeps averaged over five recordings (see Table 1). The parameter settings chosen for subsequent experiments are marked with red stars. **(a)** Morphological approach. **(b)** Masking approach.

4. EVALUATION

In this section, we report on experiments that indicate the role of the parameters and the behavior of the morphological and the masking approach. In Section 4.1, we numerically compare both approaches using a set of manually annotated stable regions in F0-trajectories from the publicly available Erkomaishvili dataset [20]. Using suitable parameter settings, we then apply both algorithms to the trajectories of all 101 recordings in the dataset (see Section 4.2). It turns out that a consistent detection of stable regions using the two conceptually different approaches is a good indicator that the results are musically meaningful. Finally, in Section 4.3, we demonstrate the potential of our approaches for enhancing harmonic interval distributions.

4.1 Evaluation Measures and Parameters

In order to compare the algorithms' performance, we annotated stable regions of F0-trajectories extracted from five representative Erkomaishvili recordings. To this end, we used an interactive interface described in [20] to manually remove all unstable trajectory regions that correspond to note transitions and other artifacts. As evaluation metrics, we use standard precision (P), recall (R) and F-measure (F) computed frame-wise on the basis of the trajectories' activations. First, all frames with no specified frequency value in the original trajectory ($\gamma(n) = *$) are left unconsidered. Frames classified as stable by our approaches are counted as *true positives* (TP) if they agree with frames annotated as stable, otherwise they are counted as *false positives* (FP). Furthermore, frames annotated as unstable are counted as *false negatives* (FN), if they are classified as unstable. Then,

$$\mathrm{P} := \frac{\mathrm{TP}}{\mathrm{TP}+\mathrm{FP}}, \quad \mathrm{R} := \frac{\mathrm{TP}}{\mathrm{TP}+\mathrm{FN}}, \quad \mathrm{F} := \frac{2\cdot\mathrm{P}\cdot\mathrm{R}}{\mathrm{P}+\mathrm{R}}. \quad (11)$$

Note that $\mathrm{P} := 0$ for $\mathrm{TP}+\mathrm{FP} = 0$, $\mathrm{R} := 0$ for $\mathrm{TP}+\mathrm{FN} = 0$, and $\mathrm{F} := 0$ for $\mathrm{P}+\mathrm{R} = 0$. Furthermore, we introduce an evaluation measure referred to as *survival rate* and denoted as ρ. This measure, which indicates the percentage of remaining trajectory values after filtering, is defined as follows:

$$\rho := \frac{|\{n : \gamma^{\text{Stable}}(n) \neq *\}|}{|\{n : \gamma(n) \neq *\}|} \cdot 100, \quad (12)$$

with $\gamma^{\text{Stable}} = \gamma^{\text{Morph}}$ for the morphological approach, $\gamma^{\text{Stable}} = \gamma^{\text{Mask}}$ for the masking approach and $\gamma^{\text{Stable}} = \gamma^{\text{Anno}}$ for an annotated trajectory γ^{Anno}.

In order to analyze the algorithms' behavior for different parameter settings, we conduct parameter sweeps over L, τ, and β, using a fixed frequency resolution of $R = 10$ cents. For each evaluation metric, we construct a matrix with each entry corresponding to a metric's value for a specific parameter setting averaged over the five annotated recordings. The resulting matrices for precision, recall, F-measure, and survival rate are depicted in Figure 5a for the morphological approach and in Figure 5b for the masking approach. The visualizations show that τ and β play a similar role: high values of τ and β make the approaches more tolerant to local frequency fluctuations in the trajectories, thus increasing the survival rates. In contrast, when decreasing τ and β, less values remain in the filtered trajectories, leading to lower survival rates. Furthermore, note that increasing the filter length L leads to an increase in precision and a decrease in recall for both approaches. In the case of the morphological approach, very large filter lengths lead to a survival rate of $\rho = 0$ (nothing is remaining), which also leads to a precision of zero.

For our further experiments, we use fixed parameter settings for both approaches that correspond to maxima in the F-measure matrices (see red stars in Figure 5). The

	P	R	F	$\rho\,(\gamma^{\mathrm{Morph}})$	$\rho\,(\gamma^{\mathrm{Mask}})$
μ	0.89	0.94	0.92	73%	77%
σ	0.02	0.01	0.02	5%	5%

Table 2. Evaluation of the masking approach against the morphological approach considering the trajectories of all 101 recordings of the Erkomaishvili dataset (with fixed parameter settings from Section 4.1). The mean μ and standard deviation σ refer to statistics taken over the dataset.

morphological approach reaches a maximum F-measure of 0.90 for $\tau = 150$ cents and $L = 29$ bins, whereas the masking approach reaches a maximum F-measure of 0.90 for $\beta = 2$ bins and $L = 41$ bins. Using these parameter settings, the evaluation results for our five annotated examples (IDs correspond to songs on the publicly available website [2]) are given in Table 1. From the table, we can see that both approaches are able to detect stable regions in all five examples. We want to note that the optimal parameter settings vary from song to song, depending on the occurring note durations, characteristics of pitch slides, and other performance aspects. As an alternative to a fixed setting, one may chose the parameters in a song-dependent way, e. g., by fixing the survival rate. In summary, our experiments on the Erkomashvili dataset showed that the specific choice of parameters is not crucial within a certain range (see also the F-measure matrices of Figure 5).

4.2 Consistency

The two approaches for detecting stable regions in trajectories are conceptually different. Nevertheless, in the case of the five annotated recordings, both approaches worked successfully and performed in a similar fashion. Based on the hypothesis that a consistent performance of both approaches is a necessary condition for obtaining meaningful results, we applied both approaches independently to all 101 recordings of the Erkomaishvili dataset. We then compared the results by evaluating the trajectories obtained by the masking approach against the trajectories obtained by the morphological approach using the evaluation metrics defined in Section 4.1. The mean μ and standard deviation σ (taken over the dataset) of the evaluation results are shown in Table 2. The numbers indicate that both approaches deliver similar results on average with a small standard deviation. Furthermore, both approaches roughly exhibit the same average survival rate for the chosen parameter settings. Beyond these overall measures, we also looked at recordings where the two approaches delivered less consistent results. A manual inspection revealed that these recordings often contain speech-like passages (rather than singing) and extremely short notes such as in the songs with ID 022 and ID 074. Results for all 101 recordings are publicly available through audio–visual interfaces. [3]

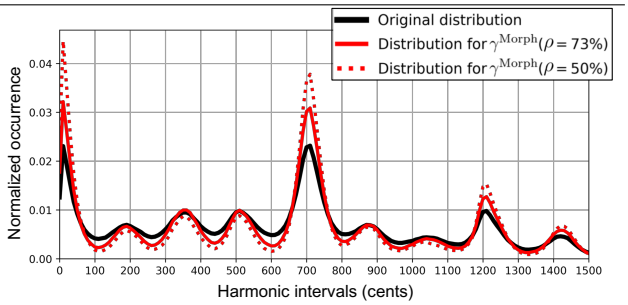

Figure 6. Harmonic interval distributions obtained from the entire Erkomaishvili dataset.

4.3 Harmonic Interval Analysis

In the following, we want to demonstrate the potential of the presented approaches for interval analysis of Georgian vocal music by computing harmonic interval size distributions from the filtered trajectories. To this end, similar to [20,31], we superimpose the filtered trajectories of lead, middle and bass voice and determine the frame-wise intervals for each voice pair (as indicated in Figure 1). Then, by accumulating the occurrences of the different intervals over time, we obtain interval histograms. These histograms are normalized (using the ℓ^1-norm) to obtain distributions. Figure 6 shows three such distributions obtained by considering all 101 recordings of the Erkomaishvili dataset. The first distribution (black solid line) is based on the original F0-trajectories. The second distribution (solid red line) is obtained by considering only stable regions after morphological filtering. (Here, we use the parameter setting discussed in Section 4.1. Filtering with the masking approach leads to similar distributions.) Note that the filtering leads to a sharper interval distribution emphasizing the peaks at the harmonically relevant intervals while not changing the respective peak locations. Using stricter parameter settings leads to a further sharpening (see red doted line in Figure 6). However, overdoing the filtering may drastically reduce the survival rate. This, in turn, may lead to a distortion or even a loss of peak structures corresponding to relevant harmonic intervals.

5. CONCLUSIONS AND FUTURE WORK

In this paper, we presented two conceptually different approaches for detecting stable regions in frequency trajectories, which perform equally well with respect to a set of manually annotated trajectories. Rather than advocating a specific parameter setting, our goal was to introduce these concepts in a mathematical rigorous way, while highlighting their potential using the Erkomaishvili dataset as example scenario. Going beyond harmonic interval analysis, future work will be concerned with applying these filtering techniques for the analysis of melodic intervals, singer interaction, and intonation drifts—aspects of foremost importance in ethnomusicological research on traditional Georgian vocal music.

ABSTRACT

This paper introduces the AcousticBrainz Genre Dataset, a large-scale collection of hierarchical multi-label genre annotations from different metadata sources. It allows researchers to explore how the same music pieces are annotated differently by different communities following their own genre taxonomies, and how this could be addressed by genre recognition systems. Genre labels for the dataset are sourced from both expert annotations and crowds, permitting comparisons between strict hierarchies and folksonomies. Music features are available via the AcousticBrainz database. To guide research, we suggest a concrete research task and provide a baseline as well as an evaluation method. This task may serve as an example of the development and validation of automatic annotation algorithms on complementary datasets with different taxonomies and coverage. With this dataset, we hope to contribute to developments in content-based music genre recognition as well as cross-disciplinary studies on genre metadata analysis.

1. INTRODUCTION

Content-based music genre recognition (MGR) is a popular task in Music Information Retrieval (MIR) research [27]. The goal is to build systems that can predict the genre or subgenre of unknown music recordings (tracks, songs) using music features automatically computed from audio of those recordings. Such research can be supported by recent developments in the context of the AcousticBrainz [1] project, which facilitates access to a large dataset of music features [21] and metadata [22]. AcousticBrainz is a community database containing music features extracted from over four million distinct audio files [2] uniquely identified by public MusicBrainz Identifiers (MBID) [3] and thus tied to rich textual metadata. Users who contribute to the project run software on their computers to process their personal music collections and submit features to the AcousticBrainz database. Based on these features, additional metadata not already included in MusicBrainz, like mood, tempo, key, and genres can be estimated from content-based features in the database.

To facilitate new research in MGR, we have curated four supplemental genre datasets mapped to recordings in AcousticBrainz and containing fine-grained, hierarchical genre annotations, derived from both crowdsourced labels and expert annotations. Each of the four datasets contains multiple labels featuring hundreds of subgenres covering in total over 2,086,000 recordings, which are connected to AcousticBrainz via MBIDs. We refer to the combination of the four datasets and the music features from AcousticBrainz as the AcousticBrainz Genre Dataset. The four main characteristics of this new dataset are:

- **Multi-source.** It allows us to explore how the same music can be annotated differently by communities who follow their own genre taxonomies, and how this can be addressed when developing and evaluating MGR systems. This is especially valuable, because it has been previously noted that the evaluation of MGR systems is difficult due to subjectivity in genre annotations, with little inter-annotator agreement [8]. We are not aware of any other dataset offering such a unique and comprehensive view on genres.
- **Multi-level.** We provide information about the hierarchy of genres and subgenres within each annotation source. Previous research typically used a small number of broad genre categories. According to Sturm's 2012 survey [26], the most popular public datasets for automatic genre recognition were GTZAN and ISMIR04 [7, 13, 28], with 10 and 6 genres, respectively. Only 3.7% of the surveyed systems used 25 or more la-

Public ID	No	No	Yes	No	No	Yes	No	No	No	Yes

[1] While the original dataset only contains free-form tags and no explicit genre labels, there have been several attempts to map MSD-tracks to genres [10, 23, 24]. [2] Available upon request. [3] 7-Digital previews have been available.

Table 1: Popular genre recognition datasets, compared to the proposed AcousticBrainz Genre Dataset.

bels. In contrast, our dataset contains dozens of genres and hundreds of subgenres.

- **Multi-label.** Genre recognition is often treated as a single category classification problem, likely because existing datasets are often single-label (e.g., GTZAN [28] or Ballroom [13]; see Table 1). Yet, previous studies suggest that if there is a diversity of responses in terms of genre labels to any particular recording, the standard evaluation methodology that uses single genre category as ground truth is not adequate [8,20]. Our data is intrinsically multi-label, which allows treating genre recognition as a multi-label classification problem.
- **Large-scale.** MIR research is often performed on small music collections. We provide a very large dataset with audio features for over two million recordings annotated with genres and subgenres. However, we only provide precomputed features, not audio.

Compared to popular MGR datasets (see Table 1), the AcousticBrainz Genre Dataset is unique in that it is the only one that has all of these characteristics, which opens up interesting research opportunities. The remainder of the paper is structured as follows. We describe the dataset in detail in Section 2. In Section 3, we report on how the data has already been used for a task held within MediaEval 2017–18 [3, 4]. Section 4 describes a baseline implementation, and finally Section 5 presents our conclusions.

2. DATASET

The AcousticBrainz Genre Dataset dataset consists of genre annotations (Section 2.1) and precomputed music features (Section 2.2), distributed in predefined splits (Section 2.3). All related information about the dataset including downloads, data format, and baselines is available online. [4]

2.1 Genre Annotations

We provide four datasets with genre and subgenre annotations extracted from different online metadata sources. Two sources feature expert annotations using a strict taxonomy, two others use free-form tags from users: [5]

- **AllMusic** [6] and **Discogs** [7] are based on editorial metadata databases maintained by music experts and enthusiasts. These sources contain explicit genre/subgenre annotations of music albums following predefined genre taxonomies. To build the datasets we assumed that the annotations for an album also correspond to all of the recordings it contains. AllMusic data has been previously used [23] to provide genre annotations for the Million Song Dataset [2], while Discogs has been recently proposed as an alternative source of genre metadata for MIR [5]. To retrieve annotations from these sources we used the artist, album name and year metadata associated with each recording in AcousticBrainz. AllMusic has no publicly available API, and therefore we used a scraper to parse HTML data directly from the website. For Discogs, its public API was used. Annotations in AllMusic contain up to three levels of hierarchy, which we simplified to two levels by taking the most generic and the most specific annotations.
- **Lastfm** [8] is based on a collaborative music tagging platform with large amounts of genre labels provided as folksonomy tags by its users for music recordings. **Tagtraum** [9] is similarly based on genre labels collected from users of the music tagging application beaTunes. [10] To retrieve labels from the Lastfm API and genre annotations from the Tagtraum database we queried them using used artist names and recording titles. We then automatically inferred a genre/subgenre taxonomy and annotations from these labels following the algorithm proposed in [24]. This procedure exploits the fact that co-occurrences for genres are usually asymmetrical. For example, while Alternative Rock almost always co-occurs with Rock, Rock does not necessarily co-occur with Alternative Rock. This lets us derive a hierarchy. We performed manual post-processing to consolidate spelling variations and to remove location and era names (e.g., "50s", "Canadian") or labels that were clearly not a genre (e.g., "awesomelyrics").

Each source's genre taxonomy varies in class space,

[4] https://mtg.github.io/acousticbrainz-genre-dataset

[5] The resulting genre metadata is licensed under CC BY-NC-SA4.0 license, except for data extracted from the AllMusic database, which is released for non-commercial scientific research purposes only.

Table 2: Overview of the AcousticBrainz Genre Dataset. Data is split in 70/15/15% for training, validation and test.

specificity, and breadth, and has its own definitions for the classes (i.e., the same label may have different meanings in difference sources). Most importantly, annotations in each source are multi-label: there may be multiple genre and subgenre annotations for the same music recording. It is guaranteed that each recording has at least one genre label, but subgenres are not always present.

Table 2 provides an overview of the entire AcousticBrainz Genre Dataset. The bottom rows show the size of the genre taxonomies in each source. Compared to the others, the AllMusic taxonomy comprises few genres, but is much richer in terms of subgenres. Conversely, the Tagtraum taxonomy has the most genres, but the least number of subgenres. Figure 1 shows the distributions of genres in all four sets, where we can appreciate clear biases towards pop, rock and electronic. [12] This bias seems less acute in the Discogs and Lastfm sets. Figure 2 shows how label counts are distributed in all four datasets. In terms of genres, most recordings are annotated with only one genre, with some having as many as 8 genres in AllMusic and Discogs. In terms of subgenres, most recordings in the simpler Tagtraum and Lastfm sets are annotated with 1 or 2 subgeners, but in the more complex AllMusic and Discogs sets we find 10 or more subgenre annotations for some recordings. We can see that the distribution in AllMusic is quite smooth, while in the other sets we see clear biases towards 1 genre and 1 or 2 subgenres. We did not aim to create a representative or unbiased dataset, instead collecting as much data as possible for recordings in AcousticBrainz. We understand that biases likely exist due to the coverage of MusicBrainz, AcousticBrainz, and the sources of genre information.

A more detailed picture of the complexity and similarity among datastets can be made in terms of entropy of the label distributions. In particular, we may compute the conditional entropy of a dataset X given another dataset Y:

$$H(X|Y) = -\sum_{x\in\mathcal{X},y\in\mathcal{Y}} p(x,y)\log\frac{p(x,y)}{p(y)}\,, \qquad (1)$$

where $\mathcal{X}$ and $\mathcal{Y}$ are the taxonomies of X and Y, respectively. Eqn (1) computes the amount of information needed to describe a recording in X given its labels in Y. For simplicity, we ignore the multi-label nature of the data and set $p(x)$ equal to the probability that a recording contains the label x, ignoring the other labels in the same recording. As a byproduct, this allows us to compute $H(X|X) \neq 0$, understood as the amount of information needed to fully describe a recording in X when some label in X is already known. To make this distinction explicit, let us refer to this as *conditional pseudo-entropy* $\tilde{H}$.

[11] https://musicbrainz.org/doc/Release_Group

[12] Details on the genre/subgenre taxonomies and their distributions are reported on the dataset website.

	Allmusic	Discogs	Lastfm	Tagtraum

Tagtraum	2.09	2.00	1.17	0.67

(b) Only genre labels.

Table 3: Conditional pseudo-entropy $\tilde{H}(X|Y)$ between pairs of datasets, where X is the dataset in the row and Y the one in the column.

Table 3a shows the conditional pseudo-entropies when considering both genre and subgenre labels. As the diagonal shows, the AllMusic dataset is much more complex than the others, as anticipated by the high number of subgenres in the taxonomy and the smooth distribution shown in Figure 2. Interestingly, the Lastfm column shows that knowing Lastfm labels provides the most information when predicting labels in the other taxonomies, only surpassed by known labels in the target taxonomies (diagonals). Lastfm and Tagtraum are the most similar sets, with AllMusic and Discogs being the most dissimilar. This suggests that labels produced by different non-expert user communities and following no common guidelines, are more similar than those produced by different set of experts following different guidelines.

Table 3b shows similar results, but considering only the genre labels. The pseudo-entropies are orders of magnitude smaller because genres encode less information, and as a result relative differences among datasets are also smaller. Discogs is the most complex dataset because of its higher variability in the number of genres per recording (see rows in Figure 2), followed by AllMusic. This time, we see that Tagtraum provides the most information when predicting labels in another taxonomy. As before, the most similar sets are Lastfm and Tagtraum, and the most dissimilar are AllMusic and Discogs.

2.2 Music Features

We provide music features precomputed from audio for all music recordings. All features are taken from the

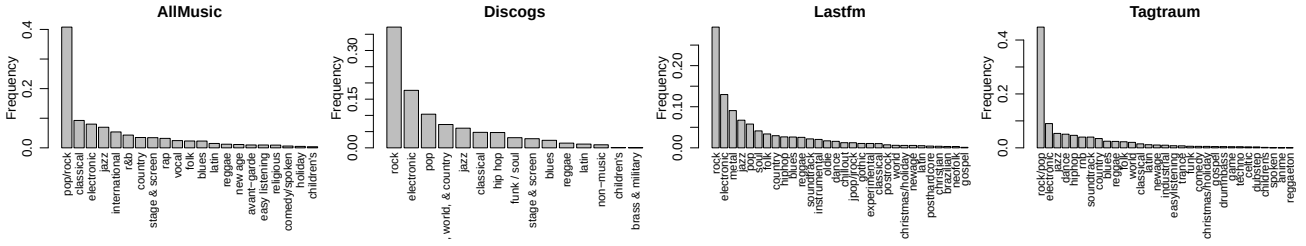

Figure 1: Distributions of genre labels.

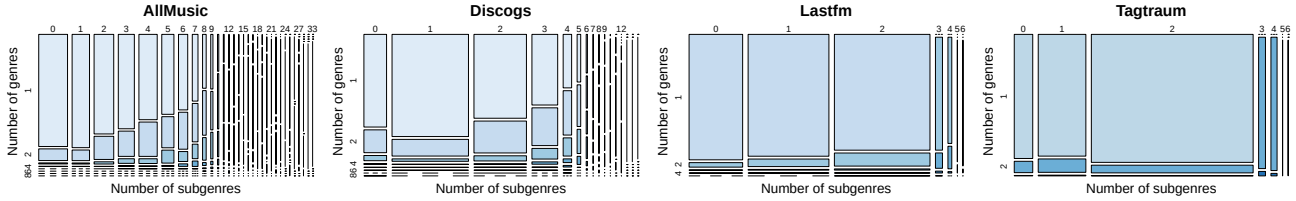

Figure 2: Distributions of label counts. Box heights represent the amount of recordings with the number of genre labels indicated in the row, and widths represent the amount of recordings with the number of subgenre labels in the column.

AcousticBrainz database and were extracted from audio using Essentia, an open-source library for music audio analysis [6]. They include features characterizing overall loudness, dynamics, and spectral shape of the signal, rhythm descriptors (including beat positions and BPM value), and tonal information (including chroma features, keys and scales). [13] Only a statistical characterization of time frames is provided (bag of features), that is, no frame-level data is available. The features for each recording are provided in a JSON file. [14]

2.3 Training, Validation and Test Sets

We provide four training sets and four validation sets with all data publicly available, and four test sets with a hidden ground truth. The training and validation sets can be used for the evaluation of MGR systems (Section 3.3). The test sets do not include a publicly available ground truth and have anonymized MBIDs; they are reserved for future MGR challenges. Nevertheless, it is possible to run an evaluation on the test sets upon request. [15]

The datasets were created by a random split of the full data ensuring that:

- No recording appears in more than one set;
- No recordings in any set are from the same release groups present in other sets (e.g., albums, singles, EPs);
- The same genre and subgenre labels are present in all three sets for the same source;
- Genre and subgenre labels are represented by at least 40 and 20 recordings from 6 and 3 release groups in training and validation/test sets, respectively.

The approximate split ratios of the datasets are 70% for training, 15% for validation, and 15% for testing. Partitioning scripts are provided to create training-validation splits ensuring these characteristics in the data. The four ground truths partially overlap. The full intersection of all training sets contains 247,716 recording, while the intersection of the two largest sets, AllMusic and Discogs, contains 831,744 recordings.

All data are published in JSON and TSV formats; details about the formats are available online. Each recording in the training and validation sets is identified by an MBID, which can be used by researchers to gather related data. Importantly, our split avoids the "album effect" [11], which leads to a potential overestimation of the performance of a system when a test set contains recordings from the same albums as the training set. We don't filter for the artist effect, in order to preserve some low-count tags and to address the fact that artists can release albums with different broad genres. MusicBrainz artist IDs allow researchers to perform this filtering if desired. The training sets additionally include information about release groups of each recording, which may be useful for researchers in order to avoid this effect when developing their systems.

3. RESEARCH TASK

MGR systems typically attempt to predict a single label per recording. Given that the AcousticBrainz Genre Dataset features multiple hierarchical labels from different sources, we suggest the following two subtasks designed for the datasets introduced in Section 2.

3.1 Subtask 1: Single-source Classification

This task, depicted in Figure 3a, explores conventional systems, each one trained on a single dataset. Researchers make predictions for the test set of each dataset separately, using their respective class spaces (genres and subgenres). These predictions will be produced by a separate system for each dataset, trained without any information from the

(b) Subtask 2: Multi-source classification

Figure 3: Suggested tasks for the AcousticBrainz Genre Dataset.

other sources. This subtask can serve as a baseline for the multi-source classification task described below.

3.2 Subtask 2: Multi-source Classification

This task (Figure 3b) explores the combination of several ground-truth sources to train, but still make predictions for each test set separately, again following the corresponding genre class spaces. These predictions may be produced by a single system for all datasets or by one system for each dataset. Researchers are free to make their own decisions about how to combine the training data from all sources.

3.3 Evaluation

The development of an appropriate methodology that models each subtask as a single experiment with a "source" factor and replicated observations, is an interesting point that we leave for future research. For simplicity, we follow traditional evaluation on each test dataset separately, as if they were four independent experiments. As for metrics, we propose ROC AUC, precision, recall and F-score at the label level for a system-oriented view, and also at the recording level for a user-oriented view. We do not use hierarchical metrics because the hierarchies in the Lastfm and Tagtraum datasets are not explicit. Instead, we compute metrics at different levels:

- Per recording: using all labels, only genre labels, or only subgenre labels
- Per label: using all recordings
- Per genre label: using all recordings
- Per subgenre label: using all recordings

The ground truth does not necessarily contain subgenre annotations for some recordings, so we only considered recordings containing subgenres for the evaluation at the subgenre level. We provide evaluation scripts for development purposes and two simple baselines:

- Random baseline reproduces the joint distribution of labels as found in the training sets.
- Popularity baseline always predicts the most popular genre in the training set.

In the context of the MediaEval 2017–18 task, [16] researchers were expected to create predictions for both subtasks, reporting whether they used the entire data available for development or only its parts for every submission. Overall, we received over 100 submissions from 7 research teams covering both subtasks.

[16] Task details and evaluation results are available online: `https://multimediaeval.github.io/2018-AcousticBrainz-Genre-Task`

4. BASELINE

In this section we present our baseline approach for the proposed MGR tasks. This baseline employs an oversimplistic deep learning architecture for the single-source task and a fusion approach that demonstrates the possibilities of merging different genre ground truth sources in the multi-source task. To this end, we explore how stacking deep feature embeddings obtained on different datasets can benefit MGR systems. We propose an early fusion approach, similar to the one proposed in [19] for multi-modal genre classification. The approach incorporates knowledge across datasets by stacking deep feature embeddings learned on each dataset individually and using those as an input to predict genres for each dataset.

4.1 Input Features

We use all available features provided for the challenge. As a pre-processing step, we apply one-hot encoding for a few categorical features related to tonality (`key_key`, `key_scale`, `chords_key`, and `chords_scale`) and standardize all features (zero mean, unit variance). In total, this amounts to 2669 input features.

4.2 Neural Network Architecture

A simple feedforward network (extractor network) is used to predict the probabilities of each genre given a track. The network consists of an input layer of 2669 units (the size of the feature vector for an input recording), followed by a hidden dense layer of 256 units with ReLu activation, and the output layer where the number of units coincides with the number of genres to be predicted in each dataset. Dropout of 0.5 is applied after the input and the hidden layer. As the targeted genre classification task is multi-label, the output layer uses sigmoid activations and is evaluated with a binary cross-entropy loss.

Mini-batches of 32 items are randomly sampled from the training data to compute the gradient. The Adam [15] optimizer is used to train the models, with the suggested

Subtask	AllMusic	Discogs	Lastfm	Tagtraum
Single-source	0.648	0.759	0.828	0.802
Multi-source	0.812	0.886	0.906	0.887

Table 4: ROC AUC on validation datasets.

default parameters. The networks are trained for a maximum of 100 epochs with early stopping on validation loss. Once trained, we extract the 256-dimensional vectors from the hidden layer for the training, validation, and test sets.

The model architecture is used to train a multi-label genre classifier on each of the four datasets. The models are trained on 80% of the training set and validated after each epoch using the other 20% using the provided split script with release group filtering. Predictions are computed for the validation and test sets.

4.3 Embedding Fusion Approach

One model per dataset is trained. These models serve for predictions in Subtask 1. For Subtask 2, the given models are used as feature extractors. All four models share the same input format, so input feature vectors from one dataset can be used as input to a model trained on other datasets. For each model we feed all tracks from the training, validation and test sets of each dataset, and obtain the activations of the hidden layer as a 256-dimensional feature embedding. Therefore, for each track in each dataset we obtain four different feature embeddings, coming from each of the four previously trained models.

Given the four feature embeddings of each track, we apply the ℓ_2-norm to each of them and then stack them together into a single 1024-dimensional feature vector. We obtain new feature vectors for every track in the training, validation and test sets of each dataset. We use these feature vectors as input to a fusion network where the input layer is directly connected to the output layer. Dropout of 0.5 is applied after the input layer. The output layer is exactly the same as in the extractor network, where sigmoid activation and binary cross-entropy loss are applied. The fusion network is trained following the same methodology and partitions described for the extractor network. We train a fusion network per dataset, and obtain the genre probability predictions of the validation and test sets for Subtask 2.

4.4 Predictions Thresholding

The predictions made by each model are continuous, while the task requires binary prediction of genre labels. We apply a plug-in rule approach thresholding the prediction values to maximize the evaluation metrics. As an example, we decided to maximize the macro F-score, and applied thresholds individual for each genre label [18].

4.5 Results and Analysis

Full results and code for the baseline are available at the dataset website. Table 4 presents the ROC AUC metric on the validation sets. Table 5 presents the final results after applying thresholding. We can clearly see the benefit of models based on the embedding fusion approach compared to the models trained individually on each dataset. While the individual models (Subtask 1) are hardly usable, the combined models got a significant improvement in performance.

		Dataset			
		AllMusic	Discogs	Lastfm	Tagtraum
Single-source					
Per recording (all labels)	P	0.016	0.069	0.075	0.124
	R	0.579	0.538	0.446	0.507
	F	0.030	0.119	0.124	0.194
Per label (all labels)	P	0.023	0.076	0.074	0.097
	R	0.492	0.249	0.238	0.232
	F	0.032	0.095	0.095	0.115
Multi-source

	F	0.195	0.339	0.305	0.349
Per label (all labels)	P	0.065	0.108	0.115	0.127
	R	0.155	0.210	0.220	0.223
	F	0.074	0.122	0.133	0.140

Table 5: Precision, recall and F-scores on validation datasets produced by our baseline approach.

In our baseline, we focused on optimizing macro F-score, however choosing this metric for threshold optimization can have a negative effect on micro-averaged metrics. In the case of infrequent subgenre labels and an uninformative classifier, an optimal, but undesirable strategy may involve always predicting those labels [18]. Indeed, this was the case for the individual models, but the fusion models did not have this issue.

Overall, we may expect further improvements in performance by means of a more sophisticated network architecture (e.g., [16, 25]). The baseline is available online at the dataset webpage.

5. CONCLUSIONS

We have presented the AcousticBrainz Genre Dataset, a large-scale dataset of music features and hierarchical multi-label genre annotations from different sources. This is unique data for MIR research, as it allows researchers to explore how the same music pieces are annotated differently by different communities following their own genre taxonomies, and how this could be addressed by genre recognition systems. To this end, we have proposed a research task for building MGR systems based on music features available in the AcousticBrainz database and to explore how multiple sources of genre annotations can be combined by MGR systems. This task was already held within the MediaEval 2017–18 evaluation campaigns, and it may serve as an example of the development and validation of automatic annotation algorithms on complementary datasets with different taxonomies and coverage.

Acknowledgments
We thank all contributors to AcousticBrainz. This research has received funding from the European Union's Horizon 2020 research and innovation programme under grant agreements No 688382 (AudioCommons) and 770376-2 (TROMPA), as well as the Ministry of Economy and Competitiveness of the Spanish Government (Reference: TIN2015-69935-P). We also thank tagtraum industries for providing the Tagtraum genre annotations.

ABSTRACT

Cultural products such as music tracks intend to be appreciated and recognized by a portion of the audience. However, no matter how highly recognized a song might be at the beginning of its life, its recognition will inevitably and progressively decay. The mechanism that governs this decreasing trajectory could be modelled as a forgetting curve or a collective memory decay process. Here, we propose a composite model, termed T-REC, that involves chart data, YouTube views, Spotify popularity of tracks and forgetting curve dynamics with the purpose of estimating song recognition levels. We also present a comparative study, involving state-of-the-art and baseline models based on ground truth data from a survey that we conducted regarding the recognition level of 100 songs in Sweden. Our method is found to perform best among this ensemble of models. A remarkable finding of our study pertains to the role of the number of weeks a song remains in the charts, which is found to be a major factor for the accurate estimation of the song recognition level.

1. INTRODUCTION

Music is a form of art that attracts the vast majority of global population and has a remarkable impact on people's emotions and behavior. In particular, in-store consumer purchase behavior has been related to background music in the research literature [9, 21, 22, 31]. Also, the role of music popularity, liking and recognition levels in shopping intentions [4, 35] and the perception of time [2] has been investigated. Background music providers supply companies with music playlists with the purpose of optimizing the in-store experience of their customers and their brand perception. Having effective means of estimating song recognition can provide such companies with a useful tool for generating better playlists. Motivated by the above, in this paper we propose an accurate song recognition model as basis for experimentally measuring the impact of song recognition on in-store purchase behavior. [1]

Although song *recognition* is the focus of this paper, song *popularity* is more frequently encountered in the research literature. The popularity of songs is a concept used to express how much attention a certain song *currently* receives. There have been attempts towards determining song popularity making use of the online available information from posts in microblog websites [12, 23, 28, 29] and in the blogosphere [1], search queries and number of shared files in peer-to-peer networks [17, 28], play counts in social media music sites such as Last.fm [3, 29], the amount of time of radio play, the music industry awards that it received [25] and popularity indices provided by streaming platforms such as Spotify [3]. Of course the traditional ways of determining music popularity such as the Billboard Magazine chart are also used for comparison with the modern web-based popularity indices [16, 17].

Music exhibits its own complex dynamics in terms of popularity growth and decay while the means used to promote it in the public constantly evolve and capitalize on the advances and trends of digital media and communication technologies. During the last decade, researchers have investigated special attributes of songs that may lead to a successful release [8, 15, 36], and have attempted to successfully predict hit songs [6, 16]. However, while song popularity is a research topic that has attracted intense academic interest the level of a music track's recognition is a notion that has been significantly less studied.

As song recognition we define the fraction of the audience that recognizes (comprehend that they have heard it before) a specific music track through audio exposure. This notion is different from the notion of song popularity as a song might no longer be trending (for instance an old song no longer placed in the charts) but at the same time a considerable portion of the music audience might recognize its tune. To further illustrate this differentiation, in Table 1 we present the most popular songs of 2018 [2] and most recognized songs of all time [3] . It is apparent that songs on the left column currently overwhelm the charts and online playlists, but songs on the right column are

[1] We consider atmospherics, such as high/low recognition music, as causal factors for consumer behavior in stores.

surely recognized by a very high percentage of the population even though they are not currently popular.

To estimate the portion of the audience that recognize a music track, one should take into account the cognitive aspects of the problem. That is to say, collective memory dynamics and more precisely the mechanisms that govern its initial increase and its decay after the initial period of popularity. For the more general concept of human memory decay many studies have been conducted [10,11,20,24] indicating forgetting curves with exponential decay dynamics. Music-specific research has adopted exponential forgetting curves [7, 14] for song "freshness" assessment, as well. A method with double exponential dynamics was proposed as a general memory decay model [5], while log-normal dynamics were employed to model the dynamics of scientific paper impact [33]. Equally important is to take into account the notions of learning curves [26] and over-learning [27] in order to determine the initial amount of learned information and the velocity of forgetting. In many studies researchers argue for the significant role of (i) repetition of a stimulus in learning [10, 13, 19, 26, 27] and (ii) the degree of original learning in the velocity of forgetting [10, 20, 30, 34]. Namely, the more exposed to a stimulus humans are the higher the initial amount of learned information is and the slower they forget it.

Here, we propose T-REC, a song recognition model that takes as input the chart positions a track has gained along with the respective dates, its current YouTube views and Spotify popularity. T-REC also considers sigmoid learning curve dynamics, exponential decay forgetting curve dynamics and a decay rate being a function of the number of weeks each track is maintained in the charts, which we consider here as a proxy of the original learning degree. In other words, the number-of-weeks feature is an indicator of how strongly the audience is exposed to a specific tune and as it increases, the forgetting procedure (i) starts from a higher point and (ii) decelerates further, as indicated by the related research literature on human memory. Eventually, T-REC results in the estimation of song recognition levels per market and globally. Other competitive models are also considered for comparison purposes. We have conducted a survey for the estimation of the current level of recognition of 100 songs in Sweden, which we then use as ground truth for the evaluation of our method's performance and for comparison with the other methods. We make the resulting data available for the community [18].

2. MATERIALS AND METHODS

2.1 Data

For estimating the recognition levels of music tracks, our starting point was a list of tracks provided by *Soundtrack Your Brand*, a collaborating background music provider. The list consists of 39,466 tracks from 21,450 artists and from 75 countries. We also make use of data from 211 charts, 198 track charts and 13 singles charts, that span long periods of time (in some cases from the 60s until today) from 62 countries around the globe including Sweden. We also used the Spotify API to annotate chart entries with the Spotify id and International Standard Recording Codes (ISRC) [4] of each of the songs. Since our user study was carried out on a Swedish population, we present the monitored charts for Sweden along with the corresponding monitored periods in Table 2.

chart name	since	until
Spotify Daily Chart	2017-01-01*	2018-03-06
Spotify Weekly Chart	2016-12-23	2018-03-01
Veckolista Svenskt Topp-20	2015-01-17	2018-06-15
Veckolista Singlar	1988-01-16	2018-06-15
Veckolista Heatseeker	2015-01-10	2018-06-15
Veckolista Svenska Singlar	2015-01-10	2015-01-16
SINGLES TOP 100	1975-11-08	2018-06-01
Sweden Top 20	2001-06-12	2018-07-07
Sweden Singles Top 100	2017-12-29	2018-07-05

Table 2: The list of Swedish charts we used in this study. The first column presents the chart name, the second and third columns present the start and end dates of monitoring respectively. *All dates are in YY-MM-DD format.

Most songs do not make it in the charts, thus we additionally employ YouTube views and Spotify popularity of tracks as current track popularity proxies. Knowing the Spotify id of the tracks and the id of an associated official video in YouTube [5], we retrieved these two signals by using the public APIs offered by Spotify and YouTube respectively. The intuition behind the use of these two metrics, is that they reflect the exposure of a song in two widely used platforms. Number of video views in YouTube is a direct measure of how many people heard a song. On the other hand, although Spotify popularity is a score generated internally by Spotify and the exact formula is not known, that score reflects the actual number of streams a song received recently. Therefore, we can safely assume that a song having a high popularity score is currently listened more than songs with a lower score.

2.2 Models

2.2.1 T-REC

The proposed song recognition model builds upon three main components, the *recognition growth* that represents the level of recognition a track reaches during its initial

[4] https://isrc.ifpi.org/

[5] To this end, we used the Soundiiz (www.soundiiz.com) service, which supports playlist conversion between platforms.

prosperity time (when it is placed in charts), the *recognition decay* that represents the collective memory decay process (i.e. the mechanism of collective forgetting of songs) and the *recognition proxy-based adjustment* that adjusts the recognition level of tracks, which is especially useful for tracks with no chart information.

Having annotated chart entries with the corresponding ISRC, we were able to retrieve the positions of tracks in the Swedish charts of Table 2. These are then used to estimate their *recognition growth* (in Sweden) according to Equation 1:

$$g(t) = \begin{cases} 100 \cdot \frac{c_K + 1 - r_K(t)}{c_K} \cdot \sigma_1, \\ \qquad\qquad \text{if track in chart } K \text{ at time } t \\ 0, \text{ otherwise} \end{cases} \tag{1}$$

where c_K is the number of tracks in chart K, $r_K(t)$ is the rank of the track in chart K at time $t \in [t_0, t_{today}]$ [6] and $\sigma_1 = \sigma_1(\theta_0, \theta_1, x) = (1 + e^{-\theta_1 \cdot x + \theta_0})^{-1}$ adjusts the rank's importance using an S-shaped learning curve with $x \in (0, +\infty)$ and $\theta_0, \theta_1 \in \mathbb{R}$. The logistic part of the model is incorporated to control the importance of a chart position given the number of weeks x the track has remained in the charts. If a track remained in the charts for only one week its rank's importance would be a lot lower (54.9%) compared to it remaining for 20 weeks (98.2%). Therefore, in the first case the decay process will begin from a much lower point. The value of $g(t)$ is assigned to all $g(t_i)$ with $t_i \in [t - n + 1, t]$ according to the chart's frequency e.g. if it is weekly $n = 7$. If a track gains multiple values at a single date, the maximum value is used.

Towards formally defining the *recognition decay*, we build on findings from research literature in the area of human memory, and more precisely on the concept of forgetting curves. A forgetting curve is the rule by which the memory regarding a specific learned item is reduced. In our case we consider as learned items the music tracks. Hence, we aim at estimating the function that describes the forgetting procedure that has been proposed to be exponentially decreasing in many studies [20, 24]. We also opt for the exponentially decreasing forgetting curve for song recognition but at a less steep rate. It is natural to consider that the level of *recognition decay* is impossible to be higher than the level of *recognition growth* at its peak for a particular track. Also, each time the track reemerges in the charts the forgetting procedure restarts from a new higher point of recognition. Additionally, we consider a variable decay rate as a reasonable consideration would be that not all songs' recognition decays with the same velocity. The *recognition decay* is defined in Equation 2:

$$d(t) = \begin{cases} g(t), \text{ if } d(t-1) \leq g(t) \\ \sigma_2 \cdot d(t-1) + (1 - \sigma_2) \cdot g(t), \text{ otherwise} \end{cases} \tag{2}$$

where $\sigma_2 = \sigma_2(\phi_0, \phi_1, x) = (1 + e^{-\phi_1 \cdot x + \phi_0})^{-1}$ is the recognition retention percentage with x being the number of weeks the track has remained in the charts and $g(t)$ is the previously defined in Equation 1 *recognition growth*. If a track has remained for a long time in the charts its retention percentage would be considerably high and its forgetting process would be rather slow, while if a track has remained in the charts for only few weeks its retention percentage would be low and its forgetting process fast.

The first logistic function σ_1 controls the initial recognition level from which the decreasing trajectory begins and the second logistic function σ_2 controls the velocity of recognition decay, both individually per track.

To model the *recognition proxy-based adjustment*, we consider a multiple linear regression model with input the track's current Spotify popularity index (P_S) and the log-transformed YouTube views (P_{YT}) as in Equation 3:

$$s(t_{today}) = \alpha_0 + \alpha_1 \cdot log(P_{YT}) + \alpha_2 \cdot P_S \tag{3}$$

The composite T-REC model is defined as a linear combination of *recognition decay* and *recognition proxy-based adjustment* at t_{today}:

$$\text{T-REC} = w_0 + w_1 \cdot d(t_{today}) + w_2 \cdot s(t_{today}) \tag{4}$$

2.2.2 Competitive Models

In order to perform a comparative study, four competitive models are employed for the task of song recognition estimation. Two of them are well-known regression models, one is related to collective memory decay while the last one is the plain Spotify popularity index (P_S).

The first model is based on Multiple Linear Regression (MLR) and the second on Random Forests (RF). The log-transformed YouTube views and the Spotify track popularity are considered as inputs to these models and actual recognition as their target. MLR actually corresponds to the proxy-based adjustment introduced in Equation 3. The third competitive model is the state-of-the-art log-normal decay model (LOGN) [33] that Wang et al. developed for modelling the decay process of scientific paper citations. We use the form of this model that is presented in the supplementary material of [5], namely Equation 5:

$$l(t) = e^{\left[ln\left(\frac{\lambda}{\sqrt{2\pi}\sigma}(c^t + m)\right) - \mu^2\right]} \cdot t^{\frac{\mu}{\sigma^2} - 1} \cdot e^{-\frac{ln^2(t)}{2\sigma^2}} \tag{5}$$

where t is time, $c^t = m\left[e^{\lambda\Phi\left(\frac{ln(t)-\mu}{\sigma}\right)} - 1\right]$, $\Phi(\cdot)$ is the cumulative distribution function of the normal distribution and λ, μ, σ, m are arbitrary parameters.

2.2.3 Optimization and Evaluation

We consider a holdout strategy (70% training, 30% test) for the models' evaluation as described in [32]. The optimization of all models' parameters is performed in the training set by the truncated Newton algorithm as implemented by the SciPy package. We use as objective function the mean absolute error between measured (by the user study) and computed (by each model) song recognition.

[6] As t_0 we set the song's release date and as t_{today} the current date.

	class	#	fraction	Sweden
gender	male	521	50.05%	50.24%
	female	520	49.95%	49.76%
age	18-24	54	5.19%	18.15%*
	25-34	422	40.54%	22.46%
	35-44	277	26.61%	20.01%
	45-54	244	23.44%	21.12%
	55-65	44	4.22%	18.26%

Table 3: Demographics of the test population and Sweden (normalized within the group of people between 15 and 65 years old). *This figure refers to 15-24 age group.

The models' performance is then evaluated in the test set by the mean absolute error (MAE) between the measured and the computed recognition as in Equation 6:

$$\text{MAE} = \frac{\sum_{i=1}^{k} \mid x_i - y_i \mid}{k} \quad (6)$$

where k is the number of tracks, x_i is the measured recognition for track i and y_i is the computed recognition for track i. A perfectly accurate model would lead to a MAE value of 0.

2.3 User study

To proceed with the user study, we employed an initial and much simpler version of the recognition score. This initial version had a constant decay rate across all tracks and for the tracks with no chart data the average recognition score of the closest, in terms of YouTube views and Spotify popularity, tracks was considered as their recognition score. [7]

After the assignment of the initial recognition score (corresponding to the time the survey was conducted) to each of the 39,466 tracks, we formed two lists. One list containing the 600 most recognized tracks in Sweden and a second containing the 600 least recognized tracks in Sweden. [8] Consequently, 50 tracks were randomly chosen out of each of these two lists as representative of high and low recognition tracks.

A study was then conducted in order to obtain the actual recognition percentages for each of these 100 songs among a test population of 1041 annotators in Sweden. [9] We divided the initial list of 100 songs in 10 groups of 10 songs (5 of low and 5 of high recognition level in a randomized order), then each participant listened to 30-second samples of all the songs of one group and for each song he/she indicated whether he/she recognized it or not. We had ∼100 respondents per song [10] so we got a score 0-100 based on the percentage of respondents who responded positively.

[7] The rationale behind the alterations on this model that led to T-REC is illustrated in the results section.

[8] Given that recognition estimation is the result of a sampling process, we expect measurements in the extremes (i.e. least and most recognised songs) to be less noisy than in intermediate recognition levels. This motivated our choice to perform the initial song selection out of two distinct sets (high, low).

[9] The study was performed through the Cint survey platform (`https://www.cint.com/`).

[10] Some variability was due to the fact that not all respondents completed the process successfully.

θ_0	θ_1	ϕ_0	ϕ_1	α_0
0.233	0.043	0.847	0.029	1.299
α_1	α_2	w_0	w_1	w_2
0.999	-0.093	22.586	0.452	0.928

Table 4: Parameter values for T-REC after fitting.

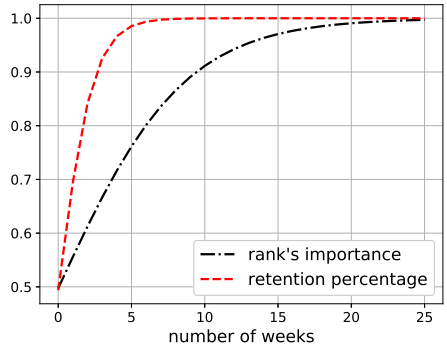

Figure 1: The logistic parts of *recognition growth* (rank's importance) and *recognition decay* (retention percentage) components as formed after the model fitting.

We consider the recorded responses as ground truth for our experiments and we evaluate our model as well as the competitive models on this basis. Demographics of the test and Swedish population [11] are illustrated in Table 3. We observe divergent age demographics, yet almost identical gender demographics between the test and actual population. As the selection of annotators was carried out by Cint, we could not better approximate the Swedish population distribution. Despite the over-representation of some age groups and under-representation of others, T-REC is still a sound methodology; given a different population sample to learn from, the model tuning step (section 2.2.3) would lead to a slightly different recognition estimation model.

3. RESULTS

The analysis of the survey data shows that the initial recognition score classified the tracks effectively with 50/50 (100%) correctly labeled as low and 37/50 (74%) correctly labeled as high recognition (measured recognition $<$50% is considered as low, while $>$50% as high). The 13 songs that were falsely classified as high recognition actually obtain a smaller recognition score than the rest (on average 6 units lower). Despite the promising classification performance the measured recognition was in many cases far from the computed score especially in cases of tracks with no chart data. Thus, we developed the updated version of the recognition score (T-REC) described in section 2.2.1.

Table 4 presents the parameter values of T-REC after optimization. The model gives significant weights on both *recognition decay* (w_1) and *recognition proxy-based adjustment* (w_2) components, but considers YouTube views

(a) Rude Boy - Rihanna

(b) All I Want for Christmas Is You - Mariah Carey

Figure 2: T-REC components (*recognition growth*, *decay* and *proxy-based adjustment*) for two highly recognized songs.

(α_1) as more important than Spotify popularity (α_2) for the under study problem. The impact of the rest of the parameters on the final model, namely the shape of the two logistic functions that control the *recognition growth* (θ_0, θ_1) and *recognition decay* (ϕ_0, ϕ_1) components is illustrated in Figure 1. The logistic part of *recognition growth* (rank's importance) is less steep than the logistic part of *recognition decay* (retention percentage), indicating that a music track will need almost 7 weeks in the charts to achieve a very slow rate towards oblivion, but at least 25 weeks to achieve its highest contemporary recognition.

Moreover, two examples of how T-REC models the mechanism of song recognition decay are illustrated in Figure 2. As illustrated in Figure 2a, the song "Rude Boy" by Rihanna stayed in Swedish charts for 19 weeks, and according to the *recognition decay* component it maintained 99.9% of its initial recognition. Consequently, the *recognition proxy-based adjustment* input adjusts T-REC very close to the measured recognition (error=3.11). A different example presented in Figure 2b shows that Mariah Carey's "All I Want for Christmas Is You" initially was not a big hit in Sweden, remaining for only three weeks in the charts back in 1995. Afterwards, its recognition exhibited a significant decrease during the next decade, but after 2007 when the song kept reemerging in the charts every year its recognition decay rate slowed down and both its *recognition growth* and *decay* components grew larger. The *recognition proxy-based adjustment* component adjusts T-REC a little lower. Although we lack ground truth for this song to compare it to T-REC's estimation (as it was not in the survey's lists), we believe that 80.99% recognition is closer to the real recognition rate [12] than the 98.99% computed by the *recognition decay* component, which is obviously too high even for a massive hit such as this.

Figure 3 illustrates the performance of T-REC on estimating the actual current recognition level of songs in Sweden. Most of the points are concentrated close to the identity line except for some tracks of intermediate recognition levels, which are overestimated. Table 5 compares the performance of T-REC with the one of all competitive models in terms of average MAE. All models (except for Spotify popularity index) are trained on 100 different training sets, each containing 70 randomly selected tracks out of the initial set of 100 tracks and then their MAE is measured on the 100 corresponding test sets, each containing the remaining 30 tracks. T-REC exhibits the best performance among all models with a very high statistical significance level as indicated by the p-value=10^{-17}, according to the Wilcoxon signed rank paired test. [13]

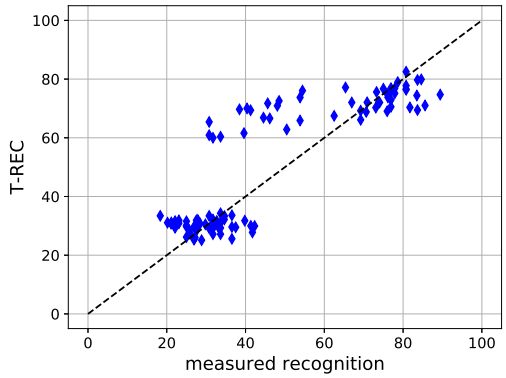

Figure 3: Scatter plot with the T-REC recognition score on the y axis and measured recognition on the x axis.

As additional information we provide long lists of Top-100 recognized songs and the corresponding Top-10 artists (according to T-REC) for Sweden and USA, in the supplementary material. Furthermore, we compare T-REC's Top-N lists with Billboard's "The Hot 100's All-Time Top 100 Songs" list.The results show that T-REC assigns top scores to most of these songs as well. This fact also holds (but to a lower degree) when the chart data from "The Hot 100" are omitted from the input list of charts.

The diverging behaviour of the songs with intermediate recognition level in Figure 3 is also apparent in YouTube

[12] Or only slightly underestimating it given that the top-3 measured recognition percentages of our survey are 89.42, 85.57 and 84.61.

[13] This is the maximum p-value among all four comparisons.

model	AMAE
P_S	20.63
MLR (Equation 3)	11.30
RF	10.27
LOGN (Wang et al. 2013 [33])	22.00
T-REC	**8.50**

Table 5: Average MAE over 100 randomly selected test sets for T-REC, Spotify popularity (P_S), Multiple Linear Regression (MLR), Random Forest (RF) and log-normal (LOGN) models. For Spotify popularity we computed once the mean absolute error over all 100 tracks.

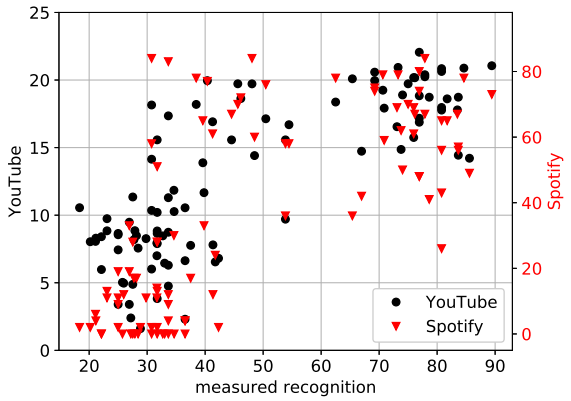

Figure 4: Scatter plot - y axes: YouTube views (log) and Spotify popularity, x axis: measured recognition.

and Spotify indices as shown in Figure 4. One possible explanation for this behavior is that 15 out of these 17 songs have been released during the last three years and they still are in their initial popularity phase. Thus, there has not passed a considerable amount of time in order for these tracks to experience significant recognition decay, which T-REC would likely capture. As exemplified in Figure 5 the more recent the track the bigger the error our model produces, which is a limitation of the proposed model, even though the average errors in all periods are small (the maximum is 9.5) and less than any other compared model.

Finally, we would like to elaborate on the rationale behind the refinements that we performed on our model in order to take its final form (Equation 4). In Figure 4 a linear interaction is observed between (i) the log-transformed YouTube views and Spotify popularity and (ii) the measured recognition, with Pearson correlation coefficients 0.79 and 0.71 respectively. Thus, we incorporated the multiple linear model with the corresponding input quantities as *recognition proxy-based adjustment* component in the final T-REC formula. The consideration of a constant decay rate in the formula of *recognition decay* is not plausible, since it would further lead to a zero rate as the best choice after model fitting, which is highly unrealistic, as the model would degenerate into the *recognition growth* component. As a result, the final form of T-REC includes a variable decay rate across music tracks that depends on

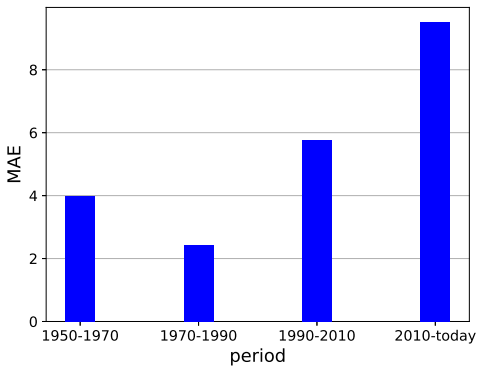

Figure 5: Mean absolute error of T-REC on tracks released in different periods of time.

the number of weeks the track has remained in the charts. This refinement resulted in significantly lower errors showcasing the major role of the number-of-weeks feature in song recognition estimation. More specifically, the initial recognition score achieved a MAE of 12.32, while T-REC a much lower MAE of 8.50 as presented in Table 5.

4. CONCLUSIONS

In this work, we studied collective memory dynamics with regards to song recognition. We proposed a model for the approximation of the corresponding decreasing trajectory and the estimation of the current song recognition level. Our recognition model comprises three main components: a) growth, b) decay, and c) proxy-based adjustment and it leverages chart data, YouTube views, Spotify popularity and forgetting curve dynamics. Also, our method considers different recognition decay rates and initial recognition levels per song, according to the number of weeks the song has remained in the charts.

We compared our model to other state-of-the art and baseline models on the task of accurately estimating the current recognition level of songs. To this end, we conducted a study in Sweden in order to measure the recognition level of 100 songs, which we then used as ground truth for the models' evaluation. The experimental results showed that our method exhibits great performance on this task, much better than the competitive models with a high statistical significance level.

Finally, we reached two remarkable conclusions:

1. according to our model's parameters, a music song needs almost 7 weeks in the charts to achieve a very slow velocity towards oblivion and at least 25 weeks to achieve its highest contemporary recognition;
2. the role of the number-of-weeks feature incorporated in our model through the logistic functions is found to be of utmost importance for the accurate estimation of a song's recognition level.

Future work will include extensions that alleviate the deviation of recent tracks' recognition estimation and also account for demographic-specific estimations.

5. ACKNOWLEDGMENTS

This work is funded by the European Commission under the contract number H2020-761634 FuturePulse. We would also like to thank our collaborators from Soundtrack Your Brand, Magnus Rydén, Jasmine Moradi and Daniel Johansson, who contributed to the problem formulation, provided the initial list of tracks, and carried out the crowd sourcing experiment to measure the recognition rates that were used as "ground truth" in our experiments.

TOWARDS INTERPRETABLE POLYPHONIC TRANSCRIPTION WITH INVERTIBLE NEURAL NETWORKS

Rainer Kelz[1], **Gerhard Widmer**[1,2]

ABSTRACT

We explore a novel way of conceptualising the task of polyphonic music transcription, using so-called invertible neural networks. Invertible models unify both discriminative and generative aspects in one function, sharing one set of parameters. Introducing invertibility enables the practitioner to directly inspect what the discriminative model has learned, and exactly determine which inputs lead to which outputs. For the task of transcribing polyphonic audio into symbolic form, these models may be especially useful as they allow us to observe, for instance, to what extent the concept of single notes could be learned from a corpus of polyphonic music alone (which has been identified as a serious problem in recent research). This is an entirely new approach to audio transcription, which first of all necessitates some groundwork. In this paper, we begin by looking at the simplest possible invertible transcription model, and then thoroughly investigate its properties. Finally, we will take first steps towards a more sophisticated and capable version. We use the task of piano transcription, and specifically the MAPS dataset, as a basis for these investigations.

1. INTRODUCTION

For practitioners who apply deep neural network models to music information retrieval tasks, interpretability of predictions is of great interest. Knowing what the model was able to learn from the data, and examining the underlying causes for a prediction increases trust in the model. Being aware of the reasons for a classification result allows us to discover whether the model has learned rules that would pass a basic sanity check with a domain expert, or if it has picked up on seemingly irrelevant factors present in the data, which made it possible for the network to solve the task in a different, unexpected, possibly unwanted way [31]. There are quite a few ways to obtain an explanation from a neural network. Several methods use the gradient of an output with respect to the input as a starting point, such as [28, 32]. There are also methods that aim to provide model agnostic explanations, for instance [24, 27], and a specialization of one of the aforementioned methods to MIR systems [23] in particular.

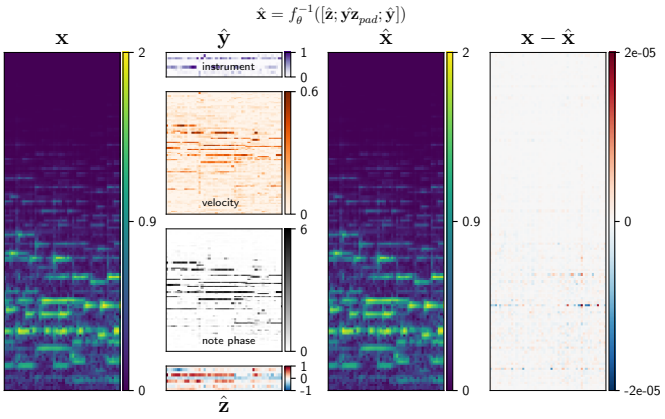

Figure 1: Computing the framewise transcription $\hat{\mathbf{y}}$ and nuisance variables $\hat{\mathbf{z}}$ from spectrogram input $\mathbf{x}$. The predictions $[\hat{\mathbf{y}}; \hat{\mathbf{y}}\mathbf{z}_{pad}; \hat{\mathbf{z}}]$ are then used to exactly reproduce $\hat{\mathbf{x}}$. The elementwise difference $\mathbf{x} - \hat{\mathbf{x}}$ is negligible. An in-depth discussion of this figure is deferred until Section 4.2.

Beyond providing explanations for predictions, a model should ideally be able to provide an answer to the question "What do you consider representative examples for a concept of interest?". Taking first steps towards producing models that are able to derive semantic information from the input, *and* are able to answer this question, we explore invertible neural networks (INNs) with respect to interpretability of predictions, their potential to identify biases and confounding factors inherent in the training dataset, and ability to generate samples for a semantic concept of interest.

Additionally, we consider ways in which these models could enable us to locate ambiguous or uncertain predictions on unlabeled data, to provide eventual users of the MIR model with hints on where manual postprocessing of the predictions might be advisable. We choose to conduct our investigation in the context of polyphonic piano transcription and provide a first glimpse at the capabilities of INNs in Figure 1. The input $\mathbf{x}$ to the INN is a magnitude spectrogram of an excerpt from a polyphonic piano piece, the output is split into a semantic part $\mathbf{y}$ containing variables of interest, and a nuisance part $\mathbf{z}$, optimistically containing all other factors of variation that are irrelevant for the MIR task the model was trained for. From these two output vectors, a hypothetical, perfectly converged in-

vertible model can faithfully reproduce the input, down to a negligible numerical difference.

Invertible neural networks are parametrized, nonlinear and bijective functions, trainable from matched pairs, similar to any other neural network in a supervised learning task. The architectures we consider here are all constructed in such a way that the inverse is available in closed form.

Networks designed in this fashion have a few desirable properties. They are both discriminative and generative models unified in one function, sharing one set of parameters. To put this into context, training a transcription system also yields a synthesizer, and vice versa training a synthesizer yields a transcription system. The term "synthesizer" is used rather loosely here, as the transcription system is trained with magnitude spectrograms.

This setup enables a direct interpretation of predictions by looking at what samples the model produces, conditioned on the predictions. This can potentially be extended until after eventual postprocessing steps, to see whether the generated samples are still close to the input in data space.

Furthermore, in order for a practitioner to understand whether the discriminatively trained network has learned to distinguish multiple concepts reasonably well, she can directly obtain samples from the model for each different concept. As an illustrative example, we choose the task of transcribing polyphonic audio into a symbolic format. This is a multi-label problem, assigning multiple note labels to each (quantized) point in time. Transcription systems based on neural networks are commonly learned from corpora containing large amounts of polyphonic music. Due to having the inverse available to us in closed form, we are able to sample all different single notes from the network to directly see whether the concept of single, isolated notes could be learned by training on our polyphonic corpus, or if multiple notes have been "smeared" together, and could not be disentangled from each other, or if the concept could not be learned at all. To the best of our knowledge, this is still an open problem that mostly affects polyphonic transcription systems based on neural networks, as discussed in [20].

2. RELATED WORK

Invertible neural networks were first introduced in [6] and rediscovered in [2]. They define a nonlinear, bijective mapping between inputs and outputs. They can be used to transform arbitrarily complex distributions into simple, factorized distributions. This concept became more widely known as normalizing flows, introduced in [11], generalized in [33], and has been used in [8] for density estimation, and improving variational inference in [26]. Various types of (more expressive) normalizing flows have been introduced in [9,34,35]. In [21] normalizing flows are employed as generative models for high resolution samples comparable to those produced by high resolution generative adversarial networks (GANs), e.g., [18].

With a greater focus on the invertibility aspect, [1] uses bijective architectures to approximate physical processes with a well defined forward model, in order to obtain the posterior distribution over inputs conditioned on desired outputs. We adopt parts of their terminology and training procedure. The differences will be discussed in more detail in Section 3. In [17] injective and bijective i-RevNets are introduced, architectures similar to ResNets [14], which are invertible up to the last layer. In [16], fully invertible RevNets in conjunction with a new objective function are used to train classifiers which are more robust against adversarial attacks. We borrow their term "nuisance" variables to describe what information is supposed to end up in the output vector $\mathbf{z}$.

Distribution matching in this work is done using the sliced Wasserstein distance. Introduced in [4, 25] as a distance measure for texture synthesis in a computer graphics setting, it has been used for encouraging the codes of autoencoders to follow a proposal distribution [22], and has also been directly applied to generative modeling of images, replacing the domain regressor in GANs [7].

Finally, we draw inspiration from [13] where a transcription-resynthesis system was introduced, consisting of three separately trained parts, a transcription system, a language model and a (neural) synthesizer.

3. METHOD

We adhere closely to the invertible neural network architectures described in [1], with a minor modification to the training procedure that will be outlined after the formal introduction of invertible neural networks. Our notation also loosely follows the one used in [1]. Given a data space $\mathcal{X}$, a label space $\mathcal{Y}$ and a nuisance space $\mathcal{Z}$, we consider a directly invertible neural network as a parametrized function $f_\theta : \mathcal{X} \to \mathcal{Y} \times \mathcal{Z}$ where we have access to its closed form inverse $f_\theta^{-1} : \mathcal{Y} \times \mathcal{Z} \to \mathcal{X}$.

The function f_θ maps the input into a label space that carries semantic information that we are interested in, and maps the rest of information into a nuisance space. Given both the semantic and nuisance information, we are able to obtain the input again via f_θ^{-1}.

There are a few different ways such a function can be implemented in practice, and they all come with various different architectural constraints. We will first define a small invertible building block with relatively weak capabilities. These building blocks are then used to construct a more expressive function.

A necessary structural restriction to a bijective block is that the dimensionality of the input must match the dimensionality of the output. Another restriction concerns the inner workings of blocks, so their inverse is available in closed form. We adopt the affine coupling layer design in [1], which is a more expressive version of the one in [9]. Its internal structure can be seen in Figure 2. The layer takes as input a vector $\mathbf{u}$, whose dimensions are first shuffled with a fixed random permutation matrix and then split into two halves $\mathbf{u}_1, \mathbf{u}_2$. Dimension shuffling causes the splits to be different from layer to layer and facilitates interaction between components whose indices might be far apart in the input vector. The permutation matrix is inverted by simply transposing it.

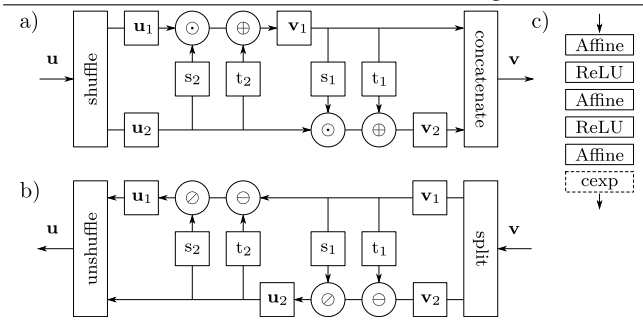

Figure 2: This sketch depicts the structure of the particular version of affine coupling layers we use. **a**) The operations as they are applied in the forward direction. **b**) The operations as they are applied in the backward direction. **c**) The parametrization of the $\mathrm{s}_{1|2}$ and $\mathrm{t}_{1|2}$ transforms. The cexp function is only applied after the $\mathrm{s}_{1|2}$ transforms.

Different operations are then applied to each half, after which the halves are concatenated again to yield the output $\mathbf{v}$. Equations (1) – (4) show the exact expressions used to compute results in both directions.

$$\mathbf{v}_1 = \mathrm{cexp}(\mathrm{s}_2(\mathbf{u}_2)) \odot \mathbf{u}_1 \oplus \mathrm{t}_2(\mathbf{u}_2) \tag{1}$$
$$\mathbf{v}_2 = \mathrm{cexp}(\mathrm{s}_1(\mathbf{v}_1)) \odot \mathbf{u}_2 \oplus \mathrm{t}_1(\mathbf{v}_1) \tag{2}$$
$$\mathbf{u}_2 = (\mathbf{v}_2 \ominus \mathrm{t}_1(\mathbf{v}_1)) \oslash \mathrm{cexp}(\mathrm{s}_1(\mathbf{v}_1)) \tag{3}$$
$$\mathbf{u}_1 = (\mathbf{v}_1 \ominus \mathrm{t}_2(\mathbf{u}_2)) \oslash \mathrm{cexp}(\mathrm{s}_2(\mathbf{u}_2)) \tag{4}$$

Operations $\oplus, \ominus, \odot, \oslash$ (addition, subtraction, multiplication, division) are applied elementwise. The function cexp is defined as $\mathrm{cexp}(x) = \exp(c \cdot \mathrm{atan}(x))$ with $c > 0$ being a hyperparameter. Its purpose is to constrain the output to a reasonable range, and to prevent runaway growth of activations. The transforms $\mathrm{s}_{1|2}$ and $\mathrm{t}_{1|2}$ are arbitrarily parametrizable functions, modeling input dependent scaling and translation respectively. All transforms are implemented as standard neural networks, and are not required to be invertible, because the transformed half of the output vector can be inverted using the untransformed half. The network structures we use are shown in Figure 2c.

If the dimensionalities of input and output vectors do not match, the vectors are padded with zeros during inference, or small scale Gaussian noise during training, to encourage the network to ignore the additional padding dimensions, as done in [1].

Each update of the model involves three passes, one forward pass, and two backward passes. Each pass has its own set of objective functions. The joint objective function to be minimized consists of a weighted sum of these terms. We specify the following notation: vectors are in boldface, writing vectors in square brackets separated by semicolons $[\mathbf{a}; \mathbf{b}]$ denotes concatenation. The vector $\mathbf{x}$ is the input to the model, $\mathbf{y}$ is the semantic part of the groundtruth, and $\mathbf{z}$ is a sample from a proposal distribution, which we choose to be $\mathcal{N}(\mathbf{0}, \mathbf{I})$. The padding vectors used during training are denoted as $\mathbf{x}_{pad}$ and $\mathbf{yz}_{pad}$ respectively, and are drawn from $\mathcal{N}(\mathbf{0}, \varepsilon)$ for each update, with $\varepsilon > 0$ a hyperparameter. Symbols with a circumflex always refer to model outputs with a direct counterpart in the groundtruth. We denote a zero vector of a size appropriate in the context it appears in as $\mathbf{0}$. A sample from the model will be written as $\mathbf{x}_{sam}$. Equation (5) fully specifies all inputs and outputs for an invertible neural network used in the forward direction, equation (6) does the same in the backward direction, and (7) specifies how samples are drawn.

Algorithm 1 Sliced Wasserstein Distance $d_{SWD}(\mathbf{A}, \mathbf{B})$

Let $S \leftarrow 0$ and $\mathbf{A}, \mathbf{B} \in \mathbb{R}^{n \times d}$ (two samples)
For $1 \,..\, m$ **do**
  $\mathbf{p} \leftarrow \mathbf{p}'/\|\mathbf{p}'\|$ such that $\mathbf{p}' \sim \mathcal{N}(\mathbf{0}, \mathbf{I})$ and $\mathbf{p}' \in \mathbb{R}^{d \times 1}$
  $\mathbf{a} \leftarrow \mathrm{sort}[\mathbf{Ap}]$; $\mathbf{b} \leftarrow \mathrm{sort}[\mathbf{Bp}]$
  $S \leftarrow S + \|\mathbf{a} - \mathbf{b}\|_2^2 / n$
Return S/m

$$[\hat{\mathbf{z}}; \hat{\mathbf{yz}}_{pad}; \hat{\mathbf{y}}] = f([\mathbf{x}; \mathbf{x}_{pad}]) \tag{5}$$
$$[\hat{\mathbf{x}}; \hat{\mathbf{x}}_{pad}] = f^{-1}[\hat{\mathbf{z}}; \mathbf{yz}_{pad}; \hat{\mathbf{y}}] \tag{6}$$
$$[\mathbf{x}_{sam}; \hat{\mathbf{x}}_{pad}] = f^{-1}[\mathbf{z}; \mathbf{0}; \mathbf{y}] \tag{7}$$

Having defined these quantities, we can now proceed with defining the individual loss terms that will make up the joint objective function. Mean squared error (8) is used to fit the labels from the groundtruth, and the reconstruction of the input (9). We deviate from [1] and use the sliced Wasserstein distance (d_{SWD}) [25] instead of the maximum mean discrepancy (d_{MMD}), to measure the distance between distributions, as we found it to be better behaved for high dimensional data. The intuition behind d_{SWD} is to decompose the high dimensional optimal transport problem into m 1-dimensional ones, by randomly projecting samples $\mathbf{A}$ and $\mathbf{B}$ onto lines, allowing the resulting 1-dimensional problems to be solved by computing the distance between sorted components. In equation (10), d_{SWD} is used to minimize the distance between samples from the joint distribution over the outputs $[\hat{\mathbf{y}}; \hat{\mathbf{z}}]$ and samples from the joint distribution over the labels and the proposal distribution $[\mathbf{y}; \mathbf{z}]$. Please note that following the advice laid out in [1], no gradient information from this objective is propagated back over $\hat{\mathbf{y}}$, to not unduly disturb the label fitting process. Informally stated, the purpose of including $\mathbf{y}$ and $\hat{\mathbf{y}}$ in the distribution matching process is to "group" samples together for which $\hat{\mathbf{z}}$ needs to follow a Gaussian distribution, resulting in the distributions $p(\hat{\mathbf{y}})$ and $p(\hat{\mathbf{z}})$ to gradually decouple, and become independent of each other, with the side effect of erasing label information from $\hat{\mathbf{z}}$. d_{SWD} is also used in (11), to minimize the distance between the distribution of samples generated from the model and the groundtruth.

$$\mathcal{L}_{\mathbf{y}}(\mathbf{y}, \hat{\mathbf{y}}) = \mathrm{MSE}(\mathbf{y}, \hat{\mathbf{y}}) \tag{8}$$
$$\mathcal{L}_{\hat{\mathbf{x}}}(\mathbf{x}, \hat{\mathbf{x}}) = \mathrm{MSE}(\mathbf{x}, \hat{\mathbf{x}}) \tag{9}$$
$$\mathcal{L}_{\mathbf{yz}}([\mathbf{y}; \mathbf{z}], [\hat{\mathbf{y}}; \hat{\mathbf{z}}]) = \mathrm{SWD}([\mathbf{y}; \mathbf{z}], [\hat{\mathbf{y}}; \hat{\mathbf{z}}]) \tag{10}$$
$$\mathcal{L}_{\mathbf{x}_{sam}}(\mathbf{x}, \mathbf{x}_{sam}) = \mathrm{SWD}(\mathbf{x}, \mathbf{x}_{sam}) \tag{11}$$
$$\mathcal{L}_{\mathbf{x}_{pad}}(\mathbf{x}_{pad}, \hat{\mathbf{x}}_{pad}) = \mathrm{MSE}(\mathbf{x}_{pad}, \hat{\mathbf{x}}_{pad}) \tag{12}$$
$$\mathcal{L}_{\mathbf{yz}_{pad}}(\mathbf{yz}_{pad}, \hat{\mathbf{yz}}_{pad}) = \mathrm{MSE}(\mathbf{yz}_{pad}, \hat{\mathbf{yz}}_{pad}) \tag{13}$$

Finally, the padding dimensions are taken care of with mean squared error terms (12) and (13), to encourage the network to disregard information in these dimensions. Following advice in [1], the individual loss terms that sum up to the joint objective are weighted such that their magnitudes are approximately equal to each other, by restarting the optimization process multiple times and adjusting the weights until this condition is met.

4. EXPERIMENTS

This section is split into multiple parts, starting out with a description of the data preparation procedure, followed by an empirical assessment of the usability of INNs for practitioners in subsection 4.1, a critical examination of the interpretability of a trained model in subsection 4.2, and finally an analysis of how well the concept of single notes could be learned from a polyphonic corpus in subsection 4.3.

All model training, testing and generative sampling experiments were carried out with the MUS subset of the MAPS corpus [10]. This subset contains 210 polyphonic piano pieces rendered with 7 sample based synthesizers, and 60 recordings of a YAMAHA Disklavier in two different recording conditions. After removing all synthesized pieces that also occur in the set of recordings, we are left with 139 pieces for training, and the 60 Disklavier recordings for testing, according to the procedure outlined in [12]. Evaluation measures are computed individually for each piece in the test set, and the mean over all pieces is reported. Groundtruth information is available as temporally aligned MIDI files. Sustain pedal control values are quantized, and the pedal considered fully engaged if its MIDI control value exceeds 64. All offsets of notes that are sounding while sustain is in effect are extended in time, until the pedal is released again.

The label information $\mathbf{y}$ that the model has to learn is derived from the MIDI groundtruth and consists of 3 parts: the note phase, its velocity and instrument information. For each piano key, the temporal evolution each note is modeled with an exponentially decaying curve, defined as $\text{curve}(\tau) = 0.99^{\tau} \cdot 5$, with $0 \leq \tau < \text{duration}$. It starts at the onset of a note, lasts for its duration, and drops off immediately after the offset. The velocity part is derived from the MIDI velocity value scaled into the interval $[0, 1]$. This procedure is also outlined in Figure 3, and repeated for each of the 88 piano keys. Finally, instruments are numbered from 0 to 8, corresponding to one of the 7 sample banks or alternatively one of the two microphone conditions for the Disklavier recordings, and are one-hot encoded. For each (quantized) point in time t all three parts are concatenated into the vector $\mathbf{y}_t$, having $9 + 88 + 88 = 185$ components. This particular label vector derivation is chosen so that $\mathbf{y}_t$ contains all necessary information to generate spectrogram frames for different instruments and notes at the right volume and the right stage of a notes' temporal evolution without any additional context information from neighboring frames. The length of $\mathbf{z}_t$ was treated as a hyperparameter, and selected via cross validation on a small subset of the training set. Its length appears to have negligible influence given all the other settings, and was set to 9 for all models subsequently used. The corresponding data $\mathbf{x}_t$ are magnitude spectrograms processed by a semi logarithmic filterbank, and the resulting bins $\mathbf{b}_t$ are elementwise processed by the function $\log(1 + \mathbf{b}_t)$, approximating human loudness perception to finally yield a vector $\mathbf{x}_t$ of length 144. All spectral feature extraction and filtering is done with the `madmom` library [3]. The frame rate at which pairs $(\mathbf{x}_t, \mathbf{y}_t)$ are extracted from the audio and MIDI files is 25 frames per second. As all input is processed in a framewise fashion everywhere, we omit the subscript t, denoting time in frames, for all plots and most equations to not add additional clutter. To increase the capacity of the INN, we add zero padding vectors to both input ($\mathbf{x}_{pad}$) and output dimensions ($\mathbf{yz}_{pad}$), so the number of components in the padded vectors sum up to 256 in total. Training follows the procedure outlined in Section 3, and all code is released [1] to facilitate reproducability.

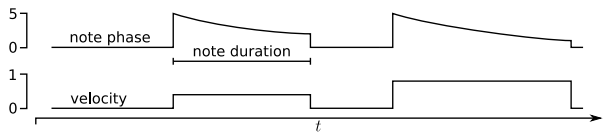

Figure 3: This illustration shows how the note phase and velocity part of the label information $\mathbf{y}$ is derived for multiple notes played by a single key.

4.1 Usability for MIR tasks

As a kind of quantitative viability test, the capability of INNs (in combination with simple temporal models) to produce predictions useful to MIR practitioners, is examined. We train small recurrent networks (RNNs) on the framewise predictions $\hat{\mathbf{y}}$ obtained from the INN, in the hope to obtain cleaner, denoised framewise predictions $\hat{\mathbf{y}}'$. The types of RNN cells we use are either LSTM [15] or GRU [5] cells. In a first attempt, RNNs with very limited capacity - 4 hidden units / cells for all keys - are employed. An input sequence to the RNN consists of the note phase and the velocity part of a *single* key over the whole length of the piece, leading to an input dimension of 2. The RNNs should output a smoothed, denoised version of the note phase and velocity sequence, and an additional framewise note activity indicator between 0 and 1, and thus all have 3 outputs. The binary piano roll used to compute framewise performance measures is obtained by thresholding the note activity indicator output of the RNNs at 0.5. Training proceeds one full sequence at a time, picked uniformly at random from all $139 \cdot 88$ single key sequences derived from all pieces in the training set. The models with highest F_1-measure on a subset of the training set are then evaluated on the test set.

In order to evaluate framewise performance for a piece, we produce framewise transcriptions for all keys with the INN. Each key is then separately smoothed, denoised, and

[1] https://github.com/rainerkelz/ISMIR19

Method	P	R	F_1
INN + GRU (S)	79.74	63.73	70.84
INN + LSTM (S)	80.12	63.91	71.10
INN + biGRU (L)	81.72	64.81	72.29
CNN only [12, 19]	81.18	65.07	71.60
CNN + RNN-NADE [12, 29]	71.99	73.32	72.22
CNN + LSTM [12]	88.53	70.89	78.30

Table 1: Framewise performance of different combinations of acoustic and temporal models on the testset.

its activity is inferred over the length of the piece. We report the results for the small models in Table 1, suffixed with "(S)". We would like to note that there was next to no hyperparameter tuning done, aside from getting the learn rates for the two different RNN cell types approximately in the right regime. A slightly larger version uses 3 layers of bi-directional GRU cells with 8 hidden units, and dropout [30] with a probability of 0.5, applied to the output of each recurrent layer, before it is passed on to the next. Results in the table for this type of RNN are suffixed with "(L)". The INN has 5 invertible layers, and 990.720 parameters in total. The parameter counts for the recurrent model variants "GRU (S)", "LSTM (S)" and "biGRU (L)" are 111, 143 and 3123 respectively.

We can see that the combination framewise INN + biGRU performs on par with the CNN + RNN-NADE combination in terms of framewise performance, and slightly outperforms the standalone CNN. The last three rows in Table 1 are taken from [12], who re-implemented the approaches in [19] and [29], and ostensibly performed additional hyperparameter tuning to improve upon the original results. They also provide the current state of the art results for this train and test protocol in the last row, achieved by supplying an additional onset target to the network during training.

4.2 Interpretability of results

This section considers how the ability to modify the output of the model, and then using it in the backward direction, can assist the practitioner in determining the causes in the data that led to a particular prediction. We start with a thought experiment, and get closer to reality step by step. Let us assume the model works perfectly, and given an input $\mathbf{x}$, the model routes all semantic information (note phases, velocities, instrument) into the $\hat{\mathbf{y}}$ vector, all nuisance information (other acoustic variability, such as microphone characteristics, room reverberation or actual noise) ends up in $\hat{\mathbf{z}}$ which is distributed as $\mathcal{N}(\mathbf{0}, \mathbf{I})$, and the padding vector $\hat{\mathbf{yz}}$ is exactly zero. Sampling $\mathbf{z}_s \sim \mathcal{N}(\mathbf{0}, \mathbf{I})$ and using $f^{-1}([\hat{\mathbf{y}}, \mathbf{0}, \mathbf{z}_s])$ to obtain the corresponding input $\mathbf{x}_s$ will change *only nuisance characteristics* in the input. This would also mean that we have *full control* over the semantic content of the input. We could add or delete notes *in the input* simply by adding or zeroing them out in $\hat{\mathbf{y}}$, much like we can insert or delete a symbolic MIDI note, the implication being that every output has a *directly* interpretable correspondence in the input.

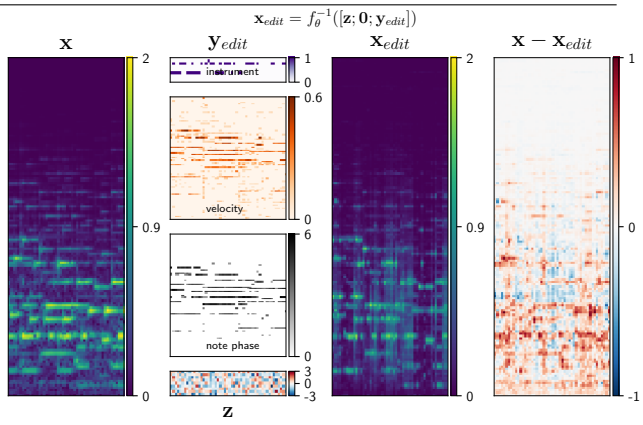

Figure 4: Gradually denoising the predictions with simple, ad-hoc rules, zero padding and sampling $\mathbf{z} \sim \mathcal{N}(\mathbf{0}, \mathbf{I})$. In practice, this would be done iteratively, always keeping an eye on how the overall structure of the input is affected.

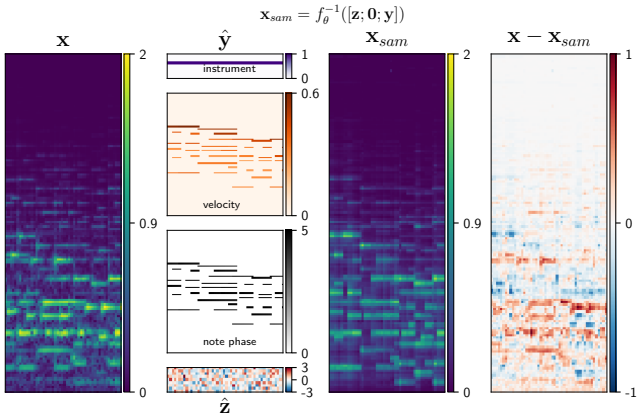

Figure 5: The hypothetical case where all predictions could be perfectly denoised. For purely demonstrational purposes, this was accomplished through consultation of an oracle, but one could imagine this to be achievable through interaction with the system. Although quite a bit of detail is missing, the majority of the structure in the original input is nonetheless recognizable in the generated sample.

A closer look at Figure 1 reveals what can realistically be achieved just by training a framewise INN with a rather limited amount of polyphonic data. It is immediately noticeable that $\hat{\mathbf{z}}$ does *not* appear to be normally distributed. There are still patterns discernible, making it apparent that it still contains semantic information. Similar patterns also exist in $\hat{\mathbf{yz}}_{pad}$ (not shown).

It is also observable that the information that is routed into $\hat{\mathbf{y}}$ is somewhat noisy. We can now attempt to "separate the wheat from the chaff" by using the INN in the backward direction with cleaned up predictions. Figure 4 shows what happens when the predictions are partially denoised by setting all predictions below a certain threshold to zero, ignoring the padding vector by zeroing it out, and sampling $\mathbf{z}$ from a unit normal distribution. These simple, ad-hoc rules cannot get rid of all the noise and discontinuities in the predictions, but are useful to determine which outputs can be ignored by observing their (collective) im-

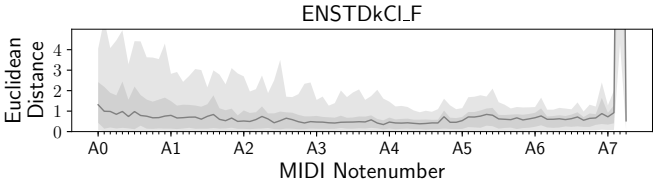

Figure 6: Interquantile ranges of the framewise Euclidean distances between isolated reference notes and samples from the model. The reference notes stem from an unseen instrument.

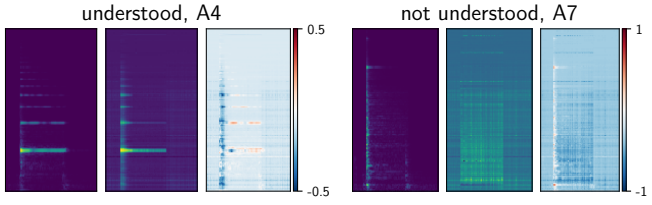

Figure 7: Samples from the model for single notes.

pact on the sample. Figure 5 depicts what can be generated by the model, assuming that the denoising process of the predictions were perfect, by consulting an oracle about the true contents of $\mathbf{y}$. In all figures discussed in this section, the same excerpt from the test set was used, meaning the model has never seen any of the examples during training.

4.3 Concept Understanding

Returning to a question raised in the introduction, in this section the model will be systematically queried about specific semantic concepts. Arguably, a polyphonic transcription system should be able to transcribe isolated notes. The MAPS dataset provides both renderings and recordings of isolated notes, which we utilize to formulate our queries. For each of the 88 keys, 30 samples are drawn from the model, using the groundtruth $\mathbf{y}$ paired with the reference recording for the key and $\mathbf{z} \sim \mathcal{N}(\mathbf{0}, \mathbf{I})$. This ensures that each sample has the same length as the reference. For each frame at time t in a sample, the Euclidean distance to the corresponding frame of the reference recording is measured, and p-quantiles are computed on the resulting lists of framewise distances, with $p \in \{0.05, 0.25, 0.5, 0.75, 0.95\}$. Figure 6 depicts the interquantile range $[0.05, 0.95]$ as light gray, the range $[0.25, 0.75]$ in a darker shade, and the median as a black line. It becomes immediately apparent that samples for rarely occuring (possibly omitted) notes, such as those in the lower and higher octaves, are highly dissimilar from the reference recordings, and indicate that these particular isolated notes could not be learned by the network (Figure 7). Admittedly, this question could have been answered for a regular feedforward network as well, but would have necessitated *more labeled* reference data of the *same* instrument. The ability to sample from the model allows us to sidestep the rather cumbersome way of aggregating prediction errors, as was necessary in [20], to arrive at a similar conclusion.

4.4 Improving Models with temporal context

The invertible models investigated so far all take single frames as input, without temporal context information. We trained fully invertible RevNets [16, 17] on a variety of different context lengths, but were not yet able to observe either quantitative or qualitative improvements over the framewise models. RevNets tend to become rather large in terms of the number of parameters, input and output padding is not as straightforward as for framewise models, the input and output space dimensionality is much larger, making the sliced Wasserstein distance gradually less effective due to an increase in necessary computational resources, which in turn further slows down training. Finally, the amount of training data we use may simply be insufficient for higher capacity models. However, we believe that all these issues have appropriate remedies. An immediate next step would be to apply the same models to the much larger MAESTRO dataset [13]. We leave these steps for future work though.

5. CONCLUSION

The viability of invertible neural networks for a selected MIR task was shown quantitatively in terms of transcription performance and a brief numerical analysis of single concept understanding. A qualitative investigation of the direct interpretability of outputs back in input space was conducted. There is ample room for improvement, such as using an adversarial distance for distribution matching in both input and output space, or alternatively using the independent cross-entropy objective from [16] in latent space. The objective for the semantic part of the output space could be similarly augmented to encourage the disentanglement of (predictions for) individual notes. Another obvious improvement would be to skip the computation of filtered spectrograms altogether, and feed in waveforms to obtain models that can in turn generate waveforms we can directly listen to.

Beyond the interpretability aspect, we are confident that invertible neural networks will prove to be useful for other MIR tasks as well, such as musical content-aware style transfer (this is already doable with the models used in this work, by simply changing the instrument encoding when sampling, although changing from one piano to a different one is not as exciting as changing it into a trumpet). These models could also be adapted for (blind) source separation, to name only two examples.

6. ACKNOWLEDGEMENTS

We would like to express our deep gratitude to Lynton Ardizzone for pointing us in the right direction and Hamid Eghbal-zadeh for noting the pitch content-aware style transfer angle. This research has received funding from the European Research Council (ERC) under the European Union's Horizon 2020 research and innovation programme (Grant agreement No. 670035, project CON ESPRESSIONE). The Tesla K40 used for this research was donated by the NVIDIA Corporation.

ABSTRACT

Deep Learning models have shown very promising results in automatically composing polyphonic music pieces. However, it is very hard to control such models in order to guide the compositions towards a desired goal. We are interested in controlling a model to automatically generate music with a given sentiment. This paper presents a generative Deep Learning model that can be directed to compose music with a given sentiment. Besides music generation, the same model can be used for sentiment analysis of symbolic music. We evaluate the accuracy of the model in classifying sentiment of symbolic music using a new dataset of video game soundtracks. Results show that our model is able to obtain good prediction accuracy. A user study shows that human subjects agreed that the generated music has the intended sentiment, however negative pieces can be ambiguous.

1. INTRODUCTION

Music Generation is an important application domain of Deep Learning in which models learn musical features from a dataset in order to generate new, interesting music. Such models have been capable of generating high quality pieces of different styles with strong short-term dependencies [1] [2]. A major challenge of this domain consists of disentangling these models to generate compositions with given characteristics. For example, one can't easily control a model trained on classical piano pieces to compose a tense piece for a horror scene of a movie. Being able to control the output of the models is specially important for the field of Affective Music Composition, whose major goal is to automatically generate music that is perceived to have a specific emotion or to evoke emotions in listeners [19]. Applications involve generating soundtracks for movies and video-games [18], sonification of biophysical data [3] and generating responsive music for the purposes of music therapy and palliative care [9].

Recently, Radford et al. [13] showed that a generative Long short-term memory (LSTM) neural network can learn an excellent representation of sentiment (positive-negative) on text, despite being trained only to predict the next character in the Amazon reviews dataset [6]. When combined to a Logistic Regression, this LSTM achieves state-of-the-art sentiment analysis accuracy on the Stanford Sentiment Treebank dataset and can match the performance of previous supervised systems using 30-100x fewer labeled examples. This LSTM stores almost all of the sentiment signal in a distinct "sentiment neuron", which can be used to control the LSTM to generate sentences with a given sentiment. In this paper, we explore this approach with the goal of composing symbolic music with a given sentiment. We also explore this approach as a sentiment classifier for symbolic music.

In order to evaluate this approach, we need a dataset of music in symbolic format that is annotated by sentiment. Even though emotion detection is an important topic in music information retrieval [7], it is typically studied on music in audio format. To the best of our knowledge, there are no datasets of symbolic music annotated according to sentiment. Therefore, we created a new dataset composed of 95 MIDI labelled piano pieces (966 phrases of 4 bars) from video game soundtracks. Each piece is annotated by 30 human subjects according to a valence-arousal (dimensional) model of emotion [15]. The sentiment of each piece is then extracted by summarizing the 30 annotations and mapping the valence axis to sentiment. The same dataset also contains another 728 non-labelled pieces, which were used for training the generative LSTM.

We combine this generative LSTM with a Logistic Regression and analyse its sentiment prediction accuracy against a traditional classification LSTM trained in a fully-supervised way. Results showed that our model (generative LSTM with Logistic Regression) outperformed the supervised LSTM by approximately 30%. We also analysed the generative capabilities of our model with a user study. Human subjects used an online annotation tool to label 3 pieces controlled to be negative and 3 pieces controlled to be positive. Results showed human annotators agree the generated positive pieces have the intended sentiment. The generated negative pieces appear to be ambiguous, having both negative and positive parts.

We believe this paper is the first work to explore sentiment analysis in symbolic music and it presents the first disentangled Deep Learning model for music generation with sentiment. Another contribution of this paper is a labelled dataset of symbolic music annotated according to sentiment. These contributions open several direction for

[1] Supporting strong long-term dependencies (music form) is still an open problem.

future research, specially music generation with emotions as both a multi-class problem and as a regression problem. Moreover, these methods could be applied to create soundtrack generation systems for films, video games, interactive narratives, audio books, etc.

2. RELATED WORK

This paper is related to previous work on Affective Algorithmic Music Composition, more specifically to works that process music in symbolic form in order to generate music with a given emotion. A common approach for this problem consists of designing a rule-based system to map musical features to a given emotion in a categorical or dimensional space [19]. For example, Williams et al. [18] propose a system to generate soundtracks for video games where each game's scene graph (defining all the possible branching of scenes in the game) is annotated according to a valence-arousal model. A second-order Markov model is used to learn melodies from a dataset and are then transformed by a rule-based system to fit the annotated emotions in the graph. Davis and Mohammad [4] follow a similar approach in TransPose, a system that composes piano melodies for novels. TransPose uses a lexicon-based approach to automatically detect emotions (categorical model) in novels and a rule-based technique to create piano melodies with these emotions.

There are a few other approaches in the literature to compose music with a given emotion. Scirea et al. [16] recently presented a framework called MetaCompose designed to create background music for games in real-time. MetaCompose generates music by (i) randomly creating a chord sequence from a pre-defined chord progression graph, (ii) evolving a melody for this chord sequence using a genetic algorithm and (iii) producing an accompaniment for the melody/chord sequence combination. Monteith et al. [10] approaches Affective Algorithmic Music Composition from a Machine Learning perspective to learn melodies and rhythms from a corpus of music labeled according to a categorical model of emotion. Individual Hidden Markov models and n-grams are trained for each category to generate pitches and underlying harmonies, respectively. Rhythms are sampled randomly from examples of a given category.

Deep Learning models have recently achieved high-quality results in music composition with short-term dependencies [2]. These models normally are trained on a corpus of MIDI files to predict the next note to be played based on a given note. In general, these models can't be manipulated to generate music with a given emotion. For example, in the system DeepBach, Hadjeres et al. [5] use a dependency network and a Gibbs-like sampling procedure to generate high-quality four-part chorales in the style of Bach. Roberts et at. [14] train recurrent variational autoencoder (VAEs) to reproduce short musical sequences and with a novel hierarchical decoder they are able to model long sequences with musical structure for both individual instruments and a three-piece band (lead, bass, and drums).

The majority of the deep learning models are trained to generate musical scores and not performances. Oore et al. [11] tackles this problem by training an LSTM with a new representation that supports tempo and velocity events from MIDI files. This model was trained on the Yamaha e-Piano Competition [1], which contains MIDI captures of ~1400 performances by skilled pianists. With this new representation and dataset, Oore et al. [11] generated more human-like performances when compared to previous models.

3. MODEL

We propose a Deep Learning method for affective algorithmic composition that can be controlled to generate music with a given sentiment. This method is based on the work of Radford et al. [13] which generates product reviews (in textual form) with sentiment. Radford et al. [13] used a single-layer multiplicative long short-term memory (mLSTM) network [8] with 4096 units to process text as a sequence of UTF-8 encoded bytes (character-based language modeling). For each byte, the model updates its hidden state of the mLSTM and predicts a probability distribution over the next possible byte.

This mLSTM was trained on the Amazon product review dataset, which contains over 82 million product reviews from May 1996 to July 2014 amounting to over 38 billion training bytes [6]. Radford et al. [13] used the trained mLSTM to encode sentences from four different Sentiment Analysis datasets. The encoding is performed by initializing the the states to zeros and processing the sequence character-by-character. The final hidden states of the mLSTM are used as a feature representation. With the encoded datasets, Radford et al. [13] trained a simple logistic regression classifier with L1 regularization and outperformed the state-of-the-art methods at the time using 30-100x fewer labeled examples.

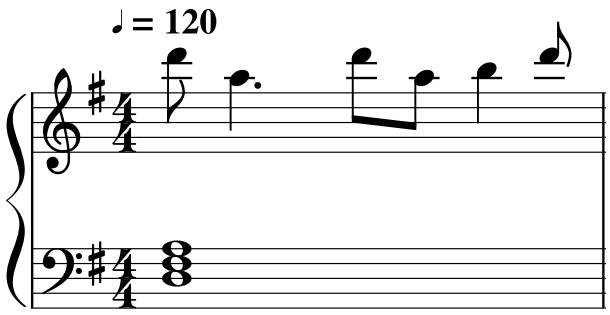
By inspecting the relative contributions of features on various datasets, Radford et al. [13] discovered a single unit within the mLSTM that directly corresponded to sentiment. Because the mLSTM was trained as a generative model, one can simply set the value of the sentiment unit to be positive or negative and the model generates corresponding positive or negative reviews.

3.1 Data Representation

We use the same combination of mLSTM and logistic regression to compose music with sentiment. To do this, we treat the music composition problem as a language modeling problem. Instead of characters, we represent a music piece as a sequence of words and punctuation marks from a vocabulary that represents events retrieved from the MIDI file. Sentiment is perceived in music due to several features such as melody, harmony, tempo, timbre, etc [7]. Our data representation attempts to encode a large part of these features [2] using a small set of words:

- "n_[pitch]": play note with given pitch number: any integer from 0 to 127.

[2] Constrained by the features one can extract from MIDI data.



```
t_120 v_76 d_whole_0 n_50 n_54 n_57
v_92 d_eighth n_86 . . v_84
d_quarter_1 n_81 . .
```

Figure 1: A short example piece encoded using our proposed representation. The encoding represents the first two time steps of the shown measure.

- "d_[duration]_[dots]": change the duration of the following notes to a given duration type with a given amount of dots. Types are breve, whole, half, quarter, eighth, 16th and 32nd. Dots can be any integer from 0 to 3.
- "v_[velocity]": change the velocity of the following notes to a given velocity (loudness) number. Velocity is discretized in bins of size 4, so it can be any integer in the set $V = 4, 8, 12, \ldots, 128$.
- "t_[tempo]": change the tempo of the piece to a given tempo in bpm. Tempo is also discretized in bins of size 4, so it can be any integer in the set $T = 24, 28, 32, \ldots, 160$.
- ".": end of time step. Each time step is one sixteenth note long.
- "\n": end of piece.

For example, Figure 1 shows the encoding of the first two time steps of the first measure of the Legend of Zelda - Ocarina of Time's Prelude of Light. The first time step sets the tempo to 120bpm, the velocity of the following notes to 76 and plays the D Major Triad for the duration of a whole note. The second time step sets the velocity to 84 and plays a dotted quarter A5 note. The total size of this vocabulary is 225 and it represents both the composition and performance elements of a piece (timing and dynamics).

4. SENTIMENT DATASET

In order to apply the Radford et al. [13] method to compose music with sentiment, we also need a dataset of MIDI files to train the LSTM and another one to train the logistic regression. There are many good datasets of music in MIDI format in the literature. However, to the best of our knowledge, none are labelled according to sentiment. Thus, we created a new dataset called VGMIDI which is composed of 823 pieces extracted from video game soundtracks in MIDI format. We choose video game soundtracks because they are normally composed to keep the player in a certain affective state and thus they are less subjective pieces. All the pieces are piano arrangements of the soundtracks and they vary in length from 26 seconds to 3 minutes. Among these pieces, 95 are annotated according to a 2-dimensional model that represents emotion using a valence-arousal pair. Valence indicates positive versus negative emotion, and arousal indicates emotional intensity [17].

We use this valence-arousal model because it allows continuous annotation of music and because of its flexibility—one can directly map a valence-arousal (v-a) pair to a multiclass (happy, sad, surprise, etc) or a binary (positive/negative) model. Thus, the same set of labelled data permits the investigation of affective algorithmic music composition as both a classification (multiclass and/or binary) and as a regression problem. The valence-arousal model is also one of the most common dimensional models used to label emotion in music [17].

Annotating a piece according to the v-a model consists of continuously listening to the piece and deciding what valence-arousal pair best represents the emotion of that piece in each moment, producing a time-series of v-a pairs. This task is subjective, hence there is no single "correct" time-series for a given piece. Thus, we decided to label the pieces by asking several human subjects to listen to the pieces and then considering the average time-series as the ground truth. This process was conducted online via Amazon Mechanical Turk, where each piece was annotated by 30 subjects using a web-based tool we designed specifically for this task. Each subject annotated 2 pieces out of 95, and got rewarded USD $0.50 for performing this task.

4.1 Annotation Tool and Data Collection

The tool we designed to annotate the video game soundtracks in MIDI format is composed of five steps, each one being a single web-page. These steps are based on the methodology proposed by Soleymani et al. [17] for annotating music pieces in audio waveform. First, participants are introduced to the annotation task with a short description explaining the goal of the task and how long it should take in average. Second, they are presented to the definitions of valence and arousal. In the same page, they are asked to play two short pieces and indicate whether arousal and valence are increasing or decreasing. Moreover, we ask the annotators to write two to three sentences describing the short pieces they listened to. This page is intended to measure their understanding of the valence-arousal model and willingness to perform the task. Third, a video tutorial was made available to the annotators explaining how to use the annotation tool. Fourth, annotators are exposed to the main annotation page.

This main page has two phases: calibration and annotation. In the calibration phase, annotators listen to the first 15 seconds of the piece in order to get used to it and to define the starting point of the annotation circle. In the anno-

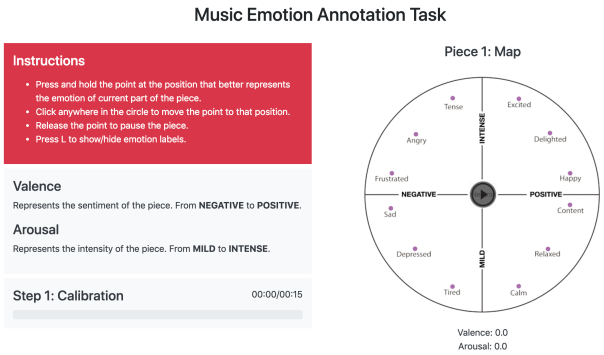


Figure 2: Screenshot of the annotation tool.

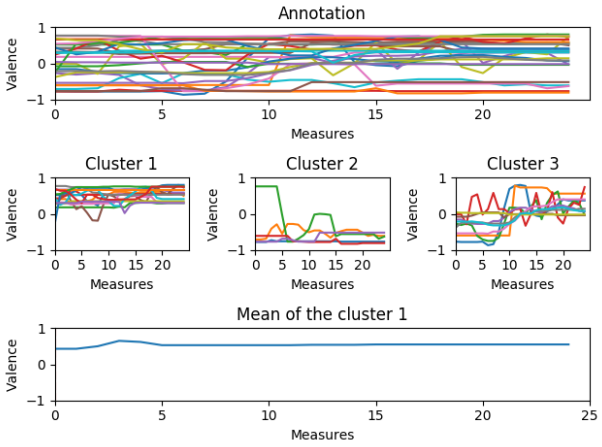

Figure 3: Data analysis process used to define the final label of the phrases of a piece.

tation phase they listen to the piece from beginning to end and label it using the annotation circle, which starts at the point defined during the calibration phase. Figure 2 shows the annotation interface for valence and arousal, where annotators click and hold the circle (with the play icon) inside the v-a model (outer circle) indicating the current emotion of the piece. In order to maximize annotators' engagement in the task, the piece is only played while they maintain a click on the play circle. In addition, basic instructions on how to use the tool are showed to the participants along with the definitions of valence and arousal. A progression bar is also showed to the annotators so they know how far they are from completing each phase. This last step (calibration and annotation) is repeated for a second piece. All of the pieces the annotators listened to are MIDI files synthesized with the "Yamaha C5 Grand" soundfont. Finally, after the main annotation step, participants provide demographic information including gender, age, location (country), musicianship experience and whether they previously knew the pieces they annotated.

4.2 Data Analysis

The annotation task was performed by 1425 annotators, where 55% are female and 42% are male. The other 3% classified themselves as transgender female, transgender male, genderqueer or choose not to disclose their gender. All annotators are from the United States and have an average age of approximately 31 years. Musicianship experience was assessed using a 5-point Likert scale where 1 means "I've never studied music theory or practice" and 5 means "I have an undergraduate degree in music". The average musicianship experience is 2.28. They spent on average 12 minutes and 6 seconds to annotate the 2 pieces.

The data collection process provides a time series of valence-arousal values for each piece, however to create a music sentiment dataset we only need the valence dimension, which encodes negative and positive sentiment. Thus, we consider that each piece has 30 time-series of valence values. The annotation of each piece was preprocessed, summarized into one time-series and split into "phrases" of same sentiment. The preprocessing is intended to remove noise caused by subjects performing the task randomly to get the reward as fast as possible. The data was preprocessed by smoothing each annotation with moving average and clustering all 30 time-series into 3 clusters (positive, negative and noise) according to the dynamic time-warping distance metric.

We consider the cluster with the highest variance to be noise cluster and so we discard it. The cluster with more time series among the two remaining ones is then selected and summarized by the mean of its time series. We split this mean into several segments with the same sentiment. This is performed by splitting the mean at all the points where the valence changes from positive to negative or vice-versa. Thus, all chunks with negative valence are considered phrases with negative sentiment and the ones with positive valence are positive phrases. Figure 3 shows an example of this three-steps process performed on a piece. All the phrases that had no notes (i.e. silence phrases) were removed. This process created a total of 966 phrases: 599 positive and 367 negative.

5. SENTIMENT ANALYSIS EVALUATION

To evaluate the sentiment classification accuracy of our method (generative mLSTM + logistic regression), we compare it to a baseline method which is a traditional classification mLSTM trained in a supervised way. Our method uses unlabelled MIDI pieces to train a generative mLSTM to predict the next word in a sequence. An additional logistic regression uses the hidden states of the generative mLSTM to encode the labelled MIDI phrases and then predict sentiment. The baseline method uses only labelled MIDI phrases to train a classification mLSTM to predict the sentiment for the phrase.

The unlabelled pieces used to train the generative mLSTM were transformed in order to create additional training examples, following the methodology of Oore et al. [11]. The transformations consist of time-stretching (making each piece up to 5% faster or slower) and transposition (raising or lowering the pitch of each piece by up to a major third). We then encoded all these pieces and transformations according to our word-based representation (see Section 3.1). Finally, the encoded pieces were shuffled and

90% of them were used for training and 10% for testing. The training set was divided into 3 shards of similar size (approximately 18500 pieces each – 325MB) and the testing set was combined into 1 shard (approximately 5800 pieces – 95MB).

We trained the generative mLSTM with 6 different sizes (number of neurons in the mLSTM layer): 128, 256, 512, 1024, 2048 and 4096. For each size, the generative mLSTM was trained for 4 epochs using the 3 training shards. Weights were updated with the Adam optimizer after processing sequences of 256 words on mini-batches of size 32. The mLSTM hidden and cell states were initialized to zero at the beginning of each shard. They were also persisted across updates to simulate full-backpropagation and allow for the forward propagation of information outside of a given sequence [13]. Each sequence is processed by an embedding layer (which is trained together with the mLSTM layer) with 64 neurons before passing through the mLSTM layer. The learning rate was set to $5 * 10^{-6}$ at the beginning and decayed linearly (after each epoch) to zero over the course of training.

We evaluated each variation of the generative mLSTM with a forward pass on test shard using mini-batches of size 32. Table 1 shows the average [3] cross entropy loss for each variation of the generative mLSTM.

mLSTM Neurons	Average Cross Entropy Loss
128	1.80
256	1.61
512	1.41
1024	1.25
2048	1.15
4096	1.11

Table 1: Average cross entropy loss of the generative mLSTM with different amount of neurons.

The average cross entropy loss decreases as the size of the mLSTM increases, reaching the best result (loss 1.11) when size is equal to 4096. Thus, we used the variation with 4096 neurons to proceed with the sentiment classification experiments.

Following the methodology of Radford et al. [13], we re-encoded each of the 966 labelled phrases using the final cell states (a 4096 dimension vector) of the trained generative mLSTM-4096. The states are calculated by initializing them to zero and processing the phrase word-by-word. We plug a logistic regression into the mLSTM-4096 to turn it into a sentiment classifier. This logistic regression model was trained with regularization "L1" to shrink the least important of the 4096 feature weights to zero. This ends up highlighting the generative mLSTM neurons that contain most of the sentiment signal.

We compared this generative mLSTM + logistic regression approach against our baseline, the supervised mLSTM. This is an mLSTM with exactly the same architecture and size of the generative version, but trained in a fully supervised way. To train this supervised mLSTM, we used the word-based representation of the phrases, but we padded each phrase with silence (the symbol ".") in order to equalize their length. Training parameters (learning rate and decay, epochs, batch size, etc) were the same ones of the the generative mLSTM. It is important to notice that in this case the mini-batches are formed of 32 labelled phrases and not words. We evaluate both methods using a 10-fold cross validation approach, where the test folds have no phrases that appear in the training folds. Table 2 shows the sentiment classification accuracy of both approaches.

Method	Test Accuracy
Gen. mLSTM-4096 + Log. Reg.	89.83 $\pm$3.14
Sup. mLSTM-4096	60.35 $\pm$3.52

Table 2: Average (10-fold cross validation) sentiment classification accuracy of both generative (with logistic regression) and supervised mLSTMs.

The generative mLSTM with logistic regression achieved an accuracy of 89.83%, outperforming the supervised mLSTM by 29.48%. The supervised mLSTM accuracy of 60.35% suggests that the amount of labelled data (966 phrases) was not enough to learn a good mapping between phrases and sentiment. The accuracy of our method shows that the generative mLSTM is capable of learning, in an unsupervised way, a good representation of sentiment in symbolic music.

This is an important result, for two reasons. First, since the higher accuracy of generative mLSTM is derived from using unlabeled data, it will be easier to improve this over time using additional (less expensive) unlabeled data, instead of the supervised mLSTM approach which requires additional (expensive) labeled data. Second, because the generative mLSTM was trained to predict the next word in a sequence, it can be used as a music generator. Since it is combined with a sentiment predictor, it opens up the possibility of generating music consistent with a desired sentiment. We explore this idea in the following section.

6. GENERATIVE EVALUATION

To control the sentiment of the music generated by our mLSTM, we find the subset of neurons that contain the sentiment signal by exploring the weights of the trained logistic regression model. Since each of the 10 generative models derived from the 10 fold splits in Table 2 are themselves a full model, we use the model with the highest accuracy. As shown in Figure 4, the logistic regression trained with regularization "L1" uses 161 neurons out of 4096. Unlike the results of Radford et al. [13], we don't have one single neuron that stores most of the sentiment signal. Instead, we have many neurons contributing in a more balanced way. Therefore, we can't simply change the values of one neuron to control the sentiment of the output music.

We used a Genetic Algorithm (GA) to optimize the weights of the 161 L1 neurons in order to lead our mL-

[3] Each mini-batch reports one loss.

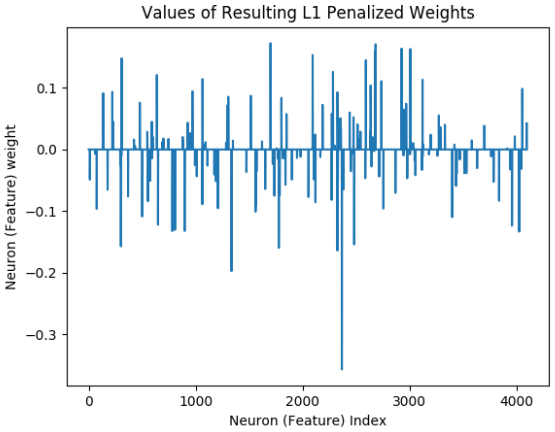

Figure 4: Weights of 161 L1 neurons. Note multiple prominent positive and negative neurons.

STM to generate only positive or negative pieces. Each individual in the population of this GA has 161 real-valued genes representing a small noise to be added to the weights of the 161 L1 neurons. The fitness of an individual is computed by (i) adding the genes of the individual to the weights (vector addition) of the 161 L1 neurons of the generative mLSTM, (ii) generating P pieces with this mLSTM, (iii) using the logistic regression model to predict these P generated pieces and (iv) calculating the mean squared error of the P predictions given a desired sentiment $s \in S = \{0, 1\}$.

The GA starts with a random population of size 100 where each gene of each individual is an uniformly sampled random number $-2 \leq r \leq 2$. For each generation, the GA (i) evaluates the current population, (ii) selects 100 parents via a roulette wheel with elitism, (iii) recombines the parents (crossover) taking the average of their genes and (iv) mutates each new recombined individual (new offspring) by randomly setting each gene to an uniformly sampled random number $-2 \leq r \leq 2$.

We performed two independent executions of this GA, one to optimize the mLSTM for generating positive pieces and another one for negative pieces. Each execution optimized the individuals during 100 epochs with crossover rate of 95% and mutation rate of 10%. To calculate the fitness of each individual, we generated P=30 pieces with 256 words each, starting with the symbol "." (end of time step). The optimization for positive and negative generation resulted in best individuals with fitness 0.16 and 0.33, respectively. This means that if we add the genes of the best individual of the final population to the weights of the generative mLSTM, we generate positive pieces with 84% accuracy and negative pieces with 67% accuracy.

After these two optimization processes, the genes of the best final individual of the positive optimization were added to the weights of the 161 L1 neurons of the trained generative mLSTM. We then generated 30 pieces with 1000 words starting with the symbol "." (end of time step) and randomly selected 3 of them. The same process was repeated using the genes of the best final individual of the negative execution. We asked annotators to label this 6 generated pieces via Amazon MTurk, using the the same methodology described in Section 4.1. Figure 5 shows the average valence per measure of each of the generated pieces.

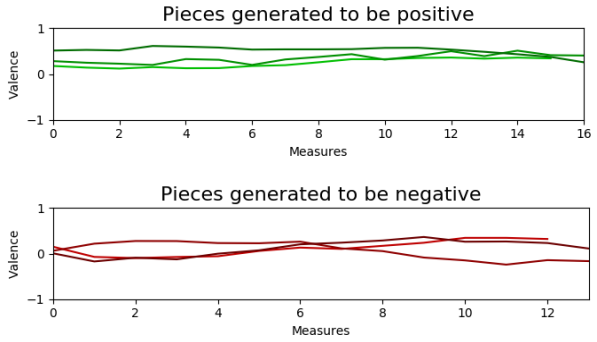

Figure 5: Average valence of the 6 generated pieces, as determined by human annotators. with least variance.

We observe that the human annotators agreed that the three positive generated pieces are indeed positive. The generated negative pieces are more ambiguous, having both negative and positive measures. However, as a whole the negative pieces have lower valence than the positive ones. This suggests that the best negative individual (with fitness 0.33) encountered by the GA wasn't good enough to control the mLSTM to generate complete negative pieces. Moreover, the challenge to optimize the L1 neurons suggests that there are more positive pieces than negative ones in the 3 shards used to train the generative mLSTM.

7. CONCLUSION AND FUTURE WORK

This paper presented a generative mLSTM that can be controlled to generate symbolic music with a given sentiment. The mLSTM is controlled by optimizing the weights of specific neurons that are responsible for the sentiment signal. Such neurons are found plugging a Logistic Regression to the mLSTM and training the Logistic Regression to classify sentiment of symbolic music encoded with the mLSTM hidden states. We evaluated this model both as a generator and as a sentiment classifier. Results showed that our model obtained good classification accuracy, outperforming a equivalent LSTM trained in a fully supervised way. Moreover, a user study showed that humans agree that our model can generate positive and negative music, with the caveat that the negative pieces are more ambiguous.

In the future, we plan to improve our model to generate less ambiguous negative pieces. Another future work consists of expanding the model to generate music with a given emotion (e.g. happy, sad, suspenseful, etc.) as well as with a given valence-arousal pair (real numbers). We also plan to use this model to compose soundtracks in real-time for oral storytelling experiences [12].

ABSTRACT

Recent efforts to model the compositional processes of Milton Babbitt have yielded a number of computationally challenging problems. One of these problems, known as the *all-partition array problem*, is a particularly hard variant of set covering, and several different approaches, including mathematical optimization, constraint satisfaction, and greedy backtracking, have been proposed for solving it. Of these previous approaches, only constraint programming has led to a successful solution. Unfortunately, this solution is expensive in terms of computation time. We present here two new search heuristics and a modification to a previously proposed heuristic, that, when applied to a greedy backtracking algorithm, allow the all-partition array problem to be solved in a practical running time. We demonstrate the success of our heuristics by solving for three different instances of the problem found in Babbitt's music, including one previously solved with constraint programming and one Babbitt himself was unable to solve. Use of the new heuristics allows each instance of the problem to be solved more quickly than was possible with previous approaches.

1. INTRODUCTION

Milton Babbitt (1916–2011) was a composer of serial music, whose work constituted a substantial contribution to 12-tone music theory and composition [2–6]. His works and the compositional techniques he developed have been studied extensively by music theorists and noted for their complexity [10, 13, 15, 18]. Recent computational work has shed further light on this complexity by looking, in particular, at a 12-tone structure and method of composition that Babbitt developed, known as the *all-partition array* [7, 9, 19, 20].

Satisfying all the constraints necessary to construct an all-partition array is challenging, not least because it involves solving a difficult variant of the set-cover problem [7, 8, 12]. In this paper, we present an improvement to a previous method, based on greedy backtracking, that applies two new search heuristics and a modification of a third heuristic that was originally proposed in [9]. These heuristics aim to facilitate the satisfaction of the most challenging of the all-partition array constraints when using a backtracking algorithm (to be discussed in section 4).

In section 2, we review the all-partition array and follow this with an overview in section 3 of recent computational work on solving the all-partition array problem. We focus in particular on the procedural greedy backtracking approach proposed in [9] to which the heuristics proposed in this paper have been applied. In section 4, we present our new heuristics and give pseudo-code for one possible implementation. In section 5, we demonstrate the effectiveness of the new heuristics by using them to discover solutions to three instances of the all-partition array problem. We report and compare the average running times as well as the number of required backtracks for these three solutions. We also provide a complete solution to one of these instances as evidence of correctness. Finally, in section 6, we summarize our results and propose some possible directions for future work.

2. THE ALL-PARTITION ARRAY

Constructing an all-partition array starts with an $I \times J$ matrix, A, in which each entry is an integer between 0 and 11, representing a pitch class, and where each row contains $J/12$ twelve-tone rows. In this paper, we focus on matrices where $I = 6$ and $J = 96$ because these figure prominently in Babbitt's music [14], and so far have proved difficult to generate [7, 9]. The resulting set of 48 tone rows in the matrix must be closed under any combination of transposition, inversion and retrograde. [1] Matrix A will therefore contain 48 occurrences of each of the integers from 0 to 11. It is important to note that not all organizations of these pitch classes in A will prove successful in constructing an all-partition array, but a desirable trait is for pitch classes to

[1] The exact instance of the type of 6×96 matrix shown throughout this paper has the following form:

$$A = \begin{bmatrix} \mathrm{R}_5 & \mathrm{I}_4 & \mathrm{RI}_7 & \mathrm{P}_2 & \mathrm{R}_{11} & \mathrm{P}_8 & \mathrm{RI}_1 & \mathrm{I}_{10} \\ \mathrm{RI}_4 & \mathrm{P}_{11} & \mathrm{R}_2 & \mathrm{I}_1 & \mathrm{RI}_{10} & \mathrm{I}_7 & \mathrm{R}_8 & \mathrm{P}_5 \\ \mathrm{P}_3 & \mathrm{R}_0 & \mathrm{I}_{11} & \mathrm{RI}_8 & \mathrm{P}_9 & \mathrm{R}_6 & \mathrm{I}_5 & \mathrm{RI}_2 \\ \mathrm{RI}_5 & \mathrm{I}_2 & \mathrm{R}_3 & \mathrm{P}_0 & \mathrm{RI}_{11} & \mathrm{I}_8 & \mathrm{R}_9 & \mathrm{P}_6 \\ \mathrm{I}_6 & \mathrm{R}_1 & \mathrm{P}_4 & \mathrm{RI}_3 & \mathrm{I}_0 & \mathrm{RI}_9 & \mathrm{P}_{10} & \mathrm{R}_7 \\ \mathrm{P}_7 & \mathrm{R}_{10} & \mathrm{I}_9 & \mathrm{R}_{10} & \mathrm{P}_1 & \mathrm{R}_4 & \mathrm{I}_3 & \mathrm{RI}_6 \end{bmatrix},$$

where $\mathrm{P}_0 = \langle 0, 1, 6, 8, 2, 7, 10, 11, 3, 5, 4, 9 \rangle$.

be evenly distributed [7]. However, the exact organizations which prove successful are still unknown [16, p. 284].

As shown in [20], a complete all-partition array is a *covering* of matrix, A, by K sets, each of which is a partition of the set $\{0, 1, \ldots, 11\}$ whose parts (1) contain consecutive row elements from A and (2) have cardinalities equal to the summands in one of the K distinct integer partitions of $L = 12$ (e.g., $6+6$ or $5+4+2+1$) containing I or fewer unordered summands greater than zero. [2] Figure 1 shows a 6×12 excerpt from a 6×96 pitch-class matrix, A, and one set forming a region in A containing every pitch class exactly once and corresponding to an integer partition, whose exact "shape" is more precisely represented as the *integer composition*, $\mathrm{IntComp}_{12}(3, 3, 2, 2, 2, 0)$ [9]. [3]

There are a total of 58 distinct integer partitions of 12 into 6 or fewer non-zero summands [14]. This means that the number of pitch classes required of an all-partition array having K regions, exceeds the number of entries in its matrix by $(K \cdot 12) - (I \cdot J)$. When $I = 6$ and $J = 96$, this difference is 120. On the musical surface, these 120 additionally required pitch classes are found through horizontal repetitions of at most one in each row from any one contiguous region to the next. As shown in [20], these horizontal row repetitions can be found instead through horizontal overlaps. These overlaps greatly simplify any computational model for generating an all-partition array because the matrix can remain fixed in size.

Figure 2 shows the same 6×12 excerpt from Figure 1, now with a second region corresponding to a distinct partition defined by the integer composition, $\mathrm{IntComp}_{12}(1, 0, 4, 3, 0, 4)$ (in light grey), with two overlaps shared with the first region. Note how the second region (in light grey) formed by its composition shares two overlapped locations (in rows 1 and 3) which lie at the rightmost column of the first region. A complete all-partition array of the type considered here is based on an $I = 6$ and $J = 96$ matrix containing $K = 58$ distinct regions with 120 overlaps.

The constraints of the all-partition array are motivated by Babbitt's desire for *maximal diversity* [14], which is the exhaustive presentation of as many musical parameters as possible (e.g., all 12 pitch classes, 48 tone rows, and K partitions). This makes the all-partition array problem appropriate for methods used in combinatorial optimization or constraint satisfaction, which often rely on either maximizing some objective function or strictly satisfying a set of constraints, respectively.

3. PREVIOUS COMPUTATIONAL WORK ON THE ALL-PARTITION ARRAY PROBLEM

Efforts to solve the all-partition array problem have resulted in a number of different approaches [9, 19, 20]. In [20], an integer programming (IP) model expressed the problem as a set of linear (in)equalities and managed to solve significantly smaller instances of the problem for matrices with six rows and up to 24 columns (requiring $(J + 2)/2$ regions which fix the number of overlaps to be 12). Solving for a matrix of this size required in excess of 30 minutes (Gurobi Optimizer v6.0 solver [1] running on a 2 GHz Intel Core i7 laptop with 8 GB RAM), and the computational time drastically increased with an increase in the number of columns. This suggests that solving for larger matrix sizes, such as the ones considered in this paper, would prove intractable for this IP model.

The first computational method to automatically generate an all-partition array from a pitch class matrix was a constraint programming (CP) model, described in [19]. This model solved a 4×96 matrix (requiring 34 regions and 24 overlaps) by splitting the whole of the matrix in half and solving each smaller sub-matrix before re-joining them to form a complete solution. Solving the second sub-matrix was made easier by discovering certain "easy-to-find" partitions and excluding these from the first sub-matrix. Finding a solution still required over 30 minutes (Sugar v2-1-0 solver [17] running on a 2 GHz Intel Core i7 laptop with 8 GB RAM) and this method of splitting the matrix unfortunately excludes possible solutions. Moreover, it is still unclear whether this model could be used to efficiently solve other instances of the all-partition array problem.

The heuristics proposed in this paper are intended to be used with the procedural greedy backtracking algorithm originally proposed in [9]. Figure 3 gives pseudo-code for a simplified version of the main backtracking procedure originally presented in [9].

[2] As in [20], we denote an integer partition of a positive integer, L, by $\mathrm{IntPart}_L(s_1, s_2, \ldots, s_I)$ and define it to be an ordered set of non-negative integers, $\langle s_1, s_2, \ldots, s_I \rangle$, where $L = \sum_{i=1}^{I} s_i$ and $s_1 \geq s_2 \geq \cdots \geq s_I$.

[3] As in [20], we define an *integer composition* of a positive integer, L, denoted by $\mathrm{IntComp}_L(s_1, s_2, \ldots, s_I)$, to be an ordered set of I non-negative integers, $\langle s_1, s_2, \ldots, s_I \rangle$, where $L = \sum_{i=1}^{I} s_i$. Unlike an integer partition, however, the summands in an integer composition need not be in descending order of size.

```

Figure 3: Pseudo-code for a simplified version of the BACKTRACKINGBABBITT algorithm originally presented in [9]. Note that $\bigoplus_{i=1}^{n}\langle x_i\rangle = \langle x_1, x_2, \ldots x_n, \rangle$, the assignment operator is denoted by '←' and scoping is indicated by indentation.

The algorithm shown in Figure 3 works from left to right in a given matrix. For each region, indexed by k, it first finds the partitions that have not yet been used in positions 1 to k (line 5) and then finds a list of candidate compositions (i.e., $\mathbf{C}[k]$) from these unused partitions (line 6) that form valid regions in the matrix according to the constraints discussed in section 2. If there are no candidate compositions, the algorithm backtracks by decrementing k by 1 (lines 7–8), otherwise it proceeds by incrementing k by 1 (line 10). In the event that the algorithm has backtracked to a previously visited k containing candidates (line 11), the next set of overlaps for the current candidate in $\mathbf{C}[k]$ is chosen (line 12). If there are no overlaps remaining (line 13) then the next candidate in $\mathbf{C}[k]$ is chosen. The algorithm then backtracks if there are no remaining candidates (lines 16–17) or proceeds after selecting the first set of overlaps (if any are available) for this new current candidate (lines 19–20). Note that we have provided here only those details necessary for understanding how our heuristics have been implemented (see section 4). [4]

Even with the help of the search heuristics described in [9], the algorithm above proved unable to generate a complete solution to the all-partition array problem after $100,000$ backtracks when tested on a 6×96 matrix. In the following section, we discuss why this failure likely occurred.

[4] More detailed pseudo-code for the original backtracking algorithm can be found in [9] and an improved implementation (written in Julia v.1.1.0 [11]) with our proposed heuristics can be found in the following repository: `https://github.com/brianm2b/generate-all-partition-arrays`.

4. PROPOSED BACKTRACKING SEARCH HEURISTICS

As noted in [9], a greedy deterministic backtracking algorithm for solving the all-partition array problem based on a depth-first search procedure which finds candidate regions from left to right in a given matrix will incur considerable computational cost in terms of time without sufficiently good heuristics for limiting the amount of backtracking required. When attempts were made to use this algorithm to solve for a 6×96 matrix, much of the backtracking was concentrated towards the far right of the matrix after the algorithm had already successfully discovered most of the required partitions. This means that the algorithm was unable to use the few remaining unused partitions to find compositions capable of forming successful regions (according to the constraints discussed in section 2) from the remaining matrix elements. If one relaxes the constraint that missing pitch classes from the final region must come from overlaps from previous contiguous regions and, instead, allows these pitch classes to be added to the end of the matrix, then the problem becomes significantly more tractable. As it turns out, this is exactly what Babbitt was forced to do in many of his works [7, 13]. It is these matrices, found for example in Babbitt's *About Time* (1982) and *Arie da Capo* (1974), that are the focus of this paper, as no known solution which satisfies all constraints exists. [5]

Figure 4 illustrates two scenarios for forming a final region in a nearly complete all-partition array where only one partition remains to be used. In Figure 4(b) the final region fails to cover one entry in the matrix due to an overlap of pitch class 9 (row 2) with the previous region. In Figure 4(c), every entry is covered, but pitch class 9 is added to the end (row 3) instead of overlapping with the previous region.

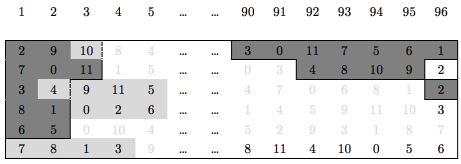
4.1 First Proposed Search Heuristic

The first of our proposed search heuristics is based on a simple assumption regarding the difficulty of finding a final region noted above. By excluding from the left-to-right search those partitions that successfully form regions in the final position K at the far right-hand side of A, it will be easier not only to form a complete matrix covering (Figure 4(c)), but also to avoid violating the constraint that all missing pitch classes from any one region must be overlaps (Figure 4(b)).

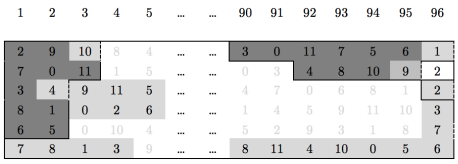
Let us suppose P_k, $1 \leq k \leq K$, is the set of all unused partitions not found in the sequence of selected candidate compositions from 1 up to k and R is the set of partitions that have been found to successfully form regions at K. The modified set of all unused partitions, P'_k, from 1 up to k is given by

$$P'_k = \begin{cases} P_k \setminus R, \text{if } (|P_k \cap R| = r \wedge \\ \qquad\qquad |P_k| > r); \text{and} \\ P_k, \text{otherwise,} \end{cases} \tag{1}$$

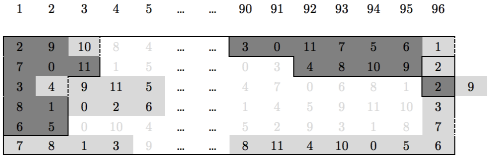
[5] See [13] for an example of an all-partition array of this type that forms an incomplete solution to the all-partition array problem.



(a) A nearly covered matrix and complete all-partition array with 9 uncovered pitch classes and one unused partition, $\mathrm{IntPart}_{12}(7,1,1,1,1,1)$, remaining.



(b) An unsuccessful matrix covering where a single pitch-class 2 remains uncovered by the final region. Note that all missing pitch classes from the uncovered elements in (a) are overlaps with previous contiguous regions.



(c) A successful matrix covering by the final region where pitch-class 2 from (b) has been covered, requiring that the missing pitch class 9 is added to the end of the matrix instead of overlapping with the previous region (as in (b)).

Figure 4: A 6×96 pitch-class matrix with 57 of its $K = 58$ partitions in (a) and two possible ways in (b) and (c) to ensure that the final unused partition, $\mathrm{IntComp}_{12}(1,1,1,1,1,7)$ (in light grey), forms a region containing every pitch class exactly once—both of which result in an incomplete solution to the all-partition array problem. For clarity, greyed out pitch classes belong to regions formed by partitions that have not been shown.

where r, $0 \leq r \leq |R|$, denotes a specified number of partitions in R to exclude from P_k. The first case in Eqn (1) states that the modified set of all unused partitions, P'_k, is the set difference of all unused partitions from 1 up to k and those found in R when (1) the number of partitions at the intersection of P_k and R is equal to r, and (2) the number of unused partitions is greater than r. When either of these two conditions are not met, P'_k is simply all unused partitions remaining (i.e., P_k). Collectively, these cases allow for partitions from R to be freely chosen so long as at least r partitions from R remain unused until there are r regions left to be found.

4.2 Second Proposed Search Heuristic

The second of our proposed heuristics is based in part on a modification to one originally proposed in [9]. A central feature of both heuristics, however, is that they work on the assumption that, since the matrix from which an all-partition array is constructed is regular (i.e., not ragged), regions should be chosen at each k so as to minimize the "raggedness" of their right hand column locations in each row. We make two significant improvements to this original heuristic which allow us to (1) work with a modification of the problem in which additionally required pitch classes appear as overlaps and not horizontal repetitions [20] and (2) minimize the raggedness of regions at each k in a way which takes into account both how far off from and in which direction their right hand column locations are from "ideal" locations specified in (1) while correcting for this same error found in the previous $k-1$ region.

For the first of our improvements, let us suppose we have a list of candidate compositions, $C_k = \langle c_{k,1}, c_{k,2}, ...c_{k,N} \rangle$ (corresponding to e.g., line 6 in Figure 3), at position k, where $1 \leq k \leq K$. Ideally, after choosing a composition for k, the rightmost column location of each row in this composition's region would be $J \cdot k/K$. This rightmost column location *after* choosing $c_{k,n}$ from C_k we denote $l'_{k,n,i}$ for a matrix row, i. For example, if we let $L'_{k,n}$ be equal to $\langle l'_{k,n,1}, \ldots, l'_{k,n,I} \rangle$, then the second region shown in Figure 2 would be $L'_{k,n} = \langle 3,3,5,5,2,4 \rangle$. To measure the raggedness or degree of difference in a region's rightmost column locations, $D_{k,n}$, that results from choosing $c_{k,n}$ in a fixed-size matrix, we use the following formula, based on city-block distance:

$$D_{k,n} = \sum_{i=1}^{I} \left| l'_{k,n,i} - \tfrac{J \cdot k}{K} \right|, \qquad (2)$$

where $|x|$ denotes the absolute value of x. The term, $J \cdot k/K$, specifies for any given region and row at k an "ideal" column location in a fixed-size matrix containing overlaps rather than in a potentially ragged matrix containing horizontal repetitions as in the original construction of an all-partition array. [6] This modification simplifies the modeling of the problem and aligns it with other proposed models [19, 20].

Our second improvement is based on the observation that Eqn (2) computes the magnitude and not the *direction* of the difference in each row between a region's right hand column location and its ideal location. This means, for example, that it is not possible to distinguish between two regions that are equally ragged according to $D_{k,n}$ but where one may be short of its ideal column locations and the other is longer. For this reason, we propose the use of an *adjustment* which captures for a given k how far off and in which direction the region chosen at $k-1$ is from its ideal column locations defined by the right hand term in Eqn (2). We can express this adjustment by defining for a region at k the rightmost column location for a matrix row, i, *before* choosing $c_{k,n}$ from C_k, which we denote $l_{k,i}$. For example, if we let $L_{k,i}$ be equal to $\langle l_{k,1}, \ldots, l_{k,I} \rangle$, then, for the second region shown in Figure 2, $L_{k,i} = \langle 3,3,2,2,2,0 \rangle$. Our second heuristic then is given by

$$S_{k,n} = \sum_{i=1}^{I} \left| \left(l'_{k,n,i} - \tfrac{J \cdot k}{K} \right) + \left(l_{k,i} - \tfrac{J \cdot (k-1)}{K} \right) \right|, \qquad (3)$$

where the adjustment, expressed as the difference $l_{k,i} - \frac{J \cdot (k-1)}{K}$, has been added to the difference shown in Eqn (2).

[6] In [9], this "ideal" column location was expressed as $12k/n$, where n is the number of matrix rows, due to the use of horizontal repetitions.

The absolute value of this sum is then taken and the resulting positive value is summed over all rows of i to form the final measure of adjusted raggedness, $S_{k,n}$. Use of Eqn (3) has the effect of preventing the accumulation of regions having the same directional error, either too short or too far past the ideal column locations for each row.

4.3 Modified backtracking algorithm with improved search heuristics

Whether only the magnitude of difference from an ideal location (Eqn (2)), or the magnitude and direction of this difference (Eqn (3)), is used, the goal of both heuristics is to minimize the degree of raggedness in the column locations of any one region formed by a candidate composition at k. We propose using a greedy strategy, for implementation with the backtracking algorithm proposed in [9], in which, for each k, we choose the candidate composition, c_n, in C_k that minimizes either $D_{k,n}$ or $S_{k,n}$. As a given region may have more than one possible set of overlaps (or none), we sort each region's sets of overlaps for each c_n according to whichever set results in the smallest value for the single heuristic, either $D_{k,n}$ or $S_{k,n}$, used globally throughout the search. The first of our heuristics shown in Eqn (1) can be implemented in two parts: one which occurs before the backtracking search begins and the other during the search when unused partitions from 1 up to k are found. Our two other heuristics shown in Eqn (2) and Eqn (3) can be implemented simply during the search when sorting the list of discovered candidate compositions in each C_k.

In Figure 5, asterisks indicate our modifications to the original backtracking algorithm in Figure 3 required to implement the new heuristics. Prior to the start of the backtracking search, the FINDCANDIDATES function finds the set of partitions, $\mathbf{R}$, that prove successful in forming regions at K, as required in Eqn (1) (see line 2 in Figure 5). These partitions are then passed to the function for finding unused partitions from 1 up to k in line 6, which returns a sorted set of lexicographically ordered compositions grouped by partition, $\mathbf{P}'$. In line 7, the pool of candidates for the kth region is chosen from this returned set. In line 11, the set of candidates found at k is sorted according to the value assigned to each candidate by either Eqn (2) or (3) (but not both).

```

Figure 5: Pseudo-code for a simplified version of modifications to the BACKTRACKINGBABBITT algorithm originally posed in [9] required to implement our new heuristics, expressed in Eqn (1), Eqn (2), and Eqn (3). The '*' denotes modified lines to the original implementation shown in Figure 3.

5. SOLUTIONS

As evidence of the correctness for the modified backtracking algorithm in Figure 5 and a demonstration of its performance using our proposed heuristics, we solved for three different instances of matrices of two sizes found in Babbitt's works. Table 2 shows the approximate times in seconds and fewest number of backtracks required by our heuristics to solve these three matrices (Julia v.1.1.0 [11] running on a 2.4 GHz Intel Core i5 laptop with 8 GB RAM).

For the purposes of bench marking, all solving times shown in Table 2 were averaged over three runs and terminated after 2×10^7 backtracks if no solution was found. The reported solutions were found by running the algorithm with the given set of heuristics for all values of the parameter, r, from 1 to $|R|$ (where $|x|$ denotes cardinality) and selecting the one which resulted in the fewest number of respective backtracks. The first of these matrices was constructed manually by Babbitt and no known complete solution has existed prior to our solving it here using P' ($r = 11$) and D, and P' ($r = 13 = |R|$) and S—the latter of which resulted in a fewer number of backtracks. The complete solution to this matrix using the best combination of heuristics appears in Table 1 below. The second matrix in Table 2 was constructed manually by a student of Babbitt named David Smalley [9] and at least one known solution (discovered by Smalley) existed prior to our solving it here using P' ($r = 22 = |R|$) and D, and P' ($r = 18$) and S. The final matrix was previously solved in [19] using constraint programming in ≈ 30 minutes, however, the combination of P' ($r = 1$ where $|R| = 7$) and S discovered a solution in ≈ 22 minutes. Overall, this matrix required the highest number of backtracks (over 5 million in the best case) of all matrices tested here. In all cases, we have used P', as solving using either D or S alone proved infeasible within the specified backtracking limit. Similarly, using P' alone also proved unsuccessful.

The significant difference in solving times and number of required backtracks in Table 2 for each of the matrices using one set of heuristics or another is interesting to note. The only difference between the first and second matrices, for example, is their organization of pitch classes, as both are the same size and require the same number of regions and overlaps. However, using P' and D solves the second matrix in approximately 1 second and 2377 backtracks but

Table 2: Approximate times and fewest number of required backtracks for solving three different matrices using the search heuristics, P', D, and S.

using P' and S is significantly more costly. The reverse is true of these sets of heuristics in the first matrix. This result appears to support the findings reported in [20], that each matrix represents a unique problem space, which, in our case, may require the use of heuristics with different considerations. Contrary to what one might expect, however, the smaller third matrix actually proved more difficult than the larger and more combinatorially expansive matrices (i.e., requiring more regions) with a best-case solving time and number of backtracks roughly 3 orders of magnitude greater. Finally, it is important to note that while the best solving times and number of backtracks for the first two matrices are low, their use of values greater than 1 for the parameter, r, in P' means that some potential solutions are excluded, namely, those in which one or more of these r partitions in P' appear at positions, k, where $k \leq K - r$. This is not true, however, in the third matrix, where only one of the possible partitions in P' was excluded (i.e., $r = 1$).

6. CONCLUSION

In this paper, we provided improvements to an existing backtracking algorithm in the form of three search heuristics which proved successful in solving the all-partition array problem for three different instances found in Babbitt's music. Our findings demonstrate that, when used together, our proposed heuristics allow the backtracking approach to outperform other approaches. However, it is also apparent from our results that the solving time and number of required backtracks required is highly dependent on the specific matrix given as input. In future work, it would prove useful to investigate methods of analyzing the organization of pitch classes in a matrix prior to searching and using these findings to modify the ideal column locations accordingly during the search.

MODELING AND LEARNING STRUCTURAL BREAKS IN SONATA FORMS

ABSTRACT

Expositions of Sonata Forms are structured towards two cadential goals, one being the Medial Caesura (MC). The MC is a gap in the musical texture between the Transition zone (TR) and the Secondary thematic zone (S). It appears as a climax of energy accumulation initiated by the TR, dividing the Exposition in two parts. We introduce high-level features relevant to formalize this energy gain and to identify MCs. These features concern rhythmic, harmonic and textural aspects of the music and characterize either the MC, its preparation or the texture contrast between TR and S. They are used to train a LSTM neural network on a corpus of 27 movements of string quartets written by Mozart. The model correctly locates the MCs on 14 movements within a leave-one-piece-out validation strategy. We discuss these results and how the network manages to model such structural breaks.

1. INTRODUCTION

1.1 Sonata Form

The classical sonata form shaped many musical works in the classical and the romantic period. It began to appear in the second half of the 18th century but was not formalized until the early 19th century. Recent theories on sonata forms emerged in the last decades, with various points of views [5, 7, 13], but nevertheless agree on its higher-level structure, involving *Exposition*, *Development* and *Recapitulation* sections, and optional *Introduction* or *Coda* sections.

According to Hepokoski and Darcy, an Exposition may be either a *two-part exposition*, featuring two contrasting thematic zones, or a *continuous exposition*, with only one thematic zone [13]. The two-part exposition is characterized by two strong punctuation breaks (Figure 1). The first one is the *Medial Caesura (MC)* which closes the first part of the exposition. The second one is the *Essential Expositional Closure (EEC)*, which is a *Perfect Authentic Cadence (PAC)* that concludes the Secondary thematic zone (S). The lack of a clearly articulated MC is the main difference between the two-part exposition and the continuous exposition [12]. Figure 1 shows the two-part exposition of a sonata form with its two punctuation points.

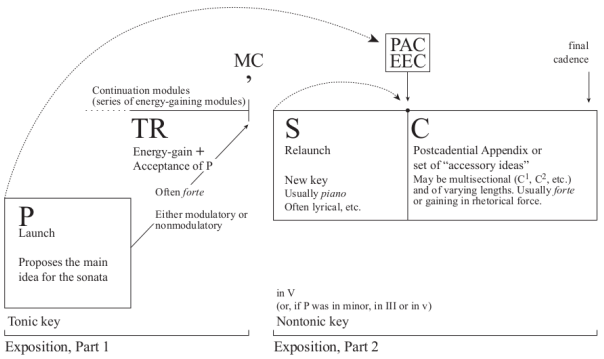

Figure 1. Structure of the two-part exposition in a sonata form, from Hepokoski and Darcy [13].

1.2 Formalizing Medial Caesuras

The MC is a "break in texture" [21] or a "textural change" [12] built around a cadence (most of the time, a half cadence (HC)), that acts as a boundary between TR and S. According to Hepokoski and Darcy, the MC has two fonctions [12, 13]: It closes the first part of the Exposition, concluding a process of energy gain initiated during the TR. It makes the second part available, opening a space for S thanks to that energy accumulated in TR. [1] Whether or not TR is modulatory, the MC is the point when the music reaches a structural dominant. [2] This dominant may be prolonged by neighbor motion, a repeated dominant pedal and a strong *forte*, and may be emphasized by *hammer strokes* (or *hammer blows*), that are repetitions of the final dominant chord. The whole process is concluded by the actual articulation of the MC. There can be a *general pause* on all voices, but there can also be a *caesura-fill*, that is a small melodic pattern or a sustained note or chord that "bridges the gap" to the S zone.Two examples of MCs are presented on Figure 2 and Figure 3.

[1] Hepokoski and Darcy suggest that the MC "may be thought of as metaphorically analogous to the moment of the opening of elevator doors onto a higher floor." [13]

[2] This structural dominant is the *arrival point* of the associated HC [6], what follows being considered as *post-cadential*.

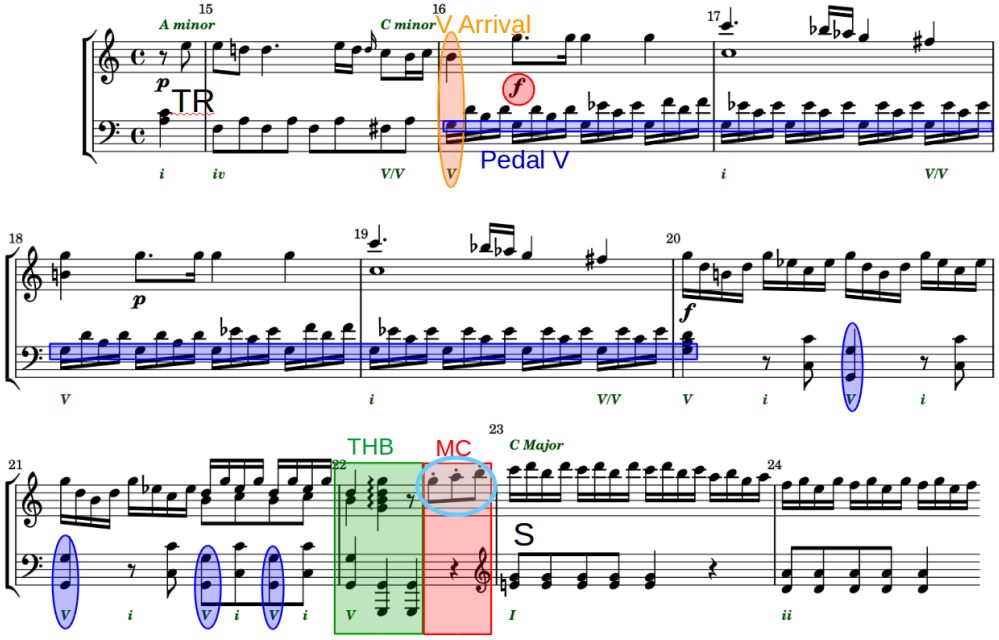

Figure 2. Mozart, *Piano sonata in A minor*, K310, 1st movement, mm15–24. The arrival point of the half cadence is on the downbeat of m16 (circled in orange). The measures 16 to 21 have a prolongational function. They are built on a *dominant pedal* (in blue) and a speeding-up harmonic oscillation between dominant and minor tonic of C minor. The dominant tension is reinforced by the *forte*/*piano*/*forte* contrast at m16, m18, and m20. This leads to a *triple hammer blow* (THB) at m22 (green) and the actual articulation of the MC on the fourth beat of m22 (red). Then *caesura-fill* at the right hand (lighter blue) leads to S and its new thematic unit.

Hepokoski and Darcy classify MCs according to the cadence occuring before the break and their position inside the Exposition [12]. A *first-level default* MC is associated with a HC in the secondary key [3] and can be denoted by V:HC MC (III:HC MC or v:HC MC in minor mode). This MC generally occurs between 25 and 50% of the length of the exposition, and sometimes at 60%. A *second-level default* MC considers a HC in the primary key (I:HC MC, between 15 and 45% of the length). A *third-level default* MC is caracterized by a PAC in the secondary key (V:PAC MC, III:PAC MC, or v:PAC MC), and occurs between 50 and 70%, sometimes at 75% of the length. The least encountered option, *fourth-level default*, is a PAC or an imperfect authentic cadence (IAC) in the primary key (I:PAC MC or IAC MC), generally at the end of P. In this case, S follows P without TR.

Another point of view on MCs is given by Richards [20], who identifies in 2013 seven *signals*, underlying the beginning of the secondary theme (S): tonic harmony of the new key, beginning function, preparation by a phrase-ending chord, textural gap of a medial caesura, change in texture, change in dynamics and characteristic melodic material. Each signal can be encountered in a *strong* or *weak* form. For example, the "Tonic harmony of new key" signal is strong when the chord encountered on the first downbeat is a tonic chord in the secondary key. It is weak when that chord is not the tonic of the secondary key, or when the chord is the tonic of another key due to a temporary modulation.

Somehow, a "textbook" MC, like the one displayed on Figure 2 is heard when all these signals, either on MC or on start of S, are strong. Of course, MCs in the classical repertoire do not strictly follow these rules and are rather heard with many deformations, like the one presented on Figure 3.

1.3 Medial Caesura, Sonata Form and MIR

Working on high-level music structures is a challenge for Music Information Retrival (MIR) research [19]. To our knowledge, no previous study in MIR has specifically targeted MC. However, several authors worked on sonata forms and designed algorithms to model or retrieve parts of its structure, on audio signals [15, 26] and on symbolic data [2, 22]. Sears and colleagues worked especially on cadences, by demonstrating that terminal events from cadential context are the most predictable thanks to a finite-context model (IDyOM) [23]. We previously worked on sonata form structure identification, modeling the MC as one state in Hidden Markov Models with 14 or 18 states and using a Viterbi algorithm to find back the sections from symbolic features [1, 4]. We also worked on PAC and HC detection thanks to features extraction and a SVM model. While PAC detection seems satisfying, HC detection was kind of disappointing due to the lack of characteristic feature for this cadence type [3].

[3] The secondary key is often the dominant major (V) for major mode primary key and the relative major (III) or the dominant minor (v) for minor mode primary key.

Figure 3. Mozart, *String Quartet in D minor*, K421, 1st movement, mm22-24. This MC is weak: No dominant arrival, no lock on degree V, nor hammer strokes, and energy depletion rather than a gain. This MC weakness can be due to a I:HC MC denial on the third beat of m14 not shown on this figure (dominant arrival at m12). The composer delays the arrival of S and continues into TR, maybe to create surprise.

Modeling MCs is a challenging subject even amongst music theorists. As the MC is a striking event, playing a role in the high-level structure, one may wonder whether it is possible to model and predict MCs with computational musicology methods. This study tries thus to model features relevant to identify structural breaks such as the MC. We propose such features that may be specific to MCs, based on music theorist works [13, 20] (Section 2) and present a neural network model that we train on a corpus of expositions in Mozart string quartets (Section 3). We finally discuss the occurences of the features, detail how the network manages to model the MC, and propose perspectives to further their study (Sections 4 and 5).

2. FEATURES INDICATING THE MEDIAL CAESURA

We mostly here introduce features to model high-level signals leading to the Medial Caesura, taking inspiration from Hepokoski and Darcy as well as from Richards [13,20]. To find the MC, we want to model the MC, but also its preparation and the textural contrast with the beginning of S. We also use low-level features inspired by dedicated extraction software as jSymbolic [18]. This section details 13 *features* that are estimated on each beat of the music piece. The features are then used in the next section to train a neural network to model the MC. In contrast to frequent uses of neural networks that consist in automatically identify most relevant features, this research aims to validate the efficiency of a set of pre-determined theory driven features to model medial caesura.

In the following, given a onset b, the $[b, b+1[$ interval means that we consider each note actually sounding in that interval, including notes whose onset is b (or before, but still sounding on b) but excluding notes whose onset is $b+1$.

2.1 Rhythm, energy and textural features

Preparations of MCs are expected to be passages of high rhythmic intensity as a consequence of the repetition of the pedal and the *forte*. It might even be the most obvious way of gaining musical energy. We also expect a change of rythmic density between TR and S and a beat filled with silence on the articulation of the MC.

Modeling textural changes with precision is a challenging topic in computational musicology [11]. To try to capture these "breaks in texture" between the end of TR and the beginning of S, we implement the following low-level features, for each beat b:

- *f-rhythm-density* counts the number of notes in $[b, b+1[$,
- *f-rest* counts the number of voices not sounding on b.

We add these features, as the textural/energy change can be seen on the range of voices:

- *f-mean-pitch* is the mean of the MIDI values of pitches in $[b, b+1[$,
- *f-range-pitch* is the difference between the maximum and minimum MIDI values of pitches in $[b, b+1[$.

We also keep track of the position in the piece:

- *f-time* is the current beat number divided by the total number of beat in the score.

We propose one high-level feature specific to MCs:

- *f-hammer-blow* tracks double, triple or more hammer strokes (see THB on Figure 2). To estimate this feature, the set of pitches on b are compared to sets of pitches on previous beats. This feature reaches its maximum when the set of pitches is the same for b for at least 2 previous beats.

2.2 Harmonic Features

We expect a (functional) dominant lock during the few beats before the articulation of the MC (whether it is a dominant on primary key or on secondary key).

Moreover, whether a TR is modulatory or not, we expect to encounter accidentals during TR or at least the beginning of S due to neighbor motion during the phase of prolongation of dominant and use of the dominant of the secondary key.

Algorithms for detecting local tonalities work well [17, 24] but tend to average variations over a window (often a few beats or measures). We propose rather two sets of features adapted to the detection of the MC.

Functional harmony compatibility. Functional harmonic analysis is a challenging problem in itself [9, 25]. The idea

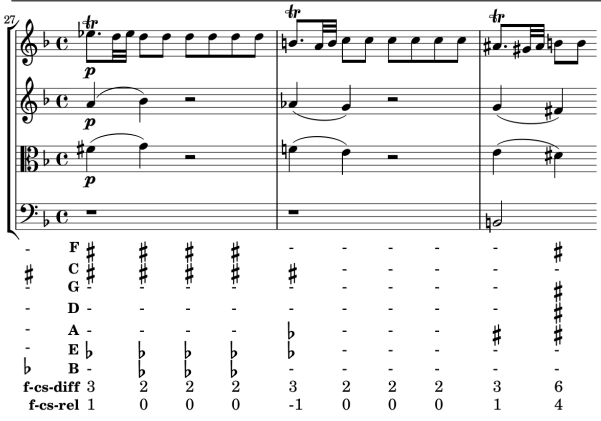

Figure 4. Estimation of the *current diatonic scale* on mm27-29 of Mozart's 1st movement of String Quartet No. 13 in D minor (K173). The D minor harmonic scale is given on the left. **f-cs-rel** stands for *f-current-scale-relative*.

here is to assert how compatible is a current harmony to a harmonic function, but without actually classifying the harmonies.

For a given functional harmony (as for example *f-predominant*, that may be either a ii or a IV/iv), we define a *compatibility profile* $h : P \rightarrow [-1, 1]$ that asserts how compatible a pitch $p \in P$ is to the given harmony. The pitch is given relative to the tonic of the primary key. Given a set of notes $c = \{p_1, p_2, ...\}$ from a given offset, the feature computes $\sum_{p \in c} h(p)$. The actual computation weights notes by their length in the given beat.

The compatibility profile h could be learned as profiles used in tonality detection [17]. We selected here a simpler approach and encoded two pitches lists coming for musical knowledge, one with relevant pitches, the other with irrelevant pitches. We define five such features, each one with a particular list of relevant and irrelevant pitches:

	relevant $h(p) = 1$	irrelevant $h(p) = -1$
f-maj-tonic	1, 3, 5	♯4, 7
f-min-tonic	1, ♭3, 5	♯4, 7
f-predominant	2, 4, ♯4, ♭6, 6, 1, ♭2	3, 5, 7
f-dominant-of-dominant	2, ♯4, ♭6, 6, 1, ♭3	3, 4, 5, ♯5, 7
f-dominant	5, 7, 2, 4, 6, ♭6	1, ♯5

These pitch lists suppose that we have a pitch space with the pitch spelling information. Pitches p that are not listed count for $h(p) = 0$.

Harmony landscape and current scale. To better capture the occurrence of new accidentals, we model the *current scale*. It is a diatonic scale containing the seven pitches with, for each of them, the last accidental encountered (Figure 4). We expect it to be different of its initial state at the beginning of the piece and to vary a lot just before the MC. We estimate two features on this scale :

- *f-current-scale-diff* counts the number of pitches differences in the current scale in $]b - 1, b]$ related to the initial current scale.

	Tonality	Cadence	MC	Tempo
K80.1	G Major	V:HC	1	Adagio
K80.2	G Major	V:HC	1	Allegro

Table 1. The corpus contains 27 expositions (21 in major, 6 in minor) in Mozart String Quartets. "MC" denotes the MC type as designed by [12].

- *f-current-scale-relative* further weights this count by $+1$ when the scale "gains" a sharp (or "loses" a flat) and by -1 in the other case.

For example, on the Figure 4, the current scales are compared with the D minor harmonic scale (primary key, with B♭ and C♯). On the downbeat of measure 28, three pitches are changed (A♭, E♭, B♮), so *f-current-scale-diff* is 3 and *f-current-scale-relative* is $1 - 2 = -1$.

3. LEARNING STRATEGY

3.1 Network Layout

A Long Short-Term Memory neural network (LSTM) is built to predict the position of the Medial Caesura in the pieces of the corpus (Figure 5).

The network takes vectors of values describing the beats of the pieces as input. The identification of a Medial Caesura at a particular beat requires also to look at several past beats and possibly future beats. This is partly taken into account by the LSTM, but we further directly provide to the network the feature values over a time window. A

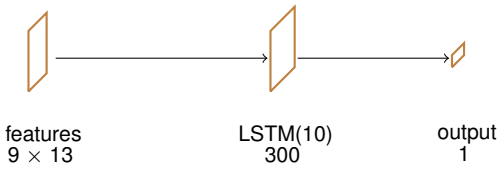

Figure 5. Network layout

vector describing a beat includes thus the 13 feature values corresponding to this beat but also those corresponding to the p previous beats and the n next beats. In this experiment, we set $p = 4$ and $n = 4$ which results in input vectors of size $9 \times 13 = 117$.

The input layer is fully connected to a recurrent hidden layer including 300 units. The time step of the LSTM is set to 10, meaning that 10 consecutive vectors are used to compute the probability of a MC occuring at one beat. Finally, the hidden layer is fully connected to the output layer that is a single unit. A sigmoid function scales the output value as a probability in the interval $[0, 1]$.

3.2 Model Training

To avoid overfitting, the position of the Medial Caesura in a piece of the corpus is predicted with a model that has been trained on the whole corpus minus the piece itself. This is referred as *leave-one-piece-out validation* process.

The 13 features are computed at every beat of every piece in the training set. Each piece is represented as a sequence of *feature vectors* of size 117, each vector being associated with a specific beat.

Every feature vector of the training set is associated with a *label* having a value 1 (presence of an annoted MC in the next 5 beats) or 0 (otherwise). During the training, pairs *(feature vector, label)* are presented to the network by batches of size 200. An Adam optimization algorithm updates the unit weights to minimize a binary cross-entropy loss function over 60 epochs.

Given the small number of medial caesura in the corpus, there was no preliminary selection of a separated test set. This research primarily focuses on the validation of the musical features rather than the classifier itself. For these reasons, the number and sizes of hidden layers, the batch size and the number of epochs as the optimization algorithm were selected among the most common values given the dimension and the quantity of input datas, with minimum optimization process in order to avoid over-fitting.

4. EVALUATION

4.1 Two-part expositions in Mozart's String Quartets

Mozart wrote 23 string quartets totaling 86 movements, including 42 in sonata form [16]. Many of these quartets are encoded as `.krn` Humdrum files [14] that we downloaded from the `humdrum-mozart-quartets` repository at `github.com/musedata/`. Some of these movements were left out because of unavailable clean encodings or of other technical inconsistencies including the absence of Medial Caesura. The corpus used finally contains 27 two-part expositions totaling 4179 beats. Medial Caesura annotations were taken from the sonata form annotation dataset we proposed in [1] and available at `www.algomus.fr/data`. These annotations include P, TR, MC, S, and C sections. Table 1 lists these 27 movements with their MC level default. We denote by K171.4 the 4th movement of K171.

	P	TR	MC	S	C
f-rhythm-density	0.442	0.517	0.524	**0.557**	**0.577**
f-hammer-blow	0.080	0.087	**0.143**	0.070	0.059
f-rest	0.223	0.194	0.099	**0.229**	0.181
f-mean-pitch	0.770	0.768	**0.786**	0.782	0.766
f-range-pitch	0.373	0.434	**0.508**	0.420	0.441
f-time	0.053	0.150	0.189	0.270	**0.350**
f-maj-tonic	**0.679**	0.621	0.593	0.575	0.595
f-min-tonic	**0.650**	0.598	0.581	0.561	0.588
f-predominant	0.568	0.553	**0.576**	0.545	0.521
f-dominant-of-dominant	0.493	0.537	**0.594**	0.561	0.525
f-dominant	0.629	0.670	**0.737**	0.699	0.719
f-current-scale-diff	0.065	0.182	**0.262**	0.228	0.237
f-current-scale-relative	0.008	0.069	0.094	**0.146**	0.134

Table 2. Average value of the features according to the section on the whole corpus.

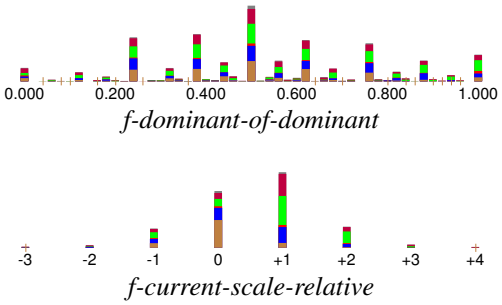

Figure 6. Distribution of two features relevant for MC identification. From bottom to top, P (brown), TR (blue), MC (red), S (green), and C (purple).

4.2 Implementation

We encoded feature extraction within the Python music21 framework [10]. The pitch space is Base40, modeling full pitch spelling information. Features described in Section 2 are computed at each beat of each piece and have their values scaled between 0 and 1 through min-max normalization. These features values are available as open data at `www.algomus.fr/data`. The neural network has been implemented with the Python framework Keras [8].

4.3 Features distribution

Table 2 shows the average values of each feature depending on the sections, and Figure 6 details the distribution of two relevant features. Several features have larger values on the MC, notably *f-dominant-of-dominant* and *f-dominant*. As expected, the features on tonic harmonies have higher values on P and TR, while features on dominant harmonies have higher values on the MC and S and C sections. The *current-scale* features are very low on P (initial tonal stability), but are then mostly activated on the other sections as the music moves to another key, and preferably one with more sharps. The *f-current-scale-diff* is maximal around the MC, reflecting the harmonic oscillations and tonal instability at this place. This behaviour is less visible on *f-current-scale-relative*. Indeed, we observe sometimes here a modal instability (as in Figure 2) that means more flats before the MC in major mode. Other relevant features

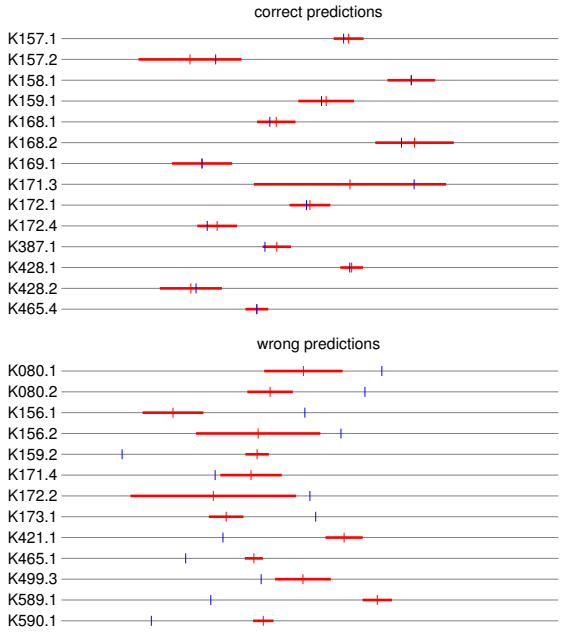

Figure 7. MC in the reference annotation (red marks on bold segments, representing ± 4 beats) and predicted by the model (blue marks).

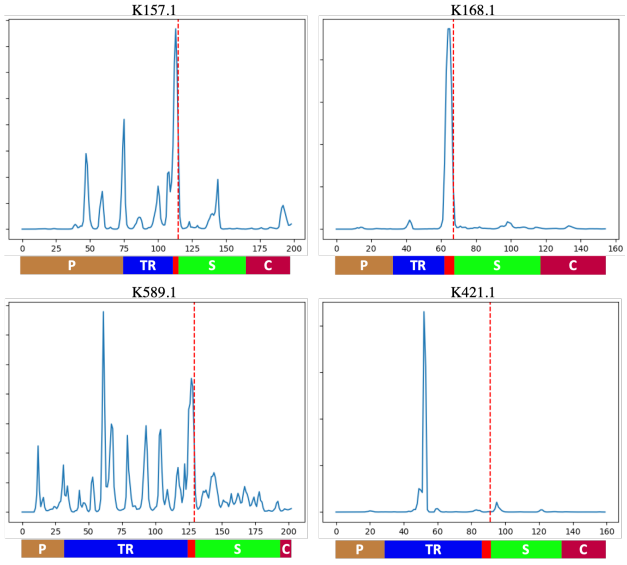

Figure 8. Probability curves for each beat to be an MC along four pieces of the corpus, two with correct MC predictions (top) and two with wrong MC predictions (bottom). Below each curve is the structure of the exposition in the reference annotation (P/TR/MC/S/C), and the red dashed lines emphasize the position of the MCs.

for the MC are, as expected, *f-hammer-blow*, and *f-range-pitch*, emphasizing the octave leap down often found on hammer blows.

4.4 MC prediction

In order to predict the position of the MC in an unseen piece, the sequence of vectors representing its beats are presented to the network. The position of the MC is identified at the offset where the network gives the maximum probability. We consider that a prediction is correct when the predicted MC is less than 4 beats before or after the annotated MC which seems reasonable given the progressive aspect of the MC phenomena.

Figure 7 displays the location at which the MC is identified as the MC original annotations for each piece of the corpus. The network correctly locates the MC of 14 of the 27 pieces of the corpus. This is a improvement from our previous work [1] where the model found only 8 MCs out of the same 27 pieces. Due to the small size of the corpus, we did not find any significant correlation between the accuracy of the prediction and the piece mode, tempo, or MC type. For example, MCs are correctly estimated in 11 out of 21 pieces in major mode and in 3 out of 6 pieces in minor mode.

Figure 8 displays the estimation of the probability of having a MC at each beat of four pieces of the corpus. These probabilities are computed by different models that have been trained on the whole corpus, except on the piece on which the prediction is performed. The model works well on some pieces. In K157.1, the highest peak predicts well the MC. The second highest peak, on beat 76, is also noteworthy as it is an HC ending the P section. Other peaks are not well explained. In K168.1, there is a unique peak at the correct position of the MC. The model fails to predict the MC in other pieces. In K421.1 (see also Figure 3), a MC is wrongly predicted with high confidence about 40 beats too early, at measure 14. This false prediction is actually a *denied MC*. In K589.1, there are more candidates for the MC location, but with low estimated probabilities, under 0.2. Another peak triggers the detection around beat 60, where there are two beats with only rests.

5. CONCLUSION AND PERSPECTIVES

We proposed theory driven features modeling structural breaks such as the Medial Caesura. Trained with only these features and without any other note information, the model succeeds in identifying about half of the MCs of the corpus. This is notable given the diversity of the realisations of MCs in such a small corpus. The success of the predictions does not seem to be correlated with the tempo, mode or the MC type.

The model might probably be improved both by enlarging the corpus and by taking into account additional elements that can not be retrieved from the files used in these experiments, such as dynamics. Features were selected based on music theory. It could be worth learning also more lower-level elements used in their computations, such as note pitches and durations. Furthermore, the performance of the model might be improved by considering additional musical features that have been proposed for other MIR tasks such as cadence detection or sonata form retrieval.

AUTO-ADAPTIVE RESONANCE EQUALIZATION USING DILATED RESIDUAL NETWORKS

Yascore, Paris, France

ABSTRACT

In music and audio production, attenuation of spectral resonances is an important step towards a technically correct result. In this paper we present a two-component system to automate the task of resonance equalization. The first component is a dynamic equalizer that automatically detects resonances, to be attenuated by a user-specified factor. The second component is a deep neural network that predicts the optimal attenuation factor based on the windowed audio. The network is trained and validated on empirical data gathered from a listening experiment. We test two distinct network architectures for the predictive model and find that an agnostic network architecture operating directly on the audio signal is on a par with a network architecture that relies on hand-designed features. Both architectures significantly improve a baseline approach to predicting human-preferred resonance attenuation factors.

1. INTRODUCTION AND RELATED WORK

Equalization is part of the audio mixing and mastering process. It is a redistribution of the energy of the signal in different frequency bands. The process has been traditionally performed by skilled sound engineers or musicians who determine the proper equalization given the characteristics of the input audio. Recently methods have been developed for semi-automatic and automatic equalization. These methods include automatic detection of frequency resonances [1], equalization derived from expert practices [7], and conformation to a target spectrum [15]. Equalization profiles may also be derived from semantic descriptors [5]. Appropriate equalization settings can be found through different means, for example by comparing the input source to previously equalized content [20], or by formulating equalization as an optimization problem where inter-track masking is used as the cost function [10]. Some automated equalization functionalities are featured in commercial products [1] [2].

[1] www.izotope.com/en/products/mix/neutron

[2] www.soundtheory.com/home

The use of machine learning, in particular neural networks, to solve audio production related tasks is recent. Automatic mixing tasks that have been addressed in this way include automatic reverbation [6], dynamic range compression [18], and demixing/remixing of tracks [17]. To our knowledge, there is no documented example of the use of neural networks for automatic equalization.

A specific form of equalization used both in mixing and mastering is the attenuation of resonating or salient frequencies, *i.e.* frequencies that are substantially louder than their neighbors [2]. Salient frequencies may originate from different phenomena, such as the acoustic resonances of a physical instrument or an acoustic space. They are considered a deficiency in the sense that they may mask the content of other frequency regions. One particular difficulty in resonance attenuation (RA) is finding the right amount of attenuation. For example, too much attenuation may unmask noise that would otherwise remain unheard, or flatten the spectrum to the point of garbling the original audio.

The subject of this paper is the automation of the RA process using machine learning. We limit our study to neural networks as the state of the art machine learning technique. Our method fully automates the RA process. It includes 1) a 0.5s windowed RA process that can be controlled with a single parameter—the *resonance attenuation factor* (RAF), 2) a deep neural network that predicts the attenuation factor from the input audio, making the process auto-adaptive [21].

For the training and validation we conduct a listening experiment determining optimal RAFs for a set of tracks, as chosen by sound engineers. We compare a neural network architecture that operates directly on the audio signal to a more traditional approach that includes a feature-extraction stage yielding a set of features commonly used in MIR. Results show that both approaches perform equally well, and significantly outperform a baseline.

The paper is organized as follows. Section 2 describes the RA process. The listening experiment is described in Section 3. The design, training, and evaluation of the predictive models is presented in Section 4, and conclusions are presented in Section 5.

2. RESONANCE EQUALIZATION

Traditionally RA has been a manual task where a sound engineer determines the resonating frequencies by ear or using a graphical tool, in order to reduce the energy of the

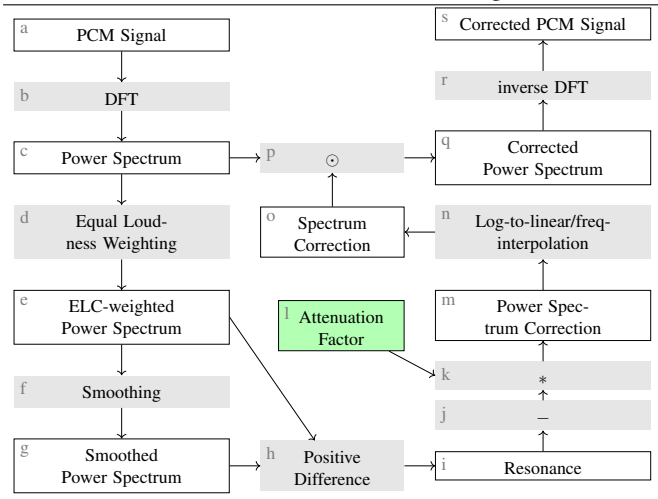

Figure 1. Resonance equalization block diagram; White and gray blocks represent data and processes respectively; The green block depicts the single user-controlled parameter; The symbols $\odot$, $*$ and $-$ represent elementwise vector/vector multiplication, elementwise scalar/vector multiplication, and unary negation respectively.

signal in those frequencies by an appropriate amount [16]. In this section, we describe a procedure that identifies resonating frequencies autonomously, and reduces the energy in those frequencies by a factor that is controlled by the user. The procedure works on overlapping audio windows that must be large enough to allow for spectral analysis at a high frequency resolution.

Figure 1 displays a block diagram of the RA process, where each element is denoted by a letter. We will use these letters to refer to the corresponding elements in the diagram. First the audio signal is used to compute a power spectrum weighted by Equal-Loudness Contours (ELC) [12] at a fixed monitoring level of 80 phon (Figure 1, element d) to reflect the perceptual salience of the signal energy at different frequency bands. The value of 80 phon is chosen in relation to the procedure detailed in Section 3.3. The ELC-weighted power spectrum (e) consists of 400 log-scaled frequency bands.

Resonances (i) are determined by smoothing ELC-weighted power spectrum [3] (e) to obtain (g) and computing the elementwise differences (e) minus (g), setting negative elements to zero (h). The negative of the resonances is then scaled by the user defined RAF (l), transformed back to a linear scale and converted back to the shape of the original spectrum using interpolation (h). The result (o) is a vector of scaling factors (one per DFT bin). Multiplying the original spectrum (c) with the scaling factors gives the corrected spectrum (q) which—by the inverse DFT (r)—yields the corrected audio signal (s).

3. LISTENING EXPERIMENT

A listening experiment was carried out to obtain ground truth in terms of optimal RAFs for a set of audio tracks. In the experimental design of the listening test it proved unpractical to ask subjects to set a varying RAF. Therefore we chose relatively homogeneous music fragments (excluding transitions between different sections of songs) and asked subjects for a single attenuation factor for the whole fragment, ensuring relatively homogeneous sound fragments.

3.1 Participants

A group of 15 subjects was recruited for the experiment, around Paris (France). All subjects are recognized professionals in the industry. Nine subjects specialize in studio recording (Classic/Jazz/Pop/Rock/Movie Music, audio post-production), three are experts in live music, and three are composer/music producers. The average age was 32 (min: 24, max: 42). The subjects were recruited and paid as if they were working on a commercial project.

3.2 Data

A set of 150 audio tracks was used for the listening experiment. The tracks are excerpts from longer pieces, with a mean duration of 46 seconds and a standard deviation of 16 seconds. All tracks were processed using Nugen AMB R128 [4] so that they were aligned to the same median loudness. The set comprised contemporary pop and rock music, as well as film scores. Of this set, 131 tracks were unique recordings, while the remaining 19 tracks were variants of some of the unique 131 recordings, with differences in mixing. None of the tracks were previously mastered.

3.3 Procedure

The listening experiment took place in a recording studio, where participants listened to the audio tracks individually, using studio monitors, at a measured loudness of 80 dBC– a typical listening loudness during audio production. The participants were presented with a web interface in which they could listen to each track with different degrees of RA, ranging from 0 (no attenuation) to 1 in 17 steps. They could select their preferred degree of RA, or alternatively decline to select any version, indicating that none of the versions sounded acceptable. The tracks were separated from each other by 10 seconds of pink noise surrounded by a short silence to give the participants a fixed reference. Sessions of 50 tracks were alternated with breaks.

3.4 Results and discussion

Basic statistics of the results per subject are given in Table 1. Subject 13 stands out because of the number of missing ratings (21 versus a median of 1 over all subjects). Subjects 1 and 15 have abnormally high rates of 0.0 ratings (72 and 58 respectively, versus a median of 16 over all subjects). Finally, Subject 7 stands out in terms of median rating (0.469 versus a median of 0.188 over all subjects).

To see how strongly the ratings are linearly related among subjects, we compute the Pearson correlation for

[3] using zero-phase low-pass filtering over the spectral bins

each pair of subjects (Figure 2). Apart from Subjects 13 and 15 (and to a lesser degree Subject 1) who appear to have different rating patterns from the majority of the subjects, the figure shows weak to moderate positive correlations between all subjects. This suggests that in spite of different preferred rating ranges, subjects made their judgments according to common criteria.

4. PREDICTING OPTIMAL ATTENUATION

In this section we describe the design and experimental validation of two modeling approaches to predict optimal attenuation factors from audio. The models are ultimately intended to be used in a real-time plugin for audio workstations. Although the real-time implementation is beyond the scope of this paper, it does guide some important design decisions for the modeling. Most importantly it implies a causal design in which the track cannot be analyzed as a whole in order to estimate the optimal attenuation factor. On the other hand, the audio latency upper-bound for real-time operation (maximum observed audio latency in real-time commercial plug-ins is 4096 samples) is too low for accurate prediction of the attenuation factor. This implies that the attenuation factor that will be applied at time t will be estimated from a windowed part of the signal (immediately) before t. Whether the predicted attenuation factor is still approximately valid for the signal at time t depends on the length of the window in relation to how quickly the resonance characteristics of the signal can change. Our aim is to target long range phenomena—3 seconds or longer, the time scale used for *short-term loudness* in EBU R128 [9]. From this perspective we consider a window size of 0.5s a good trade-off, offering sufficient data for an informed prediction and at the same time being short enough to adapt to changes in resonance characteristics at the 3s time-scale.

We describe and test two alternative neural network approaches to the problem of predicting optimal attenuation factors. The first is a more traditional approach in which a feature set is computed from an audio window, from which the attenuation factor is predicted. The second approach skips the intermediate feature representation. Instead, it takes the stereo PCM signal directly as input to a neural network that predicts the attenuation factor.

4.1 Feature-based prediction (FFN)

Performing regression or classification tasks on audio using feature descriptions of the audio has been the predominant approach for the past decades, and is based on the intuition that the prediction is determined by characteristics of the signal that can be defined explicitly and computed from the audio. These descriptors often capture spectral characteristics of the signal, but may also approximate perceptual characteristics, such as loudness. Many audio descriptors that have been proposed in the literature over time are implemented in a software library called Essentia [4]. The descriptors used in this study are listed in Table 2. All descriptors are available in the Essentia library, except *harmonics-to-noise ratio* [3] and *stereo width* (two descriptors, computed as the correlation between channels and absolute difference in RMS between channels, respectively), for which we used our own implementation.

The features are computed on shorter timescales (typically 1024 samples) than the 0.5s audio window for which our prediction will be made. Thus the feature computation stage returns a vector of values for each feature. We summarize each of these vectors by 7 statistics: the *mean*, *median*, *standard deviation*, *skew*, *kurtosis*, the 10^{th} *percentile*, and the 90^{th} *percentile*. This yields a total of 679 values per data instance, based on which a prediction must be made.

The network consists in a stack of linear layers (also called *dense*, or *fully connected*), each of which is followed by a *batch normalization* (BN) layer and a layer of *rectified linear* units (ReLU). The BN layer transforms the distribution of the output activations of the preceding linear layer to zero mean and unit variance by keeping track of mean and variance during the training of the model. The ReLU layer performs a non-linear transformation by setting negative output activations of the preceding layer to

MFCC (13 values)	zero-crossing rate
GFCC (13 values)	spectral flatness dB
inharmonicity	high frequency coefficient
pitch	barkbands (30 values)
pitch salience	pitch instantaneous confidence
spectral complexity	silence rate (at 20/30/60dB)
spectral crest	odd-to-even harmonic energy ratio
spectral decrease	spectral energy band (4 values)
spectral energy	tristimulus (3 values)
spectral flux	spectral contrast (6 values)
spectral rms	spectral valley (6 values)
spectral rolloff	stereo width (2 values)
spectral strong peak	harmonics-to-noise ratio

Table 2. List of audio descriptors used in the FFN.

zero. The number of linear layers and their sizes are not fixed in advance but determined using a hyper-parameter optimization scheme (Section 4.3). A final linear layer is added after the last ReLU layer. This layer has a single output—the predicted RAF.

4.2 Signal-based prediction (DRN)

In this section we describe a convolutional neural network that takes slices of a stereo PCM signal of the audio as input and provides an estimate of the optimal attenuation factor. Note that even for a window of moderate size and sample rate this quickly leads to tens of thousands of samples to be taken as model inputs. As opposed to a feature vector however, the inputs are ordered along a meaningful dimension (time), in which patterns can be identified, and are thus amenable to *convolution*. This approach, which was pioneered in [14], exploits the fact that such data display local patterns that may occur at different locations in the data. The strength of convolutional networks is that they learn to recognize patterns independently of their absolute location, and at the same time the convolution operation is much more space efficient than the "fully-connected" matrix dot product using in feed-forward neural networks, allowing for larger models. By stacking convolutional layers on top of each other it is possible to detect patterns of increasing size, and by interleaving the convolution operation with so-called *pooling* or *sub-sampling* operations, the patterns become somewhat invariant to local deformations.

However promising, the potential of traditional convolutional networks has been limited by a number of factors. Two limitations have been addressed by recent extensions of the traditional convolutional network approach, namely *dilated convolution*, and *residual networks*. We integrate both extensions in our convolutional network for predicting RA, and discuss each of them briefly before we describe the global architecture of the model.

4.2.1 Dilated convolution

An approach often used with traditional convolution in order to create high-level feature representations of data is pooling using *max* or *average* aggregation functions. For instance, max-pooling sub-samples the input by selecting maximal elements in a sliding window, typically using a sliding step (*stride*) equal to the size of the pooling window. Stacking convolution/pooling operations leads to features with increasing *receptive fields*, meaning that the features can describe patterns of increasing size. However, it comes at the cost of resolution loss: The relative position of features becomes less precise as their size increases.

On the contrary, dilated convolution achieves high-level features without loss of resolution. Rather than increasing stride, it increases the receptive field of the features by "dilating" the convolution kernels. A normal convolution of the kernel k with the signal s involves multiplying kernel elements with contiguous signal samples (τ is a discrete variable that increases in steps of 1):

$$(k * s)(t) = \sum_{\tau=-\infty}^{\infty} k(\tau)\, s(t-\tau) \tag{1}$$

In convolution with dilation factor $d \in \mathbb{Z}^+$ on the other hand the kernel elements are multiplied with signal samples that are equally spaced at d samples:

$$(k *_d s)(t) = \sum_{\tau=-\infty}^{\infty} k(\tau)\, s(t-d\tau) \tag{2}$$

By stacking convolutional layers with increasing dilation factors the higher level filter kernels aggregate information over input ranges of exponentially increasing size, even if the size the kernels (in terms of parameters) does not increase, and the resolution remains intact. This approach has proven successful in image processing tasks such as semantic segmentation [23].

4.2.2 Residual blocks

Another issue with convolutional networks is that as they grow deeper in order to capture higher level patterns, it becomes harder to optimize the lower level convolutional layers. This is directly related to the fact that for low level feature activations to influence the output of the model, they must pass through multiple layers of convolutions. Sometimes however, it is desirable for low level features to be able to directly influence the output of the model, not just to figure as a building block for higher level features.

This observation has led to the proposal of the *residual block* as a sub-structure used in deep networks [11, 24], an adaptation of which is depicted in Figure 3. In this structure the information flows from input to output through two pathways in parallel. The left pathway involves a typical convolution layer with configurable parameters: the kernel size k, number of kernels n, and dilation factor d. The right pathway convolution uses kernels of size 1 (the dilation factor is thus irrelevant), and thus does not compute any features from the input. Instead, it outputs n linear combinations of the input to ensure shape compatibility for elementwise addition to the n *feature maps* of the left pathway. The pathways further include batch normalization operations. After the elementwise sum of the pathways a rectified linear unit allows for a non-linear response.

The term "residual" refers to the fact that the left pathway only needs to account for variance in the output that

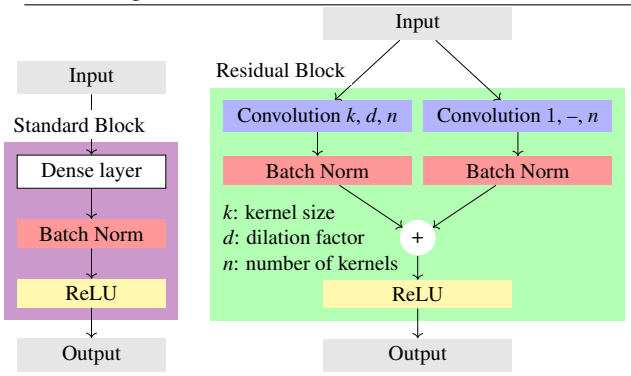

Figure 3. Building blocks for the FFN and DRN models. Left: Standard block (See Section 4.1); Right: Residual block (See Section 4.2.2).

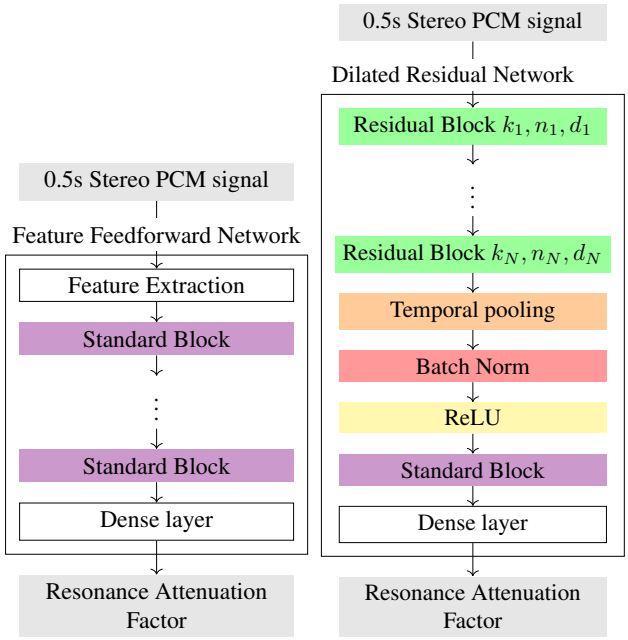

Figure 4. FFN and DRN architectures.

cannot be modeled as linear combinations of the input—the right pathway. Thus, increasing the number of layers does not hamper the ability of the network to account for its output in terms of lower level features.

4.2.3 DRN architecture

Figure 4 shows the complete model consisting of multiple residual blocks. Note that the residual blocks maintain the original temporal dimension of the data, which amounts to a size of 11025 for 0.5s of audio sampled at 22050Hz. The temporal pooling operation reduces this number by down-sampling the output using window-wise averaging, and is followed by two dense layers with intermediate batch-normalization and non-linearity in order to produce an estimated RAF.

4.3 Experiments

In this section we describe the training and evaluation procedure of both model architectures described above. We use the human ratings of the 150 tracks gathered in the listening experiment to train and evaluate both architectures.

4.3.1 Procedure

Evaluation Criterion Predicting optimal RAFs for given tracks is a regression problem, suggesting the mean squared error of the predictions with respect to the optimal value (the *target*) as an objective to be minimized. However, given the variance in the ratings across subjects in the ground truth, it may be hard to determine a unique optimal value per track. Using the mean or median of the ratings per track as a target has the drawback that the mean squared error objective does not differentiate between tracks with different degrees of rater consensus. Ideally, we wish to impose a lower penalty on errors from the mean rating when the rater consensus is low. We do so by generalizing the mean squared error objective as follows. Rather than defining the objective function to be minimal only for a single value, we define it to be minimal whenever the prediction lies within a specified interval that varies from one data instance to another. For a given data instance consisting of an audio track $A \in \mathbf{A}$ and a set of ratings $\mathbf{F}$ we define the zero penalty interval as $[\, P_l(\mathbf{F}),\ P_h(\mathbf{F})\,]$, where $P_l(\mathbf{F})$ and $P_h(\mathbf{F})$ denote the l-th and h-th percentiles of the ratings $\mathbf{F}$, respectively, with $l \leq h$. We refer to this objective (which is novel to the best of our knowledge) as the *mean squared bounds error* with bounds l, h, or $MSBE^{(l,h)}$. We use $l = 35$ and $h = 65$ throughout the experiments.

Formally, given a dataset D consisting of pairs $(A, \mathbf{F})$, the $MSBE^{(l,h)}$ of a model $f : \mathbf{A} \to \mathbb{R}$ is defined as:

$$MSBE^{(l,h)}(f, D) = \frac{1}{|D|} \sum_{(A,\,\mathbf{F})\,\in\,D} L^{(l,h)}_{A,\mathbf{F}}(f), \qquad (3)$$

where

$$L^{(l,h)}_{A,\mathbf{F}}(f) = \Big([\, f(A) - P_h(\mathbf{F})\,]^+ + [\, f(A) - P_l(\mathbf{F})\,]^-\Big)^2. \qquad (4)$$

The brackets $[\,\cdot\,]^+$ and $[\,\cdot\,]^-$ denote the positive and negative parts respectively.

Hyper-parameter optimization We use Bayesian optimization to find the optimal hyper-parameters for each of the models, most importantly the depth of the networks and the hidden layer sizes. This is a heuristic to speed up the search for appropriate hyper-parameter values compared to an exhaustive grid search. The particular form of optimization we use is based on a gaussian process approximation of the loss as a function of the hyper-parameters. This approximation gives rise to the *upper confidence bound* [13], which estimates the expected loss for hyper-parameter settings that have not yet been tested, and is used as a guide to search the space of hyper-parameters [22].

Apart from the depth of the models and the hidden layer sizes, the optimization involved hyper-parameters to control the training procedure: the *learning rate*, and the thresholds for *early stopping*, and *learning rate reduction*.

	FFN	DRN
Depth	3 Std. Blocks	10 Res. Blocks
Blk. Size (Low/Mid/High)	500 / 250 / 250	100 / 100 / 300
Temporal Pooling	–	300
Final Std. Block Size	–	10

Table 3. Optimal configuration for the FFN and the DRN architectures as found by hyper-parameter optimization.

			95% CI	
Model	Mean	Std. dev.	Low	High
Baseline	0.237	0.103	0.194	0.280
FFN	0.159	0.082	0.124	0.194
DRN	0.154	0.080	0.121	0.188

Table 4. Means, standard deviations, and the 95% confidence interval (CI) for the mean $MSBE^{(35,\,65)}$ per model.

Cross-validation To perform the hyper-parameter optimization we use two partitions of the dataset into a test set (10 tracks), a validation set (10 tracks), and a train set (130 tracks). For each of the test tracks we compute the $MSBE^{(35,\,65)}$ loss on 100 randomly selected 0.5s frames. The criterion used to optimize the hyper-parameters is the average frame-wise loss across both test sets.

With the best hyper-parameters found for the FFN and DRN architectures, respectively, we perform a further five fold cross-validation. To this end, we use the same dataset, but exclude the 20 test tracks used for hyper-parameter optimization. We repeat the five fold cross validation five times using different random seeds to reduce the effect of partitioning of the data into folds and model parameter initializations on the result.

Baseline We define a baseline approach as a reference for evaluating the FFN and DRN architectures. It consists in computing the mean RAF over all tracks in the training set, and using this value as a prediction for the test set, irrespective of the input audio.

4.3.2 Results and discussion

The optimal configuration for FFN and DRN architectures, as found by hyper-parameter optimization, are shown in Table 3. Figure 5 shows the results of these architectures on repeated five fold cross validations. A one-way repeated measures ANOVA reveals a significant effect of model on $MSBE^{(35,\,65)}$ ($F_{2,\,72} = 6.55$, $p = 0.002$). A post-hoc Tukey HSD test at $\alpha = 0.05$ indicates that DRN and FFN differ significantly from the baseline. The effect size of DRN over baseline corresponds to Cohen's $d = 0.88$, whereas the FFN over baseline effect size is $d = 0.82$. The difference between DRN and FFN is not significant.

Table 3 shows that the FFN architecture works best when it is comparatively shallow (three standard blocks, the minimal depth tested), whereas the DRN architecture performs better when it is deep (10 residual blocks, the maximal depth tested). This trend is consistent in a review of the 10 best FFN and DRN architectures as found in the hyper-parameter optimization, omitted here for the sake of brevity. The layer sizes however do not show a similarly consistent trend, and vary considerably throughout the 10 best FFN and DRN architectures.

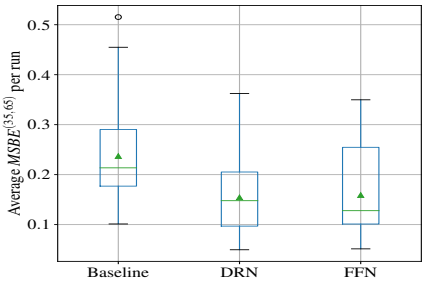

Figure 5. Boxplot of $MSBE^{(35,\,65)}$ cross-validation results for baseline, FFN, and DRN models; Horizontal lines in the boxes denote the median, triangles the mean values.

The fact that both approaches show similar prediction accuracies is in line with a general trend in the deep learning literature that computational tasks can be solved without the need for hand-designed features.

At the same time, the roughly equivalent performance of the FFN and DRN measured here is at odds with a multitude of cases where end-to-end deep networks clearly outperform prior state-of-the-art methods that rely on a hand-designed feature extraction stage, especially in image processing [25]. For audio tasks such as automatic tagging however, this does not seem to be the case however [8]—where end-to-end approaches require large training data sets in order to outperform spectrogram-based approaches [19]. Given the small data set used here—especially in combination with inter-subject variance and the non-uniform distribution of the ratings—this may explain why the DRN does not outperform the FFN.

5. CONCLUSION

We have proposed a method to attenuate automatically identified resonances by a user-controlled factor, and gathered ground-truth data for the optimal attenuation factor from sound engineers. The data—revealing general consensus in ratings among subjects—were used to train and evaluate two types of neural networks to estimate optimal resonance attenuation factors. The results show a domain-agnostic dilated residual network operating directly on the audio signal performs on a par with a neural network operating on a set of commonly used audio features. Although this does not discredit the feature-based approach to the resonance attenation problem per se, it does show that further improvements—if possible—will require specially crafted features based on expert domain knowledge.

The proposed system is a fully auto-adaptive resonance equalization system in which the attenuation factor is chosen automatically by a deep neural network. To our knowledge, this system is the first documented self-adaptive equalizer based on neural networks. Future work includes a real-time implementation of the presented model as a real-time plugin that can be used in audio work stations.

ABSTRACT

There has been little research considering eye movement as a measure when assessing user interactions with music information retrieval (MIR) systems, whereas many studies have adopted conventional user-centered measures such as user effectiveness and user perception. To bridge this research gap, this study investigates users' eye movement patterns and measures with two music retrieval tasks and two interface presentation modes. A user experiment was conducted with 16 participants whose eye movement and mouse click behaviors were recorded through professional eye trackers. Through analyzing visual patterns of eye gazes and movements as well as various metrics in prominent Areas of Interest (AOI), it is found that users' eye movement behaviors were related to task type. Besides, the results also disclosed that some eye movement metrics were related to both user effectiveness and user perception, and influenced by user characteristics. It is also found that some eye movement and user effectiveness metrics can be used to predict user perception. This study allows researchers to gain a deeper insight into user interactions with MIR systems from the perspective of eye movement measure.

1. INTRODUCTION

With the rapid development of Music Information Retrieval (MIR) as a field, user has been increasingly recognized as playing an essential or central role in the process of music retrieval [14][25]. Users' interactions with MIR systems have been drawing researchers' attention for the purposes of evaluating MIR techniques [13] and interfaces [5] from users' perspectives, as well as improving understanding of users [19].

Various approaches have been utilized to collect data of user interactions with MIR systems including listening histories [26], click streams in system logs [11], user surveys or diaries [32], etc. A series of user-centered metrics have then been proposed and used to measure users' interactions including those in user effectiveness (e.g., number of songs listened to) [11] and user perceptions (e.g., emotion, satisfaction) [32]. To facilitate this process, various tracking techniques have been employed through off-the-shelf software tools and/or self-development apps [11][32].

As an alternative approach to measuring users' interactions with various stimuli (e.g., computer systems, web interface, learning materials), eye movement has been used to explore the relationship between human's cognitive process and their behaviors [3]. It is believed that people's cognition can be reflected by their eye movement patterns [27][30]. Nowadays, fast-developing high-tech devices enable researchers to acquire eye tracking data in an accurate and reliable manner, such as eye tracking glasses and eye movement sensors. Compared to measures that rely on users' self-report, eye tracking data are objective and thus could help avoid possible response bias [4]. With current (wearable) technology, the process of collecting eye movement data is becoming less obtrusive. If relevant methodologies and techniques are appropriately applied to MIR studies, measurements of eye movement could be potentially helpful for analyzing and evaluating user interactions with MIR systems.

This study aims to explore the application of eye movement measure to investigating user interactions with a MIR system, through a user experiment involving different MIR tasks and interface modes. The relationships between eye movement measure and traditional measures such as user effectiveness and user perception are analyzed. Possible influence of user characteristics (e.g., gender) is also taken into account. The findings are expected to provide empirical evidence on exploiting eye movement data in studying user interactions in MIR.

2. RELATED WORK

2.1 User Interactions in MIR

Users' interactions with MIR systems have been mostly studied in the context of user-centered evaluation of MIR. Compared with the system-centered evaluation paradigm, user-centered evaluation is not as popular, but is increasingly adopted, with the recognition of users being the center of MIR [25]. It is advocated that user interactions provide a more direct way to understand how human perceive and use MIR systems, as serving the users is arguably the ultimate goal of MIR systems [14]. Another purpose of studying user interactions in MIR is for designing interactive systems where users' behavioral, psychological and

physiological measures could serve as input as well as feedback to systems [15][11][32].

To date, a number of user-centered measures and metrics have been applied in studying user interactions in MIR. Conventional user-centered metrics including those of user effectiveness and user perception [16] have been adopted in MIR, such as number of songs found, task completion time and user satisfaction, etc. Besides, enjoyment has been recognized as an important aspect of user perception unique in MIR [18]. Along with the line of research considering the casual-leisure nature of music retrieval, new metrics were proposed for evaluating MIR, including novelty, aesthetics, and content quality [12].

To collect and analyze the aforementioned measures and metrics, a range of methods have been employed. Traditional methods of user studies such as survey, interview and observations are included [18] and further developed to work with current technologies such as experience sampling with mobile apps [32]. Interactive behaviors are often recorded as system logs with the support of software tools that can track mouse clicks and keyword input [11]. More recently, with the development of wearable technology, studies started to collect users' physiological signals while they interact with MIR systems [22]. Nevertheless, to date there has been little research investigating user-MIR interactions with eye movement measure [29] which has been recognized as effective in capturing people's cognitive process and used in a number of domains.

2.2 Eye Movement Tracking and Cognitive Behaviors

It is recognized that eye movement can reflect human cognitive behaviors. In recent years, eye movement has been used in the domain of text retrieval, particularly on the influence of search interface design on users' search behaviors [6], as well as the relationships between document relevance and users' cognitive efforts [8]. Eye movement has also been widely employed in studies on people's reading behaviors such as identifying the sections focused on by readers during reading process [24]. In the education domain, there are many studies benefited from analyzing learners' eye movement such as computer programming [23], language learning [1], and music education [20].

In leveraging eye movement data, an important step is to find concrete measurements that can describe eye movement in an accurate and reliable manner. Fixation and saccade are two primary measures of eye movement, which are regarded as plausible evidences to detect cognitive processing during interactive tasks such as information retrieval [4]. Fixation indicates that a person stares at certain location and lasts for a period of time, presumably to process certain cognitive tasks, while saccade is a dynamic visit between two fixations [19]. Furthermore, investigators have often attempted to categorize eye movement behaviors into different patterns so as to interpret possible cognitive implications by comparing the patterns [4][8][24][30]. Relatedly, visualization of eye movement patterns such as heatmaps of eye gazes and plots of eye scan paths is also a viable and frequently adopted approach to making sense of eye movement data [4]. For instance, based on the positions of intensive fixations and the speed of saccades, authors of [30] found the correlation between eye fixation and participants' learning performance.

MIR also involves cognitively intensive activities where eye movement has great potential in studying user-system interactions. An existing research gap is that very few user studies have considered eye movement as a measurement of interactions between user and MIR systems, even though there are studies exploiting eye movement in music psychology [17] and music performance [31]. Therefore, this study aims to bridge the gap by providing empirical evidence on studying interactive MIR systems from an eye-tracking approach.

3. RESEARCH QUESTIONS

Aiming to showcase how eye movement measures can be used in MIR research, this study considers multiple constructs in typical MIR research settings: retrieval tasks, system interface modes, user-centered measures as well as user characteristics. Specifically, through conducting a user experiment involving these factors, this study focuses on three research questions as follows:

Q1. To what extent do different music retrieval tasks and system interfaces have effect on users' eye movement measure?

Q2. To what extent is eye movement measure related to user effectiveness and user perception measures?

Q3. To what extent is eye movement related to user characteristics (e.g., gender, music listening habit)?

To answer these research questions, a set of hypotheses are formulated. There are two hypotheses under Q1:

H1: eye movement measure differs in different task types.

H2: eye movement measure differs in different interface modes.

Under Q2, there are three hypotheses as well:

H3: eye movement measure is related to user effectiveness measures.

H4: eye movement measure is related to user perception measures.

H5: eye movement and user effectiveness measures can predict user perception.

Under Q3, one hypothesis is formulated:

H6: eye movement measure is related to user characteristics.

Answers to Q1 will have methodological implications on the extent to which eye movement can be used in MIR task/system design and evaluation. Answers to Q2 can reveal how eye movement measures are related to commonly used measures of user behaviors and whether they can be complimentary to one another in the context of MIR. In particular, the answer to whether or not user perception, as

a subjective measure, is predictable by other objective measures can have the potential of facilitating MIR researchers and system designers to better understand users' perceptions through objective measures. User characteristics (e.g., background in music training) have been recognized as influential in MIR process[19][25], and Q3 is to investigate their relationship with eye movement measure.

4. METHORDS

To fulfill the goals of this study, a user experiment was conducted with a mood-aware MIR system. During the experiment, users' eye movement and other user-centered measures were collected. This section describes details of the system, tasks, experiment procedure and data analysis.

4.1 The System

Moodydb is an online MIR system that supports searching and browsing music by mood [13]. Based on spectrum features extracted from the music audio, this system classifies music into five mood categories, namely *passionate*, *cheerful*, *bittersweet*, *silly/quirky* and *aggressive* [10]. There were 750 songs in the system when the study was conducted, with 738 Western popular pieces (from the U.S. and the U.K.) and 12 Chinese popular songs. The pieces were unevenly distributed across the mood categories with *bittersweet* being the largest class (226 songs) and *silly/quirky* being the smallest (35 songs). The rest categories contained 141 – 184 songs. When a user input singer's name or song's title in query box, it will prompt a set of songs that match the textual query. After user chooses one of the songs as a seed song, the system will retrieve a group of songs with similar mood to the seed song and display them as recommended songs to the user.

The system interface is presented in two different ways; one is in a traditional list-based layout and the other is visualization of album covers based on nested figures as in the treemapping display method [28]. As shown in Figure 1, the List layout ranks the recommended songs from the top of the screen down according to how similar the moods of the recommended songs are to that of the seed song. The Visual layout shown in Figure 2 uses the size of the album covers to represent the degree of similarity: the larger size an album image is in, the more similar the song is to the seed song in term of music mood.

4.2 Tasks and Topics

There were two music information retrieval tasks designed for this study: searching and browsing. As for searching, the participant was given a seed song (e.g., Irreplaceable by *Beyoncé*) to start with, and then make use of the system as a search engine to find other songs whose moods are similar to that of seed song. As for browsing, the participant was required to browse music in a given (seed) mood (e.g., *bittersweet*) and find songs in the mood. For each task, there were two topics that had different seed songs (for the searching task) or different seed moods (for the browsing task), making a total of four topics. All participants conducted both tasks (searching and browsing) with both interface modes (List and Visual), making a 2 * 2 experiment design. All participants conducted the same topics (same seed songs /moods) but the task and interface mode combinations were ordered in a Graco-Latin square arrangement to counterbalance possible sequence effect.

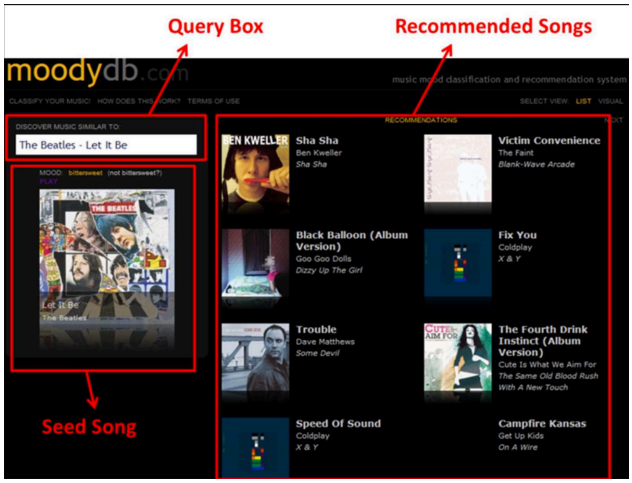

Figure 1. List-based interface mode in the system

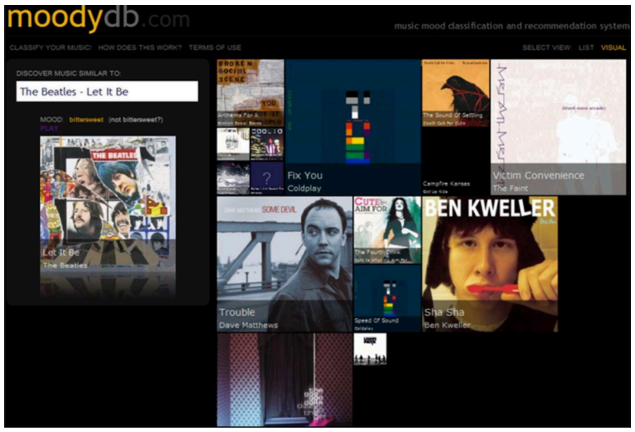

Figure 2. Visual-based interface mode in the system

4.3 Procedure

The experiment started with a pre-session questionnaire about demographic information, music knowledge, and general music information behaviors of the participants. After that, a research assistant demonstrated how the system could be used and the participants used the system for several minutes to familiarize with the system. An eye tracking sensor, Tobii T60, was used to collect data of participants' eye movements. Calibration was done with the eye tracker before a participant started working on each topic, with the assistance of a researcher. After completing all four topics (which covers both tasks and interface modes), participants were inquired about the feelings of the experiment through a post questionnaire. The experiment lasted for approximately one hour, and each participant was paid a nominal remuneration upon completing the experiment.

4.4 Measures

The following user-centered measures are used to answer the three research questions raised in this study.

User effectiveness was used to assess user performance in the experiment. It included four metrics: (a) Number of songs found to fulfill each topic; (b) Number of songs played during the process of working on each topic; (c) Completion time of each topic (measured in minute); (d) Number of mouse clicks during the process of working on each topic. The first metric came from answers submitted by the participants while others were recorded by Tobii 60.

User perception was used to understand users' feelings after they completed each topic. It included three metrics: (a) Task easiness; (b) Preference on the given seed song; (c) Satisfaction with songs found. Measured by a 7-point Likert scale, the perception degree ranges from the most negative to the most positive. Take task easiness as an example: point 1 means the user felt the topic not easy at all, while point 7 means he/she felt the topic very easy.

Eye movement was described statistically with five metrics: (a) Fixation Duration; (b) Fixation Count; (c) Visit Duration; (d) Total Visits Duration; (e) Visit Count. Metrics related to duration such as fixation duration and visit duration is measured by second. It is noteworthy that fixation and visit are two different concepts; the former indicates that participants' eyes fixate on one point, while the latter measures a process of saccade (i.e. moving the eye gaze from one point to another).

The eye movement metrics are calculated in defined Areas of Interest (AOI). In this study, the interface of system is divided into four AOIs based on their functions in the music retrieval process. They are (a) Search Box; (b) Seed Song; (c) Recommended Songs; (d) Player, which are shown in Figure 3. It is noteworthy that a Visit Duration in an AOI is defined as the interval of time between the first fixation inside the AOI and the first subsequent fixation outside the AOI. Besides, while the Visit Duration measures the duration of each individual visit within an AOI, Total Visit Duration measures the sum of duration of all the visits within an AOI. In addition to the metrics in each AOI, we also take the total across all AOIs into account. Statistics of the eye movement metrics in each AOI are generated by the Tobii Studio Analyzer.

4.5 Data Analysis

Hypotheses proposed under the research questions are tested using corresponding statistical tests. H1 and H2 compare metrics between two tasks and two interface modes respectively, for which pair wised t-tests are applied. H3 and H4 investigate relationships between metrics, and thus correlation analysis is used, including Pearson's correlation (for numerical metrics) and Spearman's correlation (for ordinal metrics). Linear regression is used to test H5 which concerns the predictive power of the metrics to user perception. Last but not least, H6 is tested through point-biserial correlation analysis (for binary metrics) and Spearman's correlation analysis. For cases where multiple tests are conducted, Bonferroni corrections are conducted to control type I errors [9].

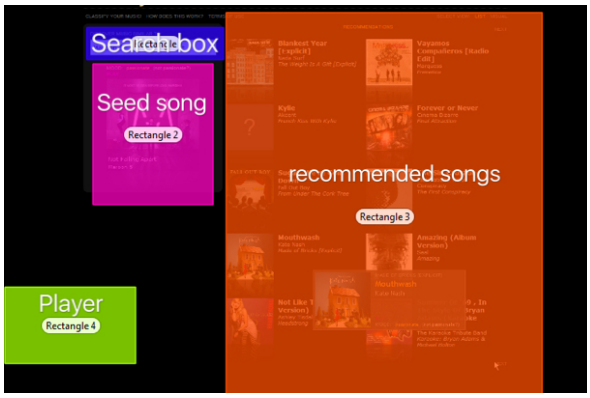

Figure 3. Four AOIs in this study

Besides, visualization as a data analysis method was used in this study as well. There are a number of visualization types in eye movement analysis, such as gaze plot and heat map. In this study, we used heat map to compare eye movement in two interface modes. Examples of heat map are shown in Figures 4 and 5 where aggregated time of fixations on the screen are illustrated by different colors. Red represents the most fixations or longest time period, while green is the least and shortest. The varying colors infer that the levels are in between.

5. RESULTS AND DISCUSSIONS

5.1 Participants

A combination of purposive and convenient sample methods was recruited in the user experiment, including 16 Japanese undergraduate and graduate students (8 female). Their ages ranged from 19 to 50, with a mean of 22.9 and a median of 21. The standard deviation of the age was 7.37. They were from a range of majors including Science, Medicine, Economics, Law and Humanities. A majority of them (11) were able to play an instrument while 5 of them could not. About half of them (7) searched for music fairly frequently, at least several times a week. While the rest of them searched music at least one a month. In term of how often they listened to music, 6 of them rated weekly, 7 daily, and 3 multiple times a day.

5.2 Influences of Task Types or Interface Modes on Eye Movement

This section aims to answer Q1 and test H1and H2. Table 1 presents means and standard deviation (in parenthesis) of eye movement metrics with significant difference in corresponding AOIs between the browsing and searching tasks, detected by paired t-test after Bonferroni correction [7]. As Table 1 shows, during the searching task, participants had longer fixation duration and more fixation count in areas of seed song as well as more visit count in total AOIs. Therefore, our hypothesis H1 is partially supported.

It is not surprising that there were more eye movement in the seed song area during searching task as users needed to compare the seed song and retrieval results, while there was no need for such comparison during the browsing task. The difference on visit count in total AOIs could possibly be attributable to the fact that comparing seed songs and retrieved songs would need a user to move eye gazes between the two AOIs which in turn generated more visits.

Measure	Browsing	Searching	*p* value
FixDur in SeedSong	16.22 (10.91)	27.66 (15.33)	.001*
FixCnt in Seedsong	69.56 (39.37)	109.72 (59.86)	.001*
VisCnt in Total	114.22 (48.98)	152.69 (69.50)	.000*

Table 1. Eye movement measures with significant differences between browsing tasks and searching tasks

The paired t-test on interface mode did not generate significant results after Bonferroni correction, and thus H2 is not supported. This can be explained by the fact (and limitation) that the difference between the two interface modes is actually within an AOI, the recommended song AOI (Figure 3). This calls for alternative methods to compare the two interface modes.

To compare eye movement in a qualitative manner, we present the heat maps of the two interface modes in Figures 4 and 5 respectively. As is shown in Figure 4, fixations from the list-based interface mode disperse along with the positions of the recommended songs. In contrast, in visual-based interface mode (Figure 5), fixations of participants nearly concentrate on the center of recommended songs area. In addition, although, by convention, the List mode ranks highly relevant results up in the list, Figures 4 shows that participants did not only focus on the top rows. For the Visual mode, while more relevant results (with bigger album images) could appear anywhere in the recommended song area, participants' attention seem to have focused on the middle only (Figure 5). These observations are somewhat anti-intuitive and worthy of future investigation.

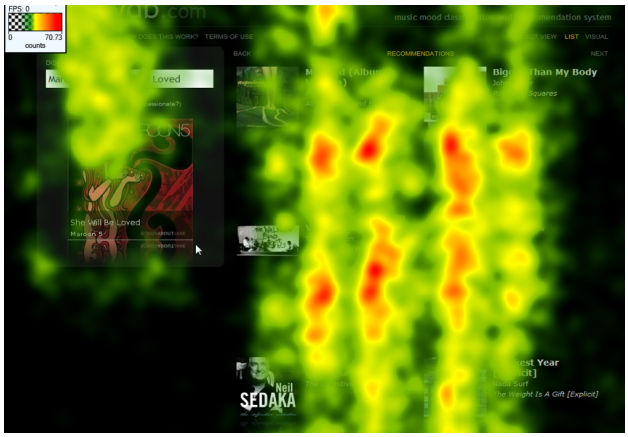

Figure 4. Eye fixation heat map of the List interface mode

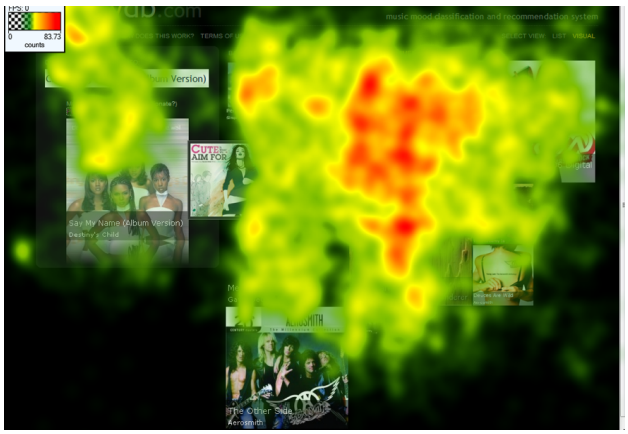

Figure 5. Eye fixation heat map of the Visual interface mode

5.3 Relationships among Eye Movement, User Effectiveness and User Perception Measures

This section aims to answer Q2 and tests H3 to H5. To test H3, Pearson's correlation coefficients were calculated for user effectiveness metrics on interval scales: number of songs found in each topic, number of songs played in each topic and completion time of each task. Significant results after Bonferroni corrections are shown in Table 2.

Effectiveness	Eye Movement	Coefficient	*p* value
Completion Time	TotVisDur in RecomSong	.416	.001*
	TotVisDur in Total	.476	.000*

Table 2. Correlation between eye movement and user effectiveness (Pearson)

As we can see in Table 2, completion time has significant correlations with total visit duration in recommended songs and in total AOIs, and the correlations were moderately positive (coefficient > 0.3). In other words, when users spent more time moving their eyes within the recommended song areas, the more time they would need to complete the tasks. In contrast, other two effectiveness metrics have no significant correlation with eye movement. Thus, our Hypothesis H3 is partially supported.

To test H4, Spearman's correlation coefficients were calculated for user perception metrics on ordinal scales: task easiness; satisfaction with songs found; preference on seed song. The significant results after Bonferroni correction are shown in Table 3.

Perception	Eye Movement	Coefficient	*p* value
Satisfaction with Songs Found	VisDur in Total	.396	.001*
	VisCnt in SeedSong	-.403	.001*

Table 3. Correlation between eye movement and user perception (Spearman)

As is shown in Table 3, satisfaction with songs found has significantly moderate correlation with visit duration in total AOIs and visit count in seed song (coefficient > 0.3). Interestingly, the correlations were positive and

negative respectively. In other words, the more time users spent in moving their eyes around the AOIs, the more satisfied they would be with the songs they found. However, the more times their eyes visited the seed song area, the less satisfied they would be with the found songs. One possible explanation of the former relationship could be from the perspective of enjoyment [18]: satisfied users presumably enjoyed the task and thus they spent more time looking around on the system interface. For the latter relationship, visiting the seed song area might have been an *effort* one had to pay in order to complete the task (e.g., comparing the seed song to a recommended song), and thus repeated visits to this area would entail more efforts and less satisfaction. As there is no significant correlation between the other two perception metrics (task easiness, preference on seed song) and eye movement, our hypotheses H4 is partially supported.

To test hypothesis H5, we ran a linear regression analysis on predicting user perception from eye movement and user effectiveness. To save space, only significant variables in the prediction models are reported (Table 4). As we can see in Table 4, several eye movement metrics have statistically significance in predicting participants' satisfaction with songs found (one user perception metric). In addition, it is noteworthy that the number of songs found, a user effectiveness measure, was significant in predicting all the three metrics of user perceptions. Thus, our hypothesis H5 is partially supported. This finding that users' eye movement and user effectiveness can contribute to predicting user perception measure has methodological implications in that eye movement and user effectiveness measures can be captured automatically in unobtrusive and objective manners. This can potentially provide novel and reliable methods for detecting user perceptions which have to rely on self-report to collect in traditional methods.

Perception	Metrics	Coefficient Beta	*t*	*p*
Task Easiness	# of songs found	.443	2.400	.021*
Satisfy with Songs Found	VisDur in Player	.533	2.308	.026
	VisDur in Total	.774	3.012	.004
	VisCnt in Search Box	-.984	-2.346	.024
	VisCnt in RecomSong	.718	2.127	.040
	# of songs found	.510	3.505	.001
Like Seed Song	# of songs found	.453	2.572	.014

*: significant at $p < 0.05$ level; R^2 = .334, .586, .394 for the three predictive models respectively

Table 4. Regression analysis on user perception

5.4 Relationship between Eye Movement Measure and User Characteristics

To answer Q3 and test H6, we calculated point-biserial correlation coefficients for user characteristics metrics on binary scales: gender (Male=1, Female=2), and being able to play music instrument (Y=1, N=2). We also ran Spearman's correlation on two ordinal variables, frequency of listening to music and frequency of searching for music. Results with significant correlation after Bonferroni correction are shown in Table 5.

Characteristics	Eye Movement	Coefficient	*p* value
Listening Freq	VisCnt in Total	.436	.001*
	VisCnt in Seed-Song	.485	.001*

Table 5. Correlation between eye movement and user characteristics

As shown in Table 5, frequency of listening to music (one user characteristic) has significant and moderately positive correlation with visit count in Total AOIs and that in the seed song area. The more often users listened to music, the more times their eyes visited the seed song area and all AOIs. As visit count of the eyes is related to attention [4], This result is possibly related to the enthusiasm that these users had in music. Nevertheless, other three user characteristics have no significant correlation with eye movement. Thus, our hypothesis H6 is partially supported.

6. CONCLUSION AND FUTURE WORK

This is an empirical study on using eye tracking method to analyze user interactions with MIR systems. We analyzed eye movement metrics in four AOIs and most of our hypotheses were partially supported by the results. Specifically, some eye movement metrics differed between different retrieval tasks. Furthermore, some eye movement metrics were related to user effective and user perception measures. It is potentially useful in research methodology that some metrics of eye movement and user effectiveness can be used to predict user perception. There was no significant difference on eye movement metrics on the different interface modes, which calls for alternative analysis methods beyond AOI-based ones. Also, through comparing visualized heat maps, we found that fixations of participants may not follow patterns found in text retrieval, which warrants further investigation.

This study aims to stimulate and encourage more work to utilize eye tracking in MIR research. There is much room for future work in investigating eye movement with different MIR tasks, use cases and user groups. It could be paradigm shifting if more findings in future work support deriving users' subjective perception (i.e. satisfaction, perceived difficulty) from unobtrusive and objective measures including eye movement.

ABSTRACT

Symbolic melodic similarity is based on measuring a pairwise distance between two songs from diverse perspectives. The distance is usually summarized as a single value for song retrieval. This obscures observing the details of similarity patterns within the two songs. In this paper, we propose a cross-scape plot representation to visualize multi-scaled melody similarity between two symbolic music encodings. The cross-scape plot is computed by stacking up a minimum local distance between two segments from each of the two songs. As the layer goes up, the segment size increases and it computes incrementally more long-term distances. This hierarchical representation allows for capturing the location and length of similar segments between two songs in a visually intuitive manner. We show the effectiveness of the cross-scape plot by evaluating it on examples from folk music collections with similarity-based categories and plagiarism cases.

1. INTRODUCTION

Melodic similarity is a key concept in the field of ethnomusicology, music analysis, musicology, music psychology, copyright issues in music, and music information retrieval [13]. From music analysis to content-based retrieval, a great deal of effort and attention have been paid to quantitative measurement of melodic similarity using knowledge from various domains [5, 12, 13, 18–20, 22, 25]. The applications of melodic similarity include song retrieval and classification, music indexing, and music alignment systems [3].

When evaluating the similarity of two songs, it is essential to extract information about what parts and how long they are similar to each other. For example, considering a plagiarism case, a short three-second segment can be regarded as qualitatively significant if it can be easily recognized as a chorus or hook of a popular song [10]. If the similar parts of these two songs are meaningfully similar or *substantially similar* [9], even if the other parts of the two songs are different, people may effectively recognize it as a plagiarized song [10]. However, existing similarity measures often summarize the distance as a single value for song retrieval. This obscures the details of similar pattern within the two songs. This way, even if the two songs has almost identical parts locally, the overall similarity may be diluted by the calculation for the entire song.

In this paper, we tackle this issue by proposing a cross-scape plot representation that visualizes multi-scaled melody similarity between two symbolic music. The cross-scape plot is computed by stacking up a minimum local distance between two segments from each of the two songs. We segment songs from small to large units, and the local similarity is performed by a sequence-based similarity algorithm for all possible segments of the two songs. As the layer goes up, the segment size increases and it computes progressively more long-term distances. This results in a hierarchical visual representation with a triangular or trapezoidal shape.

The cross-scape plot provides rich information in an intuitive way, which a single value derived from most similarity measures cannot provide. Even with a simple glance, we can observe various characteristics of similarity, such as the location and length of similar parts by the pattern shape in the plot, and the overall similarity by the color. Even when the melody has the same similarity value in a single measurement, the visual representation can be very different. We show this aspect with examples from classified folk songs Meertens Tune Collections (MTC-ANN) [21] and music plagiarism cases. We also validate the multi-scaled melodic similarity by summarizing it into a similarity value and conduct a melody classification experiment on MTC-ANN.

2. MULTI-SCALE SIMILARITY ANALYSIS

This section describes three steps of multi-scaled similarity analysis to obtain the cross-scape plot.

2.1 Feature Extraction

Many choices of features have been extracted for melodic similarity analysis including pitch, pitch interval, duration, onset, duration weighted pitch sequence or metric weights [7]. In this study, we use pitch interval as a pitch feature and inter-onset interval ratio as a rhythmic feature. Pitch interval is computed by the pitch difference between two

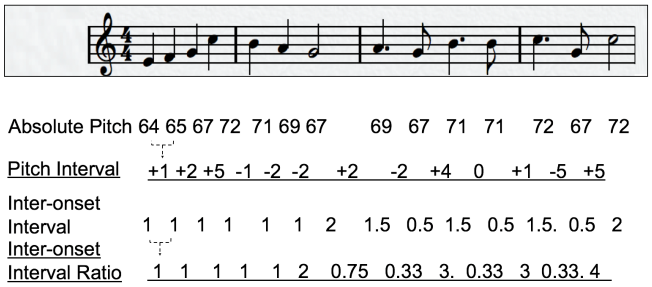

Figure 1: An example of pitch interval and inter-onset interval ratio of the rhythm extracted from melody.

successive notes. This is invariant to key of the songs. The pitch interval is limited to the range within 2 octaves in our setting. Inter-onset interval (IOI) ratio is computed from the relative IOI of three successive notes. This is invariant to tempo of the songs. The IOI is quantized to the unit of 0.5 and limited not to exceed 4 in our setting. Figure 1 shows that a melody is converted to a sequence of the pitch and rhythm features. We analyze similarity for both feature sequences independently.

2.2 Multi-segmentation

Multi-segmentation is the process of dividing the melody sequence into smaller sub-sequences of all sizes. This idea was inspired by Sapp's work [15, 16]. Sapp proposed a plotting method called *scape plot* that can display the results of an analysis of segments of varying lengths as a single image. The scape plot is a simple but effective method to understand similarity patterns that occur on every possible timescale. The scape plot was named in *landscape* because it shows small-scale features similar to the foreground of the picture, as well as large-scale features similar to the background. The original scape plot method was designed for structural analysis of harmony in musical scores [15] and has been applied in a variety of ways in different contexts, for example, tonality analysis [14, 27], musical performance analysis [17, 24] and audio thumbnailing [8].

Following the approach, we segment the sequence into multi-scale units from the smallest to the entire sequence. Figure 2 is an example of dividing the features sequences into the different sizes. The sequence $ABCDE$ is divided into 15 sub-sequences by sequentially grouping them into units of the smallest unit (that correspond to segment size of 1) to the maximum of 5, which is the length of the entire sequence (that correspond to segment size of 5). Formally speaking, given the sequence of melody features, $S = (x_1, x_2, ..., x_{|S|})$ where $|S|$ is the length of S, let s_k^n denote the kth sub-sequence with the length n of S so that $s_k^n = (x_k, x_{k+1}, ..., x_{k+n-1}), 1 <= k <= |S| - n + 1$. These sub sequences s^n are used to obtain the local distance between two songs. The following section describes how to calculate the local similarity using these multiple sub-sequences of melody.

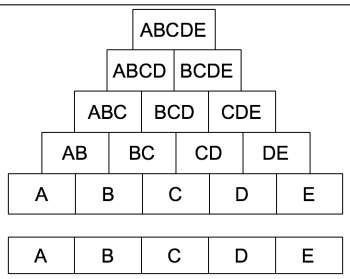

Figure 2: Example of multiple segments of melody. The sequence $ABCDE$ is divided into 15 sub-sequences.

2.3 Similarity Calculation

We use the multi-segmentation to compute multi-scale similarity between two songs. We first define the distance measure between two segments.

2.3.1 Distance Measure

In order to obtain the local distance of each segment, we adopt edit distance [11], the most commonly used string matching similarity calculation method in music research [5]. The edit distance, also known as the Levenshtein distance, is a metric that computes the minimum number of operations needed to transform one sequence into the other.

The operations between sequences include $deletion$, $insertion$, and $substitution$ of symbols. To find out the minimum path to obtain edit distance, we use dynamic programming algorithm known as Wagner—Fischer algorithm. For the compared melodic sequence $S_a = (a_1, a_2, ...a_n)$, and the $S_b = (b_1, b_2, ...b_m)$, where a_i and b_j are features of the melody. [1] We set 1 to the cost of $deletion$, $insertion$ and 2 to the cost of $substitution$. Let $d(i, j)$ denote the edit distance of sub-sequence $(a_1, a_2, ...a_i), (b_1, b_2, ...b_j)$. The calculation of edit distance $D(S_a, S_b) = d(n, m)$ is defined using a recursive algorithm as below [6]:

$$
\begin{aligned}
&d(i,0) = i, \\
&d(0,j) = j, \\
&d(i,j) = \begin{cases} d(i-1,j-1) & \text{if } a_i = b_j \\ \min \begin{cases} d(i-1,j)+1 \\ d(i,j-1)+1 \\ d(i-1,j-1)+2 \end{cases} & \text{if } a_i \neq b_j \end{cases} \\
&\qquad\qquad \text{for } 1 \leq i \leq n, 1 \leq j \leq m
\end{aligned} \tag{1}
$$

The final local distance between two sub-sequences, denoted by $\overline{D}$, is the normalized value of of $D(S_a, S_b)$ divided by the maximum possible distance (i.e., when the two sequences are completely different) as follows:

$$\overline{D}(S_a, S_b) = \frac{D(S_a, S_b)}{(|S_a| + |S_b|) \times 2} \tag{2}$$

[1] S can be either a whole melody, or a sub-sequence of it, and it can be pitch interval and the inter-onset interval ratio.

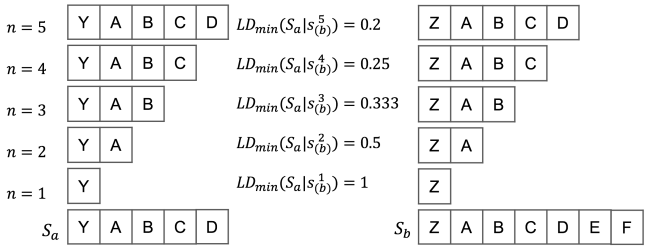

Figure 3: An example of minimum local distance calculation between S_a and S_b

We particularly define the minimum local distance between a melody S_a and $s^n_{k(b)}$, a sub-sequence of S_b at the kth position with length n:

$$LD_{min}(S_a|s^n_{k(b)}) = \min_{\forall s^n_{(a)} \in S_a} \overline{D}(s^n_{(a)}, s^n_{k(b)}) \quad (3)$$

Because $LD_{min}(S_a|s^n_{k(b)})$ is a minimum distance between a segment $s^n_{k(b)}$ and all possible sub-sequences of S_a with the same length n, it is not a commutative operation. However, we call it distance because it shows the distance between $s^n_{k(b)}$ and most-matched segment in S_a. For example, suppose that there are two melody sequences to be compared, S_b is a longer melodic sequence, and S_a is shorter (see Figure 3). S_a and S_b can be divided into sub-sequences. [2] The figure shows the LD_{min} value of the first segment for each n. For example, $LD_{min}(S_a|s^1_{1(b)})$ is 1 because in the first sub-sequence with $n = 1$ ("Z" in the example) does not match any sub-sequences of S_a. As the number of notes shared by S_a and S_b increases, $LD_{min}(S_a|s^n_{k(b)})$ becomes smaller, that is, the degree of similarity increases. Note that since the lengths of two melodies are different, the maximum size of the n is the length of S_a (the shorter).

2.3.2 Multi-scale Similarity Stack

After the operation for all segments is performed, it forms a multi-scale similarity stack for S_a and S_b. The multi-scale similarity stack is important for similarity analysis, and also for *cross-scape plot* visualization (see Figure 5) which will be discussed in Section 3. In this study, we obtain a multi-scale similarity stack based on segments of longer songs. [3] Thus, the maximum of the x-axis of the multi-scale similarity stack becomes the length of the longer song, while the maximum of the y-axis is the length of the shorter melody, respectively. For a given pair of melodic sequences S_a and S_b, with $|S_a| \leq |S_b|$ we can calculate $LD_{min}(S_a|s^n_{k(b)})$ for all sub-sequences with length n for all possible n in S_b against S_a. As a result, we create a two-dimensional multi-scale similarity stack (MSS) defined as below [4] :

$$MSS(S_a|S_b) = [a_{n,k}]_{|S_a|\times|S_b|},$$
$$a_{n,k} = 1 - LD_{min}(S_a|s^n_{k(b)}) \quad (4)$$

We can also summarize MSS and calculate the overall similarity as a single value. In this case, we discard a subset of elements in MSS which corresponds to similarity between segments less than three notes. To compensate low similarity values between longer sequence, we also define a weighted multi-scale similarity stack, $wMSS$, where the weight λ is a function of n. Finally, the overall similarity Sim_{S_a,S_b} of two songs is obtained by averaging $wMSS$. This overall similarity is derived in the same way for both pitch interval and inter-onset interval ratio of rhythm.

$$wMSS(S_a|S_b) = [\lambda(n) \times a_{n,k}]_{|S_a|\times|S_b|},$$
$$a_{n,k} = 1 - LD_{min}(S_a|s^n_{k(b)}), \quad (5)$$
$$\lambda(n) = 0.5 + 0.5 \times n/|S_a|$$

Finally, the overall similarity $Sim(S_a, S_b)$ of two songs is obtained by averaging the weighted multi-scale similarity stack:

$$Sim(S_a, S_b) = \text{mean}((wMSS(S_a|S_b))_{n,k})_{n\geq 3}) \quad (6)$$

This overall similarity can be computed in the same way for both pitch and rhythm features but using different weights. We implemented the algorithm using MATLAB and MIDI Toolbox [4]. The source code is available at the Github repository. [5]

3. CROSS-SCAPE PLOT

This section introduces the visualization method using the multi-scaled similarity of two melody sequences. As aforementioned, this method was inspired by [15, 16]. While previous studies using the original scape-plot method focused on analyzing a single song based on self-similarity, this study applies the idea to analyzing the similarity of two different songs.

3.1 Procedure

Figure 4 illustrates the procedure of drawing the cross-scape plot using the multi-scale similarity stack. We arrange the sub-sequences on top of each other to have the hierarchical patterns. Also, to increase readability, the multi-scale similarity stack is center-aligned. Unlike the original scape plot, the cross-scape plot has a trapezoidal shape because it is computed from two songs with different lengths. The more different the lengths of the two songs, the more likely the shape of the trapezoid. The x-axis indicates the position of the longer melody. The y-axis represents the segment size.

The cross-scape plot displays local similarity with a color. As the local similarity is higher, the color becomes darker, and vice versa. To distinguish the two features, we

[2] For readability, features are noted as letters.

[3] The opposite case, comparing segments of the song based on shorter songs, is also possible, but this is not covered in this study.

[4] Elements of the matrix only valid for $1 \leq n \leq |S_a|, 1 \leq k \leq |S_b| - n + 1$

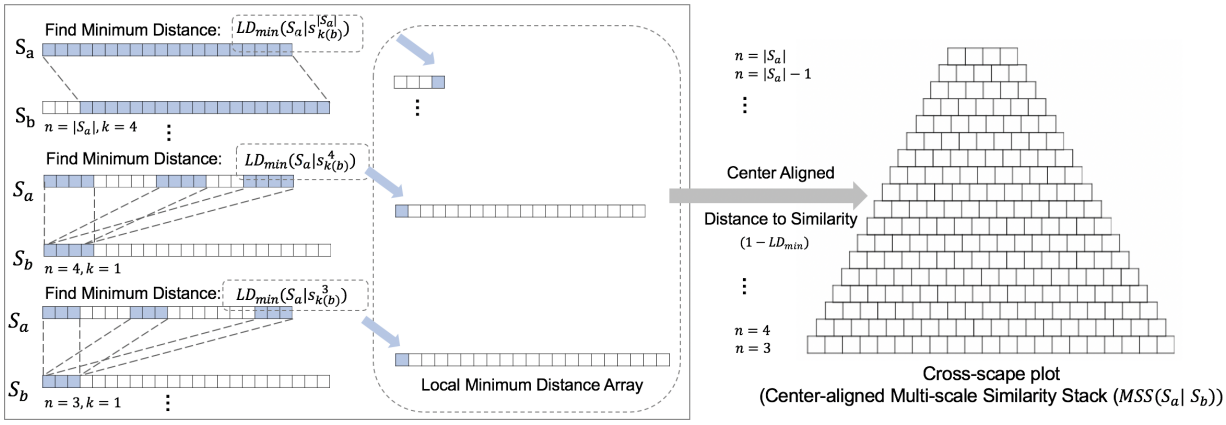

Figure 4: An illustration of steps for drawing a cross-scape plot.

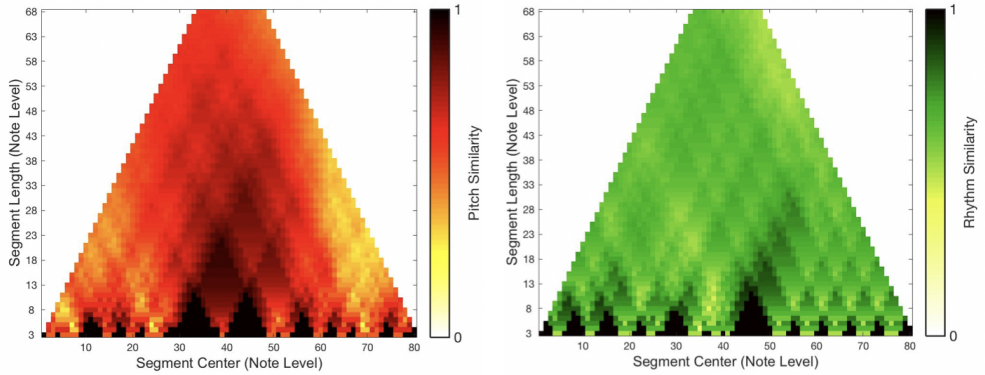

Figure 5: An example of a cross-scape plot by comparing similarities between two songs. The pixel value and the density of the color indicate the similarity score between the two sub-sequences.

set red to the cross-scape plot of the pitch feature and green to that of the rhythm feature. These different colors allows to easily recognize where and how the two songs are similar simply inspecting the plot. Figure 5 is an example of cross-scape plots where two songs are taken from the same tune family in the MTC-ANN datasets. The left part is the plot for the pitch feature and the right is for the rhythm feature. Through the cross-scape plot on the left, we can see that these two pieces are very similar in the middle parts. in the middle parts of the pitch feature, and the uppermost color suggests that the overall similarity is between 0.6 and 0.7. On the right plot, the rhythm feature shows a similarity with a certain periodicity in the latter part. Also, the slightly right part of the center represents a high similarity (black or 1) in the same way as the pitch feature, so we can assume that the melody of a particular part is nearly identical. Overall, a type of tendency is found where a large segment has a larger distance and a smaller segment has a smaller local distance. This is because the smaller the segment size is less distinct, the higher the probability that the segment is present in both songs.

3.2 Case Study: Toy Example

Figure 6 is a toy example of the cross-scape plot showing the similarity between the melodies generated such that they have the same edit distance between pitch interval sequences. One pair has exactly matching at a specific part of the melody (Song 1 and 2, left part of Figure 6). In the other pair, the specific parts are not exactly the same, but they are slightly similar overall (Song 1 and 3, right part of Figure 6). In this example, the edit distance alone yields the same distance between the melodies (in both cases $D = 12$ for pitch interval sequences). However, we can see that the first half of the song is exactly the same for both pitch and rhythm in the case of songs 1 and 2. On the other hand, the pitch features of Songs 1 and 3 are generally similar at random, but the rhythm is apparently similar to the latter half of the song. In this way, we can see various perspectives on the similarity of melody features even though they have the same similarity value.

3.3 Case Study: Plagiarism Cases

The benefits of cross-scape plots become more important for issues that require a certain level of qualitative judgment, such as originality or substantial similarity of plagiarism. Figure 7 shows cross-scape plots of the cases in our ongoing plagiarism research project. These two examples are cross-scape plots of songs with court rulings on copyright infringement. In both cases (*Mood Music v. De Wolfe* [6] : left side of figure and *MCA Music v. Earl Wilson* [7] : right side of figure), copyright infringement is ruled by the court or settled between the parties, where plagia-

[6] *Mood Music v. De Wolfe*, 1. Ch. 119 (1976).
[7] *MCA Music v. Earl Wilson* 425 F. Supp. 443 (S.D.N.Y. 1976)

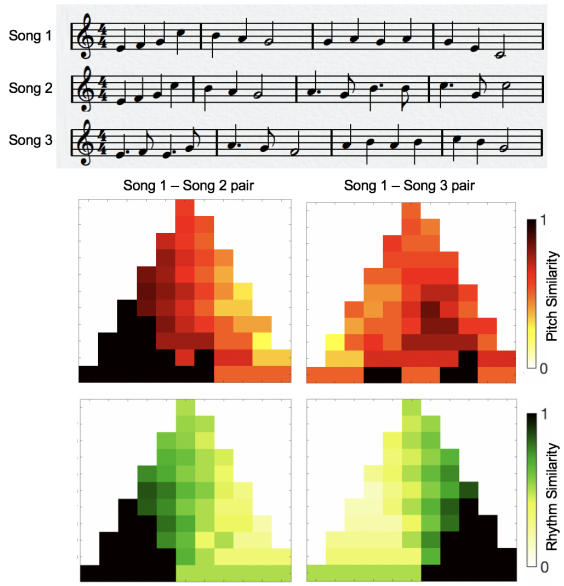

Figure 6: Toy example of an exact match pair and an overall similar pair of cross-scape plots

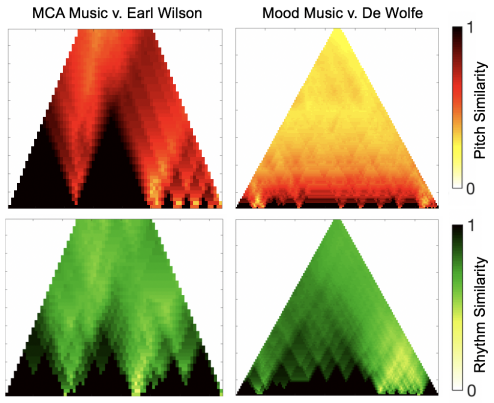

Figure 7: Cross-scape plots of plagiarism cases (*Mood Music v. De Wolfe*: top of the figure and *MCA Music v. Earl Wilson*: bottom of the figure).

rism is acknowledged. We show these cases because these are either the most confusing (case 1 where 93.5% of the participants were confused) or less confused (case 2 with 0% confusion rate) cases in a trial experiment in which the implicit memory task is performed (High confusion means two songs are very similar to each other). [8]

Although both are cases of copyright infringement, the ways in which similarities appear are very different. In *Music v. De Wolfe*, most parts of the song are almost identical on all sides of the pitch and rhythm features. On the other hand, in *MCA Music v. Earl Wilson*, the rhythm features are generally similar, but the pitch features are different. Thereby, for the case *MCA Music v. Earl Wilson*, it can be assumed that the plagiarism judgment is based on other factors such as rhythm, harmony, arrangement or lyrics rather than the tonal characteristics of the melody. [9]

[8] This experiment is an ongoing project; a similar experiment and result can be found in [28]

[9] Indeed, in spite of the defendant's arguments contending fair use of parody, infringement was considered based on identical bass line, a general harmonic similarity and certain specialized rhythmic patterns (https://blogs.law.gwu.edu/mcir/case/mca-music-v-earl-wilson/).

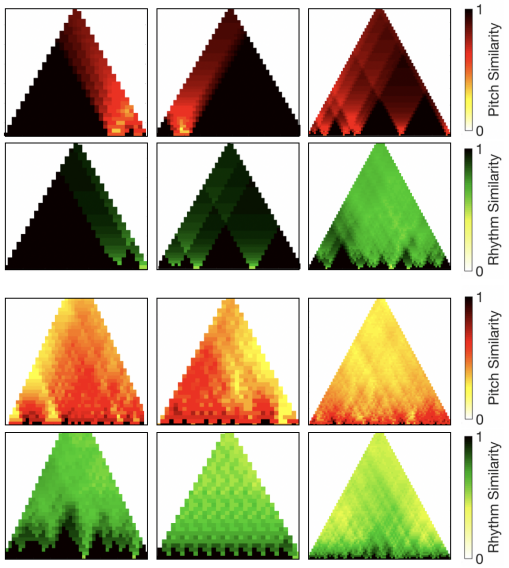

Figure 8: Cross-scape plots on examples of MTC-ANN. The three pairs on the top belong to the same tune family whereas the three on the bottom belong to different tune families.

In this way, gaining rich information about similarities can be of great help in making this kind of intuitive and sophisticated decision regarding of similarity.

3.4 Case Study: MTC-ANN

Figure 8 shows more examples of cross-scape plots showing how different pairs of MTC-ANN represent similarities of different characteristics. The three pairs on the top are similarities between songs in the same tune family, the three on the bottom are for those included in other tune families. The similarity of the two songs decreases from left to right. Looking at these pairs, we can observe that similarities in pitch, rhythm, position, and lengths of similar parts appear in a variety of ways, even in pairs in the same group.

4. MELODY CLASSIFICATION

We can utilize the outcome of cross-scape plots for the symbolic melodic similarity task. In this section, we conduct the task with a classification experiment using summarized similarity derived from the multi-scale similarity stack.

4.1 The dataset

We used the annotated corpus of the Meertens Tune Collection (MTC-ANN), version 2.0.1 [21] for the evaluation. It contains 360 melodies divided into 26 tune families annotated by musicological experts. The MTC-ANN dataset has been used in a variety of music studies. This allowed us to compare our model with recent studies of measuring melodic similarity.

	CSR	AUC	MAP
Pitch Interval	0.95	0.89	0.68
Inter-onset Interval Ratio	0.76	0.82	0.49
Combined	0.96	0.91	0.71

Table 1: Results for the proposed model

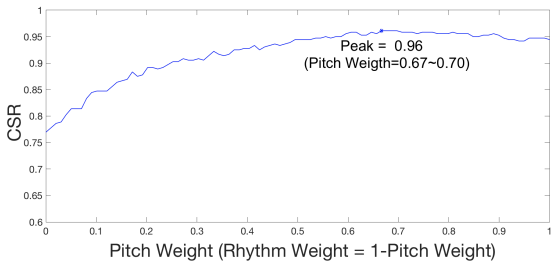

Figure 9: Accuracy that varies with the weighting value of the pitch feature and the rhythm feature.

4.2 Similarity Measures

We performed the classification of MTC-ANN songs into the same tune family with each of pitch and rhythm features or their combinations. We compared the performance to those from previous work that conducted the same task over the last three years [1, 2, 26].

4.3 Evaluation Metrics

We used the three evaluation metrics following the previous works.

Classification Success Rate (CSR) represents a correctly classified rate of the total when the melody is indexed into the same tune family using k-Nearest Neighbors (k-NN) classifier to which the melody with the highest similarity belongs. This evaluation method was used in all reference papers to be compared.

Area Under the Curve (AUC) is calculated by adaptively modifying the decision threshold of the similarity score. In this case, the songs within the same tune family is assigned to a ground truth. The ranking scores are then calculated and averaged.

Mean Average Precision (MAP): has the same ground truth as the one used in the AUC calculation. The songs are sorted by the similarity score and the songs that have the same tune family with the query song are treated as a correct one. We repeat this procedure by adjusting the number of correct answers and averaged the whole scores.

4.4 Evaluation Results

Table 1 shows the results of the proposed model to classify 360 songs of MTC-ANN into 26 family tunes, using pitch features, rhythm features and both of them. In addition, Figure 9 shows the plot of CSR when the relative weight in computing the overall similarity (λ in Equation 6) between two features changes from 0 to 1. the highest score is obtained when the weight (pitch weight) ranges between 0.67 and 0.7.

	CSR	AUC	MAP
Boot [1]	0.92	-	-
Bountouridis [2]	0.94	-	0.70
Walshaw [26]	0.93	0.89	-
Proposed	0.96	0.91	0.71

Table 2: Comparison with previous studies using the MTC-ANN dataset

As a result of the classification evaluation, the melody of a family group is sufficiently classified by a single pitch feature, whereas a rhythm feature has a limitation in performing a classification task alone. In addition, classification with pitch and rhythmic features combined with appropriate weights has achieved the highest performance, which indicates that pitch and rhythm together complement the similarity of the melody, although the pitch feature contributes to it more.

4.5 Comparison with Recent Studies

Table 2 provides a comparison with recent studies that performed classification of MTC-ANN using the entire melody. The results show that our approach not only provides the visualization but also comparable performance to them.

5. DISCUSSION AND CONCLUSION

We proposed a cross-scape plot which visualizes symbolic melodic similarity between two songs based on multi-segmentation analysis. With the examples of folk songs and plagiarism cases, we showed that the cross-scape plot can reveal the melodic similarity in various ways. We also performed a classification task of the MTC-ANN dataset based on the summarized similarity derived from the method.
