Figure 2 *Contact paths of traditional reciprocating pin on plate (pattern 1) and single pass COF mapping track (pattern 2).*

A contact track in a single pass grid pattern was traced at a speed of 20mm per second. Figure 2 illustrates the difference between a standard reciprocating program and the program used. This new technique allows for an individual-pass reading to be taken; observing the tribo-properties of the layer at various stages of being broken down by mechanical action. Cartesian co-ordinates are also logged with the load cell data to allow for a COF map of the sample surface to be generated. Photos of the samples were taken, onto which the COF maps may be overlaid for comparison.

At the start of the first, second and fourth runs for each sample, the surfaces of the substrate were sprayed with distilled water, delivering 0.1ml of water onto the surface. During these runs the surface of the samples dried out giving a continuous variation of moisture content throughout each run; however, it was not

possible to determine the exact water content on the surface at any point throughout the run. Third runs were conducted dry; without the spraying of distilled water.

4. Results and discussion

The results have been divided into two parts: the synthesised oxides and the deposited oxides.

4.1. Synthesised oxides

4.1.1. Surface analysis

The surfaces of the treated samples varied by degree of oxidation amongst the prescribed treatments. Out of all treatments, simulated condensation (treatment B) caused the least visible oxidation on the surface leaving small (~10μm across) regularly spaced patches of oxide, after which the second lowest was the sprayed droplets (treatment C), causing an even spread of larger patches of oxide, approximately 0.1mm across, as can be seen in Figure 3. The mixed treatment (D and E) resulted in large patches of oxide up to 1cm across. Finally, the flooded sample displayed a more even and continuous coverage of the sample surface. The colour of the oxides observed on all samples, an orangish brown hue, appears similar suggesting similar composition between samples.

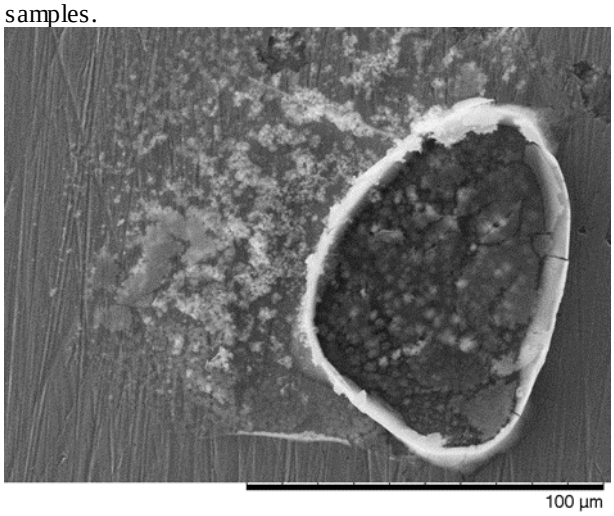

Figure 3 *SEM micrograph of sample surface treated by one humid cycle.*

The SEM micrographs of the oxides formed on the surface of the discs show a variety of morphologies as shown in figure 3; all samples apart from the control exhibited these morphologies. This, along with the XRD spectra given in Figure 5 b) and c) show that the same compounds of haematite, magnetite and lepidocrocite are present with all the synthesised oxide surfaces. Some samples appear to show a slight presence of goethite which may be the crystals like those in Figure 4 (left image) which appear to have the morphology of goethite and are much less abundant than other morphologies found on the surface of the samples. The SEM as well as the XRD findings suggest that lepidocrocite is an abundant compound formed by the treatments applied.

The XRD spectra of the control sample given in Figure 5a revealed only magnetite and haematite were present.

It should be noted that all treatments involved the introduction of no other compound than distilled water and as a result, no akageneite, wüstite or maghemite was detected on the surface. This supports that the oxide composition on the surface of the railhead is more heavily influenced by the chemical environment prior to its formation than the physical conditions. This can be seen clearly in studies where salt solutions are used to accelerate the growth of oxides on rail and wheel steel samples where the iron oxide-hydroxide phase of akageneite has been observed [15]. However, the degree of oxidation is shown to be largely affected by the environmental conditions.

4.1.2. Frictional data

As can be seen from Figure 6, the pin-on-plate testing of the synthesised oxides displayed the general relationship of the higher the degree of oxidation of the surface, the higher the mean COF. Values ranged from a control value of 0.23 to around 0.4 for substrates treated with a mix of drizzle and exposure to dew conditions. An exception to this relationship is the flooded sample which displayed a COF of around 0.35 yet displayed the highest degree of oxidation.

Both drizzle and dew oxide formation lead to an increase in the COF of around 0.1.

The reason for this increase in COF with increased oxidation is likely due to the increased surface roughness caused by oxide pitting. A limitation of the pin-on-plate test method is that the contact area is very localised to a spherical contact area with approximately 0.12mm diameter which is of a similar or smaller order of magnitude in size to that of the pitted areas for all the treatment conditions with exception to dew exposure only with physically smaller oxide pits than the contact.

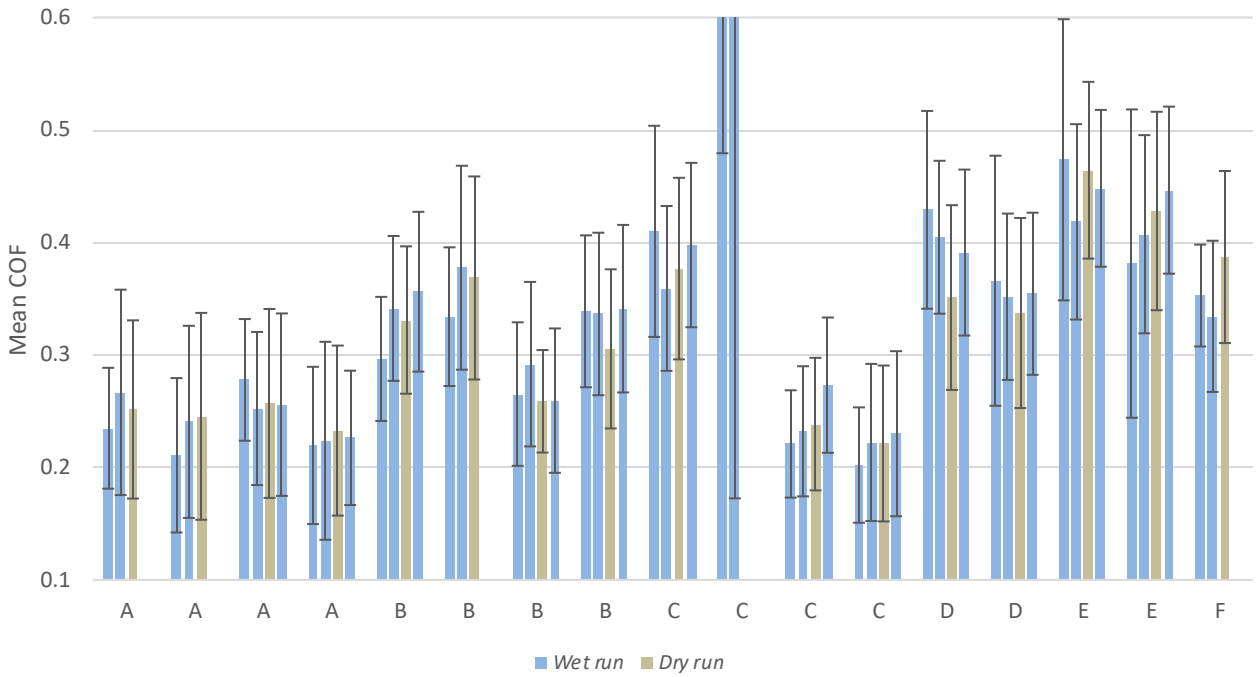

Figure 6 *Mean COF of synthesised oxides by synthesis program with standard deviation. A, Control; B, Simulated Dew; C, Simulated Drizzle; D, Mixed Dew and Drizzle; E, Mixed (conditions simulated from data); F, Flooded.*

The COF maps and histograms provide an important insight into the tests as can be seen in Figure 7. The variation of COF values is shown visually over the surface of the samples revealing that the areas pitted with corrosion display high friction values.

No average lower COF was achieved below than that of the control value; however, areas on the oxides synthesised with a mixed drizzle and dew treatment (e) display localised COF values comparable or even lower than the control values. Since railheads are unlikely to be as clean as the prepared control substrates, a result close to or lower than the COF for the control may indicate an area of low adhesion.

COF maps of the subsequent runs to those where the low friction is displayed outside the oxide patch areas show these areas shrinking and recovering to higher friction levels in successive repeat runs. This gives evidence to support that surface conditions which cause low traction events because of oxidation are extremely transient.

4.1. Oxide deposition

4.1.1. Layer analysis

The oxide layers deposited by distilled water showed discolouration and chemical changes to the substrate beneath the layer as well as oxide pitting. This suggests that the substrate under the layer had corroded during drying.

After testing the substrates were examined visually. Oxide pitting was present on the substrate surface below the layers to differing degrees between each of the samples, the greatest oxide pitting being lepidocrocite, suggesting that different degrees of corrosion resistance and / or acceleration was offered between the layers.

SEM micrographs of the surfaces seen in Figure 8 of the oxides deposited by a distilled water suspension show haematite and goethite (b, c) having a consistent surface. The magnetite particles (a) appeared to form into clusters, likely due to their magnetic properties. Lepidocrocite (d) seemingly formed two layers consisting of a lower layer of 10-20µm spaced agglomerates and a smooth top surface. XRD depth profiling analysis of this layer did not show any significant change in composition throughout the layer suggesting both layers observed are composed of lepidocrocite.

Depositing the oxide with suspensions in isopropanol gave far shorter drying times and no visible corrosion or pitting of the substrate surfaces. The layer thicknesses and coverage are given in Table 3. All oxides deposited evenly over the substrate surface with the exception to goethite which agglomerated into patches 20 - 100µm across. The deposition of magnetite was the thinnest layer at approximately only 1µm.

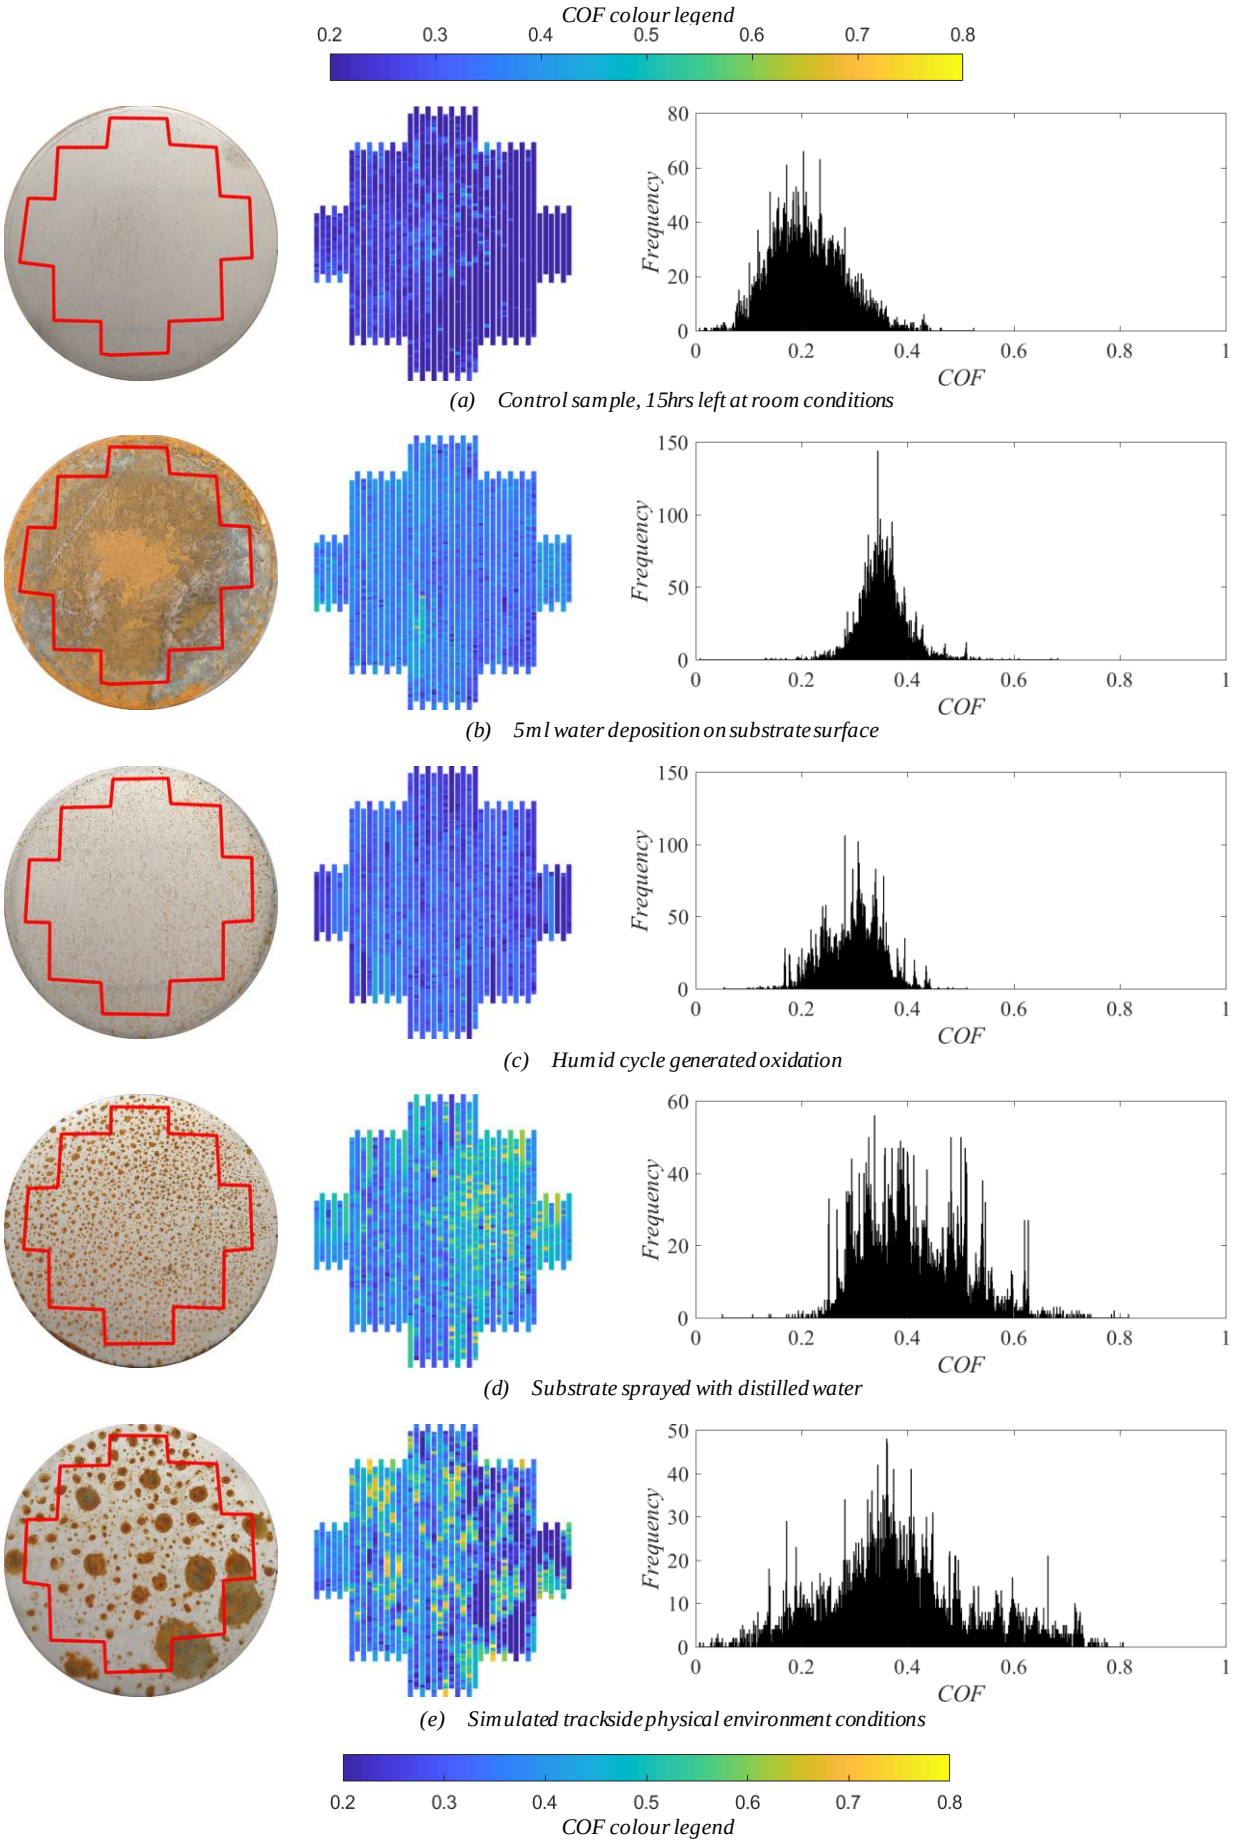

Figure 7 *COF maps and COF histogram frequency plots of synthesised oxides visualised alongside their respective samples. Tribological data is given for the first runs and under wet conditions.*

Table 3 *Thicknesses and mass density of isopropanol deposited oxide layers. Goethite base layer thickness (A), average layer thickness (B), and average height of agglomerates.*

Layer material	Magnetite		Haematite		Goethite		Lepidocrocite	
Density, $g.cm^{-2}$	0.87	0.79	1.31	1.53	1.34	1.44	1.01	0.92
Thickness, µm	0.9	0.8	5.6	5.8	A) 1.3, B) 3.8 C) 17.0	A) 1.0, B) 4.2 C) 17.0	3.5	3.6

4.1.2. Frictional data

During the runs, two behaviours were observed: ploughing of oxide leaving the surface exposed and the wet ploughing of the material whereby the water carried material back into the grooves calved out of the contact track. This suggests that the contact geometry is such that the material is pushed out of the way of the contact instead of being caught within the contact; as such a different mechanism is observed to what is seen in the wheel/rail contact.

Figure 9 reveals that the oxide layers deposited with distilled water show higher COF than those deposited in suspensions of isopropanol; COF maps of these runs show that high friction patterns associated with oxide pitting are present indicating that this increase is due to the higher surface roughness and not because of the difference between the layers.

The isopropanol deposited layers showed more consistent COF values between oxide types. On Figure 9 the layers of magnetite have the lowest COF values. The cause for this appears to be the lower thickness of this layer compared to the other layers meaning that material can be more easily pushed aside.

There are no immediately obvious differences between the effect of different deposited oxides on the COF; however, the presence of oxide on the substrate increased the COF above that of the clean control of 0.23, determined in the synthesised oxide tests. During the runs it was noticed that the trail left behind the ball head was very clean implying that the entrainment of

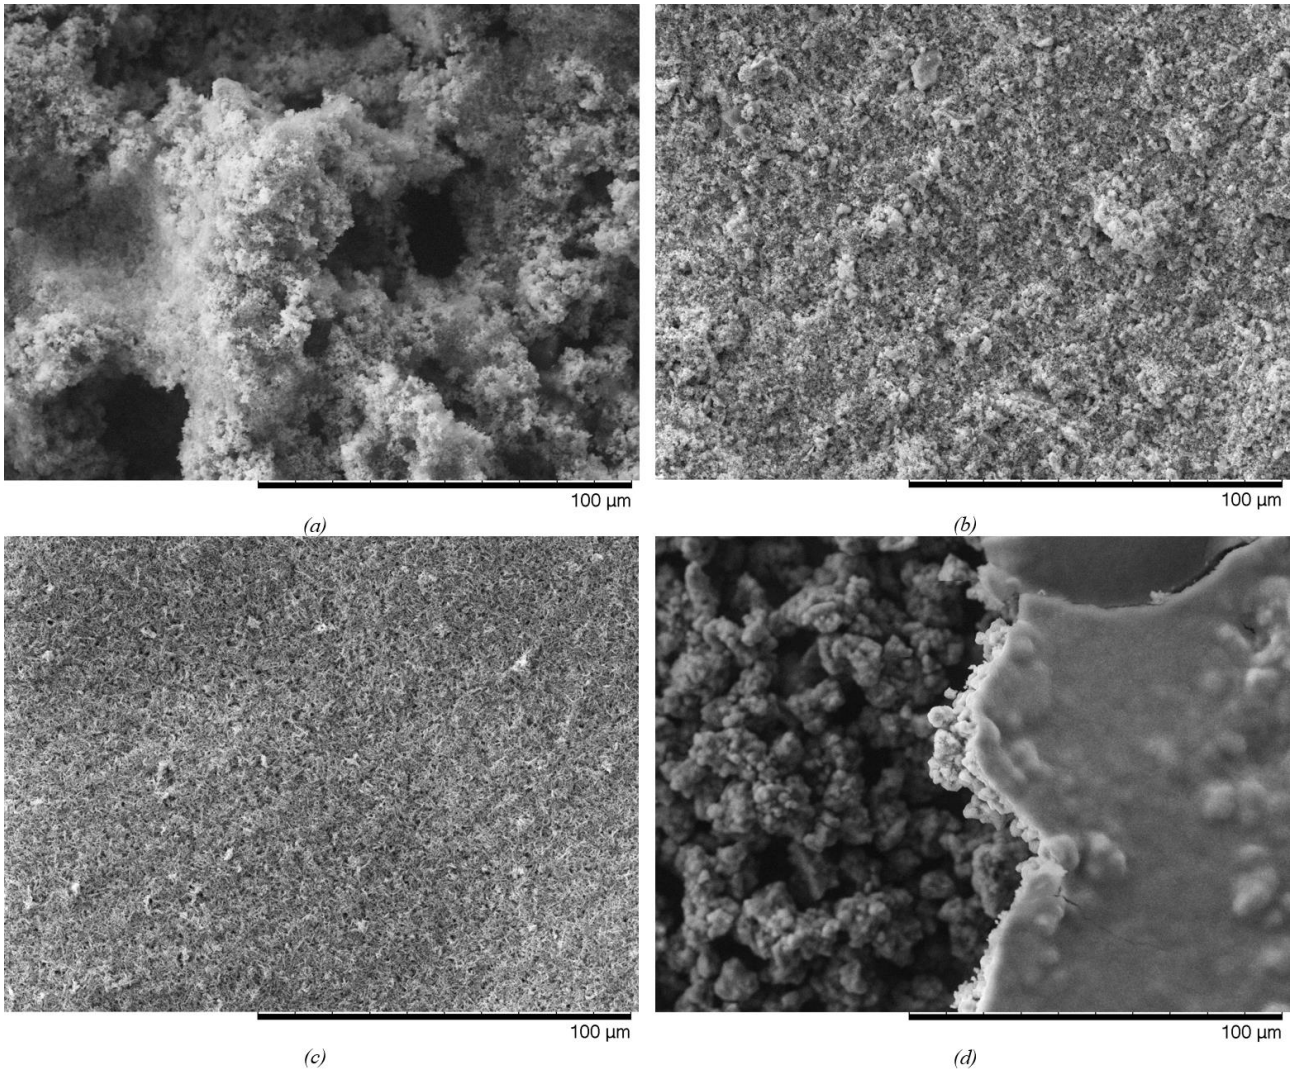

Figure 8 *Distilled water deposited oxide layer SEM micrographs, a) magnetite; b) haematite; c) goethite; d) Lepidocrocite.*

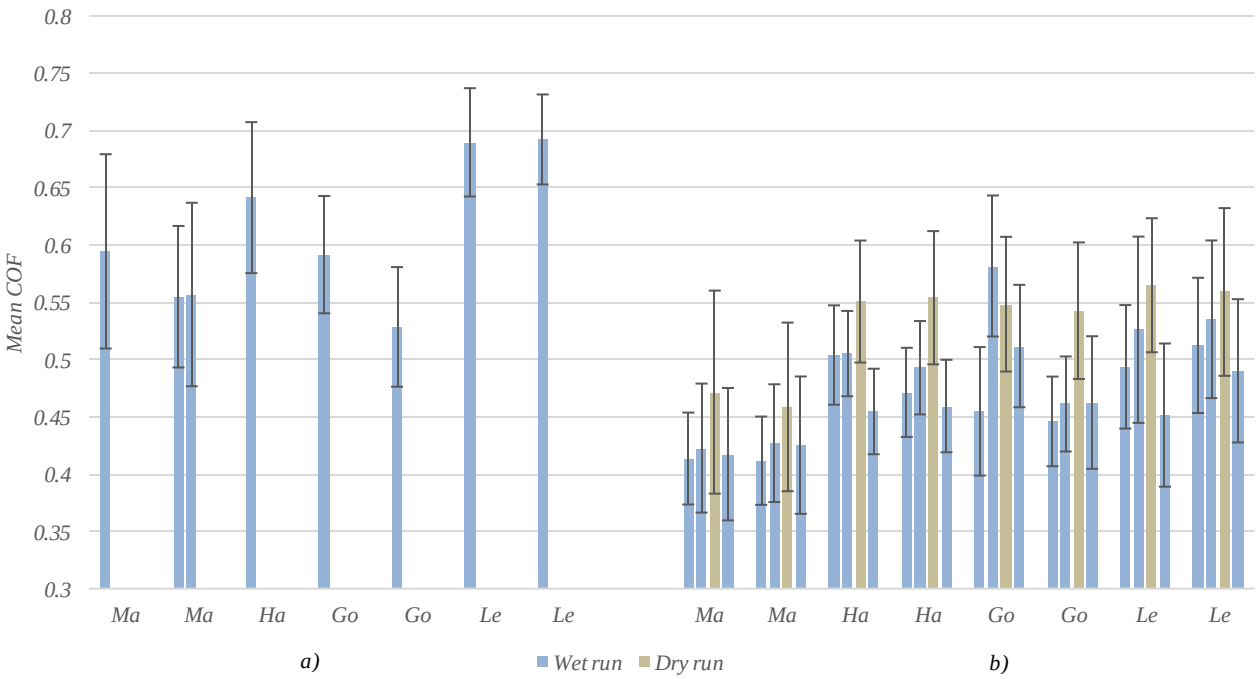

Figure 9 *Comparison between COF of oxide layers. a), oxides deposited on substrate by distilled water; b), oxides deposited on substrate in isopropanol suspension. Ma, magnetite; Ha, haematite; Go, goethite; Le, lepidocrocite.*

oxide in the contact was minimal; therefore, the effects of any mechanisms involving the oxide in the contact itself are likely to be minor and, as a result, the increased COF values of the samples with deposited oxide layers are likely due to the additional mechanical work of ploughing through the deposited layer.

Due to this undesirable behaviour, the use of this experimental technique to investigate the effect of oxides on the performance of the wheel/rail contact may not be suitable. A larger contact or a rolling-sliding contact would likely be better test methods as more material may be able to be entrained in the contact; however, no current laboratory test of the wheel rail contact encapsulates both a rolling-sliding contact and a single surface pass. It should be noted that this limitation is less of a concern with oxides grown on the surface of the substrates as, unlike a deposited powder, they are bonded more tightly with the surface.

Dry tests typically had a higher average COF of 0.05 higher than tests conducted under wet conditions.

5. Conclusions

- The COF surface mapping method presented provides a useful insight into heterogeneous surfaces as well as enabling single-pass COF data to be captured.
- In the absence of chemicals other than water, Magnetite, Haematite and – especially in wet environments - Lepidocrocite are the only significant oxides formed on the railhead; other oxides likely a result of other compounds being present on the railhead / trackside environment.
- Pitting caused by the process of oxidation increases COF; however, oxidation of surfaces may lower COF below that of a clean surface outside the heavily pitted areas.
- Low friction was observed with oxidised surfaces outside the oxide-pitted areas, but these surface conditions were shown to be very transient with friction in these layers recovering rapidly through successive mechanical action.
- Rolling-sliding test methods or a larger contact used in the tests are likely more suitable for exploring artificially deposited oxide layers than the method presented in this paper due to ploughing of the sample head through the deposited oxide layer.

Abstract: The precise calculation of wheel-rail contact points has significant influence on wheel-rail wear and rolling contact fatigue, especially when the multi-point contact occurs. This paper proposed a fast and accurate method for calculating the wheel-rail multi-point contact geometry in the straight line and curve. In addition, the calculation of the coordinates of contact points with the elastic deformation of wheelset are also investigated. On the basis of theoretical analysis, a numerical procedure computing the contact positions and wheel-rail contact normal forces was preceded. The calculating result proved the algorithm to be fast and reliable.

Keywords: Wheel-rail contact; Divided wheel profile; Multi-point contact; Calculation method; Fast algorithm.

1. Introduction

For the wheel-rail contact interface, multi-point contact may occur when the wheelset displacement overgrowth or when the tread of wheelset is worn. To deal with the problem of multi-point contact on the wheel/rail contact interface, Piotrowski carried out the multi-point contact simulation for vehicle system dynamics by using the virtual penetration theory [1,2]. Matin proposed an approximate analytical method for calculating the contact patch and pressure distribution at wheel–rail interfaces[3]. Sugiyama developed a systematic procedure for predicting the flange, as well as the back-of-flange contact points and used it for the two-point contact geometry analysis of a wheel and rail[4]. Yan and Wang developed a curve fitting method to calculate the geometry parameters of the wheel/rail system in the presence of wheelset attack angle[5]. Wang ulteriorly adopted the spatial analytical geometry method to calculate the trace curve of the wheel/rail contact in the presence of attack angle[6]. Sun and Jin investigated the wheel/rail contact geometry relationship with wheelset attack angle and obtained very simple forms of accurate calculation equations, that can easily be used to intuitively judge whether there may be two-point wheel/rail contact at a certain attack angle[7,8]. Ren used the first- and second-order derivatives to detect the extreme value points as a function of the distance between the wheel and the rail and derived a calculation and determination method for the wheel/rail multi-point contact and the wheel/turnout multi-point contact [9,10]. Gu and Yang proposed a method with improved accuracy in three dimensions to determine the contact points and the contact patches between the wheel and the rail, considering the effect of the yaw angle and the roll angle on the motion of the wheel set[11,12].

This paper proposed a fast and accurate method for calculating the wheel-rail multi-point contact geometry. The method is capable of calculating single-point and multi-point contact problems in the straight line and curve while the actual geometry of both the wheel and rail were considered. Additionally, the method also investigated the wheel-rail contact geometry when the elastic deformation of wheelset is considered.

2. The calculation of contact points

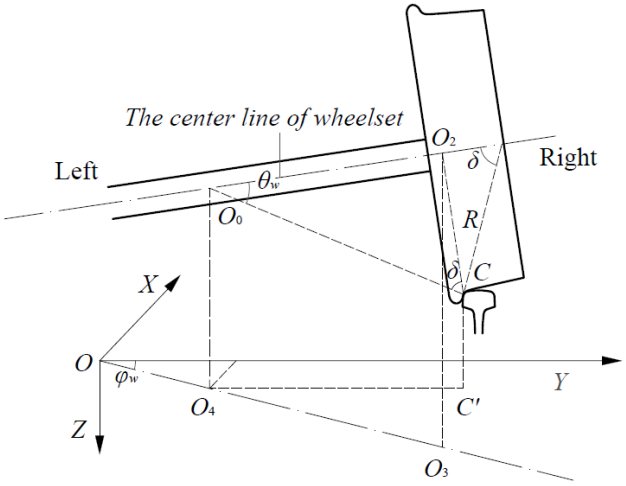

Fig. 1 *Schematic diagrams of the wheel-rail contact geometry.*

When the yaw angle and roll angle of wheelset are fixed, the wheel-rail contact point can be only on a space curve. This curve is called the trace line. The vehicle global coordinate system O-XYZ is built, whose origin is fixed on the center of mass of the static wheelset. For the interaction of wheel and rail, the wheelset has 4 DOF (degrees of freedom), namely transversal and vertical displacements, rolling and yawing, and the left and right rails have 3 DOF (degrees of freedom) separately, namely transversal displacements, rolling and yawing.

2.1. The contact points in the straight line

In the straight line, when the wheelset has the yaw angle of φ_w , roll angle of θ_w and the displacements of x_w, y_w and z_w in three directions, coordinate system O_w-$X_wY_wZ_w$ is

fixed to the wheelset that follows the translation and rotation of the wheelset, the wheelset. In this case, the actual rolling radius is R, and the distance between the center of actual rolling circle O_2 and center of wheelset O_1 is d_w. γ is the angle between the wheel section through the Y_wZ_w plane and the wheel section through both the center of wheel and the contact point.

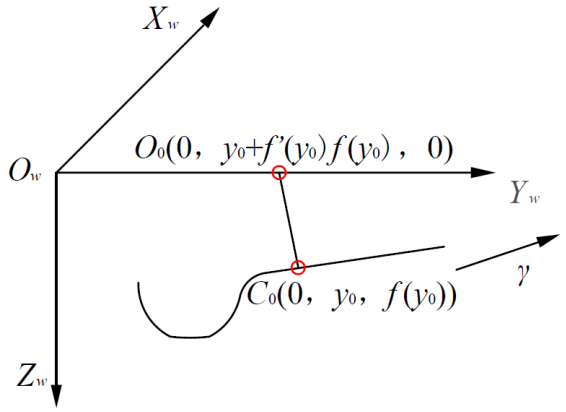

Fig. 2 *The profile and normal line of wheel.*

The profile line is defined as the intersection of the vertical plane over the center line O_wY_w of wheelset and wheel tread and flange. The profile line can be described by the function $z=f(y)$ in the coordinate system O_w-$X_wY_wZ_w$. The normal line of the profile line about the point $C_0(0, y_0, f(y_0))$ intersects line at the point O_0, whose coordinate is $(0, y_0+ f'(y_0) f(y_0), 0)$. The coordinates of potential contact point C can calculated according to the C_0 and angle γ and can be expressed as $(f(y_0)\sin\gamma, y_0, f(y_0)\cos\gamma)$.

The basic vectors of coordinate system O-XYZ and O_w-$X_wY_wZ_w$ can be exchanged by formula as follow:

$$\begin{Bmatrix} i \\ j \\ k \end{Bmatrix} = \begin{bmatrix} -\cos\varphi_w & -\cos\theta_w \sin\theta_w & \sin\theta_w \sin\varphi_w \\ \sin\varphi_w & \cos\theta_w \cos\varphi_w & -\sin\theta_w \cos\varphi_w \\ 0 & \sin\theta_w & \cos\theta_w \end{bmatrix} \tag{1}$$

The coordinates of C in the coordinate system O-XYZ can be written as :

$$\begin{cases} x = \cos\varphi_w \sin\gamma\, f(y_0) - \cos\theta_w \sin\varphi_w y_0 + \\ \sin\theta_w \sin\varphi_w \cos\gamma\, f(y_0) + x_w \\ y = \sin\varphi_w \sin\gamma\, f(y_0) + \cos\theta_w \cos\varphi_w y_0 - \\ \sin\theta_w \sin\varphi_w \cos\gamma\, f(y_0) + y_w \\ z = \cos\theta_w \cos\gamma\, f(y_0) + \sin\theta_w y_0 + z_w \end{cases} \tag{2}$$

In the coordinate system O_w-$X_wY_wZ_w$, the normal vector of profile line $\mathbf{CO_0}$ can be expressed as $\mathbf{CO_0}=\{-f(y_0)\cdot(\sin\gamma, -f'(y_0), \cos\gamma)\}$, it can be translated into the coordinates in the O-XYZ according to the translation formula (1).

$$\begin{aligned} \mathbf{CO_0} = &[-f(y_0)]\cdot[(\cos\varphi_w \sin\gamma + \cos\theta_w \sin\varphi_w f'(y_0) \\ &+ \sin\theta_w \sin\varphi_w \cos\gamma), (\sin\varphi_w \sin\gamma - \cos\theta_w \cos\varphi_w f'(y_0) \\ &- \sin\theta_w \sin\varphi_w \cos\gamma), (-\sin\theta_w f'(y_0) + \cos\theta_w \cos\gamma)] \end{aligned} \tag{3}$$

In the straight line, the profile of track and wheel have the same normal vector at the contact point. So the normal vector $\mathbf{CO_0}$ is parallel to the YOZ plane, as figure 1 shows.

$$\begin{aligned} &\mathbf{CO_0}\cdot\mathbf{i_x} = 0; \mathbf{i_x} = [1,0,0] \\ &[-f(y_0)]\cdot[(\cos\varphi_w \sin\gamma + \cos\theta_w \sin\varphi_w f'(y_0) + \\ &\sin\theta_w \sin\varphi_w \cos\gamma)] = 0 \end{aligned} \tag{4}$$

$f(y_0)$ is always positive for points in the profile line, so it can be deduced:

$$\cos\varphi_w \sin\gamma + \cos\theta_w \sin\varphi_w f'(y_0) + \sin\theta_w \sin\varphi_w \cos\gamma = 0 \tag{5}$$

So the angle γ can be written as:

$$\gamma = -\left[\arcsin\left(\frac{\cos\theta_w \tan\varphi_w \tan\delta}{\sqrt{1+\sin^2\theta_w \tan^2\varphi_w}}\right) - \arctan(\sin\theta_w \tan\varphi_w)\right] \tag{6}$$

For the contact point, $f(y_0)$=R, $y_0=d_w$, $f'(y_0)=\tan\delta$. So the coordinates of contact point C in the global coordinate system O-XYZ can be written as:

$$\begin{cases} x = R\cos\varphi_w \sin\gamma - \cos\theta_w \sin\varphi_w d_w + \\ R\sin\theta_w \sin\varphi_w \cos\gamma + x_w \\ y = R\sin\varphi_w \sin\gamma + \cos\theta_w \cos\varphi_w d_w - \\ R\sin\theta_w \sin\varphi_w \cos\gamma + y_w \\ z = R\cos\theta_w \cos\gamma + \sin\theta_w d_w + z_w \\ \gamma = -\left[\arcsin\left(\dfrac{\cos\theta_w \tan\varphi_w \tan\delta}{\sqrt{1+\sin^2\theta_w \tan^2\varphi_w}}\right)\right. \\ \left. -\arctan(\sin\theta_w \tan\varphi_w)\right] \\ \sin\varphi_r = \dfrac{b_r}{R_C}\sin\varphi_w \end{cases} \tag{7}$$

d_w is a positive value for the right wheel and a negative value for the left wheel. The value of δ is positive when the differential component of the points in the tangent line of the wheel profile $\Delta z/\Delta y$ is positive.

To investigate the value of the angle δ, the conditions of wheels profiles are distinguished. ① when the profiles of left and right wheels are same, for the right wheel, it is negative at the point with the normal vector toward the track inside and is positive conversely; for the left wheel, it is positive at the point with the normal vector toward the track inside and is negative conversely. ② when the profiles of left and right wheels are different, the value of δ is positive when the differential component of the points in the tangent line of the wheel profile $\Delta z/\Delta y$ is positive. For some worn wheel, the normal vector may be toward the track outside at some points in the profile line. But the differential component of the points in the tangent line of the wheel profile $\Delta z/\Delta y$ can determined the value of the angle δ accurately.

2.2. The contact points in curve

In the curve, where the radius is R_C, the angle between center line of wheelset C_LC_R and the radial line of track O_CC is φ_w. b_r implies the half of the distance between the two actual rolling circles. And the central angel of BC_R is φ_r.

$$\sin\varphi_r = \varphi_r = \frac{BC_R}{O_CC - b_r} \approx \frac{b_r\varphi_w}{R_C} = \frac{b_r}{R_C}\sin\varphi_w \tag{8}$$

The common normal line of the profile line of wheel and

track at the contact point must on the vertical plane through the radial line O_CO_R in the figure 3. In the figure 3, plane A is the vertical plane through the curve center and the wheelset center. The plane B is the plane through the center line and radial line of the contact point. The line C_Rn implies the normal line of the common normal line of the contact point. The angle between the X axis of O-XYZ and the vertical plane is ($\pi/2$-φ_r). The angle between the projection line of X axis in the vertical plane and the normal line C_Rn is ($\pi/2+\delta$). The angel between the X axis and normal line C_Rn is α.

$$\cos\alpha=\cos(\frac{\pi}{2}-\varphi_r)\cos(\frac{\pi}{2}+\delta)=-\sin\varphi_r\sin\delta \tag{9}$$

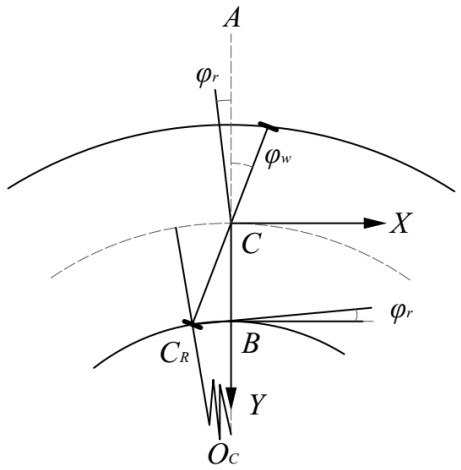

Fig. 3 *Schematic diagrams of the wheel-rail contact geometry in curve.*

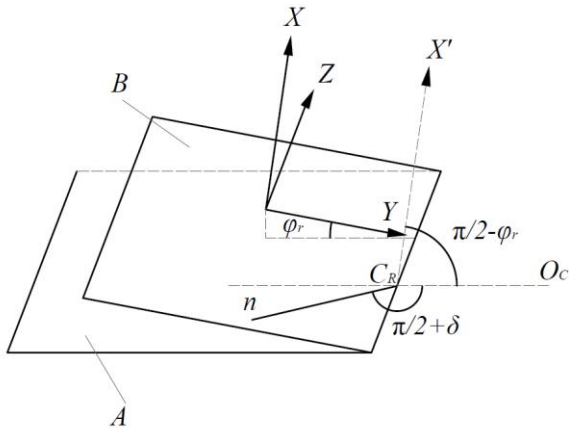

Fig. 4 *Schematic diagrams of X axis and the common normal line of the contact point.*

According to the formula (3) and $f'(y_0)=\tan\delta$,formula (8) can also written as:

$$\cos\alpha=[(-f(y_0))\bullet(\cos\varphi_w\sin\gamma+\cos\theta_w\sin\varphi_w\tan\delta+\sin\theta_w\sin\varphi_w\cos\gamma)\bullet 1]/[f(y_0)\sqrt{\Delta1+\Delta2}\times\sqrt{1}] \tag{10}$$

$$\begin{aligned}\Delta1=&\cos^2\varphi_w\sin^2\gamma+\cos^2\theta_w\sin^2\varphi_w\tan^2\delta\\&+\sin^2\theta_w\sin^2\varphi_w\cos^2\gamma+\sin^2\varphi_w\sin^2\gamma+\\&\cos^2\theta_w\cos^2\varphi_w\tan^2\delta+\sin^2\theta_w\cos^2\varphi_w\cos^2\gamma\\&+\cos^2\theta_w\cos^2\gamma+\sin^2\theta_w\tan^2\delta\\=&\sin^2\gamma(\cos^2\varphi_w+\sin^2\varphi_w)+\cos^2\gamma(\sin^2\theta_w\sin^2\varphi_w\\&+\sin^2\theta_w\cos^2\varphi_w+\cos^2\theta_w)+\tan^2\delta(\cos^2\theta_w\sin^2\varphi_w\\&+\cos^2\theta_w\cos^2\varphi_w+\sin^2\theta_w)\\=&\sin^2\gamma+\cos^2\gamma+\tan^2\delta\\=&1++\tan^2\delta\\=&\sec^2\delta\end{aligned} \tag{11}$$

$$\begin{aligned}\Delta2=&2\sin\varphi_w\cos\varphi_w\cos\theta_w\sin\gamma\tan\delta+\\&2\sin^2\varphi_w\sin\theta_w\cos\theta_w\cos\gamma\tan\delta+\\&2\sin\varphi_w\cos\varphi_w\sin\theta_w\sin\gamma\cos\gamma-\\&2\sin\varphi_w\cos\varphi_w\cos\theta_w\sin\gamma\tan\delta+\\&2\cos^2\varphi_w\sin\theta_w\cos\theta_w\cos\gamma\tan\delta-\\&2\sin\varphi_w\cos\varphi_w\sin\theta_w\sin\gamma\cos\gamma-\\&2\sin\theta_w\cos\theta_w\cos\gamma\tan\delta\\=&2\sin\theta_w\cos\theta_w\cos\gamma\tan\delta(\cos^2\varphi_w\\&+\sin^2\varphi_w)-2\sin\theta_w\cos\theta_w\cos\gamma\tan\delta\\=&0\end{aligned} \tag{12}$$

$$\cos\alpha=(-\cos\delta)\bullet(\cos\varphi_w\sin\gamma+\cos\theta_w\sin\varphi_w\tan\delta+\sin\theta_w\sin\varphi_w\cos\gamma) \tag{13}$$

$$-\sin\varphi_r\sin\delta=(-\cos\delta)\bullet(\cos\varphi_w\sin\gamma+\cos\theta_w\sin\varphi_w\tan\delta+\sin\theta_w\sin\varphi_w\cos\gamma) \tag{14}$$

With the same calculation method of the angle γ in formula (4)-(6), the angle γ in the curve can be written as:

$$\gamma=\arcsin(\frac{\sin\varphi_r\tan\delta-\cos\theta_w\sin\varphi_w\tan\delta}{\cos\varphi_w\sqrt{1+\sin^2\theta_w\tan^2\varphi_w}})-\arctan(\sin\theta_w\tan\varphi_w) \tag{15}$$

The coordinates of contact points in the global coordinate system O-XYZ in the curve can be written as:

$$\begin{cases}x=R\cos\varphi_w\sin\gamma-\cos\theta_w\sin\varphi_w d_w+R\sin\theta_w\sin\varphi_w\cos\gamma+x_w\\y=R\sin\varphi_w\sin\gamma+\cos\theta_w\cos\varphi_w d_w-R\sin\theta_w\sin\varphi_w\cos\gamma+y_w\\z=R\cos\theta_w\cos\gamma+\sin\theta_w d_w+z_w\\\gamma=\arcsin(\frac{\sin\varphi_r\tan\delta-\cos\theta_w\sin\varphi_w\tan\delta}{\cos\varphi_w\sqrt{1+\sin^2\theta_w\tan^2\varphi_w}})-\arctan(\sin\theta_w\tan\varphi_w)\\\sin\varphi_r=\frac{b_r}{R_C}\sin\varphi_w\end{cases} \tag{16}$$

From formula (1) and formula (3), it can be seen that the main difference between the coordinates of the contact points in the straight line and the curve is caused by the value of the angle γ.

From figure 2, it can be seen that the main the main difference between the coordinates of the contact points in the straight line and the curve is central angel of BC_R

—φ_r. when b_r=0.7465m, R_c=300m, cosδ=1, φ_w=1°=0.01745，φ_r=4.3e-3, which is much smaller than yaw angle φ_w. So in the equation (16), the value of sinφ_r almost quals 0. In this condition, equation (16) is same to equation (5). As a result, the calculation of coordinates of contact point in the straight and curve can use the same formula approximately.

2.1 The contact points with the elastic deformation of wheelset

The wheel-rail contact forces and suspension forces all cause the elastic deformation of wheelset which would influence the real roll angle. The elastic deformation of the axle of wheelset by mathematical calculation or FEM analysis is investigated. The roll angle of left and right wheels (θ_{Le}, θ_{Re}) about X axis caused by the elastic deformation can be obtained. The yaw angle of wheelset caused by the elastic deformation is not considered, so replacing the angle θ_w in formula (7) with the angle (θ_w+θ_e) can obtain the calculation formula of the coordinate of the contact points with the elastic deformation of wheelset approximately.

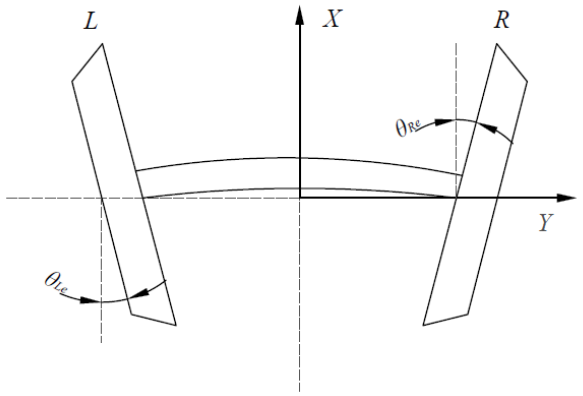

Fig.5 *Schematic diagrams of the elastic deformation of wheelset.*

$$\begin{cases} x = R\cos\varphi_w \sin\gamma - \cos(\theta_w+\theta_e)\sin\varphi_w d_w + \\ R\sin(\theta_w+\theta_e)\sin\varphi_w\cos\gamma + x_w \\ y = R\sin\varphi_w\sin\gamma + \cos(\theta_w+\theta_e)\cos\varphi_w d_w - \\ R\sin(\theta_w+\theta_e)\sin\varphi_w\cos\gamma + y_w \\ z = R\cos(\theta_w+\theta_e)\cos\gamma + \sin(\theta_w+\theta_e)d_w + z_w \\ \gamma = -\left[\arcsin\left(\dfrac{\cos(\theta_w+\theta_e)\tan\varphi_w\tan\delta}{\sqrt{1+\sin^2(\theta_w+\theta_e)\tan^2\varphi_w}}\right)\right. \\ \left. -\arctan(\sin(\theta_w+\theta_e)\tan\varphi_w)\right] \\ \sin\varphi_r = \dfrac{b_r}{R_C}\sin\varphi_w \end{cases} \quad (17)$$

3. The coordinate of contact points on rails

The transversal and vertical displacements, rolling of rails and the unevenness are all considered. So the lateral and vertical coordinates of right rail y_{re} and z_{re} can be calculated as:

$$\begin{cases} y_{re} = y_{r0}\cos(\theta_r-\theta_0) - z_{r0}\sin(\theta_r-\theta_0) + y_0 + y_{rR} + y_{riR} \\ z_{re} = y_{r0}\cos(\theta_r-\theta_0) + z_{r0}\sin(\theta_r-\theta_0) + z_0 + z_{rR} + z_{riR} \end{cases} \quad (18)$$

Where θ_0 is the rail cant, which is positive for the right rail and negative for the left rail; θ_r is the roll angle of rail; y_{rR} and z_{rR} are the transversal and vertical displacements respectively. y_{riR} and z_{riR} are the transversal and vertical unevenness respectively.

4. Calculation of normal force

The minimum gaps between wheel profile and the rail profile can be calculated as:

$$\Delta z_{\min} = \min\left\{(z_{re}-z)\big|_{y=y_{re}}\right\}_r \quad (19)$$

The wheel-rail normal compressed value δ_{3R} can be expressed as:

$$\delta_{3R} = \frac{-\Delta z_{\min R}}{\cos(\delta_R-\theta_w)} \quad (20)$$

Based on the Hertz theory, the wheel-rail contact normal force can be written as:

$$P = \left(\frac{\delta_{3R}}{G}\right)^{1.5} \quad (21)$$

5. Computing program

The wheel profile and rail profile were discretised by the step distance of d_w, the value of which may be 0.10 or 0.05 mm. For the actual geometry of both the wheel and rail, when d_w was given, the actual rolling radius R and wheel-rail contact angle were confirmed. The discretised parameters, including R and δ can be calculated with the variety of d_w and stored as a sequence of numbers accordingly.

In the same method, the left and right rail profiles were discretised by the step distance of y_{r0}, which implied the lateral coordinate of the rail surface point in the rail coordinate system. At the same time, as the profiles of wheels were defined, the vertical coordinate z_{r0} can be calculated accordingly.

For special geometries, the worn wheel profiles and the profiles of rails in turnout region should be divided into more than two sections, and the minimum gaps between each section would be calculated separately. After calculation, the natural one-point contact, two-point contact and multi-point contact were distinguished by analysing the minimum gaps.

The flow of the program is shown in the figure 6.

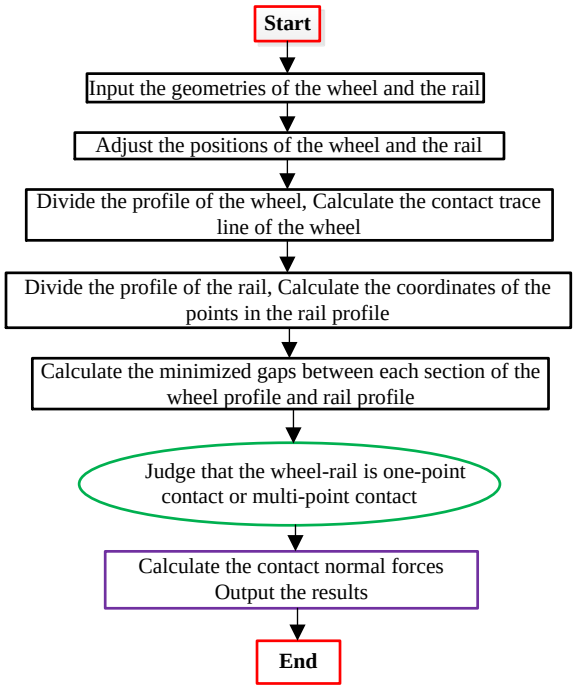

Fig. 6 *Program flow chart.*

6. Calculation case

In the calculation case, the wheel profile was Sl002 type and the rail profile was UIC60 type. The yaw angle and lateral displacement of wheelset were defined as 0.03rad and 4mm respectively. Other initial position parameters of wheelset and rails were zero. The contact trace lines of left and right wheels were showed in figure 7.

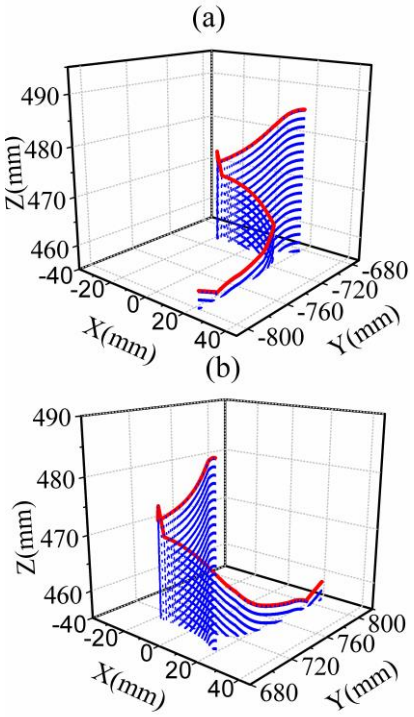

Fig. 7 *Contact trace line of left wheel(a) and right wheel(b).*

The profiles of wheels were divided into treads and flanges, and the profiles of rails were divided into rail tops and rail sides. The minimum gaps among the four sections were calculated separately. The calculation results is shown in the table 1.

Tab. 1 *Calculation result.*

Contact point	Minimized gaps(mm)
Left wheel tread -Left rail top	-0.90
Left wheel flange -Left rail side	0.18
Right wheel tread –Right rail top	-1.49
Right wheel flange -Right rail side	-1.27

The minimized gaps between left wheel flange and left rail side is 0.18mm so the left wheel and left rail is one-point contact. But the minimized gaps between right wheel flange and right rail side is -0.90mm which is less than zero, the two-point contact happened between the right wheel and right rail.

7. Conclusions

This paper proposed a fast and accurate method for calculating single-point and multi-point contact problems in the straight line and curve while the actual three-dimensional geometries of both the wheel and rail were considered.

1.The differential points of the wheel profile may contain angle δ with different signs in the calculation formula, so the value signs of the angle δ are distinguished considering the worn wheelset profiles. In conclusion, the sign of the $\Delta z/\Delta y$ can determined the value of the angle δ accurately.

2. For the contact points in the curve, the main the main difference between the coordinates of the contact points in the straight line and the curve is central angel of BC_R — φ_r, which is much smaller than yaw angle φ_w. As a result, the calculation of coordinates of contact point in the straight and curve can use the same formula approximately.

3.In addition, the calculation of the coordinates of contact points with the elastic deformation of wheelset are also investigated. After the roll angle of left and right wheels (θ_{Le}, θ_{Re}) about X axis caused by the elastic deformation are calculated, replacing the angle θ_w in formula when the deformation of wheelset is not considered with the angle (θ_w+θ_e) can obtain the calculation formula of the coordinates of the contact points with the elastic deformation of wheelset approximately.

4.With the profiles of wheels and rails divided, the natural one-point contact, two-point contact and multi-point contact were distinguished by analysing the minimum gaps of each profile section. Based on the Hertz theory, the wheel-rail contact normal forces can also be calculated at each contact point.

Abstract: The maintenance process rail milling and the rolling contact behavior of a milled rail are analyzed in detail. By using commercial finite element programs the milling process and the rolling contact of a wheel on a milled rail are simulated with 3D and 2D methods. These results are compared to experimental results and metallographic investigations of a milled rail after an actual milling process and after milling tests that were done in track together with a European infrastructure manager (IM). A satisfying agreement is shown by comparing the obtained numerical results with the experimental results and metallographic investigations.

Keywords: rail maintenance, rail milling, finite element simulation, wheel/rail interaction, residual stresses, rough contact, microscopic investigation

1. Introduction

Continuously increasing demands on rail transportation result in higher dynamic axle loads, train speeds and volume of traffic. This leads to increasing requirements on rail materials to resist wear and rolling contact fatigue (RCF). Typical RCF defects like “squats”, “head checks”, “spalling” and “shelling” as well as other defects like “wheel burns” or ”corrugation” can impact ride comfort and safety and will reduce rail life. To keep rails in a functional and safe condition and to prevent premature rail failure, different rail maintenance strategies can be applied. The two commonly used maintenance technologies to extend rail lifetime are rail grinding and rail milling. This paper is focusing on 3D and 2D simulations of the maintenance process rail milling and the rolling contact behavior of a milled rail. Milling as such is primarily used in industrial machining processes and is a rather new application for rail maintenance services. Rail milling can be described as a rotational cutting process that results in a reprofiled rail head without any defects. In addition it is a save, clean and spark-free process and has a very high level of geometrical accuracy. A further advantage of this process is the possibility to remove several millimeter deep defects in only one pass. Simulations and metallographic investigations can help to get a better understanding of this very complex metal machining process and its influence on the wheel/rail rolling-sliding contact behavior.

Several finite element studies deal with the description of machining processes in general. Predictions of the chip formation, the cutting forces and the temperature field in the process zone are demonstrated in [1-6]. Various studies focusing on the cutting process deal with the machining-induced residual stresses [7, 8]. Description of the milling process in general with respect to the temperature, the load conditions and the milling forces are investigated in [9-11].

Simulations for the description of the contact between rough surfaces are investigated in different ways. Studies of contact between single asperities work on the damage behavior and the contact pressure distribution are presented in [12-14]. Investigations of rough surfaces with purely elastic material behavior deal with the contact pressure and stress distribution can be found in [15-18]. Contact simulations with rough surfaces or single asperities under pure normal loading and with an elastic-plastic material behavior are performed in [19-24]. Numerical studies deal with the rail/wheel rolling-sliding contact between two rough surfaces and with elastic-plastic material behavior are demonstrated in [25-29].

The aim of this paper is to present 3D and 2D finite element simulations of the milling process as rail maintenance and the rolling contact of a wheel on a maintained rail by milling. The milling model results are compared to experimental and metallographic investigations of a milled rail after an actual milling process at the test track of the company partner LINSINGER/LINMAG in Austria. In addition the results of the rolling-sliding contact simulation are compared to experimental results of milling tests that were done in track together with a European IM in summer 2017.

2. Simulation models

2.1 Milling models

A general picture of the whole milling process can be shown in a 3D model set up with the finite element code DEFORM 3D. The milling tool is modeled as a rigid body and for the material description of the rail head an elastic-plastic behavior is used. For both parts, the rail and the tool holder, tetrahedral elements with a higher element density at the top surface of the rail head and the insert area of the tool holder are taken to model the chip formation process accurately. The simulated rail head has a typical 60E2 profile and is fixed in space by using vertical and horizontal constraints at its bottom. In the simulation the tool holder segment has fifteen cutting inserts in three rows where five inserts are attached per each row. The friction coefficient μ and the heat transfer coefficient are set to 0.4 and 11^{-09} W/m²K respectively. On the center point of the tool holder an angular velocity $\dot{\varphi}$ and a feed rate $\dot{x}$ are applied. A theoretical milling depth of about 1 mm is used in this study. The actual milling depth can be higher or lower due to the positioning of the insert in the tool holder and the deformation state of the worn rail profile. Fig. 1 shows the assembly of the milling tool and the rail head with the chosen boundary conditions and detailed views of the used rail profile and the location of the inserts in the tool holder segment.

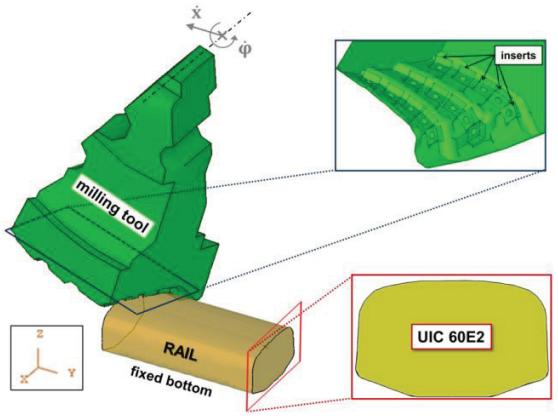

Figure 1 *3D milling model with the selected boundary conditions and detailed views of the used rail profile and the insert distribution.*

For a detailed study of the rail milling process with respect to the temperature field in the process zone a 2D model was set up using the finite element program Abaqus/Explicit and an Arbitrary-Lagrangian-Eulerian (ALE) method. This method merges a pure Lagrangian method with a pure Eulerian method to separate the mesh motion from the material flow which is often used in high dynamic nonlinear numerical calculations like milling. It prevents a large distortion of the finite element mesh and allows simulating a stable machining process. The numerical model represents a part of a rail head next to the milling area and one milling insert with a common edge radius, a negative rake angle and a positive clearance angle. The milling process is simulated accurately without any artificial numerical influences by applying a set of well-chosen boundary conditions and dimensions on the rail part and the milling insert. Special features of the model are the assumption of an initial chip with Eulerian boundary conditions to allow a material outflow at the rail top surface and the assumption of Eulerian boundary conditions on the left side of the rail to allow a material inflow. With the assumption of Lagrangian boundary conditions on the right side, the rail part is able to grow in size, which gives a general picture of the machined rail. In this 2D numerical study a precise observation of the milling process is made with regard to the development of the temperature field in the process zone and the machined rail. The mesh of the rail part is partitioned with different kinds of continuum-mechanical formulations to guarantee a stable milling simulation. The edge nodes of the initial chip are coupled with a kinematic constraint to prevent a high distortion of elements during the change of the chip thickness. The simulated milling insert is moveable by using a reference point at the top of the tool tip which is tied to an analytical rigid body. For a transient cutting process with non-constant uncut chip thickness the milling insert can be moved in vertical direction, but it is fixed in horizontal direction. In this numerical research a thermo-mechanical coupled analysis is performed to predict the temperature field in rail and milling insert. The assembly of the 2D milling model with the chosen boundary conditions is shown in Fig. 2.

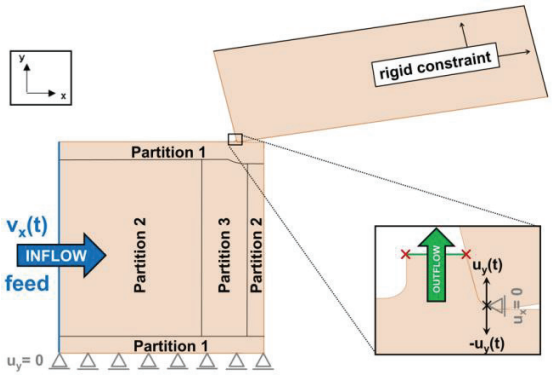

Figure 2 *The 2D milling model with the chosen partitions and boundary conditions.*

The horizontal component of the milling velocity $v_x(t)$ and the feed of the milling insert are applied on the inflow surface of the rail part. The combination of the horizontal velocity and the feed is nearly constant and

is set to a value of 3750 mm/s in this case. By using the vertical component of the milling velocity and the milling time a vertical displacement $u_y(t)$ is calculated and applied as a linear amplitude on the reference point of the milling insert. In this case one milling insert has to remove a maximum uncut chip thickness of 389 µm in a milling time of 6.8 ms for a theoretical rail milling depth of about 1 mm. In the simulation a friction coefficient μ of 0.4 and an artificial shear stress limit of 290 MPa are used. The heat produced by contact flows 50 to 50 into the milling insert and the rail part. For the conversion of the plastically dissipation energy to heat a Quinney-Taylor coefficient of 0.9 is used. An overview of the model and process parameters for this study is given in Table 1.

Table 1 *Model and process parameters of the milling simulation*

Parameter	Value
horizontal cutting velocity v_x & feed [mm/s]	3750
max. uncut chip thickness u_y(max) [µm]	389
shear stress limit τ_{max} [MPa]	290
friction coefficient μ	0.4
Quinney-Taylor coefficient β	0.9
milling time t_{milled} [ms]	6.8

2.1.1 Material parameter

The used elastic and thermos-physical material parameters of the rail part and the uncoated milling insert are shown in Table 2.

Table 2 *Elastic and thermo-physical properties of the rail material and the tool material*

Properties	Rail material (R260)	Tool material (K20)
Density ρ [kg/m³]	7850	14750
Conductivity λ [W/mK]	42	88
Specific heat c [J/kgK]	490	296
Young's Modulus E [MPa]	219000	630000
Poisson's ratio υ [–]	0.29	0.22

In addition the Johnson-Cook (JC) constitutive material model is used to describe the plastic behavior of a standard rail material of the steel grade R260. An example of the JC constitutive equation is given in [9]. For the plastic rail material description tensile tests at different temperatures, made at the Materials Center Leoben in Austria, and experimental data at elevated strain rates of rail steels demonstrated in [30] were used to calculate the required JC parameters. The calculated parameters which represent a standard rail material of the steel grade R260 are presented in Table 3.

Table 3 *JC parameters of the R260 rail steel*

A [MPa]	B [MPa]	C	$\dot{\varepsilon}_0$	n	m	T_{room} [K]	T_{melt} [K]
304.1	861.6	1.53e-02	1	0.144	0.633	293	1793

2.2 Rolling-sliding contact model

In a second step, a 2D finite element model has been developed using ABAQUS/Standard for cyclic investigations of a wheel rolling-sliding on a machined rail. The model consists of a part of a rail head and a wheel and includes the profile and surface roughness of a machined rail. To consider the influence of the milling process on the rolling contact and fatigue behavior of a machined rail, it is necessary to map the results of experiments, such as surface roughness and the residual stress field, onto the rolling-sliding contact model. In the simulation the wheel is described with elastic material behavior and the rail with plastic kinematic hardening behavior published in [26]. With these models the cyclic plastic deformation of remaining milling facets, the change of the surface roughness and the resulting residual stress field of machined rails can be determined after some passes of a wheel. Fig. 3 shows the assembly and the chosen boundary conditions of the rolling-sliding simulation with a schematic close-up view of the milling facets area. The facets dimensions, the length f_z and the height H, depend on the chosen set of milling parameters like milling velocity, feed and tool holder radius. The three idealized facets are modeled with a length f_z of 5.36 mm and a height H of 11.9 µm. The remaining surface of the rail part stays flat. This is a valid method for analyzing the influence of the roughness during a rolling-sliding contact, which has been reported in [26]. In this study normal loads F_N of about 7 kN and 12 kN with accelerating and braking slip values of 0.0 %, 0.5%, 1.0% and 1.5 % are applied. The normal loads have to be recalculated by using the load transfer methodology published in [27] and correspond approximately to wheel loads of about 4 t and 8 t.

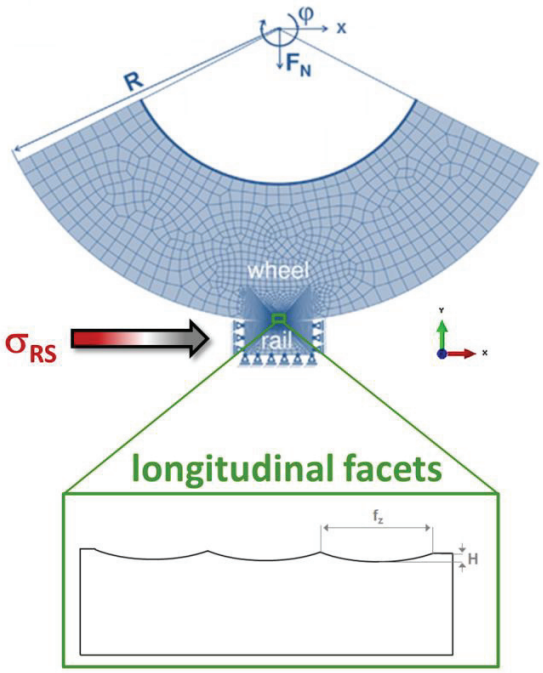

Figure 3 *2D rolling-sliding model with the chosen boundary conditions and a schematic close-up of the milling facet area.*

3. Results and Discussion

Surface contour measurements help to get a general picture of the rail profile on a milled rail. For the analysis of the rail reprofiling process by milling an arbitrary rail contour was milled on a typical 60E2 profile in an experimental test made at the construction facility of Linsinger/LINMAG in Austria. Fig. 4 above shows a superimposition of the cross section of the rail head before milling, colored in red, and the cross section of the rail head after rail reprofiling, colored in green. By comparing the superimposed rail head cross sections, a precise reprofiled rail head without any contour imperfections can be shown due to rail milling in only one pass. For the verification of the obtained simulation results, Fig. 4 below represents the cross section of the non-machined rail head, colored in red, superimposed by the cross section after the simulated milling process, colored in blue. The similarity between metallographic investigations and simulations can be shown by comparing the profile change, shown on the left side in Fig. 4, and the produced chips, shown on the right side in Fig. 4. The difference between the experiment and the simulation is only about 3 % by comparing the maximum milling depth at the gauge corner of the rail. With these results an acceptable satisfying agreement between the real and the simulated milling process can be shown.

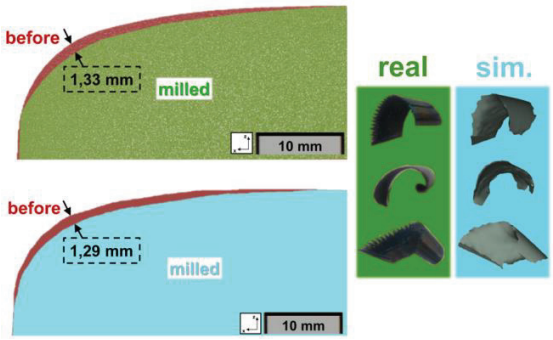

Figure 4 *Cross section of the used rail samples (above) and the simulated rail head (below) before and after the milling process. On the right side of the figure a qualitative comparison of the real and simulated chips is shown.*

For a better visualization of the rail surface conditions and the quality of the rail head after the reprofiling process by milling, Fig. 5 represents microscopic investigations at 200x magnification of the rail head at three locations in transversal direction before and after milling. An uneven and rough rail surface condition can be seen at the non-machined rail head, colored in red in Fig. 5. In contrast the milled rail head shows a smooth surface condition without damage and micro-cracks, colored in green in Fig. 5.

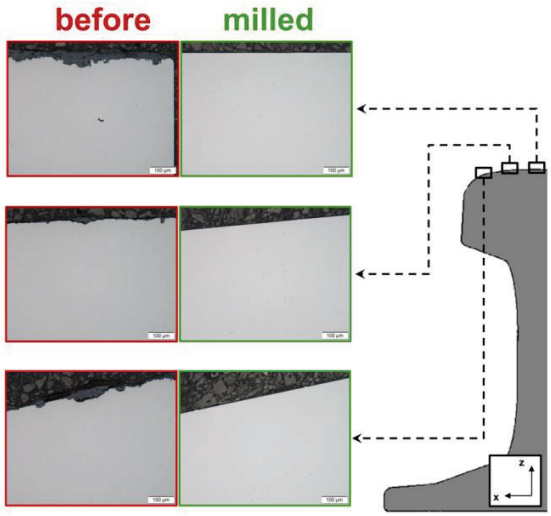

Figure 5 *Close-up views of the rail surface before and after rail reprofiling by an experimental milling test.*

The obtained results of the 2D milling simulation are illustrated in Fig. 6. The development of the temperature field in the milling area of the insert and the rail head is shown in counter plots at five chosen milling time states. A temperature of about 800° is reached in the chip nearby the contact surface after a milling time of 1.4 ms. This temperature stays constant until a milling time of 3 ms. Afterwards it decreases and reaches a value of 600° at the end of the simulated milling process. The temperature at the surface of the milling insert shows its maximum value

of about 900° after a milling time of 5 ms which subsequently decreases to 700° nearby the surface of the insert tip. The highest temperature at the surface of the machined rail is about 300° and this indicates no significant thermal influence on the remaining rail material during and after milling. The simulation demonstrates that the main part of the produced heat flows into the chip and the milling insert. Only a small part flows into the machined rail and therefore the material is uninfluenced by temperature and will not result in the formation of unwanted material transformation like martensitic layers.

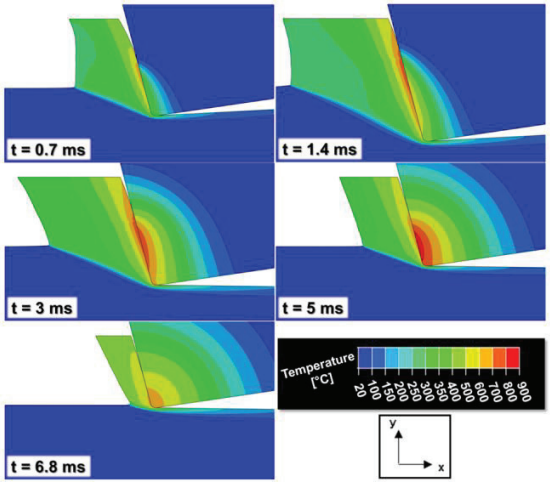

Figure 6 *The development of temperature in the rail, chip and the milling insert during the simulated milling process at five chosen milling time states.*

For the verification of the obtained simulation results metallographic investigations of the rail head after the experimental milling test were made, shown in Fig. 7 at 100x magnification. The left orange framed picture shows the microstructure of the rail head in transversal direction. The microstructure of the rail head in longitudinal direction is illustrated in the right green framed picture. The used and partitioned rail sample for the metallographic investigation is shown in Fig. 7 above. The microstructure in both directions, longitudinal and transversal, is uninfluenced by temperature and demonstrates an unchanged pearlitic microstructure. No phase changes can be seen nearby and at the rail surface. These pictures confirm the obtained results of the milling simulation. The height of the peaks of the produced milling facets at the rail surface is below the required UIC specification and the roughness between the facet peaks gets in a submicron range by the milling process.

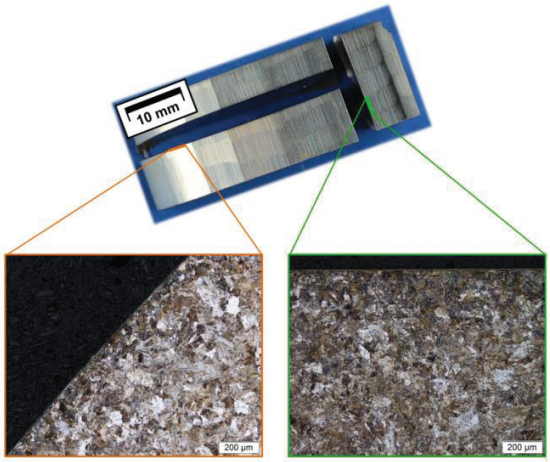

Figure 7 *Metallographic investigation of a rail head after the experimental milling test.*

Fig. 8 shows the average values of measured and simulated residual stresses in relation to rail depth in a) axial direction and b) transverse direction. The residual stress measurements were done at a milled and traffic loaded rail sample after a time interval of 11 days in track and about 120,000 tons of loading, represented by the red lines. The measurements of a worn rail sample out of the same track without any maintenance action are represented by the blue lines in the diagrams. The simulated residual stresses, represented by the black lines, are the average values of all simulated load and slip cases after five cycles of rolling-sliding contact. In the simulations the influence by the surface roughness in submicron range was not taken into account and therefore no values are indicated for the first 50µm at the rail surface. By comparing the axial residual stress of the worn rail sample with the milled and traffic loaded rail sample, both show almost the same development with increasing rail depth, demonstrated in Fig. 8a. The simulated residual stress values in axial direction differ slightly from the measured results in the region were compressive stresses are present. By comparing the transverse residual stress values of the worn rail sample with the milled and traffic loaded rail sample, a shift of the values towards the compressive range is found in the milled and traffic loaded sample, demonstrated in Fig. 8b. The simulated residual stress values in transverse direction show the same development like the milled and traffic loaded rail sample. The obtained results of the rolling-sliding contact simulation match satisfactorily with the measurements of the in-track-test samples.

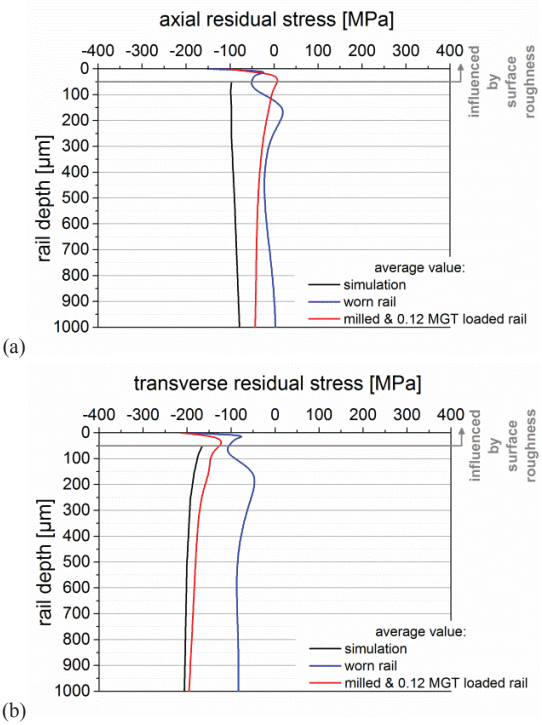

Figure 8 *The average values of the measured and simulated residual stresses over the rail depth in a) axial direction and b) transverse direction.*

4. Conclusions

This numerical and experimental study shall help to better understand and optimize rail re-profiling processes. Additionally, it shows that rail milling is an appropriate maintenance process which can remove rail defects without remarkably influencing the maintained rail.

From the developed simulations and experiments, the following main conclusions can be made:

- A similarity between metallographic investigations of a rail head after a milling test and the simulations of the milling process is shown by comparing the profile change and the produced chips. A precise reprofiled rail head without visible contour imperfections is produced due to rail milling in only one pass.
- The results of the milling simulation show that a maximum temperature of about only 300° is reached at the surface of the machined rail. This indicates no significant thermal influence on the remaining rail material during and after milling. Metallographic investigations demonstrate an unchanged pearlitic microstructure and no phase changes, like martensitic layers, after rail milling, which confirm the numerical results.
- By comparing the development of residual stresses in the rolling-sliding contact simulation and the measurements of the in-track-test a satisfying agreement is shown. The measurements and the simulations show mostly compressive residual stress fields after a specified time / tons of loadings.

Abstract: This paper focuses on computational methods for dynamics of wheel/rail systems. Such methods are needed, for instance in order to model wheel/rail noise, like rolling noise or curve squeal noise. For this purpose, the use of accurate wheel/rail rolling contact models is crucial. This is especially the case for curve squeal, characterised by high-frequency friction-induced instabilities. There are actually several wheel/rail frictional rolling models. However, in most of them, some simplifications are made to determine contact forces. The aim of this paper is to develop a full Finite Element (FE) computational method for the dynamics of wheel/rail frictional rolling contact systems in order to calculate reference solutions. The proposed method is characterized by the use of a fine FE discretization of the contact surface in an Eulerian frame, non-smooth frictional contact laws and model reduction techniques. An application to the frictional rolling contact between two cylinders is presented in both quasi-static and free dynamic cases, without instabilities. The results of the approach in both quasi-static and dynamic conditions show a good agreement with Kalker's CONTACT software.

Keywords: Contact mechanics, rail-wheel systems; elastic contact; FE method; Eulerian frame.

1. Introduction

A mechanical railway system generates rolling contact forces which are transferred within a finite area of contact between the wheel and the substrate (rail, sleepers and ballast). Even if friction mechanisms are rather weak, they may be important source of vibration and noise. As an example, in the case of a tight radius curve (radius lower than 200m), squeal can be generated due to the lateral slip of the wheel on the head of the rail. This noise is characterized by high sound pressure levels (130 dB at 0.9m from the wheel) at pure medium and high frequencies.

There are mainly two types of model used for wheel/rail rolling contact. The “point-contact” models are based on analytic formulas which are heuristic laws of contact friction [1], [2]. In slightly nonlinear dynamic cases (close to pure rolling), equivalent point stiffness and damping can be used and give good results, especially for the rolling noise modelling [3]. In other cases (large slides with dynamic contributions), “surface contact” models, where the contact zone is discretized, are more adapted. The variational theory of Kalker [4] implemented in the CONTACT program is the most used model of this type [5]. However, a number of simplifications are generally performed in these models (elastic half-space assumption, contact and friction decoupling). The impact of these simplifications is unknown in the case of vibrations in curves where instability due to friction and excitation by surface irregularities (at different scales) may occur.

The aim of this paper is to develop a full Finite Element (FE) computational method for the dynamics of frictional wheel-rail rolling contact systems in order to calculate reference solutions. Continuous equations of the problem are derived around the stationary position of rolling in an Eulerian reference frame. Local unilateral contact and Coulomb friction laws apply on the rolling interface. Weak formulation and FE discretization lead to a non linear discrete system which is solved in the time domain by a numerical integration and a point-fixed algorithm at each time step. In order to obtain reasonable computation times, two reduction strategies are proposed. An application of the method to the frictional rolling contact between two annular cylinders is presented in both quasi-static and dynamic cases. The validation of the approach in quasi-static and dynamic conditions is carried out by comparison with CONTACT software. Reduction strategies are validated by comparison with the full method.

2. Finite Element (FE) formulation in the time-domain

2.1. Contact problem in the Eulerian frame

A rolling contact between two bodies, lower and upper denoted in *Figure 1*, is considered. The system is in two domains with boundary **Ω**. is the part of where displacement is prescribed. is the part of where surface load is applied. In Ω, volume load is applied. is the potential contact interface. and are respectively noted as the displacement and velocity fields.

The z-axis is chosen to coincide with the common normal to the two surfaces at the origin. The longitudinal x-axis is the rolling direction. The y-axis is chosen to be the lateral direction. The rolling speed is V in the rolling direction.

In the Eulerian frame which moves with the point of contact , according to [6] the creep velocities between contacting points are given by:

(1)

(2)

where ΔV_x , ΔV_y and $\Delta\omega_z$ are the relative lateral longitudinal and angular velocities between the two rigid bodies.

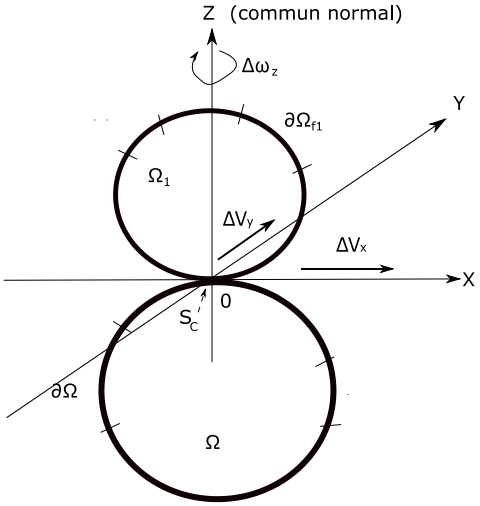

Figure 1 *Contact between two bodies*

2.2. Formulations and FE discretization

To deal with the unilateral contact and frictional contact, a non-smooth Signorini and a Coulomb law with a constant friction coefficient are chosen. The contact and friction laws can be rewritten in terms of projections on the negative real set $Proj_{\mathbb{R}^-}$ and on the Coulomb cone j [7]. The dynamics of the system is then given by the principle of virtual power and the contact laws are written in the weak forms [8]. Finite element discretization of theses equations gives then:

(3)

where $\mathbf{M}, \mathbf{C}, \mathbf{K}, \mathbf{U}, \mathbf{F}, \mathbf{R_n}, \mathbf{R_t}$ are respectively the mass, damping and rigidity matrix, the nodal displacement vector, the generalized force, normal contact reaction and tangent contact reaction. $\mathbf{N}$ are shape function vectors on the contact interface, $\mathbf{ds}$, and are matrix allowing to pass the normal and tangential contact reactions from the local frame to the global frame. $\mathbf{U_n}$ is the gap and $\mathbf{V}$ is the creep velocities at contact interface. ρ are are two arbitrary positive scalars called normal displacement augmentation parameter and tangential augmentation parameter respectively.

For the computation of the transient solution, with chosen no-smooth contact and friction laws , from the literature, a modified θ method is adapted. This is a first-order time integration scheme developed by Jean [9]. This scheme allows to impose inelastic shock. A fixed point statement on contact reactions is chosen for non-linear resolution of the system of equations (3).

2.3. Reduction strategies

As the size of the system is often large and the nonlinear solving process implies several resolutions of a linear system at each time step, reducing the size of the system is necessary to obtain reasonable computation times.

The principle is to search an approximated solution $\mathbf{q}$ of the problem spanned by a reduced basis which leads to a reduced dynamics equation:

) (4)

where $(\mathbf{M_r}, \mathbf{C_r}, \mathbf{K_r}) = \mathbf{B^T}(\mathbf{M_r}, \mathbf{C_r}, \mathbf{K_r})\,\mathbf{B}$ and the size of the system is reduced to the number of modes in basis $\mathbf{B}$.

In this paper, two reduced basis are proposed as followings:

3.3.1 Component Mode Synthesis (CMS) with free-interface modes

The first proposed basis $\mathbf{B}$ includes free-interface normal modes of the structure and static attachment modes $B = [\Phi \ \Phi_s]$. Matrix Φ contains the real solutions of the free and undamped system:

(5)

whereas Φ_s make the base statically complete by adding static solutions to unitary forces (normal and tangential) on the contact interface:

(6)

where $\mathbf{P_c^T} = [\mathbf{P_n}\ \mathbf{P_t}]$ is the matrix allowing to pass the contact reactions from the local frame to the global frame.

In order to improve the numerical efficiency, the basis is then orthogonalized in relation to stiffness matrix $\mathbf{K}$ before use. It is well-known that static attachment modes are useful to provide a better approximation of the dynamics by comparison with normal modes alone.

3.3.2 Contact static approximation (CSA)

A stronger approximation consists in neglecting the dynamic terms in the reduced equations corresponding to attachment modes. However, bases Φ and Φ_s are not orthogonal, which is a necessary condition in order to separate the contributions of normal modes and attachments modes. This can be fixed by using residual attachment modes defined by:

(7)

These modes are the static displacement responses to unit contact reactions after the elimination of the contribution of normal modes. It can be easily verified that $\widetilde{\boldsymbol{\Phi}}_{\mathbf{s}}\ \mathbf{K}\boldsymbol{\Phi} = \mathbf{0}$.
The use of basis $\mathbf{B} = [\boldsymbol{\Phi}\ \widetilde{\boldsymbol{\Phi}}_{\mathbf{s}}]$ in the equation (4) together with the elimination of the dynamic terms relating to attachments modes gives:

(8)

Where $\mathbf{q}$ and $\mathbf{q_s}$ are the generalized coordinate vectors corresponding respectively to normal modes and residual attachment modes such that $\mathbf{U} = \boldsymbol{\Phi}\mathbf{q} + \widetilde{\boldsymbol{\Phi}}_{\mathbf{s}}\mathbf{q}_{\mathbf{s}}$. A total decoupling between the generalized equations corresponding to free-interface normal modes and residual static attachment modes is obtained.

This reduction strategy consists in solving the global dynamics using free-interface normal modes and adding a local static residual flexibility controlled by matrix $\widetilde{\boldsymbol{\Phi}}$ in the expression of the contact displacements. This method gets very close to models such Pieringer's one [12] combining modal dynamics and static local resolutions of the kind of CONTACT software. However, in the proposed method, the local flexibility is calculated numerically by finite elements instead of using semi-analytical influence functions derived from Boussinesq's approximations. In addition, it takes into account the static normal/tangential coupling in the contact zone.

3. Numerical application

In this section, an application of the methodology presented in the previous sections is proposed for the case of rolling contact between two annular cylinders. The model is firstly described. Secondly, the model is validated in quasi-static conditions with CONTACT software. Free transient calculations without instabilities nor without harmonic forces are finally performed with and without reduction and results are discussed and compared.

3.1. Description of the model

A rolling contact between two same annular cylinders is considered, as shown in *Figure 2*. The material behavior is assumed to be linearly elastic, isotropic and undergoing small deformations. A Rayleigh damping with coefficients α and β is introduced in the model. The material and geometrical parameters of the cylinders are listed in *Table 1*.

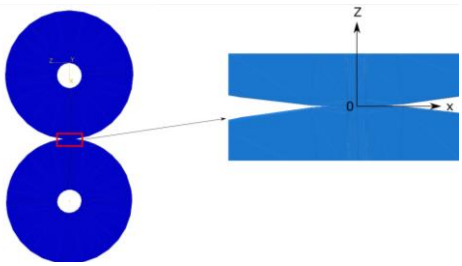

Figure 2 *Contact between two annular cylinders*

A vertical displacement $\mathbf{u_{zo}}$ is applied at the hub of the upper cylinder whereas a rigid constraint is applied at the lower cylinder. For the discretization by finite elements, compatible meshes on the interface are considered: facing nodes of the two cylinders in potential contact have identical tangential coordinates x and y. The potential contact area is meshed with elements of length 1~mm as shown in *Figure 3*.

Figure 3 *FE model of a cylinder with fine mesh on the contact zone*

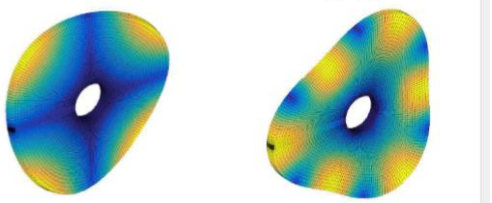

Table 1:

Table 1 *Material and geometrical parameters of the cylinders.*

Parameter	Value
Young's modulus	205 GPa
Poisson's ratio	0.3
Density	7800 kg/m^3
Rayleigh's damping coefficients	(1)
Internal rayon	0.1 (m)
External rayon	0.5 (m)
Thickness	0.1 (m)

3.2. Free-interface normal modes

The 75 first natural frequencies and corresponding free-interface modes have been calculated up to 7310 Hz. The eigenmodes are classified according to their predominant deformations (axial, radial or circumferential) and their numbers (**n,m**) of nodal diameters and nodal circles. Two modes are represented in *Figure 4*.

a) *b)*

Figure 4 *Examples of free eigenmodes of a cylinder : (a) Axial mode (0,2) (316 Hz). (b) Radial mode (0,3)(3695 Hz)*

3.3. Quasi-static results

In this subsection the quasi-static rolling contact of the two cylinders is considered. The contact zone is supposed to be laterally centered. As shown in *Figure 5*, the geometry of the lateral profiles of the two cylinders has been curved in order to obtain an effective 3-dimensional contact. For each cylinder the applied radius of curvature is 0.5 m. The rolling is performed in the x direction with V=10 m/s. An vertical displacement .1 mm is applied leading to a resultant vertical contact force of about 75 kN. A friction coefficient is considered.

Three cases of longitudinal, lateral and spin creepages are performed and compared with CONTACT software in following subsubsections.

3.3.3 Lateral creep velocity

For an imposed lateral creepage $\Delta V_y/V = 0.3\%$ and other creepages set to zero, the longitudinal distributions of the normal contact pressures and frictional stresses on the center line of the contact zone (y=0) are presented in *Figure 6*. As expected, a stick zone occurs at the leading edge of the contact and a slip zone occurs at the trailing edge of the contact (*Figure 7*). The comparison of the results obtained with the proposed full FE method and the results provided by CONTACT software shows a good agreement with some small differences for the tangential stresses in the transition between the stick zone and the slip zone.

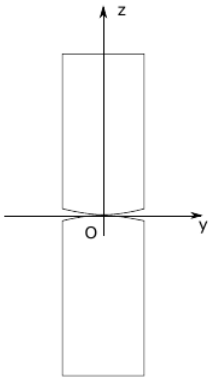

Figure 5 *Lateral curvatures of the cylinders and contact point in center*

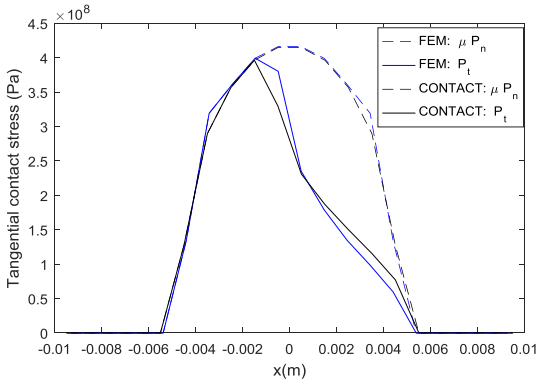

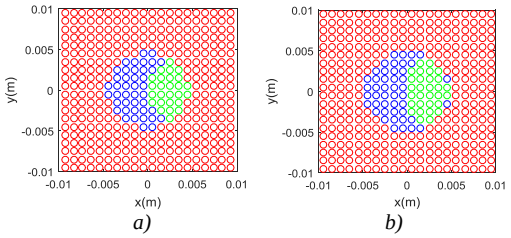

Figure 6 *Quasi-static frictional reactions on a line y=0 for and* μ

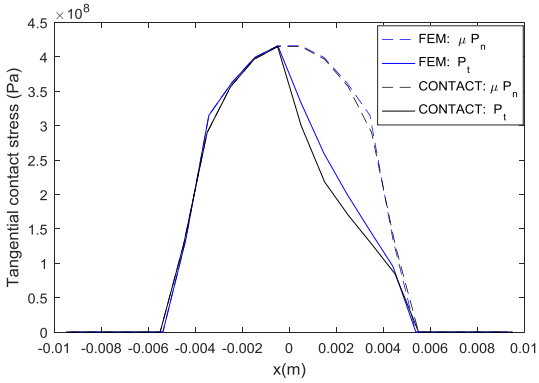
a) *b)*

Figure 7 *Status of nodes in the potential contact zone: no contact zone (red), slip zone (blue) and stick zone (green) for and* $\mu = 0$. *(a) FEM. (b) CONTACT.*

3.3.4 Longitudinal creep velocity

For an imposed lateral creepage $\Delta V_x/V = 0.3\%$ and other creepages set to zero, the longitudinal distributions of the normal contact pressures and frictional stresses on the center line of the contact zone (y=0) are presented in *Figure 8*. As in the case of lateral creep velocity, a stick zone occurs at the leading edge of the contact and a slip zone occurs at the trailing edge of the contact (*Figure 9*). The comparison of the results obtained with the proposed full FE method and the results provided by CONTACT software shows a good agreement with some small differences for the tangential stresses in the transition between the stick zone and the slip zone.



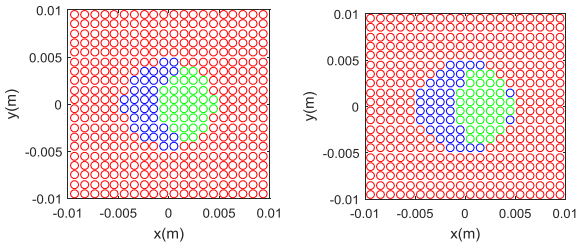


Figure 8 *Quasi-static frictional reactions on a line y=0 for and* μ

a) *b)*

Figure 9 *Status of nodes in the potential contact zone: no contact zone (red), slip zone (blue) and stick zone (green) for* % and μ = 0.3 *(a) FEM. (b) CONTACT.*

3.3.5 Spin velocity

For an imposed angular creepage and other creepages set to zero, the longitudinal distributions of the normal contact pressures and frictional stresses on the center line of the contact zone (y=0) are presented in *Figure 10*. The comparison of this result obtained with the proposed full FE method and the results provided by CONTACT software shows a

significant difference. The status of nodes in the potential contact zone shows a relative agreement in the triangle form of the stick zone (*Figure 11*) .

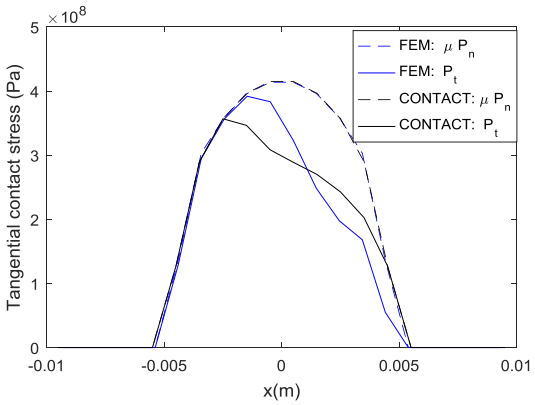

Figure 10 *Quasi-static frictional reactions on a line y=0 for and* μ

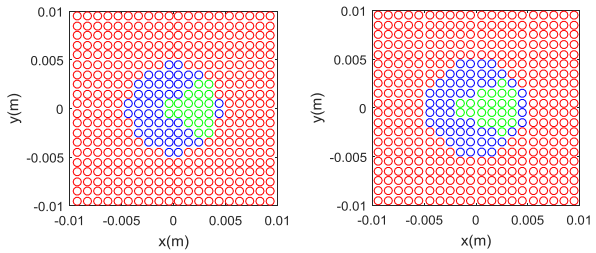

Figure 11 *Status of nodes in the potential contact zone: no contact zone (red), slip zone (blue) and stick zone (green) for and* $\mu = 0.3$ *(a) FEM. (b) CONTACT.*

3.3.1 Saturation curves

Saturation curve is the relation between the tangential contact resulting force and creep velocities. *Figure 12*, *Figure 13* and *Figure 14* show these curves for imposed longitudinal, lateral and spin creepage respectively in the quasi-static case. The curves corresponding to FE model and CONTACT software are in good agreement even in the case of angular creep velocity.

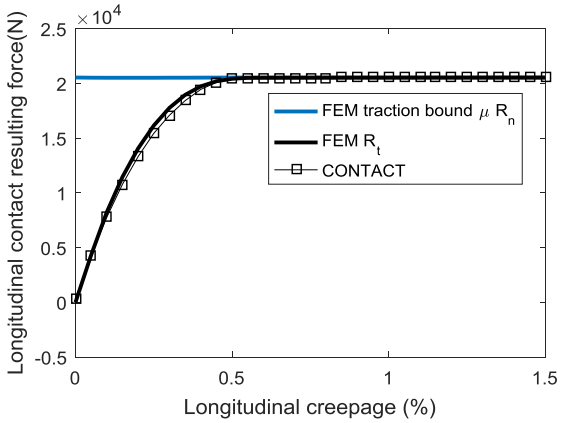

Figure 12 *Curve saturation for imposed longitudinal creepage* V *and* μ

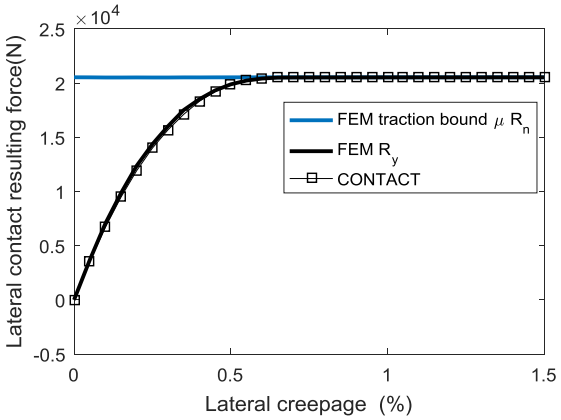

Figure 13 *Curve saturation for imposed lateral creepage* $\Delta V_y/V$ *and* μ

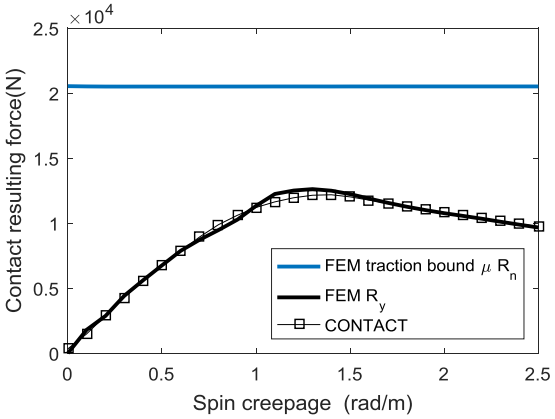

Figure 14 *Curve saturation for imposed angular creepage* $\Delta\omega_z/V$ *and* μ*=0.3*

In this subsection, the quasi-static solution of the rolling contact between two cylinders is calculated and compared with that obtained by CONTACT software. In the following subsection, the transient calculation in the case without instability is going to be performed and then compared with quasi-static solution and CONTACT software.

3.4. Dynamic results

The initial displacements are the displacements obtained from the quasi-static solution in the case of pure rolling ($\Delta V_x = \Delta V_y = \Delta\omega_z = 0$) and the initial velocities are null. The parameters $V = 10$ m/s, are used. The time step for the integration is s.

The computation duration for the two proposed basis CMS and CSA are reduced around 15 and 20 times respectively in comparison with the computation duration for the full FE.

Results obtained with the full FE model and reduced solutions are then discussed.

3.4.1. Lateral creepage

In the case of lateral creepage $\Delta V_y/V = 0.3\%$ and other creepages set to zero, *Figure 15* shows the temporal evolution of the tangential contact resulting forces obtained by the full FE model and reduction models. These forces increase until a quasi-unchanged value. The results obtained by the reduced basis get close to that obtained by the full model.

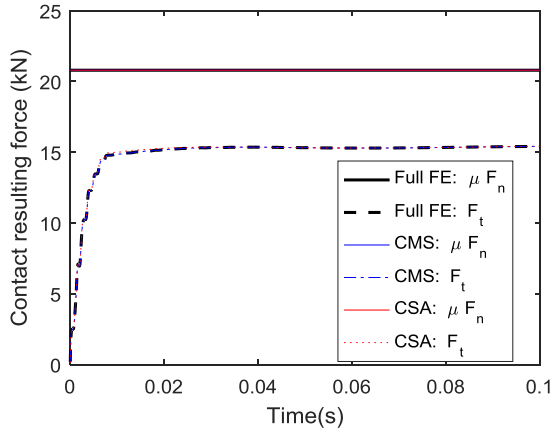

Figure 15 *Evolution of the tangential contact resulting force for and* μ

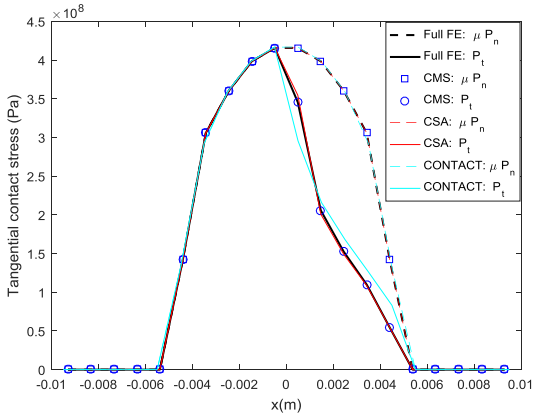
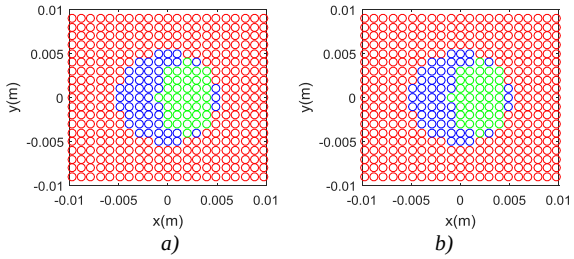
The longitudinal distributions of the normal contact reactions and frictional reactions on the center line of the contact zone (y=0) are presented in *Figure 16*. In comparison to the solution obtained by CONTACT software, the dynamic solution shows a light different in the stick zone.





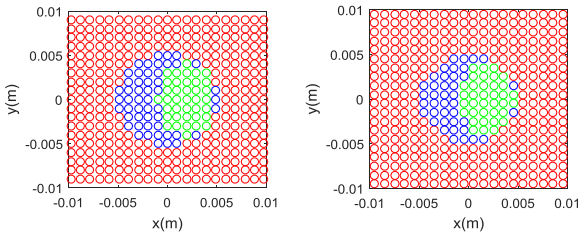


Figure 16 *Dynamic frictional reactions on a line y=0 for and* μ

As in the quasi-static case, a stick zone occurs at the leading edge of the contact and a slip zone occurs at the trailing edge of the contact (*Figure 17*). The results obtained with the full FE method, the two proposed reduced basis and by CONTACT software shows a good agreement in the status of nodes in the potential contact zone.

a) *b)*

c) *d)*

Figure 18 shows the temporal evolution of the tangential velocity at a point outside the contact zone. The results obtained by the reduced basis also get close to that obtained by the full model.

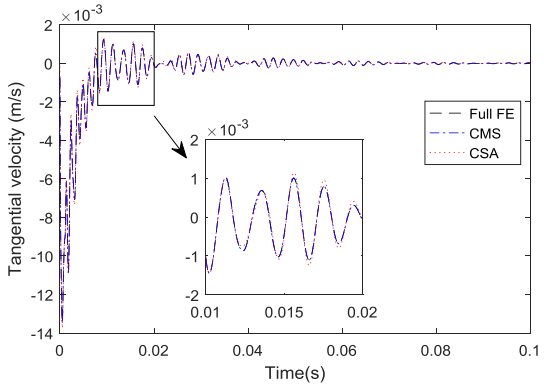

Figure 18 *Evolution of the tangential velocity at a point outside the contact zone*

3.4.2. Longitudinal creepage

In the case of longitudinal creepage $\Delta V_x/V = 0.3\%$ and other creepages set to zero, as the case of lateral creepage, the dynamic results obtained by the reduced basis also get close to that obtained by the full model in *Figure 19*, *Figure 20* and *Figure 21*. The results obtained with the full FE method, the two proposed reduced basis and by CONTACT software shows a good agreement in *Figure 20* and *Figure 21*.

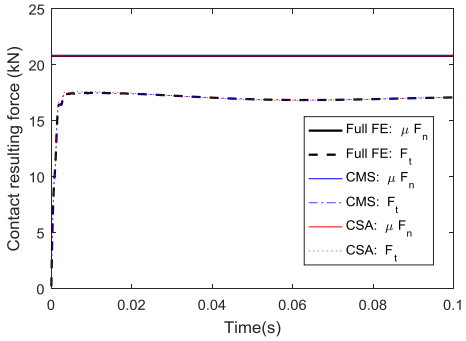

Figure 19 *Evolution of the tangential contact resulting force for and*

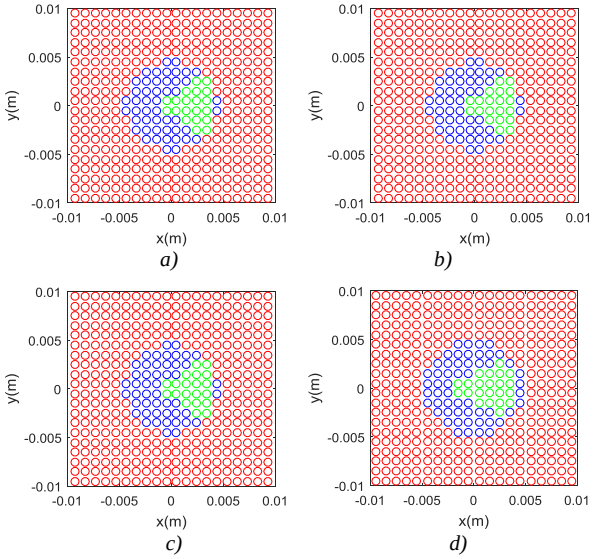

Figure 24 *Status of nodes in the potential contact zone: no contact zone (red), slip zone (blue) and stick zone (green) for* rad/m *and* μ = 0.3 *(a) Full FE. (b)CMS. (c)CSA. (d) CONTACT.*

4. Conclusions

In this paper, a method is proposed for the modeling of dynamic wheel/rail frictional rolling contact. A full finite element formulation around the stationary position in an Eulerian reference frame is derived with a fine discretization of the contact surface combined with unilateral and Coulomb friction laws with constant friction coefficient. Appropriate numerical techniques are used in order to solve the non linear discrete equations in quasi-static or dynamic conditions.

In order to reduce the computational effort, reduction strategies are proposed for both domains. The first technique uses a classical CMS reduced basis including free-interface normal modes and static attachments modes. A second technique consists in simply adding a residual static contact flexibility to the free-interface

normal modes when solving the frictional contact equations (contact static approximation).

The method is tested in the case of frictional rolling contact between two annular cylinders. The quasi-static results show a good agreement with the ones obtained with Kalker's CONTACT software. The free dynamic results show a good agreement in the slip zone and a difference in the stick zone.

Concerning the performance of the reduction strategies, as expected, the result obtained by the CMS basis gets closer to that obtained by the full model than that obtained by the CSA basis. However, both reduced basis provide a good agreement with the full model in the status of nodes in the potential contact zone.

This methodology is currently used in realistic wheel/rail rolling contact problems. It proved to be effective to simulate curve squeal characterized by large slips, high frequency dynamics and very fast evolutions in the contact zone.

* E-mail: j.lanigan@sheffield.ac.uk

Abstract: There are two options for testing the performance of rail vehicles in a low adhesion environment: laboratory work which is not representative of conditions in the field, and expensive track tests using fully instrumented modern vehicles. This paper presents a third option: low-cost track tests. We determined the minimum of equipment and resources needed to produce low adhesion and monitor the performance of rail vehicles when braking on it. We present the methodology that we have developed, and some initial results showing that using it we can generate a low adhesion scenario when braking from 10 mph.

Keywords: Wheel-rail interface; low adhesion; railhead contamination; friction; brake testing.

1. Introduction

A long-term challenge for the rail industry is that of low adhesion at the rail/wheel interface. This is caused by the presence of a third-body layer between the wheel and the rail that does not support high shear stresses. This can be formed from a variety of contaminants, including leaves, dust, and oxides of the rail [1-3]. In certain circumstances, typically involving small quantities of water, such contaminants can reduce the braking performance of trains. There are obvious safety concerns if trains cannot stop when required, so once low adhesion is identified, speed restrictions are imposed. This then has a large impact on both train operation and the associated customer experience. In the worst scenario, low adhesion can cause trains to pass a signal set to "danger" (a SPAD) and cause an accident.

Currently, there are several test methods for assessing adhesion in train-braking scenarios using smaller scale, laboratory based tribometers. This testing is very useful for furthering the understanding of the rail/wheel interface. However, some aspects of this type of testing do not accurately reflect the full-scale application. One tribometer used frequently is the twin disc type machine [4]. With this system, two railway grade steel discs are placed in contact with each other, with conditions designed to match the wheel/rail interface (such as speed, creepage or slip). It has been established that twin disc machines do not allow for the heat dissipation that would occur as a locomotive continues normal travel [5]. Full-scale rigs are another common method used in railway tribology. These more-accurately model certain aspects of full-scale behaviour; both components are fully representative of the application. However, the limitation of running at much lower speeds and to a limited distance cannot be mitigated. Employing a much lower speed could affect braking predictions; some such test rigs are limited to speeds of 1 m/s [6]. Despite some factors being absent during laboratory testing, the results typically found in academic literature are in-line with those found in the real application [5, 7]. Therefore, although laboratory testing is not a perfect model, it is still highly useful for this type of research.

To ensure safety, the railway industry requires full-scale field tests in representative conditions before proceeding with the implementation of new technology. The current brake test standard suggests three possible methods to treat the rail for assessing the performance of brakes under very low adhesion conditions (friction less than 0.06): liquid soap solution, wet kraft paper tape, and colza (rapeseed) oil [8]. For low adhesion (friction between 0.06 and 0.13) water sprays, possibly containing varying concentrations of detergents are recommended. The standard that specifies the minimum criteria for system acceptance/type approval of new wheel slide protection (WSP) systems only specifies the application of soapy water as a low adhesion simulant, although a range of "real world" lubricants are suggested to be used for producing test data for a hardware-in-the-loop simulator [8].

For assessing mitigation methods that involve application of material to the wheel/rail interface, it is important that the conditions that result in low adhesion are representative of real-low adhesion world conditions. Field brake tests are also typically very expensive and time consuming to arrange and carry out. There is a need for a simpler, cheaper approach that can be used for filtering of solutions prior to more representative testing. The aim of this work was to develop an easy to implement methodology that produced a realistic low adhesion simulation.

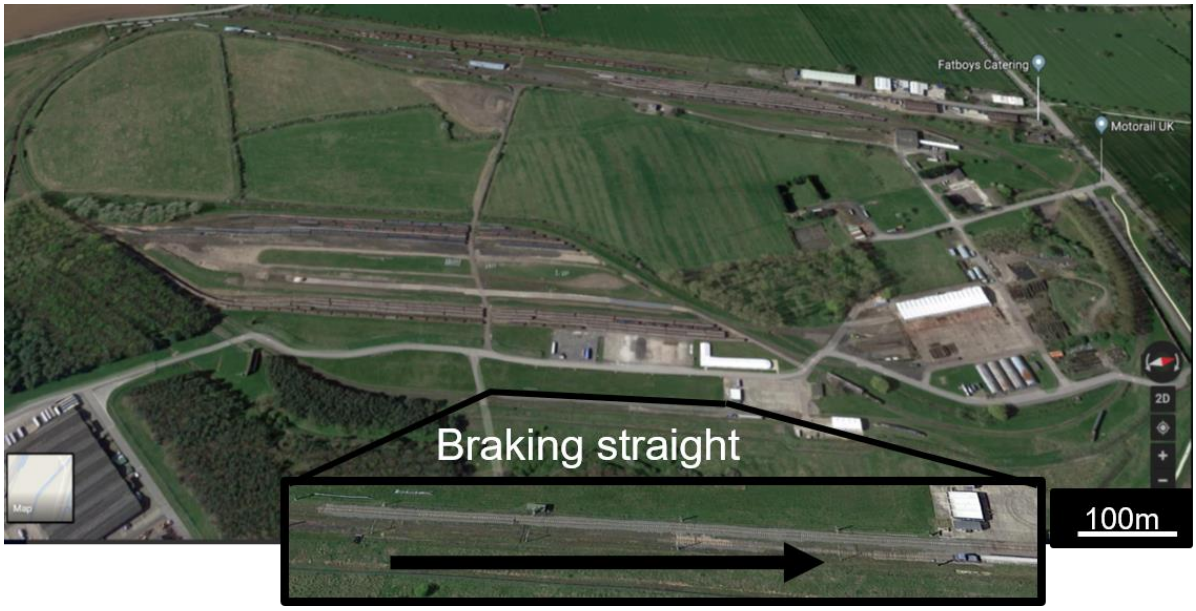
2. Methodology

2.1. Test Site

A lower-cost track test requires that the minimum of equipment be used. We identified a small test loop at the Quinton Rail Technology Centre at Long Marston in the

UK. We had access to a Class 117 DMU (see Figure 1a and Table 1 for full details) that we thought could be adapted to provide sufficient data. The track at Long Marston is a 2.4 km loop with a 300 m straight where the DMU can get up to a maximum speed of 25 mph. The track on the straight is representative of that seen in the UK (see Figure 1b).

Table 1 *Class 117 DMU details.*



Parameter	**Value**
Car length (m)	19.51
Width (m)	2.82
Height (m)	3.87
Axles	4
Brakes	Tread braked (2 per wheel)
Maximum speed (mph)	70 (30 on site)

2.2. Trackside measurements

Both a push tribometer and a pendulum tribometer were brought to the test site to measure railhead friction. The pendulum tribometer was severely affected by wind and the friction results from this were found to be unreliable because of this. The push tribometer gave results with less data spread than the pendulum tribometer, however only a slight difference was recorded between the friction measured on the low adhesion layer and on the railhead after wire-brush cleaning. We continued to use the push tribometer to measure railhead friction to compare with the DMU's braking performance.

The trackside measurements that were taken were stopping distances, and photographic evidence of track condition. Localized weather data was also collected, this allowed for comparison of all datasets against weather conditions. To check for any roughness evolution, at various intervals, moulds were taken of the railhead using a silicone polymer designed for replication of metal surfaces.

(a)

(b)

Figure 1 *(a) Satellite view of the Quinton Rail Technology Centre at Long Marston in Warwickshire (the braking zone is superimposed at a larger magnification) and (b) the Class 117 DMU used for testing.*

2.3. Onboard train measurements

The inability of trackside measurements to identify LA meant that the data from on-board measurements had to be used to infer friction levels from information on the performance on the DMU. The on-board system was found to be highly effective compared to the two trackside tribometers. On-board measurements of stopping time, location, and velocity were recorded using an accurate GPS system with a roof-mounted aerial to ensure the maximum number of satellites was used [9]. Videos of wheel behaviour were also taken for analysis after the tests. The location of the brake lever was recorded to determine when braking was demanded, though there was a variable, indeterminate delay before the system changed the pressure at the brake blocks.

2.4. Test procedure

Initially, the track was conditioned to ensure it was representative of normal rail. This conditioning consisted of 5 passes of the DMU around the track. Three methods for achieving low adhesion conditions were tested: a wet paper tape layer, a wet leaf layer, and water. The layers were laid down over a 3-metre stretch of line, using methods tailored to each contaminant:

- Light pressure was applied to the tape on the pre-wetted track. 5 DMU passes over the tape were used to condition the layer. As the DMU looped around the track, additional water was sprayed onto the tape/railhead
- For leaf layer creation, representative leaves gathered from a sycamore-rich location in Yorkshire were used. Wet leaves were affixed to the rail using adhesive tape that was kept away from the railhead to ensure that only leaf material was in the contact band. 5 DMU passes were used to condition the layer.
- To generate a wet rail, water was sprayed onto the track at a controlled rate. This took place just prior to the DMUs passage over the test area. No conditioning with the DMU was undertaken for this dataset; the water would have evaporated before testing.

Photographs of the railhead were frequently taken to monitor layer formation and railhead condition (see Figure 2 for leaf layer conditioning and post-test appearance). To remove railhead contaminants after the tests, a petrol-powered railhead scrubber was used. This device returns the line to a 'normal' condition through rotation of a metal brush against the railhead.

During a brake test, the protocol was as follows: video recording on the front wheel was started as the DMU approached the test area. The driver then accelerated the vehicle to 10 or 25 mph prior to entering the braking zone. The driver then applied the brake at a set position in the low adhesion (LA) zone. The DMU had no WSP, and there was inevitably human error introduced by the driver associated with the initiation and rate of braking.

2.5. Data analysis

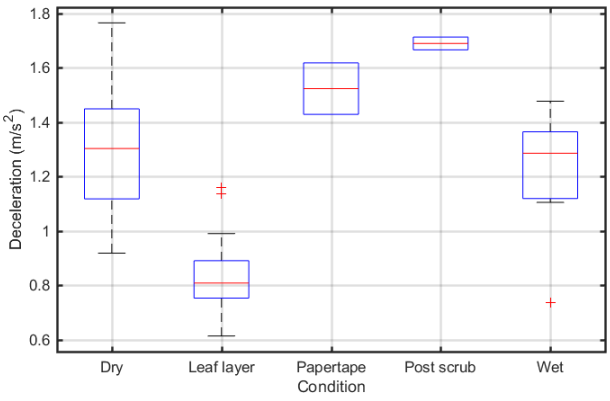
The velocity-time plots of raw data could be compared once the initial braking point had been determined. The plots were aligned either using the GPS position of the intended braking point, or using the time at which the brake lever was determined to have been moved. Initial attempts to align using the first noticeable deceleration were unsatisfactory. Dividing the initial train speed by the time for the train to stop gives an approximation of the deceleration.

Figure 2 *(a-c) Leaf layer generation and (d) post-test appearance.*

3. Results

3.1. DMU deceleration data

The results from 48 braking tests from 10 mph are shown in Figure 3, and 30 braking tests from 25 mph are shown in Figure 4. For each condition, the box encloses the first to third quartile of the data with the median marked. Points more than 1.5 times away from the median are designated "outliers" and marked separately, and the range of the other data points is indicated by the horizontal lines.



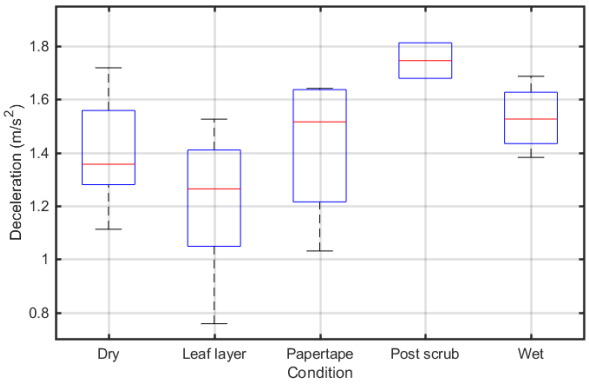


Figure 3 *DMU braked from 10 mph: deceleration by condition.*

When the DMU braked from 10 mph (Figure 3), leaf layers were shown to act effectively as LA simulants when compared with dry rail. The other LA simulants do not seem to have been effective, when compared to dry rail. However, the paper tape and water LA simulants were seen to affect the DMU's deceleration when compared to post-scrubbed railhead (after cleaning with the petrol-powered wire brush).

When the DMU braked from 25 mph (Figure 4), none of the low adhesion simulants had an effect on train deceleration; it was always similar to that for braking on dry rail. The leaf layer did affect deceleration when compared to post-scrubbed railhead.

Figure 5 shows the velocity history of runs on dry rail and leaf layers. It can be seen that the average time taken for the DMU to stop (reach a velocity of 0) on leaf layers is increased on average by 4 seconds, when compared with the dry rail. Also, note that the slope of the leaf layer plots do not increase significantly at the end, indicating that low adhesion continues throughout braking.

Figure 4 *DMU braked from 25 mph: deceleration by condition.*

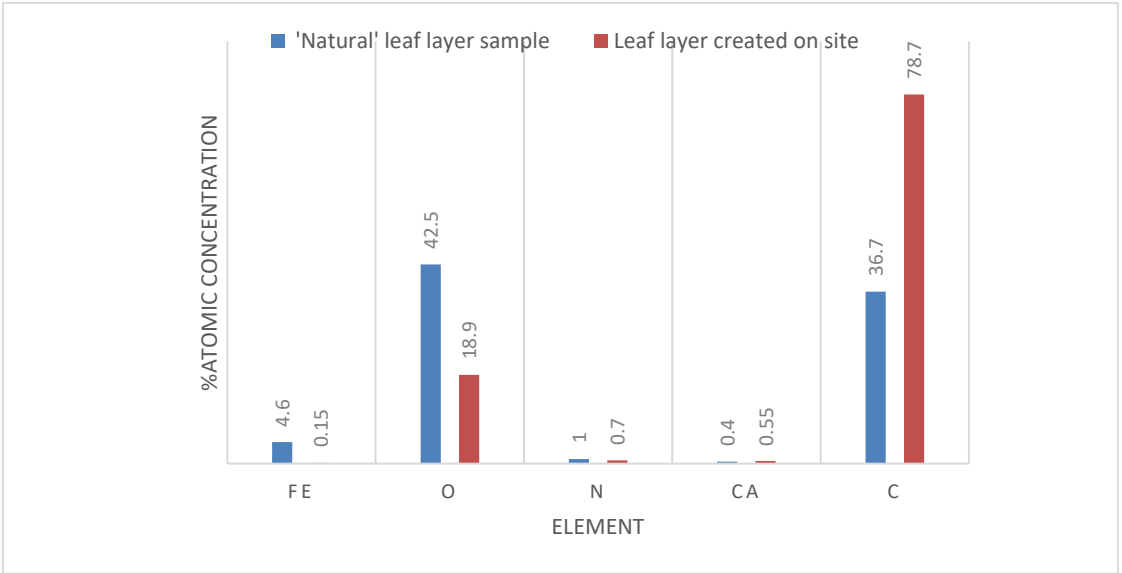

Figure 6 *XPS data from naturally formed vs created leaf layers.*

Figure 7 *Leaf layer transfer down the railhead (left), leaf layer as encountered in the field (right).*

3.2. Leaf layer formation

XPS samples were taken from the leaf layer created in the field, and compared to those found 'naturally' on UK rail. This is shown in Figure 6. The chemical composition of the two show a large amount of similarities. The main differences between the two are that the leaf layer created by hand had larger amounts of carbon and less amounts of oxygen in the sample. This is to be expected as the leaf layer has not been exposed to natural conditions (UV/heat/oxygen) for extended periods. The sample taken from UK train was from an infrequently used track, this allows it time to oxidize and lose carbon as carbon dioxide gas. Also, it is noted that the %atomic concentration of Fe is higher in the naturally found leaf layer, again this is to be expected as the layer has had a long time at the wheel/rail interface where enhanced iron incorporation into the leaf layer is expected. It is noted that sulphur is not detected in either sample, this is likely due to the low % atomic content in any layer generated and the tenacious nature of metallic soaps, such as Fe-S based ones. These combined factors would explain why no S is detected, but is likely present.

3.3. Leaf layer transfer down the railhead

Leaf layers were transferred and converted to a 'black layer', as far as 10 m down the railhead, from the area of application of the leaves (see Figure 7). A similar black layer is often associated with low adhesion in descriptions given by rail workers [10]. It has been described as a 'Teflon-like leaf layer' due to its colour, low shear strength, and difficulty to remove. The layer produced on the railhead matches the colouration, friction reducing properties, and tenacious nature, requiring scrubbing to fully remove. The transfer along the railhead is encouraging as it indicates that a 3 m 'artificial' leaf layer creates a longer length of low adhesion zone (as observed in Figure 7).

4. Discussion

The results presented above indicate that, using leaves, the test methodology is able to provide consistent and reproducible low adhesion when braking from 10 mph. A key finding is that the characteristics of the leaf layer that produced low adhesion are similar to those of the leaf layer seen on the network. This gives confidence that techniques that improve braking performance in these tests will also perform well on the network. The following subsections give more details.

4.1. Baseline: dry rail or scrubbed

The "post scrub" data in Figure 3 and Figure 4 consistently gave high decelerations. The post-scrubbed rail is regarded as a freshly cleaned railhead, and is not regarded as the baseline standard for the data sets. This is because railheads are not frequently petrol-scrubbed to cleanliness; it is considered that the dry rail of our tests is more representative of mainline rail. Such rail has natural rust layers and similar surface contaminants [11], so the lower deceleration compared to scrubbed rail was expected.

4.2. Water as an LA simulant

From Figure 3 and Figure 4 it can be seen that using our methodology, water alone has not behaved as a LA simulant; the relatively small amount of water required to compromise train braking was not supplied. When there are large amounts of water, such as heavy rainfall, both anecdotally and in the literature it is reported that low adhesion is not an issue [11]. After heavy rainfall a coefficient of friction of 0.2 on the railhead has been reported, while a low amount of water can result in a coefficient of friction of 0.015 [11]. We were not able to produce low adhesion when testing because, in order to ensure the rail was not dry when the train arrived, the high evaporation rate associated with warm and windy weather had to be countered by adding a large amount of water.

For future testing, if the wet-rail phenomenon is to be simulated, then using low volume pumps and hosing could be investigated. However, the costs and complexity of testing would rise significantly, and it would still be difficult to ensure consistency, because evaporation rates in the field are unpredictable.

4.3. Paper tape as an LA simulant

Paper tape was not seen to reduce deceleration in these tests. This was unexpected, as it has been successfully used in other industry testing [8]. The paper tape used was the type typically used for railhead testing. It could be the case that either defensive drying (as seen with the leaf layer), or local weather changes (causing increased evaporation) could have influenced deceleration data.

Further work to improve the effect of paper tape in this methodology was not undertaken because:

- although the surface layer has some chemical similarities to a real leaf layer in the field, it will never be completely representative of it
- the leaf layers produced in our tests were producing good results

It is typically used to create a surface seal, when activated by water. The gum tape is able to penetrate into some porous surfaces, however it is not known to what extent this would occur on the railhead [12]. Gummed paper tape is known to age differently when compared to other standard packing tapes, and is reported to have a resistance to variations in temperature and humidity, as supported by the manufacturer's information.

This resistance to temperature and humidity could be exerting an influence within the wheel/rail contact. It may influence the levels of water in the contact, and is also able to act as a physical barrier to tribo-chemical reactions such as metal-on-metal wearing that would typically take place at the wheel/rail interface. The function of the adhesive when typically employed (when not in use as a LA simulant) is to resist the relative motion of solid bodies (adherents) with which it is in contact. The mechanism of adhesion is reported to be broadly split into two: the molecular forces at the interfaces between the adhesive and the surface being one, with the other being the effect of strain. Although this is not looked at in depth it is noted that strains are caused by flow, changes in temperature and humidity, as well as by chemical reactions and external loads [13]. All these factors indicate that paper tape may not be the optimum low adhesion simulant.

4.4. Leaf-layers as an LA simulant

Figure 3 shows that for the 10 mph test speed, leaf layers are effective as LA simulants. As well as these results, video recording of the front wheels on the left side of the DMU showed that the wheel rapidly began to slide. The mechanism for this tribological effect is still to be fully established. Laboratory values for the coefficient of friction leaf layers have been shown to be between 0.01 - 0.04, indicating leaf layers reduce friction to a greater extent than water derived railhead debris [10]. A study into the characteristics of leaf layer contamination was undertaken on a full-scale wheel-on-rail test rig. It was established that the shear strength of the leaf layer was found to be inversely proportional to the moisture level. The thickness of the layer ranged was between 10-100 μm [14]. From this, it was concluded that the metal surface asperities of the wheel and rail will not be in contact in the presence of a leaf layer [10].

It is highly likely that additional components in leaves, such as naturally presence organometallic species could be playing a key role in the observed low adhesion. The main tribo-chemically relevant elements present in plants are copper (Cu), iron (Fe), manganese (Mn) and zinc (Zn) which are all crucial to plant photosynthesis [15]. It is also important to note that these elements are widely used as catalysts for chemical reactions, increasing the likelihood of 'black-layer' formation on the railhead by increasing the rate of surface reaction. This would appear to be the case as seen with these tests. Layer transfer was noted down the railhead, and the layer was observed to be distinctly different from the initial leaf layer affixed onto the railhead.

Furthermore, chemical species found in plants are particularly rich in Fe–S compounds. This is highly relevant to the tribology of the system, as Fe-S layers are encountered in many common tribology applications [16]. The prevalence of SAPS (sulphated ash and phosphorous species) in formulations for most modern lubricants makes it clearly to the wheel/rail interface, as a source of sulphur is present, as is iron. The key reason for this is that organic sulphides (such as those contained in plants) are the most widely used sulphur-containing extreme pressure (EP) additives[17]. EP additives are most effective at high pressures, such as those found at the wheel/rail interface, which can be in excess of 900 MPa [18, 19]. The load-carrying capacity of sulphur compounds has been shown to be directly related to their reactivity with nascent steel surfaces, which is an inevitable consequence of tribo-chemical wear processes. Molecular adsorption of sulphur when a critical temperature is reached is the mechanism of this effect[16]. Heat spikes in tribo-chemical contacts are known to be very high, and would meet this criteria. Wheel/rail interfaces can encounter heat spikes of up to 400 ° C [20]. This high temperature would provide the energy required to create thin films, rich in tribo-chemically relevant elements know to decrease friction at interfaces.

4.5. 25 mph testing

From Figure 4, it can be seen that there were no clear differences in results when the DMU was had a velocity of 25 mph. This was not in line with experimental expectations or data in the literature. Further tests at 25 mph will be carried out. Various factors could have affected the DMU at this speed. It is possible that the wheels may not be in contact with the leaf layers for a long enough time (at 25 mph the DMU travels 3 m in only 0.27 seconds) for an effective leaf layer to form. Typically, leaf layers on the network are longer than the layer created in the field. Again, increased defensive driving at the higher speed may have affected the deceleration rates, monitoring of the brake application does appear to indicated this is the case [21]. Further research will be undertaken to try to mitigate the impact of defensive driving when examining the data set, the use of the on-board GPS data will facilitate this [22].

4.6. Factors associated with field testing

Due to the nature of field testing, some factors are outside of laboratory type, high-level control:

- Wheel flats were detected during some of the testing; this is an expected side effect of compromised brake performance on a vehicle without wheel slide protection. However, once a wheel flat had formed, it could not be remedied

within the same testing week.

- The brake applications could not be automated, so relied on the behaviour of individual drivers and their reactions to the braking event. Defensive driving could be seen in some cases: when the driver was aware that leaf layers were deployed, sometimes there was a slower velocity when braking commenced. Enhanced data processing to mitigate these factors is described in Section 4.7 below.
- As is common with field testing, there were some inevitable changes in weather during testing, which are likely to influence results. Weather monitoring was used to cross-reference data points and check for any affects.
- The effect of train passage and railhead heating will have influenced the data to a certain degree. This is somewhat difficult to account for, as the leaf layer will act as a natural insulator (as will the paper tape) and alter the thermal activity at the interface. For the leaf layer, thermal effects could be involved in the formation of the 'black layer'.
- The wheelsets were not cleaned between runs. The action of the brake block on the running surface appeared effectively to control wheel surface contamination between braking events.
- The railhead was cleaned with a petrol scrubber to remove strongly adhered layers from either paper tape or leaf derived layers, when required. Conditioning runs would then be used to return the railhead to the 'dry' baseline standard.

4.7. Data processing

The time at which the DMU entered the LA zone was known from the GPS data. From the DMU's velocity/time plots, it was clear that the driver had not braked at exactly this time. Data processing using MATLAB was able to account for this to a certain extent, using voltage readings to indicate at which point and how severely the driver had deployed the brakes. The GPS and brake lever data had first to be synchronised.

However, the reaction of the brake system to deployment depended on how recently the brakes had been applied (the compressor took some time to restore pressure in the brake system). This delay could also result in reduced contact time between the DMU wheels and the leaf layer, to a greater extent that at the 10 mph testing. This is in addition to the factors that may affect 10 mph testing, such as defensive driving and weather fluctuations/wheel flats. Figure 6 shows that it took about 3 seconds for a significant drop in speed to occur. For future work, to avoid these uncertainties, it is proposed that deceleration is calculated from a speed at which it is certain that the brakes have been applied, e.g. from 9 mph for tests of braking from 10 mph.

5. Conclusions

Data from field testing confirms that a novel, cost effective methodology has been developed for assessing train-braking performance. Some results for braking from 10 mph:

- The 'dry rail' data set can be used as a baseline for comparison with the LA simulants
- Representative LA layers can be successfully created using leaves
- Optical inspection of the leaf layer confirmed formation of a 'black layer'

The other two LA simulants were not seen to generate this effect reliably. The test methodology, with respect to leaf layer generation, is therefore deemed suitable for assessing railhead cleaning and mitigation methods for resolving low adhesion problems.

DYNAMIC PERFORMANCE STUDY OF TRANSVERSE FRICTION-COUPLED WHEELSET

Han Leng[1], Huijie Wang [1], Lihui Ren [1,*]

[1] Institute of Rail Transit of Tongji University, Shanghai 201804, P.R China

[*] E-mail: renlihui@tongji.edu.cn

Abstract: According to the structure of limited slip differential for the friction-type, mechanical models of transverse friction-coupled wheelset (TFCW) were built. The curving performance and critical speed of TFCW, independently rotating wheelset (IRW) and rigid wheelset (RW) were investigated and compared through dynamic simulation, and the influence that friction torque has on the dynamic performance of TFCW was also analyzed. Research result shows that TFCW has good guiding performance on curve. During curve negotiation, dynamic parameters of TFCW including lateral wheel force, lateral wheelset force, derailment coefficient, wheel load reduction rate and longitudinal creep force lie between the values of IRW and RW. The nonlinear critical speed of TFCW is lower than that of RW. Within a certain range, the larger the friction torque value is, the closer the curving performance of TFCW is to that of RW. However, friction torque makes little influence on critical speed. Therefore, TFCW is similar to RW in both guiding performance and critical speed, and has a good curving performance.

Keywords: Transverse friction-coupled wheelset; Dynamic performance; Independently rotating wheelset; Rigid wheelset

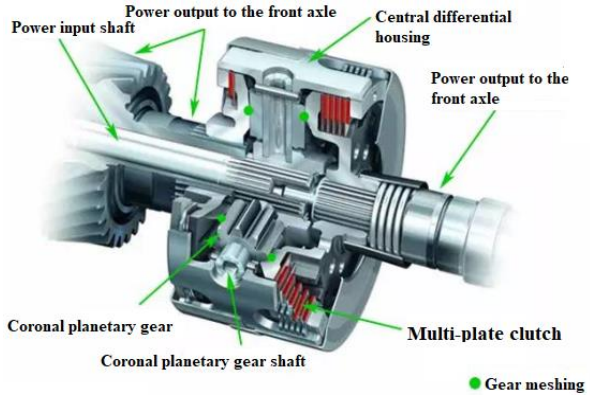
1. Introduction

As a new type of urban rail transit, modern trams have many advantages, such as environmental protection and comfortable operation, which have been accepted by many cities in China. Low-floor vehicles are adapted to facilitate passengers boarding, and in order to achieve it, various new technologies such as IRW, longitudinal coupled wheelset (LCW) and TFCW are applied.

The IRW refers to the wheelset of two free rotating wheels connected with one axle. When the left and right wheels are no longer rotating at the same speed, the axle is made into a crankshaft. Compared with traditional RW, the IRW lacks longitudinal creep torque so that the running performance to the centre decline in the straight track, leading to flange contact. Besides, it can only be guided by flange on curves, which results in serious wear of the flange and even the derailment accident.

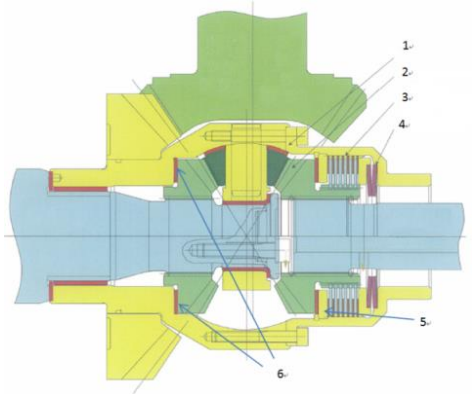
In order to improve the guiding ability of IRW, LCW, transverse elastic damping-coupled wheelset and TFCW emerge as the times require. The LCW means that the front and rear wheels of a bogie are coupled by mechanical transmission, so that the speed of the front and rear wheels tend to be the same. Wang Huan and other authors studied the guiding mechanism of the bogies with LCW, compared the curving performance of LCW, RW and IRW from the wheel/rail creep force produced by LCW and proved that the LCW has certain guiding ability [1-2].

The transverse elastic damping-coupled wheelset is the IRW with two wheels connected by elastic and damping elements. Ahmed first carried out the study of transverse stability and curving performance of the elastic damping-coupled wheelset, and analyzed the influence of the coupling torsional stiffness on the hunting critical speed [3-4]. Zhang Liping's eigenvalue method was used to analyze the transverse stability of the elastic damping-coupled wheelset system. The influence of torsional stiffness and torsional damping on the dynamic performance was studied. It is shown that the selection of proper torsional damping and torsional stiffness can improve the hunting critical speed of the vehicle [5]. When there are only damping in the transverse elastic damping-coupled wheelset, it becomes damping coupled wheelsets. Chi Maoru and other authors studied the dynamic performance of the magneto-rheological damping-coupled wheelset and analyzed the effect of coupling damping on the hunting motion stability and the curving performance. It was found that the appropriate coupling degree could coordinate the contradiction between the hunting motion stability and the curving performance [6-7].



In the studies above, the elastic damping elements between left and right wheels were linearized, and the study on the dynamic performance of the wheelset with friction coupling is still a blank. Compared with the elastic damping-coupled wheelset such as magneto-rheological damping-coupled wheelset, the friction-coupled wheelset is easier to realize in structure.

In this paper, the TFCW is taken as the research object. According to the structure of TFCW, the mechanical model was established. The dynamic properties of TFCW, RW and IRW were compared. The influence of friction torque on the guiding ability and critical speed of the TFCW was discussed.



2. The structure of TFCW

2.1. Friction disc type limited slip differential

The friction disc type limited slip differential is based on ordinary gear differential, and some friction discs are added to greatly increase the internal friction torque of the differential (Fig. 1). The edge of the pressure ring is machined with a V-groove that matches with the V-shaped wedge surface on the planetary gear shaft. There is also a certain gap after the match, which allows the pressure ring to move slightly in the axial direction，and facilitates the pressing of the friction element. At the same time, there is a key on the outer surface of the pressure ring, which matches with the keyway on the differential housing, so that the orientation and torque transferring between the two components can be well realized. During the process of power transferring, the V-groove receives the circumferential force that the planetary gear provides and then converts it into pressing force to the friction element in the limited slip differential, forming an internal friction torque between the friction elements to achieve an ideal limited slip performance [8]. A lug is machined on the outer edge of each inner friction disc in the clutch and matches with a keyway on the differential housing to realize the radial orientation and power transferring. A lot of grooves are engraved on the surface of the friction discs to increase the friction coefficient and the friction torque effectively. The Belleville spring is embedded in the differential housing as the outer end of the elastic element and inserted between the friction discs, which also serves as a friction ruffing pair [9].

(a) Diagram of real product

(b) Assembly diagram

Figure 1*Friction disc type limited slip differential*

1. Differential housing 2. Differential gear set 3.Multi-plate clutch 4. Belleville spring 5. Pressure ring 6. Gasket

The axial normal pressure of friction in the friction disc type limited slip differential comes from three aspects: (a) the normal pressure of the Belleville spring; (b) the axial force, generated by the bevel gear transmission when the planetary gears rotate; (c) the axial component force caused by the left and right sides of the V-shaped surface when the planetary gear carrier transmits the driving torque [9].

2.2. TFCW

The left and right wheels of TFCW are coupled by the friction disc type limited slip differential described above (Fig. 2). The torque from drive shaft is transmitted to the left and right wheels via the differential to drive the wheels forward. It is well known that the self-guiding ability of conventional RW mainly depends on the longitudinal creep force of wheel and rail [10-13]. The existence of coupling friction torque can generate the longitudinal creep force that IRW lacks, so the self-guiding ability of TFCW will get significant improvement compared with that of IRW theoretically.

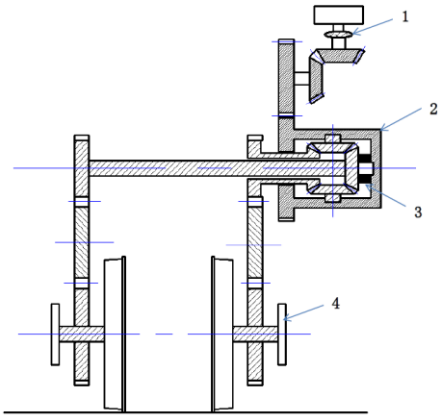


Figure 2*Structure of TFCW*

1. Drive gear meshing 2. Differential 3.Clutch 4. Brake disc

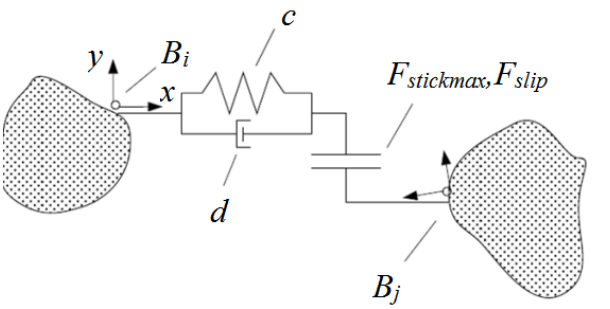
In the friction disc type limited slip differential, the relationship between the internal friction torque and the torque of the left and right wheels is:

$$T = M_2 - M_1 \quad (1)$$

where M_1 is the torque of half-shaft with faster speed, M_2 is the torque of half-shaft with lower speed, T is the internal friction torque of the differential.

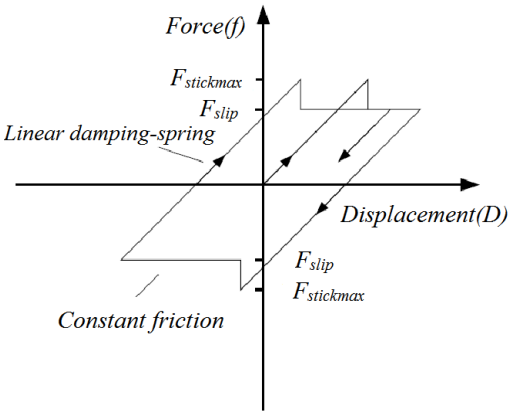
When TFCW-bogie runs on a straight line or a large radius curve, the torque difference between the left and right wheels is smaller than the internal friction torque of the differential, and the differential is now in the locked state, similar to RW; when the radius of the curve is small enough, the rotational moment difference will be large enough to overcome the friction torque, and the planetary gears start to rotate along the half-shaft gear with slow rotation speed besides revolution motion, i.e. the differential operates. With differential operation, the left and right wheels can rotate independently, and the wheelset behaves like IRW.

3. Mechanical model of TFCW



It is known from the tribological theory that friction coefficient has two characteristics: the static friction coefficient is greater than the dynamic friction coefficient, and friction coefficient decreases with the increase of the relative sliding velocity within a certain range. The former may lead to stick-slip phenomenon in the system, while the latter results in the negative damping effect of the system. Because the mechanism of the negative slope between the friction force and relative sliding velocity and the physical model are the same as that of the stick-slip mechanism, the negative slope mechanism and the stick-slip mechanism are regarded as the same kind in many studies, that is, the mechanism of the stick-slip is also called the negative slope mechanism [14].

In the structure of TFCW, it is common to occur sliding motion because there is an elastic degree of freedom between two sliding surfaces. Its notable feature is that the trend of friction force varies as sawtooth, which is usually caused by the fact that coefficient of static friction is greater than the that of dynamic friction. The results observed by Stribeck in 1992 show that when overcoming the static friction, the dynamic friction force decreases with the increase of relative velocity in the range of low relative sliding velocity, which is a continuous function of the velocity [15].



The friction pairs of TFCW have two states of stick and slip, and the mechanical model are shown in Fig. 3. In this model, the spring-damping element is combined with the friction element. When the torque of the left and right wheels is smaller than the preset value $m_{stick(\max)}$, the force element is equivalent to linear spring-damping system. When the torque is greater than the preset value, the relative torque becomes a constant m_{slip}. The calculation formula is as follows:

$$torque = \begin{cases} c * \varphi + d * \dot{\varphi}, |torque| \le m_{stick(\max)} \\ m_{slip} * sign(\dot{\varphi}),\ sign(\dot{\varphi}^{(n)}) = sign(\dot{\varphi}^{(n-1)}) \end{cases} \quad (2)$$

In the model shown in Fig. 3, the parameters of the force element are mainly adhesive torque M_{stick} (i.e. the internal friction torque of the differential), sliding torque M_{slip}, torsion stiffness c and damping d. According to the differential structure above, the adhesion torque M_{stick} depends on the normal pressure of the Belleville spring, the axial force from the drive gear and the axial component of the driving torque from the planetary gears. Referring to the parameters of a low-floor tram gearbox, the adhesion torque M_{stick}=1500Nm was obtained according to the friction torque and transmission ratio of the differential. The sliding torque $M_{slip} = 1250Nm$ was obtained according to the relationship between the adhesive torque M_{stick} and the ratio of dynamic and static friction coefficients; the stiffness $c = 8E5\ N/m$ and the transmission ratio were obtained according to the stiffness of the transmission rod and transmission ratio; the damping d is related to the stiffness c, which has smaller influence on the friction effect, so a small value is suitable($d = 1000\ Ns/m$).

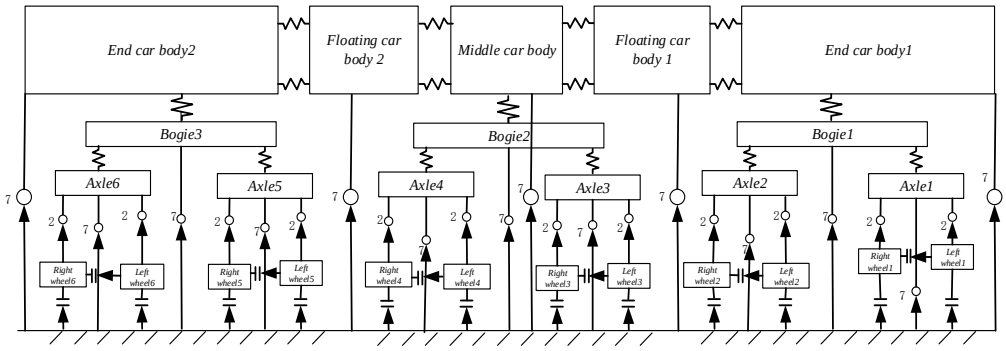
4. Dynamic performance of TFCW

4.1. Dynamic model of Five-module low-floor tram

In the Simpack software, a dynamic model of a five -module tram was established, including 5 car bodies, 3 bogies, 6 axles of IRWs and 12 independent wheels. The topology structure is shown in Fig. 4.

In order to compare the dynamic performance of TFCW with RW and IRW, three bogie schemes were adopted: (a)the TFCW-bogies (the Stick-slip friction model shown in Fig. 3 was adopted as the force element between left and right wheels); (b) the RW-bogies; (c) the IRW-bogies.



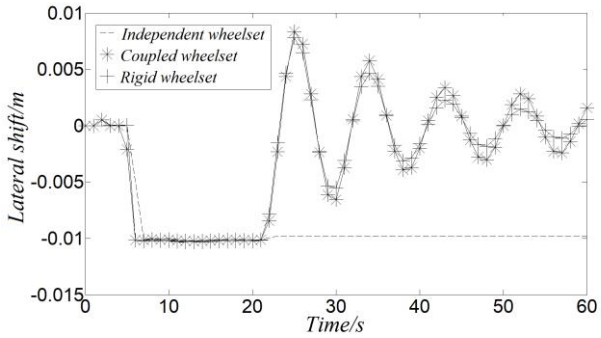


Figure 4*Topology structure of five-module low-floor tram*

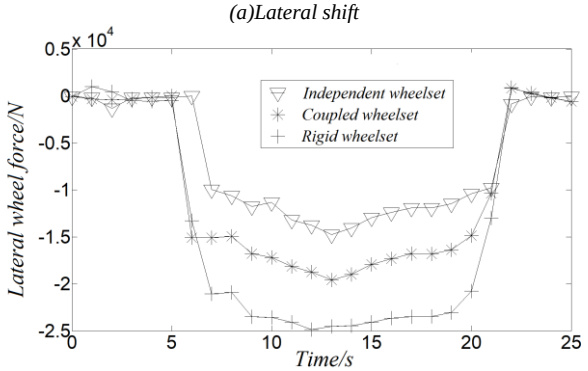
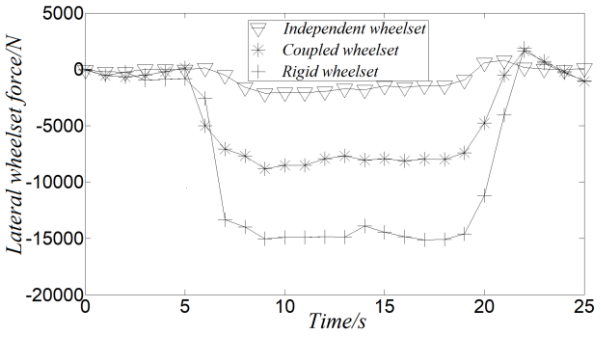
4.2. Dynamic performance



4.2.1. Curving performance

Fig. 5 shows the curves of lateral shift, lateral wheel force, lateral wheelset force, derailment coefficient, wheel load reduction rate and longitudinal creep force in the first axle of TFCW-bogie, RW-bogie and IRW-bogie when the vehicle passes a curve with radius of 50m. As shown in Fig. 5(a), when the lateral shift occurs, the steady-state position of IRW is maintained at the distance of 10mm to the centre of the track, indicating that the ability to restoring on tangent track of the IRW is very poor, while the lateral shifts of TFCW and RW are gradually attenuated and converge to 0, indicating that these two types of wheelset have better automatic centralization ability. Fig. 5(b) shows that the lateral wheel force of TFCW is 15kN, while IRW is 13kN and RW is 21kN respectively, that is, the lateral wheel force of TFCW is between that of IRW and RW; Similarly, the lateral wheelset force, derailment coefficient and, wheel load reduction rate and longitudinal creep force of TFCW are all between those of IRW and RW as is seen from Fig. 5(c)~(f). On curves of other radius, dynamic performance of the three types of wheelset has similar trend. What is worth mentioning is that



It is worth mentioning in Fig. 5(f) that when TFCW-bogie enters transition curve, the value of the longitudinal creep force reaches a peak (point A). This indicates that the torque of wheels caused by longitudinal creep force torque increases gradually when TFCW-bogie enters transition curve and the differential starts to operate when it is greater than $m_{stick(\max)}$. And the value drops sharply to a constant (from point B to point C) after that, which means the left and right wheels rotate relatively until the bogie runs out of circular curve and smaller longitudinal creep force is needed to balance sliding friction torque m_{slip}.

(f) Longitudinal creep force

Figure 5*Curving performance on curve of R50m*

In Fig. 6, the trends of friction torque of Axle1, 3 and 5 (the first axle of the each TFCW-bogie) are similar to what is explained above, indicating that the differentials have worked and left and right wheels' relative rotation occurs on curve negotiation. The friction torque of Axle2, 4 and 6 (the second axle of each TFCW-bogie) reaches 1500Nm when the train enters transition curve, and then decreases rapidly to less than 1250N, indicating that the differentials in these three TFCWs do not work under this condition.

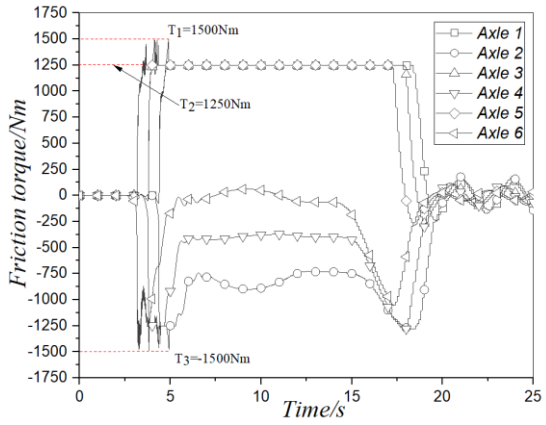

Figure 6*Friction torque of TFCW-bogie*

4.2.2. Critical speed

For TFCW, it is difficult to linearize the nonlinear link in the system, so the nonlinear critical speed was calculated. The method is to let the tram pass a short section of unsmoothed track firstly， and then run on ideal smooth track. By observing the lateral shift curve of the vehicle system, the critical speed can be calculated.

Fig. 7 shows the lateral shift of the first axle of TFCW-bogie. When the speed is 83km/h, the lateral shift decreases over time and reaches 0 after 10 seconds, indicating that the system is stable. When the speed is 84km/h, the lateral shift value oscillates around its equilibrium position, and the system is in critical state. Therefore, the nonlinear critical speed of TFCW-bogie vehicle is 83km/h. Similarly, the nonlinear critical speed of RW vehicle is 86km/h. Thus, the nonlinear critical speed of TFCW is close to that of RW.

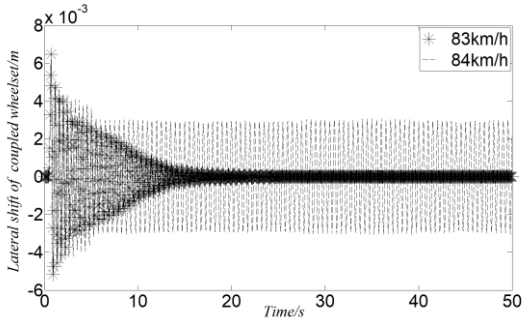

Figure 7*Lateral shift of transverse friction-coupled wheelset*

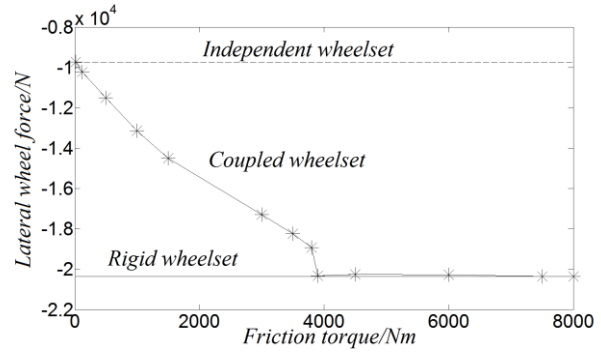
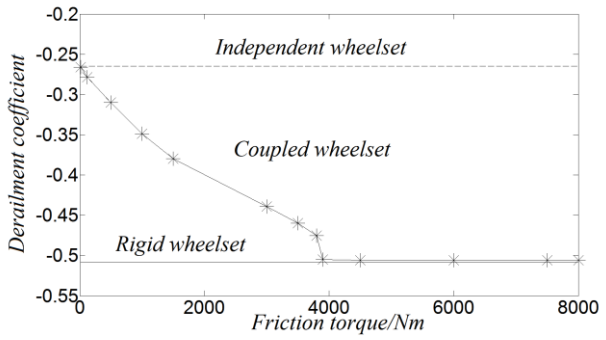
5. Influence of friction torque on dynamic performance



5.1. Influence on curving performance

According to the analysis of the structure of TFCW, the friction torque in the differential is the decisive factor determining the dynamic performance of TFCW. If the value is too small, the left and right wheels are easy to rotate relatively to each other like IRW, and the automatic centralization ability is very poor. If the value is too large, differential will be kept in locked state, and cannot optimize the curving performance.



The influence of friction torque on vehicle dynamic performance was analysed in the following study. The initial value of friction torque T was set to 1500Nm, and the radius of the curve was 25m.

Fig. 8(a) shows that the steady-state value of the lateral wheel force of IRW is about 9.7kN when the vehicle passes the curve of R25m, while RW is about 21kN. When $T = 1500Nm$, the lateral wheel force of TFCW is 14.5kN which is between that of IRW and RW. With the decrease of friction torque, the absolute value of the lateral wheel force of TFCW is linearly decreased and gradually approaches that of IRW. Conversely, it gradually approaches that of RW. When $T = 3900Nm$, inflection point appears in the curve. When $T \geq 3900Nm$, the lateral wheel force of TFCW almost remains unchanged and is equal to that of RW.

According to Fig. 8(b), the steady-state value of derailment coefficient of the IRW is about 0.252, while RW is about 0.51. When $T = 1500Nm$, the derailment coefficient of TFCW is 0.38, which is between that of IRW and RW. Similarly, as the value of T decreases, the absolute value of the derailment coefficient of TFCW decreases gradually and approaches that of the IRW. Conversely, it is close to that of RW. When $T \geq 3900Nm$, the derailment coefficient of TFCW is almost equal to that of RW.

(a)Influence of friction torque on lateral wheel force

(b)Influence of friction torque on derailment coefficient

Figure 8*Influence of friction torque on curving performance*

According to the analysis above, it is known that when the friction torque is very small, the curving performance of TFCW is similar to that of IRW. As the value increases, the parameters of curving performance of TFCW increase gradually and are almost unchanged when the value of T is above 3900Nm, which are close to those of RW.

5.2. Influence on critical speed

As shown in Fig. 9, with the increase of friction torque, the nonlinear critical speed of the TFCW-bogie vehicle is always around 83km/h, which is close to that of RW-bogie vehicle. Therefore, the influence of friction torque on critical speed is not significant.

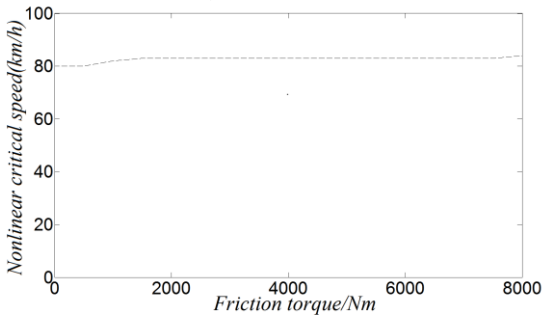


Figure 9*Influence of friction torque on critical speed*

6. Conclusions

The values of dynamic parameters of TFCW including lateral wheel force, lateral wheelset force, derailment coefficient and wheel load reduction rate are slightly higher than those of IRW and smaller than those of RW, that is, the curving performance of TFCW is between IRW and RW. When the tram runs on a straight line, TFCW can automatically returns to the centre of the track, and the guiding performance is close to RW. Therefore, TFCW not only maintains good curving performance of the IRW, but also has the self-guiding ability of RW.

The value of friction torque in TFCW has a significant effect on the curving performance, but the effect on critical speed is not obvious. When the friction torque is small, the curving performance of TFCW is similar to IRW, but it lacks self-guiding ability. With the increase of the friction torque, the curving performance of TFCW gradually approaches RW, and when the friction torque increases to a certain critical value, the curving performance will remain unchanged, which is close to the RW.

Compared with magneto-rheological and other elastic damping-coupled wheelsets, easier to realize in structure is the biggest advantage of TFCW, therefore, it has high value for application.

Abstract: Some railway managers and practitioners fear that introducing premium rail materials will have a detrimental effect on the wheels of trains that use them. A review of relevant investigations across all scales in the laboratory, and in the field, has been carried out. This showed that, as rail hardness increases, its wear, and overall system wear reduces. Wheel wear does increase with increasing rail hardness, but only for wheels running on rails that are relatively softer.

Varying work hardening, and the related issue of test duration have been identified as gaps in the reporting of several of these tests.

Keywords: Wheel materials; rail materials; hardness effects; wear rates; work hardening; wear mechanisms; laser cladding.

1. Introduction

The wheel/rail interface is critical in determining both the operating performance of a railway network and its safety. Maintaining this contact interface can be extremely expensive: it is unlike any other tribological interface. Not only does it support loads that mean that the yield stress in the materials are exceeded locally, it is also open, which means that it is influenced by environmental conditions and other contaminants. Over the past few decades, demand for improved performance of trains has led to higher accelerations, speeds, and braking forces which have increased the stresses in the wheel/rail interface [1]. The changing loads in the contact have a large effect on the rail and wheel damage mechanisms, such as wear and rolling contact fatigue (RCF), both of which are driven by the contact stresses and relative sliding in the wheel/rail contact.

Materials can be chosen to try to control the damage occurring at the interface, and increasingly durable wheel and rail materials have been developed [2, 3]. Ideally materials would be selected to give the optimal system response. In the UK, however, the rails and wheel have different owners, both of whom want what is best for their assets. While track access charges are intended to recompense the infrastructure manager for the wear and tear caused by each vehicle, and are a function of the vehicle's mass and suspension characteristics (its 'track-friendliness'), they are not sufficiently granular to account for all changes in wheel characteristics. Any changes to material properties on either side of the interface, especially those involving the introduction of harder, more durable, materials, are viewed with suspicion by those responsible for the opposite side of the interface; they are fearful that such changes may lead to their component wearing more. It is critical, therefore, that the effect of changing the wheel or rail material on both its own wear and that of the opposing surface is completely understood.

There are a number of methods that can be used to modify the properties of the wheel or rail: a different material can be used; a material can be heat treated; or a layer of harder, more durable, material can be clad or coated onto the wheel or rail. Of course, in all of these it is not the hardness alone that is being altered. The microstructure is also different in different steel grades and is also altered by heat treatment. It is therefore important to not only understand how hardness affects wear, but also to consider the effect of microstructural features on wear.

The aim of this paper was to draw together three fields of work:

1. Work carried out to look at the effect of changing rail or wheel hardness on the wear of the opposing material to identify the common trends and to identify gaps in available data or knowledge of the prevalent mechanisms of wear.
2. To try to fill some of the identified gaps, data from recent work on laser cladding of rail using materials with a wide range of hardness and microstructures. In this work, detailed information on both wheel and rail materials was available from which it was possible to enhance understanding of the mechanisms occurring.
3. Results from testing on premium rail materials, which was carried out over a range of interface conditions to see if the trends hold as slip (and the contact patch frictional work, $T\gamma$) is changed.

This work was carried out as part of the International Collaborative Research Initiative (ICRI) initiative which aims to bring together wheel/rail interface researchers from across the world to collate data and knowledge to try to solve some of the common problems that are faced.

2. Review of Extant Work on Hardness Effects

2.1. Rail and Wheel Wear Data

Before the year 2000, very few of the studies on wear of wheel and rail materials had focused on the effects of changing hardness. Research up to that date was summarized in a report by Burstow [4]. This highlighted the conclusion drawn from one review that "the belief that an increase in the hardness of the rail, while giving a decrease in the rail wear rate, will give an increase in wheel wear is not generally felt to be justified" [5]. The effect on wheel wear of increasing rail hardness, however, varied across all the studies reviewed. In a British Rail twin disc study on different Pearlitic rail steels it was found that wheel wear was independent of rail hardness. A British Rail full-scale test program, however, showed that wheel wear reduced with rail hardness increases [6]. This lack of a consistent pattern was backed up by research carried out in other laboratories (for example [7] and [8]). However, while no clear trend in wheel wear emerged, it was noted that rail hardness increases almost always led to a drop in overall system wear.

In the studies mentioned above, the wheel steel was not changed, and it was generally softer than the vaious rail materials used. Markov [9] took the opposite approach and kept rail disc hardness the same and increased the wheel disc hardness in twin disc tests. Testing was carried out over a wide range of conditions, but the conclusions were that increasing wheel hardness decreased wheel wear and increased rail wear. The overall wear appeared to be independent of wheel hardness. Sato et al. [10] ran twin disc tests keeping the wheel material constant, and changed rail hardness, but all the rail materials had the same or lower hardness than the wheel material. Two rail microstructures were tested, Pearlitic and Bainitic. It was found that the rail wear reduced with increasing rail hardness. The wheel wear did not change a great deal as the Pearlitic rail hardness increased, although for the wheel wear against a Bainitic rail there was a slight increase.

Steele and Reiff [11] reported on some field trials from which similar trends to those described above were seen. These were used to propose trends for wheel, rail, and whole system wear depending on the ratio of rail to wheel hardness. This will be discussed later.

Most regions of the world now have a set of standard rail and wheel material grades with a range of properties, refined over many years in an effort to improve wear and RCF performance. Those established for Europe are shown in Table 1 along with two Japanese materials (CrB1400 rail steel and CM64 wheel steel). The European rail steels are Pearlitic and consist of R260, the stock material used in the UK, and the heat-treated ("head-hardened") grades R350HT and R400HT (details in EN 13674-1). The Japanese CrB1400 is a Bainitic steel. Bainitic rail steels were developed as the maximum hardness that could be achieved by heat treating Pearlitic rail had been reached [12]; to reach higher levels different microstructures were required. Wheel material ER8 is most commonly used on multiple units, ER7 on freight cars and the Japanese CM64 is found mainly on high-speed vehicles.

After the year 2000, there have been a number of studies, both small and full-scale, to investigate the wear when the different standard grades of wheel and rail material are run against each other. A wide-ranging full-scale study was carried out very recently by Heyder & Maedler [1]. They considered the standard European materials as well as the Japanese steels shown in Table 1 for comparison. As shown in Figure 1, overall system wear reduced below that for R260 versus ER7 if a harder rail steel (R350HT) was used. This harder rail reduced rail wear with a simultaneous reduction in wheel wear to almost the same order of magnitude. Higher strength wheel materials reduced wheel wear, but did not give a simultaneous reduction in rail wear.

Table 1 *European (E)/Japanese (J) Wheel and Rail Steels (adapted from [1])*

Application	Identifier	Tensile Strength /MPa
Rail	R260 (E)	≥880
	R350HT (E)	≥1175
	R400HT (E)	≥1280
	CrB1400 (J)	≥1400
Wheel	ER7 (E)	820 - 940
	ER8 (E)	860 - 980
	C64M (J)	940 - 1100

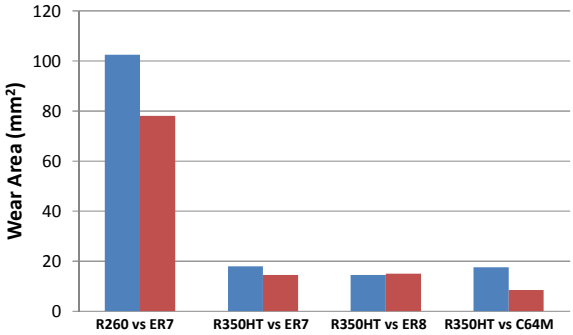

Figure 1 *Wheel and Rail Wear from Full-Scale Laboratory Tests (blue – rail; red – wheel) (adapted from [1])*

Stock et al. [13] have seen similar trends in full-scale laboratory tests on ER7 wheel material against R260, R350HT, and R400HT rail. This consistency gives confidence that these trends are real, but in neither case was any examination of the mechanisms leading to the effects made.

Twin disc testing carried out within the EC funded *Innotrack* project [14] using combinations of ER7, ER8

wheel steels, and R260, R35HT and R400HT rail steels, showed that increasing rail hardness decreased rail wear. Tests were run for either 5,000 or 15,000 cycles. It was found that after 5,000 cycles the wear rate of the wheels rose when running against harder rails, but after 15,000 it reduced. Clearly the wheel material was work hardening which was affecting the wear rate. The effect of work hardening has also been noted in full-scale tests carried out by Jin et al. [15] using standard Chinese wheel and rail materials. A rail hardness increase from 250 HB to 380 HB reduced the wear rate of the rail gauge corner by half and gave a slight wear reduction for the rail head. The wear rate of the wheel flange increased with an increase in the rail hardness when tested for 1.26 million cycles. After 2.1 million cycles, the wear rate of wheel flange decreased below that of the wheel run against the softer rail.

It should be noted that, in the studies referred to so far, hardness was not measured after the tests, so relationships have been assessed based on pre-test bulk values.

Work hardening effects on Pearlitic versus Bainitic rail steels have been examined in detail by Lee & Polycarpou [12]. This was in response to field testing of both materials that showed, contrary to expectations, that the Pearlitic rail wore less than the Bainitic material despite having a lower bulk hardness (for details see [16]). Vickers micro-indentation testing of rail sections revealed that the Pearlitic steel had work hardened far more than the Bainitic material to the point where the surface hardness was higher. Tyfour et al. [17] also noted considerable work hardening in a Pearlitic rail steel. Run against W8A wheel material, surface hardness values 2.5 times higher than the bulk hardness were measured.

2.2. Discussion of Extant Knowledge

2.2.1. Wheel/Rail Interface System Wear

As mentioned earlier, the field studies reported by Steel & Reiff [11] led to the proposed relationships between wheel, rail, and whole system wear, and the ratio of rail to wheel hardness (see Figure 2). The explanation proposed for the trends shown is based around the material dictating the contact patch size. In the left side (rail/wheel hardness ratio $\leq$ 1), the rail is softer compared to the wheel. The rail, therefore determines the size of the contact patch. With increasing rail hardness, the rail wear will fall, and as the contact patch size decreases it is hypothesised that the wheel wear will increase. However, the system wear decreases. On the right hand side (rail/wheel hardness ratio $\geq$ 1) if the wheel material is kept constant the size of the contact patch remains constant and independent of the rail grade. This would lead to constant wheel wear as shown. The rail wear decreases as rail hardness is increasing and system wear also decreases. Of course this is all based on bulk hardness measurements, which, as shown earlier can be misleading.

Most of the work reviewed in earlier sections falls to the right hand side of the 1:1 ratio, i.e. rail is harder than wheel. On the whole the work follows the trend proposed: which states as rail hardness increases and wheel material remains relatively constant, rail and system wear decrease and wheel wear remains constant. There may be some exceptions to this, which may result from microstructural features varying. The work carried out by Markov [9] and Sato et al. [10] involved rail hardness to wheel hardness ratios of less than one and therefore it falls on the left hand side of the chart. Again, their relationships approximately follow those proposed by Steel & Reiff [11].

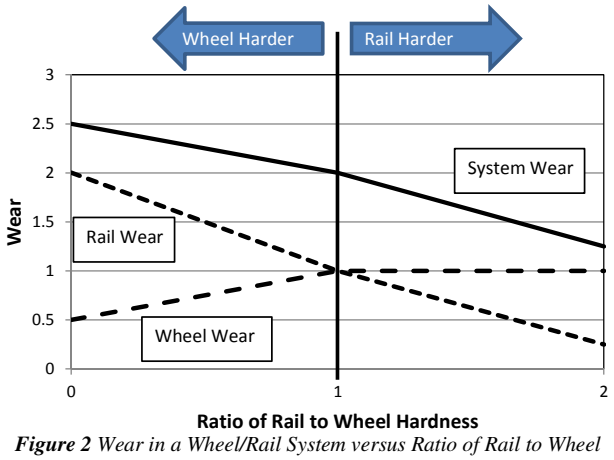

Figure 2 *Wear in a Wheel/Rail System versus Ratio of Rail to Wheel Hardness [11]*

2.2.2. Work Hardening and Steady State Wear

The observations made on work hardening show how it can vary considerably between materials. Typically all that is measured is the bulk hardness of the materials but clearly indicates that when making comparisons, hardness values after work hardening measured just below the surface need to be considered. Analysis of how the corresponding wheel material work hardens may help reveal more about the underlaying mechanisms behind wheel and rail wear. As mentioned previously, in most cases this kind of information is not always captured in some experiments.

Another issue is that, in most studies, only one contact condition (usually relatively mild) has been assessed. At more severe conditions, temperatures will rise and may reach a level that can affect the material hardness [18, 19]. The effects of this temperature rise would not necessarily be apparent after the test when test specimens have cooled to room temperature, but it would have affected the measured wear rates and microstructure.

Aside from highlighting the need for measurement of work hardening effects, the outcomes described in the earlier sections with different wear rates for longer tests, raises an issue regarding appropriate test length and in deciding how many cycles to run-in order to achieve a steady-state wear regime. This is an issue discussed at length in a recent review by Blau [20]. The only way to really know is to stop the tests frequently to assess wear rate rather than simply measuring material loss at the end of tests. This was done in the Tyfour et al. study [17] and adopted by Lewis et al [21].It was found in

[21] that wear reached steady state at around 20,000 cycles, although this number varies according to materials used, test conditions, and scales. It is impossible to know in most studies reviewed whether steady state was reached or not, as intermediate wear rates are rarely determined. As highlighted in [21] steady state is not always reached thorough out the duration of the test. This means making assessments of whether wheel wear has increased or decreased is less straight-forward. A "standard" approach to wear testing has now been proposed, also as part of the ICRI initiative [22], but it will be a while before this can take effect.

2.2.3. Possible Wear Mechanisms

In the work reviewed, few potential mechanisms were proposed to explain the observations made, except for in the work by Marich & Curcio [8]: it was hypothesized that a reduction in wear of the rail would reduce the amount of wear debris within the interface which may lead to less abrasive wear on the wheel. This highlights another deficiency in almost all wheel/rail interface studies: wear debris analysis is rarely included.

The work by Vasic [14] also showed that with water in the contact there was a clear decrease in wheel wear for harder rails, unlike for the dry case. This may back up the theory that reducing wear debris (in this case by flushing it out with water) affects wheel wear rate.

It is well known that a ratchetting mechanism is the main cause of wear/crack initiation in wheels and rail. In harder materials, however, this is less likely to occur. If a shakedown plot is considered (see Figure 3), it can be seen that the harder rail materials (with higher values of k) will be less likely to fall in the ratchetting regime (it can be assumed that all materials will exhibit the same levels of friction for a given slip level).

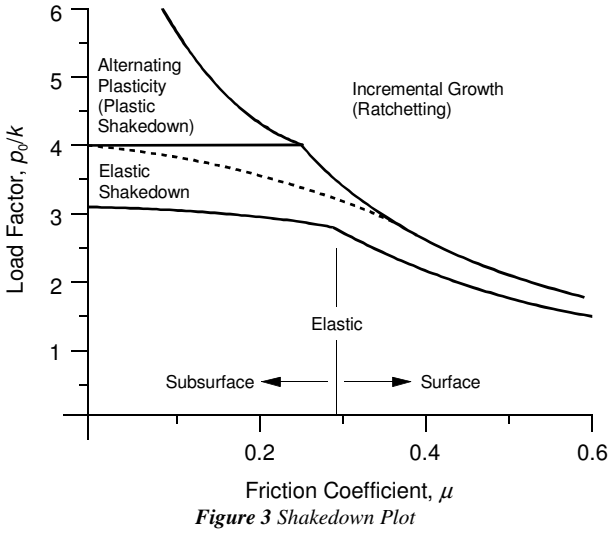

***Figure 3** Shakedown Plot*

Another issue that should be analysed is the third body layer formed in the contact between wheel and rail. These have been studied in previous twin disc testing by encapsulating discs post-test and then sectioning them [23]. An example of a wheel third-body layer is shown in Figure 4. The third-body layer formed may well vary with different materials which could affect wear rate.

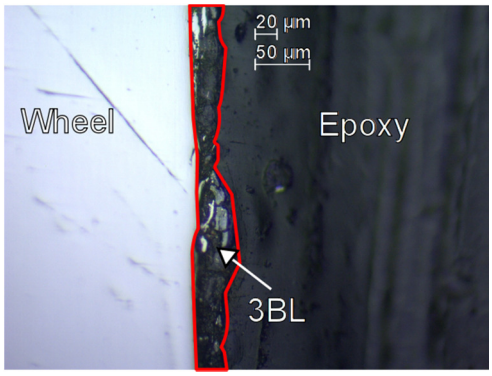

***Figure 4** Third-Body Layer on a Wheel Disc*

Another issue that may affect the relative wear is whether the wheel or rail disc is driving. In most twin disc tests the rail disc brakes and the wheel disc drives. However, it is not clear, in all the work reviewed, which disc is taking which role.

2.3. Knowledge Gaps

Tests across all scales in the laboratory and in the field have shown similar trends and follow the model proposed by Steele & Reiff [11] based on the rail to wheel hardness ratio (see Figure 2). If the rail is softer than the wheel, then rail wear decreases with increasing rail hardness, and wheel wear increases. If the rail is harder than the wheel, then again rail wear decreases with increasing rail hardness, but wheel wear remains constant. In both cases, however, as rail hardness increases overall system wear reduces. This information will help allay fears held by those that may think that introduction of premium rail or wheel materials will have a detrimental effect on the opposing material.

In order to help understand why the trends seen in wear rate have occurred, the following need to be considered in future work:

- Closer analysis of material on both sides of the contact is needed post-test to understand the prevalent mechanisms.
- Wear rate needs to be more closely monitored to check that steady state wear has been achieved.
- Hardness must be quantified post-test to characterise work hardening.
- Material properties must be considered, other than hardness, as it may not be this alone that dictates wear.
- A wide range of contact conditions should be used so the effect of temperature can be evaluated.

3. Laser Cladding of Rail

Recent testing on hard clad layers [24-25] has shown big improvements in wear performance over unclad rail and has given the opportunity to investigate hardness effects in greater detail, especially those of the opposing wheel material.

3.1. Analysis of Clad Rail Specimens

In a very recent twin disc trial (1% slip, 1500 MPa and 400 rpm) of a wide range of clad layers (of varying hardness and microstructure) [21] it was reaffirmed that a rail hardness increase (note that this is post-test hardness to take account of work hardening in the clad layer) reduces rail wear (see Figure 5a) and it was also clearly shown that overall system (wheel added to rail) wear decreases in most cases (see Figure 5b). The wheel wear was virtually independent of hardness (as shown in Figure 5c).

Sub-surface examination of the clad layers indicated that deformation was too small to measure (see example of Stellite 12 shown in Figure 6, compared to the R260 grade baseline). It is clear that very little ratchetting was occurring and that the likely wear mechanisms were mild adhesion or abrasion. This is confirmed by examination of the surface images shown in Figure 6, where it is apparent that the R260 grade material exhibits classic evidence of ratchetting behaviour, whereas the Stellite 12 is showing mild scoring and some evidence of adhesion.

Rail wear versus time for all the cladding materials is shown in Figure 7. It is clear that in many cases steady-state wear has been achieved. While in some it has not, those seem to be the less promising materials.

3.2. Analysis of Wheel Specimens

The key opportunity from this work was that the wheel discs could also be analysed in the hope that this would reveal more about the mechanisms behind the wear rate observations. Wheel discs run against a range of clad layers were sectioned, mounted, polished and etched before hardness profiles were taken using a Vickers micro-indentation technique and microstructural analysis was undertaken.

Figure 8 shows the pre and post-test wheel surface hardness data plotted against the post-test rail surface hardness values. It can be seen that the final wheel hardness value is completely independent of the rail hardness. Further detail in Figure 9 shows the change of hardness with depth. This reveals that the hardness changes in the same way for each disc as the depth increases.

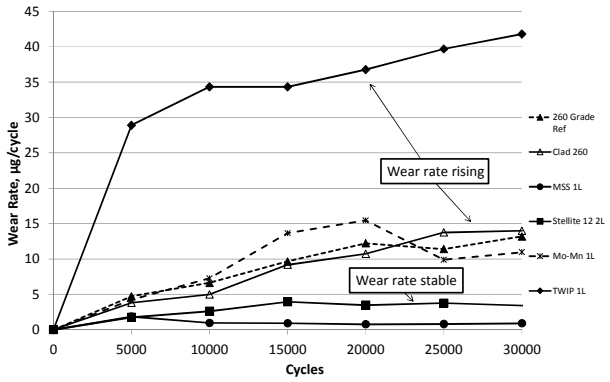

Figure 7 *Wear Rates of Clad Layers during Twin Disc Tests (replotted from [21])*

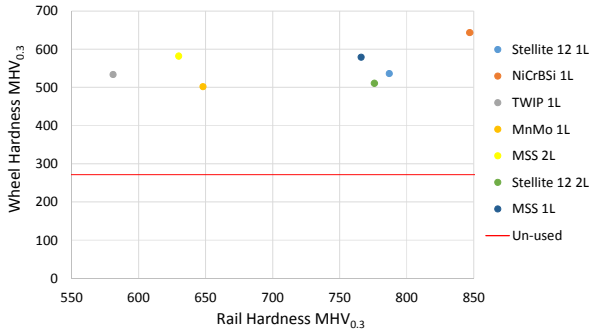

Figure 8 *Wheel versus Rail Post-Test Surface Hardness*

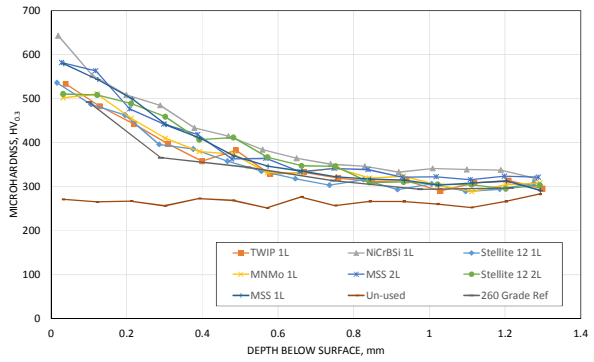

Figure 9 *Hardness Change with Depth for Wheel Discs*

3.3. Damage Mechanisms

The wheel wear rates determined when running against clad rail discs at one contact condition showed that hardening and wear of the wheel material is completely independent of rail material properties. Wear must therefore be driven by the contact stress and be a result of a ratchetting mechanism rather than abrasion or adhesion.

Where there is evidence of abrasive wear (on wheel and rail) it is driven by third body abrasion rather than two body, i.e., it has resulted from wear debris

Looking at the roughness data in Figure 10, it can be seen that, as the rail surface hardens, there is a step change in roughness evolution. For harder materials, hardness reduces during the test. This suggests a form of abrasive wear is occurring that is relatively mild, acting to "polish" the surface. For the softer rails, the roughness is increasing quite significantly which suggests either more severe abrasion is occurring, or adhesion. Wheel material follows a similar trend, but we know that the wheel wear rate is not changing much as rail hardness varies (see Figure 5c). This suggests that roughness is simply following that of the rail rather than it being influenced by the wheel wear mechanism.

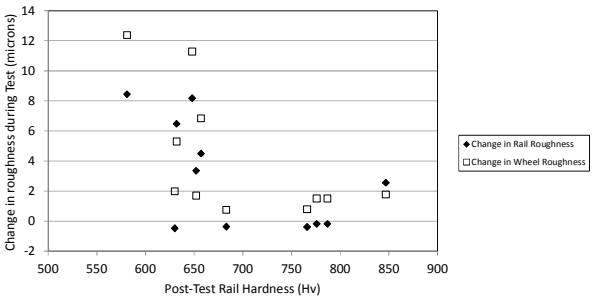

Figure 10 *Roughness Change for Wheel and Clad Rails versus Post-Test Rail Hardness*

4. Wear of Premium Rail

A series of twin disc tests has been carried out across a range of conditions for a number of premium rail materials (350HT, and two bespoke alloys, A and B) [26]. Slip values of 1, 10 and 20% were used with a contact pressure of 1500 MPa and a nominal rotational speed of 400 rpm.

The rail and wheel wear results plotted against rail bulk hardness are shown in Figures 11 and 12. All previous work looking at hardness effects had been carried out at a single set of conditions and usually using a relatively low slip value. At higher slip, temperature rises and could potentially act to soften the material making relationships harder to draw out. Here hot hardness during the test becomes a more useful indicator of performance. The results at 1% slip reflect those seen in previous studies (e.g. [13]). In this mild regime, wear mechanisms such as oxidation, adhesion, and abrasion would dominate [18, 27, 28]. These reduce with material hardness so the wear rates are as would be expected. At 10% slip the wear rates are relatively independent of hardness. This also ties up with previous observations. In this regime wear is driven by contact pressure and here this was constant. As slip increases to 20%, wear again is reduced by material hardness. In this regime, resistance to high temperatures is key and clearly the harder materials perform better. It is evident that the clad layer gives a much better performance at the more extreme conditions than the premium rail materials.

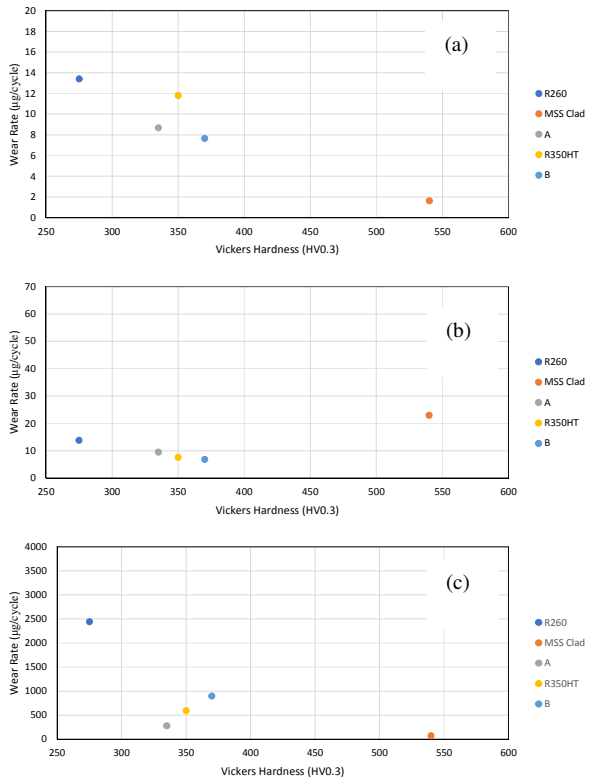

Figure 11 *Rail Wear Rates versus Bulk Rail Final Hardness: (a) 1% Slip; (b) 10% Slip; (c) 20% Slip [REF?]*

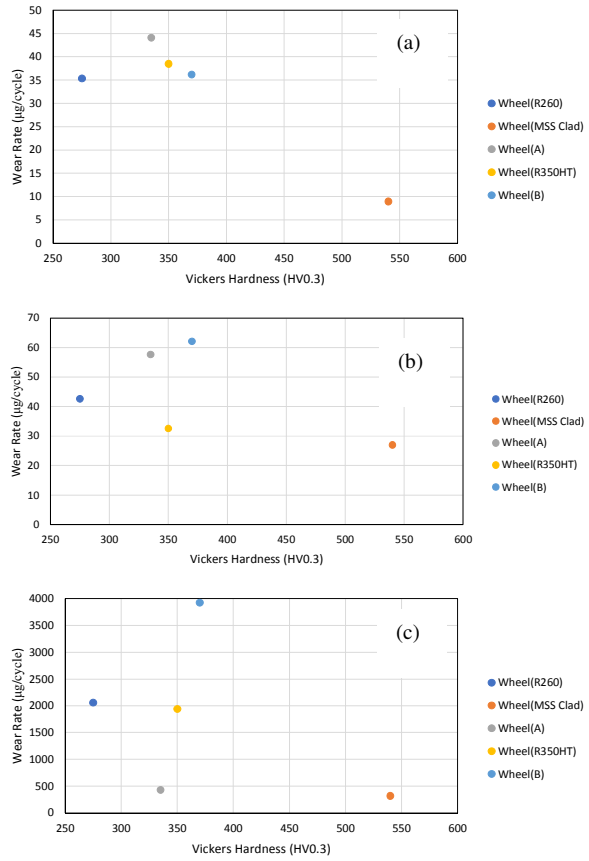

Figure 12 *Wheel Wear Rates versus Bulk Rail Final Hardness: (a) 1% Slip; (b) 10% Slip; (c) 20% Slip [REF?]*

The wheel wear rates do not follow the previous trends observed. And fluctuate a lot more. The harder clad layer certainly does not act to increase wheel wear though.

The post-test hardness values have been measured as recommended in the earlier review (Section 2). For these tests, relationships were harder to pull out though. There could be a number of reasons for this. The standard and premium rail materials work harden a lot more than the clad layers, where very little flow of material was observed (see Figure 6). The rate of work hardening would need to be characterized and taken into account to establish the effect on wear with time to provide a better comparison. At high slip, temperatures will be high enough to affect the hardness of some of the materials [18]. As mentioned above, hot hardness would be a more useful indicator than the final hardness of a cooled disc. Further analysis can be done in the future to investigate these and establish if the trends from previous work at low slip really do extend to different conditions based on in-situ hardness or post-test hardness.

5. Conclusions

A review of existing work on the effects of rail and wheel hardness on the opposing material was carried out. There was a consensus on wear trends, but little in the way of explanation or proposed mechanisms. A series of gaps were identified: a lack of knowledge of materials of both sides on contacts in a test; a lack of clarity over whether tests reached steady state wear; no post-test hardness data; a limited number of contact conditions tested.

Analysis of studies on laser-clad layers and premium rails was then carried out. The work on clad layers showed that, as rail hardness increased, wheel wear rates stayed constant, consistent with previous results. However, it was shown that wheel hardness was constant, which indicates that the wear of wheels is dictated only by the properties of the wheel. Different wheel materials need to be tested to see the effect of their properties.

The work on premium rails was carried out at different slip values. At the higher slip (20%), the resulting temperatures could have been high enough to soften the materials. This implies that hot hardness during tests is more important than post-test hardness. Plots of wear relationships against bulk rail hardness showed expected trends at low slip:

- At 10% slip, rail wear was independent of hardness. Previous work has shown that in this regime wear is largely driven by contact stress, this was constant across all the tests and therefore it explains the wear trend seen.
- At 20% slip, the harder rails again wore less. The harder materials were clearly more resistant to temperature changes.

This work has confirmed the results of previous work, but provided some important new data on wear trends at

different contact conditions that will be helpful in making material choices for points on the track where more extreme wheel/rail interface conditions can be expected. Clad layers seem to perform particularly well.

Abstract: A Full-Scale wheel/rail Test Facitlity (FSTF), originally built and operated by British Rail Research has been re-commissioned for testing at The University of Sheffield. Its control system has been completely rebuilt and modernised and a variety of structural and component improvements made. This paper describes the rigs capabilities and recent overhauls to the instrumentation, hydraulic and control systems before outlining some case studies that illustrate its novel use across a range of applications: These show how adaptable the rig is and the wide range of issues related to wheel/rail management that can be investigated using actual track and vehicle components.

Keywords: Contact mechanics, full-scale rail-wheel; experimentation; laser cladding; sanding.

1. Introduction

1.1 History of the FSTF

The Full-Scale wheel/rail Test Facitlity (FSTF) was built between 1970–1972 by the British Rail Research & Development Division and the first documented evidence of its construction and use is dated September 1972 [1]. Here it is described how the rig was built out of necessity in order to provide a lab based true full-scale representation of the wheel/rail contact which none of the small scale testers at the time offered. The primary design function of the new rig was to enable the assessment of the frictional performance of certain materials under controlled rolling/sliding conditions facilitated by an actual wheel/rail contact. The mode of operation of the rig at the time was somewhat different to how it operates at the time of writing this paper (described in more detail below). Whereas currently there is a pulley and chain assembly which is used to control the slip of the wheel (fitted in 2003 [2]), in 1972 there was a lever arm attached to the wheel which was pulled on by an actuator causing the wheel to rotate. The rotation of the wheel then caused the rail to move underneath it causing a reaction force as the movement of the rail was resisted by a second actuator. The resistance force would increase to a certain amount by which point it exceeded the adhesive/tractive forces in the contact and the wheel would slip. The friction coefficient would then be calculated using the maximum reaction force at the instance of slip and the vertical force on the wheel. At the time of writing the same actuators are still present but they have different functions. There is no longer a lever arm attached to the wheel but a chain and pulley which is pulled on by an actuator to provide continuous slipping of the wheel as the rail is traversed using the same actuator which previously tried to restrict the movement of the rail. The major advantage of this new mode of operation is that traction/friction can be continuously measured throughout a single test cycle where as in 1972 only a single friction value could be obtained per equivalent test cycle. McEwen & Colbourne [3] used an alternative method for measuring the friction/traction at the contact, before the introduction of a chain drive system and load cell in 2003. The method utilised was to simultaneously monitor the lateral creep forces, from, and the vertical load, on, the negatively yawed wheel as it traversed the rail. However, since the modifications in 2003, traction is now measured by applying a certain creep to the wheel and continuously monitoring the force required to maintain this level of creep divided by the vertical load on the wheel.

Interestingly in the first reported tests on the FSTF the effect of different sand rates on adhesion recovery was investigated [1]. Exactly 40 years later similar experiments were performed using the FSTF and reported in [4]. Although the two tests used different methods to simulate low adhesion conditions, strikingly similar results were seen. In both tests it was shown that only low amounts of sand are needed to restore adhesion from low levels. It was also shown in both accounts that there is a point whereby increasing amounts of sand have little effect on the rate of adhesion recovery. Later Cooper [5] looked at the effect of sand particle size on the efficacy of sand on restoring adhesion. Sand particle size was not found to have a major influence on friction levels although particles of less than 53 microns were slightly less effective. This showed that the performance of sand was not seriously reduced by crushing action as it enters the wheel/rail contact. While it was at British Rail Research the rig was also used for the study of: rail lubricants [3,6,7], rail corrugation [8], wheel and rail wear [9,10,11,12] and leaf contamination [13].

In 2003 [2] the rig was modified as part of the Whole

Life Rail project with the biggest changes being the introduction of a chain drive system, with load cell connected to allow a specified creepage to be applied to the wheel and the measurement of tangential tractive forces. Balance weights were also added to the wheel in order to keep the chain under tension while the wheel was raised clear of the rail.

1.2. Mode of Operation

The FSTF has four axes which are illustrated in Figure 1 :

1. Vertical axis. This exerts a downward load on the wheel at the beginning of a cycle and also raises the wheel at the end of each cycle. This axis is controlled exclusively under load control using a 180 kN load cell.
2. Rail axis. A horizontal axis which controls the linier rail position. This axis can be controlled in either load or position control via a magnetostrictive position sensor and load cell. For general operation this axis is operated in position control only.
3. Slip axis. A horizontal axis which imparts wheel slip by pulling on the chain drive system. The slip axis actuator is mounted on the slider bed on which the rail is mounted. Thus displacement of the slip axis is relative to the displacement of the rail axis. This axis can be controlled in either load or position control via a load cell and an LVDT position sensor. For general operation this axis is operated in position control only. Before a test cycle commences the slip axis is pre-tensioned to remove any slack and fully extend the chain. The amount of pre-load can be adjusted for friction conditions and is dependent on the level of vertical load applied to the wheel.
4. Jockey wheel (see Figure 2). A fourth axis which allows control of the lateral position of the wheel. The wheel is free to float axially in its bearings and will thus either roll in or out of flange contact with the rail if un-restricted. The pivot arm effectively replaces the axle and opposite wheel of a full wheel-set by imparting lateral locating forces to the wheel. This axis is fitted with a load cell and can monitor the lateral forces needed to keep the wheel in a certain lateral position on the rail.

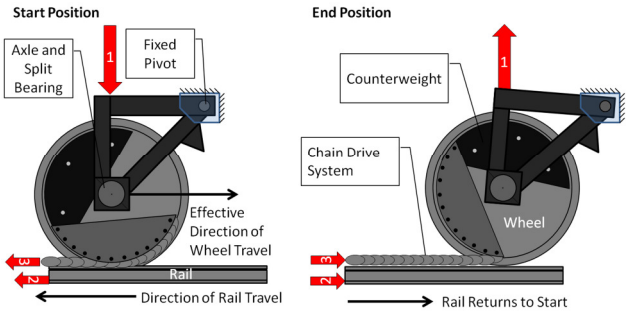

Figure 1 *Working schematic of the FSTF.*

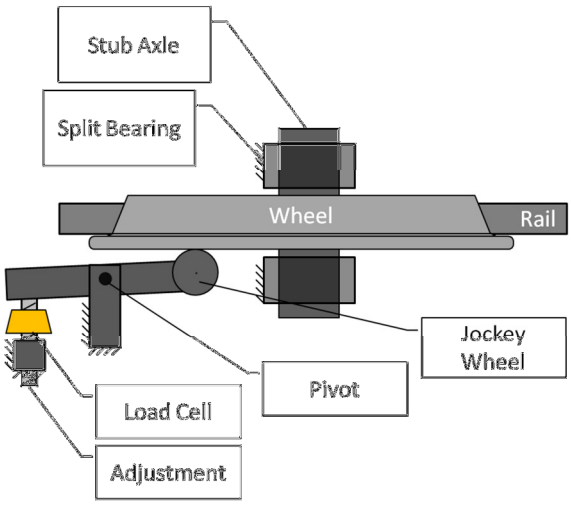

Figure 2 *Schematic of Jockey Wheel Axis.*

2. Re-Commissioning of the Rig

In 2011 the rig was acquired by the Department of Mechanical Engineering at The University of Sheffield in the same guise as it was after the modifications in 2003. The original control hardware which consisted of a combination of 1970s British Rail hydraulic 19" control racks, a DAQ system from the late 1990s and a Kelsey hydraulic servo controller was replaced with a modern DAQ system and a PLC. A PC running Labview was also added giving a modern user interface. The first tests on the newly named University of Sheffield Full-Scale Test Facility (UoS FSTF) were undertaken as part of RSSB project T979 "Performance and Installation Criteria for Sanding Systems" and looked into the effect of various set-up parameters on the efficacy of a train borne sanding system [4,14]. After these tests, further updates were made to the rig between 2012–2013 including a fully interlocked safety barrier to allow unsupervised running, a hydraulic oil run-off and scavenge system, a new rail clamping arrangement to allow the rig to support a taller 60-E2 profiled rail (compared to the original 113A profile) and further fine tuning to the PID control system to reduce the cycle time of the machine to approximately 11 seconds.

3. Technical Specification

The following is a list of the rigs capabilities with references to Figure 1 andFigure *2*:

- Vertical wheel axis (1) – 180 kN load capacity no displacement control
- Horizontal rail axis (2) – 600 mm of travel, maximum speed 100 mm/s
- Horizontal slip axis (3) – 100 kN load capacity with 110 mm of travel, maximum speed 100 mm/s
- Lateral jockey wheel axis 100 kN load capacity, optional hydraulic movement of this axis
- Data from all axis are recorded to a CSV file and the download rate can be adjusted

Slip is imparted to the wheel by operating the slip axis (3) in either load or displacement control. When operating the axis in displacement control then load will be recorded and when operated in load control then it is

displacement which is monitored and recorded. Creep curves can be generated when operating the axis in either mode. Slip is defined by the following:

$$slip\ (\%) = \frac{Velocity\ of\ slip\ axis\ (3)}{Velocity\ of\ Rail\ Axis\ (2)} \qquad (1)$$

4. Application Case Studies

A number of case studies illustrating the rigs use since re-commissioning are outlined below. These are at various stages of development from well established (i.e., those involving wear and friction measurement) to those that are in progress and finally those that are just at the pilot study stage. All have aspects of novelty as will be highlighted.

4.1. Top of Rail Friction Modifier Retentivity and Creep Curve Generation

4.1.1. *Test Overview*

Friction Modifiers (FM) are applied to the top of the rail to control friction and have many benefits, including reducing rolling contact fatigue and wear. Two types of friction modifiers (FM-A and FM-B) retention propertes were tested as part of a study to develop benchmark tests for users to be able to understand and rank product behaviour and to compare small-scale and full-scale test approaches [15]. Retentivity is defined as how long the beneficial effects of the applied product can be seen. Creep curves were also generated for the products. These curves are used as inputs in design simulations and define the performance characteristics of the product. FM-A is a water-based polymer suspension which dries and mixes with oxides on top of the rail to provide a solid layer between the wheel and rail. FM-B is an oil-based product which stays wet. Wet and dry oxide creep curves were also generated. Test conditions used are shown in Table 1.

Table 1 *Summary of Test Conditions.*

Variable	Conditions tested	
	Retentivity	Creep Curves
Contact pressure (MPa)	1200	1200
Rail velocity (mm/s)	40	40
Slip (%)	2	0.5-5
Number of Cycles	800	5
Applied amounts (g)	11.8	11.8

4.1.2 *Results*

Figure 3 ***Evolution of Traction Coefficient against Cycles*** shows how the traction coefficient evolves with number of cycles. FM-A initially provides a very low traction coefficient that rapidly increases before plateauing and increasing at a slow rate. FM-B initially provides a higher traction coefficient but increases steadily at a slower rate than FM-A. At the end of the test, both FM's are providing the same traction coefficient. Further testing to analyse what happens beyond this point is needed as the traction coefficient has not reached "dry" condition 0.5-0.6). This means that there is still product present in the interface.

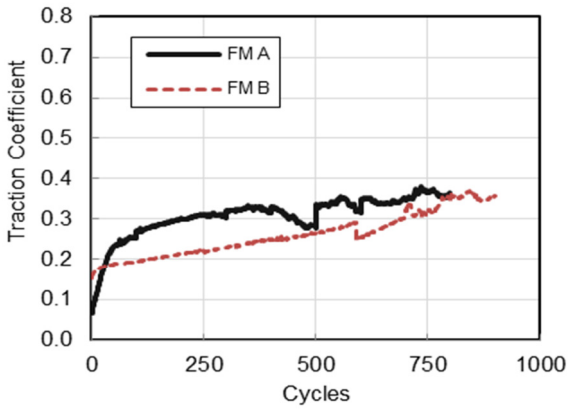

Figure 3 *Evolution of Traction Coefficient against Cycles.*

Figure 4 ***Creep Curves.*** shows creep curves for the different conditions tested. During the dry and dry oxide tests, it was found that the slip actuator was not able to provide the higher levels of slip. This leads to the cluster of data points near the 2% slip level. FM-A (dry) and FM-B have similar low slip characteristics, but their performance differs at higher slip levels (above 2%).

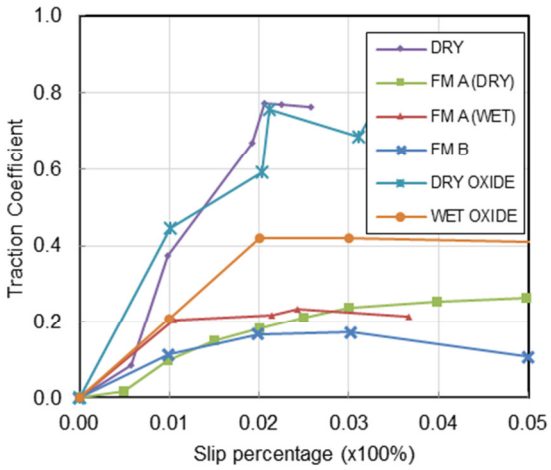

Figure 4 *Creep Curves.*

4.2 Wear Performance of Laser Clad Rail

4.2.1 Test Overview

The cladding of standard R260 grade rail steel with premium metals has already been shown to vastly improve its wear performance at the small scale [16, 17]. In order to prove the viability of laser cladding rail at the full-scale two of the best performing materials from previous work [16,17] were selected for wear testing on the FSTF [18]. Three lengths of R260 grade rail were prepared for testing in the FSTF including; a standard R260 grade reference sample, a length of R260 cladded with Stellite 6 and a length of R260 material cladded with martensitic stainless steel. R260 rail grade was used as a baseline and as a substrate for the clad samples in these tests.

To test the wear performance of the two different types of clad rail both types of clad; test specimens were prepared to use in the FSTF using a standard R260

grade one metre long section with a 60-E2 profile. The crown radius and the gauge corners of the rails were machined away to a depth of 2mm. The profiles of the rails were then restored by cladding the deposit materials in two layers which were then ground to restore the original profile and achieve a good surface finish leaving a 2mm thick layer of clad at the surface as shown in Figure 5 *A Section of R260 60-E2 Rail Clad to a Depth of 2mm for Wear Tests.*. A standard un-clad R260 rail was also tested as a reference. All specimens were tested to 80,000 cycles at a half axle load of 120 kN and a creep of 1%.

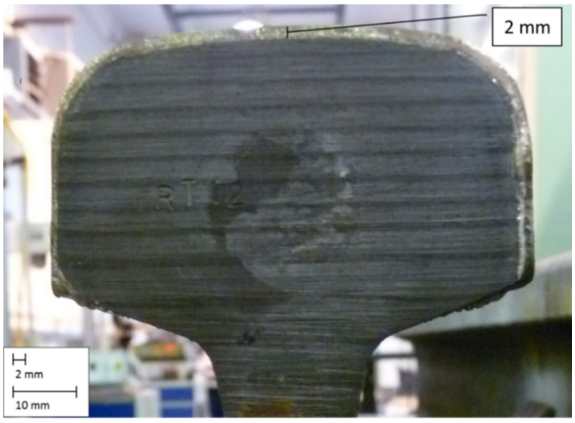

Figure 5 *A Section of R260 60-E2 Rail Clad to a Depth of 2mm for Wear Tests.*

4.2.2. Results

Wear on all of the samples was too low to be measured by profilometer so instead the taper of the wear band in the longitudinal direction was measured for all of the rails and compared and are shown in Error! Reference source not found.. The clad material was shown to stay intact and improve wear performance. Full-scale tests showed similar trends to the previous twin disc tests results.

Table 2 *Wear Band Taper Results at 80,000 Cycles.*

Sample	Width of Wear Band (mm)		Taper	
	Start	End	Length (mm)	As % of R260
R260	13	22	9	-
Stellite 6	12	14	2	22%
MSS13	13	14	1	11%

4.3. Simulation of Insulated Block Joint (IBJ) lipping

4.3.1. Test Overview

A significant problem with Insulated Block Joints used to separate track into circuits used for train detection is flow of rail material across the insulating endpost. Track circuit failure can be very costly. In this unique study to aim was to reproduce the lipping behaviour, already seen in twin disc simulations [19] at full-scale and see if clad rail could reduce the problem.

For the clad IBJ lipping tests the specimens consisted of a clad one metre long R260 base-rail with a 6.4 mm wide groove machined into the railhead approximately halfway along its length. A nylon endpost was glued into the groove which had the same profile as the rail and sat flush with the rail crown as shown in Figure 6 ***IBJ sample.***. Two clad rails were tested along with two baseline non-clad R260 rails. The two clad rails were clad with Stellite 6 or MSS to a depth of 2 mm but unlike in the wear performance tests only the head of the rail was clad approximately 170 mm either side of the endpost in the longitudinal direction. The rails were tested at a half-axle load of 120 kN with a creep of between 1–3%. The endpost gap was measured every 5,000 cycles.

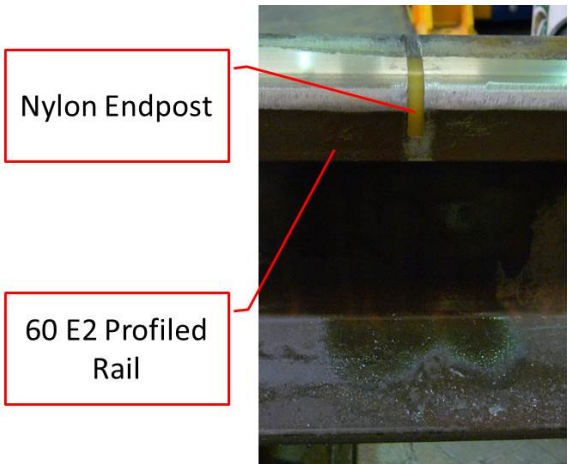

Figure 6 *IBJ sample.*

4.3.2. Results

Results in Figure 7 show that the lipping behaviour could be replicated in the rig. The reference unclad R260 rail tested at 3% creep showed a reduction of the endpost gap of over 3.4 mm in only 5,000 cycles. Both of the clad rails which were tested under the same conditions both experienced a reduction of less than 1mm in the same number of cycles. Both of the clad rails were tested to a further 30,000 and 40,000 cycles in the cases of the Stellite 6 and the MSS clads and experienced total gap closures of 1.1mm and 1.6 mm respectively. Note that the Stellite 6 specimen had to be stopped after 30,000 cycles due to a breakage of a machine component while testing between 30–35,000 cycles which meant the sample could not be tested any further. Figure 8 ***R260 IBJ Specimen before the Test and after 5,000 Cycles at 3% Slip (the rolling direction of the wheel is from left to right).*** and

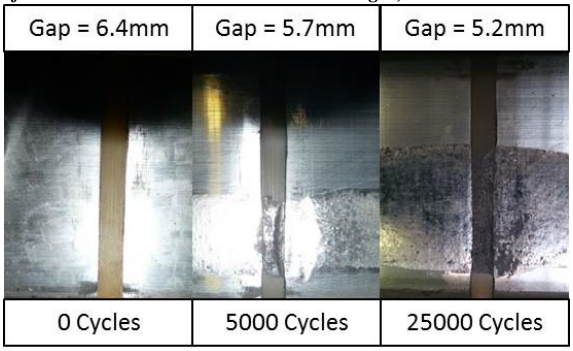

Figure *9* ***Stellite 6 IBJ Specimen before the Test and after 5,000 Cycles and 25,000 Cycles at 3%Sslip (the rolling direction of the wheel is from left to right and reflection from the Nylon endpost indicates transfer of metal).*** show top views of the IBJ specimens before and after testing. The clad rail clearly

reduces material flow significantly. These results have paved the way for field tests of the clad layers on IBJs.

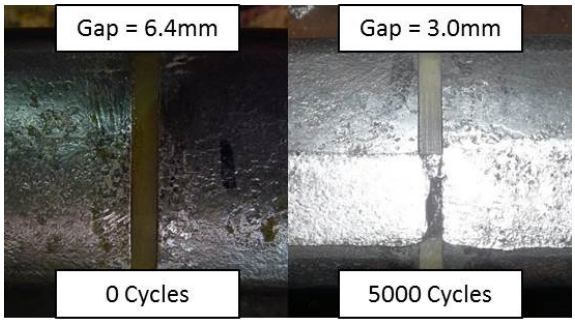

Figure 8 *R260 IBJ Specimen before the Test and after 5,000 Cycles at 3% Slip (the rolling direction of the wheel is from left to right).*

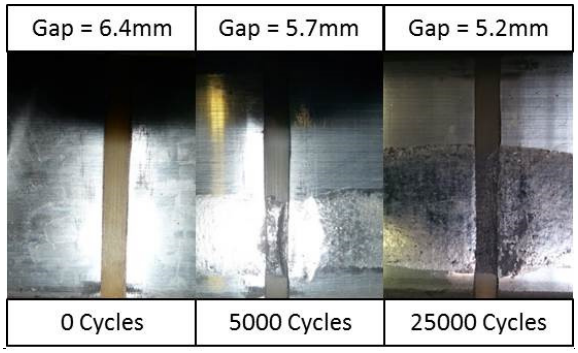

Figure 9 *Stellite 6 IBJ Specimen before the Test and after 5,000 Cycles and 25,000 Cycles at 3%Sslip (the rolling direction of the wheel is from left to right and reflection from the Nylon endpost indicates transfer of metal).*

4.4. Sanding System Optimisation

4.4.1. Test Overview

In [4,14] the FSTF was used to investigate the efficacy of train-borne sanding systems which are used widely to restore braking capacity of vehicles during low adhesion situations. For this project the FSTF was fitted with an actual sanding valve used on many of the UK's passenger trains (see Figure 10 *Sanding Valve Set-up on the FSTF [14] (1 – wheel; 3 – rail; 12 – rubber hose; 14 – aluminium sheath; 15 – supporting bracket).*). A mock hopper was fabricated to reflect the dimensions of a real hopper. A Bambi 150/500 air compressor with 50 litre reservoir and a maximum pressure of 8 bar was connected to the valve in order to agitate the sand and fire it toward the wheel and rail via a length of anti-static hose. The orientation of the hose relative to the wheel and rail could be adjusted as well as the regulator pressure of the air compressor in order to change the sand flow rate. The first series of experiments looked at the effect of changing the hose position and sand flow rates on the amount of sand which passed through the wheel/rail nip [14]. These tests were to find the ideal positioning of the hose. Further experiments were conducted to then look at measurable changes in traction from artificially created low adhesion when sand is blasted at the wheel/rail nip [4].

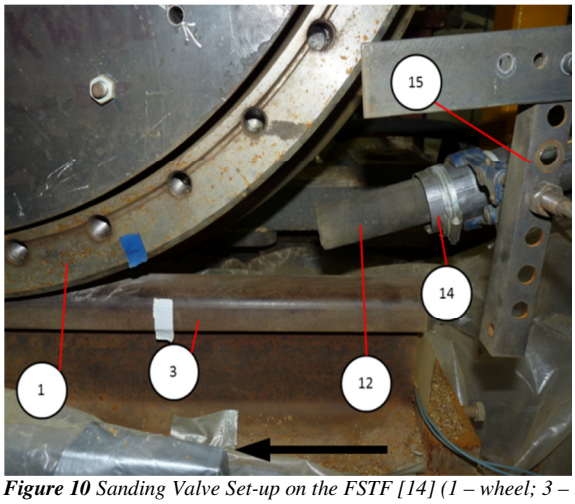

Figure 10 *Sanding Valve Set-up on the FSTF [14] (1 – wheel; 3 – rail; 12 – rubber hose; 14 – aluminium sheath; 15 – supporting bracket).*

4.4.2. Results

Figure 11 ***Mass of Sand Collected from Rail at three different Positions, Average of Three Readings: (a) Hose Aimed at Rail; (b) Hose Aimed at Wheel/Rail Nip; (c) Hose Aimed at Wheel (error bars show maximum and minimum readings) [14].*** shows some of the initial results from [14] where the effect of hose position on sand entering the wheel/rail nip was investigated. Results show that it is possible to draw clear distinctions in results using the FSTF for sanding investigations.

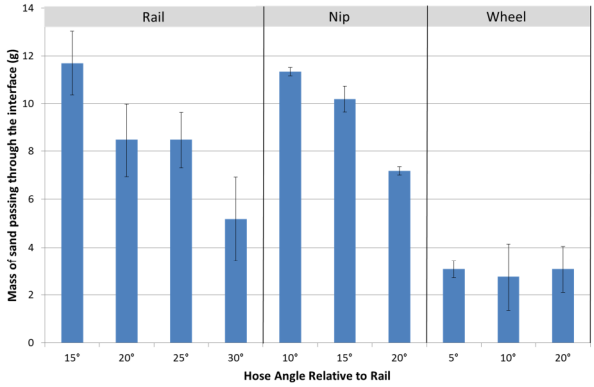

Figure 11 *Mass of Sand Collected from Rail at three different Positions, Average of Three Readings: (a) Hose Aimed at Rail; (b) Hose Aimed at Wheel/Rail Nip; (c) Hose Aimed at Wheel (error bars show maximum and minimum readings) [14].*

Figure 12 ***Picture demonstrating the creation of an artificial low adhesion layer using paper tape.*** shows a picture of the rail in the FSTF where an artificial low adhesion layer was created using wetted paper tape which was broken down by rolling the wheel over with multiple passes.

Figure 13 *Traction Curves for Sand Blasting Test. with Sand being Blasted from a Hopper into the Wheel/Rail Nip at a Flow Rate of 2.0*

kg/min [4].

shows results of the sand adhesion tests from [4] where the adhesion curve for a dry rail and low adhesion rail are shown. The results of two other tests where a low adhesion layer was created on the rail and then sand was blasted at the wheel/rail nip with just a standard hose and with a nozzle fitted to the end of the hose. Again clear distinctions can be seen between all the test cases. Fitting a nozzle to the sanding hose was initially investigated in [14] and was seen to have a substantial effect on the amount of sand which passed through the wheel/rail nip.

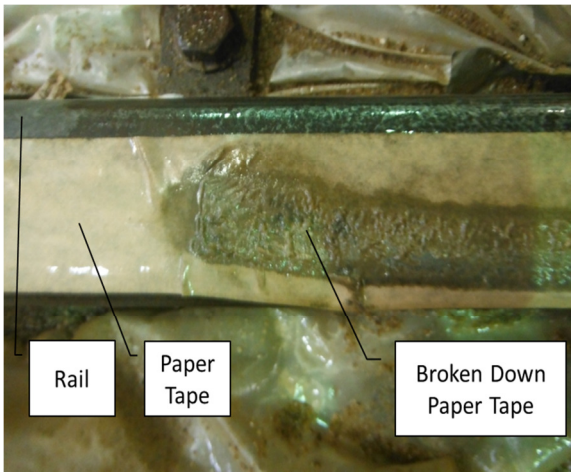

Figure 12 *Picture demonstrating the creation of an artificial low adhesion layer using paper tape.*

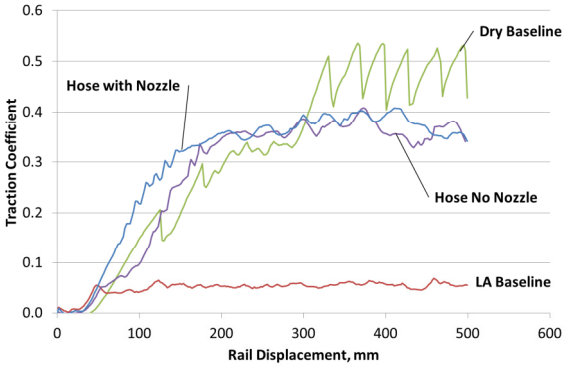

Figure 13 *Traction Curves for Sand Blasting Test. with Sand being Blasted from a Hopper into the Wheel/Rail Nip at a Flow Rate of 2.0 kg/min [4].*

The oscillation seen at the end of the "Dry Baseline" curve in Figure 13 *Traction Curves for Sand Blasting Test. with Sand being Blasted from a Hopper into the Wheel/Rail Nip at a Flow Rate of 2.0 kg/min [4].*

is a result of stick/slip action in the contact and the systems response from the rigs servo-hydraulic system. An upgrade to the FSTFs hydraulic and control systems since conducting these experiments means that this effect is no longer seen.

4.5. Traction Gel Testing

4.5.1. Test Overview

Traction gels (made up of particles suspended in a water based gel) are applied to rail head via wayside applicators or Rail Head Treatment Trains. Despite widespread use, evidence for their efficacy beyond twin-disc tests [20] is not available. The aim of this work was to study gel pick-up/carry down and adhesion recovery effects. For pick-up tests traction gel was applied to the rail head (see Figure 14 ***Traction Gel as Applied to the Rail Head before and After One Wheel Pass.***) and the wheel was rolled over it. The gel was then cleaned from the wheel and it was rolled over again to simulate pick-up by trailing wheels. The same was done for the carry down tests except that the rail was cleaned to see how much of the traction gel was transferred back to the rail from the wheel. Friction data was collected from all tests and benchmarked against wet and dry conditions.

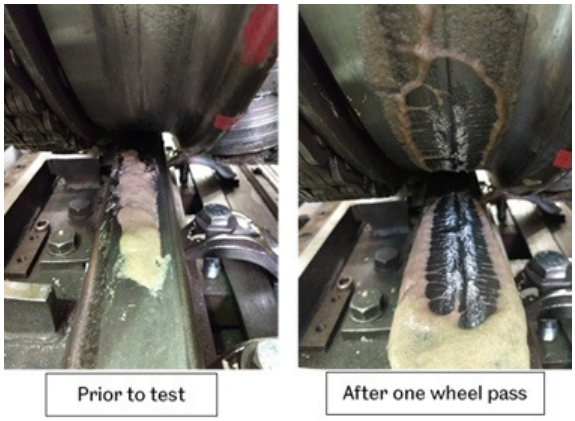

Figure 14 *Traction Gel as Applied to the Rail Head before and After One Wheel Pass.*

4.5.2. Results

Figure 14 *Traction Gel as Applied to the Rail Head before and After One Wheel Pass.*

shows the wheel and rail after one wheel pass over the traction gel. It can be seen that the gel component is squeezed out leaving just particles. The friction data in Figure 15 *Adhesion Recovery Tests with Traction Gel*

clearly shows that these particles help increase the traction level even when gel is applied to dry rail.

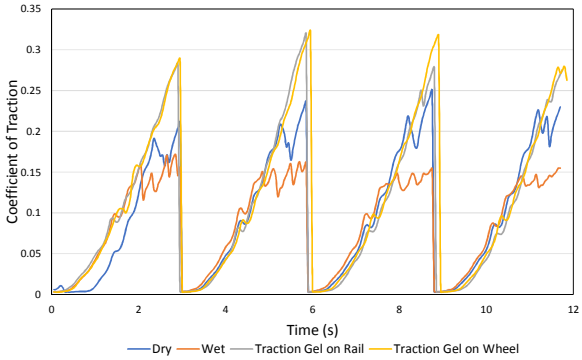

Figure 15 *Adhesion Recovery Tests with Traction Gel*

4.6. Grease Pick-Up

4.6.1. Test Overview

Previous work at The University of Sheffield has used a Scaled-Wheel Rig (SWR) to analyse various parameters affecting grease pick-up [21]. Various grease distribution units (GDU's) were installed onto the FSR and tests carried out to match testing conditions in the SWR study. This was done to understand and validate the use of the scaled wheel. Figure 16 ***(a) Set-up of MC4-GDU on FSR, Pick-up of Grease onto Wheel from one Wheel Pass using; (b) Standard MC4 GDU, C) MC4-GG.***

shows the setup of one of the GDU's on the FSR and examples of grease pick-up to the wheel. Test conditions are shown in **Error! Reference source not found.**.

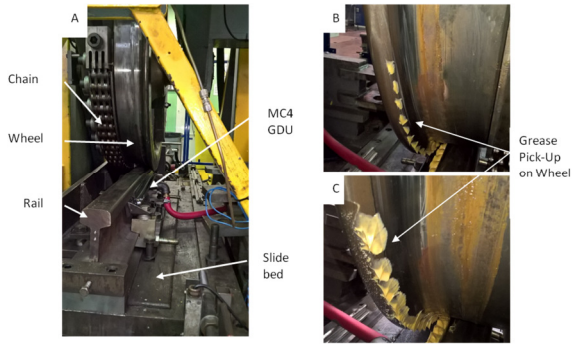

Figure 16 *(a) Set-up of MC4-GDU on FSR, Pick-up of Grease onto Wheel from one Wheel Pass using; (b) Standard MC4 GDU, C) MC4-GG.*

Table 3 *Test Conditions.*

Variable	Conditions tested
Contact Pressure (MPa)	1000
Rail Velocity (mm/s)	100
Slip (%)	0.5
Pumping Duration (s)	0.1, 0.2, 0.3
Wheel Lateral Displacements (mm)	2, 3, 4, 5.5, 6.5, 7.5, 8.5
GDU's	Standard MC4 and MC4-GG

4.6.2. Results

Figure 17 ***Lateral Displacement vs Mass of Pick-up for both the SWR and FSR, for Different Pump durations using the MC-GG applicator.***

shows how the FSR results compare with the SWR results for one of the GDU types tested. The graph shows that whilst there are clear differences in the actual mass of grease pick-up between the two test rigs and the overall trends observed are the same:

- The mass of grease pick-up increases for an increasing pump duration.
- The mass of grease pick-up increases for an increasing lateral displacement

This leads to the conclusion that while there are differences, the observed trends are the same. Further work is now focussing on developing a test methodology to analyse carry-down using the FSR as pick-up and carry-down are intrinsically linked, and one cannot be studied without considering the effect it has on the other.

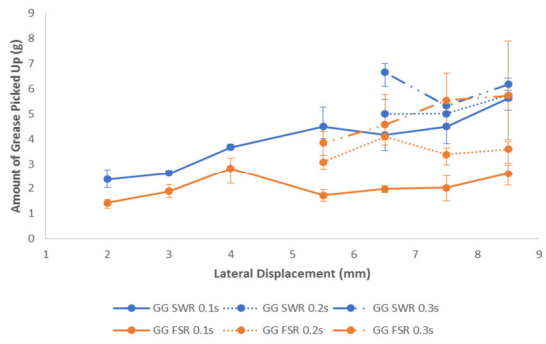

Figure 17 *Lateral Displacement vs Mass of Pick-up for both the SWR and FSR, for Different Pump durations using the MC-GG applicator.*

4.7. Wheel/Rail Contact Measurement

4.7.1. Test Overview

Many studies have used ultrasound to study static machine element contact conditions [22,23,24]. The wheel/rail interface has been characterised to relatively high resolution [24]. In this unique work measurements were taken during movement of the wheel using an ultrasonic array mounted in the rail (see Figure 19 ***Ultrasonic Contact Pressure Maps [25]***.
) [25].

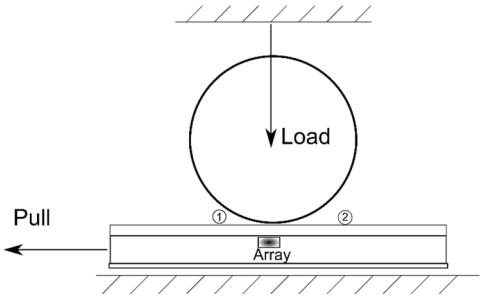

Figure 18 *Array Longitudinal Position in the Rail [25].*

4.7.2 Results

Initial scans captured during single wheel passes are shown in Figure 19 ***Ultrasonic Contact Pressure Maps [25]***.
. The multiple point contacts result from using heavily worn wheel and rail. The technique is clearly viable and in theory would work at full line speed. The array needs to be redesigned, however, to be mounted on the rail without requiring a hole to be machined into the rail.

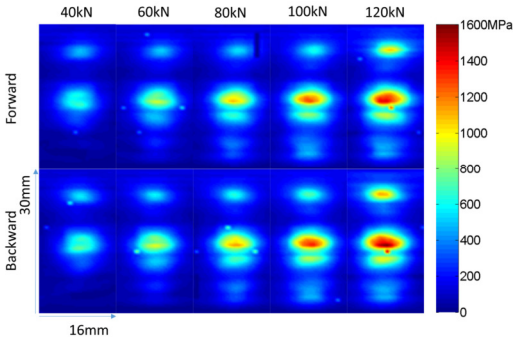

Figure 19 *Ultrasonic Contact Pressure Maps [25].*

4.8. Steel Shim Surface Testing

4.8.1 Test Overview

In a study into the influence of contaminants and conditions on the wheel/rail contact, it was found that a major limitation of many research methods has been an inability to conduct chemical and surface analysis in-situ, on full-scale rigs, or in the field. Some devices have been adapted to perform field testing of railhead conditions [26,27], but they have limitations and often require the construction of bespoke specialist equipment.

An alternative to sampling in-situ is to remove samples from the railhead for testing ex-situ (this is very difficult to carry out as it is very disruption to networks). This has been done in the past by extraction of rail section from the track and machining the sample surfaces from the rail-stock to the required size. This allows for a wider variety of chemical analysis techniques to be used

to investigate the surface such as GD-OES and SEM [28] which require high vacuum environments. Disadvantages of this is that the machining processes used to remove the sample from the railhead can disturb the surfaces and take considerable time to process leading to possible chemical or structural changes in the surfaces to be analysed. In addition, these are also destructive methods requiring time and effort to renew the extracted section.

The procedure presented here investigates a novel railhead sampling technique using a low profile thin steel shim mounted onto the railhead to generate surface samples of the contact patch. It may be applied to full scale rail / wheel rigs as well as in the field to allow samples to be non-destructively extracted from track and prepared for testing rapidly and with minimal disturbance to both the rail section and the extracted sample surface. Sample surfaces measuring 75 by 300 mm were cut from pieces of non-stainless steel shim. The shim thicknesses was between 0.1 and 0.2 mm. In this work the potential of the shim method was demonstrated using the FSTF.

The shim was affixed to the railhead using magnetic clamps rated to give approximately 1.7 kN of perpendicular holding force. The first clamp was applied to hold one side of the shim after which the shim is pulled taught by hand before the second clamp is applied, pulling the surface taught and flush with the railhead. This set-up is shown in Figure 20 ***Shim Track Mounting Set-up***..

Figure 20 *Shim Track Mounting Set-up.*

Removal of the steel shim from the railhead surface was achieved by switching off and removing the magnetic clamps before the removal of the shim, taking care not to disturb the contact patch. If required, the shim contact patch may be cut into smaller pieces by heavy duty scissors or tin snips, for testing in XPS apparatus for instance. If care can be taken, multiple contact patches can be obtained from the same shim piece by moving the location of the shim on the railhead.

Testing of the experimental set-up was conducted with creeps up to 7% and loads of 120kN to assess the holding potential of the clamping system which was found to be robust. A sample of the contact patch was obtained from a 50 cycle run under the following conditions: Shim thickness 0.1mm; wheel load 75 kN; slip 0.5%; rail velocity 100 mm/s.

4.8.2. Results

The sample formed from the testing, shown in Figure 21 ***Retrieved Contact Patch Sample***. revealed a contact patch of approximately 9 mm across and shows similarity to the surface of the railhead. The steel shim was deformed slightly and the edge showed some spalling as a result of material movement. No visible damage to the wheel or rail was observed.

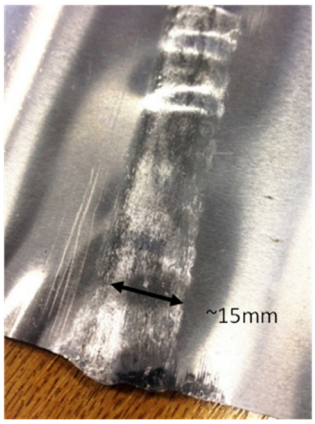

Figure 21 *Retrieved Contact Patch Sample.*

The initial testing showed the successful sampling of a shim surface appeared to have captured the physical characteristics of the contact patch. The mechanical properties of the steel shim differ from that of the railhead significantly due to the "non-confinement" of the material (i.e., it is a thin layer and can spread differently under load to a larger specimen).

The influence of contaminants such as leaves, oxides and oils and greases on the rail head which only interact with the near-surface material may benefit most from this sampling method. Tribofilms may be formed on the steel shim sample under the realistic operating conditions of the full-scale rig and analysed externally with minimal disturbance to the contact.

5. Discussion

Since its first construction in the early 1970's by British Rail in Derby, UK, to its current updated condition at the University of Sheffield; the FSTF has recorded may test hours on a range of different rail phenomena. Today the rig is still mostly used for same original purpose for which it was built; because of its ability to provide a lab based true full-scale representation of the wheel/rail contact which, even today, few small scale testers offer. Another of those original construction intentions was to enable the assessment of the frictional performance of certain materials under controlled rolling/sliding conditions facilitated by an actual wheel/rail contact which as has been demonstrated above is what the rig is still intensively used for today. Upgrades and retrofits first in 2003 and culminating in the latest significant upgrades at UoS in 2013 mean that the rig is more reliable, adaptable and safe.

The rig is now able to operate up to 1 cycle every 11 seconds for over 100,000 cycles. With a vertical axis which is able to provide up to 180 kN axle loads of up to 36.5 tonnes can be applied, which is well in excess of 25.4 tonnes per axle the maximum permitted in the Network Rail – Route Availability (RA 10) for freight

vehicles. This demonstrates that the FSTF is easily able to operate to loads representative of commuter, express and freight vehicles.

The rail sample in FSTF can be easily changed and Most EN rail profiles including 54, 56 and kg/metre can be easily accommodated although larger AREMA profiles have been successfully tested.

The speed of the rail axis ranges from 0 – 100 mm/s.

Slip can be applied up to 20% but at this level causes heavy damage to the wheel and rail within a few test cycles. But long term (100,000 cycles) tests can be carried out at slips up to 3%.

The adaptability of the rig has been demonstrated as in the sections above. Sanding equipment has been successfully fitted [4, 14], a grease dispenser unit has been tested [21] and an experimental rail with embedded ultrasonic transducer has been fitted [25]. This shows that a range of experimental or readily proven technologies can be fitted to the rig either for experimental, benchmarking or design improvement purposes. It is conceivable that switch and crossing components, new joining technologies, rail repair methods or new rail welding technologies could be tested in the FSTF.

The FSTF has been designed to test a 1010mm length of rail. This can be an issue when it comes to testing experimental rail materials as in [18]. In this project the clad rails were relatively expensive to manufacture and only one test was realistically able to be performed on each sample. In order to improve the test efficiency (number of tests per sample manufactured/cost of manufacture a pocketed rail solution was designed. The pocketed rail solution is not a new Idea and was originally developed by British Rail Research. When the FSTF arrived at UoS in 2011 it had a pocketed rail with it. However, this rail was an aged and thoroughly tested BS 113 profile. In order to develop a more up to date solution a pocketed rail has been designed with a 60E2 profiled rail as show in Figure 22.

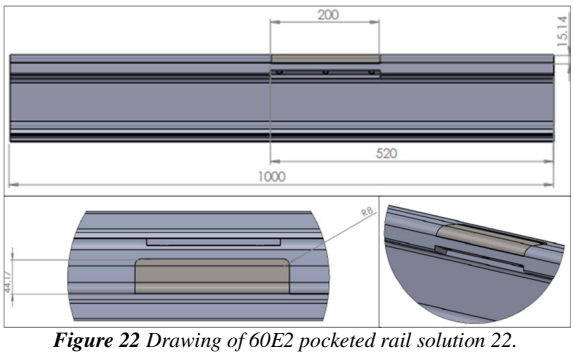

Figure 22 *Drawing of 60E2 pocketed rail solution 22.*

Figure 22 shows that the pocket is offset from the centre of the rail. The rail has been designed this way so that access into the FSR to insert and remove the segment is easier. Part of the reason why this pocketed solution was also developed is to reduce the amount of time which was taken by having to remove and re-insert the entire rail for inspection in between tests. This solution allows quick and easy access to be able to remove the 200mm segment for inter-test analysis. The sample is small enough so that it can be observed under a microscope. The sample is however long enough that the wheel/rail contact can be operated exclusively on the 200mm segment meaning that there are no edge stress issues caused as the wheel passes from the parent rail to the segment. This solution also maximises the number of samples which can be manufactured from a rail which can be successfully tested.

Another feature of the rig is its ability to directly control the creep rate of the wheel either as a displacement or a force. This is a major advantage over other full-scale wheel/rail rigs such as in [29,30]. With both of these rigs creep can only be controlled in-directly by adjusting the angle of attack of the wheel relative to the rail. With the FSTF the slip at the wheel can either be controlled directly as a percentage whereby the friction force at the contact can be monitored or a constant tangential force can be applied to the wheel whereby the displacement of the wheel is monitored. This offers a new way of developing creep curves for different wheel and rail materials or third body materials.

One major disadvantage of all full/large scale test rigs of this type, which can be defined as slow full scale test rigs, SFSRs, is their operating speed which is a physical constraint. The current maximum speed of the FSTF is 100 mm per second which equates to 0.36 km/h (0.22 mph). This is not very representative of a train travelling at its regular speed. There are other full/large scale rigs which can be classed at fast full scale test rigs, FFSRs such as those used for adhesion studies by Voltr et al. [31,32], or the those consisting of a large ring of rail, which can achieve full dynamic loading and representative speeds, such as the Luchinni owned rig [33]. However, FFSRs are physically much larger than SFTRs and are much more resource intensive to operate with high running costs and significantly higher specimen costs. This somewhat limits the use of FFSRs to high technology readiness level, TRL, research. A big advantage of SFSRs, particularly the FSTF, is the high degree of controllability of test variables such as vertical load and slip which makes it comparable to small scale testers in this respect.

The redeveloped test-rig, has many advantages:

- It can use actual wheel and rail so specimens are simple and relatively cheap to procure.
- Wear and RCF tests are straightforward to set-up and run, especially using the pocket set-up which allows easy and accurate measurements to be carried out.
- The rig can incorporate friction management product application devices such as those mounted to the track: GDUs and TGAs and to vehicles: sanding valves.
- It is possible to achieve low adhesion conditions through the additions of leaf layers or wet paper tape.
- It is possible to capture images of the rail to see how the wheel interacts with products applied to the rail.

- Contact conditions such as normal and lateral force as well as slip can be accurately controlled (while there are other linear rigs, many do not feature slip control, such as those used by Stock et al. [27] and Heyder & Maedler [28].

Compared to twin-disc testers such as the SUROS machine [34] the FSTF offers the benefit of being a direct representation of the actual wheel/rail contact; with no scaling issues. This can be highlighted in the sanding tests as discussed above [4, 14] whereby there were no scaling issues of the sand particles in relation to the size of the contact. These tests hence were a direct representation of what might be seen in the field. In terms of operating velocity the FSTF is comparable to the SUROS at 400 rpm with a 47mm diameter disc. In terms of controllability of test parameters the FSTF does not have many compromises over small-scale testers such as twin disc or pin on disc. However, the true reflection of the actual wheel rail contact is very good for a laboratory based tester. The FSTF will be more resource demanding than small-scale testers in terms of specimen manufacture, energy costs and maintenance and as such is ideal as an intermediary stage of testing between small-scale laboratory test and field test. For example in [16] small-scale testing was used to benchmark a range of potential cladding materials. The best two performing materials at the small-scale stage were then taken on to full-scale testing in the FSTF. After satisfactory performance of the materials tested using the FSTF these materials are now to be field tested at an active heavy haul railway in the UK.

6. Conclusions

A re-commissioned full-scale wheel on rail test machine has been successfully used across a range of applications. In this paper the adaptability and reliability of the rig has been demonstrated through a series of case studies including:

- Top of Rail Friction Modifier Retentivity and Creep Curve Generation
- Wear Performance of Laser Clad Rail
- Simulation of Insulated Block Joint (IBJ) lipping
- Sanding System Optimisation
- Traction Gel Testing
- Grease Pick-Up
- Wheel/Rail Contact Measurement
- Steel Shim Surface Testing

The adaptability of the rig mean that a variety of rail components can be tested and the pocketed rail solution mean that tested rail samples can be quickly removed from the machine and accurately analysed intra-test.

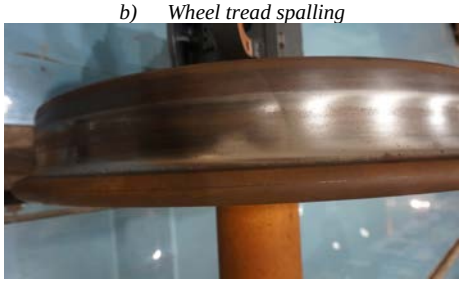
Abstract: Aiming at the wheel OOR problem in a newly opened subway vehicle, starting from the wheel-rail contact geometry, vehicle dynamics behaviour, wheel-rail coupling vibration, it is concluded that the abnormality of the rail profile causes the actual matching equivalent conicity to be too large, which is the reason for the wheel wears too fast. It is pointed out that the objective P_2 force in the wheel and rail contact is the origin of the resonance frequency of the wheel OOR.

Keywords: Contact geometry; wheel OOR; P_2 force; Modal analysis;

1. Introduction



In early summer 2017, report on bogie and coach with very bad running behaviour started to come into the Bogie Development Department of CRRC Puzhen. The report said that when the MTR passes under the residential buildings there is a lot of noise in the room and the passenger complains that the noise inside the coach is very big, too. After interviewed the crews and a portable running behaviour test carried on the car body, we came to the conclusion that the noise might be caused by the out of round (OOR) roughness of the wheel.
Wheel irregularity is one of the common problems in the operation of railway vehicles, the form of wheel out of round can be divided into the periodic out of round and the partial out of round. The partial out of round of the wheel mainly includes the wheel tread flatting and tread spalling. Wheel's periodicity out of round mainly refers to the wheel polygonization. Figure 1 illustrate some typical wheel irregularity, Figure 1(a) for the wheel flatting, Figure 1(b) for the wheel tread spalling and Figure 1(c) for the wheel polygonization.

a) Wheel flatting

b) Wheel tread spalling

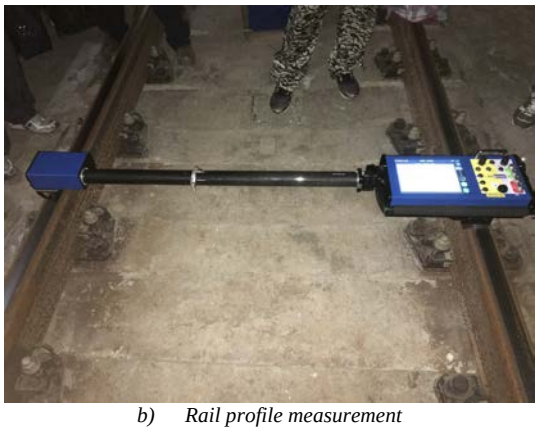
c) Wheel polygonization

Figure 1 typical wheel out-of-round

Currently, research home and abroad mainly focuses on the problem of the wheel 1~10 order polygon [1]-[5]. Jin X and Wu L[6] made a detailed investigation into the mechanism of the polygonal wear of the wheels of the metro trains through extensive experiments conducted at the sites. They regard the first bending resonance of the wheelset as the root causes of the ninth-order polygonal wear. Chen G, Jin X, WU P[7] investigate the motion stability of the wheel-rail coupling system, the results show that there are serious propensities of unstable self-excited vibrations whose frequencies are not more than 150 Hz under certain conditions. The mode shapes demonstrate that wheels slide against rails in the lateral direction when these unstable vibrations occur. The self-excite vibration of the wheel-rail system is a possible mechanism to cause polygonal wear of railway wheels.
Wang J, Song C, Wu P[8] indicates that wheel polygonization generate and evolution in a very short time.

2. Experimental investigation into the problem

The metro line with the problem is an extremely new line which opened in early 2017, the typical feature of this line is the massive use of flexible track beds and flexible faster, which intend to reduce the impact on the surrounding environment. Half of the rail was pre-grinded before the line opened.



To solve the problem, measurement of wheel profile, rail profile, wheels out-of-round roughness level and the dynamic test of track and vehicle were carried out by Traction Power State Key Laboratory of SWJTU.

2.1. Wear and contact geometry of the wheel

The initial wheel profile is a worn adopted profile LM and the rail profile is CHN60. Figure 3 shows the measurement of wheel and rail profile. Compared with the initial wheel profile, the wheel wear was calculated.
Figure 3 illustrates the evolution of the wheel wear as the reprofiled mileage from 0 km to 80,000 km. The mean wear of the wheel reached to 1.395mm, which is significant larger than the similar subway train. It can be seen from the evolution rule of the wheel wear that the wheel wear rate gradually slows down during the tracking test period. At the initial stage of wheel reprofiled, the wheel rolling circle wear rate is largest and then gradually decreases.

a) Wheel profile measurement

b) Rail profile measurement

Figure 2 *Wheel and rail profile measurement*

Figure 3 *Evolution of wheel wear*

For problems such as excessive wheel wear, we suspect that there are some problems with the wheel-rail contact geometry. The worn profile of the wheel and rail were measured before the dynamic test. The initial equivalent conicity of standard LM wheel profile matched with CHN60 rail profiles is 0.10. However, after less than 50,000 km operation, the equivalent conicity reach to 0.455 while the wheel reprofiling interval expected is longer than 300,000 km.
When we matched the measured wheel profile with the standard CHN60 profile, the equivalent conicity decrease to 0.290. Figure 4 and Figure 5 illustrate the contact geometry of measured wheel profile matched measured rail profile and standard CHN60. We found that the worn rail profile was flatter at the top of the rail surface than the standard rail. Due to this, the lateral displacement of wheelset is larger, and the flange is much easier to contact with the rail. Therefor, the conicity of measured wheel and rail are larger than the standard one.
On the other hand, a larger equivalent conicity leads to a greater possibility of bogie instability, which always point to the increase of the wheel wear rate.

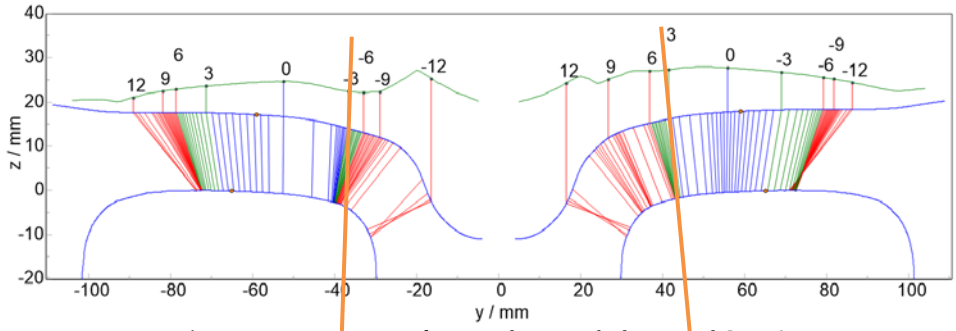


Figure 4 *contact geometry of measured LM matched measured CHN60*

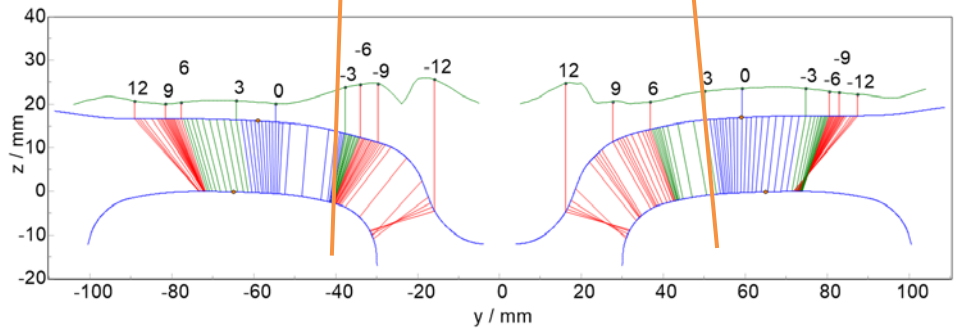

Figure 5 *contact geometry of measured LM matched standard CHN60*

2.2. Measurement of wheel OOR roughness level

As reported, several months after a new wheel or a reprofiled wheel put into service, the noise level inside the coach became awful. A continuous tracking measurement of wheel roughness level was carried out. The contact test method is used to measure the wheel roughness level at a relatively fixed interval, 20,000km. Figure 6 illustrates wheel OOR measuring device.

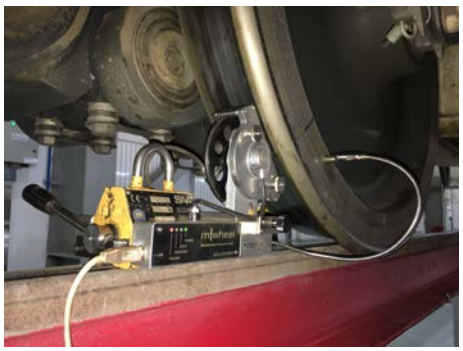

Figure 6 *Wheel OOR Measuring and test device*

Figure 7 illustrates OOR roughness evolution of a typical wheel as the reprofiled mileage increase from 0km to 78,900km. We have found from the Figure 7 that the wheel roughness level increases rapidly in the first 30,000 km (from the blue line to the red line) after the wheel reprofiled. After 30,000 km (from the red line to green line), the growth rate of the wheel roughness slows down, from 57,600 km (green line) to 78,900 km (yellow line), the wheel roughness value almost no longer grows and keep stable.

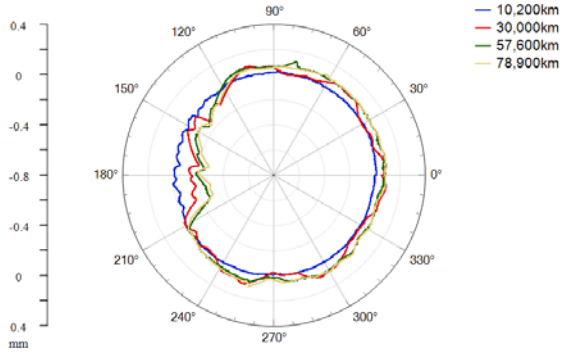

Figure 7 *Wheel roughness evolution*

As can be seen from Figure 7, the wheel tread appears irregular out-of-round, instead of regular wheel polygonization wear.

Figure 7 also illustrates that the wheel out-of-round is first generated locally in the circumferential direction, which may be caused by scratches such as tread flatting. When there is a specific resonance frequency between the wheel and rail, the wheel tread generates wavy wear at the defect.

As the running mileage increases, the wavy wear of the wheel tread increases, the new wavy wear continuously enlarges the vibration between wheel and rail, and continues to extend forward and backward, gradually forming a continues wavy wear in a whole wheel circle. As shown by the red line in the Figure 7. The wavy wear of the wheel tread has appeared on the entire wheel circumference.

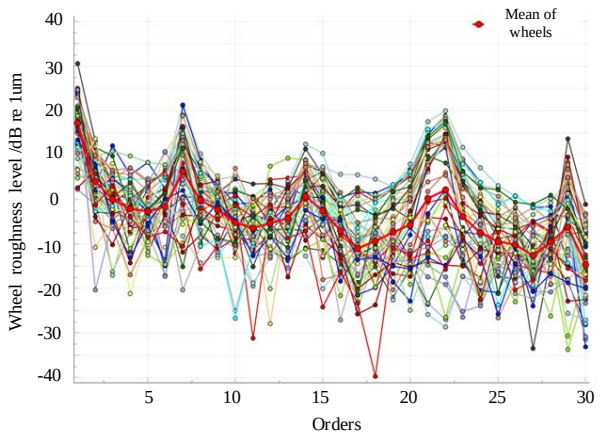

Figure 8 *Order view of wheel OOR*

Figure 8 illustrates wheel OOR orders of the subway train which contains 6 vehicles. The maximum wheel roughness level of 7th order has exceeded 20dB and average value reach to 10dB. In the order view diagram, the seventh order and its 2 times, 3 times, and 4times orders are obvious. The subway has a maximum operating speed of 90km/h and a wheel diameter of 830mm. It is easy to get the rotation frequency of the wheel at around 9.58Hz.

Corresponding to the 7th order of the wheel, we believe that there should be a resonance frequency of about 67Hz in the wheel and track. This resonant frequency may come from the track, or the wheel, or the wheel-rail contact system.

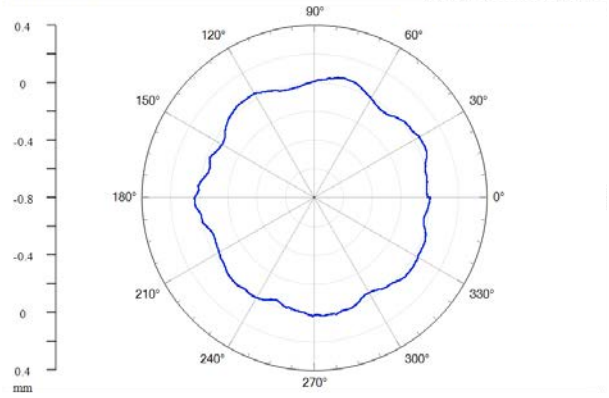

Figure 9 *A typical wheel OOR of the train*

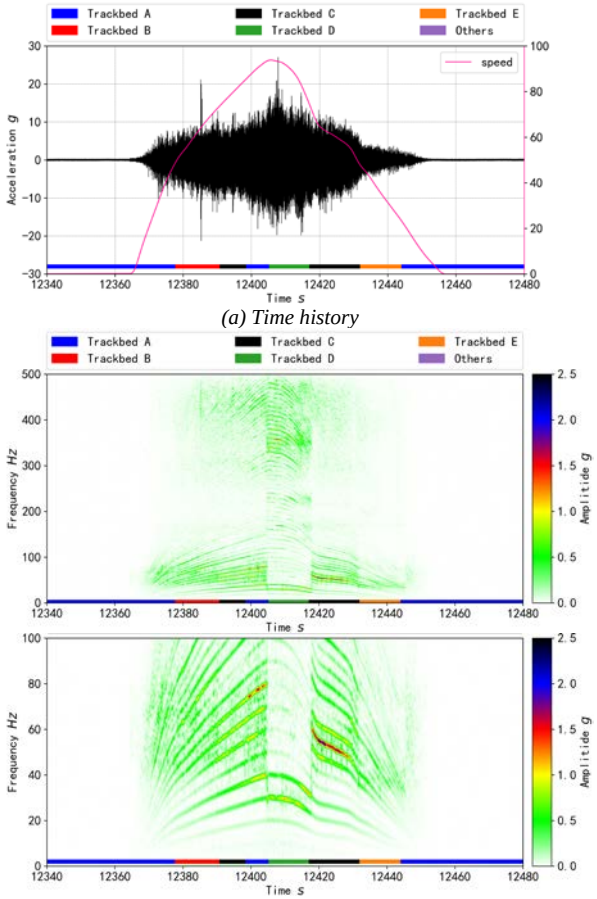
Figure 9 illustrates the wave wear of a typical wheel out-of-round. We can see that the overall shape of the wheel is 7-order out-of-round, and we can also see the existence of local defects.

Actually, we measured the out-of-round roughness of more than five hundred wheels of the metro trains operating on the same line. The mileage of these vehicles is distributed from 0 to 150,000km after it reprofiled last time. Among 580 wheels, 220 wheels roughness exceed 0.3 mm, and almost all of them appear varying level roughness. So, we have the conclusion that the wheel out-of-round roughness in these trains is a common phenomenon, not a special case of a special train.

2.3. Dynamic test of vehicle



At the same time of the measurement of wheel OOR, we carried out the dynamic test on the bogie and the track. The dynamic test mainly focused on the dynamic response of bogie and the operation modal test of rail and track. Figure 10 shows the tested bogie

Figure 10 *the bogie assembled sensors*

The test is carried out while the vehicle is in normal operation, which means the running speed and loads of the train are as usual. As we mentioned earlier, a major feature of this subway line is the massive use of flexible damping track beds, which intend to reduce the vibration influence on the environment.

The dynamic test results of the vehicle illustrate the dominant frequency of the axle box's vertical vibration shows great differences in different sections of the subway line. These demarcation points are based on the distribution of the different trackbed.

(a) Time history

(b) Short-time Fourier transform

Figure 11 *Vertical vibration of Axlebox*

Figure 11 shows the time-history and time-frequency

plots of the axlebox vertical acceleration in a typical section. Within this section of length less than 1500m, five different track beds are concentrated.

In the vertical vibration of the axle box, there are a large number of frequency components that vary with the speed of the vehicle, which are multiples of the wheel rotation frequency caused by wheel OOR.

The results of the wheel roughness measurement show that the wheel OOR of the tested train is mainly characterized by irregular irregularities rather than regular wheel polygonization.

The same is true for vehicle dynamics test results. The multiples of the wheel rotation frequency distributed in the vertical acceleration of the axlebox does not act as a single one or more dominant frequency in most sections.

When the test vehicle was running on trackbed A, a dominant frequency band that changed with the running speed of the vehicle began to appear near 70 Hz.

As the vehicle speed continues to increase to 90km/h, after the vehicle runs to trackbed D, the energy of the frequency multiplication between 50-100Hz is significantly reduced, and the dominant frequency displayed in trackbed B also disappears. After the vehicle enters the trackbed D, the frequency band that changes with the speed of the vehicle near 60 Hz becomes the dominant frequency again.

At the same time, we also found that when the vehicle is running on trackbed D, although the vibration energy below 100Hz is the lowest, the energy in the high frequency band is obviously increased, and a new main frequency appears near 350Hz, which have been confirmed as the frequency of the rail corrugation.

In order to eliminate the influence of wheel OOR on the vibration frequency of the axlebox, we carried out the dynamic test again after the whole train wheel was reprofiled.

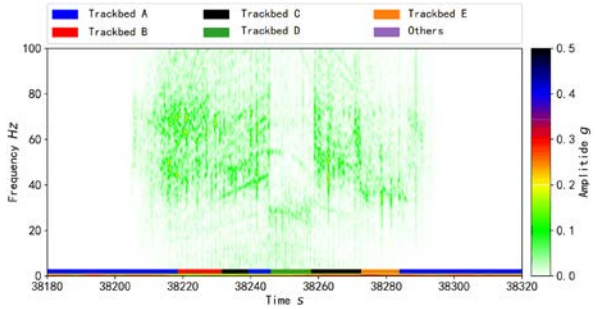


Figure 12 *Vertical vibration of Axlebox (after wheel reprofiled)*

Figure 12 illustrates the time frequency characteristic of vertical vibration of axlebox after wheel reprofiled.

After the wheel reprofiled, the difference of resonance frequency of the axlebox vertical vibration in the different trackbeds still exists. When the vehicle is running on trackbed A and trackbed C, the axle box has a dominant frequency band at 50-80 Hz, while running on trackbed D, there is energy concentration at 30 Hz. This is consistent with the frequency characteristic distribution before the wheel reprofiled.

As mentioned above, the resonant frequency present in axle boxes in some of the trackbeds is consistent with the characteristic frequency of the wheel's out-of-round, so we decided to look for the origin of this frequency from the track and wheel-rail coupling system.

3. Origin of the resonance frequency

Compared to the above several trackbeds, trackbed A and trackbed B are two different floating trackbeds with ZX-2 fasteners, trackbed C is a common unballasted track with ZX2 fasteners, trackbed D and trackbed E are ordinary unballasted beds with damping fasteners. The details are shown in Table 1.

Table 1 *Track type and fastener type*

	Track type	**Fastener type**
Trackbed A	Steel spring floating trackbed	ZX-2 Ordinary fastener
Trackbed B	Damping pad floating trackbed	ZX-2 Ordinary fastener
Trackbed C	Unballasted	ZX-2 Ordinary fastener
Trackbed D	Unballasted	Shear type vibration damping fastener
Trackbed E	Unballasted	Compression type vibration damping fastener

As shown in the Table 1, there are mainly three kinds of tracks and three kinds of fasteners in the subway line. Two of the floating trackbeds have smaller support stiffness under the track compared to general unballasted tracks due to the presence of elastic and damping elements.

As for the fastener, the shear and compression type vibration-damping fastener have a smaller support stiffness than the ZX2 fastener.

Figure 13 *rail dynamic test*

Aiming at the difference in the vibration frequency characteristics of the axlebox in various tracks, we carry out dynamic and modal tests on each track to find the source of the resonant frequency.

Unfortunately, although the use of the damping fastener and damping track does reduce the modal frequency, the lowest bending frequency of rail we identified in the working modal test is still much larger than the wheel's out-of-round resonance frequency.

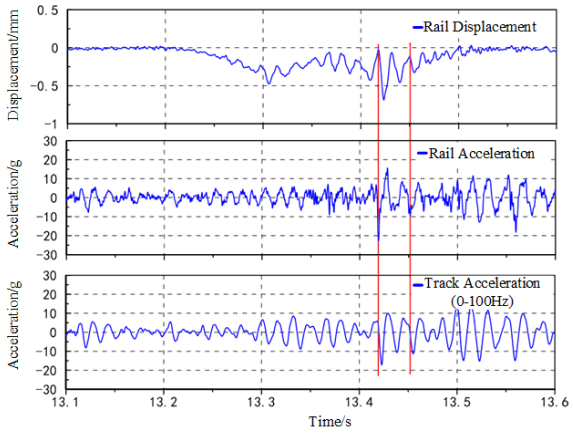

Figure 14 *Vibration trans on Trackbed A*

As for the modal vibration characteristics of the floating trackbed, the rigid body vibration dominant frequency of the floating trackbed and the low-order bending mode dominant frequency are too small. As Figure 14 shows，at the moment of wheel and rail contact, there are 66Hz vibrations in the rail and trackbed. The amplitude of the trackbed vibration is larger than the rail, and the phase behind the rail. After the wheel rail contact, the frequency of 66Hz still exists in the floating trackbed, but it decays rapidly in the rail, which has little effect on the vibration between the wheel and rail.

Although the other high-order modal frequencies coincide with the resonance frequency of the wheel OOR but the order is too high and will not be excited in the actual vibration.

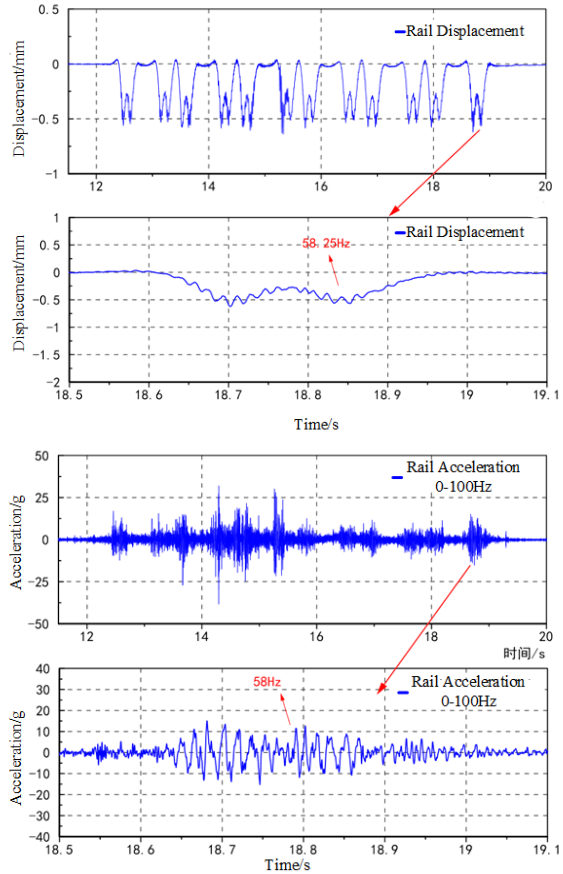

Figure 15 *Vibration trans on Trackbed C*

On the Trackbed C, the rails vibrate at 58 Hz when contacted with wheels, and the dominant frequency of axlebox vertical acceleration is 58 Hz at the same time.

At the moment of wheel rail contact, the displacement and acceleration of the rail reach the maximum at the same time. At this time, the wheel-rail contact system vibrate in-phase, it means the P_2 force generate when rail and wheel contact. The measured frequency of the P_2 force is consistent with the characteristic frequency of the above-mentioned wheel OOR. Therefore, the main source of the resonance frequency is the low-frequency response force P_2 between the wheel and rail on the Trackbed C. The length of Trackbed C accounts for more than 50% of this subway.

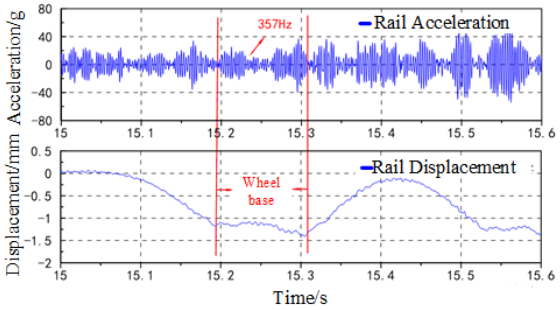

Figure 16 *Vibration trans on Trackbed D*

Figure 16 illustrates the rail vibration when the vehicle passes. The vertical acceleration of the rail between the two wheelsets appears to be beaten. With the wheel-rail contact point as the node, there are two beats in the wheelbase range. It means the second vertical bending modal of the rail between the wheelsets is exceeded. Interestingly, the dominant frequency of the mode is consistent with the rail corrugation.

4. Conclusions

It is concluded that the abnormality of the rail profile causes the actual matching equivalent conicity to be too large, which is the reason for the wheel wears too fast. It is pointed out that the objective P_2 force in the wheel and rail contact is the origin of the resonance frequency of the wheel OOR.

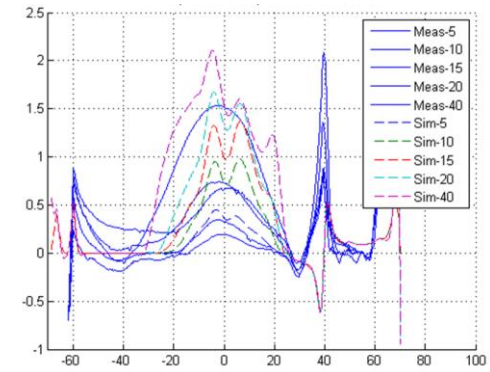
Abstract: Wheel wear determines the service life of wheelset and affects the vehicle system dynamics, which plays a crucial role in the vehicle design. It is quite difficult to make an accurate prediction on the characteristics of wheel wear by only using the numerical simulation or lab test. In this paper, the effects of vehicle speed, climate and rail conditions on the wheel wear is comparatively studied according to the field tests. Regarding the characteristics of wheel wear and operation experiences, a newly designed wheel profile has been applied on the high-speed trains to extend the reprofiling distance of wheel.

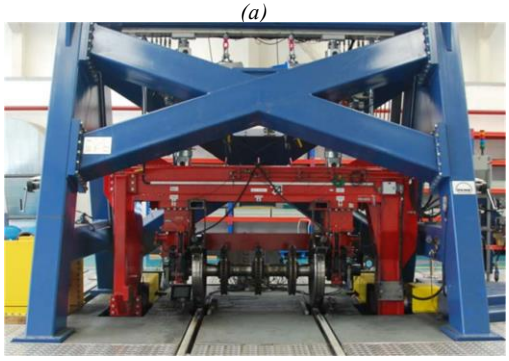
Keywords: Wheel wear; service environment; field test; wheel/rail interaction; high-speed train.

1. Introduction



Since 2007, thousands of high-speed trains have been put into operation in China, with a continuous and maximum operation speed of 200-350 km/h and a total running distance more than 3 billion km. The wheel wear leads to a profile change on tread which in turn affects the wheel-rail interaction, which straightforwardly determines the running stability and ride quality of railway vehicle. In the field operation, wheel reprofiling is commonly performed to turn the worn profile of wheel to the predefined one. In case of a long reprofiling distance/cycle, unexpected profile shape and wheel-rail interaction occurs, while a quite short reprofiling distance leads to a short service life. It is, therefore, important to have a reasonable reprofiling cycle for the wheel. Additionally, a high-speed trainset has to be put into different lines for operational needs for the operator. The trainset has to suffer different track geometry and irregularity due concerning the maintenance condition of track. In this case, a quite different wheel/rail interacting conditions, such as the position of contact point on tread and the equivalent conicity, an obvious wear difference and vehicle dynamics behaviour shall be encountered. It is necessary to design a tread shape has good adaptability [1-3].

The prediction of wheel wear is crucial to perform the wheel profile designing, evaluate the vehicle dynamics and determine the reprofiling cycle. The numerical simulation, bench test and field test on track are the generally methods used to study the wheel wear. Whereas the field test costs much and needs more time than other methods. Then great efforts have been put into the numerical analysis and bench test in the wheel wear prediction [4-11]. In order to numerically predict the worn shape of wheel profile and its evolution with travelling distance, there needs a cross-discipline model depending on several parameters requiring inputs from different disciplines, including the contact mechanics, wear models, surface plasticity and traffic simulation, etc.



A method for wheel wear simulation was proposed by Kalker [4] and achieves reasonable results with measurements for a metro, in which the FASTSIM algorithm was proposed to calculate the frictional work and corresponding wear for a number of unit wear steps. The wear was assumed to be proportional to the frictional work. An early approach used in the prediction of wheel profile evolution was presented by Pearce and Sherratt [5], in which the material loss was assumed to be proportional to the dissipated energy within a contact patch. Simulated results have been compared with measurements in terms of the development of equivalent conicity and worn profile over running distance. It pointed that the wear predicted was greatly sensitive to the rail profiles and track arrangements as well as profile update procedure. In order to accurately predict the evolution of wheel wear and related vehicle dynamics for high-speed trains, the stochastic wheel/rail interactions which experience quite variants with time and along long distance are concerned in literature [6]. The variants include the rail profiles, track geometries, track irregularities and interface characteristics associated with each track segment. Mathematic normal distribution is introduced to rationally describe these stochastic parameters. Twin disc test was performed to obtain the regimes of the wheel material and determine the wear constants necessary for the wear index analysis, and a systematic model combing the multibody vehicle system, local contact examination and wear calculation is described by Braghin, et al. [7].

In aforementioned numerical studies, the multibody code was mainly used for the dynamic railway vehicle simulation and the local contact analysis using Archard wear model. The wear coefficient in Archard model shows evident effects on the wear predication, as shown in Fig.1, in which the lateral axis shows lateral positons at wheel tread, the vertical axis shows tread wear(mm), the solid line stands measured result and the dash line stands the simulated result. In the simulation, the coefficient need to be corrected according to the field measurement for obtaining a better result filled with measurement. This

cannot be done or accurate enough without the inputs from field measurements. Moreover, the lab test method cannot completely reproduce the operation condition of vehicle, such as the track irregularity and contact conditions between wheel and rail surfaces. Both the numerical analysis and lab tests give a general analysis of wheel wear with an idealized service condition or environment.

(a)

(b)

Figure 1 *Wear prediction of wheel using numerical simulation and lab test method: (a) simulation result. (b) bench test device.*

Since the wheel wear is strongly dependent on the track condition and service environment of railway vehicle, it is impossible to give an accurate worn profile of wheel or its evolution with travelling distance. In addition, the wheel wear changes among various reprofiling cycles due to the change of vehicle condition. The wheel, therefore, cannot be entirely simulated or predicted by performing the numerical simulation or lab tests. Then the associated analysis results cannot be directly put into field operation, which has a higher possibility shows different results with respect to the field outcome.

For the high-speed trains of China, a long-term field measurement on the wheel wear has been conducted for various types of vehicles and tracks, then the worn profile, wear characteristics and its evolution are comparatively studied within various reprofiling cycles. Moreover, a further study of the wear difference between various service conditions are investigated based on the massive measured data concerns the vehicle speed, season climate, operated lines, et al. The analyzed results can be used to validate the wheel wear prediction and tread profile design. In order to improve the wheel-rail interacting conditions within a reprofiling cycle, a new designed wheel profile is promoted named as LMB_10 for the high-speed train has a continuous operation speed of 300 km/h. This wheel tread has been put into operation more than 2,200,000 km, which has good wear performance and vehicle dynamics.

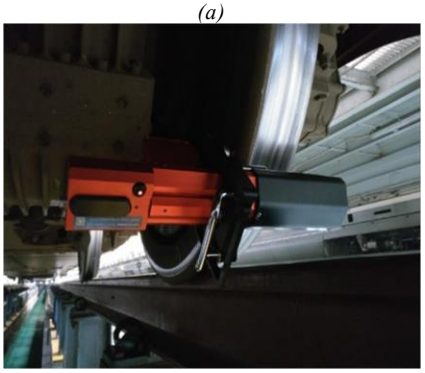
2. Field measurement of wheel wear

The tested trainsets are mainly operated on the high-speed railway network, with a maximum speed about 200 ~ 350 km/h. The stiffness of rubber bush in the axle guidance has a high value for a good running stability. According to the range of equivalent conicity of wheelset, the dynamics parameters are optimized considering the vehicle hunting characteristic.

2.1. Measuring scheme of wheel wear

The test for the bogie dynamics has been carried out on field for different high-speed lines in China since from 2011, and a total of 15 trainsets has been measured. In this field test, the wheel wear measurement is one of the key tasks. Wheel profiles LMB and LMB_10 were used for the tested trains.

The total travelling mileage of the test vehicle reaches up to 2.4 million km. During the test, the suspension parameters of bogie was slightly modified with the running mileage for a better running dynamics behaviour. The vehicle runs both in the south and north regions of China and the atmosphere environment is quite different. The environment conditions include low/high temperature, snow, rain and sand, etc., which have great effects on the wheel wear as discussed in the following content. In addition, the track structure has a bit difference regards of ballast and ballastless types. Moreover, the rail profile changes significantly resulting from different grinding profiles and worn conditions. Therefore, the service environment affects the wear state of the wheel, which in turn affects the vehicle dynamics performance on track.



2.2. Instruments for wheel wear

Portable devices are usually used for the wheel profile recording on field. According to the measurement physics, instruments for wheel wear are generally divided into contact type and non-contact type, in which a mechanical roller and a laser projector are used respectively, as shown in Fig.2 (a) and (b). The Miniprof wheel produced by Danish Greenwood Company is mostly used as the contact measuring instrument. For the case of non-contact measurement, the Optimess laser wheel produced by Elag in Switzerland is generally used in railway industry.

In the daily operation of high-speed trains, a large number of trainsets is needed to be evaluated for their wheel wear. Whereas there is only limited number of portable instruments can be used. Then the reprofiling data form the wheel turning machine, shown in Fig.2 (c) can be regarded as an additional measurement for the wheel wear analysis. The recently upgraded wheel turning machine can also provide some information about the wheel wear, such as the profile of tread, worn parameters and the equivalent conicity of wheelset.

(a)

(b)

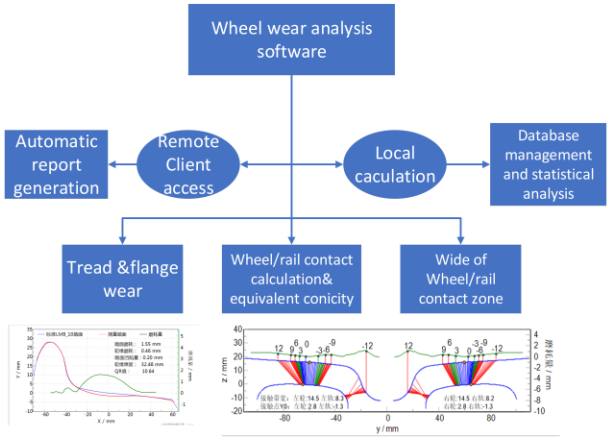
(c)

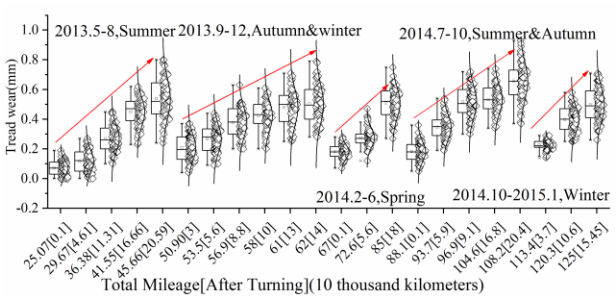
Figure 2 *Instruments of wheel tread profile: (a) Contact measuring. (b) Laser measuring. (c)Tuning machine measuring.*

2.3. Data processing and analysis

The recorded profile of wheel tread is centered firstly about its origin, then its wear conditions can be evaluated including the equivalent conicity of wheelset when matching with specified rail profile, the wear of the nominal rolling radius, the wear on flange and the contact bandwidth on tread or rail head, etc. The equivalent conicity can be calculated according to UIC519, which can be used to evaluate the vehicle dynamics behaviour of high-speed trains.

Due to the great needs in the processing of a huge amount of data measured, a software for the wheel wear analysis is developed to improve the efficiency in the statistical analysis, see Fig.3. In addition, a database management subsystem is built which helps in the on-site judgment for a quick wear analysis. Statistical indicators such as maximum/minimum, average and variance, etc., are employed when performing the data analysis. The outcomes can be used to analyze the wear characteristics from multiple models, multiple trains, multiple vehicles and multiple wheel wear data, then to conclude the wear behaviour and its evolution over running distance and environmental parameters.





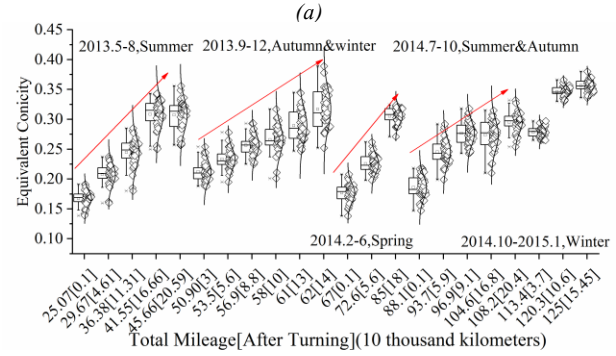


Figure 3 *Data analysis flow-chart.*

3. Analysis of wheel wear and its evolution

Through the field measurement, the evolution law of wheel wear between trainsets can be obtained. The test lasts two years and the train was operated in northeast China. In winter (from October to March), the minimum temperature is below -30 °C with snow and ice. The spring and autumn are short and dry. Figure 4 illustrates the evolution of wear on tread with the running distance in several reprofiling cycles. The wear rate on the nominal rolling radius is about 0.25 ~ 0.4 mm/100,000 km. The growth rate in summer is slightly faster than that in winter. The wear rate is similar in the two adjacent months, as shown in Fig.4 (a). The growth rate of equivalent conicity is about 0.08 ~ 0.1/100,000 km, as shown in Fig.4(b), and its variation with the travelling distance is consistent with that of tread wear. The conicity rises approximately linearly from 0.12 to 0.40 within a reprofiling cycle, and has similar evolution for other continuous cycles.

(a)

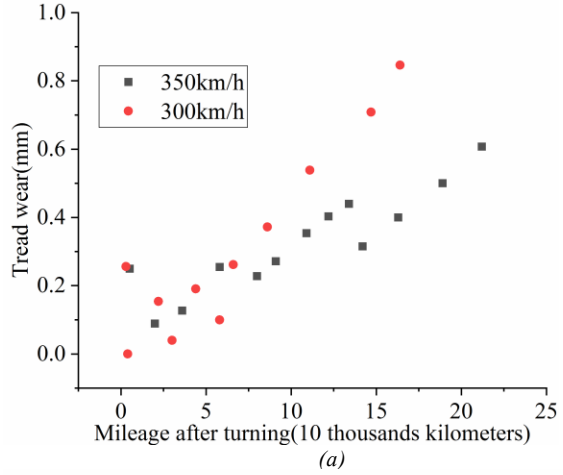
(b)

Figure 4 *Wheel wear evolution : (a) wheel tread wear. (b) equivalent conicity.*

For a specific high-speed trainset, the evolution of wheel wear can be analyzed with respect to specified wear

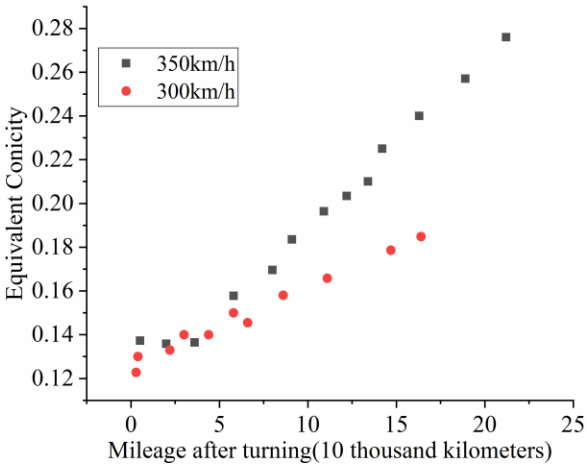
influenced parameters. Differences in wear for different seasons in one year can be noticed. Moreover, it is hard to give a quantitative analysis for the effects of wear influencing factors on the field wear of wheel, since different running speeds were operated for the train in winter and summer. Besides the environmental difference during field operation of high-speed train, the equivalent conicity of wheelset increases with the running mileage. As shown in Fig. 4(b), the physics for the abnormal value of conicity cannot be properly explained. Therefore, on the basis of mastering the overall law of wheel wear, it needs further analysis regarding the wear difference among various reprofiling cycles to have a more comprehensive understanding of wheel wear. This is going to be useful for the wheel maintenance and potential extends of reprofiling distance.

4. Influence of service environment on the wheel wear



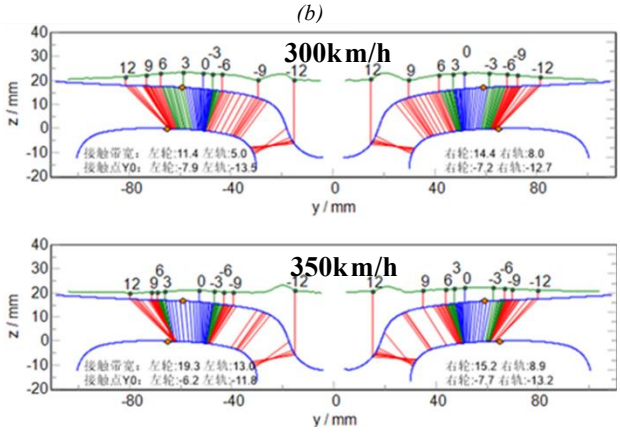
From a general overview of the wear difference from the field measurements on track, this section mainly concerns on the influence of operational environment of high-speed train on the wheel wear. Several factors that have potential effects on the wheel wear have been investigated based on the field data analysis.

4.1. Vehicle speed



The maximum operation speed of high-speed trains in China is about 300 ~ 350 km/h. As the speed increases, the wheel-rail contact force increases, which has a solid influence on the wheel wear. The field data associated with trainsets share the same wheel profile and bogie structures are chosen for further analysis, the maximum wear depth on tread, equivalent conicity of wheelset and contact points on tread are illustrated in Fig.5 with respect to the running distance of vehicle.

It is found that the equivalent conicity grows slightly faster when the vehicle has a speed of 350 km/h than that at 300 km/h. In the contrast, the wear depth on tread shows lower amount in the case of 350 km/h than that at 300 km/h, this can be explained that a wider contact area on tread can be expected for a higher conicity condition. Additionally, the average daily stops of vehicle when running at 300 km/h is about 25 ~ 30 times, which stops more frequently than that (about 6 ~ 8 times) at 350 km/h. If the vehicle has more stops, more traction and braking times. The vehicle will experience a higher creep rate between wheel and rail, which leads to an increase on the tread wear.



The difference in the equivalent conicity is mainly due to the difference in the worn shape of tread which in turn affects the wheel-rail contact relationship. For the contact bandwidth on wheel tread, the wheel has a uniform worn shape and a wide bandwidth in the case of running speed of 300 km/h. For the same running mileage, the tread wear when the running speed is 300 km/h ranges -25 ~ 30 mm, and it is -18 ~ 15 mm in case of 350 km/h. It is because the vehicle runs mainly on tangent tracks or curved tracks with large radius in the case of running speed of 350 km/h. In this situation, it may lead a narrow contact bandwidth on the wheel tread.

(a)

(b)

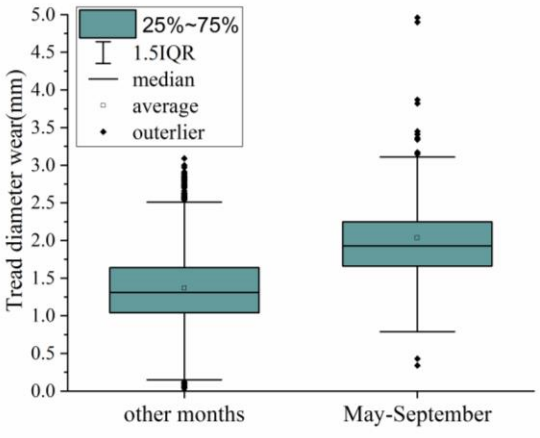
(c)

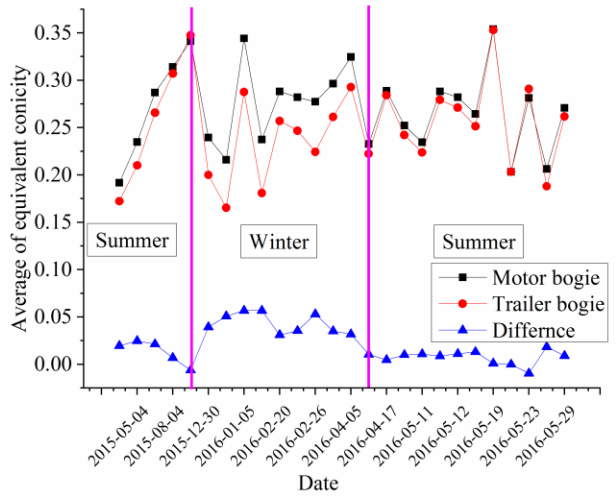
Figure 5 *Effect of vehicle speed on wheel wear: (a) tread wear. (b) equivalent conicity. (c) contact points between wheel and rail.*

4.2. Climate or season

The high-speed rail lines usually cover a wide region, and experience quite different climates and environmental conditions, which in turn affects the wheel wear and vehicle dynamics. According to the statistics of the wheel reprofiling data in one year for 30 trainsets have the same wheel profile type, the wear difference can be categorized in months and is demonstrated in Fig.6. It shows that the wear from May to September is quite larger than that in other months. The associated statistical data in Fig.6 comes from the trainsets operated in south and north China, and the temperature and humidity in May to

September are higher than other months. With the increase of humidity, the friction coefficient in the wheel/rail interacting surface drops. In addition, as the temperature change, the stiffness and damping of rubber components and oil dampers in the suspension system of vehicle and vibration isolation system of track are also different. As a consequence, the vehicle dynamics and wheel/rail interactions are strongly dependent on the climates or months in a year.





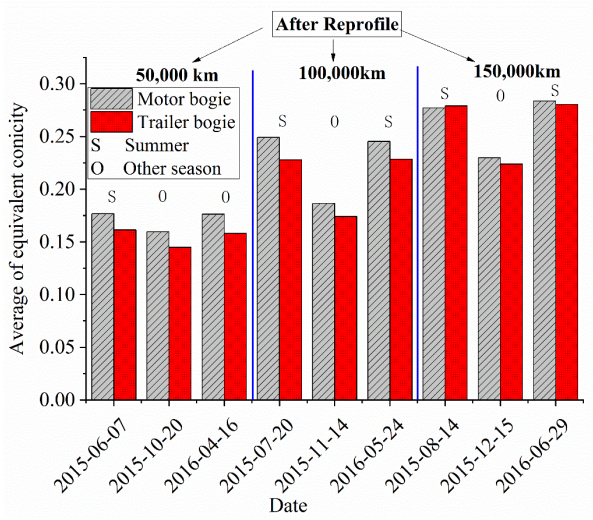


Figure 6 *Wear difference in months.*

Furthermore, it is dry and snowy at winter in north China, but it is hot and rainy in south China during summer months. This leads to difference in wear between north and south operated trains. The statistical analysis in Fig.7 (a) demonstrates that the equivalent conicity of motor bogie is larger than that of trailer bogie for the trainsets operated in the north at winter, but there is no difference in the months during summer. For the trainsets operated in south China, equivalent conicity at summer is larger than that at other seasons, but there is no significant difference between motor and trailer bogie, as shown in Fig.7(b). Similarly, the wear law on wheel tread is similar with the conicity. It can be seen that the climate has various influence on the wheel wear, which may affect the dynamics of vehicle.

(a)

(b)

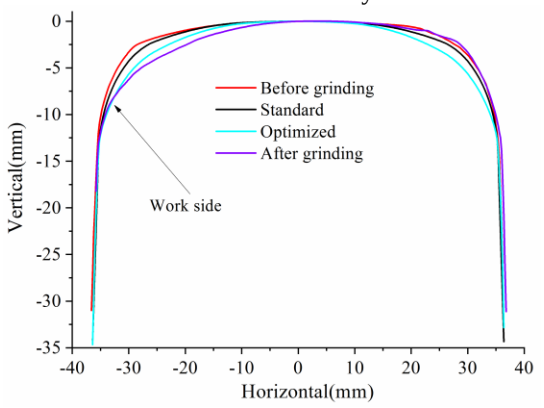

Figure 7 *Influence of different climates on wheel wear: (a) in north China. (b) in south China.*

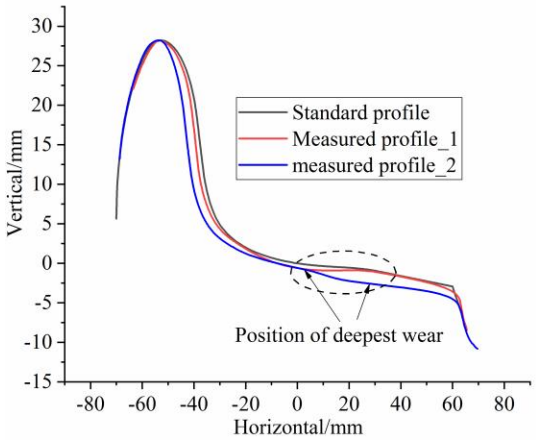
4.3. Track condition and operation arrangement



The track condition can also affect the wheel wear, it includes the rail profile, track gauge, rail inclination and surface hardness of rail head, etc. The track geometry also has an effect on the wheel wear, such as the curve distribution for a specific line. Regarding these potential influencing factors on wheel wear, the track gauge and rail inclination are generally strictly controlled through the maintenance work from the railway operator. The surface hardness of rail head changes with the total weight of vehicle passing through it, but remains a constant value after a certain point. Then the most influencing parameter should be attributed to the rail profile, which varies significantly in different track segments depending on the grinding states. Figure 8 shows the various rail profiles on track and the corresponded wheel profile after a certain running distance of a high-speed train. The difference among rail profiles at different maintenance stages is mainly concentrated at the gauge corner as shown in Fig.8(a). It is found that the real rail profile is higher and lower than the standard one for the 'before grinding' and 'after grinding' cases, respectively. This slight difference in the rail profile on-track can significantly affect the wheel/rail interaction. Additionally, the maximum worn position on tread is quite different for the vehicles operated on different high-speed railways. For the two measured wheel profiles, one has its maximum wear locates outside of the nominal rolling radius, as depicted by the blue curve in Fig.8(b). While the other one has its maximum wear mostly around the nominal rolling radius, as the red curve depicted in Fig.8(b).

According to the statistics for the 60 trainsets, the maximum wear position on wheel tread locates about 1 ~ 2 mm toward the inner side of the rolling circle for the vehicles transported on railway line A, and it is about 0.5 ~ 2 mm outside the rolling circle for line B. Due to this small difference in the maximum position of wear, an abnormal wheel/rail interaction may occur when the trainset runs across the lines A and B. This across operation of vehicle leads to an increase in the equivalent

conicity of wheelset, which in turn decrease the lateral stability of bogie. Therefore, it is recommended to make the wheels reprofiled before the trainset was put into operation on another high-speed railway to avoid severe wheel/rail interactions and vehicle dynamics.

(a)

(b)

Figure 8 *influence of rail profile on wheel wear: (a) rail profile. (b) maximum wear position on tread.*

4.4. Wheel diameter

With the increasing of travelling mileage of a high-speed train, the wheel diameter decreases and the rate of wear changes correspondingly. From the data recorded in 2017, the wheel wear increases faster as the wheel diameter decreases within a reprofiling cycle of wheel (about 20 ~ 25 million km), as shown in Fig.9. It is because that the surface hardness on wheel tread decreases as the wheel diameter decreases and the removal of material, see Fig.10.

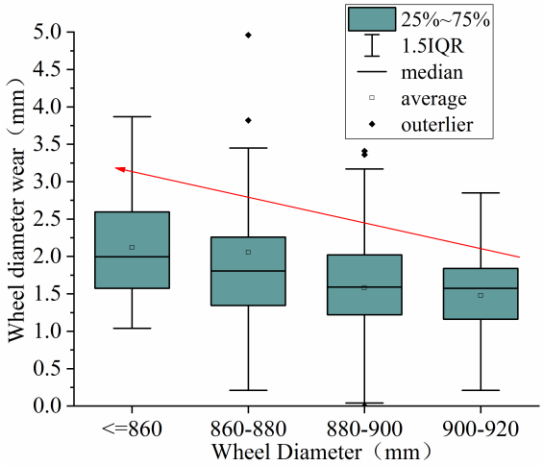


Figure 9 *Reduction of wheel diameter after a reprofiling cycle.*

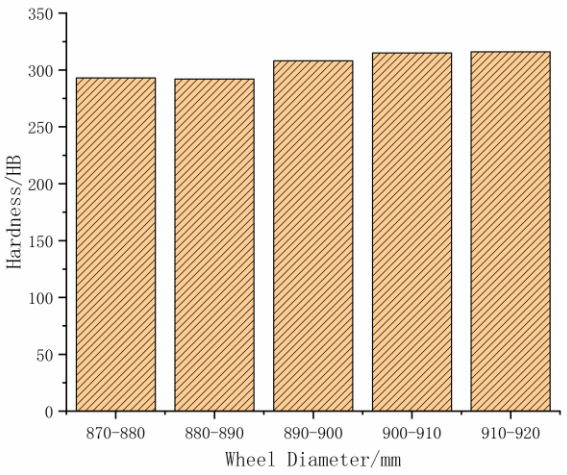

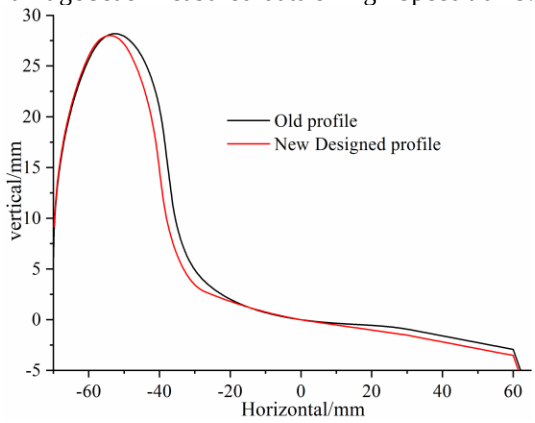

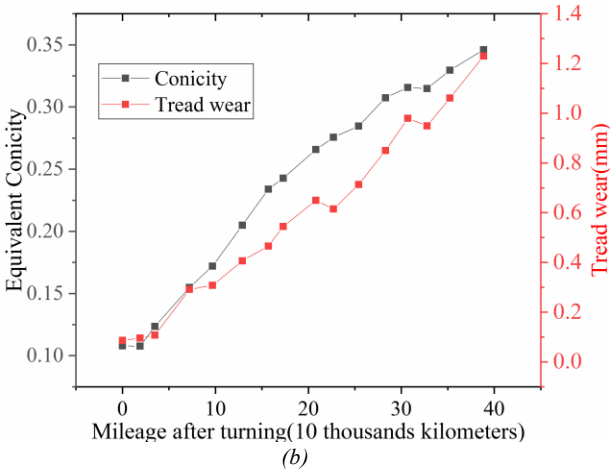

Figure 10 *Hardness of tread in various wheel diameter cases.*

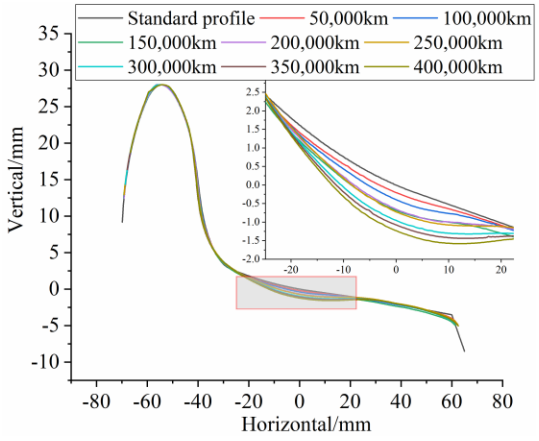
5. New wheel profile design and application



Aforementioned data analysis concludes that the amount and rate of wear on wheel is dependent on the vehicle speed, climate/season, track condition/operation arrangement and the wheel diameter, etc. Then a newly designed wheel profile plotted in Fig.11 is proposed for Chinese standardized high-speed trains concerning the wheel wear of original profile, rail profile changes and the operational experience based on the statistical analysis from a huge set of measured data of high-speed trains.

(a)

(b)

(c)

Figure 11 *Newly designed wheel profile for high-speed trains: (a) profiles. (b) Equivalent conicity and tread wear. (c) worn profiles.*

As a consequence, the longest reprofiling distance for this profile reaches up to 400,000 km with an equivalent conicity of wheelset about 0.33 and tread wear of 1.2 mm, see Fig.11 (a) and (b). In addition, it has a uniform wear concentrated on the nominal rolling radius which provides a stable wheel/rail interacting condition, see Fig.11 (c). This profile has been widely used in the new generation high-speed trains with an operational speed of 350 km/h. Even the continuous running speed rises to 350 km/h, the equivalent conicity of wheelset usually reaches its maximum around 0.28 ~ 0.3 within a reprofiling cycle. According to the field application experience and theoretical analysis for this new wheel profile, the reprofiling distance can be further extended.

6. Conclusions

Considering the wheel wear of high-speed trains cannot be accurately predicted by performing numerical simulations and lab tests, the potential affecting parameters on wheel wear are summarized and generally named as the service environment of vehicle. In order to know the actual worn state of wheel and extend its reprofiling distance/cycle, long-term field measurements have been conducted on track.

(1) The influence of operation speed of high-speed trains on the wheel wear is not obvious, while the operation arrangement on different railways affects the wheel wear a lot, such as the total number of stops, rail profile, curve distribution, etc.

(2) The climate/season shows obvious influence on the wheel wear, and the reprofiling distance of a cycle should be flexibly adjusted according the wear rate and wear difference between the motor and trailer bogies. A short reprofiling distance in some seasons or months with high wear rate should be followed but an extended distance in other seasons with low wear rate. This flexible reprofiling cycle on wheel helps to extend its service life. Moreover, the reprofiling cycle can be shortened appropriately when the wheel has a smaller diameter. Hardness improvements are needed in this case and help to slow down the wheel wear and polygonization.

(3) The newly designed wheel profile can improve the wheel-rail interacting condition and has a longer reprofiling distance, which is more suitable for the new generation and standardized high-speed trains.

(4) Concerning the costs and difficulties when performing field tests, the numerical simulation and lab test techniques need further improvement in the service environmental reproduction with respect to that on field of high-speed trains. Above all, a new method for the wheel profile design shall be proposed based on a huge amount of measured data.

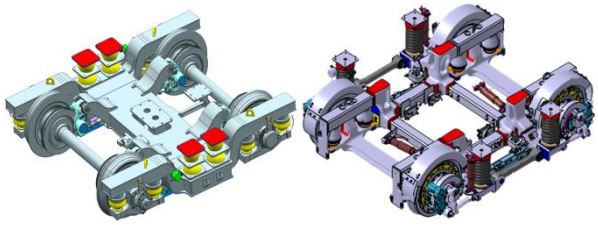
* dingjunjun@swjtu.cn

Abstract: We researched the dynamic performance and the wear between the wheels and the rails of two types of 70% low-floor trams. We analyzed the steering mechanism of rigid wheelsets and independent rotating wheels. Two kinds of vehicle model were considered, with traditional rigid wheelsets and independent rotating wheels in the trailer bogies, respectively. Moreover, we compared the wheel wear condition based on the Archard wear model.



Keywords: 70% low-floor, trailers; independent rotating wheel; wear.

1. Introduction

The most common light-rail vehicles are 70% low-floor and 100% low-floor trams. Compared to 100% low-floor trams, the technology of 70% low-floor trams is more mature and more widely used. The head and tail cars of 70% low-floor trams generally have power bogies and traditional rigid wheelsets. Therefore, the floor of the vehicle body is high. Intermediate cars have trailer bogies and independent rotating wheels or small-radius wheelsets to achieve a low floor.

There has been a significant amount of research on the performance of independent rotating wheels in rail vehicles. Elkins [5] undertook a comparative analysis of a single bogie using rigid wheelsets, independently rotating wheels, and various combinations of these. He proved that bogies with independent rotating wheels had the highest critical speed. Bogies with rigid wheelsets in front and independent wheels behind had good guiding ability. These calculations are consistent with the research of Suda et al [6]. Huang et al [7,8] analyzed the dynamic performance on straights and curves of a single vehicle with independent rotating wheels through the derailment coefficient and considered the wheel flange wear problem. They suggested that the centering ability of independent rotating wheels was an urgent problem to be solved. Ren [9] looked at the guiding ability of independent rotating wheels and compared the feasibility and effect of two types of suspension technology: passive suspension and active guiding. He also described an integrated control method for the stability of independent rotating wheels. Shen et al. [10] analyzed the derailment coefficient and flange wear of low-floor vehicles with independent rotating wheels, and proposed suggestions for reducing the derailment coefficient and wheel/rail wear.

Low-floor vehicles in Berne, Switzerland, the S70 trams produced by Siemens, and the 70% low-floor trailers produced by Guangzhou Electric Locomotive Co. Ltd. all have rigid wheelsets. Trams in Rostock and Bochum, Germany, 70% low-floor trailers in Boston, USA, and, Shenyang Lightning Railway cars in Hunnan, China, have independent rotating wheels. The structure of Guangzhou's 70% low-floor trailer bogie with rigid wheelsets (a) and that of the 70% low-floor trailer bogie used in Hunnan, Shenyang with independent rotating wheels (b) are shown in Figure 1.

(a) *(b)*

Figure 1 *Two different non-powered bogies of tram*

Both trailer bogies have a frame, a primary suspension, a secondary suspension, a basic braking device, and other parts. They have the same wheel diameter. The biggest difference is that the former has rigid wheelsets and the latter has independent rotating wheels. In this paper, we compare the straight running stability, smoothness, and curve passing performance of these two types of 70% low-floor trams. Based on the Archard wear model, we calculated the wear distribution of the two vehicles in straight running and their wear evolution patterns while running in a curve, to provide a theoretical basis for independent rotating wheels in trams and for reducing wheel/rail wear.

2. Guiding Principle of Wheels

When a vehicle is running on a curve or a straight line, the wheels will traverse and be subject to yaw due to irregularities in the line. The lateral creep force T_y between the wheels and the rail and the lateral force F_g between the wheels and the rail interact to reduce the lateral displacement of the wheel y and the yaw angle ψ. The lateral force component of the normal force between the wheels and the rail is expressed as the difference S between the gravitational restoring force of the left and right wheels when the wheel tread makes contact with the rail. That is, $S=S_l - S_r$. When the flange makes contact

with the rail, the resultant force of the flange force N_y and the gravity restoring force difference S is

$$F_g = \begin{cases} S_l - S_r & \Delta y > 0 \\ S_l - S_r + N_y & \Delta y = 0 \end{cases} \quad (1)$$

where Δy is the distance of the wheel flange from the rail.

When a vehicle with rigid wheels is running, the left and right wheels are coupled through the axles, and there is no relative rotation. The lateral displacement and the yaw change together, as shown in Figure 2.

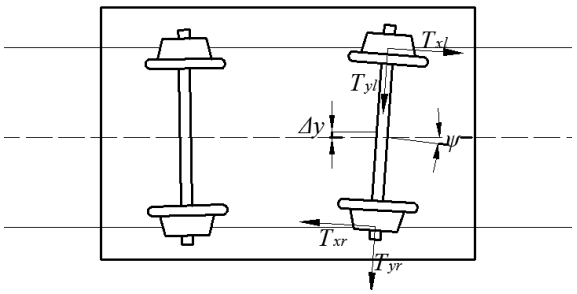


Figure 2 *The guide of rigid wheelset running straight*

When the vehicle is running in a straight line, the wheelset is offset to the left by a certain distance y with respect to the center of the track due to line irregularities. The longitudinal creep moment generated by the left and right wheels will cause the wheelset to deflect clockwise by a certain angle ψ. The lateral creep force generated by deflection with the gravity restoring force S generated by the wheels on the left and right sides act together to return the wheelset to the center position. The slewing moment produced by the longitudinal creep force can reduce the steering angle and the amount of lateral displacement of the wheelset when the vehicle is running in a straight line, acting as a guide.

Independent rotating wheels on the left and right can rotate freely. When the wheels are offset from the center of the track by a certain distance, although there may be a difference in the rolling diameters of the two wheels, there is no longitudinal creep force. The wheels will not be subject to yaw. Only the difference in the gravity restoring forces between the right and left wheels will act to adjust the position of the wheels. The gravity restoring force plays a significant role when the lateral displacement of the wheels is large. This effect decreases as the lateral displacement decreases, so it can take a long time for the independent rotating wheels to return to the center and they may waggle if there are continuous irregularities. If a wheel undergoes yaw ψ, the lateral creep force causes the wheel to traverse. Because there is no longitudinal creep moment, the wheel will traverse through angle ψ until the lateral creep force balances the gravitational restoring force. An independent rotating wheel has no longitudinal creep and no hunting motion. Although the linear running speed of the vehicle can, theoretically, be infinite, the line running performance is not necessarily better than that of a rigid wheelset due to line excitation disturbances [11].

Because of the running speed, there may be a large difference between the position of the wheelset when a bogie is running on a large radius curve and on a small radius curve. However, according to D'Alembert's theorem, the force and moment of a bogie are balanced at all times when moving. Taking a bogie with a rigid wheelset as an example, when the vehicle passes through a curve, the balance between the force and moment of the bogie is

$$T_{y1l} + T_{y1r} + T_{y2l} + T_{y2r} + F_{g1} + F_{g2} + F_C = 0 \quad (2)$$

$$M_{zx1} + M_{zx2} + M_{zy1} + M_{zy2} + M_{g1} + M_{g2} + M_{zS} = 0 \quad (3)$$

whereT_{y1l}, T_{y1r}, T_{y2l}, and T_{y2r} are, respectively, the horizontal creep forces of the left and right wheels of the first and second wheelsets of the bogie. F_{g1} *and* F_{g2} are, respectively, the lateral force components of the normal forces between the wheels and the rail of the first and second wheelsets of the bogies. F_C is the centrifugal force acting on the bogie. M_{zx1} and M_{zx2} are, respectively, the longitudinal creep moments of the first and second wheelsets of the bogie. M_{zy1} and M_{zy2} are, respectively, the slewing moment circling at the center of the bogie generated by the lateral creep from the first and second wheelsets of the bogie. M_{g1} and M_{g2} are, respectively, the moments generated by the lateral force components of the normal force between the wheels and the rail of the first and second wheelsets of the bogie. M_{zS} is the other moment acting on the bogie from other components, such as the car body.

When the vehicle is running on a large radius curve, the first and second wheelsets of the bogie are offset toward the outer side of the curve, and generally there is no flange contact. The force and moment are shown in Figure 3.

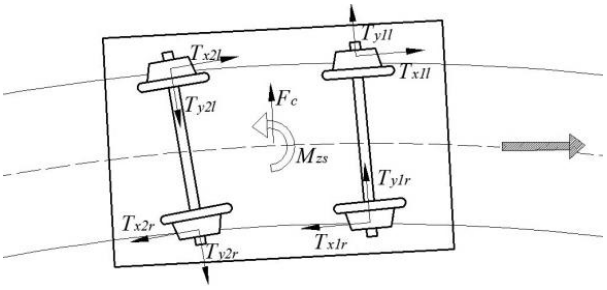

Figure 3 *The wheelset position when vehicle passes through the large radius curve*

The moments of the other components acting on the bogie running on a curve are counterclockwise. These moments are not conducive to the passing of the bogie through the curve and they are called non-guiding moments. In contrast, the longitudinal moment generated by the longitudinal creep of the wheel is conducive to the passage of the bogie through the curve. It is called a guiding moment. Independent rotating wheels do not have longitudinal creep. We can see from formulae (2) and (3) that the lack of a longitudinal creep moment results in an increase in the lateral force between the wheels and the rail. To increase the guiding force, an independent rotating wheel often adheres to the flange guide on large radius curves, so that its dynamic performance is generally poorer than that of a rigid wheelset.

When the bogie is running on a small radius curve, the relative position of the wheelset is as shown in Figure 4. The bogie is in the maximum deflection position. The first wheel flange is in contact with the rail, and the second wheel is offset on the inner side of the curve. As with the large radius curve, the moments acting on the bogie due to the other components are non-guiding moments. The longitudinal creep moment generated by the first wheelset is a guiding moment, but now, the longitudinal creep moment generated by the second wheelset is opposite to the first wheelset and it is a non-guiding moment. Compared with a large radius curve, this moment can weaken or eliminate the guiding moment since it can be larger than the guiding moment generated by the first wheelset. It is not conducive to the vehicle passing through the curve. Independent rotating wheels do not have longitudinal creep. The first wheelset does not generate a guiding moment, and similarly, the second wheelset does not produce a non-guiding moment. Therefore, according to formulae (2) and (3), it is impossible to compare directly the advantages and disadvantages of the dynamic performance of the two model vehicles on a small radius curve.

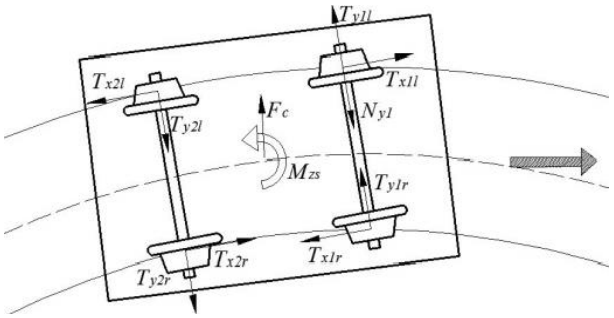

Figure 4 *The wheelset position when vehicle passes through the small radius curve*

3. Vehicle Dynamics Model

In the model, the 70% low-floor tram consists of two power units of the same type and a trailer vehicle, with the configuration power unit–trailer–power unit. The power units have a vehicle body, bolster, frame, motor gearbox, wheelsets, and various connecting components. The trailer vehicle is not powered, so it does not have a bolster or motor gearbox parts. The powered vehicles and trailer are connected by articulated devices and dampers. It runs on a 59R2 groove track with a non-standard tread suitable for a 59R2 track to achieve good matching between the wheels and rails.

We built two 70% low-floor vehicle models in the dynamic simulation software Universal Mechanism. The first model is a low-floor vehicle from Guangzhou with a rigid wheelset (Figure 5). In the second model, the trailer wheels were changed to independent rotating wheels, while the other parameters were unchanged.

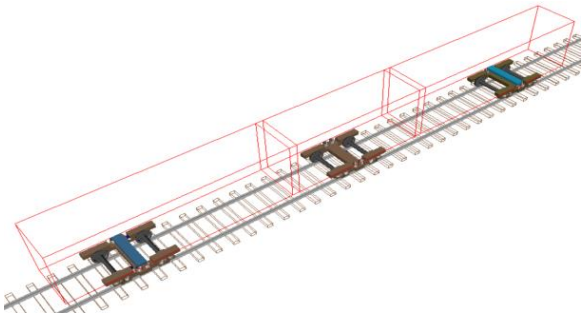

Figure 5 *The dynamic model of 70% low floor tram.*

4. Wheel Wear Prediction Model

There are two categories for the classical methods of wear calculation. The first is based on energy consumption, such as the wear index model and the Specht model, and the second is based on the wear volume, such as the Archard wear model. The Archard model is widely used in tribology analysis and in bearing wear calculations. The macro expression of the wear model is

$$V_{wear}=k_wNL/H \quad (4)$$

where V_{wear} is the wear volume, k_w is the wear coefficient, N is the contact normal force, L is the slide distance, and H is the material hardness.

The Archard wear model is applied to the wheel/rail contact calculation. By considering the position of the contact point and the microscopic slip, as shown in Figure 6, formula (4) can be rewritten as

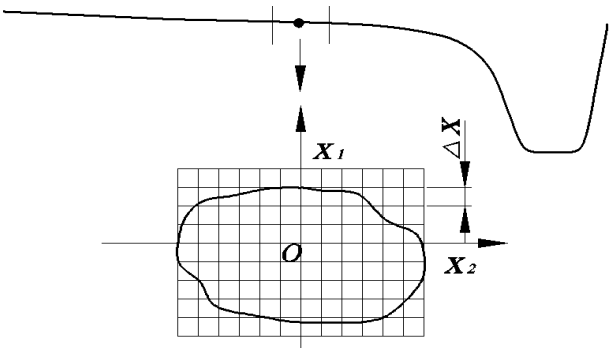

Figure 6 *The unit division wheel - rail contact spot*

$$\Delta z(x_1,x_2)=\frac{3Nk_w}{2\pi abH}\sqrt{1-(\frac{x_1}{a})^2-(\frac{x_2}{b})^2}\sqrt{s_{x_1}{}^2+s_{x_2}{}^2}\frac{\Delta x}{V_c} \quad (5)$$

where $\Delta z(x_1, x_2)$ is the amount of wear at $(x1, x2)$ within the contact spot. Δx is the unit length divided by the contact area. a and b are the length of the longitudinal and horizontal axes of the contact spot respectively. s_{x1} and s_{x2} are the sliding speed in the x_1 and x_2 directions. V_c is the calculated point speed. Ignoring the plastic deformation of the material, the above formula can be rewritten as

$$\Delta z(x_1, x_2) = \frac{3\Delta x N k_w}{2\pi abH}\sqrt{1-(\frac{x_1}{a})-(\frac{x_2}{b})} \times\sqrt{(\zeta-\Phi x_2)^2+(\eta+\Phi x_1)^2}\,\frac{V_x}{V_c} \quad (6)$$

where ζ, η, and Φ are the longitudinal creep rate, the lateral creep rate, and the self-rotating creep rate, respectively. V_x is the wheel rolling speed.

The Archard model takes into account the relative sliding speed; the longitudinal, horizontal, and self-rotating creep rates; material hardness; normal force; and other factors of the wheel/rail contact position [12]. By comparing the calculation results of the Archard model and the Specht model with measured data, the Archard model has been shown to be superior. In this paper, we use a wear model to calculate the wheel wear distribution of two low-floor trams. The FASTSIM algorithm based on Kalker's theory runs quickly and produces accurate calculation results. It is fully consistent with the Archard wear model. We calculate the normal force of the wheel/rail contact with this method.

5. Wheel Wear Calculation

5.1 Simulation of Wheel Wear

The wheel wear simulation incorporates a vehicle system, a wheel/rail contact model, a wheel wear model, a calculation simulation program, and a tread update strategy. The wheel wear process is shown in Figure 7.

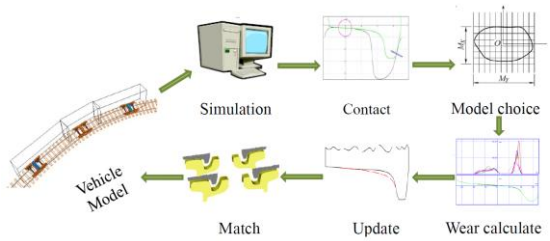

Figure 7 *The simulation flow of wheel wear*

In general, when the wear on a wheel reaches a certain depth or the vehicle has run for a certain mileage, the tread should be replaced. This changes the wheel/rail matching relation, which is used by the vehicle dynamic model to calculate wheel wear. To compare the wear for our two vehicles, we change the tread based on the mileage.

The wear for each position in the contact area is calculated using the Archard wear theory after the wheel has rotated one cycle. After the vehicle has run a certain mileage, the current total wear of the wheel is calculated using

$$\Delta V = \sum_{i=1}^{MAX}\Delta z(x_1, x_2) \quad (7)$$

where ΔV is the total wear amount after the wheel has run a certain distance.

5.2 Simulation Result for Wheel Wear

For a vehicle operating in a straight line, we divide its running speed into six ranges, and consider the average for each range in calculating the wear for the two vehicle models. We found that the wear increases as the speed increases. Under the same conditions, the wear patterns of the wheels of the two vehicles at each speed level were exactly the same.

Figure 8 shows the proportion of the time spent traveling at each speed when the vehicle is operating in a straight line. Using the proportions shown in Figure 16, we weight the vehicle operating speeds and calculate the wear for different wheels after the two vehicle models have run for 100,000 km, as shown in Figures 9 and 10. The results show that the wear amount and the wear distribution of the first wheelset of the head car of the two low-floor vehicles are basically the same. The most wear occurs around the nominal rolling circle of the wheels. The maximum difference between the wear for the head cars of the two vehicles is 5.96%.

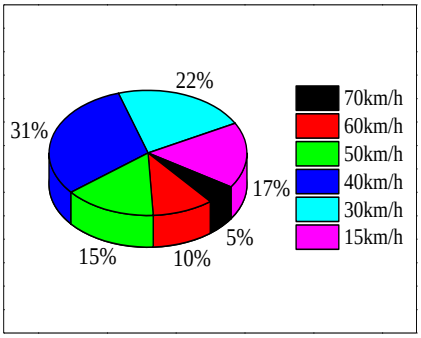

Figure 8 *The proportion of vehicle speed*

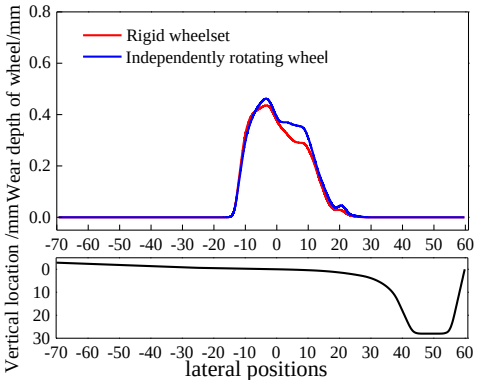

Figure 9 *Wheel wear of first wheel of motor car in straight line*

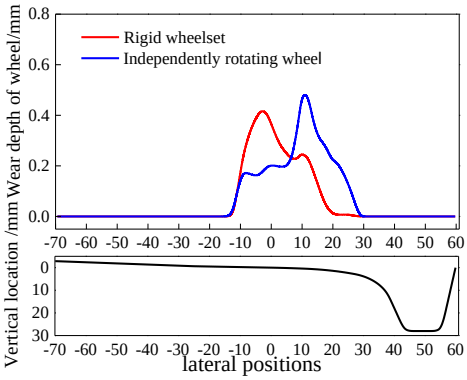

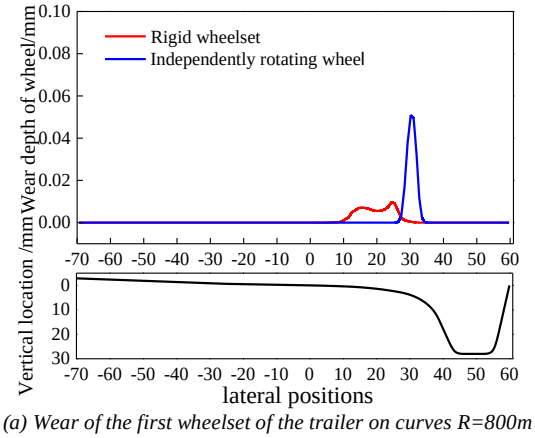

Figure 10 *Wheel wear of trailer in straight line*

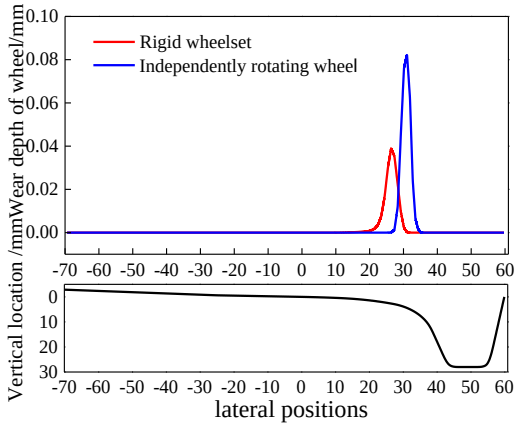
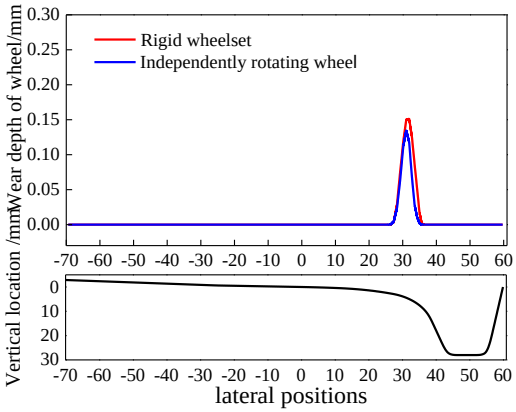
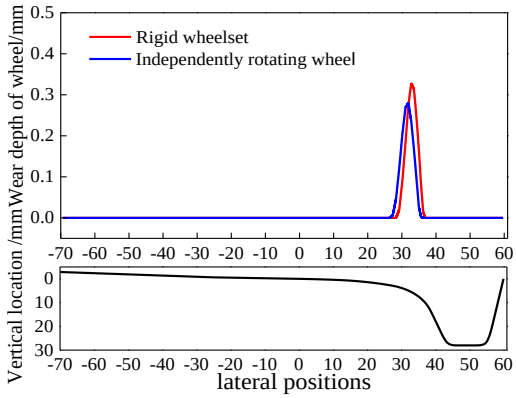


Compared to the wheelsets of the head cars, the wheel wear value and distribution of the first wheelset of the trailers of the two models differ greatly. The wheel wear distribution of the rigid wheelset is consistent with the wheel wear distribution of the first wheelset of the head car, but the peak is slightly smaller. The wear for the independent rotating wheels is relatively large and the wear range is wide. Compared with the rigid wheelset, the peak wear for the independent rotating wheels is 15% larger and closer to the flange. This is because the independent rotating wheels have no longitudinal creep, and their guiding ability with line irregularities is poorer. Moreover, the equivalent conicity of the wheel tread at the flange is large. This can provide a greater gravity restoring force to the independent rotating wheels, allowing them to guide. However, the head car with a rigid wheelset has a good centering ability when driving in a straight line, acting through the articulated device to drive the trailer bogie to the center of the track. Under continuous horizontal irregularities, the lateral shaking of the independent rotating wheels is large, resulting in a larger lateral creep force, wide wear position, and high amount of wear.

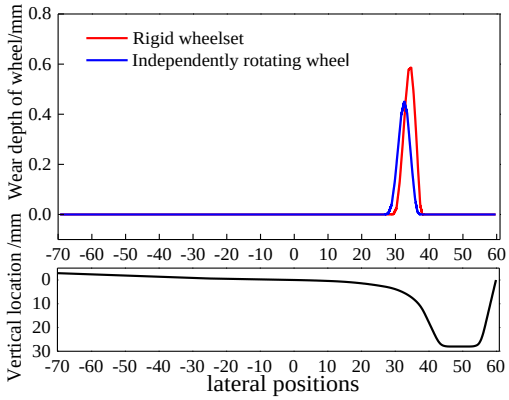
The combination of a head car with a rigid wheelset and a trailer with independent rotating wheels is similar to the combination where the front wheelset of a bogie has a rigid wheelset and the rear wheelset has independent wheels. However, the connection between the vehicle bodies is weak, so the effect of the former is weaker than the latter but is stronger than for a vehicle with only independent rotating wheels [11].



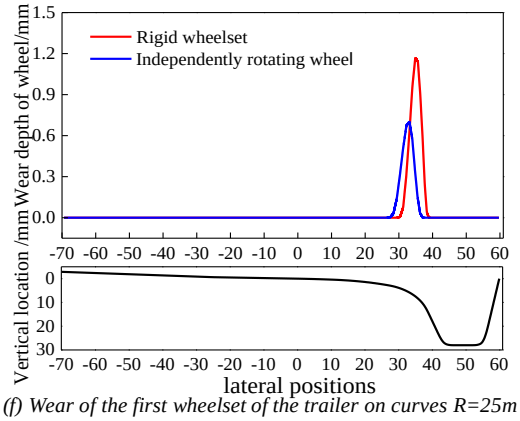
To study the wear state of the outer wheel passing through curves with different radii, the vehicle is driven in a single direction. The rest of the analysis uses this method. On comparing the wheel wear of the two vehicles running on different curves, we found that it depends on the curve passing performance. That is, as the radius of curvature decreases, the wheel wear increases and the wear is closer to the flange. The wear distribution of the wheelsets of the head cars of the two vehicles is basically the same. The maximum difference between the two for various curves is 6.87%. However, the wheel wear distribution of the trailers of the two vehicles is quite different. The wheel wear of the trailers of the two vehicles after running for 100 km on curves with various radii is shown in Figure 11.



(a) Wear of the first wheelset of the trailer on curves R=800m



(b) Wear of the first wheelset of the trailer on curves R=500m



(c) Wear of the first wheelset of the trailer on curves R=200m

(f) Wear of the first wheelset of the trailer on curves R=25m

Figure 11 *Wheel wear for different curves*

The simulation results show that when a vehicle is running on a large radius curve, the rigid wheelset has better guiding performance and the wear position is closer to the pure rolling line. The wear for independent rotating wheels is closer to the flange and the wear amount is much larger than that of the rigid wheelsets. As the radius of curvature decreases, the wear for both vehicles increases and the wear position approaches the flange. The wear position of the independent rotating wheels has a smaller offset and the wear position of the rigid wheelset changes significantly with a decrease of the radius of curvature. When the radius of curvature is R = 200 m, the wear position for the two vehicles is the same. When the radius of curvature is reduced to $R \leqslant$ 100 m, the lateral displacement of the rigid wheelsets is greater than that of the independent rotating wheels. The wear is closer to the wheel flange and is larger than for the independent rotating wheels. As the radius of curvature decreases, the longitudinal creep force of the rigid wheelsets rapidly increases and the longitudinal creep moment generated by the second wheelset changes from a guiding moment to a non-guiding moment, which is unfavorable. When the radius of curvature is R = 25 m, the wear for the independent rotating wheels is only 60% of that for the rigid wheelsets.

6. Conclusion

In this paper, we analyzed the guiding mechanism of a rigid wheelset and independent rotating wheels and established dynamic simulation models for two 70% low-floor trams, one with a trailer with rigid wheelsets and one with a trailer with independent rotating wheels. We compared the wheel wear for the two vehicle models running on a straight line and on curves with different radii. We obtained the following conclusions:

- When the vehicle is running in a straight line or a curve, there is little difference in the wear distribution of the wheels of the head cars between the two vehicles, whereas the wear position and wear volume of the wheels between the two trailers have a large difference. The variation of the wear distribution of the two trailers depends on the curve passing performance. A rigid wheelset has less wear on straight lines and large radius curves, and independent rotating wheels are more advantageous on small radius curves.

Abstract: A short-pitch rail corrugation occurred in tracks with Vanguard fastener is extensively found on different metros in China. Field measurement and numerical calculations are used to study the cause of corrugation formation. Corrugations with wavelengths of 30-60 mm occur on the tracks for both curves and straights. The corrugation frequency is in the range of 340-700 Hz. Wavelength of corrugations mainly depends on stiffness of fastener. Tracks with resilient fasteners with vertical stiffness of less than 20 MN/mm are easily produced corrugations with wavelengths of 30-63 mm. Initiation of the corrugations is strongly related to vertical dynamic characteristics of tracks.

Keywords: short-pitch rail corrugation; metro; tracks; resilient rail fastenings; wheel-rail contact; finite element method.

1. Introduction

The rail corrugation is one of the damage for wheel-rail system. Short-pitch rail corrugations with a wavelength of 25-60 mm have become popular at the metro lines in china. Resilient fasteners are used at these lines. Short-pitch corrugations cause the wheel-rail high-frequency vibrations which resulting in the annoying noise and components failures of train and track.

Stiffness of rail fastener plays a key role in generation and growth of corrugation, which is verified by different researchers[1-2,7-8]. The influence of rail pad stiffness on rail corrugation growth and vertical track receptance were studied by Ilias[1]. The vertical value of rail pad stiffness varied from 500 MN/m to 60 MN/m. it was found that antiresonance of track system becomes more obvious when increasing pad stiffness, which produces higher contact forces and a higher corrugation growth rate[1]. Egana et al[2] studied the influence of the stiffness of rail pads on corrugation by field test in the curved track. It was found that soft pads with a stiffness of 60MN/m were sufficient to reduce corrugation growth and a corrugation with wavelengths developed when using stiff pads could be eliminated. Hiensch et al[3] studied rail roughness growth by using numerical simulation of dynamic train/track interaction. It was concluded that the roughness growth rate for ballasted tracks could be decreased by changing stiff rail pads to softer rail pads. Grassie and Elkins[4] investigated rail corrugations on North American transit systems by observation, measurement and simulation. In order to avoid a corrugation at passing frequency of about 100 Hz arising from excitation of the vehicle's unsprung mass on the track stiffness, more resilient fastening with stiffness of less than 30 MN/m should be employed [4]. Diana et al. [5] showed a rail corrugation phenomenon in sharp curves at the Milano subway. It was observed that rail corrugation was alleviated by adopting softer rail pads on the same track. Li[6]presented a vehicle-track dynamic interaction model which predicted a short-pitch corrugation initiation and growth. It concluded the longitudinal vibration modes are probably dominant for the corrugation initiation. The main frequencies of longitudinal vibration mode for tracks could be changed by the control of certain track parameters, such as rail fastening.

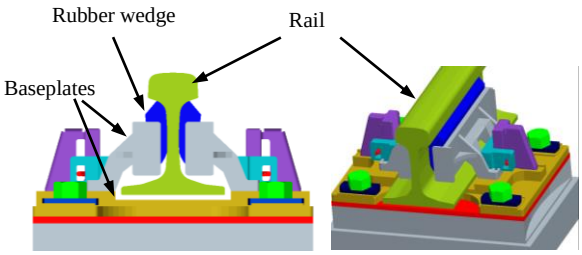
At all, characteristics of rail corrugation are related to the fastener stiffness. This paper investigates a type of short-pitch rail corrugation which occurs on the track with a resilient fastener called 'Vanguard'. Measurement and numerical calculations are employed to study the cause of the corrugation formation. Characteristics of rail corrugations on the track with Vanguard fasteners, such as the wavelength, passing frequency and radius of track, are investigated at metro lines in different China cities. Influence of fastener systems on corrugation wavelengths is analysed. In order to investigate the influence of dynamic behaviour of tracks on the corrugation, railhead vibration is measured by the accelerometers during the vehicle passing through the tracks with Vanguard fasteners. A finite element model for wheel-rail transient rolling contact is also established to investigate the influence of flexible tracks on the wheel-rail force.

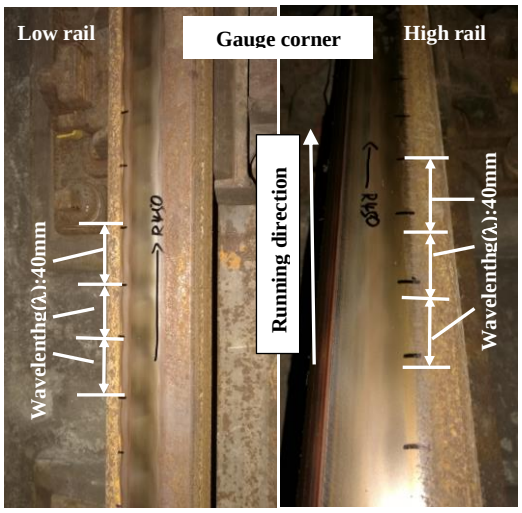
2. Field measurement for short-pitch rail corrugation

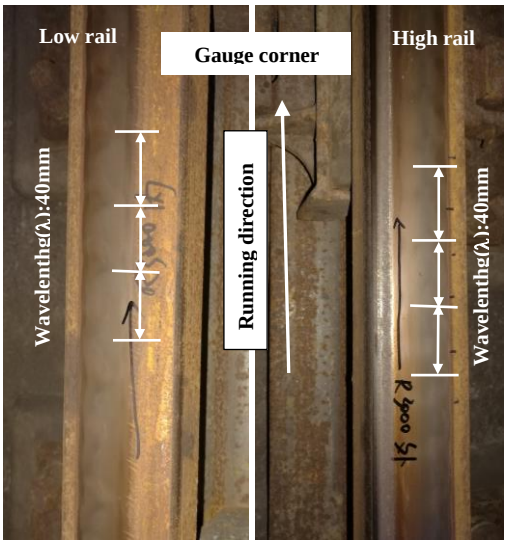
2.1. Wavelength and frequency for rail corrugations

Vanguard fastener which delivers high vibration attenuation for tracks is mounted on a concrete slab through concrete sleepers. The value of its vertical stiffness is about 5-8 MN/m. It is used to isolate the wheel-rail vibration through floating rail and provide damper of tracks, as shown in Figure 1. A type of short-pitch rail corrugation phenomena is found both on

curved and straight tracks with Vanguard fastener in different metro lines of china, as shown in Figure 2.







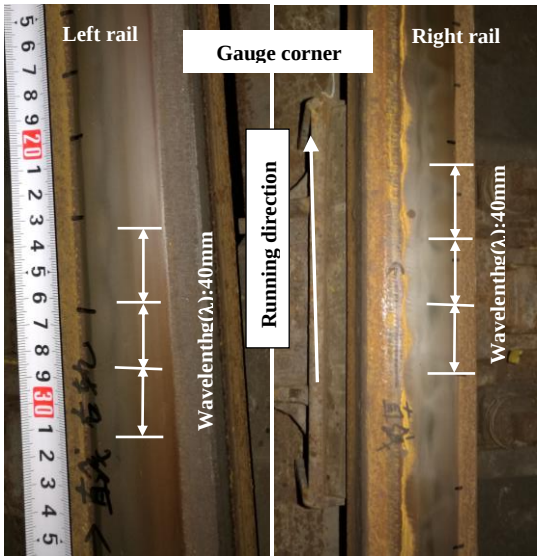


Figure 1 A resilient fastener called 'Vanguard'（Rubber wedges are used to support the rail at the web and under its head）

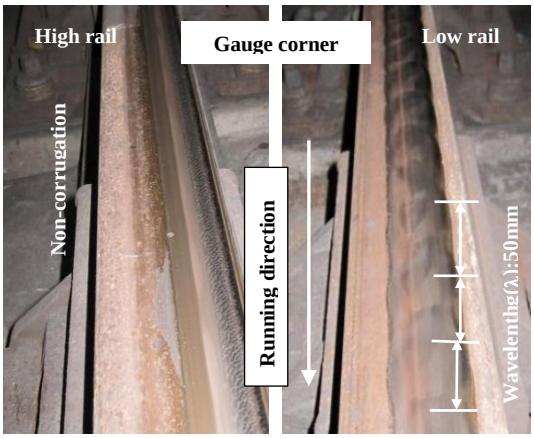


(a) Sharp curved track (Changsha metro line 2：R=450 m, 74km/h)

(b) Gentle curved track (Changsha metro line 2：R=3000 m, 75km/h)

(c) Straight track (Changsha metro line 2：74km/h)

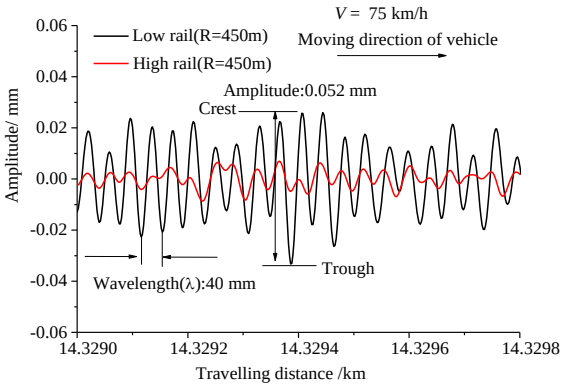
(d) Curved track (Guangzhou metro line5：R=550 m, 83 km/h)

***Figure 2** Short-pitch rail corrugations phenomena on the tracks with a resilient fastener called "Vanguard"*

In order to obtain characteristics of rail corrugations, a device called "Corrugation Analysis Trolley (CAT)" is used to measure rail roughness at metro lines in different China cities. The cities investigated include Guangzhou, Chengdu, Changsha, etc. Corrugation measurements are carried out on both curves and straights.

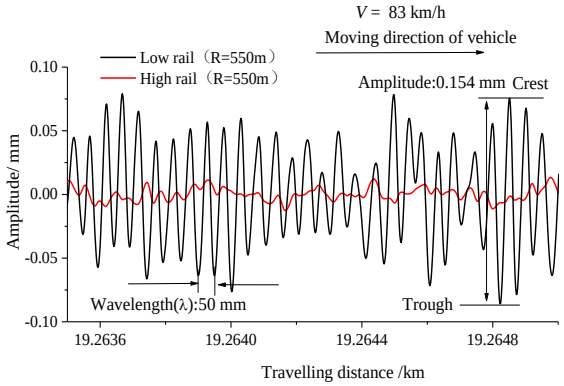
To obtain comprehensive characteristics of rail corrugations, field results for two metro lines on which Vanguard fasteners are extensively employed are selected to analyze. One line is Guangzhou metro line 5 which is abbreviated as GZ5. Another is Changsha metro line 2 which is abbreviated as CS2. On each line, only one type of vehicle is used. Characteristics of vehicles and tracks in two metro lines are given in Table1.

Table 1 *Characteristics for two metro lines*



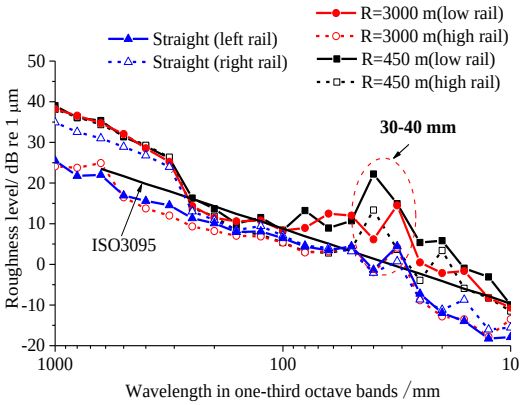
Characteristics		Guangzhou metro line 5(GZ5)	Changsha metro line 2(CS2)
Track	Rail type	60 kg/m	60 kg/m
	Fastening system	Conventional and resilient fasteners	Conventional and resilient fasteners
	Sleeper type	Long, concrete	Short, concrete
	Track layer	Concrete	Concrete
	rail inclination	1/40	1/40
	Sleeper spacing(mm)	625	600
Vehicle	Axle load(t)	13	14
	Type	Linear-motor-driven subway system	A traditional vehicle
	Average speed(km/h)	85	75
	Diameter of axles(mm)	136	195
	Nominal diameter of new wheels(mm)	730	840

Figure 3 shows rail roughness on tracks with Vanguard fasteners at CS2 and GZ5 metros after about 2.5 years of operation. Figure 3 (a) illustrates a section of rail roughness in a curve with a radius of 450 m at CS2 metro. Figure 3 (b) illustrates a section of rail roughness in a curve with a radius of 550 m at GZ5 metro. Figure 3 (c) and (d) shows rail roughness level spectra for different curves in one-third octave bands. In Figure 3 (c) and (d), solid and dotted lines represent results of low and high rails, respectively.



It can be found that serious short-pitch rail corrugation happened both on the tracks with Vanguard fasteners at CS2 and GZ5 metros after 2.5 years of vehicle operation.

At CS2 metro, corrugations with wavelengths of 30-40 mm occur both on straights and curves with radii of 450m and 3000 m. Level of the corrugation in low rail for curves is significant higher than that in high rail. This is because higher lateral creepage forces of leading wheelset happening on low rails. On the straight, level of corrugations on left and right rails is the same due to the similar wheel-rail longitudinal creepage forces.



At GZ5 metro, corrugation with wavelengths of 40-50 mm also occurs on straights and curves. The smaller radius of the curve is, the higher rail roughness level is. Compared with the result for CS2 metro, the amplitude of short-pitch corrugations at GZ5 metro is larger. However, the unspring mass of vehicle including wheelset and bogie at GZ5 metro is smaller than that at CS2 metro. Wheel roughness at two metros may be one of important factors for this difference, which could result in large fluctuated wheel-rail force. Out-of-round of wheels for the vehicle at GZ5 metro in which disc brakes are used is serious. Wheel roughness of the vehicle at CS2 metro in which tread brakes are used is lower.

Figure 3 *Measured results of rail roughness on the tracks with Vanguard fasteners*

Detailed results of rail corrugations for CS2 and GZ5 metros, such as passing frequency, wavelength, amplitude， are respectively summarized in Table 2 and Table 3. In the tables, passing frequency of rail corrugations (f) is calculated by using a formula $f = v/\lambda$. Predominant speed of vehicles (v) and main wavelength of corrugations (λ) are obtained through measurement. Amplitude is obtained after filter processing from 25 to 80 mm. A linear-motor-driven subway system is used at GZ5 metro. Its vehicle is about a linear induction motor. A traditional vehicle is used at CS2 metro.

From Table 2, it can be seen that the main wavelength of corrugation is about 30-40 mm and 50-60 mm at the CS2 metro. Their passing frequencies vary from 340 to 700 Hz. The main wavelength of corrugation at the GZ5 metro is about 30-40 mm and 40-50 mm. Their passing frequencies vary from 455 to 650 Hz. In all, the corrugation wavelengths at metro tracks with Vanguard fastener exhibit short pitch of about 30-60 mm. The corrugation passing frequencies exhibit high frequencies of about 340-700 Hz. And the type of short-pitch corrugation observed on the track of Vanguard fastener arises by “wavelength-fixing mechanism” which is described in reference [9].

Besides, the same wavelength bandwidth and passing frequencies for corrugations also have taken place on tracks installed the Vanguard fasteners on other metro lines, such as Guangzhou metro line3, Chengdu metro line2 etc.

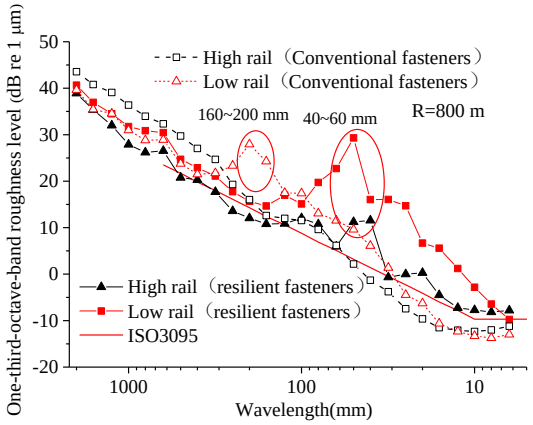
2.2. Field investigations on the cause of rail corrugation formation



2.2.1 Characteristic of corrugations on one curve with two types of fasteners at GZ5 metro

Figure 4(a) shows values of root-mean-square (RMS) for rail roughness on a sharp curve with a radius of 800 m at GZ5 metro. In Figure4 (a), the length of block is about 0.125 m. Two fastening systems are used to support the rail at the curved track, as shown in Figure 4(a). One is about a conventional fastener called “DTVI”. It covers the distance of 340 m. Its vertical stiffness is about 40 MN/m. Another is about the Vanguard fastener which covers the distance of 180 m. Figure 4(b) shows spectra of rail roughness level for the tracks with two fasteners in the curve. Speed of vehicle running on the curve is the same and about 83 km/h.

Two types of rail corrugation have been found in one curved track. A type of corrugation with a main wavelength of 160-200 mm occurs on the curve with the conventional fasteners. Passing frequency of the corrugation is about 114-142 Hz. In addition, a short-pitch corrugation with a main wavelength of 40-60 mm occurs on the curve with the Vanguard fasteners. Passing frequency of the corrugation is about 380-570 Hz.

(a) Root-mean-square (RMS) of rail roughness along the travelling distance

(b) Spectra of rail roughness level for tracks

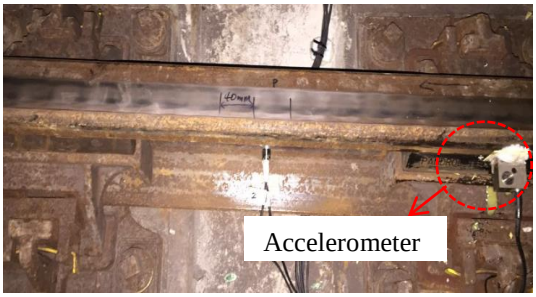


Figure 4 *Rail roughness level for tracks in one curved track with two types of rail fastening system*

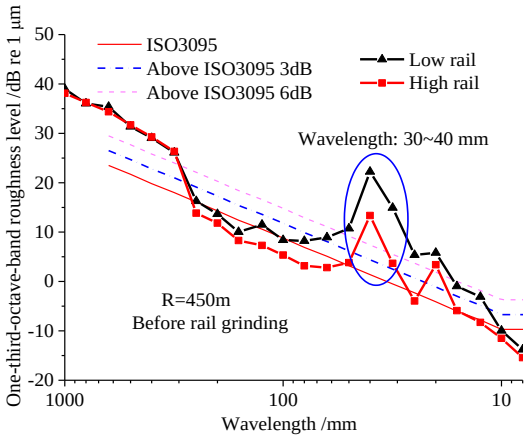
According to measurement and observation, two types of rail corrugation with different wavelengths and different passing frequencies have occurred on the same curve. It is caused by the discrepancy in rail fastening systems. It is deduced that the short-pitch corrugation occurred on the track with Vanguard fastener is related to the dynamic characteristic of the track. To investigate the dynamic behavior of the track, accelerations of track components were measured and analyzed when the tested vehicle passing by. Due to a limitation of field conditions for GZ5 metro, the measurement was carried out at CS2 metro

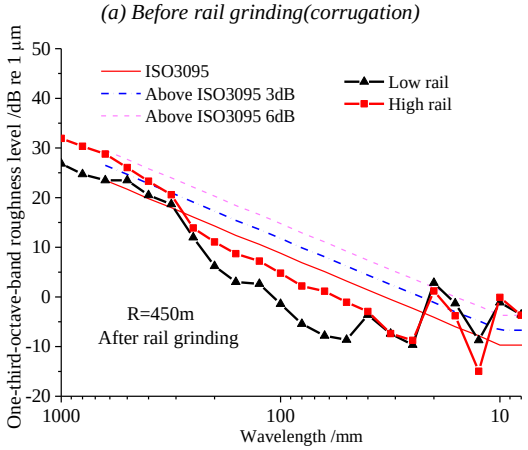
2.2.2 Vibration behaviors of railhead on corrugated and non-corrugated track at CS2 metro

Railhead vibrations are measured by accelerometers during a vehicle passing through tracks with Vanguard fasteners at CS2 metro, as shown in Figure 5. Figure 5 shows photos of rail surface before and after rail grinding in a tested track section with a radius of 450 m. Figure 6 shows one-third octave band frequency spectra of rail roughness level before and after rail grinding. In the field test, wheelsets of the tested vehicle are re-profiled to keep roundness of wheel surface.

Before rail grinding, it can be found that there are severe rail corrugations on the tested track, as shown in Figure 5(a) and Figure 6(a). Main wavelength of the corrugations is about 30-40 mm. After rail grinding, the corrugations occurred are remedied thoroughly, as shown in Figure 5(b) and Figure 6(b).



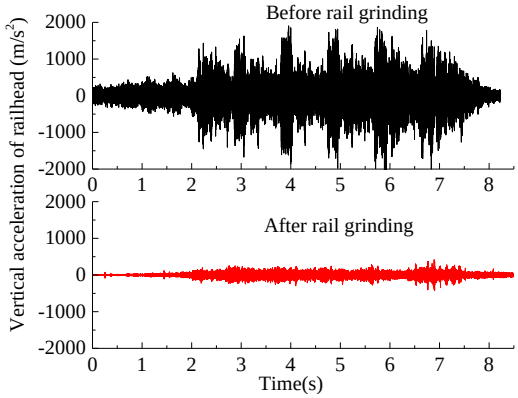
(a) Before rail grinding



(b) After rail grinding

Figure 5 *Rail surface photos before and after rail grinding on the track with Vanguard fasteners*

(a) Before rail grinding(corrugation)



(b) After rail grinding(non-corrugation)

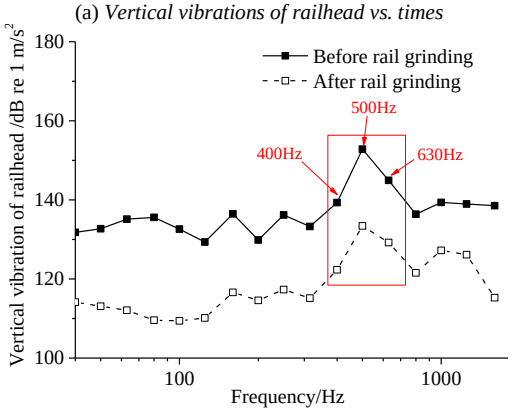


Figure 6 *Spectra of rail roughness level in tracks with Vanguard fasteners*

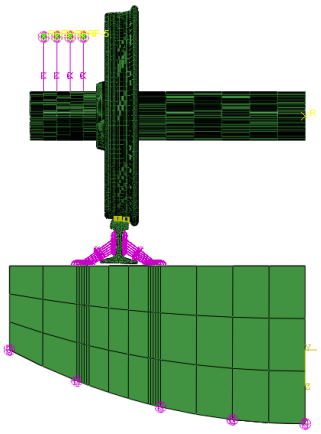
Figure 7 shows vertical vibration accelerations of railhead during the vehicle passing through the tracks with Vanguard fasteners before and after rail grinding. It can be noticed that level of rail vibrations with rail corrugations is higher than that without rail corrugations on the test track. Peaks of rail vibrations in dominant frequencies of 400Hz、500 Hz and 630 Hz occurred in the range of 400 and 630 Hz. These frequencies are approaching to passing frequencies of rail corrugations with wavelength of 30-40 mm. Of course, rail vibrations at these frequencies are strongly related to the existence of the short-pitch corrugations before rail grinding. However, the dominant frequencies of railhead vibration were generally still located between 400 and 600 Hz after rail grinding. Besides, the peaks of the dominant frequencies for rail vibrations at other sections of tracks with conventional fasteners don't occur under the same

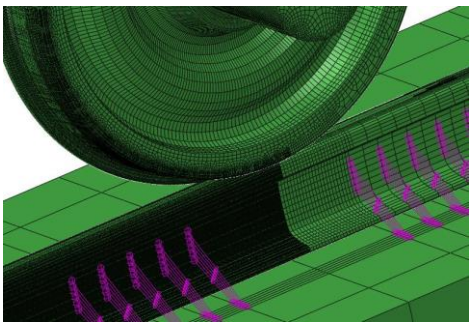
operation condition. Thus, vibrations of railhead after grinding at the dominant frequency range probably stem from dynamic characteristics of the track. The dynamic characteristic of the track is highly probable one main factor for cause of short-pitch corrugation formation.

(a) *Vertical vibrations of railhead vs. times*



(b) Spectra of railhead vibrations

Figure 7 *Vertical vibration of railhead during vehicle passing through tracks with Vanguard fasteners before and rail grinding*

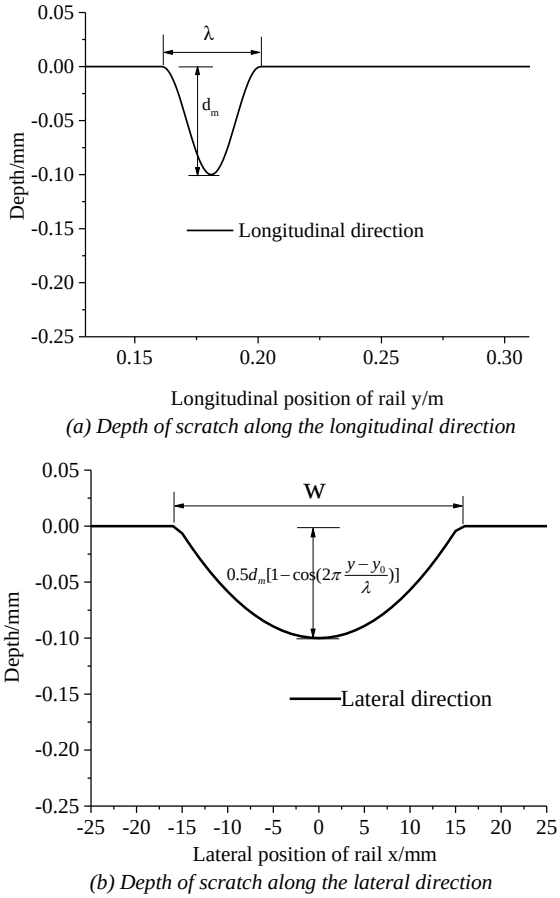


3. Numerical analysis

In order to simulate wheel-rail contact forces during wheelset running tracks with Vanguard fasteners, a numerical analysis is employed. The commercial software ABAQUS is used to establish a three-dimensional finite model of wheel-rail transient contact with considering the flexible track, as shown in Figure 8. In order to only study influence of track characteristics, wheelset is considered as a rigid body in the numerical model. The primary suspension is simulated by springs and dampers elements. It supports the bogie. The second suspension of a vehicle is not considered because the influence of the vibration of car body on the transient state of wheel-rail contact could be negligible. Vanguard fasteners are also simulated by springs and dampers elements, which connect rail web to sleepers. Sleepers inlay in the concrete slabs and there is no relative motion between the slab and sleeper, which means that the sleepers could be modeled as part of the slab in the track modeling.

The rail type considered is CN60 of China, and the rail cant is about 1/40. The track calculation length is 12.5m which covers 20 sleeper pitches. Eight-node linear brick elements are used. The model has 1023833 elements and 891898 nodes. Size of elements near the contact surface is 1 mm. The material in the model is considered as linearity. Besides, the lateral movement of the wheelset is constrained by symmetric boundary conditions. All the longitudinal displacement of the nodes at t two ends of the rail is restricted.

(a) Vehicle and track with *Vanguard fasteners interaction model*



(b) Mesh of contact area

Figure 8 *Representation of 3D vehicle–track FE model*

Wheel-rail contact forces are obtained through the numerical model when a wheelset passes through rails with surface scratch. The scratch irregularity is assumed on the running surface of the rail and described with the following function:

$$d(x,y) = 0.5d_{\mathrm{m}}[1-\cos(2\pi\frac{y-y_0}{\lambda})][1-(\frac{2x-2x_0}{w})^2] \qquad (1)$$

Where, d is depth of scratch at different locations of rail surface. d_{m} is maximum of the depth. λ is length longitudinal of scratch. y is the location of rail along the longitudinal direction. y_0 is the start point of scratch. w is lateral length of scratch. x is the location of rail along the lateral direction, x_0 is the central location of contact patch. The maximum depth (d_{m}) of scratch is about 0.1 mm, as shown in Figure 9(a). The lateral length (w) of scratch is about 32 mm, as shown in Figure 9(b).

(a) Depth of scratch along the longitudinal direction

(b) Depth of scratch along the lateral direction

Figure 9 *The longitudinal-vertical and lateral-vertical profile of the scratch*

Figure 10 shows wheel-rail vertical loads along the rolling direction under different wavelengths of scratch at a vehicle speed of 70 km/h. Figure 11 shows linear spectrums of the vertical loads under different wavelengths of scratch obtained by using Fast Fourier Transform. It can be found that when wavelength of rail scratch is about 40 mm, amplitude of vertical load at major frequency range is largest. The major frequency range is about 420-600 Hz. Second peaks of vertical loads at this frequency range happen when wavelengths of the scratch are about 30 and 50 mm. Besides, when wavelength of the scratch is far way from 30-50 mm, peaks of the loads at major frequencies of 400-630 Hz decrease. Therefore, the wheel-rail force at frequencies of 400-630 Hz appears maximum value at the scratch wavelength of 30-50 mm. It indicates a wheel-rail fluctuating normal forces at frequencies of 400-630 Hz easily occur when the vehicle-track system is excited by random irregularity of wheel-rail interface. The fluctuating normal forces which could cause fluctuating of wheel-rail creepages easily lead to corrugations. The peak frequencies of the wheel-rail force are close to some modal frequencies of the track, as shown in Figure 12. Figure 12 shows modal shapes of the track at frequencies of 480, 560, and 630 Hz. In Figure 12, the length of track is 12.5 m, which covers the distance of a slab. The modes indicate that vertical bending resonances of the rail at those frequencies. Therefore, the peaks of wheel-rail force at frequencies of 400-630 Hz occurred are related to vibration behaviours of the track.

In all, the corrugations with wavelengths of 30-49 mm easily develop at the vehicle speed of about 70 km/h due to the wheel-rail fluctuating normal force at frequencies of 400-630 Hz. The simulation results obtained are in agreement with results of the field test.

4. Discussions

In china metro lines, other two types of resilient fastening systems called "Cologne", "GJ-Ⅲ" are also used to isolate wheel-rail vibration. Their values of vertical stiffness are 10~12 MN/m and 12~14 MN/m, respectively. Short-pitch corrugations with the same wavelength of about 30-63 mm also occurred both in curves and straights, as shown in Table 4. Table 4 summarized measurement results of rail corrugations on tracks with the resilient fasteners. Sleeper distance of the tracks is 0.625 m. It can be found that passing frequencies of the corrugations on tracks with different resilient fasteners are similar. These frequencies are close to modal frequencies of tracks at which modal shapes represent rail vibrating relative to slab. However, this type of short-pitch corrugations has not occurred on tracks with a stiffer fastener called "DTVI" in the same operation conditions and radius curve. On the tracks for stiffer fasteners, most of serve corrugations happened on curves with radii of less than 800 m. Besides, their wavelengths are mainly in the range of 100-300 mm, by which passing frequencies caused are lower than 140 Hz. Therefore, the short-pitch corrugations on tracks with resilient fasteners arise by wavelength-fixing mechanism. Initiation and development of short-pitch rail corrugations are strongly related to dynamic characteristic of the track, which depends on stiffness of fasteners [7,8]. For tracks with resilient fasteners, the short-pitch corrugations with wavelengths of 30-60 mm can be suppressed by increasing the stiffness of fasteners. Its explanations and field applications are referred to in references [7,8]. This phenomenon is different from the results found by other authors like Grassie and Elkins [5], Egana [2] and so on.

Table 4 *Rail corrugation characteristic for other type of resilient fasteners*

Metro line	Wavelength(mm)	Amplitude (mm)	Passing frequency (Hz)	Speed (km/h)	Type of fastener systems	Radius of tracks
Guangzhou A	30-40	0.12	625-833	80-90	GJ-III	Straights and curves with radius of more than 800 m
Beijing metro A	40-50	0.15	194-382	35-40	Egg-type fastening system	350 m
	50-63	0.25	255-389	55-70		Straights and curves with radius of 800m、1000 m
Beijing metro B	50-63	0.05	308-444	70-80	Egg-type fastening system	Straight and curves with radius of 2004 m
Guangzhou metro D	30-40	0.12	486-648	70	GJ-III	950 m and straight
Guangzhou metro C	30-40	0.05	347-556	50-60	GJ-III	300 m (2 months after grinding)

5. Conclusions

A short-pitch rail corrugation occurred on the tracks with a resilient fastener called "Vanguard" is extensively found on different metro lines in china. To study of the short-pitch corrugation, field measurement for rail irregularity and vibration acceleration of track components in different sites is employed. A three-dimensional finite model for wheel-rail transient rolling contact is established to analyse the wheel-rail forces on the track with Vanguard fasteners. The fluctuating normal force at different frequencies is calculated to identify the influence of flexible tracks on the corrugation. The conclusions investigated are as follows:

The short-pitch corrugation with wavelength of 30-60 mm occurs on tracks with Vanguard fasteners for both the curve and straight lines. The predominant speed of vehicle is about 70-85 km/h. A typical corrugation frequency is in the range of 340-700 Hz. For the track with the resilient fasteners at metro, rail corrugations with the wavelength of 30-63 mm easily happen when the speed of train is large than 30 km/h. The short-pitch rail corrugation with a same wavelength develops faster on the curve than on the straight.

The wheel-rail fluctuating normal force at frequencies of 400-630 Hz on tracks with Vanguard fasteners easily occurs when the vehicle-track system is excited by random irregularity of wheel-rail interface. The short-pitch corrugation occurs on the track of Vanguard fastener is strongly related to the vertical dynamic

characteristic of the track. The wavelength of the corrugation depends on the stiffness of rail fastener. The tracks with resilient fasteners for the vertical stiffness of less than 20 MN/m are easily produced the short-pitch rail corrugation with the wavelength of 30-63 mm in china metro lines.

Abstract: This work aims to improve the understanding of the wear behaviour in grease-lubricated axle roller bearings. Wear debris were extracted from grease samples and then examined by using scanning electron microscopy (SEM) and energy dispersive X-ray microscopy (EDX). Results suggest that metallic debris found in examined bearings is predominantly generated under rolling contact wear. Spherical particles with dendritic and hollow interiors were found exclusively in the early life bearings, whereas those found in the medium and heavily used bearings have a very smooth surface. External wear debris, possibly due to the degradation of seals, was seen frequently in the heavily used field bearings.

Keywords: Axle roller bearing, EDX, SEM, wear debris analysis

1. Introduction

Rail axle bearings are a critical component of railway vehicles when considering operational life and transportation safety issues. Damage and/or failure of a bearing due to solid contamination in the lubricating system may adversely affect the operational capability of the entire train. Inadequate lubrication can lead to an increase in bearing vibration, excessive clearance between raceways and rollers which may in turn result in derailments or other disruptions to the rail network. For a rail operator, the replacement of a damaged bearing and the maintenance throughout a train's lifetime may prove very costly even in the absence of severe failure.

Different wear mechanisms generated different wear debris with different sizes, shapes and surface morphologies. Wear debris carried into the lubrication system resulting in contamination, is a major factor contributing to the shortening of rolling element bearing life [1, 2]. In the past, extensive studies have focused on establishing the representative relationship among wear debris, wear mechanisms and wear mode by analysing the debris generated in different lubricated systems, such as gearboxes [3~6], jet engines [7~9], helicopters [10], electric motors [11] and laboratory test rigs [12~14]. Among these studies, the investigation of wear debris analysis was carried out using scanning electron microscopy (SEM) and energy dispersive spectrometer (EDX) techniques. As a principal conclusion, seven types of wear particles, their corresponding wear mechanisms and the possible origins based on the different debris morphologies (i.e. shape, size and surface texture) [5, 7~9, 15~17] were identified.

For rail axle bearings, much attention was paid to investigating the bearing damage and/or failure modes caused predominantly by rolling contact fatigue (RCF). The characterization of RCF was accomplished by analysing the roughness and microstructure bearing surfaces using optical microscopy [18, 19], micro-Computed Tomography [20], SEM/EDX [19, 21~23] and the Taylor Hobson measurement system [24].

Unlike other lubricated systems, mentioned above (i.e. gearboxes, jet engines etc.) limited work has been done for the axle roller bearings. Among these studies, solid particles with known sizes and chemical compositions were introduced into experimental rigs [25~29]. These studies concluded that the bearing life is affected by solid contaminations and the reduction of particle size was also observed. Most recently, Gurumooethy and Ghosh [19] reported finding naturally metallic generated particles near cages. The size of these particles ranges from 50-1600 μm. However, no detailed descriptions on the particle morphology and associated wear mechanisms were discussed.

To date, the formation of wear debris generated by the mild wear process in rail axle bearings has yet to be fully investigated and there is a lack of research to adequately describe the features of wear debris. Therefore, the aim of this study was to provide a detailed investigation of wear debris naturally generated in grease-lubricated rail axle bearings. To achieve this, SEM/EDX were utilized to examine the wear particle types, their corresponding sizes and chemical compositions. The wear mechanisms for the examined axle bearings were then identified. The results will enhance the current understanding of wear mechanisms involved in the rail axle roller bearings leading to the improved accuracy of wear predictions in the rail axle bearings and the optimisation of bearing maintenance practices in the future.

2. Materials and Methods

Spherical roller bearings were originally lubricated with mineral oil based, lithium soap grease (Shell S2 traction motor bearing grease, Australia). The bearing raceways and rollers are made of 100Cr6 steel. The cages are made of high carbon chrome bearing steel (JIS G 3141) with a 2 mm thick coating material containing high

concentrations of C (Carbon), P (Phosphorus) and Mn (Manganese). A total of 20 bearings were examined, as shown in Table 1. The conditions of each bearing were determined by the total estimated operating distances that the bearing had travelled. Approximately 2 grams of grease were sampled from each field bearing to study the wear debris that had been captured during bearing operation. The grease samples were collected either from the raceways or the regions between the rollers and the cages. The visual observation of different aged grease samples (due to bearing condition) are summarised in Table 1.

Table 1 *Grease samples collected from different field bearings.*

Bearing condition	Est. distance (M.km)	# examined bearings	Grease colour	Rubber seal fragments
Early life	< 0.05	6	Light brown	×
Medium used	~ 0.39	1	Light brown	×
	~ 0.49	1	Light brown	×
	~ 0.59	2	Medium brown	×
Heavily used	~ 1.82	2	Dark/green brown	×
	2.0	8	Dark brown – Reddish brown-jet black	√

2.1. Isolation of Wear Debris

The procedure employed to isolate wear debris from each grease sample is as follows: 1:10 ratio of the grease sample to n-hexane. The mixture was stirred for 1 minute at 35 °C, cleaned ultrasonically for 3 minutes and left to settle. The solvent was carefully replaced 3 to 4 times per day until the base oil extraction was completed. Subsequently, sieves with mesh sizes ranging from 20-100 µm were used to separate the wear debris into sized groups. The differential centrifugation technique was applied to collect the remaining small wear debris (< 20 µm). The differential centrifugation method was done in a refrigerated centrifuge (5424 R, Eppenforf, Australia). The solvent/lithium soap mixture was spun through a series of centrifugation cycles. Each cycle was done at different speed and started at 8500 ×g and finished at 18500 ×g for various durations. The pellet collected from each spinning cycle was mixed with the distilled water, followed by the sonication for 5 minutes in order to break up any agglomerates of particles formed during the centrifugation process. Finally, the wear debris were attached to pin mount specimen holders and dried at room temperature.

2.2. SEM/EDX

Wear debris analysis was carried out by a SEM (JEOL JSM 6610, Tokyo, Japan) equipped with EDX and the images of wear debris were taken in a ranging magnification from 500× to 18000× depending on the size of wear particles. Samples were imaged and analysed using a beam energy of 25 keV for metallic debris and 15 keV for the organic debris at 10 mm working distance. EDX analysis was only performed on particles of size greater than 2 µm. Prior to their examination; particles were coated with a thin layer (~ 25 nm) of Iridium (Ir). About 70-80 debris particles per grease sample per bearing were examined. In this work, SEM was used to examine the morphology (i.e. debris shape, size, surface texture) of the wear debris. The size of wear particle debris was evaluated by the greatest distance between any 2 points along the particle boundary (Feret's diameter) [17]. The wear mechanisms of the examined bearings were identified by examining the particle morphology based on the published work [15, 17, 30].

3. Results

A total of 1500 wear debris over 20 grease samples were collected and examined in this work. The variation of the morphology of wear debris is due to the complexity of the wear motions occurring inside the bearings. Seven types of wear debris were successfully identified by the SEM observations (Table 2), differentiating by surface texture, shape and size of examined particles.

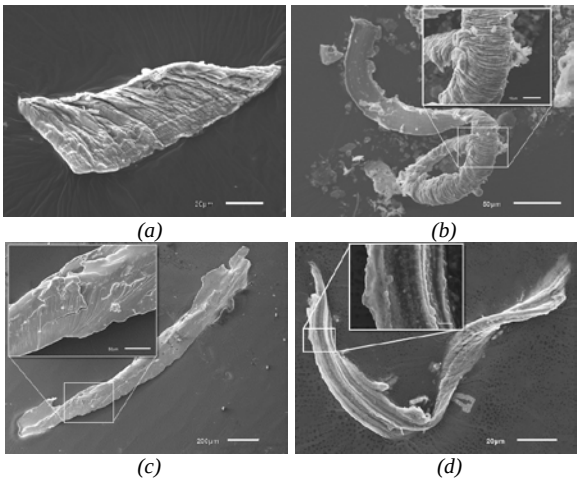
Overall, spherical, laminar, chunk and microspall wear debris were frequently observed in the early life bearings. Severe sliding wear debris were absent and less than 1% fibre particles of examined debris were present in the early life bearings. The majority of debris found in medium and heavily used field bearings were chunk wear debris. Unlike the early life bearings, only small spherical wear debris with the diameter less than 20 µm were detected in the medium and heavily used bearings. Furthermore, the number of fibre particles increases in medium used and heavily used bearings compared to the early life bearings.

Table 2 *Comparisons in particle types and size of wear debris collected from different bearing conditions.*

		Particle Type Distribution (% of Total Examined Debris)		
Particle type	**Size (µm)**	**Early life**	**Medium used**	**Heavily used**
Cutting	> 20	6	4	5
Spherical	< 20	11	23	27
	20-300	9	0	0
Laminar	10-50	22	21	20
Chunk	>20	30	40	33
Microspall	<15	21	8	5
Severe Sliding	>100	0	2	5
Fibre	>50	~1	2	5

Table 3 summarise the possible origin of wear debris collected in this study. Wear debris, with chemical compositions similar to 100Cr6 steel, were identified as being generated predominately in the contact regions between rollers and raceways and/or between rollers and the cages. Wear debris with of high concentrations of C, P and/or Mn were considered to originate from the cage coating materials. For debris, with chemical compositions that were neither similar with 100Cr6 materials nor the cage coating materials, were categorized as foreign particles.

Overall, the majority of examined debris were naturally generated in the bearings (Table 3). Approximately 2%

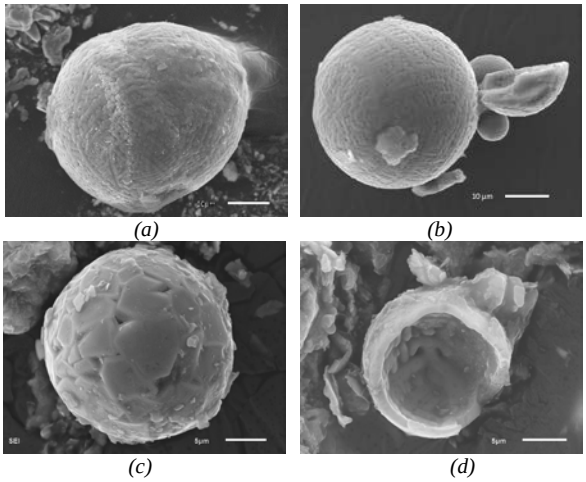


and 7% of examined debris came from the cage coating materials in the medium and heavily used field bearings, respectively. In this work, the sources of the external debris predominately come from the operation environment, such as sand/airborne dusts as well as organic fibres. Compared to the medium and heavily used field bearings, foreign debris were found less frequently in the early life bearings.

Table 3 Possible sources of debris collected from different bearing conditions.

			Particle Type Distribution (% of Total Examined Debris)		
			Early life	**Medium used**	**Heavily used**
Origins of debris	Internal	Bearing parts	100	96	82
		Cage coating materials	0	~2	~7
	External	Sands/airborne dusts	0	0	6
		Organic fibres	0	2	5

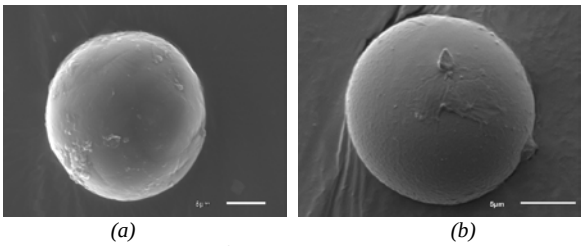
3.1. Morphological Characterization of internal wear debris



Scanning electron micrographs showed differences in surface morphology of the internal wear debris (Figure 1 - Figure 7). Typical cutting wear particles, shown in Figure 1, can be easily differentiated from other types due to the shape. Cutting wear particles were found to be long, relatively thin and curved. The morphology of the cutting wear debris found in the early life bearings appears to have a swarf-like feature in one surface and a smooth surface on the other side (Figure 1a and Figure 1b), whereas particles observed in the medium used (Figure 1c) and heavily used (Figure 1d) bearings exhibited a relatively rough surface. Figure 1c shows the trace of sliding and crack-like features in the cutting particles.

(a) *(b)* *(c)* *(d)*

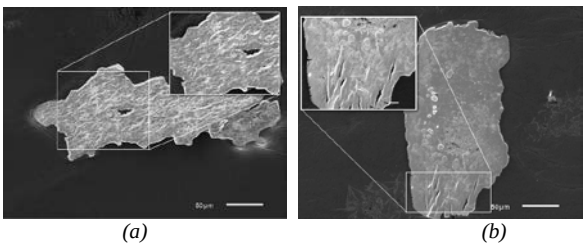
Figure 1 *SEM images of representative cutting wear particles collecting from (a,b) early life bearings, (c) medium used bearings and (d)heavily used bearings.*



Two types of spherical debris were differentiated according to surface morphology. In the early life bearings, spherical particles were found to have dendritic patterns (Figure 2a, Figure 2b and Figure 2c) and/or hollow shell structure (Figure 2d). Breakages were also observed on the dendritic hollow spherical particles.

(a) *(b)* *(c)* *(d)*

Figure 2 *SEM images of representative spherical wear particles collected form early-life bearings.*

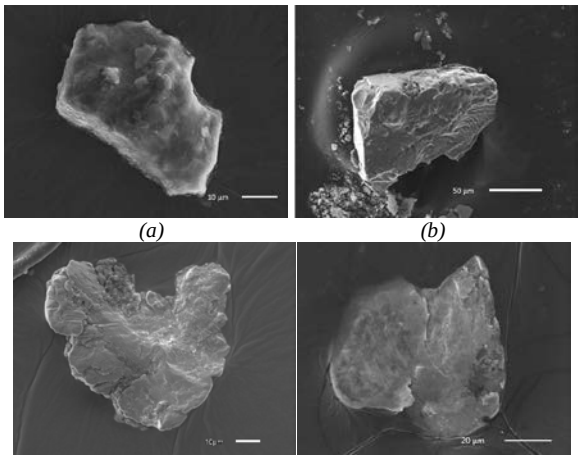


Compared to early life bearing, the spherical debris found in the medium used and heavily used bearings have a relatively smoothly surface (Figure 3) with the dendritic pattern becoming less obvious or disappearing entirely. The particles were typically also found to be smaller than those found in early life bearings with the average size being no larger than 20 µm.

(a) *(b)*

Figure 3 SEM images of representative spherical wear particles collected from medium used and heavily used bearings.

Sheet-like laminar particles were common for all bearing conditions examined. The predominant feature of the debris is a thin and flat surface as exhibited in Figure 4. Small holes (Figure 4a), crack-like features and a thin metal tongue structure (Figure 4b) were also present on the surface of the parti0cles.

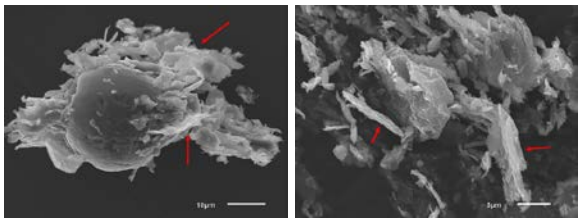


(a) *(b)*

Figure 4 *SEM images of representative laminar wear particles found in the bearings.*

The chunk particle, as shown in Figure 5, was another commonly observed debris in the bearings. In comparison with the laminar wear particles, chunk particles found in the field bearings were thick and have rough surfaces. The sizes of chunk particles found in the

early life bearings can vary from 20 µm up to 50 µm (Figure 5a and Figure 5b). In Figure 5b, the trace of sliding marks and a spalling-like feature are observed. For the heavily used bearings, the chunk wear particles have irregular shape profiles and traces of striations and microcracks (Figure 5c and Figure 5d).



(a) *(b)*

(c) *(d)*

Figure 5 SEM images of representative chunk wear particles collected from (a,b) early life bearings and (c,d) the heavily used bearing.

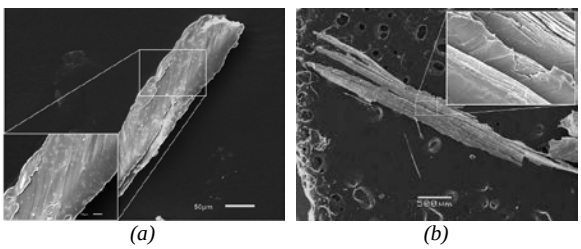


Figure 6 shows microspall wear particles consisting of flat platelets. Generally, they are about 1 µm or less in thickness and tend to be agglomerated and compacted with other types of particles. Generally, the size of the wear particles found in all bearings were no greater than 15 µm. In Figure 6a, for example, the microspall wear debris has agglomerated with a spherical-like wear particle.

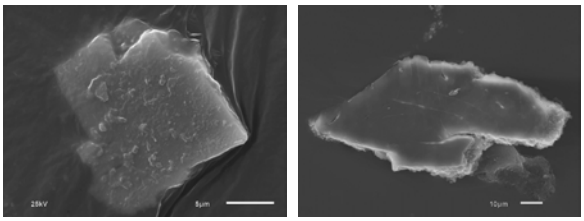
(a) *(b)*

Figure 6 *SEM images of representative microspall wear particles, indicated with red arrows, collected from the early life bearings.*

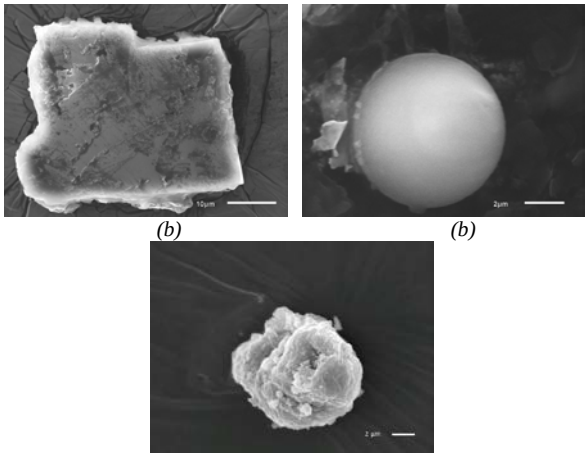
Typical severe sliding wear particles are shown in Figure 7. They were absent in the early life bearings, but a small number were found in medium and heavily used bearings. The scratches and scuffing marks appear on the surface of severe sliding wear particles oriented almost parallel to each other. Additionally, the surface fatigue due to cracking can be seen, as shown in Figure 7.



(a) *(b)*

Figure 7 *SEM images of representative severe sliding particles collected from heavily used bearings.*

3.2. Morphological Characterization of external debris

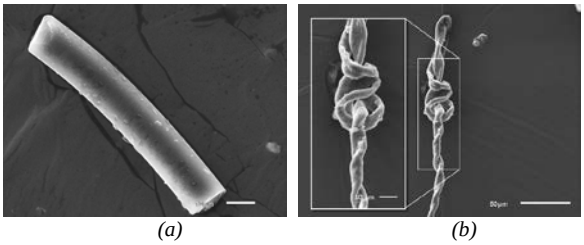


Overall, the external debris have less complex shapes compared to the internal wear debris of the examined field bearings (Figure 8 - Figure 10). Airborne mineral dusts, shown in Figure 8, were rarely found in the early life bearings, but more frequently in the heavily used bearings. Compared to wear particles naturally generated within the bearings part, they have sharp angular features. The average size of the airborne mineral dusts ranged from 20 µm up to 100 µm.

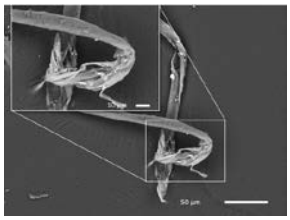
(a) *(b)*

Figure 8 *SEM images of representative airborne mineral dusts found in heavily used bearings.*

The morphologies of sands debris include a regular shape (Figure 9a), perfect spherical shape with smooth surface (Figure 9b) and a multilayer structure (Figure 9c). Similar with the airborne mineral dusts, they can primarily be observed in the heavily used field bearings.



(b) *(b)*

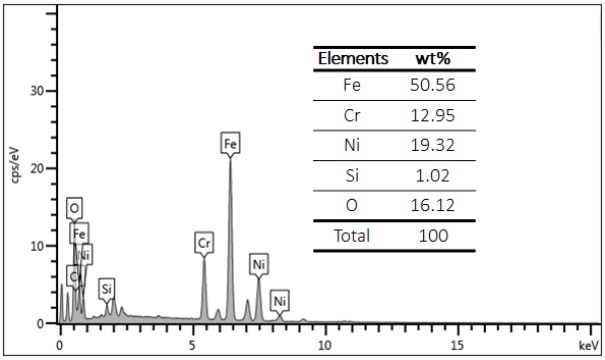


(c)

Figure 9 *SEM images of representative sand debris found in heavily used bearings.*

Figure 10 reveals the typical appearance of particles with fabric-like features, including cylindrical debris (Figure 10a) and a ribbon-like structure (Figure 10b and Figure 10c). The ribbon-like fibers tend to have self-twisted configuration (Figure 10b) and/or have a tear feature (Figure 10c). The average diameter of fibers was about 10-25 µm. The length of the fiber ranged from 100 µm up to 1 mm.

(a) *(b)*



(c)

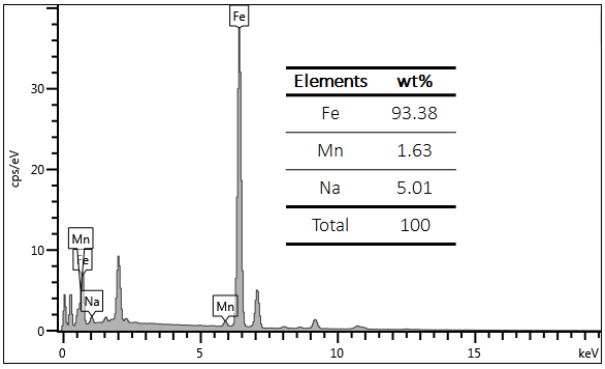


Figure 10 *SEM images of representative organic debris.*

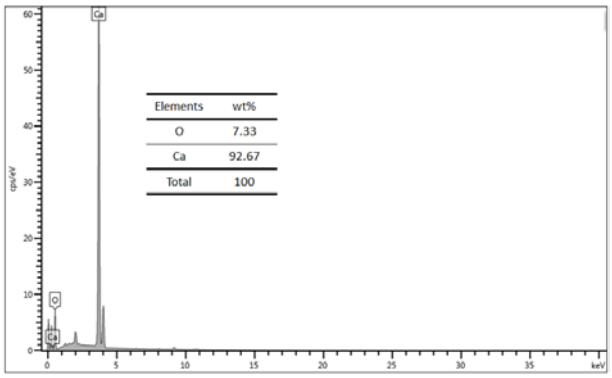
3.3. Chemical characterization of internal wear debris

Figure 11 shows representative spectra of metallic wear debris from energy dispersive X-ray analysis obtained using a SEM. Iron (Fe), Chromium (Cr) and Nickel (Ni) were found to be present in most of the debris and almost exclusively in those generated due to wear occurring in the bearings. Manganese (Mn) and Silicon (Si) were found in minor concentrations between 1-2wt%. Unlike other types of debris generated internally in the bearings, spherical particles found in the early life bearings (Figure 2) contains about 15wt% of oxygen (O). Occasionally, the trace of additive elements, such as sodium (Na), were found in the debris as shown in Figure 11b.

(a)



(b)

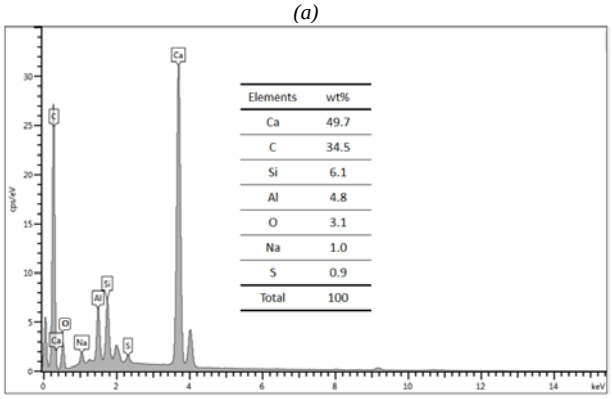


Figure 11 *Representative EDX spectra of metallic wear debris.*

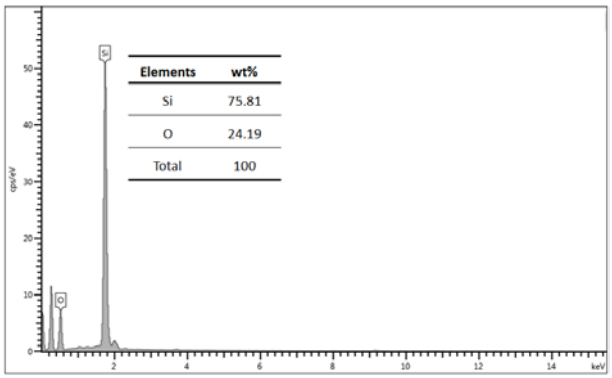
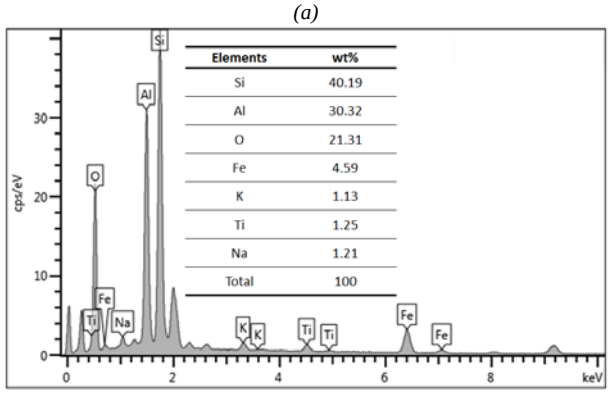
3.4. Chemical characterization of external debris

Sand and airborne dusts are the most abundant foreign particles found in the medium and heavily used field bearings. EDX spectra show the airborne mineral particles were predominately carbonated compounds (Figure 12a) and aluminosilicates (Figure 12b).



(a)



(b)

Figure 12 *Representative EDX spectra of Ca-rich mineral debris: (a) Calcium oxide, (b) Aluminosilicate mineral dust.*

Two types of sand with Si-dominant debris were found in the study. Figure 13a shows the debris consist6 of high concentrations of SiO_2 quartz. The debris, which consist of abundant of Al_2O_3 and SiO_2 with a small percentage of Fe, K, Ti and Na, are considered to be feldspar (Figure 13b).

(a)

(b)

Figure 13 *Representative EDX spectra of Si-rich debris: (a) Quartz, (b) Aluminum silicates.*

In addition to the debris described above, the carbon-rich fibres were found in the grease samples. The chemical compositions of carbon-rich fibers (Figure 10a) are presented in Figure 14.

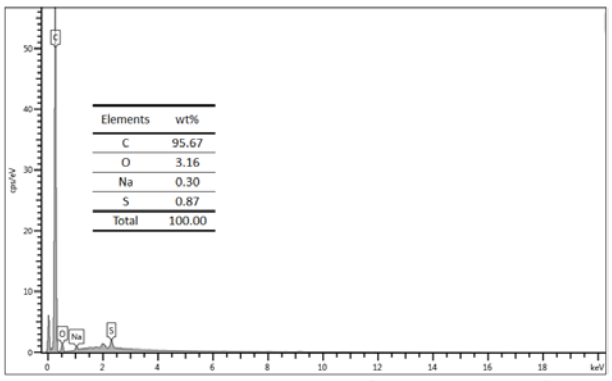


Figure 14 *Representative EDX spectra for the Carbon-rich fiber.*

4. Discussion

In this work, SEM/EDX was employed to characterize wear debris, which were collected from the field bearings with different operational distances. Examined wear debris were categorized into seven types considering their size and morphology. The identification of wear debris types were based on previously published work [15, 17, 30]. The wear mechanisms of different bearing conditions were then identified.

SEM/EDX results suggest that the predominant wear of examined field bearings is associated with rolling contact mechanism, resulting in high distribution of chunk and laminar wear debris (Table 1). The occurrences of spherical particles (about 20% of total examined particles) found in the grease samples also supports the results because these are normally generated under rolling contact conditions [9, 31, 32]. Interestingly, the disappearance of larger spherical particles (i.e. average size 20-300 µm) in the medium and heavily used bearings may contribute to the increased number of smaller spherical and chunk particles.

The occurrences of microspall particles in the early life bearings, which is likely associated with running-in wear mode. A relatively large amounts of microspall wear debris (i.e. 21% of examined wear debris) were seen in the early life bearings compared to medium and heavily used bearings. Considering the early life bearings travelled less than 50000 km, particles are likely to have been generated by the interaction between residual finishing marks of raceways and rollers, which have different surface asperities, leading to higher localized stress under asperity contact [33]. As a result, the chemical compositions of microspall wear particles are similar to the bearing materials. SEM image, shown Figure 6a, indicates that some of the microspall particles can be over-rolled into sphere-like particle by continuously passing through a region of rolling contact. Spherical wear debris found in the early life bearings have dendritic morphology and/or a hollow interior structure (Figure 2), whereas spheres with smooth surface were found in medium and heavily used bearings (Figure 3). The average diameters of spherical particles are more uniform in the latter, however, a variety of sizes of spheres can be found in the former. In this work, spheres were observed having thin and thick dendritic arms. Thin dendritic patterns on the spheres, shown in Figure 2a and Figure 2b, are very similar with other studies [30, 34-36]. The formation, therefore, is considered to be due to grinding and/or rapid cooling from a localized molten state. This is also indicative of extremely high local flash temperature and pressure on the surface.

On the other hand, the thick dendritic arm morphology on the spheres, shown in Figure 2c and Figure 2d, may be formed by the assembly of small individual platelets and /or microspall wear debris. An example is shown in Figure 6a, where microspall wear debris are attached to a spherical-like debris particle. In this case, the outer shell of the spheres, as shown in Figure 2c and Figure 2d, consists of small overlapping platelets and/or regions where localized melting has occurred between particles due to continuous rolling and shearing motions, resulting in highly uniform spherical particles. These spherical particles are also unique as the interiors are hollow, as shown in Figure 2b and Figure 2d.

As mentioned earlier, spherical debris seen in the medium and heavily used bearings have smaller diameter (less than 20 µm) and a relatively smooth surface compared to those seen in the early life bearings. Such a morphology can be attributed to the effect of continuous rolling contact, resulting in a smooth surface. EDX analysis (Figure 11b) revealed the spherical particles found in the early-life bearings are of similar composition to the bearing material, 100Cr6 steel, but oxidized, as indicated by the EDX oxygen peak. This confirms that these debris originaged mainly from the contact of the bearing materials. The formation of spherical particles have been investigated in previous studies and it is thought to involve different mechanisms depending on the lubrication systems, including rolling contact fatigue [9, 31, 32], abrasion [32], sliding wear [36, 37] and grinding [8, 34] etc. However, the majority of these previous studies were done using experimental rigs, tribology and oil lubrication system. The formation of spherical particles with dendritic patterns and hollow interior structure may involve a more complicated process in a grease lubrication system. Further studies are required to clarify the formation mechanism(s) of spherical particles in grease systems.

SEM images clearly demonstrated the differences in the morphologies of wear debris generated internally and externally. Overall, the metallic wear particles generated due to wear occurring in the bearings exhibited more complicated surface textures, such as crack, spalling-like features and scratch traces, compared to airborne mineral dust (Figure 8) and sand debris (Figure 9c), which generally have smoother surface. The occurrences of wear debris from external sources were seen in the medium and heavily used bearings (Table 3). In the case of heavily used field bearings, the ingested particles may have chance to enter the contact areas of bearings due to degradation of seals. This is supported by the observation of rubber seal fragments were found in the bearings

(Table 1). External wear particles seen in the early life bearings may have come from the grease manufacturing process, which involves manufacture, transport, supply and dispensing into containers suitable for end users. [30, 38].

5. Conclusions

This work has improved the understanding of the wear behavior in rail/wheel bearings, by examining the wear debris collected from the grease-lubricated axle roller bearings with various operational distances. SEM micrographs indicate that the formation of wear debris seen in rail/wheel bearings is predominantly associated with rolling contact mechanism. As a result, chunk (~ 30% of examined debris), laminar (~20% of examined debris) and spherical (~20% of examined debris) wear debris were frequently found in the lubricated axle bearings. The trace of microcracks, surface deformation and distinguished striations were also observed on the wear particle surfaces. Spherical wear debris with dendritic patterns and hollow interior structure were found in the early-life bearings, whereas spheres with smooth surface were found in the medium and heavily used bearings. Elemental composition analysis reveals most wear debris are metallic (> 80% of examined debris) and are likely to originate from the bearing materials. In the heavily used bearing, 5% of examined debris were from the external sources, including sands, airborne dusts and organic fibers. This evidence indicates the degradation of the rubber seals of the bearings, which allowed the ingestion of these external wear particles into the contact zone. These findings provide an insight of understanding micro-mechanisms of wear involved in railway bearing rolling contact.

CHIBA TEST TRACK 2.0 WITH SPECIAL TURNOUT

Shihpin LIN [1*], Yoshihiro SUDA [1]

[1] Institute of Industrial Science, The University of Tokyo

[*] E-mail: lin@iis.u-tokyo.ac.jp

Abstract: In this paper, three trials tried on the Chiba test track, the special turnout corresponding to the use of the outer flange type independently rotating wheelset with Negative Tread conicity, friction design on the rail considering track environmental conditions, and trial use of flange way filler in railroad crossing section are described.

Keywords: rail-wheel systems, independently rotating wheelset with negative tread conicity, outer flange wheel, special turnout, railroad crossing, test track, friction design, flange way filler.

1. Introduction

The performance demanded for the railway vehicle has changed dramatically as compared to the age when the wheelset appeared. In recent years, high-speed trains have been required for service operations over 300 km/h, whereas LRT (Light Rail Transit) should have smooth curving ability in tight curve section at intersection for left or right turning. In the design of the conventional railway bogie with two solid axle wheelsets, the optimization design method for suspension stiffness and the theory of asymmetric suspension design have been developed. The LRT system attracts attention as the urban traffic system for next generation mobility, because of eco-ability and accessibility. Many light rail vehicle (LRV) has independently rotating wheels to achieve low-floor design. However, conventional independently rotating wheels do not have a self-steering ability. In order to obtain self-steering ability with independently rotating wheels, the EEF bogie which makes use of gravity stiffness was proposed. However, this system was not widely used because of complex structure with linkage mechanism in the bogie. As a next step, the use of outer flange independently rotating wheels with the negative tread conicity (NCIRW) to achieve self-steering ability without any complex bogie structure was proposed. The effectiveness of the vehicle with two single-axle bogies using two wheels units with negative tread conicity was proved by 1/10 scale model experiment and full-scale model simulation [1].

New wheel units having a structure different from the conventional one need to consider the relationship between the wheel and rail contact mechanics in straight and curved section of track, and the ground equipment as turn out and railroad crossings. Institute of Industrial Science and Technology, the University of Tokyo, was constructed a new experiment field including railway test track to conduct mobility research including railway in April 2017. Several new attempts were made to contribute to the safety of railway system in the initial state of test track.

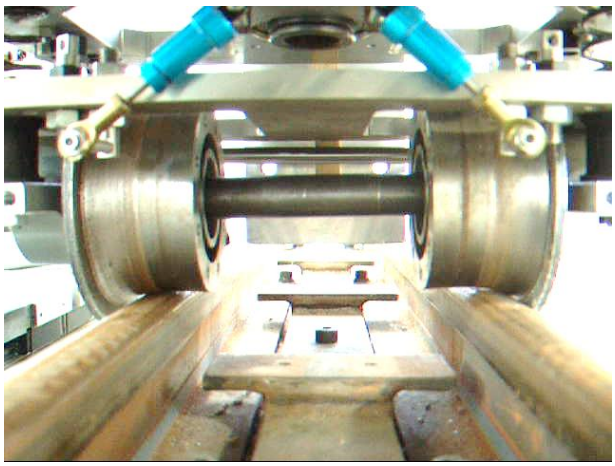

Figure 1 1/10 Scale model of experimental railway vehicle using outer flange type independently rotating wheels with negative tread conicity.

2. Chiba test track (version 2) in ITS R&R experiment field

The authors have conducted mobility research using fields including the Chiba test line (version 1) at Nishi Chiba Campus. On the other hand, in the fields of mobility and transportation systems, interest in automated driving technology has been increasing due to progress of electronics, computer engineering and production engineering. In recent years, various research and development projects are being conducted all over the world at the government level and the private level. Actual verification and development in a realistic field is very important in implementing new technologies to society. A research environment related to advanced vehicles has been established at the Institute of Industrial Science, the University of Tokyo, was restructured as an ITS R&R experiment field including Chiba test track (version 2) at Kashiwa Campus in April 2017.

The ITS R&R Experiment Field comprised of proving ground for road, experimental traffic lights for road, driving simulator for heavy truck and 333m length Chiba Test Track 2.0 with R33 curve section, railroad crossing and special turnout for railway which railway vehicle using NCIRW and conventional wheelset can be used together.

3. Special turnout

For Chiba test track 2, it is necessary to consider the running of the railway vehicle using outer flange type NCIRW and traditional wheelset. Chiba test track 2 has a 33 m radius constant curve section and turnout section with 30 m radius curve. It is necessary to provide slack in order to pass the railway vehicle using the normal wheelset. The multibody dynamics simulation using SIMPACK was performed, and the value of slack at turnout and constant curve section were determined to be 15 mm.

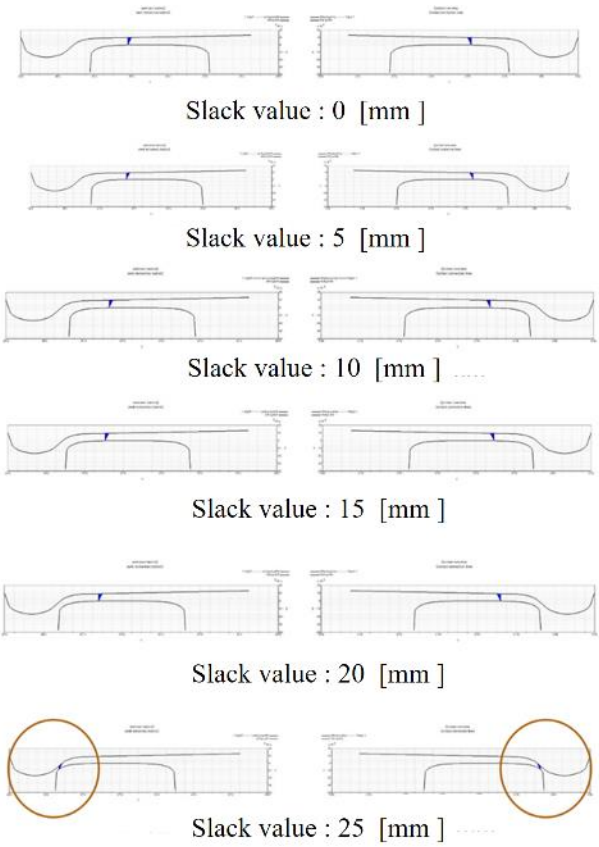

Figure10 Simulation results ofNCIR contact position on standard gauge track of 30 m radius constant curve section with slack value as design parameter.

Figure15 Switching operation of turnout (step 3 of 4).

Figure16 Switching operation of turnout (step 4 of 4).

Since this turnout uses movable rail, there is no missing portion similar to normal turnout. Guardrail similar to a normal turnout is unnecessary, but in a derailment prevention guard which can use at this turnout was designed together.

Figure23 Prevention guard for special turnout end rail

4. Friction design of Chiba test track 2

Chiba Test Line 2 uses three kinds of friction conditions setting to adapt the use environment and to improve operation efficiency. Normal section without anything, curve section and turnout section apply lubrication of gauge corners by solid lubricants, and railroad crossing section apply increase in friction coefficient of the rail head top surface. Lubrication with solid lubricants is intended to reduce running resistance and noise when bogie and vehicle passing these section, and to keep clean track in biological habitats. The increase in friction coefficient of the rail head top surface at railroad crossing section is intended to improve the safety of the railroad crossing portion, bicycle user and the car. There is a risk of inducing derailment of the wheelset in the worst case, so using the high friction coefficient of the rail head top surface is limited to the straight section corresponding to the derailment prevention girth function in first stage. One worst case condition, where the friction coefficient of left rails (dry) and right rails (ice) is extremely different was tried in Chiba test track 2. The wheelset got a large yaw motion when input the traction in this kind of condition.

Figure 30 The rail where car passing frequency, applied high friction coefficient paint 6 months ago, only lost at wheel trace.

Figure 31 One example of worst case, ice snow on the grove rail.

Figure 32 Compressed snow between wheel and rail.

5. Flange way filler

Since Chiba test track 2 realizes both normal wheelset and outer flange type NCIRW running, there are more flange way areas at railroad crossing section than usual. Also, groove rails also exist in part. In order to improve safety, we have tried several different flange way filler.
The flange way filler used are designed for normal I type rail and groove rail. Materials selection of was made so that flange way appeared only when the experiment bogie and the experiment vehicle passed through the flange way filler. In addition, veloSTRAIL made by STRAIL is also used experimentally.

6. Conclusions

Three trials around track tried on the Chiba test track 2, the special turnout corresponding to the use of the outer flange type independently rotating wheelset with Negative Tread conicity, friction design on the rail considering track environmental conditions, and trial use of flange way filler in railroad crossing section are described.

PERFORMANCE INVESTIGATIONS OF ON-LINE HEAT TREATED BAINITIC RAILS

Yunlei Lin [1], Qingyue Zhou [1,*], Yinhua Zhang [1], Fengshou Liu [1]

[1] Metals & Chemistry Research Institute, China Academy of Railway Sciences

[*] E-mail: zhouqingyue93480@126.com

Abstract: In this paper, the properties and microstructures of the on-line heat treated baintic rail have been studied, the bainitic rail has tensile strength value of over 1380MPa, and elongation of over 14% with Charpy U-notch impact energy of over 150J. It is shown that heat treatment refined the microstructures of bainitic rail and improved the combination of strength and toughness. Dry rolling/sliding wear behavior of bainitic rail was investigated and compared with pearlitc rail, the results showed that the wear of wheel caused by bainitic rail was only 20% of which caused by pearlitic rail.

Keywords: Bainitic rail; wheel/rail wear; on-line heat treatment; rolling contact fatigue; bainite.

1. Introduction

Rail plays an important role in the safety, efficiency and stability transportation, as a key part of railway. At present, the heavy haul railway in China mainly uses high strength pearlitic rail, which has been used for many years due to its good wear resistance. However, with the increasing of annual traffic volume and axle weight of the heavy haul railway, the service condition of rail is more and more severe. In the sharp-radius curve, upper rails appear side abrasion and spalling defects, lower rails appear corrugation and crack on surface. Wear and rolling contact fatigue increase the replacement and maintenance cost of wheel and rail, so rail material have to focus on steel with high strength and toughness, good abrasion resistance and resistance to RCF[1-3].

The research of bainitic rail began from 1960s, after years of development, the United Kingdom, Germany, the United States, Japan and other countries have run bainitic rail/turnout tests and put it into use [4-6]. Bainitic rail steel has the advantages of high strength, good ductility, good toughness (2~5 times of pearlitic rail steel), and the service life of bainitic rail is significantly higher than that of pearlitic rail. China Academy of Railway Science (CARS) has carried out the research of bainitic rail since 1999, and many achievements have been made. In 2002, CARS and Anshan Steel Corporation successfully developed a strong and ductile air cooled bainitic rail, it showed good resistance to RCF and wear. There are two ways to improve performances of rail: alloying and heat treatment. And rails can be divided into two types, off-line heat treated rails and on-line heat treated rails, depending on heat treatment process. The on-line heat treatment means adopting the rolling waste heat instead of reheating to quench rail. It is effective to improve the performance of rails, and more, the combination of alloying and on-line heat treatment can not only reduce the use of precious alloys to save cost, but also reduce the micro segregation and improve the welding performance, which is an effective technical route to obtain a higher strength grade bainitic rail.

In this paper, the mechanical properties and microstructures of on-line heat treated bainitic rails were studied in laboratory, and the effect of bainitic rail steel on the wear of wheel is discussed by using Amsler test machine for dry rolling-sliding wear test.

2. Test procedure

Three low carbon bainitic rails were designed for the industrial test, and the chemical compositions of bainitic steels are shown in table 2-1. The rail production process is: converter smelting, LF furnace refining, vacuum degassing (RH), bloom continuous casting, universal rolling, on-line heat treatment, straightening and tempering treatment.

Mechanical properties were investigated by using Material Testing Machine, semi-automatic impact testing machine, WILSON RB2000 rockwell hardness machine, brinell hardness tester etc., and microstructures analyses were studied by using DMI 5000M Optical Microscope, and Hitachi H-800 Transmission Electron Microscope.

The rolling-sliding wear test was carried out on the Amsler tester, the slip ratio was 10%, the CL60 wheel steel was used for the grinding specimen, and the rail samples were on-line heated bainitic rails, on-line heated U75VH and on-line heated U78CrVH rails. U75V rail and U78CrVH rail were pearlitic rails, and the chemical compositions are listed in table 2-1.

Table 2-1 Chemical compositions of tested rails (wt%)

Steel No.	C	Si	Mn	P	S	Others
1#	0.21	1.47	1.87	0.013	0.006	1.08
2#	0.20	1.48	1.87	0.011	0.006	1.11

U78CrVH	0.72~0.82	0.50~0.80	0.70~1.05	⩽0.025	⩽0.025	0.50

3. Results and discussion

3.1. Mechanical properties of on-line heat treated bainitic rail

3.1.1 Tensile test

The tensile properties of three bainitic rails obtained by on-line heat treatment were listed in table 3-1(1#~3#). In order to compare performances, another two different baintiic rails 4# and 5#, which were tempered after rolled, has been tested either. The tensile strength of on-line heat treated bainitic steel rail was 1387~1409MPa, the elongation at room temperature was 14.0~15.5%. The strength, especially the yield strength, was significantly high, with good elongation and reduction. The tensile strengths of 4# and 5# were 1022MPa, 1207 MPa respectively, with the reductions of area decreased. So on-line heat treatment can effectively improve the threshold of crack initiation in the contact surface and certain depth of rail, that is, the crack initiation is more difficult. On-line heat treated bainitic rails has higher strength than another bainitic rails. Tensile strengths and yield strengths of on-line heat treated baintiic rails was bigger and bigger with the increase of carbon content (from 0.19 to 0.21 wt%).

The results show that the bainitic rails 1#-3# has obtained a good combination of strength and toughness through on-line heat treatment.

Table 3-1 Tensile properties of bainitic rail

Steel No.	Tensile properties			
	$R_{p0.2}$/MPa	R_m/MPa	A/%	Z/%
1#	1334	1409	14.5	64
2#	1320	1387	15.5	68
3#	1308	1391	14.0	64
4#	1022	1318	16.5	42
5#	1207	1305	13.5	59

3.1.2 Hardness test

Hardness of the top surface in rail head： The brinell hardness of top surface of 1#~3# bainitic rails were tested in table 3-2. It showed that the hardness of on-line heated bainitic rail was 442.2~437.4 HB, and the hardness value of single rail was less fluctuation.

Cross section hardness of rail head: According to the positions shown in Fig. 3-1, the hardness of the rail head section of 1#~3# bainitic rails were tested respectively, and the results were shown in table 3-3, and the results of two kinds of hot rolled tempering bainitic steel 4# and 5# were also listed. The results showed that the hardness of bainitic rail with on-line heat treatment has been significantly improved, especially in the position of the rail head with high cooling strength, and the hardness within 25mm of the surface of the rail head was not less than 40HRC, which was obviously higher than the hardness value of the same part A and B. The great increase of hardness has significant benefit to improve the wear resistance of bainitic rail. At the same time, because of its material characteristics, bainitic rail has better resistance to contact fatigue than pearlite rail, and the combination of the two is advantageous to improve the service life of rail.

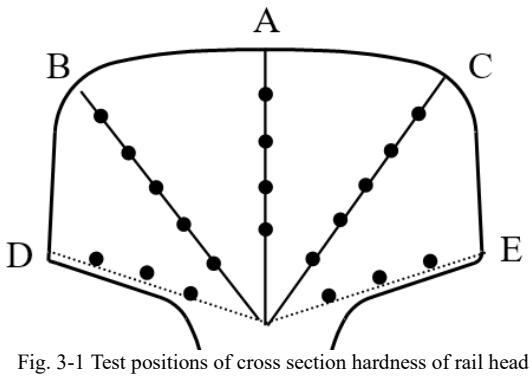

Fig. 3-1 Test positions of cross section hardness of rail head

3.1.3 Impact test

In order to analyze the impact toughness of on-line heat treated bainitic rails, sampling was performed from 5mm under the center of top surface of rail head. The test results (seen in Table 3-4) showed that KU_2(AVG) of on-line heat treated bainitic rail was more than 150J, and the average impact toughness of 4# and 5# bainitic rail was 71J and 63J. It was obviously that the on-line heat-treated bainitic rail possess higher toughness. It provides the necessary guarantee for the bainitic rail to exert excellent resistance to contact fatigue and improve the service safety of the rail.

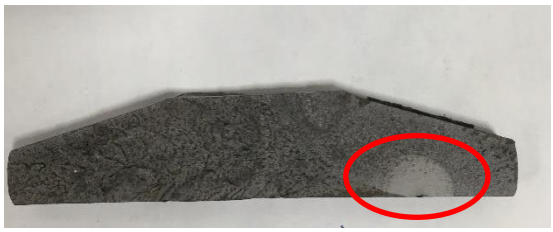
3.1.4 Fracture toughness test

The fracture toughness K_{IC} of on-line heat treated bainitic rail 1# under -20℃ has been tested. The results showed that the fracture toughness was distributed between 63~80 MPa $m^{1/2}$, which was much higher than that of the current technical conditions of pearlite rail: single value was not lower than 26MPa $m^{1/2}$, and the average value was not lower than that of 29 MPa $m^{1/2}$, seen in table 3-5.

Table 3-5 K_{IC}(-20℃) of bainitic rail 1#

Specimen size（B×W） mm	Average crack length mm	K_{IC} MPa·$m^{0.5}$
25.03×40.01	20.59	68.9
24.99×40.08	20.72	79.9
25.02×40.09	20.73	69.2
25.00×40.06	20.51	63.4
25.01×40.10	20.66	64.6

3.1.5 Fatigue test



In order to further study the physical fatigue properties of on-line heat treated bainitic rails, five rails were selected to carry out fatigue tests, where the load frequency was set as 7Hz. The results were shown in table 3-6, and the fracture morphology and microstructure were shown in Fig. 3-2, 3-3.

Table 3-6 Results of fatigue test

Yield ratio	Load/Times/Results	Load superposition/ Times/Results
0.946	470/95kN 2 million times/non-breaking	611/122kN 0.22 million times/breaking
0.946	470/95kN 2 million times/non-breaking	611/122kN 0.588 million times/breaking
0.951	470/95kN 2 million times/non-breaking	611/122kN 0.248 million times/ breaking
0.951	470/95kN 2 million times/non-breaking	611/122kN 0.238 million times/breaking
0.940	470/95kN 2 million times/non-breaking	705/141kN 0.34 million times/ breaking

(b) fracture macro-appearance of bainitic U78CrV rail

Fig. 3-2 bainitic rail fracture macro-appearance

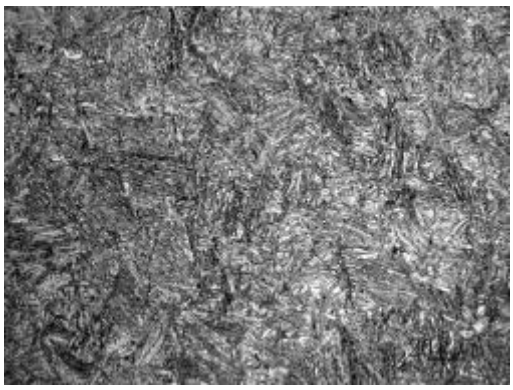
(a) fracture morphology of on-line heat treated bainitic rail

(b) TEM morphology of cracks initiation of on-line heat treated bainitic rail

Fig 3-3 Fatigue fracture microstructure of on-line heat treated bainitic rail

The results of rail fatigue test showed that, even if the ratio of the bainitic rail was over 0.94, the cyclic frequency did not break at 2 million times under the 470kN/95kN load condition of the test rail. On this basis, it increased 30% load, up to 611kN/122kN and carried out the test continue. It showed that the number of cycles before the rupture reached more than 200,000 times. From the view of the extended area, the width of the fatigue crack growth zone of bainitic rail was obviously higher than that of U78CrV rail (Fig 3-2), which showed that the ability of suppressing crack initiation of bainitic rail was obviously better than that of pearlite rail, which created conditions for the timely processing of line flaw detection and had more advantages.

Generally speaking, compared with pearlite rail, bainitic rail has the characteristics of high crack initiation difficulty and long stable expansion stage, which can effectively avoid short time brittle fracture of rail and is advantageous to safety of line service.



Tests on very high cycle fatigue The research on very high cycle fatigue has been attracted a great interest in the fatigue field. Fatigue behavior of on-line heat treated bainitic rail steel was studied with very high cycle fatigue tests, and the results are shown in table 3-7. From the test results, the fatigue life of on-line heat treated bainitic rail was more than 1.75E+07 cycles in the range of load stress amplitude 230-650MPa.

3.2. Microstructures of on-line heat treatment bainitic rail

The microstructure of the rail was sampled from the round angle of the bainitic rail head and the center of the rail head, as shown in Fig. 3-4. At the same time, the fine structure of bainitic microstructure was observed by transmission electron microscope, as shown in Fig. 3-5. The results of microstructure analysis showed that the bainitic rail was a typical type of carbide-free bainitic structure, and the microstructure was homogeneous under metallographic microscope, and the thin-strip bainitic ferrite and the film-like residual austenite which were arranged in the approximate parallel manner.

3.3. Wear performance

In order to study the wear performance of bainitic rail, the rolling-sliding wear tests of bainitic steel were conducted on Amsler test machine, the CL60 wheel steel was grinding specimen, and the results of on-line heat treated U75VH and U78CrVH rails under the same test conditions were also listed in table 3-9. The mechanical properties of U75VH and U78CrVH rails were shown in table 3-8. The surface status of rail specimen after grinding was shown in Fig. 3-7, and the surface status of wheel specimen after grinding was shown in Fig. 3-8.

5	U78CrVH	0.3903	2.3301

Bainitic rail U75VH U78CrVH

Fig. 3-7 The surface status of the rail specimen after grinding

Bainitic rail U75VH U78CrVH

Fig. 3-8 The surface status of CL60 after grinding with different rails

The rolling-sliding wear tests of bainitic rail showed that the wear resistance of bainitic rail was between the on-line heat treated rail U75VH and U78CrVH. At the same time, the use of bainitic rail could not only reduce their own wear, but also significantly reduced the wear on the wheel. The wear of the bainitic rail steel to the wheel steel was about 1/5 of the wear of the steel of the pearlite steel to the wheel. After grinding the wheel and rail specimen, the surface state of the wheel with bainitic rail was smooth, and the two kinds of pearlite steel had different damages to the wheel surface after grinding, and the roughness was large, which indicated that bainitic steel had slight wear on the wheel.

4. Conclusions

The application of alloying and on-line heat treated in the production of bainitic rail was carried out in this paper, and the comprehensive mechanical properties and microstructure were analyzed and the rolling-sliding wear test was carried out. The following conclusions are obtained as follow:

a) The tensile strength of on-line heat treated bainitic steel rail head reaches 1387~1409MPa, the elongation rate reaches 14.0~15.5%, and the section shrinkage rate is 64~68%, after on-line heat treatment process. The hardness of the rail head is 442~437HB, the hardness within 25mm of the surface of the rail is not lower than 40HRC;-20℃ fracture toughness is 63~80 MPa $m^{1/2}$; Under the condition of test rail 470kN/95kN load, the on-line heat treated bainitic rail is not broken until 2 million cycle times, the results show that the on-line heat treated bainitic rail has good strength and toughness and excellent comprehensive mechanical properties.

b) The results of microstructure analysis show that the on-line heat treated bainitic rail is a typical type of carbide-free bainitic structure, which consists of a strip-like bainitic ferrite and a film-like residual austenite distributed between them. Compared with pearlite rail, it has the characteristics of difficult crack initiation and long stable expansion stage, which can effectively avoid short brittle fracture of rail and is advantageous to safety of line service.

c) Rolling-sliding wear test results show that the weight loss of on-line heat treated bainitic rail is between the on-line heat treated rails U75VH and U78CrVH. The wear of wheel caused by the bainitic rail is about 20% of the wear caused by the pearlite rail.

WEAR RULES AND PROFILE CHANGES OF HIGH-SPEED RAILWAY RAIL IN CHINA

Fengshou Liu, Guang Yang*, Chuang Li, Shaobo Zhou, Yinhua Zhang

Metals and Chemistry Research Institute, China Academy of Railway Sciences Corporation Limited, Beijing, China

* E-mail: yang1231456@hotmail.com

Abstract: It is of great significance to grasp the current status and rules of high-speed railway rail wear to ensure good wheel-rail contact relationship. On the basis of rail profile tracking test of the typical high-speed railways in China, the profile changes and wear rules of high-speed railway rail are obtained in this article. The results show that, the rail wear in tangent track of high-speed railway is small, and it is positively related to the traffic load. The annual vertical wear is less than 0.05 mm while the traffic load exceeded 10Mt per year. The distribution range of the maximum rail wear is 0~5 mm from the center to the gage line of rail head. In all test lines, the wear rate of the curves with the radius not less than 2495m is not obviously different from that of the tangent track. The rail wear rate of the curve track with the radius less than 2495m is obviously increased with the decrease of the curve radius.

Keywords: High-speed Railway, Rail, Profile, Wear

1. Introduction

Rail wear of high-speed railway is of great concern. The changes of rail profile caused by wear will change the wheel-rail contact relationship and affect the operation performance of high-speed train [1]. The uneven wear of rail may cause rail surface damage, rail nuclear injury and other fatigue problems [2]. Rail corrugation will greatly aggravate the wheel-rail dynamic interaction and endanger the train operation [3, 4]. The abnormal wear of rail will aggravate the task of rail grinding, shorten the service life of rail and affect the economy of railway transportation [5].

Therefore, it is of great significance to grasp the current status and law of rail wear of high speed railway to ensure good wheel-rail contact relationship and improve the efficiency of rail maintenance.

By the end of 2017, the mileage of high-speed railway has exceeded 25 thousand kilometers in China, and the high speed rail network has begun to take shape. Considering the complex geographical environment and various operating conditions in China, 6 typical high-speed railways, such as Beijing-Shanghai high-speed railway, Wuhan-Guangzhou high-speed railway, and Harbin-Dalian high-speed railway, have been selected for rail profile tracking test about 2 years. The rail profile changes and wear rules of typical high speed railway are obtained, which provide the basic data to the research on the wheel-rail contact relationship and the vehicle operation performance effected by rail wear and rail profile changes.

2. Rail profile changes and wear rules

Rail profiles of six typical high-speed railway lines are traced and tested, including the Beijing-Shanghai High-speed Railway (JH-1, JH-2 and JH-3), the Wuhan-Guangzhou High-speed Railway (WG), Harbin-Dalian High-speed Railway (HD), Lanzhou-Xinjiang High-speed Railway (LX), Guiyang-Guangzhou High-speed Railway (GG) and Dandong-Dalian Rapid Railway (DD).

On the basis of the first measurement, the changes of the rail profile are characterized by two methods. One method is the profile change in the vertical wear measuring point which is 1/3 rail head wide from standard gage line (Figure 1a), and the other method is the profile change area which is the rail head wear area (Figure 1b).

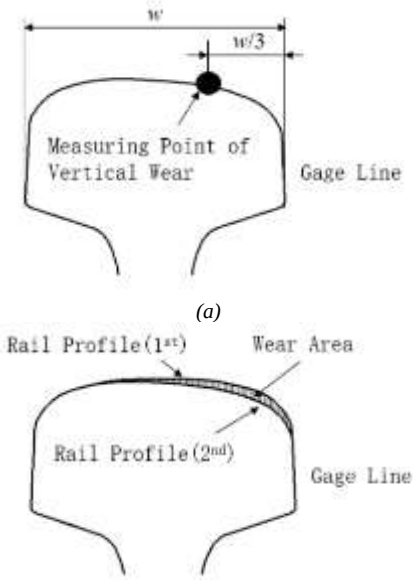

Figure 1 *Different characterization methods of rail wear: (a) Vertical wear. (b) Wear area*

2.1. Tangent track

2.1.1. Changes of rail profile and wear

The rail profile will change with the increase of its service time. The factors affecting the changes of rail profile are rail grinding and rail wear. As shown in Table 1 and Figure 2, in the section with rail grinding, rail grinding is the main factor affecting the change of the profile. The change area of rail profile is 10.5 mm^2, and which caused by rail grinding is 90 %. In the section without rail grinding, the profile change area is smaller than the grinding section, and the maximum of rail profile change area is 1.41 mm^2.

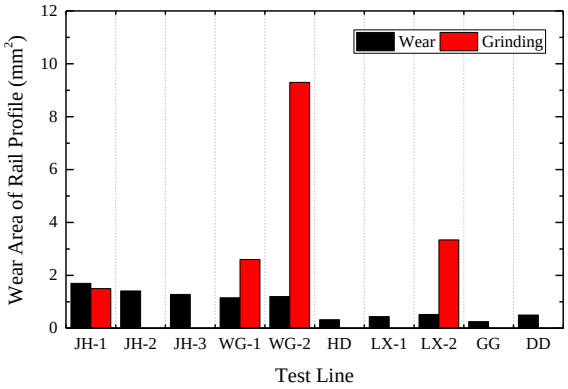

Figure 2 Area changes of rail profile in different test lines

As there is a certain difference in the grinding method and grinding process, the profile change varies greatly in different grinding sections. The high-speed grinding method is a kind of passive grinding method without power, and the amount of rail material removal in single grinding process is small. The grinding method is the active grinding method of 96-stone grinding machine, the amount and the angle of which can be controlled in single grinding. As shown in the Table 1, the amount of rail material removal in single grinding process by the grinding method is larger than the high-speed grinding method.

It can also be obtained from Table 1 that the vertical wear of rail in tangent track is small during the test. The rail vertical wear in different sections of Beijing-Shanghai High-speed Railway are 0.05mm, 0.03 mm and 0.04 mm. The traffic load of JH-1 section in the Beijing-Shanghai High-speed Railway is 66 Mt, while the time of tracking test in this section is about 21 months. The traffic load of JH-2 section is 39.4 Mt, and the test time of which is about 12 months. The traffic load of JH-2 section is 42 Mt, and the test time of which is about 14 months.

The rail vertical wear in the WG-1 section and WG-2 section of Wuhan-Guangzhou High-speed Railway are both 0.04mm, and the traffic load of these two test sections are 44 Mt and 45Mt respectively.

The rail vertical wear in the test sections of the other four high-speed railways are only 0.01 mm, and the traffic load of these four railways are less than 11 Mt while the tracking test time of these sections is beyond 12 months.

Table 1 *Statistical results of rail profile changes*

Test Section	Profile change in the vertical wear measuring point (mm)		Profile change in area (mm^2)		Traffic load (Mt)

DD	0.01	0	0.50	0	4.2

2.1.2. Distribution of rail wear

The distribution of rail wear can reflect the wheel-rail contact range, and it has a certain effect on judging the performance of the train. On the basis of the rail profile in the first test, the changing distribution of rail profile can be calculated and then distribution of rail wear can be obtained.

As shown in Figure 3, the center of the rail head is zero, and the positive value indicates that the rail wear is distributed through the center to the gage line of the rail head. The rail wear distribution of all tested high-speed railways is within the range of -25~25 mm. The rail wear distribution in test sections of Beijing-Shanghai High-speed Railway, Wuhan-Guangzhou High-speed Railway and Harbin-Dalian High-speed Railway are beyond 30mm.

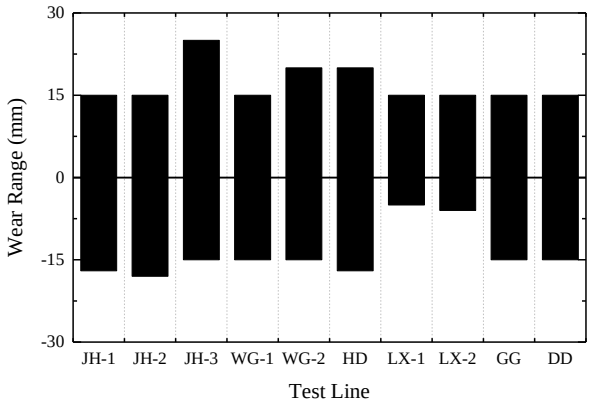

Figure 3 *Wear range in different test lines*

Through the analysis of the maximum rail wear distribution, the most easily worn area of the high-speed railway rail can be clearly defined, which can provide the basis for the rail wear detection.

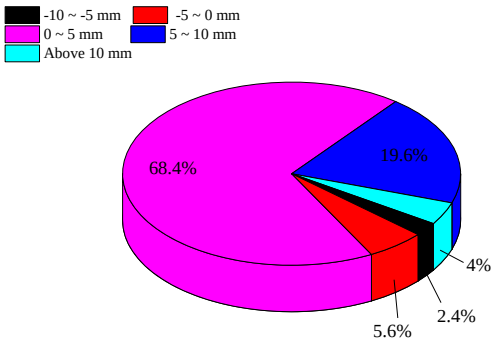

Figure 4 *Distribution of maximum wear position*

The maximum rail wear distribution of all high-speed railways is statistically analyzed in Figure 4. The positive value indicates that the maximum rail wear distribution is biased toward the gage line. As shown in the Figure 4, in all test results, the maximum vertical wear location of 68.4% rail is in the distribution of 0~5 mm. There are 19.6% rail the maximum vertical wear location of which is in the distribution of 5~10 mm.

The maximum rail wear is mainly distributed within the range of 0 ~ 5 mm. It can be seen that the rail wear of high speed railway is mainly concentrated near the center of the rail head.

2.1.3. Influence factors of rail wear

During the service of high-speed railway rail, many factors may have a certain influence on rail wear such as traffic load, rail profile, wheel profile, operation speed of train, wheel rail hardness ratio and so on. The Table 2 gives the basic conditions of rail wear in tested high-speed railways. In the tested high-speed railways, the rail profiles are 60N and 60D [6], and the wheel profiles are LMA, LMB and LMC [7]. Each wheel profile corresponds to a certain type of high-speed train. The matching relationship between wheel profile and rail profile is very complicated in high-speed railways in China.

The Table 2 shows that, there is a clear correlation between the rail vertical wear and the traffic load. The maximum of rail vertical wear is 0.04mm while the annual traffic load is 40 Mt such as Beijing-Shanghai and Wuhan-Guangzhou, and the rail vertical wear is very small and close to 0.01mm while the annual traffic load is less than 10Mt. Other factors have not shown a clear correlation with rail vertical wear, so the simulation technology needs to be used to analyze the impact of single factor on rail wear.

Table 2 *Influence factors on rail wear*

Test Line	Vertical Wear(mm)	Traffic Load(Mt)	Rail Profile	Wheel Profile	Maximum Speed(km/h)	Wheel-rail Hardness Ratio（Original）		
						LMA	LMB	LMC
JH-1	0.05	66	60D	LMA, LMB	300	0.95	0.95	/
JH-2	0.03	39.4						
JH-3	0.04	42

GG	0.01	6.3	60D	LMA	250	/	0.95	/
DD	0.01	4.2	60N	LMC	200	/	/	0.97

2.2. Rail wear in curves

The high-speed railway line in China is mainly tangent tracks and curves the radius of which are more than 8000 m. There will be some small radius curves in the entering and leaving of the station in a few railway lines. This section will focus on the analysis of rail wear of the curve with a radius of 460m (R460) and the curve with a radius of 800m (R800).

The rail wear of this curve will be analyzed by the vertical wear rate and the side wear rate. The wear rate is the wear change per unit traffic load. The effect of rail material and curve radius on the rail wear of curves will be discussed and analyzed in this section.

The R460 curve is a curve with the smallest radius in the tested high-speed railway lines, and the rail material of it is different at different times. The high rail of the R460 rail is laid U75VH rail since November 2014, and it was laid U71Mn rail before November 2014. The U75VH rail is the U75V head-hardened rail.

The vertical and the side wear rate of the U75VH rail are 0.009 mm/Mt and 0.034 mm/Mt. The vertical wear rate of the high rail is about 0.038 mm/Mt and the side wear rate of the high rail is 0.1 mm/Mt while using U71Mn rail. The low rail of R460 curve is laid U71Mn rail since 2011. The vertical wear rate of the low rail is about 0.028 mm/Mt.

As shown in Figure 5, after using the U75VH rail, the rail wear is obviously reduced. In comparison, the wear resistance of the head-hardened rail is better as the hardness is higher than the U71Mn rail.

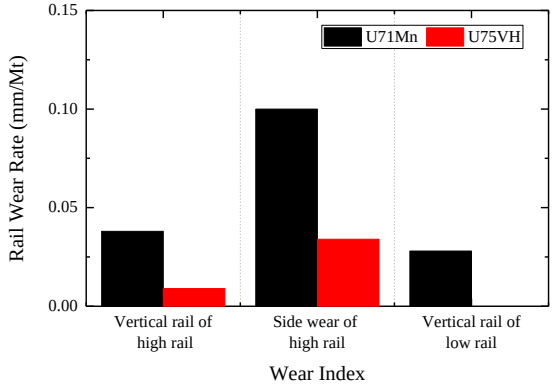

Figure 5 *Rail wear rate of R460 curve*

The rail material of the R800 curve is U71Mn. The U71Mn rail has been in service for about six years. As shown in Figure 6, the vertical wear rate of high rail is about 0.006mm/Mt, the side wear rate of low rail is about 0.025mm/Mt, the vertical wear rate of low rail is about 0.013mm/Mt. In comparison, the rail wear of R800 curve is obviously less than the rail wear of R460 curve when the material of these two curves is U71Mn, especially the side wear of the high rail.

The distribution of high rail wear in curve track is vertical wear and side wear. The distribution of low rail is mainly vertical wear. The rail wear of curve track is influenced by the rail material and the curve radius. With the same radius of the curve, the rail wear can be obviously reduced by using the heat treated rail. The rail wear of curves with the same material increases with the decrease of the radius.

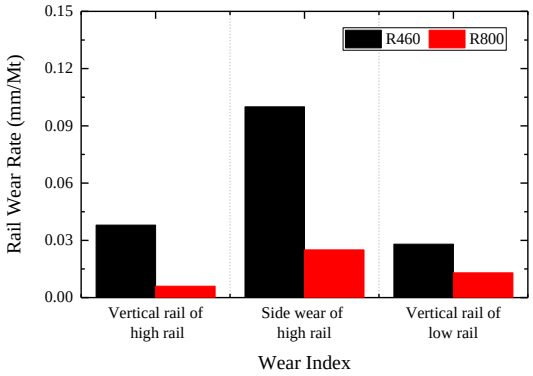

Figure 6 *Rail wear rate comparison between R460 curve and R800 rail (U71Mn rail)*

2.3. Comparison between curves and tangent tracks

The rail wear area rate is taken as the index to compare the difference between the rail wear of curves and tangent tracks, which is defined as the rail wear area change per unit traffic load. The average wear area rate of the tangent tracks and the large radius curve (the radius is not less than 8000m) is given in Figure 7. The gap between the two is within 10%. Thus, it can be seen that the rail wear of the large radius curves and the tangent tracks is very close.

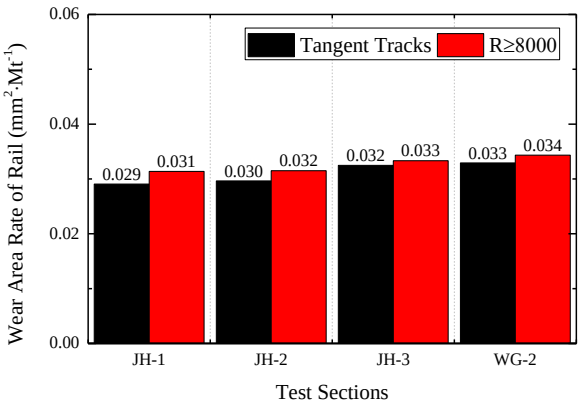

Figure 7 *Comparison of wear area rate in tangent tracks and curve tracks (R≥8000m)*

The rules of rail wear area rate change with the curve radius is further analyzed. As shown in Figure 8, the rail wear area rate of all tested railways lines decreases with the increase of curve radius. The rail wear area rate decreases rapidly when the radius of curves is more than 2495 m. There is no obvious difference on the wear area rate between curves and tangent tracks.

When the radius of curves is less than 2495 m, the rail wear area rate in curves, the radius of which are 460m and 800m, is obviously larger than that of the other lines. Especially the wear area rate of R460 curve is about 1.5 times the rail wear rate of R800 curve.

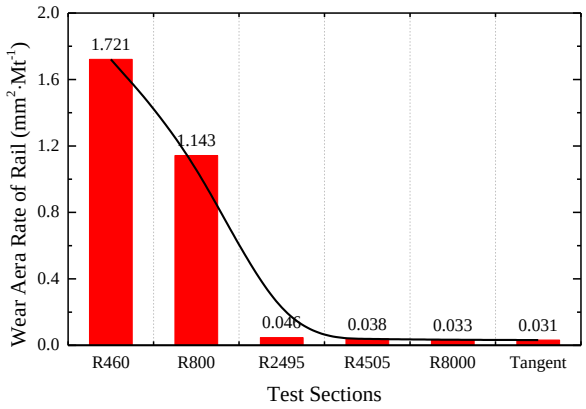

Figure 8 *Comparison of wear area rate in different radius*

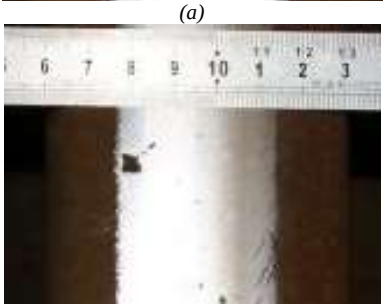

Through the comparison of the wear area rate, it can be seen that the rail wear is the main factor affecting the rail profile in the curves while the radius is less than 800 m. The rail wear in high rail is the vertical wear and the side wear, and the wear in low rail is mainly vertical wear.

The field test results show that head checking appeared in the rail gauge angle of curves when the radius are 800 m, 2495 m and 4505 m, as shown in Figure 9, which is significantly different from the smooth state of rail surface in tangent tracks and the large radius curves.

As the head checking of the curve with a radius of 460m will be worn off quickly, the surface state of the curve is slightly better than that of the curve with a radius of 800m. Therefore, the large radius curve section of the high speed railway should focus on the possible fatigue problems of the rail. The small radius curve should focus on the wear problem, and it is necessary to make a thorough study of the competitive relationship between wear and fatigue.

3. Discussion

According to the rail wear tracking test of the six typical high-speed railway lines in China for 2 years, the rail wear rules of high speed railway has been obtained.

Rail profile changes are affected by rail wear and rail grinding. The area changes of rail profile caused by grinding is 90% in grinding sections, which is the main factor that affects the change of rail profile. In the unpolished section, the change of the rail profile is very small.

The rail vertical wear of the tangent track and the larger radius curve is small. The rail vertical wear of the Beijing-Shanghai high-speed railway (traffic load is 66Mt) is 0.05mm. The rail vertical wear of Wuhan-Guangzhou high-speed railway (traffic load is 45Mt), is 0.04mm. The rail wear of Harbin-Dalian high speed railway (traffic load is 10.9Mt), the Lanzhou-Xinjiang high-speed railway (traffic load is 4.2Mt), the Guizhou-Guangzhou high-speed railway (traffic load is 6.3Mt) and Dandong-Dalian rapid railway (traffic load is 4.2Mt) are all only 0.01mm.

In all test lines, the wear rate of the curves with the radius not less than 2495m is not obviously different

from that of the tangent track. The rail wear rate of the curve track with the radius less than 2495m is obviously increased with the decrease of the curve radius.

4. Conclusion

Based on the track test of six typical high-speed railways in China, the rail wear rules and rail profile changes of high-speed railway lines are analyzed. The conclusions are as follows:

- The rail wear in tangent track of high-speed railway is small, and it is positively related to the transport volume. The annual vertical wear is less than 0.05 mm while the traffic load exceeded 10Mt per year. The distribution range of the maximum rail wear is 0~5 mm from the center to the gage line of rail head.
- In all test lines, the wear rate of the curves with the radius not less than 2495m is not obviously different from that of the tangent track. The rail wear rate of the curve track with the radius less than 2495m is obviously increased with the decrease of the curve radius

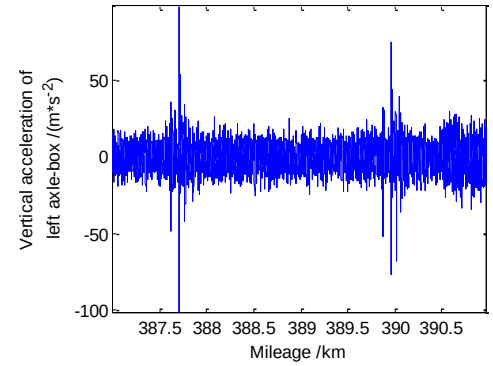
Abstract: The amplitudes of track short-wave diseases of high speed railways, such as steel rail corrugation, welded joint irregularity, the improper heightening of wing rail and so on, are small but they could cause great impulse response and big damage on the wheel-rail system components and reduce the passenger comfortability. We propose two new criterions called track impact index (TII) and steel rail corrugation index (RCI) to diagnose track short-wave diseases by use of axle-box acceleration and wheel-rail contact force. The procedures of the algorithm are introduced in this paper and the effectiveness of the method is verified by measured data.

Keywords: Track impact Index, steel rail corrugation index, track short-wave irregularity, axle-box acceleration, high speed railway

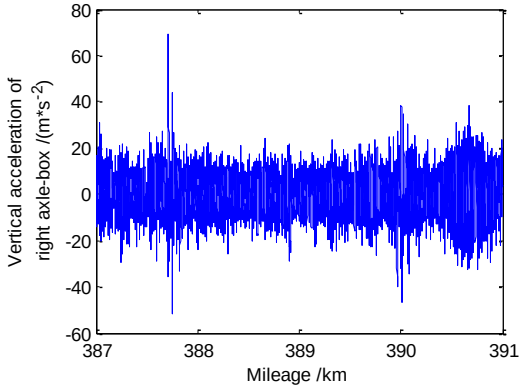
1. Introduction

The safety and comfort of track-vehicle system are affected by the track status directly. Higher speed means higher requirements for track irregularity [1]. Track Irregularity of 0.01~120m wavelength is most common in many irregularity frequency components which usually could be divided into short wave, medium wave and long wave. Amplitude of short wave track irregularity whose wavelength is under 1m is usually in the range of 0.1~2.0mm which is very small and mainly caused by rail corrugation, welded joint irregularity and the improper heightening of wing rail. Usually the wavelength of track irregularity obtained from track geometry inspection system is between 2m and 150m, which make it hard to evaluate the safety and comfort under short wavelength irregularity condition, so it's necessary to develop other auxiliary means.



The vibration caused by track irregularity directly transmit to the axle-box which is connected to wheelset, so the vertical and lateral vibration of axle-box are triggered. Therefore, the axle-box acceleration can directly reflect the impact of the external disturbing force on the vehicle dynamics caused by the shortwave irregularity of the track, which is the reason why a lot of scholars using ABA method to assist judging the impact of short track irregularities on the vehicle dynamics. The advantages of ABA method in judging shortwave irregularity status are summarized by Grassie[2], including that it is easy to install and maintain, economical and practical compared with instrumented wheelset systems, and also it could be applied to commercial train. Caprioli[3] et al. extracted frequency characteristics of shortwave track irregularity from vertical vibration of axle-box using wavelet. References [4-6] used vertical axle-box acceleration to diagnose the rail corrugation. Reference [7-8] used vertical axle-box acceleration to diagnose shortwave track irregularity, and suggested that different band-passing filter frequencies should be used to deal with different types of short track irregularities. Hirofumi[9] et al. analyzed the relationship between the variance of vertical axle-box acceleration and the fluctuation of wheel load. Eric[10] et al. used the power spectrum of vertical axle-box acceleration to assess the roughness of the rail surface. Remennikov[11] et al. used axle-box acceleration to estimate wheel-rail force. Molodova[12] et al. analyzed the relationship between short-wave track irregularity and vertical axle-box acceleration using finite element model. Molodova[13] et al. used the Scale Averaged Wavelet Power (SAWP) to characterize the size of track squat. Yu Feng[14] et al applied the change of vertical axle-box acceleration to inversely predict the change of track bed stiffness. Based on the resonance demodulation, Kang Xiong[15] et al. presented new methods and indexes for evaluating the status of high-speed railway welded joints by using the vertical axle-box acceleration.

The axle-box acceleration is the result of wheel and rail dynamic coupling, with high-frequency and highly nonlinear characteristics. It's influenced not only by short wave track irregularity but also by wheel-rail profiles and material, vehicle suspension parameters, roughness of wheel and rail contact surface, installation position of the accelerometers. All of these factors increase the randomness of the result, which makes it difficult to evaluate the impact with raw axle-box acceleration data. In order to handle this problem, papers [4,7,9] proposed the use of root mean square of axle-box acceleration. In this paper, two new feature indexes called Track Impact Index (TII) and Steel rail corrugation Index (RCI) are proposed to characterize the high-frequency characteristics from the energy point of view.



2. The Method to Evaluate Shortwave Track Irregularity by Use of Vertical Axle-box Acceleration

The vertical and lateral acceleration of axle-box, bogie-frame and car body acceleration can be collected by vehicle dynamic response inspection system at the same time with a 2000Hz sampling frequency. Speed and mileage information are obtained from the integrated system using synchronous message transmission, and the

mileage is then corrected based on the length of the vehicle and the location of the sensor. The measured axle-box acceleration data can be seen in Fig.1. Fig.1 shows when vehicle rolling through a bad conditioned welded joint area, a huge impact occurred with more than 20 $\mathrm{m}*\mathrm{s}^{-2}$.

(a) Vertical acceleration of left axle-box

(b) Vertical acceleration of right axle-box

Figure 1 *Measured vertical axle-box acceleration*

Since the vertical axle-box acceleration is high-frequency signal, it is inevitable to encounter the problem of large randomness when evaluating the shortwave track irregularity by using of its amplitude, that is, even the track is unmaintained during two inspection cycles, the axle-box acceleration repeatability is not good. From the physical point of view, the axle-box acceleration is a random signal, but the impact energy is essentially the same. Based on this principle, this paper proposes a method using moving RMS value instead of the raw acceleration data to characterize the high-frequency characteristics of wheel-rail impact and evaluate shortwave track irregularity status from the energy point of view.

The set of filtered vertical axle-box acceleration is $\left\{x_i \middle| i=1,2,\cdots,N\right\}$, in which N is the number of vertical axle-box acceleration signal. The set of moving RMS value of vertical axle-box acceleration can be written as $\left\{S_r \middle| r=1,2,\cdots,N-K+1\right\}$, and S_r is described as follow:

$$S_r=\sqrt{\frac{\sum_{i=r}^{r+K-1}x_i^2}{K}} \tag{1}$$

where the parameter K is the forward window length.

Different to axle-box acceleration signal, the corresponding moving RMS is a low frequency signal. From the mathematical point of view, the process of calculating the moving RMS signal is the smoothing process of the signal. The repeatability of moving RMS value is good, that is, the moving RMS signals of axle-box acceleration obtained from two inspections before and after are basically the same, so there is no random issues.

The average value of the moving RMS value of the vertical axle-box acceleration will change with wheel-rail profiles and material, vehicle suspension parameters, roughness of wheel and rail contact surface, installation position of the accelerometers. So we proposed Track Impact Index (TII) and Steel rail corrugation Index (RCI) to evaluate shortwave track diseases by normalizing the moving RMS.

TII is defined as the ratio of the moving RMS of the vertical axle-box acceleration to its average value, that is, TII can be obtained by using the average value of moving RMS to normalize the moving RMS. Its expression is as follow:

$$T_{II}=\frac{S_r}{\overline{S_r}} \tag{2}$$

where T_{II} is track impact index; S_r is the moving RMS at measuring point r; $\overline{S_r}$ is the average value of the moving RMS.

Steel rail corrugation index is defined as the ratio of the moving RMS of the vertical axle-box acceleration to its average value, and it is used to evaluate the effect of steel rail corrugation on track-vehicle system. Its expression is as follow:

$$R_{CI}=\frac{S_m}{\overline{S_m}} \tag{3}$$

In which RCI is steel rail corrugation index; S_{m} is the moving RMS at measuring point m; $\overline{S_m}$ is the average value of the moving RMS. Different cut-off frequencies are used in equations (2) and (3) for the calculation of the moving RMS. The energy factor E_{F} is defined as the ratio of the energy at the first energy peak to the total energy, i.e.

$$E_F=\frac{E_P}{E_S} \tag{4}$$

Where E_P is the energy at the first energy peak and E_S is the total energy.

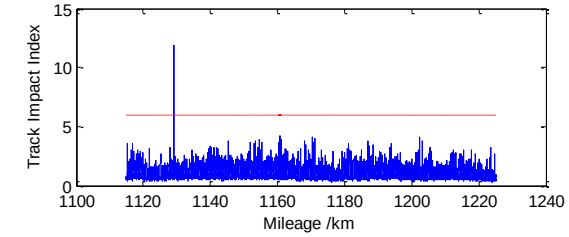
The calculation process of $\overline{S_r}$ is as follow:

1) Band-pass filtering the measured vertical axle-box acceleration, the band pass frequency is generally taken between 10 to 500Hz;
2) Calculate the moving RMS of the vertical axle-box acceleration after filtering;
3) Divide track into units whose length is generally taken as 50m;

4) Calculate the maximum value of the moving RMS of each track unit, then the value is saved as the RMS of the track unit;
5) Calculate the average value $\overline{S_r}$ of the moving RMS of the track unit of the same speed grade.

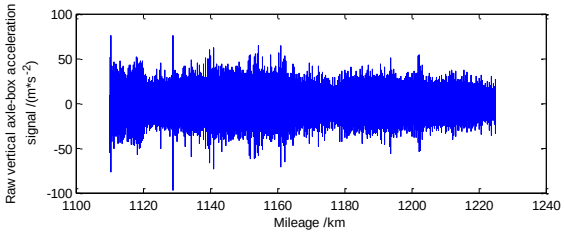
The use of track impact index to evaluate shortwave track disease can be divided into two stages: Firstly, calculate the moving RMS of vertical axle-box acceleration based on the recurrence relation. Secondly, calculate TII and evaluate shortwave track disease. The detailed process of evaluation is described as follows:

1) Band-pass filtering the measured vertical axle-box acceleration, the band pass frequency is generally taken between 10 to 500Hz;
2) Calculate the moving RMS of the vertical axle-box acceleration after filtering;
3) Calculate the track impact index of each measured point;
4) Divide track into units whose length is generally taken as 50m;
5) Extracting the maximum value of TII in each track unit, denoted as T_{II}^{max} and meanwhile record the mileage information of the corresponding point;
6) Evaluate the shortwave track status with the threshold value, viz. if the maximum value of a certain point is greater than the threshold value then there is a shortwave track disease at that point.



Compared with the method of using the raw axle-box acceleration inspection data, the shortwave track disease can be evaluated by track impact index, which can not only avoid the influence of randomness but also determine the threshold easily.

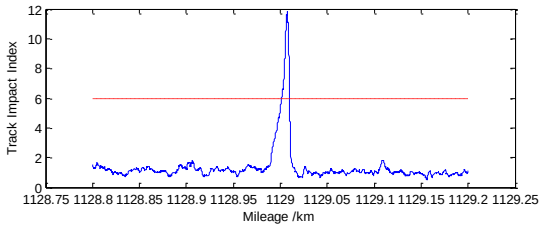
First of all, to avoid the influence of randomness, the RMS value is used instead of raw axle-box acceleration inspection data, which can convert high frequency problems to low frequency problems, thus the randomness of the evaluation result is greatly reduced. Besides, the threshold value is obtained according to its distribution by using the average value of moving RMS to normalize the moving RMS value, which has the same distribution characteristics. (According to a large number of inspection data analysis, the author takes a threshold of 6.0)



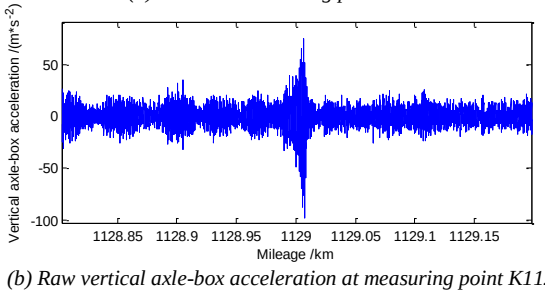
3. Case Study

This article analyzed the dynamic response inspection data from comprehensive inspection train to evaluate the shortwave track disease, which is verified to be correct by comparing with wheel-rail force inspection data analysis results. Besides, the results of multiple tests at different speeds in the same section show that this method has good stability.

Track impact index obtained from vertical axle-box acceleration can be seen in Fig.2. It shows when the comprehensive inspection train passed the measuring point K1129 at the speed of $360\,\mathrm{km}\cdot\mathrm{h}^{-1}$, the track impact index is 10.9, far exceeding the threshold value of 6.0. Therefore, it is judged that the track condition at this point is not good. In addition, the reduction rate of wheel load at this point is 0.73and is close to the derailment threshold 0.8, which indicates that there is a large wheel-rail force and large risk of derailment. Comparing with the diagnosis results of ABA and wheel-rail force, it can be verified that the proposed method can effectively evaluate the shortwave track disease. Furthermore, as can be seen from Fig. 2 (b), the amplitude of the point K1129 is larger but its difference is not particularly significant compared to the amplitudes everywhere else, which shows that it is difficult to diagnose the shortwave track disease by directly using the raw axle-box acceleration signal.



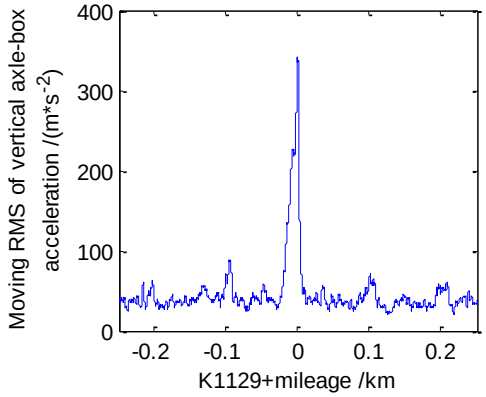
(a) Track Impact Index



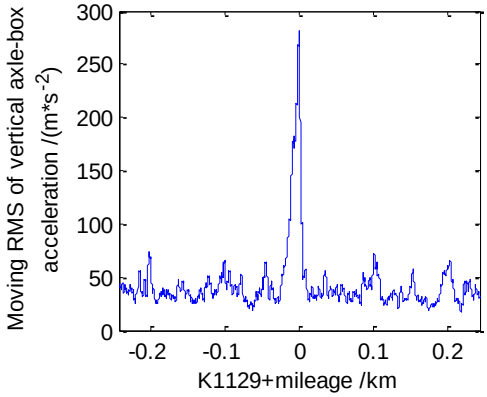
(b) Raw vertical axle-box acceleration signal

Figure 2 *Raw vertical axle-box acceleration signal and its corresponding TII*

The locally amplified track impact index and original axle-box acceleration signal can be seen in Fig. 3. As can be seen from Fig. 3, where there is a shortwave track disease there is a large impact, and there is an increasing and decaying phenomenon occurred in the original axle-box acceleration, whose amplitude is not necessarily large but the impact energy is usually very large. The track impact index can effectively diagnose the shortwave track disease because TII can characterize the characteristics of vertical axle-box acceleration from the energy point of view.

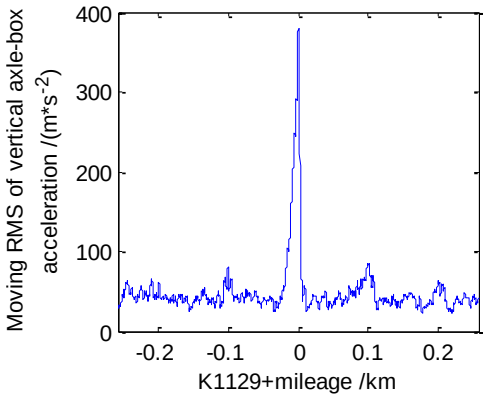


(a) TII at the measuring point K1129



(b) Raw vertical axle-box acceleration at measuring point K1129

Figure 3 *Raw vertical axle-box acceleration and its corresponding TII at measuring point K1129*



The moving RMS of vertical axle-box acceleration when comprehensive train rolling through the measuring point K1129 twice at speed of 350 km · h^{-1} and twice at speed of 360 km · h^{-1} are shown in Fig. 4. As can be seen in Fig. 4 that a large value of moving RMS occurred at the point K1129 every time and the waveform is similar. Taking the waveform of the moving RMS when the comprehensive inspection train passing through the point K1129 at speed of 360km · h^{-1} which is shown in the Fig. 4 (a) as the basic waveform, and the correlation coefficient with the waveforms of the other three pictures are 0.95, 0.95 and 0.89, which shows that proposed method in this article is stable and repeatable.

4. Conclusion

The safety and comfort of track-vehicle system are affected by the track status directly. Usually the wavelength of track irregularity obtained from track geometry inspection system is between 2m and 150m, which make it hard to evaluate the safety and comfort under short wavelength irregularity conditions like bad conditioned welded joints and steel rail corrugation. Since the axle-box is connected to the wheelset directly, and it is able to characterize the wheel-rail contact high frequency characteristics caused by shortwave track disease. This article proposes track impact index and steel rail corrugation index based on band-pass filtered vertical axle-box acceleration to diagnose the shortwave track disease. These new evaluation methods can improve the track irregularity evaluation system and make better guidance for track maintenance.

Abstract:

A test rig is used to measure the adhesion ratio under dry and wet condition, and the results show that after the application of water the lateral adhesion ratio decreases. This reduction is remarkable for low speed, but neglectable for high speed. The lateral adhesion ratio decreases with rolling speed under dry condition; after the application of water, the measured results show an opposite trend. Furthermore, a model is developed based on previous models, and the simulated friction creep curves shift down with the increase of rolling speed; the correlations with the measured lateral adhesion ratio are much improved.

Keywords:
Lateral adhesion ratio; Rolling speed; Water lubrication; Friction creep curve.

1. Introduction

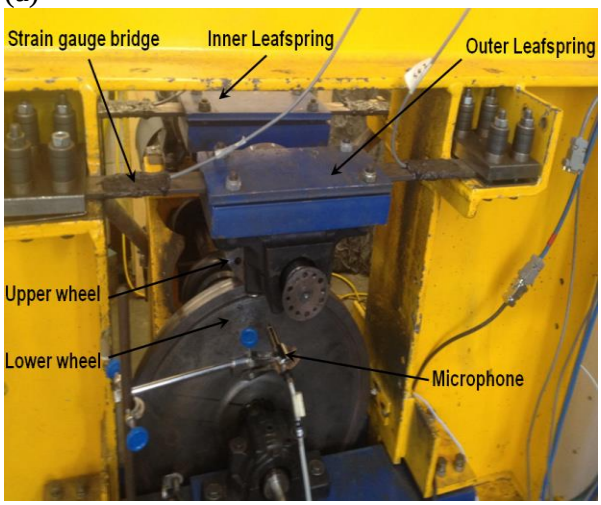
The adhesion between wheel and rail affects not only running stability and safety of railway vehicle, but also corrugation and wear of rail and wheel. The static friction force is defined as the horizontal force required to initiate sliding, while the kinetic friction force is the horizontal force required to maintain sliding. Generally, the static friction should be higher than the kinetic friction. For the railway industry, the third body, such as debris, rust, leaves and water, might be exists at the contact point. To distinguish from friction measured at ideal condition, the measurements between wheel and rail are often referred as adhesion ratio.

Normally the adhesion ratio between wheel and rail is quite stable, but some times insufficient for wet condition, when the wet weather would reduce adhesion coefficient, which is an important factor affecting the operation of train [1], and the reduction is substantial when the water is mixed with solid wear debris or rust [2]. Some research found that the boundary friction coefficient between wheel and rail under wet conditions is estimated to be in range of 0.2 – 0.45 [3]. The adhesion ratio in the longitudinal direction was measured and found that with an increase in the contact pressure, the maximum traction coefficient remains unchanged [4]. Recently， relevant research found that For high speed vehicles ,when the surface roughness of wheel and rail is large,the adhesion coefficient shows an increasing trend with reduction of the axle load. Meanwhile, if the surface roughness is small, the adhesion coefficient turns to a decreasing trend [5]. As to the effect of rolling speed on adhesion ratio, it was found that the adhesion coefficient between wheel and rail decreases with an increase of running speed under wet conditions [6]. Recently, similar measurement results were acquired in [7] and [8] supporting the conclusion that the longitudinal adhesion ratio decreases with rolling speed. The effect of rolling speed on lateral adhesion ratio under wet condition, however, has not been investigated in detail yet.

Currently, more derail accidents happens at the curve of track, because when the train enter the straight part of the rail from the curve of a rail, the lateral adhesion between wheel and rail is insufficient to hold the inertia of the train. Therefore, it is necessary to investigate the contact mechanics between wheel and rail at the curve of rail. The study on the contact mechanics at the curve of track has been investigated intensively since it is relevant to curve squeal, corrugation and wear of the rail. Theory has been developed over decades to describe the force and creepage conditions in rolling contact. In the early stage, one description for contact forces in rolling contact was formulated by Kalker [9]. The contact theory was developed further by Johnson [10] and Kalker [11, 12] in three dimensional case. Besides the models introduced above, Polach's nonlinear creep-force model is also based on Kalker's theory, which enables the simulation of various wheel/rail contact conditions in the longitudinal condition [13]. The relevant theory was also applied to model the creep force by Shen et al. [14]. Actually, the friction coefficient is velocity dependent, as expressed by Kraft [15]. To include the effect of rolling speed on the adhesion ratio, De Beer et al. [16] integrated this model with the model of Shen et al. [14] and developed a more sophisticated model. This model is also applied in a research conducted recently [17]. Whether this model can describe the effect of rolling speed on adhesion ratio sufficiently, however, have not been investigated in detail.

In order to complete the two investigations summarised above, the lateral adhesion ratios under dry and wet conditions are measured at different rolling speeds. Furthermore, the simulation friction creep curves in the

lateral direction using current model for wheel/rail contact mechanics are compared with experimental measurements. An introduction about relevant methodologies is provided in the next section.



2. Methodologies

Both experimental analysis and numerical analysis are applied in this research. The methodologies used in this research for relevant analyses are introduced in this section.

2.1. Experimental method

In this research, a rolling contact two disk test rig is used to investigate friction characteristics in rolling contact under wet condition. The main components of the test rig are marked in Figure 1 (a). The angle of attack θ between upper and lower wheel marked in Figure 1 (b) can be adjusted to simulate the misalignment between the rolling direction of the wheel and the tangential direction of the rail.

(a)

(b)

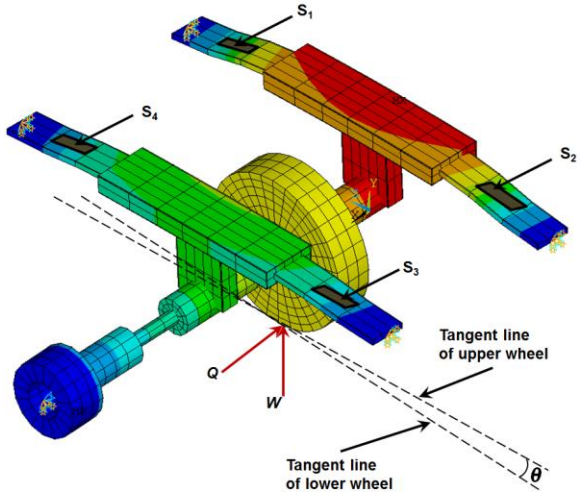


Figure 1. *Rolling contact two disk test rig: (a) Front view of the test rig. (b) The deformation of the test rig due to contact forces [17]*

Strain gauges were applied on the test rig, based on the Wheatstone full-bridge configuration. This configuration consists of four active strain gauge elements, two mounted in the direction of bending strain on the top of the leaf spring, the other two mounted on the opposite side. This configuration provides maximum bending strain output ignoring axial strain and twisting of the leaf spring, which can minimise the noise in measurement. It can also compensate the thermal effect on the resistance of sensing elements. The feasibility of this measurement method for contact forces has been investigated with finite element method [18]. The finite element analysis results show that the vertical force W deforms the outer leaf spring and inner leaf spring evenly, and a lateral force Q applied on the edge of the upper wheel increases the deformation of the outer leaf spring and decreases that of the inner leaf spring, which can be measured by the strain gauges bridges S_1, S_2, S_3 and S_4 indicated in Figure 1 (b). The diameters of the wheels have been listed in Table 1 along with some other relevant parameters, while more introduction about the measurement method are introduced in [19]. In the experimental process, the test rig is adjusted to certain angle of attack, and the lateral force and normal loading are measured simultaneously at different rolling speeds, so the adhesion ratio can be acquired reliably. The lateral adhesion ratio at each rolling speed is measured three times under dry condition. Afterwards, water is dropped on the tread of the lower wheel at a rate of 2 drops per second. At the same time the test rig is run at different rolling speeds, and for each speed the lateral adhesion ratio are also measured three times.

Table 1. *Parameters of the test rig [19]*

Description	Value
Radii of longitudinal and tangential curvature for the lower wheel (R_1, R_{1t})	0.213 m, 0.300 m
Thickness of the lower wheel (rim, web)	0.026 m, 0.015 m
Density (ρ)	7800 kg/m^3
Inner radius of lower wheel (R_1')	0.0325 m
Young's modulus of upper and lower wheel (E)	175 GPa
Radii of longitudinal and tangential curvature for the upper wheel (R_2, $R2$t)	0.085 m, 0.040 m
Thickness of the upper wheel	0.080 m
Contact velocity range	0 ~ 17.84 m/s
Lower wheel rolling speed range	0 ~ 800 RPM
Poisson's ratio (v)	0.28
Angle of attack range	0 ~ 26 mrad
Creep coefficient (C_{22})	3.14
Normal loading (W)	1000 N
Modal mass (m)	3.1 kg
Modal damping (c)	42 Ns/m
Modal stiffness (k)	1.6E8 N/m

2.2. Theoretical method

In this research, the contact mechanics in the lateral direction is modelled analytically, integrating the effect of angle of attack, rolling speed and contact conditions, based on the models of Jonson and Kalker. The creepage dependent lateral adhesion ratio in rolling contact $\mu(\zeta)$, which is defined as the ratio of lateral force on normal

force, can be expressed as,

$$\mu(\zeta)=\begin{cases}\mu_K(\zeta)\{\zeta'-\frac{1}{3}\zeta'^2+\frac{1}{27}\zeta'^3\} & \text{for } \zeta'\le 3\\ \mu_K(\zeta) & \text{for } \zeta'>3\end{cases} \quad (1)$$

where the lateral creepage ζ is defined as whee/rail lateral relative velocity V_{rel} divided by the forward rolling speed V_0 [20].

$$\zeta = V_{rel}/V_0 \quad (2)$$

The lateral relative velocity V_{rel} is composed of crabbing velocity V_c and the vibration velocity [21].

$$V_{rel} = V_c + \dot{y}(t) \quad (3)$$

where $\dot{y}(t)$ is the vibration velocity of the wheel. The crabbing velocity V_c in Equation (3) and can be calculated with angle of attack θ and rolling speed V_0, i.e., $V_c = V_0 sin\,\theta$. As the angle of attack is normally less than 3 degree, this equation can be described with an expression in [22].

$$V_c = \theta V_0 \quad (4)$$

In Equation (1), μ is the realistic friction characteristic given by Kraft [15].

$$\mu_K(\zeta) = 0.5\mu_0\{2-e^{-0.138/|V_{rel}|}-e^{-6.9/|V_{rel}|}\} \quad (5)$$

Considering the relationship given in Equation (3), the equation above can be expressed as,

$$\mu_K(\zeta) = \mu_0\{1-0.5e^{-0.138/|\zeta V_0|}-0.5e^{-6.9/|\zeta V_0|}\} \quad (6)$$

The ζ' in Equation (1) is a normalised creep proposed by Vermeulen and Johnson [23] and modified by Kalker [9].

$$\zeta' = \frac{\zeta G a b C_{22}}{\mu_0 W} \quad (7)$$

where $G=E/2(1+\upsilon)$, and the elastic modulus E is 175 GPa for the wheel, υ is 0.28 for Poisson's ratio, C_{22} is a constant tabulated by Kalker [11], the value for the test rig is 3.14, W is the normal loading, a and b are the dimensions of elliptical contact patch that determined by the normal contact theory of Hertz as introduced in [10]. μ is the stationary friction coefficient of the non-rolling contact, which can be calculated with

$$\mu_0 = \frac{\tau_R\tau_W}{(\tau_R+\tau_W)}\frac{\pi a b}{W} \quad (8)$$

where τ_w, τ_R are the shear strength of the wheel and rail material.

If the lower wheel and upper wheel have radii of curvatures R_1 and R_2 in the rolling direction and R_{1t} and R_{2t} in the transverse direction, the contact will exist over an ellipse of semi-axes a in the rolling direction,

$$a = c(R'/R'')^{1/3} \quad (9)$$

and b in the transverse directions,

$$b = c(R''/R')^{1/3} \quad (10)$$

where R' and R'' are effective radiuses determined with

$$R' = \frac{R_1 R_{2t}}{R_1+R_{2t}} \quad (11)$$

and

$$R'' = \frac{R_2 R_{1t}}{R_2+R_{1t}} \quad (12)$$

where the R_1 and R_2 are the longitudinal radii of lower and upper wheel; R_{1t} and R_{2t} are the transverse radii of lower and upper wheel. The parameter c can be calculated with

$$c = \left(\frac{3W\sqrt{R'R''}}{4E^*}\right)^{1/3}F_1(e) \quad (13)$$

When the material of both wheels are the same, E^* can be calculated with

$$E^* = \frac{E}{2(1-\upsilon^2)} \quad (14)$$

and

$$F_1(e) = \left\{\frac{4}{\pi e^2}\left(\frac{b}{a}\right)^{3/2}\sqrt{\left[\left(\frac{b}{a}\right)^2 E(e)-K(e)\right]\left[K(e)-E(e)\right]}\right\}^{1/3} \quad (15)$$

where $E(e)$ and $K(e)$ are complete elliptic integrals of the argument e, which can be expressed as

$$e = \sqrt{1-b^2/a^2} \quad b<a \quad (16)$$

Equation (2) shows that for the same rolling speed and contact status, the lateral adhesion ratio in rolling contact is determined by the lateral creepage. Furthermore, at the contact patch, the lateral creepage ζ can be related to the transverse vibration, by integrating Equations (3) and (4).

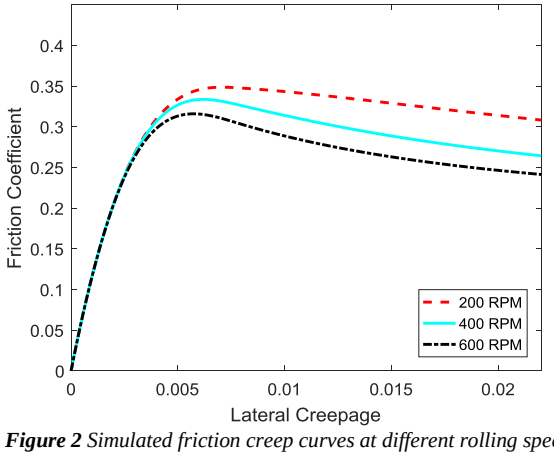
$$\zeta = \theta + \dot{y}(t)/V_0 \quad (17)$$

The equation above is a transient expression of lateral creepage, and quasi-static value equals to the angle of attack .

3. Results Analyses

The simulation results using the model introduced in the previous section as well the experimental results are presented in this section.

The friction creepage curves at the rolling speed of 200, 400 and 600 RPM are simulated using the model introduced in the previous section as presented in Figure 2. In this figure, this lateral creepage is the ratio of lateral sliding velocity on the rolling speed. The lateral creepage is determined by the yaw angle between wheel and rail, and is also called angle of attack.



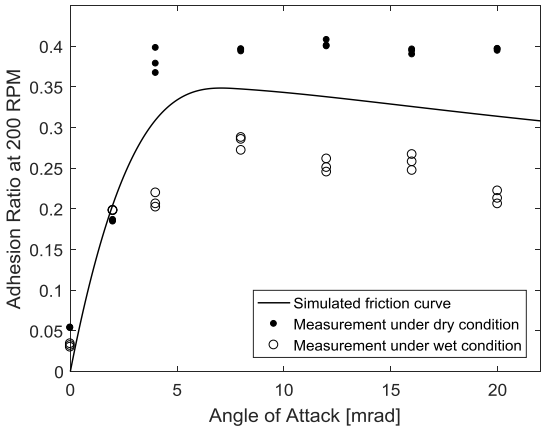


***Figure 2** Simulated friction creep curves at different rolling speeds.*

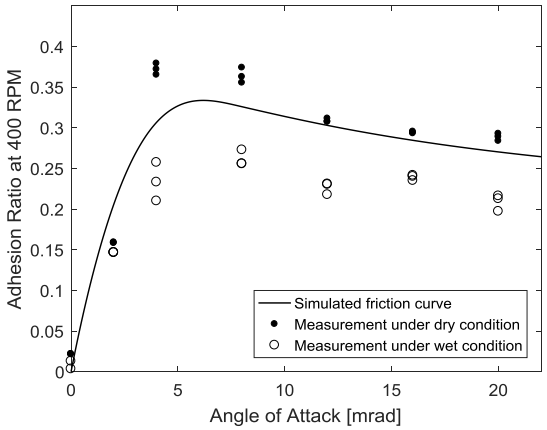
As can be seen that the simulated friction coefficient decreases with the increase of rolling speed, especially for the part of high creepage. The simulated friction curves indicates an evident negative slope at the high creepage.



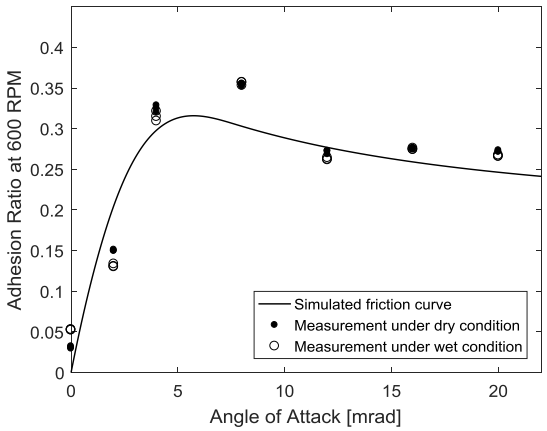
Using the test rig, the lateral force and vertical force at the contact interface can be measured simultaneously, so the lateral adhesion ratio can be acquired reliably. The contact forces are measured at the angles of attack 0, 2, 4, 8, 12, 16 and 20 mrad. For each angle of attack, the contact forces at the rolling speed of 200, 400 and 600 RPM are measured under dry condition first. Afterwards, water is applied on the tread of lower wheel constantly when the test rig is running and the contact forces at the rolling speed of 200, 400 and 600 RPM are measured again under wet condition. With this method, adhesion ratio at different rolling speeds under dry and wet condition can be acquired as presented in Figure 3 (a), (b) and (c). It can be seen in Figure 3 (a) and (b) that the adhesion ratio decreases when water is applied at the contact interface at low speed (200 RPM) and medium speed (400 RPM). The difference between adhesion ratios under dry and wet condition decreases with the increase of rolling speed and the measured adhesion ratio under wet condition at the rolling speed of 600 RPM in Figure 3 (c) approximates to the measurements under dry condition.

Friction curves at different speeds simulated are presented along with measured results in Figure 3, respectively. The results show the measured results correlate well with the predicted friction curve for the case at high speed at 600 RPM. For the low speed, however, the discrepancy is not neglectable.

(a)

(b)

(c)



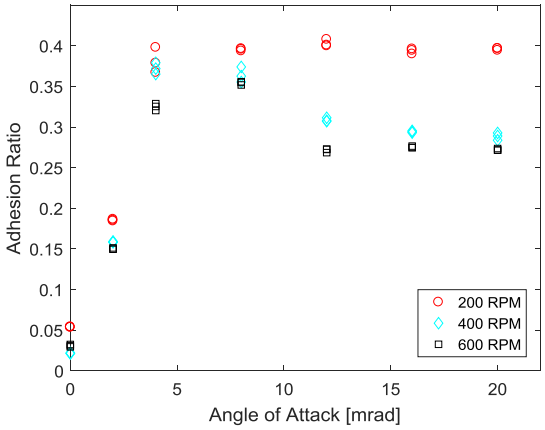


Figure 3 *Measured adhesion ratio at different rolling speeds: (a) 200 RPM. (b) 400 RPM. (c) 600 RPM.*

At each angle of attack and rolling speed, the adhesion ratio is measured three times. It can be observed from Figure 3 that the consistency of the measurement under dry condition is quite high; for the measurement results under wet condition, however, is a bit dispersed in comparison. In particular, for the measurements under wet condition, the consistency at small angle of attack, such as 0 and 2 mrad is quit high in comparison with the measurement at large angle of attack.

The adhesion ratios measured at different rolling speeds under dry condition and wet condition are presented in Figure 4 (a) and Figure 4 (b) respectively. Figure 4 (a) shows that the adhesion ratio measured under dry condition decreases with rolling speed from 200 RPM to 600 RPM, and this trend is more evident for the measurements at large angle of attack.

(a)

(b)

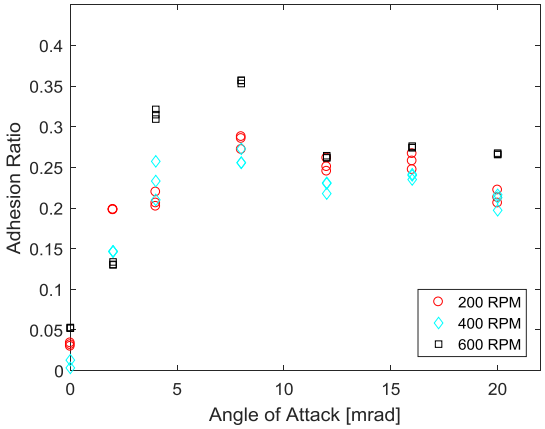

Figure 4. *Measured adhesion ratio under dry and wet conditions (a) Dry condition. (b) Wet condition.*

Figure 4 (b) shows that the lateral adhesion ratio at high speed of 600 RPM is slightly higher than the measurements at lower speeds. Therefore, the lateral adhesion ratio under wet condition has a trend that increases with with rolling speed. Comparing the measured lateral adhesion ratio under dry condition and wet condition in Figure 4 (a) and Figure 4 (b) respectively, one can notice that the presence of water at wheel/rail interface can change the effect of rolling speed on lateral adhesion ratio, i.e., the lateral adhesion ratio decreases with rolling speed under dry condition, while after the application of water at wheel/rail interface, the measurements show a trend that the lateral adhesion ratio increases with rolling speed.

4. Discussions

In order to illustrate the effect of water lubrication on lateral adhesion ratio, the difference in the measured lateral adhesion ratio between dry and wet condition is presented in Figure 5.

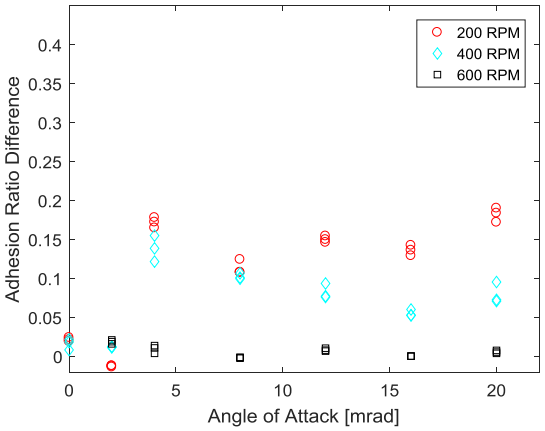

Figure 5 *The difference between measured adhesion ratio under dry and wet conditions*

It can be seen in Figure 5 that the reduction in adhesion ratio after the application of water in more evident for low speed (200 RPM), while the effect on the lateral adhesion is almost neglectable for high speed (600 RPM). In particular, the reduction in adhesion ratio after the application of water is more evident for the measurement at large angles of attack.

For the convenience of comparison, the simulation results in Figure 2 that based on the model developed previously are presented along with experimental measurements in Figure 6.

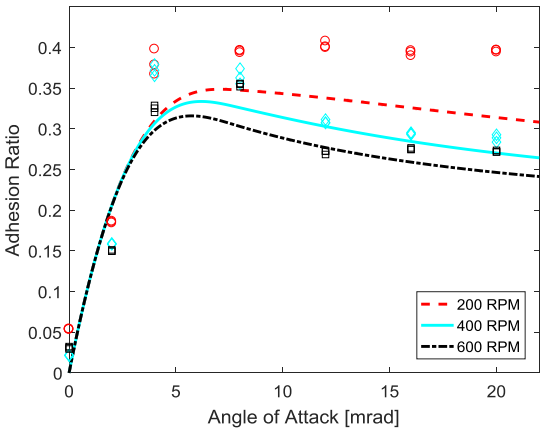

Figure 6 *The comparison between the simulations based on previous model and experimental measurements*

For the high speed (600 RPM), the measured lateral adhesion ratios in Figure 6 are in good correlation with the simulated friction creep curves. For the low speed (200 RPM), however, the discrepancy is not neglectable. Furthermore, for the adhesion ratio under dry condition, Figure 6 shows that current model for contact mechanics in the lateral direction includes the effect of rolling speed, but the discrepancy with the experimental results indicates that the effect of rolling speed on lateral adhesion ratio is not taken into account sufficiently. With reference to the experimental measurements in this research, these two problems can be solved by modifying Equation (6) to the expression as presented below.

$$\mu_K(\zeta) = \mu_0(1.45 - 0.5e^{-3./|V_0|})\{1 - 0.5e^{-0.138/|\zeta V_0|} - 0.5e^{-6.9/|\zeta V_0|}\} \quad (18)$$

Using this modified model, the friction creep curves at different rolling speeds can be simulated as presented in Figure 7.

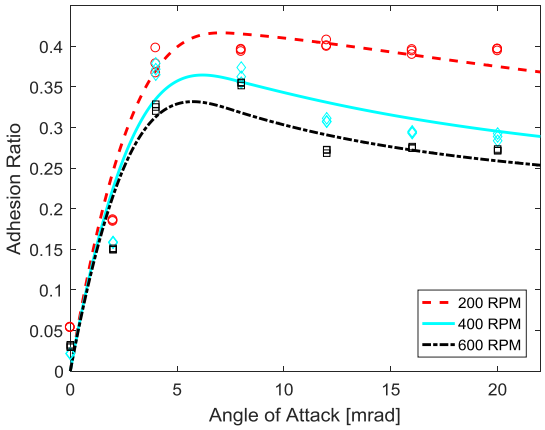

Figure 7 *The comparison between the simulations based on new model and experimental measurement*

It can be noticed in Figure 7 that lateral adhesion ratio simulated with the modified model also decrease with rolling speed as observed in the experiments. Furthermore, simulated results at each rolling speed are correlated well with experimental measurements.

5. Conclusions

In this research, the adhesion ratios under dry and wet condition are measured using a two disc rolling contact test rig. In general, the results show that after the application of water, the lateral adhesion ratio decreases. This reduction is quite remarkable for low speed (200 RPM), up to almost 0.2. In contrast, this reduction is almost neglectable for high speed (600 RPM). On the other hand, the results show that the lateral adhesion ratio decreases with rolling speed under dry condition; after the application of water, however, the measured results show a trend that the lateral adhesion ratio increases with rolling speed. Therefore, the presence of water at the wheel/rail interface can change the contact mechanics magically.

In this paper, a model for contact mechanics in the lateral direction is developed further, which is based on the models of Jonson and Kalker. The simulated friction creep curves shift down with the increase of rolling speed. Moreover, the correlations with the measured lateral adhesion ratio at different rolling speeds are much better. Therefore, this newly developed model can provide a more precise description on the wheel/rail contact mechanics.

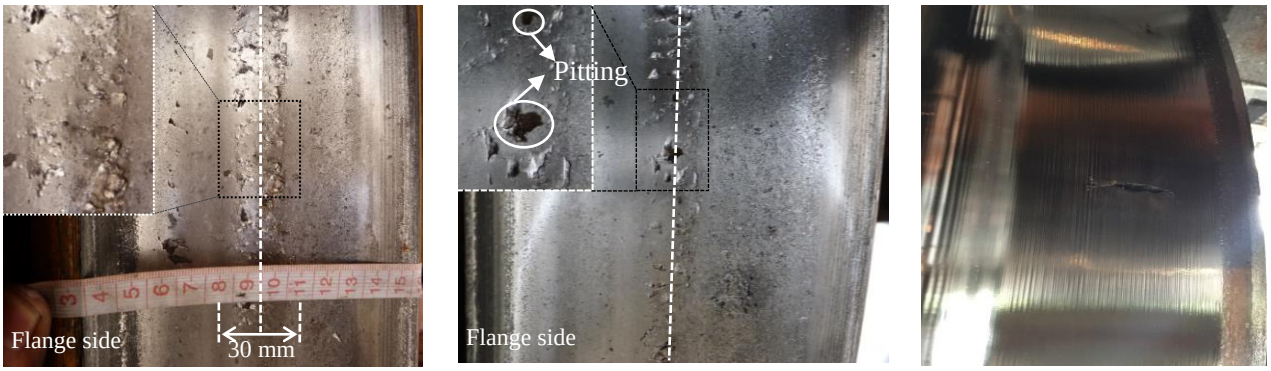
Abstract: Severe rolling contact fatigue (RCF) has occurred on wheels of some high-power (>7200 kW) AC locomotives in China. It occurs around the nominal rolling circle (NRC) with laterally propagated cracks of typically 2-15 mm deep. Main characteristics of the RCF are figured out during field observations and monitoring tests, based on which its initiation mechanism is revealed and confirmed through multi-body dynamic simulations in combination with shakedown map and Tγ model for RCF prediction. Unqualified sand used for adhesion enhancement and complicated environments such as sharp curves and large slope are found to be the main causes of the RCF.



Keywords: AC locomotive; rolling contact fatigue; field observations; sand; complicated environments; numerical simulations.

1. Introduction

High-power (>7200 kW) AC locomotives introduced into Chinese railway about 10 years ago significantly modified the industry due to their large hauling capacities. During operations on existing tracks, many problems occurred of these locomotives, e.g., wear and rolling contact fatigue (RCF) of wheels, especially for those running in complicated environments such as sharp curves, steep and undulating slopes etc. This investigation focuses on the wheel RCF of a type of high-power locomotives running in north China, typically occurring around the nominal rolling circle (NRC, 70 mm away from the inside of the flange back) of a wheel, as shown in Figure 1. Under certain conditions, a crack of the RCF may propagate downward into a depth up to 14.5 mm, leading to unacceptable material removal during reprofiling, see Figure 1(c) for an example. A companion paper [1] published at this conference as well studies the wear of wheels of another type of high-power locomotives.

Considering the importance of material defects on RCF initiation [2-4], the wheel material had first been examined in laboratory by the locomotive maker. It was found that the chemical composition, microstructure and hardness of the material all met the requirements of standards, i.e., material defects should not be the cause of the RCF. Therefore, a research project was launched in 2016 to study the initiation mechanism of the RCF from the aspect of dynamic wheel-rail interactions on the basis of field observations and monitoring tests. From the collected/obtained results the direct causes and initiation mechanisms have been figured out, which will be presented in this paper together with some proposals for counter measures.

Besides material defects, other factors influencing RCF have also been intensively studied in the literature, e.g., the third body layer, geometric defects etc. For the third body layer, the enhancement of liquid on crack propagation by the mechanisms of hydro-pressurization and crack face lubrication [5-7], and cracks resulting from sand used for adhesion enhancement [8-11] have been widely recognized. RCF initiated from geometric defects such as hollow-tread, out-of-roundness, flats and

Figure 1 *Typical wheel RCF of a type of 6-axle high-power AC locomotives (7200 kW and 120 km / h max) in China occurring around NRC (the white dotted line): (a) Typical tread surfaces 1 and (b) 2 at relatively late stages. (c) Another wheel with a deep crack after turning a radial cut of 4 mm.*

Indentations [12-15], and the influences of track geometry and irregularities on RCF [16-18] have also been reported by various authors. In addition to all above mentioned factors, tangential contact forces resulting from traction, braking and curving are believed to be the determinant factors of continuously distributed RCF, as specified by Tunna [19], along the circumference of wheels or the longitudinal direction of rails. Deuce [20] classified the continuous RCF of wheels into categories I~IV based on its location and the direction of surface cracks.

Recently, Simson *et. al* [21] investigated the RCF of wagon wheels used for coal operations in Australia and the USA. Classes I, II and III RCF were all observed on wheels of 100T coal wagons operating on the Blue Mountains in Australia, as a consequence of high contact stress, and the occurrence rate of class III was less than 1.4%. Molyneux-Berry and Bevan [22] found that class I RCF often occurred on wheels of a modern diesel multiple-unit trains (for passenger transport), resulting from curving on sharp curves, while class III only occasionally on some wheels. Nia *et. al* [23] using a dynamic model studied the effects of an optimized wheel profile on classes I, II and III RCF occurring on wheels of locomotives running on the Iron Ore Line in northern Sweden and Norway. Ekberg *et. al* [24] studied classes I, II and III RCF on wheels of locomotives running on the Iron Ore Line, and concluded their causes of season variations, improper profiles of inner rails on some curves, and insufficient lubrication. According to [24], for the investigated locomotives the occurrence rate of class III RCF is much lower than those of classes I and II.

This paper first explains the RCF phenomena occurring on wheels of the high-power locomotives in detail from different aspects. Afterwards, a numerical model is developed to explain the observed phenomena, from which the initiation mechanism of the RCF is clarified. At the end, further counter measures are proposed and conclusions are drawn.

2. Field observations and monitoring tests

The concerned locomotives are of an AC type with Co-Co axle arrangement. Its maximum power and design speed are 7200 kW (1200 kW/axle) and 120 km, respectively. The first locomotive of this type was produced in 2010, and over 1300 locomotives have been delivered in total to 33 bureaus/companies over China until the end of 2017. Operations in the past 8 years have shown that these locomotives performed very well in most bureaus (no damage was reported to the maker) except for one bureau where in total 40 locomotives of this type are equipped and severe wheel RCF was observed.

Hence, the authors travelled to the bureau to collect information of the wheels and tracks there. Photos of wheel treads were taken, and wheel profiles, tread surface hardness and out-of-roundness were measured. In the first time, 15 locomotives (180 wheels) with distributed mileages after re-profiling were observed and measured, based on which 8 typical ones were selected for further monitoring tests lasting for 8.5 months, during which 5 rounds of measurements were conducted in total. In the meantime, the re-profiling records of wheels and design parameters of a typical track on which the locomotives mostly run were also acquired for analyses. It should be noted that not long before the first measurement, two trial counter measures, namely change of adhesion enhancement sand and TCMS (Train Control and Management System) update targeting at smoother transitions between traction/braking levels, had been applied, so that their effects on depressing the RCF are also evaluated in this study.

2.1. The problem of RCF before the measures

2.1.1. Surface appearance and cracks

As shown in Figure 1(a) and (b), the RCF occurs continuously along the circumference, and are typically located in a zone approximately 30 mm wide cantered at NRC. The cracks are typically at angles of −30°～30° to the axle, and pitting is often visible. Obviously, the RCF belongs to class III RCF by Deuce [20]. Out of the observed 180 wheels, 159 ones were infected by the RCF, i.e. it is a very common problem for the locomotives there.

Besides class III RCF, classes I and II (outside and inside NRC, respectively) and pitting were also observed on the wheel treads during tests, as shown in Figure 2. Practice, however, has shown that those types of RCF do not result in deep cracks (at least under current conditions). In other words, they can be repaired\controlled easily by periodical re-profiling with limited cutting amount(typically a radial cut of 2 mm). Therefore, this

(a) *(b)* *(c)*

Figure 2 *More RCF types on the wheels: (a) Class I and (b) Class II RCF located outside and inside the NRC, respectively. (c) Pitting damage.*

paper only focuses on class III RCF, which is referred to as the RCF hereinafter for simplification.

It should be specified that most cracks of the RCF can only propagate into a shallow layer and results in the pitting or relatively small detachments indicated in Figure 1(b). Only a few cracks may propagate into significant depths under certain conditions, requiring radial cuts up to 14.5 mm on lathe to restore the wheel tread. The deep cracks are approximately laterally propagated at depth, as shown in Figure 1(c). The pitting or relatively small detachments have limited influence on the wheel-rail contact due to its relatively small sizes.

2.1.2. Reduced re-profiling periods

Figure 3 shows the turning records of the observed 15 locomotives before the counter measures, in which each horizontal line represents a locomotive, and solid circles attached to the horizontal lines correspond to turning operations. In total 48 turning operations were conducted, among which 41 operations were caused by the deep cracks around NRC. It is seen that the re-profiling period is as low as 18,000 km, and is 71,000 km on average, corresponding to 4～5 months. Consequently, the service lives of wheels were shortened greatly, and bitter complains were often heard from the turning workers in the depot. It should be noted that all the damaged wheels had been repaired by deep cutting like those shown in Figure 1(c), suggesting that no cracks further propagate radially into the bulk, i.e. the cracks can hardly result in rim breaks. Moreover, no correlations are found between specific seasons and turning operation density, being different from that reported in [24].

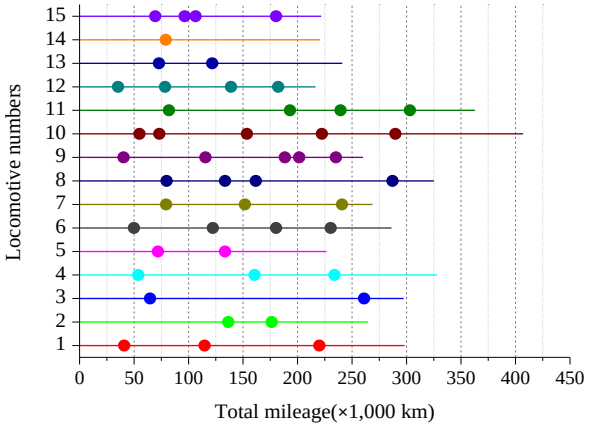

Figure 3 *Turning history of the 15 observed locomotives. The horizontal lines end right before the counter measures.*

2.1.3. Amount of radial cut and axle preference

In the above mentioned 41 turning operations caused by deep cracks, 89 axles were confirmed to be infected, i.e. more than one axle infected in each operation. From the distribution of the infected axles shown in Figure 4 (a) it is seen that deep cracks occurred mainly on axles 1, 3, 4 and 6. The required cutting amount on lathe, as shown in Figure 4(b), suggests that the deep cracks are typically 2 ~14.5 mm deep. A simple algebraic average of all the crack depths is 6.4 mm, requiring a cut of 12.8 mm in diameter. Such deep cuts are unacceptable, especially considering that other un-damaged wheels have to be turned together with the damaged one to keep the diameter difference acceptable among wheels.

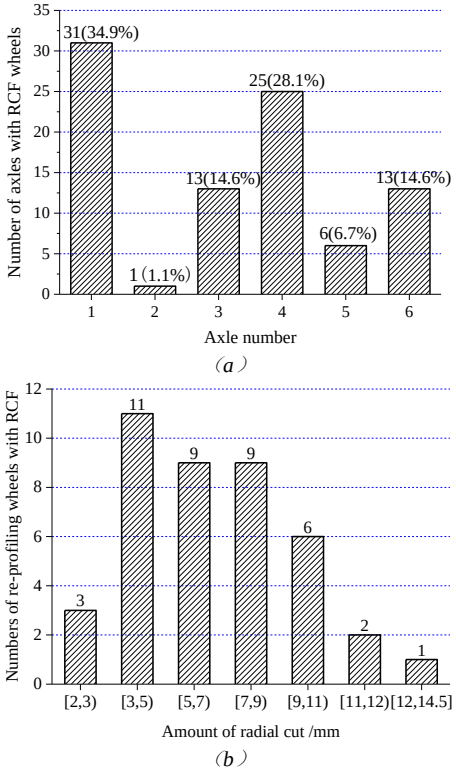

Figure 4 *Statistics of re-profiled wheels caused by deep RCF cracks (Jan. 2014~Mar. 2016): (a) Axle preference. (b) Amount of radial cut.*

2.1.4. Estimation of RCF crack growth rate

Based on the reprofiling periods and cutting amount shown above, the growth rate of the RCF cracks is estimated in this section. To such an end, the following assumptions are made: (i) the cracks initiated on the first day after re-profiling operations; (ii) the cracks were just removed by natural wear and wheel re-profiling; (iii) the re-profiling operations did not affect the cracks; and (iv) the crack growth rate was constant. The last two assumptions suggest that an average growth rate of crack is estimated. Figure 5(a) shows the crack depths of the 41 operations versus the reprofiling periods (although 89 axles infected, only 41 records of depth were reliable), from which it is seen that the depth approximately increases linearly with the period or mileage after re-profiling. The crack growth rates plotted in Figure 5(b) are derived from the results in Figure 5(a). It is observed that the average growth rate of crack depth varies between 0.03 mm/1000 km and 0.19 mm/1000 km, and it first decreases with the period and gradually stabilizes. Note that the ignored crack initiation and stabilization after a certain depth will result in underestimation of the growth rate, while the second assumption will lead to overestimation because the material cut during re-profiling is usually more than necessary to ensure complete removal of cracks and for easy operations. Thus, it is uncertain whether the estimates are conservative.

2.2. Typical tracks

The Taiyuan – Datong line, built up in 1939 and electrified in 1989, is a typical line on which the locomotives with severe RCF damages mostly run. The

total length of the line is 669.5 km back and forth. The maximum slope is 24‰, and the sections with slopes of -12‰～-24‰ (downhill) or 12‰～24‰ (uphill) are 108.8 km in total, as shown in Figure 6(a). Meanwhile, many sharp curves also exist on the line, the minimum radius is 250 m, and the sections with radii between 250～800 m are 98.7 km long in total, as shown in Figure 6(b). Obviously, the running condition on this line is very harsh, and the worst running condition occurs on sharp curves with large slopes. Typical rail profiles, measured on another similar line (measurements on Taiyuan – Datong line was not arranged due to many difficulties) in October 2016, are shown in Figure 7.

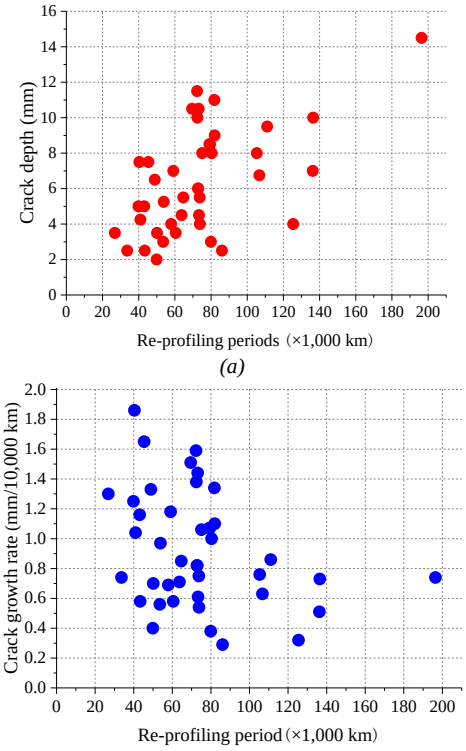

Figure 5 *The 41 wheel turning operations caused by the RCF (of the 15 observed locomotives): (a) Crack depth. (b) Estimated average growth rate of crack depth.*

2.3. Counter measures and their effects

TCMS update started in July 2015 and ended in March 2016, while sand change was conducted in March 2016. Figure 8 shows a picture of the old sand and the substituted new one used for adhesion enhancement. From the chemical compositions listed in Table 1, it is found that the alumina and ferric oxide contents (hard components) are much higher in the old sand, while the new sand is almost purely silica. Furthermore, particles of the new sand are more regular in size than the old one, and the largest particles are similar in size for both sands, as seen from Figure 8. The intention of the TCMS update is to reduce the longitudinal impact suffered by the locomotives and to increase the smoothness in operation (detailed information is confidential).

Concrete mileages at which the measures were applied are illustrated in Figure 9 for each monitored locomotive. It is seen that the sand change was applied to all the 8 monitored locomotives, while the TCMS update was only applied to 5 of them. After the counter measures, the reprofiling period is prolonged to 100,000～280,000 km,

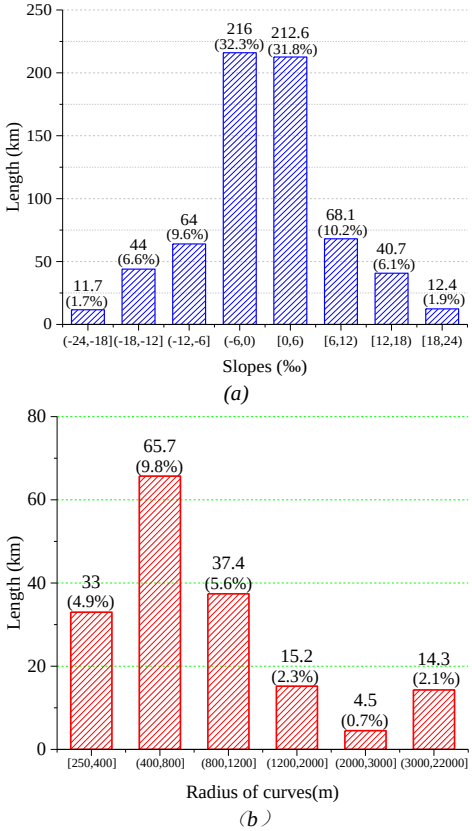

Figure 6 *Statistics of the Taiyuan – Datong line: (a) Slopes (negative and positive represent downhill and uphill, respectively). (b) Curves.*

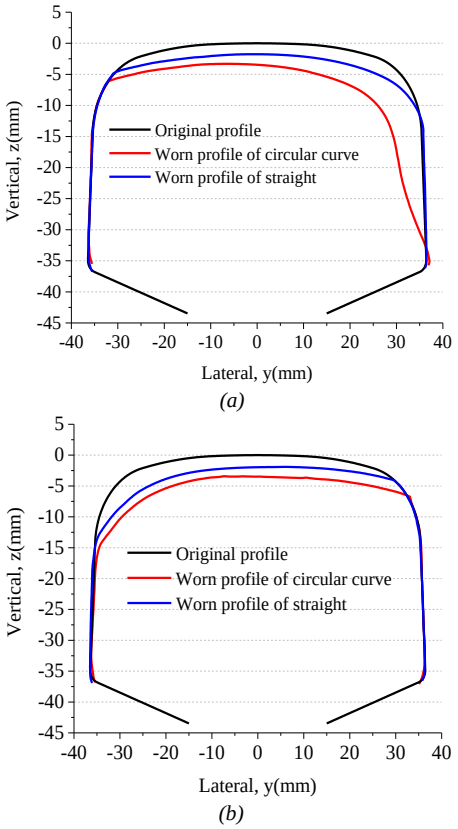

Figure 7 *Measured rail profiles on a curve with a radius of 800 m: (a) Outer rail. (b) Inter rail.*

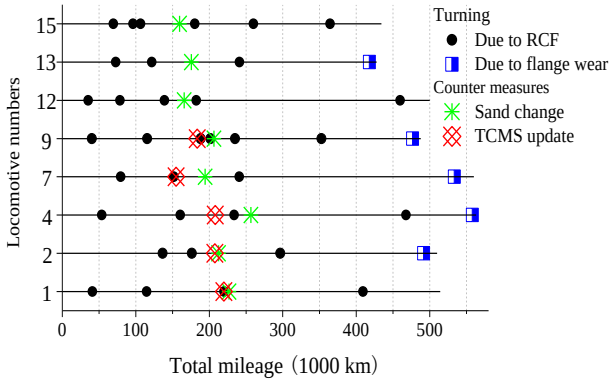
being much longer than 50,000～120,000 km before.

Furthermore, those without TCMS update also showed similar improvement, suggesting the dominant role of sand on the RCF. Consequently, the dominant factor of wheel re-profiling shifted from the RCF to the RCF and flange wear, as illustrated in Figure 9.

Figure 8 *Pictures of the old and new sands.*

Table 1 *Chemical compositions of the old and new sands.*

Sand	Al_2O_3	Fe_2O_3	SiO_2	Other
Old	11%	1%	86%	2%
New	0.63%	0.03%	98.87%	0.57%



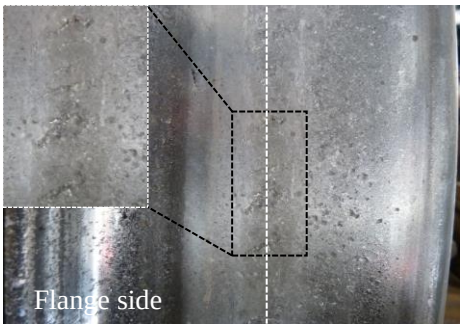


Figure 9 *Re-profiling history of the 8 monitored locomotives.*

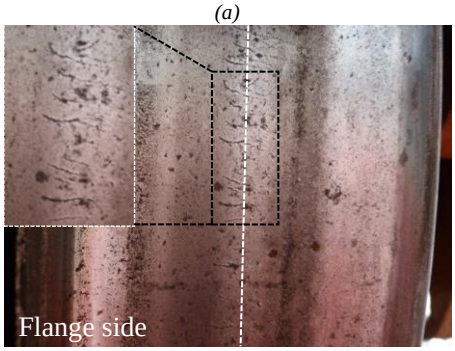
Table 2 shows more detailed information of the reprofiling operations of the 8 locomotives caused by the RCF after the measures. It is seen that the infected wheels are still axles 1, 3, 4 and 6, and cracks are typically 6-10.5 mm deep, corresponding to a growth rate of crack depth of 0.022～0.099 mm/1000 km. These are comparable to those before the measures. Therefore, the RCF problem was not solved completely by the measures, but the occurrence rate was reduced significantly, which can be drawn from the fact that the number of reprofiling operations of all 40 locomotives caused by the RCF dropped from 82 in 2015 to 70 in 2016, and further to 30 in 2017.



Comparing typical tread pictures with the RCF shown in Figure 10 to those before the measures shown above, it is seen that pitting has been greatly reduced, being consistent with the observations reported in [8-11], but lateral cracks remain similar. In a conclusion, sand plays an important role in initiation of the RCF, but is probably not the only cause, and should not affect much the propagation of initiated cracks. More analyses will be discussed in Section 3.

Table 2 *Information of wheel re-profiling caused by the RCF after the measures, only the 8 monitored locomotives are counted*

Loco number	Infected axle	Re-profiling period (km)	Cutting depth (mm)	Crack depth growth rate (mm/1000 km)

3. Numerical analyses

3.1. A multi-body dynamic model

A multi-body dynamic model of train-track interaction has been established, as shown in Figure 11, using SIMPACK to calculate the wheel-rail contact forces and the corresponding creepages. A locomotive of the type mentioned above and a 25G trailer are considered with a coupler in between. The locomotive is represented by 6 wheel-sets, 6 motors, 2 bogie frames, 1 car body and 2 traction rods, in total 64 degrees of freedom (DOF), and the trailer by 4 wheel-sets, 2 bogie frames and 1 car body, in total 42 DOFs. Two rigid rails are used to simulate the track, and parameters such as curves, cant, slopes etc. are considered properly. Table 3 listed values of parameters involved in the model.

For the studied system, the wheel and rail profiles are JM3 and CHN60, respectively. Typical worn profiles of wheel and rail measured during the monitoring tests (see Figure 7 and Figure 12) are implemented for simulations. It is seen from the profiles that significant contact occurs

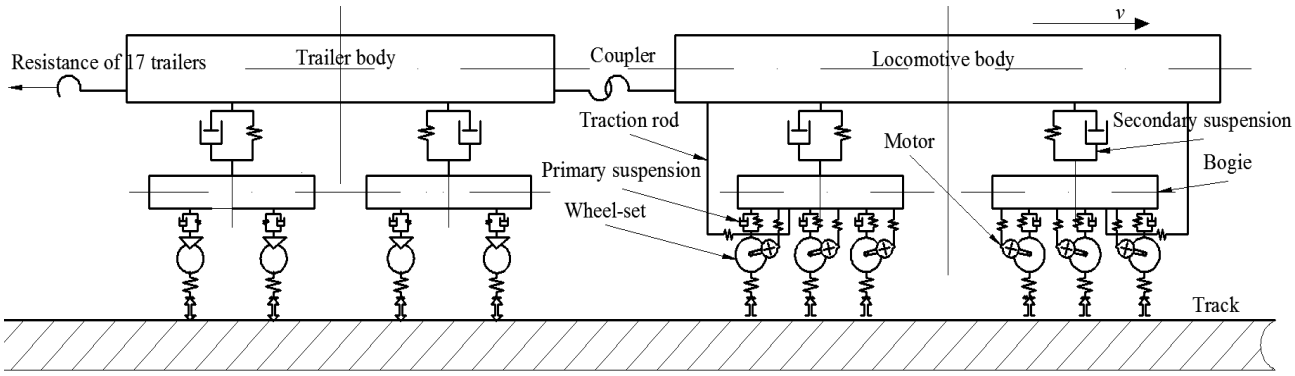

Figure 11 *A Schematic diagram of the dynamic model.*

between the wheel flange and rail gauge side. The vertical and tangential wheel-rail interactions are solved by Hertzian spring and Polach's model [25], respectively. Considering the environment of the studied line, typical friction parameters under dry conditions listed in Table 4 are used. Excitations of ARR5 are applied to take into account track irregularities.

Table 3 *Value of parameters involved in the model.*

During a simulation, driving torques are applied at the motors, and total resistance W_s (unit: N) calculated by Equation (1) is applied as the balance force. W_1, W_2 and W_3, determined by Equations (2)～ Equation (4), are the resistance caused by the rest 17 trailers of a train (typical composed of 18 trailers), the locomotive, and the trailer, respectively. They are applied at the end of the trailer (where another coupler exists), the locomotive body and the trailer body, correspondingly.

$$W_s = W_1 + W_2 + W_3 \tag{1}$$

$$W_1 = 17 \cdot G' \left(w_i + w_r + w_0' \right) \cdot g \tag{2}$$

$$W_2 = G \cdot w_0 \cdot g \tag{3}$$

$$W_3 = G' \cdot w_0' \cdot g \tag{4}$$

where G and G' (unit: kg) are the masses of the locomotive and the trailer, respectively, and g is the gravity acceleration. The unit resistance w_0 and w_0' (unit: N/kN) composed of mechanical and aerodynamic resistance are calculated by Equation (5), unit curve resistance w_r by Equation (6), and unit slope resistance w_i by Equation (7).

$$\begin{cases} w_0 = 1.67 + 0.002v + 0.000243v^2 & \text{For loco} \\ w_0' = 1.66 + 0.0075v + 0.000155v^2 & \text{For trailer} \end{cases} \tag{5}$$

$$w_r = \begin{cases} \dfrac{600}{R} & L_c \le L_r \\ \dfrac{600}{R} \times \dfrac{L_r}{L_c} & L_c > L_r \end{cases} \tag{6}$$

$$w_i = i \tag{7}$$

where v is velocity (km/h), R is the radius of a curve, L_c is the length of the curve (1,000 m) and L_r is the length of the train (479 m).

In simulations, the track is set to be 2000 m long, which includes tangent tracks, transition and circular curves in curve cases. For analyses, only the results in the middle part (500 m~1500 m), also the middle of circular curves for curve cases, are used for RCF prediction where stable wheel-rail interaction has been established. The speed is assumed to be constant in every case and its value depending on the radii of curves and slopes is taken based on the actual running speeds of trains on the Taiyuan – Datong line. Thus, the applied resistance calculated by Equations (1)～(4) is balanced with the drive or braking efforts applied at motors. The combinations of speed and slope at tangent tracks and curves of R=800 m used in simulated cases are shown in Figure 13 as examples,. Without loss of generality, the 1st axle leads the train in all cases, and right curves are always assumed where required.

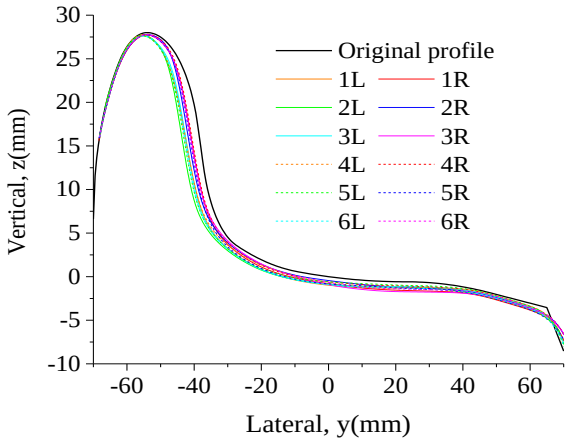

Figure 12 *Measured wheel profiles of locomotive 2 at 9,2000 km after reprofiling. 1L represents 1st axle and left wheel.*

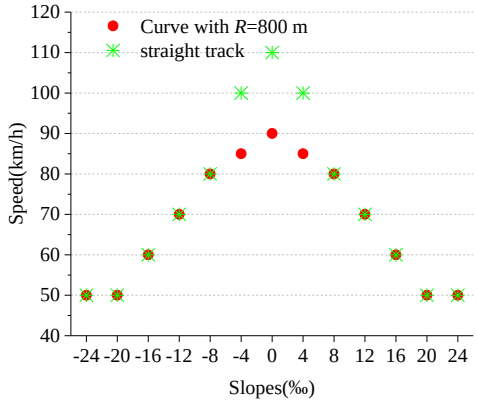

Figure 13 *The combinations of speed and slope at tangent tracks and curves of* R=*800 m assumed in simulations.*

3.2. RCF predictions

RCF predictions are conducted using shakedown map [26] and *Tγ* model [27] based on the dynamic results outputted from the dynamic model explained above. A typical analysis is as follows: 1) first check if the contact position is in the RCF zone (i.e., −15～15 mm); 2) predict if the RCF initiates; 3) examine the directions of the creep forces to determine if lateral cracks (−30˚～30˚ with respect to the axle) propagate. In the *Tγ* approach crack damage is only counted when the direction of the longitudinal creep force is opposite to the travel direction of the wheel (i.e., the effects of liquid on initiation and propagation of RCF considered), while wear damage is always accumulated. After calculating the total damage with the *Tγ* approach, it is further distributed over the contact patch, for which the patch is divided into longitudinal bands with a width of 0.1 mm and the damage distribution is assumed to be semi-elliptical along the lateral. Table 5 lists values of parameters involved in the shakedown map and *Tγ* model.

Table 5 *Parameters used in shakedown map and Tγ model.*

Parameters		Value
Tγ model	RCF initiation threshold	22.8 N
	Crack Rate	3.6×10^{-6}/revolution/N
	Wear initiation threshold	106 N
	Wear Rate	-5.4×10^{-6}/revolution/N
Shakedown map	Shear yield strength *(k)*	311 MPa

3.3. Wheel damage results

3.3.1. Tangent tracks

Trial simulations have shown that wheel profile evolution has negligible influences on predicted results of tangent tracks. In this section, profiles of locomotive 02 measured at 92,000 km mileage are used in match with measured rail profiles on a tangent track section (see Figure 7 and 12). Results of wheel 1L (1st axle, left side), being the same as the other wheels on straight lines, are presented for explanation here.

Figure 14(a) shows the damage distribution along lateral, which are obtained by accumulating the damage between 500 m and 1500 m and then divided by the number of rolled cycles of wheel. The positive and negative damage represents wear and RCF, respectively. A wheel profile is plotted for easy reference. Note that only the RCF damage resulting in lateral cracks is included in the figure (the same for similar figures hereinafter). It is seen that the RCF is expected on the zone centered by NRC (−15 mm～15 mm) if running on tracks with negative slopes (downhill). Further, the RCF damage roughly increases to 1.5～2 times as the absolute value of the negative slope increases by 4‰, as shown in Figure 14(b).

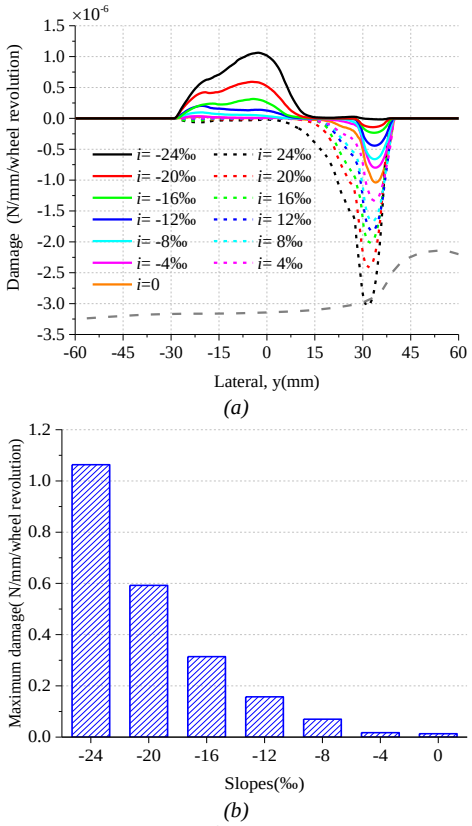

Figure 14 *Predicted damage of wheel 1L running on tangent tracks using Tγ model: (a) Damage distribution. (b) Variation of the maximum damage with slope.*

The significance of slopes on the RCF can also be seen from the predictions of shakedown map shown in Figure 15. I.e., the larger the slope is, the more symbols are in the plastic shakedown or ratcheting zones where RCF is expected. In the figure, every symbol corresponds to a discrete instant when the contact point is in the RCF zone (−15 mm ～ 15 mm, the same for similar figures

hereinafter). Note that the results on tracks with positive slopes are not presented in Figure 15 because RCF can hardly initiate there due to the direction of the creep force as mentioned above.

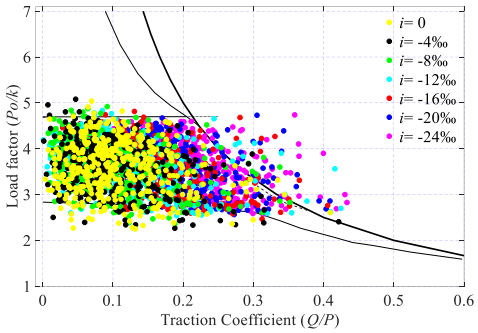

Figure 15 *Shakedown map results of wheel 1L running on tangent tracks with negative slopes (downhill).*

3.3.2. Curves

In this section, wheel profiles in Figure 7 and rail profiles Figure 7 are used by default. Figure 17 shows the damage distributions of wheels of the 1st bogie when the locomotive with measured profiles runs on a curve with *R*=800 m and different slopes. Since uphill and downhill usually co-exists with similar slopes and lengths in a track, especially for back and forth running on double tracks, results of the positive and negative slopes are plotted in the same figures for comparison.

It is seen that only wheel 3L may initiate the RCF after passing an uphill and a downhill, i.e. the RCF damage on the downhill is larger in absolute value than the wear damage on the uphill under the same slope. An explanation for this phenomenon is as follows: i) the contact point of wheel 3L has much larger chance to occur in the RCF zone due to much smaller lateral shift of the 3rd axle; ii) the longitudinal creep force of wheel 3L is backward on a plane curve (*i*=0), while that of wheel 3R forward; on the other hand, negative slopes further increase the amplitude of the longitudinal creep force of wheel 3L, i.e. increase the chance of RCF development there (for wheel 3R the direction of its longitudinal force also become backward at large negative slopes, as can be seen from the predicted RCF occurrence at −24% slope); iii) the resultant longitudinal creep force of wheel 3L (components caused by curving and driving) is not sufficient to trigger wear damage in uphill cases.

In Figure 16, the maximum damage of wheel 3L running on curves with *R*=800 m and different negative slopes is compared to those on corresponding tangent tracks. The damage on the curve is seen to be more than 8 times larger under the same slopes, indicating the significance of curves on the RCF. The same conclusion can also be drawn from the shakedown map results shown in Figure 18 in comparison with those in Figure 15.

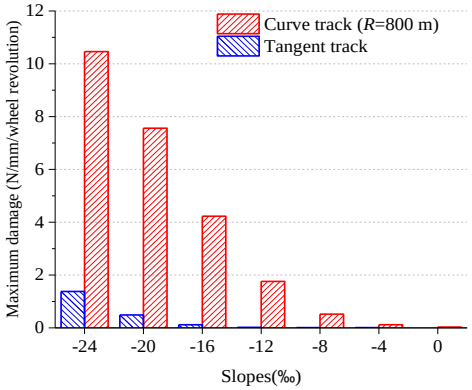

Figure 16 *Variations of the maximum damage of wheel 3L running on curves and tangent tracks with different slopes.*

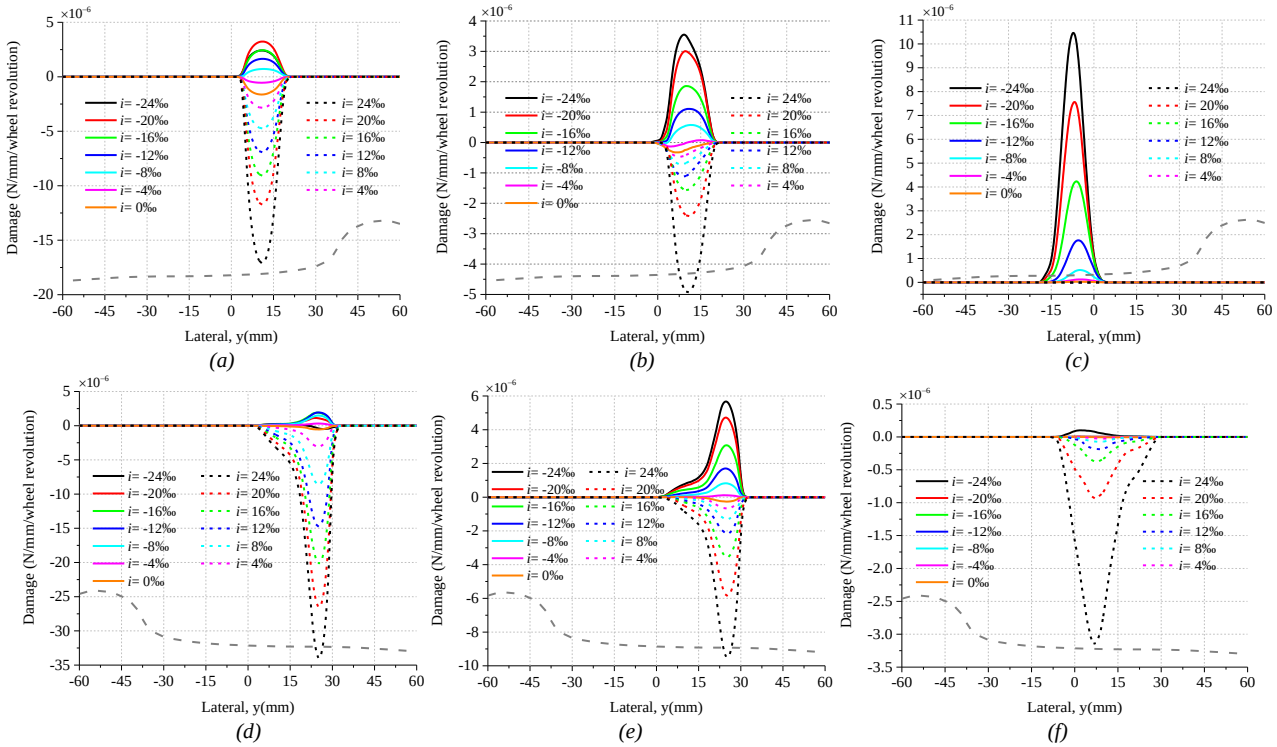

Figure 17 *Damage distribution of wheels of the 1st bogie running on a curve with R=800 m: (a)1L. (b)2L. (c)3L. (d)1R. (e)2R. (f)3R.*

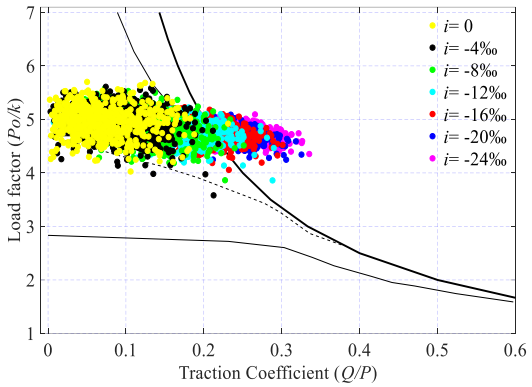

Figure 18 *Shakedown map predictions of wheel 3L running on R=800 m curve with the different slopes.*

The measured worn wheel and rail profiles shown in Figure 7 and Figure **7** are used in results of this section shown above. Figure 19 shows the damage distributions of wheel 3L when the JM3 wheel profile and CHN60 rail profiles are used, for which all the other parameters keep unchanged. Figure 20 further shows the comparison of the obtained maximum damage to those of worn wheel profiles calculated above. Obviously, the trends with slopes are similar for the two profile matches, i.e. the influence of wheel and rail profiles is insignificant to an extent.

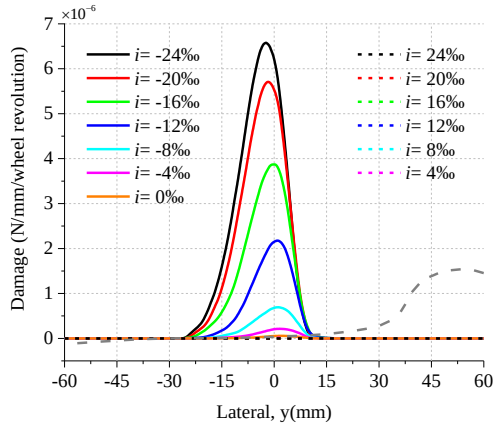

Figure 19 *Damage distributions of wheel 3L running on a curve with R=800 m when JM3 wheel profile and CHN60 rail profiles are used.*

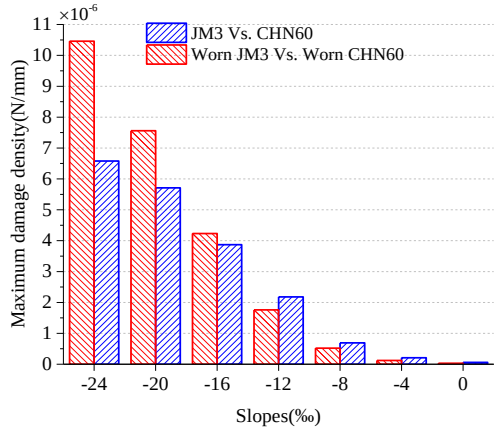

Figure 20 *Comparison of the maximum damage of wheel 3L under the worn profiles matching and the original profiles matching.*

Figure 21 shows the damage distributions of wheel 3L running on plane curves with different radii, for which the JM3 wheel profile and CHN60 rail profiles are used.

It is seen that as the radius reduces from 1000 m to 300 m, the RCF damage increases in magnitude due to larger longitudinal creep force, and shifts to the field side in its position because of larger lateral shift of the wheelset; when the radius further decreases, the damage starts to reduce in magnitude and its position shifts further to the field side.

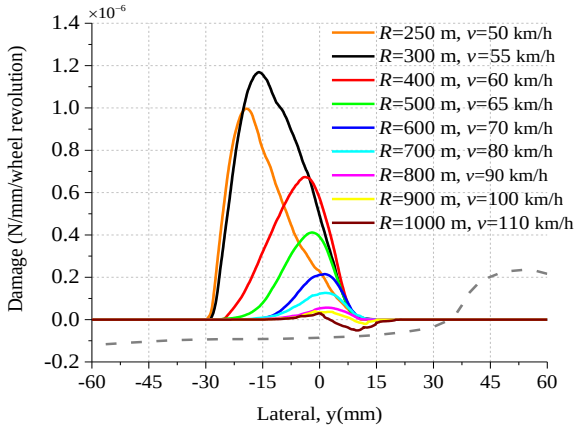

Figure 21 *Damage function of 3L wheel running on the different radii of right curve (i=0)under the original profiles matching.*

4. Discussion and recommendations

4.1. RCF initiation mechanism

The unqualify sand will inevitably lead to the damage of the wheel surface, the damage characteristics of the wheel surface are the lateral crack coexisting with the pitting, big pitting and fatigue crack appear on surface or subsurface, and sever crack initiate from big pitting and develops into material a depth, which are filled by crushed and sand particles, and such particles may then be incorporated into the wheel steel, forming a network of incoherent material in the subsurface layer that leads to crack propagation and material detachment [8-11]. After the old sand is replaced, the new sand obviously reduces the pitting damage to the wheel surface, but RCF has not been completely eliminated, these shown the sand is not the only factor affecting RCF, but the sand actually accelerates the initiation and propagation of RCF.

RCF wheels of small curves with the different negative slopes are recorded in Table 6, which can be explain the RCF of axles preference. Considering that Taiyuan and Datong are at the same altitude (see Figure 6), the length of the tracks with the positive and negative slopes is basically equal, the RCF initiated at the negative slopes is not enough to be worn away at the positive slopes, so the RCF initiation will be accumulated and eventually propagated. Therefore, RCF initiation is co-dominated by the sand and the complicated operating environments before the sand replaced and is only dominated by the complicated operating environments after the sand replaced.

Table 6 *Statistics of RCF wheels under curves with the negative slopes*

Drivers position	Direction of curves	RCF wheels
Cab.1	Right curve	3L,6L
	Left curve	3R,6R
Cab.2	Right curve	4R,1R
	Left curve	4L,1L

4.2. Recommendations against RCF

Based on the results shown above, the authors would like to recommend the following counter measures against the RCF: (1) use qualified sands for adhesion enhancement to reduce the initial damage on wheel surface from which deep cracks may initiates; (2) try to avoid running only on a line with many complicated environments such as sharp curves and large slope; (3) install tread cleaning devices to properly increase the wear rate to a level balancing the RCF initiation; (4) automatically apply more braking force to trailers when braking a train to reduce the braking force requirement from locomotives, especially on curves.

5. Conclusions

Severe RCF occurring around the nominal rolling circle (NRC) of some high-power (>7200 kW) AC locomotives (1200 kW per axle) is investigated by means of field observations, monitoring tests and numerical simulations. Conclusions drawn from the analyses are as follows:

a) The RCF cracks typically occur on the zone centered by NRC (−15 mm～15 mm), and propagate into 2-15 mm deep with an angle of −30° ~ 30° to the axle on the surface. Its occurrence is not related to material defects and not season dependent, but occurs more on axles 1, 3, 4 and 6.

b) By substituting the old sand (used for adhesion enhancement) with qualified one, the average re-profiling interval of wheels is prolonged from 50,000～120,000 km to 100,000～280,000 km, and the dominant factor of wheel re-profiling shifted from the RCF to the RCF and flange wear. Correspondingly, the average growth rates of crack depth reduced from 0.03 mm/1,000 km ～0.19 mm/1,000 to 0.022/1,000 km～0.099 mm/1,000 km.

c) Negative slope (downhill running) is one of main causes of the RCF. In the case of tangent tracks, the RCF damage roughly increases to 1.5～2 times as the slope increases by 4‰.

d) The RCF damage is much severe on curves than on tangent tracks for wheels 3L and 6L, especially on those with large slopes. For the other wheels, however, wear is the dominant damage mechanism.

e) The wheel/rail profiles are insignificant for the RCF.

Abstract: This paper presents a study comparing the wear performance of laser clad rails. A grade of martensitic stainless steel (MSS) was deposited on two substrate materials: The Europe standard rail steel R260, and a lower grade rail steel R200. A twin-disc method has been used to simulate the contact of wheel and rail under closely controlled conditions. Although cladding on a lesser grade of rail does have an effect on the hardness and wear performance of the clad layer, the resulting wear performance of the clad layer assessed using this approach is still vastly improved over R260 material alone.

Keywords: laser cladding, wheel/rail contact, wear, microstructure, twin-disc testing.

1. Introduction and Background

A major proportion of a train network operational cost is the rail maintenance. The cost of replacement of the worn rail or improvement of the rail's tribological properties, corrosion properties and contact fatigue resistance, is significant. Meanwhile network downtime caused by rail maintenance also has a great impact on the disruption to commuters and cargo shipping.

Railway rail is rolled from a single grade of steel yet different parts of the rail section require their own operating properties. For example, the rail head requires strong tribological properties while the web and foot are required to be structurally robust. There are two main factors that affect the durability of rail track: wear and rolling contact fatigue (RCF) [1, 2]. Wear and RCF resistant materials are available [3], however, it would be either difficult or costly to manufacture entire rail sections from them. One solution is to use premium grade rail steels which have good wear and RCF resistance. These premium rails are usually heat treated. This procedure is an additional step during the rail manufacturing process and hence has increased cost. Another common method to alleviate RCF, is to periodically grind the rail head which reduces crack development [4]. Other solutions such as surface treatments by peening, case hardening or surface coating can also enhance the wear and RCF performance of many engineering materials. However, rails are usually rolled in lengths of over 100 metres so incorporating these processes into rail manufacture would be impractical and costly. The maximum shear stress, which is a primary driver of RCF, occurs below the surface of the material in most cases. Therefore, traditional surface coatings are not sufficiently thick to prevent damage caused by this sub-surface shear stress. In recent research [5-8], laser cladding technology was shown to be an alternative way to improve the durability of rail both in terms of wear and RCF [7, 8]. Laser cladding technology can deposit a wide range of beneficial materials onto a certain area or an entire existing rail surface. Instead of rolling the entire rail section with costly premium material, laser cladding allows the deposition of the premium material onto the surface of a standard or cheaper structural base steel. Tests performed in [7, 8] show significantly enhanced performance and durability of rail which had been laser clad. In addition, rail not only consists of straight track, but is also made up of other rail constructed components such as switches and crossings (S&C), insulated block joints (IBJs), check rails and tight radius curves. The related maintenance costs of these components are much greater than that of straight track [9, 10]. The laser cladding process offers the possibility to locally treat those components where they are more prone to damage, leading to new enhanced components with potentially reduced overall lifetime costs. Laser cladding offers the opportunity of altering certain surfaces of components and constructions to meet each individual requirement.

As mentioned above, resistance to wear and RCF play two vital roles in the maintenance of a rail network. Anti-wear characteristics are related to the hardness and microstructure of the material, which can be improved with laser cladding technology. For example, Guo et al. [11] investigated the microstructure and tribological properties of a Ni-based coating after laser cladding with Tungsten carbide Nickel (WC–Ni) particles, and they found that the hardness of the conventional alloy coatings is greatly improved due to the formation of a new hard WC phase. Guo et al. [12] proved that the wear rate was dramatically reduced after investigating the microstructure of the laser cladding layer (Co-based alloy) on the rail-wheel or rail surface. Wang et al. [13] investigated the effect of the amount of lanthanum oxide (Fe-based alloy), in a laser cladding deposit and they achieved a more refined microstructure, which had a greater RCF resistance without sacrificing the surface hardness. Research on laser cladding has not only been performed at a scaled model test. Lewis et al. [14] conducted a series of full-scale tests on a rail that had been laser clad with a layer of high performance material. In these tests it was shown that the clad rails

not only had decreased wear rates, but also improved fatigue resistance over standard rail.

It can be seen that wear and RCF resistance of laser clad coatings is becoming an important research issue and the current state of the art focuses on characterising the wear and RCF resistance over a wide range of laser clad materials, such as in [11-13, 15-18].

In contrast to the previous laser cladding research, there is little work in investigating the contribution of the substrate material. When the head of a rail is clad with premium material the requirements of the substrate become purely structural and it becomes shielded from damage at the rail surface. Moreover, the migration of peak sub-surface shear stress towards the rail surface under high rail-wheel traction conditions places this particularly damaging stress into the harder clad layer, rather than the more vulnerable bulk material. This is especially beneficial as cyclic shear stress combined with compressive wheel load is responsible for rail plastic damage accumulation and crack initiation by the ratchetting mechanism. As such, the work described in this paper was intended to investigate the usage of different substrate materials, namely R200 and R260, using the same cladding material. This also provides an insight into how the substrate affects the properties of the cladding layer, dilution zone and overall rail durability.

2. Method and Materials

2.1. Experimental apparatus

The wear experiments were carried out using the Sheffield University ROlling Sliding (SUROS) twin-disc test machine [19]. Fig. 1 shows a schematic of the SUROS rig and typical discs used. This machine uses a line contact between twin-disc specimens to simulate the normal load and rolling-sliding behaviour at the wheel/rail interface. Two discs with diameters of 47 ± 0.2 mm serve as a rail disc (upper specimen) and a wheel disc (lower specimen). These discs are powered and controlled by an AC motor and a Colchester lathe. The difference of speed of wheel and rail discs is used to control the creep. The slip ratio is defined in Eq. 1, where ω and r are the rotational speed and rolling radius of the discs, respectively. The load is applied to the wheel disc by a hydraulic piston and load cell.

$$Slip = \frac{\omega_{wheel} \cdot r_{wheel} - \omega_{rail} \cdot r_{rail}}{\omega_{wheel} \cdot r_{wheel} + \omega_{rail} \cdot r_{rail}} \quad (1)$$

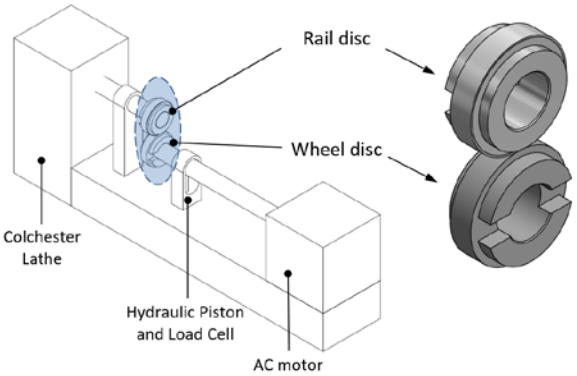

***Figure 1** SUROS machine and samples.*

2.2. Specimens

2.2.1. Sample materials

All the wheel and the rail discs' materials were manufactured from actual wheel and rail. The wheel discs were made from R8 wheel steel, with the properties shown in Table 1.

***Table 1** R8 Steel grades specified by EN.*

Region	Specification	Steel grade	Carbon content	Hardness
			(% by mass)	(HB)
Europe	EN 13262	ER 8	≤ 0.56	258-296

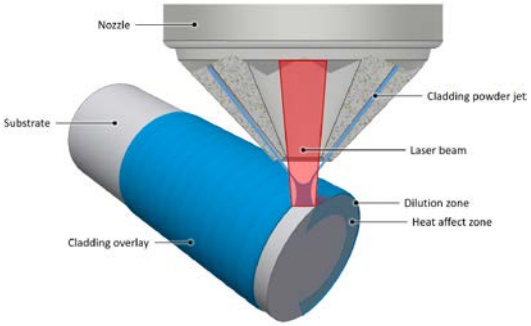
For the rail substrates, two materials were chosen for comparison, R260 and R200, with the properties shown in Table. 2.

***Table 2** R200 and R260 Steel grades specified by EN.*

Region	Specification	Steel grade	Carbon content	Hardness
			(% by mass)	(HB)
Europe	EN 13674-1	R 200	0.4-0.6	200-240
		R 260	0.62-0.8	260-300

The R260 grade material, as the current standard rail material widely used in UK and some other countries in Europe, was chosen to provide representative results for comparison. While the other lower grade steel substrate R200 is still widely used throughout Europe. R200 has some properties which potentially make it an ideal substrate candidate for laser cladding, for instance:

- lower carbon content than R260 (0.4-0.6% compared to 0.62-0.8%) and hence a lower bulk hardness of 200 HB minimum as compared to roughly 260 HB minimum for R260 grade.
- easier machinability, better weld-ability, and lower rates of foot failure [20].



Both rail substrates (R200 and R260) were machined to cylinders with a diameter of 46 ± 0.2 mm, clad and then machined into discs.

2.2.2. Laser cladding

In this study, one-step laser cladding by powder injection was employed to clad the rail cylinder specimens. A grade of martensitic stainless steel (MSS), which was found to be less susceptible to ratchetting due to its high hardness and shear yield strength in previous tribological tests [16], was deposited onto the two different grades of rail material. Fig. 2(a) shows a schematic of this cladding process, where the high energy laser beam is focused on and scanned across the curved surface of the rail substrate. As the MSS powder passes through the laser it is melted and fuses with the melt pool on the surface of the substrate material. The shaft rotates under the laser to allow a single track of clad to be deposited on the surface. Individual tracks are then overlapped side-by-side to cover the shaft surface. As the laser passes the substrate will start to cool at a rapid rate. This high rate of cooling is due to the greater

volume of substrate which is at a lower temperature than the freshly laid deposit. This heating and rapid cooling of the substrate causes changes in its microstructure throughout a certain depth of the bulk, which is called the heat affected zone (HAZ).

Fig. 2 (b) gives an example of the shafts covered by cladding tracks. It should be noted that all the machining parameters including the MSS powder feeding rate, the laser power and the rotating speed of the shaft were all optimized to achieve a poreless clad layer with outstanding mechanical properties, as well as a satisfactory bonding between the substrate and deposit.

(a)

(b)

Figure 2 *Laser cladding (a) laser cladding scheme (b) laser clad cylinders prior to finish grinding.*

Once cooled the clad layer was ground back to give a smooth surface finish which was suitable for testing. The single layer of MSS material had a mean post-grinding thickness of 1.10 mm. The ground cylinders were then sectioned and machined into SUROS rail specimens with dimensions as shown in Fig. 3. The wheel discs were not clad as the focus of this work was the cladding of rails only.

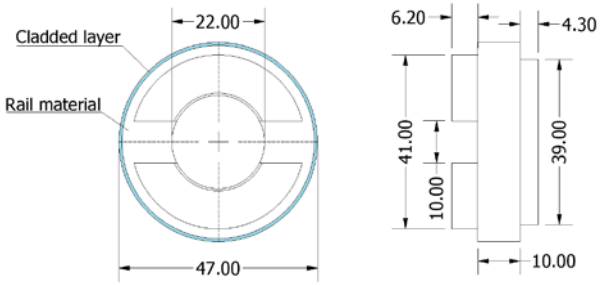


Figure 3 *Cladded rail disc parameters.*

2.2.3. Micro-hardness & Microstructure analysis

For the microhardness mapping and microstructure analysis, the discs were sectioned, mounted in conductive Bakelite base and polished down to a $1\mu m$ Ra finish for the micro-hardness and microstructural analysis. Pre-test micro-hardness measurements were taken with un-tested discs. These results were generated after cladding, but prior to any load application, so did not capture any strain hardening under load. Vickers micro-hardness measurements were taken using a load of 1.00 kg and dwell time of 10 seconds. The indentation process started from the cladding edge towards the centre of the specimen, and the edge was defined as the zero position, see Fig.4.

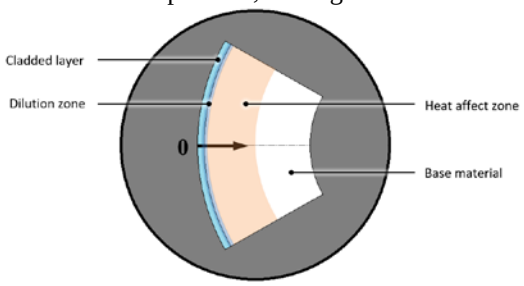

Figure 4 *Hardness mapping direction and location.*

Fig. 5 shows results of microhardness case measurements for the R200 and R260 rail material clad with a single layer of MSS material. As shown in Fig. 5, the hardness of the MSS clad layer ranges from $530HV$ to $630HV$. It can also be seen that the increase of the hardness of the substrate material leads to a corresponding increase in the hardness of the MSS deposit. This will be caused by mixing of the deposit material with the softer or harder substrate during the fusion stage of the cladding process. However, prior to the measurements it was not expected that this mixing effect would extend into the entirety of the clad layer or have such a marked effect.

The material in the “dilution” zone, where the clad material mixed with the base material, has a hardness value between that of the cladded layer and the base material. While in the HAZ, where the base material’s microstructure is changed during the heating and cooling process, the hardness reduced gradually towards the boundary with the base material.

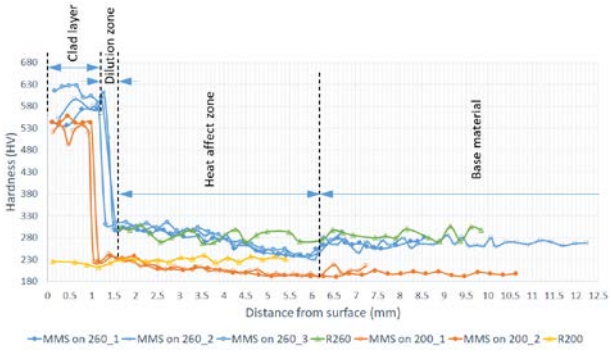

Figure 5 *Hardness mapping for untested samples.*

The microstructure images are shown in Fig. 6 and Fig. 7. These heat affect zones were classified according to the term system of Farichild [21]. The overview images were taken using an optical microscope (CARLZEISS axio imager a2m, Zeiss Göttingen, Germany), and the backscattered electron (BSE) SEM analyse on the HAZ was conducted by using a SEM (Hitachi TM-3030 Tabletop Scanning Electron Microscope, Tokyo, Japan). All the polished specimens for microscope and SEM analysis were etched with 2% Nital solution to expose the grain boundaries.

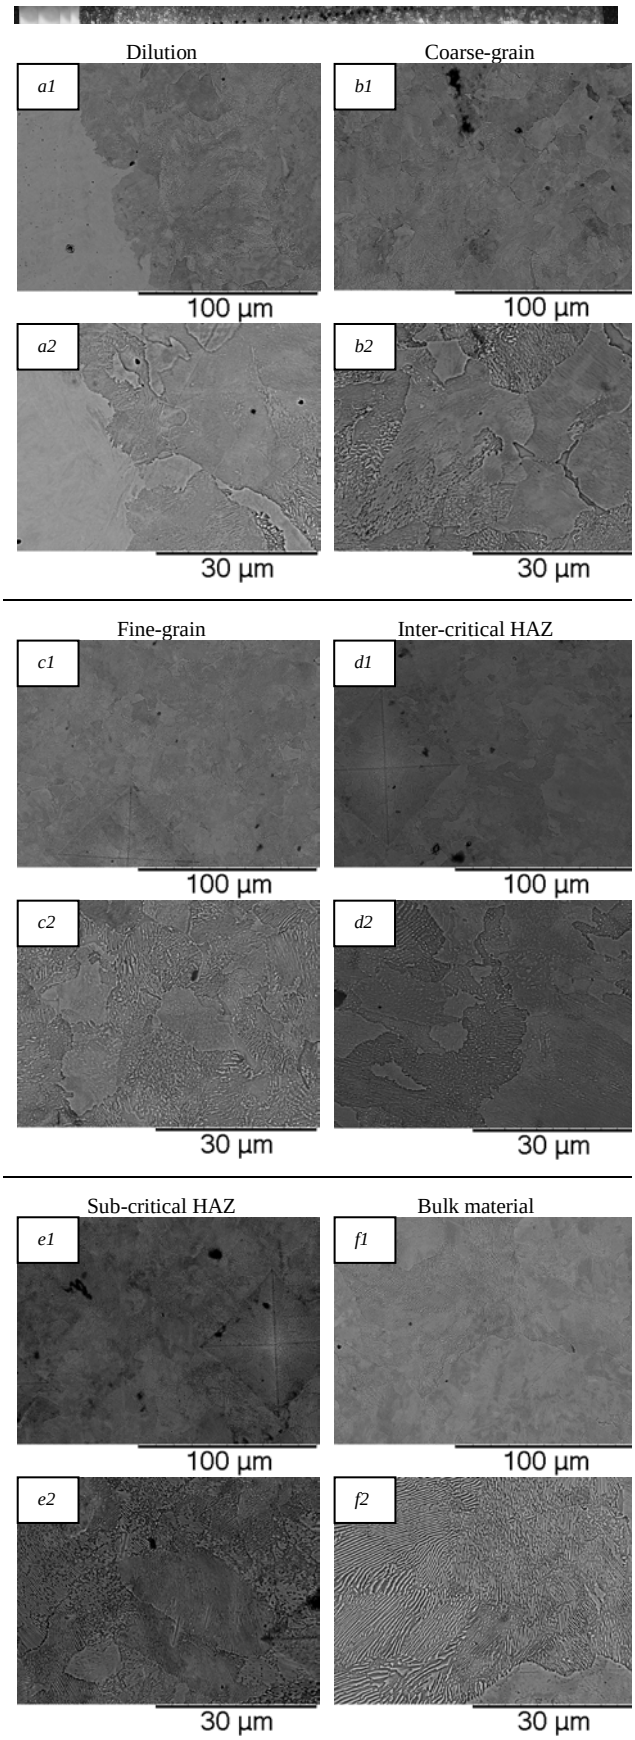

Figure 6 *Microstructure of HAZ in untested MSS on R260 (2% Nital etched): (a1), (a2) are for the Dilution zone. (b1), (b2) are for the Coarse-grain. (c1), (c2) are for the Fine-grain zone. (d1), (d2) are for the Inter-critical zone. (e1), (e2) are for the Sub-critical zone. (f1), (f2) are for the Base material.*

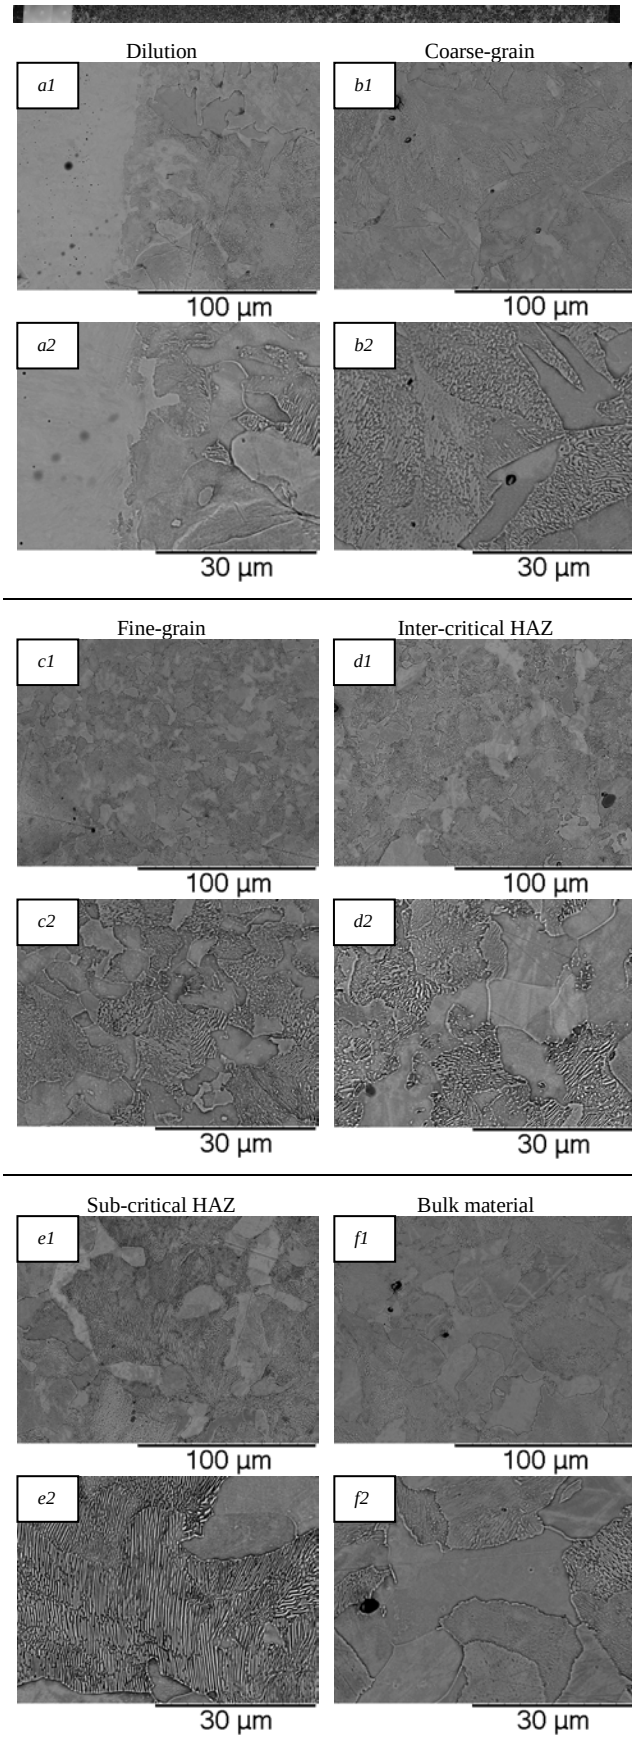

Figure 7 *Microstructure of HAZ in untested MSS on R200 (2% Nital etched): (a1), (a2) are for the Dilution zone. (b1), (b2) are for the Coarse-grain. (c1), (c2) are for the Fine-grain zone. (d1), (d2) are for the Inter-critical zone. (e1), (e2) are for the Sub-critical zone. (f1), (f2) are for the Base material.*

While for the cladded layers, the 2% Nital acid solution could not expose any grain boundaries, therefore a more corrosive solution, 4.76% Nitric, 47.62% hydrochloric and 47.62% water, was used to reveal their microstructure, and the results are shown in Fig. 8 and Fig. 9 for MSS on R260 and MSS on R200, respectively. It should be note that these tiny pores were caused by the strong etchant, as none of them can be observed from the 2% Nital etched samples shown in Fig. 6 and Fig. 7.

2.3. Tribological testing

Testing was conducted using the SUROS twin-disc testing machine shown in Fig. 1, taking the 47mm diameter wheel and rail discs and loading them to produce a small-scale contact capturing the key elements of combined rolling-sliding behaviour characteristic of a rail-wheel contact. With a line contact length in the lateral dimension of wheel/rail rollers of 10 mm, contact load of 7.14 kN which gives a maximum Hertzian contact pressure of 1500 MPa was used with a rail disc rotational speed of 400 rpm and creep of 1% representing a driving wheel condition. Wear tests were conducted under dry conditions. During the wear testing the tests were stopped every 5,000 cycles so that the evolution of the wear rate could be measured. These are standard wear settings for SUROS testing [19].

Material loss was measured in the tests with microstructural analysis. Microhardness measurements of the specimens was carried out before and after testing to investigate what effect the substrate grade had on the performance of the clad MSS deposit. Comparisons were also made to baseline measurements for R200 and R260.

3. Results and discussion

3.1. Wear results

Figure. 10 shows the evolution of the wear rates of the rail and wheel discs. All tests depicted in this section were conducted under dry contact condition with a maximum Hertzian contact pressure of 1500 MPa and 1% creep. These results were also compared with tests done under identical conditions in [8].

Tests were conducted with the MSS R260 and MSS R200 samples with compressed air jet spraying on samples for temperature control. The results have been compared with the results from Lewis et al. [8], in which tests were done with cooling air. With the cooling air, the contact temperature between discs were kept at 37 ± 1℃ during the whole test.

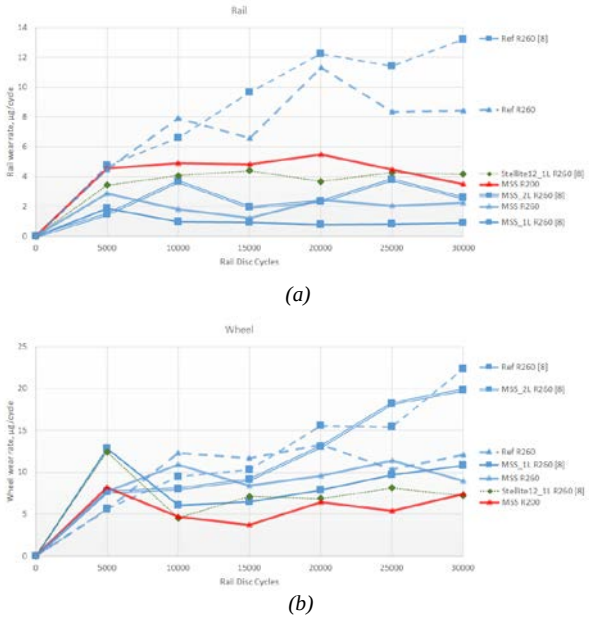

Figure 10 *Wear rate evolution of (a) the rail discs and (b) with the number of test cycles for the R200 clad with MSS and R260 clad with MSS. The chart includes data from [8] with various material deposited onto R260 material. All tests were performed under identical conditions. 1L indicates 1 layer and 2L indicates a 2-layer sample. All samples tested in the work reported in this paper were made with 1 layer.*

From Fig. 10 (a), it can be seen that the MSS on R200 and MSS on R260 rail discs wore at similar rates and had similar performance to an R260 disc clad with

Stellite 12 tested in [8]. As Stellite 12 was seen to be the second best performer of all the deposit materials tested in [8]. It is encouraging that an MSS clad layer on a lower grade of rail steel is still giving a good improvement in wear resistance over the R260 baseline. Even though, as Figure 5 demonstrates, its hardness post cladding, but before load application, was affected. Mechanisms for this will only be revealed, however, once the tested samples are sectioned and case hardness measurements performed. Interestingly the post-test surface hardness of the MSS 1L tested in [8] was 766HV compared to 630 HV for the MSS clad on R260 sample tested here (see Figure 5). This indicates that it could be inferred that a significant degree of work hardening may have occurred during the tests performed in this research. It must also be noted though that the 1 layer samples tested in this work wore more severely than the 1 layer MSS sample tested in [8]. There are a few potential explanations for this: a) that the powder and hence the eventual deposited MSS was from a different batch for the tests reporting in this paper as compared to the samples in [8]. Also in this work whole cylinders of R200 and R260 material were clad and then manufactured into SUROS samples. In [8] the SUROS samples were first machined and then individually clad. This latter approach caused issues with heat dissipation during the cladding process and very high cooling rates of the clad were observed.

Table. 3 summarises the wear rate of all the rail specimens shown in Figure 10 averaged over the whole 30,000 cycle test period. The average for the MSS clad on 200 is distorted by the wear rate at 25,000 cycles. Otherwise it is only slightly above MSS on R260. In Table. 3 any wear rate which was in excess of either the Reference (R260 Grade) wheel or rail, i.e. 100% or greater, has been highlighted red. Any wear rate which is less than the reference is highlighted green indicating good wear performance. Wear rates which are less than 50% of the reference case are highlighted light green indicating superior wear performance.

It should be noted that the wear rates of the tests in [8] were slightly higher (both wheel and rail around 20%) than the current tests, when comparing the results of reference R260 tests. It can be seen from Table. 3 that all of the clad rail discs tested are in the good/ superior wear category. The MSS on R260 rail discs have shown superior wear resistance, which gave a 65%-73% wear rate reduction. Even the MSS on R200 rail discs have presented a 40% wear rate reduction compared to the standard R260 samples. At the same time, the wear rate of corresponding wheel discs also fell within the good wear category.

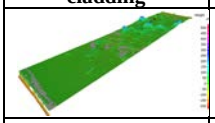
Table 3 *Averaged wear rates of rail specimens over the entire 30,000 cycles (Data from similar tests performed in [8] included for comparison).*

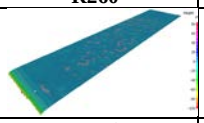
	Wear Rate		**Wear Rate**	
	$\mu g/cycle$		**Percentage of Ref R260**	
Clad	**W**	**R**	**W**	**R**
Ref R260	10.88	7.84	100%	100%
Ref R260 [8]	13.14	9.64	121%	123%
MSS R200	5.97	4.62	55%	59%
MSS R260	9.49	2.11	87%	27%
MSS_1L R260 [8]	8.96	1.04	82%	13%
MSS_2L R260 [8]	12.65	2.63	116%	34%
Stellite12_1L R260 [8]	7.72	4	71%	51%

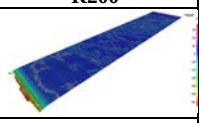
3.2. Traction

Table 4 shows average traction results for each of the different claddings compared to an unclad reference R260 grade rail disc.

Table 4 *Traction coefficient comparison with results from [8].*







Ref R260	Ref R260 [8]	MSS R200	MSS R260	MSS_ 1L R260 [8]	MSS_ 2L R260 [8]	Stellite 12_1L R260 [8]
0.37	0.39	0.36	0.38	0.395	0.385	0.405

It can be observed that the cladded samples had a similar traction coefficient with the ref R260 samples, which suggests the cladded layer does not influence the traction properties of rail.

3.3. Topography measurements

All surfaces were examined using the optical (non-contact) Alicona Infinite-Focus SL profilometer (Alicona Imagine GmbH, Raaba, Austria) after 30000 cycles, producing high-resolution images and 3D surface profiles measurements with a vertical resolution of up to 10 nm.

Table 5 *Traction coefficient comparison with results from [8].*

Ref 260 without cladding	**MSS cladding on R260**	**MSS cladding on R200**
		
Ra: 6.0614μm Rq: 18.6459μm Rz: 71.4973μm	Ra: 0.6450μm Rq: 0.8080μm Rz: 3.4856μm	Ra: 0.7464μm Rq: 0.9542μm Rz: 4.1182μm

As can be seen from Table. 5, both MSS on R260 and MSS on R200 specimens have shown a smooth surface finish after tests, with a surface roughness $R_a < 0.75\mu m$. This indicates that only mild wear occurred during tests, and these smooth surfaces show no sign of flake formation characteristic of a significant depth of material reaching the ductility exhaustion strain at which large flakes would form. In contract, on the reference R260 rail disc it can be observed that the top layer of material was peeling up from the surfaces, and the surface roughness was 10 times higher than that of the cladded specimens. This suggests that strain in the surface has accumulated (i.e. by a ratchetting mechanism) to the point of ductility exhaustion at which

it loses integrity and breaks away from the main body of the steel.

3.4. Sub-surfaces inspection

After the surface topography measurements, tested rail specimens were then sectioned and examined for: micro hardness and micro- structural changes. Fig. 11 gives a comparison of the hardness pier and after the test. It should be noted that these hardness values were gathered from different specimens, but all were taken from the same parent material.

As can be seen from Fig. 11 (a), the outside layer of material has worked hardened after testing, and a hardness of around 480 HV was achieved near the top surface of the tested specimen. While for the cladded rail specimens, the work-hardened effects were not as marked as for the reference R260 sample as shown in Fig. 11 (b) and Fig. 11 (c).

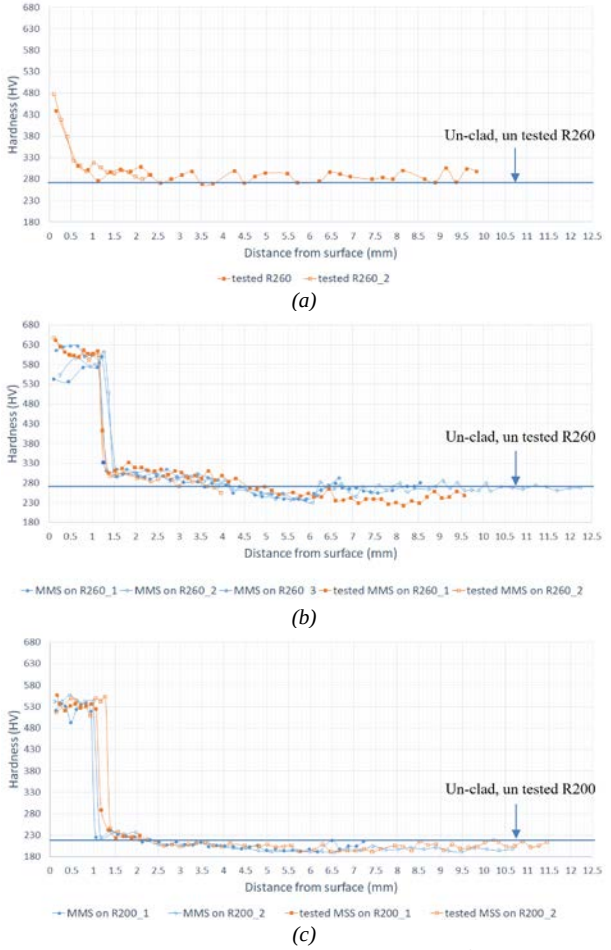


Figure 11 *Microhardness case depth measurements for the (a) tested reference R260 sample (b) MSS clad on R260 and (c) MSS clad on R200 with the straight line representing the mean microhardness of standard un-clad, un-tested rail material. All measurements were performed with a load of 1kg.*

The sub-section of samples was also examined under SEM to check the plastic deformation depth caused by testing. According to measurements judged by visually observation, see Fig. 12 (a), the R260 samples had a plastic deformation depth of approximately $400\,\mu m$ while the clad rail samples only had $10-20\,\mu m$. As shown in Fig. 12 (b), only a very thin layer of the MSS clad layer shows material flow, and no cracks could be observed within this deformation layer, i.e. the material had not reached its ratchetting strain ductility exhaustion strain. The rest of the clad layer had the same structure as the untested samples shown in Fig.7 and Fig. 8. The low amount of plastic deformation in the clad rail specimens also explains why no cracks were seen in all of the clad rail specimens.

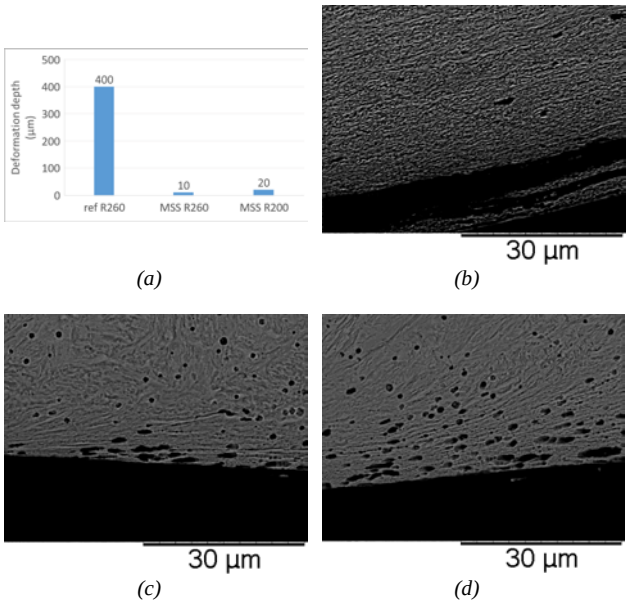

Figure 12 *(a) plastic deformation depth comparison and clad edge's microstructure deformation of tested samples: (b) is the Reference R260 sample without cladding. (c) and (d) are the clad edge of MSS on R260 and MSS on R200 samples, respectively. All samples were tested under 1500 MPa contact pressure, and 1% slip ratio with cooling air.*

4. Conclusions

Twin-disc tests have been performed on both R200 and R260 rail after being laser clad with a single layer of MSS material. It has been shown that:

- MSS can be successfully deposited on a R200 grade of rail material which is softer than previously the used R260.
- A sample with the softer R200 substrate material also showed a corresponding reduction in the hardness of the clad layer relative to the R260 substrate. Additional tests are needed to isolate the cause, which may be due to mixing of the softer/harder substrate material with the clad layer, but could also be influenced by the different thermal route taken in preparing the samples.
- The hardness differential between the clad R200 and R260 is reflected in the wear rates between the two samples with the R200 clad sample giving a higher wear rate.
- Despite differences between clads on R200 and R260 both samples wore below $5\mu g/cycle$. This represents a wear rate of 50% or less relative to the reference R260 sample without cladding.

Although cladding on a lesser grade of rail does have an effect on the hardness and wear performance of the clad layer, the resulting wear performance of the clad layer assessed using the twin disc approach is still improved, with the wear rate reduced to 0.59 times of the R260 material alone. R260 material alone. In addition, the minimum plastic deformation depth and the smooth surface finish after tests indicates the clad rail specimen are also beneficial for wear rate reduction of the untreated wheel.

[*] E-mail: mathias.luther@deutschebahn.com

Abstract: To quantify the extent to which different parameters influence the creation of multiple squats in practice, a systematic analysis of more than 1,000 multiple squat findings from DB Netz AG inspection runs between 2014 and 2017 was carried out. The findings were compared with the track parameters such as track layout, load, types of rolling stock and speed, as well as with the records of carried out maintenance measures during this period. The most significant results of the analysis are used to develop scenarios for trials on a full-scale wheel-on-rail test rig, on the basis of which effective remedial measures are to be derived for rail maintenance.

Keywords: rails, rolling contact fatigue, squats, material behaviour, white etching layers, wheel-rail interface, rail grinding.

1. Introduction

For a several years now, squats have been a growing cause for concern in the track maintenance activities of all European rail companies. Squats are cracks caused by rolling contact. They mainly spread few millimetres below the running surface and are therefore not accessible for common non-destructive testing until they have reached an advanced state. Multiple squats, the repeated occurrence of such rail defects over distances as long as several kilometres, lead therefore to high costs, as they often necessitate the immediate replacement of the rails concerned, once they have passed the threshold for detectability. The size of the defects at this stage often makes corrective measures such as grinding or milling uneconomical.

The factors leading to the occurrence of multiple squats have been extensively examined in technical literature, usually based on individual cases [1~7]. According to the literature, the major factors are vehicle behaviour – especially the slip resulting from traction and braking – as well as rail grinding [8, 9], both of which can produce brittle martensitic zones on the running surface, so called white etching layers (WEL), as initial defects from which the squats develop.

In recent laboratory tests, DB Systemtechnik examined several squat-rails, which showed an elaborate amount of thermal influence on the running surface (Figure 1). The material must have experienced multiple cycles of thermal treatment, resulting in a structure that can be described as a kind of heat affected zone more properly than a WEL resulting from "normal" wheel-rail contact.

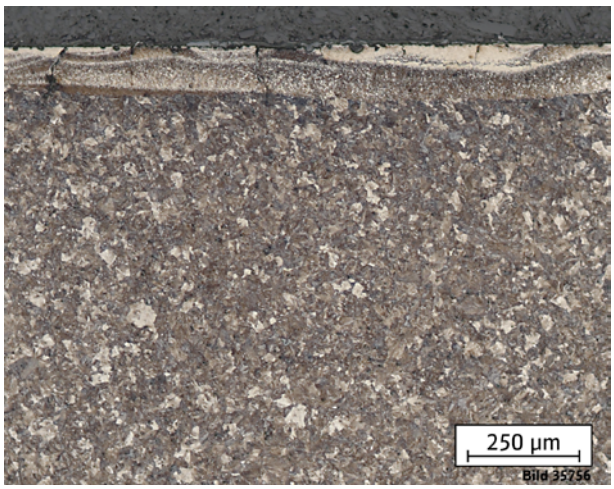

Figure 1 *Heat-affected-zone-like microstructure at the running surface of a tongue-rail made from R350 HT directly at the squat*

The cumulative load on the track also plays a role of course, as do the properties of the rail material [10]. However, it is not yet known to what extent the various influences affect the occurrence of multiple squats. Such quantification, however, is essential for developing an effective maintenance strategy against multiple squats.

In 2016, DB Systemtechnik drew up a study on behalf of DB Netz AG as the basis for a project on the prevention and long-term elimination multiple squats. The first step in the project involved systematically analysing squat and multiple squat findings from DB Netz AG inspection runs between 2014 and 2017. The findings were compared with the track-related parameters such as track layout, speed, types of vehicle used and track load as well as with the records of carried out maintenance grinding during this period. The second step was to check the extent to which the various influencing factors correlated with the occurrence of multiple squats and to estimate the frequency of the various damage mechanisms and causes.

2. Data sources

As a starting point for the analysis, it was necessary to gain an overview of, preferably, all track sections containing squats in the Deutsche Bahn AG network. The information should generally be available in the same

form and gathered according to the same objective criteria. Such a network-wide survey is only performed by inspection runs of the track-geometry and rail inspection cars. In 2014, a routine has been established, that whenever a multiple defect has been detected during ultrasonic testing (more than three defects on two metres of track), the rail inspection cars automatically send out and record an instant report message. In the period from 2014 to 2017, this has resulted in a list of more than 1,000 entries that were registered during track inspection runs over the entire network. This data record has been used as the basis for the following surveys.

In addition to the time and place of measurement, the list of instant reports also records additional information such as the rail identification markings. In 2014, all squat-sites recorded were visually inspected on site and documented photographically after the instant reports. This data was also evaluated.

Additional information on the track layout, permanent way etc. was obtained by comparing the instant reports with the data platform "Integrated Inspection System (IIS)" of DB Netz AG.

Information about the rolling stock operating on the track was obtained from a listing from the network control centre based on timetable data. This divides the trains into the categories light rail, local transport, long distance, and freight traffic.

By "travelling" the instant reports in the visual route database DBVIS, it was determined whether a signal or station was located within the average braking distance before or after the affected position in order to identify acceleration or braking areas.

How the type and time of rail machining measures is recorded lies in the responsibility of local rail machining officers and differs from region to region. For about 50% of the existing instant reports, it was possible to research the rail machining procedures carried out in the period from 2014 to 2017.

3. Results

3.1 Track layout

The curve radius in the respective section of the instant reports was obtained from the IIS. The distribution among the quantity of instant reports was then compared with the distribution of the corresponding radii in the entire DB network (Figure 2). For this purpose, reference was made to an analysis carried out in 2012, which itemises the frequency of the individual radius classes in the entire network based on geodata.

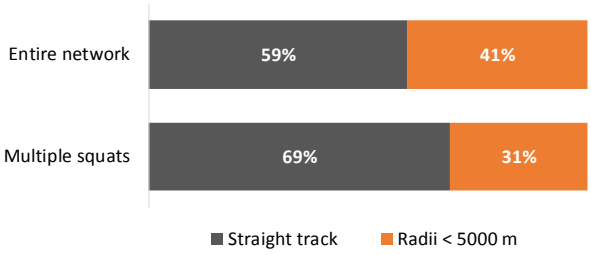

Figure 2 *Percentage of straight tracks and curved tracks with a radius <5,000 m in the entire network as well as frequency of multiple squats in straight track sections and in track curves with radii <5,000 m*

The result shows that instant reports about multiple squats occur with a disproportionally higher frequency in straight track sections compared to those in track curves - relative to the proportion of these sections in the overall network.

The quantity of the curve radii was then examined separately in 500 m steps (Figure 3). In the rails with multiple squats, track curves with a radius of less than 1000 m were significantly less evident than in the overall network. Track curves with a radius of more than 1500 m, on the other hand, occurred more frequently than in the network overall.

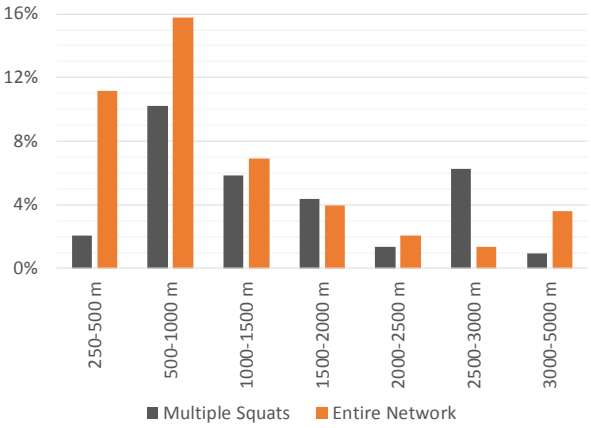

Figure 3 *Percentage of track curves of different radius classes in the overall network as well as frequency of multiple squats in track curves of different radius classes*

3.2 Rail material

The data on the rail steel grade was obtained from the IIS. Figure 4 shows the percentages of the rail steel grades used at DB Netz AG in the entire network and their frequency among the instant reports.

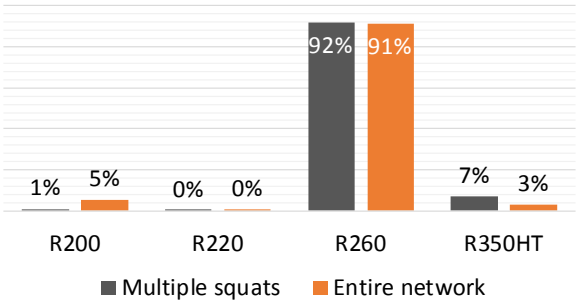

Figure 4 *Percentage of rail steel grades used by DB Netz AG in the entire network and the frequency of instant reports relative to the respective steel grades*

The steel grade R260 is by far the most common rail material, not only in the overall network, but also among the rails with multiple squats. There are, however, significant differences among the other rail steel grades. Whereas the lower steel grades R200 and R220 are severely underrepresented and exhibit virtually no multiple squats, the percentage of instant reports for the higher-strength R350HT head-hardened rails is more than twice as high as the proportion of this steel grade within the network overall.

This correlation becomes even clearer when looking at the proportion of rails with multiple squats among the overall rail length for the different types of steel. For this purpose, the unit "squat metres per 100 km rail" was introduced (Figure 5).

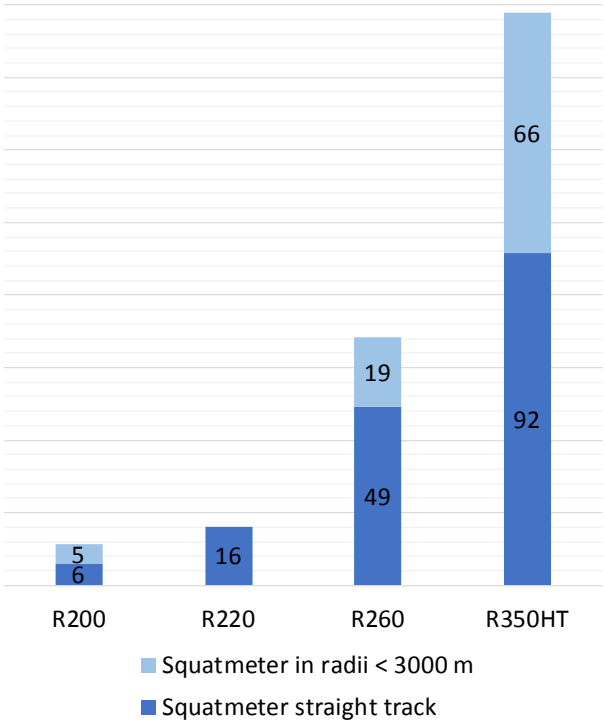

Figure 5 *Length of the sections with multiple squats relative to the total length of the respective rail steel grade in the entire network (squat metres per 100 km of rail)*

In this standardized presentation a trend becomes apparent that, with increasing strength of the rails, the proportion of multiple squats grows both on straight tracks and in curves. In the case of head-hardened rails, the amount of “squatmeters” is more than twice as high as for the standard steel grade R260.

Although the resistance to wear increases with increasing strength, a high wear-resistance also prevents the removal of initial surface defects, that can later develop into squats. This is particularly evident on the rails using steel grade R350HT which, according to the DB Netz AG equipment standard, are only to be used on curves with a radius of up to 3000 m, but are patently also used on straight track.

3.3 Type of traffic

In the network control centre a log is kept, showing the traffic load and the type of rolling stock for all sections of the German rail network. For this purpose, the trains are assigned to one of the four categories: light rail, local transport, long distance, and freight traffic.

The data analysis examined whether certain types of traffic correlate with the occurrence of multiple squats. To this end, track sections were considered that are subject to homogeneous use by only one type of traffic. As in Germany the vast majority of track sections have mixed traffic conditions, and tracks used exclusively by long-distance or freight traffic are very rare, a compromise was made for the analysis by considering all track sections with multiple squats that are used at least up to 70% by just one type of traffic. Figure 6 shows the percentage of these rail sections in the entire network, as well as the frequency of instant reports relative to these track sections.

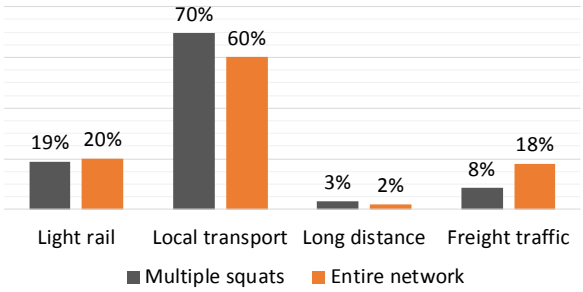

Figure 6 *Percentage of track sections showing predominant traffic types in the entire network and the frequency of instant reports relative to the respective track sections*

It becomes apparent that, on track sections used predominantly by local traffic, multiple squats occur with a slightly higher frequency than in the entire network. The frequency of track sections used predominantly by freight trains, on the other hand, is less than half as great for sections with multiple squats than in the overall network.

On the homogeneous long-distance routes, the number of corresponding sections is too low for a meaningful statistical analysis.

3.4 Traction

In order to examine the effect of traction and braking processes on the formation of multiple squats, the track layout data and the visual route database DBVIS were used to examine whether they are located in the vicinity of a station, a signal or points, i.e. in areas subject to frequent braking or acceleration for operational reasons, for each of the sections exhibiting multiple squats.

Figure 7 shows that two thirds of the affected sections were located less than 600 m from a signal or station, or were near points.

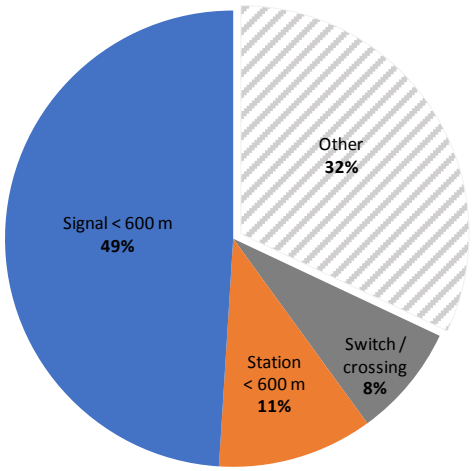

Figure 7 *Percentage of track sections with multiple squats in relation to their location*

Considering the total network track length of 60,512 km in relation to the 5,367 stations and halts, it becomes apparent that almost 11% of the entire network consists of entry and exit zones in the context of this evaluation (+/- 600 m). Therefore, multiple squats in the vicinity of stations do not occur with any greater frequency than would be expected in normal distribution.

Conservatively assuming an average length of approximately 50 m for the total number of 66,500 switches and crossings, their "total length" amounts to approximately 5.5% of the entire network. The majority of them is located in train formation facilities and other seldom run locations that are not subject to regular inspection by rail inspection vehicles. Even if this aspect is disregarded, points and crossings are significantly more common at 8% in the sections with multiple squats than in the overall network.

Unfortunately, no dependable data could be obtained for the precise number of lineside signals in the entire network, so that no statement could be made about their frequency in relation to the sections with multiple squats.

3.5 Rail machining

Sufficient data on rail machining maintenance in the years 2014 to 2017 could be researched for three major regions of DB Netz AG. Almost half of the instant reports available for analysis originated from these regions.

Figure 8 shows the percentage of route sections with multiple squats that were machined before the detection of multiple squats, after their detection, or not machined at all.

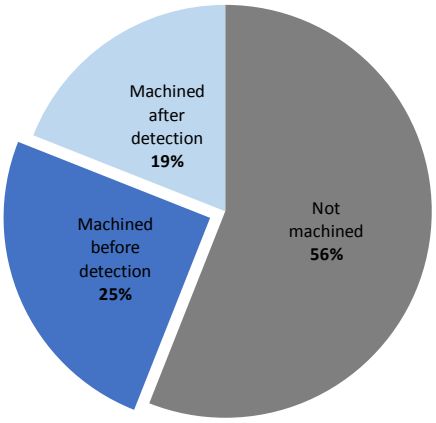

Figure 8 *Percentage of track sections with instant reports (SOFO), relative to rail machining*

In a quarter of the evaluated cases, the detection of multiple squats was preceded by a rail machining procedure. That almost corresponds to the proportion of rails in the entire network that were subjected to rail machining, varying between 20 and 28% in the years 2014 to 2017. In the vast majority of cases the used grinding method was preventive high-speed grinding.

19% of the evaluated route sections were machined after detection of multiple squats. In more than half of the evaluated cases, no machining at all was documented during the period under consideration.

4. Discussion

The submitted analysis is based on the currently available data. The heterogeneous quality and density of this data therefore has an impact on the validity of the analysis.

The criterion by which rails with multiple squats were selected for analysis is to be regarded as the most limiting factor for its validity: Due to the procedure used, such a rail defect cannot be detected by train-mounted ultrasonic testing until it has reached a depth of about 5 mm. This already represents an advanced stage of growth that a squat in general reaches long after its initiation, depending on the heaviness and frequency of traffic up to several years. To track down the causes of squats, the detection must be as early as possible after the inception of the crack. Unfortunately, no testing technology is currently in use at DB Netz AG that would allow an earlier detection.

A further restriction is presented in some cases by unavailable or inaccessible data for the existing network, e.g. the number of signals. The influence of these parameters on the formation of multiple squats could therefore not be determined, as the frequency on the squat rails could not be compared with that in the network overall.

Nevertheless, the analysed data in some cases show clear correlations that sustain theories that have only been supported by singular track observations until now. The data prove that multiple squats occur especially in sections with low wear. Higher-strength rail steel grades favour the formation of squats significantly.

With regard to the influencing factors of traction and rail machining, the database is not explicit. At least the entry and exit areas of stations are evidently not disproportionately affected by multiple squats. The effect of rail machining on squat formation can barely be quantified on the basis of existing data, due to the lack of reliable data about the frequency of grinding in the overall network and the documented period being too short to draw conclusions. The maintenance measures that possibly triggered the crack initiation could lie far more than three years in the past. Again, the late detection of defects restricts the possibilities of analysis.

The considerable over-representation of switches among the sections with multiple squats can possibly be attributed to the dynamic excitation caused by the passing wheels, as such a periodic excitation in a fixed location can result in the formation of squats.

5. Outlook

There are remaining gaps in the database, in particular regarding the aspects of rail grinding, crack initiation resulting from surface defects under certain loading conditions and crack growth speed of squats in different steel grades. However, as there will be no inspection method used in the DB rail network in the short term, that would be capable to record multiple squats at an earlier stage of development, the possibilities for a statistical analysis of their causes appear to be exhausted for the time being.

Therefore, DB Systemtechnik will make use of its self-developed on-board diagnosis system ESAH for electronic system analysis of rails and frogs [11] to find and monitor multiple squats in their early-stage.

At the same time, one of the wheel-on-rail test rigs of DB Systemtechnik is modernized to enable full scale tests with the application of traction power (Figure 9).

Based on the key results of the analysis, a test programme will be carried out on that test rig, where critical parameter constellations are recreated and investigated under reproducible conditions. First tests involve test rails, which have been grinded with varying degrees of aggression to determine the limits for permissible surface quality following grinding.

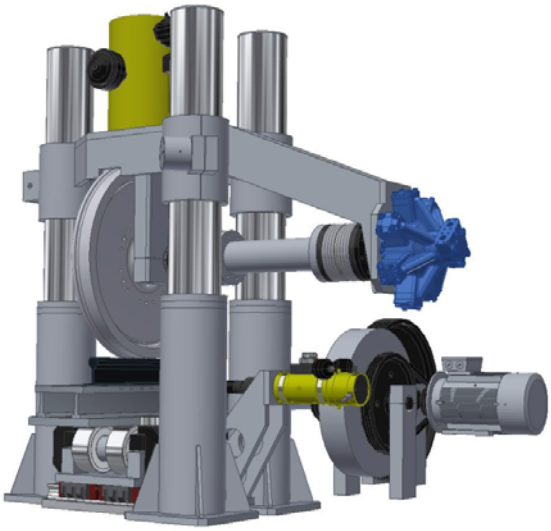

Figure 9 *Full-scale wheel-on-rail test rig B of DB Systemtechnik after the completed modernization in 2019*

Subsequent tests will focus on the effects of slip-related material changes at the rail surface on the development of squats. Specially developed test objects made of different rail materials with WEL of differing thickness will be subjected to roll-over tests on the wheel-on-rail test rig and real vertical, lateral and longitudinal forces will be applied. In this way, it is expected to gain fundamental know-how of damage development in squats.

Later on in the project, the results of the analysis and the laboratory tests will be supplemented by field observations at selected measuring points. This will involve, for example, regular track inspections on foot and documentation of rail condition at selected points on the railway network to examine the speed at which multiple squats grow by means of frequent non-destructive testing and visual inspections.

Recommended action for preventing multiple squats will be identified based on the project results and intervention thresholds will be defined for condition-based maintenance so that, in future, expensive rail replacement can be avoided.

Abstract: This paper presents the typical spalling on wheel tread of heavy haul locomotive based on field measurements, and its propagation is also illustrated. To find out the main causes for the spalling, the wheel tread states on two types of locomotives and in two operation lines are compared. The influence of locomotive types and curve radiuses on the wheel/rail dynamic interaction is also simulated and compared. The results show that, the wheel/rail longitudinal creep force and creepage have great influence on the wheel tread spalling. The low wheel/rail friction coefficient, traction/breaking forces, and sharp curve aggravate the longitudinal dynamic interaction between wheel and rail.

Keywords: heavy haul locomotive; wheel tread spalling; sharp curve; longitudinal; creep force and creepage.

1. Introduction

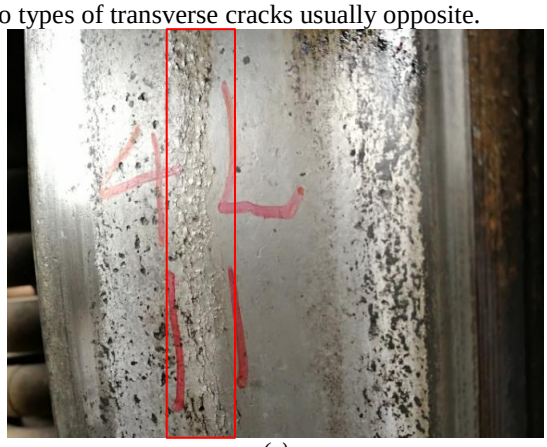
With the continuous increase in axle-loads, speeds, and traction tonnage of heavy haul locomotive, the wheel tread spalling increase the need for wheel turning, which leads to significant operational disturbances and economic costs. To relieve the serious problem, the root causes for different spalling patterns are essential before puts forward suitable countermeasures. A lot of studies have focused on the wheel tread spalling. Anders Ekberg [1] provides a brief summary on the rolling contact fatigue (RCF) of wheel and rail, which includes the probe, predict and prevent of the phenomena. Several prediction models of the wheel/rail fatigue have been developed [2-5], shakedown map and damage function are widely used. The shakedown map is based on the full slip conditions and the materials wear is not considered. But the relationship between wheel materials wear and the crack propagation should not be separated to solve these issues [6]. The damage function takes the materials wear and liquid influence into consideration. Ref 7 gives the damage patterns, potential root causes, and mitigating actions focus on the RCF of locomotive wheels. S. Stichel [8] investigated the risk for rolling contact fatigue on wheels of different passenger trains using both the shakedown theory and the damage function. Paul Molyneux-Berry [9] gives a new method to demonstrate the wheel/rail forces and its relationship with the observed wheel damage. Michela Faccoli [10] studies the effect of desert sand on the wheel/rail contact interface. D.I. Fletcher [11] tests the influence of the fluid on the penetration of the cracks. Refs 12 and 13 both give the evidence that the slip ratio between wheel and rail has great influence on the wear and RCF of wheel and rail. Wei Liu [14] researches the wheel tread spalling in the respect of wheelset longitudinal vibration.

According to above studies, the sand, fluid, traction and braking operation, and curves all have a certain degree of influence on wheel tread spalling. For a certain wheel tread spalling, the position and direction of the cracks can give evidence to its dominant courses. On some types of Chinese heavy haul locomotive, wheel tread spalling also appeared. This paper firstly presents the characteristic of wheel tread spalling from field measurement, which includes the cracks position, direction, and propagation. Secondly, in order to find out the main reason for the spalling, the wheel tread states on two types of locomotives and in two operation lines are compared. Finally, the wheel/rail dynamic interaction of the two types of locomotives is simulated and compared to confirm the dynamic index related to wheel tread spalling, and the influence of wheel/rail coefficient, curve radius on the spalling is also analysed.

2. Characteristic of the observed wheel tread spalling

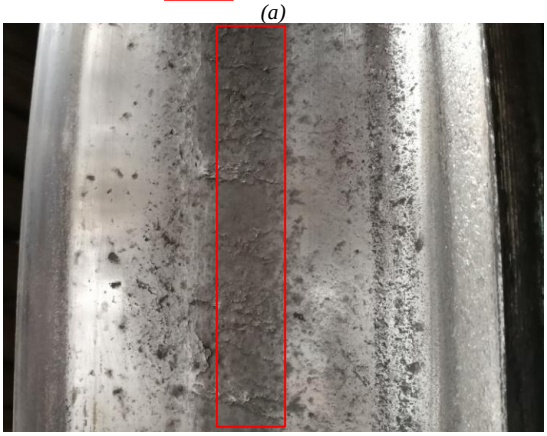
The studied locomotive is widely used in China heavy haul railway, which is six-axle locomotive (consists of double three-axle bogies). All wheels are motored. The maximum traction tonnage is 5000t. The locomotive suffered severe wheel tread spalling, which leads to frequent wheel turning. The service life of the wheel is only 20,000-30,000 km, which is far less than the designed 60,000km.

2.1. Three types of surface cracks



To confirm the probability of the wheel tread spalling, a series of field measurement was conducted at the locomotive depot. The measured wheels include a large range of service mileage. The locomotive wheel tread exhibits severe spalling, and cracks can be obviously seen.

According to the running mileage, there are three typical cracks observed on the wheel tread surface. The first type of cracks is shown as Figure 1(a). These cracks can be observed at both small and large running mileage, and not show obvious deterioration, which indicates that these cracks usually not propagate deep into the material.



As observation, these cracks are usually uniform around the wheel circumference. The measured results show that these cracks is distributing between 75-100mm from the back of flange, which band width is about 25mm. The sharp edges can be felt and the cracks opening towards to the flange.

With the increase of running distance, another pattern of cracks appeared near the center of wheel tread, as shown in Figure 1(b). This type of cracks usually shows transverse, uniformed to the axle. Often, these transverse cracks are observed between 65-90mm from the back of flange. In the measurement, these cracks are first appeared at wheel tread surface at the running distance of about 40,000km, and will deteriorate when the running distance increased. Therefore, these transverse surface cracks have chance to propagate deep into the material.

Another transverse surface cracks nearing the throat of flange are occasionally seen on the wheel tread with large running distance, as shown in Figure 1(c). These cracks are always less severe than the aforementioned transverse cracks. In the observation, the opening direction of these two types of transverse cracks usually opposite.

(b)

(c)

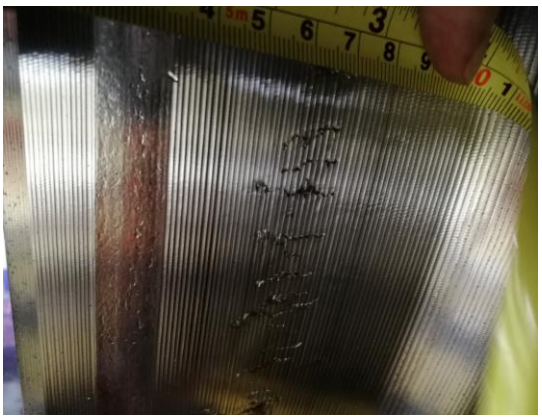

Figure 1. *Wheel surface cracks observations: (a) Circumferential cracks at field side of wheel tread. (b) Transverse cracks near the tread centre. (c) Transverse cracks near flange.*

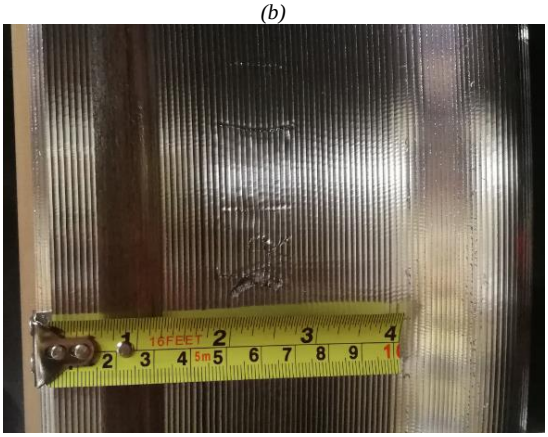
2.2. Cracks propagation



Although there are three typical cracks observed on the wheel tread surface, each crack shows different propagation trend with the increase of running mileage. When turning the wheel with spalling in locomotive depot, the amount of removed material usually depends on the depth of cracks. In other words, the surface of the turned wheel should not have obvious cracks. In order to determine which types of crack propagated deeper, the measurement is also carried out in wheel turned process. Figure 2(a) shows the wheel surface condition before turning, it can be seen that the most serious cracks are near the wheel center, the shelling pieces and cavities also can be found. Figure 2(b) shows the wheel surface condition after turned a depth of 1mm (wheel radius reduced 1mm). It is clearly found that only the transverse cracks near wheel tread center left, the other two types of cracks are eliminated after turned small depth material. This can be proven that the circumferential cracks at the wheel field side and the transverse cracks near the flange usually do not propagate deep into the material. Figure 2(c) shows the wheel surface condition after turned a depth of 7mm (wheel radius reduced 7mm), the transverse cracks near the tread center is still not eliminated. Finally, the total turned depth is 12mm (wheel radius reduced 7mm) until the transverse cracks eliminated completely.

(a)

(b)

(c)

Figure 2. *Wheel surface condition: (a) Before turned. (b) After turned 1mm. (c) After turned 7mm.*

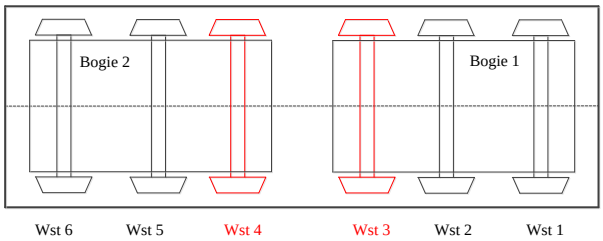
Table 1 gives the summary of the three types of cracks observed on wheel tread surface. The position, direction, and propagation of these cracks could give the potential courses of these cracks.

Table 1 *Characteristic of the observed wheel tread cracks*

type	position	direction	propagation
I	between 75-100mm from the back of flange	uniform around the wheel circumference	eliminated after turning 1 mm
II	between 65-90mm from the back of the flange	transverse	eliminated after turning 12 mm
III	nearing the throat of flange	transverse	eliminated after turning 1 mm

2.3 Surface conditions of different wheelsets

In the field observation, an interesting phenomenon is that the third and fourth wheelsets suffer more serious wheel tread spalling than others, and convention for numbering wheelsets is shown in Figure 3.



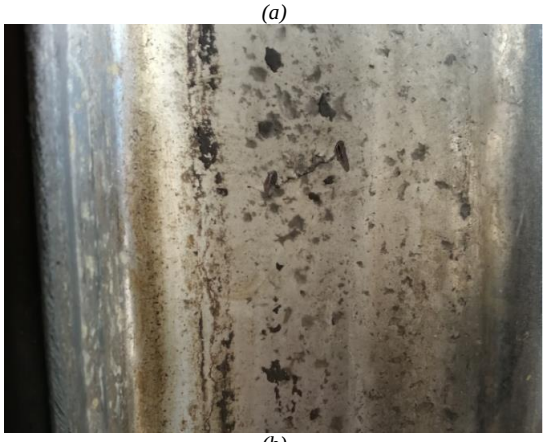


Figure 3. *Wheelsets numbering convention*

The locomotive will change the direction during operation, so the experience of wheelset 3 and wheelset 4 are generally same. In other word, the rear wheelset of the bogie not the front wheelset suffers more severe spalling.

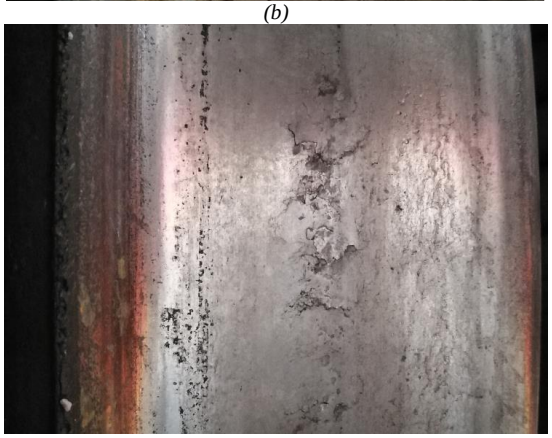

Figure 4 gives the wheel tread surface condition of different wheelset on a same bogie. It can be seen that, there are serious transverse cracks on the third wheelset. But the front and middle wheelsets are cleaner. From the wheel turning experience of the locomotive depot, to eliminate the cracks, the turned depth of the material for the rear wheelset is much more than the others.

(a)

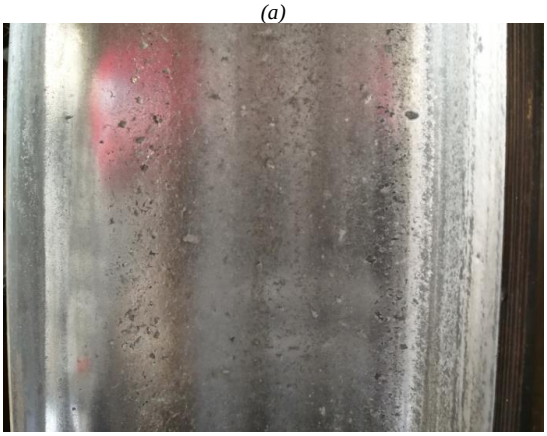
(b)

(c)

Figure 4. *Wheel surface condition on a bogie: (a) Front wheelset. (b) Middle wheelset. (c) Rear wheelset.*

3. Potential causes of the transverse cracks near the tread center

The location and the direction of the cracks can give some evidence for the potential causes. The transverse surface cracks are possibly caused by the additional longitudinal force due to braking and traction. The



observed transverse surface cracks are usually between 65-90mm from the back of the flange, which maybe relates to low rail contact during curve negotiation. To give more proof that the curves and braking/ traction operation are promoting the cracks propagation, the compared measurements are conducted. The wheel tread surface conditions are compared between two types of locomotives used in the same line, and the same type of locomotive used in two different lines are also compared.

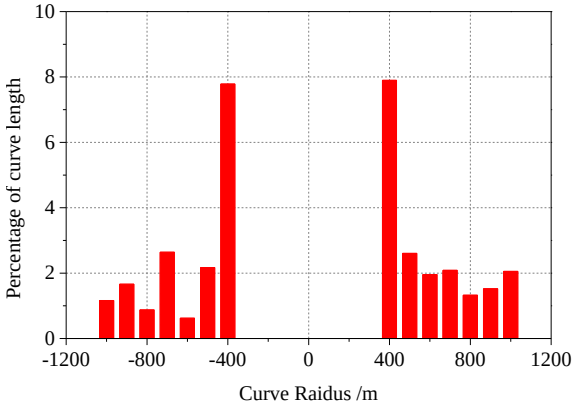
3.1. The comparison of two types of locomotives

The wheel tread conditions are observed between two types of locomotives, the locomotives both operated in the same railway line. One type is locomotive with six-axle (each bogie has three axles), another is eight-axle locomotive (each bogie has two axles). These two types locomotives are both used in the same railway line, and their traction weight are same, both 5000t. In the measurement, the locomotive with three-axle bogie suffers serious wheel tread spalling, as above mentioned. But for the locomotive with two-axle bogie, the wheel tread damage is rare observed. Figure 5 gives the wheel surface conditions of these two types of locomotives after running about 12,000km.

(a)

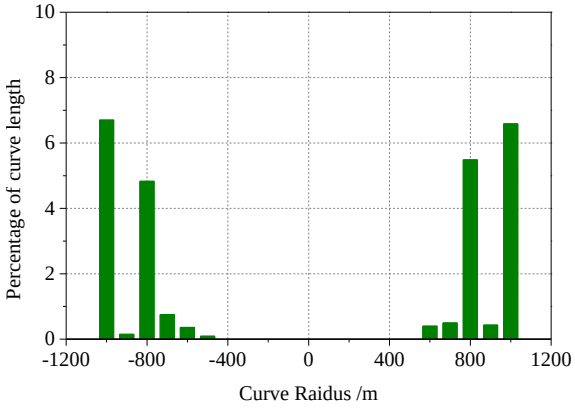
(b)

Figure 5. *Wheel surface condition of two types of locomotives: (a) With three-axle bogie. (b) With two-axle bogie*



It can be found that, when running in the same mileage, the obvious wheel tread spalling appeared on the six-axle locomotive with three-axle bogie, especially at the zone near the wheel centre. The cracks are mostly transversely distributed, as above described. But for the eight-axle locomotive with two-axle bogie, the wheel tread surface is cleaner, and obvious spalling is rarely found. From the field experience of the locomotive depot, the six-axle locomotive is more prone to wheel surface spalling than the eight-axle locomotive.

The difference in the observed states of the wheel tread surface on two types of locomotives mainly comes from two reasons. For a certain traction weight, the six-axle locomotive needs to bearing greater traction and braking forces for each axle. With same axle load, greater traction and braking forces mean more serious wheel/rail interaction, especially for the longitudinal dynamic interaction. On the other hand, the different types of bogies mean that the dynamic performance of curve passing is difference. In general, the two-axle bogie has better capacity of curve passing than three-axle bogie.

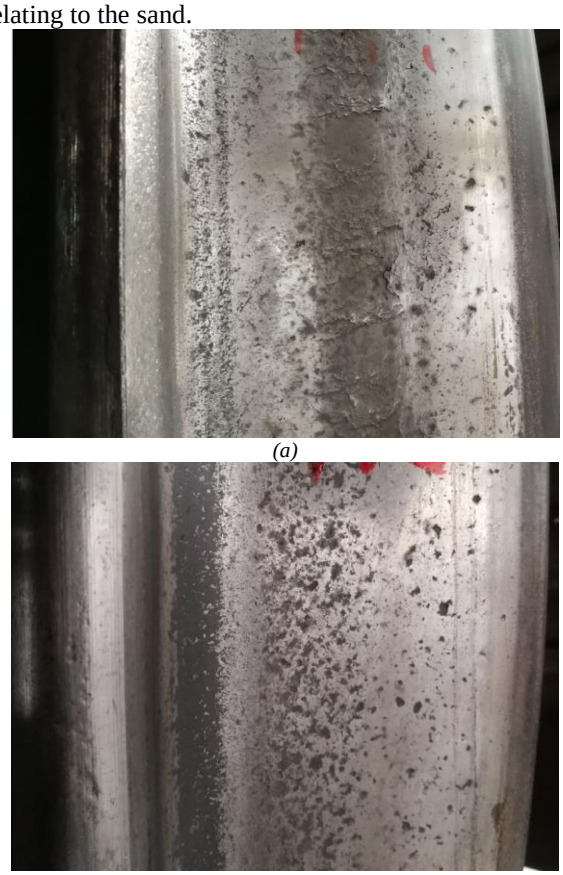


3.2. The comparison of two railway line

In section 3.1, the wheel surface condition of two types of locomotives were compared, the curve passing performance of the locomotive is a possible reason for the wheel tread spalling. In the field measurement, the wheel tread surface of the locomotive with three-axle bogie used on two different railway lines is also measured and compared. The same type of locomotive is used in two different lines and their traction weight is both about 5000t.

Figure 6 gives the distribution of left hand (negative radius) and right hand (positive radius) curves according to the actual running lines.

(a)



(b)

Fig. 6 *Distribution of curves in two railway lines: (a) Line A. (b) Line B*

The most obvious distinction of these two lines is the curves distribution. In general, the curve distribution shows that the left and right curves are distributed equally both in line A and line B. But it could be found obviously

that the sharp curve in the range of 400-500m is much more in line A. And in the line B, there are more curves with radius greater than 800m.
Figure 7 gives the wheel tread surface states observed in line A and line B, the operating mileage of these wheels is about 12,000km. It can be seen that, in line B, although there are sand spots near the wheel center, obvious cracks are rarely observed. In general, the sand spots are mainly relating to the sand.

(a) *(b)*

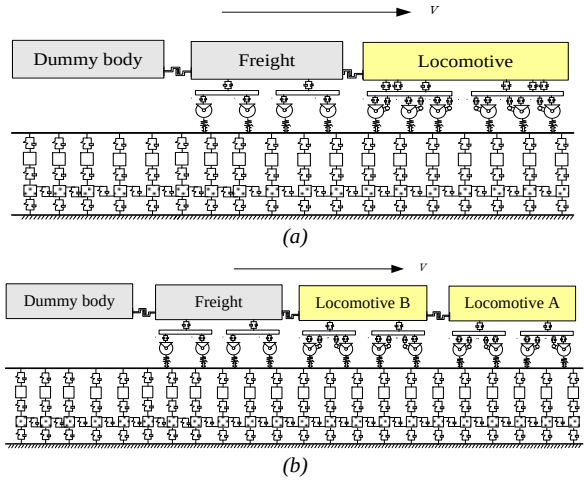


Figure 7. *Wheel surface condition observed in: (a) Line A. (b) Line B*

Form the comparison of Figure 7, the wheel tread surface show different states in the line A and line B. In line A with lots of small radius curves, there is more serious wheel tread spalling. And in line B with larger radius curves, the wheel tread damage reduced. Therefore, the small radius curves have obvious influence on the wheel tread spalling.
The cracks observed on the wheel tread of locomotive is accumulated from operation in many different conditions, such as different radius curves, speeds, traction/braking, turnout, and changing directions. From the observation and comparison, the traction/braking and the curve radius can significantly promote the wheel tread spalling.
To associate the wheel tread spalling to the wheel/rail dynamic interaction, multi-body dynamic simulations for the two types of locomotives are conducted, and the wheel/rail dynamic indices are compared and analysed. The calculated results can give evidence to confirm the dynamic index related to wheel tread spalling

4. Multi-body dynamic simulation

4.1. The dynamic model

To analyse the difference of the dynamic performance of the two types of locomotives, their multi-body dynamic models are built based on the vehicle-track coupled dynamics. [15, 16] Figure 8 shows the schematic diagram of their models, in which only the locomotives are different. The track is the ballasted track commonly used for heavy haul railway. The locomotive generally consists of carbody, bogie frames, traction motors, wheelsets and the suspensions. The freight wagon consists of carbody, side frames, bolsters, wheelset and the suspensions.
In the simulation, the traction and braking forces are both considered. In practical operation, the braking force is mainly electric braking force provided by the locomotives. Therefore, the traction and braking force are applied on each wheelset, and its value is obtained from the real-time monitoring system mounted on locomotive. The dummy body only has 1 independent degree of freedom along the track, which is modelled to provide the constant velocity.

(a) *(b)*

Fig. 8 *Heavy haul locomotive/track coupled dynamic model: (a) With six-axle locomotive. (b) With eight-axle locomotive.*

In the simulation, both the straight line and curve with 400m radius are considered. The traction and braking forces are also applied to the wheelset. Although the two types of locomotive have the same axle power, the total traction or braking force of the locomotives are the same in the calculation, this is mainly due to the running speed and the traction weight are equally in practical operation. The largest traction and braking forces are both 400kN, and the running speed is 72km/h.

4.2. Comparison of the wheel/rail dynamic interaction for the two types of locomotives

In order to understand the difference of the wheel/rail interaction between the two types of locomotives, the wheel/rail dynamic indices are calculated and compared. The considered indices in the study include wheel/rail vertical force, wheel/rail lateral creep force and creepage, wheel/rail longitudinal creep force and creepage. The wheel/rail friction coefficient u is set to 0.4.
When the locomotives pass the straight line, the calculated results show that the main difference between these two types of locomotive are wheel/rail longitudinal creep force and creepage, and the vertical and lateral

wheel/rail interaction are almost similar. This is mainly due to the axle load of the locomotives are same.

Figure 9 gives the calculated results of the wheel/rail longitudinal creep force and creepage with different traction and braking force in straight line. In the condition of certain traction and braking force, the wheel/rail creep force and creepage of each axle are different for these two types of locomotives. It is sure that the axle of the six-axle locomotive suffers more serious longitudinal interaction than the eight-axle locomotive. With the increase of the traction and braking force, the increase of the wheel/rail longitudinal creepage for six-axle locomotive is more significant. From the perspective of wheel/rail longitudinal creep force and creepage, decreasing the longitudinal interaction of the six-axle locomotive to the same level as the eight-axle locomotive, the wheel tread spalling could be relieve.

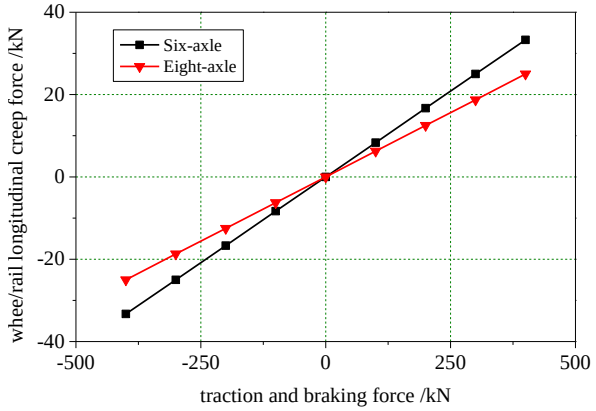

Fig. 9 *Calculated results of the wheel/rail interaction in straight line: (a) Longitudinal creep force. (b) Longitudinal creepage.*

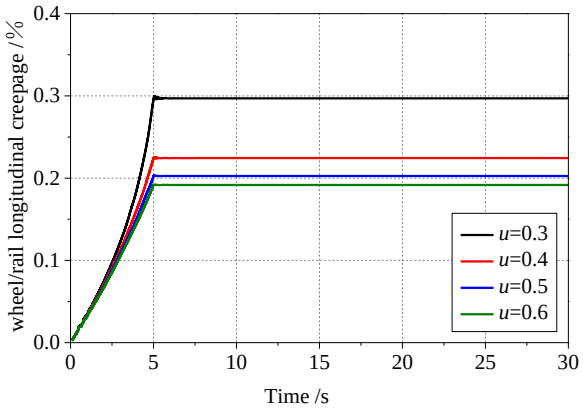
In the practice, the wheel/rail friction coefficient is significantly influence by the cleanliness of rail surface, over lubrication, rain and snow, sand quality. In order to analyse the influence of the friction coefficient on the wheel/rail longitudinal interaction, the longitudinal creepage of the six-axle locomotive is calculated in the friction coefficient of 0.3-0.6, taking the requirement of traction and braking forces into consideration. The braking force is 400kN, and the running speed is 72km/h. Figure 10 shows the calculated results of longitudinal creepages in different wheel/rail friction coefficient.



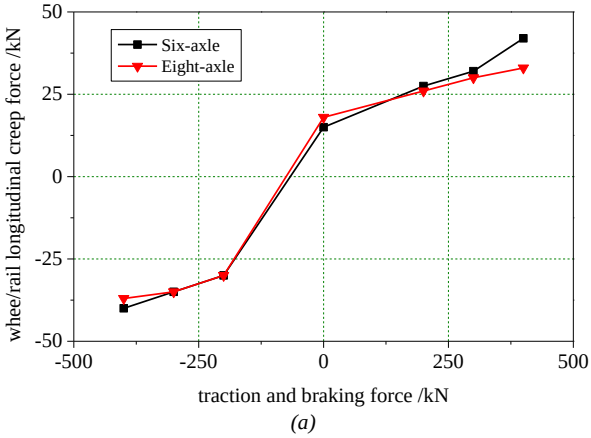


Fig. 10 *Longitudinal creepages in different friction coefficient*

It can be seen from Figure 10 that, the wheel/rail friction coefficient has significant influence on the wheel/rail longitudinal creepage. When the friction coefficient is set to 0.3, the calculated longitudinal creepage is about 0.3%. The creepage decreases to 0.22% when the friction coefficient increased to 0.4. To relieve the wheel tread damage, controlling the wheel/rail friction coefficient above 0.4 is reasonable.

4.3. The influence of curve on wheel/rail longitudinal interaction

As analysed in section 3.2, the small curve has significant relation to the wheel tread damage. The wheel/rail longitudinal interaction of the two types of locomotives in curves is simulated in different traction and braking. The curve radiuses are set to 400m, the wheel/rail friction coefficient is 0.4 and the running speed is set to 72km/h。Figure 11 gives the calculated results. It can be seen that, the difference of wheel/rail longitudinal creep force between these two types of locomotives seems not so obvious. But for the wheel/rail longitudinal creepage, the differences between these locomotives are increasing with the increase of the traction or braking forces. The results show that, when passing the small radius curves, the locomotive with two-axle bogie performs greater than the locomotive with three-axle bogie. The small radius curve has significant influence on the wheel/rail longitudinal creepage. When the traction or braking force increased, the wheel/rail longitudinal creepage increased rapidly. Even when the locomotive passing small radius curve without traction or braking force, the creepage is reached 0.5%, which is greater than passing straight lines with traction or braking force of 400kN.

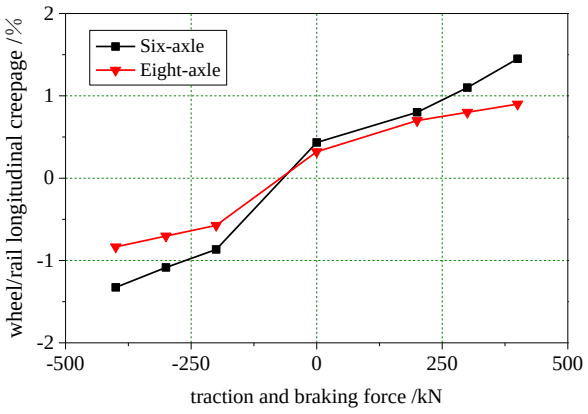

Fig. 11 *Calculated results of the wheel/rail interaction in curve: (a) Longitudinal creep force. (b) Longitudinal creepage.*

The wheel/rail longitudinal interaction of the locomotive with six-axle bogie is simulated when passing curves with different radiuses, as shown in Figure 12. The curve radiuses are set to 400m, 600m, 800m, and 1000m, the braking force is 400kN and the wheel/rail friction coefficient is 0.4. It can be clearly seen that the wheel/rail longitudinal creepage is decreased with the increase of the curve radius. When the curve radius is 400m, the calculated longitudinal creepage is about 1.33%, and the creepage is obviously decreased to 0.8% when the curve radius increased to 1000m.

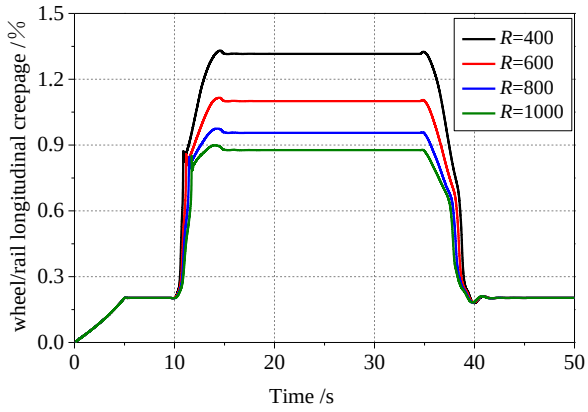

Fig. 12 *Longitudinal creepages in different radius curves*

In this part, the wheel/rail dynamic interaction is calculated and analysed. The locomotive types, straight and curve lines, traction and braking forces are considered in the simulation. The noticeable differences between the two types of locomotives are the wheel/rail longitudinal creep force and creepage, and these two indices are greater for locomotive with three-axle bogie than locomotive with two-axle bogie. Therefore, taking strategy to reduce the wheel/rail longitudinal creep force and creepage of the locomotive with three-axle bogie could be helpful for reducing the wheel tread spalling.

In general, the larger longitudinal creep force and creepage mean more relative sliding between whee and rail, the high temperature and large stress are generated in the wheel/rail contact area, and then the wheel tread damage possibly appeared. From this point of view, decreasing the wheel/rain longitudinal creep force and creepage is helpful to relieve the intractable problem.

5. Wheel/rail dynamic interaction relating to the position and direction of observed crack

In the observation, there are always serious transverse cracks on the wheelset 3 and wheelset 4 (as Figure 3 shows), and located between 65-90mm from the back of the flange. A lot of studies prove that the crack mouth is (ideally) orientated perpendicular to the resultant direction of the frictional force. Therefore, the simulated results of the wheel/rail creep force and contact position of the rear wheelset on the first bogie are given.

5.1. Wheel/rail contact position during curving

Figure 13 gives direction of the wheelset lateral displacement of the three-axle bogie during passing the 400m radius curve. It can be seen that, the front and middle wheelsets move to outside of the curve, wherevers the rear wheelset moves to inside. For the interested rear wheelset, the wheel/rail contact point of the outside wheel is in the area suffering serious spalling.

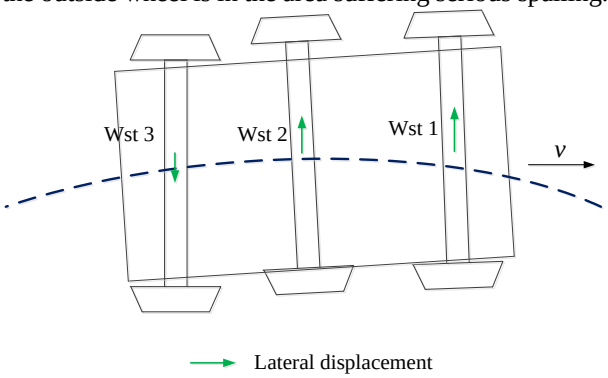

Fig. 13 *Wheelset lateral displacement direction during curving*

Figure 14 shows the calculated wheel/rail contact position on the wheel from the back of flange. The observed serious transverse crack is between 65-90mm from the back of the flange. The calculated wheel/rail contact position shows that the inside wheels of front and middle wheelset and the outside wheel of rear wheelset are located in the damage band. The contact position of the outside wheel of rear wheelset is about 85mm from back of flange, which is closer to the damage band.

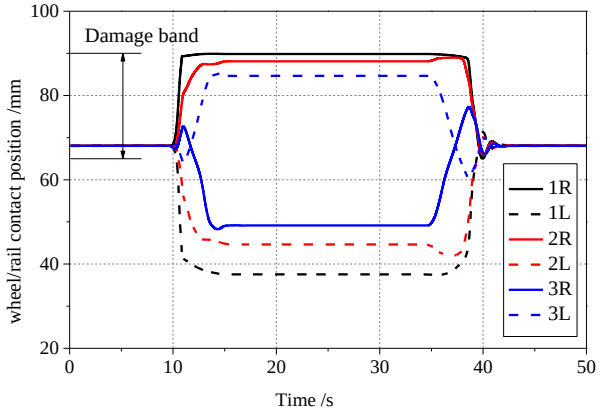

Fig. 14 *Calculated wheel/rail contact position during curving*

5.2. Wheel/rail creep forces during curving

Figure 15 gives direction of the wheel/rail creep force during passing the 400m radius curve. The longitudinal creep forces of inside wheels of front and middle

wheelsets are contrary to the running direction, so as the outside wheel of rear wheelset. When the electric braking force is applied, these wheels will suffer serious longitudinal force.

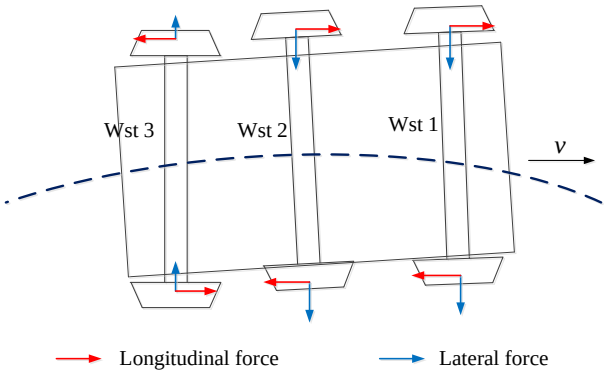

Fig. 15 *Wheel/rail creep forces direction during curving*

In the observation, the rear wheelset seems to suffer more serious wheel tread damage. And the cracks usually shows transverse, uniformed to the axle. From the point of the relationship of the crack and force, the crack mouth is orientated perpendicular to the resultant direction of the frictional force. Figure 16 gives the calculated results of the creep forces and its resultant direction of rear wheelset when passing curve.

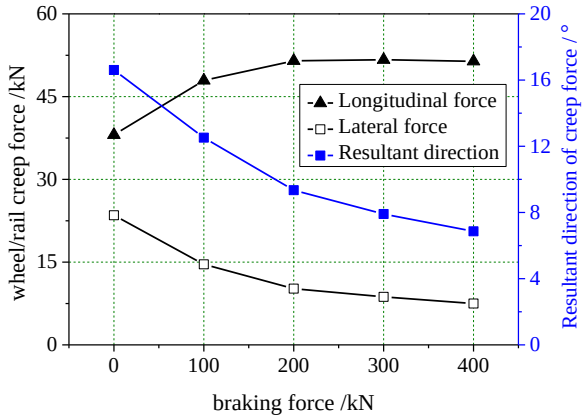

Fig. 16 *Calculated creep force and its resultant direction.*

From the calculation, with the increase of braking force, the wheel/rail longitudinal creep force increased. When the braking force increased to 200kN, the wheel/rail longitudinal creep force reached its maximum value of 51.5kN. For the wheel/rail lateral creep force, it is decreased with the increase of braking force. Therefore, the resultant direction of creep force is generally consistent to the running direction. In this condition, the transverse cracks are more likely appeared.

6. Conclusions

This paper is a primary introduction for wheel tread spalling on heavy haul locomotive. The characteristic of the observed wheel tread surface cracks is demonstrated, and the cracks propagation is also observed when turning. To determine the main influence factors, the wheel tread conditions on two types of locomotive and in two operational railway lines are observed and compared. Finally, the simulation is conducted to confirm the main wheel/rail interacted indices in relation to the wheel tread spalling. The major conclusions are as follows:

(1) There are three patterns of cracks observed on the wheel tread surface: the first type is the cracks uniformed around the wheel circumference, between 75-100mm from the back of the flange. The secondary type is the transverse tracks observed between 65-90mm from the back of the flange. The third type is the transverse cracks nearing the throat of flange. The transverse tracks near the wheel center are usually propagated to the material.
(2) From the comparison of the wheel tread states on two types of locomotives and two operation lines, the bogie types and the small radius curve both have obvious influence on the wheel tread spalling.
(3) The wheel/rail longitudinal creep force and creepage are the mainly difference indices between these two types of locomotives, decreasing its values are helpful to relieve the wheel tread spalling.
(4) When the locomotive passing curves with 400m radius, the direction of resultant creep force of the rear wheelset is generally consistent to the running direction, which is likely producing the transverse cracks.
Future extensions of our present work will be focused on the strategy to decrease the wheel/rail longitudinal creep force and creepage, such as optimal operation, suspension parameter adjustment, wheel/rail adhesion control, and so on.

Abstract: When conducting a rolling test of freight wagon on roller rig, the acting level and status of its wheel/rail forces directly related to the test system safety should be acknowledged. Interaction of the wheel/rail system is a significant basic factor in wheel/rail relations as well as a basis for numerous vehicle system dynamics studies, which requires a deep understanding of researchers. Wheel/rail force test was acted on a general purpose gondola wagon on the roller rig, and a multi-body dynamic simulation model of the tested wagon on the roller rig was built by Simpack software, of which the results are comparable. The simulation model shall be further optimized to achieve better effect of simulation analysis in freight wagon design and performance evaluation.

Keywords: wheel/rail force; test; analysis; roller rig; instrumented wheelset

1. Introduction

When conducting a rolling test of freight wagon on roller rig, the acting level and status of its wheel/rail forces directly related to the test system safety should be acknowledged. Interaction of the wheel/rail system is a significant basic factor in wheel/rail relations as well as a basis for numerous vehicle system dynamics studies[1], which requires a deep understanding of researchers. Typically, it is hard to measure the wheel/rail forces on the route in the case of wagon hunting and especially when the hunting instability occurs. It needs to conduct rolling test under special test equipment conditions and test with instrumented wheelsets. Because the testing is limited by many conditions, simulation research can be used as a necessary research method[2]. The interaction of wheel/rail is the basic content of vehicle system dynamics studies[3]. Only with clear and accurate understanding of the wheel/rail forces can we develop further research on vehicle system dynamics better.

2. Current research status of wheel/rail (roller) forces of a wagon on roller rig

Wheel/rail force measurement on the route is a conventional, measurement, which needs to be finished with instrumented wheelset or bogie frame. With respect to wheel/rail force in the event of hunting instability, for security reasons, it is not allowed for a wagon to reach the operation speed of hunting instability under general application conditions, therefore, it is seldom to measure the wheel/rail forces when hunting instability occurs.

Since testing on roller rig is done in lab conditions, it is easier to realize protective methods compared with route operation condition in terms of safety, so it is measurable.

The lab also needs to further understanding the systemic performance of freight wagons and to evaluate the safety in the event of hunting instability through wheel/rail force.

3. Wagon and roller rig system

To test wheel/rail (roller) force of freight wagon on roller rig, inspect action level of wheel/rail force at various speeds during roller rig operation and in the event of hunting instability, and provide evaluation on the safety of the rolling test.

In order to further study the stability of freight wagon and improve its product development capability, the test division of our company develops and establishes the rolling and braking rig for a complete wagon. The test system is as shown in Photo 1.

3.1. Roller rig

The roller rig is the complete wagon equipment developed by our company, in addition to doing hunting stability test, which also has the function of testing braking system of the wagon.

The roller rig provides wagon with rolling operation conditions, the operation speed is controlled by its control system, and it is possible to exert excitation on the wagon body. The excitation is controlled by hydraulic system to meet the variable requirements of customers. The track gauge and axle base of the roller rig is adjustable within a rather wide range, and the four

groups of wheel sets on the roller rig can simulate most types of four-axle freight wagons.

Photo 1 *A certain type open freight wagon on roller rig*

3.2. Wagon

It is available for a wide scope of wagons. The wagon accepting the test here refers to generally used a certain open freight wagon running on current routes of China railways.

4. Test of wheel/rail force

The paper aims at researching and evaluating the safety of complete wagon and roller rig system via series tests of wagon system on the roller rig during its rolling and operating.

The test shall cover pure rolling and rolling plus excitation at one end of the wagon cases. Pure rolling case: wagon place on roller rig, the track roller shall drive the wagon wheel sets to turn without any other excitation. Excitation case: the hydraulic actuator shall apply nominated lateral excitation to the end of the body bolster to let the carbody displace laterally, and the carbody shall suffer from free vibration once the excitation was removed.

4.1. Instrumented wheelset

The instrumented wheelset is special load gauge used to substitute wagon wheelset, rather than a part of the roller rig.

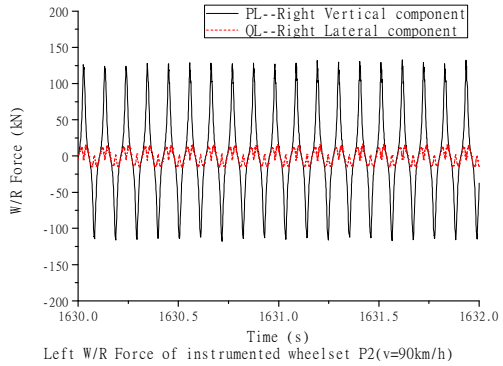
In the said test, the instrumented wheelset is a wheelset consisting of RE_2-type axle shaft of 25t axle load and HESA wheels. Wheel/rail forces are measured by arranging wagon bridge circuits at specified positions on spoke of wheels. The bridge circuits can compensate the impact of temperature. The wheel/rail force is divided into vertical and lateral force, which needs to be calibrated separately. The test circuits are led out via collecting ring devices and connected with acquisition system.

4.2. Test contents

Measuring wheel/rail forces at different rolling speeds.

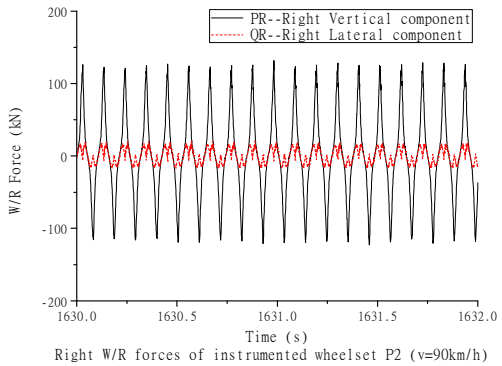
5. Test results of wheel/rail forces

5.1. Wheel/rail forces under general operating conditions



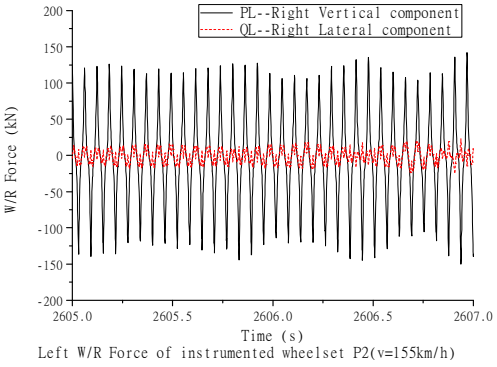
Under general operating conditions, the wagon operates stably at a series of constant speeds. Some pieces of test data are shown in fig.1 (a), (b).

5.2. Wheel/rail forces under hunting instability conditions



Under hunting instability conditions, all components of the wagon operate intensely, especially the wheelset will keep a continuous hunting state. Under such circumstances, it normally only conducts a short-time test before decelerating the rig to recover to stable status. During this period, the data of wheel/rail force is collected continuously. Some pieces of test data are shown in fig.1(c), (d).

Wheel/rail forces on roller rig of empty and loaded wagon condition significantly change after hunting ocurring.



Please refer to Table 1 and 2 for some indexes of the test data.

6. Simulation calculation of wheel/rail forces

Besides measuring wheel/rail force on roller rig, the wagon simulation model is also established. With the help of simulation model, the dynamics analysis is made and simulation calculation is conducted for wheel/rail force.

6.1. Dynamic model

Railway wagon is a complicated multi-body system, and there are not only interaction force and motion between wagon parts, but also interaction between wheel and rail. Therefore, the theoretical calculation model can only be simplified by focusing on the main target and requirements, and the main factors shall have great effect on dynamic performance shall be made close to the realities as possible. The following assumptions are made in the said model:

1) The mass of the parts shall not have great effect on dynamic performance is added to its adjacent or attached major parts.
2) The flexibility of some parts, like wheelset, sideframe, bolster and carbody, is much smaller than the suspension system, and they all deem as solid piece, i.e. no elastic deformation of such parts is considered.
3) No impact from draft, braking or neighboring wagons is considered, i.e. only single wagon model is considered. (The longitudinal pull rod is applied for safety consideration, rather than the impact form adjacent wagon, therefore, only single side pull rod is considered).
4) The carbody, bogie and suspension are arranged symmetrically.

SIMPACK software is used in modeling and calculation, as shown in Figure 2. The model consists of a carbody, two bolsters, four sideframes, eight axle boxes, and four wheelsets, with a total sum of 19 solid bodies. The carbody, bolster, sideframe and wheelset all have 6 freedoms (longitudinal, lateral, vertical, side roll, pitching, yawing); the axle box has one freedom (pitching), and there are totally 74 freedoms in the wagon model. The roller rig model has one longitudinal pull rod, four track rollers and four driving motors, with a total sum of 28 solid bodies. The longitudinal pull rod has three freedoms (side roll, pitching, yawing); the track roller has on freedom (pitching, nonindependent motion); the driving motor has zero freedom (only turning around axis y at nominated speed), with a total sum of 77 independent freedom.

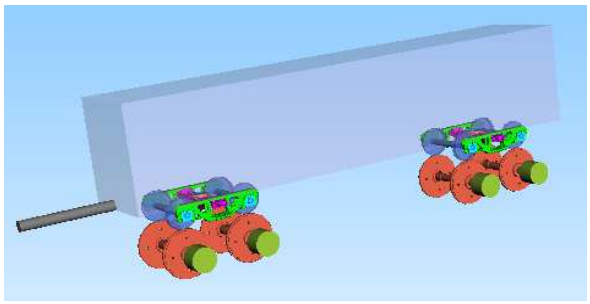

Figure 2. *Dynamic model of roller rig*

Please refer to Figure 3 for the wheel/rail force calculation results.

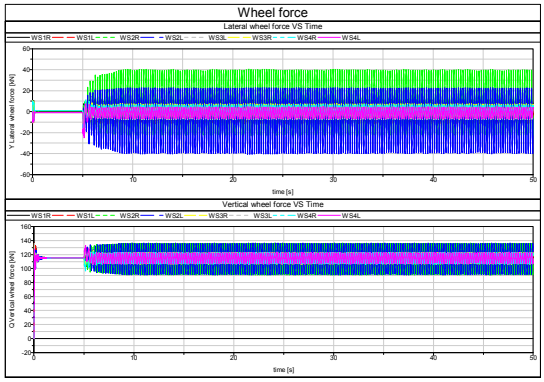

Figure 3 *Wheel/rail force of loaded wagon with excitation under 130km/h speed (hunting excited)*

As results of the simulation, Max. wheel/rail lateral forces of loaded wagon under pure rolling at 30s-50s ars shown in Table 3, Max. Wheel/rail lateral forces of loaded wagon under excitation at 30s-50s are shown in Table 4.

7. Analysis of wheel/rail forces

Under empty and loaded condition of a wagon, the wheel/rail forces at series of operating speeds are tested and analyzed. Besides the impact of wagon excitation on wheel/rail force is also analyzed.

Under pure rolling case, the wheel/rail force only change slightly before carbody hunting instability, and after the instability, the wheel/rail lateral force and vertical force shall become fluctuating along with the wheelset lateral displacement and yawing motions magnifying.

8. Conclusions and suggestions

During the test, the wheel/rail forces (vertical and lateral) are measured while considering the impact of empty, loaded, rolling speed and wagon excitation. Under normal status (stable operation and without the occurrence of hunting instability), the wheel/rail forces on roller rig are at a normal level. However, in the event of wagon hunting instability, the effect of wheel/rail forces are reinforced obviously especially the lateral force. Compared with specific limits for lateral force of the wagon, it is still within a permissible scope of safety, and the safety still can be guaranteed when hunting instability of the test system occurs.

The pure rolling and excitation test results of the wagon on roller rig are repeatable, which means that the testing system combined of tested wagon and roller rig has reliable function within the certain speed range.

At present, there are similar variations between the physical rolling test and the dynamic simulation results

in a certain speed range, but there are still some differences in the critical speed of the hunting instability, and the assumptions of the simulation model and the connection forms and parameters of the elements in the model shall need further modifications to enhance the correlation between the simulation model results and the test results, so that the simulation model can play a greater role in the development of railway freight wagons

Abstract: Wheel/Rail contact is the most important contact pair in rail transport system. Predicting traction coefficient is critical for safe operation of high-speed train. Traditional numerical methods assume ideally smooth contact geometry between rail and wheel, namely neglecting surface roughness, and apply Coulomb friction law to every point within the contact patch. Although surface roughness is known to be vital for frictional contact, few models are proposed to predict traction coefficient and reveal the mechanism of rail/wheel contact in a finer scale. Considering of the surface roughness of the wheel/rail contact and focusing on the meso-scale physical dynamics of friction, this paper presents a meso-scale modelling method of wheel/rail contact under dry friction condition. To be specific, this model simulates the frictional contact by mimicking the life cycle of each contact asperity at the contact patch: from establishing contact to stretching, to necking, to finally breaking and re-establishing after a short resting time. Each asperity's life-cycle is independent from each other's and the resultant force/torque exerted by all asperities is the frictional contact force/torque between rail and wheel. The effects of surface roughness, train speed and creep rate on the wheel/rail adhesion are investigated with this model. Comparison are made between this model and experimental/simulation data in literatures and they fit well. Further stochasticity analysis also explains the distribution of slipping and sticking area in contact patch. This model, by its multi-scale nature, presents details of sticking/slipping transition and sheds light on the understanding of rail/wheel contact in a dynamic and stochastic perspective.

1. Introduction

High-speed wheel-rail adhesion mechanism and theory are the core of the research on wheel-rail contact. Research on the interaction between wheels and rails has been going on ever since railway transportation was invented. Carter [1] took the lead in this filed and built the two-dimensional elastic rolling contact theory. Carter employed Coulomb friction law and Hertz's theory to calculate the tangential stress, dividing the contact patch into sticking area and the sliding area, which is fundamental for wheel-rail adhesion study thereafter. Vermulen and Johnson [21] expands Carter's theory to three-dimensional non-spin elliptical contacts. The most successful work in this field is Kalker's creep theory, which included linear theory, FASTSIM and CONTACT. Kalker's theory has become the 'standard' for rail/wheel contact simulation.

All the above theories employ the Coulomb friction law and assume ideally smooth contact geometry between rail and wheel. Although surface roughness is known to be vital for frictional contact, few models have been proposed to account for the effect of different surface roughness and reveal the mechanism of rail/wheel contact in a finer scale.

On the other hand, many researchers have noticed the velocity-dependent nature of friction. In order to depict this feature, scholars included velocity-dependent friction coefficients for Coulomb friction in their models. For example, Polach [3] introduced velocity-dependent friction coefficients in its model to consider shear stiffness in the contact patch; Zhang Weihua et al. [4] adopted Modified Kalker's FASTSIM algorithm to consider the velocity-dependent friction coefficient; Chang Chongyi [5] used ABAQUS to simulate the steady-state wheel-rail rolling contact with finite element method, and introduced the friction coefficient that changes with the slip speed. Vollebregt [5] extended the CONTACT program to consider the effect of velocity-dependent friction coefficient. Results in these researches indicate that the application of velocity-dependent friction model can improve the performance of wheel-rail contact simulation. This approach successfully explains some of the experiment observations, but the mechanism is still not well understood.

To answer this question of why, some scholars cast their eyes on surface roughness and study friction in a deeper scale. Sun Qiong implemented elasto-plastic contact model [10] to simulate contacting asperities between rough surfaces and sum the contact force of all the contact asperities as contact force between wheel and rail. Wu Bing [8] *et al.* implemented elasto-hydrodynamic

lubrication theory and multigrid method to simulate the contact of rough wheel-rail with the third medium such as water or oil. The focus of Wu's research [9] is the temperature effect of rail-wheel adhesion in lubricated condition. These researches showed people's interest of understanding the frictional interaction in a smaller scale. But how is the traction coefficient determined by dynamics at surface roughness is still an open problem.

This paper is to investigate the rail-wheel contact in meso scale under dry condition, aiming to understand friction behaviour in a smaller scale but stochastic approach. We've noticed that Braun [13] introduced a meso scale friction model to explain the onset of friction, namely the transition of friction from sticking to sliding. Braun's model [13] explained much of the experimental finding on stick-slipping transition which were obtained with high-speed camera on sampling rate higher than 10,000 fps [14][15][16]. We'd like to employ similar approach to model to contact between wheel and rail, considering not only sliding but also rolling. Aghababaei's numerical investigation on the whole process from contact to separation of asperities between two rough surfaces with molecular dynamics simulation [18] confirmed the effectiveness of modelling frictional contact with dynamics of asperities and shed light on lots of details involved. Compared to traditional wheel-rail contact model which is based on the Coulomb friction and ideally smooth contact geometry, the model proposed in this paper describes the frictional interaction with surface roughness of micron size. To be more specific, this model simulates the frictional contact by mimicking the life cycle of each contact asperity between rail and wheel: from establishing contact to stretching, to necking, to finally breaking and re-establishing after a short resting time. It can not only depict the longitudinal creep effect of wheel / rail contact, but also reveal the influence of sliding velocity on the frictional properties of wheel / rail contact.

The proposed model, in which rolling and sliding works together, deeply characterizes the wheel-rail contact behavior and reveal the mechanism of friction evolution. We believe that such a model is of importance for understanding the dynamic behavior of rail/wheel contact. The rest of paper is organized as follows: Section 2 describes how we model the meso scale dynamics of asperities, which includes sampling of surface roughness, modelling of normal and tangential forces of each asperity; Then the results and comparison with experimental results in literature are reported in Section 3; We summarize and conclude this paper in section 4.

2. Modelling

The model proposed in this paper is to calculate the adhesion force/torque between wheel and rail with the contacting surface roughness. Since longitudinal creep force is of greater importance and interest, in this paper we show mainly the simulation the longitudinal creep force. Meanwhile, since we're focusing on depiction of creep force, only one wheel/rail contact is concerned. This chapter will show the how the model is built.

2.1 Surface roughness

Under microscope, the surfaces of wheel and rail are not smooth at all. Surface roughness means there are lots of irregular peaks, which are called asperities. When two rough bodies contact to each other, the actual contact area is much less than nominal one since the actual contact between bodies between asperities. From the perspective of tribology, the contact between two rough surfaces can be simplified as the contact between a rough surface and a smooth surface. Therefore, to simplify the simulation, we take the wheel as a geometrically smooth rigid body while the rail has surface roughness. Based on experimental observation of the stochastic feature of surface roughness for a rail by [20], as shown Fig.1, we assume that the height of asperity on the rail follows Guassian distribution, so that a series of randomly distributed asperities are generated accordingly. The average size of surface roughness, as well as variance, are also reported[24]. We would use Guassian distribution to simulate the surface roughness whose mean is 5mm and variance is 2.5mm.

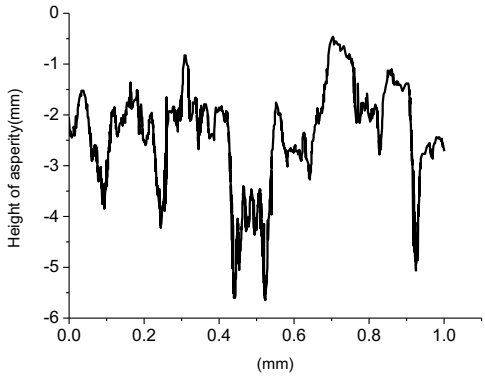

Figure 1 *Measured data of surface roughness on rail [20].*

Prior to simulate the process of friction dynamics, asperities should be generated on the elliptical rail/wheel contact patch, as shown in Figure 2. Each circle in the picture represents an asperity. All of the asperities are independent of each other. In order to simplify the contact between asperity and wheel, we assume each asperity is a cone, which indicates that the height of asperity, h_i ,is proportional to radius of circle r_i: $h_i \propto r_i$.

Experimental observation reports that the actual contour area of contact is about 5%-15% of the nominal area of contact. With this ratio and the distribution of asperity size, we can determine the number of asperities in the rail/wheel contact patch we should generate.

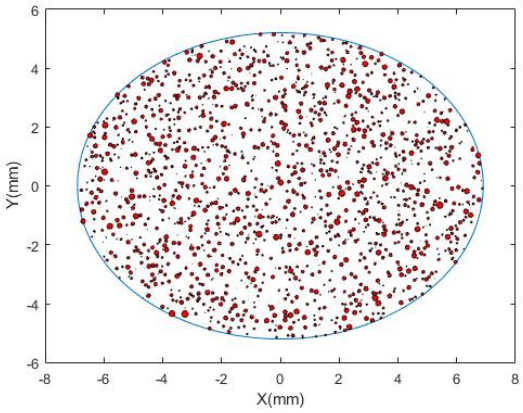

Figure 2 *the randomly sampled asperities in contact patch. The blue ellipse is the outline of the contact patch, while the small circles in the ellipse represents the asperity on rail. (a=6.9mm, b=5.2mm)*

2.2 Modelling of asperity contact

2.2.1 Normal force

Hertzian theory is employed to calculate the size of contact patch and the distribution stress in normal direction.

The formula is as follows:

$$\begin{cases} \mathrm{a} = \mathrm{m}\left[\frac{3}{2}\times\frac{G^*}{2(A+B)}P\right]^{1/3} & (1) \\ \mathrm{b} = \mathrm{n}\left[\frac{3}{2}\times\frac{G^*}{2(A+B)}P\right]^{1/3} & (2) \\ p_z(x,y) = \frac{3P}{2\pi ab}\sqrt{1-\left(\frac{x}{a}\right)^2-\left(\frac{y}{b}\right)^2} & (3) \end{cases}$$

where $\mathrm{m} = \left[\frac{2E(e)}{\pi(1-e^2)}\right]^{1/3}$; $\mathrm{n} = \mathrm{m}\sqrt{1-e^2}$; $G^* = \frac{1-\nu_1^1}{E_1} + \frac{1-\nu_2^1}{E_2}$; $\mathrm{A}+\mathrm{B} = \frac{1}{R_{x1}}+\frac{1}{R_{x2}}+\frac{1}{R_{y1}}+\frac{1}{R_{y2}}$,
where a is the long axis of contact ellipse, b is the short axis of contact ellipse, ν_1 and ν_2 are poisson's ratios of wheel and rail, p is hydrodynamic pressure, E_1 and E_2 are elastic modulus of wheel and rail, R_{x1}, R_{x2}, $R_{y1}$and R_{y2} is principal radius of curvature of wheel and rail, e and $E(e)$ is parameter of elliptic integral.

Although Hertzian theory is for geometrically smooth surface and our model is including surface roughness, Hertzian theory is still suitable to describe the distribution of normal force because the roughness is of a much smaller scale and we are using the distribution predicted by Hertzian theory in a special way. However, a correlation is needed to apply normal forces to each of the contacting asperity. If we denote α_i as the compression degree of an asperity, and s_i as the area of an asperity when completely pressed, H as the hardness of wheel and rail and P as the axle load of one wheel, then

$$\mathrm{H}\sum\alpha_i s_i = \mathrm{P} \quad (4)$$

$$\frac{\sigma_i}{\sigma_1} = \frac{\alpha_i}{\alpha_1} \quad (5)$$

where σ_i is the stress on the centre of circle predicted by Hertz theory. Since $r_i \ll a(b)$, σ_i can be treated as the average stress of the whole asperity.

Under the dry friction condition, the force wheel and rail exert against each other is all transmitted through the asperities. Each circle in Figure. 2 represents the maximum area of the cone. But it doesn't mean all of the asperities can be compressed to the maximum area of the cone it represents. Thus, the temporal compression area for an asperity is a portion of the area of the circle.

2.2.2 Tangential force

Tangential contact is the core of this model while the emphasis is laid on the physical constitutive relation of each asperity to depict the adhesion of wheel/rail in detail.

All the asperities are repeating the life cycle consisted of the following 4 phases:

i. Contact established and Stretching
ii. Steady stage
iii. Necking
iv. Contact broken and asperity resting

We simulate the constitutive law for each asperity as a 3-stage linear spring. As shown in Figure 4, when contact of an asperity is established, normal and tangential load begins to apply on it. The asperity is gradually stretching due to creepage between wheel and rail. The stretching makes the tangential force grow gradually. The increasing phase in Figure. 4 makes the stretching process look like typical a 'loading' curve. However, it cannot monotonically increase because the stretching also makes the asperity thinner and thinner. The tangential force on this asperity reaches a maximum before the asperity is stretched too much so that necking dominates. At the time the asperity contact reaches maximum, the maximum force will last for a short time before the force decreases. The decreasing phase in Figure. 4 makes the necking effect look like typical 'unloading' curve.

The stiffness for all asperities is generally different. The bigger an asperity is, the stiffer it is. Thus, we assume $k_1 \propto h_i$. The maximum threshold of each spring can be determined by the following formula:

$$f_i = \mu \times \alpha_i \times s_i \times H \quad (6)$$

where μ is coefficient of maximum static friction of the asperity. This is a parameter that differs from usual static coefficient of friction and it can be confirmed by the calculation of junction in mechanology, ranging from 0.53 to 0.63 [22]. We set $\mu = 0.54$ in our simulation. For comparison, Chen [17] has performed a series of experiments confirming that the friction coefficient on the condition of boundary lubrication is ranging from 0.2 to 0.45.

Based on the result of Aghababaei's simulation [18], the 'unloading' stiffness is relatively lower than the 'loading' stiffness. Therefore, we assume that the 'unloading' stiffness k_2 is proportional to the 'loading' stiffness k_1 in the part of rising: $k_2 = \alpha k_1$, with $-1 < \alpha < 0$.

After a contact is broken, there is a resting time Δt for the asperity before a new contact is established with it. Physically, it represents the time it takes for the asperity

to recover and 'meet' an asperity on the counter surface. Braun [13] first introduced this important feature to explain the wave propagation during onset of friction, and it depicted the phase change from sticking to sliding friction very well. Thus, we also include this feature in our model.

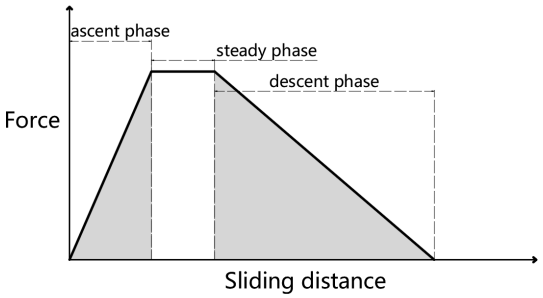

Figure 3 *Force diagram of a single stretching asperity (when normal load is constant).*

At every timestep, the longitudinal creep force is the sum of forces on all asperities in the contact patch. It's worth to note that, for different time step, since the normal load of an asperity changes, the threshold f_i is also being updated. Therefore, the actual force history of an asperity in wheel/rail contact patch is not strictly the same as that in Figure 3.

2.3 Model summary

The whole simulation is performed on Matlab. The simulation flow chart is shown in Figure. 4. In the model, based on the parameter of wheel and rail, we first get the geometry of contact spot and normal stress distribution in contact spot with Hertz contact theory on the condition of one wheel one rail contact. Then, according to the method mentioned on chapter 2.1, we generate a rough surface where lots of asperities are seeded. After that, the longitudinal creep force is calculated based on the method mentioned on chapter 2.2.

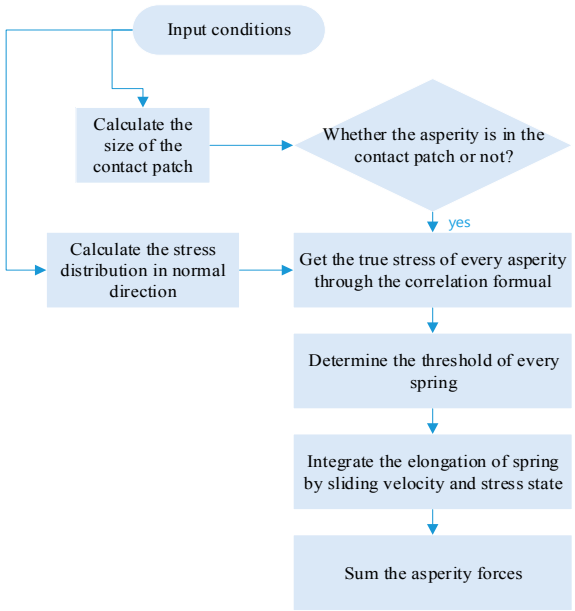

Figure 4 *Simulation scheme at each timestep.*

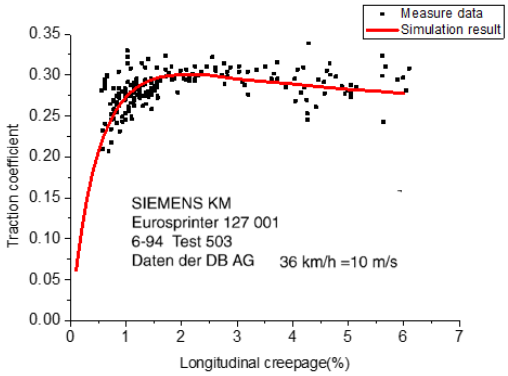
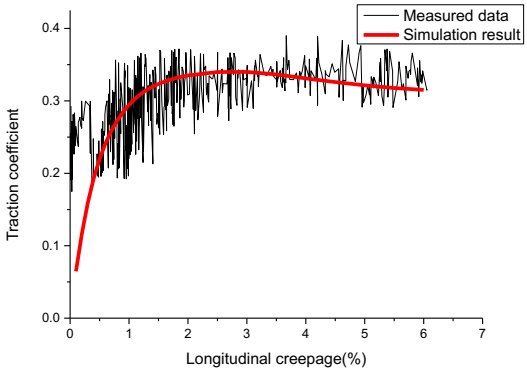


3. Simulation Results

In order to verify the model, we analyse the dependence of traction coefficient on train velocity, creepage as well as roughness and have them compared with experimental or numerical results in literature. Furthermore, we discuss how this simulation method reveals detailed dynamics for onset of slippage and the distribution of stick/slip areas in the contact patch.



3.1 Validation of the model

Considering the difficulty of reproducing high speed wheel/rail rolling contact on dry condition in laboratory, we just compare the calculation result with de measured data in filed.

Figure. 5 shows the comparison with observation of traction coefficient in field on different locomotives, with forward velocity of 30km/h and 36km/h respectively. We can see that both simulation results fit well the filed measurement. When creepage is relatively small, traction coefficient is increasing almost proportionally to the creepage. After that, the traction coefficient-creepage curve has a nonlinear increase until reaching the maximum. Then, a descending trend follows.

(a) Siemens locomotive Eurosprinter 127001 (dry, v=36km/h)

(b) Siemens locomotive S (dry, v=30 km/h).

Figure 5 Comparison between measured data and simulation results.

Table 1 shows the simulation parameters we use in the numerical investigation. For the parameters reported in literature, we follow the reported values. But for the missing ones, we provide the values within reasonable

range based on the material commonly used in railway engineering.

Table 1 Simulation parameter list

Parameters	Value
Radius of curvature of wheel R_{x1}, R_{x2} (m)	0.46, ∞
Radius of curvature of rail R_{y1}, R_{y2} (m)	∞, 0.3
Elastic modulus of wheel and rail E_1, E_2 (Pa)	2.1×10^{11}
Poisson Ratio υ_1, υ_2	0.3, 0.3
Axle load w_t (t)	18
Surface roughness of wheel/rail σ (μm)	2.5
Hardness of wheel/rail (MPa)	240
Mean of spring stiffness (N/mm)	10^4
Simulation time step (s)	5×10^{-7}
Time of steady phase (s)	5×10^{-7}
Rest time (s)	6×10^{-6}

3.2 Onset of friction

It's well known that classical numerical methods, such as CONTACT, are used to predict the traction coefficient at steady state. A steady state assumption means that those models are not designed to depict the transition of traction coefficient if the system has not reached equilibrium yet. For example, if the wheel is initially static relative to the rail and starts moving with a constant velocity and a constant creepage, what does the temporal traction coefficient look like? Is there a sudden jump from zero to a value predicted by CONTACT?

Figure. 6 shows the time history of traction coefficient when starting from still. The figure illustrates that the creep force starts from zero and increases fast within 0.5 second, which is quite reasonable.

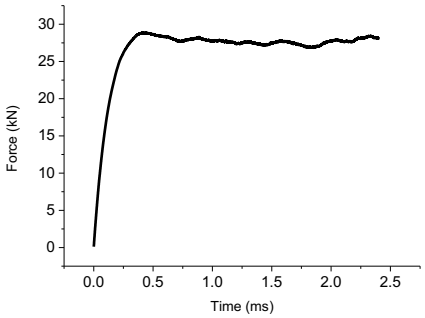


Figure 6 Temporal history of longitudinal creep force when wheel starts moving from zero velocity.

When the rail starts moving, relative displacements at all the asperities in the contact patch are increasing and it is causing a fast growing of traction force. However, since each asperity has its own limit, the creep force cannot increase unlimitedly. Some asperities would be in ascending phase and some others would be in descending or resting phase. After the contribution of ascending asperities and descending asperities reaches equilibrium, the traction force maintains a stochastically constant value and the steady state is achieved.

3.3 Effect of longitudinal creepage

During the operation of the trains, large slip might occur, especially at the acceleration or the deceleration stages. Figure. 7 shows the relation between creepage and traction coefficient for the train speed 300km/h. As known, the prediction of CONTACT indicates that traction increases with the increase of creepage, and then become a constant when friction reaches saturated. However, Figure.7 shows that, with the model proposed in this paper, after the creep force reaches saturated, traction will decrease with the increase of creepage. Some researchers believe the decline of traction coefficient is the result of rise of temperature on the contact spot. We show with our model that even without the effect that temperature takes, the mechanism of asperity contacts also results in a descending trend at high longitudinal creepage. The reason of decline will be discussed in later chapter.

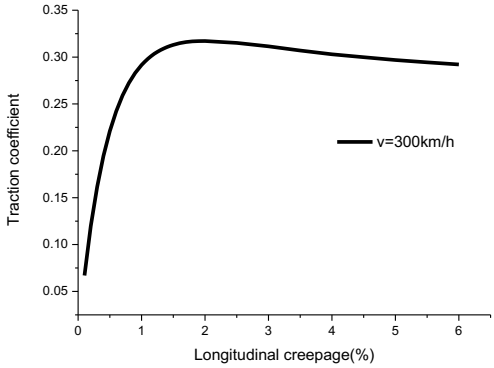

Figure 7 Effect of the creepage on traction coefficient.

3.4 Effect of surface roughness

The surface of the wheel/rail contact includes uneven asperities due to processing, wear and other factors during operation. In general, the core parameters for surface roughness are the mean and variance of the distribution of height of asperity. In this part, we present discussion for the effect of surface roughness on the traction coefficient.

Figure 8 shows the relation between the traction coefficient and the height of the asperity under the condition of dry friction. As the height of the asperity increases, the adhesion coefficient also increases. This trend is consistent with the trend measured in Ohyama's test [23] . It also shows that, with the same average height of asperity, the adhesion coefficient is slightly lower when train runs at a higher speed.

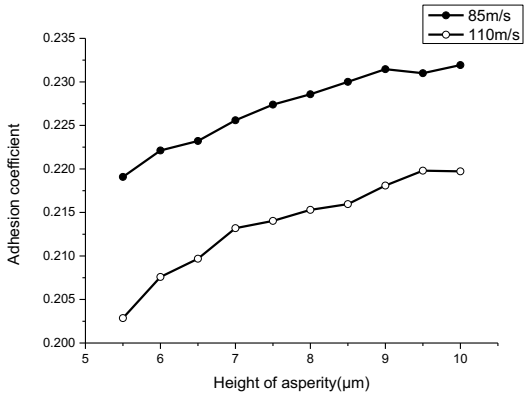

Figure 8 Relation between adhesion coefficient and the height of asperity.

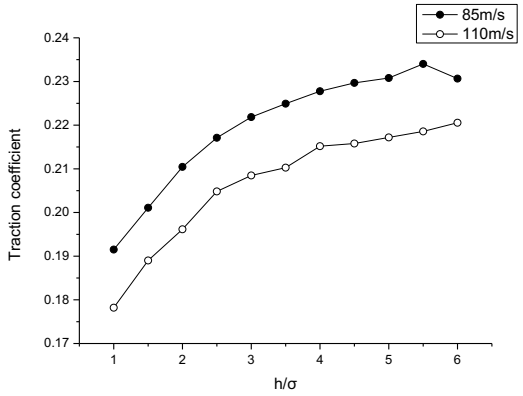

Figure 9 Relation between traction coefficient and roughness parameter h/σ.

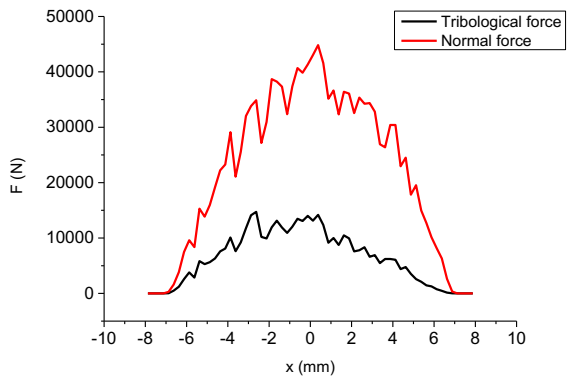
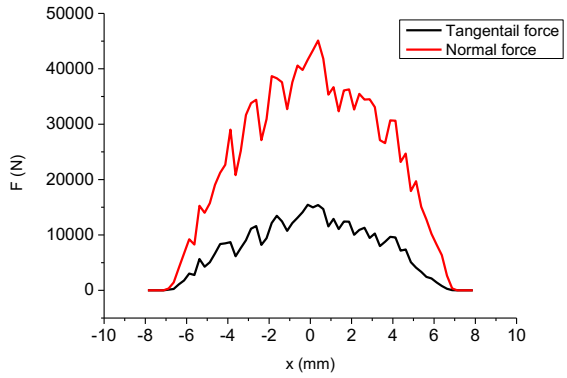
It can be seen in Figure. 9 that the traction coefficient becomes larger as the ratio of the mean height to the standard deviation of the roughness distribution increases. However, in the actual case, h/σ does not become infinitely large, because the asperities would converge to a certain stable distribution in both shape and size during train operation. The ratio can be determined according to the wheel-rail roughness value measured in the field.

As the height of the convex surface of the micro-asperity increases, the contact micro-asperities in the contact area are larger, which makes the maximum contact force larger as well. This might be the main reason for the increase of the traction coefficient as roughness height becomes larger.



It can also be seen from Fig. 9 that, with the same roughness, greater the running speed of the wheel is, smaller the traction coefficient is. This is consistent with the conclusions in Section 3.2. It can be seen that the roughness is a favourable factor for increasing the wheel-rail traction coefficient. In the design and maintenance of the wheel-rail profile, if the surface roughness can be controlled effectively, it is beneficial for improving adhesion.

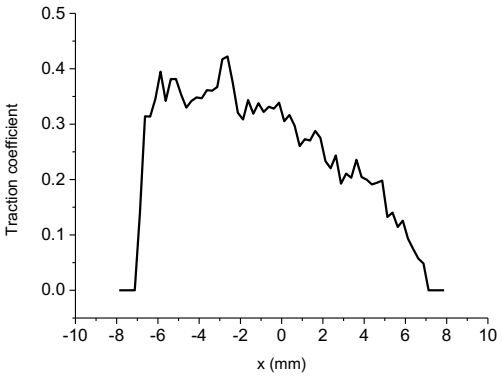
3.5 Friction coefficient distribution



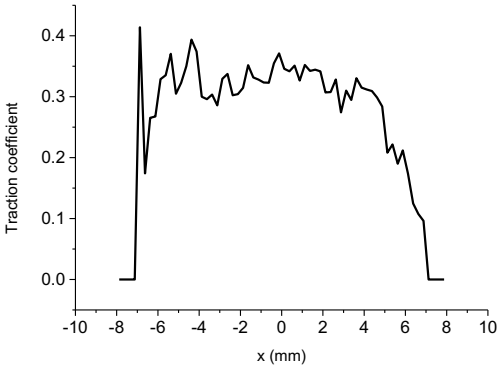
Different from the traditional model calculating wheel-rail force, the sliding area and the stick area inside the contact patch are not directly divided in the contact patch by this model. In this chapter we illustrate how the model can depict the friction coefficient distribution without dividing these areas explicitly.

Since this model calculates tangential force of each asperity, we can output the force distribution inside the contact patch. Figure. 10 shows both the normal and frictional forces when the running velocity is 36km/h. Axis x is the direction that wheel rolling along. Figure. 10(a) and Figure. 10(b) show simulation result with two different creepage, which is 1% and 2% respectively.

Form two figures we can see there is no difference for the vertical force because Hertz contact theory is used for vertical calculation which change with different velocity and creepage. As for the tangential force, from right to left, peak force is reached earlier with creepage of 2% than that of 1%. Recall that in Figure. 5(a), we have shown that traction coefficient is coming to the maximum at the creepage of 2% with this speed. It indicates that only the creepage exceed 2%, the whole is stochastically on the state of complete sliding.



(a)



(b)

Figure 10 Normal and tangential force distribution inside the contact patch (a. $\zeta = 1\%$; b. $\zeta = 2\%$).

(a)

(b)

Figure 11 Traction coefficient distribution inside the contact patch (a. $\zeta = 1\%$; b. $\zeta = 2\%$).

To validate this inference, Figure. 11 shows the coefficient distribution at one timestep in the direction of the velocity is 36km/h. From the figures we can see that in the front edge of the contact patch, which is x plus direction in this case, traction coefficient is gradually increase then comes to a relative stable value. The stable value should be the dynamic friction coefficient, which can be estimated with average. Figure. 11 indicates that it's natural image a boundary between sliding area and sticking area, although the boundary is not intended in this model. Nevertheless, the dynamic friction coefficient for creepage of 1% is about 0.35 while it's about 0.32 for the creepage of 2%.

As shown in Figure. 11, when the rolling speed is 36km/h, the traction coefficient of each unit in the contact patch changes obviously with the increase of the creep rate.

3.6 Stick/Slip area in contact patch

As mentioned above, the model doesn't divide the sliding area from the sticking area. But we can analyse the distribution by calculating the traction coefficient of each element in the contact patch.

Figure. 12 shows the coefficient of friction distribution in whole contact patch. From the Figure. 12, we can see that the traction coefficient is gradually increase from the front edge(right) of the contact patch to the rear edge(left). It clearly depicts the change of traction coefficient with the increase of creepage. Through this tendency, it can explain why the traction coefficient have the tendency of decline.

The spring stiffness at different creep rates is the same. Therefore, the linear springs used to simulate asperity contacts will be easier to stretch to its limit as the creepage increases, thus triggering the declination phase and resting. At the same time, during the resting time, the spring is on the state of unstressed. As a result, the mechanism of having resting time before resuming contact makes the total tangential force have a rising and falling nature.

Nevertheless, the yellow areas in Figure. 12 indicates sliding area while the blue region represents sticking area. The division of sliding/sticking areas fits well with conclusions in earlier models and experimental observation.

4. Conclusion

This paper presents a meso-scale dynamic wheel/rail contact model. With this model, we study the factors of speed, creep rate and roughness of the wheel-rail that affects the traction coefficient.

The simulation results of the model agree well with fundamentally important facts in field or experimental observation, which indicates that the model's ability to predict steady state traction factor although it's designed as a dynamic model.

The model can explain well the declining tendency of traction coefficient with the increase of creepage. Besides, as the average height of the micro-asperity on the wheel-rail surface increases, the wheel-rail traction coefficient at high speed becomes larger. It indicates that rougher surface can is generally preferable for increasing adhesion.

The sliding area and sticking area are also depicted with this model. Instead of defining binary sticking or sliding like traditional model, this model calculates the distribution of coefficient of friction inside the contact patch first, and we can observe the division of sliding/sticking areas afterwards. Nevertheless, the division of sliding/sticking areas fits well with earlier models as well as experimental or numerical observations.

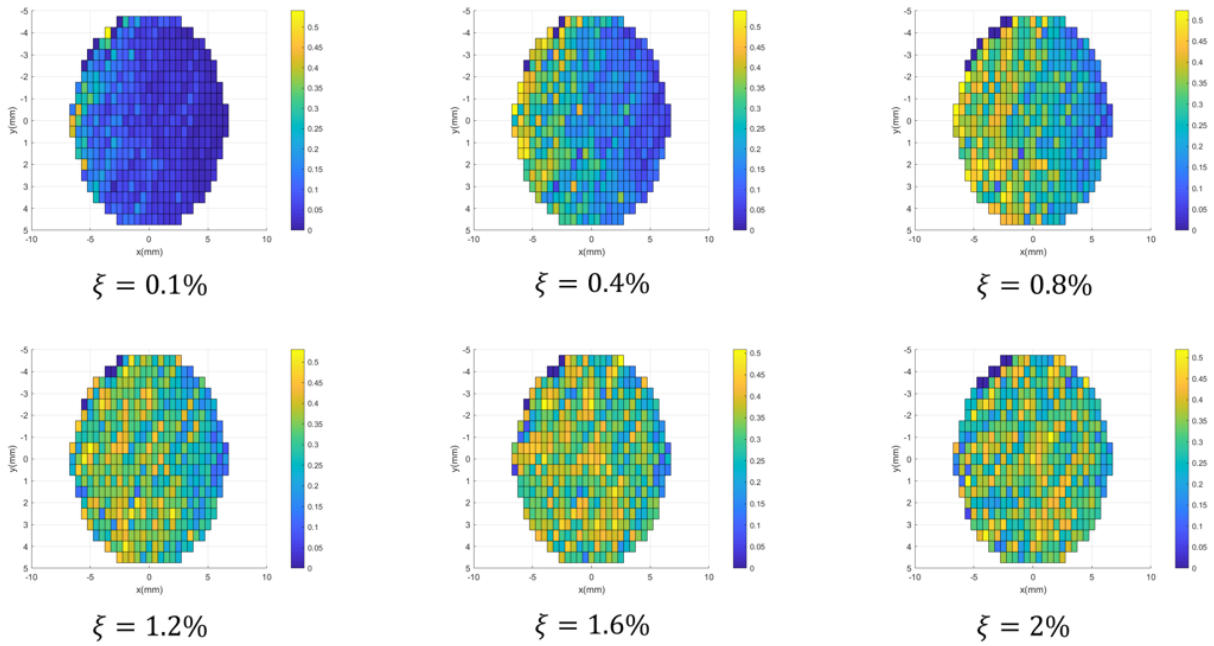


***Figure* 12** *Traction coefficient of each unit in contact spot under different longitudinal creep rate(v=36km/h)*

Although the model can explain well many features with rail/wheel contact, there is one drawback that needs attention. As shown in Figure. 13, traction coefficient is not quite sensitive to speed. Recall that temperature is a factor that is missing in this model, we need to investigate whether temperature effect is the reason.

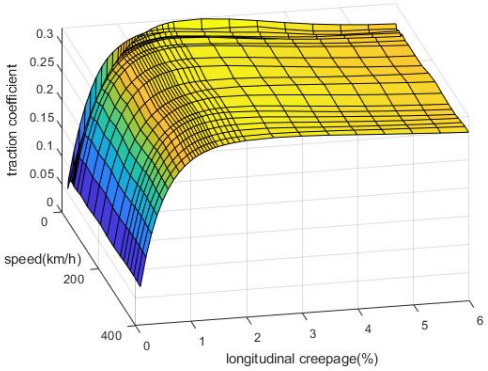

Figure 13 The relation between traction coefficient and speed

As illustrated in this paper, the meso-scale model can characterize dynamic behaviors of friction on rail/wheel contact, which is an important feature to study the traction performance during accelerating or braking. Although we have shown results about these problems, the numerical investigation in this paper is limited. We are interested in investigation on the friction details in these cases with the model employed in full train dynamics simulation.

Abstract: In order to evaluate the calculation accuracy and efficiency of different non-Hertzian wheel-rail contact approaches for simulating the rail damages of railway turnout, three approaches, i.e. Kik-Piotrowski, Ayasse-Chollet and Sichani, are adopted to simulate the rail wear and surface initiated rolling contact fatigue (RCF), and a comparison is made considering the results calculated based on Kalker's three-dimensional (3D) rolling contact theory. The results show that the calculation accuracy and efficiency of the Sichani method is the highest for simulating the damages and the Sichani approach should be preferred for simulating rail damages in railway turnout switch panels.

Keywords: Rail damages; Non-Hertzian; Wheel-rail rolling contact; Railway turnout; Numerical simulation.

1. Introduction

A railway turnout is an important piece of equipment for guiding locomotives to turn. It consists of three parts, the switch panel, closure panel and crossing panel[1]. The main function of the switch panel is to guide locomotives passing a main line or a side line. The wheel-rail contact relation for a switch panel is more complicated than that for a sectional line. Wheel-rail contact point skipping between a switch rail and a stock rail can cause strong dynamic wheel-rail interaction, which is one of the main reasons why the switch panel is subject to damage such as rail wear (Fig. 1) and RCF (Fig. 2)[2~4], directly influencing the service life of the switch rail of the turnout. Numerical simulation of rail damage in railway turnouts can be selected to avoid high cost and low efficiency on-site tests, but also to analyze the causes of rail damage, and put forward relevant improvement measures in order to prolong the service life of high-speed railway turnouts.

Figure 1 *Wear damage.*

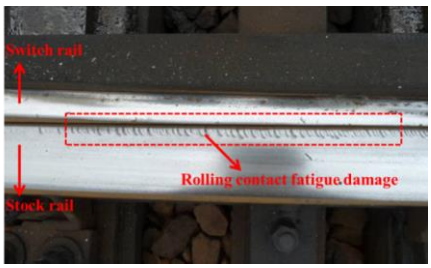

Figure 2 *RCF damage.*

Damages such as rail wear and RCF are closely related to parameters like wheel-rail contact stress and relative slip speed, therefore, for the numerical simulation of rail damage, the selection of wheel-rail rolling contact models can directly influence the accuracy of the calculated results. As early as 1880, Hertz presented an approach for calculating the wheel-rail contact region and contact stress[5], and Carter[6] and Johnson[7] successively presented the two dimensional (2D) and 3D wheel-rail rolling contact theories based on this approach. Later Kalker, a researcher from Holland, presented a linear creep theory [8] and a simplified theory in order to solve the tangential wheel-rail contact problem[9]. In the 1990s, Polach[10] presented a method for calculating tangential wheel-rail forces; however, its calculation accuracy is low [11] under high spin creep conditions. Railway turnouts are always liable to multi-point wheel-rail contact, however the Hertzian contact theory is only applicable to single-point wheel-rail contact problems, and the calculated results are quite different from those obtained in actual wheel-rail contact conditions, especially when the wheels and rails are worn out. Therefore, researchers at home and abroad have successively presented non-Hertzian wheel-rail contact models considering multi-point wheel-rail contact problems. The 3D non-Hertzian wheel-rail contact theory presented by Kalker is by far the most applicable for the calculation of wheel-rail rolling contact problems[12], however the calculation efficiency of this approach is low and it is inapplicable to numerical simulation of vehicle-track system dynamics and wheel-rail damage. Therefore, an approximation approach with high calculation efficiency is needed in order to solve the wheel-rail contact problems. Sauvage[13], Piotrowski[14] and Pascal[15,16] et al. introduced several approximate

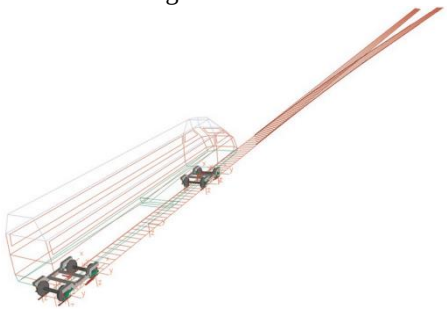
multi-Hertz wheel-rail contact models through which the contact interface between two objects could be considered as a series of equivalent Hertz ellipses during the calculation. Later, based on the basic principle of the virtual penetration method, Piotrowski[17], Linder[18], Ayasse[19] and Sichani[20,21] et al. made the calculated wheel-rail contact conditions more consistent with real conditions by modifying the wheel-rail contact regions, which is also called a semi-Hertz approach since the distribution of the normal contact stress along the rolling direction of the wheels coincide with the hypothesis of the Hertzian theory. The semi-Hertz approach is a good method considering the calculation accuracy and efficiency during the calculation of wheel-rail rolling contact problems[22].

In recent years, researchers at home and abroad have studied the wheel-rail wear and rolling fatigue prediction models. According to different deduction principles, wheel-rail wear prediction models can be divided into slip friction wear models, wear work models and wear index models. Based on the adhesion wear mechanism, Archard[23] presented a slip friction wear model; he considered that the wear of wheel-rail materials only occurred in the slip regions of contact patches rather than in the adhesion regions. Based on Archard's model, Jendel[24] and Enblom[25] et al. predicted wheel profiles, and the calculated results were quite similar to the measured results. Zobory[26] conducted a number of experiments and found that adhesion regions were subject to slight wear . He presented a wear work prediction model in relation to the wear work in contact patches. Braghin et al. [27] performed a rolling friction test with two 1:1 actual size wheels, during which they found that the material wear in contact patches was related to wear indices and introduced this relationship based on a large number of experiments in order to calculate the wheel-rail wear depth. Ekberg et al. divided the wheel-rail RCF damage into surface fatigue, subsurface fatigue and fatigue caused by internal defects [28]; they then presented the corresponding engineering prediction models [29] for the three types of fatigue damage by developing and improving the Dang Van stress criterion. Burstow[30], through his further effort, presented a prediction model for rail RCF damage when the coupled competitive relation between rail wear and RCF is considered.

The analysis of rail damage simulation consists of three parts: simulation of dynamic wheel-rail interaction, simulation of wheel-rail rolling contact and finally simulation of rail damages. This paper compares the advantages and disadvantages of four non-Hertzian wheel-rail contact models (Kalker's 3D contact theory, Kik-Piotrowski, Ayasse-Chollet and Sichani) in simulating the rail damage in turnout rails from the point of view of calculation accuracy and efficiency with a Chinese CN60-1100-1:18 high-speed turnout switch panel rail as the study object. The research findings can be adopted as theoretical guidance for selecting wheel-rail contact models for simulating turnout rail damage.

2. Simulation of dynamic vehicle-turnout interaction

Strong dynamic wheel-rail interaction is the main cause of turnout rail wear and RCF. Therefore, during the simulation of turnout rail damage, the dynamic wheel-rail interaction of a turnout area is considered as the input condition of rail damage prediction models; it includes the wheel-rail contact force, lateral wheelset displacement and wheel-rail creepage. In this paper, the SIMPACK commercial multibody dynamics software is adopted to simulate the dynamic wheel-rail interaction when a vehicle is passing the turnout. In this model, the vehicle model is a 3D multi-rigid-body model established according to a Chinese CRH2 vehicle (Fig. 3), the turnout model is an elastic track model established according to a Chinese CN60-1100-1:18 high-speed turnout (Fig. 4), see references [31,32] for the detailed establishment method and parameters with regard to the models.



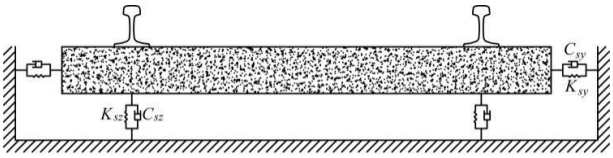


Figure 3 *Three-dimensional multi-rigid-body vehicle model.*

C_{sy}=49000Ns/m; K_{sy}=5.0∗10^{7}N/m

C_{sz}=94000Ns/m; K_{sz}=1.0∗10^{8}N/m

Figure 4 *Elastic foundation model.*

In this paper, the dynamic wheel-rail interaction of a vehicle passing the turnout at 80km/h in diverging line with facing move is simulated and calculated; this is considered the input condition for the turnout rail damage prediction model. During the simulation, the wheels have LMA treads.

When the vehicle is passing the turnout in facing move, the wheels will gradually transition to the switch rail from the stock rail. The switch rail is designed with a variable cross-section in order to realize a stable wheel transfer during this transition, and the top height gradually increases until it is equivalent to that of the stock rail. According to the processing of the switch rail profile, the switch rail is cut based on the given full profile size. Therefore, in this paper the switch / stock rail profiles at different sections are calculated according to the top height difference between the switch / stock rails, the top width of the switch rail and the cutting slope of the non-working edges of the switch rail, see Fig. 5. In this figure, *x*, *y* and *z* are the longitudinal, lateral and vertical directions of the line, respectively. The red part refers to the stock rail profile, the blue part, the switch rail profile.

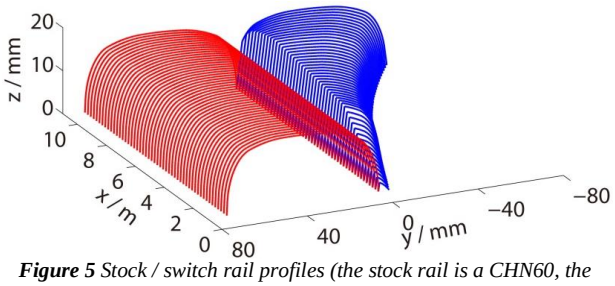

Figure 5 *Stock / switch rail profiles (the stock rail is a CHN60, the switch rail is generated based on the 60AT rail profile).*

3. Simulation of wheel-rail rolling contact

3.1. Non-Hertzian wheel-rail rolling contact model

The rail damage is closely related to the local wheel-rail contact conditions. The wheel-rail contact relationship is very complicated for the rail turnout switch panel due to the influence of factors such as the wheelset moving posture and track structure asymmetry. It is common for the wheels and rails to have two-point or even multi-point contact. Many hypothetical conditions should be considered for the wheel-rail rolling contact model deduced based on the Hertzian contact theory, and therefore it can't accurately reflect the wheel-rail contact relationship of the turnout. In the past 30 years, researchers have begun to pay more and more attention to the real shapes and stress distribution of wheel-rail contact patches and have developed many kinds of non-Hertzian wheel-rail rolling contact models, including the popular ones, i.e. Kalker's 3D non-Hertzian rolling contact theory, as well as the three non-Hertzian wheel-rail rolling contact models of Kik-Piotrowski, Ayasse-Chollet and Sichani deduced according to the virtual penetration principle.

3.1.1. Kalker's 3D rolling contact theory

Based on the complementary virtual work principle, Kalker, a researcher from Holland, presented an accurate non-Hertzian 3D rolling contact theory[12]. This approach is introduced based on the elasticity theory and half-space hypothesis, i.e. the contact object is made of linear elastic isotropic materials, the size of the contact region is far smaller than the object, the stress caused by the surface load gest lower as the distance to the contact point increases, and stress far from the contact point can be ignored. Kalker's 3D non-Herztian rolling contact theory is by far the most applicable for solving wheel-rail contact problems, and the CONTACT numerical program developed through it can be adopted to accurately calculate wheel-rail contact patch shapes, contact stress distribution and wheel-rail adhesion / slide distribution . However, considering the long calculation time and low efficiency, the CONTACT program is not suitable for the prediction of vehicle-track dynamics and wheel-rail damage, therefore the calculated CONTACT results are generally adopted to verify the accuracy of other engineering approximation approaches, known as the "golden standard" for wheel-rail contact behavior.

3.1.2. Kik-Piotrowski approach

Based on the basic principle of the virtual penetration method, when the Kik-Piotrowski approach is used to solve normal wheel-rail contact problems and the permeability is set at 0.55 times the penetration during wheel-rail contact, the calculated contact patch shape will be more consistent with the actual one. In addition, a method for correcting shapes of contact regions is presented in this approach according to the Hertzian contact theory. The Kik-Piotrowski approach can be adopted to solve tangential contact problems based on Kalker's simplified theory. During the calculations, the most difficult aspect is solving the flexibility coefficient with regard to non-Hertzian contact. Considering this, a contact patch can be divided into infinite rectangles of sufficient smallness along the lateral direction of the line in this approach and then the flexibility coefficients of each rectangle can be calculated according to the equivalent ellipse method in order to obtain the final flexibility coefficient with regard to non-Hertzian contact, see Reference [17], for the detailed information about this approach.

3.1.3. Ayasse-Chollet approach

The material deformation of wheel-rail contact surfaces is not considered in the Kik-Piotrowski approach. To remedy this problem, the Ayasse-Chollet approach provides two kinds of curvature correction measures for solving normal wheel-rail contact problems. The first one only relates to the correction of longitudinal relative curvatures and the smoothing of lateral relative curvatures. The second one relates to the correction of both longitudinal and lateral relative curvatures. The second correction measure is selected in this paper when this approach is adopted. The Ayasse-Chollet approach is also suitable for solving the tangential contact problems based on Kalker's simplified theory and the method adopted in the Kik-Piotrowski approach for calculating the flexibility coefficient is referenced. In order to realize a further improvement of the calculation accuracy, methods for correcting the flexibility coefficient and handling the spin creepage in this approach are presented, see Reference [19] for the detailed information about this approach.

3.1.4. Sichani approach

When solving normal wheel-rail contact problems, the Kik-Piotrowski and Ayasse-Chollet approaches both calculate the wheel-rail contact permeability through estimation. The material deformation of wheel-rail contact surfaces is considered in the ASD (Approximate Surface Deformation) method, so the accuracy in calculating the wheel-rail permeability is greatly increased in the Sichani approach, improving the overall calculation accuracy of the model. For the detailed information about this approach in solving normal contact problems, see Reference [20].

In the Sichani approach, the tangential wheel-rail contact problems are solved according to Kalker's simplified theory and strip theory. In order to realize a further improvement of the calculation accuracy, a method for modifying non-dimensional coefficients in three directions is presented in this approach for solving the problem of low calculation accuracy when both the major and minor axes of an equivalent ellipse are large. In addition, this approach also presents that the weighted average of flexibility coefficients in three directions can be calculated, namely one single flexibility coefficient

can be adopted instead of those in three directions in order to solve the problem of low calculation accuracy when the wheel-rail creepage is high. For the detailed information about this approach in solving tangential contact problems, see Reference [21].

3.2. *Wheel-switch rail / stock rail contact model*

Fig. 6 shows the combined structure of a stock rail and a switch rail for a railway turnout switch panel. The slide baseplate is a rigid support for the switch rail, and the stock rail is connected with the slide baseplate through the fastening system. The mutual constraint between the switch and stock rails is very weak, therefore relative motion will certainly occur between the switch and stock rails under wheel load, and their combined profile will change due to height difference and this will influence the wheel-rail contact conditions.

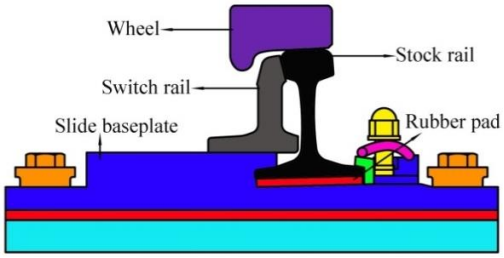

Figure 6 *Combined structure of the switch and stock rails.*

A wheel-rail rolling contact solution considering the relative motion between the switch and stock rails is presented in the above study based on the relative spatial position between the switch and stock rails and the elastic support condition under the rails. The solution consists of the following steps: a) calculating the wheel-switch rail and wheel-stock rail contact points respectively according to the track line method and analyzing the positions of the primary and secondary contact points and their relative height difference; b) distinguishing the actual wheel-switch rail and wheel-stock rail contact conditions according to the presented distinguishing method; c) calculating the distribution of the wheel-rail force on the switch and stock rails according to the coordinative force-displacement relation among the wheels, switch rail and stock rail, see Reference [33] for the detailed information about this method.

In this paper wheel-switch rail and wheel-stock rail rolling contact models are established according to Kalker's 3D contact theory as well as the Kik-Piotrowski, Ayasse-Chollet and Sichani approaches in order to analyze the wheel-rail rolling contact conditions, which are called T-CONTACT, T-KIKPIO, T-STRIPES and T-ANALYN, respectively.

4. Rail damage prediction model

Rail damage is related to the local wheel-rail contact parameters, including the shapes and positions of wheel-rail contact patches, the normal and tangential wheel-rail contact stresses and the relative wheel-rail sliding velocities. These parameters are used for the simulation of rail damage in turnout switches. This paper analyzes the influence of different non-Hertzian wheel-rail contact models on the simulation of rail damage by taking rail wear and surface rolling contact fatigue as examples.

4.1. Wear model

The rail wear is calculated according to Archard's sliding friction wear model[23] for which the wear of materials only occurs in the sliding regions of the wheel-rail contact patches rather than the adhesion regions. The wear of materials is expressed by Equation (1):

$$V_w = k_w(p_z, s)\frac{F_N d}{H} \tag{1}$$

Where, k_w is the wear coefficient in relation to the normal contact stress p_z and the relative wheel-rail sliding velocity s, which can be obtained according to the wear figure (Fig. 7). This figure only shows the ranges of wear coefficients in each zone. In this paper the averages of wear coefficients in each zone will be selected as the wear coefficients of their respective zones when the rail wear is calculated, for example, $k_1=5\times10^{-4}$. F_N is the normal wheel-rail contact force, d is the relative wheel-rail sliding distance, H is the hardness of the rail material (supposing that the hardness of the rail material is lower than that of the wheel material), which is 2.94GPa in this paper.

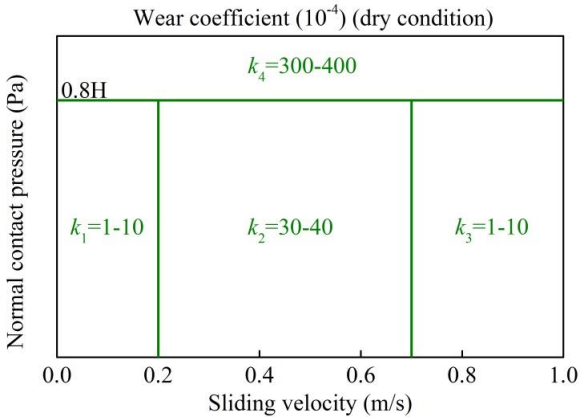

Figure 7 *Wear figure for Archard's wear model.*

In order to calculate the distribution of the rail wear within a wheel-rail contact patch, a deduction is made using the meshing method based on Equation (1). The rail wear Δz at any position (x, y) within the wheel-rail contact patch can be calculated according to Equation (2).

$$\begin{cases} \Delta z(x,y) = k_w(p_z,s)\dfrac{p_z(x,y)\cdot\Delta d(x,y)}{H} \\ \Delta d(x,y) = \sqrt{s_x^2(x,y)+s_y^2(x,y)}\,\dfrac{\Delta x}{V} \end{cases} \tag{2}$$

Where, Δd is the relative wheel-rail sliding distance within the cells, s_x and s_y are the relative wheel-rail sliding velocities along the longitudinal and lateral directions within the cells respectively. Δx is the longitudinal length of the cells, V is the speed of wheels. In addition, the influence of the shear deformation of materials should be considered when calculating the relative wheel-rail sliding velocity[34].

As shown in Fig. 8, the wear depth distribution of a rail section profile can be obtained by superposing the rail wear distribution within a wheel-rail contact patch on the rail profile.

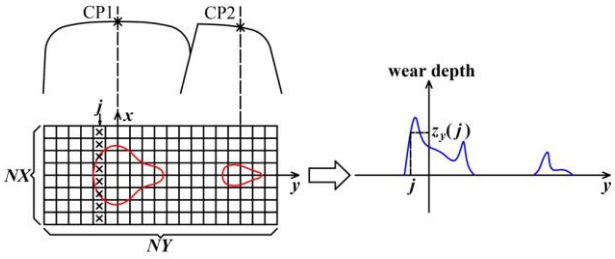

Figure 8 *Simplified rail section wear calculation method, CP: Contact Point.*

In this paper the simplified calculation method [2] is adopted to calculate the wear depth distribution of any rail section, see Equation (3):

$$z_y(j)=\sum_{i=1}^{NX}\Delta z(i,j),\ i=1,2,...,NX,\ \ j=1,2,...,NY \quad (3)$$

Where, i and j are the cell numbers along the longitudinal and lateral directions of the line, respectively, and NX and NY are the numbers of the cells along the longitudinal and lateral directions of the line, respectively. $\Delta z(i, j)$ is the rail wear of cell (i, j), $z_y(j)$ is the wear depth of a rail section corresponding to the j^{th} cell along the lateral direction of the line.

4.2. Surface initiated RCF model

The rail surface RCF is related to the ratcheting effect and low cycle fatigue [29], while the shakedown theory can be adopted to realize the quick and correct identification of the relation among factors such as ratcheting effect and low cycle fatigue under a certain loading level and surface RCF damage. Based on the shakedown theory, an index is presented in Reference [30] in order to predict the ratcheting effect of materials caused by rolling contact loads. This index is deduced according to the full wheel-rail sliding conditions and always adopts the integrated calculation of wheel-rail contact patches. If the local shear stress within a wheel-rail contact patch fails to meet the full sliding requirement, the situation will be very complicated, therefore in Reference [35,36] a method that can be adopted to directly correlate the surface RCF to the local shear stress is presented, see Equation (4):

$$\begin{cases} FI_{surf}(x,y)=f_t(x,y)-\dfrac{k}{p_z(x,y)} \\ f_t(x,y)=\dfrac{\sqrt{(p_x(x,y))^2+(p_y(x,y)^2)}}{p_z(x,y)} \end{cases} \quad (4)$$

Where, (x, y) refer to the coordinates of any position within a contact patch, p_z, p_x and p_y are the normal, longitudinal and lateral wheel-rail contact stresses, respectively. f_t is the traction coefficient, k is the shear yield strength of the materials, which is 300MPa[30] in this paper. When FI_{surf} is greater than 0, it is predicted that the rail will be subject to surface RCF.

The rail wear has a coupled competitive relation with the surface RCF, i.e., when the wear is low, the rail will mainly be subject to surface RCF damage, and when the wear is high, the fatigue cracks on the surface will be worn out before growth, and at this time the rail will mainly exhibit wear damage [36]. In order to analyze this coupled competitive relation, the RSSB (Rail Safety and Standards Board of the UK) presented rail surface RCF damage functions based on the principle of energy dissipation, see Fig. 9 [30].

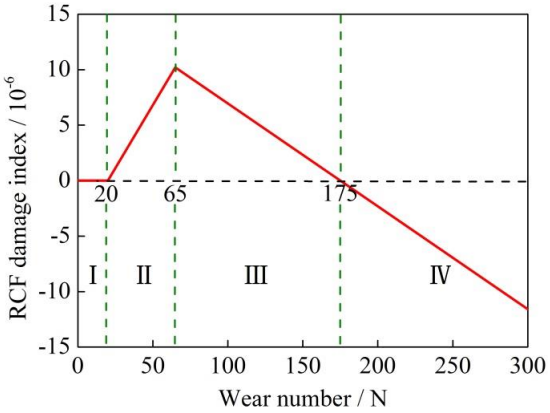

Figure 9 *Rail surface initiated RCF damage functions.*

As shown in Fig. 9, when the wear number is less than 65N, the surface RCF will not be weakened. When the wear number is higher than 175N, rail wear will dominate and it can be considered that the rail is not subject to surface RCF damage at this time. The coupled competitive relation between wear and surface RCF is explained via penalty functions in this paper, see Equation (5):

$$p_f=\begin{cases} 1,\ T_\gamma \le 65N \\ 35/22-T_\gamma/110,\ 65N<T_\gamma<175N \\ 0,\ T_\gamma \ge 175N \end{cases} \quad (5)$$

Where, T_γ is the wear number, which is calculated according to Equation (6):

$$T_\gamma = F_x\xi_x + F_y\xi_y \quad (6)$$

Where, F_x and F_y are the longitudinal and lateral wheel-rail creep forces, respectively; ξ_x and ξ_y are the longitudinal and lateral wheel-rail creepages, respectively. The surface RCF damage caused when a wheel passes by can be expressed as:

$$D(x,y)=\frac{(p_f\cdot FI_{surf}(x,y))^\delta}{\varepsilon},\ \ \forall FI_{surf}(x,y)>0 \quad (7)$$

Where, δ and ε are the preferred matching values obtained from three curve fitting bench tests (double-disk friction test, wheel-rail friction test and linearity test). In this paper δ=4 and ε=10 are the preferred matching values[3]. finally, the surface RCF distribution of a rail section can be obtained as shown in Fig. 10.

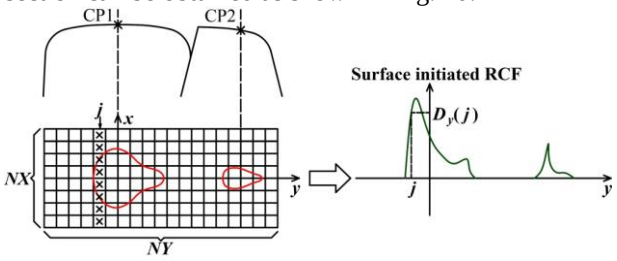

Figure 10 *Simplified calculation method of surface RCF of rail sections, CP: Contact Point.*

The simplified calculation method [3] is adopted in this paper; the surface RCF distribution of any rail section can be calculated according to Equation (8):

$$D_y(j) = \max_{i=1}^{NX} D(i, j),\ i = 1,2...,NX,\ \ j = 1,2,...,NY \quad (8)$$

Where, i and j are the cell numbers along the longitudinal and lateral directions of the line, respectively; NX and NY are the numbers of cells along the longitudinal and lateral directions of the line. $D(i, j)$ is the rail surface RCF damage within cell number (i, j), $D_y(j)$ is the corresponding rail surface RCF damage of the j^{th} cell along the lateral direction of the line.

5. Result and discussion

5.1. Wear simulation

In this paper the dynamic interaction between the first wheel of the vehicle model and the rail is selected as the input condition, and the wear depth distribution of the switch panel rail along the longitudinal direction of the line is simulated and calculated according to the Kik-Piotrowski, Ayasse-Chollet and Sichani approaches, respectively, see Fig. 11. In this figure, x is the distance to the switch rail point along the longitudinal direction of the line; y is the position along the lateral direction of the line. The blue solid line is the boundary between the stock and switch rails. The blue dotted line is the boundary between the working edge and non-working edge of the switch rail.

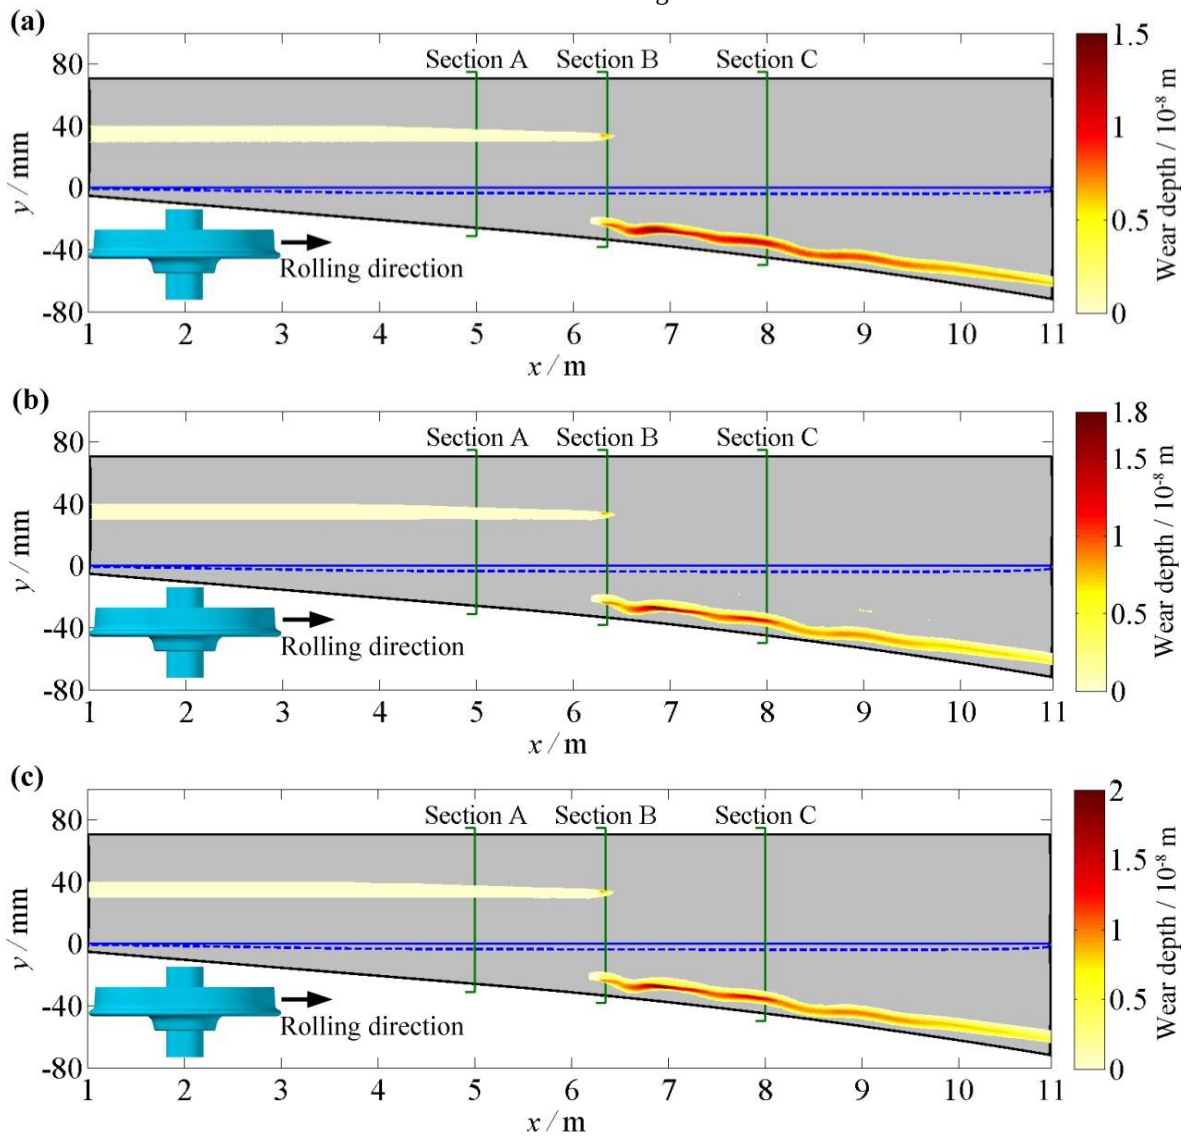

Figure 11 *Distribution of rail wear depth. (a)T-KIKPIO; (b)T-STRIPES; (c)T-ANALYN.*

As shown in Fig. 11, when a vehicle is passing the turnout in facing move, the wear depth of the switch rail is far higher than that of the stock rail. The maximum rail wear depths of the switch rail calculated according to the three approaches are 1.5×10^{-8}m, 1.8×10^{-8}m and 2.0×10^{-8}m, respectively. In order to further evaluate the calculation accuracies of the three approaches for simulating rail wear depth, the distributions of rail wear depths at three sections, i.e. Section A, B and C, are selected and the comparison shown in Fig. 12 is made considering the results calculated based on Kalker' s 3D contact theory. Section A, B and C are 5m, 6.35m and 8m away from the switch rail point, respectively. The three sections correspond to three typical wheel-rail contact conditions in the turnout switch area i.e. wheel-stock rail contact, wheel-switch rail contact, and wheel-switch/ stock rails contact and.

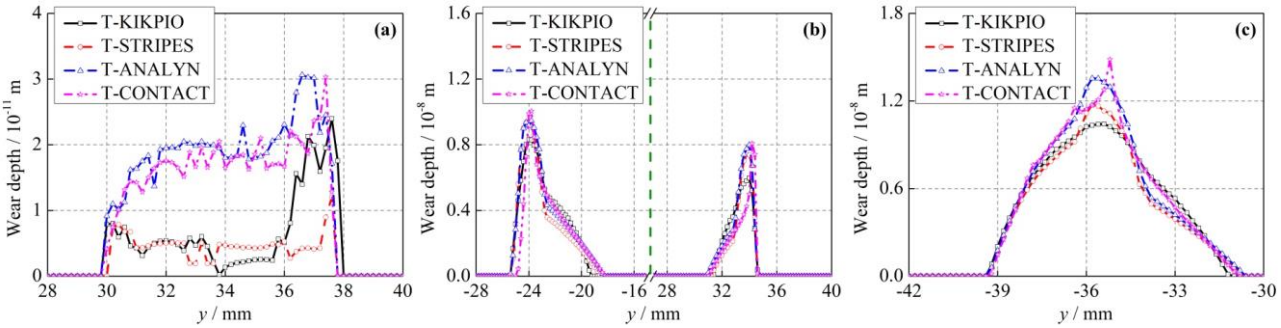

Figure 12 *Distributions of rail wear depths at selected sections. (a)Section A; (b) Section B; (c) Section C.*

As shown in Fig. 12, the result at Section A calculated according to Sichani is most similar to that obtained based on CONTACT. The result at Section B calculated according to the approaches other than Kik-Piotrowski is rather similar to that obtained based on CONTACT. The result at Section C calculated according to Sichani is most similar to that obtained based on CONTACT. In summary, the calculation accuracy of Sichani is the highest in simulating the rail wear of turnout switch panels.

5.2. Surface initiated RCF simulation

Analogous to the simulation of rail wear, the dynamic interaction between the first wheel of the vehicle model and the rail is selected as the input condition, and the rail surface RCF damage distribution of the switch panel along the longitudinal direction of the line is simulated and calculated according to the Kik-Piotrowski, Ayasse-Chollet and Sichani approaches, respectively, see Fig. 13. In this figure, x is the distance to the switch rail point along the longitudinal direction of the line; y is the position along the lateral direction of the line. The blue dotted line is the boundary between the working edge and non-working edge of the switch rail.

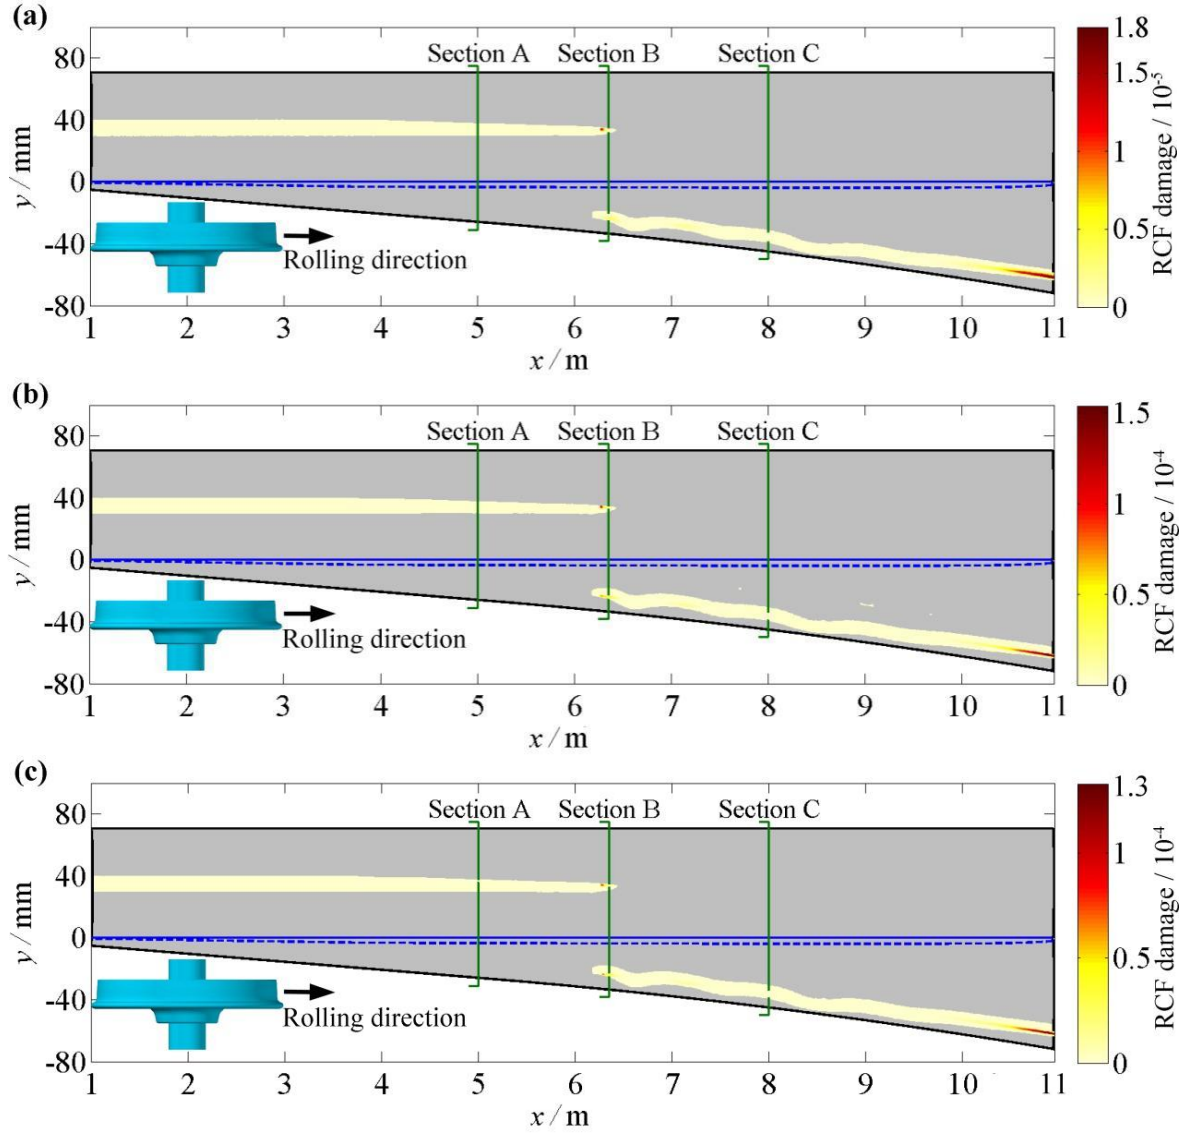

Figure 13 *Rail surface initiated RCF damage distribution. (a)T-KIKPIO; (b)T-STRIPES; (c)T-ANALYN.*

As shown in Fig. 13, when the vehicle is passing the turnout in facing move, the rail surface RCF mainly occurs at the back end of the switch rail, because the front end of the switch is worn out (Fig. 11), weakening the rail surface RCF damage. The maximum surface RCF damages calculated according to the three approaches are 1.8×10^{-5}, 1.5×10^{-4} and 1.3×10^{-4}, respectively.

Similarly, in order to further evaluate the calculation accuracies of the three approaches for simulating rail surface RCF damage, the rail surface RCF distributions at three sections i.e. Section A, B and C, are selected and the comparison shown in Fig. 14 is made considering the results calculated based on Kalker' s 3D contact theory.

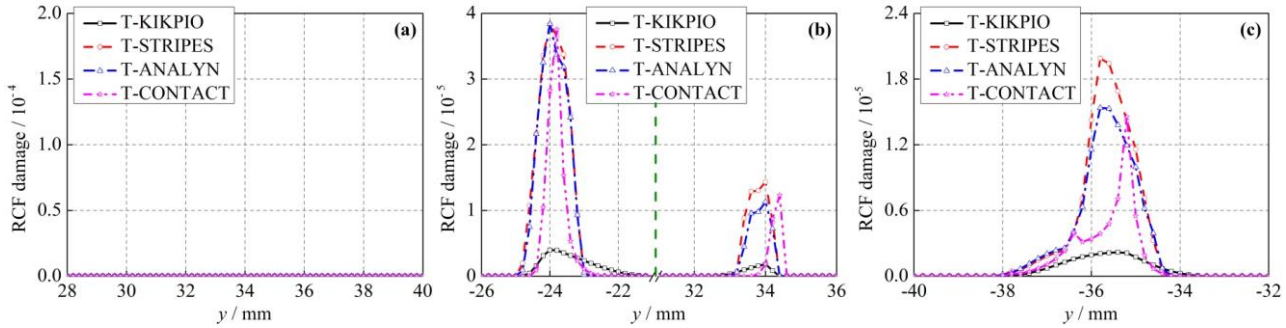

Figure 14 *Rail surface RCF damage distributions at selected sections. (a)Section A; (b) Section B; (c) Section C.*

As shown in Fig. 14, no rail surface RCF occurs at Section A. The result at Section B calculated according to Sichani and Ayasse-Chollet is rather similar to that obtained based on CONTACT. The result at Section C calculated according to Sichani is rather similar to that obtained based on CONTACT. In summary, the calculation accuracy of Sichani is the highest in simulating the rail surface RCF damages of turnout switch panels.

5.3. Calculation efficiency

The calculation efficiencies of the three engineering models of Kik-Piotrowski, Ayasse-Chollet and Sichani are far higher than that of Kalker's 3D non-Hertzian rolling contact theory[17,19,20]. In order to evaluate the calculation efficiencies of the three engineering approximation models for simulating rail damage in turnout switches, Table 1 shows the time needed for calculating the rail wear and surface RCF damage at Section A, B and C by the three approaches. It should be noted that the simulations of rail damage are run on the MATLAB language platform, and the specification of the processor for the selected computer is 3.2GHz.

Table 1 *Calculation time for different engineering approximation models*

Approach	Time needed for rail wear calculation / s			Time needed for rail surface RCF calculation / s			Average calculation time / s
	Section A	Section B	Section C	Section A	Section B	Section C	
T-KIKPIO	0.62	0.74	0.51	0.60	0.72	0.50	0.62
T-STRIPES	0.67	0.72	0.56	0.69	0.71	0.58	0.66
T-ANALYN	0.72	0.79	0.65	0.75	0.78	0.66	0.73

As shown in Table 2, the average calculation time results for the three engineering approximation models are 0.62s, 0.66s and 0.73s, respectively; the calculation efficiencies for the three engineering approximation models are similar to each other and can satisfy the requirements of simulation analysis on turnout switch rail damage.

6. Conclusion

The simulation analysis of rail damage in railway turnouts includes three components, i.e. the dynamic simulation of the vehicle-turnout coupling system, the calculation approach of wheel-rail rolling contact behavior and the prediction model of rail damage. Information about the actual shapes, positions and contact stress distribution and so on can directly influence the prediction of rail damage. Therefore, the calculation approaches of Kik-Piotrowski, Ayasse-Chollet and Sichani are adopted to simulate the distributions of rail wear and surface RCF damage with a Chinese CN60-1100-1:18 high-speed turnout switch panel rail as the example, and a comparison is made considering the results calculated based on Kalker's 3D rolling contact theory. The analysis results show that the calculation accuracy of Sichani is the highest when simulating the rail wear and surface RCF damage in turnout switch panels. In addition, the calculation efficiencies of the three approaches are high and can satisfy the calculation requirements of simulation analysis of turnout switch rail damage, so considering calculation accuracy and efficiency, the calculation approach of Sichani should be preferred for simulating railway turnout rail damage.

It should be noted that both the calculation accuracy and efficiency of the Sichani approach are high under elastic conditions. However, rail damage always occurs under elastic conditions, for example the occurrence of RCF cracks and the accumulated plastic deformation of wheel-rail materials [37]. In recent years many models of wheel-rail rolling contact under elastic conditions have been presented [38,39], therefore more advanced wheel-rail rolling contact models for analyzing the rail damage in turnout switches will be studied in the future.

QUALITY INDICES FOR MANAGING RAIL THROUGH GRINDING

Eric Magel[1]* and Kevin Oldknow[2]

*E-mail: Eric.Magel@nrc-cnrc.gc.ca

Abstract: Properly designed rail shapes are crucial to wheel-rail interface performance, and it is critical that these rail shapes are regularly and correctly applied. The grind quality index (GQI) is commonly used by some railroads to assess the quality of rail shape produced by maintenance grinding. The utility of this metric in determining whether the final profile meets certain wheel-rail contact goals is reviewed, with several illustrative cases suggesting that there is room for significant improvement. Quality indices for surface damage and rail corrugation are also explored and proposed, and an equivalent grinding index that aggregates all three areas is suggested.

Keywords: rail grinding, grinding quality index (GQI), equivalent grinding index (EGI), surface damage index, rail corrugation index.

1 Introduction

A key objective of rail grinding is to manage rail shape. As many technical publications and practical experience will affirm, "optimal" rail shapes are crucial to a well performing wheel/rail interface. Rail templates properly designed for application to high, low and tangent rails will work with the vehicles and worn wheel population to control both wheel and rail wear [1] and rolling contact fatigue [2], minimize hollow tread wear and the development of a false flange on the wheel, lower lateral forces [3] and wheel climb risk, improve ride quality, minimize wheel/rail noise, forestall the development of rail corrugations and more. So it is critical that those optimal rail shapes be regularly and correctly applied to the rail.

Currently, rail shape is assessed in North America using a Grind Quality Index (GQI), called Profile Quality Index (PQI) in this paper. In a general sense, the PQI assesses the difference between the measured rail profile and the desired or target rail shape (a grinding template) and develops a score depending on the magnitude of those deviations. There are at least three different scoring algorithms currently in place. They are described in this paper.

Recent application of PQI on one freight railroad found that PQI values improved with wear and decreased as a result of grinding (opposite to an express goal of grinding), and is perhaps overly sensitive to very small changes in shape. This finding compelled the authors to explore the causes and stimulated the effort to develop more robust and useful indices to support the rail grinding processes. During this investigation, data from heavy haul and transit systems are considered. Pre- and post-grind shapes are analysed using several different approaches to contrast the calculated values of profile conformance to the target shape. In some cases, measured profiles with quite different shapes were found to have the same PQI. These were then analysed using vehicle/track interaction tools and those results used to make an argument for a grinding quality approach that not only supports and is relevant to the rail grinding process, but also indicates whether the shape is meeting the design goals for stability, curving, stress and wear performance.

But shape is only one objective of grinding. Improving the surface condition to minimize surface-initiated internal defects, broken rails and interference with ultrasonic testing is an important benefit of rail grinding. While many railroads do not target rail condition in a systematic way, the emergence of high-speed electromagnetic and machine vision approaches to quantifying surface condition enables at least the conceptualization of a surface damage index (SDI) that can, like the PQI, be targeted, trended and managed. Similarly, a rail corrugation index (RCI) can be developed based on measurements now readily available using commercial instruments. The three indices, PQI/SDI/RCI, together are the basis for the equivalent grinding index (EGI) that is the ultimate target of the investigations and developments covered in this paper.

1.1 Rail Grinding

The goals of rail grinding are most often:

1. To progress the rail profile towards the shapes prescribed by the rail grinding templates. This is evaluated using the (rail) Profile Quality Index (PQI).
2. To address rail surface damage, removing it either immediately or progressively to facilitate reliable ultrasonic testing, remove the weak, broken surface material to expose clean and hardened material beneath, and minimize the probability of an RCF (rolling contact fatigue) caused broken rail. The effectiveness of rail grinding towards improving rail surface condition is evaluated using a Surface Damage Index (SDI) that is the subject of ongoing work [4].
3. To remove rail corrugation that contributes to noise, vibration and rapid track deterioration. A Rail Corrugation Index (RCI) is proposed for application chiefly to passenger rails.

Devadoss et al [5], in planning for rail grinding in Queensland Australia recognized that while the shape is one appropriate requirement for rail grinding, it is also necessary to consider RCF cracking in rails and advise that additional depth of cut and extra passes could be applied, utilizing operator experience with the track for guidance. They proposed an Equivalent Grinding Index (EGI) to consider both those factors and also the amount of traffic passing over the rail. They suggested further that the EGI would be influenced by the track curvature, axle load, rail material, and lubrication conditions. We will take their lead here and use EGI to describe combinations of quality indices for measuring the effectiveness of a rail grinding cycle.

1.2 Profile Quality Index (PQI)

The PQI is a measure of the difference between the measured or existing shape and the desired or target shape usually described by a rail grinding template. Different techniques for calculating PQI exist. All have the following common approach:

- The measured left and right rail profiles are oriented with respect to track level (an imaginary line that connects the tops of the two rails), such that static cant remains in the measured rail shapes.
- The appropriate rail template is selected. The template for tangent rail might be different from that being applied to a high/outside rail or low/inside rail on curved track segments.
- The rail template is aligned to the measured profile. Different alignment techniques are used, and have a modest effect on the calculated PQI.
- The distance (e.g. vertical or perpendicular depending on the specific PQI) between the target (template) and the measured profile is calculated and plotted as a function of lateral position across the railhead.
- An algorithm is applied to that difference curve to assess a score.

Palese et al [6] introduced a PQI in 2004. This PQI, which we will call PQI_A has the following characteristics:

- The template alignment uses an area minimization technique, such that the template "always lies below the rail (measured profile) with the area between the two minimized". Alignment ignores the extreme field side of the template, only the first 5/6th of the template width (from the gauge point) is employed.
- The vertical distance between the template and measured profile is used in the calculation.
- A tolerance band ("acceptance envelope") is developed for each template. A finer tolerance might be set near the gauge corner to ensure satisfactory contact conditions, while areas outside the designed running band may have more lenient tolerances.

The PQI is then calculated as the percentage of area below the acceptance envelope;

$$PQI_A = 100\ \frac{A_b}{A_a + A_b}$$

Where

A_a = area of the difference profile above the acceptance envelope

A_b = area of difference profile below the acceptance envelope

If no part of the difference curve lies above the tolerance band then a PQI of 100% is reported. Conversely, if all points fall above the tolerance limit, a PQI of 0% is assessed.

The AREMA standard takes a different approach, looking at the perpendicular difference between profile and template at 8 discrete points. The profile alignment method used in this case allows for the calculated differences to be positive or negative values. The discrete measurement points can vary with the template - on a high rail for example more of the points might be applied near the gauge corner where the template shape is especially crucial. Those points that fall outside the tolerance band are penalized and subtract from the maximize quality value of 100, while those that fall within tolerance are assigned zero value. Figure 1 illustrates how the AREMA PQI, referred to in this paper as PQI_B, is applied to a high rail on the left and low rail on the right.

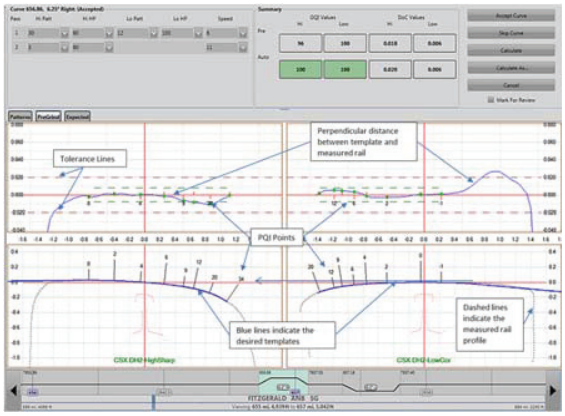

Figure 1 *Screen capture illustrating the essential features of the AREMA PQI_B calculation. Image courtesy of LORAM Maintenance of Way.*

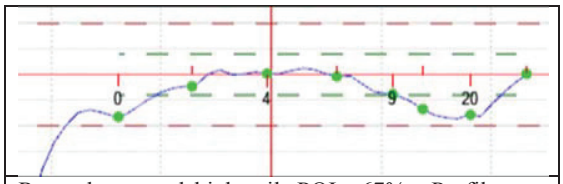
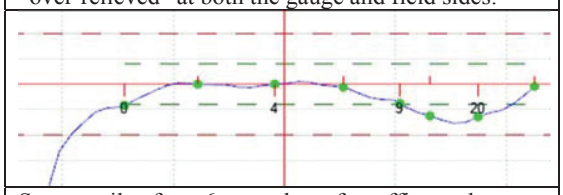


A third PQI is that used by Advanced Rail Management and Holland LP. Their approach divides the rail into four regions (extreme gauge, mid-gauge, centre and field side of the rail), calculates the largest vertical deviation between the aligned template and the measured rail in thousandths of an inch, and sums those values. For this PQI (which we will call PQI_C) perfect conformance has a value of zero, good fits have values of 20 or less and poor fits are up to 100 or even greater.

In this paper we will work chiefly with the PQI_B, which is most widely used in North America.



2 Analysis

PQI_B was applied to a set of heavy haul rail profiles from a North American Class 1 operation that includes

tangents and curves up to 6.5 degrees. This railroad employs three templates – one for tangent rail, one for the high rail of curves, and one for the low rail. An example of the pre- and post-grind values for one test curve is shown in Figure 2. In this case, the PQI_B value increased from 67% to 85% as the rail wore between the time of grinding to just before the next grinding.

Recently ground high rail: PQI_B=67%. Profile was "over-relieved" at both the gauge and field sides.

Same rail after 6 months of traffic and wear: PQI_B=85%. The rail flattens with wear and becomes closer in shape to the target profile.

Figure 2 *Example of pre- and post-grind from one particular test site, showing that as the rail profile wears in, the PQI improves from 67% to 85%.*

A summary of the PQI_B values for 13 test curves on this freight railroad is shown in Figure 3. Figure 4 summarizes how the PQI_B values changed as a result of 5 months of natural wear ($PQI_{B\ OCT2016}$ minus $PQI_{B\ MAR2017}$) and then as a result of the next rail grinding cycle ($PQI_{B\ MAR2017}$ minus $PQI_{B\ MAY2017}$). Normally, one would expect the profile to deteriorate with wear and to improve with rail grinding but the opposite occurs here.

The following observations can be made from the values shown in Figure 3 (these are specific to this sample of data and do not necessarily reflect experience of other railroads):

a) Low rails generally have a higher PQI_B (i.e. better conform to the prescribed shape than high rails).
b) PQI_B has little relationship to curvature. It would have been sensible to expect that change (probably a decrease) in PQI_B with wear would be larger for sharper curves but that was not the case here.
c) On high rails, PQI_B generally improves with natural wear and is generally made worse by rail grinding.
d) For low rails, PQI_B improved consistently with wear, but with rail grinding it sometimes improved or worsened.

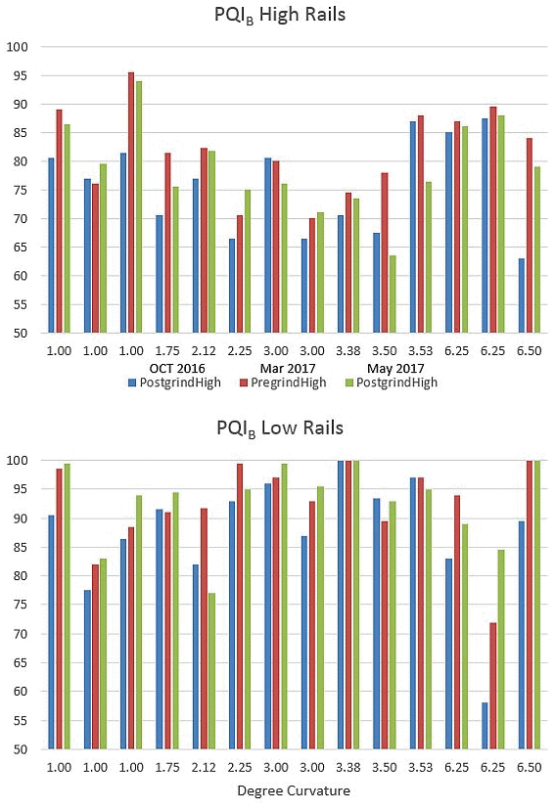


Figure 3 *Summary of PQI_B values for the high and low rails of 14 curves, with degree curvature ranging from 1 to 6.5.*

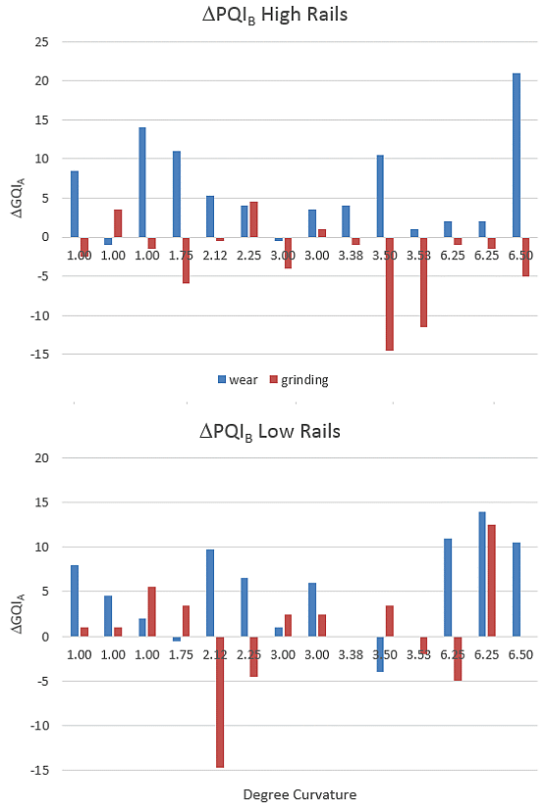

Figure 4 *Change in PQI_B as a result of grinding calculated from the values of Figure 3.*

Several factors will affect the PQI calculation including:

- Appropriate alignment of template.
- The accuracy of the measurement system.
- Selection of the measured profile on which the PQI is evaluated.

Template alignment and profile selection are specifically considered in the sections that follow.

2.1 Template alignment

Alignment of the template refers to its position compared with the rail and thus different techniques will affect both the required metal removal and the PQI. Ultimately, the template should be aligned so that the region of intended contact is properly addressed through grinding. When the first author designs rail templates, the objective is to locate a running band at a specific position on the rail that also provides favourable contact conditions (controls contact stress, stability and curving performance) [7]. For example the high rail has two contact regions: the gauge corner for leading axles and the rail crown for the trailing axles. The low rail and tangent rails are usually designed for a contact near the rail crown. To best match with a wheel that has a 1:20 taper, the contact may specifically focus around the +3 degree position on the template. In practice, wheels do tend to wear flatter and lose their conicity over time, so that a design contact angle of 1.5 or 0.5 might be a better target. One simple, consistent and reliable method for locating a template on measured rails is to align the template's far gauge point and a 1° or 0° tangency point to the rail. Examples of this are shown in Figure 5.

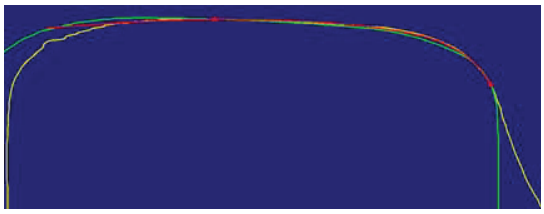

Figure 5 *Simple and robust alignment algorithm uses just two crossing points on the rail profile. The template (red) is aligned to worn high rail (yellow) and a flat low rail (green).*

Other alignment approaches include placing the template entirely within the rail (as with the alignment method for PQI_A, described above), aligning at the gauge point and middle of rail head, and iterative techniques aimed at minimizing the area difference (positive and negative) between the rail and template. PQI_B and Area of metal removal were calculated for the two measured profiles and template of Figure 5. The effect on PQI is generally not large, as the examples of Table 1 illustrate, though the influence on metal removal can be considerable.

Table 1 *Example of PQI and metal removal area for different alignment algorithms.*

Alignment method	Left/High rail		Right/Low rail	
	PQI_B	Area	PQI_B	Area
Default – 2pt	99.2	4.51	77.8	12.99
2pt – middle of rail	98.6	4.87	72.8	9.41
Under	98.7	4.85	45.5	30.62
Area minimize	100	2.10	67.3	12.09

2.2 Selection of measured profile(s) on which the PQI algorithm is applied

It is common in rail grinding to select a typical or representative profile for a track segment, calculate the PQI for that shape and state that this applies to the entire track segment. This approach presumes that the rail profile is consistent through that track segment and that a representative profile can be identified. Figure 6 shows the PQI_B for all values through a length of track, with the limits of an 8 degree (200 m radius) curve outlined by the box. While the average PQI over the full 300 metres is about 80, segmenting the curve into smaller lengths, such as halves or thirds, leads to average PQI values between 75 and 86. For planning how much grinding effort will be required, the overall average is probably sufficient. But for understanding whether the curve will provided the desired wheel-rail contact performance, it might be more appropriate to select something like the 10th or 25th percentile value to truly illustrate the relatively poor fit at the latter potion of the curve. The 10th percentile, for example, give values of 75, 73 and 65 for the first, second and last thirds of the curve, respectively.

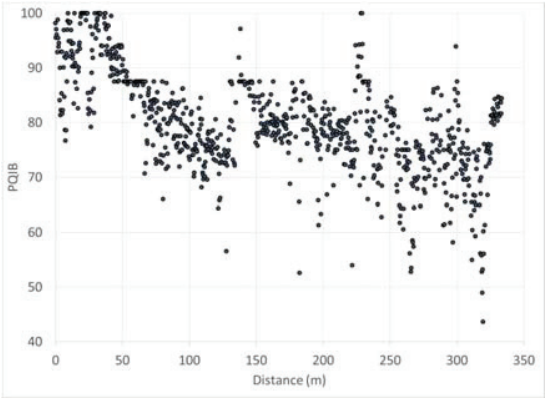

Figure 6 *The average PQI_B values over the body of this 330 metre long curve varied between 85 and 92 depending on whether the curve was considered as one, two or three segments.*

For another curve we evaluated PQI_B at each of the roughly 1100 available high rail profiles for both the pre-grind and post-grind shapes (see Figure 7). From this we see that grinding improved the shape of the rail considerably in the body of the curve (between chainages 31 and 41), with the pre-grind having a mean value of PQI_B=89.8%, while the post-grind is very close to tolerance, having a mean value of 99.56 percent. The standard deviations of those values are 5.7 and 1.17, respectively. The colour chart at the bottom of Figure 7 illustrates the 5th percentile PQI value for every 25 feet and associates a colour where blue ≡ 100% < green < 90% < yellow < 80% orange < 70% < red. This colour scheme provides a useful visualization of the general improvement of rail profile as a result of grinding. It is also easily implemented in GIS (Geographic Information System) applications and other mapping methods to provide a quick view (e.g. Figure 8) of system condition.

A comparison of the average shape pre- and post-grind profiles tells the same story – the post grind profile is

closer to the target than the pre-grind (Figure 9). The PQI_B of these average profiles at 100% and 88.9% is very close to the average of all the PQI_B values.

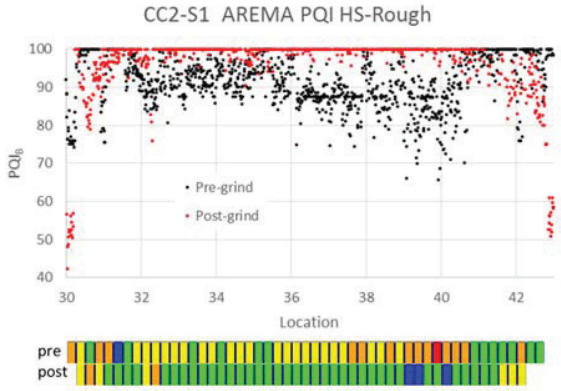

Figure 7 *PQI_B calculated for all high rail profiles in one unrestrained transit curve, before (pre-) and after (post-) grinding*

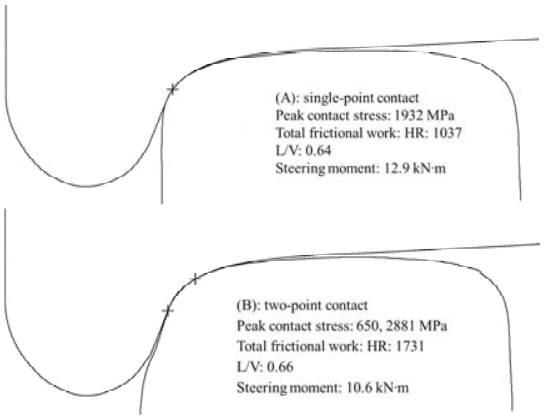
Figure 8 *The coloured strip chart can be effectively used with a GIS map to show the intensity of damage, noise, corrugation or any other parameter.*

Figure 9 *The average post-grind profile (yellow) is closer to the (red) target template than the average pre-grind profile (green).*

The deviations of the 88.9% PQI_B value from the target may not look substantial in Figure 9, but since wheel-rail contact occurs between hard (steel) bodies that undergo very little elastic deflection even under heavy freight axle loads, deviations as small as 0.1 mm can make a large difference in the contact conditions. As an illustration, we compare two post-grind high rail profiles both having 100% PQI_B using a quasi-static curving model that included a flexible suspension model and a designed wheel profile based on the average of worn shapes. Even though both rail profiles have 100% PQI_B, with a tolerance of plus-minus 0.25 mm there could be as much as 0.5 mm difference between two shapes having the same 100% PQI_B rating. The results for the leading axle are shown in Figure 10. One develops a single point of contact with the wheel while the other is a two-point contact. The single-point contact, as expected, has better curving performance (larger steering moment and slightly lower L/V) and a considerably lower frictional work value (i.e. wear).



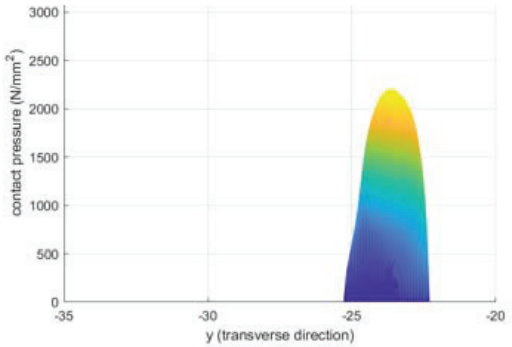


Figure 10 *Results of quasi-static curving analysis on two 100% PQI_A rail profiles. Dry friction of 0.5 is applied.*

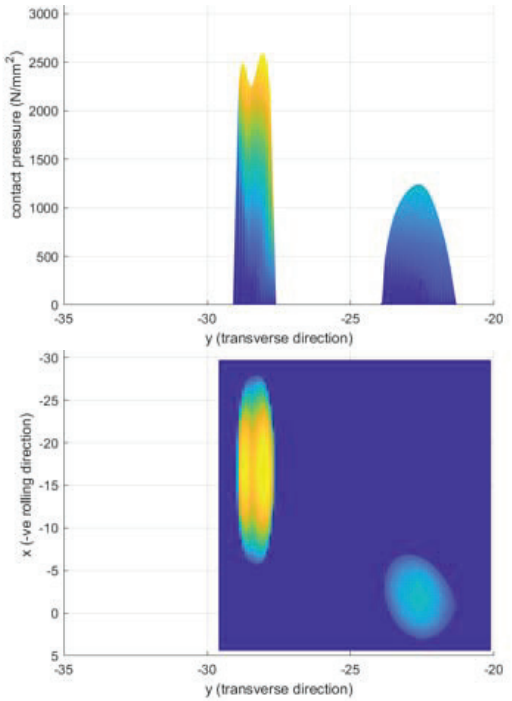

The peak contact stresses listed in Figure 10 were calculated in the curving analysis using an elliptical contact model based on local radii of curvature. To more accurately calculate contact stress distributions for the cases shown, the CONTACT software library from VORtech CMCC was used. For each case, the corresponding wheel and rail profiles were imported and re-sampled using a cubic spline at 0.1 mm intervals to allow for a contact grid discretization on the same scale. Equivalent vehicle and track conditions to those used in the contact model were specified as follows:

- Vertical wheel load: 53,362 N
- Track gauge: 1,442 mm
- Back-to-back flange distance: 1,355 mm
- Coefficient of friction (all surfaces): 0.5

The lateral displacement and angle of attack produced by the curving model for each case were used as an initial set of conditions within the CONTACT library, along with a nominal rolling speed for the wheel based on the vehicle's forward velocity (45 km/h) and tape line wheel radius (430 mm). Subsequent adjustments were made iteratively to lateral displacement and rolling speed (vis a vis creepage) to produce the closest possible match in normal and tangential forces (between curving model and CONTACT results) at each contact patch. The resulting set of conditions were considered equivalent between the two models, and are shown along with the corresponding contact pressure distributions in Figure 11. In concert with the observations noted above, it can be seen that the two cases (Location A, Location B) produce substantially different contact conditions, pressure distributions and peak stress values despite having equivalent PQI_B values of 100%.

(A): single point contact. **Peak contact stress: 2204 MPa,** Lateral displacement: 13.3 mm, Angle of attack: 9.74 mRad, Rotational speed: 28.85 rad/sec

(B): two point contact. **Peak contact stresses: 1243, 2596 MPa**, Lateral displacement: 14.2 mm, Angle of attack: 9.93 mRad, Rotational speed: 28.81 rad/sec.

Figure 11 *CONTACT model of the wheel-rail contact stress further illustrates the considerable difference between two rail profiles having the same 100% PQI classification.*

The PQI tolerance limit of plus or minus 0.25mm has been chosen as being practical within a production grinding environment, given the limited accuracy of both the machining and measurement processes. But such a loose tolerance is inadequate for assuring the designed wheel-rail contact conditions. Refinement of the local tolerances (e.g. reducing the tolerance at the gauge corner to 0.1 mm), or penalty functions that encourage greater accuracy of grinding around the designed contact band could improve the utility and credibility of both PQI_A and PQI_B. PQI_C, which is based on absolute deviations of rail from the template has the potential for greater accuracy, but further analysis is clearly required before a quality index that respects both the performance requirements of the wheel-rail contact and the practical implementation requirements can be developed.

3 A Surface Damage Index (SDI)

With the emergence of machine vision tools capable of collecting high resolution images of the rail surface at high speed, and electromagnetic systems capable of quantifying surface-breaking cracks, railroads now have tools to support the development of surface quality estimates over long lengths of track. Machine vision has been explored in [4],[8] and electromagnetic approaches (eddy current and magnetic flux) in [4],[9]. But challenges remain in both cases.

Machine vision systems require an interpreter that estimates the depth of cracking based on visual clues from the surface images, relationships that have so far eluded researchers in North America. In Britain there is apparently a workable framework in place; the so-called "Blue book" has been developed for Network Rail that states a crack depth range associated with certain visible surface damage. A similar effort was undertaken in North America [10] with more than 20 rail samples sectioned or milled. But considering that there are different rail positions (e.g. high, low and tangent), varying tonnage intervals since last grinding, dry and lubricated territories, different rail metallurgies, single- and two-point contacts and numerous other differences, it will take many more than 20 rail samples to characterize North American railroads. Despite these challenges, a preliminary translation has been proposed (see Figure 12 and Table 2) and is being reviewed by one freight railroad [4].

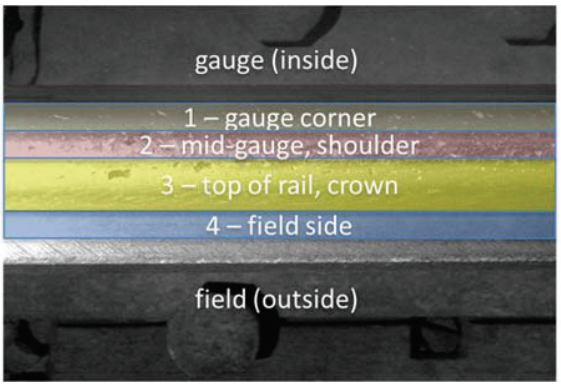

Figure 12 *The KLD translator for interpreting damage depth from photographs of the rail surface divides the rail into four bands: gauge corner, mid-gauge, top of rail, and field. Each band receives a severity score using the guidelines of Table 2.*

Table 2 *Proposed RCF severity scale based on field observations and experience.*

0	None
1	Barely perceptible, but clearly regular pattern. Unable to feel with a finger nail. Depth < 0.5 mm → Preventive grinding
2	Clear, well-defined, distinct individual cracks – but no pitting. Might detect with finger nail. Depth < 1.0 mm → Maintenance grind
3	Strong, regular cracks, consistent spacing. Easily snags skin or cloth Depth < 2.0 mm → alternate maintenance and corrective grinding
4	Clear cracking, pits up to 4 mm diameter. Depth: 1.0 - 2.5 mm → Corrective grinding
5	Pitting greater than 4 mm < 10 mm. "Heavy", well defined gauge corner cracks Depth: < 3.5 mm → Heavy corrective, or Preventive gradual grinding
6	Shelling/spalling: regular pitting, > 10 mm diameter Depth: 3-5 mm, nearly impossible to catch up on cracks → regular heavy corrective grinding
7	Shelling/spalling: any defect > 16 mm diameter or > 20 mm length Depth > 5 mm Interferes with UT detection so is unsafe. Requires very aggressive grinding and then ultrasonic inspection to verify it is safe to leave in track, or else replacement.

Electromagnetic systems have a significant advantage over vision systems in that they (at least theoretically) directly measure the depth of cracks. But eddy current systems actually measure crack length, not crack depth, and so an average crack propagation angle is required to translate length to depth for use in rail grinding. In the UK, an angle of 25 degrees is applied. This number largely over-predicted crack depth for North American freight railroads [10]. Sectioning of cracked rail samples found a large range of crack propagation angles was possible. Magnetic flux systems also exhibited problems in testing, including measurements that are influenced by rail grinding marks and a consistent over-prediction of depth. Neither technology was able to reliably detect short, recently initiated cracks as would be required for best practice preventive grinding [11]. There also remain questions about their applicability to low rails (having largely longitudinal cracks) and to systems of overlapping cracks. Nonetheless, electromagnetic systems do appear able to tell the difference between little and much cracking (e.g. "high" versus "low" densities of cracks), can locate where across and along the railhead the cracking is appearing and could be used to trend cracking at a zone over time. With experience, it could be used to classify surface condition into a category (e.g. none, mild, moderate, heavy, severe) that the rail grinding supervisor could use to guide the grinding plan. These features are all valuable for the rail management process. As long as measurements show that the surface cracking is progressively declining, then the rail grinding process is controlling and improving surface condition.

Eddy current measurements along one rail of a 24 km section of track are shown in Figure 13A. On the basis of "practical experience", a categorization for crack severity is proposed in Table 3. It is expected that this classification scheme will be refined over time as more knowledge is gained about crack propagation angles and the practical impact of cracking with respect to profile deterioration and risk at various positions across the rail head and the type of operation. Calculating the block average over 160 m track segments (Figure 13B) and then applying the categorization of Table 3 gives the colored strip chart of Figure 13C.

Table 3 *Proposed categorization for electro-magnetic crack depth measurements.*

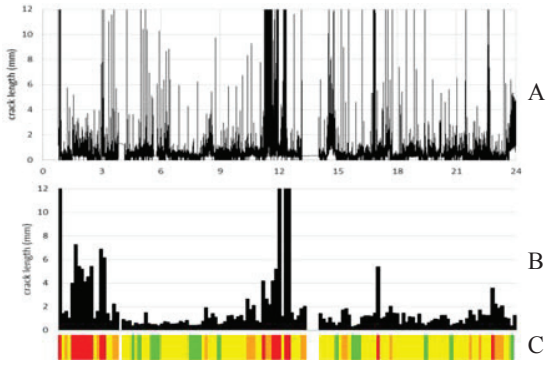
Thresholds		Severity / classification
Depth	Length	
No measureable depth	No measureable length	100% (blue)
< 0.5 mm	< 1.0 mm	90% (green)
< 1.5 mm	< 3.0 mm	75% (yellow)
< 3.0 mm	< 6.0 mm	40% (orange)
> 3.0 mm	> 6.0 mm	0% (red)

Efforts to quantify the SDI continue through various field studies being conducted under the auspices of the International Collaborative Research Initiative on RCF and Wear of Rail and Wheels (ICRI-RCF) with support from government and industry collaborators, and sponsors.

4 A Rail Corrugation Index (RCI)

Rail corrugation and associated noise are sometimes the prime drivers of a rail grinding program. Passenger railroads, and transits in particular, often have intimate contact with communities over a significant fraction of their lines, with right of ways sometime being only metres from the adjacent buildings and/or having direct line of sight (and sound) to homes, offices and businesses. As government agencies, transit systems are particularly sensitive to complaints from their neighbours and so aim

to respond as quickly and effectively to those complaints as possible. Unfortunately, this sometimes means a railroad is forever in a "fire-fighting" mode, treating short lengths of "noisy track" for remediation and failing to take a system-wide view of the problem.



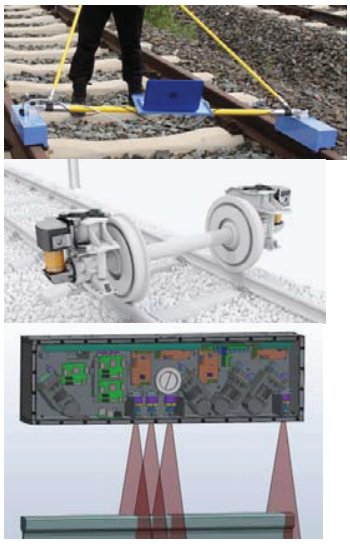


Figure 13 *Eddy current crack length measurements for 24 km of one rail on a transit system (A), the 95th percentile value for 160 metre blocks (B) and the Surface Damage Index (SDI) bar plot (C). Note that the raw data measurements of 12 mm almost always correspond to locations of rail welds and do not reflect crack length.*

Corrugation is a problem that is very amenable to measurement and characterization [12]. Several different tools are available, ranging from metre-long measurement bars that are set down on the rail, to walking stick units and others mounted on moving platforms (Figure 14). Indirect measurements via axlebox accelerations and noise are also effective approaches.

The Corrugation Analysis Trolley (CAT)

Measurement of wheelset displacement or axlebox accelerations

Technogamma RCMS "3-point versine system"

Figure 14 *Examples of technologies for measuring rail corrugations.*

A corrugation index for grinding will sensibly be based on a relationship between the measured depth of the corrugation (or amplitude of accelerations and noise) and some allowable threshold. For one transit agency where the Corrugation Analysis Trolley (CAT [12]) is used regularly, an RCI has been proposed related to the RMS value reported by the CAT software. Using the band of 30-100 mm, the reported "block RMS value" (see Figure 15) is compared to the tolerance value (TOL = 4 microns in this case). Then the RCI is calculated as 100*[1-(RMSblock-TOL)/(6*TOL)] for 4 < RMSblock < 28. For values less than 4 microns, RCI is 100%, at 16 microns it is 50% and at 28 microns it is zero. A high value of RCI is desired, but it is not yet possible to say at what levels the vehicle-track performance is significantly affected.

Table 4 *Proposed Scale for RCI based on the RMS block value of corrugation depth.*

RMS block	RCI	Colour scheme
<4	100.0	BLUE
<8	83.3	GREEN
<12	66.7	YELLOW
<16	50.0	ORANGE
<28	0.0	RED

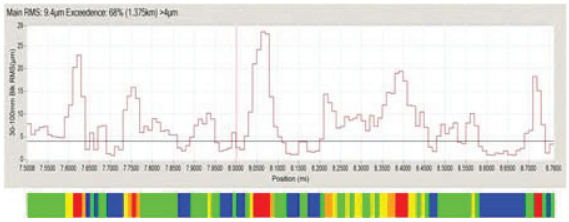

Figure 15 *An example of the block RMS value report by the CAT software (top) and plot of the resulting RCI values (bottom).*

5 The Equivalent Grinding Index (EGI)

The PQI, SDI and RCI continue to evolve in step with improved measurement and (grinding) control technologies, and management processes. The next challenge will be to rationalize the SDI-PQI-RCI trade-off to optimize the EGI. There will undoubtedly be instances where the SDI is suggesting one course of action while the PQI suggests another. For example, in the case of a rail showing heavy RCF at the gauge corner but a template demanding to further load the rail at this location there is a conflict that if not optimized will (erroneously) call for extremely heavy grinding. For this scenario there might be several causes, but the two most likely are:

1. The rail template is incorrect for that particular set of conditions (curvature, cant deficiency, metallurgy, etc.) and an alternate is required.
2. The rail grinding interval is too long for that particular design. For example, a conformal one-point contact condition improves steering to reduce lateral forces, stress and wear. But if not refreshed (lightly ground) regularly, the running band develops surface fatigue that weakens the material and cracks can propagate deep into the rail. The single-point contact condition might be appropriate for "healthy" rail material, but not for a cracked and "unhealthy" surface. A new template that considers both the capabilities of the steel and the longer grinding intervals should be engineered and employed.

The simplest technique is to allow a railroad (e.g. the grinding manager) to decide for itself what the relative importance of each is by assigning values between 1 and

0 (100% and 0%) to the scalar weighting coefficients W_{PQI}, W_{SDI} and W_{RCI} and using the equation below:

$$EGI = \frac{W_{PQI} \cdot PQI + W_{SDI} \cdot SDI + W_{RCI} \cdot RCI}{W_{PQI} + W_{SDI} + W_{RCI}}$$

Another approach that might be considered is expressing the EGI as a scaled vector, e.g:

$$\overrightarrow{EGI} = \frac{W_{PQI} \cdot PQI \cdot \hat{\imath} + W_{SDI} \cdot SDI \cdot \hat{\jmath} + W_{RCI} \cdot RCI \cdot \hat{k}}{\left[{W_{PQI}}^2 + {W_{SDI}}^2 + {W_{RCI}}^2\right]^{\frac{1}{2}}}$$

While somewhat more complicated than a scalar metric, this would provide a means to preserve information about the individual damage types. An aggregate scalar metric could still be produced by taking the magnitude of the vector ($|EGI|$), and this might be used as a first approximation to estimate grinding effort required.

For freight railroads, where RCI is generally not a priority, the value for W_{RCI} could be zero. If the target rail templates are believed to be strong contributors to reducing stresses that contribute to RCF, it would be reasonable to assign values of 1.0 and 0.5 to W_{PQI} and W_{SDI}, respectively. On a transit system, values closer to 1.0 for all parameters might be appropriate.

6 Conclusions

The use of PQI is a practical approach to rail profile quality assurance, with calculations and tolerances that are suited to the production grinding environment and corresponding measurement systems. This paper has explored, in a preliminary way, the relationship between PQI and detailed wheel-rail contact conditions. The results suggest that there are significant limitations in using PQI, as currently applied, as an indicator of wheel-rail contact conditions, and thus the effectiveness of the grinding process in achieving the desired contact conditions. Example observations include the following:

- A macroscopic study of 13 test curves over a seven-month period in a freight rail operating environment showed an improvement in PQI_B with accumulating traffic (wear), and a deterioration in PQI_B with rail grinding (whereas the opposite would be expected and intended).
- The method of aligning the target template to the measured profile can yield moderately different PQI values, and considerably different values for area of metal to be removed in grinding.
- Using an average value of PQI for profiles measured along a given track segment (e.g. curve), or using an "average" rail profile is probably adequate for deciding how much grinding effort will be required. But to determine whether the curve shape is matching the desired template, it would be more appropriate to use something like the 10th percentile value – i.e. a value that identifies whether a significant fraction of the curve has poor shape.
- PQI_A and PQI_B methodologies, at least as currently applied, can assign values of 100% to rail profiles that have entirely different contact conditions with the same wheel (e.g. single point versus two point contact).

Based on these observations, there are likely opportunities to improve the index or indices used to assess rail profile quality. Additionally, there is merit in considering the use of an aggregate or equivalent index (EGI) that considers profile quality (PQI), surface damage (SDI) and corrugations (RFI). Measurement systems in each of these areas have limitations but are also demonstrating a level of utility and reliability that offers promise.

The authors have further plans to investigate and improve upon the quality indices presented in this paper as follows:

- Correlations, trade-offs and usefulness of alternative approaches for the calculation of PQI, SDI, RCI and EGI will be explored in future projects and publications.
- A study of the sensitivities and correlations between wheel-rail profile performance characteristics, PQI and measurement accuracy is planned.
- The applications in this paper focussed mostly on transit systems, simply because that is where the authors had access to quality data sets. But freight railroads could clearly benefit from better management and trending of their rail condition and understanding the effectiveness of their rail grinding efforts. The challenge here is that few have surface damage data and even fewer have rail corrugation information. But high-speed eddy current and machine vision systems are being increasingly applied on freight railroads. A suitable railroad needs to be identified.

7 Acknowledgments

The authors are grateful to Mr. Sean Regehr of Advanced Rail Management for providing data used in Figures 12 and 14.

[*] E-mail: si-hai.mai@sncf.fr

Abstract: In this paper, an explicit dynamic finite element model is introduced to simulate the impact of a wheelset on a rail joint. The rolling of the wheelset, the bending of the rail, the friction between the wheel and the rail and the elastoplastic materials are taken into account. The model provides vertical dynamic contact forces between the wheel and the rail, the stress field and the plastic deformations. The influence of different parameters, such as the train speed and the rail material model, is investigated.

Keywords: 3D wheel/rail contact; impact; explicit finite element (FE) method; bolted rail joint; elastoplastic.

1. Introduction

In the railway infrastructure, rail joints connect two rail ends to achieve geometric and mechanical requirements of rails. When the train runs over the rail joints, large dynamic impact forces are developed. The dynamic wheel/rail contact forces can be several times greater than the static force. Those dynamic forces can cause damage and fracture of different railway components.

In the design of railway system, the actual stresses in the various components of the track and the rolling stock must be determined from the dynamic forces imposed by designed moving vehicles. The general method used in the determination of the design vertical wheel load P_{dyn} is to empirically express it as a function of the static wheel load P_{sta}, i.e.

$$P_{dyn} = \alpha_{dyn} P_{sta} \quad (1)$$

The expression used for calculating the dynamic factor α_{dyn} is determined empirically and is always expressed in terms of train speed. This dynamic factor depends on the train speed and the properties and qualities of the train and the track. Some recommended relations [1] for this dynamic factor are summarized in the Table 1.

Table 1 *recommended relations for dynamic factor [1].*

Relation	Recommender
$\alpha_{dyn} = 1 + 5.21\frac{V}{D}$	AREA (1974)
$\alpha_{dyn} = (1 + 3.86 \times 10^{-5} V^2)^{2/3}$	WMATA (1974)
$\alpha_{dyn} = 1 + \alpha' + \beta' + \gamma'$	ORE (1965)
$\alpha_{dyn} = 1 + \frac{V}{58.14\sqrt{K_{track}}}$	Indian Railways (1974)
$\alpha_{dyn} = 1 + 4.92\frac{V}{D}$	South African (1974)

V = Vehicle speed [km/h], D = wheel diameter [mm]

K_{track} = track modulus [MPa]

α' = coefficient depending on the vehicle speed, the suspension of the vehicle and the level of the track. For the most unfavorable case: $\alpha' = 0.04\ (V/100)^3$.

β' = coefficient depending on the vehicle speed, the superelevation deficiency and the center of gravity of the vehicle. Birmann states that $\beta' = 0.13 \div 0.17$ for the SNCF operating conditions.

γ' = coefficient depending on the vehicle speed, the age of the track, the possibility of hanging sleepers, the vehicle design and the maintenance conditions of the locomotive.

AREA = American Railroad Engineering Association

WMATA = Washington Metropolitan Transit Authority

ORE = Office of Research and Experiments of the International Union of Railways

The empirical dynamic factor proposed in the Table 1 can be used in general case for the design vertical wheel load without considering a particular irregularity.

Field and laboratory studies have been conducted to estimate applied dynamic force on the rail when wheel runs over a rail joint area [2-5, 9]. Figure 1 shows a typical result.

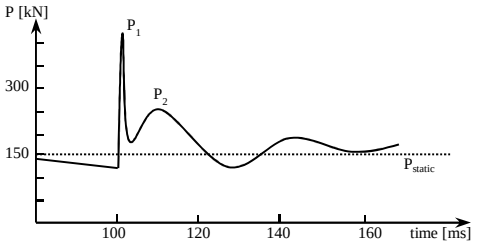

Figure 1: *Dynamic forces when a joint is passed [5].*

Two impact forces are observed (P_1 and P_2 forces). The P_1 force is a short-duration high frequency force (>500Hz). It is associated mainly to the battering of the unsprung mass on the rail end and is absorbed mainly by the rail and sleeper inertias. Its effects are largely limited to rail surface failure. This force peak occurs 0.25-0.5ms after crossing the joint [2]. The P_2 force occurs several milliseconds after the impact and lasts for a longer period. Contrary to the P_1 force, the P_2 force (medium frequency, 30 ÷ 90 Hz) is associated to the rail bending and it is transmitted to the ballast. It causes sleeper breakage and ballast degradation. For this reason, the P_2 force is of great interest to the railway operators.

Jenkins et al. [2] investigated the influence of various parameters on the level of P_1 and P_2 over three years of field tests. They proposed the following equations to calculate dynamic contact forces:

$$P_1 = P_0 + 2\alpha V\sqrt{\frac{K_H m_e}{1+m_e/m_u}} \quad (2)$$

$$P_2 = P_0 + 2\alpha V\sqrt{\frac{m_u}{m_u+m_t}}\left[1-\frac{c_t\pi}{4K_t(m_u+m_t)}\right]\sqrt{K_t m_u} \quad (3)$$

In which:

P_0 : static wheel rail contact force [kN]
2α : total dip angle at joint [rad]
V : train speed [m/s]
K_H : linearized Hertzian contact stiffness [N/m]
m_e : effective track mass for P_1 calculation [kg]
m_u : unsprung mass [kg]
m_t : equivalent track mass for P_2 calculation [kg]
K_t : equivalent track stiffness [N/m]
c_t : equivalent track damping [Ns/m]

Different numerical models are proposed in the literature for estimating the wheel rail dynamic contact force when a train runs over a joint. The first category concerns two-dimensional (2D) vehicle-track coupling models [6-9] (figure 2).

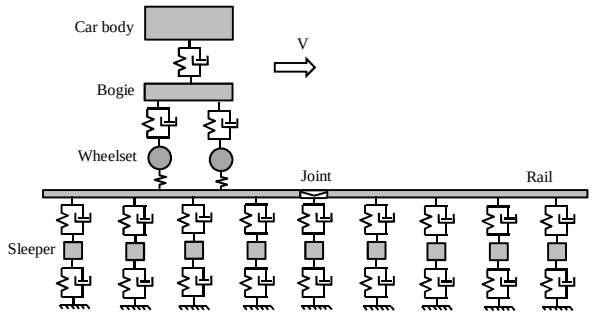

Figure 2: *An example of 2D vehicle track vertical interaction model.*

For 2D models, the track system is modeled as a finite length beam (rail) resting on one foundation with one [6], two [7-8] or three [9] discrete viscous-elastic layers. The vehicle is represented through mass-spring-damper system with one bogie and one haft car body [7-8] (figure 2) or two bogies [9]. These subsystems (track and vehicle) are solved independently and coupled together by the Hertzian wheel/rail contact model. The joint fishplates contribution to the local stiffness can be modeled by using beam elements connected to the rail by springs [7]. A second order polynomial [8] can be used to model the irregularity due to the rail joint.

Using the 2D models, different parametric studies have been carried out [8-9]. Two impact forces (P_1 and P_2 forces) were well reproduced by simulations. Some conclusions from those parametric studies are summarized below:

- The impact forces (P_1 and P_2 forces) increase dramatically when the train speed increases. Those forces depend also on the actual shape of the rail joint (the joint dip angle).
- The P_1 force is influenced by the wheelset mass, the railpad stiffness, the rail mass and the joint angle [8].
- The P_2 force is affected by the wheelset mass, the railpad stiffness, the support stiffness and the joint angle [8].
- The increase in P_2 force is more pronounced than in the P_1 force when the wheelset mass increases. The value of the P_2 force exceeds that of the P_1 force when the wheelset mass is greater than 5000 kg [9].
- The impact forces (P_1 and P_2 forces) are almost constant when railpad stiffness value is between 0.1 and 50 MN/m (most commercial railpad stiffness values ranging from 20 to 300 MN/m). When the railpad stiffness value is greater than 50 MN/m, both impact forces increase rapidly with increasing railpad stiffness value [9].

The advantage of 2D models is the simplicity and the low computing time. However, those models can not consider the following phenomena:

- The real 3D wheel and rail profiles and the elasto-plastic wheel rail contact,
- The real contribution of the fishplates in local track stiffness and the frictional contact between the fishplates and the rail,
- The bolt tightness condition.

In order to more realistically model the wheel rail contact at the joint, 3D finite element (FE) models must be used [10-12].

Wen et al. [10] developed a 3D FE model using ANSYS/LS-DYNA software where the wheel, the rail and the fishplates are modeled by solid elements using their real geometry (figure 3a). Their model considered the gap as well as the contact between the rail and the fishplates, but excluded the holes on the rail. The fastening, the sleepers and the ballast were simplified to an equivalent support (only springs, no dampers). The bolt pretension caused by the tightening of the bolt was applied on the bolt hole position of the fishplates. A bilinear elastic-plastic constitutive material model with kinematic strain hardening was used for the rail and the wheel. Sensitivity studies were conducted using the model to determine the effects of axle load and train speed on dynamic vertical forces, stresses and strains distributions in the railhead. Higher dynamic forces, stresses and strains were obtained when increasing axle load or train speed, but the influence of the speed was weak.

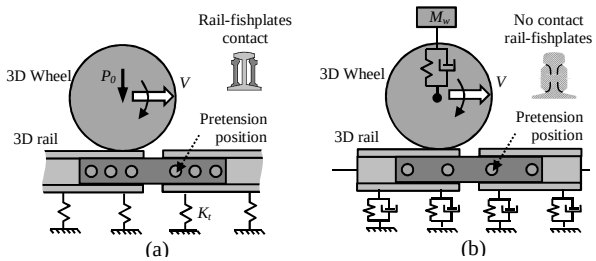

Figure 3: *Wen's (a) [10] and Pang's (b) [11] 3D FE models.*

Pang and Dhanasekar (figure 3b) modeled a whole joint with an explicit integration scheme using the software ABAQUS Explicit to account for the high frequency dynamics [11]. The difference between Pang's model and Wen's model is listed below:

- Pang and Dhanasekar modeled the fastening, the sleepers and the ballast by springs and dampers, while

Wen et al. used only springs;
- The wheel is connected to a mass by one system springs-damper in Pang's model, while it is applied by a constant load in Wen's model;
- In Pang's model, the rail, the fishplates and the isolating material were modeled as one component, which means no contact was defined between them, while Wen et al. modeled the contact between the rails and the fishplates.
Pang and Dhanasekar reaffirmed the significant influence of the discontinuity on the wheel/rail contact. The impact factor was determined to be around 1.2 for the type of problem investigated. They showed that not only the pressure distribution, but also the contact patch size and the maximum contact pressure differed from Hetzian solution.

Oregui [12] proposed a 3D FE model using ABAQUS Explicit which is similar to Pang's model. However, Oregui modeled the track using two springs-dampers layers: railpads and ballast (figure 4). The sleepers were modeled with their real 3D geometry using solid elements. The measured rail vertical geometry was taken into account and the contact between the rails and sleepers was defined.

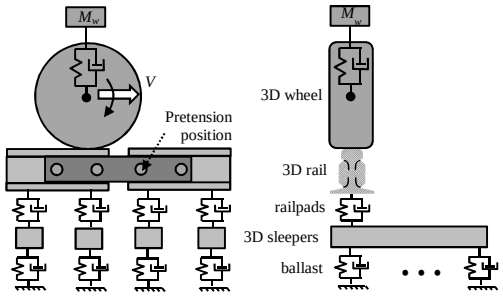

Figure 4: *Oregui's [12] 3D FE models.*

Oregui et al. validated their model between 150 and 800 Hz with measured axle box accelerations of resilient wheels. This validated model was used for studying the influence of the train speed and the bolt tightness on the wheel/rail contact force. They concluded that both train speed and bolt tightness had strong influence.

In this paper, an explicit dynamic finite element model is introduced to simulate the impact of a wheelset on a rail joint. Firstly, the mesh is performed by the software CAST3M. Then, the software EUROPLEXUS is employed to simulate the rolling of the wheelset on the bolted rail joint.

In our model, the rolling of the wheelset, the bending of the rail, the friction between the wheel and the rail and the elastoplastic materials are taken into account. The model provides vertical dynamic contact forces between the wheel and the rail, the stress field and the plastic deformations. The influence of different parameters, such as the rail material model and the train speed, is investigated. The wheel-rail contact forces calculated by this model will be used as inputs for another research on fatigue and fracture of the rail joints.

2. Finite element model

The model allows to simulate the impact of a wheelset on a bolted rail joint. It includes a wheelset and a detailed track where rail, railpads, sleepers, bolts and joint bars are modeled with their real 3D geometry using solid elements.

Firstly, the mesh is performed by the software CAST3M. Then, the software EUROPLEXUS is employed to simulate the rolling of the wheelset on the bolted rail joint.

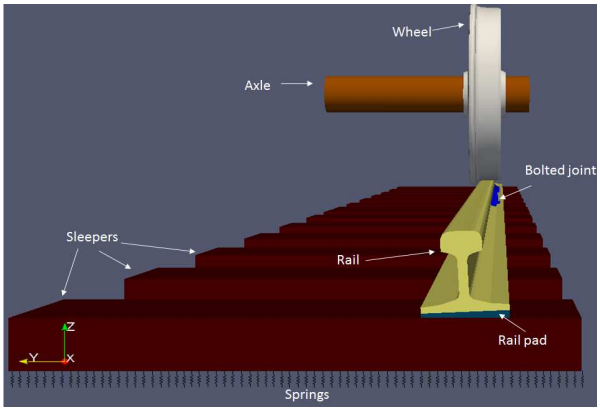

Figure 5: *Geometry-based 3D FE half-track model.*

A geometry-based 3D FE half-track model is developed (figure 5). The model is 14 sleeper bays long. This track length is sufficient for the loading cases and frequency range studied in this paper.

2.1. Rails

The rails are modeled using solid elements with heterogeneous meshes. The gap between the rail ends is included. In order to reduce the computational time, small size elements are only used in particular areas: the rail tops beside the gap (figure 6). The smallest element is about 1mm. Absorbed elements are employed to avoid wave reflection at the rail ends.

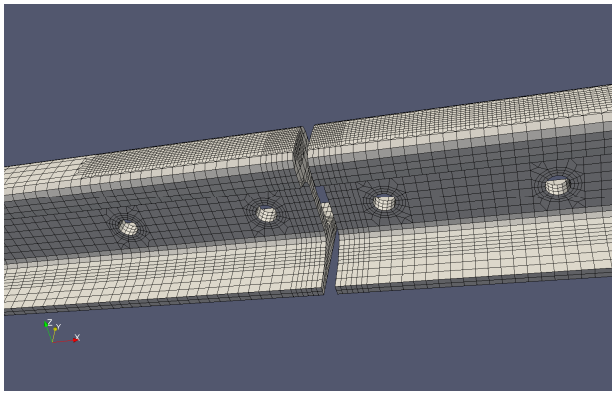

Figure 6: *Mesh of the rail.*

The profile of the rails is UIC60 (60 kg/m), with 1/20 inclination. The rail model accounts for plastic deformation and kinematic hardening with a bilinear elastoplastic material.

2.2. Joint bars and bolts

Two joint bars and four bolts are modeled using solid elements with elastic materials. The length of the joint bars is 600 mm. The mesh of the joint bars is compatible with the mesh of the rails (same number of nodes at the contact surfaces).

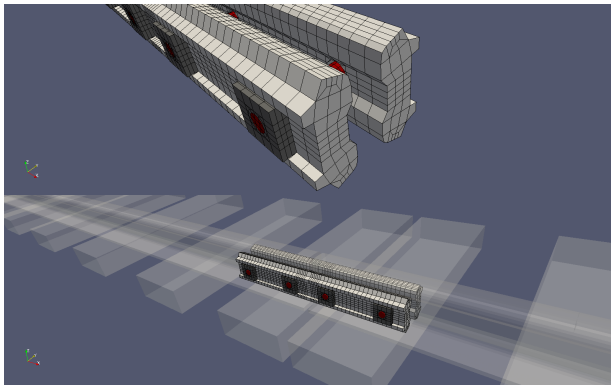

Figure 7: *Mesh of the joint bars and bolts.*

In this paper, the joint bars are glued to the rails. This means that there is no relative movement between the joint bars and the rails.

2.3. Railpads, sleepers and ballast

The railpads and the monoblock sleepers are modeled with solid elements according to their respective nominal geometry (figure 8). The sleepers are defined as elastic material which is considered suitable for the loads investigated [13-14]. The size of one haft-sleeper is 100x250x900 mm. Its mass is about 57kg (concrete sleeper). The distance between two normal sleepers is 600 mm. The distance between two sleepers next to the gap is 290 mm.

The railpads are also defined as elastic material. Damper elements are used to model the damping of the railpads.

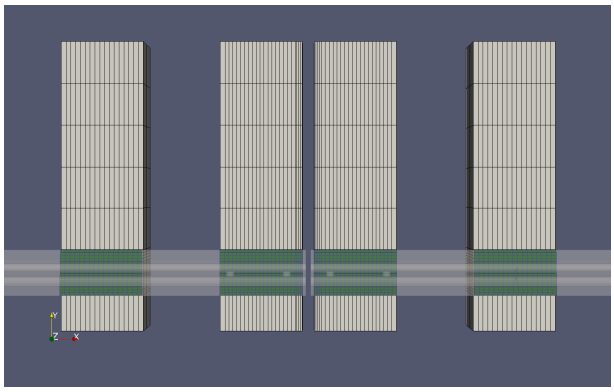

Figure 8: *Mesh of the railpads and sleepers.*

In this paper, the railpads are glued to the rails and the sleepers (no relative movements). The mesh of the railpads is compatible with the mesh of the rails and the sleepers (figure 9).

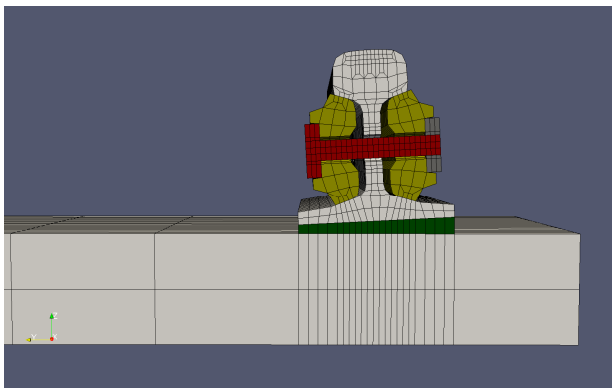

Figure 9: *Mesh of the track with bolted rail joint.*

The ballast is modelled with multiple pairs of one linear spring and one viscous damper. The spring-damper pairs are defined homogeneously under the sleepers. With the software EUROPLEXUS, the elements of type APPUI (material points with 6 degrees of freedom) are used to model the ballast. We can give the evolution curve of force applied by the support as a function of its displacement (for the springs) or of its velocity (for the dampers).

The sub-ballast and foundation layers are not considered because they contribute to dynamic response of the track for frequencies lower than 50 Hz [13], whereas in this paper the frequency range of interest is greater than 250 Hz.

2.4. Wheelset

One haft of the wheelset is modeled using solid elements (figure 10).

The profile of the wheel is S1002. The nominal rolling radius of the wheel is R = 460 mm. The wheel model accounts for plastic deformation and kinematic hardening with a bilinear elastoplastic material.

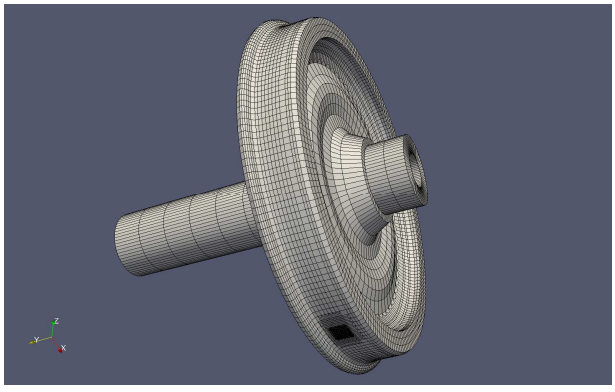

Figure 10*: Mesh of the wheelset.*

The mass of the haft-wheelset (wheel and axle) in our model is about 845 kg. Symmetrical condition in lateral direction is applied at one end of the axle. A vertical load of 100 kN is applied at the other end of the axle.

3. Numerical simulations and results

The explicit finite element codes EUROPLEXUS (http://europlexus.jrc.ec.europa.eu/) is used for simulating the impact between the wheelset and the bolted rail joint. This software allows performing nonlinear transient dynamic analysis of three-dimensional structures.

EUROPLEXUS uses the explicit central difference scheme to integrate the equations of motion. It is conditionally stable. So the time step size needs to satisfy the following condition:

$$\Delta t \leq \frac{L}{c} = \frac{L\sqrt{\rho}}{\sqrt{E}} \quad (4)$$

Where L is the minimum element length, c is the velocity of wave propagation, E is the Young's modulus and ρ is the density of the material.

In our model, the time step is about 1E-7 seconds. This means that we need 200000 time steps for simulating 20 milliseconds or 1 meter of movement at train speed of 180 km/h.

In this paper, we are only interested in the vertical wheel/rail contact force when the wheelset runs over the bolted rail joint. Firstly, a quasi-static step is performed to put the wheel and the rail in contact. An initial deformed stationary state is established. Then, the wheelset is moving with a constant velocity from the left side of the gap to the right side of the gap (figure 11).

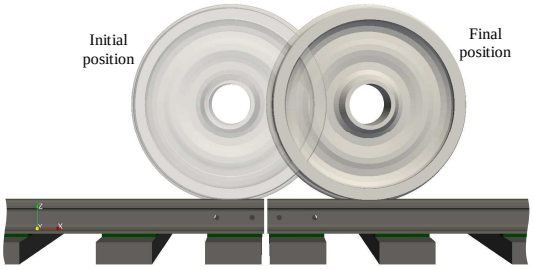

***Figure 11**: Positions of the wheelset on the track.*

The method of Lagrange multipliers is employed for solving the contact between the wheel and the rail. This method allows to couple the computation of contact forces with the permanent connections (relations, boundary conditions …). The material parameters are summarized in the Table 2.

***Table 2** Material data.*

Component	Parameter	[ ]	Value
Wheel and rail	Young's modulus Poisson's ratio Density Yield stress	GPa - kg/m^3 MPa	200 0.3 7829 800
Axle and joint (bars, bolts)	Young's modulus Poisson's ratio Density	GPa - kg/m^3	200 0.3 7829
Railpad	Young's modulus Poisson's ratio Density Damping	GPa - kg/m^3 kNs/m	14E-3 0.45 1000 0.1
Sleeper (concrete)	Young's modulus Poisson's ratio Density	GPa - kg/m^3	20 0.2 2500
Ballast	Stiffness Damping	MN/m kNs/m	50 5 ÷ 50

The vertical dynamic wheel/rail contact force calculated using the model presented previously was saved for each 10^{-5} seconds ($f = 10^5$ Hz). However, the 2-order Butterworth low pass filter (available in the software MATLAB) with different cut-off frequency (f_c) was used in order to better represent the results for frequency bands of interest. The figure 12 shows the vertical wheel/rail contact force when the wheelset runs over the rail joint at 36 km/h. The light gray curve corresponds to the result without using the low pass filter and the blue one is the result using the low pass filter with the cut-off frequency of 1500 Hz.

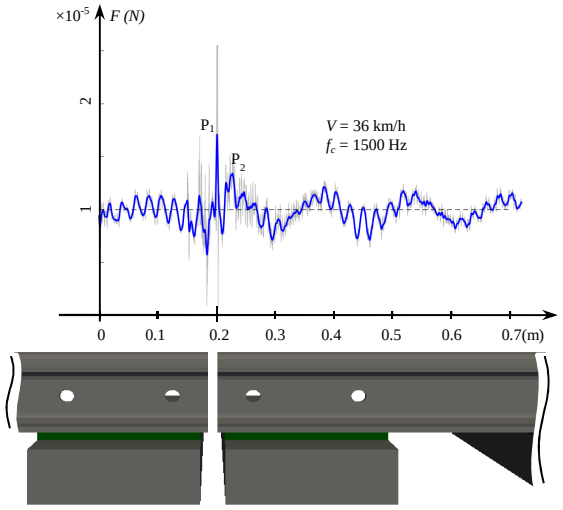

***Figure 12**: Vertical wheel/rail contact force vs. wheel position.*

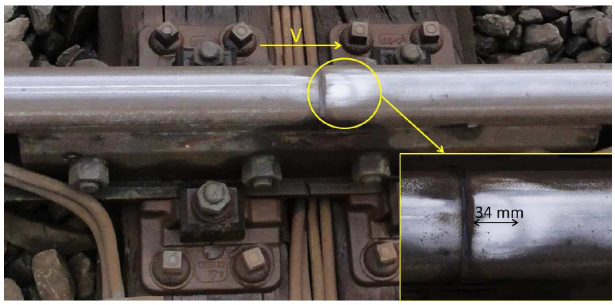
The general shape with two impact forces (P_1 and P_2 forces) is well reproduced by simulations (comparison between the figure 1 and the figure 12). The plastic deformation observed at the rail end (figure 13) caused by high amplitude impact force P_1 is also obtained by simulation (figure 14).



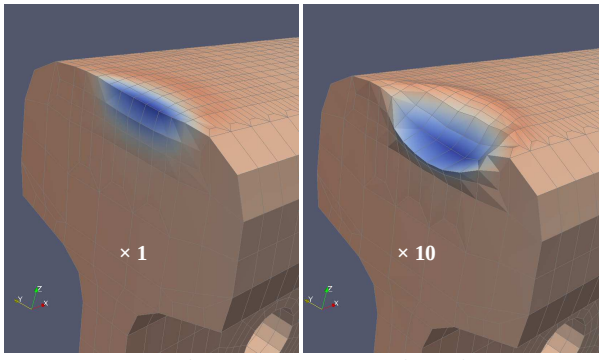


***Figure 13**: An insulated rail joint with plastic deformation [13].*

(a) Real scale deformation *(b) Amplified deformation (x10)*

***Figure 14**: Simulated plastic deformation at the rail end.*

As mentioned at the beginning of this paper, the two impact forces have different characteristic: the P_1 force is a short-duration high frequency force (>500Hz) and is absorbed mainly by the rail; the P_2 is a medium frequency force (<200Hz) and is transmitted to the ballast. To facilitate the analyses, we propose to use three different following cut-off frequencies (f_c) for the Butterworth filter (figure 15):

- Before hitting the gap: f_c = 1000 Hz;
- During the P_1 force duration: f_c = 1500 Hz;
- After the P_1 force duration: f_c = 200 Hz;

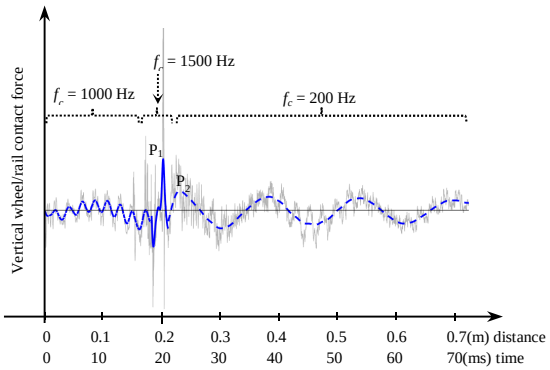

***Figure 15**: Different cut-off frequencies.*

The influence of the train speed and the rail material model on the vertical wheel/rail contact force has been investigated by using the model proposed. The results are presented in the following sections.

3.1. Effect of train speed

Figure 16 shows the effect of the train speed on the vertical wheel/rail contact force.

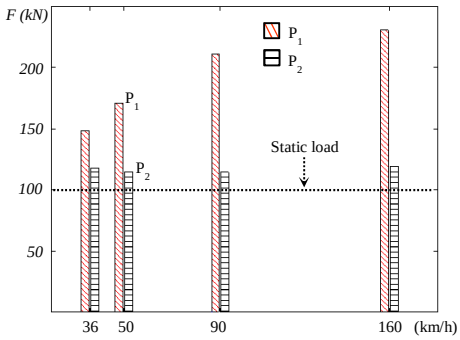

***Figure 16**: Vertical wheel/rail contact force vs. speed.*

The result indicates that the P_1 force increases as the speed of the train increases while the P_2 force is insensitive to speed. The dynamic factor for the P_2 force is about 1.2. The weak dependence of the impact forces on the speed of the train can be explained by the fact that the rail end at the joint in our actual model is smooth. The effect of train speed will probably be more noticeable when the real rail vertical geometry around the rail ends is considered [10, 12].

The position of the impact forces on the rail for different speeds of the train is showed in the figure 17. The P_1 force occurs at the rail end. The P_2 force occurs about 4 milliseconds after the P_1 force which corresponds to 40 mm for a train speed of 36 km/h and about 180 mm for a train speed of 160 km/h.

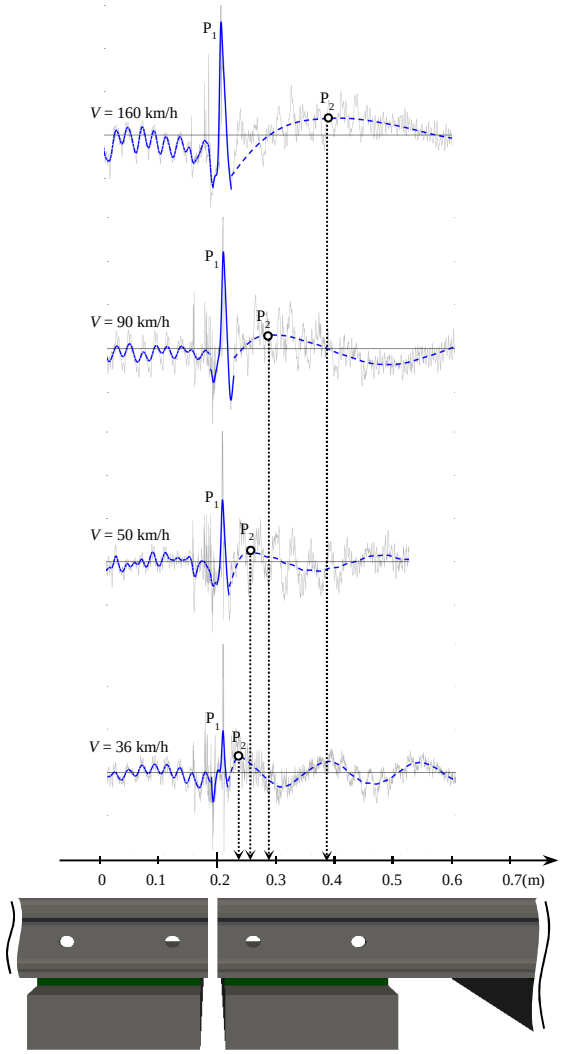

***Figure 17**: Position of the impact forces (P_1, P_2) on the rail.*

3.2. Effect of rail material model

As mentioned in the introduction, the 2D models using Hertzian wheel/rail contact model cannot consider the real 3D contact with elastoplastic material. In this section, we use our 3D FE model to study the difference between one simulation using wheel and rail elastic material and one simulation using wheel and rail bilinear kinematic elastoplastic material with yield stress of 800 MPa. The results obtained are showed in the figure 18.

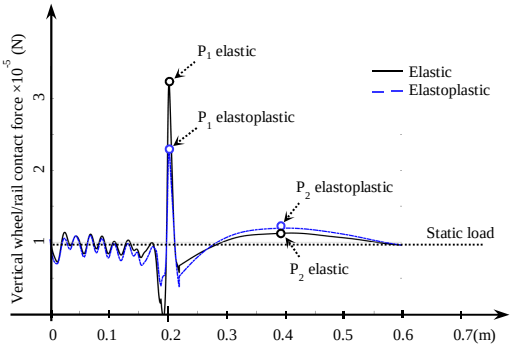

***Figure 18**: Influence of rail material models.*

The figure 18 indicates that the P_1 force obtained with the elastic rail model (323 kN) is 40% higher than that with the elastoplastic rail model (231 kN), while the P_2 force is almost the same between two models (5% difference). This means that 2D models with elastic Hertzian contact can be used to study the behavior of the substructure (P_2 dominant contribution). However, 3D elastoplastic wheel/rail contact must be used when studying the behaviour (wear, fatigue, fracture…) of the rail.

4. Conclusions

In this paper, an explicit dynamic finite element model was introduced to simulate the impact of a wheelset on a rail joint. The model reproduced well the plastic deformation of the rail end. The vertical dynamic contact forces between the wheel and the rail was investigated. By using the 2-order Butterworth low pass filter with different cut-off frequencies, two impact forces (P_1 and P_2 forces) were well observed. Finally, the influence of different parameters, such as the rail material model and the train speed, was investigated. The numerical results are summarized below:

- The result indicates that the P_1 force increases as the speed of the train increases while the P_2 force is insensitive to speed. The dynamic factor for the P_2 force is about 1.2. The weak dependence of the impact forces on the speed of the train can be explained by the fact that the rail end at the joint in our actual model is smooth (small dip angle).
- The 2D elastic Hertzian contact models can be used to study the behaviour of the substructure (P_2 dominant contribution). However, the 3D elastoplastic wheel/rail contact models must be used when studying the behaviour (wear, fatigue, fracture…) of the rail (P_1 dominant contribution).

For future work, the following tasks will be studied:

- Taking into account the real vertical rail end geometry.
- Considering the frequency-dependent stiffness of railpad: In the actual model, a constant stiffness of the railpad is used. However, some experimental tests performed at SNCF showed that the stiffness of the railpad is dependent on the frequency of the solicitation.
- Studying the influence of other parameters such as the stiffness of the railpad, the stiffness of the ballast, the bolt tightness, the length of the fishplate (4 and 6 holes), the unsprung mass and the mass of sleeper (wooden and concrete sleepers).
- Using the dynamic forces calculated by this 3D explicit FE model as inputs for another research on fatigue and fracture of the rail joints.

Acknowledgments

The author gratefully acknowledges Professor Anthony GRAVOUIL for his prestige advice and SNCF Innovation & Research for the financial support. Many thank also goes to Pierre MATRAY and Joao ARRUDA for their contribution to the development of numerical models.

Abstract: A 3D FEA is carried out to investigate stress and strain conditions of joint bars of insulated rail joints considering vertical wheel/rail cyclic impact loadings. The Australian Standard design is used to model the insulated rail joints and associated bars. The von-Mises stresses at the critical locations of the joint bars are presented. Although the stress conditions are in the elastic range, early failure of joint bars is expected due to fatigue effects. Stress based fatigue life models are compared and assessed to identify a model that simulates closely the real fatigue life of the existing joint bars. That model can then be used to examine possible geometric design changes to joint bars that are considered to have potential to improve their stress conditions to avoid failures.

Keywords: Rail joints, Joint bars; Wheel/rail contact conditions; Stress analysis; FE method; Fatigue life; Joint bar failures.

1. Introduction

The structural integrity of insulated rail joints (IRJs) is very important to efficient railway operations and safety. Joint bars (fishplates) are used to obtain bending stiffness at the rail ends. IRJs are considered the weakest links in the railway track as they can provide only 2/3 the bending rigidity of the continuous rail.

Because of the lesser bending strength of the joint compared to that of continuous rail, various problems can occur. These include:

- Life: 12-18 months, 10 times less than for rail.
- Chipping out of railhead material because of severe rail surface permanent plastic deformation increases dynamic impact loads, hastening failure of joint bars.
- Narrowing of rail end gap because of permanent material damage can compromise track circuit insulation.
- Costs: replacement costs in the USA of $625/km/year, 50% of rail replacement in China is because of rail joints.

When joint bars fail (Figure 1), it can lead to derailments [1]. In December 2015, 31,000 litres of sulphuric acid leaked to the environment near Julia Creek, North Queensland, Australia because of the problems of insulated rail joints. A safe and efficient railway network can produce huge economic benefits. In Australia, freight transport earned $8.2 billion and passenger transport $8.8 billion in 2014-15.

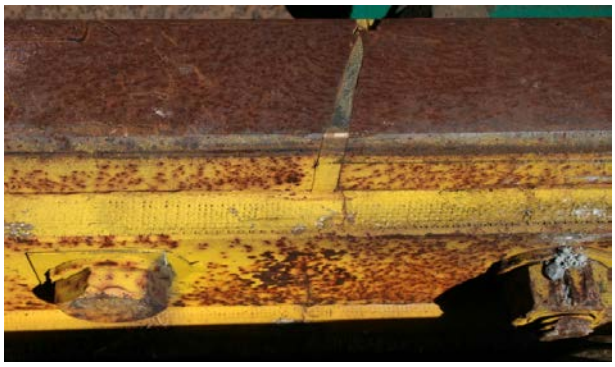

Figure 1: Failure of joint bars of insulated rail joints

Many research projects have been conducted focussing on dynamics and material damage of IRJs. The effects of track and vehicle parameters on wheel/rail vertical dynamics forces were estimated empirically as early as 1974 [2, 3]. Those authors formulated *P1* and *P2* forces in their study. A detailed discussion on this follows in the next section. Subsequently, stress analysis of railhead material in the vicinity of the IRJs yielded much attention targeting on railhead edges [4~7], sensitivity of endpost material and thickness [8, 9], special design, reinforcement and railhead material improvements [10~12], transient contact solutions with noise and vibration [13-14], and load effects [15~17].

Some limited research has also been carried out at the John A. Volpe National Transportation Systems Centre and the Transportation Technology Center Inc. (TTCI) targeting problems in joint bars in the USA. It focuses on joint bar fatigue life using Miner's law [1, 18, 19] and using residual stresses [20], detecting joint bar cracks [21, 22], and the anatomy of joint bar failure [23~26].

This literature suggests that adequate research on joint bar failure had not been carried out. A detailed stress distribution due to applied bolt loads and cyclic vertical wheel loads is necessary to demonstrate a fatigue failure strategy. It is also necessary to determine the critical

stress component that is responsible for fatigue crack initiation. The simulation results can be used to estimate fatigue life of joints due to cyclic wheel loads applied vertically on the IRJs using Miner's law as fatigue failure may happen because of stress variations.

2. Theory

IRJs have many parts and joint bars are rigidly connected to the rail web (Figure 1) with various numbers of bolts depending upon particular designs, but 6 bolts are usual in Australia. The wheel load is applied on the railhead and then it is transferred to the joint bars though the bolts. The thermal loads (axial) on rails also transfer to the joint bar through the bolts. The load transfer to joint bars is based on moments and its theoretical aspects are discussed in the next subsection. However, due to wheel impact at IRJs, related contact impact forces are illustrated first.

There are two types of contact impact forces that occur in wheel/rail interactions at dipped rail joints. They are referred to as P_1 and P_2 forces. The time history of wheel impact force exhibits a high frequency force P_1 immediately after the impact known as the short peak force, followed by a low frequency force P_2 of reduced magnitude known as the delayed peak force as shown in Figure 2. The equations of P_1 and P_2 forces are presented empirically by many authors [1~3] incorporating static wheel load, unsprung mass, Hertzian wheel/rail contact stiffness, vehicle speed, equivalent track system parameters, joint angles etc. The P_1 force remains only for a very short duration whilst the P_2 force acts for a relatively longer duration. As such, the P_1 force potentially damages the local contact region of the wheel tread and railhead whilst the P_2 force has the potential to damage most wagon and track components located in the vicinity of the contact zone. Both types of peak force are therefore of significance.

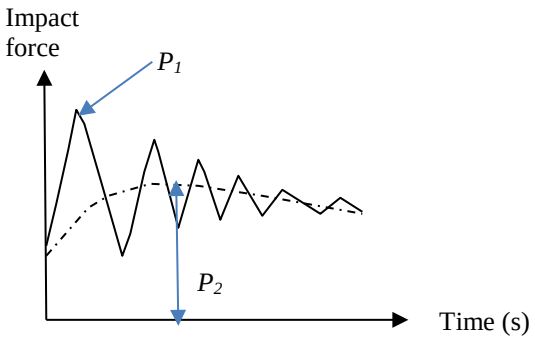

Figure 2: Impact forces are rail joints

2.1. Beam on elastic foundation theory

The rail bending due to vertical wheel load on rail can be formulated classically by the beam on elastic foundation theory – it is quite old but still valid for analysis (Figure 3).

The deflection of rail due to the vertical wheel load has a direct influence on rail's flexural rigidity EI_r and the deflection curve can be presented as [27]

$$EI_r \frac{d^y y}{dx^4} = -ky \tag{1}$$

where k is the foundation modulus, E is the modulus of elasticity of the rail steel and Ir is the rail vertical bending inertia. For an infinite long rail with P acting in the vertical plane, the deflection curve can be estimated as a simple case as [1]

$$y = \frac{\lambda P_0}{2k} e^{-\lambda x}(\cos \lambda x + \sin \lambda x) \tag{2}$$

where the factor λ can be defined as $\sqrt[4]{\frac{k}{4EI_r}}$.

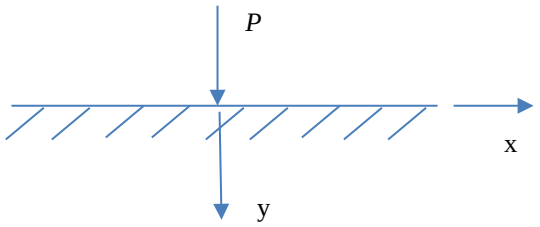

Figure 3: Rail on elastic foundation model with P the wheel load

For continuous rail using the infinite beam on elastic foundation theory, the longitudinal bending moment distribution is calculated as

$$M_r(x) = \frac{P}{4\lambda} e^{-\lambda x}(\cos \lambda x + \sin \lambda x) \tag{3}$$

The dynamic wheel load P can be the P_2 force for the track and the bending moment on the rail will be maximum at x=0 and can be formulated as

$$M_r(0) = \frac{P_2}{4\lambda} \tag{4}$$

Transfer of bending moment onto joint bars can also be calculated by considering that joint bars behave as a beam in bending. It is assumed that the joint bars are to carry a fraction of the bending moment in a continuous rail. It was pointed out before that the bending rigidity of two joint bars are about 2/3 that of the continuous rail. This fraction is called the joint efficiency factor, ξ and its value can be calculated by laboratory or field test data. It is also dependent on the conditions of the joint, i.e., looseness of the joints. For a new joint, ξ varies from 0.6 to 0.8 [2]. The theoretical maximum joint efficiency factor, ξ is therefore

$$\xi_{\max} = \left(\frac{M_j}{M_r}\right)_{\max} = \sqrt[4]{\frac{I_j}{I_r}} \tag{5}$$

where I_j is the vertical bending inertia of joint bars. The looseness of rail joint influences the integrity and health of the joint. It is related to the tension of the bolts applied by the torque wrench. For a new rail joint, the tension of the bolts is about 200kN [15]. The effect of the looseness of the joint is not examined here. A separate paper will be prepared on this issue.

The bending moment carried by the joint bars, M_j is assumed to be

$$M_j = \xi M_r = \xi \frac{P_2}{4\lambda} \quad (6)$$

Using the classical bending theory, the flexural or bending stresses can be calculated accordingly at the top and bottom of the joint bars. The maximum bending stress at the top of the bars is compressive and it is formulated as

$$\sigma_j = \frac{M_j c_j}{I_j} \quad (7)$$

where c_j is the distance of the top of the joint bar from its neutral axis. The tensile bending stress at the bottom of the bars can be calculated by putting c_j as the distance from the bottom to the neutral axis of the joint bars.

2.2. Fatigue life of joint bars

The Miner's law for fatigue life is used here to express the mathematical formulation of fatigue life of joint bar due to cyclic wheel loadings on railhead. A local plastic zone is created at the wheel/rail contact zone. Therefore, stress level in the joint bars is elastic and the Miner's law is valid to calculate the fatigue life. The Miner's law is expressed [1] as

$$N = N_0 \left\{ \frac{\sigma_0(\sigma_u - \sigma_m)}{\sigma_u \sigma_a} \right\}^{1/z} \quad (8)$$

Where N is the fatigue life in cycles, N_0 is the infinite fatigue life, σ_0 is the endurance limit, σ_u is the ultimate strength of the joint bar steel, σ_m and σ_a are the mean and alternating stress components in joint bars respectively and z is equal to 0.14 [1]. The mean and alternating components of stress in joint bars are calculated as

$$\sigma_m = \frac{1}{2}(\sigma_{\max} + \sigma_{\min}) \quad (9)$$

$$\sigma_a = \frac{1}{2}(\sigma_{\max} - \sigma_{\min}) \quad (10)$$

3. Finite element modelling

A 3D finite element analysis was carried out to simulate the actual performance of IRJs (Figure 1) in a heavy haul coal network in Queensland, Australia. ABAQUS code was used for this purpose.

Figure 4 shows a part of the FEA model of the IRJ shown in Figure 1. Total length of the IRJ model considered for this study is 12m. Out of the 12m, a 2.4m length is a solid rail model as per Australian Standard 1085.12 with a 1/20 rail cant profile. Two 4.8m long beam models (not shown) are connected to the ends of the solid model by equation constraints in ABAQUS to ensure zero displacement and rotation of beams and rail relative to one another. This ensures all six DOFs are transferred from the solid rail model to the beam models. Other parameters are: 5mm endpost thickness, 6 bolt joint plates, IRJ is centrally suspended between two adjacent sleepers, 0.7m centre to centre sleeper spacing. Figure 5 shows the 174kN wheel loading in pressure form on the IRJ. ABAQUS's part and section modules are used to construct the IRJ model and apply homogeneous section and elastic plastic material properties respectively. The top critical area of the head of the rail (dark part of Figure 4) is defined with high mesh density so as to account for elastic-plastic material deformation. The high mesh density part is created separately and connected to the remaining part of the IRJ model by tie constraints. The other part of the IRJ model is elastic. Table 1 presents the elastic material properties and Table 2 the elastic-plastic material properties. Elastic properties include Young's Modulus and Poisson's Ratio of the solid rail material and the fiberglass endpost materials. The elastic-plastic material properties include material and hardening parameters. The definitions of all parameters are: σ_y is the yield strength of rail steel, K_∞ is the maximum change in size of the yield surface, γ is the rate at which the kinematic hardening modulus decreases with the increase of plastic deformation, b' is the rate at which the size of the yield surface changes as plastic straining develops and c is the kinematic hardening modulus. The material modelling parameters have been published previously [17].

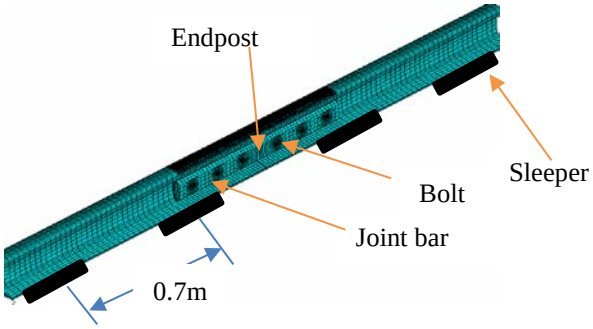

Figure 4: FEA model of IRJ (sleepers not shown)

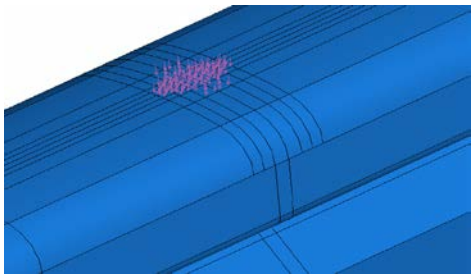

Figure 5: Pressure loading on rail end of IRJ model

Table 1: Elastic material properties

Name	E (MPa)	Poisson's ratio
Rail steel	207000	0.3
Fibre-glass	4500	0.19

Table 2: Elastic-plastic material properties

σ_y (MPa)	K_∞ (MPa)	b'	C (MPa)	γ
780	152	3.97	393000	8.3

There are three steps considered: an initial step for boundary conditions, step 2 for bolt load and step 3 for wheel load. The bolt load *Pb* can be calculated from the bolt torque *T*, the bolt diameter *D* and a coefficient *Kb* (0.19-0.25) [17]. The bolt load of 200 kN was calculated from *T* = 1050 Nm, *D* = 24 mm, and *Kb* = 0.22 as per the standard set by the IRJ manufacturer Thermit Australia. In step 3, a static wheel load of 150kN was considered. Incorporating a dynamic load factor of 1.16, a dynamic wheel load of 174 kN was applied in pressure form. The impact factor of 1.16 was determined based on a dynamic analysis [3] of IRJs employing a dipped joint. Stepwise pressure intensities are applied to the corresponding areas of contact in the contact zone to produce the total force of 174kN. The magnitude of the wheel impact load varies vertically from 0 kN to 174kN cyclically. Three steps pressure of 2500MPa, 610MPa and 73MPa are considered in the both the longitudinal and lateral directions of the contact patch.

In the mesh model, the structural meshing technique is used. An eight node fully integrated trilinear brick element (C3D8) is used for all parts in the solid rail model. The job module is used to complete the simulation statically. The resulting odb files are considered for post-processing.

4. Results and discussion

In this paper, the mechanical behaviour of the joint bars is the main focus. Therefore, stress, deformation data are presented here for the joint bar only (Figure 6). For railhead top and sub-surface information, previous publications are useful [5, 9, 15, 17]. Although the wheel loads are applied at the top of the railhead in the vicinity of the endpost, a fraction of that load in the form of moment is passed to the joint bars. The load applied on the rail is transmitted to the joint bars though the bolts (Figure 7).

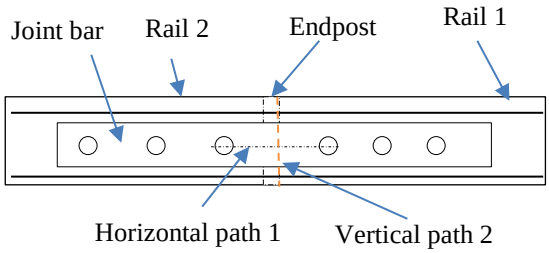

Figure 6: A simple sketch of short IRJ model showing measurement paths of joint bar section

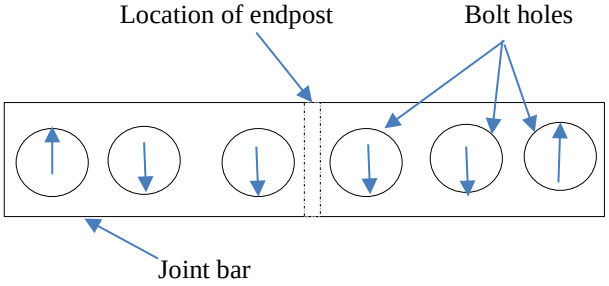

Figure 7: Applied load on joint bar holes

Directions of applied load as shown in Figure 7 and applied in the form of pressure are very typical when the wheel is on the IRJs and at the edge of the rail end.

In Figure 8, both vertical U2 and longitudinal deformation (mm) are presented considering the variation of nodal deformation along the path 1 indicated in Figure 6. It is clear that vertical deformation is maximum in the middle of the joint bar and is less at the centre of the bolts (Figure 9) because of the influence of supports of sleepers. This forms a dip (a typical bending of joint bars). Because of the dipped condition, a Poisson's effects type longitudinal deformation, U3 (deformation towards the endpost) exists (Figure 8). From this figure it is clear that U3 is positive close to one bolt centre and negative towards the other bolt centre, suggesting that it is helping to narrow the endpost gap. This is a common problem in Australia and can lead to disturbing electrical signalling systems to detect broken rails for a quick maintenance works to avoid derailments.

Figure 8 shows the cyclic variations of U2 at bolt centre and in the middle of the bar for four seconds of simulation time involving 2000 loading cycles. Both the spread and magnitude of U2 in the middle of the bar are larger. It supports a general trend of beam bending theory. It is also important to note that, when there is no load (unloading conditions), the deformation is zero. This suggests that the mechanical behaviour is fully elastic and a stress based fatigue life method (Equation 8) can be used to calculate its life.

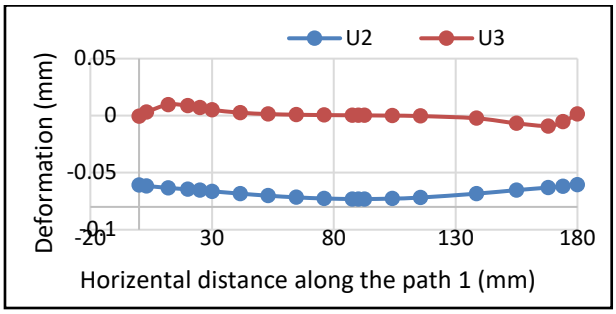

Figure 8: Vertical and longitudinal deformation along the nodal points of joint bar (path 1, Figure 6)

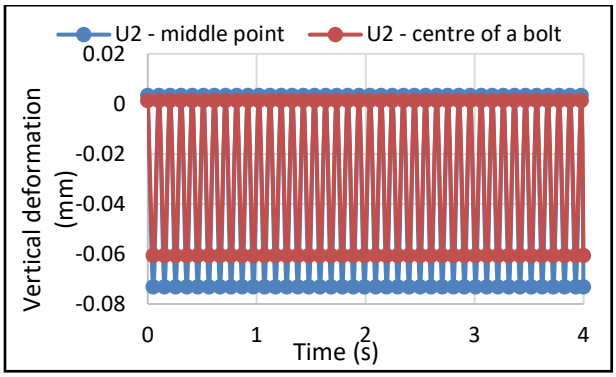

Figure 9: Vertical and longitudinal deformation from nodes at one bolt centre and at the middle of the joint bar

In addition, variations of von-Mises and vertical stresses at the bolt centre are shown in Figure 10. During the simulation time over the 2000 loading cycles, both vertical and von-Mises stresses are maintaining nearly a constant magnitude. This supports that there is no residual stresses present and the behaviour is elastic.

Figure 11 shows variations of von-Mises, vertical (S22) and longitudinal (S33) stresses along the path 1. It is clear that all the targeted stress components are significant at the bolt centre locations where wheel load is passing to the joint bars. The values are less at the middle of the joint bars.

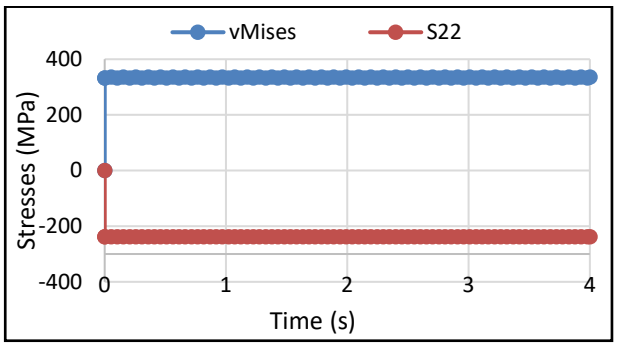

Figure 10: von-Mises and vertical stresses at the bolt centre in the vicinity of endpost

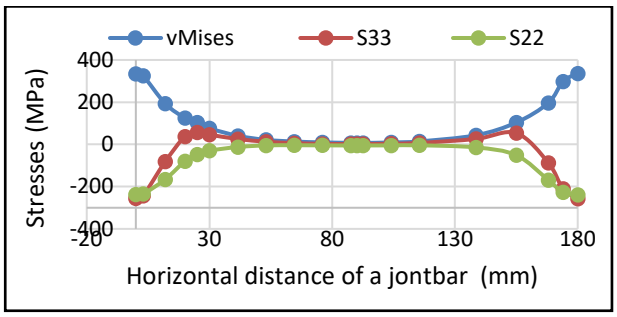

Figure 11: Variations of von-Mises, vertical (S22) and longitudinal (S33) stresses along the path 1

Another interesting observation can be pointed out from the data in Figures 12 and 13. Figure 12 shows the transverse variations of U2 and U3 through a nodal path in the vertical direction in the middle of the joint bar (path 2, Figure 6). It is seen that U3 is zero there and U2 has small magnitudes. It is also the case that there are similar trends of stress variations in the same path. As per the classical bending theory, longitudinal stress is maximum at the top and at the bottom of a beam (joint bar) section. This is evident from Figure 13. The S33 is zero in the middle (neutral axis) of the beam. Compressive and tensile bending stresses are available in the top and bottom of the joint bar respectively. This supports the general bending theory.

From these observations, it is clear that the critical locations of stress concentration are at the bolt hole centre. All the stress components such as von-Mises, S22 and S33 have significant magnitudes. It is also true that vertical deformation is larger in the middle of the bars. If we consider cyclic effects, fatigue problems can come at the bolt centre and perhaps in the middle of the bar in some extent. As a result, bolt-hole cracks and joint bar breakage due to cyclic effects are the most likely modes of failure.

As the mechanical behaviour of the joint bars are elastic, fatigue life consideration will be relating to the stress based models such as Miner's rule (Equation 8).

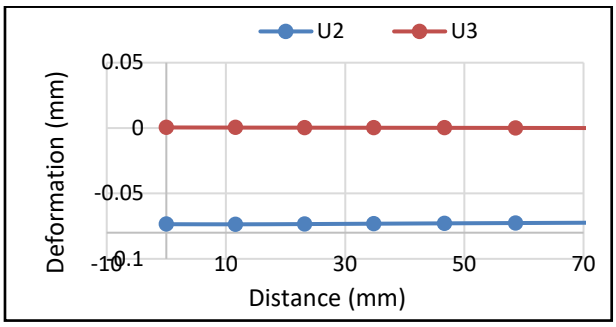

Figure 12: Transverse variations of U2 and U3 in the middle of a joint bar

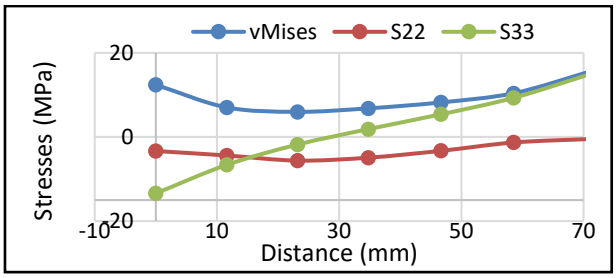

Figure 13: Transverse variations of von-Mises, S33 and S22 stresses in the middle of a joint bar

Further improvement/research on this paper can be made by applying more cyclic variation data, considering effects of different endpost materials on joint bar behaviour and undertaking calculations of fatigue life to investigate the influences of support stiffness etc.

5. Conclusions

A dynamic wheel load of 174kN in the form of pressure is applied on the crown surface of the rail top surface in the vicinity of a rail joint. The behaviour of the joint bars under this load are presented. Based on the data, the following conclusions can be made:

- Although the applied pressure is over the yield point of the rail steel, the mechanical behaviour of joint bars is fully elastic.
- Critical locations of stress concentration are the bolt hole centre through which a fraction of the applied load is passing to the bars.
- Due to the cyclic effects, if fatigue problems occur, it can be in the bolt centre, and may be in the middle of the bars.
- Bolt hole crack is the likely mode of failure.

- Due to elastic behaviour of joint bars, the fatigue life estimation is stress based approach such as Miner's rule.

Abstract: The interpolation of lookup tables (LUTs) has been used to compute forces developed in wheel-rail interaction to reduce the computational effort. However, the generation of LUTs with multiple inputs and multiple outputs consists of a challenging task since there is no methodology to reach a minimal size and uniform accuracy over the LUT domain. This paper presents a methodology to perform a detailed analysis of a general LUT, namely the interpolation error is assessed over the study domain, and the published Kalker Book of Tables for Non-Hertzian contact (KBTNH) is used as a case study. From this analysis, a new and enhanced LUT is suggested, which is approximately 5 times smaller than the original one, and whose accuracy is more balanced over the domain.

Keywords: Wheel-Rail Contact; Lookup Tables; Accuracy; Efficiency; Non-Hertzian;

1. Introduction

The wheel-rail contact interaction plays a fundamental role within the simulation of railway vehicles, namely in vehicle dynamics, prediction of wear or rolling contact fatigue, traction and braking system design, among others. Many researchers have been devoted to the development of more advanced contact models to improve the existing algorithms either in terms of accuracy or efficiency [1-4]. It has been shown that the selected methodology for the evaluation of creepage forces has paramount influence on the dynamic response of the vehicle [5]. Therefore, several authors developed techniques to deal with non-Hertzian contact shapes seeking higher accuracy on the forces evaluation. However, in most cases, this leads to a significant increase of computational cost. An alternative approach relies on the utilization of a lookup table methodology, since it is not necessary online calculation. The contact forces are precalculated for a wide range of scenarios and, during a dynamic simulation, they are determined through the interpolation of the tabulated values [6].

The main advantage of a LUT methodology is the reduction of the computation time, since it replaces the online calculation of a given function, for instance, the calculation of creep forces and moment, by the interpolation of precalculated points. However, this approach can be a major source of error if the parameterization of the LUT domain is not properly designed. Thus, the main goal is the generation of a LUT with minimal size while the accuracy of interpolation is kept under control. Although the increase of the number of points of the LUT tends to improve its accuracy, it also increases the size of the table, the time needed to generate it, and the time needed to search and interpolate a given point. Therefore, these issues make the selection of the number of LUT points and their location of extreme importance. Typically, this selection is made empirically, since there is no systematic technique to generate a LUT, namely, for LUT with multiple inputs and outputs.

The main objective of the current work is to study the Kalker Book of Tables for Non-Hertzian contact [6], and to provide an improved lookup table with controlled error and lower size. The remainder of the paper is organized as follows. Section 2 describes briefly the KBTNH parametrization, as well as the initial domain distribution. The assessment of the LUT accuracy through a sensitivity analysis and evaluation of the interpolation error in the cells and edges of the LUT is presented in Section 3. Then, an enhanced version of the KBTNH is proposed in Section 4. Finally, the main conclusions of this work are drawn in Section 5.

2. The Kalker Book of Tables

A regularization of non-elliptical contact patches has been introduced by Piotrowski et al. [6, 7], in which the contact patch is constrained to be a Simple Double-Elliptical Contact region (SDEC), as represented in Fig. 1. This regularization allowed to build a LUT for the creep forces and moment calculation based on CONTACT software [1] which has been called Kalker Book of Tables for Non-Hertzian contact. Thus, the SDEC region is suitable to regularize most of the

contact shapes obtained with approximate non-Hertzian methods for solving normal contact problem. Moreover, the SDEC shape holds some quasi-Hertzian properties and symmetry relations, and it requires a small number of parameters to be fully described. Hence, in a nondimensionalized analysis, it can be characterized by the semi-axes ratio as

$$g = a / b \tag{1}$$

and the shape number as

$$\psi = y_0 / b \tag{2}$$

For a given pair of materials, recurring to the parametrization of variables, the creep forces and moment generated due to wheel-rail interaction only depend on the contact patch geometry (g and ψ) and parametrized creepages (longitudinal ξ, lateral η and spin χ). Moreover, the parametrized creepages can be calculated as

$$\xi = \frac{\rho \upsilon_x}{\mu c} \quad , \quad \eta = \frac{\rho \upsilon_y}{\mu c} \quad , \quad \chi = \frac{\rho \varphi}{\mu} \tag{3}$$

where ρ is a characteristic length of the elliptical contact patch, μ denotes the friction coefficient, υ_x represents the longitudinal creepage, υ_y is the lateral creepage, φ denotes the spin creepage, and $c = \sqrt{ab}$. For sake of simplicity, the regularized longitudinal and lateral creepages are replaced by the creepage angle and modulus of creepage, which can be defined by

$$\nu = \sqrt{\xi^2 + \eta^2} \quad , \quad \alpha = \tan^{-1}\left(\frac{\eta}{\xi}\right) \tag{4}$$

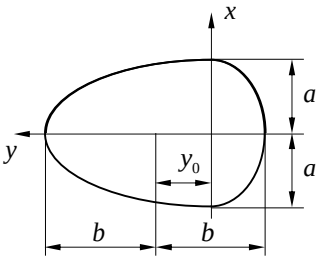

Figure 1 *Simple Double-Elliptical Contact region (SDEC).*

Therefore, for this case, the generation of the lookup table involves five input variables with the following domains:

- χ, parametrized spin creepage [0 , 2];
- g, semi-axes ratio [0.2 , 5];
- α, creepage angle [-π/2 , π/2];
- ν, parametrized creepage modulus [0 , 12];
- ψ, shape number [-0.9 , 0.9];

and three output quantities:

- f_x, normalized longitudinal creep force;
- f_y, normalized lateral creep force;
- m_z, normalized moment.

The normalized creep forces and moment are obtained from the contact loads calculated with CONTACT as

$$f_x(\chi, g, \alpha, \nu, \psi) = \frac{F_x}{\mu N} \tag{5}$$

$$f_y(\chi, g, \alpha, \nu, \psi) = \frac{F_y}{\mu N} \tag{6}$$

$$m_z(\chi, g, \alpha, \nu, \psi) = \frac{M_z}{\mu c N} \tag{7}$$

where F_x, F_y and M_z are, respectively, the longitudinal and lateral creep forces and the moment computed by CONTACT, and N represents the normal contact force.

A reasonable lookup table has been built which comprehends the expected contact scenarios for typical vehicle-track interaction. This justifies the chosen limits for the spin creepage and semi-axes ratio. Furthermore, it should be noted that the domain of the longitudinal and spin creepages is reduced to positive values due to symmetry relations provided by the SDEC shape [6], which diminishes significantly the size of the table.

Table 1 shows the distribution of points of the LUT proposed in [6]. As can be observed, a different number of points was utilized for the several independent parameters. In this case, the selection of the number and position of the LUT points has been done empirically, recurring to the users' experience. The most refined parameter is by far the parametrized creepage modulus. Thus, the total number of LUT points, and runs of program CONTACT, can be given by the combination of these points as

$$N_p = \prod_{i=1}^{5} n_i = 113\,344 \tag{8}$$

This number represents the LUT size and it has direct impact on the storage volume and on the searching time. It is of great interest to keep it as low as possible.

Table 1 *Domain of the Kalker Book of Tables for Non-Hertzian (KBTNH) contact.*

$\chi = \{0.00 \;\; 0.25 \;\; 0.50 \;\; 1.00 \;\; 1.25 \;\; 1.50 \;\; 1.75 \;\; 2.00\}$	n_χ=8

3. Lookup Table Accuracy Assessment

This section provides a comprehensive evaluation of the LUT accuracy. For this purpose, a sensitivity analysis is conducted to understand how the input parameters affect the resultant contact forces. Then, the assessment of the interpolation error is performed by comparing the values for the middle point of each cell and edge obtained through linear interpolation of LUT points and the exact value obtained with CONTACT. In this work, a mesh of 60x60 elements is utilized in CONTACT to discretize the contact patch.

3.1. Sensitivity Analysis

Firstly, it is analyzed the impact that each input variable has on the three output variables (forces and moment), since this study allows to understand which are the parameters that need a finer or courser spacing. Bearing

this in mind, ten points inside the domain of the lookup table were randomly selected using a Latin Hypercube Sampling (LHS), as listed in Table 2. This sampling allows a suitable inspection of the domain.
Then, for each point, the five input parameters were varied separately inside their boundaries for 100 points (much more than a reasonable LUT could have). Figure 2 presents the results of this sensitivity analysis. For instance, Fig.2(a) shows the influence of varying the parametrized spin creepage on the obtained forces and moment for the 10 points listed on Table 2 (from left to right).

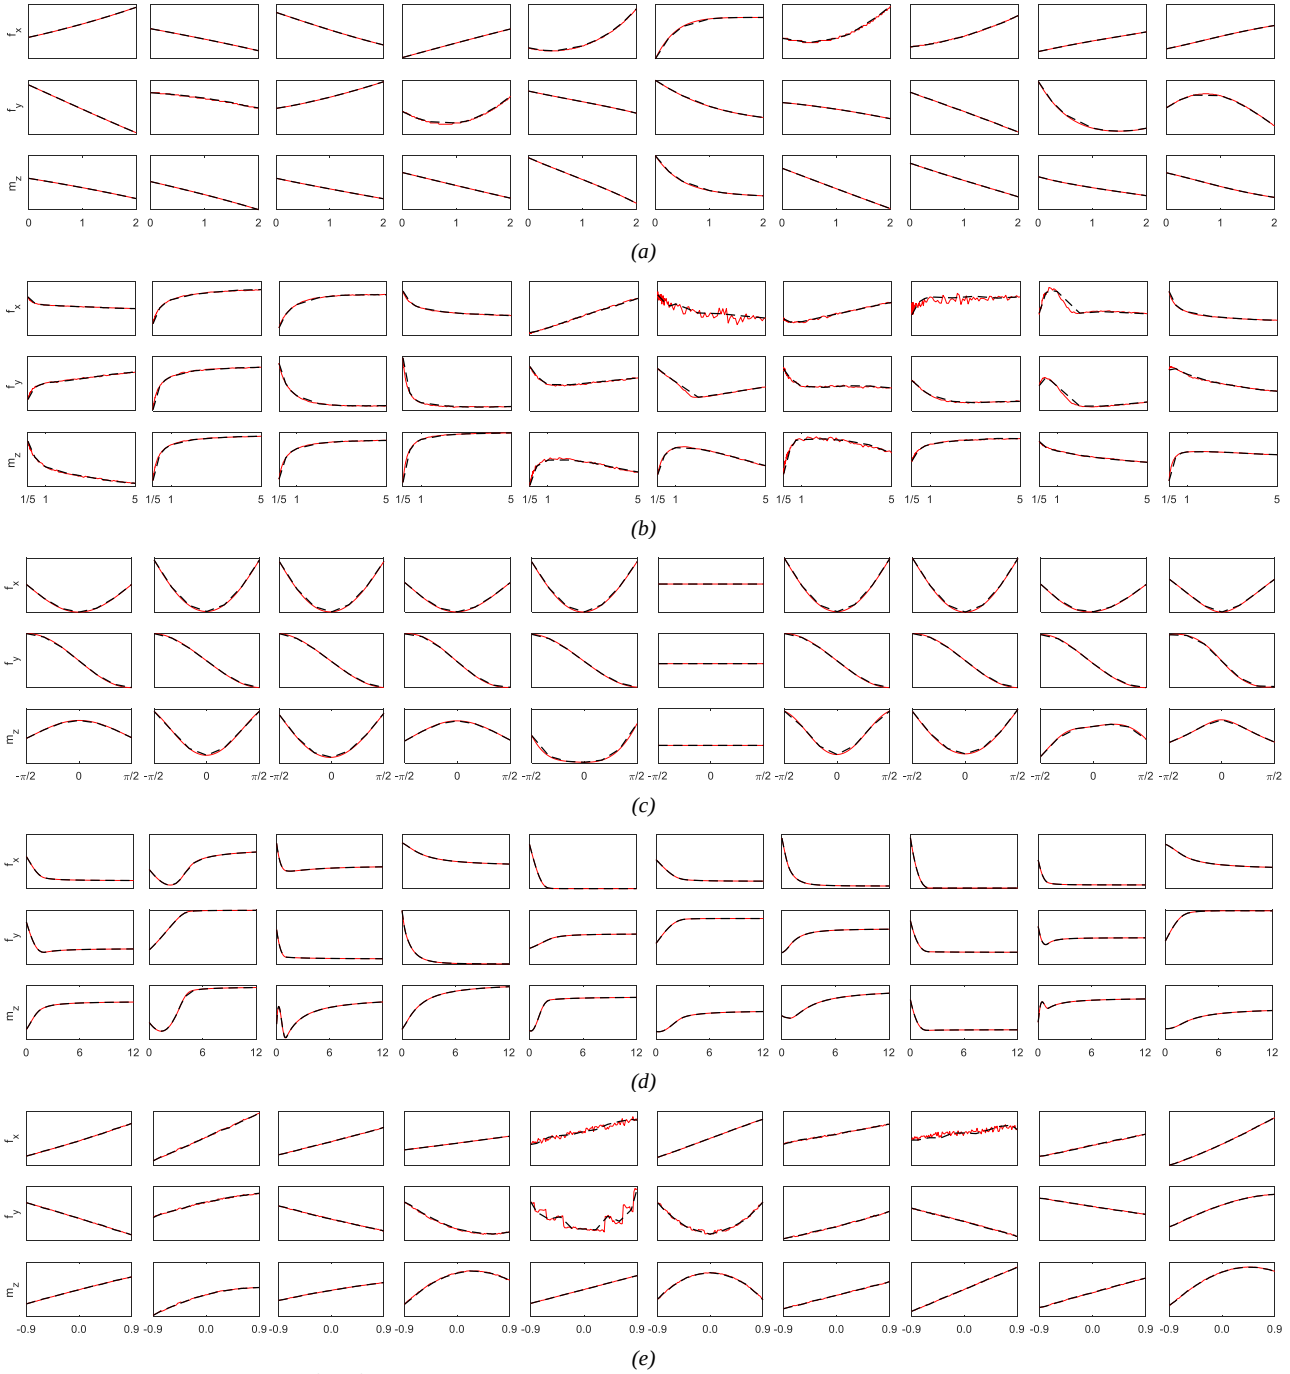

Figure 2 *Sensitivity analysis of the function used to generate the KBTNH based on CONTACT using a LHS with 10 points listed in Table 2 (– solid red line - results for a 100 points refinement; -- dashed black line - results for the LUT points): (a) parametrized spin creepage, χ; (b) semi-axes ratio, g; (c) creepage angle, α; (d) parametrized creepage modulus, ν; (e) shape number, ψ.*

From the analysis of the plots of Fig. 2, some findings can be highlighted. The spin creepage shows a more nonlinear behavior in the first half of the domain. The semi-axes ratio seems to have a logarithmic tendency, which means it should have an equivalent refinement from 1/5 to 1 and from 1 to 5. Moreover, the creepage angle has a sinusoidal behavior. It can be noticed in Fig. 2(d) that the creepage modulus is highly nonlinear for low values which demands a good refinement, while it is almost linear for high values of creepage. Finally, the

shape number shows a smooth tendency, thus, a small number of points are needed to provide a good approximation. As can be noticed, some of the plots present a noisy curve, this happens for the variations of the semi-axes ratio and the shape number, since the change of these input parameters implies a change of the shape of the contact patch and, hence, the mesh used in CONTACT. Thus, the change of the mesh may cause a non-smooth variation of the output quantities.

Table 2 *Points of the Lookup Table randomly selected using a Latin Hypercube Sampling.*

Point	χ	g	α	v	ψ
1	0.76	0.63	0.79	9.00	0.378
2	1.88	4.52	-1.48	11.04	-0.702
3	0.50	1.90	1.13	3.12	-0.900
4	1.72	1.18	1.48	6.60	0.612
5	0.96	0.32	-0.06	3.84	-0.252
6	1.36	0.24	-0.75	0.00	0.090
7	1.48	4.20	-0.31	10.20	-0.162
8	0.14	0.49	0.16	7.32	-0.360
9	0.28	2.61	0.53	1.44	0.342
10	1.02	0.21	-1.26	5.28	0.828

Hence, this analysis allowed to identify which are the variables that produce a more nonlinear response on the output quantities and, therefore, need more divisions in the lookup table.

3.2. Interpolation error in cells

The assessment of the accuracy of the current LUT can be achieved by the evaluation of the interpolation error, i.e., the difference between the exact value calculated with CONTACT and the value interpolated from the LUT data for a given set of input parameters. In order to have a proper error analysis, it is of paramount importance to select suitable points where the evaluation is performed. For instance, in the LUT points, the interpolation error is null. Thus, the error is evaluated in the middle point of each cell of the LUT (see Fig. 3, in which the cell is represented in 3D instead of 5D for sake of simplicity). Considering that the error is equally distributed, the center of each cell represents the highest error, since it is the farthest from the lookup table points (exact values).

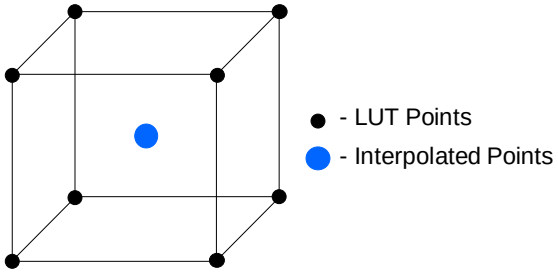

Figure 3 *Schematic representation of the error evaluation at the center of a cell of the lookup table.*

Moreover, the number of cells to interpolate can be given by the following expression

$$N_c = \prod_{i=1}^{5}(n_i - 1) = 64\ 680 \qquad (9)$$

The error of interpolation for the center of each cell of the LUT is presented in Fig. 4 for the three output quantities. Since all the parameters are interpolated at the same time, it is not possible to check which one is the main source of error. However, the results allow to identify the order of magnitude of the maximum interpolation error.

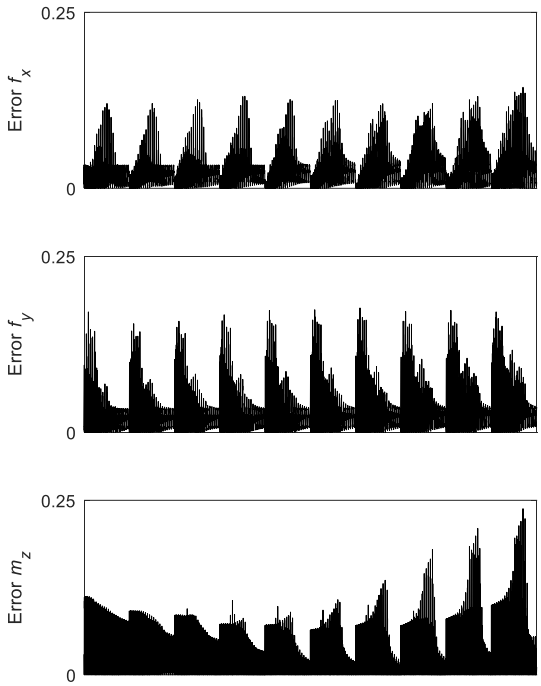

Figure 4 *Interpolation error at the middle point of the LUT cells for different outputs over the domain.*

3.3. Interpolation error in edges

To overcome the problem of not being able to identify which variables are the main sources of error, the interpolation error must also be evaluated in the LUT edges as represented in Fig. 5. In this case, when interpolating at an edge of the LUT, for each point of the analysis, four input parameters are kept constant, and the interpolation is performed using only the two extremities of the edge in which only one parameter varies. Thus, it allows to determine the error introduced by the discretization of each input parameter.

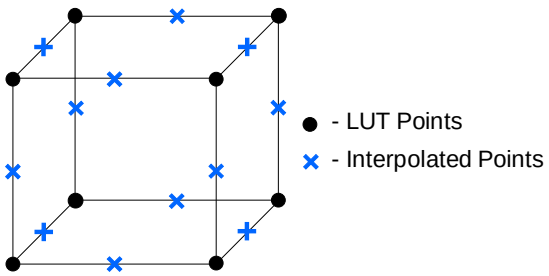

Figure 5 *Schematic representation of the error evaluation at the edges of a cell of the lookup table.*

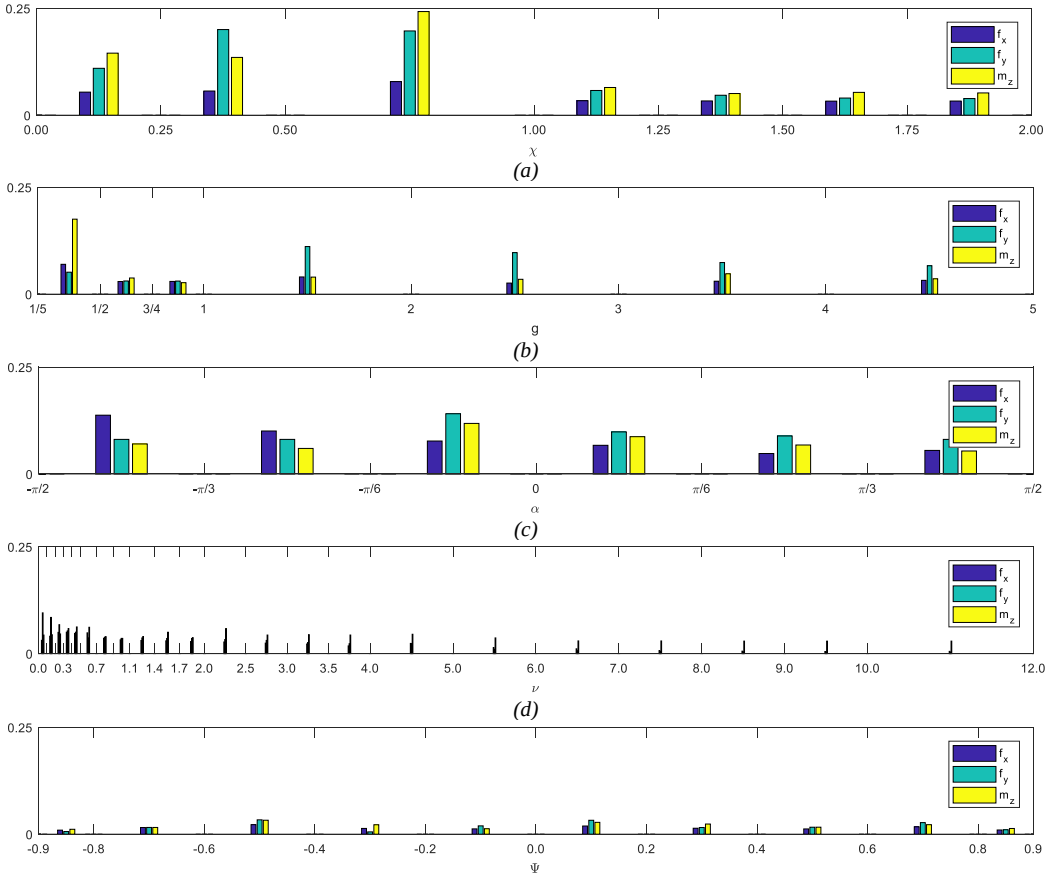

Figure 6 *Maximum interpolation error between two consecutive points of the same independent parameter for each output quantity: (a) parametrized spin creepage, χ; (b) semi-axes ratio, g; (c) creepage angle, α; (d) parametrized creepage modulus, ν; (e) shape number, ψ.*

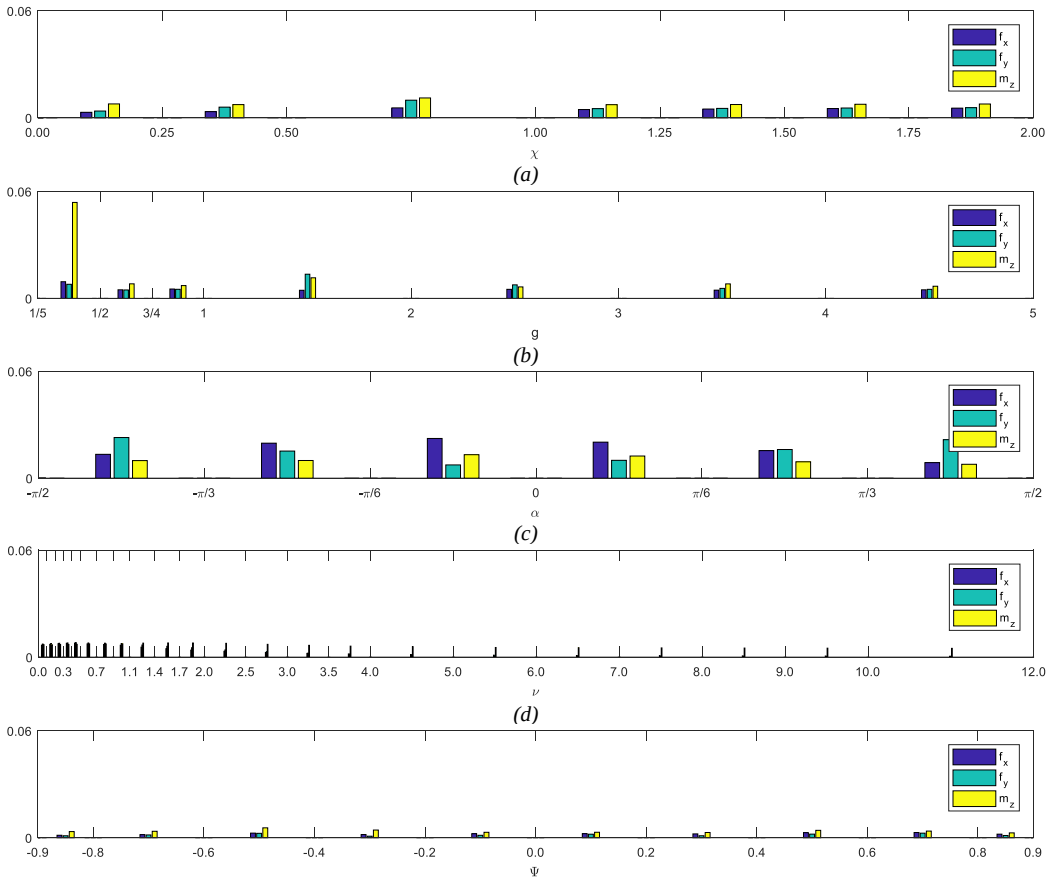

Figure 7 *Mean interpolation error between two consecutive points of the same independent parameter for each output quantity: (a) parametrized spin creepage, χ; (b) semi-axes ratio, g; (c) creepage angle, α; (d) parametrized creepage modulus, ν; (e) shape number, ψ.*

The number of edges of the LUT is significantly higher than the number of cells, and can be estimated as

$$N_e = \sum_{i=1}^{5} \frac{(n_i - 1)\prod_{j=1}^{5} n_j}{n_i} = 506\,960 \qquad (10)$$

The maximum and mean error are evaluated for each space of the lookup table domain, and the results are displayed in Figs. 6 and 7, respectively. The plots distinguish the different outputs, and have the same scale for easier readability and comparison.

From the analysis of the maximum interpolation error (Fig. 6), the maximum value is found on the interpolation of the spin creepage, which suggests that an additional point should be placed. Moreover, the highest values of spin creepages present lower interpolation error. The semi-axis ratio shows a peak error for the first interval when compared with the remaining ones. Referring to the creepage angle and modulus and the shape number, they have an evenly distributed error along each domain. However, the interpolation error from the creepage modulus and the shape number present a maximum error magnitude much lower than the remaining parameters, which means that they could have a coarser refinement without damaging the LUT accuracy.

In what concerns to the mean error, the magnitude of error is significantly lower (see Fig. 7), but a similar analysis can be made. The maximum mean error is found to be in the first interval of the semi-axis ratio. Relatively to the mean interpolation error, the remaining input variable seem to have a discretization which favors the uniform error distribution. However, the creepage angle establishes clearly the highest interpolation error.

There is no advantage of having different levels of error for the different input parameters, since the accuracy of the table is limited by the variable that introduces the highest error. This means that the design of the LUT could be enhanced by either improving the discretization where the error is higher or using a coarser discretization where the error is smaller, which will increase the accuracy or diminish the size, respectively.

4. Generation of an enhanced KBTNH

As it was previously shown, the current KBTNH has an unbalanced interpolation error for the different input parameters. Therefore, a new distribution has been proposed to improve the LUT efficiency. Thus, the aim is to achieve a LUT with a similar accuracy, but a significantly smaller size.

In order to preserve the same accuracy, the parameters that presented a highest error must be kept with the same discretization. Thus, the creepage angle, which has an equally spaced distribution, was unchanged. The spin creepage can have less points on the end of the domain. Regarding the semi-axis ratio, since it represents a ratio, the distribution must be logarithmic, avoiding the peak error in the first interval. In which refers to the creepage modulus and shape number, the number of points can be significantly reduced, since the current error is much lower.

Bearing these guidelines in mind, an enhanced version of the KBTNH has been proposed, and its discretization is described in Table 3. As it is observed, the number of points for each parameter was reduced. Hence, the total number of data points can be recalculated as

$$N_p = \prod_{i=1}^{5} n_i = 24\,010 \qquad (11)$$

Comparing this value with the size of the original LUT given in Eq. (8), it is obtained a ratio of 4.72. This has a substantial impact on the time to generate the LUT, and to search and interpolate during a dynamic simulation, and even on the memory usage.

Table 3 *Domain of the enhanced Kalker Book of Tables for Non-Hertzian (KBTNH) contact.*

$\chi = \{0.00 \quad 0.25 \quad 0.50 \quad 0.75 \quad 1.00 \quad 1.50 \quad 2.00\}$	n_χ=7	-1
$g = \left\{\frac{1}{5} \quad \frac{1}{3} \quad \frac{1}{2} \quad 1 \quad 2 \quad 3 \quad 5\right\}$	n_g=7	-1
$\alpha = \left\{-\frac{\pi}{2} \quad -\frac{\pi}{3} \quad -\frac{\pi}{6} \quad 0 \quad \frac{\pi}{6} \quad \frac{\pi}{3} \quad \frac{\pi}{2}\right\}$	n_α=7	0
$\nu = \{0.0 \quad 0.2 \quad 0.4 \quad 0.7 \quad 1.2 \quad 2.0 \quad 3.5 \quad 5.0 \quad 8.0 \quad 12.0\}$	n_ν=10	-13
$\psi = \{-0.9 \quad -0.6 \quad -0.3 \quad 0.0 \quad 0.3 \quad 0.6 \quad 0.9\}$	n_ψ=7	-4

To assess the accuracy of the enhanced KBTNH and compare it with the original one, the evaluation of the interpolation error on the center of the edges of the LUT was performed similarly to Section 3.3. Figures 8 and 9 depict, respectively, the maximum and mean errors of interpolation, analogously to Figs. 6 and 7.

From the analysis of the results, it can be concluded that the level of maximum error is similar to the original one, although the maximum mean was reduced even with the decreasing of number of points. Moreover, the two parameters which were more affected by this change (creepage modulus and shape number) keep their interpolation error lower than the creepage angle, as represented in Fig. 9.

5. Conclusions

The improvement of efficiency and accuracy in railway simulations demands the development of advanced computational tools. This works presented the analysis and improvement of the KBTNH utilized for the calculation of creep forces and moment in the context of wheel-rail interaction. Firstly, the current LUT was characterized, then, the assessment of its accuracy was performed through a sensitivity analysis and interpolation error evaluation. This analysis showed that the interpolation error introduced by the distribution of the LUT points was significantly different for the several input parameters. This allowed to redistribute the points locations, and even eliminate some of them where the LUT was too refined. The new KBTNH demonstrated to have similar accuracy, and its size was decreased by a ratio of 4.72.

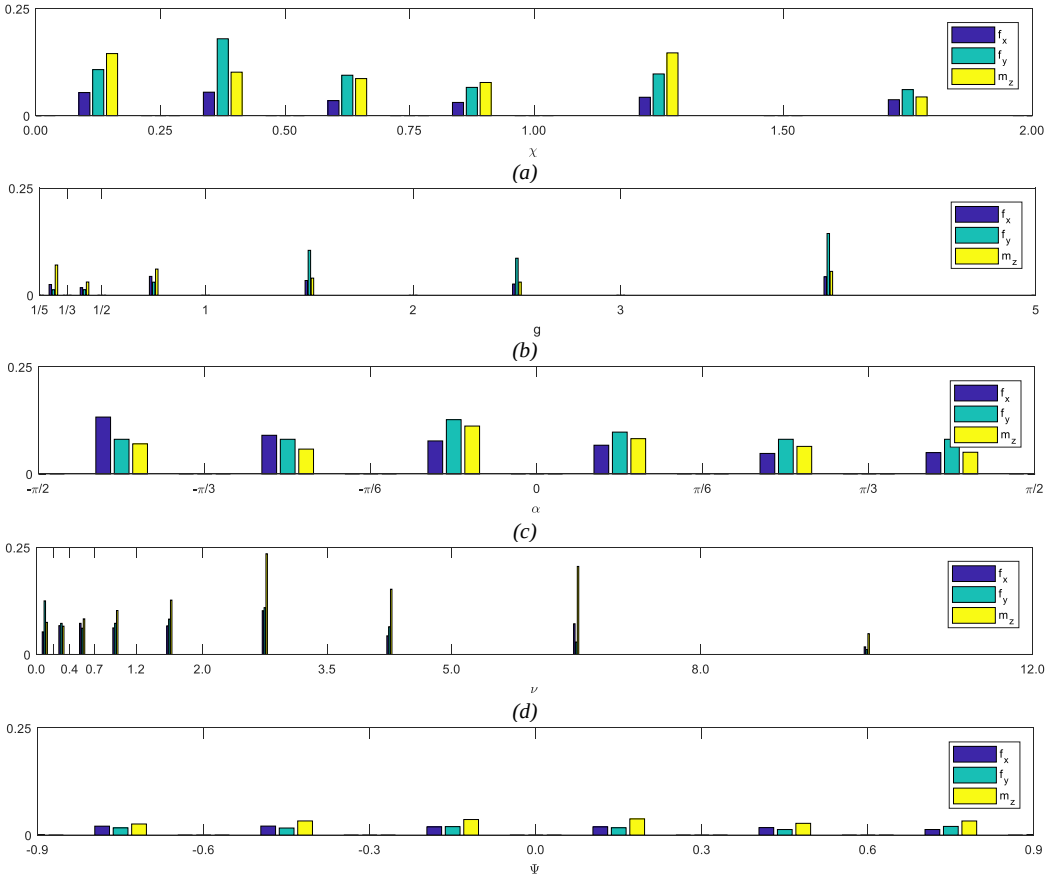

Figure 8 *Maximum interpolation error between two consecutive points of the same independent parameter for each output quantity of the enhanced LUT: (a) parametrized spin creepage, χ; (b) semi-axes ratio, g; (c) creepage angle, α; (d) parametrized creepage modulus, ν; (e) shape number, ψ.*

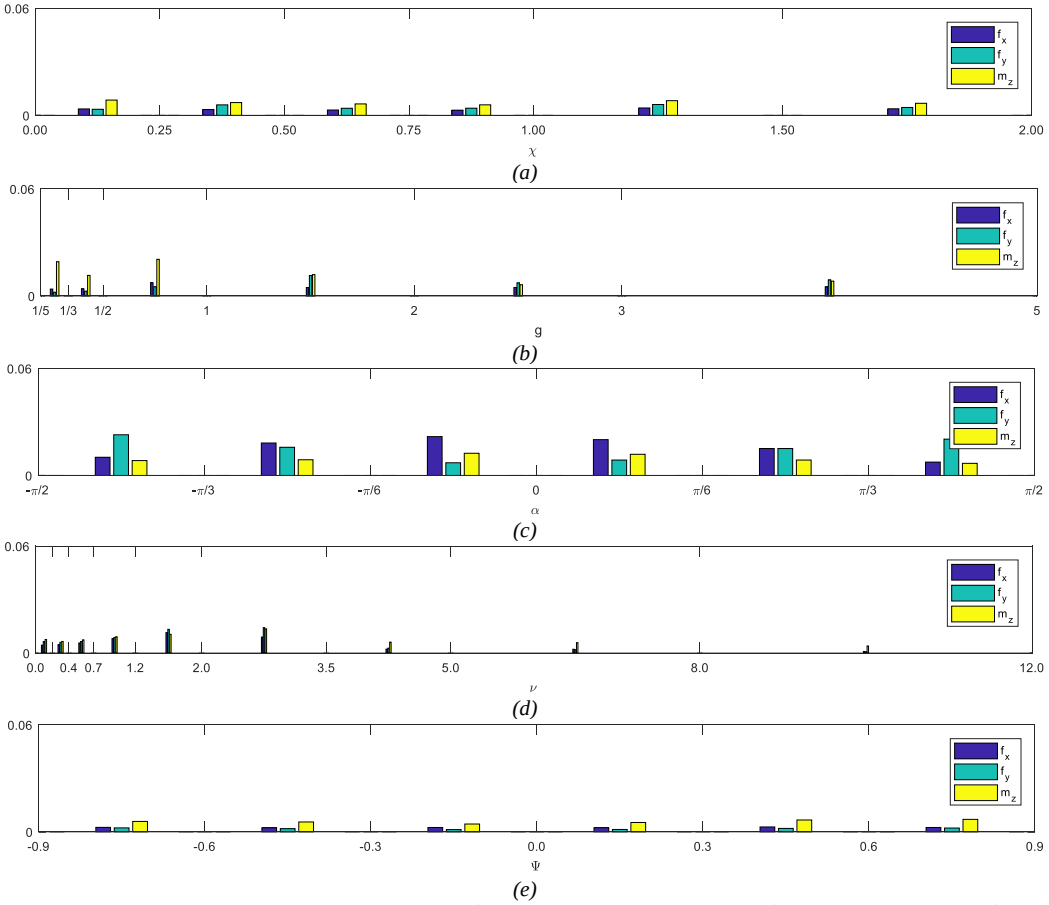

Figure 9 *Mean interpolation error between two consecutive points of the same independent parameter for each output quantity of the enhanced LUT: (a) parametrized spin creepage, χ; (b) semi-axes ratio, g; (c) creepage angle, α; (d) parametrized creepage modulus, ν; (e) shape number, ψ.*

This methodology to perform the accuracy assessment of the KBNHT can be employed in other types of LUTs to help the generation of a LUT with evenly distributed error. Therefore, this approach may have a comprehensive application range. Moreover, an extension of this work consists on the development of an optimization technique to generate LUTs with prescribed accuracy and minimal size.

Abstract: The friction coefficient between wheel and rail affects curving performance significantly. For example, low friction coefficient leads wheel slip and skid, otherwise high friction coefficient leads derailment and wheel/rail wear. In these friction coefficients, the authors focus on the friction coefficient of flange of outside wheel of leading axle, because the friction of this part is very important for the wear of flange and rail side. First capability of finding the friction of this part was investigated in the bench test, and next the way for identifying friction coefficient of this part was developed by using Multi Body Dynamic (MBD)simulation.

Keywords: wheel-rail contact; derailment coefficient Y/Q; MBD simulation; condition monitoring of contact forces; flange wear; rail side wear; squeal noise

1. Introduction

Tokyo Metro is managing 9-lines in the city of Tokyo. The number of passengers is approximately 7.2 million people per day. To construct lines in the underground along the roads in the city, there are many sharp curves. Fig.1 shows the percentage of curves and lines occupying the service line. It is characteristic that sharp curves with a radius of 100m to 300m occupy 15% of the whole line. In the fact that the vehicle passes through a sharp curve, problems relating to contact between various wheels and rails occur. These problems are derailment coefficient increase with increasing lateral force, occurrence of squeal noise and wear of wheel flange and rail side. The friction coefficient between wheel and rail is greatly related to these problems.

In particular, it has been found that the friction coefficient between outside flange and rail is greatly related to these various problems. For example, if the flange is grease lubricated, the flange will not wear. Furthermore, the Nadal's equation that determines the limits of derailment coefficient has been influenced greatly on the friction coefficient of flange. In this study the authors developed the way of measuring friction coefficient between outside flange and rail (μ_{1out}).

2. Verification experiment by bogie test stand

In the service lines, the oil applicators are installed on the inside and outside rail at the entrance of the curved track. Since it is very difficult to grasp the lubrication condition between the wheel and the rail in the service line, the authors conducted the bench test by using bogie test stand. In the bench test it is easy to change lubrication condition to find the change of forces between wheel and rail.

2.1. Experiment condition

Photo 1 shows the bogie test stand. This test stand can simulate a curve condition with setting the attack angle between bogie and track and with controlling speed difference between right and left roller according to the running distance difference between inside and outside rail. Table 1 shows the test conditions and specifications of the bogie.

Table 1 *Test condition and specification of test stand and bogie*

Running velocity	20 km/h
Curve radius	800,600,400,350,300,250,200,180, 160, 130m
Experimental bogie	Mono-link type axle-box, bogie with a bolster
Wheel tread profile	Arc. profile tread suitable to sharp curve used in Tokyo metro company
Rail profile	50 kgN

Table 2 shows the condition of lubrication between the wheel and rail. In condition 1 the whole wheels of the bogie are dry. In the case of condition 2, only outside wheel flange on the leading axle is lubricated. Condition 4 is the case where the inner wheels of leading and trailing axle are lubricated, and condition 3 is the case where the outer wheel flange of the leading axle is further lubricated under condition 4.

Table 2 *Condition of lubrication between the wheel and rail*

Condition	Markers	Leading axle		Trailing axle	
		Outside rail	Inside rail	Outside rail	Inside rail
No.1	○	dry	dry	dry	dry
No.2	△	oil	dry	dry	dry
No.3	▲	oil	oil	dry	oil
No.4	□	dry	oil	dry	oil

2.2. Experiment results

2.2.1. Contact forces between wheel and rail on several lubrication conditions

The special wheelset to measure the forces acting between the wheel and the rail was used. (See photo.2) This wheelset can measure the lateral force(L) and vertical force(V) acting on the wheel by measuring strain of wheel web. And the tangential force between wheel and rail of moving direction can be measured by the strain gauges attached to the axle. Fig.3 shows the relation between lateral force and curvature in several wheel/rail lubrication conditions. In the condition of lubricated only at the outside wheel flange (Condition 2), the lateral force observed larger than dry condition (Condition1). On the conditions of the lubrication between inside wheel and rail (Condition 3 and 4), a little lateral force was generated. Next Fig.4 shows the tangential force between wheel and rail in the several lubrication conditions. This tangential force becomes maximum at the curvature of 1/300. On the condition of oil lubricated at the flange of outside wheel of leading axle, this tangential force became smaller significantly than that of on the wheel/rail dry condition. This reduction of wheel/rail tangential force lead the reduction of steering force, as the result, the lateral force became larger than that of dry condition. In the same way, this tangential force became small on the condition of oil lubricated between inside wheel and rail. (Condition 3 and 4)

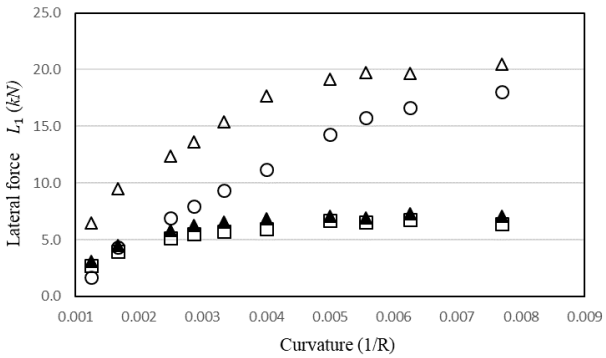

Fig 3 *Comparison of lateral force in various lubrication condition and curvatures. Each marker is defined in table 2.*

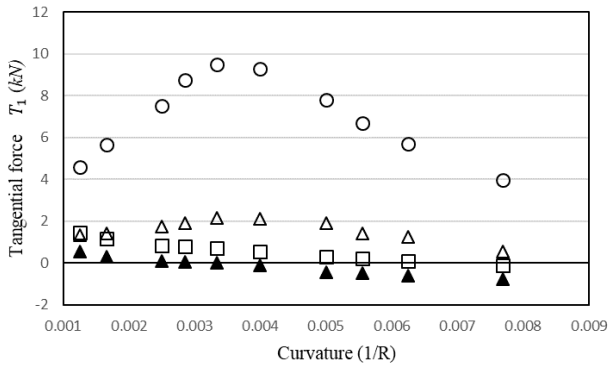

Fig 4 *Comparison of tangential forces of leading wheelset. Tangential forces are estimated by strain gauge attached to the axle*

2.2.2. Friction condition diagram between wheel and rail

Fig 5 shows the friction condition diagram between wheel and rail. The horizontal axis shows L/V (κ) of the inside wheel/rail corresponding to the friction coefficient in the lateral direction, and the vertical axis shows the coefficient of friction (T/V) between the wheel and the rail in the moving direction. On several lubrication conditions of small curves as the radius of 250m,200m,180m,160m, L/V vs T/V are plotted on this diagram. In this figure, we can find the three areas of friction conditions between wheel and rail. In the figure, plotted data in area A are high friction coefficient of both L/V and T/V with dry condition. And the plotted data in area B show high L/V and low T/V. In the small curve, if L/V and T/V of the leading axle of the bogie plotted in area B, we can find that this bogie has high friction coefficient on the top of inner rail and low friction coefficient at outside flange. From these results, if the lubrication condition between inside wheel and rail is high we can find the friction condition between outside flange and rail. And in the figure, plotted data in the area C show low L/V and low T/V. In the small curve, if we can get the L/V and T/V in this area C, the bogie has 2 wheel/rail lubrication conditions. One is the case of oil lubricated both flange of outside wheel and top of inside rail. And the other is the case of only oil lubricated at the top of inside rail. In these results, we find that it is very difficult to separate these lubrication conditions. (Condition 3 and 4)

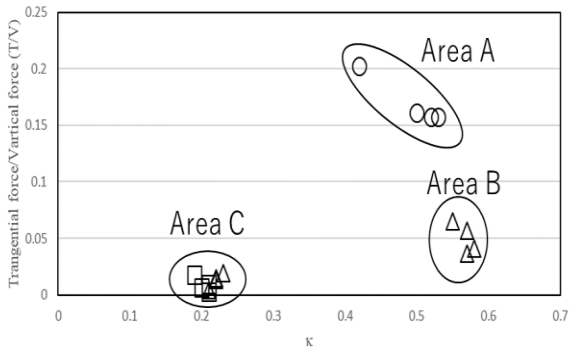

Fig 5 *Relation between T/V and* κ*.*
Each marker is defined in table 2.

3. Estimation of friction coefficient between outside flange and rail surface (μ_{1out})

As mentioned before section, the friction condition between outside flange and rail surface can be found in the specific condition. (Here we define μ_{1out} as the friction coefficient between outside flange and rail surface) But in general it is very difficult to estimate the μ_{1out} and there are few examples of measuring it. Therefore, the authors focused on the tangential force generated in the moving direction between wheel and rail in curving. (See Fig. 2) When μ_{1out} is low, this tangential force also becomes small, and when μ_{1out} increases, this force also increases. However, this force is also related to the curvature and the wheel diameter difference between the right and left wheel, so μ_{1out} can not be easily obtained. Therefore, to evaluate μ_{1out} , we carried out the vehicle dynamics analysis with the target curve and the vehicle. By comparing the analysis result with several wheel/rail friction coefficient measured by special bogie, μ_{1out} can be estimated. In this study, General Purpose Multi body / Dynamics (MBD) analysis software Simpack was carried out. From the analysis results, an estimator of μ_{1out} was developed. Fig.6 shows the schematic diagram of the bogie, and Fig.7 shows the system of the estimator. Fig.8 shows simulation results of the relationship between μ_{1out} and the friction coefficient of wheel tread on inside rail (κ) and the tangential friction coefficient of between wheel and rail ($\overline{T_1}/V_1'$). Actually to get μ_{1out}, the κ and $\overline{T_1}/V_1'$ are input to the estimator.

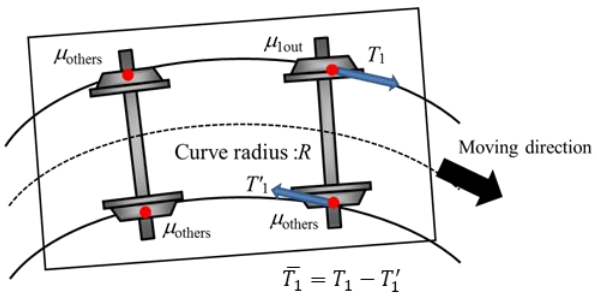

Fig 6 *Schematic diagram of the bogie*

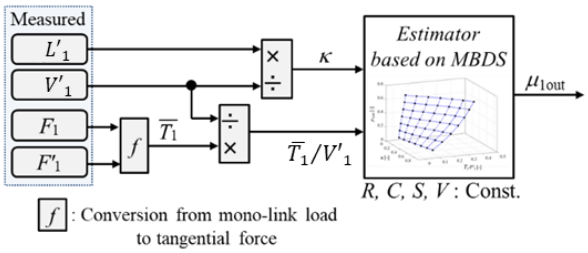

Fig 7 *System of the estimator*

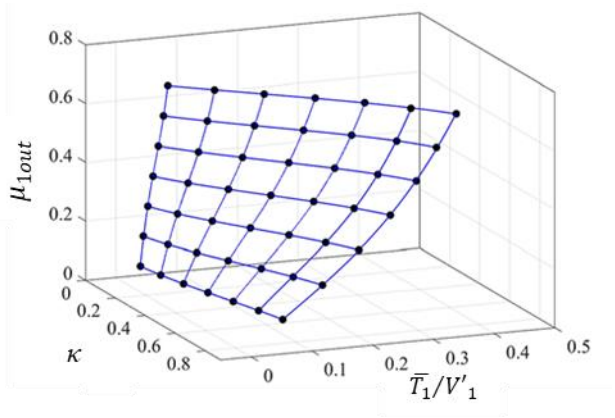

Fig 8 Map for estimated friction coefficient μ_{1out} vs $\overline{T_1}/V_1'$ and κ.

4. Special bogie to measure the forces between wheel and rail [1],[2],[3]

To estimate μ_{1out} the authors used the bogie which can measure the forces between wheel and rail in service line. By using this bogie, we can obtain the vertical force (V), the lateral force (L) and the force (T) acting in the traveling direction of the wheels and the rail in the service line. Photo 3(a) shows the whole bogie, (b) shows the measurement of the vertical displacement of the axle box with a non-contact sensor which is proportional vertical force , and (c) shows the eddy current sensor for measuring the lateral force. In (d), a strain gauge is attached to the link connecting the truck frame and the axle box in order to obtain the tangential force. We call this special bogie as PQ monitoring bogie (In Japan P and Q are defined as follows; Q means Lateral force and P means Vertical force ,so the derailment coefficient is expressed as Q/P, which is same as Y/Q or L/V).

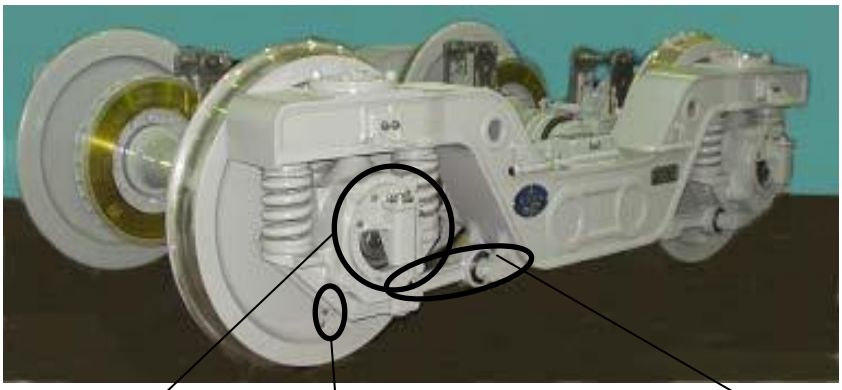

Photo 3(a) *PQ monitoring bogie*

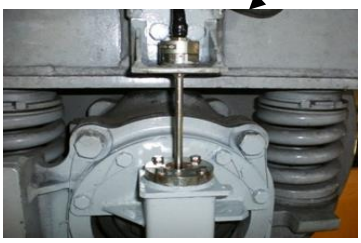

Photo 3(b) *Vertical force device*

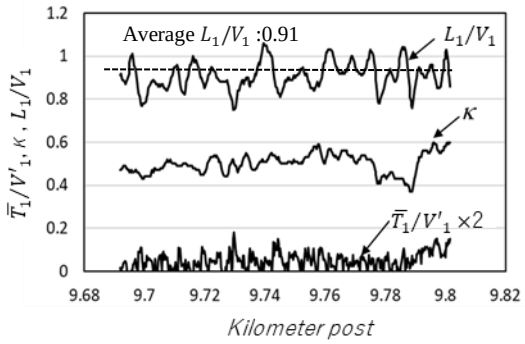

Photo 3(c) *Lateral force device*

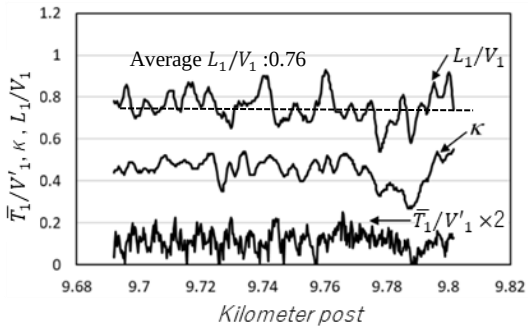

Photo 3(d) *Tangential force device*

5. Estimated results of friction coefficient between outside flange and rail surface (μ_{1out}) [4]

Fig.8 shows an example of estimated results. When the value of κ (inside L/V ratio) is low, the slope of μ_{1out} vs $\overline{T_1}/V'_1$ is large. Then μ_{1out} changes greatly by a small change in the $\overline{T_1}/V'_1$. Therefore, in this research, in order to estimate accuracy, the data in which the value of κ is 0.45 <κ <0.55 was gathered. Waveforms of L_1/V_1, κ, and the tangential friction coefficient are shown in Fig.9. Fig.9(a) is the case of low μ_{1out} and Fig.9(b) is the case of high μ_{1out}.

(a) The case of low μ_{1out} (μ_{1out} =0.12)

(b) The case of high (μ_{1out}=0.26)

Fig 9 *Wave forms of* L_1/V_1, κ *and* $\overline{T_1}/V'_1$

Comparing the derailment coefficients, it can be seen that when the μ_{1out} is high, the derailment coefficient 0.76 on average, and when the μ_{1out} is low the derailment coefficient is 0.91 on average. This tendency is explained as follows. At first, high μ_{1out} produces high steering force (tangential force). High steering force makes low lateral force and low derailment coefficient. On the other hand, low μ_{1out} produces low steering force. Low steering force makes high lateral force and high derailment coefficient. Fig 10 shows the results of observing the μ_{1out} for one month in the service line. The value of μ_{1out} varied from 0.1 to 0.3. In this curve, there is an oil lubricator at the entrance of the curve, μ_{1out} decreases when oiled, and then μ_{1out} increases without oil. The relationship between μ_{1out} and derailment coefficient (L/V) is same as mentioned above. In addition, Photo 4 shows the rail side of the curve. The iron powder thought to be due to the wheel wear. And the wear of the rail side was observed.

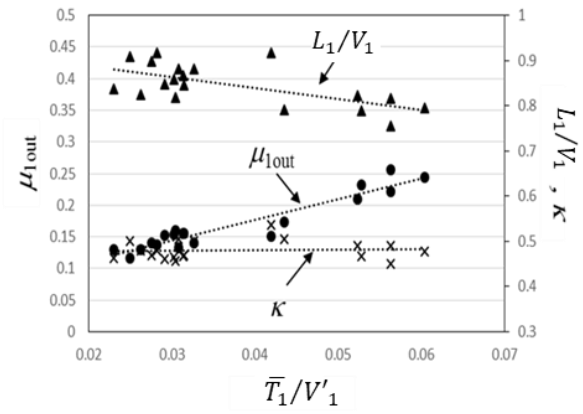

Fig 10 *Measurement results for 1 month in the service line*

Photo 4 *Rail in the measured curve*

6. Conclusions

In this study the authors propose a method to estimate the friction coefficient of outside flange and rail surface with using the data gathered by PQ monitoring bogie in the service line. Moreover, we evaluate the influence of this friction coefficient on the curving performance in the sharp curve. As a result, when the value of μ_{1out} is high(low), the value of L/V decreases(increase). These results are consistent with previous experiment using the bogie test stand. And where the friction coefficient (μ_{1out}) is high, iron powder was confirmed. This is because the friction coefficient (μ_{1out}) is high, the wheel flange has been worn. From the above it is possible to qualitatively estimate the friction coefficient between outside flange and rail surface (μ_{1out}).

Abstract: To estimate the safety against flange-climb derailments the safety measure based on Nadal's formula has been used. This measure is effective, but the actual friction condition between rail and wheel flange is not considered. In this paper, the authors propose a new safety measure, "flange-climb index" (FCI) which considers the actual wheel flange friction coefficient and quantitatively estimates the margin for safety against flange-climb occurrences.

Keywords: rail-wheel contact; derailment quotient Y/Q; L/V; estimation of derailment safety; Nadal's formula; MBD simulation; condition monitoring.

1. Introduction

Flange-climb derailments result in such serious catastrophes that various studies for its prevention have been carried out around the world. In Japan, governmental preventative measures were implemented after the Tokyo-Eidan-Subway Hibiya Line accident in 2000. The first half of this paper examines the government measures—including the Ministry's safety measure—and presents the related studies carried out by the authors' group on the monitoring of actual states of rail-wheel contact and the prevention of flange-climb derailments. In the second half, the authors consider the influence of rail-wheel friction on flange-climb occurrences and propose a new measure of safety against flange-climb.

2. Previous safety measures in Japan [1]

A flange-climb derailment accident occurred in 2000 when a train, running a sharp curve (160m radius) of the Tokyo-Eidan-Subway Hibiya Line, derailed and collided with the train running on the adjacent track. The derailed train was travelling at 13km/h on the exit-side transition curve, where the track is twisted due to decreasing cant. Following the accident, the Ministry of Transport (MOT, the former organization of MLIT) carried out running tests repeatedly with related organizations, such as NTSEL and RTRI. According to investigations, no fatal errors were found, and they concluded that the derailment was caused by a combination of factors, such as "wheel-load imbalance of both sides", "increased friction coefficient", "track twist" and "over-canting due to low speed operation". After the investigations, the Ministry decided to enact the safety measure for equipment of "guard rail" in sharp curves. The safety measure proposed by the Ministry has been used as the guideline for flange-climb derailment prevention on sharp curves in Japan [2, 3].

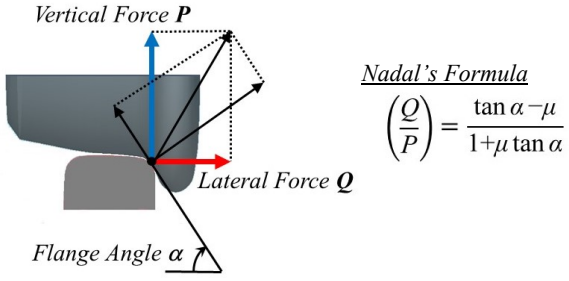

Figure 1 *Contact forces between wheel and rail.*

The Ministry's safety measure, "Estimated derailment Q/P ratio", is defined as the ratio of the "critical" and "estimated" derailment coefficients, *Q/P,* of the leading-outside wheel of the bogie:

$$"Estimated\ Q/P\ ratio" = \frac{(Q/P)_{cri}}{(Q/P)_{est}}$$

$(Q/P)_{est}$ is the estimated derailment coefficient calculated by the ratio of the estimated lateral contact force, Q_{est}, and the estimated vertical contact force, P_{est}. (*In this paper, the derailment coefficient, or the derailment quotient is expressed as Q/P, which is*

equivalent to Y/Q, or L/V in western countries [4].) In this process, Q_{est} is calculated considering the friction coefficient, unbalanced centrifugal force, yawing resistance of bogie, etc.; P_{est} is calculated considering the unbalanced centrifugal force and the track twist, etc.; and the critical $(Q/P)_{cri}$ is calculated by the modified Nadal's equation using the "equivalent friction coefficient", μ_e —which is varied by the angle-of-attack of the wheel.

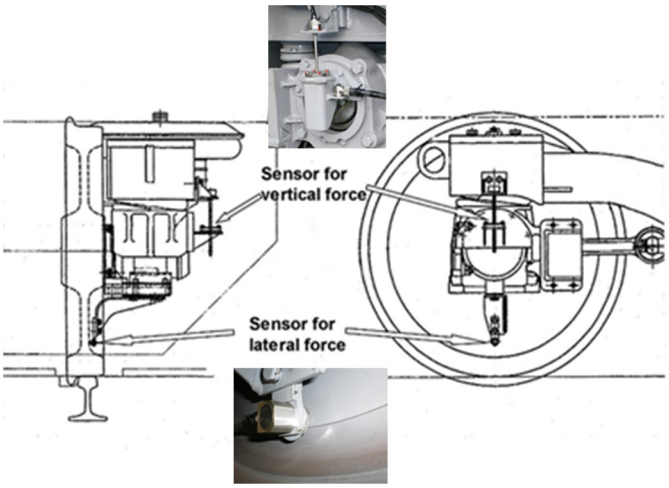
The philosophies of the safety measures used in Japan [3] and Europe [5] are effective in preventing similar derailments, but they are not problem-free. For example, the true value of friction coefficient μ between the flange surface and rail head—which can be changed by lubrication—is impossible to measure by existing measuring methods. As a solution to this problem, the authors propose a new safety measure "flange climb index" (FCI), which will be described in Chapter 4.

3. Our trial approach to derailment prevention

3.1. Development of Q/P continuous monitoring system by in-service trains

In the running tests after the accident it is found that the friction coefficients between wheels and rails can change in a short period, for example 0.2 to 0.6 [1, 3], accordingly the continuous observation of them is required. The previous methods used "instrumented wheels" with strain gauges and slip rings or telemeters were hard to handle and had poor durability. As such, the authors group began R&D of a new measuring system without strain gauges and data transmitting devices, by using gap sensors on a bogie frame, which could be implemented on a commercial service train.

The new system, called "PQ monitoring bogies", was successfully developed (see Figure 2) [6]. Trains with the PQ monitoring bogies have been running every day for commercial trains on three subway lines and collecting large quantities of actual-state data on rail-wheel contact.



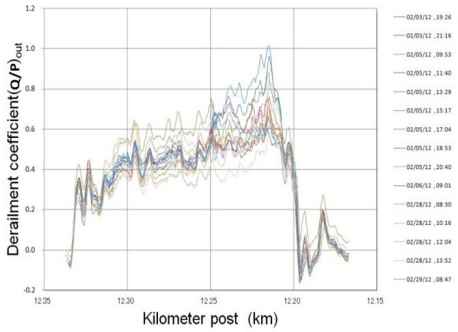


Figure 2 *Measuring mechanism of rail-wheel contact forces in "PQ monitoring bogie".*

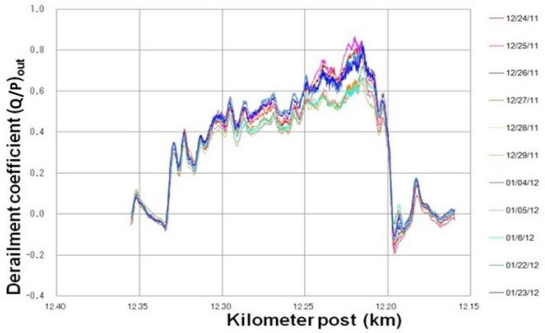

3.2. Observation of actual state of rail-wheel contact in sharp curves

The actual-state data collected by PQ monitoring bogies were very useful and important, influencing the implementation of condition-based maintenance of tracks and vehicles in the Tokyo Metro [7].

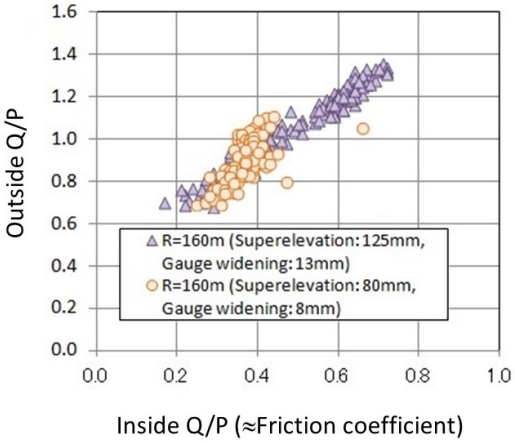

Figure 3(a) shows *Q/P* values for each pass of a train through a sharp curve of 160m radius, and Figure 3(b) shows daily average values of *Q/P* for 11 days, and Figure 3(c) shows the relationship of the inside *Q/P*—which is almost equivalent to the inside-rail friction coefficient—to the out-side wheel *Q/P*.

(a) Measured outside Q/P for each pass of a train.

(b) Measured outside Q/P of daily average value for 11 days.

(c) Relationship between measured inside Q/P (friction coef.) and outside Q/P (derailment coef.).

Figure 3 *Actual states of Q/P in sharp curve measured by "PQ monitoring bogie" (a 160m radius curve) [7].*

The authors have obtained many findings on sharp-curve running including large datasets involving actual states of rail-wheel contact [8], as well as data from full-scale bogie running tests using a roller rig in the NTSEL (see Figure 4) [9]. The following chapter examines the results of these experiments.

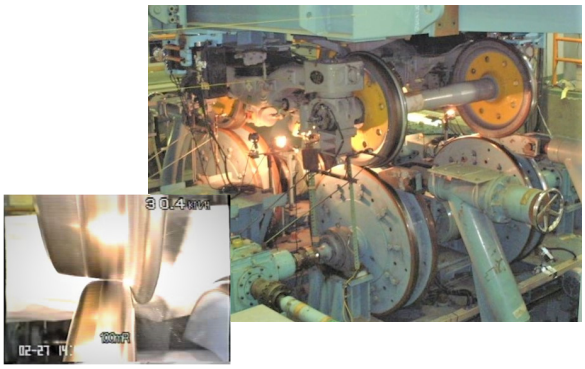

Figure 4 *Bogie running test on roller rig in NTSEL. Characteristics of rail-wheel contact in curving can be tested.*

4. Influences of friction on flange-climb and proposal of safety measure considering friction condition

4.1 Difference of contact points and friction conditions among four wheels in a bogie during curving

Figure 5 illustrates the difference of contact points of four wheels in a bogie during curving. The figure was drawn according to SMPACK simulation results, but similar results were observed from track-side measurements. As shown in Figure 5, the wheel-rail contact points are different among the four wheels in a bogie during curving. Generally, the outside wheel of the leading axle contacts to the rail at the flange, while both wheels of the trailing axle contact at the tread—near neutral position. As shown in Figure 6, rail lubrication devices are attached at the beginning of curves. Typically, the outside rail is lubricated from the gauge corner, and the inside rail from the field corner. Consequently, the friction conditions of four wheels are different, and the difference of friction coefficients among four wheels gives great influence on the curving dynamics [10].

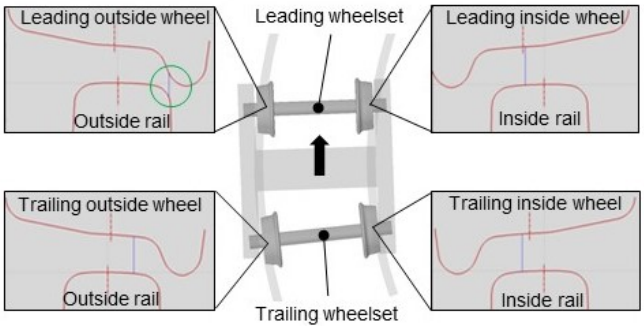

Figure 5 *Contact points when the vehicle runs on a sharp curve. This figure was drawn by results of SMPACK simulation, but similar results were observed in track side measurements.*

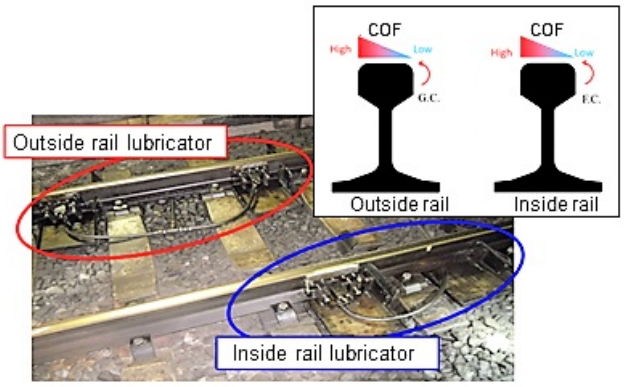

Figure 6 *Rail lubrication devices attached at the beginning of a curve.*

4.2 Relationship between friction condition and derailment coefficient of each wheel

When the flange of leading/outside wheel is lubricated, the derailment coefficient *Q/P* increases compared with dry condition. These phenomena occur in commercial train operations as well as in roller rig tests and in SIMPACK simulations. This tendency is produced by a decrease in the steering ability of the wheelset, but it does not decrease the safety, because the critical derailment coefficient is further increased.

Figure 7 shows the relationship of the real *Q/P* against the critical value of *Q/P*. In this figure the critical values of *Q/P* are drawn in the relationship to the friction coefficient between wheel flange and rail gauge corner. At point B the value of *Q/P* is greater than the critical value and it may be dangerous for flange-climb derailment. Contrarily at point A the value of *Q/P* is smaller than the critical value and it is safe enough against flange-climb derailment.

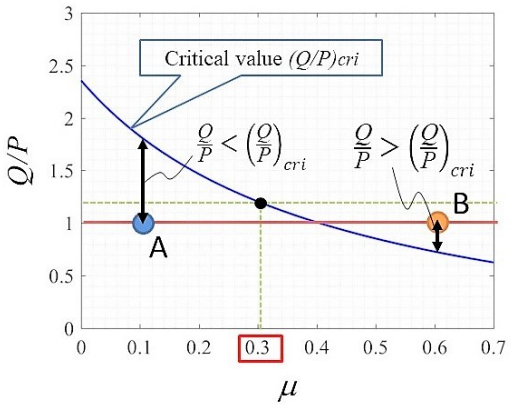

Figure 7 *Relationship of real Q/P to critical value of Q/P (flange angle = 67°).*

In this way, the absolute value of *Q/P* cannot serve as safety estimate only by itself and the ratio to the critical value is more important. Therefore, the authors introduce "flange climb index" (FCI) as the measure of safety against flange-climb derailments.

$$\mathrm{FCI} = \left(\frac{Q}{P}\right) / \left(\frac{Q}{P}\right)_{cri}$$

In cases where the FCI is larger than 1.0, flange-climb is possible, as shown Figure 8.

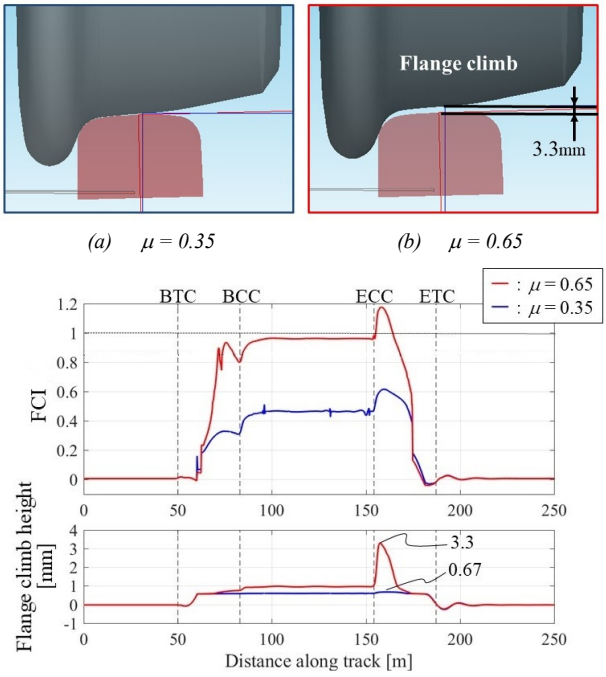

Figure 8 *FCI increase and occurrence of flange-climb. Flange-climb occurs just after ECC where FCI increases over 1.0.*

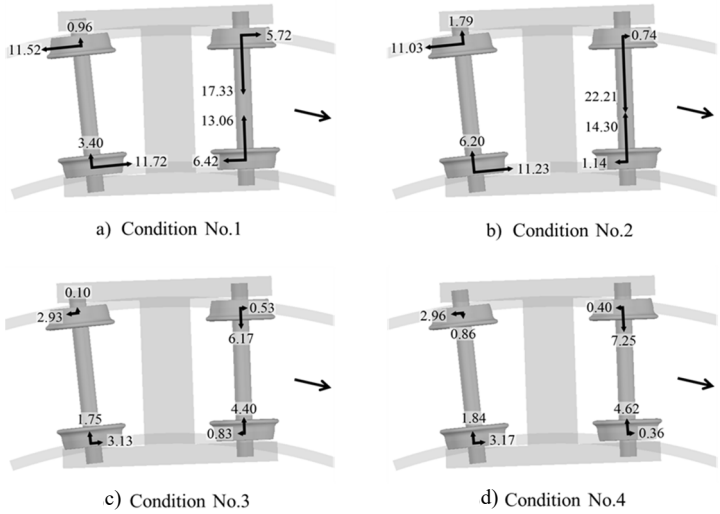
Figure 8 shows the calculated FCI for a curve of 160m radius for the case of $\mu = 0.35$ and $\mu = 0.65$. In the case of $\mu = 0.65$, the FCI increases immediately following ECC—the entrance of the exit-side transit curve—and exceeds 1.0. Subsequently, a flange-climb of 3.3 mm occurs (see Figure 8(b)) near the instance of maximum FCI. In contrast, flange-climb does not occur in the case of $\mu = 0.35$ where the FCI value does not exceed 0.6. Thus, the FCI is effective for determining the possibility of flange-climb.

Table 1 presents the relationship between lubrication conditions and the values of Q/P and $(Q/P)_{cri}$ of the leading/outside wheel—which are calculated by SIMPACK simulation. As shown in the table, the "inside lubrication" is most desirable, because it leads to a decrease in the outside Q/P. "Outside lubrication"—which reduces flange wear—results in an increase of the critical Q/P in spite of a small increase to the actual Q/P value. According to Table 1, the cases of "inside lubrication" conditions are good for derailment prevention, while the case of "4 wheels: dry" provides the narrowest margin against flange-climb. FCI values can quantitatively indicate the differences between these situations.

Table 1 *Safety ranking among lubrication conditions -simulation results of Q/P and FCI by SIMPACK. (number) shows the ranking for safety against flange-climb.*

Lubrication condition	**a) Condition 1** 4 wheels: dry $\boldsymbol{\mu = 0.5}$	**b) Condition 2** Only leading/outside wheel lubricated $\boldsymbol{\mu_{1out} = 0.1}$ $\mu_{1in} = \mu_{2out} = \mu_{2in} = 0.5$	**c) Condition 3** Inside wheels lubricated $\boldsymbol{\mu_{1in} = \mu_{2in} = 0.1}$ $\mu_{1out} = \mu_{2out} = 0.5$	**d) Condition 4** Leading/outside and inside wheels lubricated $\boldsymbol{\mu_{1out} = \mu_{1in} = \mu_{2in} = 0.1}$ $\mu_{2out} = 0.5$
Q/P	0.52 (3)	0.65 (4)	0.19 (1)	0.22 (2)
$(Q/P)_{cri}$	0.86 (3)	1.84 (1)	0.86 (3)	1.84 (1)
FCI	0.60 (4)	0.35 (3)	0.22 (2)	0.12 (1)
Figure of typical state	Figure 9(a)	Figure 9(b)	Figure 9(c)	Figure 9(d)



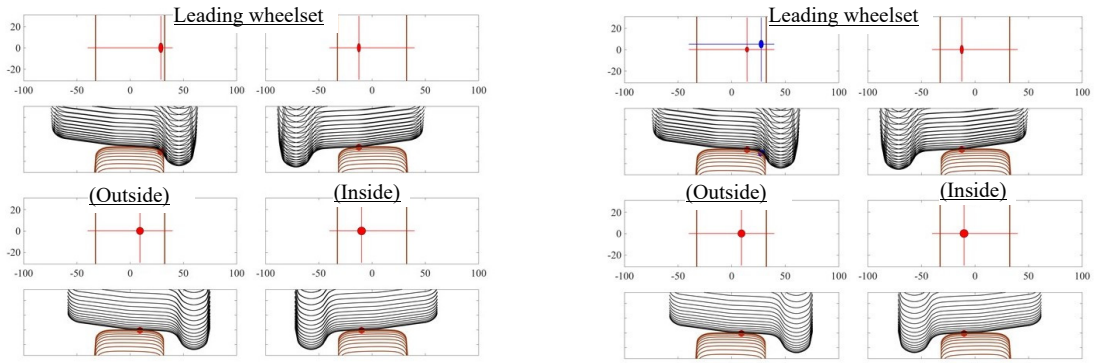


Figure 9 *Typical values of rail-wheel contact forces of a curving bogie considering the difference between the four wheels [10]. The forces are calculated by the numerical simulation where the curve radius is set to 160m.*

(b) Condition 1 (a) Condition 3

Figure 10 *Contact position and contact ellipses in each condition.*
The leading wheelset contacts at a flange while the trailing wheelset is nearly at a neutral position in all conditions.

Figure 9 shows the contact forces on the wheels in each condition, while Figure 10 shows the contact positions and contact ellipses in conditions 1 and 3. In all conditions, the leading wheelset contacts at a flange, while the trailing wheelset is nearly at a neutral position. However, the rail-wheel contact points of flange-rail are different according to conditions—one-point contact in condition 1, and two-points contact in other conditions. The tangential forces of rail-wheel contacts will be reduced in a wheelset when the inside or outside force is reduced by lubrication. This is because the moment by couple of tangential forces is decreased.

As mentioned above, the FCI provides a useful safety measure, but is difficult to apply in cases where the friction coefficient is unknown.

4.3 Proposal of a new measure of safety against flange-climb: FCI

To estimate safety from derailment with the FCI, value of friction coefficient is required. So, the authors propose an estimation method for the friction coefficient μ_{1out}—the coefficient of the leading/outside wheel flange—by using SIMPACK simulation data. μ_{1out} is determined with the estimator table that shows the relationship of μ_{1out} vs. tangential force T/P and κ (inside Q/P ratio)—calculated by SIMPACK simulations in advance [11]. Figure 11 shows the flow chart to calculate the FCI from data measured by PQ monitoring bogies.

Figure 11 shows the estimation diagram of μ_{1out}. As for the combination of various values of friction coefficients μ_{1out}, μ_{1in}, μ_{2out}, and μ_{2in}, SIMPACK simulations are carried out for different curving radii R; and forces P, Q and T are calculated for all wheels of a bogie. T is the tangential force acted at the rail-wheel contact point. Tangential forces are estimated from longitudinal forces on mono-links (components connecting axle boxes to a bogie frame), which are measured by additional strain gauges. Subsequently, the values are converted into non-dimensional values, such as κ, T_1/P_{1in} and T_2/P_{2in}. Using these results, "look-up tables" are created for determining μ_{1out} according to various R values.

The estimated values of μ_{1out} can be derived from the look-up tables as shown in Figure 12. The values κ *(approximately equal to* $(Q/P)_{in}$ *),* T_1/P_{1in} and T_2/P_{2in} introduce the value of μ_{1out}. The dotted arrow lines in the figure leads to the value $\mu_{1out} = 0.5$ from the values $\kappa = 0.5$ and $T_1/P_{1in} = 0.23$.

By this computation method of friction coefficient estimation, the FCI value at each curve can be obtained and safety evaliation against flange-climb derailments can be conducted from measured data by PQ monitoring bogies.

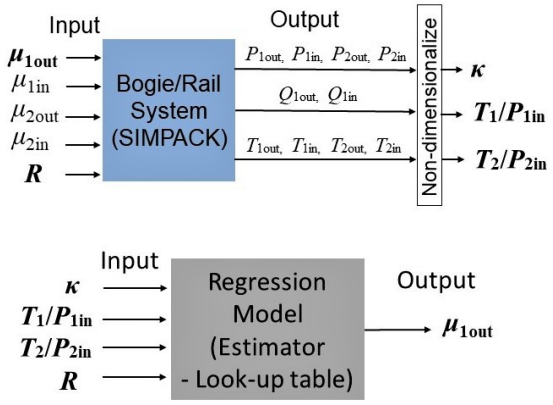

Figure 11 *Diagram of estimation of friction coefficient between flange and rail head of leading/outside wheel* μ_{1out}.

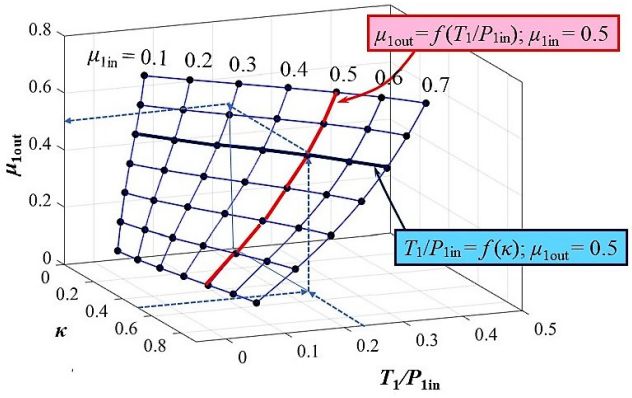

Figure 12 *Example of look-up table for seeking* μ_{1out}.

These outcomes described above are the result of numerical simulations, so the authors consider it necessary to validate the accuracy of the estimated μ_{lout} by using real bogies in roller rig tests and/or on-track tests.

5. Conclusions

As a new measure of safety against flange-climb derailments, "flange-climb index" (FCI) was proposed. The FCI is the ratio of the measured *Q/P* to the critical *Q/P* calculated by a modified Nadal's equation in the leading/outside wheel. To find the FCI, it is necessary to determine the actual friction coefficient value μ_{lout}, between wheel flange and rail head. In the proposed procedure, μ_{lout} is estimated using look-up tables calculated by SIMPACK simulations. Using the FCI, the safety margin against flange-climb derailment can be estimated quantitively.

For further study, the relationship between the FCI and the probability of flange-climb occurrence will be examined using roller rig tests and/or on-track tests with real vehicles—if possible.

Abstract – The purpose of this work is to evaluate the effect of changing cyclic yield strength levels of either wheels or rails on the plastic strain through FEM analysis. The simulations have been carried out with implicit two-dimensional finite element models both in clean contact conditions and in presence of solid contaminants. The materials used are some of the most traded in Europe and in America, with the addition of SANDLOS®S, an innovative steel designed specifically for sandy environments. FEM results were correlated to worn mass and optical micrographs previously achieved in rolling contact tests performed on small-scale specimens.

Keywords: wheel/rail contacts; wheel/rail materials; solid contaminants; cyclic plasticity; wear; finite element.

1. Introduction

The choice of the correct material coupling is crucial for optimizing the life of both the railway wheels and rails. An analysis of the typical material couplings used in Europe and USA showed that the hardness of the wheels is always lower than the hardness of the rails in cases of both straight lines and curves. Typically, the ratio of the wheel hardness to the rail hardness approximately ranges from 0.8 to 1 in straight lines and from 0.6 to 0.9 in curve. This means that the coupling system is designed so that the "sacrificial" element is the wheel, which can be re-profiled or replaced off site with a small direct impact on the exercise, if compared with the rail.

There is often concern about the impact that changes to one side of the wheel/rail interface will have on the opposite side of the interface, as it is commonly thought that increasing the hardness of one of the contacting elements, while reducing wear on itself, increases wear on the other body. However, a review of recent studies on this topic lead to conclude that this belief is not always justified [1]. Indeed, in a clean and dry environment, a hardness change of one of the bodies is expected to slightly change the size and shape of the contact patch, with a limited effect on the stress field of the other body. Lewis et al. [2] investigated the effect of hardness ratio on wear changing the rail and maintaining the same wheel; increasing rail hardness has the effect of lowering its wear rate, whereas wheel wear rate is constant when rail is harder than wheel but decreases when rail gradually softens. Liu et al. [3] focused on the effect of axle load on rail materials and reached the conclusion the hardness ratio of wheel/rail did not have a significant impact on wear rate at low axle load but, on the other hand, when a higher load was applied the ratio considered had a higher impact.

The presence of solid contaminants (such as sand, wear debris, crushed ballast, dust, etc.) significantly affects the damage process of both bodies [4~7]. The solid contaminants can be “exogenous”, e.g. coming from the external environment (such as sand or ballast), or “endogenous”, e.g. generated at the wheel-rail interface (such as wear debris). These contaminants influence the wear process by means of two mechanisms. First, they can indent and scratch the contacting bodies, generating the so-called “third body abrasion” [4, 5]. Secondarily, they can generate a thin layer of extremely high plastic strain, whose thickness is related to the dimensional scale of the contact area between a particle of contaminant and the contacting body. This body is clearly separated from a deeper layer of moderate plastic strain, whose thickness is related to the dimensional scale of the wheel-rail contact area. In the thin surface layer, the interaction between the plastic flow and third body abrasion can lead to the incorporation of the contaminant, enhancing high rate delamination wear [6, 7]. These wear mechanisms are strongly influenced by the material hardness and their coupling.

Rolling contact between rail and wheel gives some problems in finite element simulations due to plasticity, large rotation, friction, and contact. So far, most of FE models have been developed to study the contact problems in clean conditions both in elastic regime and considering plasticity [8~10], the crack nucleation and propagation [11, 12] and to improve the wheel geometry [13]. About the geometry models involved, we find 2D and 3D simulations and, as regards 2D, it is common to exploit only portions of wheel and rail [11, 12]. The presence of solid contaminants has mainly been discussed in the light of small-scale experimental tests. The contaminants used were sand [7, 14~17], alumina [18] and leaves [19]; in [20] the effect of wear debris was investigated. The aims of these works limited to investigate how parameters like the contaminant dimension or the feeding rate influenced the adherence and the surface damage. Anyway, FEM literature lacks studying the effect of solid contaminants in contact surface. Faccoli et al. [7] proposed a first attempt in analyzing the phenomenon considering two ring sectors rolling one on the other with two particles simulating the sand interposed between the discs; the analysis considered plasticity.

In this paper the effect of material coupling on the plastic strain of rails and wheels in presence of solid contaminants was analyzed by means of finite element simulation, taking into account some typical material couplings in curve and straight line. Analyses without contaminants were carried out as well for comparison. In particular, the effect of various cyclic yield strength ${}_cYS_{0.2}$ (which can be correlated to the material hardness) was investigated.

2. Materials

The materials involved in the simulations are some of the typically used in railway systems (see *Table 1* [6]). The wheel-rail couplings are only indicative and we can distinguish two groups of typical couplings: the European and the American. Separate mention should be made of SANDLOS®S, one innovative steel specifically designed for sandy environment; SANDLOS® S steel complies with AAR Standards and it represents an upgraded version of AAR CLASS C. For further details on this material see Ref. [6-7]. The hardness ranges reported in *Table 1* refer to European and American Standards for wheels (EN 13262 and AAR M107/M208 respectively) and rails (EN 13674-1 and AREMA). As concerns the investigated materials, at first sight, the following comments can be done: firstly, the American wheel materials are harder than the European ones, which implies higher yield strength and, consequently, lower plastic deformation; secondly, the rails are generally harder than the wheels (the only significant exception is the couple R260-SANDLOS® S); thirdly, for each group, passing from the straight-line to the curve condition, changing the rail material with a harder one is recommended. Rails EN 13674-1 R260 and AREMA325 are typically used in straight lines, whereas EN 13674-1 R350HT and AREMA370 in curves.

Since hardness values cannot be used to define material properties in FEM software, another mechanical property related to hardness was considered: the cyclic yield strength ${}_cYS_{0.2}$. Furthermore, this property will be necessary to define the constitutive law (see *Section 3*). Cyclic yield strengths for wheels refer to experimental data available in [6] and [21].

${}_cYS_{0.2}$ of rails were estimated on the basis of the trend of wheel strengths plotted against the average hardness in *Table 1* (*Figure 1*).

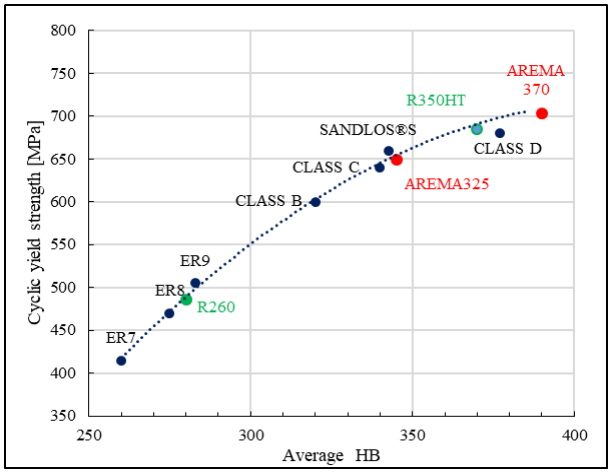

Figure 1 *– Correlation between cyclic yield strength and Brinell hardness in wheels. Isolated points show the predicted strengths of rails.*

3. FEM model

Standard implicit simulations were performed with Abaqus software. Two 2D finite elements models of full-scale wheel/rail interaction were considered: the former represents the rolling condition in the clean condition, whereas the latter shows the effect of solid contaminants between wheel and rail. In order to simulate the straight line and the curve conditions exploiting a bi-dimensional model, two levels of loads have been considered: 90 kN and 240 kN. These loading conditions match to Hertz pressures equal to 490 MPa and 800 MPa and semi-amplitude of pressure applications of 3.90 mm and 6.36 mm. The value of pressure in curve condition is coherent with one foreseen in [22], although it is much lower than the maximum contact pressure, which can reach about 1500 MPa. Choosing 800 MPa relies on the difficulties in convergence with too high pressures in presence of solid contaminants as well.

When it comes to the material constitutive law, the linear-elastic behaviour was applied until cyclic yield strength, and then the model is approximated through the Ramberg-Osgood plastic model:

$$\varepsilon = \frac{\sigma}{E} + \alpha \left(\frac{\sigma}{{}_cYS_{0.2}}\right)^n \qquad (2)$$

where σ and ε are the stress and the strain, respectively, E = 206,000 MPa is the elastic modulus, α = 0.2% is the conventional cyclic yield deformation, ${}_cYS_{0.2}$ is the cyclic yield stress and n is the plastic exponent. n is set to 5, a common value for many steels. A Coulomb friction law and a penalty contact formulation using in Abaqus's default stiffness were employed. The Coulomb friction is set to 0.5 for all the surface contacts (steel vs. steel and steel vs. sand). The mesh is made by linear plane strain elements, it is coarser at the boundaries and finer in the contact region.
As regards the couplings, we proceeded in the following way: firstly, we focused on the conventional couplings in straight-line (softer rails: R260 and AREMA325); secondly, we focused on to the same couplings but in curve conditions; finally, we changed the rails with the one suggested for curve conditions (harder rails: R350HT and AREMA370).
The models include many approximations of the real conditions: for instance, they do not take into account the uneven distribution of particle size and spacing, the problem three-dimensionality, the particle crushing, the cyclic load repetition, relative wheel-rail sliding even in presence of sand, and so on. However, the aim of the approach is not to provide a quantitative evaluation of the involved phenomena; instead, it is to highlight the role and the region of influence of solid contaminants, with particular focus on the plasticisation field, to which wear and fatigue are related. Further details of the models are described in Section 3.1 and Section 3.2.

3.1 Clean contact simulations

The model uses parts of the wheel and the rail, the dimensions were chosen so that the boundary conditions may not influence the stresses and the strains in the contact area. This was verified after some previous model sizes. The radius of the wheel is 450 mm with a plane strain thickness of 30 mm. The rail part has a rectangular shape with the same thickness as the wheel. The layout of the model is shown in *Figure 2*. The bottom of the rail is fixed. The portion of the wheel is tie constrained to a reference point, which represents the centre of the wheel itself. Rolling condition was obtained making the aforementioned point move towards a direction. Moreover, we considered also slipping condition; the slip rate was set to 0.01 and it was achieved forcing the wheel rotate a quantity equal to:

$$\vartheta = \frac{u}{R\,(1-s)} \tag{3}$$

where ϑ is the rotation imposed, u the translational displacement of the wheel, R the wheel-radius and, s the slip we want to obtain.
The simulations are broken up in two steps: in the former, the two components were brought to contact, in the latter the wheel portion was made roll over the rail for 30 mm. This rolling distance ensures that a steady state contact may be achieved.

3.2 Simulations of contact with sand

In simulations involving the contaminants, we considered the same dimensions of wheel and rail as in clean conditions. Due to problems of convergence and time needed, we could not consider rolling condition but a compression condition. Moreover, contact stabilization was employed. Wheel was fixed at the top, whereas the rail was made to move towards the wheel in a vertical direction. In order to simplify the model, only a half model was represented and the boundary condition of symmetry was imposed (*Figure 3*).
Sand was simulated adding elastic round particles of 40 µm diameter (representative of the sand fraction that can be transported by the wind [23]) having an axle spread of 60 µm. The number of particles was set to 180 because, in so doing, the rollers cover all the contact-area foreseen by the hertzian theory. In nature, the values of sand-rocks mixture stiffness may vary in a wide range (from about 1 GPa till 100 GPa) [24]. For this reason, preliminary simulations with different stiffness were run. Needless to say, more-rigid particles implied higher plastic strains in wheels and rails (see *Figure 4*). For this reason, we limit to consider the 100 GPa to compare straight line with curved one, as it represents the most deleterious condition.

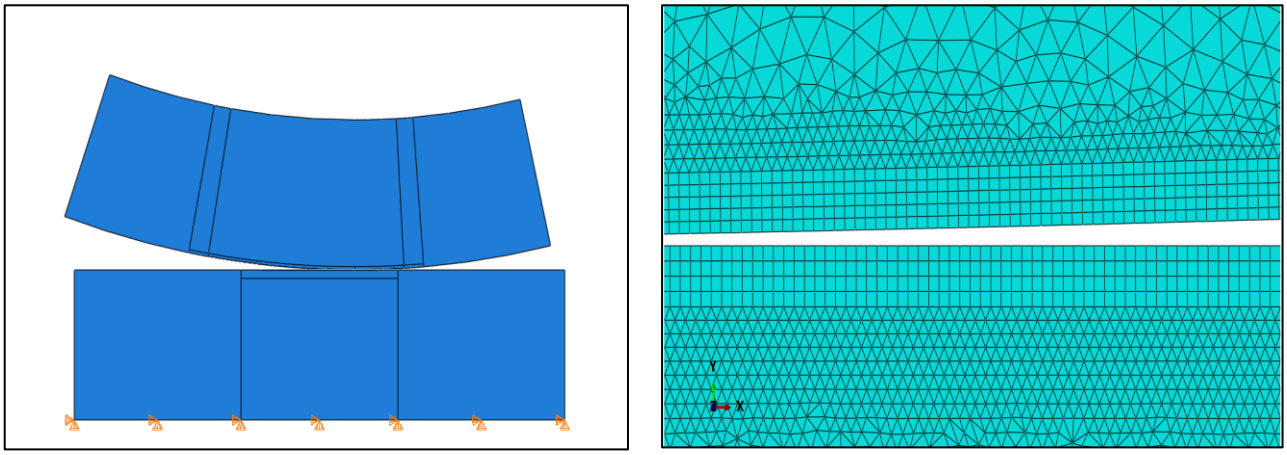

Figure 2 *- Wheel-rail model for clean simulations.*

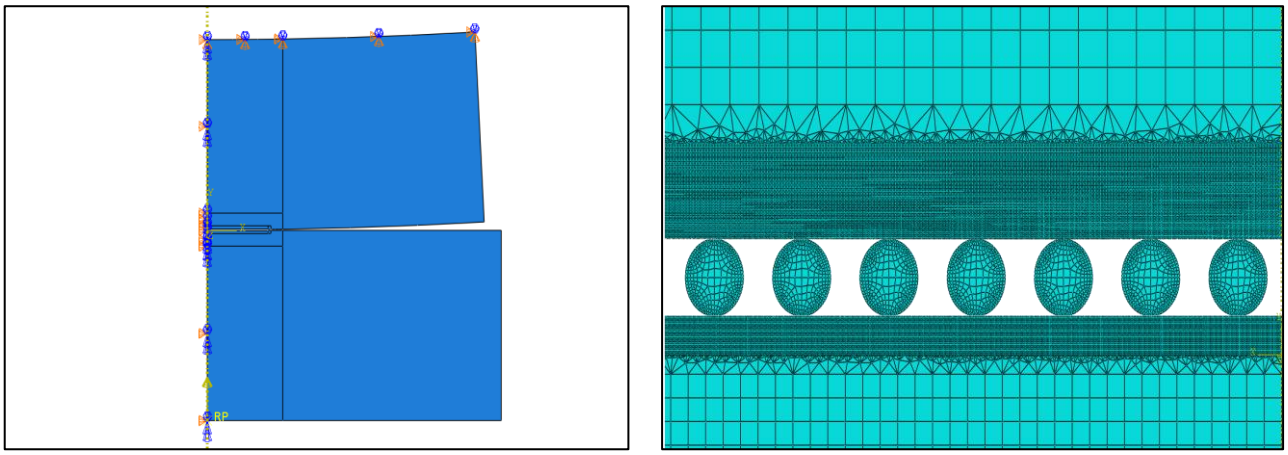

Figure 3 *- Wheel-rail model in presence of solid contaminants: on the left, the overall assembly model; on the right, a detail of the contaminants represented as rollers.*

It should be highlighted this kind of model is rather more simplistic than the abrasive wear process. Grieve et al. [17] observed the following: firstly, the ballast particles trapped between rail and wheel are fractured; secondly, the particles agglomerates into flakes and embeds into the softer material ploughing the harder one.

Despite the model here proposed does not consider the fracture of particles and their embedment and the results do not include the effects of shear stress (since only compression load was considered), as we will see, it is sufficient to qualitatively investigate some of the phenomena induced by contact fatigue, for instance the effect on plastic strain on different couples of materials.

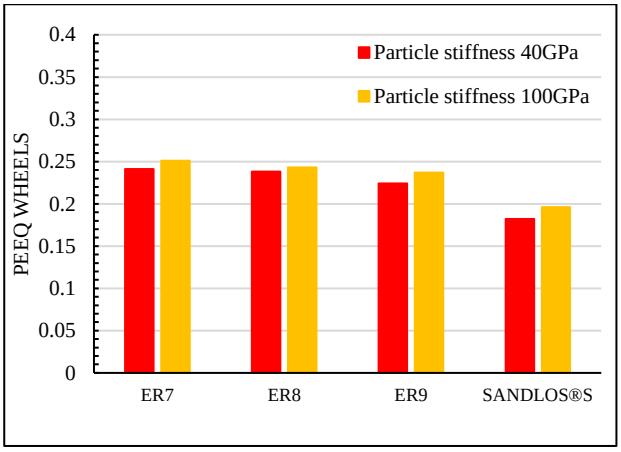

Figure 4 *– Maximum plastic deformation in European wheels with varying particle stiffness; applied load 90kN, rail R260.*

4. FE results and discussion

Results obtained were evaluated mainly in terms of plastic deformation, comparing the equivalent plastic strain (henceforth called PEEQ) calculated through Abaqus software. The considered values were taken from the surface contact in both clean and sandy conditions. Regarding the latter condition, a precision must be made. *Figure 5* shows the distribution of Von-Mises stress in CLASS B and CLASS D wheels (the considered American wheels with the lowest and the highest ${}_{C}YS_{0.2}$, respectively) coupled with AREMA370 in presence of sand, but the same reasoning can be applied to all the wheels and rails. There is a gradient of stress around the wheel surface deformed by the particle. At the centre of the sand-wheel contact surface, this stress is lower than in the lateral side and, therefore, so is the PEEQ value. For this reason, all the results considered in surface and below will be referred to the path represented in a dashed line, located at a distance of 5 µm from the central line.

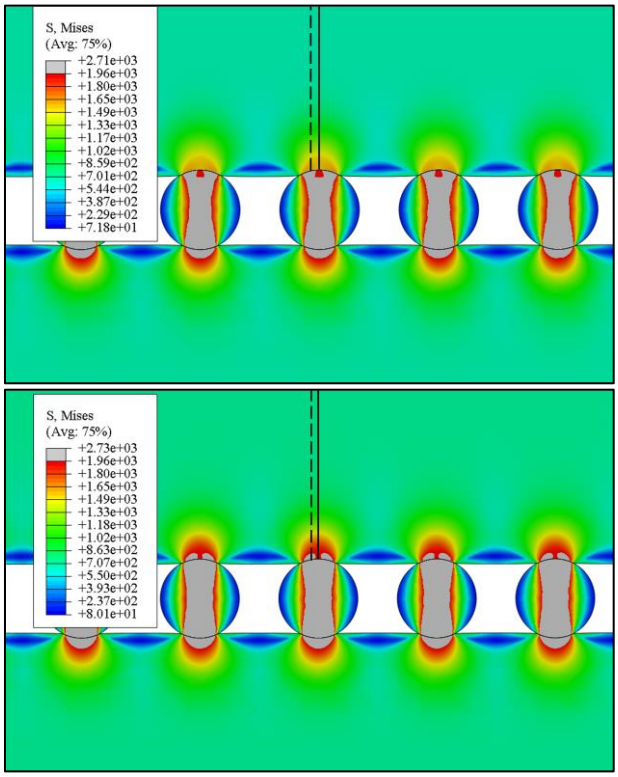

Figure 5 *- Example of stress distribution in presence of sand: the picture above shows CLASS B wheel vs. AREMA370 rail (240kN); the picture below CLASS D wheel vs. AREMA370 rail (240kN).*

Figure 6 shows the trends of the maxima PEEQ calculated in surface for all the simulations. The dashed lines refer to simulations with softer rails (R260 and AREMA325), the solid lines to those with harder rails (R350HT and AREMA370). The solid icons refer to European wheels, the empty ones to American. Analysing 90 kN results for the clean condition, it should be noted that American rails and wheels do not plasticize or their plastic strain is negligible. European rail (R260) plasticizes less than ER7 and ER8, whose ${}_{C}YS_{0.2}$ are lower than the rail one, but more than ER9 and

SANDLOS®S, whose strengths, on the contrary, are higher. Plastic strain in wheels decreases with increasing of wheel ${}_cYS_{0.2}$.

When the load of 240 kN is applied in the clean condition, replacing the softer rail with a harder one brings benefits to the rail itself, causing the plastic strain of wheels to increase. Notice that the softer rails (R260 and AREMA325) plasticize more than the wheels when the cyclic strength ratio (wheel/rail) is higher than 1. On the contrary, the harder rails (R350HT and AREMA370) always plasticise less than the wheels. This is coherent with the rules of rail system design according to which the sacrificial element is the wheel. Overall, we can state as wheel ${}_cYS_{0.2}$ increases and rail material remains the same, wheel plastic strain shows a downward trend; on the other hand, rail plastic strain slightly increases and it seems to reach a steady state when ${}_cYS_{0.2}$ wheel becomes higher than the rail one. These results remind of the ones achieved in [2] where the following model for clean condition have been validated: given a couple of materials A and B in contact and fixed one of them (B, for instance), increasing the hardness of A implies a decrease of A-wear and, in the meanwhile, B-wear increases till the hardness of the two materials are the same.

When a third element is interposed between wheel and rail, the strain in the surface is much higher than in clean condition and the PEEQ is one order of magnitude higher. Plastic strains in wheels still have a decreasing trend. If we consider the couplings referring to the same loading conditions, we can notice that the results of the wheels lie on the same straight line, meaning that the wheels behaviour is not affected by the coupled rail but only by the cyclic yield strength. As far as the rails are concerned, here again, the softest American one (AREMA325) behaves better than European one (R260).

The relevant gap in the results between clean and sand conditions may be justified by the contact pressure distribution. *Figure 7* reports, for instance, the pressure distribution in the curve condition with European and American couplings compared to the pressure foreseen by the hertzian theory (for practical reasons we report only the 240kN case). In plastic regime and in presence of slip rate, the contact area is wider and the maximum pressure is lower; in particular, the lower the ${}_cYS_{0.2}$ is, the lower the maximum strain. Furthermore, the pressure distribution is asymmetric, which means the resulting force direction is slightly displaced from the centre of the contact area, generating a momentum due to the friction force on the contact surface. In sand-simulations, the maximum pressure is much higher than the one in clean condition; the distribution is not uniform and, in the region of contact with the rollers, peaks appear. The peaks are surrounded by regions with zero pressure, because of the separation of the wheel contact surface (see *Figure 5*). *Figure 8* and *Figure 9* show examples of the abovementioned phenomenon for ER9 wheel, but the same conclusions may be transferred to other wheels. An interesting comment can be made: when the load is lower (*Figure 9*) the overall trend from the centre is downward resembling the one in clean condition, whereas increasing the load (*Figure 8*) the contact pressure is almost uniform with the maximum on the border of the wheel-rail contact area.

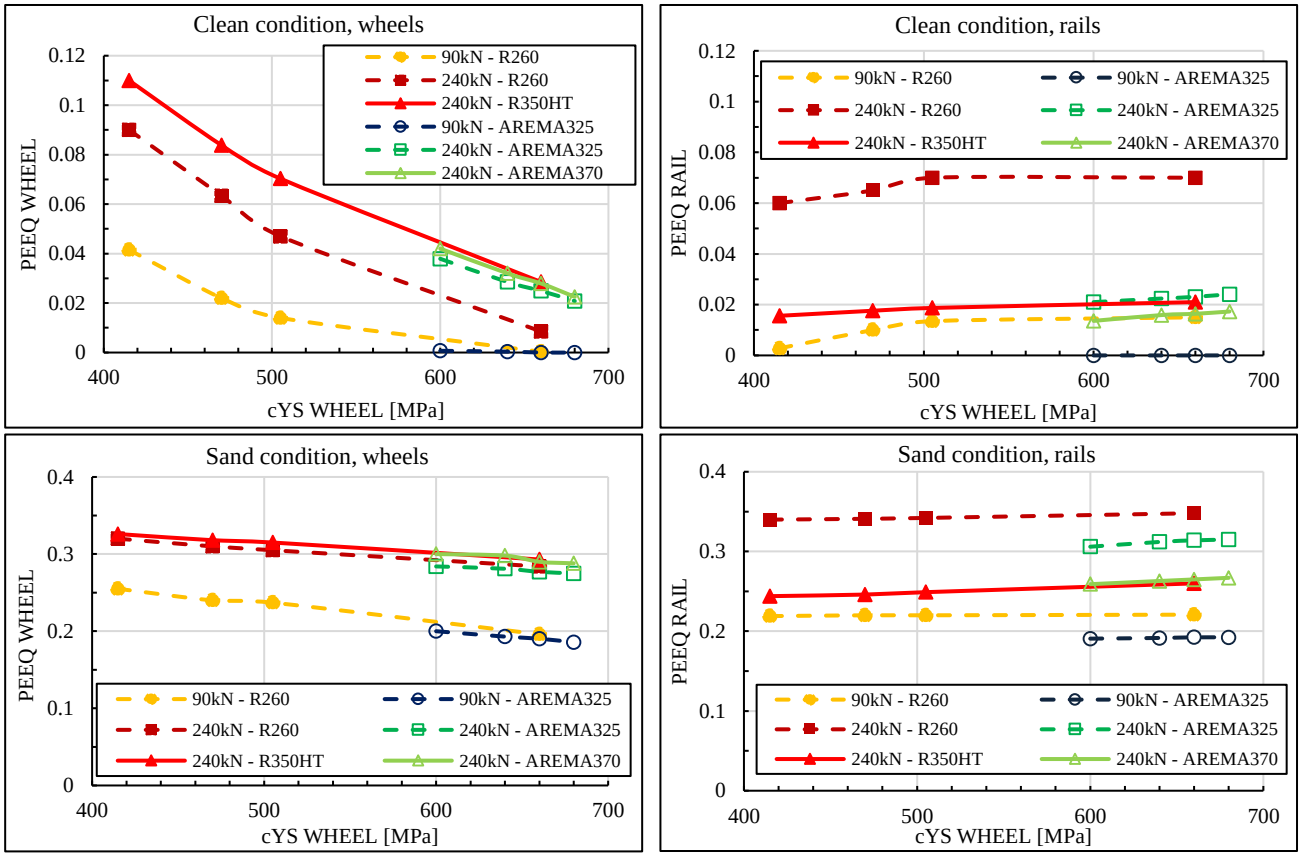

***Figure 6** – Maximum plastic deformation in surface vs. cyclic yield strength of wheels. On the left PEEQ values of wheels are shown, on the right the values referred to the rails. About the rails, the results are illustrated in respect of the strength of the coupled wheels.*

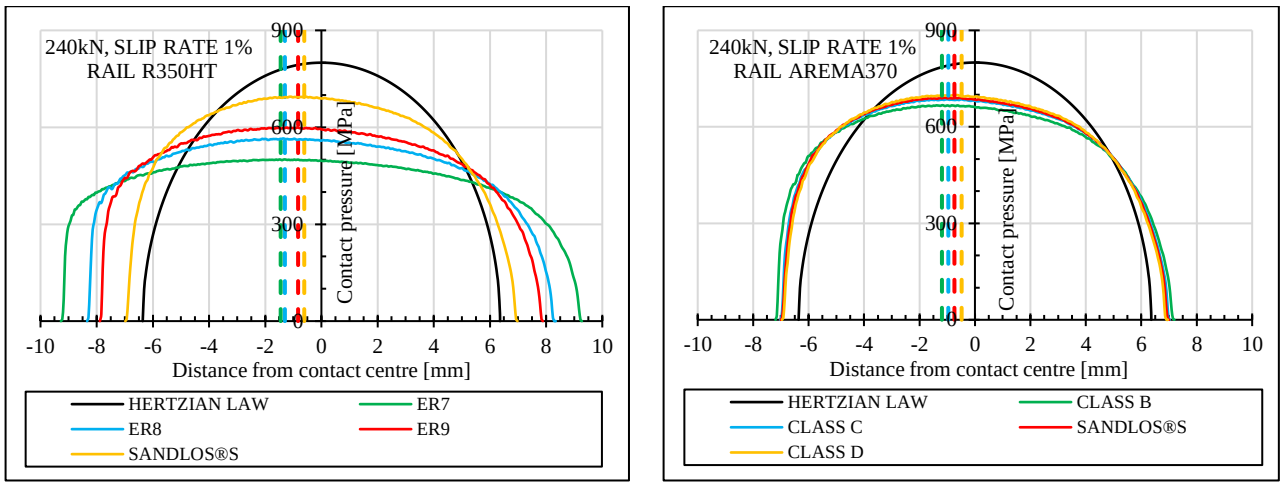

Figure 7 *- Contact pressure distribution on the wheel contact area without sand, compared to the Hertz distribution (applied load 240kN): on the left the European couplings, on the right the American ones. The dashed lines show the location of the maxima contact pressures.*

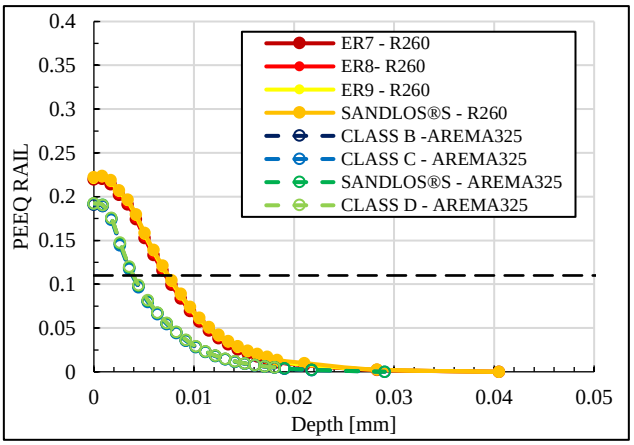

Figure 14 - *Equivalent plastic strain trend vs. depth in* ***rails*** *with solid contaminants (90kN).*

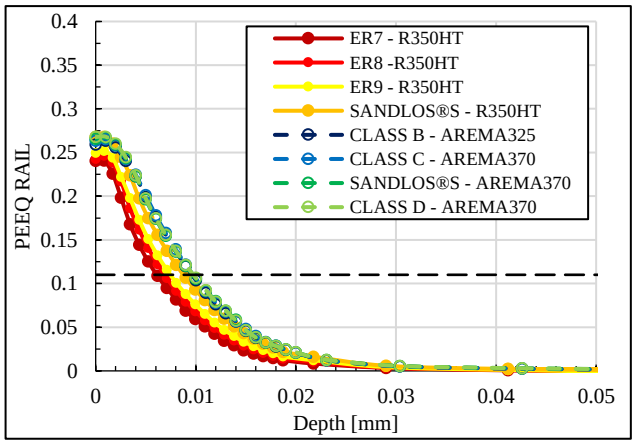

Figure 15 *- Equivalent plastic strain trend vs. depth in* ***rails*** *with solid contaminants (240kN).*

This phenomenon may rely on the fact the number of sand particles in the 240kN-model is not enough to cover the surface contact with such a high load and in presence of contaminants, the increasing of the number of particles may lead to a decreasing trend of contact pressure as well. Analysing PEEQ values in the wheel subsurface in the clean condition (*Figure 10* and *Figure 11*), we can see the depth where the PEEQ becomes null is strongly influenced by the cyclic yield strength of wheels; in some circumstances, passing from the softest wheel to the hardest one, plastic strain becomes zero since the wheels remain in elastic regime (*Figure 10*). Quantifying the depth of this layer is extremely important since it represents the plasticized depth. Irrespective of materials involved in presence of sand particles the following should be highlighted: when a load of 90 kN is applied (*Figure 12*), PEEQ becomes zero between 0.020 and 0.045 mm of depth; when a load of 240 kN is applied *(Figure 13*), the charts reach a steady state of plastic strain at the depth of about 0.035-0.040 mm. In both loading conditions, an increasing trend until a certain depth can be noted, after which plastic strain begins to

decrease away from the surface. Moreover, the higher the cyclic strength, the lower is the maximum. If we compare wheel and rail behaviour, once again, rails are less swayed by the change of the wheels (*Figure 14* and *Figure 15*); however, in presence of contaminants, rail plastic strain order of magnitude is comparable to the one of the coupled wheel (especially in American couplings). Other relevant information can be obtained analysing the plasticized layers in both wheels and rails.

The presence of sand particles induced in all couplings the creation of a shallow field near the regions in contact with rail and wheel characterized by huge permanent plastic deformation. The dashed lines in *Figures 12~15* represent the maximum PEEQ calculated in clean environment (about 0.011 for ER7 steel, see *Figure 11*) and, as can be seen, irrespective the load condition and the materials, this value is shifted at a certain depth leaving above a more deformed region. The depth of this layer is approximately of the same order of magnitude as the dimension of the sand-wheel contact.

Below the conventional threshold of 0.011 we can find a moderate plasticized field. In 90kN-simulations, this field extends to a limited depth (about 0.045 mm in the worst case, ER7 wheel, *Figure 12*); in 240kN-simulations, as already said, beyond a certain depth, the PEEQ remains constant. The absence of this area characterized by constant plastic strain in 90kN-simulations may rely on the fact the load is not high enough to cause plasticization around the areas in contact with particles, and, as predicted in [6], increasing the number of particles causes the strain field to relax in their proximity.

The existence of these two layers was confirmed by optical micrographs. *Figure 16*, for instance, shows a comparison between micrographs obtained with an optical microscope and the FEM results about ER8 wheel against R350HT rail.

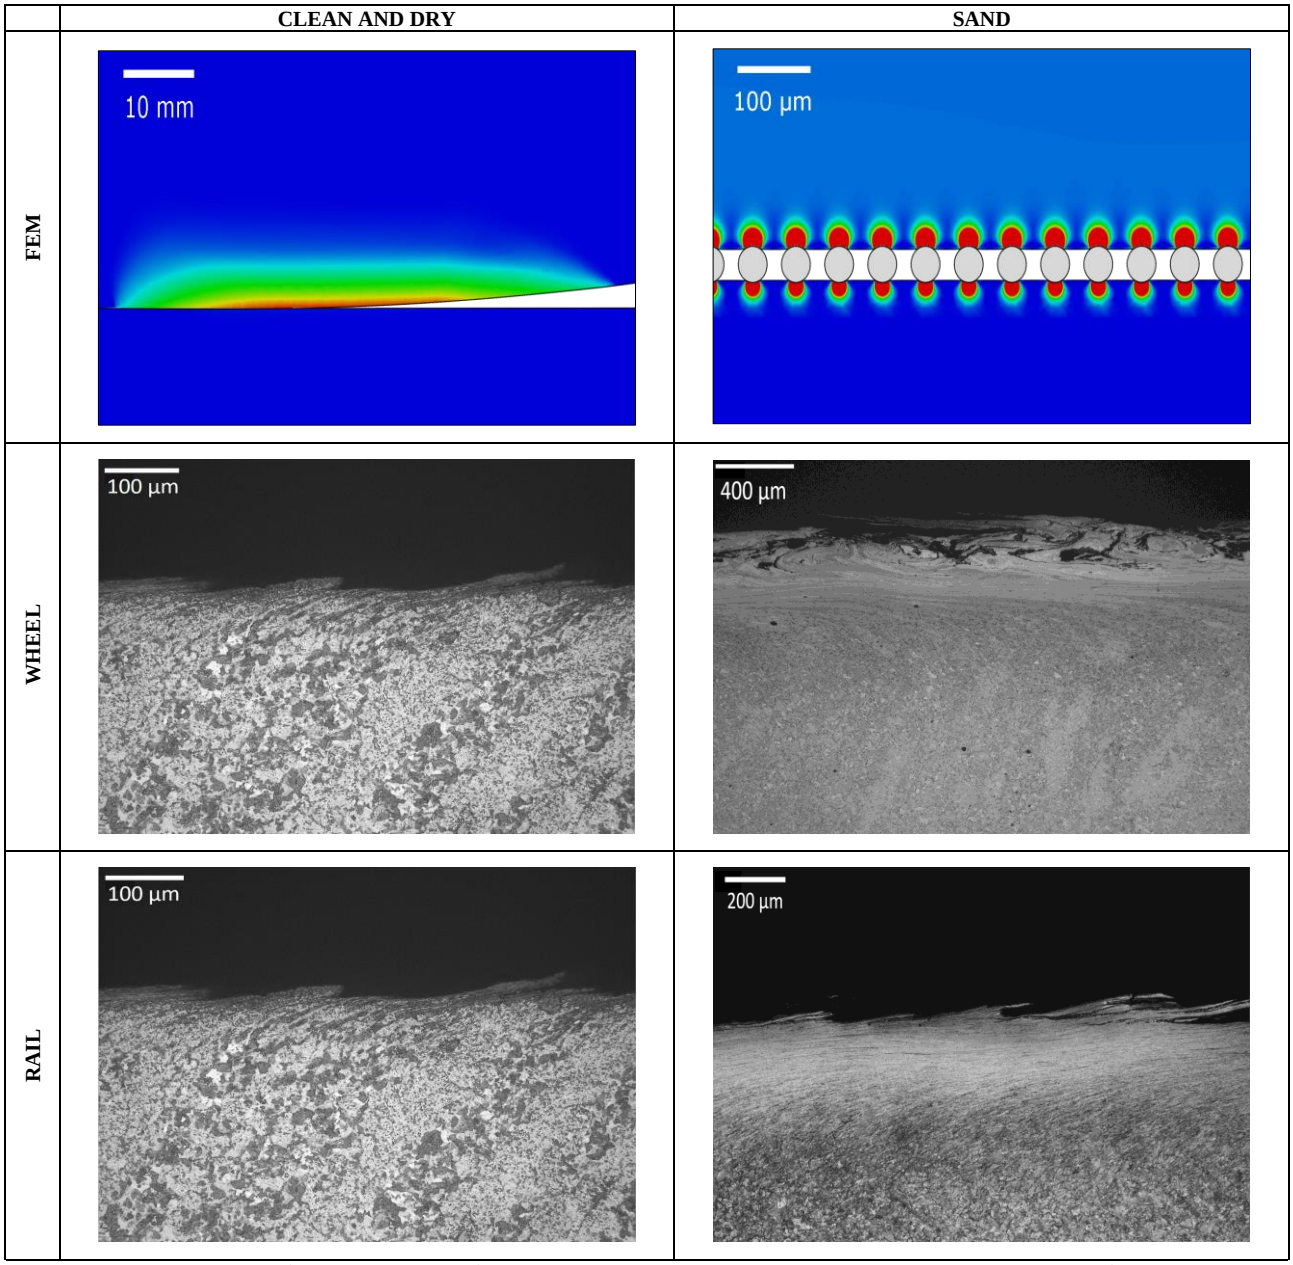

***Figure 16** – Micrographs of the etched sections of ER8 and R350HT tested in [7] compared to the calculated plastic strain field. In order to compare FEM results, the PEEQ conventional threshold was set to 0.11 (the maximum strain in the wheel with sand).*

It should be made clear what follows is a qualitative comparison since the micrographs refer to experimental tests carried out in clean and sand conditions on small-scale specimen with contact pressures different from the ones adopted in simulations (for more details about the test refer to [7]). On the left side, the experimental evidences in both wheel and rail show a uniform plasticized field, in accordance with FEM; on the right side, the incorporation of sand particles in the wheel due to high pressure induced a high plastic flow in a thin region of the surface and the deviation of the plastic flow lines near the englobed particles. Furthermore, even the region far away from the contact with sand is subjected to moderate plastic flow. Likely, the rail in sand condition shows a more intense plastic deformation than in clean environment but the damage is less severe than that occurring in the wheel. As underlined above, a direct quantitative comparison between the calculation and experimental results has not to be searched, as the FEM mode contains many approximations of the real working conditions, among which, in particular, the fact that only a single load cycle is simulated. However, the simulation well explains the role of contaminants particles in originating the surface heavily strained layer.

The permanent plastic strain accumulated can be related to wear. In fact, ratcheting (plastic strain accumulation), leading to surface cracking and material removal, is one of the mechanisms responsible of wear, although not the only one. In [7], ER8, SANDLOS® S and CLASS C were tested against R350-HT rail. The existence of a qualitative correspondence between wear and plastic strain emerges if we compare the worn mass after 130,000 cycles and plastic strain calculated with finite elements. *Figure 17* reports the experimental worn mass obtained in the tests. As for the equivalent plastic strain, the experimental worn mass is much higher in the presence of sand, this result is also coherent with other works dealing with solid contaminants [16, 17].

The trend of wear recalls the one foreseen by FEM: as the cyclic yield strength of the wheels increases, the wheel worn mass decreases and so the plastic strain does; on the contrary, rail worn mass increases. As concerns experimental tests with sand, other observations can be made: firstly, if the wheel/rail cyclic strength ratio of materials is low, the worn mass of wheel (ER8) is higher than the one of rail; secondly, when wheel and rail hardness are comparable, the worn masses are comparable as well. FEM results lead to the same conclusions.

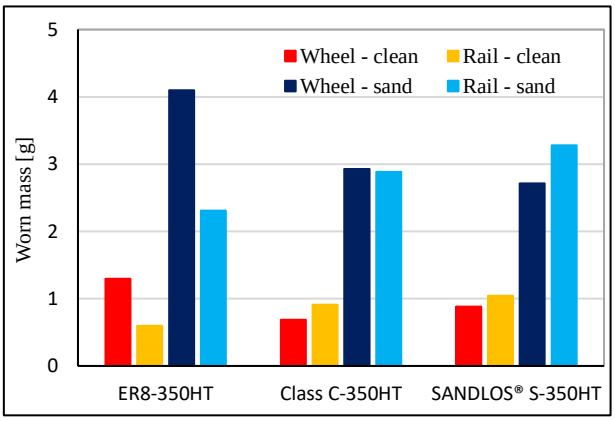

Figure 17 *– Experimental worn mass at the end of the tests shown in [7].*

5. Conclusions

In this paper, the effect of changing the cyclic yield strength ratio between wheel and rail in presence of solid contaminants was investigated with the help of implicit 2D element analysis. Simulations were carried out with two levels of loads, portraying the straight line and the curve conditions. Furthermore, for a better comparison, clean conditions were simulated as well. The results were mainly discussed in terms of plastic deformation.

The main findings are listed in the following points:

- In clean and dry condition, increasing ${}_cYS_{0.2}$of wheel, maintaining the same rail, strongly affects the plastic strain in surface of the wheel itself. Nevertheless, strain values in rails slightly increase till the cyclic yield strength ratio wheel/rail is >1, then no variations are foreseen. Irrespective of load conditions, the considered American materials, harder than European ones, behave better.
- The presence of particles in the contact area significantly increases the plastic deformation. Increasing ${}_cYS_{0.2}$ leads to a reduction of surface plastic strain in wheels but the effect is less significant than the one obtained in the clean condition. Again, rail strain slightly increases but its value is comparable to the one of the wheel.
- Both clean and sandy simulations confirm that the changing of rails with harder ones is suitable when the loads are higher, especially in clean conditions.
- Both FEM and experimental tests show the two deformed layers with contaminants: the surface layer with severe deformation, whose dimension is related to the wheel-particle contact, and a deeper layer with moderate plastic strain, related to the wheel-rail contact. Worn mass shows the same trend of plastic strain in FEM.
- All the results achieved, both numerical and empirical, lead to the conclusion the parameter to be improved is the cyclic yield strength of wheel assuming the rail has good properties. This is why the innovative steel for sandy environment, SANDLOS®S, was designed from traditional American wheels.
- Despite models adopted to analyze the effect of contaminants were simplified, they lead to good results, consistent with experimental tests as well.

Abstract:
The research into the adhesion is vital for the wheel-rail contact modelling, but also challenging due to the complex non-linear characteristics of the adhesion coefficient. To obtain higher accuracy on the wheel-rail contact model, an innovative degraded adhesion model has been developed, taking complex phenomena including large sliding at the contact interface, energy dissipation and adhesion recovery into consideration. A new approach based on FASTSIM algorithm and Polach theory to solve the tangential contact problem has been developed specifically designed for the wheel-rail contact and multibody vehicle models. The simulated results have been validated by the comparison with experimental results.
Keywords: Degraded adhesion, adhesion recovery, wheel-rail contact model, multibody modelling, railway vehicles

1. Introduction

The accurate modelling of the wheel-rail contact plays a fundamental role in the railway field since the contact forces heavily affect wear, vehicle dynamics and vehicle safety. Typically, simplified and efficient multibody contact models are characterized by three main logical parts: the contact point detection, the normal problem solution, and the tangential problem solution, including the adhesion model. The contact point detection allows the calculation of the contact point position on the wheel and rail surfaces. The general approaches make use of constraint equations [1], or analytical methods aimed at reducing the algebraic problem dimension [2-4]. The normal problem solution is generally based on Lagrange multipliers [5, 6] and on improved Hertz theory [7-9]. Concerning the solution of the tangential problem, different approaches have been taken into account in the last decades. The most significant strategies comprise the linear Kalker theory (saturated according to Johnson-Vermulen formula [10-13]), the non linear Kalker theory implemented in the FASTSIM algorithm [13-16], and Polach theory [17, 18] that allows to describe the decrease of the adhesion coefficient with increasing creepage (excluding the contact spin) and to better fit the experimental data. The tangential problem is particularly challenging because of the difficulty to obtain a realistic adhesion law, due to the complex non-linear behaviour of the adhesion coefficient and the presence of external unknown contaminants (third body layer). This is especially true when the degraded adhesion yields a high energy dissipation and, consequently, an adhesion recovery. In the past, the authors developed a preliminary degraded adhesion with the aim of extending the Polach approach. This approximated model was global, i.e. the local behaviour of the contact pressures inside the contact area was neglected [19].

During the years, many studies have been performed to investigate the role of the third body between the contact surfaces, and many analyses have been carried out through both laboratory test rigs and on-track railway tests [20-27]. At the same time phenomena as the dissipation of energy and the adhesion recovery has begun to be more accurately studied, in order to have a better understanding of the non-linear behaviour of the degraded adhesion [28- 30].

The new model proposed by the authors in this work focuses on the main phenomena characterising the degraded adhesion, paying particular attention to the energy dissipation at the contact interface, the consequent cleaning effect and the resulting adhesion recovery due to the removal of external unknown contaminants. This phenomenon is caused by the high energy dissipation on the contact surfaces and by the consequent cleaning effect due to friction. The final adhesion recovery caused by the removal of external contaminants may deeply affect both the vehicle dynamics and the traction and braking manoeuvres.

Besides, since most of the physical characteristics of the contaminants are totally unknown in practice, the followed approach will have to minimize the number of hardly measurable physical quantities required by the model.

The model here proposed is local (pressure and slip are locally calculated inside the discretized contact surface), and has been thought to cover all the main scenarios of the railway field, e.g. to different wheel and rail profiles, generic railway track and multiple contact points. As railway dynamic simulations are usually carried out by means of multibody models, the contact models have to be suitable to be implemented directly online and in real time within the multibody software (e.g. Matlab-Simulink or Simpack environments), and so they

have to guarantee a good accuracy and a high numerical efficiency (computation time and memory consumption). For this reason, since the numerical performance is a primary concern, in practice it is impossible to model the contact by considering the wheel and the rail as generic elastic continuous bodies. Finally, the adhesion model has been preliminarly validated through to experimental data provided by Trenitalia S.p.A. and coming from on-track tests performed in Velim (Czech Republic) with the railway vehicle UIC-Z1, showing good accuracy and high numerical efficiency.

2. General architecture of the model

The multibody model consists of two different parts that mutually interact during the dynamical simulation: the 3D model of the railway vehicle and the 3D wheel-rail contact model (Fig. 1). At each time step, the multibody vehicle model calculates the kinematic variables of each wheel (position $\underline{G}_w$, orientation $\underline{\Phi}_w$, velocity $\underline{v}_w$ and angular velocity $\underline{\omega}_w$) while the contact model, starting from the knowledge of these quantities, evaluates the normal and tangential contact pressures p_n, $\underline{p}_t$ applied to the wheel into the contact area associated to the contact point $\underline{P}_c$, the sliding $\underline{s}$ in the contact patch and the friction coefficient μ inside the contact area.

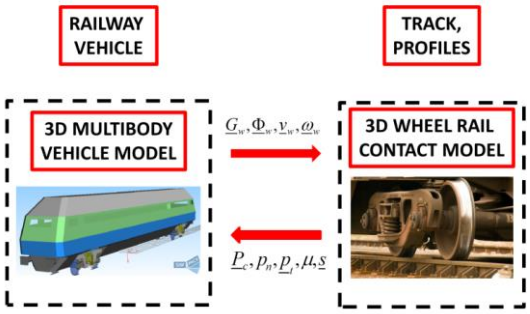

Figure 1 *Architecture of the multibody model*

Typically, simplified and efficient multibody contact models are characterized by three main submodels: the contact point ($\underline{P}_c$) detection, here based on some innovative procedures recently developed by the authors in previous works [4] [16] [31], the normal problem, solved through the global Hertz theory to evaluate the normal contact pressures ($\underline{p}_n$), and the tangential problem to compute the tangential contact pressure $\underline{p}_t$, the sliding $\underline{s}$ and the friction coefficient μ(Fig. 2).

The strategy to solve the tangential problem is based on the new local degraded adhesion model developed by the authors in this work. The main inputs of the degraded adhesion model are the wheel kinematic variables, the position $\underline{G}_w$, the orientation $\underline{\Phi}_w$, the wheel velocity $\underline{v}_w$, the wheel angular velocity $\underline{\omega}_w$, the normal pressure at the contact interface p_n and the position of the contact points $\underline{P}_c$. The model also requires the knowledge of some geometrical and physical wheel-rail and contact parameters that will be introduced along the paper.

The new degraded adhesion contact model is local because it enables the calculation of tangential pressure $\underline{p}_t$, sliding $\underline{s}$ and friction coefficient inside the discretized contact patch by extending the Kalker's FASTSIM algorithm and the Polach theory to properly take into account energy dissipation and adhesion recovery.

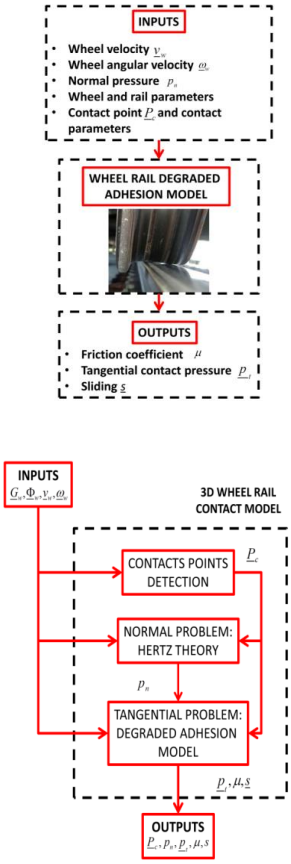

Figure 2 *Inputs and outputs of the degraded adhesion model and architecture of the wheel-rail contact model*

3. The vehicle multibody model

In this chapter the vehicle multibody model is described in detail. The considered railway vehicle is the UIC-Z1 wagon; its geometrical and physical characteristics are provided by Trenitalia S.p.A.[33]. The vehicle is equipped with a Wheel Slide Protection (WSP) system [32-34]. The wagon is composed of one carbody, two bogie frames, eight axle boxes and four wheelsets. The primary suspension, including flex coil springs (two coaxial helical compression springs), vertical hydraulic dampers and axle box bushings, connects the bogie frame to the four axle boxes while the secondary suspension (vertical lateral and longitudinal ant-yaw dampers, lateral bump-stops, anti-roll bar and traction rod), connects the carbody to the bogie frames. In Tab.1 the main properties of the railway vehicle are given.

Table 1*. Main characteristics of the railway vehicle.*

Parameters	Units	Value
Total mass	[kg]	≈ 43000
Bogie wheelbase	[m]	2.56
Bogie distance	[m]	19
Wheel diameter	[m]	0.89
Primary suspended masses own frequency	[Hz]	≈ 4.5
Secondary suspended masses (carbody) own frequency	[Hz]	≈ 0.8
Wheel profile	-	ORE S 1002
Rail profile	-	UIC 60

The multibody vehicle model takes into account all the degrees of freedom (DOFs) of the system bodies (one carbody, two bogie frames, eight axle boxes, and four wheelsets). Considering the kinematic constraints that link the axle boxes and the wheelsets (cylindrical 1DOF joints) and without including the wheel-rail contacts, the whole system has 50 DOFs.

The main inertial properties of the bodies are summarized in Tab. 2. Both the primary suspension (springs, dampers and axle box bushings) and the secondary suspension (springs, dampers, lateral bump-stops, anti-roll bar and traction rod) have been modelled through 3D visco-elastic force elements able to describe all the main non-linearities of the system.

***Table 2**. Main characteristics of the railway vehicle.*

Body	Mass [kg]	I_{xx} [kgm^2]	I_{yy} [kgm^2]	I_{zz} [kgm^2]
Carbody	≈ 29000	76400	1494400	1467160
Bogie	≈ 3000	2400	1900	4000
Wheelset	≈ 1300	800	160	800
Axlebox	≈ 200	3	12	12

In Tab. 3 the characteristics of the main linear elastic force elements of both the suspension stages are listed. The non-linear elastic force elements have been modelled through non-linear functions that correlate the displacements and the related velocities of the force elements connection points to the elastic and damping forces exchanged by the bodies. By way of example the non-linear characteristic of a vertical damper of the primary suspension is illustrated in Fig. 6. Finally, also the Wheel Slide Protection (WSP) system of the railway wagon UICZ1 has been modelled to better investigate the vehicle behaviour during the braking phase under degraded adhesion conditions [19]. The whole vehicle model has been implemented in the Matlab-Simulink environment.

***Table 3**. Main linear elastic characteristics of the two stage suspensions.*

Element	Transl. Stiff. x [N/m]	Transl. Stiff. y [N/m]	Transl. Stiff. z [N/m]	Rotat. Stiff. x [Nm/rad]	Rotat. Stiff. y [Nm/rad]	Rotat. Stiff. z [Nm/rad]
Springs of the primary suspension	844000	844000	790000	10700	10700	0
Springs of the secondary suspension	124000	124000	340000	0	0	0
Axle bushing	$4*10^7$	$6.5*10^6$	$4*10^7$	45000	9700	45000
Anti-roll bar	0	0	0	$2.5*10^6$	0	0

4. The contact model

Detailed presentation on the contact point detection and the normal problem solution can be referenced in [19]. In this section, the attention is focused on the solution of the tangential problem. The tangential problem is particularly challenging because of the difficulty to obtain a realistic adhesion law due to the complex non-linear behaviour of the adhesion coefficient and the presence of external unknown contaminants. This is especially true when the degraded adhesion produces a high energy dissipation and, consequently, an adhesion recovery. For these reasons, the solution of the tangential problem requires a new and improved local adhesion model especially developed for degraded adhesion conditions. More precisely, the main inputs of the degraded adhesion model are the kinematic variables of the wheel (position $\underline{G}_w$, orientation $\underline{\Phi}_w$, velocity $\underline{v}_w$ and angular velocity $\underline{\omega}_w$), the normal pressures at the contact interface p_n and the position of the contact points $\underline{P}_c$ (see the Fig. 2). On the contrary, the outputs of the tangential model (tangential pressures $\underline{p}_t$, sliding $\underline{s}$ and friction coefficient μ inside the contact area) are now calculated within the discretized contact patch through the new degraded adhesion model based on an extension of the FASTSIM algorithm and the Polach theory able to properly consider energy dissipation at the contact and adhesion recovery.

The low adhesion model, on which the local tangential contact model is based, is an improvement of the Polach adhesion law [1,17] and of the FASTSIM algorithm [16], taking into account the energy dissipation at the contact interface and the adhesion recovery (critical phenomena in presence of degraded adhesion).

The purpose of the local tangential contact model is the calculation of the local tangential contact variables (tangential contact pressures $\underline{p}_t$ and local sliding $\underline{s}$, all evaluated within the contact patch) starting from the corresponding normal pressures p_n (contact points $\underline{P}_{cw}$, wheel kinematic variables $\underline{G}_w$, $\underline{v}_w$, $\underline{\omega}_w$, and R).

For the local analysis a new reference system is defined at the wheel–rail interface on the contact plane (i.e. the common tangent plane between the wheel and rail surfaces): the *x* and *y* axes are the longitudinal and the transversal direction of the contact plane, respectively (see Figs. 3 and 4), while *z* is the normal axis.

The first step consists in the discretisation of the contact surface: from Hertz theory, the elliptical contact patch and its semi-axes *a* and *b* are divided in a bidimensional grid, by using a not constant grid resolution to discretize the elliptical contact patch in a grid of points in which the quantities p_n, p_t and *s* will be evaluated.

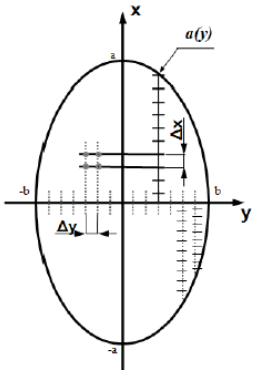

***Figure 3** Contact patch discretization*

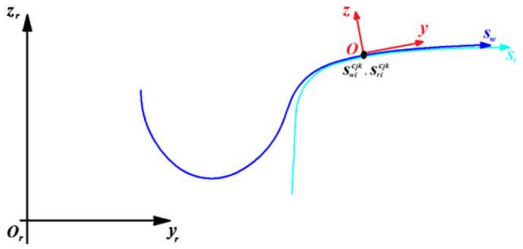

***Figure 4** Normal abscissa for the wheel and rail profile.*

Initially the transversal axis (with respect to the motion direction) of the contact ellipse has been divided in $(n_y - 1)$ equal parts of magnitude Δy by means of n_y equidistant nodes. Then the longitudinal sections of the patch have been divided in $(n_x - 1)$ equal parts of magnitude Δx by means of n_x equidistant nodes (see Fig. 3).

$$\Delta y = \frac{2b}{n_y - 1} \quad \Delta x(y) = \frac{2a(y)}{n_x - 1} \qquad a(y) = a\sqrt{1 - \frac{y^2}{b^2}} \tag{1}$$

Due to this strategy the longitudinal grid resolution is not constant but increases near the lateral edges of the ellipse, where the lengths *a(y)* are smaller. This procedure provides more accurate results right next to the edges of the ellipse, where a constant resolution grid would generate excessive numerical noise. The values of the n_x and n_y parameters have to assure the right balance between precision and computational load; good values of compromise are in the range 25-50.

The new FASTSIM algorithm is always based on the proportionality hypothesis between the tangential contact pressure $\underline{p}_t$ and the tangential elastic displacements $\underline{u}_t$, both evaluated within the contact patch:

$$\begin{aligned} \underline{u}_t(x,y) &= L\,\underline{p}_t(x,y) \\ L &= L(\varepsilon, a, b, G, \nu) \end{aligned} \tag{2}$$

where the flexibility L (function of the global creepages ε, the semi axes of the contact patch a, b, the wheel and rail combined shear modulus G and the wheel and rail combined Poisson's ratio ν) can be calculated as follows:

$$\begin{aligned} L &= \frac{|\varepsilon_x| L_1 + |\varepsilon_y| L_2 + c|\varepsilon_{sp}| L_3}{\left(\varepsilon_x^2 + \varepsilon_y^2 + c^2 \varepsilon_{sp}^2\right)^{1/2}} \\ \underline{v}_{pc} &= \underline{v}_\omega + \omega_w \times (\underline{P}_c - \underline{G}_w) \\ \varepsilon_x &= v_{pcx} / \|\underline{v}_w\| \\ \varepsilon_y &= v_{pcy} / \|\underline{v}_w\| \\ \varepsilon_{sp} &= \frac{\omega_w \cdot \underline{n}}{\|\underline{v}_w\|} \end{aligned} \tag{3}$$

with $L_1 = 8a/(3GC_{11})$, $L_2 = 8a/(3GC_{22})$, $L_3 = \pi a^2/(4GC_{23})$ *and* $c = \sqrt{ab}$ (the constants C_{ij}, functions both of the Poisson's ratio ν and of the ratio a/b, are the Kalker's parameters and can be found in literature [13]). The local sliding $\underline{s}$ can be calculated by derivation considering both the elastic creepages and the rigid ones:

$$\underline{s}(x,y) = \dot{\underline{u}}(x,y) + V \begin{pmatrix} e_x \\ e_y \end{pmatrix} \tag{4}$$

With

$$\begin{pmatrix} e_x \\ e_y \end{pmatrix} = \begin{pmatrix} \varepsilon_x - y_j \varepsilon_{sp} \\ \varepsilon_y - x_i \varepsilon_{sp} \end{pmatrix} \tag{5}$$

where $V = \|\underline{v}_\omega\|$ is the longitudinal vehicle speed, and e_x, e_y are the rigid local creepages. Once the contact patch is discretized, the FASTSIM algorithm allows the iterative evaluation of both the contact pressures value p_n, $\underline{p}_t$ and the local sliding $\underline{s}$ in order to divide the contact patch in adhesion and slip zone. Indicating the generic point of the grid with (x_i, y_j), $1 \le i \le n_x$, $1 \le j \le n_y$, the normal contact pressure can be expressed as:

$$p_n(x_i, y_j) = \frac{3}{2} \frac{N_c}{\pi a b} \sqrt{1 - \frac{x_i^2}{a^2} - \frac{y_j^2}{b^2}} \tag{6}$$

where N_c is the normal contact force, while the limit adhesion pressure $\underline{p}_A$ is:

$$\underline{p}_A(x_i, y_i) = \underline{p}_t(x_{i-1}, y_j) - \begin{pmatrix} e_x \\ e_y \end{pmatrix} \frac{\Delta x(y_i)}{L} \tag{7}$$

thus, knowing the variable values in the point (x_{i-1}, y_j), it is possible to pass to the point (x_i, y_j) as follows:

if $\quad \left\|\underline{p}_A(x_i, y_j)\right\| \le \mu(x_i, y_j)\, p_n(x_i, y_j)$

$$\begin{cases} \underline{p}_t(x_i, y_j) = \underline{p}_A(x_i, y_j) \\ \underline{s}(x_i, y_j) = 0 \end{cases} \tag{8}$$

if $\quad \left\|\underline{p}_A(x_i, y_j)\right\| > \mu(x_i, y_j)\, p_n(x_i, y_j)$

$$\begin{cases} \underline{p}_t(x_i, y_j) = \mu(x_i, y_j)\, \underline{p}_n(x_i, y_j)\, \underline{p}_A(x_i, y_j) / \left\|\underline{p}_A(x_i, y_j)\right\| \\ \underline{s}(x_i, y_j) = \dfrac{LV}{\Delta x(y_j)} \left[(\underline{p}_t(x_i, y_j) - \underline{p}_A(x_i, y_j) \right] \end{cases} \tag{9}$$

where $\mu(x_i, y_i)$ is the friction coefficient; Eqs. (8) and (9) hold respectively in the adhesion and slip zone. Iterating the procedure for $2 \le i \le n_x$ and successively for $1 \le j \le n_y$ and assuming as boundary conditions $\underline{p}_t(x_1, y_j) = 0$, $\underline{s}(x_1, y_j) = 0$ for $1 \le j \le n_y$ (i.e. stresses and sliding zero out of the contact patch), the desired distribution of $p_n(x_i, y_j)$, $\underline{p}_t(x_i, y_j)$ and $\underline{s}(x_i, y_j)$ can be determined.

In the previous equations the local value of the friction coefficient $\mu(x_i, y_j)$ is still unknown, and has to be modelled. The main phenomena characterising the degraded adhesion are the large sliding occurring at the contact interface and, consequently, the high energy dissipation. Such a dissipation causes a cleaning effect on the contact surfaces and finally an adhesion recovery due to the removal of external contaminants. When the specific dissipated energy W_{sp} is low the cleaning effect is almost absent, the contaminant level h does not change and the friction coefficient μ is equal to its original value in degraded adhesion conditions μ_d. As the energy W_{sp} increases, the cleaning effect increases too, the contaminant level h becomes thinner and the adhesion coefficient μ raises. In the end, for large values of W_{sp}, all the contaminant is removed (h is null) and the adhesion coefficient μ reaches its maximum value μ_r; the adhesion recovery due to the removal of external contaminants is now completed. At the same time if the energy dissipation begins to decrease, due for example to a lower sliding, the reverse process occurs. Since the contaminant level hand its characteristics are usually totally unknown, it is useful trying to experimentally correlate the friction coefficient μ directly with the specific dissipated energy W_{sp}. To reproduce the qualitative trend previously described and to allow the friction coefficient to vary between the extreme values μ_d and μ_r, the following expression for μ is proposed:

$$\mu = \left[1 - \lambda(W_{sp})\right] \mu_d + \lambda(W_{sp}) \mu_r \tag{10}$$

where $\lambda(W_{sp})$ is an unknown transition function between degraded adhesion and adhesion recovery. The function $\lambda(W_{sp})$ has to be positive and monotonous increasing; moreover the following boundary conditions are supposed to be verified: $\lambda(0) = 0$ and $\lambda(+\infty) = 1$. This way the authors suppose that the transition between

degraded adhesion and adhesion recovery only depends on W_{sp}. This hypothesis is obviously only an approximation but, as it will be clearer in the next chapters, it well describes the adhesion behaviour.

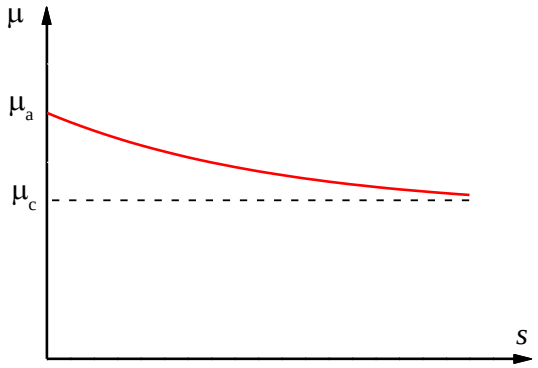

Figure 5 *Standard behaviour of the frictional coefficient μ as a function of the sliding s.*

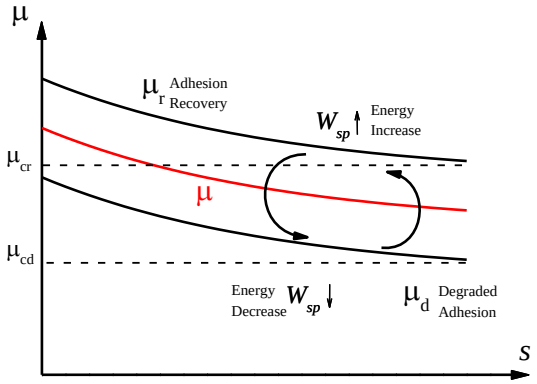

Figure 6 *Friction coefficient μ as a function of sliding s and the specific dissipated energy W_{sp}*

Initially, to catch the physical essence of the problem without introducing a large number of unmanageable and unmeasurable parameters, the authors have chosen the following simple expression for $\lambda(W_{sp})$:

$$\lambda(W_{sp}) = 1 - e^{-\tau|Wsp|} \tag{11}$$

where τ is now the only unknown parameter to be tuned on the base of the experimental data. In this research activity the two main friction coefficients μ_d and μ_r (degraded adhesion and adhesion recovery) have been calculated according to:

$$\begin{cases} \mu_d(x_i, y_j) = \left(\frac{\mu_{cd}}{A_d} - \mu_{cd}\right) e^{-s(x_{i-1}, y_j)\gamma_d} + \mu_{cd} \\ \mu_r(x_i, y_j) = \left(\frac{\mu_{cr}}{A_r} - \mu_{cr}\right) e^{-s(x_{i-1}, y_j)\gamma_r} + \mu_{cr} \end{cases} \tag{12}$$

Where $s = \|\underline{s}\|$, μ_{cd}, μ_{cr} are the kinematic values of μ_d, μ_r, $\frac{\mu_{cd}}{A_d}$, $\frac{\mu_{cr}}{A_r}$ are the static values of μ_d, μ_r , and γ_r , γ_d are the parameters that relate the static and the kinematic friction. Consequently, according to what previously written:

$$\begin{cases} \mu(x_i, y_j) = (1-\lambda)\mu_d(x_i, y_j) + \lambda\mu_r(x_i, y_j) \\ \lambda = 1 - e^{-\tau|Wsp|} \end{cases} \tag{13}$$

The specific dissipated energy W_{sp} can be calculated as:

$$W_{sp}(x_i, y_i) = \underline{p}_A(x_i, y_j) \cdot \underline{s}(x_{i-1}, y_j) \tag{14}$$

This process is repeated for each point of the grid that discretises the contact patch, and requires boundary conditions on the points (x_1 , y_j). In particular, sliding $\underline{s}$ and pressures $\underline{p_t}$ on the edge of the contact patch are set equal to zero, while the adhesion coefficients μ_d, μ_r are equal to the static values:

$$\begin{cases} \underline{s}(x_1, y_j) = \underline{0} \\ \underline{p_t}(x_1, y_j) = \underline{0} \\ \begin{cases} \mu_d(x_1, y_j) = \mu_{cd}/A_d \\ \mu_r(x_1, y_j) = \mu_{cr}/A_r \end{cases} \\ \mu(x_1, y_j) = \mu_d(x_1, y_j) \\ \text{with} \\ W_{sp}(x_1, y_j) = 0 \end{cases} \tag{15}$$

Finally it is possible to evaluate the tangential force acting on the contact patch area by integration:

$$\begin{cases} \underline{T}_x = \int \underline{p}_{tx}\, dA \\ \underline{T}_y = \int \underline{p}_{ty}\, dA \\ M_{sp} = \int_A (x p_{ty} - y p_{tx}) dA \\ T_c = T_x \underline{J}_1 + T_y \underline{J}_2 \\ \underline{M}_{sp} = M_{sp} \underline{n} \end{cases} \tag{16}$$

5. Experimental campaign and measured data

The local degraded adhesion model has been validated by means of experimental data [33-34], provided by Trenitalia s.p.a., coming from on-track tests performed in Velim (Czech Republic) with the coach UIC-Z1. The considered vehicle is equipped with a fully-working Wheel Slide Protection (WSP) system. The experimental tests have been carried out on a straight railway track. The wheel profile is the ORE S1002 (with a wheelset width d_w equal to 1.5m and a wheel radius r equal to 0.445m) while the rail profile is the UIC60 (with a gauge d_r equal to 1.435 m and a laying angle equal to 1/20 rad).

Table 4. Main wheel-rail contact characteristics

Parameters	Unit	Value
Young modulus	[Pa]	$2.1*10^{11}$
Shear modulus	[Pa]	$8*10^{10}$
Poisson coefficient	[Ns/m]	0.3
Contact damping constant	-	$1*10^{5}$
Polach reduction factor k_{ad}	-	0.3
Polach reduction factor k_{sd}	-	0.1
Polach reduction factor k_{ar}	-	1.0
Polach reduction factor k_{sr}	-	0.4
Kinetic friction coefficient μ_{cd}	-	0.04
Kinetic friction coefficient μ_{cr}	-	0.28
Friction ratio A_d	-	0.4
Friction ratio A_r		0.4
Friction decrease rate γ_d	[s/m]	0.2
Friction decrease rate γ_r	[s/m]	0.6

In Tab. 4 the main wheel, rail and contact parameters are

reported. The value of the kinetic friction coefficient under degraded adhesion conditions μ_{cd} depends on the test performed on the track. According to the current regulations in force, the degraded adhesion conditions are usually reproduced using a watery solution containing surface-active agents, e.g. a solution sprinkled by a specially provided nozzle directly on the wheel-rail interface on the first wheelset in the running direction. The surface-active agent concentration in the solution varies according to the type of test and the desired friction level. The value of the kinetic friction coefficient under full adhesion recovery μ_{cr} corresponds to the classical kinetic friction coefficient under dry conditions. During the experimental campaign, for each test, the following physical quantities have been experimentally measured (with a sample time Δt_s equal to 0.01s):

- the longitudinal vehicle velocity v_v^{sp}. For the sake of simplicity all the longitudinal wheel velocities v_{wj}^{sp} (j represents the *j-th* wheel) are considered equal to v_v^{sp}. The acceleration of the vehicle a_v^{sp} and of the wheels a_{wj}^{sp} can be obtained by derivation and by properly filtering the numerical noise.
- the rotation velocities of all the wheels ω_{wj}^{sp}. The angular accelerations $\dot{\omega}_{wj}^{sp}$ can be calculated by derivation and by properly filtering.
- the vertical loads N_{wj}^{sp} on the wheels. The vertical contact forces N_{cj}^{sp} can be approximately evaluated starting from N_{wj}^{sp} by taking into account the weight of the wheels.
- the traction or braking torques C_{wj}^{sp} applied to the wheels.

By way of example in Fig. 14 the wheel longitudinal and rotational velocities v_{w1}^{sp} and $r\omega_{w1}^{sp}$ are reported for one of the tests of the experimental campaign; both the WSP intervention and the adhesion recovery in the second part of the braking manoeuvre are clearly visible.

6. Experimental and validation of the new local adhesion model

In this chapter the behaviour of the local adhesion model described in chapter 4 will be validated. Particular attention will be paid to the influence of the parameter τ on the results.

6.1 Influence of the parameter τ on the results

In this preliminary phase, the effect of the parameter τ on the dynamics response of the vehicle is investigated. The chosen simulation starts from a vehicle velocity of $34\ m/s$ and, after few seconds, a braking torque for each wheelset is applied. The values of each braking torque are modulated by the WSP during the run of the train depending by the dynamics of the system.

With the reference on the trend of the simulated first wheelset velocity $r\omega_{w1}^{sp}$, varying only the parameter τ, the adhesion increases as the parameter τ grows, until the limit condition $\tau = 3 \cdot 10^{-8} \frac{m^2}{W}$, corresponding to a complete (immediate adhesion recovery) adhesion.

For these simulations the optimized value chosen for τ has been $\tau = 9 * 10^{-9}$ m²/W, the one that best reflects the experimental data.

6.2 Model validation

The adhesion model is focused on the velocities v_v^{sm}, $r\omega_{wj}^{sm}$; v_v^{sm} is the longitudinal vehicle velocity, ω_{wj}^{sm} is the rotational wheelset velocity and, for the sake of simplicity, r is always the nominal wheel radius. These variables have been chosen because they are the most important physical quantities in a braking manoeuvre under degraded adhesion conditions. The variables coming from the 3D multibody model have been compared with the correspondent experimental quantities v_v^{sp}, $r\omega_{wj}^{sp}$. By way of example the time histories of the velocities v_v^{sm}, v_v^{sp} and $r\omega_{w1}$, $r\omega_{w1}^{sp}$, are presented in Fig.7, with a chosen $\tau = 9 * 10^{-9} m^2/W$.

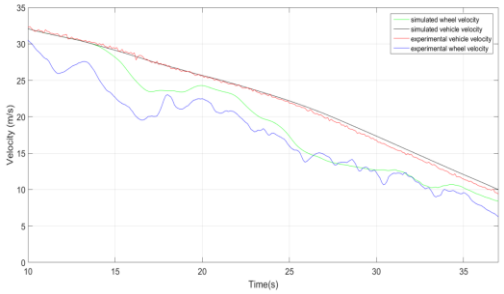

Figure 7 *Comparison between the experimental and simulated longitudinal velocities of the vehicle and the first wheelset*

The results of the analysis show a good agreement in terms of translational velocities v_v^{sm}, v_v^{sp}. Concerning the velocities $r\omega_{w1}^{sm}$, $r\omega_{w1}^{sp}$ (and thus the angular velocities) the matching is satisfying. However these physical quantities cannot be locally compared to each other because of the complexity and the chaoticity of the system due, for instance, to the presence of discontinuous and non-linear threshold elements like the WSP. To better evaluate the behaviour of $r\omega_{w1}^{sm}$ and $r\omega_{wj}^{sp}$ from a global point of view, it is useful to introduce the statistical means $\bar{s}_j^{sm}$, $\bar{s}_j^{sp}$ and standard deviations Δ_j^{sm}, Δ_j^{sp} of the calculated sliding s_j^{sm} and of the experimental ones s_j^{sp}:

$$\begin{aligned} s_j^{sm} &= v_v^{sm} - r\omega_{wj}^{sm} \\ s_j^{sp} &= v_v^{sp} - r\omega_{wj}^{sp} \end{aligned} \tag{17}$$

the statistical indices are then evaluated as follows:

$$\begin{aligned} \bar{s}_j^{sm} &= \frac{1}{T_F - T_I}\int_{T_I}^{T_F} s_j^{sm} dt \\ \bar{s}_j^{sp} &= \frac{1}{T_F - T_I}\int_{T_I}^{T_F} s_j^{sp} dt \\ \Delta_j^{sm} &= \sqrt{\frac{1}{T_F - T_I}\int_{T_I}^{T_F} (s_j^{sm} - \bar{s}_j^{sm})^2 dt} \\ \Delta_j^{sp} &= \sqrt{\frac{1}{T_F - T_I}\int_{T_I}^{T_F} (s_j^{sp} - \bar{s}_j^{sp})^2 dt} \end{aligned} \tag{18}$$

where T_I and T_F are initial and final times of the

simulation, respectively. For instance, the means $\bar{s}_1^{sm}$, $\bar{s}_1^{sp}$ and the standard deviations Δs_1^{sm}, Δs_1^{sp} of the slidings s_1^{sm}, s_1^{sp} are summarized in Tab. 5; they confirm the good matching also in terms of sliding and rotational velocities.

***Table 5**. Statistical comparison between some experimental and simulated sliding , .*

Parameters		Mean	Standard Deviation
Adhesion Coefficient	real	0.111	0.0156
	simulated	0.110	0.0098
Sliding	real	3.23 m/s	1.65
	simulated	3.07 m/s	2.70

In Fig. 8 and table 5 is also shown the trend of the experimental and simulated adhesion coefficient $f_j^{sp} = \frac{T_{cj}^{sp}}{N_{cj}^{sp}}$ $f_j^{sim} = \frac{T_{cj}^{sm}}{N_{cj}^{sm}}$, where T_{cj}^{sp} and T_{cj}^{sm} are approximately estimated as $I_j^{sm/sp}\dot{\omega}_{wj}^{sm/sp} = C_{wj}^{sm/sp} - T_{cj}^{sm/sp} \cdot r$. Additionally the normal contact forces have been evaluated for the first wheelset (Fig. 9), and to have a complete overview of the trend of sliding involved, a comparison between the experimental and simulated sliding s has been performed and reported in Fig. 10.

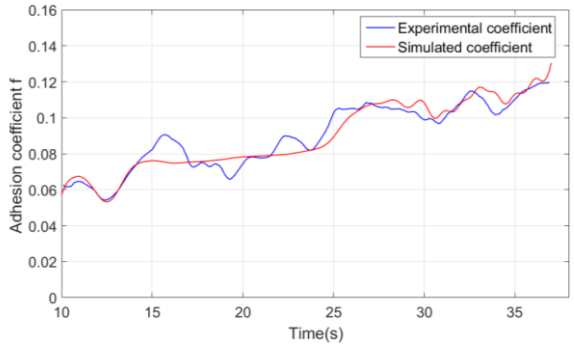

***Figure 8** Comparison between the experimental and simulated adhesion coefficients f_j^{sp}, f_j^{sm}*

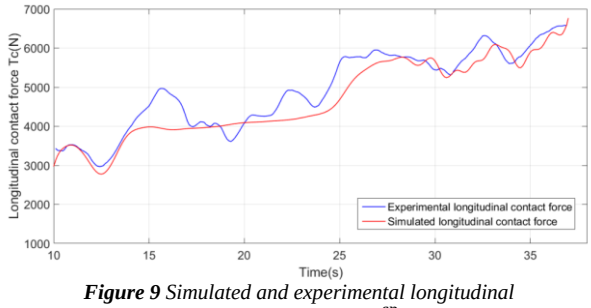

***Figure 9** Simulated and experimental longitudinal contact force T_{c1}^{sm}, T_{c1}^{sp}*

In conclusion, the numerical simulations of the vehicle dynamics during the braking manoeuvre highlight again the capability of the developed model in approximating the complex and highly non-linear behaviour of the degraded adhesion.

7. Simulation results

Considering the local reference system (Fig. 2), in Fig. 11 a comparison of the local tangential pressures $\underline{p_t}$ in a pure sliding condition and in a partial adherence recovery condition is shown. A comparison of the local sliding $\underline{s}$ in a pure sliding and in a partial adherence condition is also shown in Fig. 12. Finally, in Fig. 13, it is possible to observe the different distribution of the W_{sp} in the two abovementioned conditions.

8. Conclusions and Further Developments

In this work the authors presented a model aimed to obtain a better accuracy in describing degraded adhesion conditions at the wheel-rail interface in railway vehicle dynamics. The new approach is suitable for multibody applications (e.g. in Matlab Simulink and Simpack environments) and assures high computational performances, making possible the direct online implementation of the degraded adhesion model within more general vehicle multibody models. The new model is based on the main phenomena characterising the degraded adhesion, such as the energy dissipation at the contact interface, the consequent cleaning effect and the resulting adhesion recovery due to the removal of external unknown contaminants. Since most of the physical characteristics of the contaminants are totally unknown in practice, the new approach minimizes the number of hardly measurable physical quantities required by the model.

The adhesion model has been validated thanks to experimental data provided by Trenitalia S. p. A. coming from on-track tests performed in Velim (Czech Republic) with the railway vehicle UIC-Z1. The tests have been carried out on a straight railway track under degraded adhesion conditions with a vehicle equipped with a Wheel Slide Protection (WSP) system. Many important developments are scheduled for the future. Some improvements of the model will be taken into account, and finally the new degraded adhesion model will be applied to the study of the railway vehicle dynamics and of the wheel-rail contact on generic railway tracks and networks. This way some important topics such as the profile evolution due to wear, the profile optimization and the development of innovative railway bogies will be further and more deeply investigated.

9. Acknowledgements

The authors would like to thank Trenitalia S.p.A. for supplying the technical data and the experimental data related to the braking tests under degraded adhesion conditions needed for the model validation.

PREDICTION OF WHEEL SQUEAL NOISE UNDER WATER-BASED FRICTION MODIFIERS BASED ON INSTANTANEOUS ROLLING CONTACT MECHANICS

Paul A. Meehan [1,*], Xiaogang Liu [2]

[*] E-mail: meehan@uq.edu.au

Abstract: Friction modifiers have been shown to be effective in reducing wheel squeal noise but not reliable in eliminating the phenomenon. To investigate this, wheel squeal vibration and noise under the presence of water-based friction modifiers is predicted using a mathematical model taking into account instantaneous traction-creep behaviour. The instantaneous rolling contact traction-creep curves are inferred from quasistatically measured ones under dry and water-based friction modified conditions. The analytical solution for wheel squeal is then compared with both numerical and experimental measurements of squeal vibrations and sound pressure level amplitude over a range of angle of attacks on a two disk testrig. Squeal is shown to occur in both the dry and friction modified conditions at about the same steady state amplitude even though the measured friction modified traction-creep curve doesn't show a negative sloped region. This provides quantified insight into why squeal noise can still occur under friction modification.

Keywords: Wheel squeal, Friction modifier, Full sliding rolling contact, Traction-creep curve.

1. Introduction

As a train negotiates a sharp curve (corner) of a railway line, an annoying high-pitched tonal noise, known as wheel squeal, sometimes occurs. The unstable excitation of the wheel is conventionally due to a lateral 'stick-slip' rolling contact phenomena [1] analogous to the bowing of a violin string. The instability (or negative damping) arises from the negative slope of the lateral traction-creepage curve beyond the critical creepage. Friction modifiers have been used to mitigate squeal based on their ability to change a negatively sloped creep curve into a positive one [2]. Although, friction modifiers applied on the top of rail can effectively reduce squeal noise and lateral forces, it has been found that they do not necessarily eliminate squeal occurrence reliably [2][4][5][9]. One possible explanation could be due to an alternative squeal mechanism known as modal coupling [6], however experimental and field evidence of this type of squeal is only qualitative at this stage [7].

In the field, it is difficult to control or measure important parameters to investigate this variable performance of friction modifiers and squeal. Alternatively two disk test rigs have been used to measure and control wheel squeal parameters under friction modified conditions eg [5][9]. In [5] it was found that it can be quite difficult to achieve a reasonable noise reduction due to (oil-based) friction modifiers without a significant impact on braking distance. In [9] conventional wheel squeal was found to sometimes still occur after the application of friction modifiers and a possible explanation is that friction modified instantaneous creep behaviours can differ from measured quasistatic curves due to temperature effects ie [10].

To further this research, presently, the quantitative prediction of vibration amplitude and sound pressure level of wheel squeal noise under water based friction modifiers is investigated using an efficient mathematical model. In particular, measured quasistatic traction-creep curves are used to infer critical instantaneous creep curve parameters to predict how squeal sound pressure levels varied under different angle of attacks with friction modifiers. The immediate mathematical predictions are compared with previous measurements of squeal [9] on a two disk test rig over a range of angle of attack.

2. Methodology

The experimental results presented in this paper have been obtained previously in [9] using a rolling contact two disc test rig developed for the investigation of squeal noise (described in the following for convenience in section 2.1). A theoretical model in the time domain (based on [8] and [9]) is modified here in section 2.2. Subsequently the analytical methodology for determining the amplitude of squeal oscillation under friction modifiers is detailed in section 2.3. The parameters used for numerical and analytical simulation are also derived from the characteristics of the test rig described.

2.1. Experimental Methods

A rolling contact two disc test rig is used to investigate the lateral traction creep behavior and the corresponding effect of friction modifiers on squeal noise as described in [9] and shown in Figure 1.

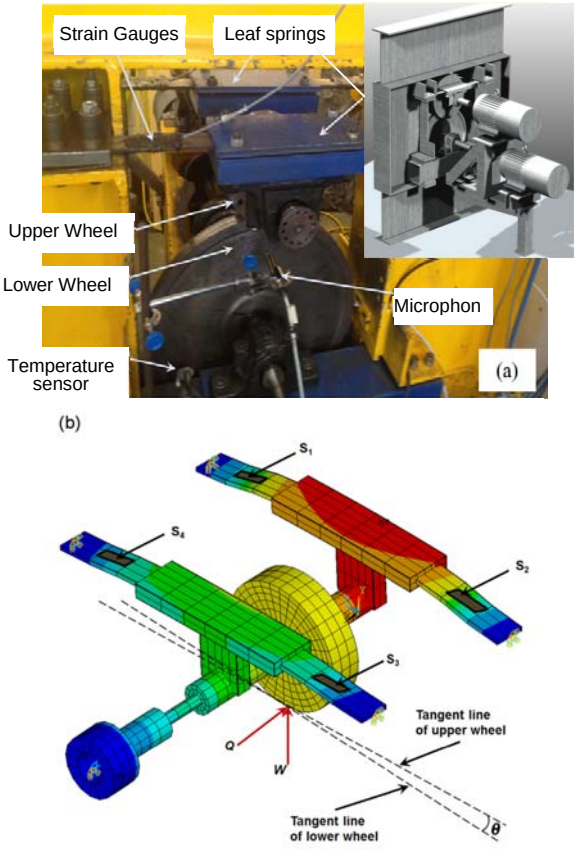

Figure 1 *Rolling contact two disc test rig used for the investigation of squeal noise (a) front view of the test rig, (b) the FEM model of the test rig structure showing strain gauge systems S1-4 for load measurement [8][9].*

The angle of attack between the upper and lower wheel were adjusted and measured using the laser-based methods described in [12]. The lateral force between the upper and lower wheel was measured with four Wheatstone strain gauge bridges as marked in Figure 1(b) that were compensated for thermal, axial and twisting strains of the leaf spring. More details of the strain gauge measurement accuracy and finite element validation is provided in [12]. Dry parameters of this test rig are listed in Table 1 and remain unchanged from previous research. In addition, creep curve parameters under water-based friction modification are also provided as tuned to quasistatic measurements.

The sound pressure levels of the test rig squealing were recorded using a microphone placed adjacent to (5cm away from) the lower disk and 80 cm above the ground as displayed in Figure 1. A conditioning amplifier, an analogue digital converter (ADC) and Labview's Signal Express 3.0 by National Instruments and Matlab was used to process the signal with the reference pressure set at 20 μPa RMS. The sound was recorded each time for 2 seconds, twice for each crabbing velocity increment at a sample rate of 8000Hz. The vibration characteristics of the test rig were investigated with modal tests conducted with a hard tip impact hammer and analysed with the finite element method. The lower wheel was found to have a resonant mode close to the squeal frequency of three nodal diameters and zero nodal circles at 1124 Hz that was present in the impact hammer tests at 1130 Hz. Since the first mode of the upper wheel was well above this at 4867 Hz, it was assumed that the lower wheel was representative of a squealing railway wheel.

Table. 1 *Parameters of the test rig and simulation.*

Description	**Value**
Radii of longitudinal and tangential curvature for the lower wheel (R_1, R_{1t})	0.213 m, 0.300 m
Thickness of the lower wheel (rim, web)	0.026 m, 0.015 m
Density (ρ)	7800 kg/m^3
Inner radius of lower wheel (R_1')	0.0325 m
Young's modulus of upper and lower wheel (E)	175 GPa
Radii of longitudinal and tangential curvature for the upper wheel (R_2, R_{2t})	0.085 m, 0.040 m
Thickness of the upper wheel	0.080 m
Poisson's ratio (v)	0.28
Angle of attack range	0 ~ 25 mrad
Creep coefficient (C_{22} . dry, friction modified)	3.14, 15.7
Normal loading (W)	1000 N
Creep curve parameters (dry and water-based friction modified)	
Static friction coefficient constant (K_L - dry, friction modified)	0.5, 0.296
Friction modified static friction linear coefficient (K_{S1})	0.528
Friction modified static friction squared coefficient (K_{S2})	-0.392
Critical creep (ζ_c - dry, friction modified)	0.007, 0.007
Creep curve slip region slope (k_1 – dry, friction modified [8 - 24mrad]) – analytical model	0.398, [0.289–0.358]
Creep curve full sliding region slope (k_2 – dry, friction modified[8 - 24mrad]) – analytical model	-0.031, [-0.016–0.018]
Contact parameter (patch size/friction coef) (k_3) – simulation model	2.733E5 N
Squeal vibration parameters	
Modal mass (m)	3.1 kg
Modal damping (c_d)	42 Ns/m
Modal stiffness (k)	1.6E8 N/m
Squeal nominal conditions	
Angle of Attack (θ)	16 mrad
Rolling velocity (V_o)	17.8 m/s

One kind of water-based friction modifier was applied by brushing or spraying on the top head of the rail disk. After the friction modifier dried, a thin film was formed, which contains inorganic material, polymers for film forming and contaminants on the contact patch. The rate of applying this friction modifier on one rail in the field can be 0.3 g/m. On the testrig, the friction modifiers were brushed on the tread of the disk evenly and about one hour of drying was provided for a film to be formed. Afterwards, the test rig was run at different rolling speeds and three sets of data were recorded for each speed with a test duration of 3 min. The results at different rolling speeds were repeatable, indicating that the status of friction modifier on the disks was

approximately constant. In the present paper we focus on the results at 800 RPM where squeal occurred under both dry and friction modified conditions.

2.2. Mathematical Modelling

The conventional wheel squeal mechanism was modelled based on the interaction between the vehicle curving mechanics, instantaneous rolling contact mechanics and vibrational modal dynamics resulting in a limit cycle squeal oscillation of the wheel. As an overview, a conceptual block diagram of the model is shown in Figure 2.

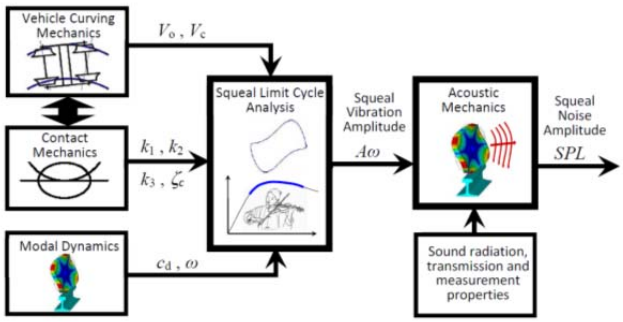

Figure 2 *Concept block diagram of analytical model (thicker blocks) for wheel squeal noise amplitude. [8].*

The vehicle curving and contact mechanics including the effects of friction modification define the lateral traction creep curve behaviour that excites and is coupled to the squeal vibration leading to noise propagation. The key parameters are distilled to provide a very efficient calculation of the corresponding vibration amplitude and noise level under friction modifiers, as described in the following.

2.2.1. Wheel Squeal Modelling under Friction Modification

The vehicle curving mechanics, rolling contact mechanics and modal dynamics of Figure 2 may be concisely modelled based on the conceptual diagram of Figure 3. An important parameter, the (lateral) crabbing velocity arises due to the misalignment between the wheel velocity and rolling velocity as shown in Figure 3(a). The lateral force Q arises at the contact point due to the crabbing velocity according to the rolling frictional behaviour. In the lateral direction, the dominant vibration of the wheel is analogous to the friction self-excited oscillation of mass connected to a spring and damping on a rolling belt as demonstrated in Figure 3(b).

The wheel squeal modal dynamics can be described by an effective spring-mass-damper system that can be expressed as,

$$m\ddot{y}(t)+c_{\mathrm{d}}\dot{y}(t)+ky(t)=Q(\zeta)\,, \tag{1}$$

where m is the modal mass, c_{d} is the modal damping coefficient, k is the modal stiffness that also account intrinsically for the modal participation from the lateral force Q.

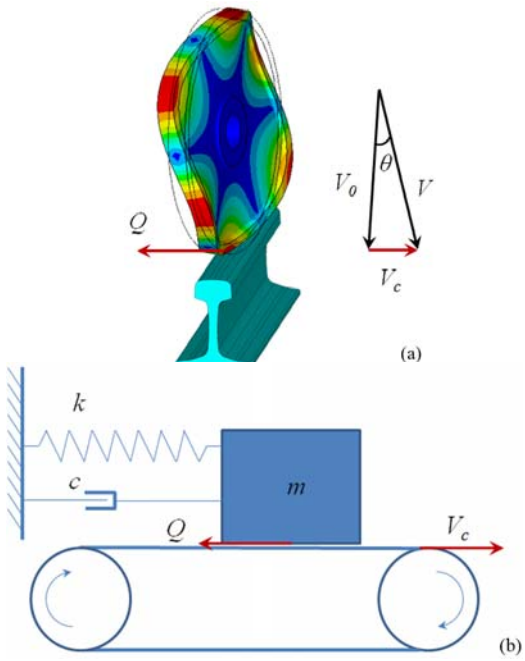

Figure 3 (a) *3D model of a squealing wheel rolling on rail top, (b) SDOF friction self-excited oscillation in lateral direction.*

The modal parameters of the dominant mode were curve fitted from a receptance spectrum of a modal test as detailed in [11] and are listed in Table 1. The modal parameters could also be determined via finite element analysis. The rolling contact mechanics may be simplified to focus on the lateral force Q that is dependent on the normal loading, W, according to,

$$Q=-\mu(\zeta)W \tag{2}$$

where $\mu(\zeta)$ is the creepage dependent lateral adhesion ratio in rolling contact. Many models exist for this, however, de Beer et al [13] developed and tested a lateral creep model for squeal that accounts for both positive slip and negative sloped, full sliding behaviour that can be expressed as,

$$\mu(\zeta)=\begin{cases}\mu_s\{\zeta'-\frac{1}{3}\zeta'^2+\frac{1}{27}\zeta'^3\}\{1-0.5e^{-0.138/|\zeta V_0|}-0.5e^{-6.9/|\zeta V_0|}\} & \text{for } \zeta'\le 3\\ \mu_s\{1-0.5e^{-0.138/|\zeta V_0|}-0.5e^{-6.9/|\zeta V_0|}\} & \text{for } \zeta'>3\end{cases} \tag{3}$$

The lateral creepage ζ is the ratio of the lateral relative velocity between the wheel and rail divided by rolling speed V_0,

$$\zeta=\left(V_{\mathrm{c}}+\dot{y}(t)\right)/V_0 \tag{4}$$

where $\dot{y}(t)$ is the vibration velocity of the wheel and V_{c} is the crabbing velocity. The lateral crabbing velocity between two wheels is quasistatic and can be calculated with the angle of attack, θ, and rolling speed, V_0, i.e., $V_{\mathrm{c}}= V_0 sin\theta$. As the angle of attack is less than 1 degree, the crabbing velocity can be approximated accurately as,

$$V_{\mathrm{c}}=\theta V_0\,. \tag{5}$$

The ζ' in Equation (3) is a normalised creepage that can be described with,

$$\zeta' = \frac{\zeta GabC_{22}}{\mu_s W} = \frac{\zeta k_3}{W}, \quad (6)$$

where $G=E/2(1+\upsilon)$. The values used for the simulated creep contact parameter k_3, elastic modulus E, Poisson's ratio υ, stationary friction coefficient μ_s (of non-rolling contact), the Kalker constant C_{22} and the normal loading W are listed in Table 1. The dimensions of the elliptical contact patch, a and b, can be determined by the contact theory of Hertz [14] or other means. More details of the experimental and simulation models are provided in [9] and [12] (including experimental modal analysis) although the present paper includes all detail required to rebuild the simulations.

The influence of friction modifier on creep is via its effects on the stationary (or quasistatic) friction coefficient (of non-rolling contact). In particular, under friction modified conditions, the friction coefficient, μ_s, has been shown to increase with the quasistatic lateral sliding velocity (or rolling velocity x angle of attack) [9],[15]. This is most likely due to sliding dissipation causing increased local temperatures as described in [9],[10]. The temperature changes are likely to occur with a much slower time constant than the wheel squeal vibrations that have a period less than 1 ms. Hence the friction coefficient, μ_s, is likely to be quasistatic under squeal vibrations. In order, to capture and tune this trend to experimental measurements, a quadratic law is proposed of the form,

$$\mu_s = K_L + K_{S1}(V_o\theta) + K_{S2}(V_o\theta)^2 \quad (7)$$

where K_L is the stationary friction coefficient under no quasistatic lateral sliding velocity and K_{S1} and K_{S2} are the linear and squared coefficients of the component effects of the friction modified quasistatic lateral sliding velocity. It is important to note that the instantaneous and quasistatic creep curves can both be represented by Eqs. (3)-(7). In particular, for a typical quasistatic creep curve experiment, both the angle of attack, θ, and lateral creep, ζ, are varied and approximately equal (according to (4) and (5)) while the instantaneous creep curve for a particular angle of attack will have a constant θ.

2.2.2. Wheel Squeal Noise Amplitude under Friction Modification

The equations of motion (1-7) may be solved for limit cycle analysis under instantaneous creep conditions using a simplification of the instantaneous creep behaviour as detailed in [8]. In particular, it is assumed that the instantaneous creep behaviour of (3) can be characterised by linear slopes, k_1 and k_2, for the slip and full sliding regions, respectively, as described by:

$$\mu(\zeta) = \begin{cases} k_1\zeta' & \text{for } \zeta' \le 1 \\ k_1 + k_2(\zeta' - 1) & \text{for } \zeta' > 1 \end{cases} \quad (8)$$

The parameters for this simplified creep law may be obtained by tuning k_2 to the full sliding region slope at the nominal lateral creep and k_1 to match the critical creep of the instantaneous creep curve (ie Equation (3)). Under friction modified conditions the instantaneous creep curve is used while for dry conditions this curve reduces to the quasistatic curve. In addition, it is assumed wheel squeal is characterised by an initial growth in vibration until a steady state amplitude A is reached as,

$$y(t) = -A\sin(\omega t). \quad (9)$$

The nonlinear limit cycle amplitude of the squeal associated with the noise is governed by an energy balance process based on the effective positive or negative damping characteristic of the slopes of the creep curve. In particular, for small vibrations, in the fully sliding region of the creep curve, the negative slope of k_2 causes a positive power input to the squeal vibration which causes growth if it is greater than the power output due to damping c_d. The vibration amplitude grows to larger creep oscillations that start to impinge on the positive slip side of the creep curve. This positive slope k_1 of the creep cycle causes a negative power input (or power output) to the vibration which acts like additional damping to c_d and retards the growth. The vibration will continue to grow until a balance is achieved between the power input and output over the different slopes of the creep curve so that a steady state (limit cycle) amplitude is reached. This vibration amplitude $A\omega$ may be obtained by solving equations (1-7) to obtain

$$A\omega = \left(V_c - \zeta_c V_0\right)/\cos(\omega t_c) \quad \text{where}$$
$$\sin(2\omega t_c) - 2\omega t_c = 2\pi\left(V_0 c_d + k_2 k_3\right)/\left(k_3\left(k_1 - k_2\right)\right) \quad (10)$$

where ζ_c is the critical creep (between the positive and negative sloped sides of the creep curve). Equation (10) can be easily solved for the critical value of ωt_c using any root finding function and hence the steady state squeal vibration velocity amplitude $A\omega$. This provides an almost instantaneous solution that may be used to investigate a wide range of conditions efficiently.

The squeal sound pressure level may be calculated from the radiated sound power from the squealing wheel vibrations as (see [1],[16]),

$$SPL = 10\log(\sigma\,\rho c_o S\overline{\langle v^2\rangle}) + SPL_{trans} = 20\log(A\omega) + SPL_{const} \quad (11)$$

where σ is the radiation efficiency (or ratio), ρc_o is the characteristic impedance of air and S is the surface area of the wheel. $\overline{\langle v^2\rangle}$ is the squared velocity normal to the wheel surface at the squealing frequency which is averaged both over time ($\bar{}$) and surface area ($\langle\ \rangle$). SPL_{trans} represents the transmission component effects including the distance from the microphone to the squealing wheel, any reflections and/or sound absorption, viewing angle, weightings and other corrections. SPL_{const} is a constant for a given case study (or microphone setup) when the transmission and radiation components are independent of the vibration velocity.

Hence prediction of the squeal noise amplitude trends under friction modifiers can be obtained almost instantaneously via equations (10) and (11) once the creep curve slopes k_1 and k_2 can be determined from experimental measurements.

3. Results

Results for the modelling predictions of wheel squeal vibration amplitude and noise levels under dry and friction modified conditions were compared to experimental measurements on the two disk testrig. Numerical integration of the Equations (1) to (7) were performed in MathCad using the Radua method as part of the "Odesolve" function with sampling rate set at least 20 times the squealing frequency, $\omega = \sqrt{(k/m)}$, and initial velocity of 0.01 m/s. The parameters were chosen as described in the previous experimental investigation of squeal under friction modifiers [9] and listed in Table 1. The nominal angle of attack and rolling speed was 16mrad and 800 rpm (17.8 m/s), respectively, and the sound radiation and transmission constant was set at SPL_{const}=130dB according to [8].

The simulated quasistatic creep curves were first tuned to match the measured creep curves from the testrig by tuning the friction coefficient parameters to the values described in Table 1. A good match between the simulated and experimental creep curves for the dry and water-based friction modified conditions is shown in Fig. 4 a). The water-based friction modifier is shown to effectively alter the dry curve shape by lowering it to an intermediate adhesion ratio of approximately 0.3 as well as eliminating the negatively sloped full sliding region. The instantaneous creep curve for the dry condition is the same as the quasistatic measured curve. However temperature effects cause unique instantaneous friction modified creep curves depending on the crabbing velocity (or angle of attack) according to eqn (7) (corresponding to non-zero values of K_{S1} and K_{S2}). Using the same parameter values tuned to the quasistatic conditions while holding the angle of attack constant, the instantaneous creep curves can be obtained from eqns (3) to (7) for three representative angles of attacks as shown in Fig. 4 b). This figure highlights that the instantaneous creep curves under friction modified conditions have a negative sloped region associated with negative damping while the measured quasistatic curve does not.

For the analytical predictions, unique, approximated, instantaneous creep curves for each angle of attack (eqn (8)) were developed in an automated fashion from the simulated creep curves (eqn (3)). In particular, the simplified creep parameter k_2 was approximated as the average slope of twice the range between the critical creep and the angle of attack and k_1 as the slope from zero to the critical creep, respectively.

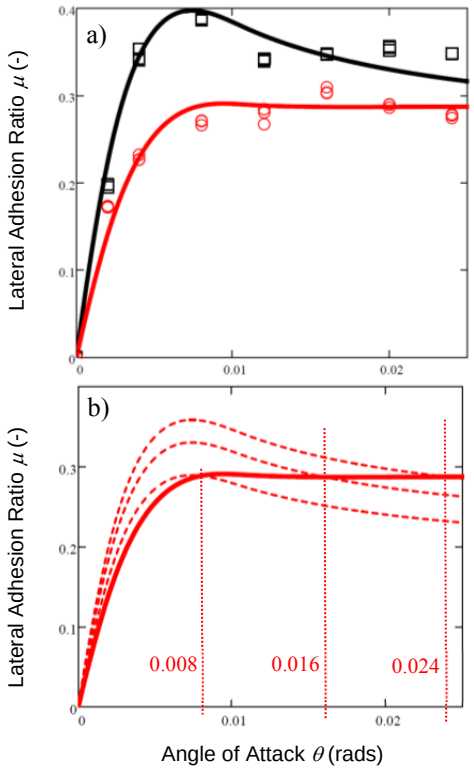

Fig. 4 *a) The simulated dry (-) and (water-based) friction modified (-) quasistatic creep curve and experimental measurements [9] under dry (□) and friction modified (○) conditions at a rolling speed of 17.8m/s. b) The simulated instantaneous creep curves at 8, 16 and 24 mrads under friction modified conditions (--) (- -).*

Fig. 5 shows the approximated instantaneous creep curves for an angle of attack at θ=16 mrad as an example.

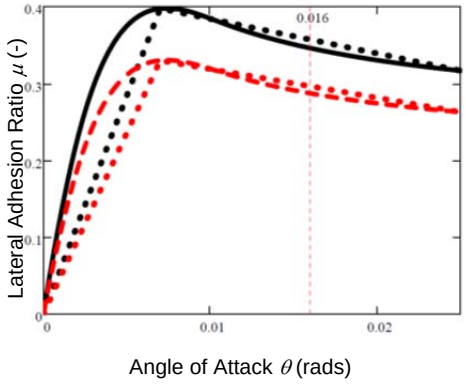

Fig. 5 *The simulated dry (-) and (water-based) friction modified (--) instantaneous creep curves and the corresponding approximated creep curves (··) for 16 mrads at a rolling speed of 17.8m/s.*

Figure 5 indicates that a reasonable approximation of the negatively sloped regions of the instantaneous creep curves are achieved over the expected range of creep oscillation during squeal. It is noted that the approximation is less accurate near the critical creep.

The tuned creep curves under dry and water-based friction modified conditions were then used to obtain analytical and numerical predictions of the steady state vibration amplitude of squeal. Fig 6 shows the numerical simulations of the time histories and corresponding creep oscillations at a nominal angle of

a)

attack of 16 mrad and includes the analytical prediction of squeal vibration steady state amplitude in Fig 6 a).

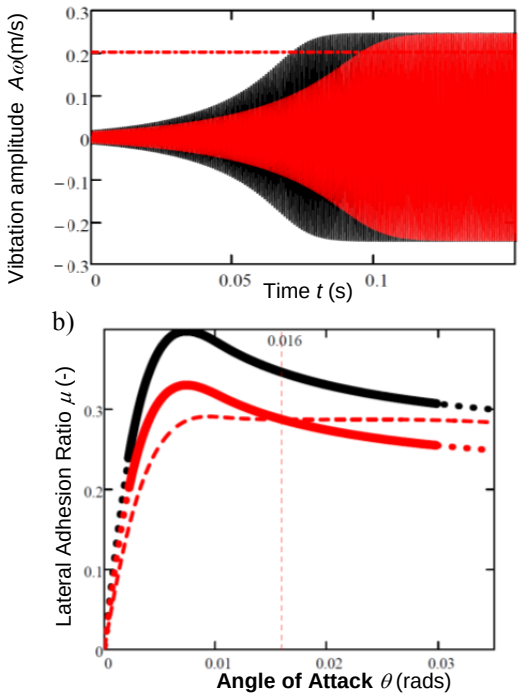

Fig. 6 *a) simulated time histories of squeal vibration growth under dry (-) and (water-based) friction modified (-) conditions and corresponding analytical predictions of squeal amplitude under (water-based) friction modified (.-.) conditions, b) instantaneous creep curve (··) and oscillation range (-) under dry conditions and (water-based) friction modified conditions; creep curve (··) and range (-)for 16 mrads at a rolling speed of 17.8m/s. The quasitstatic creep curve is also shown under (water-based) friction modified (--) conditions.*

Figure 6 a) shows that simulated squeal grows under both dry and friction modified conditions at a similar rate and to about the same steady state amplitude. This is likely because the instantaneous creep curve shapes (and therefore the effective system negative damping) is very similar in both cases with the friction modified case being slightly less. The creep curves in Figure 6 b) show that although the quasistatic friction modified curve is not negatively sloped, squeal is occurring due to the negatively sloped instantaneous creep curve. Note that the creep oscillation ranges impinge on the positive sloped regions to balance the energy input from the negatively sloped region [8]. The analytical prediction of steady state squeal amplitude in Figure 6 a) is close to the simulated results but underestimates by approximately 20% (or 1.6dB). This was investigated further along with comparisons with experimental results over a range of angle of attacks as shown in Figure 7.

The experimental, simulated and analytically predicted squeal noise level trends in Fig. 7 are in good agreement to within 10dB error above critical creep. Near and below critical creep the experimental levels exceed the predictions as the measurement includes other sources of noise such as rolling and other equipment operation noise. Squeal does not occur at angle of attacks below the critical creep where the curves are positively sloped (see Fig 6b) for both dry and friction modified conditions.

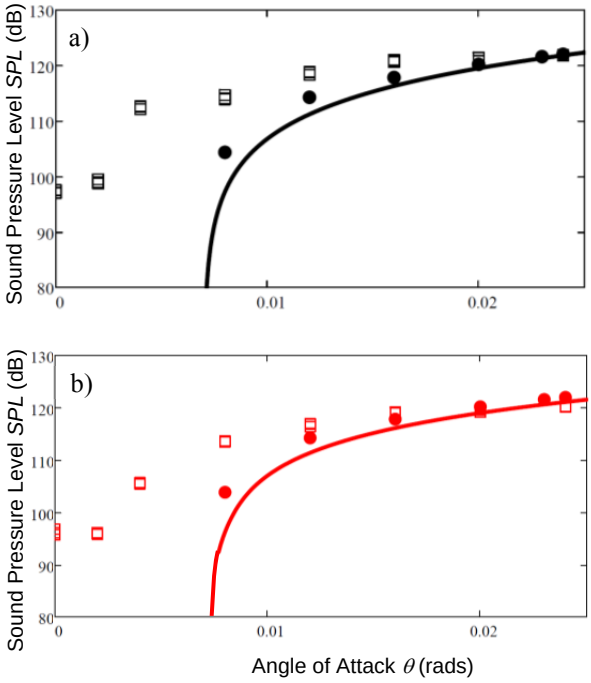

Fig. 7 *a) analytical (-), simulated (●) and experimental (□) sound pressure level vs angle of attack under dry conditions, b) analytical (-), simulated (●) and experimental (□) sound pressure level vs angle of attack under (water-based) friction modified conditions at a rolling speed of 17.8m/s.●.*

Again it is highlighted that squeal noise still occurs under friction modified conditions due to the instantaneous creep behaviour rather than the quasistatic. There is a small error in the predicted results compared to the simulations at low angle of attacks due to the simplification of the creep slope near the critical creep. This could be investigated further, however for this case, the analytical solution is seen to provide a very efficient prediction of squeal noise behaviour over a range of angle of attacks under both dry and friction modified conditions.

4. Conclusions

Wheel squeal vibration and noise under the presence of water-based friction modifiers has been investigated using a mathematical model taking into account instantaneous traction-creep behaviour. The instantaneous rolling contact traction-creep curves are determined from quasistatically measured ones using a two disk testrig. An efficient analytical solution is then compared with squeal sound level trends recorded over a range of angle of attacks. Even though the quasistatic friction modified curve is not negatively sloped, squeal is shown to occur in both the dry and friction modified conditions at about the same steady state amplitude at a nominal speed of 17.8m/s. The results provide insight into why friction modifiers have been shown to be effective in reducing wheel squeal noise but not reliable in eliminating the phenomenon. Further investigation of the effect of rolling speed and critical creep parameters under friction modifiers could be performed.

HOW THE WEATHER IN AUTUMN INFLUENCED THE WHEEL-RAIL TRACTION CHARACTERISTIC DURING VEHICLE TESTS

A. Meierhofer [1,*], G. Trummer [1], C. Bernsteiner [1], K. Six [1]

Abstract: Train operators reported low adhesion in autumn, which they suspect is caused by fallen leaves. To investigate and quantify this effect, vehicle tests have been performed in autumn on a track partially surrounded by forest. To also investigate the influence of different whether conditions, the tests were performed on a day with sunny weather and one with high humidity in the morning and drizzle at noon. The results were then compared to other tests and different creep force models from the literature. The results showed a significant influence of a surrounding forest on the traction especially for dry conditions.

Keywords: leaves, rain, traction, traction coefficient, third body layer, creep force, adhesion.

1. Introduction

Accurate knowledge of the contact forces between wheels and rails, especially the creep force, is essential for a multitude of applications in railway systems, some examples include design of traction control systems, damage and wear predictions as well as simulation of vehicle and drive-train dynamics. To estimate these forces, creep force models are of high importance, which must be parametrized and validated by test data, which can be collected by vehicle tests.

Looking at the literature, there are a few publicly available creep curves, i.e. the dependency of the traction coefficient on the creepage, collected from vehicle tests investigating the influence of different weather conditions. A summary of some existing publications that focus on dry, wet, and oiled conditions can be found in a paper by Polach [1].

Further research on the influence of water and sand on the creep curve during vehicle tests was published by Meierhofer et al., which led to the development of a new creep force model, the so-called ECF model [2].

An interesting topic that was not satisfyingly covered in the past is the investigation of the stochastic nature of traction due to the variation of environment, weather, etc. depending on track-position. For example, train operators report that the traction is different if the track is surrounded by forest or by farmland. This is especially pronounced in autumn, when fallen leaves cover parts of the track [3].

Therefore, the goal of the presented work was to conduct a new series of vehicle tests to investigate the influence of environmental conditions in autumn on the creep curve on different track sections, some of which are surrounded by farmland and others by forest. The results are then compared to vehicle tests from the literature [2] and the ECF-model [2].

2. Vehicle Tests

The tests were performed by Siemens, who also provided the locomotives, on the test ring belonging to the Test Centre VUZ Velim (Czech Republic). This ring is 13.276 km long with a curve radius of 1400 m and mostly surrounded by farmland except for some parts that lead through small forests.

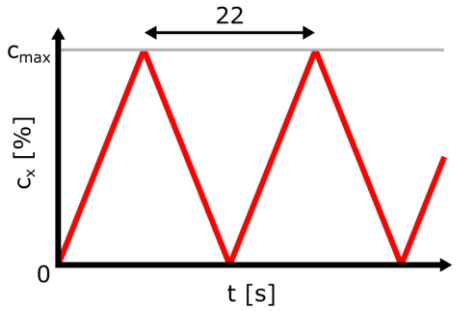

Figure 1: *Modified creepage control strategy used during tests.*

To measure the traction characteristic, two locomotives were used. One was needed to achieve a constant speed during the tests while the other was used for the measurements. There, the creepage control of one of the axles was modified according to the sketch shown in Figure 1. One measurement cycle took 22 s. The other axles were in pure rolling mode and used to determine the actual reference speed of the vehicle.

The tests were performed on two different days in autumn. In the morning of the first day (Day01), there was also no rain or fog and the temperatures were between 6°C and 10°C. Although some residual moisture was present due to drizzle on the day before, this was considered as dry conditions in the context of this work and used as reference for all presented measurements. The morning of the second day had a humidity of close to 100% and temperatures in between 1°C and 7°C. In the following, this will be called damp conditions. Around noon, it started to drizzle, which will be called wet.

2.1. Dry Conditions

The first section that was investigated (Section 1) is surrounded by farmland and shown in Figure 2. The results of these repeated measurements for v = 10 m/s are presented in Figure 3. There, the anonymized creepage denotes the actual values as percentage of the maximum creepage of the modified controller and the anonymized traction value is the percentage of the highest traction.

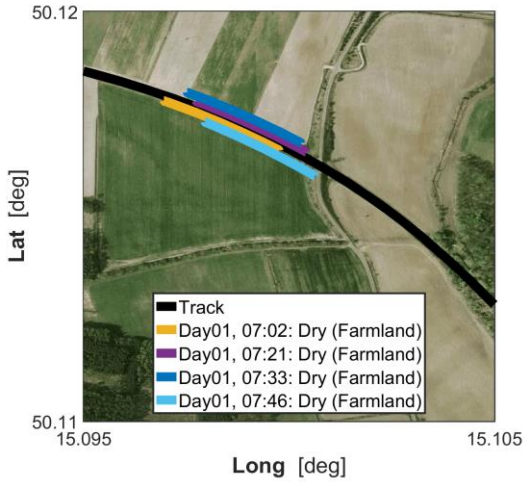

Figure 2: *Section 1 of the test ring, where repeated measurements were performed with a vehicle speed of v = 10 m/s.*

Also plotted there is the mean creep curve calculated from the results. The maximum values approach 100% but are slightly below most of the time. In addition, a steep initial gradient and a traction loss for high creepages are visible similar to the results from the literature [1],[2]. In between, areas with lower traction can be seen, which might be caused by undetermined contaminations of the rail.

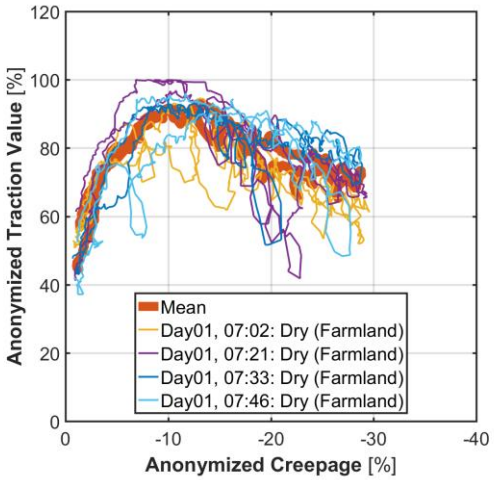

Figure 3: *Creep curves repeatedly measured in Section 1 (see Figure 2) for v = 10 m/s on the first day for dry conditions.*

These measurements were repeated in the same section (Section 1) with a velocity of v = 20 m/s on the same day as shown in Figure 4. It can be seen there, that during one measurement cycle, a longer part of the track was passed due to the higher vehicle speed. The overlap between the two presented measurements is also smaller than for v = 10 m/s. The results for the traction characteristic are shown in Figure 5. While this agrees qualitatively with Figure 3 (it shows a very similar steep increase at low creepages, a maximum, and a traction loss for high creepages), the values themselves are lower for the higher vehicle speed. This influence of the speed is very well documented in the literature [1,2].

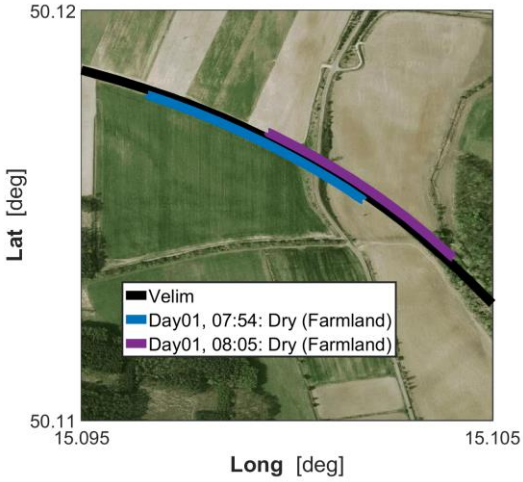

Figure 4: *Section 1 on the test ring, vehicle speed during measurements was v = 20 m/s.*

The traction curves show drops, especially the purple curve, measured at 08:05. The drop at cx = -10% was measured at the position where the track leaves the small wood (see Figure 4). Hence, it might be assumed that, the rail was contaminated there, e.g., by residual water or dew from the night before and by leaves that were visibly lying on and next to the track. The second significant drop at around cx = -20% is harder to explain as there is nothing remarkable visible on the satellite images. However, similar contaminations as the ones mentioned above might be responsible.

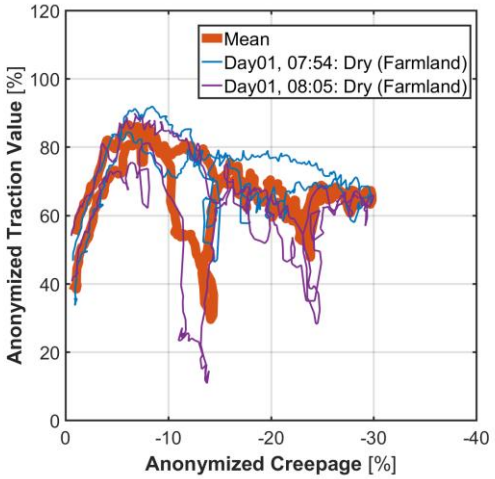

Figure 5: *Creep curves measured in section 1 (see Figure 4) for v = 20 m/s on the first day and for dry conditions.*

Additional tests were performed for a third vehicle speed of v = 5 m/s, but these tests were performed on a different section of the track (Section 2) as shown in Figure 6. This section was partially surrounded by a small number of trees but not enough to consider it a forest. Following a similar train of thought as in the previous case, these trees might lead to more variety in contaminations and, therefore, leading to a higher stochastic influence. This

might explain the hysteresis visible for the test performed at 08:08 which was not visible at 07:57 (see Figure 7).

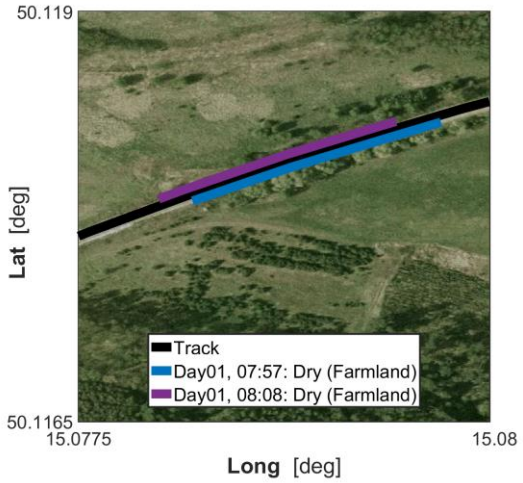

Figure 6: *Section 2 on the test ring, the vehicle speed during the measurement was v = 5 m/s.*

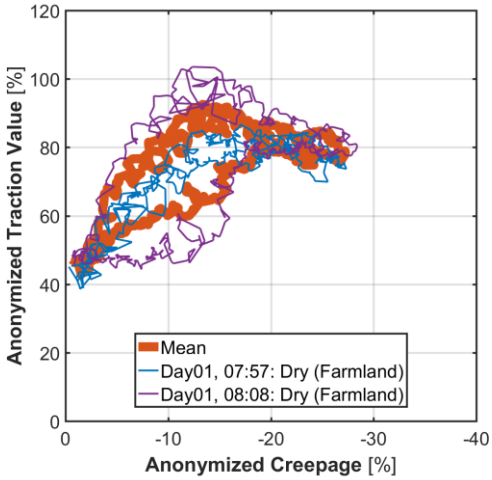

Figure 7: *Creep curves measured in Section 2 (see Figure 6) for a vehicle speed of v = 5 m/s on the first day for dry conditions.*

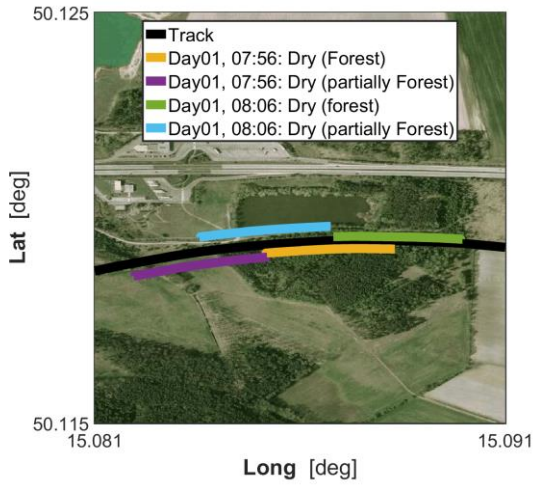

Figure 8: *Section 3 on the test ring, the vehicle speed during the measurement was v = 10 m/s.*

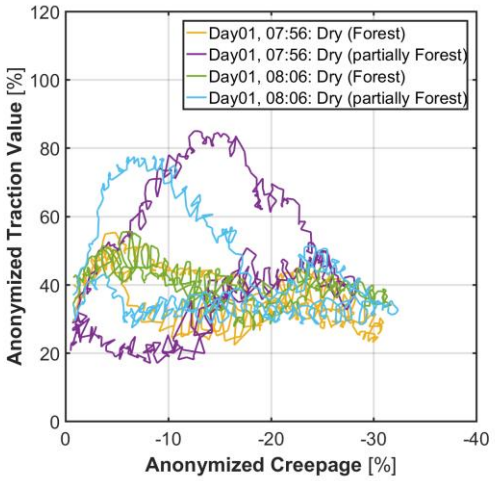

Figure 9: *Creep curves measured in Section 3 (see **Figure 8**) for a vehicle speed of v = 10 m/s on the first day for dry conditions.*

To further investigate this, a different section (Section 3) was chosen which was partially surrounded by forest and on one side a small lake was close by (see Figure 8). The corresponding traction curves are presented in Figure 9. The traction curves in the forest show very low values (around 40%) compared to the results with farmland and the results of the curves only partially surrounded by forest. To further investigate this, the anonymized traction values have been plotted in dependency of the track distance together with the satellite picture of section 3 in Figure 10. The increase in traction is right where the train leaves the forest while it is generally low in the forest itself.

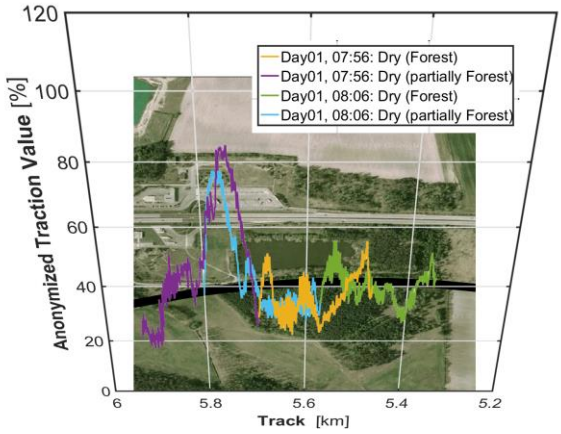

Figure 10: *Anonymized traction value for dry conditions on Day01 in dependency of track distance together with the satellite picture of Section 3.*

2.2. Damp and Wet Conditions

Section 4 (see Figure 11) was the straight track surrounded by farmland. There, measurements were performed for v = 5 m/s for damp and wet conditions. The results are presented in Figure 12. The damp conditions show a higher overall traction than the wet conditions.

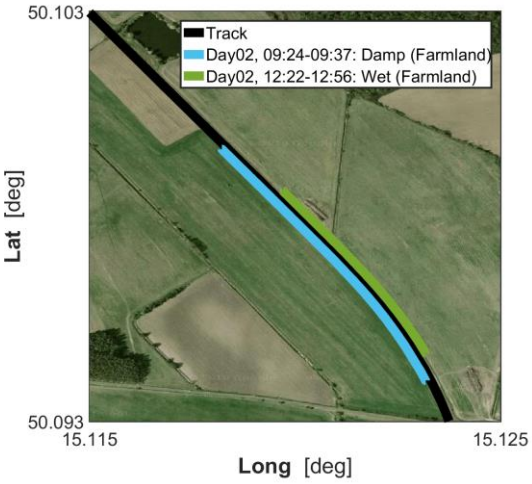

Figure 11: *Section 4 on the test ring, the vehicle speed during the measurement was v = 05 m/s.*

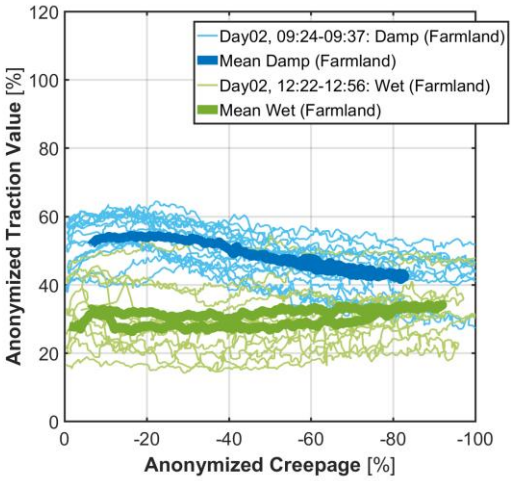

Figure 12: *Creep curves measured on Section 4 (see Figure 11) for a vehicle speed of v = 05 m/s on the second day for damp and wet conditions.*

The tests have been repeated on a slightly different section (see Section 5 in Figure 13) for v= 10 m/s. The results are shown in Figure 14. The mean of the damp conditions shows a distinct maximum and a pronounced decrease in traction for high creepages compared to a rather flat curve for wet conditions. For very high creepages, the results for damp conditions are even lower than for wet conditions. This behaviour agrees with data from the literature from a full-scale roller test rig where a very similar behaviour is reported [4].

Comparing the results of v = 10 m/s (Figure 14) to v = 5 m/s (Figure 12), the damp conditions show a similar maximum but a higher decrease in traction for the higher vehicle speed. For wet conditions, the characteristics for v = 5 m/s start rather low and then continually increase while results for v = 10 m/s reach a first plateau and then decrease for high creepages.

A similar behaviour is observed for wet conditions in Section 6 (see Figure 15) for v = 20 m/s as shown in Figure 16.

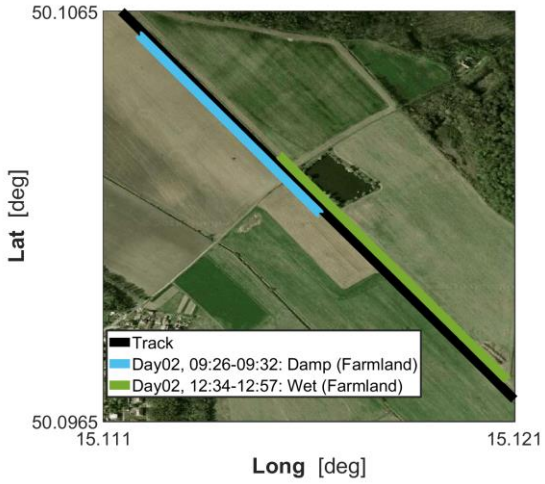

Figure 13: *Section 5 on the test ring, the vehicle speed during the measurement was v = 10 m/s.*

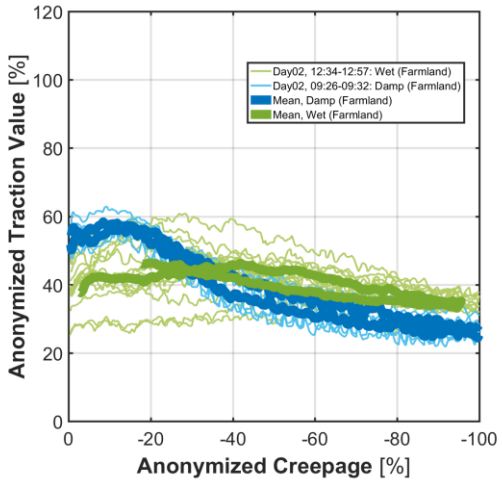

Figure 14: *Creep curves measured in Section 5 (see Figure 13) for a vehicle speed of v = 10 m/s on the second day for damp and wet conditions.*

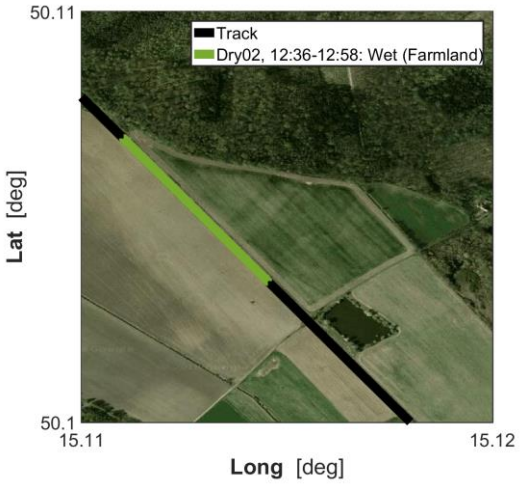

Figure 15: *Section 6 on the test ring, the vehicle speed during the measurement was v = 20 m/s.*

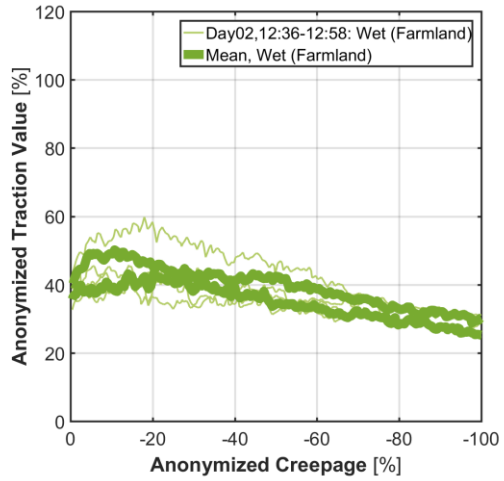

Figure 16: *Creep curves measured in section 6 (see Figure 15) for a vehicle speed of v = 20 m/s on the second day for wet conditions.*

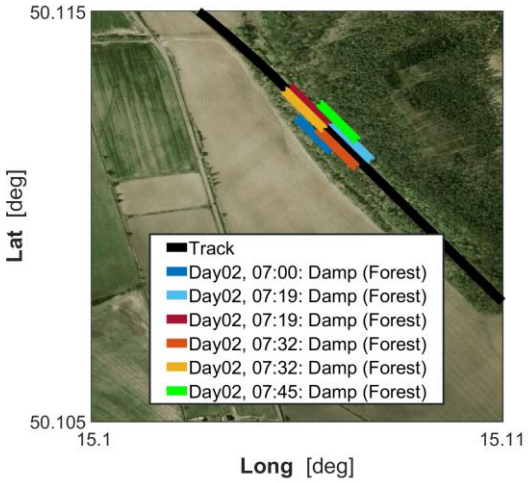

Figure 17: *Section 7 on the test ring.*

Next, the influence of the forest was investigated. Therefore, tests under damp conditions were performed with a vehicle velocity of v = 5 m/s in Section 7 (Figure 17). The creep curves are presented in Figure 18.

The range of the results for forest is between 20% and 70%. Comparing these to Figure 12, Figure 14 and Figure 16 shows that the forest results are more widely distributed, ranging from the lowest farmland values to the highest independent of wet or damp conditions.

This makes sense if one assumes that the track in a forest is probably only partially shaded by the surrounding trees and that there might be more moisture on the rail on some places than on others. The same should be true for leaves, which do not form a homogeneous layer but also only cover parts of the rail. Although, in this case, there should be a certain stochastic to the results as the distribution of the leaves should change with each passing.

Thus, Figure 19 shows the anonymized traction values depending on the track distance. Both presented passages look similar but with small differences. It could be concluded that the remaining moisture on the rail might be more important than the leaves as the effect seems to be longer lasting, But, this is not a definitive proof and the answer is somewhat inconclusive.

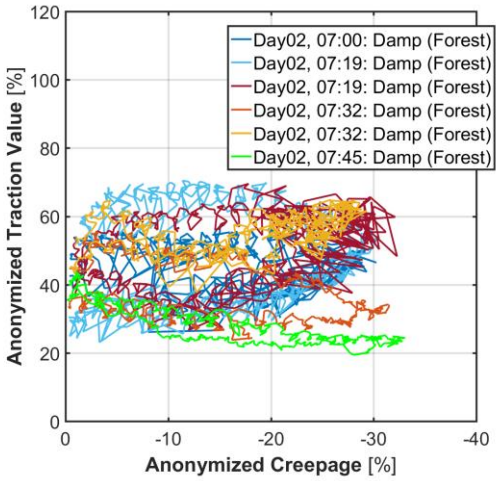

Figure 18: *Creep curves measured in Section 7 (see Figure 17) for a vehicle speed of v = 5 m/s on the second day for damp conditions.*

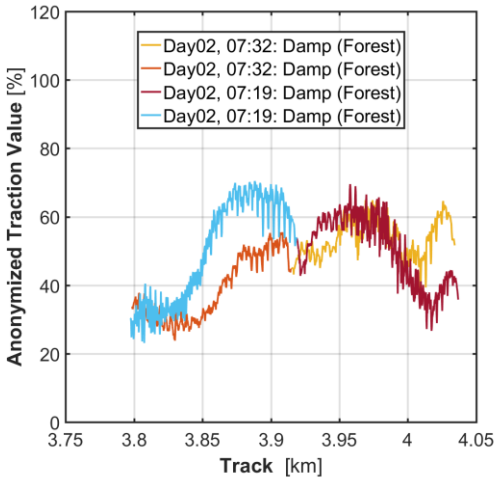

Figure 19: *Anonymized traction values depending on the track distance for two passages of section 5 (see Figure 17) for a vehicle speed of v = 5 m/s on the second day for damp conditions.*

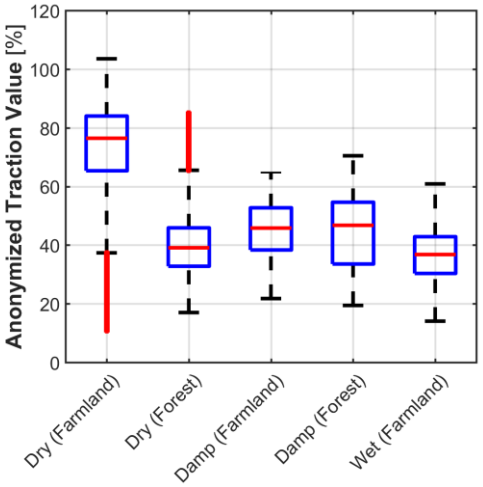

Figure 20: *Boxplot using all traction values for the different conditions.*

A boxplot of the results for all vehicle speeds and creepages depending on the different tested conditions can be found in Figure 20. In the blue boxes are 50% of

the results, in between the whiskers are approximately 99.3% of the data and the red dots are the outliers. Dry conditions surrounded by farmland shows the highest traction while wet conditions show the lowest results. Interesting to note is that the results for damp (forest) cover the values of dry (forest) and damp (farmland). This is further evidence that there was no homogeneous contamination on the rail in Section 7 on Day02 (see also Figure 18) in contrast to the results of Section 3 on Day01 (Figure 9).

3. Comparison to Literature

To investigate the quality of the results, the tests have been compared to available data from the literature [2] in Figure 21. There, the same locomotive was used but the measurements were performed on different test ring. This comparison was done for three different velocities and dry conditions as well as results taken from a section of the track surrounded by farmland (see also Figure 3, Figure 5, and Figure 7).
It shows a quite good agreement with some minor deviations. The most significant difference is the large hysteresis for v = 5 m/s and some deviations for v = 20 m/s, which were discussed in the previous chapter and can probably be attributed to contaminants on the rail.

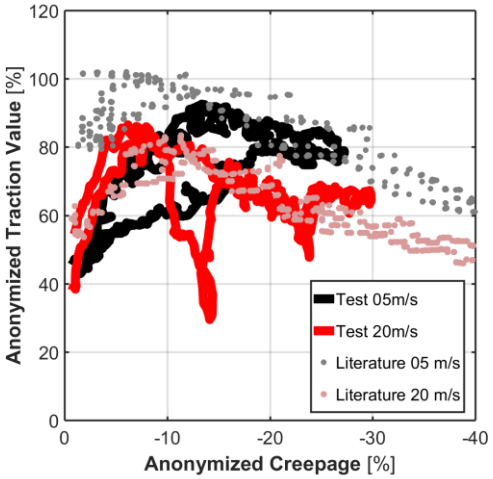

Figure 21: *Measured creep curves for three different vehicle speeds under dry conditions compared to data from the literature [2]*

The same results were also compared to a model from the literature, the so called ECF model [2] in Figure 22. This model was developed to consider the properties of a third body layer with elasto-plastic material behaviour in between wheel and rail. Using the standard parametrization of the model, the model can satisfyingly reproduce the measured test data.
To predict the behaviour for damp and wet conditions in the future, the ECF model has been further parametrized by the test results. Therefore, the results from Figure 9 were used for dry (forest) and the data from Figure 12 for damp (farmland) and wet (farmland). The comparison is shown in Figure 23.

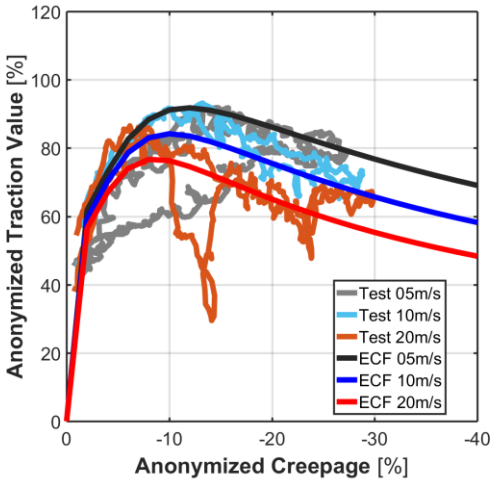

Figure 22: *Comparison of the measured creep curves and the results of the ECF model[2] for three different vehicle speeds under dry conditions for a section surrounded by farmland*

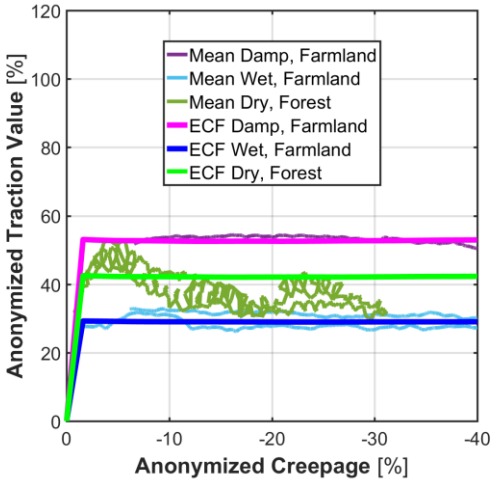

Figure 23: *Comparison of the measured creep curves and the results of the ECF model [2] for damp and wet conditions on a track surrounded by farmland as well as dry conditions and forest.*

4. Summary

The goal of this work was to investigate the claim that the creep force changes significantly if the track is surrounded by farmland or forest. This is said to be especially pronounced in autumn due to a combination of moisture and fallen leaves on the track [3]. Therefore, Vehicle tests were performed by Siemens with a Vectron locomotive on the test ring belonging to the Test Centre VUZ Velim (Czech Republic), where parts of the ring were surrounded by farmland and others by forest. The tests were conducted in autumn on two different days with two different weather conditions.
The results for farmland showed that dry conditions had the highest traction level while damp conditions were lower (around 40% to 55% of the maximum transmissible force). Wet conditions had the lowest traction. For a track surrounded by forest, the results showed a broader distribution of traction values, especially for damp conditions. These results were also much more depending on the actual location, which might be explained by an

uneven distribution of contaminants, i.e., moisture and leaves, on the rail. A summary of the test results can be found in Figure 20.
The results were also compared to measurements from the literature (Figure 21) as well as the ECF model (Figure 22) [2], which resulted in good agreements for both. Finally, the data was used to further parametrize the ECF model for different conditions (Figure 23).
The knowledge gained during these tests gives important information about the stochastic nature of traction in railway operations due to the variation in environment (farmland or forest) and weather (dry, damp, wet) dependent on track-position.
This is important regarding the development of creep force models as well as their application. For example, this might be a good basis to estimate online the application-rates for lubricants or friction modifiers according to the friction conditions encountered during operation to generate a desired friction level.

SUSCEPTIBILITY OF PEARLITIC RAIL GRADES TO THERMAL WHITE ETCHING LAYER FORMATION

Maha Messaadi[1,*], Michael Steenbergen [1]

[1] Delft University of Technology, Faculty of Civil Engineering and Geosciences, Railway Engineering Group, Stevinweg 1, 2628 CN Delft, The Netherlands

[*] E-mail: m.messaadi@tudelft.nl

Abstract: One of the most critical issues in railway engineering is the rail lifetime optimization. In track, rails suffer from various degradation forms like the head checks, squats and studs. The white etching layer (WEL) is considered as a primary stage of damage. The WEL usually appears as a metallurgical change due to the severe loading in the rail running band. This work addresses their generation based on the wheel-rail contact together with a metallurgical analysis. Influences of microstructure and stress on the austenite transformation kinetic are simulated. Consequently, the isothermal austenization diagrams for R260Mn, R350HT and R370CrHT grades under stress are discussed. It turns out that the austenitic transformation is possible within a comparable time to the wheel-rail contact duration.

Keywords: Wheel-rail contact, heat treated grades, white etching layer (WEL); isothermal transformation, shifting time transformation under stress.

1. Introduction

Rail steel development has substantially progressed last decades. For example, the pearlite heat-treated grades are in a continuous increase of use in the construction of modern train networks. Stock [1] and Pointner [2] discussed the interest of these steels in terms of wear and RCF (Rolling Contact Fatigue) resistance. They attributed the damage improvement to the steel microstructure. However, the relationship between their microstructure and the white etching layer (WEL) generation, a frequent degradation feature, still not well established precisely in traffic conditions.

Regarding the literature, two formation mechanisms of the WEL are studied; thermal assumption and mechanical assumption [3]. In fact, the thermal framework assumes that the metallurgical changes; WEL formation occur due to the heating above the austenization temperature followed by a rapid cooling; the austenite is quenched and leads to a 'thermal-martensitic'.

The inconvenience of this assumption is the presence of the plastic deformation underneath the WEL. Zhang et al. indicated the occurrence of a transition region below the WEL, where a plastic deformation appears in a cross-sectioned running band of a rail that has been in service [4]. The mechanical assumption considers that the 'friction-martensitic' results from the metallurgical transformations active at temperatures below the austenization.

Recent research works showed that the thermal assumption is possible to occur [3,5,6]. Flash temperature simulations in the wheel-rail interface reveal to reach higher values than the austenization temperature. Meanwhile, the mechanical loading; hydrostatic pressure and surface shear can affect the local transformation by reducing the austenization temperature and by shifting the steel chemical composition as proposed by Wu et al. [3].

Based on the thermal assumption, this research paper attempts to compare the WEL susceptibility between the pearlitic grades; R260Mn and premium grades R350HT and R370CrHT. The current investigation aims to look deeper at metallurgical properties that could point to the missing link between the metallurgical transformations, namely the WEL, and the local wheel-rail contact loading.

2. Assumptions of white etching layer generation

2.1. Rail steel metallurgy

For railway steels, the carbon amount is in the range of 0.5 to 0.8 wt. % [11]. The heat-treated grades; R350HT and R370CrHT have higher carbon content compared to the standards. This contributes to achieve a finer microstructure for heat treated steels. Fig. 1 presents optical micrographs of rail steels studied in this work. The grain refinement is noteworthy between R260Mn; Fig.1a and the heat-treated steels; R350HT in Fig.1b and R370CrHT in Fig.1c.

The grain size was measured using the mean linear intercept method. The results showed that the average diameter of grains in the R370CrHT grade is around 13.3 µm, R350HT has slightly higher diameter estimated to 18.9 µm and for R260M, it around 37,8 µm according to the ASTM E112-12 standard [7]. In Fig.1, all steels have a pearlite microstructure. The pearlitic structure is an agglomerate of ferrite and

cementite in a lamellar structure. In Fig.1a, the insert is a magnification of R260Mn microstructure showing the pearlitic colonies a^P.

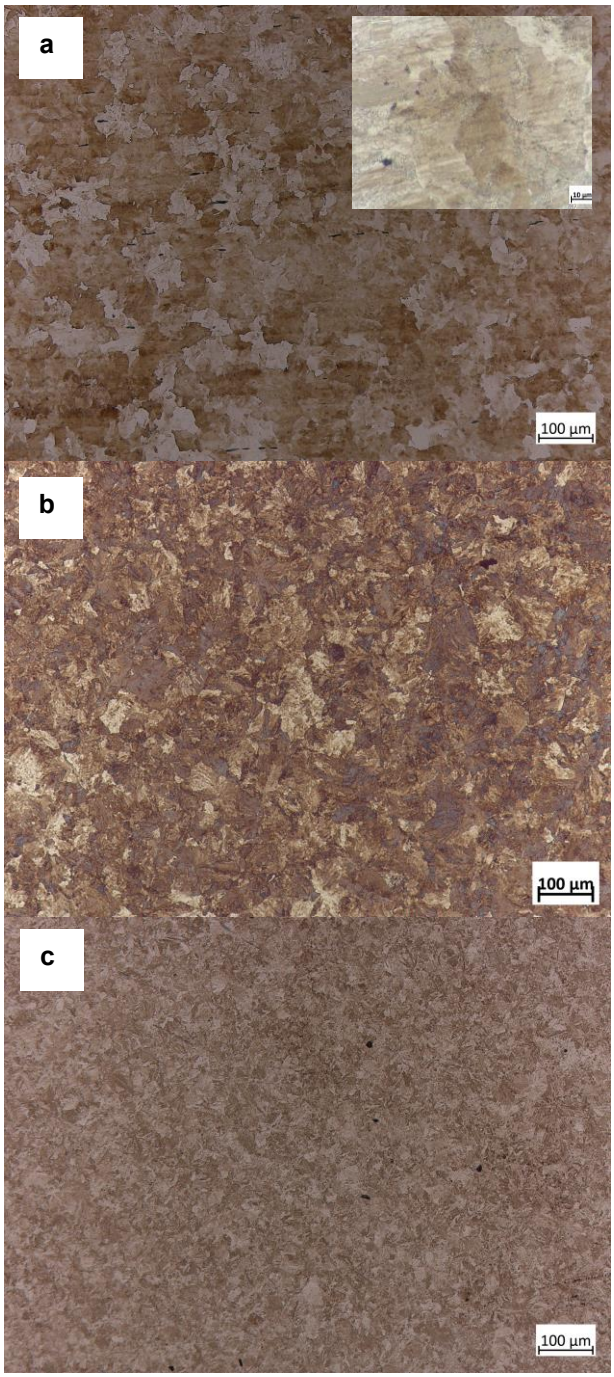

Fig. 1. *Optical microscopy of rail steel microstructures; a- R260Mn; b-R350HT; c-R370CrTH.*

It is well known that not only grain size has a relevant influence on mechanical properties but also the inter-lamellar spacing. Thereby, the thickness of the cementite and ferrite layers changes intimately with the alloying elements and the heat treatment. The average distance between two layers of the same kind is called the inter-lamellar distance, σ_0.

The pearlite colony size and the inter-lamellar distance vary between the three grades. Tab. 1 provides a comparison between these microstructure parameters. Further data concerning the transformation temperature are also included. T_{Ac1} is the transformation temperature from pearlite to austenite, and T_{ms}, the start temperature of martensitic transformation that can be estimated from the chemical composition of the steel [8].

Tab.1. Rail grades characteristics.

	R260Mn	**R350HT**	**R370CrHT**
a^P (mm)	0,02	0,01	0,01
σ_0 (mm)	0,00018	0,00009	0,000053
T_{Ac1} (°C)	723	735	730
T_{ms} (°C)	275	221	227
$Rp_{0.2\%}$ (MPa)	481	685	894

2.2. Approach to compare WEL susceptibility

Rail grade microstructures affect their ability to form austenite at high temperature. The comparison of their austenitization diagrams, by assuming an isothermal transformation, is possible. Roosz et al. have established austenitization diagrams for eutectoid steels in [9]. They assumed that the austenite nucleates and grows by interface diffusion. Avrami equation describes the austenite transformed volume fraction:

$$x = 1 - \exp(-k_1 t^n) \qquad \text{eq.1}$$

where
x represents the austenite transformed volume fraction, t is the time and n is a constant characterizing the transformation kinetics.

Assuming that the nucleation rate N and the grain growth rate G are constant in time, the transformation kinetics was set to $n = 4$. As ought to be, the equation of k_1 arises from the regression analysis proposed by Roosz et al. [9] giving :

$$k_1 = \frac{\pi}{3} N G^3 \qquad \text{eq.2}$$

k_1, is a temperature dependent through the nucleation and growth rates that take into consideration microstructural parameters of pearlitic steel as following:

$$N = \frac{1.378\ 10^{-12}}{\left[(a^P)^2\ (\sigma_0)\right]^2} exp\left(\frac{-25.38}{\Delta T}\right) \qquad \text{eq.3}$$

$$G = \frac{7\ 10^{-11}}{{\sigma_0}^2} exp\left(\frac{-29.7}{\Delta T}\right) \qquad \text{eq.4}$$

Austenitization kinetic during continuous heating and constant stress are rarely studied for eutectoid steel. To the best of the authors' knowledge, research works addressed low carbon steels [10–13]. Moreover, these studies focused on the relationship between the applied stress and the induced transformation plasticity rather

than on the austenitization kinetic except Lui et al. [13]. According to Coret et al. [10], the TRansformation Induced Plasticity (TRIP) is a residual deformation generated by the applied stress during phase transformation. This residual transformation occurs in all phase transformations; austenitic, martensitic, bainitic, pearlitic and ferritic.

The pearlitic transformation was intensively studied by Denis et al. [14] and Gautier et al. [15,16]. They conducted experiments where stress or strain was applied to the austenitic phase; stress rang was close to austenite yield, 80 MPa. The investigation of the correlation between the stress and the phase transformation kinetic showed:

- An acceleration of the pearlitic transformation kinetic proportional to the applied stress,
- A time shorting of the isothermal and the continuous cooling temperature diagrams.

In other words, the time for pearlitic transformation beginning and ending becomes shorter under loading conditions. Denis et al. [14,17] studied experimentally this time shifting. They found either linear or logarithmic correlations in dependence on the isothermal temperature. The function relating the IT curve shift to the stress magnitude (Von Mises stress) is, *D*:

$$D = g(\sigma_e) \qquad \text{eq.5}$$

In a further step, [14] proposed to express the Avrami equation (eq.1) of austenite decomposition using *D* function. Accordingly, they reformulated the kinetics coefficients k_1 by taking into consideration the stress. Thus, the temperature-dependent coefficient $k_{1\sigma}$ and n_σ factors under stress are:

$$k_{1\sigma} = \frac{k_1}{(1-D)^{n\sigma}} \qquad \text{eq.6}$$

$$n_\sigma = n \qquad \text{eq.7}$$

Where

k_1 is calculated in isothermal transformation,
n is the kinetic constant of the in isothermal transformation.

Consequently, eq.6 could express mutually the initial microstructure parameters; included in k_1 factor (see eq.2), and also the effect of the stress; the denominator contains the *D* function. Even though Denis et al. macroscopic assumption, Gautier et al. showed that the nucleation rate *N* increases in dependence on the stress when the growth rate *G* is constant and not affected [18]. Our approach fulfills Denis et al. [17] methodology, however, the time shifting during austenitization should be reviewed.

In the following, the austenization kinetics under stress is discussed. Generally, it appears that the beginning and ending temperatures of austenitic transformation change with pressure. Wu et al. [3] compared the binary iron-carbon diagram under atmospheric pressure and under hydrostatic pressure of 1.8 GPa ; an approximation of the wheel/rail contact pressure. They found that the main differences are :

- the eutectoid composition shifting towards lower carbon values. This is also reported by Denis et al. [14],
- under high wheel/rail contact pressure, the rail composition moves from (near) eutectoid to hypereutectoid,
- as a consequence, a decrease of the T_{Ac1} temperature from 700 to 670 °C in case of R260Mn steel grade,
- and an increase of the T_{Ac3} temperature from 716 to 777°C.

Afterwards, the shifting of chemical composition induces a shifting of transformation temperatures. Even if the gap transformation temperature increases; from 16 to 90°C, the kinetic of austenitization could speed up leading to time transformation shortening. Indeed, Lui et al. [13] showed that the overall austenitic transformation time decreases when the stress increases despite the fact that both beginning and ending transformation temperature increase.

To access to the time shifting in relation to applied stress during austenitic transformation, the author analysed available data from literature; results provided by Lui et al. [13] and Coret et al.[10] for low carbon steels. Both studies proffer the raw curves of the length change as a function of temperature and stress.

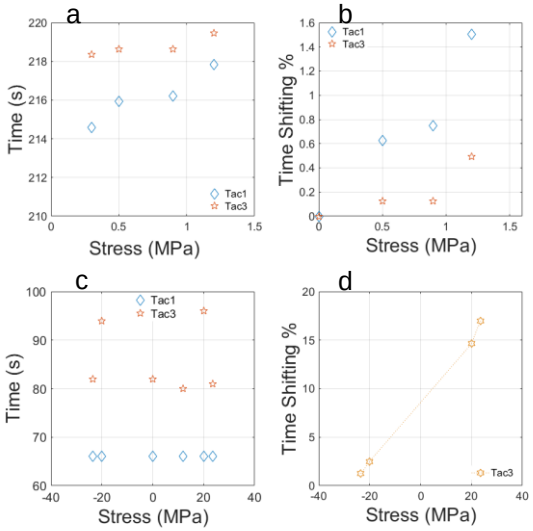

Fig. 2: Variation of the austenitic time transformation T_{Ac1} and T_{Ac3} and the relationship between the time shifting of austenitic transformation and the applied stresses; a-b results from Lui et al. research, c-d results from Coret et al. research.

Lui exanimated the behavior of Fe–2.96 at.% Ni steel subjected to uniaxial compressive stresses. As well as Coret studied the 16MND5 low carbon steel under

biaxial loading paths. Firstly, the transformation times T_{Ac1} and T_{Ac3} were extracted from dilatometry curves and plotted as a function of applied stress in Fig.2a and c. It appears that the stress rang experimented by Coret is relatively higher compared to Lui loading. Later, the shifting in time of transformations was calculated and presented in Fig.2b and d with the aim to estimate the linear shifting time functions. Table 2 compares values of the linear deviation of the time shifting as a function of stress. The *D* function is then expressed as:

$D = C\ \sigma_e$;

Tab. 2: comparison of C values obtained by different researches.

	Lui et al. [13]		**Coret et al. [10]**	**Denis et al. [14]**
***C* (*MPa*$^{-1}$)**	T_{Ac1} 11.410^{-3}	T_{Ac3} 3.510^{-3}	$3.2\ 10^{-3}$	$8.5\ 10^{-3}$

It seems that the calculated data in Tab.2 is comparable. Precisely, values obtained for the T_{Ac3} shifting of Lui and Coret are similar. Consequently, the calculation of austenitization diagrams will be performed by taking into consideration $C = 3.510^{-3}$ MPa^{-1}.

As the last step for the comparison of the white etching layer susceptibility of pearlitic grades, it is assumed that the austenite transforms instantaneously into 'thermal-martensite' in free stress stage. That means the cooling rates are considered to be enough high to ensure the steel quenching. This assumption is widely used in studies focusing on WEL matter [6,19]. Eventually, the rail surface cooling will be discussed in terms of successive heating- cooling cycling and martensite start temperatures (T_{ms}) respectively to each rail grade.

3. Results and discussion

3.1. Comparison of austenitic transformation susceptibility

3.1.1. Influence of steel microstructure on austenitizing diagrams

The austenitization diagram indicates the time for heat at a given temperature to obtain a given amount of austenite transformation. Fig.3 presents the isothermal austenitizing diagram computed from R260 rail grade microstructural parameters. It shows that at 760°C, 16 s of heating are required to start the transformation of pearlite, cementite+ ferrite, to austenite (x = 0.01) and 45 s are required for half pearlite transformation (x = 0.5). A full austenitic phase; x = 0.99%, is obtained after 81 s of heating.

Fig. 4. compares the austenitizing diagrams of the R260 and premium grades. The thick lines indicate the required time for a full austenite transformation. It appears that R370CrHT takes the shortest time to accomplish a full austenitic transformation.

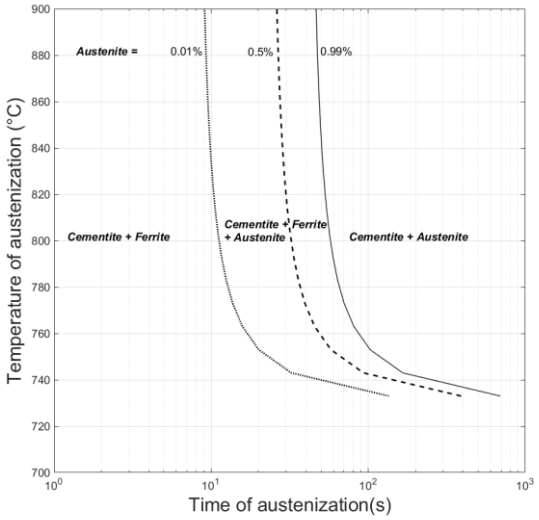

Fig. 3. *Austenitizing diagram of R260Mn grade.*

At 760°C, it requires 1.5 s to start the transformation and 4 s for a full transformation. In addition, the half austenitic transformation of R370CrHT; x = 0.5, overlaps the start of R350HT for temperatures higher than 820°C. The full transformation of R350HT takes around 10s of heating at 760°C.

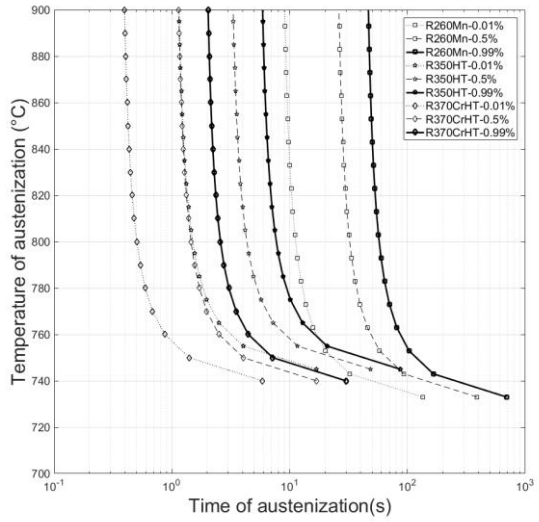

Fig. 4. *Comparison of isothermal austenitizing diagrams of pearlitic rail grades; R260, R350HT and R370CrHT.*

In view of the above results, it seems that the R260Mn grade is less susceptible to form austenite under isothermal transformation. This finding is in agreement with Cho et al.[11] and Fridberg et al. [20] who explained that the austenite growth rate increases with the reduction of inter-lamellar spacing because of the effective diffusion distance decreases. Therefore the refined microstructure of heat-treated steels leads to speed up the austenitic transformation; to a great degree R370CrHT grade. These results can be verified the austenitizing diagram proposed by Roosz et al. [9] by considering structural factors $F = a^P * \sigma_0^2$; $F_{R260Mn} = 6.5\ 10^{-10}$, $F_{R350HT} = 8\ 10^{-11}$ and $F_{R370CrHT} = 2.8\ 10^{-11}$.

3.1.2. *Influence of stress on austenitizing diagrams*

During heating under external stress, the steel experiences three stages [12]:

- Firstly a creep within the initial microstructure; ferrite/pearlite,
- Secondly, the transformation plasticity during austenitization,
- And finally, a creep within austenite.

The creep of the austenite occurs for a stress higher than his yield stress; 80 MPa. Regarding the shear stress that can be generated under Wheel-rail contact, the austenite creep seems to be inevitable. That is why three stress magnitudes are evaluated.

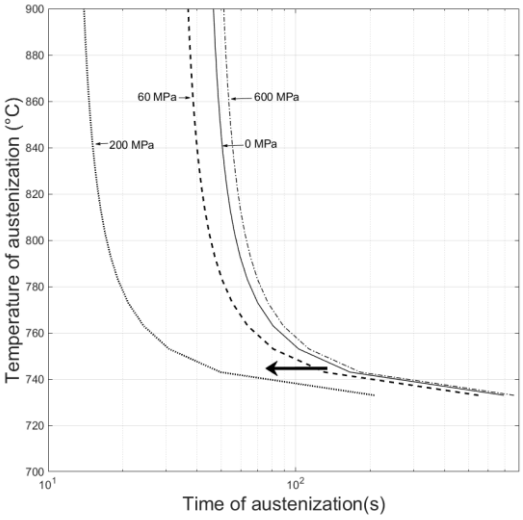

***Fig**. 5. Effect of applied stress on the austenitizing diagram of R260Mn grade to form x = 0.99% of austenite.*

Fig.5 differentiates austenitizing diagrams of R260Mn grade with a stress range of 60, 200, 600 MPa. It appears that the required time to form austenite diminishes under 60 and 200 MPa and slightly increases in the case of 600 MPa. The stress 200 MPa corresponds to the shortest heating time, at 760°C, it moves from 81 to 24s. The high-stress curve slides to longer heating duration but still close to the unstressed diagram.

The influence of the stress on the isothermal transformation of austenite is not well elaborated in literature. Hunkel et al. [21] summarized the findings of several types of research interested in transformations during cooling. They inferred that Dalgic showed that compressive stresses could induce both a decrease and increase of transformation times which seems to be in agreement with our results for austenitic transformation.

This paper addresses the influence of the stress on the isothermal diagram of the R260Mn grade. It is important to notice that for the heat-treated steels, similar shifting behaviours were obtained under-investigated stresses. Based on previous results, Fig.6 compares the shifting in time of the three steel grades under 280 MPa. It corresponds to the minimum time shifting of the isothermal diagrams of all steel grades. Two transformed austenite amounts are presented x = 0.01 and 0.99%.

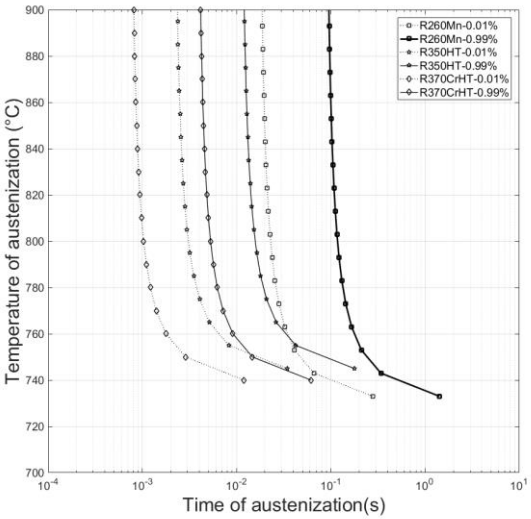

Fig. 6:Time shifting of austenitizing diagrams of pearlitic steels under 280MPa.

The heating time required to transform 0.01% of austenite at 760°C decreases noticeably compared to the isothermal condition. For instance, in the case of R370CrHT grade, a heating duration of 2 ms leads to start the transformation and 10 ms is sufficient to ensure a full austenitic transformation. Longer periods are needed for R350HT and R260Mn. The beginning of austenite transformation is around 33 ms and complete transformation occurs after 0.16s of continuous heating.

The obtained heating times under 280 MPa stress are in the same leagues as the Wheel-rail contact duration which is estimated to 16 ms [6]. Results show that even under stress, the R370CrHT is the most susceptible steel to form austenite compared to R350HT and R260Mn.

3.1.3. *Role of heating rates*

The analysis of the isothermal austenitizing diagrams of pearlitic steels, as well as the influence of external stress, showed that the finer microstructure is the most susceptible to generate austenite. This effect seems to fit with the influence of the heating rate on the austenitization. Indeed, Caballero et al. [22] investigated the relationship between microstructural parameters, heating rates and kinetics of austenite formation in pearlitic steel. Therefore they performed an experimental studied and concluded that the T_{Ac1} and T_{Ac3} temperatures increase with heating rate, which is a comparable feature to that highlighted by Lui et al. [13] for the influence of the stress on the kinetics of austenitization. Besides, Caballero found that a coarse initial pearlite microstructure with a high heating rate slows the kinetics of austenite formation.

Katsamas [23] looked deeper into the influence of a rapid heating on phase transformation from pearlite/ferrite microstructure to austenite. He considered higher heating rates vary from 10^3 to 10^6 K/s

for a maximal temperature range 750-900°C. He established that the volume fraction of pearlite transforming to austenite depends on the maximum temperature, dwell time and pearlite inter-lamellar spacing. Likewise, he assumed that the transformed volume fraction follows a relationship of the form:

$$f_{p\to\gamma} = \left(\frac{T_{max}}{T_{Ac1}} - 1\right)\frac{\sqrt{D\tau}}{\sigma_0} \qquad \text{eq.8}$$

Where

$f_{p\to\gamma}$ is the volume fraction transformed from pearlite to austenite,

T_{max} maximal temperature reached during continuous heating, $T_{max} > T_{Ac1}$,

D the diffusion coefficient of carbon, it varies depending on the maximal heating temperature between the diffusion in austenite phase and the mean value of the diffusion coefficient in both ferrite and austenite phases,

τ the dwell time is the period of time spent above the critical temperature T_{Ac1}.

Eq.8 indicates that, at high heating rates, the volume fraction transformed to austenite is inversely proportional to the inter-lamellar spacing. Smaller inter-lamellar distance (σ_0) induces higher transformed pearlite would be. Once again, R370CrHT grade seems to be the most susceptible to rapidly generate austenite even under external stress or within high heating rates.

Hunkel [12] experienced diverse heating rates on stressed samples. He highlighted that the austenite creepage is the most affected by heating. For low rates, the creepage occurs at a similar amount to the transformation plasticity. However, the increase of the heating rate leads to creep reduction.

3.2. WEL susceptibility under wheel-rail contact conditions

Rare studies investigated the role of microstructure parameters to understand the eventual interaction between the microscopic scale; steel microstructure and the wheel-rail loading condition. The following paragraphs discuss the occurrence of austenitization and the rail surface cooling under Wheel-rail conditions. The first paragraph presents the maximal contact temperature and the thermal penetration. Eventually, these parameters are discussed in relation to Katsamas equation (eq.8). Secondly, the cooling process of the rail surface is reviewed. Finally, the expertise of field samples is presented to support the thermal origin of the WEL, and the different susceptibilities of rail grades to this damage.

3.2.1. Austenitization under wheel-rail contact

Ertz et al. [24] and Knothe et al. [25] investigated analytically the maximum surface temperature that can be generated by sliding friction in wheel-rail interface during rolling. Both of them concluded that in case of a normal rolling condition the austenization temperature is hardly achievable. However, Knothe et al . agreed that for the extreme running condition: high train speed and high creepage (>>1%), the temperature may reach 600°C. Nevertheless, Ertz et al. considered that the WEL results likely from a combined of high mechanical stress and moderate temperature.

Recent studies exanimated further the influence of wheel-rail creepage on temperature distribution in contact patch [5][6]. On one hand, Bernsteiner et al. [6] established a relationship between the vehicle speed and the creepage amount assuming a surface temperature of 720°C. On the other hand, Naeimi et al. [5] demonstrated a linear correlation between the longitudinal creepage and the maximal surface temperature. Temperatures were simulated using Ertz et al. equations in both works [24]. Furthermore, both authors agreed that temperature around austenization is possible for high creepage values. Several researchers consider the occurrence of high creepage is unlikely to happen in normal rolling condition. Nevertheless, in a recent work [26], Naeimi et al. assumed that they were able to measure high creepage around 26% in passenger trains of the Dutch railway.

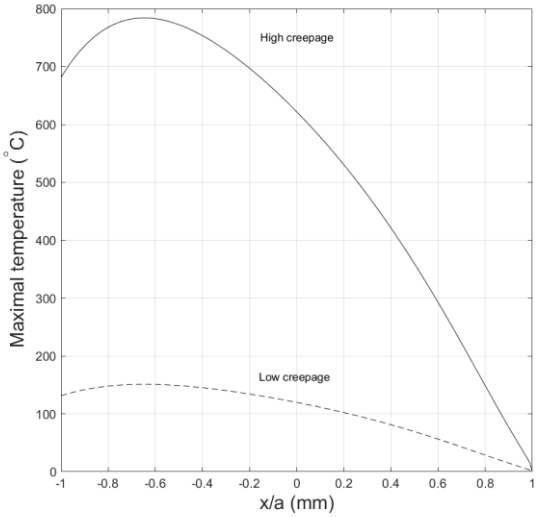

Fig. 7. Comparison of the maximal temperature in contact patch at high and low creepage values.

Fig.7 compares maximal temperatures distributions in wheel-rail contact at low and high creepage values. Temperatures were calculated using Ertz et al. solutions for a Hertzian contact [24], and for the same contact configuration, parameters are detailed in Tab.3.

Regardless of the creepage magnitude, the temperature raises progressively and has a peak close to the trailing edge of the contact patch. For high creepage, Tmax exceeded the austenitization temperature. Consequently, it more likely that the austenitic transformation occurs.

Tab. 3. Details of the maximal rail surface temperature illustrated in Fig.7.

Parameter	*Description*	*Value*
a	semi-axis contact ellipse	8 mm
μ	traction coefficient	0.4
υ_s	sliding velocity	0.4-2.1m/s
υ_0	forward velocity	38m/s
P_0	maximal vertical pressure	1352 MPa
β_r	the thermal penetration coefficient	$1{,}3x10^4$

For high-speed trains, the wheel-rail contact duration is around 10^{-4} s leading to relatively high heating rates that can vary between 10^3 and 10^6. It is then possible to use Katsamas equation (eq.8) to evaluate the volume fraction of pearlite that will transform to austenite under extreme wheel- rail contact. Fig.8 presents curves of the volume fractions for R260Mn and R370CrHT, in other words for different inter-lamellar distance (σ_0). This graph takes into account also the influence of the dwell time on the volume fraction.

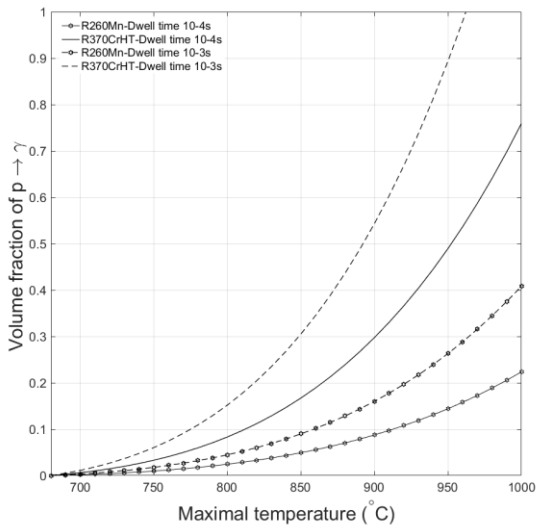

Fig. 8. Curves showing the volume fraction of pearlite transform to austenite as a function of maximal contact temperature, rail grade and dwell time.

The volume fraction of pearlite transforming to austenite in R260Mn grade is relatively inferior to the amount obtained in R370CrHT regardless the maximal temperature and the dwell time. A large inter-lamellar distance does not promote the transformation. It appears from curves in Fig.8 that for a maximal contact temperature around 950°C and a dwell time about 1 ms, the full pearlite volume in R370CrHT can transform to austenite when it does not exceed 0.3 for R260Mn. It is important to notice that the longer the dwell time is, the more the transformation is promoted.

Regarding the wheel-rail rolling conditions, it is difficult access to the highest maximal temperature and their dwell time at a specific spatial zone in the rail surface. Usually, a rail running band explores several wheel passages within divers loading histories. Lojkowski et al. [27] summarized possible loading circumstances with the aim to find out a mechanism explaining the formation of WEL as a mechanically nanostructured layer. Hereby, a review and comments on the proposed stress-temperature cycling described by Lojkowski et al.:

- First, a stress lower than the rail material yield R_p and low creepage; a temperature lower than 300°C, it is almost elastic loading and does not induce WEL,
- Second, a high stress over the Rp coupled with low creepage leading to a frail temperature increase. Consequences of the severe shear deformation are the tilting of microstructural grains, the alignment of the cementite and a decrease of the lamellae spacing [28][29]. However, Lojkowski et al. overlooked the effect of grain refinement. This cyclic loading widely considered as the origin of the mechanically nanostructured layers in rail surface.
- Third, a high stress over the Rp coupled with high creepage leading to an austenitization temperature. This case is the most probable mechanism to generate the thermal martensite, WEL.
- Last, a lower stress than the Rp coupled with high creepage leading to an austenitization. This case may occur as a wheel slip or also in case of grinding. Moreover, it can be considered as a cyclic re-austenitizing which can occur once the WEL is formed. Chraska et al.[30] explained that in a high carbon content material, austenitization cycling increases the number of fine carbide particles. So the fine carbide precipitates in WEL can have a thermal origin.

As explained above, the applied stress has a crucial role in the development of austenitic transformation on the rail surface. Otherwise, the three pearlitic steels have distinctive mechanical properties, yield stresses of steels are highlighted in Tab.1. Grade R260Mn has the lowest yield stress leading to higher susceptibility to plastic deformation compared to the heat-treated steels.

Plastic deformation affects the rail surface by cyclic shear inducing a progressive hardening. From the microstructural point of view, the ratcheting can involve a morphological evolution of the pearlite colonies in the shear direction and the decrease of the inter-lamellar spacing of aligned cementite lamellae with the total traffic load [31]. That means an excessively deformed R260Mn steel may present lower pearlite colonies size and inter-lamellar distance than R370CrHT in the top surface of the rail. Afterwards, a higher thermal susceptibility to austenitization.

3.2.2. Cooling of the rail surface

After wheel passages, the austenite formed in the top rail is instantaneously cooled. It transforms into thermal martensite. The martensite reaction is widely considered

as athermal governed by the undercooling below the start martensitic temperature. Andersson et al. [19] made a similar assumption to estimate the formation of martensite spots in rail surface by using the Koistinen–Marburger equation.

Tab.1 compares T_{ms} of the rail grades. The grade R260Mn exhibits the highest value, it is 50 °C higher than the heat treated grades. Subsequently, it is likely that the martensitic reaction starts in R260Mn before the other grades for a similar austenitic condition.

Regarding the kinetics of the athermal martensitic reaction, Bhadeshia cited three types [8]:

- normal athermal transformations, the austenite-martensite reaction depends exclusively on temperature. It assumes that the transformation occurs at a fixed amount of austenite. It is possible to neglect the time.
- athermal transformations initiated by a burst phenomenon, this reaction commences from a previous existent isothermal martensite, the spread of the martensitic phase occurs by autocatalysis.
- isothermal transformation, the austenite-martensite reaction depends on time and temperature. Nucleation and martensite growth are decisive in the case of composition fluctuations.

Looking at the literature, most studies consider the normal athermal transformation to justify the martensite formation on the top layer of railhead: a sudden decrease of temperature within a very short time [6][19][26]. Nevertheless, this athermal transformation cannot explain thermally the generation of the brown etching layer, or stratification beneath the WEL [32]. The cooling conditions of the rail surface could be also influenced by the modification of the material proprieties in the extreme surface of the rail.

3.2.3. Field examples

This paragraph presents illustrations of WELs developed in rail grades wherein a case study of the R370CrHT grade is compared to R260Mn in similar initial and in-service conditions.

3.2.3.1. WEL susceptibility after milling operation

Fig.9 presents optical cross-sections of new rail grades R260Mn and R370CrHT. The two rails experienced analogous milling operations. These rails have never been in the track. In both grades, high milling temperatures induced the generation of continuous WELs. In Fig.9b, the thickness of the WEL does not exceed 3 µm. Moreover, a tiny plastic deformation appears under the layer. Concerning Fig.9a, the white layer is more visible. Her thickness reaches 6,3 µm. The thickness variation could be linked to milling parameters and to the steel microstructures.

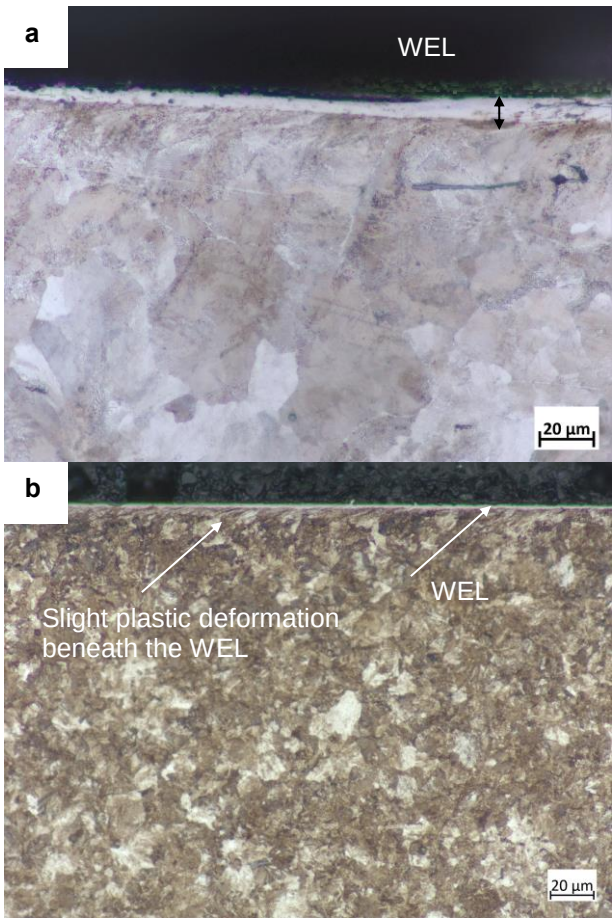

Fig.9. Optical longitudinal cross-sections of new rail grades; R260Mn (a) and R370CrHT (b) in the running band.

Looking deeper to microstructure parameters, WELs are considered as thermal martensite that is formed from a complete transformed pearlite to austenite, Roosz et al.[9] were able to determine the length of the transformed austenite. The length expression depends on the size of the pearlite colony and on the temperature difference.

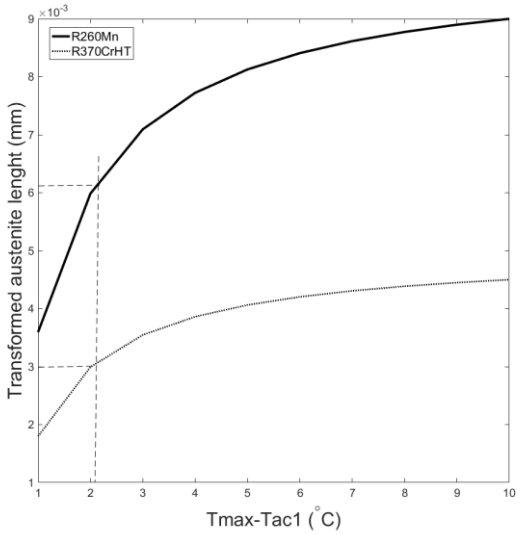

Fig. 10. Comparison of the transformed austenite length of rail grades R260Mn and R370CrHT.

Fig.10 depicts the relation between the transformed austenite length and the temperature difference of two

rail grades. It shows that for an almost comparable temperature difference, the length of transformed austenite fits well with the thicknesses of WELs.

3.2.3.2. WEL susceptibility after 2 weeks in-service

Milled rails, equivalent to those discussed previously, were installed in the Netherlands Networks for two weeks and they were subjected to similar train traffic loading. Fig.11 presents the evolution of the microstructures after service.

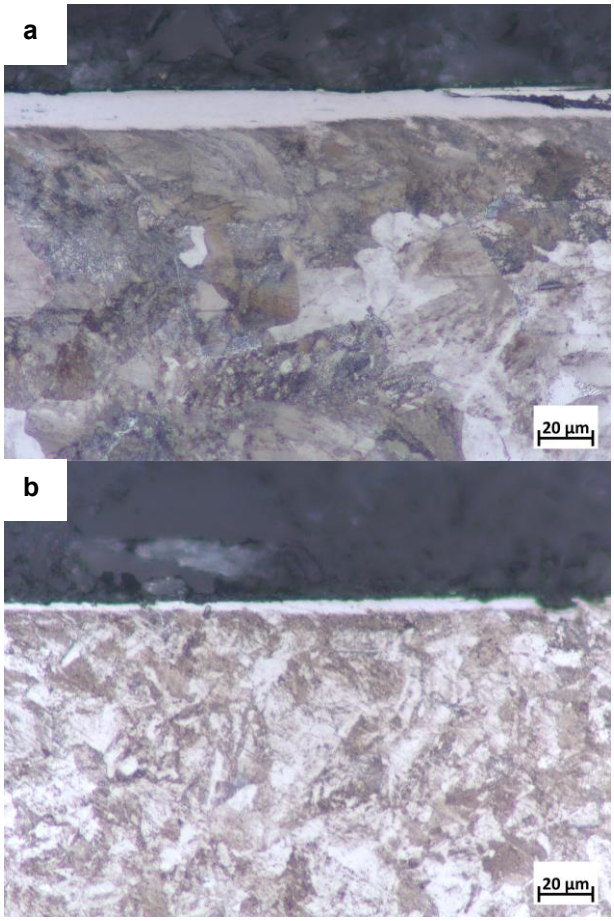

Fig. 11. *Optical longitudinal cross-sections of rail grades after 2 weeks in-service; R260Mn (a) and R370CrHT (b) in the running band.*

Fig.11a shows the longitudinal cross-section of the running band in R260Mn rail. It appears that the WEL is well developed compared to the initial microstructure presented in Fig.10a. The WEL thickness is 17 µm. Fig.11b. reveals the presence of WEL on the top surface of R370CrHT grade after 2 weeks in-service. The thickness of this layer is less than 10 µm. It is relatively higher than the milled WEL but it is lower than the WEL developed in R260Mn after the same service period.

This example shows that even the heat treated grade has the lower inter-lamellar distance, it is not the most susceptible to the thermal WEL. Indeed, the small inter-lamellar distance improves the mechanical properties leading to the reduction of the plastic deformation in both surface and subsurface. The steel microstructure parameters remain for longer working time un-altered by the cyclic loading. The increase of the contact temperature above austenitization affects a thin layer.
In the case of the standard grades, the deep plastic deformation alters faster the subsurface microstructure which promotes the austenitic transformation.

4. Conclusions

The present work is an effort to understand the microstructural parameters influences on the development of the thermal defects; WEL in pearlitic rail grades. The pearlite colonies size and the inter-lamellar distance of R260Mn, R350HT and R370CrHT are the key parameters to establish the austenitizing diagrams and to compare their thermal susceptibilities. The relevant results of this work are:

- Based on Roosz et al. formulation to build austenitizing diagrams, we showed that the steel R370CrHT is the most susceptible to transform from pearlite to austenite due to the low inter-lamellar distance.
- The external stress could accelerate the kinetics of the austenitic transformation in pearlitic steel. The starting time of austenitic transformation can be at the same magnitude of the wheel-rail contact;10^{-4}-10^{-3} s.
- Under the wheel-rail condition, the maximal contact temperature and the dwell time have an important effect on pearlite to austenite transformation. Nevertheless, it is still difficult to experimentally measure these variables.
- The field examples give evidence about the role of the plastic deformation on changing the initial microstructural parameters under wheel-rail contact.
- The WEL susceptibility in pearlitic grades depends on the reached temperature above T_{AC1} and the degree of the altered microstructure of railhead.

Abstract: In order to analyze the material state in the rail surface layer during service, R260 rail steel has been subjected to large shear strains. The evolution of the yield surface at different amounts of predeformation, corresponding to different depths in the railhead, has been characterized. As expected, it is found that the size of the yield surface and the degree of anisotropy increase with the amount of predeformation. However, the major changes occur already after the first of six predeformation cycles, indicating that the yield surface is anisotropic several millimeters into the railhead.

Keywords: pearlitic rail steel, anisotropic yield surface, rail running band, large shear strains

1. Introduction

It is well known that large shear strains accumulate in the rail surface layer during service. Rolling Contact Fatigue (RCF) typically initiates in this region, but the material behavior of the surface layer is still not very well known. One challenge is that the strain gradient in the thin surface layer of the rail makes it difficult to obtain homogeneous test bars from field samples. The shear strains have been replicated using equal angular channel pressing and high pressure torsion experiments [1]–[3]. From these experiments, a pronounced anisotropy was observed in the fracture toughness and crack propagation. Furthermore, Larijani et. al. [4] showed that this anisotropy can explain the direction of crack growth. Hence, the anisotropy of the surface layer of rails seems to have a significant influence on RCF crack initiation and propagation.

In a recent publication by the authors [5] it was found that an equivalent material state also could be obtained by a compression-torsion predeformation of cylindrical test bars. In another publication [6], the authors showed that this predeformation could be modeled quite accurately using a model with an isotropic yield surface. However, several authors have shown that deformation of steel leads to a distorted yield surface (see e.g. [7], [8]). The shape of the yield surface will have a strong influence when the loading direction varies. It is therefore interesting to evaluate the evolution of the yield surface after subjecting the pearlitic R260 steel to the predeformation method in [5]. The main difference from previous experiments on yield surface evolution is the magnitude of the predeformation, which in this work is more than two orders of magnitude larger than in e.g. [8]. It is not possible to achieve such large strains with tubular test bars due to buckling. Solid test bars are therefore used for the predeformation part. These are then machined into tubular test bars for the evaluation of the yield surfaces.

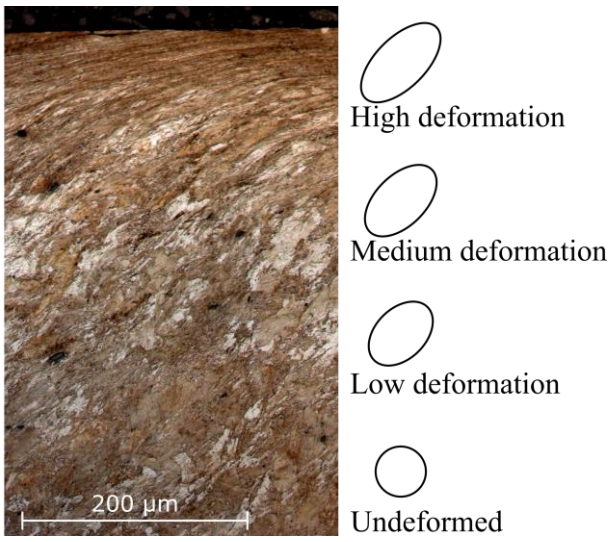

Figure 1: Sketch of yield surface evolution due to different amounts of deformation at different depths in rails

By investigating the yield surface at different levels of predeformation, we aim to understand how the yield surface differ throughout the railhead. Figure 1 is a sketch how this can look, noting that the exact depth of the different deformation levels are not known. In order to quantify the changes of the yield surface, we use the well-known anisotropic yield criterion by Hill [9]. The goal of this study is to quantify how the yield surface changes with different amounts of plastic predeformation. This information can later be used when simulating stresses, strains and fatigue life of rails in the vicinity of the wheel-rail contact.

2. Methods and material

As previously mentioned, the material used in this study is the fully pearlitic railway steel R260. Its measured chemical composition can be found in [5].

2.1. Predeformation

26 mm cylindrical bars were extracted from unused railheads, with their center roughly 20 mm below the surface. These bars were then machined according to the geometry shown in Figure 2. This geometry was obtained by minimizing the shear strain variation on the outer surface. The minimization was conducted using a 2D axi-symmetric finite element model with the OB2 material model from [6]. The gauge diameter was chosen to be 14 mm to make it easier to obtain thin-walled tubular test bars at the later stage. Larger diameters were not possible due to the axial force limitations of the MTS 809 biaxial test rig (±100 kN).

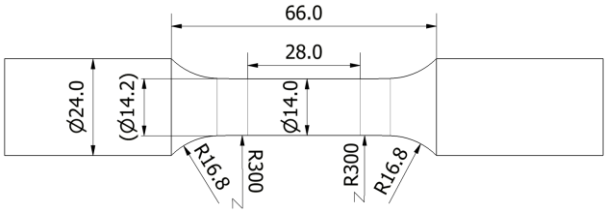

Figure 2: Test bar geometry for the predeformation.

The general method is described in [6], and the exact loading scheme used in this work can be described as follows:

1. Ramp the axial load to a nominal axial stress of -600 MPa, during 5 seconds.
2. Rotate 90 degrees during 90 seconds.
3. Relax torque and axial force simultaneously during 5 seconds.
4. Ungrip, rotate lower grip back, regrip. Go to 1).

The different levels of predeformation are denoted PDx where x=0, 1, 3 or 6 denotes the number of repetitions of the loading scheme above. Digital image correlation (DIC) was used to obtain the average surface strains on some of the test bars. The shear strain values at different radii were calculated using the assumptions of homogeneous axial strains and that straight radial lines remain straight.

2.2. Manufacturing of hollow specimens

The solid predeformed test bars have a linear variation of shear strain with the radius, making them unsuitable for evaluation of the material yield point. In order to evaluate the yield behavior at a specific amount of predeformation, the test bars were therefore machined into tubular test bars. The outer dimensions of the specimen were machined first. This was possible due to the increase of the diameter during the compression-torsion loading. For the outer diameter of 14 mm, a 1 mm wall thickness is considered thin-walled according to the ASTM E2207 standard [10]. The specimen geometry used for the yield surface evaluation is given in Figure 3.

Figure 3: Test bar geometry for the yield surface evaluation.

The most challenging part of this machining process was to achieve sufficient concentricity between the outer gauge diameter and the drilled hole. For the given dimensions, ASTM E2207 allows a wall thickness variation of ±0.015 mm. To meet these strict demands a single fluted gun drilled was used to drill the holes. Several specimens were machined before a method producing reliable results was identified. All of the bars with 3 and 6 predeformation cycles were within the standards, while this is not the case for all of the undeformed and the ones with 1 predeformation cycle. To minimize the influence of this, those with the worst concentricity were used in pure axial loading.

2.3. Yield surface measurements

As the material does not exhibit a distinct yielding behavior, an exact yield point cannot be determined. An offset plastic strain, sufficiently large to not be masked by the uncertainties in the measurements, was therefore required. The most common method for measuring yield surfaces in the literature is by probing different directions using the same test bar. This method requires the offset strain to be small in order to reduce the influence on subsequent measurements. Offset values for probing measurements in the literature range from 5μ [11] to 50μ [12]. A challenge with using very small offset strain values is the accuracy of the measurements, as pointed out by Liu and co-workers [13]. They studied the difference between yield surfaces measured using probing with a single test bar and using one test bar for each loading direction. They conclude that the probing method produces questionable results. The controversy regarding the probing of yield surfaces was also brought up by Zhang et. al. [14], showing that they could model many of the probing experiments with a model with an isotropic yield surface and multilinear kinematic hardening. While less expensive in terms of the number of test bars, we concluded that the probing method is not sufficiently reliable for the current study.

The plastic offset strain was previously discussed, but never properly introduced. The most common method in the literature (see e.g. [7], [8], [15]) is to calculate this as the offset from the linear elastic response, and taking the effective value as the plastic von Mises strain $\epsilon_{\mathrm{p}}^{\mathrm{vM}}$:

$$\epsilon_{\mathrm{p}}^{\mathrm{vM}} = \sqrt{\epsilon_{\mathrm{p}}^2 + \frac{\gamma_{\mathrm{p}}^2}{3}} \tag{1}$$

$$\epsilon_{\mathrm{p}} = \epsilon - \frac{\sigma}{E}, \qquad \gamma_{\mathrm{p}} = \gamma - \frac{\tau}{G} \tag{2}$$

Here ϵ and γ are the axial and shear engineering strains measured with the predeformed reference lengths, and ϵ_{p} and γ_{p} are their plastic counterparts. Furthermore, σ and τ are the axial and shear stresses, while E and G are the elastic and shear moduli. For each experiment E and G were calibrated by linear regression up to an effective von Mises stress of 50 MPa. For pure torsion or axial loading, the constant pertinent to the perpendicular loading

direction was taken from [6]. An offset value of 0.1 % was chosen to evaluate the yield surfaces.

As previously noted, the tubular test bars are considered thin-walled and hence the average stresses and strains are used. The torque T, the axial force F, the rotation θ over the gauge length $L = 12$ mm and the axial strain ϵ were measured in the experiments. The average stresses and shear strain can then be calculated as

$$\tau = \frac{2T}{\pi(r_o^2 - r_i^2)(r_o + r_i)} \quad (3)$$

$$\sigma = \frac{F}{\pi(r_o^2 - r_i^2)} \quad (4)$$

$$\gamma = \theta\frac{r_o + r_i}{2L} \quad (5)$$

where r_o and r_i are the outer and inner radii.

2.4. Experimental program

As previously mentioned, three different levels of predeformation are evaluated, in addition to the virgin material. The test bars were loaded in different directions using strain control, linearly ramped from zero to their end values γ_{end} and ϵ_{end} in 2 seconds. Considering the load angle α and the max effective strain value $\epsilon_{max} = 0.8$ %, the end values were calculated as

$$\gamma_{end} = \frac{r_o + r_i}{2r_o}\sqrt{3}\epsilon_{max}\cos\alpha$$
$$\epsilon_{end} = \epsilon_{max}\sin\alpha \quad (6)$$

The factor $\sqrt{3}$ on the shear strain is motivated by the effective von Mises strain in Equation 1. Furthermore, the factor $(r_o + r_i)/2r_o$ comes from that the surface shear strain was used during the testing, while the shear strain in Equation 5 is in the middle of the test bar wall.

The load angles for the different levels of predeformation are summarized in Table 1. To better understand the behavior for loads occurring during the rail wheel contact, more emphasis is put on directions giving compressive loads ($\alpha \in \langle 180,360 \rangle$). For the virgin material and for the fully predeformed material (PD6), some angles are repeated in order to obtain knowledge about the uncertainties in the measurements.

Table 1: Experimental program

PD	Load angles	N
0	0˚, 45˚, 2*90˚, 135˚, 2*180°, 3*270°, 2*315°	12
1	0°, 90°, 180°, 225°, 270°, 292.5°, 315°, 337.5°	8
3	0°, 90°, 180°, 225°, 270°, 292.5°, 315°, 337.5°	8
6	2*0°, 45°, 90°, 2*135°, 2*180°, 225°, 247.5°, 2*270°, 292.5°, 315°, 337.5°	15

3. Theory

3.1. Yielding in pearlitic steels

Yielding in crystalline materials is enabled by dislocation motion. The most basic strain hardening effect is seen as an expansion of the yield surface due to increased dislocation density and microstructure refinement. Furthermore, pileup of dislocations at grain boundaries is often the explanation for the Bauschinger effect, which can be modeled as a translation of the yield surface. Finally, alignment of grain orientations can explain how an initially isotropic material may experience yield surface distortion.

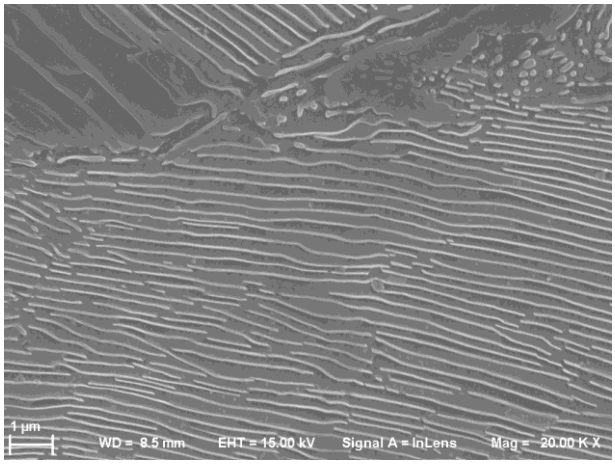

Figure 4: Undeformed pearlitic R260 rail steel from [16]

Pearlitic steels (see Figure 4) consists of hard cementite lamellas (white), surrounded by a soft ferrite phase (black). The lamellas contribute to the strength of the steel by providing additional obstacles for dislocation motion. Similarly to grain boundaries, these may also enable dislocation pileup. Furthermore, their reorientation may produce favorable directions for plastic flow and hence a distorted yield surface. However, at large plastic strains (Figure 5) one can see that also the lamellas experience plastic deformation, and are therefore not as efficient at hindering dislocation motion. Such results were studied in more detail by Izotov et al. [17]. They concluded that in coarse pearlitic structures (lamellar spacing > 0.5 µm) the lamellas are efficient obstacles. However, in fine pearlitic structures (lamellar spacing 0.1-0.2 µm) the two phases are deforming as one.

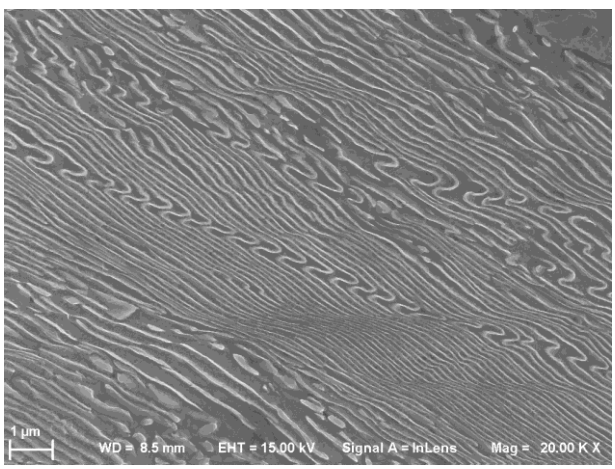

Figure 5: Deformed material in a test bar from [16]

3.2. Yield surface modeling

In material modeling the yield criterion is often described by a function Φ as

$$\Phi(\boldsymbol{\sigma} - \boldsymbol{b}, \boldsymbol{k}) = 0 \tag{7}$$

where $\boldsymbol{\sigma}$ is the stress tensor, $\boldsymbol{b}$ is the back-stress describing the Bauschinger effect and $\boldsymbol{k}$ is an array of internal variables describing the material state. In this work, separate yield surfaces will be considered for each state and $\boldsymbol{k}$ will therefore not enter the yield criterion. Furthermore, only an axial stress $\sigma = \sigma_{zz}$ and a shear stress $\tau = \sigma_{z\theta}$ are present, leading to a yield criterion on the form

$$\Phi(\sigma - b_\sigma, \tau - b_\tau) = 0 \tag{8}$$

From each experiment i, a stress combination σ_i and τ_i giving a certain effective plastic strain is determined. Each of these stress combinations define a yield point. The error of a yield model for a certain combination can then be calculated as

$$\begin{aligned} e_i^2 &= \min_{\sigma,\tau}[(\sigma_i - \sigma)^2 + 3(\tau_i - \tau)^2] \\ &\text{subject to } \Phi(\sigma - \mathrm{b}_\sigma, \tau - \mathrm{b}_\tau) = 0 \end{aligned} \tag{9}$$

The scaling factor of 3 for the shear stress contribution comes from the von Mises yield criterion. This is motivated by the accurate fit of the von Mises yield criterion that is shown for the undeformed material state later. The models discussed below are fitted in order to minimize the total error E for n experimental data points:

$$E = \frac{1}{n}\sum_{i=1}^{n} e_i^2 \tag{10}$$

3.2.1. Von Mises

When only the axial stress σ and the torsional shear stress τ are non-zero, the von Mises yield criterion can be written as

$$\Phi_{\mathrm{vM}} = \sqrt{(\sigma - b_\sigma)^2 + 3(\tau - b_\tau)^2} - \sigma_y = 0 \tag{11}$$

Hence, it can be represented by a circle in the $\sqrt{3}\tau - \sigma$ plane, centered at $(\sqrt{3}b_\tau, b_\sigma)$ and with the yield stress σ_y as the radius. In order to fit the circle to the experimental data, the equation for a circle is solved directly as a least squares problem.

3.2.2. Hill

Hill's [9] orthotropic yield criterion takes the following form when the axes of the anisotropy coincides with the coordinate axes:

$$\Phi_H = \sqrt{\begin{matrix} F(\sigma_{yy} - \sigma_{zz})^2 + 2L\sigma_{yz}^2 \\ + G(\sigma_{zz} - \sigma_{xx})^2 + 2M\sigma_{zx}^2 - 1 \\ + H(\sigma_{xx} - \sigma_{yy})^2 + 2N\sigma_{xy}^2 \end{matrix}} \tag{12}$$

In his publication, Hill noted that the principal axes of anisotropy will change during torsional deformation of tubular test bars. By rotating the stress tensor, it can be shown that the Hill criterion becomes a rotated ellipse in the $\sqrt{3}\tau - \sigma$ plane. For this criterion we therefore have 5 degrees of freedoms:

- 2 back-stresses b_τ and b_σ
- 2 semi-axes of the ellipse, denoted σ_{y1} and σ_{y2}
- 1 rotation angle of the ellipse major axis, denoted β

In order to fit the experiment data to an ellipse, the direct method for performing a least square fit of ellipses by Halir [18] is employed.

4. Results

The predeformation resulted in the strain values given in Table 2, measured using DIC. These are calculated for the location in the center of the wall of the tubular bars, before re-machining.

Table 2: Mean predeformation strain values in the tubular cross section.

PD	1	3	6
$\bar{\gamma_0} = \frac{\theta_0(r_i + r_o)}{2L_0}$	0.21	0.60	1.13
$\bar{\epsilon_0} = \frac{\Delta L}{L_0}$	-0.06	-0.13	-0.21
$\overline{\epsilon_{r,0}} \approx \overline{\epsilon_{\theta,0}} = \frac{\Delta R}{R_0}$	0.03	0.07	0.13

Different yield surfaces are measured for each predeformation state. In Figure 6, the circle based on von Mises yield criterion is fitted for the initial yield surface. Ellipses, based on Hill's [9] criterion, are fitted for the subsequent yield surfaces. The markers in the center of the yield surfaces show the centers calculated by the fitting procedure. The parameters of the ellipses shown in Figure 6 are given in Table 3.

4.1. Back-stress evolution

After the initial predeformation cycle the back-stresses b_τ and b_σ are not evolving much. For 6 cycles of predeformation it even appears that their magnitudes are smaller than for medium smaller amounts of predeformation. One possible reason for the lack of further evolution may be the unloading occurring after each predeformation cycle. When analyzing the torque versus rotation curves for the predeformation in [6], it is clear that the test bars plastify upon unloading. This reduces the magnitudes of the back-stresses. Since solid test bars are used for the predeformation, it is not possible to evaluate the yield surface before unloading.

4.2. Yield surface shape and rotation

The ratio r between the semi-axes of the yield surface can be used to describe the shape evolution, and is a measure of the degree of anisotropy. The majority of the change

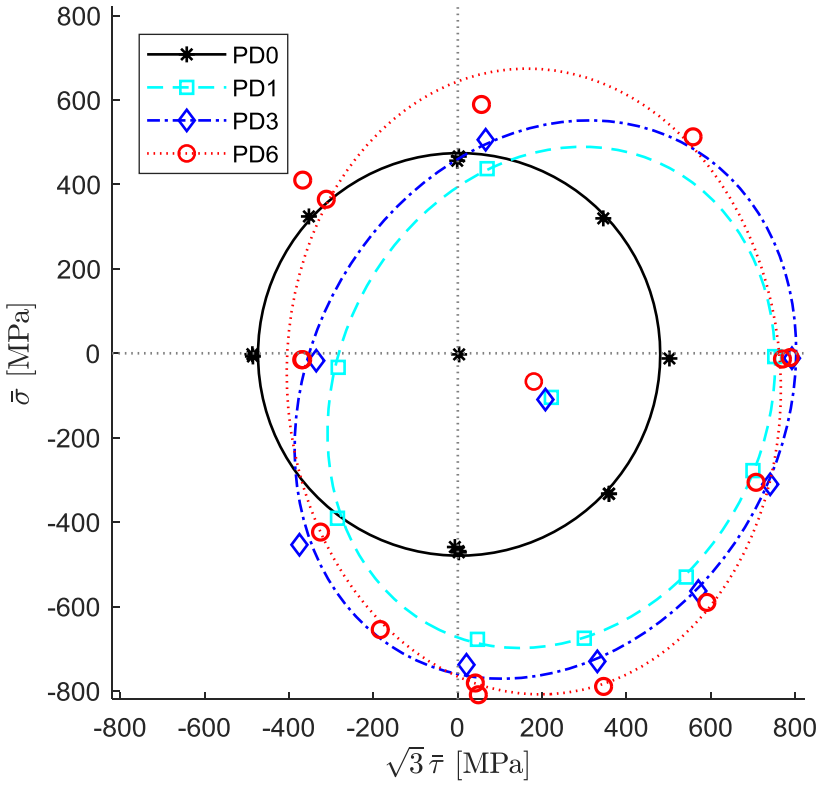

Figure 6: Yield surfaces at different levels of predeformation

Table 3: Yield surface parameters at different levels of predeformation (PD)

PD	0	1	3	6	6*
b_τ [MPa]	1.79	128	120	104	115
b_σ [MPa]	-2.62	-105	-110	-66.8	-91.8
σ_{y1} [MPa]	477	612	690	742	725
σ_{y2} [MPa]	–	510	561	586	570
$r = \sigma_{y1}/\sigma_{y2}$	1.00	1.20	1.23	1.27	1.27
$\hat{A} = \frac{\sigma_{y1}\sigma_{y2}}{\sigma_0^2}$**	1.00	1.37	1.70	1.91	1.82
β [°]	–	64.3	60.7	93.2	81.5

*The ellipse is fitted by only using load directions α in common with PD1 and PD3.
**σ_0 is σ_{y1} for PD0.

occurs in the first predeformation cycle, followed by a weak evolution in the subsequent cycles. The evolution of the yield surface orientation is, however, not as clear. After 1 and 3 cycles the orientation is roughly the same, while a large difference is observed after 6 cycles. In order to verify that this is not an artifact of having more directions tested for this case, and additional test case 6* has been added. For this case, only load directions available for PD1 and PD3 are used when fitting the ellipse. While the shape is relatively unchanged, the angle differs by more than 10° indicating that there are not enough sample points to accurately determine the yield surface rotation.

4.3. Yield surface size

The normalized area of the yield surface $\hat{A}$ is the parameter in Table 3 showing the most evolution with the amount of predeformation. Although a large amount occurs already after the first predeformation loading, the size of the yield surface continues to increase with the amount of predeformation.

4.4. Stress strain response

In order to better understand the characteristics of the yield surfaces in Figure 6, it is important to consider the stress versus strain response used to calculate the yield points. Figure 7 therefore shows the stress versus strain response for both positive and negative pure torsion. The identified yield points are marked with the same symbols as in Figure 6.

The elastic to plastic transition for the undeformed test bars are much more distinct than for the predeformed. This phenomena is well known from cyclic plasticity where the first cycle often is significantly different from the other cycles (see e.g. [19]–[21]).

Another interesting observation is the order of the lines in positive torsion: For low strains the stress is slightly higher for lower amounts of predeformation, while the opposite is true at larger strains. This shows that the measured yield surfaces are very dependent on the choice

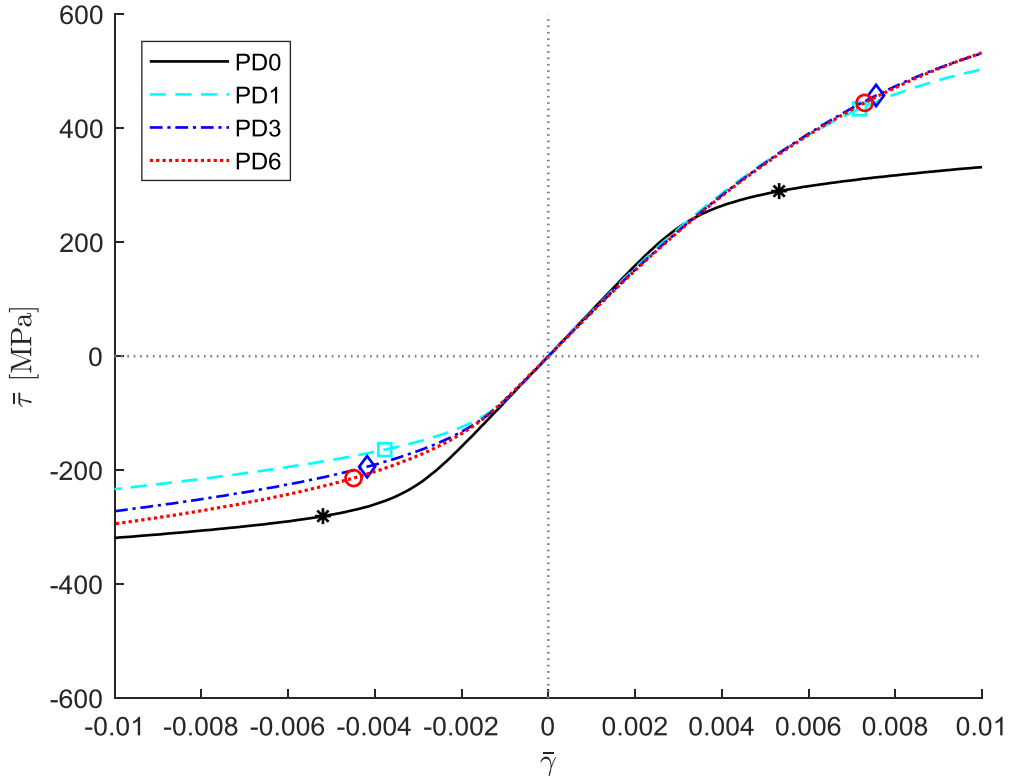

Figure 7: Stress-strain curves in pure torsion with identified yield point

of offset strain, which in this study was set to 0.1 %. However, in order to fulfill the goal of this study, the larger plastic increments are of most interests, and hence the yield surface measured with this offset strain value are more representative than those with very small offsets. The latter is certainly of great academic interest and will be considered in future works. This can give a better understanding of the influence that processes in the material microstructure have on the mechanical behavior of the rail steel.

5. Discussion

In general, it seems that most changes of the material's yielding behavior occurs already after the first predeformation cycle. In particular the back-stresses do not change much after this point. The size and degree of anisotropy of the yield surface continue to evolve after the initial predeformation cycle, although with a decreasing rate. These findings suggest that going to larger predeformation levels will not vastly improve the understanding of the yield surface evolution. However, with the microstructure refinement occurring at large predeformations, the deformation processes in the material changes. This is seen in Figure 5 where plastic deformation of the cementite lamellas occur. This process is discussed in detail by Izotov et al. [17]. It may therefore seem that the underlying processes during yielding change at larger predeformation levels. This could cause different behavior after larger predeformation levels than what can be reached with the method used in this paper. It would therefore be interesting to further investigate if and how the behavior changes and when this transition occurs.

Based on the findings in [5] the current results are valid for rails at a depth greater than 0.1 mm. The method used in [5] is, however, unable to characterize the smaller shear strains deeper into the rail. A method for measuring these strains would therefore be a useful complement to the current study. Some efforts have been made in simulating the plastic deformation during service, but the number of loading cycles is quite small. The results by Daves et. al. [22] show equivalent plastic strains of roughly 10 % at a depth of 3 mm after 25 cycles. The effective plastic strain for one cycle of predeformation in this study was 37 %. By extrapolating the results from [22] it seems reasonable that the anisotropy may extend several millimeters into the railhead. It is therefore important to consider this effect when modeling the inelastic rail behavior during rolling contact simulations.

The repeated directions for the undeformed test bar shows very good accuracy. Not unexpectedly, the uncertainties are larger for the predeformed test bars. In particular at $\alpha = 135°$ there is a large difference between the two yield points. Both of the test bars have a low runout, so this is not the reason. Furthermore, the torques and axial displacements during the predeformation are quite similar, so we are unfortunately unable to explain this discrepancy. These uncertainties are very important when comparing different yield criteria. However, they

are small enough not to hide the general evolution, which is main focus of the current study.

6. Conclusions

The yield surface evolution in R260 rail steel during large shear deformations has been characterized. This translates to the yield surface at different depths in a used rail. It is found that most of the changes occur after a relatively small amount of predeformation, indicating that it is not only the highly deformed surface layer that is anisotropic, but also the less deformed material deeper in the rail.

Acknowledgments

This work has been conducted as part of the activities within the CHARMEC Centre of Excellence at Chalmers University of Technology. It is partly financed by the European Horizon 2020 Joint Technology Initiative Shift2Rail through contract no. 730841. The authors would like to thank voestalpine Schienen GmbH for supplying the virgin rail material for manufacturing of test bars.

Abstract: This paper is concerned with the simulation of the wheel-rail contact problems including friction, frictional heat generation as well as wear. The contact with Coulomb friction of a rigid wheel with an rail lying on a rigid foundation is considered. The wear phenomenon is modeled by the dissipated energy method combined with Archard phenomenological model. This contact phenomenon is governed by the coupled system of elastoplastic and heat conductive equations. The contact problem is solved numerically using the semi-smooth Newton method. The evolution of the shape of the contact surfaces and the wear depth is reported and discussed.

Keywords: frictional contact; frictional heat generation; wear; dissipated energy method; FE model.

1. Introduction

Wear is a complex physical process characterized by the deformation and removal of material from a solid surface due to the mechanical action exerted by another solid [1, 2]. It frequently occurs as a progressive loss of material resulting from the frictional contact interaction of two loaded sliding surfaces. Many different physical or chemical factors may generate the occurrence of the wear phenomenon on contacting surfaces. In literature [1, 2, 3] as well as in engineering practice usually adhesive, abrasive, corrosive and surface-fatigue wear are regarded as the four basic types of wear. The wear rate of contacting surfaces under nominal operating conditions usually changes from low values, through the phase of steady wear till high rate of wear where surfaces are subject to rapid damage. This wear evolution process is usually slow and depends on the materials and surface properties of the contacting bodies as well as on the contact conditions. Experimental and numerical tests indicate that high temperatures or stress rates may accelerate the wear of structures [1, 2, 3]. Many attempts have been made to understand the variables influencing the wear phenomenon and to formulate the equations governing it. A comprehensive literature review of wear models and predictive equations is presented in [1~5].

The Archard phenomenological model [2] based on the theory of asperity contact is most frequently used to describe the sliding wear effects. The Archard wear equation states [2, 3] that the total volume of wear debris [4] is proportional to the product of the wear coefficient, the total normal load, the sliding distance and the inverse of the hardness of the softest among contacting surfaces. Numerous experimental studies have shown [2] that for a same material, the wear coefficient and the friction coefficient strongly depend on the wear mode, displacement amplitude, contact geometry and other parameters. The volume of wear appears also to be directly proportional to the energy dissipated by friction force [5]. This fact demonstrates the existence of a relationship between the wear and the friction. Dissipated energy approach [6~9] is an alternative extended model to describe the evolution of wear process. Using the energy wear coefficient [6] this model relates the wear volume and the accumulated dissipated energy. Experimental studies indicate that this approach provides rather consistent results in problems with unidirectional sliding [10].

The wear evolution may have significant impact on the analysis and numerical solution of the contact problem. The material loss in the contact area can generate significant change of its shape and the redistribution of the contact tractions. This in turn may have change the evolution of wear. Therefore the solution of this class of problem is subject of intensive investigation. There are two main approaches to solve frictional contact problems with wear. The first approach assumes the amount of generated wear debris is small therefore the shape changes in numerical computations may be neglected. The accumulated wear is added to the normal gap in the post processing step what alters the contact non-penetration condition. In the second approach the contact surface evolution due to the changing wear is computed in each iteration and the coupling between deformation and wear is taken into account in numerical treatment. In this approach different methods are proposed in literature. In one group of methods the wear depth is calculated using the chosen wear model and next the contact surface is updated based on it and the repositioning of nodes in wear-box to prevent the degeneration of the finite elements close to the contact surface. Other methods are based on adaptive re-meshing of the finite elements to avoid the distortion of the finite elements or the introducing a time-dependent material configuration corresponding to the undeformed body of the shape changed due to wear.

This paper deals with the numerical solution of the elasto-plastic wheel-rail contact problems including Coulomb friction [11~13], frictional heat generation [14] and wear evolution governed by the combined Archard and dissipated energy laws [1, 2].

In literature the thermo-elastoplastic contact problems with friction, heat flow and wear has been considered by many authors [6~22]. Among others, monographs [11~13] deal with the different models of the frictional contact problems and the numerical methods to solve them. Papers [6, 7] deals with the analysis and evaluation of hard coating wear mechanisms focusing on abrasion and oxidation phenomena. The local energy wear approach is applied to analyze hard coating wear mechanisms focusing on abrasion and oxidation phenomena allowing to quantify the lifetime of these coatings. In [8] the energetic approach is used for analyzing the data of experimental studies for thin coated structures. In [15] the wear behavior of sliding contact composites was experimentally investigated using an energy dissipation approach. Paper [17] deals with the investigation of the power dissipation in a wheel/rail system through friction work modelling. Using the 3D multibody model of a railway vehicle implemented in the software package VI-Rail Adams the dependence of the power dissipation on the friction coefficient has been studied. Moreover assuming that the wear is proportional to the frictional work it has been also analyzed using the Tγ method including the spin, in combination with Kalker's simplified theory Fastsim. 2D anisotropic model of wear is developed in [18]. Papers [19, 20] deals with primal-dual active set method as well as semi-smooth Newton methods for numerical solving elastoplastic contact problems with hardening for additively decomposed strain and for the finite strain, respectively. Rolling contact problems are considered in [21, 22]. A 3D transient finite element model is presented in paper [21] to solve both the normal and the tangential contact problems simultaneously for arbitrary geometry. The explicit time integration scheme employed renders it intrinsically suitable for transient analysis of high frequency dynamic processes. Paper [22] extends multi-Hertzian approach for elastoplastic wheel-rail problems. The application of the coating elastic and elasto-plastic functionally graded materials in contact problem to reduce the stress is discussed in [23~25].

This paper concerns the simulation of the wear evolution in a frictional elastic-plastic wheel-rail contact problem with the frictional heat flow. The plastically graded model of the rail coating layer is assumed. This contact problem is governed by the system of the mildly coupled time-dependent equations. The elastic and plastic responses of the graded layer are approximated, respectively, by Hooke's law and the von Mises yield criterion with isotropic power law hardening. The wear phenomenon is modelled using an internal state variable called the wear function. The evolution of this function is governed by the Dissipative energy method, i.e., the work of the friction force. This function directly enters into the contact conditions enforcing the update of a gap between contacting surfaces as well as the modification of the non-penetration condition. The finite element method is used as a discretization method. The non-penetration, friction and wear conditions generate inequality type constraints. These conditions are reformulated in an equivalent set of nonlinear complementarity functions and transformed into the set of equality constraints. The coupled nonlinear and non-differentiable system of the equilibrium equations including nonlinear constitutive material behavior and heat flow as well as these equality constraints imposed on nonlinear complementarity functions is solved numerically using semi-smooth Newton method. This paper, focusing on wear evolution in wheel-rail elasto-plastic contact problems extends the authors results from [27]. Taking into account thermal effects it also extends the results in [17] where the impact of the friction coefficient and the rail profile quality on the wear rate is studied.

2. Contact problem formulation

Consider elastoplastic deformations of a rail strip lying on a rigid foundation (see Figure 1). The strip has constant height $h=h_c+h_s$ and occupies domain $\Omega \subset R^2$ with the boundary Γ. Assume domain is split into two subdomains Ω_c and Ω_s such that $\Omega = \Omega_c \cup \Omega_s$, and the intersection of Ω_c and Ω_s is an empty set, i.e., $\Omega_c \cap \Omega_s = \varnothing$. Subdomain Ω_c denotes upper part of the strip representing a coating layer.

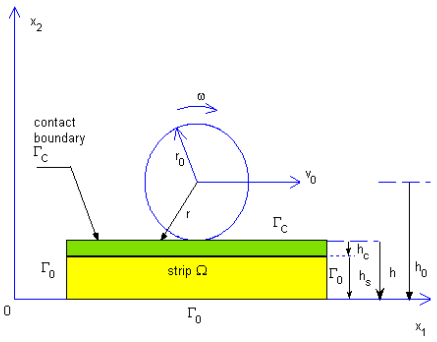

Figure 1 Wheel rolling over the strip.

A wheel rolls along the upper surface Γ_C of the strip. The wheel has radius r_0, rotating speed ω and linear velocity V. The axis of the wheel is moving along a straight line at a constant altitude h_0 where $h_0 < h+r_0$, i.e., the wheel is pressed in the elastic strip. It is assumed, that the head and tail ends of the strip are clamped, i.e., we assume that the length of the strip is much bigger than the radius of the wheel. Moreover it is assumed, that there is no mass forces in the strip. The body is clamped along a portion Γ_0 of the boundary Γ of the domain Ω. The contact conditions are prescribed on a portion Γ_C of the boundary Γ. Moreover, $\overline{\Gamma}_0 \cap \overline{\Gamma}_C = \varnothing$, $\overline{\Gamma} = \overline{\Gamma}_0 \cup \overline{\Gamma}_C$. We denote by $u=(u_1,u_2)$, $u=u(x, t)$, $x=(x_1,x_2) \in \Omega$, $t \in [0,T]$, $T>0$ a displacement of the strip and by $\theta = \theta(x, t)$ the

absolute temperature of the strip. The Cauchy stress and the linearized strain tensor will be denoted by $\sigma=(\sigma_{11}, \sigma_{22}, \sigma_{12})$ and ε, respectively. The strain $\varepsilon=\varepsilon(u)$ is additively decomposed [11, 12] into its elastic and plastic parts, i.e.,

$$\varepsilon= \varepsilon^e+ \varepsilon^p, \tag{1}$$

and in domain Ω is equal to

$$\varepsilon(u)= ½(\nabla u + \nabla^T u). \tag{2}$$

Here ∇u denotes the gradient of the displacement u with respect to spatial variables x and $\nabla^T u$ denotes a transpose of gradient ∇u. The Cauchy stress tensor σ in domain Ω is given by the relation :

$$\sigma=C^e\varepsilon^e=C^e(\varepsilon(u)-\varepsilon^p) \text{ and } tr(\varepsilon^p)=0. \tag{3}$$

Symbol C^e denotes the Hooke's tensor which can be written either in terms of the Lamé parameters λ and γ, i.e.,

$$C^e=\begin{pmatrix} \lambda+2\gamma & \lambda & 0 \\ \lambda & \lambda+2\lambda & 0 \\ 0 & 0 & \gamma \end{pmatrix}, \tag{4}$$

or with respect [11, 12] to the Young modulus E and the Poisson's ratio ν. In Ω^c tensor C^e is assumed to depend on the depth of the rail.

The displacement u as well as the temperature θ of the strip satisfy in domain Ω and time interval (0,T) the system of the coupled evolution equations:

$$\rho c_p \frac{\partial^2 u}{\partial t^2} = div\,\sigma - \alpha(3\lambda+2\gamma)\nabla\theta, \tag{5}$$

$$\rho c_p \frac{\partial \theta}{\partial t} = \bar{\kappa}\Delta\theta, \tag{6}$$

with the following boundary and initial conditions:

$$u = 0 \quad \text{on } \Gamma_0 \times (0,T), \tag{7}$$

$$\sigma n= F \quad \text{on } \Gamma_C \times (0,T), \tag{8}$$

$$\frac{\partial \theta}{\partial n} = q \quad \text{on } \Gamma, \tag{9}$$

$$u(0)= u_{0i}, \quad u'(0)= u_{1i}, \quad \theta(0)= \theta_g \text{ in } \Omega, \tag{10}$$

where the Laplacian equals to

$$\Delta u = \frac{\partial^2 u}{\partial x_1} + \frac{\partial^2 u}{\partial x_2}$$

and $u(0)= u(x,0)$, $u' = du/dt$, and u_{0i}, u_{1i}, θ_g, q are given functions, ρ is a mass density of the strip material, α is a coefficient of thermal expansion, κ is a thermal conductivity coefficient, c_p is a heat capacity coefficient, $\Gamma_0 = \Gamma \setminus \Gamma_C$ and $n=(n_1,n_2)$ is outward normal versor to the boundary Γ of the domain Ω. By $F=(F_1,F_2)$ we denote the surface traction vector on the boundary Γ. This vector on the boundary Γ_C is a priori unknown and is given by the conditions of contact and friction.

Under the assumptions that the strip displacement is small the contact conditions on the boundary Γ_C in time interval (0,T) take a form : the surface non-penetration is governed by the condition:

$$u_2+g_r+w \le 0, \qquad F_2 \le 0, \quad (u_2+g_r+w)F_2 = 0, \tag{11}$$

$$g_r=h-h_0+\sqrt{r_0^2-(u_1+x_1)^2},$$

with g_r and w denoting the gap and the wear functions, respectively. The Coulomb friction condition has the form:

$$|F_1| \le \mu |F_2|, \qquad F_1 u'_1 \le 0, \qquad (|F_1| - \mu |F_2|)u'_1 = 0, \tag{12}$$

where μ is a friction coefficient. The unknown function ε^p is assumed to satisfy[5] the laws of plasticity with linear isotropic or kinetic hardening:

$$f^p(\alpha,\eta) \le 0, \; g^p \ge 0, \; f^p(\alpha,\eta)\, g^p = 0, \tag{13}$$

$$d\varepsilon^p=g^p\, \eta/\|\eta\| \text{ for } \|\eta\| > 0 \text{ and } d\varepsilon^p=0 \text{ for } \|\eta\| = 0, \tag{14}$$

$$\varepsilon^p(0)=0, \; \alpha(0)=0, \; d\alpha=g^p. \tag{15}$$

In (14) and (15) $d\varepsilon^p$ denotes time derivative of ε^p. The relative deviatoric stress η is equal to

$$\eta = dev\sigma - 1/2(K\varepsilon^p), \tag{16}$$

where $dev\sigma=\varepsilon-tr(\varepsilon)I$, I is 2x2 identity matrix and $tr(\varepsilon)$ is the trace of tensor ε. The definition of the yield function $f^p(\alpha,\eta)$ in (13)

$$f^p(\alpha,\eta)=\|\eta\|-\sigma_0-H\alpha, \tag{17}$$

employs the hardening parameters K, $H \ge 0$, the equivalent plastic strain α as well as the yield stress σ_0. The evolution law (14) makes the plasticity law associative, i.e., the set of inner variables (z,ε^p) with $z=-H\alpha$ satisfies:

$$dz = g^p\, \partial f^p/\partial\alpha \quad d\varepsilon^p = g^p\, \partial f^p/\partial\eta \tag{18}$$

2.1 Dissipated energy method

The dissipated energy method in local form [7] assumes that the wear volume V is proportional to the total friction dissipation energy E_f, i.e. the following relation holds:

$$V = \alpha_f E_f = \alpha_f \sum_i E_f^i. \tag{19}$$

The proportional coefficient α_f is called the energy wear coefficient and is an independent material parameter [6]. The energy E_f^i dissipated in one slip cycle i is a sum of all contributions of the energy dissipated by the frictional force F_T on the distance from u_{1min} to u_{1max} :

$$E_f^i = \int_{t-\Delta t}^{t} |F_T|\, dt = \int_{t-\Delta t}^{t} \mu |F_1| u_1\, dt = \tag{20}$$

$$\mu |F_1| (u_1(t) - u_1(t-\Delta t)).$$

Recall [10] the evolution of wear phenomenon is obtained using the frictional force and the history of sliding displacement. This feature makes it specially designed for the analysis of contact between solids undergoing plastic strains. The energy wear coefficient may be used for any normal load or displacement amplitude subject to change during the wear process. The local form of this approach is suitable in finite element simulations.

2.2 Archard wear model

Remark that the change rate of the sliding position is equivalent the approximation of the relative tangential velocity u_1'. Therefore based on the Archard law of wear it is expressed in terms of the wear rate function w' in the form [1] :

$$w' = kF_1u'_1 \qquad (21)$$

Constant k>0 denotes the local energy wear coefficient [10]. This formulation is referred to the spatial configuration and w quantifies the wear depth of the contacting bodies. This wear depth appears in non-penetration condition (11). It modifies the gap between the bodies as well as normal traction force.

2.3 Material properties of functionally graded materials

The material property of graded layer Ω_c is a function of its height and is described by the following power equation[11]

$$P = P(x) = P_s + (P_c - P_s)\left(\frac{h_c + x_2}{h_c}\right)^{\alpha}, \qquad (22)$$

$$x_2 \in [-h_c, 0].$$

P, P_s, P_c are the material properties which is height dependent, the steel property and the coating property, respectively. α denotes the non-homogenity parameter of the graded material. P may be used for the elastic modulus, the yield stress, the thermal conductivity, the expansion or the diffusivity of the graded layer. Figure 2 shows the dependence of elastic modulus on the depth of the material for different values of non-homogenity parameter α. Model (22) implies that in domain Ω_c the tensor $C^e=C^e(x)$ plastic and thermal coefficients are dependent on x. In domain Ω_s all elastoplastic and thermal coefficients are constant. The solution (u, θ) in domains Ω_c and Ω_s is denoted by (u_c, θ_c) and (u_s, θs), respectively. The continuity of temperatures, displacement and stresses along the interface $\partial\Omega_c \cap \partial\Omega_s$ is assumed.

3. Solution algorithm

Since in the system (1)-(22) the contact traction depends on the thermal distortion of the bodies and on the other hand, the amount of heat generated due to friction depends on the contact traction system (1)-(12) is a coupled thermo-elastoplastic problem. The main solution strategies for coupled problems are global solution algorithms where the differential systems for the different variables are solved together or operator splitting methods. In this paper we employ operator split algorithm.

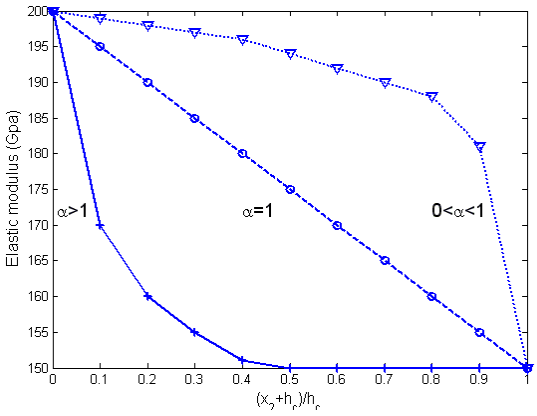

Figure 2 The dependence of elastic modulus on the depth of the material.

Therefore in the simulation procedure, the elastoplastic contact and thermal problems are solved sequentially in time. Denote by Δt a time step. First at time t the elastoplastic contact problem is solved, i.e., the normal contact traction F_2^t is calculated for a given θ^t . Next in the thermal analysis, the heat flux at time t+ k Δt, where t is the time at which the solution to the elastoplastic contact problem is known and k=1,2,3,… K, is approximated by $q^{t+\Delta t}=\mu\ V\ F_2^t$ and the temperature $\theta^{t+\Delta t}$ satisfying the heat equation is calculated. If the Stop criterium is not satisfied the elastoplastic contact problem at the time t+Δt is solved. Therefore the conceptual algorithm for solving system (1) - (22) is as follows:

Step 1: Choose $\theta=\theta^0$. Choose $\eta \in (0,1)$. Set k=0.
Step 2: For given θ^k find u^k, w^k, ε_p^k, α^k and F_2^k satisfying system (5), (7), (8), (10), (11)-(15).
Step 3: For given u^p , w^k and F_2^k find θ^{k+1} satisfying equations (6), (9).
Step 4: If $\| \theta^{k+1} - \theta^k \| \leq \eta$, Stop. Otherwise: set k=k+1, go to Step 2.

The convergence of the operator split algorithm is shown using Fixed Point Theorem (see references in [11, 12]). Finite element method [13] is used as the approximation method.

In literature there are described many methods to solve mechanical sub-problem in Step 2. Recall in order to calculate the solutions to the problem (1)-(22) we have to regularize it, i.e., we will consider this problem as problem with the prescribed friction. Let ε > 0 be a regularization parameter. We use the following formula [27] relating tangential and normal tractions on the contact boundary Γ_C:

$$F_1 = F_1(\varepsilon, F_2, u_1) = -\mu\,|F_2|\,\arctan\left(\frac{du_1}{dt}\right). \qquad (23)$$

The list of methods to solve the mechanical sub-problem includes [10, 19, 20] interior point methods, SQP algorithms, radial return mappings, Augmented Lagrangian methods. Here we use semi-smooth Newton

method [10, 19] to solve elastoplastic contact problem. This approach consists in reformulating the complementarity conditions as a set of semi-smooth equations. A family of nonlinear complementarity functions C^p and C^c applied to frictional and plastic yield conditions combined with the equilibrium equations generates a system of semi-smooth equations. This system is solved using the semi-smooth Newton method. This method can be interpreted as a primal-dual optimization method with the active set strategy [10]. In matrix notation the solution of system in Step 2 is equivalent to find (u^k, w^k, (ε_p^k, α^k), F_2^k) such that

$$Au^k+B^p\,\varepsilon_p^k+B^cF_2^k-M_1\theta^k = 0 \quad (24)$$

$$w^k=A^wu^k \quad (25)$$

$$C^p(u^k,w^k,(\varepsilon_p^k,\alpha^k))=0 \quad (26)$$

$$C^c(u^k,w^k,F_2^k)=0 \quad (27)$$

where A, A^w, B^c, B^p, M_1, C^p, C^c are given matrices. The solution of system in Step 3 consists in solving the system of linear equations. The material removal process due to wear is based on two step procedure using the wear box [10]. First the weighted wear depth is evaluated and the deformation of the body. Next using the dissipated energy method the finite elements close to the surface are evaluated and if necessary the worn material is redistributed among these elements.

4. Numerical results and discussion

The computations has been performed for ceramic and steel materials [23, 24, 26]. Assuming elastoplastic model of material we can observe that the length of the contact zone is greater than in elastic model. For the maximum load the ratio of normal stress to the yield stress is much higher in the elastic than in the elastoplastic case. Figures 3 and 4 show contact stresses in x_1 and x_2 planes, respectively.

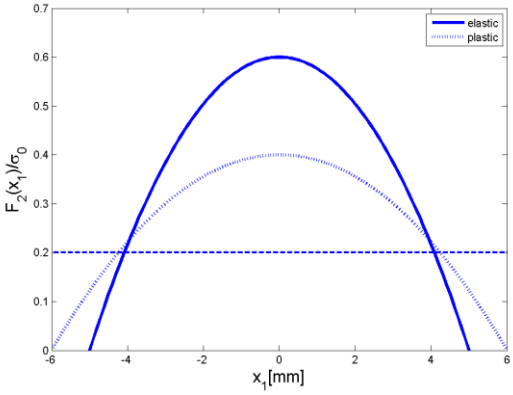

Figure 3 Normal contact distribution x_1 plane

The horizontal dotted line indicates the yield stress. On Figure 3 the normal contact stress in the elastic case is higher than in the elastoplastic case at a cost of the shrinking of the contact zone. The similar relation can be observed on Figure 4 for stress in y-plane. The value of it is rapidly decreasing in depth of the body. The difference between the elastic and plastic stresses justifies the necessity to take material plastic behavior into account.

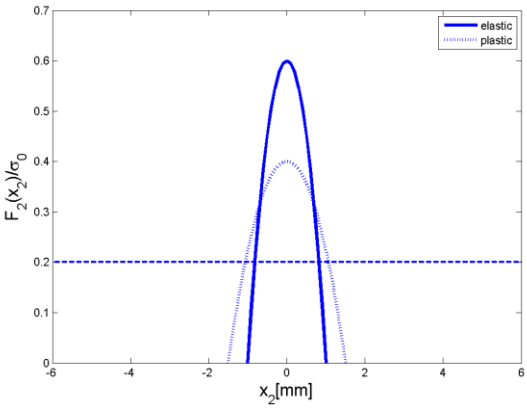

Figure 4 Normal contact distribution x_2 plane.

The obtained distributions of stress and temperature along the contact boundary for different values of the non-homogenity parameter are displayed in Figures 3 and 4, respectively. These distributions are dependent on non-homogenity parameter α. The obtained maximal values are lower than in pure homogeneous case, i.e., α = 0. As it is shown in Figure 5 the decrease in the non homogenity index α from 5 to 0.5 reduces the maximum normal contact pressure at a cost of widening the contact zone. This decrease implies also (see Figure 6) in the decreasing of the maximal temperature value at a contact point and quicker temperature reduction behind the rolling wheel. In front of the rolling wheel the temperature distribution is almost not dependent on α.

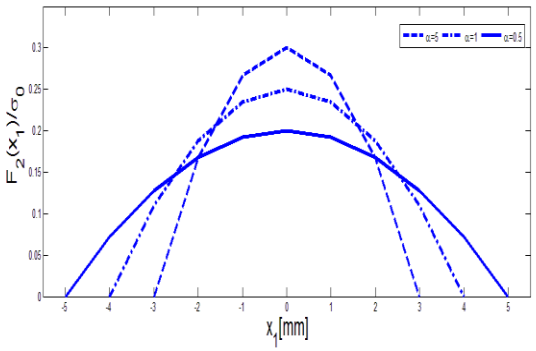

Figure 5 Normal contact distribution.

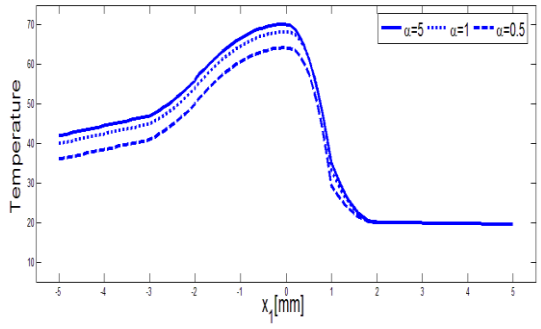

Figure 6 Tangential temperature distribution along the contact zone.

Figures 7 and 8 display the evolution of the contact interface after 100 and 150 cycles, respectively. Gradually the worn area is being increased. Figure 7 shows that after 100 cycles the first layer of finite elements is worn out – the majority of elements achieved the wear depth limit. The part of the material is removed from the next layer. Increasing the number of cycles it follows from Figure 8 that the next layer in terms of finite elements is worn out. These results indicate that the shape update strategy is robust and effective.

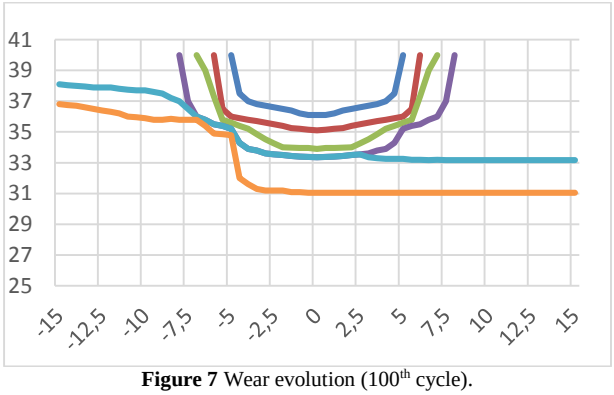

Figure 7 Wear evolution (100th cycle).

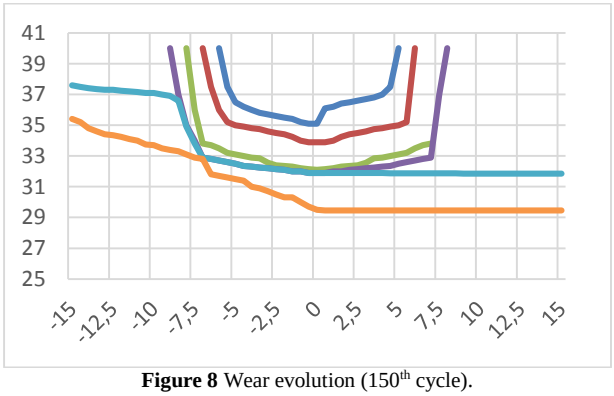

Figure 8 Wear evolution (150th cycle).

5. Conclusions

The thermo-elastoplastic rolling contact problem with wear where the properties of the upper coating layer of the rail surface are dependent on its depth has been solved numerically using the semi-smooth Newton method. The material properties of the graded layer are assumed to be governed by the power equation. The wear phenomenon is governed by the dissipation energy model.

The obtained numerical results indicate that the obtained contact patches are characterized by longer zones and lower stress intensity than in the elastic case. Moreover the graded layer can reduce the values of the normal contact stress and the maximal temperature in the contact zone. The obtained stress and temperature distributions are dependent on the non-homogenity index α. For higher values of α one can obtain the higher differences in the maximal contact stress and temperature in comparison to the homogeneous material case. In order to improve the model one could consider finite strain plasticity. The dissipated energy method and contact interface shape update strategy are efficient and precise tools to evaluate the wear distribution. The choice of parameters ensuring the minimization of the worn material volume may be considered and formulated as the shape optimization problem where the dissipated energy is the criterion of optimization.

Abstract: This paper deals with numerical simulations of rail joint.
A detailed 3D Finite Element Model of a step-up joint was developed and used as a reference for comparison with multi-body approach to model the wheel-rail contact force. In this latter model, a stiffness is used to represent the contact flexibility in series with the wheel and rail local flexibility, which is not accounted for neither in the rigid body wheelset model nor in the rail beam model, in series with.
For this type of short defects, it is showed that the contact patch area varies rapidly and hence the evolution of Hertzian stiffness must be accounted for in contact force formulation.
However, the model is able to capture the P1 peak value, which is mainly responsible for the wheel and rail damage on these rail joint defects.
The 3D FEM is also used to assess the influence of rail plasticity on the contact force. A Chaboche model is used to describe the material behavior.
The results show a variation of 15% of the P1 peak value when including rail plasticity compared to elastic material model. The next step will be to use the deformed profile and iterate computations for several wheel passages.

Keywords: dynamic forces, rail joint, rail defects, wheel and track FE model in time domain, rail plasticity.

1. Introduction

Rail singularities, such as rail joints, are of main importance for wheel-rail interaction, because they involve high level of contact force, which can lead to plastic deformation, fatigue and premature ruin of track components [1].

The numerical control of these rail component comes along with some challenges.
The geometry can be complex, which implies to use a 3D representation. The generated shock includes a frequency content of up to 2000 Hz (P1 peak), and hence requires significant computational efforts.
The phenomenon is transient so that time domain is preferred.

On the other hand, experimental control is also challenging: direct wheel-rail contact force measurement is virtually impossible, and indirect measurements require great attention [2].

Numerical wheel-track interaction models are usually based on Hertzian theory, in which a non-linear stiffness is used to calculate the wheel-rail contact force [3], [4]. The Hertzian theory is based on small contact patch area compared to characteristic dimensions of the problem. Here the geometrical evolution is in the same order of magnitude of the contact dimensions, and hence this assumption is no longer valid.

The high impact force due to the wheel pass-by involves high strain and plastic deformation. This make the computations even more complex, as material non-linearity must be accounted for. Rail plasticity and wheel plasticity models has been used by several authors, for example to compute wear-fatigue in straight lines or in curves [5].

This paper follows a previous paper [6], in which the 3D FEM was presented and contact force results were detailed and analysed for three rail joint types: levelled gap, step-up joint and step-down joint.
The focus is here on the step-up joint, which generates the highest contact force amplitude.

2. Step-up joint case study presentation

The case of a 1 mm step-up joint (see figure 1) is chosen to perform the comparison between the numerical approaches and the study of rail plasticity. The gap joint (d, in figure 1) is set up to 15 mm.

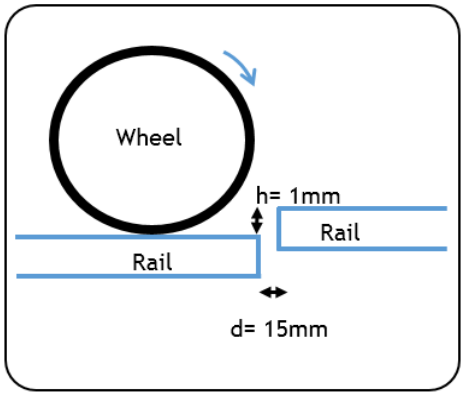

Figure 1 *Schematic diagrams of the step-up joint.*

The considered track is a ballasted track with UIC 60 rails, laid on flexible wooden sleepers.
The vehicle is a simplified model consisting of a wheelset with static load. The wheel radius is 460 mm, and the train speed is 160 km/h over the rail joint.
Table 1 presents the track and vehicle parameters used for the computations.

Table 1 *Parameters for model of track and vehicle.*

Track Description	Value
Rail-pad stiffness	500 kN/mm
Rail pad damping loss factor	0.2
Sleeper density	580 kg/m^3
Sleeper mass	120 kg
Sleeper young modulus	10 GPa
Ballast stiffness per half sleeper	150 kN/mm
Ballast damping loss factor	0.8

Vehicle Description	Value
Wheel load	10 600 daN
Wheel + semi axle mass	593 kg
Radius	0.46 m
Speed	160 km/h

3. Comparison of 3D FEM with Hertzian model

3.1. Description of 3D Finite Element Model

A wheelset and track FE model is built in MSC MARC software (Figure 2). A left-right symmetry plan (figure 3) is used to limit the mesh size and reduce computation time. However, this means that the rail joint is experienced by both wheels simultaneously.

The wheel is modelled using 3D solid elements, while the axle is represented by beam elements. A rotation speed of 457 rpm is applied to the wheel, so that the wheel centre travels at 160 km/h.

The track (Figure 4) is made of 3D elements for the rail, the splice bars and screws, the rail pads and base plates, the sleepers and the ballast.
The ballast material properties are adapted to obtain the ballast stiffness and damping presented in Table 1.
This 3D model makes it possible to describe the exact geometry around the joints: the rail inclination, the sleeper position, the splice bars…
At the rail extremities, absorbing boundaries using PML (perfectly matched layers) [7] are used to avoid wave reflection (figure 5).

The computations are performed in the time domain, using an implicit full Newton-Raphson integration scheme.
The contact is calculated at each time step, using a segment to segment contact research algorithm, as used by Saint Aimé in ABAQUS software [5]. This formulation allows the meshes to be of different size and nature between the contact faces.

In the contact area, the mesh is refined on the circumference of the wheel tread (Figure 3) and also on the rail head (Figure 5), in order to obtain precise description of the contact patch area and obtain precise contact force.

The computation starts at a short distance before the joint, so that numerical stability is obtained before entering the singularities. The time step is adapted: a broader time step is used before the singularity, and a finer time step is used inside the zone of interest.
The wheel-rail contact force is obtained by integration of the contact pressure on the wheel.

3.2. Description of train-track model in VOCO

The train-track interaction model is developed under the software VOCO [8], [9], which is available as a Matlab toolbox.

The train model is a rigid wheelset (mass and inertia) with a static load.
The track is represented by beam (rail) on discrete supports, as illustrated in figure 6. The portion presented in the figure is repeated in the computation scheme to obtain a virtually infinite track through cyclic conditions. Hence, the sleeper spacing is constant, compared to the 3D geometry used in the FE model.
The VOCO track model includes the rail pads as springs and dampers, the sleepers as masses, and the ballast as springs and dampers.

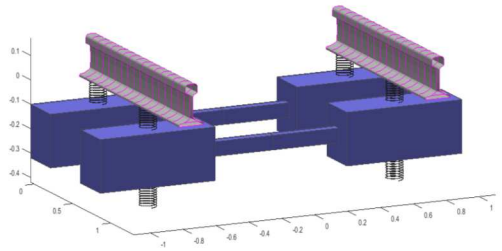

Figure 6 *Portion of track model in VOCO.*

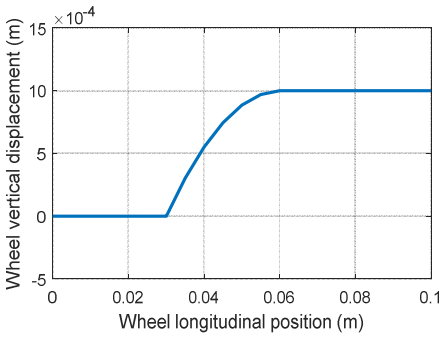

The rail joint is modelled as a prescribed relative displacement between the wheel and the rail (figure 7). The wheel centre kinematic trajectory is applied in this representation. Equation (1) relates the vertical displacement z of the wheel centre as a function of its longitudinal position x, the wheel radius R and the step size h $(= 1mm)$.

$$\begin{cases} z = (h - R) + \sqrt{R^2 - (x - D)^2} & 0 \le x \le D \\ z = h & x \ge D \end{cases} \quad (1)$$

With

$$D = \sqrt{2Rh - h^2} \quad (2)$$

With the radius of 460mm and the step size h of 1mm, the distance D is about 30mm, which means that the longitudinal gap between the rail ends won't be seen by the wheel if the size is below this value. In our case, the size is 15 mm, so it is below 30 mm. This is one of the flaw of this representation: in reality, the gap size could modify locally the track stiffness seen from the wheel, and hence the wheel trajectory could be locally affected.

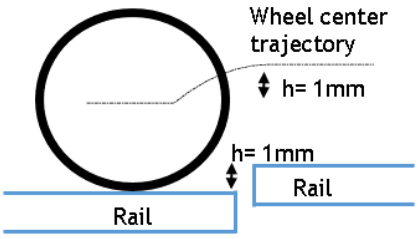

Figure 7 *Wheel centre trajectory, applied as prescribed relative displacement to represent the rail step up joint.*

As the wheelset is rigid and the rail is flexible, the force between the centres of gravity of the wheelset and the rail includes the wheel flexibility, the local rail flexibility and also the contact flexibility.

This contact force can hence be written as in equation (3).

$$F = k_s \Delta z \quad (3)$$

With k_s the stiffness and Δz the relative displacement between the wheel and the rail, including the contact deformation and the relative prescribed displacement (wheel vertical trajectory).

The model is illustrated in figure 8.

For numerical stability reason, a damper is added in parallel to the stiffness, but the value is kept low so that

it does not modify significantly the force, and so that only the only varying parameter is the stiffness.

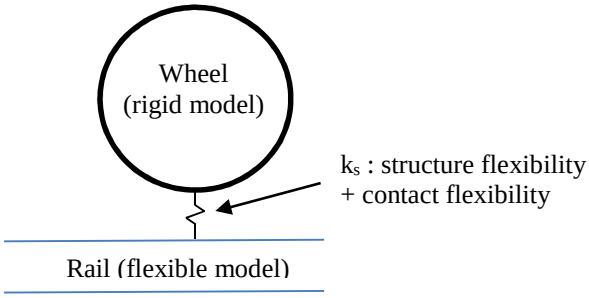

Figure 8 *Illustration of structure flexibility in series with contact patch, between the wheel rigid model and the rail flexible model (beam on springs-dampers-masses).*

At each time step, the contact is computed through an explicit scheme [10], which gives the contact deformation, and the models of the wheelset and rail give their respective displacement value. The contact force can then be computed for the next time step.

3.3. Results

The 3D FEM results has already been presented and analyzed in [6]. Here, the focus is on the comparison between the two modelling approaches, and the influence of the fixed parameter in the VOCO model.
The influence of the vertical stiffness k_s is hence assessed.

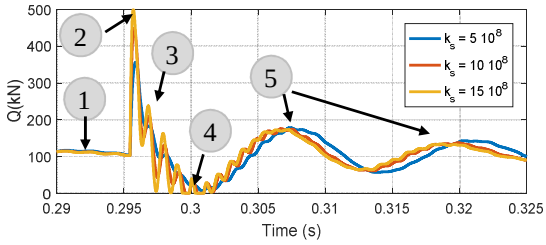

Figure 9 *Vertical contact force computed with VOCO for the 3 $k_{H\,vert}$ values.*

Figure 9 plots the computed vertical wheel-rail contact force for the three values of $k_s = 5\ 10^8 N/m$, $k_s = 10\ 10^8 N/$ and $k_s = 15\ 10^8 N/$. For comparison, the linearized Hertzian stiffness value is about $10^9 N/m$.
The overall behaviour is the same for the three values. Five zones are highlighted in the figure. The first zone is before the joint, where the contact force equals the static load. As the model includes discrete description of sleepers, the contact force value is not flat, but a slight variation is observed. The second zone is the first peak response due to the wheel impact on the rail. This peak is generally referred as the P1 peak [3]. The third zone shows oscillations at a high frequency of about 900 Hz, which corresponds to the resonance of the moving mass of the rail and wheel tread on the Hertzian stiffness. This is why the frequency and amplitude of oscillations depend on the k_s stiffness as it can be observed from the comparison of the three curves.
The fourth zone still presents the same oscillations for the two highest stiffness values, and sometimes the contact force becomes zero, indicating a loss of contact.

The fifth zone shows oscillation with frequency of about 80 Hz, which corresponds to the resonance of the axle unsprung mass on the track stiffness. It can be observed that the frequency is shifted with the lowest structure stiffness value of 0.5 10^9 N/m, compared to the two other stiffness values. This is because the track stiffness is about 0.23 10^9 N/m, so that the lowest value of structure stiffness is in the order of magnitude, and hence acts as a significant in series stiffness.

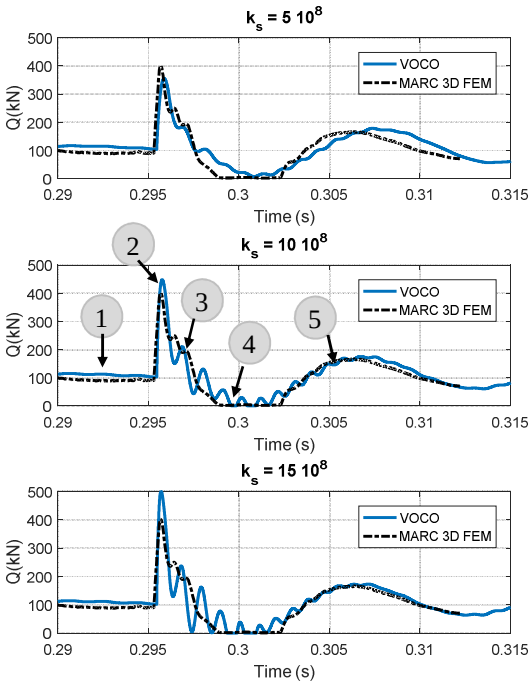

Figure 10 *Vertical contact force computed with VOCO for the 3 $k_{H\,vert}$ values, compared to 3D FEM results.*

Figure 10 compares the VOCO results with the results obtained with the 3D FEM in MARC software.
The same five zones are observed.
In the first zone, the static load presents slight discrepancy between the two models. In the VOCO model, the track geometry is periodic, while in the 3D FEM the track geometry accounts for the splice bar and exact sleeper positions.
The P1 peak (zone 2) is about 400kN in the 3D FEM. As showed by table 2, the appropriate value of the k_s stiffness is between 0.5 and 1.0 10^9 N/m, probably about 0.75 10^9 N/m.
In the third zone, the amplitudes and frequency of oscillations is better described by the value of 0.5 10^9 N/m; indicating that the contact area decreases, which corresponds to visual observation in the 3D FEM. The contact area even decreases down to zero in zone four, where a loss of contact is observed in the 3D FEM. This behaviour is expectedly not well captured by the constant structure stiffness model, and none of the tested values enables to predict correctly this loss of contact.
In the fifth zone, the contact area goes back to normal size shape and the P2 resonance appears. The higher stiffness values give the best fit with the 3D FEM result.

Table 2 *P1 peak values for the different models*

	P1 peak (kN)
3D FEM	400
VOCO $k_s = 0.5\ 10^9 N/m.$	355
VOCO $k_s = 1.0\ 10^9 N/m$	445
VOCO $k_s = 1.5\ 10^9 N/m$	500

As a conclusion for this comparison, the approach with a constant structure k_s stiffness is not valid in this case, because this high frequency dynamics involve local mass close to the wheel-rail contact, while the models of train and rail are global. In the computations performed for this article, the k_s stiffness ranges from 0.5 to 1.5 10^9 N/m, and a value of about 0.75 10^9 N/m was determined to be the best fit to obtain the correct P1 peak amplitude. This value will depend on the situation (type of short defect, train, track…).

The reader must bear in mind that the computations were here performed with simultaneous joints on the left and right rails. This is due to FE model size reduction to limit the computation durations.

For information, Figure 11 plots the results obtained with the VOCO model for a joint only on the right rail. The stiffness k_s was set to 1.0 10^9 N/m.
The right wheel-contact force is very similar for both cases, and it can be seen that the P1 peak has the same amplitude with joint on both rails or with joint only on the right rail. The main difference is that only one side is subjected to this force.

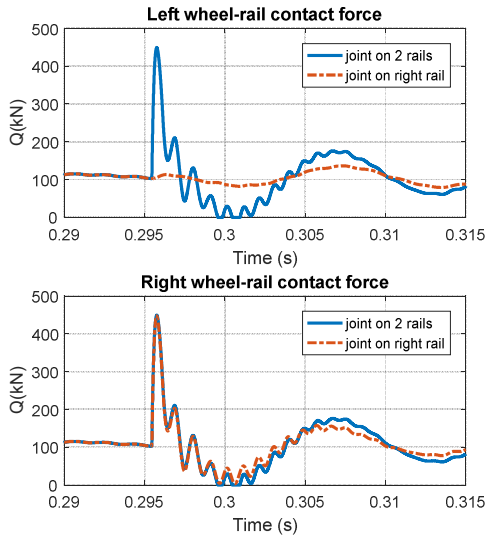

Figure 11 *Vertical contact force (top: left wheel, bottom: right wheel) computed with VOCO for a joint on both rails (blue curve) compared to a joint only on the right rail (red curve).*

4. Including rail plastic behavior

4.1. Rail material

The rail material plastic behaviour has been studied by several authors.
Among the most recent use of material models, Saint Aimé [5] used a Chaboche [11] description to account for the isotropic and nonlinear kinematic hardening in cyclic loadings for fatigue and wear analysis.

In the present study, only one cycle is simulated because the simulation duration is too high to perform many cycles.

The rail plastic behaviour is based on stress-strain curve derived from [12] for one cycle (see Figure 12).
The elastic linear part is described by: Yield stress of 379 MPa, Young's Modulus of 206 GPa, Poisson's ratio of 0.28.

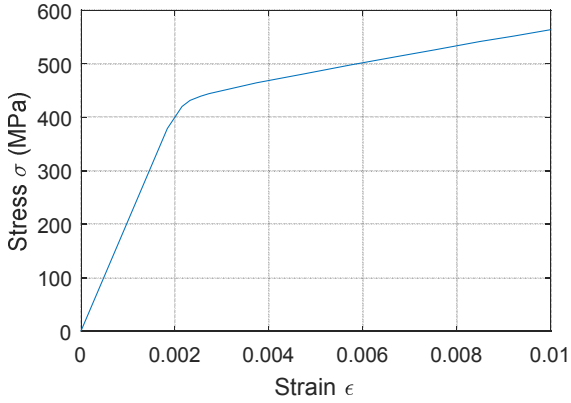

Figure 12 *Stress-Strain curve used for the rail steel. Yield stress of 379 MPa, Young's Modulus of 206 GPa, Poisson's ratio of 0.28*

4.2. Results

Figure 13 plots the vertical contact force Q(kN) as a function of the time for the two models: elastic rail (dark curve, same result as in figure 9) and elasto-platic rail (red dashed curve).
The results have the same shape, but as expected, the use of elasto-plastic material reduces the P1 peak. In this case, the reduction is 15% compared to the fully elastic material (Table 3).

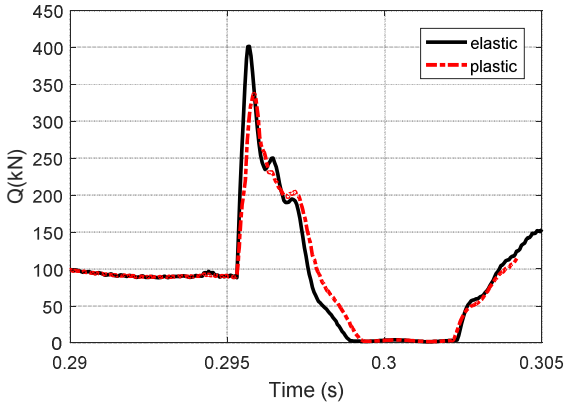

Figure 13 *Wheel-rail contact force computed with 3D FEM for the rail joint passage for an elastic rail () and for an elasto-plastic rail*

Table 3 *P1 peak values for the different models*

	P1 peak (kN)
3D FEM – elastic	400
3D FEM – elasto-platic rail	340

Figure 14 presents a cartography of the residual plastic stress after the wheel passage. The deformation (exaggerated) is also observed.

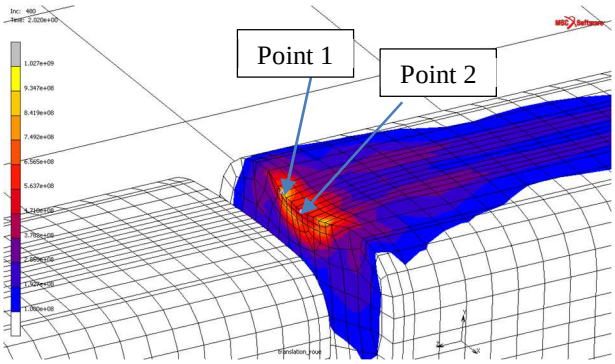

Figure 14 *Residual stress (colors) and deformation after wheel passage*

Figure 15 plots the Von-Mises stress of two points during the wheel passby. The points corresponds to the points with maximum residual stress and strain.
The localization of each point is showed in figure 14.
During the wheel passage, the equivalent Von Mises stress goes up to 1.54 GPa at point 1, and the maximum residual stress is about 1 GPa.
Material degradation is expected with such high values.

Figure 16 plots the strain of the same two points during the wheel passby.
The maximum residual strain is 0.058 at point 2.

The residual displacement is 0.66mm, at point 2 location, where the wheel impacts the rail.

All the values are summarized in Table 4.

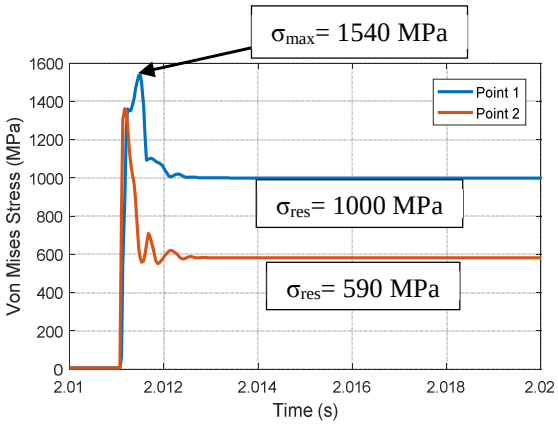

Figure 15 *Evolution of Von-Mises stress during the wheel passby. For two points at the edge of the rail joint.*

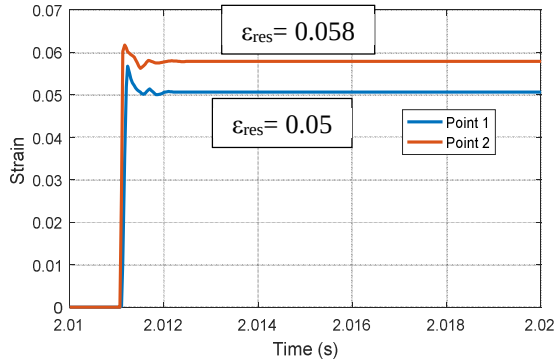

Figure 16 *Evolution of strain during the wheel passby. For two points at the edge of the rail joint.*

Table 4 *Stress strain and displacement results*

	3D FEM – elasto-plastic rail
Maximum stress during wheel pass by	1540 MPa
Residual VM stress (max)	1000 MPa
Residual normal stress (max)	355 MPa
Residual shear stress (max)	341 MPa
Residual total strain (max)	0.058
Residual normal strain (max)	0.015
Residual shear strain (max)	0.05
Residual displacement (max)	0.66 mm

5. Conclusions

The previously developed 3D FE model of a step-up joint was used as a reference for comparison with simplified global approach using multi-body (MB) models and wheel-rail contact simplified description (VOCO software).
The main idea behind this comparison is to be able to perform parametric studies in reasonable time, using fast MB models instead of costly 3D FEM. The dynamic response with MB model is close to the 3D FEM, and hence the MB approach can be used, but the contact stiffness must be carefully chosen.

The same 3D model was set-up with a plastic rail in order to assess the influence of plasticity on the contact force peak value: a reduction of 15% was observed.

The next step is to use the deformed profile and iterate to observe the effect of repeated wheel passages, as it was done by [5] on local wheel-rail model.
However, this last part is still a challenge in terms of computation cost.

Acknowledgments

The authors thank Hugues Chollet and Michel Sebès, both from IFSTTAR, for their support in the use of VOCO and analysis of results.
The authors also thank SNCF for bringing up the initial topic that sparks all these analyses.

Abstract: The dynamical response of a train rolling on a real track depends on several parameters. Most of them cannot be accurately identified and have to be considered as uncertain. The aim of this thesis is the construction of a probabilistic model of the rail fatigue life considering the track geometry and the rail wear as random fields modelled with the Karhunen-Loève expansion. The multivariate distributions of the random projection coefficients are characterized using a Polynomial Chaos Expansion (PCE) calibrated on measurements data of the track irregularities. The curve radius, the rail age and the train operational velocity introduce non-stationary effects that have to be taken into account to model the track. A validation of the random models is therefore performed using a set of measurements of the wheel-rail contact forces. A global sensitivity analysis is performed on some dynamical quantities of interest in order to quantify the impact of the random fields on the vehicle dynamics and the rail fatigue initiation. Since this step is computationally expensive, a PCE-based meta-modelling technique is employed to estimate the fatigue index.

Keywords: Track geometry irregularities, Rail wear, Rail fatigue, Sensitivity analysis.

1. Introduction

The track conditions play an important role in railway dynamics. Concerning the rail positions, a lot of studies about the track geometry irregularities have been carried out. A small variation of the track geometry can produce large changes of the rail-wheel contact patch and forces, as experimentally described in [1]. A long-term evolution of the train dynamics is observed when the track geometry deteriorates over time, as studied in [2] using a probabilistic approach. The variations of the contact forces acting on the rails, caused by track geometry irregularities, impact the dynamical response of the train, showing that the spectra of forces and accelerations are strongly modified by the introduction of the geometry irregularities [3, 4, 5]. However, in these latter references, a sensitivity analysis to quantify the impact of the irregularities is not carried out. The wheel-rail contact forces also determine the rolling contact fatigue mechanisms. The track geometry irregularities can produce contact forces variations that lead to rail fatigue. For instance the track lateral irregularities can be responsible for the contact forces that initiate the surface fatigue as shown in [6, 7]. It is also numerically and experimentally observed that the squat phenomena can be related to the track irregularities [8].

Similarly, the rail wear affects the train-track interactions by determining the contact patches position and the stresses distributions, and therefore the RCF initiation. Moreover the wear has a strong relationship with the RCF. In some cases, the RCF and the wear can be in competition for the determination of the operation life of the rail [9]. For severe wear rates, the strong removal of the material from the contact surface, tends to limit the propagation of cracks formed by cyclic contact stresses.

A random model of the track geometry and rails wear irregularities has been built using experimental data from measurements [10]. The features of this random fields are identified using measurement data and a parametric model of them is proposed In this way, it is possible to obtain independent realisations of the random fields. The curve radius, the rail age and the train operational velocity introduce non-stationary effects that have to be taken into account to model the track. In this paper, these random models are used to generate samples of the track geometry irregularities and rail wear in order to perform a sensitivity analysis on quantities of interest related to the train dynamics and the rail fatigue. The novelty introduced in this work is the methodology for constructing a probabilistic model of the rail fatigue index (and some dynamical QoIs) and quantifying the impact of the irregularities on it.

A global variance-based sensitivity analysis is carried out to have an estimation of the impact of geometry irregularities for different operation scenarios. Differently from a local sensitivity analysis, which is based on the computation of the gradient of the response with respect to its parameters around a nominal value, the global sensitivity analysis quantifies the output uncertainty due to the uncertainty in the input parameters by means of indices defined in the whole input random space [11, 12].

The fatigue initiation is evaluated using the Dang Van crite-

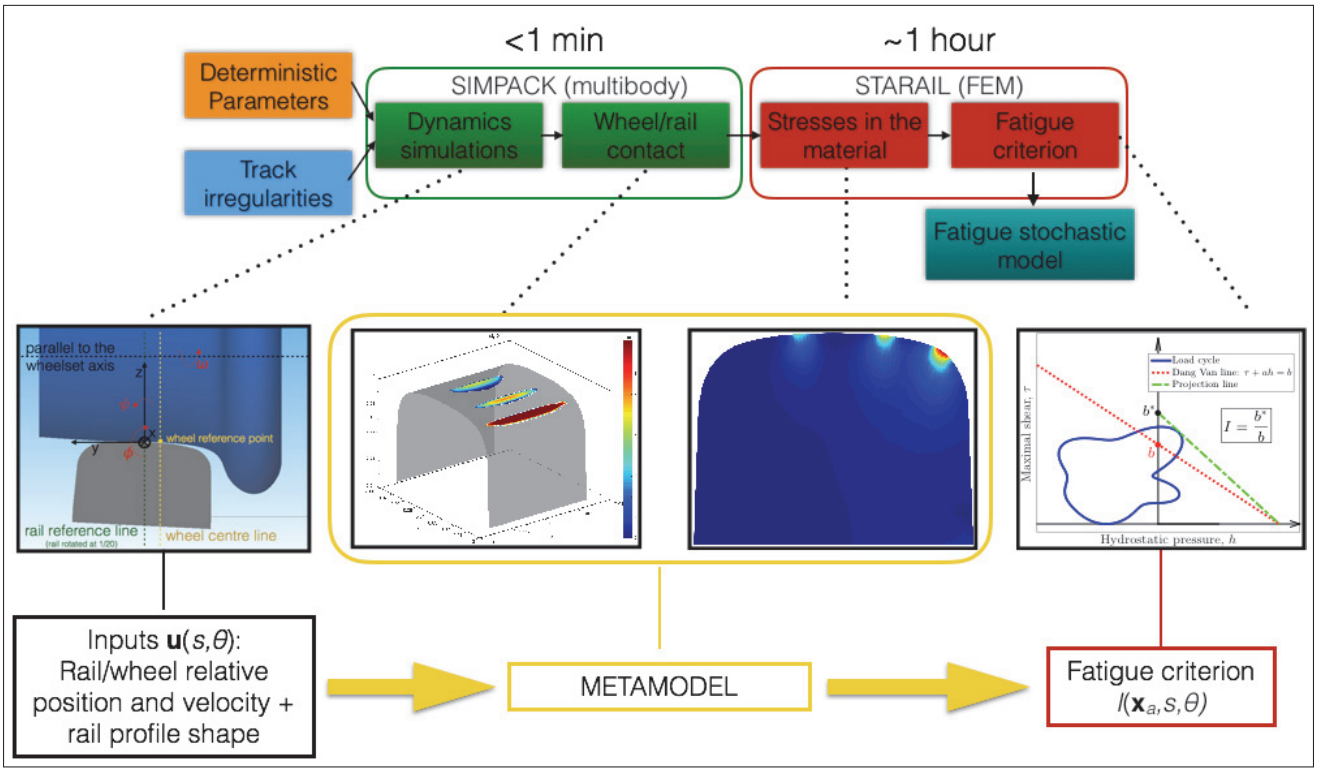

Figure 1: *Schema: from the track irregularities to the fatigue criterion.*

rion. This latter is based on the assumption of elastic shakedown of the structure, that occurs for relative low friction coefficient and surface stresses [13]. The rail fatigue represents a major issue on the modern railway network. Recent research has been carried out to evaluate the influence of the composition and heat treatment [14], the internal defects shape [15], the surface stress gradient [16], the relationship with the grinding maintenance operations [17] and the heterogeneity in the materials [18]. In this paper, the purpose is to understand the influence of the geometrical irregularities of the track and the wear.

Since the computation of the internal stresses in the rail is a computational expensive stage, a metamodel is built to link some outputs of the dynamical simulations to the estimation of the fatigue index. In Figure 1, a schema summarizes the computational steps of this paper.

2. Track geometry irregularities and wear model

The collected data from the measurement of the geometry, concerning an urban rail network (Paris region), are processed in order to extract realizations of the random fields indexed by the curvilinear abscissa, s.

Concerning the track geometry irregularities four quantities are measured:

- Gauge, $G(s)$, the spacing of the rails measured between the inner faces
- Superelevation, $E(s)$, the difference in height between the two rails
- Horizontal curvature, $C_H(s)$, referred to the track median line
- Vertical curvature, $C_V(s)$, referred to the track median line

The irregularities are defined as the differences between the measurements and the corresponding design (or theoretical) known values. The irregularities fields thus defined are centred and decorrelated from the horizontal layout of the track. A combination of the Karhunen-Loève expansion (KLE), [19], and Polynomial Chaos expansion (PCE), [20], is used to model the irregularities random fields. This technique and the model validation through dynamical simulations are described in [10].

Another database of measurements concerns the rail profiles. These measurements are processed and compared to a theoretical rail profile to estimate the wear field (Figure 2). This latter is modelled as a random field indexed by the rail and the track curvilinear abscissa.

The main steps of the wear modelling are here listed. Let $(\Theta, \mathcal{F}, P)$ be a probability space and $w(s, r, \theta)$ the wear random field, with $\theta \in \Theta$ and s and r being respectively the curvilinear abscissa of the track and the rail profile. Using a KLE on the rail abscissa r, the wear field , is approximated by its truncated projection on an orthogonal basis. Using this methodology, it is expressed as a sum of M deterministic functions $\Phi_i(r)$ (modal forms of the wear) multiplied by random decor-

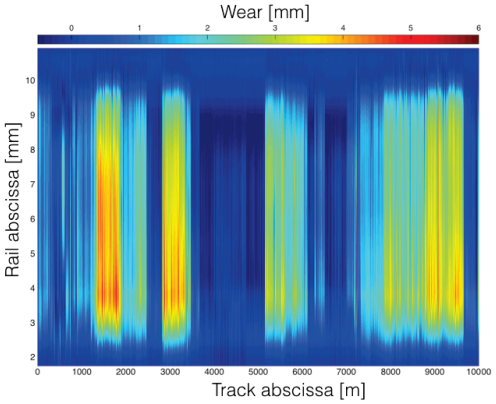

Figure 2: *Example of measured rail wear.*

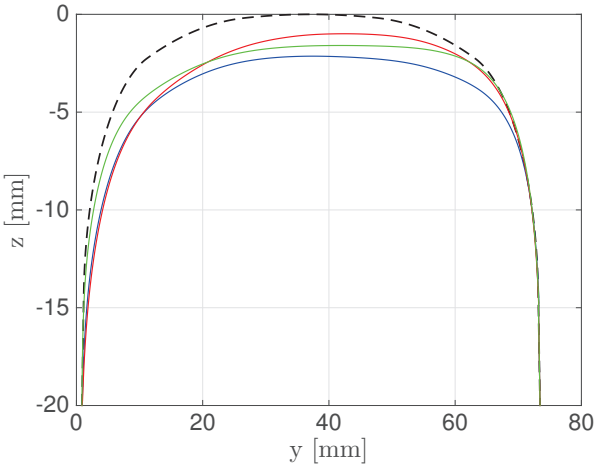

Figure 3: *Karhunen-Loève modes of the wear fields: 1st (blue), 2nd (red) and 3rd (green). Theoretical rail profile in dashed black.*

related and normalized coefficients $\eta_i(s,\theta)$:

$$w(s,r,\theta) \approx \sum_{i=1}^{M} \sqrt{\lambda_i}\Phi_i(r)\eta_i(s,\theta) \tag{1}$$

where $\Phi_i(r)$ and λ_i are the eigenfunctions and the eigenvalues of the covariance function. Only three modes (shown in Figure 3) are necessary to get a truncation error lower than 1%. Note that the random coefficient are correlated to some track features: tonnage, curve radius and velocity. A linear regression is strategy is used at this stage to decorrelate these coefficients from these quantities. Let $\hat{\eta}_i$ be the new KLE coefficients after the regression.

Then the random fields corresponding to the random coefficients $\hat{\eta}_i$ are expressed using a spectral expansion followed by a transformation depending on the marginal density distribution of the coefficient [21]:

$$\hat{\eta}_i(s,\theta) \approx F^{-1}\left(G\left(\sum_{j=1}^{N}\sqrt{2\Delta\omega S_i(j\Delta\omega)}\cos(j\Delta\omega s+\phi_j(\theta))\right)\right) \tag{2}$$

where S_i represents the power spectral density at the frequency $j\Delta\omega$ and $\phi_n(\theta)$ are uniform random variables. F and G represent respectively the cumulative density function of the modelled field (η_i) and the standard gaussian random variable.

3. Uncertainty propagation

3.1. Dynamical computation of the rail-wheel contact stresses

To characterize the wheel-rail contact patch in a point of the track, a semi-Hertzian contact model [22] is used in the simulations. The rail profile is discretized in strips along the lateral direction and in each strip the contact problem is solved as Hertzian. In order to consider the rail plasticity, the contact stresses are limited and the shape of the contact zone is slightly modified [23].

Using the formulation described above, the contact stresses entirely depend on the wheel-rail relative position and velocity in each strip and the rail profile geometry. Since the wheel is perfect solid of revolution and the friction coefficient is constant, the wheel rotational angle and the track curvilinear abscissa are not involved.

Since the dynamical simulations are not heavily time-consuming (around 1 minute for a simulation of a 100 m track portion), the random space, is explored through Monte Carlo sampling, in which each simulation corresponds to a generation if the track irregularities and the wear fields. Let $\mathbf{u} = \mathbf{u}(s,\theta)$ be the vectorial random fields collecting the evolution of the rail-wheel kinematic parameters and the rail wear KLE modes. When all the input parameters of the dynamical simulations are stationary in the space, the field $\mathbf{u}$ is stationary, i.e. its statistics do not depend on the track curvilinear abscissa s.

3.2. Rail internal stresses computation

The surface wheel-rail contact stresses, extracted at a given track position, are employed as boundary condition of the Finite Element calculation of the internal rail stresses resulting from the passage of the wheel [24]. Two global hypotheses are made:

- The surface contact stresses field is stationary and is moving on the rail at constant velocity.
- The rail is infinitely long along the longitudinal direction.

These hypotheses imply that each rail transversal section is subjected to the same load cycle and the time variable can be replaced by the longitudinal spatial coordinate [24].

The rail material plasticity behaviour is introduced by using a bilinear stress-strain law. At each passage of the load, the plastic strain tensor varies. After a different number of passages a steady state during repeated rolling-sliding is reached. This steady state corresponds to the condition according to which the plastic deformation does not change after another passage.

3.3. *Dang Van fatigue criterion*

The steady state stress cycle in the rail section is used for the application of the Dang Van fatigue criterion [25]. This is a multi-axial fatigue criterion based on the passage from the macroscopic to the mesoscopic scale. If the material is isotropic, the mesoscopic stress tensor $\overline{\overline{\sigma}}(\mathbf{x}, t, s_i)$ is calculated as:

$$\overline{\overline{\sigma}}(\mathbf{x}, t, s_i) = \overline{\overline{\Sigma}}(\mathbf{x}, t, s_i) - \overline{\overline{\rho}}(\mathbf{x}, s_i) \tag{3}$$

where $\overline{\overline{\Sigma}}(\mathbf{x}, t, s_i)$ is the macroscopic stress tensor and $\overline{\overline{\rho}}(\mathbf{x}, s_i)$ is the centre of the smallest hypersphere circumscribed to the macroscopic stress deviator, $\overline{\overline{s}}(\mathbf{x}, t)$, temporal cycle. The maximal shear stress is calculated as:

$$\tau(\mathbf{x}, t, s_i) = \frac{1}{2}(\sigma_1(\mathbf{x}, t, s_i) - \sigma_3(\mathbf{x}, t, s_i)) \tag{4}$$

where $\sigma_1(\mathbf{x}, t)$ and $\sigma_3(\mathbf{x}, t)$ are respectively the highest and the lowest principal mesoscopic stresses. At the end the fatigue index $I(\mathbf{x}, s_i)$ is defined as:

$$I(\mathbf{x}, s_i) = \max_t \left(\frac{\tau(\mathbf{x}, t, s_i)}{b - ah(\mathbf{x}, t, s_i)} \right) \tag{5}$$

where a and b are material constant (coming the torsion and traction fatigue tests) and $h(\mathbf{x}, t)$ is the mesoscopic hydrostatic pressure. When the index is bigger than 1, the structure is subject to fatigue and the biggest the index is, the less load cycles the structure can be subjected to.

3.4. *Polynomial chaos metamodel of the fatigue criterion*

The computation of the rail internal steady state stress cycle, described in Section 3.2, is the most expensive stage, making the Monte Carlo sampling not advisable for exploring the random space. For this reason the computation of the internal load cycle and the application of the Dang Van fatigue index on them (Section 3.3) is replaced by a metamodel. After its construction the metamodel allows the exploration of the random space without computational effort.

The fatigue index only depends on the boundary condition (the surface contact stresses) and the rail form (wear). Therefore the input random space of the metamodel is the stationary random field $\mathbf{u}(s, \theta)$ introduced in Section 3.1. The PCE metamodel of the fatigue index is equal to:

$$I(\mathbf{x}, s, \theta) \approx \sum_{k=1}^{T} \alpha_k(\mathbf{x}) \zeta_k(\mathbf{u}(s, \theta), s) \tag{6}$$

The PCE basis $\{\zeta_k(\mathbf{u}(s, \theta), s\})$ has to be orthogonal with respect to the random space [26]. As proposed in [27], the PCE basis can be obtained by Gram-Schmidt orthogonalization method. The PCE coefficients $\{\alpha_k\}$ in Eqn. 6 are computed by least-square regression [28]. This technique minimizes the mean squared error between the prediction and the solution. Let $\{\mathbf{u}(s_1, \theta_1), \ldots, \mathbf{u}(s_R, \theta_R)\}$ be the set collecting R regression points. This set is obtained by Monte Carlo sampling R realizations of the field $\mathbf{u}(s, \theta)$ at curvilinear abscissa s randomly chosen in the interval $[0, S]$. Because of the stationarity of $\mathbf{u}(s, \theta)$, the choice of s is completely arbitrary.

4. Results

Different scenarios are presented in this paper considering a variation of the curve radius (1000 m and 450 m) and the velocity (80 km/h and 110 km/h), Table 1. The design superelevation is set in order to have a null cant deficiency at the lower speed.

All the quantities of interest processed are extracted at established design track geometry, i.e., if the track is curved, they are extracted at a position far enough from the curve entry (the dynamical non-stationary effects due to the curve negotiation are not considered).

By choosing a maximal polynomial degree equal to 3, a complete PCE basis for a 10-dimensional random space would be composed by 286 terms. After the reduction only a few terms are retained in the metamodel. The number of terms in the PCE, varies in the rail section area. For all the considered operating scenarios this number varies between 6 and 44.

The mean value and the standard deviation, on the track curvilinear abscissa s, of the fatigue index random field $I(\mathbf{x}_a, s, \theta)$, whose realisations are obtained by propagating the uncertainties using the metamodel of Eqn. (6), are shown in Figure 4 and Figure 5 for a wide and a tight curved track test case without and with random wear. The highest values of the fatigue index are related to the contact patch on the wheel flange (gauge corner), that corresponds to the largest values of normal and tangential surface stresses. This is the rail region mostly affected the RCF in a curved track.

When the random wear is introduced in the simulations, the wheel-rail contact patch can take more possible positions, while when the profile is constant, the contact zones are much more stable. The mean value of the fatigue index, in the rail section, is therefore smaller, for a fixed location, when the wear is considered. Conversely, the standard deviation is larger on almost all the rail section (this can deteriorate the rail fatigue life in some cases). In a tight curve, the stresses concentrated near the gauge corner are higher than the wide curved track cases. Note also that, for both curves, the wear of the rail contributes to displace the contact patch around the gauge corner in a position having a higher contact angle. This implies a higher value of the lateral force Y absorbed by the

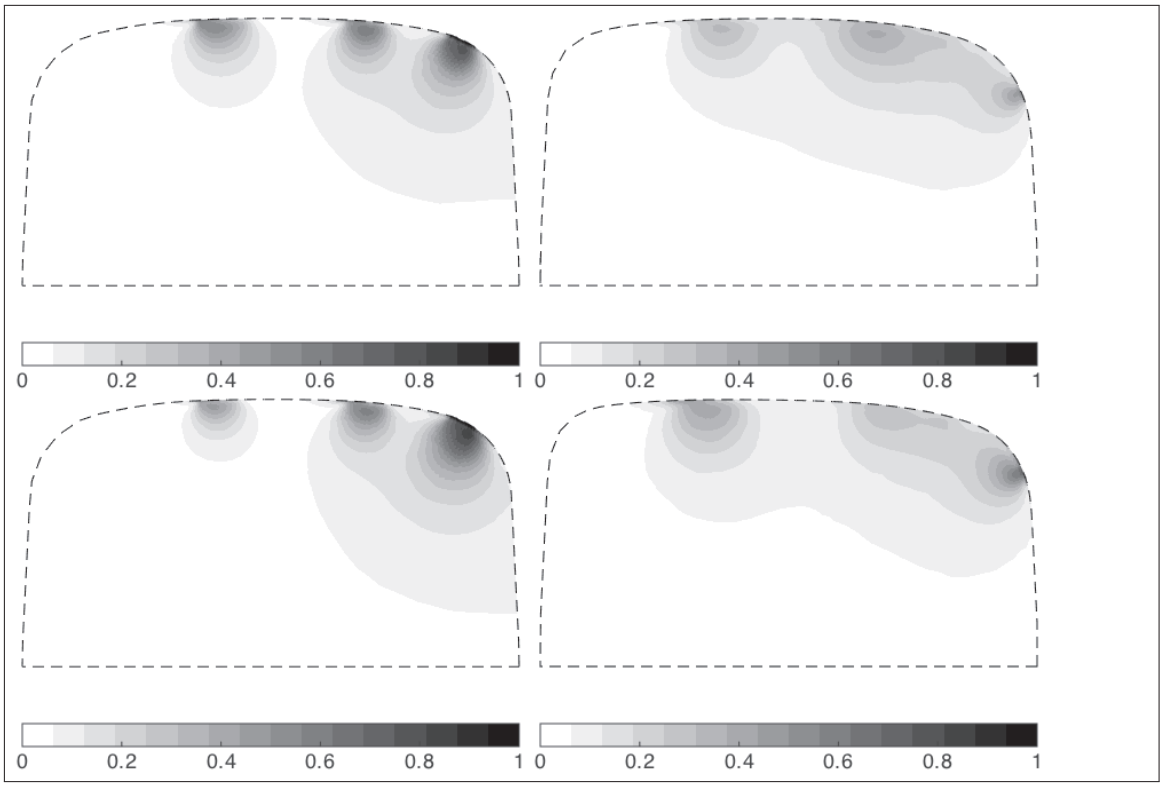

Figure 4: *Mean value of the fatigue index in the rail section: empty slow vehicle; wide (top) and tight curve (bottom); without (left) and with (right) random wear included.*

track.

In a tangent track (Figures 6 and 7), the contact patch is essentially localized on the surface tread. The mean values of the new and worn rails cases are similar, even if, in some cases (due to high geometrical irregularities), the contact patches can move toward the gauge corner region (as the standard deviation of the fatigue index on the rail section shows).

The fatigue index takes high values only in the rail section regions close to the contact patch (higher at the borders of the contact patches of the gauge corner because of the high stress gradient). The maximal value of the index on the rail section is the most important quantity which would represent the first crack starting propagating. The PDFs of the maximal fatigue index, for the curved track cases, are shown in Figure 8 and its mean value, standard deviation and coefficient of variation are shown in Table 2.

The PDF tends to shift towards highest values when the curve is tighter and the velocity is the highest one (increase of the contact forces). In a tight curve the standard deviation of the fatigue index is lower, because contact patches are more stable. Moreover, the standard deviation tends to be slightly lower when the velocity (cant deficiency) increases.

The fatigue index is always larger than the threshold 1 when the wear is not included in the simulations. Considering a variable shape of the rail profile has a beneficial effect on the fatigue index: the mean value decreases and the index can take values smaller than 1. For instance, at the slower running velocity, around 70% (wide curve) and 50% (tight curve) of the total area of the PDF corresponds to fatigue indices smaller than 1. Note, however, that this strong reduction of the mean value due to the worn shape of the rail is also associated with

Table 2: *Mean (μ), standard deviation (σ), coefficient of variation (c_v) and 1st order Sobol indices of Dang Van fatigue index on the rail section. "Inter" indicates the indices whose order is higher than one (interactions).*

a raise of the standard deviation on almost all the rail section (Figure 5). This means that, in some situations, a worn profile can deteriorate the rail fatigue.

Note also that, in a tangent track, the increase of the passenger load has a small beneficial effect on the fatigue index mean value. This is due to the higher values of the compressive hydrostatic pressure due to the load when the contact zone is localized on the rail surface tread.

5. Conclusion

The steps to lead to a stochastic characterisation of the track geometry irregularities and the rail wear of a railway network are presented in this work. A large set of experimental measurements is used to model the irregularities as random fields. The model is able to capture the statistical and the spatial variability of the geometry irregularities and the rail wear on the considered track. A stochastic model of the rail fatigue is constructed by means of numerical simulations. This rail fatigue model can be used to improve the railway network maintenance. Indeed, a sensitivity analysis study can be performed by means of this model in order to identify which kind of irregularities affects the rail life.

Abstract: This paper is focused on the influence of the wheelset flexibility on the development of railway wheel polygonalization. A developed method for predicting the evolution of wheel polygonalization is adopted to compare the formation and growth rate of wheel polygonalization in between rigid and flexible wheelsets. Results show that, if the lateral creepage is at a high level, the wheelset flexibility can accelerate the wheel polygonalization; the torsional mode of the wheelset is found to dominate the wheel polygonalization in the case of extreme small radius curve.

Keywords: Wheelset flexibility; railway wheel polygonalization; Archard wear model; rail/wheel contact parameters; torsional mode.

1. Introduction

The phenomena of wheel polygonalization has been found in all kinds of railway vehicles throughout the world for decades [1-7]. It introduces extra periodic excitation to the wheel-rail interface which can be very harmful to the vehicle-track system. The consequences can be noise, reduction of comfort, increased maintenance requirements and component damage. As speeds or axle loads increase the wheel polygonalization has emerged as a critical issue for the safe and efficient operation of the rail network.

Researchers are continuing efforts to investigate the mechanism of railway wheel polygonalization from varied perspectives. Some potential influencing factors have been revealed through simulation or field test, such as vehicle speed, wheelset flexibility [3, 8-11], track modes [12], wheelset imbalance [13], self-induced vibration [14], and so on. Among previous studies, a popular view is that the wheelset flexibility presents a leading influence on the development of wheel polygonalization. Specifically, the first bending mode of the wheelset has been argued to be the root cause for some orders of polygonalization developed dominantly in particular vehicles (e.g. 18th order for a locomotive [9], 9th order for a metro train [1]). This hypothesis is supported by experiments finding that the natural frequency of the first bending mode of the wheelset is approximately corresponding to the passing frequency of the dominant orders of the wheel polygonalization [1, 9]. In addition, the lateral mode (the second bending mode) of the wheelset is also suspected to drive the development of the 24th order of wheel polygonalization in a Chinese locomotive, which however has not been verified [9].

The work here is carrying out fundamental research by simulation with the specific aim of checking whether the wheelset flexibility can influence the development of railway wheel polygonalization in a general sense. If it is true, the subsequent objective is to assess the discrepancy in the formation and growth rate of the wheel polygonalization with and without considering the wheelset flexibility in simulation.

2. Methodology

The flexibility of the wheelset is investigated by importing a Finite Element (FE) model of the wheelset into Multiple-Body System (MBS). A developed method [15] is applied to predict the evolution of wheel polygonalization. After a long distance of running in simulation, the influence of the wheelset flexibility on the wheel polygonalization can be obtained by comparing the evolution of the wheel polygonalization for rigid and flexible wheelsets.

A simple wheelset instead of a full vehicle is deliberately adopted here to minimise interfering factors, as the major influencing factor being investigated in this paper is the flexibility of the wheelset. A simple sleeper following the wheelset is used to simply represent the track flexibility. The guidance forces with stiffness and damping are applied at both sides of the wheelset axle, representing the dynamic coupling effect from the bogie frame. The wheel profile is JM3 [16], which is a typical type for Chinese locomotives. The rail profile is 60_kg rail. The wheel radius is 0.625 m. All the other parameters of the dynamic model are representative of a typical Chinese high axle load locomotive.

2.1. Wheelset flexibility modeling

After successively using SolidWorks for geometry modelling, Hypermesh for meshing, and Abaqus for generating the FE substructure, the flexible wheelset was imported into Simpack through the 'Craig-Bampton' method, which is a method for reducing the size (degree of freedom) of the FE model to integrate the flexible model (known as superelement) into the MBS software.

One difficulty in the above procedures is the selection of the master nodes from all the FE nodes. On the one hand, the selected set of master nodes must be sufficient to reflect the relevant modal characters of the flexible wheelset, on the other hand, too many master nodes can lead to extremely slow speed in MBS simulation and potentially calculation failure. Figure 1 shows the meshing and the selection of the master nodes of the wheelset.

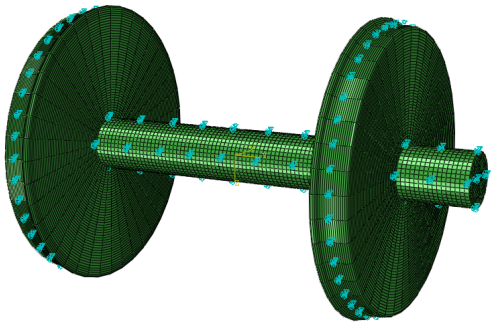

Figure 1 *Meshing and selection of master nodes of the wheelset*

To validate the accuracy of the modal frequencies of the wheelset substructure, the modal frequencies calculated by Abaqus modal analysis and Abaqus substructure analysis respectively are compared. As can be seen from Table 1, the discrepancy becomes larger with the increase of the modal frequency. However, for the first 12 modes, the discrepancies are within 10% which is acceptable. Knowing that the operational speed of the locomotive being investigated in this paper is relative slow (below 80km/h), the first 12 modes with frequencies below 500Hz are chosen for the simulation.

Table 1 *Comparison of wheelset mode frequency.*

Modes	Modal analysis frequency [Hz]	Substructure frequency [Hz]	Discrepancy [%]
1	50.03	50.05	0.04%
2	71.181	71.305	0.17%
3	71.182	71.305	0.17%
4	135.33	136.001	0.50%
5	135.33	136.002	0.50%
6	278.65	288.066	3.38%
7	421.42	452.778	7.44%
8	421.42	452.778	7.44%
9	442.48	452.923	2.36%
10	442.48	452.924	2.36%
11	442.60	466.061	5.30%
12	442.60	466.696	5.44%
13	576.97	667.918	15.76%
14	807.26	988.665	22.47%
15	807.35	988.666	22.46%
16	874.74	988.665	13.02%
17	874.89	988.667	13.00%
18	877.56	1063.793	21.22%
19	927.06	1065.625	14.95%

In addition, a very small wheelset imbalance is unavoidably introduced to Simpack along with the transfer of the flexible wheelset body due to the FE meshing. This imbalance cannot be eliminated, but can only be minimised by refining the mesh. In order to get comparable results, the rigid wheelset, used for comparison, is configured with the same initial imbalance.

2.2. Prediction of the evolution of wheel polygonalization

A developed method [15] is adopted to predict the evolution of wheel polygonalization. Similar to the prediction for wheel profile wear [17-19], the basic idea is to establish a feed-back loop program by coupling a short-term vehicle-track dynamic model with a long-term wear model. The transient contact parameters in the rail/wheel interface are calculated in Simpack. The Archard wear model combined with FASTSIM, which is also known as KTH wear model [17, 19], is adopted to calculate the abrasive wear depth against the wheelset rolling angle at discrete time steps. The program structure is shown in Figure 2.

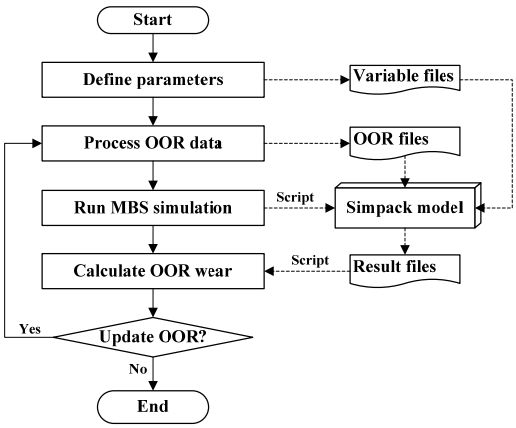

Figure 2 *Program structure for predicting the evolution of wheel polygonalization*

The program structure is configured to realize automatic and parametric simulation. All the Simpack parameters, including configuration parameters and vehicle/track model parameters, are defined in variable files. The OOR data, namely the radius deviation, will be pre-processed before subsequent iteration. The processing includes spikes/pits removal and curvature processing according to EN 15610:2009 [20]. One Simpack script is coded for implementing the preload calculation and subsequent time integration in Simpack. Another Simpack script is coded to import the needed data from Simpack to Matlab. The circumferential wear depth is calculated in Matlab, and then the circumferential wheel profile is updated for the next run. After several iterations, the evolution of wheel polygonalization can be obtained. With this programme structure, the whole simulation procedure is completely controlled in Matlab. More details are illustrated in Reference [15].

2.3. Wear model

As mentioned before, the Archard & FASTSIM wear model is adopted to calculate the abrasive wear depth

around the wheel profile. The Archard [21] wear Equation is given by:

$$V_{wear} = k_w \frac{Nd}{H} \quad (1)$$

Where V_{wear} is the volume of worn material, d is the sliding distance, N is the normal force, H is the hardness of the softer material, and k_w is the wear coefficient depending on the contact pressure and sliding velocity. By dividing the contact ellipse into grid elements according to the FASTSIM algorithm, the wear depth Δz within each element can be obtained by Equation (2).

$$\Delta z = k_w \frac{p_z \Delta d}{H} \quad (2)$$

Using Hertz contact theory, the normal pressure distribution p_z can be expressed as Equation (3).

$$p_z(x,y) = \frac{3N}{2\pi ab}\sqrt{1-(\frac{x}{a})^2-(\frac{y}{b})^2} \quad (3)$$

According to FASTSIM, The sliding distance Δd can be derived by Equation (4).

$$\Delta d = |s|\Delta t_c = v_X \left(\begin{bmatrix} v_x - \phi y \\ v_y + \phi x \end{bmatrix} - \begin{bmatrix} \frac{\partial u_x}{\partial x} \\ \frac{\partial u_y}{\partial x} \end{bmatrix} \right) \frac{\Delta x}{v_X} = \left(\begin{bmatrix} v_x - \phi y \\ v_y + \phi x \end{bmatrix} - \begin{bmatrix} \frac{\partial u_x}{\partial x} \\ \frac{\partial u_y}{\partial x} \end{bmatrix} \right) \Delta x \quad (4)$$

Combing Equations (1) – (4), the final formula for the wear depth Δz becomes:

$$\Delta z(x,y) = \frac{3N_w \Delta x}{2\pi abH}\sqrt{1-(\frac{x}{a})^2-(\frac{y}{b})^2}\sqrt{(v_x - \phi y - \partial u_x/\partial x)^2 + (v_y + \phi x - \partial u_y/\partial x)^2} \quad (5)$$

In Equation (5), x and y are the only independent variables, with the other parameters being obtained from Simpack directly or calculated in FASTSIM. Note that Δz will depend on the element size Δx . However, the sum of the wear depth in each longitudinal strip is stable if the longitudinal element number assigned is sufficient enough. Consequently, only the sum of the wear depth in longitudinal strips is meaningful to be adopted as the result. Normally the longitudinal position of the wear depth is chosen as the position where the maximum wear depth is found in each longitudinal strip. And then, from each contact patch, one incremental wear depth curve can be obtained. One example is shown in Figure 3.

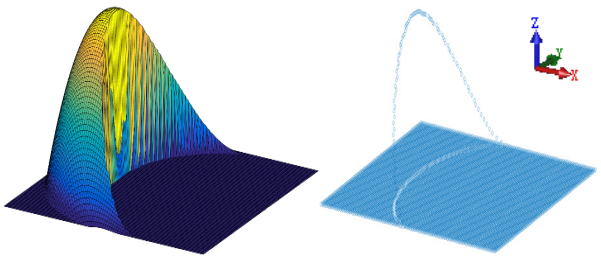

Figure 3 *Example of the wear depth distribution (top) and the incremental wear depth (bottom)*

The averaged incremental wear depth, instead of the maximum, is chosen as the final wear depth for the specific point on the wheel circumference, as the circumferential wear of the wheel is limited in a 2D sense.

3. Influence of the wheelset flexibility on the contact parameters

For calculating the wear depth at a position with the Archard & FASTSIM combined model, nine contact parameters are needed. These are: normal force; creepages (longitudinal, lateral, and spin); contact patch size (semi-axis a and b); and Kalker coefficient (C11, C22, and C23). Note that the contact patch size and Kalker coefficients are dependent on the normal force. As a result, only the normal force and the creepages (Spin is not shown below) are in the scope of investigation.

White noise was used as the excitation to investigate the responses of the contact parameters both in time domain and frequency domain. At the meantime, the wear number (T γ , N) and the Archard wear depth (m) are also compared both in time domain and frequency domain to check the difference between these two kinds of wear index. Scenarios of straight track and curved track are carried out respectively.

3.1. Straight track

At the speed of 70km/h, with vertical rail irregularity of white noise (amplitude 0.1mm) as the excitation, the wheelset is run on a straight track for 50 revolutions. The responses of the contact parameters, wear number and Archard wear for both rigid and flexible wheelsets are shown from Figure 4 to 8.

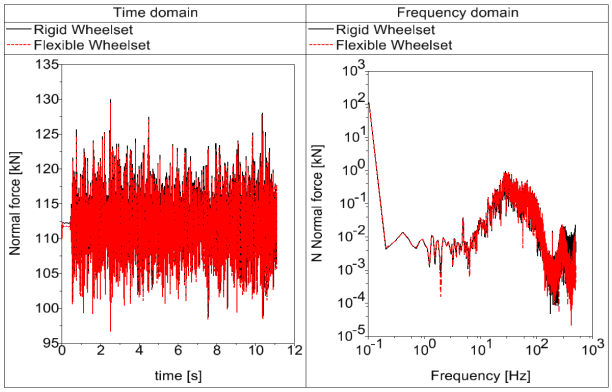

Figure 4 *Normal force excited by white noise on straight track*

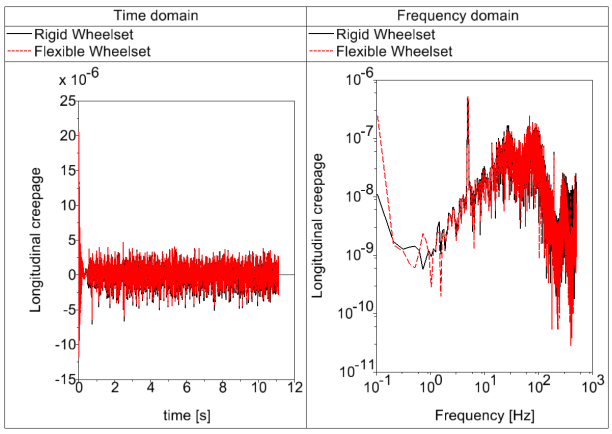

Figure 5 *Longitudinal creepage excited by white noise on straight track*

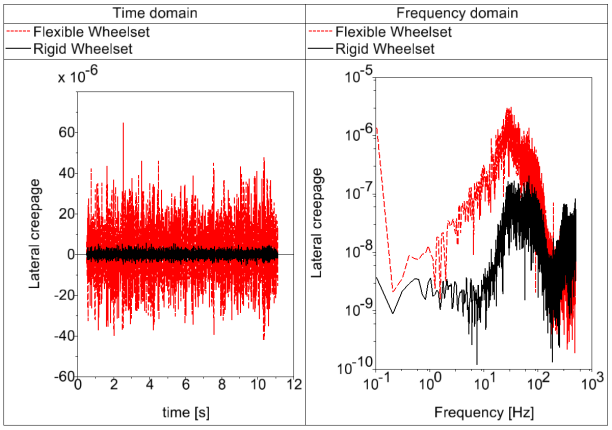

Figure 6 *Lateral creepage excited by white noise on straight track*

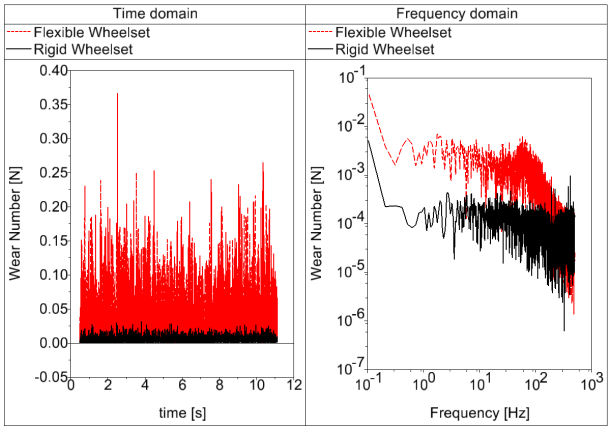

Figure 7 *Wear number excited by white noise on straight track*

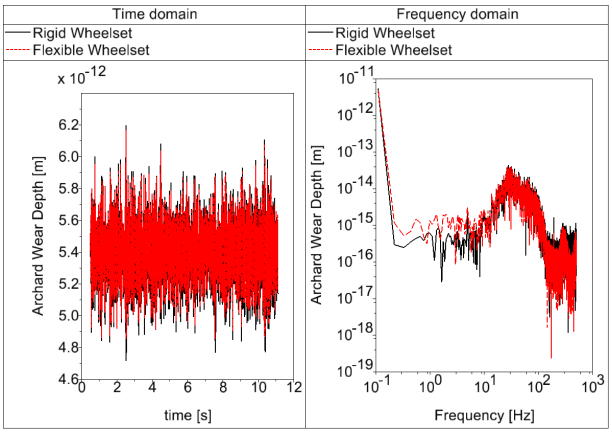

Figure 8 *Archard wear depth excited by white noise on straight track*

As can be seen from Figure 4 to 8, the normal force and the longitudinal creepage appear similar for rigid and flexible wheelsets compared to each other. While the lateral creepage presents significant difference between rigid and flexible wheelsets. The lateral creepage is largely increased due to the wheelset flexibility. This difference is reflected in the wear number (see Figure 7), but not in the Archard wear depth (see Figure 8). Nevertheless, it is worth noticing that, the amplitude of the lateral creepage is very small (in the order of 10^{-7}) in this case, and the shape of the frequency spectrum of the Archard wear depth just follows that of the normal force. So it is assumed that, in this case with the relevant parameters, the influence of the lateral creepage on the Archard wear depth is far less than that of the normal force, when the lateral creepage is at a very low level.

This assumption is verified by carrying out a sensitivity analysis of the lateral creepage, with a set of typical contact parameters from this case as the input for the Archard & FASTSIM wear model. The main input parameters for the calculation are: normal force 113kN; longitudinal creepage 3.2e-7; lateral creepage 2.37e-7; spin 8.58e-2; a 8.6mm; b 6mm; and friction coefficient 0.3. The result of the sensitivity analysis is shown in Figure 9. As can be seen from Figure 9, even the lateral creepage is amplified by 100 times, the magnification of the Archard wear depth only increase less than 1.02. This can explain why the large discrepancy in the lateral creepage cannot be reflected in the result of the Archard wear depth.

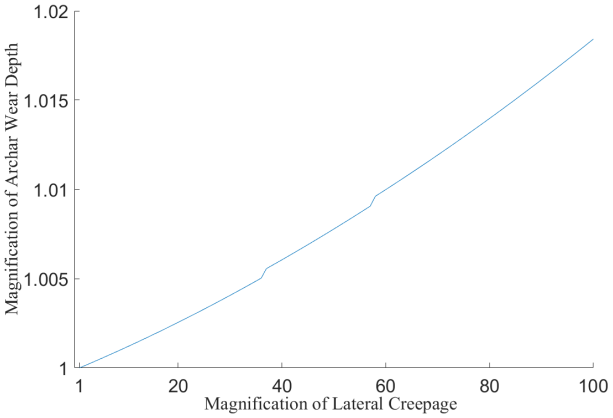

Figure 9 *Sensitivity analysis of the lateral creepage*

3.2. Curved track

A curved track with a very small radius of 100 m is used to demonstrate the difference of the contact parameter responses between rigid and flexible wheelsets, compared to the straight track. At the speed of 40km/h, with vertical rail irregularity of white noise (amplitude 0.1mm) as the excitation, the wheelset is run on a curve of radius 100 m for 50 revolutions. The respective results are followed below.

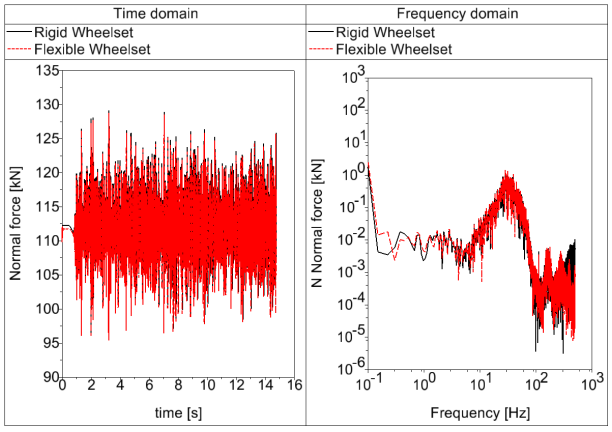

Figure 10 *Normal force excited by white noise on curved track*

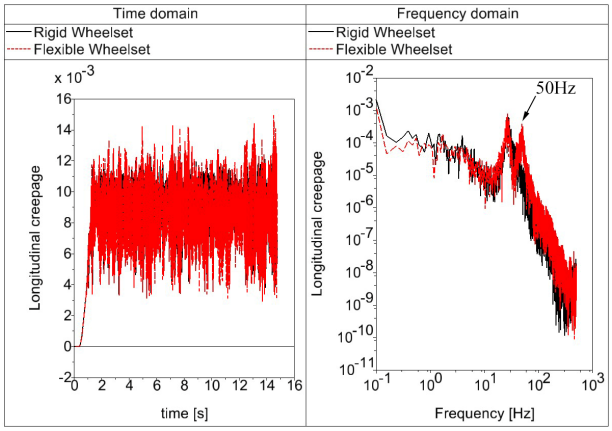

Figure 11 *Longitudinal creepage excited by white noise on curved track*

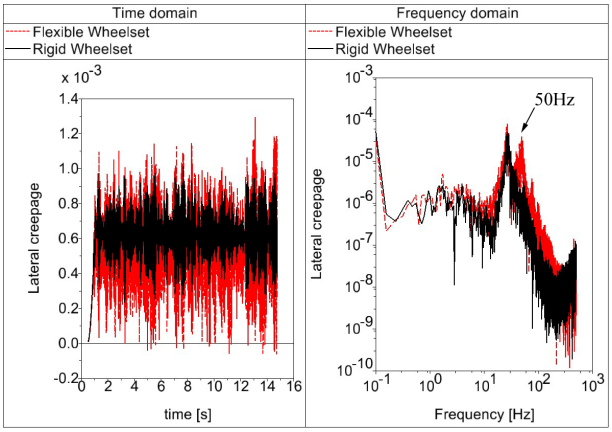

Figure 12 *Lateral creepage excited by white noise on curved track*

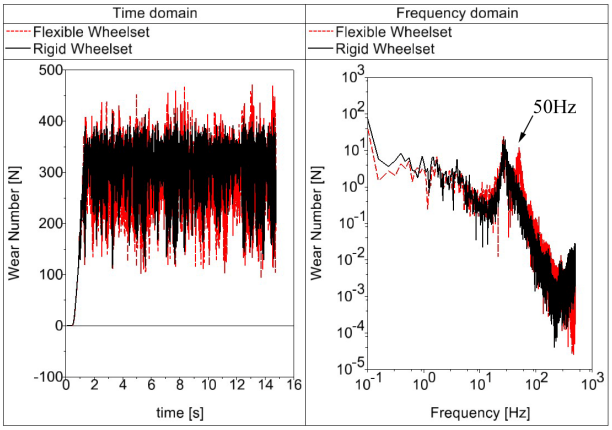

Figure 13 *Wear number excited by white noise on curved track*

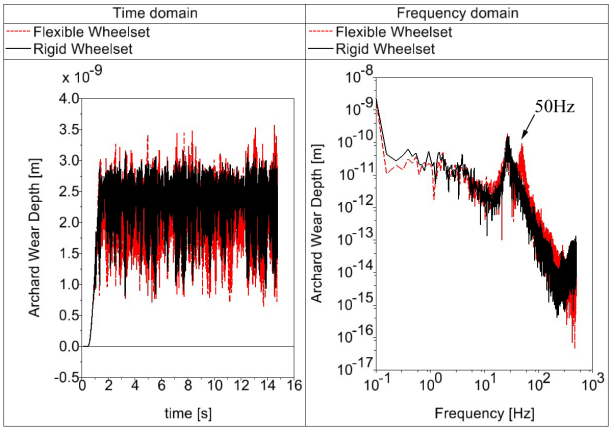

Figure 14 *Archard wear depth excited by white noise on curved track*

As can be seen from Figure 10 to 14, the normal force still remains similar for rigid and flexible wheelsets compared to each other. However, the frequency spectrums for both longitudinal creepage and lateral creepage present obvious discrepancy between rigid and flexible wheelsets. From around 40 to 300 Hz, the frequency spectrum amplitude of the flexible wheelset is bigger than that of the rigid wheelset. Most importantly, there appears a peak at around 50 Hz in the frequency spectrum of both longitudinal creepage and lateral creepage. It can be seen from Table 1 that, 50 Hz corresponds to the torsional modal frequency of the flexible wheelset, and the first 6 modal frequencies are just within the range from 40 to 300 Hz. Consequently, it is believed that the torsional mode of the flexible wheelset is effectively excited to fluctuate the longitudinal creepage and the lateral creepage in this case, which contributes to the peak at 50 Hz. And the first 6 modes of the flexible wheelset are also excited contributing, more or less, to the discrepancy in the frequency spectrum from around 40 to 300 Hz.

Moreover, it is well found that the frequency spectrum distribution of the Archard wear depth is very similar to that of the wear number in this case of curve track, although these two wear indexes have different physical meaning. And the discrepancy in the frequency spectrum of creepages is reflected in both of these two wear indexes. Compared to the previous simulation results (see Figure 5 and 6) for a straight track, the creepages are of a much higher level (in the order of 10^{-3}) in this case of a curved track. As a result, it can be drawn that, in the case of large creepages, the ability of the Archard wear model in predicting the abrasive wear is comparable to that of the wear number.

Apart from the comparison between wear number and Archard wear depth, the most important finding is that, the wheelset flexibility cannot be excited easily to influence the wear on tangent track, however it can be significantly excited to influence the wear on curves. Further simulation shows, the smaller the curve radius is, the more easily the wheelset flexibility can influence the wear (see Figures from 16 to 20). Nevertheless, it has to be admitted that the rather small radius curved track is normally in a very small percentage of the total route. For large radius curved tracks, the influence of the wheelset flexibility is not as obvious as this case shows, which is shown in the following simulation results.

4. Influence of the wheelset flexibility on the development of wheel polygonalization

As stated in the authors' previous study [15], a continuous excitation with a sole constant frequency (rail irregularity or sleeper passing frequency, etc), that can fluctuate the contact parameters (normal force, creepages, etc) in the same frequency, will lead to a corresponding order development of the wheel polygonalization, according to the Equation 6 below.

$$\text{Order} = \frac{Perimeter}{Wavelength} = \frac{Perimeter}{\frac{Speed}{Frequency}} \tag{6}$$

As an example, assigning a vertical rail irregularity with a single sinusoidal distance wavelength of 1/10 wheel perimeter, the corresponding developed order of the wheel polygonalization will be exactly 10. Figure 15 shows the development result for a flexible wheelset running on a straight track. The main simulation parameters for this example are: speed 70km/h, wavelength Perimeter/10 (0.3925m), excitation amplitude 0.1mm, simulation iterations 10, amplification coefficient 1e6, total running distance 39,250 km.

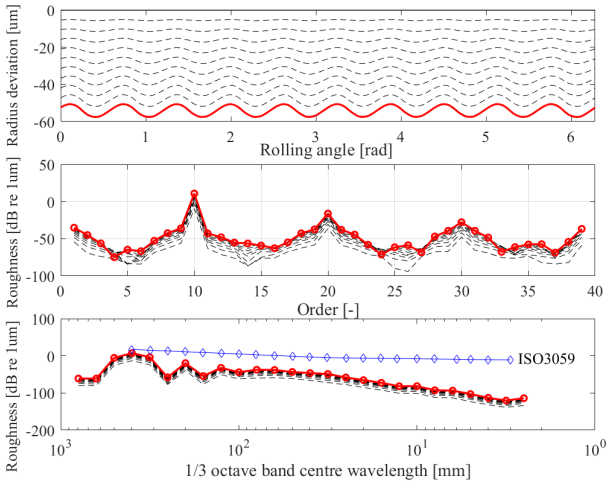

Figure 15 *Development of wheel polygonalization due to a single sinusoidal vertical excitation corresponding to the 10th order*

This feature can be extended to the situation of multiple excitation frequencies, which means fluctuation with multiple frequency components occurring in the contact parameters can lead to multiple corresponding orders to develop.

The prime interest of this paper lies in that whether the wheelset flexibility plays an important role in the formation and the growth rate of the wheel polygonalization. The idea is that, under the excitation of white noise that has a wide range of frequency components, if one or more structural mode of the vehicle-track dynamic system can be successfully excited to fluctuate the contact parameters, and therefore the circumferential wheel wear in the same modal frequency, these modal frequencies will result in the development of the corresponding orders of the wheel polygonalization. By comparing the evolution of wheel polygonalization in between rigid and flexible wheelsets, the influence of the wheelset flexibility can be identified.

The comparisons were carried out for a straight line and 4 curves with radii of 1200 m, 900 m, 600 m, and 300 m respectively. To facilitate the comparison, all the parameters are intentionally set the same for all the scenarios. The main parameters are: white noise amplitude 0.01mm; running speed 70 km/h; and running distance 39,250 km. One exception is that, for the curved track of radius 300 m, only 27,475 km is run, as wheel-rail contact detachment will occur for further running due to big roughness developed. The simulation results are shown from Figure 16 to 20 for each scenario respectively. The left wheel, which is at the outer side of the curve, is selected for the comparison for curves, as the wheel polygonalization of the left wheel is more obvious than that of the right wheel in these cases.

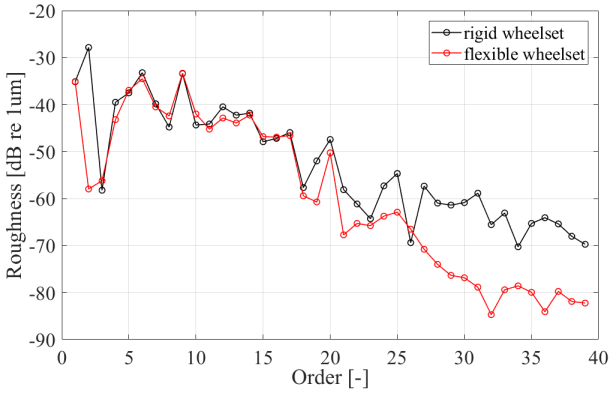

Figure 16 *Development of wheel polygonalization due to white noise on a straight track (running distance: 39,250 km)*

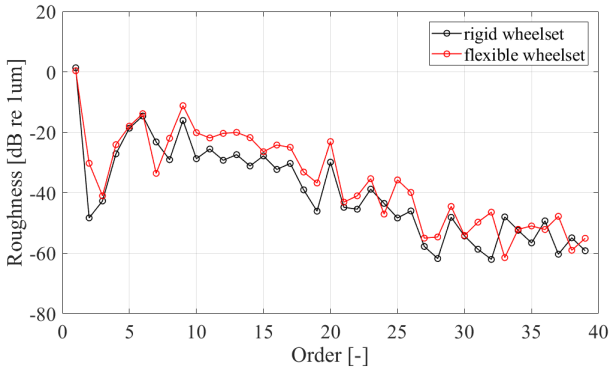

Figure 17 *Development of wheel polygonalization due to white noise on a curved track of radius 1200 m (running distance: 39,250 km)*

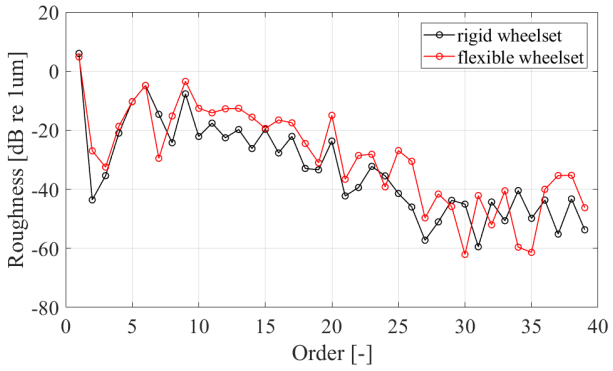

Figure 18 *Development of wheel polygonalization due to white noise on a curved track of radius 900 m (running distance: 39,250 km)*

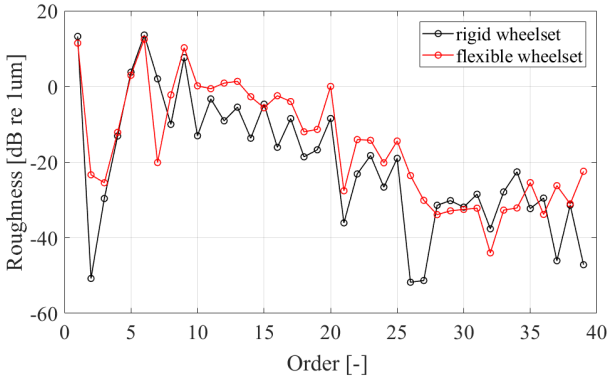

Figure 19 *Development of wheel polygonalization due to white noise on a curved track of radius 600 m (running distance: 39,250 km)*

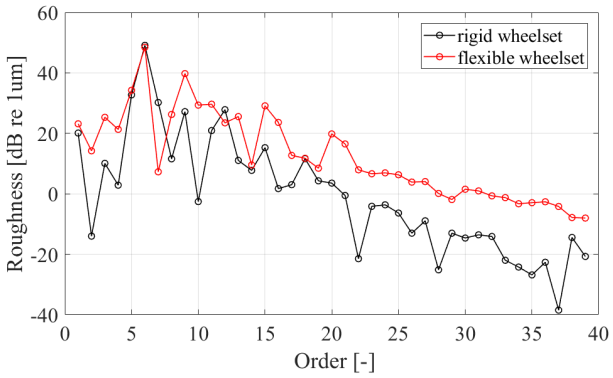

Figure 20 *Development of wheel polygonalization due to white noise on a curved track of radius 300 m (running distance: 27,475 km)*

By comparing these Figures (from 16 to 20) to each other, the influence of wheelset flexibility can be summarized in two aspects, which are the growth rate and the developed orders.

In terms of the growth rate of the wheel polygonalization, firstly, there is a general trend that, the smaller the curve radius is, the faster the development of the wheel polygonalization will be, and the more obviously the wheelset flexibility can influence the wear. Secondly, the wheelset flexibility does not contribute to the growth rate of wheel polygonalization for a straight track, but on the contrary, slows down the growth rate slightly, especially for higher orders above 18. This is because, for a straight track the creepages are very small (see Figure 4 and 5) and the normal force is the sole dominant factor determining the Archard wear depth (see Section 3.1). It is likely that the wheelset flexibility attenuates the normal force, especially for some high frequency components (see Figure 4), so that the resultant Archard wear depth is decreased. Thirdly, for curved tracks, the wheelset flexibility has an obvious effect on accelerating the growth rate for most orders above the 9th. Note that the flexible modal frequency of the wheelset starts from 50.05 Hz (see Table 1), and the corresponding frequency of the 9th order at the speed of 70 km/h is 44.6 Hz, according to Equation 6. It is naturally believed that the flexible modes of the wheelset are attributable to the accelerated growth of orders above 9th.

With respect to the developed orders, firstly, there is always a development in the 1st order because of the wheelset imbalance introduced from the FE modelling of the wheelset (see Section 2.1). This is an artefact of the modelling method, however, it is still reasonable as the wheelsets will always have an imbalance in reality. Secondly, the developed order of 6 appearing in all the Figures (for 16 to 20) is due to the vertical rigid body mode of the wheelset & sleeper with respect to the ground. The frequency of this mode is 27.8 Hz, determined by the mass of wheelset & sleeper and the vertical stiffness of the sleeper. The corresponding order of 27.8 Hz at the speed of 70 km/h is 5.62. As 5.62 is closer to integer 6 than integer 5, the order 6 is developed dominantly followed by the order 5 developed relatively smaller. This dominant order will change with the speed correspondingly, according to Equation 6. In addition, it should be noted that the 6th order is always the most dominant for all scenarios. This is because the vertical rigid mode of wheelset & sleeper is most readily excited by a vertical excitation as in this case. Of course, the wheelset flexibility is not responsible for the development of the 6th order, as it is due to a rigid mode in this case.

Thirdly, another development in the 9th order apparent in all the Figures, from 16 to 20, is rather confusing. Because on the one hand, this particular order is also dominant indicating there must be a significant driver, however on the other hand, this order will not change correspondingly with the speed, meaning that it cannot be explained by the frequency-fixed mechanism, as the Equation 6 is not satisfied any more. The reason for the development at this order is not clear, and more investigation is needed.

Finally, the major focus of the work presented here is to check whether any flexible modes of the wheelset can be significantly excited to cause some orders of out-of-roundness to grow, just like the above mentioned rigid mode. Knowing that the first 3 flexible modal frequencies are 50.05 Hz (torsional mode), 71.305 Hz (the first bending mode), and 136 Hz (the second bending mode), the corresponding orders at speed of 70 km/h are 10.1, 14.4, and 27.5 respectively. However, there are not obvious peaks that can be found at the position of these orders in all the Figures from 16 to 20. However, in the case of a curve of 100 m radius illustrated in Section 3.2, the torsional mode of the wheelset is found to be effectively excited to fluctuate the creepages. Based on this finding, a further simulation is carried out to check the effect of the torsional mode on the development of wheel polygonalization in the case of an extreme small radius curved track. The speed is set to 50 km/h, the running distance is set to only 2,355 km to avoid contact detachment in simulation due to very large wear. The excitation is still vertical white noise with amplitude of 0.01 mm. The result is shown in Figure 20 below.

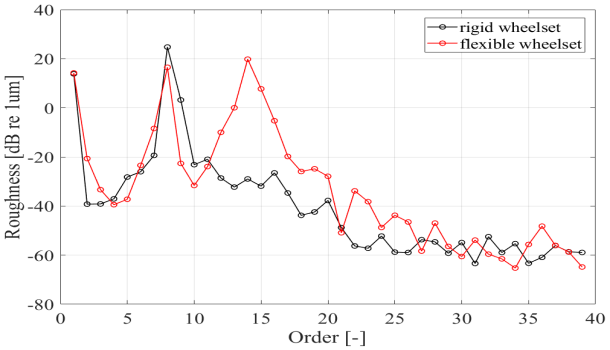

Figure 20 *Development of wheel polygonalization due to white noise on a curved track of radius 100 m (running distance: 2,355 km)*

The order that is expected to develop due to the torsional mode frequency 50.05 Hz at speed of 50 km/h is $50.05/(50/3.6)/(2\times pi\times 0.625) \approx 14$. In Figure 20, it can be clearly seen that, the 14th order of the wheel polygonalization is dominantly developed in the presence of wheelset flexibility, compared to the rigid wheelset. More simulation shows that the Equation 6 is satisfied when the speed changes. So it is confirmed that the

torsional mode of the wheelset is the reason for the formation of the 14th order in this case of an extreme small curve radius. In addition, the development of the 8th order persists because of the vertical rigid mode of wheelset & sleeper, which has been explained before (noting that the speed is 50km/h for this time).

5. Discussion

Currently the popular interpretation of the mechanism of railway wheel polygonalization is that it must be a frequency-fixed issue. Specifically, there must be some structural modes of the vehicle/track dynamic system that can excite the initiation of wheel polygonalization with particular orders at particular speeds. Based on this view, researchers are trying to find the structural mode frequency matching the passing frequency of the dominant orders of wheel polygonalization.

However, even the matched structural mode frequency has been successfully found through experiments [1, 7, 9], why this particular structural mode of the matched frequency can lead to the wheel polygonalization is not testified thoroughly. In other words, among all the structural modes of the vehicle/track system, why some can lead to the wheel polygonalization while others cannot?

A hypothesis is that, if a structure mode can significantly influence the circumferential wheel wear in a periodic way, this structure mode is very likely to contribute to the wheel polygonalization. This is the start point of this research.

6. Conclusion

Based on the assumption that the wheelset flexibility (especially the first bending mode) may have an important influence on the development of railway wheel polygonalization, this work originally aimed to confirm this by simulation. However, the simulation did not provide the expected results. The bending modes of the wheelset were not found to initiate the wheel polygonalization in an obvious way in any cases studied here. Despite this, some key findings of this paper can be summarized below:

1. The wheelset flexibility cannot effectively intensify the normal force in the wheel/rail interface, on the contrary, may attenuate the normal force. Meanwhile, the wheelset flexibility can always lead to the increase of the lateral creepage, however, if the lateral creepage is at a very small level (e.g. 10^{-7}), a proportionally very large increase of the lateral creepage does not contribute to the Archard wear depth. In such cases, the normal force is the sole dominant factor determining the Archard wear depth. Therefore, under this circumstance, if using the Archard wear model to calculate the development of wheel polygonalization, the results cannot reflect the increase of lateral creepage brought about by the wheelset flexibility.

2. If the lateral creepage is at a high level (e.g. 10^{-3}), for example in the case of curved track, the wheelset flexibility can accelerate the growth rate of wheel polygonalization. The range of the orders being accelerated depends on the flexible mode frequencies of the wheelset and the speed. Under this circumstance, the ability of the Archard wear model in predicting the abrasive wear is comparable to that of the wear number.

3. A general trend is that, the smaller the curve radius is, the faster the development of the wheel polygonalization will be, and the more obviously the wheelset flexibility can influence the wear.

4. On extreme small radius curved track (e.g. 100 m), the torsional mode of the wheelset can be effectively excited to dominate the development of wheel polygonalization.

Abstract: A quasistatic FE model for calculating plastic deformations caused by rolling/sliding wheels is introduced. A method for transferring 3D loads to 2D rolling models is shown, and its limitations are demonstrated. The necessary mesh size and rolling length are derived for an efficient modelling of many cycles. Main results of the model are accumulated equivalent plastic strains PEEQ and plastic longitudinal displacements u_x. For similar loads, 2D models calculate severely higher PEEQ and u_x values than the 3D models. Calculations are done for up to 100 cycles and the model is ready for calculating higher, more relevant cycle numbers.

Keywords: finite element modelling; shear deformation; rolling contact fatigue; ratchetting.

1. Introduction

As rails are repeatedly loaded by wheels running over them, a zone of plastically deformed material is produced, which causes residual stresses to evolve [1]. This zone goes from the loaded surface down to a certain depth, which depends on the rail material, the rail geometry and the loads. The near-surface plastic deformations are mainly shear deformations. From metallographic examinations of rail cross-sections, as shown in Fig. 1, those shear deformations can be estimated [2]. They can reach values of up to 2000% with the maximum values reached at the surface.

Those shear deformations play a key role in wear, crack initiation and crack growth (rolling contact fatigue). As a very simple damage model, a critical strain for crack initiation can be defined [2]. Concerning crack growth, the shear deformation causes an anisotropic fracture toughness in the material [3] and thus the deformation lines define directions of preferred crack growth, as described with finite element models in [4]. A model that can reliably calculate proceeding plastic shear deformations in rails depending on the rail material, rail shape and loading for a relevant number of load cycles would be a big step towards understanding wear and rolling contact fatigue. There are some rather empirical and simplified models for describing rolling contact fatigue, but they do not calculate plastic shear deformations, do not consider the full stress- and strain fields, or are limited to simple plastic material laws.

One method for describing plastic shear deformation due to rolling contact with regarding the full stress- and strain fields are quasistatic Finite Element (FE) models. Their main drawback is the high computational cost, because a multiple-step nonlinear analysis has to be performed in each cycle. The authors, however, believe that such a model should be set up to be the basis for new, simplified models. Whereas limited to some hundred load cycles, they will limit the uncertainties due to model assumptions to a minimum.

Figure 1 *Cross-section of a plastically deformed rail (standard rail material after 20,000 load cycles.)*

Using quasistatic FE models to describe the proceeding plastic deformation in rails, three challenges arise:

a) *Multiple load cycles*: In rails, signs of relevant rolling contact fatigue, such as head checks, usually start to occur after several thousand load cycles. Quasistatic FE models as introduced in [5] have typical computation times of about 5 minutes (2D model) and 50 minutes (3D model). It is thus not practical to model the full number of cycles – Instead, a method for extrapolation of deformation should be developed or the working quasistatic models can be used to develop faster methods.
b) *Rolling length:* In the quasistatic FE model, the rolling length should be chosen to only reach a steady-state stress- and strain distribution, because for a longer rolling length, the computational times would be considerably higher. The appropriate rolling length depends on the loads, the plastic

material properties and the number of load cycles. For rails that feature severe plastic deformation due to the rolling contact, an issue concerning both rolling length and the multiple load cycles develops: The plastic deformation in the rail leads to special deformations in the beginning and the end of the contact region. The residual stresses in those regions then effect what happens in the rolling region, particularly the shear deformation.

c) *Material models*: Typical elastic/plastic material models are based on cyclic, uniaxial material tests in the low cycle fatigue (LCF) regime. Two issues arise with the material models when using FE models to calculate rail deformations: I) Providing a material model that is both accurate for small plastic deformations that occur in the first few cycles but also for the regions of high plastic deformation of more than 500% and II) dealing with the fact that occurring stresses in rails are as far away from uniaxial stresses as one can get. The high hydrostatic stresses, combined with shear stresses, cause the plastic deformation. More accurate material models could be based on compression/shear tests.

This work describes a quasistatic FE model of a wheel rolling over a rail. Necessary element lengths and rolling lengths for calculating plastic strains and shear deformations in the rail surface are obtained for a typical wheel/rail geometry and plastic rail properties. With those values, the model is run for 100 cycles to show typical results and computational costs.

2. Quasistatic FE model for rolling contact loading

The quasistatic rolling model considers a wheel and a rail, both modelled with solid finite elements in the implicit formulation. As introduced in [5] and further investigated in 2D models in [6] and [7], the wheel is moved over the rail with a certain creepage (defined according to Carter [8]) while the rail is fixed. Both 2D and 3D models are created with geometries that represent a cylindrical wheel running on a VI 60 E1-type rail.

Fig. 2 shows a schematic of the model geometry. The x-coordinate, the y-coordinate and the z-coordinate are defined in the longitudinal direction, the vertical direction and the lateral direction, respectively. Both wheel and rail are divided into regions of different mesh size, defined by their width values b_i, height values h_i and depth values t_i (in z-direction and not shown in Fig. 2). Those parameters are shown in Fig. 2 for the rail – For the wheel, the same values are used. Table 1 shows the values of those parameters. Note that for the variation of the rolling length, the b_2 and b_3 values are adapted. In the region defined by b_2, h_2 and t_2, the wheel and the rail are divided into different parts that are then connected by surface-based tie constraints. This allows for a more efficient meshing of the geometry. The mesh is refined towards the region where contact between wheel and rail will occur and that lies within b_3, h_3 and t_1. The element lengths for those regions are stated in Table 1. In the region of contact of the rail, the element edge length is reduced towards the surface with a bias factor of 1.5.

The grey lines in Fig. 2 are rigidly connected to a reference point in the wheel center. All displacements and forces of and on the wheel can be applied in this reference point. The bottom area of the rail is fixed. The x-displacement is constrained in the outer areas in longitudinal direction of the rail. In the 3D model, a half model with z-symmetry is defined. The outer side (z-direction) of the 3D-rail is not constrained in lateral direction. Between wheel and rail, contact is modelled with a *penalty* algorithm. The coefficient of friction is set to 0.5 to represent dry wheel-rail contact.

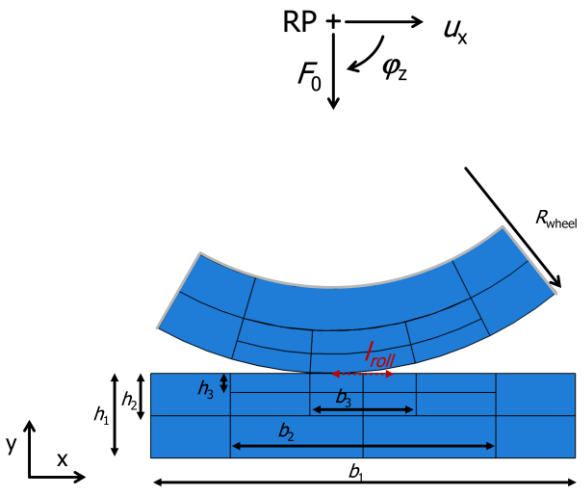

Figure 2 *Geometry and parameters of the wheel/rail model.*

The wheel is brought into contact with the rail by a certain vertical displacement and then pressed with a certain *normal load* onto a rail. In the next step, the wheel runs over the rail for a *rolling length* l_{roll} with a certain creepage c. The angular movement φ_z of the wheel can be calculated from the wheel radius R_{wheel}, l_{roll} and c as:

$$\varphi_z = \frac{l_{roll}(2+c)}{R_{wheel}(2-c)}$$

To model additional cycles, the wheel is lifted from the rail, moved back, and can then be pressed again onto the rail and so on. Note that several small solutions steps have to be calculated in one cycle to model the plastic deformations. The number of those steps depends on the *mesh size* and the *rolling length*.

Table 1 *Geometry parameters in the model. The values marked with * are changed with varied rolling length and mesh size.*

Parameter name	***Value 1***	***Value 2***	***Value 3***
width b [mm]	400	250*	100*
height h [mm]	80	40	18
depth t [mm]	35	22	14
el_{size} [mm]	10	4	2*

The key results of the model are contact stresses, i.e. the

contact pressure p and the traction stresses τ, the plastic deformations (the accumulated equivalent plastic deformations PEEQ will be shown) and the longitudinal displacements u_x associated with the plastic shear deformations.

2.1. Material models

Since the interest of the study lies in the rail's deformation, the wheel is modelled with linear elastic material behavior (Young's modulus and Poisson's ratio of 210 GPa and 0.3, respectively). The rail can have any plastic material behavior, e.g. with a *Chaboche*-type hardening law [5], but also more sophisticated models such as the one presented in [9]. In this study, the same *Chaboche*-type hardening law for standard rail material as in [5] is used. The Young's modulus and Poisson's ratio for that material are 205 GPa and 0.3, respectively. The initial yield stress σ_y, the Q_∞ and b are set to 320 MPa, -40 MPa and 0.04, respectively. Table 2 shows the C_i and γ_i values for the 6 backstresses defining the material's kinematic hardening.

Table 2 *Parameters for the kinematic hardening of the used standard rail material model.*

C_i [GPa]	γ_i [-]
350	5000
80	1000
15	150
10	20
8	20
0.19	0.01

2.2. Basic load case and 2D model setup

A basic load case for the model is selected to mimic typical loads that can be applied in experiments at the wheel-rail test rig described in [10]. A simple case with a wheel (radius of 460 mm), featuring a cylindrical running surface, rolling over the top of a UIC 60 E1 rail head (head radius of 300 mm) is selected. The applied normal load is set to 150 kN. No angle of attack is set. A creepage of either 1.5% (accelerating) or 0% is applied. For a creepage of 0%, the friction coefficient between wheel and rail is set to 0 to not obtain any traction stresses in the contact to model free rolling. For a creepage of 1.5%, the coefficient of friction of 0.5 is used. With the Hertz formulas (as described for the general case in [11]), the contact patch half lengths a_0 and b_0 and the maximum contact pressure p_0 for this case are calculated as:

a_0 8.198 mm
b_0 6.167 mm
p_0 1417 MPa

To model this case with an elliptical contact patch in a 2D model, a cut through the contact patch is made in longitudinal direction (getting a_0 and p_0) and a wheel radius and normal load in the 2D model is defined that create a contact patch with the same a_0 and p_0 in an lastic calculation. Note that the wheel radius for the 2D model can be different from the actual 3D radius. To obtain the same a_0 and p_0 values of the 3D model in a 2D model, the necessary wheel radius R_{2D} (assumption of flat rail) and load per thickness f_{2D} can be calculated with the simplifications introduced in [12] as:

$$R_{2D}(a_{3D}, p_{0,3D}, E, \nu) = \frac{0.2496\ a_{3D} E}{p_{0,3D}(1-\nu^2)}$$

$$f_{2D}(a_{3D}, p_{0,3D}) = 1.569\ a_{3D} p_{0,3D}$$

With those formulas, the R_{2D} and f_{2D} values for the above load case are calculated for use in the 2D models:

R_{2D} 333.3 mm
F_{2D} 18222 N/mm

When severe plastic deformations occur, there might be significant differences between the stress- and strain results in the longitudinal cut of the 3D model and the results of the 2D models. This issue will be addressed in the following sections.

3. Results and discussion

Fig. 3 shows typical results obtained with the FE models for the 2D model with standard rail material, one cycle of loading and a rolling length l_{roll} of 60 mm. The wheel rolls from left to right with an accelerating creepage of 1.5%. Fig. 3a shows the field of the von Mises stresses when the wheel has rolled for half of l_{roll}. Below, see Fig. 3b, the contact stresses, i.e. contact pressure p and traction τ, are shown for that instance. The contact pressure curve is not symmetric due to the creepage and plastic deformations in the rail. Maximum p values of 1210 MPa arise. Fig. 3c and 3d show plastic strains (accumulated equivalent plastic strains PEEQ) and deformations (displacement in x-direction u_x) after the wheel has rolled over the rail once, and has been lifted off. The highest PEEQ values arise at the rail surface with maximum values of 4%. The u_x values are due to plastic shear deformation and reach maximum values of 0.23 mm. The maximum values for each longitudinal position are plotted in Fig. 3d: Opposite to the u_x values, the PEEQ field has a region of nearly uniform values over the length.

Those results of Fig. 3c already show one issue of the cyclic rolling models: Due to the plastic shear deformation, there evolves a small hill left of the region where the wheel rolls on the rail and a dent right to that region. Those deformations also cause stress fields that are not uniform over the rolling length and affect the plastic deformations that are calculated in the model. The next sections will show, if uniform and reliable deformation fields can be reached with bigger *rolling lengths*.

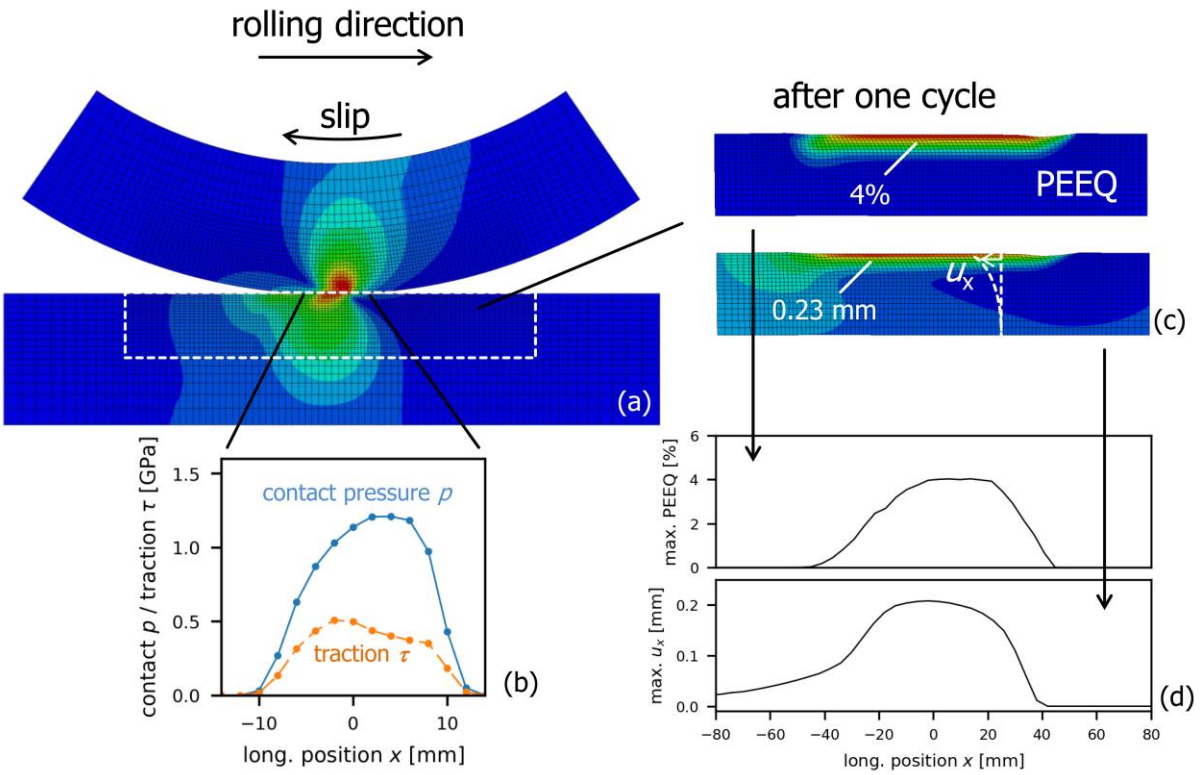

Figure 3 *Schematic results of the model(2D, c value of 1.5%, standard rail material): a) contour plot of the stress field as the wheel has rolled for half the rolling length, b) contact pressure p and traction as the wheel is running over the rail, c) contour plot of accumulated equivalent plastic strains (PEEQ) and displacements in longitudinal direction u_x after the wheel has run one time over the rail and d) the maximum values of PEEQ and u_x along the longitudinal position.*

3.1. Mesh size study

For typical contact patches of wheel-rail contact, the necessary mesh size for obtaining accurate results in the FE model has to be evaluated. This is done in this section with a rolling length l_{roll} of 60 mm for both elastic and standard rail material, 2D and 3D models and slip of 0% and 1.5%. Furthermore, the method for simplifying a 3D contact loading by a 2D contact model described in section 2.2 can be evaluated: The 2D model is built up to have the same contact patch in the Hertz solution (elastic material behavior) as the 3D model, but there might be some differences for plastic material models.

Fig. 4 plots the contact pressures p and traction stresses τ as the wheel has rolled half of l_{roll} over the rail for the

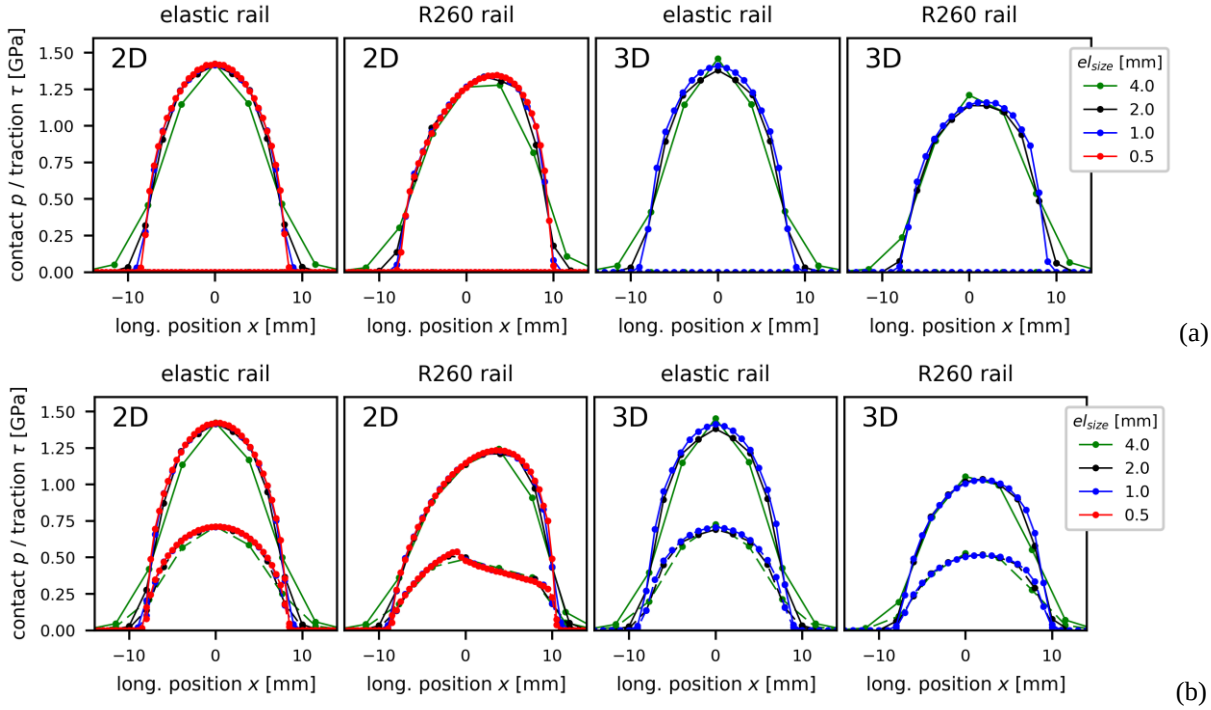

Figure 4 *Contact patches with contact pressure p and traction stress τ for the 2D and 3D model, different mesh size and a) an applied slip of 0% and b) an applied slip of 1.5% (accelerating).*

first time. Fig. 4a shows the results for a slip of 0% and a friction coefficient of 0. Accordingly, the τ values are 0.

The different curve colors indicate different mesh sizes (varied between 4 mm and 0.5 mm in the 2D model and between 4 mm and 1 mm in the 3D model). In the regions of high contact pressures p, a mesh size of 2 mm already calculates the p curve quite well. However, there are some slight differences between the 2 mm elements and 1 mm elements in the 3D model. In the outer regions of the contact patch, there are bigger differences between the mesh densities: In all cases, the contact patch is bigger in size for the bigger elements. This is the case also for the contact patch results for a creepage of 1.5%, see Fig. 4b.

There is good agreement between the p curves in 2D and 3D for a creepage of 0% and the elastic rail, because the 2D model was set up to fit in that case. For a creepage of 0% and the standard rail material, however, the maximum p values are by 78 MPa lower than for elastic material (which reaches max. p values of 1424 MPa). For the models with a creepage of 1.5%, this effect is more distinct, see Fig. 4b: maximum p values for standard rail material are with 1233 MPa by 189 MPa lower than maximum p values of the elastic rail material (1422 MPa).

Concerning the traction stresses of the model with a creepage of 1.5%, the 2D and 3D results for the elastic rail material fit well. On the other hand, the traction stresses with a c value of 1.5% differ significantly for the standard rail material: p is considerably lower in the 3D model (1030 MPa) than in the 2D model (1233 MPa) and the maximum τ values are approximately the same, but have a different shape. This difference between plastic contact patches of the 2D and 3D model already indicate that plastic deformations in 2D models are higher than in the 3D models.

Fig. 5 shows maximum accumulated equivalent plastic strain PEEQ and maximum longitudinal displacements on the surface u_x for different mesh sizes after one cycle. Curves for both 2D and 3D models can be compared for a creepage of 0% and a creepage of 1.5% in Fig 5a and Fig. 5b, respectively. Note that the scales for the two c values are different, because the 1.5% slip produces higher plastic deformations.

With decreasing element size el_{size}, maximum PEEQ values generally increase, except for the 3D model and a c value of 0%, where the highest PEEQ values are calculated for an el_{size} value of 4 mm. This PEEQ increase with finer mesh is more pronounced for the model with a c value of 1.5%. This can be explained by the steep gradient of the plastic deformation towards the surface. For calculating the u_x values, already a mesh size of 2 mm seems to be sufficient: above this el_{size}, the u_x values do only change slightly. It can be seen that the 3D model has long regions with a uniform level of maximum PEEQ and u_x values.

For the curves with a creepage of 1.5%, the PEEQ values of the 2D and the 3D models differ only little, but the u_x values differ clearly (by a factor of about 2). The reason for this difference is the different representation of material in the lateral direction of the rail: For the 2D model, there is no material in the lateral direction which is not loaded, and deforms accordingly. For the 3D model, there is some material in the lateral direction outside the contact patch, which hinders the shear deformation of the rail surface. This can also explain the more uniform results in the 3D model: The beginning and end region of the rolling length play less of a role.

3.2. Rolling length study

To study the influence of the rolling length l_{roll} on the plastic deformations, l_{roll} is varied and obtained results

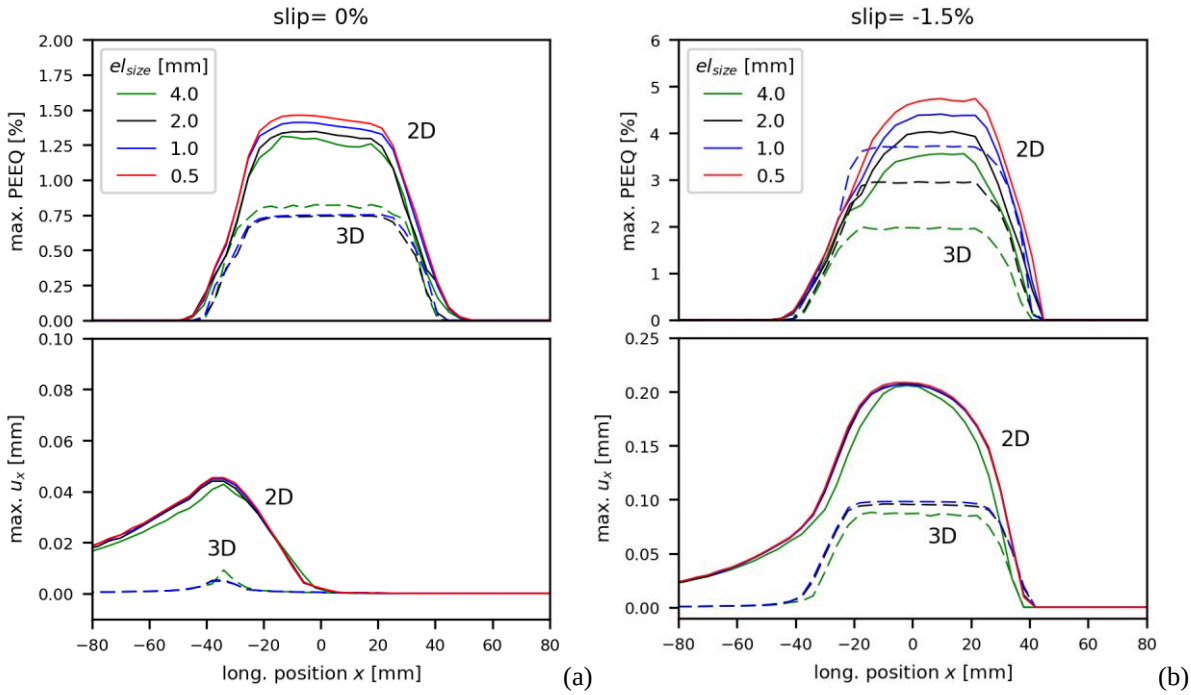

Figure 5 *Maximum accumulated equivalent plastic strain PEEQ and maximum longitudinal displacements of rail surface u_x for different mesh sizes and a) slip of 0% and b) slip of 1.5% (accelerating). The solid lines indicate results for the 2D model and the dashed lines results for the 3D model.*

are compared. This is done for standard rail material, a creepage of 1.5%, an element edge length of 2 mm and 5 cycles of loading. Three l_{roll} values are compared: 60 mm, 120 mm and 200 mm. Because the contact region should lie in the region with the smallest element size, the width values are changed for the higher rolling lengths, see Table 3.

Table 3 *Chosen rolling lengths and corresponding width values in the model.*

rolling length l_{roll} [mm]	width b_1 [mm]	width b_2 [mm]	width b_3 [mm]
60	400	250	100
120	400	250	160
200	400	300	240

Fig. 6 shows PEEQ and u_x results of the rolling length study: The different colors indicate the cycle number (from 1 to 5) and the line style the different rolling lengths (solid, dashed and dotted for 60 mm, 120 mm and 200 mm, respectively). Fig. 6a shows results of the 2D model. For the first cycle (black curves), the PEEQ values of the 2D model have a region of constant values, which is short for a l_{roll} of 60 mm, but reaches the same max. PEEQ values as for the bigger l_{roll} values. For higher cycles, the PEEQ values of the 2D model become less uniform and develop a maximum in the end (right side) of the rolling region. Concerning the u_x values, the 2D model results show a clear dependence on the rolling length, which becomes more distinct with increasing load cycles. This shows that at least for the investigated rolling lengths, the 2D model always has a dependence of u_x values on the l_{roll}. To obtain accurate results for 2D rolling contact problems with cyclic plastic deformations and slip, the full rolling length should thus be modelled.

For the 3D model results shown in Fig. 6b, a uniform level of both PEEQ and u_x values is reached for all rolling lengths. Their maximum values also do not differ for the investigated rolling lengths. This shows that the 3D model calculates accurate plastic deformations already with a rolling length of 60 mm. However, the regions of uniform PEEQ and u_x become smaller with increasing cycle numbers: For many cycles, it should be checked that such a uniform region still exists.

3.3. Towards realistic cycle numbers

Since it takes some thousand cycles in the test rig for RCF damage to evolve, the model should be able to calculate considerably more than 5 cycles. The 2D and 3D model are thus set up with 100 cycles of loading, a el_{size} of 2 mm, a slip of 1.5% and a l_{roll} of 120 mm for the 2D model and 60 mm for the 3D model to show trends and possible issues for higher cycle numbers. Calculation times are the main disadvantage of such FE models to describe high cycle numbers, but with those parameters one cycle took 15 min to run for the 3D model on 4 CPUs and 10 min to run for the 2D model on 2 CPUs. The bigger l_{roll} in the 2D model was chosen because 2D models show less uniform plastic deformation over the length.

Fig. 7a shows maximum PEEQ and u_x results over the cycle numbers for the 2D model (magenta curve) and the 3D model (black curve). The 2D model shows a nearly linear increase in the PEEQ values over the cycles with considerable higher plastic deformations than the 3D model. The difference between the u_x values between the 2D and 3D model is even bigger: While the maximum shear displacements u_x in the 2D model reach 11.6 mm after 100 cycles, the max. u_x in the 3D model reach only 0.72 mm. Fig. 7b plots the curves for the 100 cycle 3D model with adapted scales to show the development of PEEQ and u_x over the cycles. It shows that the u_x increment is gradually decreasing with the cycle numbers, but does not reach a linear region which could be easily extrapolated.

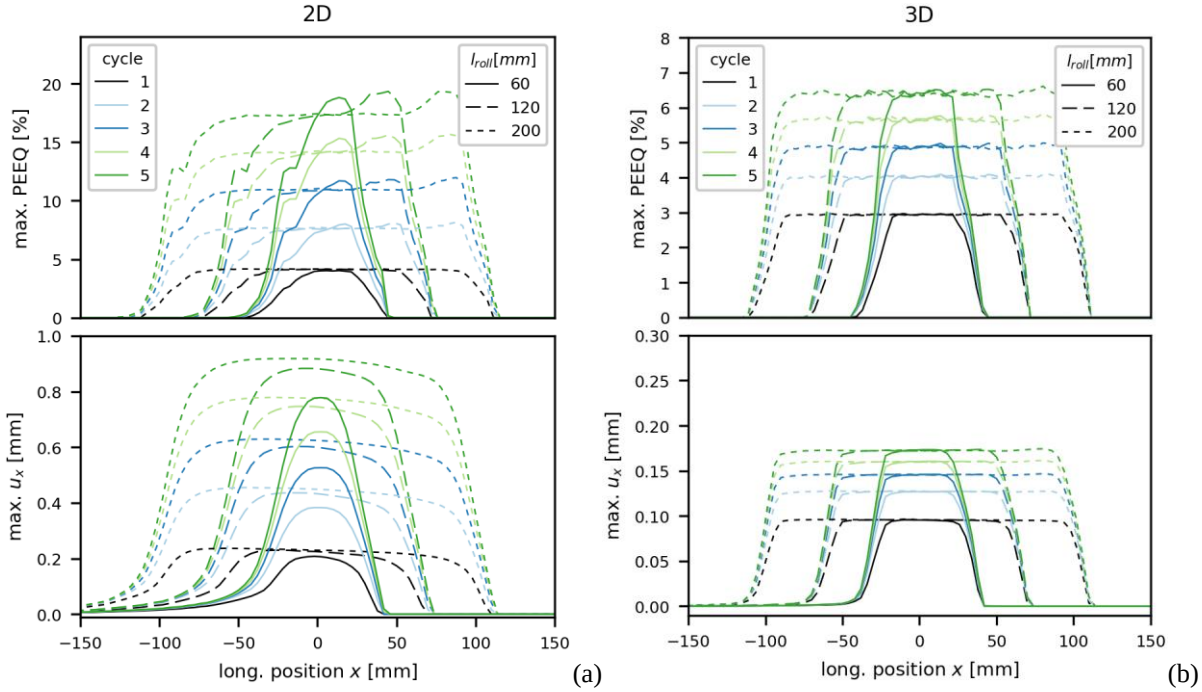

Figure 6 *Maximum accumulated equivalent plastic strain PEEQ and maximum longitudinal displacement of rail surface u_x for 5 cycles of loading and a slip of 1.5% (accelerating) for a) the 2D and b) the 3D model. The solid, dashed and the dash-dotted lines indicate rolling lengths of 60 mm, 120 mm and 200 mm, respectively.*

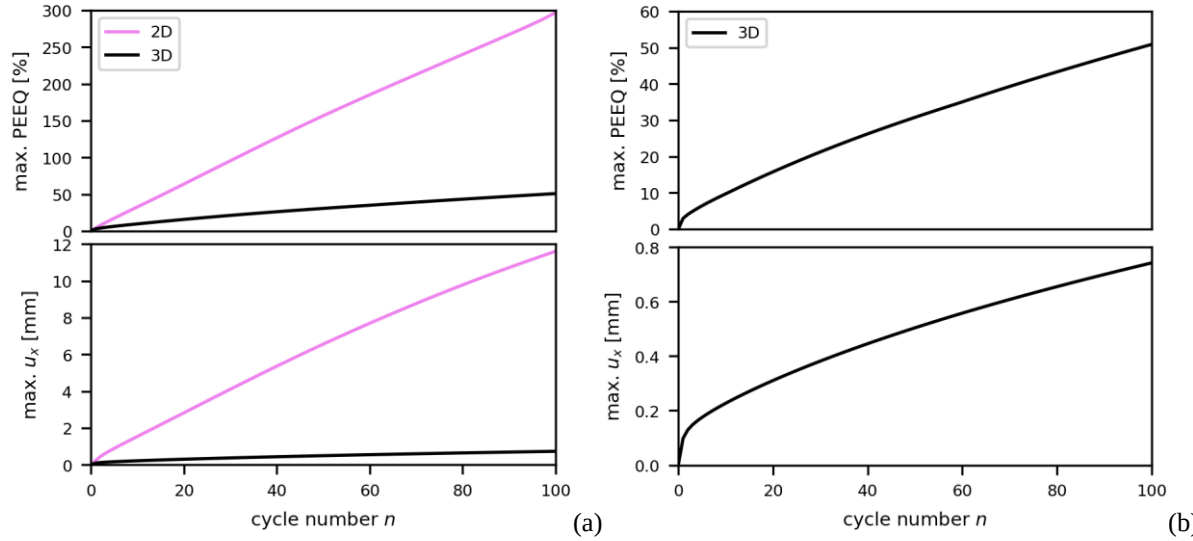

Figure 7 *Maximum accumulated equivalent plastic strain PEEQ and maximum longitudinal displacements of rail surface u_x for the model with 1.5% slip plotted over the cycle number n for a) the 2D & 3D model and b) only the 3D model with adapted limits.*

4. Conclusions

A quasistatic 2D and 3D model for a cylindrical wheel running on a rail head is presented. It can calculate cyclic plastic deformations in the rail due to a wheel rolled over it for a rolling length l_{roll}. A method for transferring the 3D loads to a 2D model is introduced. For realistic wheel-rail contact patches and a creepage of 1.5% (accelerating), the following conclusions can be drawn:

- A mesh size of 2 mm is sufficient for the calculation of contact patches and plastic shear displacements u_x. The accumulated equivalent plastic strains (PEEQ), however, increase with finer mesh sizes.
- The 2D model calculates PEEQ and u_x values that depend on the rolling length and are considerably higher than the results of the 3D model. This questions the usability of 2D models for a faster representation of the 3D contact loads in such models.
- The 3D models develop a zone of rather uniform PEEQ and u_x values and can thus be efficiently used for cyclic calculations.
- It was possible to calculate 100 cycles of loading for the 2D model and the 3D model in less than 24h on a common computer.
-

These 3D models are with a computation time of about 15 min/cycle (4 CPU machine) ready for the use in models that use more sophisticated material models and can be compared to experimental results of the wheel-rail test rig. A then validated model that can calculate the plastic shear displacement of rail regarding the full stress/strain fields will help to understand mechanisms of crack initiation and wear in rails.

Abstract: The benefits of using premium pearlitic rail steels in heavy haul operations may be offset by the potential occurrence of localized degradation at flashbutt welds due to the discontinuous nature of both microstructure and mechanical properties between the heat-affected zone and the parent rail. In this study, the influence of the width of the softened zone on ratcheting behaviour of flashbutt welds has been investigated for three rail steels. The results show that both maximum ratcheting strain and maximum ratcheting strain rate can be significantly reduced for all three rail steels by narrowing the width of the softened zones. This indicates that the performance of flashbutt welds can be improved by reducing the width of the softened zones.

Keywords: Flashbutt weld; Softened zone; Ratcheting behaviour; Premium pearlitic rail steels; Finite element analysis.

1. Introduction

Rail degradation due to wear and rolling contact fatigue (RCF) is a major consideration in heavy haul rail systems due to combination of high axle loads and annual haulage rates. Premium rail steel grades, with either eutectoid or hypereutectoid carbon content and hardness levels of 380-420 HB, are commonly used under such conditions in order to mitigate rail degradation and increase rail life. An additional benefit of these rail steel grades is the potential to extend rail grinding cycles. However, it has been found that these benefits can be offset by the potential occurrence of localised degradation at the rail welds [1-3].

The two welding techniques currently used in heavy haul railway are electric flashbutt welding and aluminothermic welding. Of these, aluminothermic welds are generally more likely to suffer localised damage at the running surface as the width of the softened zones is larger than that of flashbutt welds. Aluminothermic welds are also more sensitive to failure from fatigue defects, which develop in the weld collar [4], and for these reasons their use in heavy haul rail systems is limited.

Flashbutt welding can be considered as a thermo-mechanical process which does not require any filler material. The welding process consists of several major stages - preheating, flashing, upsetting, trimming of excess weld and cooling. During the heating, upsetting, and cooling processes, different regions in the heat-affected zone (HAZ) may experience different thermal histories. In addition, the region surrounding the bond line is subjected to plastic deformation during the upsetting or forging stage. Therefore, the finished weld contains a range of microstructure and resulting hardness levels within HAZ.

Of particular interest to researchers and railway operators is the degradation behaviour of the softened zones, which are normally located away from the bond line at the boundary between the parent rail and the HAZ, as shown in Figure 1. The metallurgical characteristics of the softened zones depend on the composition of the parent rail in combination with welding parameters such as heating rate, upsetting distance and cooling rate.

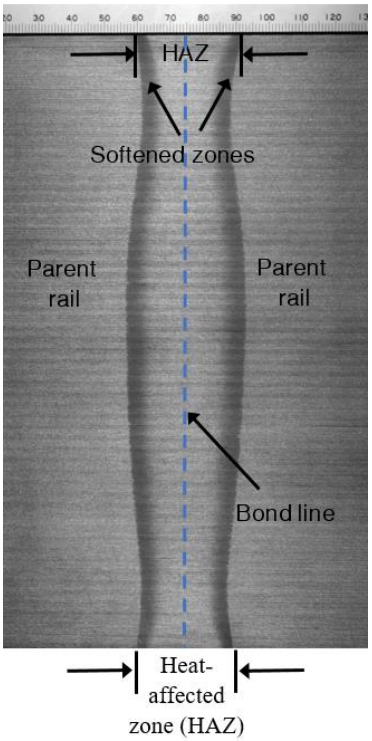

Figure 1 *Appearance of visible HAZ at rail centreline*

The hardness within the softened zone is generally lower than that of the parent rail and also other regions within the HAZ, as shown in Figure 2. In particular, the

minimum hardness of the softened zone in flashbutt welds in premium pearlitic rail steels can be up to 30 % lower than that of the parent rail, although the width of the softened zone may vary depending on the actual welding conditions. The softened zone and the parent rail therefore differ in both microstructural characteristics and mechanical properties [1, 5]. It has also been found that the softened zone is more sensitive to the initiation and growth of RCF cracks [1, 6, 7]. An example of RCF damage at a flashbutt weld in hypereutectoid rail is shown in Figure 3(a). Failure to address this damage at an early stage can lead to the development of transverse defects, Figure 3(b), increasing the risk of rail failure.

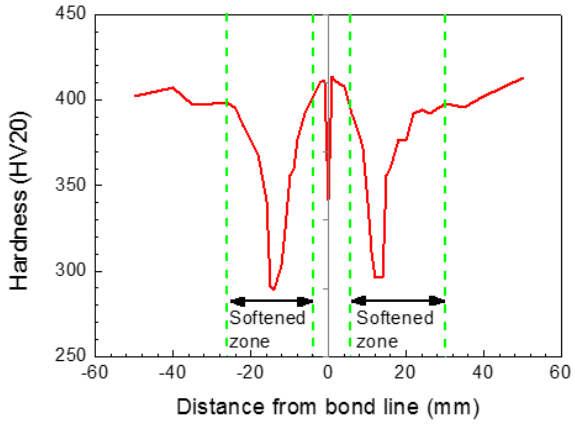

Figure 2 *Hardness distribution at 5 mm below running surface*

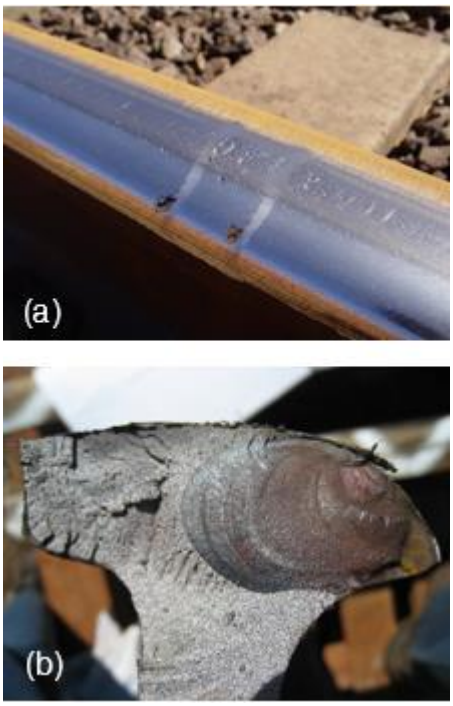

Figure 3 *(a) Localised spalling at flashbutt weld in hypereutectoid rail; (b) transverse defect at HAZ of flashbutt weld [1, 8]*

Some recent studies have been carried out to improve the reliability and performance of flashbutt welds by implementing new technologies into the welding procedures. These include additional thermal treatments to increase surface hardness levels in the softened zones [3], and altering the welding conditions to reduce the width of the softened zones [9].

During wheel-rail contact, the rail is subjected to cyclic loading and the running surface is subjected to combined rolling/sliding contact with high contact stresses. It has been found that cyclic stresses and plastic deformation are the major factors influencing the degradation processes of the rail [10]. If the wheel-rail contact conditions result in a stress level above the plastic shakedown limit or ratcheting threshold, new plastic deformation will occur and accumulate, i.e. ratcheting occurs, under each loading cycle [11]. When the ratcheting strain reaches the limiting ductility of the material, it will fail resulting in the initiation of RCF damage [11-14]. The ratcheting behaviour therefore plays a key role in causing rolling contact failure of the rail. For this reason, it is essential to evaluate the ratcheting performance of both the parent rail and the flashbutt welds under the service conditions in order to improve the performance of the welds and reduce the risk of defect development. However, prediction of the ratcheting behaviour at rail welds is more complex than that for the parent rail, and requires:

a) A satisfactory material model which takes into account the variation in material strength and the microstructure-dependence of these parameters; and
b) A wheel-rail impact model incorporating the dynamic response of track and vehicle components to a longitudinal irregularity which may develop at the rail surface, and the wheel-rail contact conditions.

The influence of longitudinal profile or geometry at the running surface of rail welds on dynamic loading has been extensively studied [e.g. 15, 16].

Wen et al [7] utilised a coupled vehicle-track interaction model, in conjunction with a single yield stress value to represent the weld, to estimate the extent of plastic deformation at welds under high speed operations. Li et al extended this approach, using different yield strength values for the weld metal and heat-affected zones [17]. More recently, Sichani and Bezin [18] have proposed a general methodology for simulating the long-term surface geometry that arises from the hardness differential across welds. This approach incorporates the Archard wear model, which is based on material hardness, and the dynamic vehicle-track interaction. Application of this approach to aluminothermic welds has shown that limiting the length over which the hardness varies in welds reduces the extent of surface degradation.

The approaches outlined above are aimed at estimating the extent of plastic deformation or wear based solely on either yield strength or hardness, and are therefore reliant on the accuracy of the material models used. In addition, they do not take into account any differences in the cyclic deformation (ratcheting) behaviour of the respective regions in rail welds at higher contact stress levels.

In the current study, a constitutive cyclic plasticity material model previously developed by the authors to examine the ratcheting performance of three high

strength pearlitic rail steels [19, 20] is used to investigate the influence of different welding parameters on the ratcheting behaviour of flashbutt welds in these rail steels. The outcomes of this study can then be applied to modify or develop improved flashbutt welding techniques for high axle load conditions

2. Methodology

In this study, the cyclic rolling contact between wheel and the rail weld was simulated by the finite element method, which has been widely applied to numerically simulate wheel-rail rolling contact problems due to its convenience and cost-effectiveness compared to field tests.

2.1. Constitutive Cyclic Plasticity Material Model

The reliability and accuracy of quantifying plastic deformation of a material under cyclic loading from finite element analysis depends on the capability of the constitutive cyclic plasticity material model. The constitutive cyclic plasticity material model developed by the authors [19, 20] was based on the experimental results obtained from both uniaxial and bi-axial compression-torsion cyclic loading tests. It has been shown that the developed material model can reasonably and simultaneously describe both uniaxial and non-proportional multi-axial ratcheting behaviour of the tested pearlitic rail steels compared to other general constitutive material models [20, 21]. This was done by coupling a non-proportional multi-axial parameter into isotropic softening and kinematic hardening rules.

In the current study, an assumption was made to define the material properties of the rail weld based on those of the parent rail. As described in the introduction, flashbutt welding does not require any filler material during the welding process. The formation of the softened zones within the HAZ at the flashbutt weld is therefore due to thermo-mechanical processing of the parent rail. Therefore, the current study assumed that the ratcheting behaviour of the rail weld is similar to that of the parent rail. However, this approach may not take into consideration any variation in ratcheting behaviour that arises from the distinct microstructural changes present in the HAZ of rail welds [1]. A more precise conclusion on the ratcheting behaviour of the flashbutt weld can be drawn once a systematic experimental program on samples from the respective zones of flashbutt welds is completed as part of future work.

Using the above approach, the developed constitutive cyclic plasticity material model was applied to describe the ratcheting behaviour of both the parent rail and the rail weld in the current study.

2.2. Prediction of Pressure Distribution and Longitudinal Traction Distribution

The use of Hertzian contact pressure in the simulations of wheel-rail rolling problems can lead to discrepancies between the numerical results and the reality due to the limitations and assumptions employed, i.e. linear elastic material properties and half-space assumptions [22, 23]. According to this, non-Hertzian contact pressure distribution, which is not restricted by those limitations and assumptions and can provide a more realistic prediction on the contact patch, is applied in the current study.

The non-Hertzian contact pressure distribution was obtained from a separate three-dimensional quasi-static wheel-rail contact simulation using finite element analysis. The resulting non-Hertzian contact pressure distribution was then used to represent the vertical load applied to the rail during the wheel-rail cyclic rolling contact simulations. Based on the non-Hertzian contact pressure distribution, the longitudinal tangential traction was then estimated from Carter's theory [24].

2.3. Investigation of Ratcheting Behaviour on Rail Weld

Under wheel-rail cyclic rolling contact conditions, the components of both normal and shear plastic strains accumulate, i.e. ratcheting occurs. Therefore, the effective plastic strain ε_{eff}^{p} in each loading cycle can be applied to investigate the ratcheting behaviour of both the parent rail and the rail weld. The effective plastic strain is defined in terms of the individual components of both normal and shear plastic strains by following the analogy with multi-axial fatigue analysis [19, 25, 26]. The ratcheting strain in each loading cycle under multi-axial cyclic loading conditions in the rail head due to wheel-rail cyclic rolling contact can then be represented by the maximum effective plastic strain $\left(\varepsilon_{\mathrm{eff}}^{\mathrm{p}}\right)_{\max}$ obtained in each cycle as follow,

$$\varepsilon_{\mathrm{r}} = \left(\varepsilon_{\mathrm{eff}}^{\mathrm{p}}\right)_{\max} = \left(\sqrt{\frac{2}{3}\boldsymbol{\varepsilon}^{\mathrm{p}}:\boldsymbol{\varepsilon}^{\mathrm{p}}}\right)_{\max} \quad (1)$$

where $\boldsymbol{\varepsilon}^{p}$ is the plastic strain tensor.

The ratcheting strain rate $d\varepsilon_{\mathrm{r}}/d\mathrm{N}$ is then represented by the rate of maximum effective plastic strain $d\left(\varepsilon_{\mathrm{eff}}^{\mathrm{p}}\right)_{\max}/d\mathrm{N}$, which can be applied to estimate the crack initiation life of the rail steel in the rail head if a stabilised maximum ratcheting strain rate is obtained. As this paper mainly focuses on the influence of welding parameters on the ratcheting behaviour of the rail weld, prediction of the crack initiation life within the rail weld is not covered.

3. Finite Element Analysis

3.1. Numerical Model

The commercial finite element software package, Abaqus [27], was applied to simulate the wheel-rail cyclic rolling contact conditions. Due to the nature of three-dimensional rolling contact between the wheel and the rail, no symmetry can be found. Therefore, a full three-dimensional finite element model was developed as shown in Figure 4.

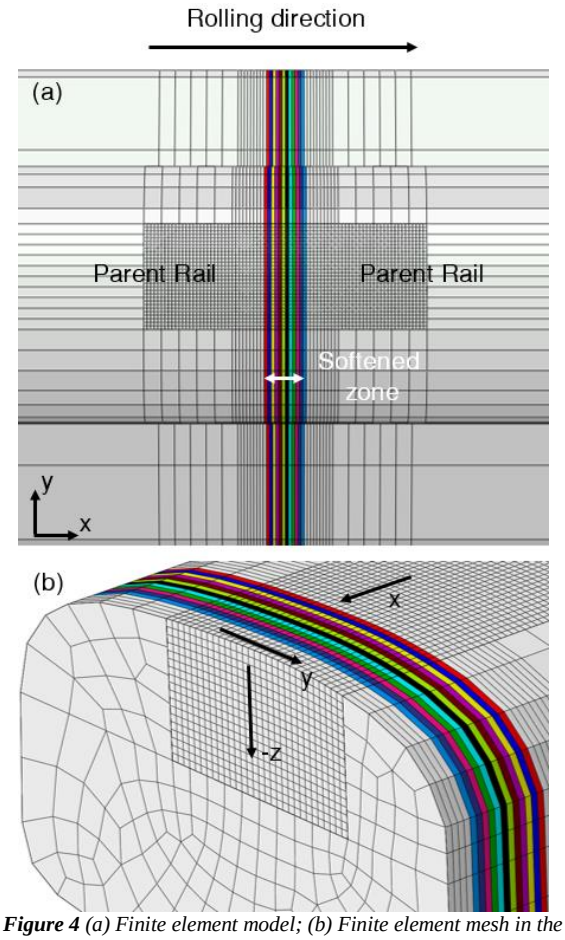

Figure 4 *(a) Finite element model; (b) Finite element mesh in the contact region for simulating wheel-rail cyclic rolling contact on the parent rail and the flashbutt weld.*

The three-dimensional rail model was generated by extruding the two-dimensional rail transverse profile of a flat bottom rail, which has a crown radius of 254 mm and gauge radius of 31.75 mm. This rail model represents 700 mm of a track and is divided into three parts, the fine mesh contact zone, fine mesh region and the coarse mesh region. The fine mesh contact zone is located at the top of the rail head in the weld HAZ, and is generated for capturing the high stress and strain gradients near the rolling contact surface. The fine mesh contact zone incorporates 30 mm width of the top of the rail head, which is three times larger than the contact patch, and is defined to a depth of 18 mm. The length of the fine mesh region is 80 mm along the rolling direction.

To simulate wheel-rail cyclic rolling contact on both rail and rail weld, the fine mesh region was partitioned into several sections; the sections highlighted grey in colour in Figure 4 represent the parent rail, while the other sections represent the softened zones with variations of hardness and mechanical properties. Following a validation stage in which both softened zones and a single softened zone were modelled, a single softened zone only was considered in the current study in order to reduce the computational costs.

A structural mesh was then applied, resulting in 43200 elements and 47709 nodes within the fine mesh contact zone. The surface-based mesh tie constraint was applied to connect the three parts. The entire finite element model consists of 51826 C3D8 elements and it has 353652 degrees of freedom in total.

3.2. Flashbutt Weld Parameters and Material Properties

Three premium pearlitic rails steels, which are commonly used in heavy haul railway operations in Australia, were considered in the current study. They are a low alloy heat-treated (LAHT) grade with carbon content of 0.8 % and two hypereutectoid grades with carbon content of 1 % (HE1) and 0.82 % (HE2), respectively. These three rail steels have similar nominal surface hardness of 400 – 420 HV.

Following the assumptions made in Section 2.1, the deformation behaviour of both parent rail and softened zone under cyclic rolling contact conditions are described by the constitutive cyclic plasticity material model recently developed by the authors.

The material parameters required by the material model for parent rail of these three rail steels were those calibrated from experimental data as provided in [20]. In the absence of experimental data for different regions within the weld HAZ, the material parameters that are essential for modelling the ratcheting behaviour at the softened zone was then estimated based on the hardness and yield strength differentials between the parent rail and the flashbutt weld.

Based on hardness measurements on a flashbutt weld in a LAHT rail steel [1], the width of softened zone Ws is about 12 mm. The hardness distribution for the 12 mm case was obtained from the measurement in [1] as shown in Figure 5. It is found that hardness of the softest region within the weld HAZ is about 24 % lower than that of the parent rail.

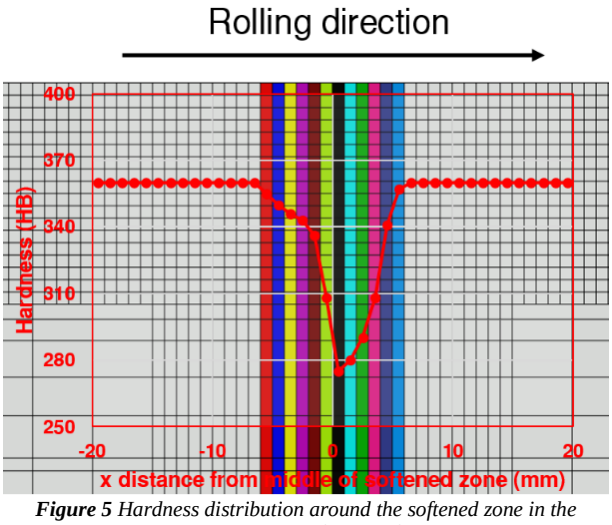

Figure 5 *Hardness distribution around the softened zone in the numerical model with W_s of 12 mm for LAHT steel.*

For the purpose of comparing the ratcheting performance between the three rail steels, the ratio of measured hardness differential between different regions within the weld HAZ and the parent rail for LAHT steel is applied to the other two rail steels. The hardness of the parent rail

of HE1 and HE2 steels were measured as 412 HB and 392 HB, respectively, in the previous study.

To investigate the influence of width of the softened zone on the ratcheting behaviour of rail weld, five cases representing softened zone widths of 12 mm; 10 mm; 8 mm; 6 mm and 4 mm were considered for each rail steel. The hardness distribution for different widths of softened zone were estimated by averaging the measured hardness distribution of the 12 mm case for each rail steel without changing the minimum hardness within the softened zone. Figure 6 shows the hardness distribution for all the cases considered in the current study.

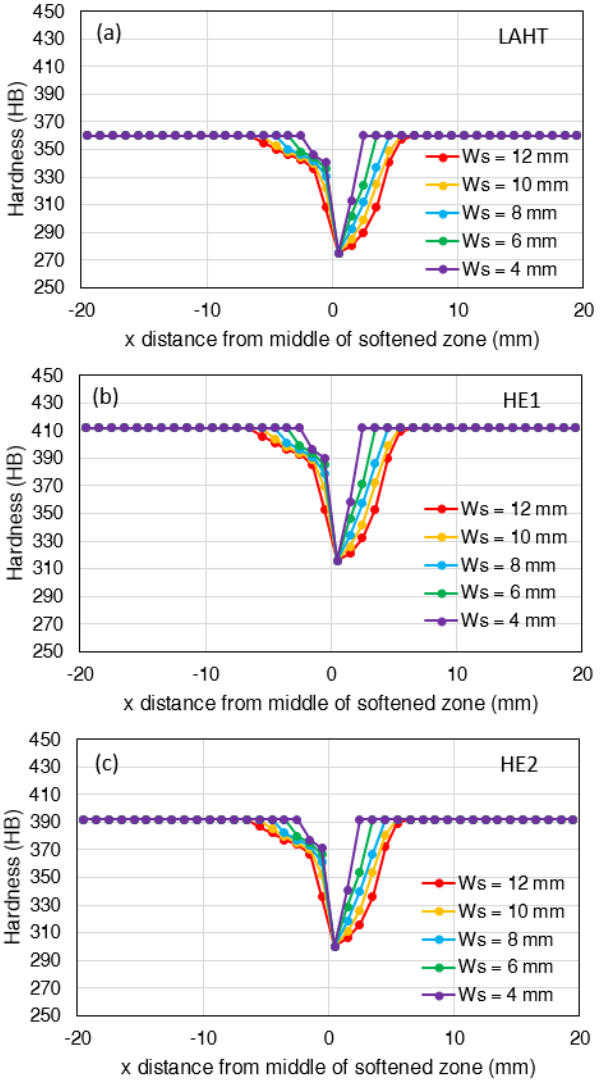

Figure 6 *Comparison of hardness distribution for different W_s for (a) LAHT; (b) HE1; and (c) HE2 steel.*

3.3. Loading and Boundary Conditions

To simulate the wheel-rail cyclic rolling contact problems, both normal pressure distribution and tangential traction distribution were applied on the rail surface. The non-Hertzian contact pressure was applied to represent the normal pressure distribution.

The interfacial friction plays a role in the normal contact only if two non-conformable bodies with dissimilar elastic properties are brought into contact. However, there is only a small loss of precision if the normal pressure is determined with the assumption of frictionless contact for two dissimilar deformable bodies [28]. Therefore, the non-Hertzian contact pressure distribution, which was obtained from a separate quasi-static finite element method with the assumption of normal pressure distribution independent of the friction coefficient, was applied in this study.

The numerical results of the non-Hertzian contact pressure were obtained at the nodes within the contact area of the numerical model and then applied to determine the longitudinal tangential distribution. It is worth noting that the non-Hertzian contact pressure on the surface of each single element was determined by averaging the corresponding nodal values of contact pressure as the size of the element is one cubic millimetre. In this study, the non-Hertzian contact pressure distribution over the softened zone was assumed to be the same as that over the parent rail.

To consider the partial slip condition, the contact area was divided into slip and stick zones. In the slip zone, the tangential force is proportional to the normal pressure. Therefore, it is necessary to identify the stick and slip zone for estimating the tangential traction. In the current study, the Haines and Ollerton's strip theory [29] was applied to identify the stick and slip zone in the contact area. The size of the stick zone is a function of the normalized tangential traction ξ, which is defined by,

$$\xi = \frac{|P_t|}{fL} \qquad (2)$$

where P_t is the tangential force. f is the friction coefficient at the wheel-rail interface and L is the normal force which is the axle load in the current study. A friction coefficient of 0.4 and a normalised tangential traction of 0.5 were considered in all the cases presented herein.

The philosophy of the Haines and Ollerton's strip theory is to divide the two-dimensional contact area into thin strips parallel to the rolling direction of the wheel by neglecting the interaction between adjacent strips. Therefore, the existing theories, i.e. Carter's theory [24], for determining the tangential traction for one-dimensional contact patch can be applied to every single strip. The capability of these theories has been verified by Johnson [28], which demonstrates that the estimated results are satisfactory to the numerical results obtained from Kalker's theory [30].

Figure 7 schematically illustrates the moving load distributions on the rail surface in a loading cycle. The wheel-rail cyclic rolling contact was simulated by repeatedly translating the distributed normal pressure and the distributed tangential traction on the rail surface from left to right of the fine mesh contact zone. The translation of both normal pressure and longitudinal tangential traction distributions was modelled by time-dependent amplitude function with fixed time interval [27] of every contact element within the fine mesh contact zone.

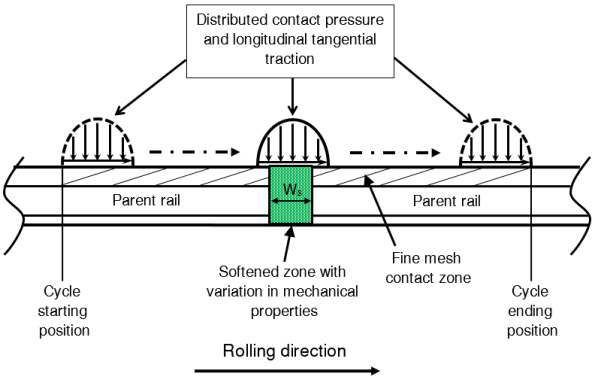

Figure 7 *Schematic illustration of the moving contact load distributions on the rail surface within the fine mesh region in a loading cycle.*

4. Numerical Results

For all the cases considered in this study, 30 cycles were considered in the cyclic rolling contact simulations. By following Eq. (1), the maximum ratcheting strain $(\varepsilon_r)_{max}$, which is the maximum value of ratcheting strain of the entire numerical model, at each loading cycle for each cases was determined. Figure 8 demonstrates the distribution of ratcheting strain at the plane with the maximum value after 30 cycles for a softened zone width of 12 mm for all three rail steels.

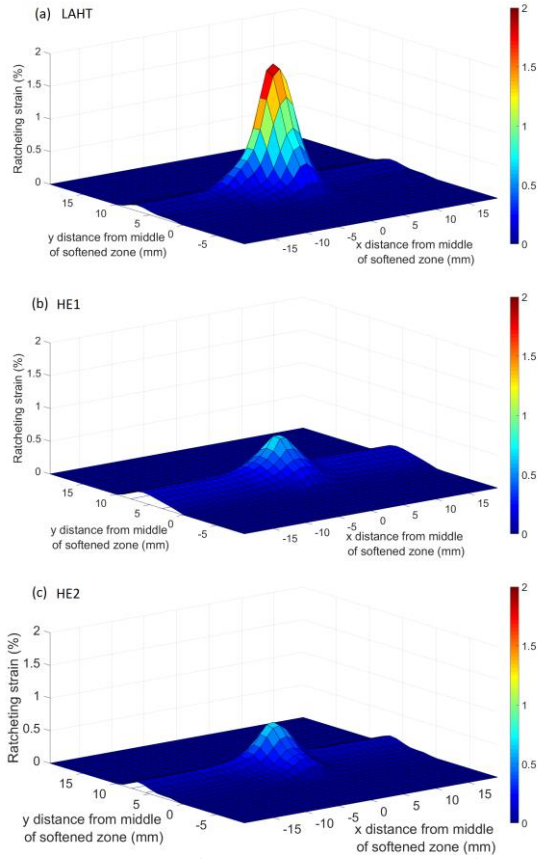

Figure 8 *Distribution of ratcheting strain at the plane of maximum ratcheting strain after 30 cycles for (a) LAHT; (b) HE1; and (c) HE2 steel.*

It can be seen that the ratcheting strain is concentrated around the centre where the softened zone is. The maximum ratcheting strain is found near the region with the lowest hardness within the softened zone. Similar results were also observed in other cases. This indicates that the softened zone is more sensitive to plastic deformation than that of the parent rail. It can also be seen that the size of the distribution and the peak value varies between different rail materials. In comparison, the maximum ratcheting strain for the LAHT steel within the softened zone is much higher (~65 %) than that of the HE1 and the HE2 steels. This phenomenon is possibly due to the lowest hardness level and hence yield strength within the softened zone for the LAHT steel. As the mechanical properties within the softened zone for LAHT steel are much lower than that of the other two steels, it is expected that the softened zone of the LAHT steel suffers a higher degree of plastic deformation than the other two steels under the same loading conditions.

However, the higher value of ratcheting strain for LAHT steel does not indicate that it has the shortest crack initiation life as the crack initiation life is also governed by the ductility of the material. It should be noted that the current study mainly focused on the influence of the width of softened zone on the ratcheting behaviour of the three premium rail steels while prediction of crack initiation life is not included.

As noted in Section 2.3, the maximum ratcheting strain of the entire finite element model in each loading cycle is the most representative value for investigating the ratcheting behavior of a material. Figure 9 shows the maximum ratcheting strain versus number of loading cycles for different W_s for each rail steel.

For the HE2 steel, the results show that the maximum ratcheting strain is almost constant; in fact, it slightly increases with the increasing number of loading cycles. Similar to the HE2 steel, the maximum ratcheting strain for the 4 mm, 6 mm and 8 mm cases for the HE1 steel slightly increases with number of loading cycles. However, for the 8 mm, 10 mm and 12 mm cases, a more rapid increase of maximum ratcheting strain is observed after 27, 25 and 18 cycles, respectively. In comparison, the increase of maximum ratcheting strain for the LAHT steel is more significant than that of the HE1 and the HE2 steels.

In addition, the results clearly show that the maximum ratcheting strain is reduced by narrowing the width of the softened zone for all the three rail steels. The relationship between the maximum ratcheting strain and the width of softened zone can be shown more simply by using the results for width of softened zone of 12 mm of each steel as the reference, see Figure 10.

It can be seen that the maximum ratcheting strain is significantly reduced by minimising the width of softened zone for all three rail steels. For the LAHT steel, the maximum ratcheting strain can be reduced by up to 57 % if the width of softened zone is reduced from 12 mm to 4 mm while it is about 45 % and 43 % for the HE1 and the HE2 steels, respectively. On average, the maximum ratcheting strain can be reduced by about 14 % for every 2 mm reduction on the width of softened zone

for LAHT steel, while it is about 11 % for both HE1 and HE2 steels.

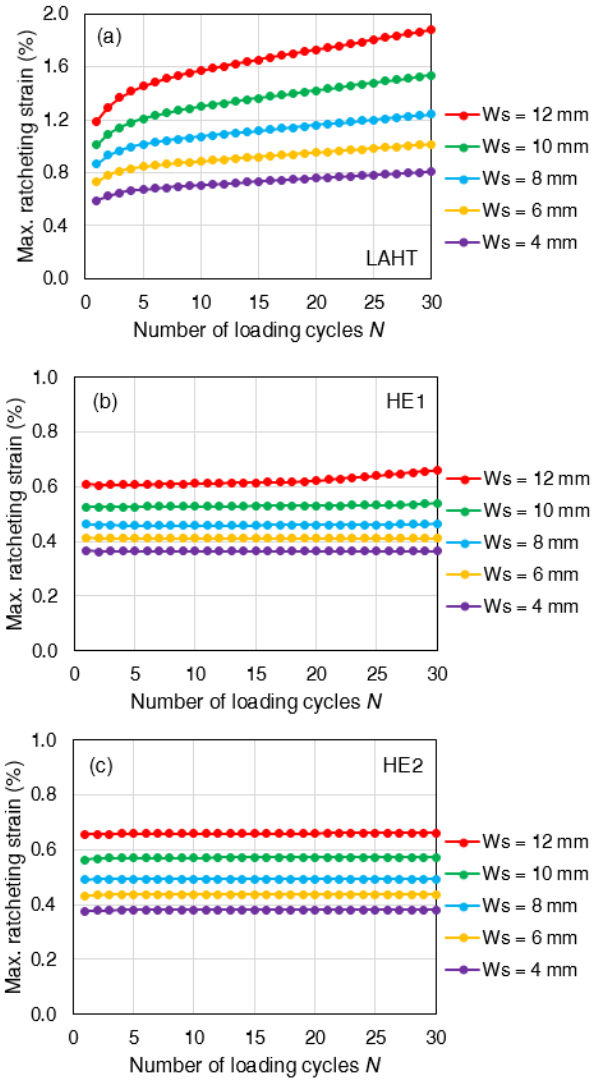

Figure 9 *Maximum ratcheting strain for (a) LAHT; (b) HE1; and (c) HE2 steel.*

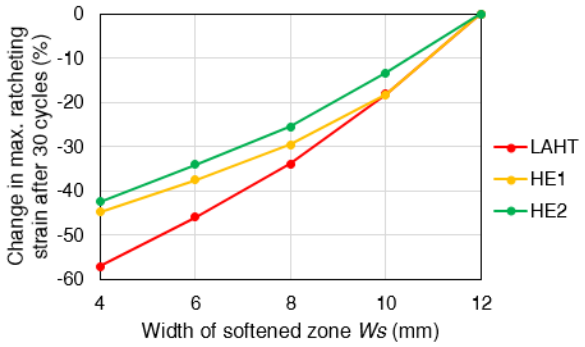

Figure 10 *Change in maximum ratcheting strain after 30 cycles versus width of softened zone.*

Figure 11 shows the maximum ratcheting strain rate of the entire finite element model at each loading cycle for each considered rail steel. The results illustrate that the maximum ratcheting strain rate decreases with increasing number of loading cycles for most of the cases.

All the considered cases give a non-zero maximum ratcheting strain rate. This indicates that non-zero net plastic deformation occurs and accumulates in every loading cycle, i.e. ratcheting occurs.

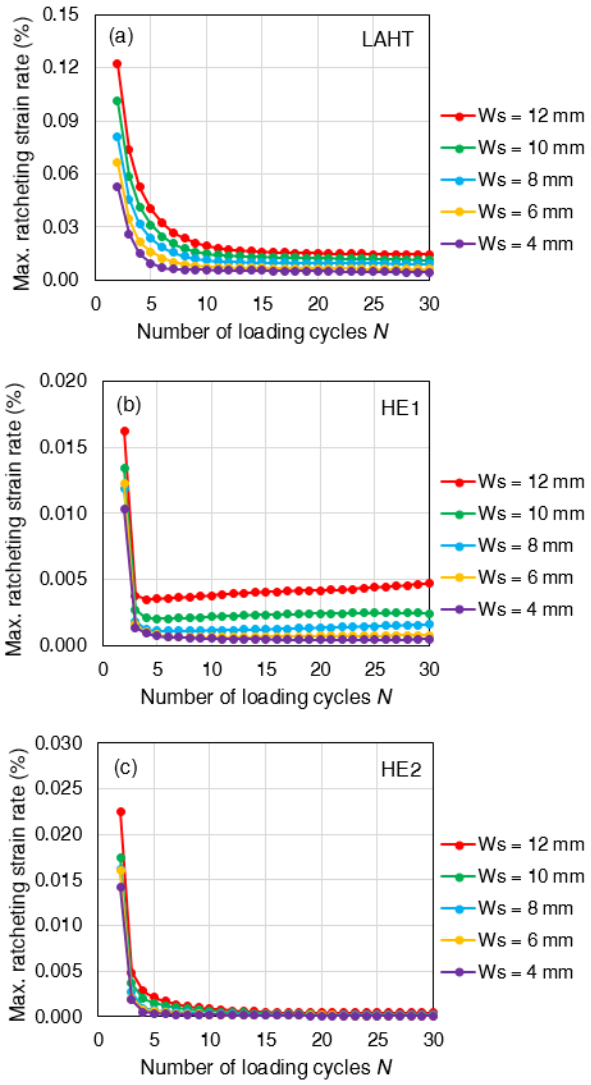

Figure 11 *Maximum ratcheting strain rate $d\varepsilon_{r,max}/dN$ for (a) LAHT; (b) HE1; and (c) HE2 steel.*

For the LAHT steel, the rate of change in the maximum ratcheting strain rate, i.e. gradient of the curve, for all the considered cases is less than 1 % after 25 cycles. Similar results were also obtained for all the cases for the HE2 steel and the 4 mm and 6 mm cases for the HE1 steel. This indicates that the material is approaching a cyclically stable state. However, it should be noted that the maximum ratcheting strain rate for the 12 mm, 10 mm and 8 mm cases of HE1 steel decreases in the first 5 cycles and then gradually increases with increasing number of loading cycles.

Similar to the results for maximum ratcheting strain, the maximum ratcheting strain rate reduces when the width of softened zone is decreased. In addition, it appears that the narrower the width of softened zone, cyclic stability can be achieved in a lower number of loading cycles.

The relationship between the maximum ratcheting strain rate and the width of softened zone is illustrated in Figure

12 by using the results for the 12 mm case in each material as the reference . The results obviously show that the maximum ratcheting strain rate is reduced by minimising the width of softened zone for all three rail steels. However, it can be seen that the relationship between change in maximum ratcheting strain rate and width of softened zone for the LAHT steel is almost linear while it is non-linear for both HE1 and HE2 steels.

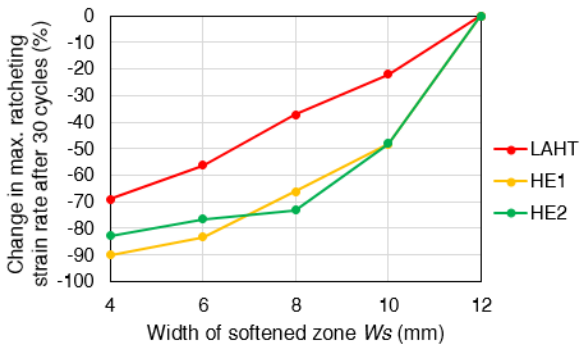

Figure 12 *Change in maximum ratcheting strain rate $d\varepsilon_{r,max}/dN$ after 30 cycles versus width of softened zone*

For the LAHT steel, the maximum ratcheting strain rate can be reduced by up to 70 % if the width of softened zone is reduced from 12 mm to 4 mm. On average, 17 % of reduction on the maximum ratcheting strain rate can be obtained for every 2 mm reduction on the width of softened zone.

For both HE1 and HE2 steels, the maximum ratcheting strain rate can be reduced by 48 % when the width of softened zone is reduced from 12 mm to 10 mm while the reduction of the maximum ratcheting strain rate becomes smaller when the width of softened zone is further reduced. For the HE1 steel, about 34 % reduction of the maximum ratcheting strain rate can be obtained by narrowing the width of softened zone from 10 mm to 6 mm while it is only 6 % reduction if the width is further reduced from 6 mm to 4 mm. For the HE2 steel, a 25 % reduction in the maximum ratcheting strain rate can be obtained if the width of softened zone is reduced from 10 mm to 8 mm, and about 9 % if the width of softened zone is further reduced from 8 mm to 4 mm.

5. Discussion

The results presented in Section 4 indicate that the ratcheting behaviour varies between material types although the loading conditions and the ratio of hardness differential between the region within the softened zone and the parent rail are identical.

For a material subjected to cyclic loading conditions, the ratcheting behaviour is governed by its cyclic hardening/softening characteristics [31, 32]. Generally, a material which exhibits cyclic hardening has increased resistance to plastic deformation, i.e. ratcheting strain rate decreases with increasing number of loading cycles, while a material which exhibits cyclic softening has reduced resistance to plastic deformation, i.e. ratcheting strain rate increases with number of loading cycles.

Referring to Figure 11, the maximum ratcheting strain rate for the 4 mm and 6 mm cases of HE1 steel and all the cases of both LAHT and HE2 steels decreases with increasing number of loading cycles. This indicates that the softened zone in these cases exhibit cyclic hardening. However, the maximum ratcheting strain rate for the 12 mm, 10 mm and 8 mm cases of HE1 steel decreases in the first 5 cycles and then gradually increases with increasing number of loading cycles. This indicates that the softened zone of the HE1 steel in these three cases exhibited cyclic hardening initially and followed by cyclic softening.

It was found that an initially hard or hardened material has relatively higher tendency to exhibit cyclic softening [33] under the same cyclic loading condition. Among the three rail steels considered herein, both the parent rail and the HAZ for the HE1 steel have the highest hardness level and the highest cyclic yield strength. Therefore, the HE1 steel should have the highest tendency to exhibit cyclic softening than the other two steels. This is also reflected by a more rapid increase of maximum ratcheting strain after certain cycles as shown in Figure 9(b). It should also be noted that the forementioned phenomenon of change in ratcheting strain and ratcheting strain rate was not observed in the 4 mm and 6 mm cases for the HE1 steel. This indicates that reduction of the width of softened zone can influence the ratcheting behaviour of rail welds under the same cyclic loading condition.

Referring to Figures 8, 9 and 11, the results show that maximum ratcheting strain and maximum ratcheting strain rate for LAHT steel are significantly higher than that for HE1 and HE2 steels. This is due to the lowest cyclic yield strength of LAHT steel among all three rail steels. Therefore, the LAHT steel may suffer a higher degree of plastic deformation and require a longer period to reach a cyclically stable state than the two hypereutectoid rail steels. However, it should be noted that the largest value of maximum ratcheting strain rate for the LAHT steel does not mean the shortest crack initiation life. It is because prediction of crack initiation life is governed by the ductility of material and the stabilised maximum ratcheting strain rate [19]. Since the current study mainly focused on investigating the influence of width of softened zone on the ratcheting behaviour of the three rail steels, prediction of crack initiation life is not included and so comparison of the performance of welds in these three rail steels is not considered at this stage. However, it is known that the crack initiation life increases with decreasing stabilised maximum ratcheting strain rate.

Although the results presented in this study demonstrate that a cyclically stable state has not yet occurred, they still indicate that the life of the rail weld for each considered rail steel should be improved by reducing the width of softened zones as the maximum ratcheting strain rate decreases by narrowing the width of softened zone.

The results presented in this paper also agree with some recent studies [9, 18] on improving the performance of rail welds (aluminothermic welds and flashbutt welds) by

narrowing the width of the softened zones. This provides the confidence to apply this method to further investigate the influence of different welding parameters on the ratcheting performance of the flashbutt weld under in-service loading conditions.

A reduction of the softened zone width in flashbutt welds would normally be associated with a reduction in the overall width of the HAZ. Although the current study demonstrates that the tendency for localised damage at wheel-rail interface can be reduced, reducing of the width of HAZ may also result in changes to other characteristics associated with rail welds, in particular the residual stress distribution [34]. Therefore, consideration of other aspects of weld performance, i.e. the propensity to develop fatigue cracking in the web, which may result in an increased risk of horizontal split web failures [35], should also be taken into account in future work.

6. Conclusions

Improvement of the reliability and performance of flashbutt weld has been given particular attention to railway operators and researchers in order to mitigate the problems of localised degradation at flashbutt weld, particularly under high axle load conditions.

In this study, a constitutive cyclic plasticity material model, which can reasonably and satisfactorily describe both uniaxial and non-proportional multi-axial ratcheting behaviour of high strength pearlitic rail steels, was applied to describe the deformation behaviour of the flashbutt weld under cyclic loading conditions. Three high strength rail steels, which include a low alloy heat-treated grade with carbon content of 0.8 % and two hypereutectoid rail steels with carbon content of 1 % (HE1) and 0.85 % (HE2) were considered. Simulation of the wheel-rail cyclic rolling contact conditions was carried out by the finite element method. Different widths of softened zone varying from 12 mm to 4 mm with 2 mm decrement were considered in order to investigate the influence of the width of softened zone on the ratcheting behaviour of flashbutt welds of the three rail steels.

The results show that ratcheting occurs at the rail weld during the wheel-rail cyclic rolling contact as non-zero ratcheting strain rate was obtained for all three rail steels. However, the maximum ratcheting strain rate decreases with increasing number of loading cycles for most of the cases. This demonstrates that the flashbutt weld is approaching a cyclically stable state. In addition, both maximum ratcheting strain and ratcheting strain rate can be significantly reduced by narrowing the width of the softened zone for all three rail steels. Furthermore, the ratcheting behaviour of one of the hypereutectoid rail steels can be altered by narrowing the width of softened zone.

The results obtained in this study agree with some recent studies on improving the reliability and the performance of flashbutt welds. This provides confidence to apply the presented methodology to further investigate the influence of different welding parameters on the ratcheting performance of flashbutt welds.

7. Future Work

In the work to date, some assumptions have been made regarding the ratcheting characteristics of the softened zones in rail flashbutt welds. The carbide morphology in these zones varies depending on the time-temperature history during the welding process, with predominantly spheroidized cementite at the point of minimum hardness, and varying degrees of carbide degradation on either side [1]. Furthermore, for any given welding conditions, the rate at which carbide degradation occurs is influenced by the composition of the rail steel.

Fegredo et al [36] examined the influence of progressive minor spheroidization on the wear behaviour of two as-rolled rail steels, and found that thermal treatments that increase the mean true ferrite path (MTFP) in pearlitic steels increase the wear rate significantly, and that the MTFP may be a more suitable parameter than hardness in defining the wear rate. This observation is consistent with the findings of Gensamer et al [37], who systematically examined the influence of carbide morphology on the tensile properties of two eutectoid steels and found that the resistance to deformation varies linearly with the logarithm of the mean uninterrupted path through the continuous (ferrite) phase, for both pearlitic and spheroidized structures in the same steel. Furthermore, a spheroidized structure is markedly superior in ductility to pearlite of the same tensile strength.

Both of the above studies indicate that the current work, in which the cyclic deformation characteristics of the material in the softened zones were assumed to be similar to those of the parent rail material, adjusted for the differences in hardness levels, may under- or over-estimate the extent of deformation that occurs in flashbutt welds. Furthermore, the inherent variability in the carbide morphology means that a range of cyclic plasticity material models may be required, depending on the width of the softened zone.

In order to further improve the methodology of the current work, experimental studies will be conducted on test pieces extracted from the heat-affected zones of flashbutt welds in these steel grades, to obtain the local ratcheting behavior and ratcheting parameters essential for the modeling work. A more realistic non-Hertzian contact non-Hertzian contact pressure distribution over the entire heat-affected zone will be obtained from a separate rolling contact simulation instead of a quasi-static simulation and implemented into cyclic rolling contact simulation.

The entire heat-affected zone with a pair of softened zones will be considered in the finite element analysis. In addition, more simulations and analyses will be conducted to investigate the influence of different parameters associated with flashbutt welds on the ratcheting performance. These parameters include but are not limited to the overall width of the weld, and the

respective hardness levels in parent rail, softened zones and reaustenitised zone surrounding the bond line.

The overall outcomes of this study can then be applied to modify or develop improved flashbutt welding techniques for high strength pearlitic rail steels.

Acknowledgments

All numerical simulations were carried out at the NCI National Facility in Canberra, Australia, which is supported by the Australian Commonwealth Government.

Abstract: Numerical analysis of material responses for three premium pearlitic rail steels subjected to multiaxial cyclic loading conditions have been carried out to examine the shakedown limits. The material responses were simulated by using a constitutive cyclic plasticity material model, which can reasonably and satisfactorily describe both uniaxial and non-proportional multiaxial ratcheting behaviour of the considered rail steels. The results obtained provide evidence that the limiting stress for different types of material response under non-proportional multiaxial cyclic loading can vary between different rail steels.

Keywords: Shakedown Analysis; Multiaxial cyclic loading; Elliptical loading path; Premium pearlitic rail steels; Numerical analysis.

1. Introduction

Rolling contact fatigue (RCF) damage has become one of the major forms of material degradation occurring at the wheel-rail interface across all sectors of the rail industry. In the wheel-rail rolling contact process, the rail is subjected to cyclic loading and the rail surface is subjected to rolling and sliding loading with high contact stresses. The stresses endured by the rail are always multiaxial, non-proportional and randomly fluctuating in magnitude and direction [1]. Generally, the responses for materials subjected to multiaxial cyclic loading conditions can be divided into four categories: purely elastic; elastic shakedown; plastic shakedown; and ratcheting.

The shakedown map [2] has been commonly applied to predict the material responses in bodies which are subjected to cyclic rolling contact conditions, without the requirement of neither experimental nor numerical results. The upper and lower bounds to the shakedown limit in the shakedown map were developed based on the shakedown theorems of the theory of plasticity [2-4] and the Hertzian contact theory [5], with the assumption of full slip conditions. The influence of partial slip on the shakedown limits was also investigated in [6], which found that the shakedown limits under partial slip conditions reduce relative to those under full slip conditions. For loading conditions above the plastic shakedown limit, which corresponds to the upper bound in the shakedown map, new plastic deformation occurs with each wheel passage and accumulates, i.e. ratcheting occurs. When the ratcheting strain reaches the limiting ductility of the material, it will fail resulting in the initiation of RCF damage [7, 8].

Figure 1 shows examples of rolling contact fatigue damage on the rail gauge corner of three different types of rail steels under heavy haul conditions in similar curve radii. The steels are an as-rolled eutectoid rail steel (nominal hardness 280 HB), the same steel in the heat treated condition (360 HB), and a heat-treated hypereutectoid rail steel (420 HB). It can be seen that the characteristics of surface cracks vary between the different rail steel grades, with much finer cracks in the hypereutectoid heat-treated grade and much coarser cracks in the as-rolled grade. In addition, field observations have found that the tonnage required for initiating surface cracks in similar curve radii vary between different rail steel grades. These differences arise from the differences in composition, mechanical properties and the ratcheting behaviour of the rail steels. Therefore, minimising the occurrence of ratcheting by maintaining the load, or in other words, the resulting stress level, below the plastic shakedown limit of the rail steel grades is crucial in order to extend the rail life.

Generally, the plastic shakedown limit can be obtained by conducting finite element analysis to simulate rolling-sliding contact between two deformable bodies, or by solving the theories of plasticity. The latter approach has been widely used in the previous research conducted by Johnson and his co-workers [e.g. 2, 4, 9], and Kapoor and his co-workers [e.g. 10-12]. However, it is found that there is a lack of information with regard to the plastic shakedown limits for the premium rail steel grades typically used in heavy haul conditions. The latter steels have finer pearlitic microstructures than steels used in the previous studies; in addition, compositions are more diverse, with carbon levels of up to 1%, in some grades.

The plastic shakedown limit is strongly dependent on both isotropic and kinematic hardening rules, which describe the ratcheting behaviour of the material. For a material subjected to cyclic loading conditions, ratcheting behaviour is governed by its cyclic hardening/softening characteristics [13, 14]. Generally, a material which exhibits cyclic hardening indicates that its resistance to plastic deformation increases, i.e. strain amplitude decreases, with increasing number of loading

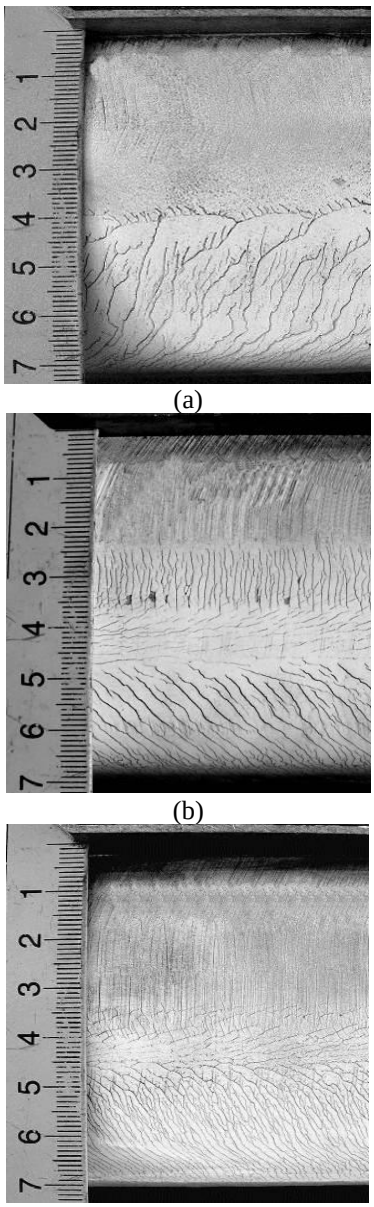

Figure 1 *Examples of dense surface cracks observed on different rail steel grades, (a) as-rolled eutectoid; (b) heat-treated eutectoid; and (c) hypereutectoid heat-treated*

cycles under stress-controlled cyclic loading tests. Conversely, a material which exhibits cyclic softening indicates that its resistance to plastic deformation decreases, i.e. strain amplitude increases, with increasing number of loading cycles under stress-controlled cyclic loading tests.

Some studies have been conducted to investigate the ratcheting behaviour of different types of rail steels [15-18]. Both uniaxial and biaxial tension-torsion tests were conducted by McDowell [15] on an ordinary carbon rail and a heat treated high strength rail steel. The results indicated that both rail steels exhibited cyclic softening under uniaxial cyclic loading conditions. However, under biaxial cyclic loading conditions, the ordinary carbon steel ratcheted at a constant rate while the heat-treated rail steel exhibited cyclic hardening with the ratcheting strain rate decreasing with increasing number of loading cycles.

The ratcheting behaviour of three high strength pearlitic rail steels were also investigated under both uniaxial and biaxial cyclic loading tests by Pun et al. [16]. Their results indicated that all the three steels exhibited cyclic softening under uniaxial cyclic loading conditions. However, under biaxial cyclic loading conditions involving an elliptical loading path, the two rail steels with lower carbon content exhibited cyclic hardening, while the rail steel with the highest carbon content exhibited initial cyclic hardening followed by cyclic softening. It was found that the uniaxial ratcheting behaviour of the three pearlitic rail steels examined by Pun et al. [16] was similar to that of the ordinary carbon and the heat-treated rail steels examined by McDowell [15]. However, the cyclic softening characteristics of the three high strength pearlitic rail steels were more significant, i.e. higher reduction of stress amplitude in uniaxial strain cycling at lower strain amplitude, than that of the ordinary carbon and the heat-treated rail steels. Kang et al. [17, 18] investigated both uniaxial and multi-axial ratcheting behaviour of a U71Mn rail steel. Their reported results show that the U71Mn rail steel exhibits cyclic stability (neither hardening nor softening). The results of these previous studies indicate that different rail steels with varying material characteristics exhibit different ratcheting behaviour.

Generally, one of the factors which influences the tendency for cyclic softening/hardening of a material is its microstructure, i.e. the density and arrangement of the dislocation structure and substructure of the material [19]. It has been found that the existing dislocation structure of an initially hard or hardened material tends to rearrange into a configuration with less resistance to deformation under cyclic loading and results in promotion of greater dislocation mobility. Therefore, dislocations are able to circumnavigate around microstructural barriers, i.e. precipitates and grain boundaries, which generally restrict deformation and the material has higher tendency to exhibit cyclic softening. In contrast, the dislocation density of the individual grains of a softened or initially soft material is relatively low. Therefore, the dislocation density increases rapidly and results in a decrease in dislocation mobility under cyclic loading conditions. Hence, a softened or initially soft material has a higher tendency to exhibit cyclic hardening. This behaviour was confirmed by Sunwoo et al. [20], who examined the influence of interlamellar spacing on the ratcheting behaviour of pearlitic eutectoid rail steels. Their results indicated that rail steels with coarser pearlite spacing, i.e. in lower strength grades, exhibited cyclic hardening, whereas rail steels with finer pearlite spacing may exhibit cyclic hardening.

According to the above discussion, the plastic shakedown limit may vary between different materials. Therefore, it is essential to have a better understanding of the precise mechanical meaning and implication of the shakedown limit, especially for premium rail steels which have much finer pearlitic microstructures and much higher hardness than those used in the initial experimental tests carried out to validate shakedown theory [6]. These steels

normally have high carbon contents, which range from eutectoid levels (about 0.8%) to up to ~1.0% in the harder grades, and may also contain higher levels of alloying elements, such as silicon which strengthens the ferritic phase.

To examine these aspects in more detail, the current study aims to investigate the material responses with respect to the shakedown limits for three premium rail steels which are commonly used in heavy haul railways in Australia. The approach is based on non-proportional multiaxial cyclic loading conditions using a numerical method. While this work is part of an ongoing project, the methodology applied and the results obtained to date are provided in the following sections.

2. Methodology

2.1. Materials

The rail materials considered in this study are three premium pearlitic rail steels commonly used in heavy haul railways in Australia. They include a low alloy heat-treated (LAHT) grade with carbon content of 0.8 % and two hypereutectoid grades with carbon content of 1 % (HE1) and 0.85 % (HE2), respectively. All three rail steels have similar nominal surface hardness of 400 – 420 HV. The ratcheting behaviour of these three rail steels have been recently examined by Pun et al. [16].

2.2. Constitutive Cyclic Plasticity Material Model

To numerically simulate the material responses of the three steels when subjected to cyclic loading conditions, the capacity and the reliability of the constitutive cyclic plasticity material model to describe the ratcheting behaviour are essential for the outcome of the analysis. As noted earlier, the ratcheting behaviour of the three premium pearlitic rail steels considered in this study have been examined by Pun et al. [16]. It was found that the ratcheting behaviour of all three rail steels was similar.

Following a systematic experimental study of these three rail steels, a constitutive cyclic plasticity material model was developed by Pun et al. [16]. The cyclic softening rule was incorporated in the constitutive cyclic plasticity material model and used together with the combined hardening model, which considers both isotropic and kinematic hardening rules to capture the forementioned cyclic softening characteristics and ratcheting behaviour [16, 21]. The effects of load history and non-proportional loading paths are considered by adopting the following evolution equations for the isotropic deformation resistance to plastic flow Q in the constitutive cyclic plasticity material model.

$$\dot{Q} = \gamma(Q_{sa} - Q)\dot{p} \tag{1}$$

where

$$Q_{sa}(\Phi) = \Phi[Q_{sa1} - Q_{sa0}] + Q_{sa0} \tag{2}$$

$\dot{Q}$ is the evolution rate of the isotropic deformation resistance to plastic flow, while $\dot{p}$ is the effective plastic strain rate. Q_{sa} is the saturated isotropic deformation resistance to plastic flow relating to non-proportional factor Φ, and γ is a material parameter to control the evolution rate of Q_{sa}. Q_{sa0} and Q_{sa1} are the saturated isotropic deformation resistance to plastic flow under proportional uniaxial loading for $\Phi = 0$ and non-proportional circular cyclic loading paths for $\Phi \approx 1$, respectively. The initial value of Q is denoted as Q_0.

The material parameters that are essential for the material model for all three rail steels were calibrated from the experimental results as provided in [16] and are summarised in Table 1.

It has been shown that this material model, together with the calibrated material parameters for the three rail steels, can reasonably and simultaneously describe both uniaxial and non-proportional multiaxial ratcheting behaviour of pearlitic rail steels [16, 21, 22]. The cyclic plasticity material model recently developed by Pun et al. [16] was applied in the current study to investigate the material responses with respect to the shakedown limits of the three premium pearlitic rail steels.

2.3. Loading Conditions

For this study, an elliptical loading path, which is a non-proportional loading path and was found to best represent the normal and shear stress responses in numerical simulations of wheel-rail contact, was considered.

Two multiaxial loading conditions were considered. One is asymmetric compressive loading with symmetric shear loading, while the other one is asymmetric tensile-compressive loading with symmetric shear loading. The latter loading condition represents the presence of residual axial stress, which is about 10 % of the axial stress amplitude. Asymmetric loading indicates that non-zero mean stress was applied, while symmetric loading indicates that the mean stress equals to zero. Examples of the elliptical loading path under these two loading conditions are provided in Figure 2.

To simulate the material responses of the three rail steels, different loading conditions were considered. The applied axial stress amplitude σ_a was considered as a function of the cyclic yield strength Y_c of the rail material, while the applied shear stress amplitude τ_a was considered as a function of the cyclic shear yield strength k_c. It should be noted that the shear stress applied in the current study is the equivalent shear stress $\sqrt{3}\tau$. The cyclic yield strength Yc of all three rail steels was determined from the experimental results obtained from uniaxial symmetric strain-controlled cyclic loading tests [16], while the cyclic shear yield strength k_c was determined by dividing the cyclic yield strength Y_c by $\sqrt{3}$, as summarised in Table 2.

3. Results

Based on the methodology described in Section 2, combinations of different axial stress amplitude σ_a and different shear stress amplitude τ_a were applied to simulate the material responses of the three rail steels under non-proportional multiaxial loading conditions. For each loading case, 200 loading cycles were considered. The type of material response of the rail steel under a given loading condition was then identified based on the criteria as provided in Table 3. An example for each type of material response is shown in Figure 3.

3.1. Asymmetric Compressive Loading and Symmetric Shear Loading

Material response results for all three rail steels under a non-proportional elliptical loading path, with different asymmetric compressive loading and symmetric shear loading conditions, are provided in Figure 4. The maximum stresses are presented in normalised term with maximum axial stress σ_{max} relative to the material's cyclic yield strength Y_c and maximum shear stress τ_{max} relative to the material's cyclic shear yield strength k_c. It is worth noting that the negative sign of the normalised maximum axial stress indicates compressive loading.

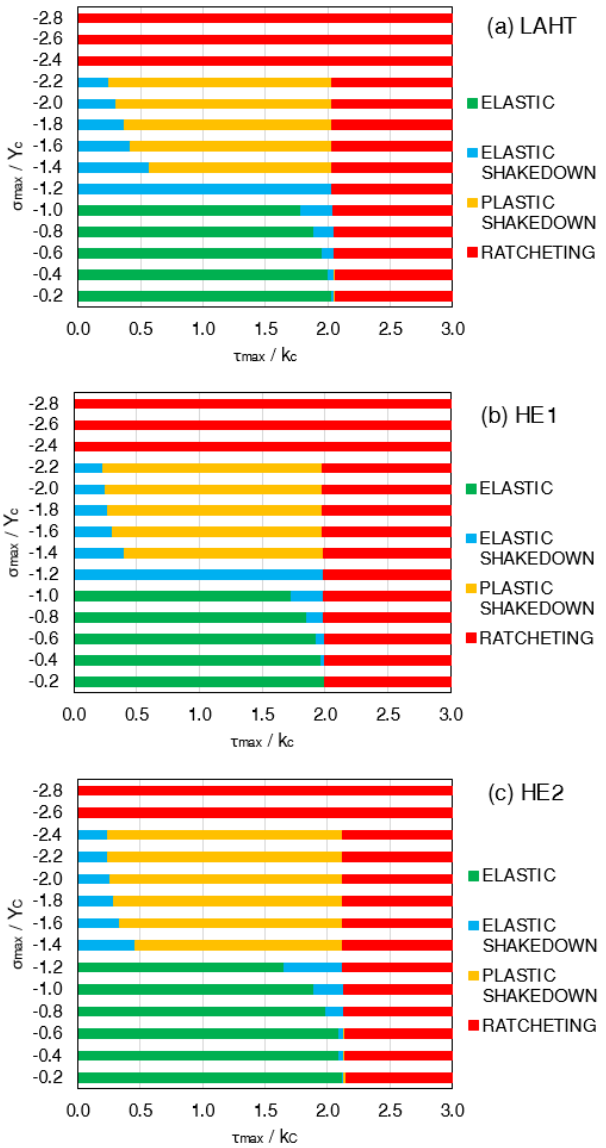

Figure 4 *Simulated material responses for (a) LAHT; (b) HE1; and (c) HE2 rail steels, under non-proportional asymmetric compressive loading and symmetric shear loading with different combination of maximum axial stress σ_{max} and maximum shear stress τ_{max}.*

For the LAHT rail steel, ratcheting occurs under all normalised shear stress levels when normalised axial stress is higher than 2.2. For lower normalised axial stress, the boundary of normalised shear stress for resulting ratcheting response gradually increases from 2.03 to 2.06 with decreasing normalised axial stress. Pure elastic deformation occurs when the normalised axial stress is less than 1.2 and the boundary of normalised shear stress for resulting pure elastic deformation decreases with increasing normalised axial stress. When the normalised axial stress equals 1.2 and the normalised shear stress is less than 2.03, elastic shakedown takes place. When the normalised axial stress increases from 1.4 up to 2.2, the boundary of normalised shear stress between elastic and plastic shakedown responses decreases from 0.57 to 0.25.

The results for the HE1 rail steel show that ratcheting occurs under all normalised shear stress levels when the normalised axial stress is also larger than 2.2. For normalised axial stress lower than that, the boundary of

normalised shear stress for resulting ratcheting increases from 1.96 to 2.0, with decreasing normalised axial stress. Pure elastic deformation occurs when the normalised axial stress is less than 1.2 and the boundary of normalised shear stress for resulting elastic deformation decreases with increasing normalised axial stress. When the normalised axial stress equals 1.2 and the normalised shear stress is less than 1.99, elastic shakedown occurs. When the normalised axial stress increases from 1.4 up to 2.2, the boundary of normalised shear stress between elastic and plastic shakedown responses decreases from 0.4 to 0.23.

For the HE2 rail steel, ratcheting occurs under all normalised shear stress levels when the normalised axial stress is higher than 2.4. For normalised axial stress lower than that, the boundary of normalised shear stress for resulting ratcheting response increases from 2.12 to 2.15 with decreasing normalised axial stress. Pure elastic deformation occurs when the normalised axial stress is less than 1.4. The boundary of normalised shear stress for resulting pure elastic deformation decreases with increasing normalised axial stress when normalised axial stress is larger than 0.6. When the normalised axial stress increases from 1.4 up to 2.4, the boundary of normalised shear stress between elastic and plastic shakedown responses decreases from 0.46 to 0.24.

3.2. Asymmetric Tensile-Compressive Loading and Symmetric Shear Loading

Figure 5 shows the simulated material responses for all three rail steels under different non-proportional asymmetric tensile-compressive and symmetric shear loading conditions. As noted in Section 2.3, the asymmetric tensile-compressive loading considered herein represents the presence of residual stress, which is about 10 % of the maximum axial stress $\sigma_{max.}$

For the LAHT rail steel, ratcheting occurs under all normalised shear stress levels when the normalised axial stress is larger than 2.2. For lower normalised axial stress, the boundary of normalised shear stress for resulting ratcheting increases from 2.03 to 2.09 with decreasing normalised axial stress. Pure elastic deformation occurs when the normalised axial stress is less than 1.2 and the boundary of normalised shear stress for resulting elastic deformation decreases with increasing normalised axial stress. When the normalised axial stress equals 1.2 and the normalised shear stress is less than 1.5, elastic shakedown occurs. When the normalised axial stress increases from 1.2 up to 2.2, the boundary of normalised shear stress between elastic and plastic shakedown responses decreases from 1.5 to 0.25.

Results for the HE1 rail steel show that ratcheting occurs under all normalised shear stress levels when the normalised axial stress is also larger than 2.2. For lower normalised axial stress, the boundary of normalised shear stress for resulting ratcheting increases from 1.97 to 2.01 with decreasing normalised axial stress. Pure elastic deformation occurs when normalised axial stress is less

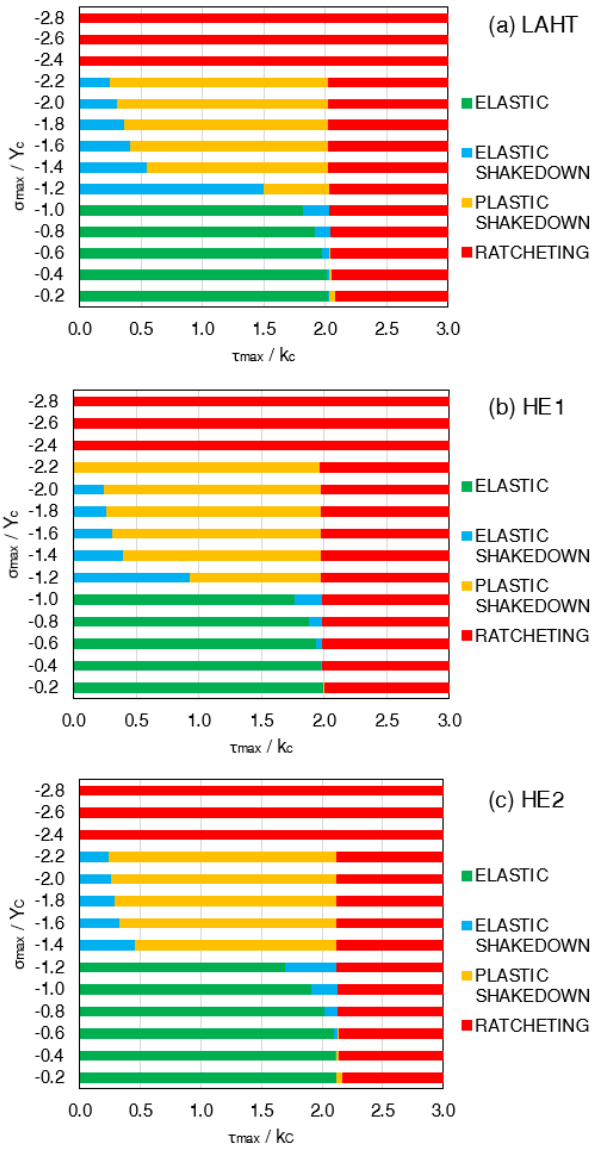

Figure 5 *Simulated material responses for (a) LAHT; (b) HE1; and (c) HE2 rail steels, under non-proportional asymmetric tensile-compressive loading and symmetric shear loading with different combination of maximum axial stress σ_{max} and maximum shear stress τ_{max}.*

than 1.2 and the boundary of normalised shear stress for resulting elastic deformation decreases with increasing normalised axial stress. When the normalised axial stress equals to 1.2 and the normalised shear stress is less than 0.93, elastic shakedown occurs. When the normalised axial stress level increases from 1.2 up to 2.0, the boundary of normalised shear stress between elastic and plastic shakedown responses decreases from 0.93 to 0.25. When the normalised axial stress equals to 2.2 and the normalised shear stress is less than 1.97, only plastic shakedown takes place.

For the HE2 rail steel, ratcheting occurs under all normalised shear stress levels when the normalised axial stress is also higher than 2.2. For lower normalised axial stress, the boundary of normalised shear stress for resulting ratcheting response increases from 2.12 to 2.17, with decreasing normalised axial stress. Pure elastic deformation occurs when the normalised axial stress is less than 1.4. The boundary of normalised shear stress for

resulting pure elastic deformation decreases with increasing normalised axial stress. When the normalised axial stress increases from 1.4 up to 2.2, the boundary of normalised shear stress between elastic and plastic shakedown responses decreases from 0.46 to 0.24.

4. Discussion

The results as shown in Section 3 clearly illustrate that the material responses for all three rail steels under multiaxial loading conditions are strongly dependent on both the normalised axial stress level σ_{max}/Y_c and the normalised shear stress level τ_{max}/k_c. In addition, it can be seen that the limiting stress for different types of material response vary between the different rail steels.

Under asymmetric compressive loading and symmetric shear loading conditions, the HE2 rail steel appears to have the highest normalised axial and shear stress levels for the occurrence of ratcheting, while the HE1 rail steel, which has the highest carbon content among the three rail steels, has the lowest. In addition, the HE2 rail steel has the widest boundaries of normalised axial and shear stress levels for plastic shakedown response, while the LAHT rail steel has the smallest.

Under asymmetric tensile-compressive loading and symmetric shear loading conditions, the boundary of normalised axial stress level for the occurrence of ratcheting for all three rail steels is similar. While the HE2 rail steel has the highest normalised shear stress levels for the occurrence of ratcheting, the HE1 rail steel has the lowest. However, the HE1 has the widest boundaries of axial and shear stress levels for plastic shakedown response, while the HE2 has the smallest.

When comparing the results in Figure 4 with those in Figure 5, it can be seen that the presence of residual tensile stress significantly affects the boundaries of normalised axial and shear stress levels for plastic shakedown response in all three rail steels. For the normalised axial stress of 1.2 for both LAHT and HE1 rail steel under asymmetric compressive loading and symmetric shear loading conditions, only elastic shakedown takes place when the normalised shear stress is less than the boundary of normalised shear stress for ratcheting. However, under the same normalised axial stress level in asymmetric tensile-compressive loading and symmetric shear loading conditions, the boundary of normalised shear stress for elastic shakedown reduces, and plastic shakedown occurs when normalised shear stress is higher than or equal to 1.5 and 0.93 for the LAHT and the HE1 rail steels, respectively. In addition, the elastic shakedown region for the HE1 rail steel vanishes and plastic shakedown occurs when normalised axial stress equals to 2.2. In comparison, the influence of the presence of residual tensile stress on the boundaries of ratcheting for both LAHT and HE1 rail steels is minor. For the HE2 rail steel, the presence of residual tensile stress significantly reduces the boundary of normalised axial stress for the occurrence of ratcheting from 2.4 to 2.2. This indicates that the presence of residual tensile stress can affect the shakedown limits in terms of stress levels and in some cases can shift the material response from plastic shakedown to ratcheting, which may then increase the possibility of crack initiation.

As noted in Section 2, the three rail steels considered in this study have similar ratcheting behaviour [16]. The constitutive cyclic plasticity material model used to describe the ratcheting behaviour of the three rail steels considers the effects of loading history and non-proportional loading path by adopting the evolution equations for isotropic deformation resistance Q as shown in Eqs (1) and (2). Based on the calibrated material parameters, summarised in Table 1, the saturated isotropic deformation resistance to plastic flow Q_{sa} under non-proportional elliptical loading path can be estimated by Eq (2). It was found that the HE1 rail steel, which has the highest carbon content and the highest nominal hardness, has the lowest value of Q_{sa} while the HE2 rail steel has the highest. This indicates that the HE1 rail steel has the lowest resistance to plastic flow and is more sensitive to cyclic softening than the other two rail steels. It is therefore expected that the HE1 rail steel has the lowest normalised axial and shear stress levels for the occurrence of ratcheting, while the HE2 rail steel has the highest among all three rail steels under non-proportional cyclic loading. It is also important to note that these results are consistent with the in-service performance of the three rail steels.

In actual wheel-rail cyclic rolling-sliding contact, the resulting cyclic stress level endured by the rail material is governed by the combination of contact pressure and tangential traction at the wheel-rail interfaces. Following this general approach, the axial and shear stress amplitudes applied in this study correspond to the resulting axial and shear stress levels suffered by the rail material under different wheel-rail rolling-sliding contact conditions. This indicates that the material responses presented here is not limited to Hertzian contact pressure distribution and full slip conditions.

The results obtained in this study provide evidence that the limiting stress for different types of material response under multiaxial cyclic loading conditions can vary between rail steels, although their ratcheting behaviour may be similar. As noted in Section 1, the three rail steels examined in this work are all premium grades that have much finer pearlitic microstructures and much higher carbon content than those used in the initial experimental tests carried out to validate shakedown theory [6]. Therefore, it is essential to have a better understanding of the precise mechanical meaning and implication of shakedown limits for premium rail steels in the future.

Although both the shakedown map and the results presented in the current study provide information about the material response in bodies which are subjected to cyclic loading conditions, these do not provide any information on damage prediction, i.e. crack initiation life, for the rail materials. It is generally understood that guarding against the occurrence of ratcheting by maintaining the load, or in other words, the resulting stress level, endured by the rails below the plastic

shakedown limit can reduce rail maintenance requirements and extend the rail life. However, the service conditions in heavy haul operations in Australia typically involve combinations of high axle load and dry rail surfaces, i.e. no lubrication, which can often lead to stress levels higher than the plastic shakedown limit of the rail material and consequently result in RCF damage.

Field observations have shown that the tonnage required for the initiation of RCF cracks also varies between different rail steels. From a heavy haul operator's perspective, it is necessary to understand the performance of different rail steels under the range of wheel-rail contact (operating) conditions in their network in order to select appropriate rail steels. To address this requirement, future work will take into consideration damage prediction in terms of the crack initiation life. The overall outcomes of the study can then provide useful information to railway operators for the selection of rail steels and the development of effective preventative grinding strategy in order to mitigate rail degradation.

5. Summary

In this study, a constitutive cyclic plasticity material model, which can reasonably and simultaneously describe both uniaxial and non-proportional multiaxial ratcheting behaviour of premium pearlitic rail steels, was applied to numerically analyse the material responses with respect to shakedown limits for three premium rail steels.

Three premium rail steels, which included a low alloy-heat-treated grade with carbon content of 0.8 % and two hypereutectoid rail steels with carbon content of 1 % (HE1) and 0.85 % (HE2), were considered. To numerically simulate the material responses of these steels under different multiaxial cyclic loading conditions, an elliptical loading path, which is a non-proportional loading path and was found to best represent the normal and shear stress responses in numerical simulations of wheel-rail contact, was considered. Two multiaxial loading conditions, asymmetric compressive loading with symmetric shear loading; and asymmetric tensile-compressive loading with symmetric shear loading, were also considered.

Results show that the material response for all three rail steels under multiaxial loading conditions are strongly dependent on the magnitude of both the normalised axial stress and normalised shear stress level. Of the three rail steels, the HE2 rail steel has the highest normalised axial and shear stress resistance to ratcheting, while the HE1 rail steel has the lowest, when under asymmetric compressive loading and symmetric loading conditions. Under asymmetric tensile-compressive loading and symmetric shear loading conditions, the boundary of normalised axial stress level for the occurrence of ratcheting for all three rail steels is similar, while the HE2 rail steel has the highest normalised shear stress level for ratcheting under the same level of normalised axial stress.

The results obtained in this study provide evidence that the limiting stress for different types of material responses under multiaxial cyclic loading conditions vary between different rail steels, although their ratcheting behaviour may be similar. These results are also consistent with in-service performance observations.

6. Future Work

In order to gain a better understanding of the precise mechanical meaning and implication of shakedown limits for premium rail steels, further simulations and analysis will be conducted.

For the purpose of examining the correlations between different wheel-rail contact conditions and the resulting stress level experienced by the rail material, analysis of contact stresses at the wheel-rail interface under different wheel-rail rolling-sliding contact conditions will be conducted. Hertzian contact theory has been widely used to determine the contact pressure at the wheel-rail interface due to its simplicity. However, the assumptions in Hertz contact theory, i.e. linear elastic material model and half-space assumptions, lead to discrepancies between the calculated and the actual normal pressure distribution [1, 23-26]. In comparison, the non-Hertzian contact pressure distribution, which is not limited by these assumptions, is believed to best represent the actual contact stresses at the wheel-rail interface, especially for the operating conditions in heavy haul railways with high axle load and high traction. Accordingly, a systematic analysis will be conducted to investigate the influence of using Hertzian and non-Hertzian contact pressure for both elastic and elastic-plastic contacts on the resulting stress level in the rail material. This analysis will incorporate both multi-body dynamic simulations and finite element analysis. A matrix of different wheel-rail contact conditions, which include both conformal and non-conformal contacts, will be considered.

In addition, further variations in wheel-rail cyclic rolling-sliding contact will be assessed through finite element analysis. In conjunction with the experimental studies and the dimensional analysis, the correlation between the material parameters and the crack initiation life will be investigated. The results obtained will then be incorporated with the shakedown analysis. Field studies will also be carried out to confirm the reliability and capability of the results.

The overall objective is to provide useful information for the assessment and selection of rail steels and the development of effective maintenance strategies tailored to specific material characteristics and operating conditions.

Acknowledgments

The constitutive material model applied in the current study was developed with the help from A/Prof. Qianhua Kan and Prof. Guozheng Kang in Department of Applied Mechanics and Engineering, Southwest Jiaotang University during the PhD study of Chung Lun Pun, the first author of this paper.

Abstract: Characteristics of wheel-rail creep curve affect wear and RCF of wheel-rail directly then it continues to affect stationarity with safety of train operation.It has important engineering essence of researching characteristics about wheel-rail creep curve for studying wheel-rail wear of high-speed turnout area under special conditions. This paper aims at Chinese No.18 turnout of high-speed rail through methods of Kalker. It researched factors which affects change of rail creep curve like Kalker weight coefficient , friction coefficient the turnout zones. And compare to analyze different rail creep curve and train traction power affect wheel-rail wear with dynamics or not.

Keywords: creep curve, turnout, high speed, Kalker weight coefficient, friction coefficient.

1. Introduction

Turnouts are weak links and important maintenance points in high-speed railway lines due to their complicated structure, various parts and risk of severe damage. They are also a key component of the infrastructure that influencing the running stability and safety of trains.[1] When a high-speed train is passing through a turnout, the variable cross-section of the turnout leads to the wheels impacting the switch rail and point rail under the effect of decreasing turnout top surface, changing top width and the inherent structural irregularity caused by the curve of the stock rail and wing rail., and wheel load transit to the switch rail and point rail under lateral creep force.[2] At the same time, the wheel-rail creep characteristics influence the wheel-rail wear and wheel-rail dynamics.

In the contact process of locomotive wheelset rolling along the rail, the wheel-rail contact patch will not only carry a high normal load but also transfer the tangential traction force and braking force of the locomotive. The ratio of the wheel-rail tangential force to the normal force is defined as the traction coefficient. The change of the traction coefficient with creepage are called creep curves. Many researchers have studied the characteristics of wheel-rail creep curves.[3-6] Kalker discussed the three-dimensional (3D) rolling contact problems of elliptic contact areas according to the series method and presented a quick calculation model- simplified theory based on the linear theory model. [7-8] Shen Z Y et al.[9]considered the influence of spin creepage on the creep force in the creepage / creep force calculation model. Jin X S et al. [10] made a non-Hertz creep force table (TPLR) in order to achieve a quick search for calculated results with regard to dynamic vehicle simulation.

The above discussions relate to the wheel-rail creep theory obtained under ideal dry wheel-rail surface conditions. When the wheel-rail contact interface is wet, contaminated by sand, leaves or rust, or applied with a friction modifier or lubricant[11-13], creep curves with regard to creep characteristics must be readjusted in order to allow the calculated wheel-rail contact force to coincide with the actual situation. Polach[14] introduced function-type friction coefficients and attenuation factors based on the quick algorithm. The validity of this method could be verified by comparison to the measured data. He also presented parameters suitable for this method under dry and wet conditions. Fries et al.[15] simulated the creep characteristics obtained based on tests in the literature according to the theoretical Kalker curves of creep characteristics (Fig. 1). He thought that under the actual situation of wheel-rail contact interfaces (coated with a friction modifier), the theoretical Kalker curves of creep characteristics could be adjusted via the Kalker weight and friction coefficients and thus the influence of the friction modifier on the wheel-rail force could be simulated.Joel et al.[16] showed that creep characteristic curves, generally, could make the simulated results coincide better with the measured data through multiplying by a Kalker coefficient. These references show that the parameters of the creep curve calculation model should be adjusted in order to simulate wheel-rail curves based on the actual rail surface . Therefore, wheel-rail curves obtained based on actual wheel-rail surfaces are crucial for describing the actual wheel-rail relationship and reflecting the dynamic wheel-rail performance.

Creep curves are very important for describing wheel-rail interaction and can influence the traction / brake control, running stability and safety of vehicles. At present, there are many researches about friction modifier or friction coefficient on wheel-rail relationship of the railway line. Eadie et al.[17] analyzed the influence of rail top friction modifier on wheel rail contact wear and rolling contact fatigue through experiments. Stock et al.[18] tested the

effect of friction modifier on wear and rolling contact fatigue on standard and high quality material rail in laboratory. Under their experimental conditions, it is found that the original rolling contact fatigue crack will not accelerate development if the friction modifier is applied on the dry rail. Makowsky et al.[19] Investigated the effect of rail top friction modifier on rail rail lateral wear rate. Yao X et al.[20] think that the friction modifier will change the friction factor and the weight coefficient of Kalker, which can obviously improve the lateral stability of the body in the interval line, and have little effect on the vertical stability of the car body.

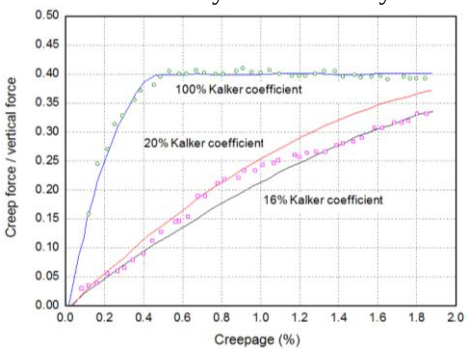

Fig. 1 *Creep characteristic curves obtained after Kalker weight coefficient matching[18]*

But at present, there is no effect of wheel rail creep curve on wheel rail wear and wheel rail dynamic performance in high speed turnout area. In order to describe the actual wheel-rail contact relationship in turnout areas, find the most applicable creep characteristics of high-speed turnouts and decrease the wear while prolonging the service life of turnouts, this paper studies the wheel-rail creep characteristics and dynamic wheel-rail behaviour of high-speed turnouts with different wheel-rail surfaces by simulating the wheel-rail surfaces through adjusting the friction and Kalker weight coefficients based on Kalker's simplified theory. The paper then attempts to put forward applicable friction coefficients and Kalker weight coefficients for the switch and crossing areas of high-speed turnouts.

2. Establishment of models

This paper focus on studying the influence of friction coefficients and Kalker weight coefficients on wheel-rail creep force and improve the dynamic wheel-rail conditions of high-speed turnouts by considering CRH2 vehicle passing through a Chinese high-speed railway 18# turnout at 80Km/h. The modeling is based on the principle of vehicle-turnout coupling dynamics and SIMPACK simulation software of multi-body system dynamics in order to analyse the influence of different creep coefficients and Kalker weight coefficients on the dynamic behaviour when high-speed vehicle wheels passing through the turnout in reverse along the sidetrack. The change of creep curves under different friction coefficient and Kalker weight coefficients are analyze based on the FASTSIM method. The wheel-rail wear caused when high-speed wheels are passing through a turnout is evaluated based on the damage function model.

2.1. Dynamic model

Based on the dynamic vehicle-turnout coupling theory [21-22], a high-speed railway dynamic vehicle-turnout coupling model is established by using Simpack simulation software. The model consists of three parts, namely the vehicle model, turnout model and wheel-rail contact model.

In the vehicle model, 31 DOFs (degree of freedom) with regard to the body, 1 bogie and 4 wheelsets are considered. The vehicle model consist the body, bolster, wheels and rail. The wheels and rails are connected with the side frame of the bogie via the primary suspension. The side frame is connected with the bolster via the secondary suspension. The bolster in connected with the body via the core plate and side bearing. In addition, some vertical, lateral and anti-hunting motion dampers are installed between the body and each frame.

In the turnout model, the elements are set by taking the turnout tie support points as nodes. Each rail node has 4 DOFs, namely vertical displacement, vertical inclination, lateral displacement and lateral inclination. A sleeper can be considered as a rigid mass in the lateral direction, which has 1 DOF - lateral displacement. In the vertical direction, the sleepers are set as finite beam elements by the rail support points. Each element has 2 DOFs - vertical displacement and vertical rotation angle. In order to simulate the deformation of the sub-rail foundation, this model has been provided with a sub-rail foundation model considering 3 DOFs - lateral displacement, up-and-down motion and side-rolling.

The relationship between vehicle model and turnout model is developed by wheel-rail contact model including the calculation of wheel-rail dynamic contact geometry and the analysis of wheel-rail contact behavior. The calculation of wheel-rail dynamic contact geometry is based on the principle of classical trace line method with considering turnout rail profile. It mainly includes the position of wheel-rail contact point and the determination of contact angle. The analysis of wheel-rail rolling contact behavior mainly based on Hertz nonlinear elastic contact and Kalker linear theory. The wheel-rail normal force can be obtained by calculating the wheel-rail equivalent penetration considering the half-axis length of the contact ellipse and the properties of the wheel-rail material. The relationship between shear stress and creep rate is obtained, and the wheel-rail normal force and tangential forces are determined.

2.2. Kalker's simplified theory[7,8]

In 1973, Kalker developed a more advanced and efficient model the simplified theory, based on the linear creep theory, assuming that the tangential displacement of any point in the contact area is only related to the tangential force acting on the point, and that the displacement in one direction is only related to the tangential forces in that direction.

The expression of the tangential force and the elastic displacement of a point can be obtained:

$$u_F = L \bullet p_F \quad (1)$$

Where: u_F is the elastic deformation at a point; p_F is the tangential force at the same point; L is the flexibility coefficient.

In order to satisfy the geometric deformation coordination principle of the elasticity theory, Kalker improved the normal pressure distribution within a contact patch, which can be expressed as:

$$P_Z = 2N(1-x^2/a^2-y^2/b^2)/\pi ab \quad (2)$$

Since no slippage is caused within the contact patch, the flexibility coefficientsL_1, L_2 and L_3 can be calculated according to the creepage-creep force relation described in the linear theory.

$$L_1 = 8a/(3C_{11}G) \quad L_2 = 8a/(3C_{22}G) \quad L_2 = \pi a\sqrt{a/b}/(4C_{23}G) \quad (3)$$

If an elliptical contact patch is divided into $n_x \times n_y$ cells, and the lengths of each in the x and y directions are Δx and Δy, respectively, then the slippage s of any cell will consist of elastic displacement u_F and rigid slippage w_F, i.e.:

$$s(x,y)\Delta x = u_F(x,y) - u_F(x-\Delta x,y) + w_F(x,y)\Delta x \quad (4)$$

Where: (x-Δx) is the position of the previous cell in the direction of x.

The following can be obtained by substituting Equation (2) into (4):

$$s(x,y)\Delta x = L \cdot p_F(x,y) - L \cdot p_F(x-\Delta x,y) + w_F(x,y)\Delta x \quad (5)$$

Suppose that a cell (x, y) is in the adhesion zone, namely the slippage of this cell is s(x,y)=0, then the surface force p_A of the cell will be:

$$p_A(x,y) = p_F(x-\Delta x,y) - w_F\Delta x/L \quad (6)$$

According to the Hertzian contact theory and Coulomb's friction law, the limit surface force P_L of the cell (x, y) will be:

$$p_L(x,y) = 2\mu N(1-x^2/a^2-y^2/b^2)/\pi ab \quad (7)$$

If P_A<P_L, adhesion will occur, otherwise the cell will be in the slippage zone, where the surface force P_S will be:

$$p_S(x,y) = p_L(x,y)\,p_A(x,y)/|p_A(x,y)| \quad (8)$$

The adhesion zone distribution of the contact patch and the creep force of all cells needed for wear calculation can be obtained according to Equations (4) - (8). The elliptical contact patch can be transformed into a unit round contact patch first through dimensionless processing. The FASTSIM program is developed for realising the numerical calculation of the simplified theory and obtaining the tangential force and slippage under normal conditions.

2.3. Damage function model[23,24]

In 2004, the British Railway Safety and Standards Commission (RSSB) developed a complete rail service life model in order to understand and describe the growth stage of fatigue cracks and rail safety. The damage function mode is based on contact patch capacity dissipation wear number and it has been validated through large amount of measured data from field observation and experiment. This model considers the influence of the lateral and longitudinal creep forces and creepage on wheel rolling contact fatigue and it relies on the wear value of Tγ, as defined below:

$$T\gamma = T_x\gamma_x + T_y\gamma_y \quad (9)$$

Where, T is the tangential force on wheels, γ is the creepage. x and y are the longitudinal and lateral directions.

This paper makes a qualitative analysis of turnout wear performance via the damage function. This damage function is a multi-linear function that describes the relationship between the wear number and rolling contact fatigue cracks. The damage function is consists of four different regions (Fig. 2),these are:

i. Damage does not occur when the wear number is below the fatigue threshold. This fatigue threshold represents a point below the shakedown limit on the shakedown graph. The work done in this region do not cause an increase in the plastic strain of the material and it will not contribute to rolling contact fatigue damage (A).

ii. The damage increases linearly with the wear number until it reaches the peak of fatigue damage (B).

iii. The fatigue damage decreases with the increase of wear number until the fatigue damage reaches 0 (C).

iv. The fatigue damage value in negative region is subjected to a severe wear and the previous fatigue damage material removed due to high wear. (D).

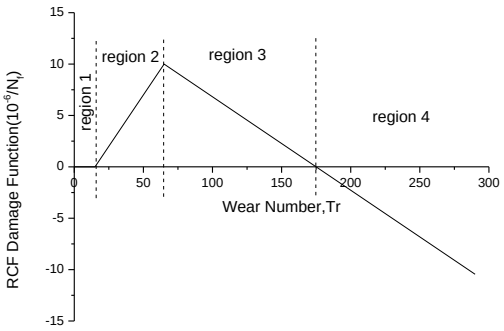

***Figure 2** RCF damage function*

3. Different creep characteristics in high-speed turnout areas

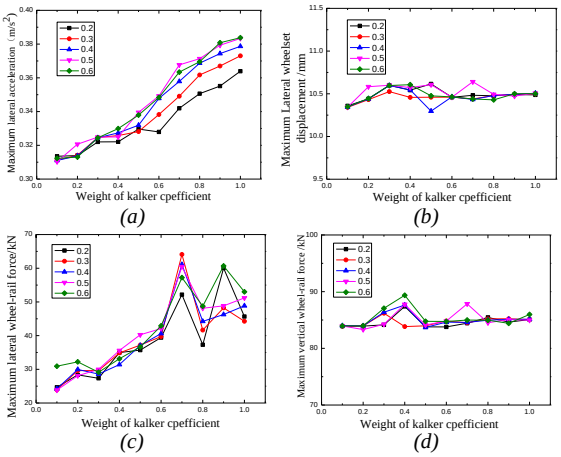
This paper study the influence of the Kalker weight and friction coefficients on the creep curve of the switch rail at the side of turnout areas as well as the wheel-rail dynamics response by selecting suitable parameters for the switch and crossing areas. The Kalker weight coefficients are changed within the range of 0.1-1 by an interval of 0.1 and the friction coefficients are changed within 0.2-0.6 by an interval of 0.1. Different results are obtained from the analysis on the dynamic performance and damage coefficients by using to the Simpack simulation software, Fastsim theory and damage function model when the CRH2 vehicle passes through the 18# turnout at 80Km/h in reverse along the sidetrack is made under different Kalker weight and friction coefficients.

3.1. Analysis on wheel-rail dynamics under different creep characteristics

According to the analysis on wheel-rail dynamics performed under ideal conditions, the wheel-rail force at

the switch rail side measured when the train passes through the turnout is higher than that at the stock rail side, so in this paper the wheel-rail force at the switch rail is selected for the study. Fig. 8-10 show the maximum lateral wheel-rail acceleration, lateral wheelset displacement and wheel-rail force on the crossing, closure panel and switch areas when the train passes through the turnout at 80Km/h in reverse along the sidetrack under different Kalker weight and friction coefficients.

3.1.1. Switch area



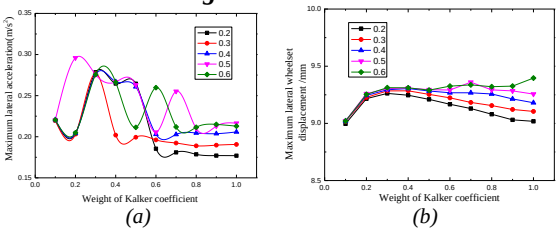


Fig. 3 *Dynamics of switch area: (a) Acceleration of vehicle body, (b) Lateral displacement of the first wheelset, (c) Lateral wheel-rail force, (d) Vertical wheel-rail force*

Fig. 3 (a) and (c) show that the maximum vehicle body acceleration and lateral wheel-rail force at the switch area increase continuously as the Kalker weight coefficient increases. When the Kalker weight coefficient changes within the range of 0.1-0.5, the maximum vehicle body acceleration and lateral wheel-rail force at the switch area basically do not change with the increase of the friction coefficient, and increase as the Kalker weight coefficient increases. When the Kalker weight coefficient changes within the range of 0.6-1, the vehicle body acceleration will increase with the increase of the friction coefficient. The change of the friction does not significantly influence the lateral wheel-rail force due to the structural irregularity of the switch area. As shown in Fig. 3 (b) and (d), the change of Kalker weight and friction coefficients has little influence on the maximum lateral wheelset displacement and vertical wheel-rail force at the switch area.

3.1.2. Crossing area

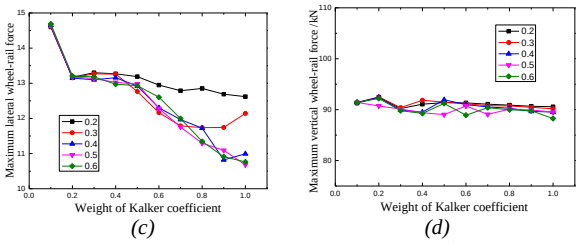

Fig. 4 *Dynamics of crossing area: (a) Acceleration of vehicle body, (b) Lateral displacement of the first wheelset, (c) Lateral wheel-rail force, (d) Vertical wheel-rail force*

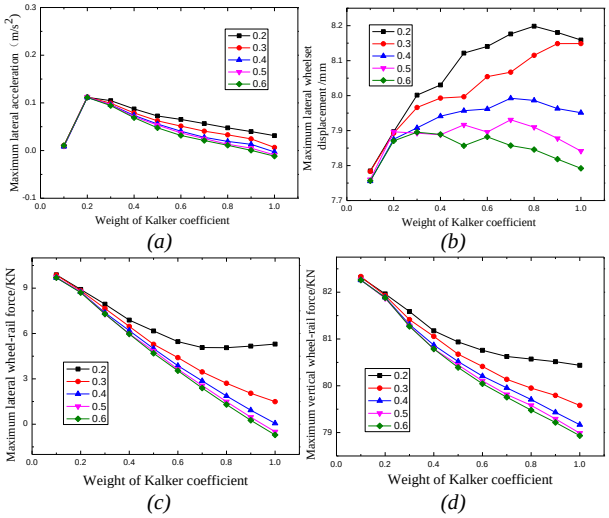
Fig. 4 shows the influence of different Kalker weight and friction coefficients on the dynamic wheel-rail behaviour of the crossing area. As shown in Fig. 4 (a) and (c), when the Kalker coefficient changes within the range of 0.6-1, the maximum vehicle body acceleration will increase as friction increases. The maximum lateral wheel-rail force at the crossing area decreases as the Kalker weight coefficient increases, because with the change of the Kalker coefficient, the wheel-rail adhesion and vehicle body motion change, leading to change of the lateral wheel-rail force. According to Fig. 4 (b) and (d), the Kalker weight and friction coefficients have little influence on the lateral wheelset displacement and vertical wheel-rail force at the crossing area.

3.1.3 Closure panel



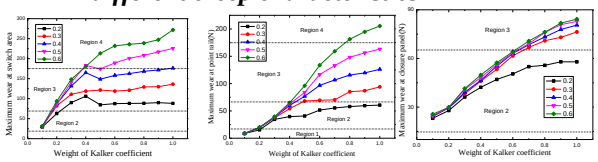


Fig. 5 *Dynamics of crossing area: (a) Acceleration of vehicle body, (b) Lateral displacement of the first wheelset, (c) Lateral wheel-rail force, (d) Vertical wheel-rail force*

As shown in Fig. 5, there is no wheel load transition at the closure panel of the turnout area as the rail section does not change, therefore the dynamic characteristics of the closure panel change as the Kalker weight and friction coefficients change. According to Fig. 5 (a), when the Kalker coefficient changes within the range of 0.2-1, the maximum vehicle body acceleration will decrease as the Kalker coefficient increases. The change of the friction coefficient has little influence on the maximum vehicle body acceleration at the closure panel. According to Fig. 5 (b), the maximum lateral wheelset displacement increases and then decreases with the increase of the Kalker coefficient, and decreases with the increase of the friction coefficient, however the amplitude does not change much as it is less than 1mm. As shown in Fig. 5 (c), the lateral wheel-rail force at the closure panel

decreases as the Kalker and friction coefficients increase, and even the direction of the lateral wheel-rail force changes. Due to the fact that the curve for the closure panel is not set with a superelevation, the wheel-rail motion changes with the change of the wheel-rail creep characteristics. The maximum lateral wheel-rail force is not a high value, because the closure panel is not subject to wheel load transition. According to Fig. 5 (d), the lateral and vertical wheel-rail forces at the closure panel decrease with the increase of the Kalker and friction coefficients, however the amplitude does not change much since it is less than 4KN, because the creep characteristics have little influence on the vertical wheel-rail force.

3.2. Analysis on RCF damage coefficient with different creep characteristics

(a) *(b)* *(c)*

Fig. 6 *Wheel-rail wear number of turnout area: (a) Wear number at switch area, (b) Wear number at crossing area*

Fig. 6 shows the maximum wear numbers of the switch area, crossing area and closure panel at the turnout switch rail side. According to this figure, the maximum wear numbers of the switch area, crossing area and closure panel increase when the Kalker weight and friction coefficients increase.

As shown in Fig. 6 (a), when the Kalker weight coefficient changes within the range of 0.1-0.4, the maximum wear number will increase as the Kalker weight coefficient increases. The maximum wear number does not increase much with the increase of the friction coefficient. When the Kalker weight coefficient changes within the range of 0.5-1, the maximum wear number will increase as the friction coefficient increases. The maximum wear number basically doesn't change as the Kalker coefficient increases when the friction coefficient is 0.2 or 0.3. When the friction coefficient changes within the range of 0.4-0.6, the maximum wear number will increase slightly as the Kalker coefficient increases. According to the fatigue damage function, when the friction coefficient is 0.4 and the Kalker weight coefficient is higher than 0.4, the maximum wear number at the switch area will be close to the upper limit of 175N at the third region, indicating that the fatigue damage and wear cancel each other out and the contribution of the fatigue damage is close to zero.

As shown in Fig. 6 (b), when the Kalker weight coefficient changes within the range of 0.1-0.3, the maximum wear number at the crossing area will increase as the Kalker weight coefficient increases, and the change of the friction coefficient has little influence on it. When the Kalker weight coefficient gradually increases within the range of 0.4-1, the amplitude of increase of the maximum wear number at the crossing area will be higher and higher as the friction coefficient increase. It can be seen from the fatigue damage function, when the Kalker weight coefficient is 2.0, the maximum wear number at the crossing area will be close to the lower limit of the second region, namely the shakedown limit, and therefore it is unlikely to cause increase of material plastic strain and both the fatigue damage and wear are very low.

As shown in Fig. 6 (c), since there are no wheel load transition problems and the rail section is constant at the closure panel, the maximum wear number at the closure panel is lower than those at the switch and crossing areas. When the friction coefficient changes within the range of 0.3-0.6, the maximum wear number at the closure panel will increase as the Kalker weight coefficient increases, and the friction coefficient has little influence on the maximum wear number. When the friction coefficient is 0.2, all maximum wear numbers will be within the second region of the fatigue damage functions, which are obviously lower than those obtained with other friction coefficients. The damage increases linearly with the wear number, and rolling contact cracks are the main damage type. When the Kalker weight coefficient is 0.1, the maximum wear number at the closure panel will be close to the lower limit of the second region, and both the fatigue damage and wear are very low.

4. Conclusions

This paper focus on the influence of Kalker weight coefficient and friction coefficient on the wheel-rail relationship in the reverse operation of Chinese high-speed railway turnout zone and it analysed from two aspects of dynamic behavior and wheel-rail abrasion performance. The creep-slip parameters suitable for the contact relation between the wheel and rail of the high speed turnout switch, the frog area and the connecting part are given respectively.The research results show that:

i. The smaller kalker weight coefficient and friction coefficient have less influence on wheel-rail dynamic behavior and wear performance because the smaller Kalker coefficient make a smooth change on creep curve and the influence of the friction coefficient on the creep curve will be lower at this time.

ii When the high speed vehicle wheel passes through the switch area with considering the kalker weight coefficienvalue 0.1, the peak values of the lateral wheel-rail force and lateral acceleration at the switch area become minimum. The stability of the running vehicle is high, both the fatigue damage and wear become very small.

iii When the high speed vehicle wheel passes through the crossing area with considering the kalker weight coefficient. value and friction coefficient ranges between 0.3~0.6, the peak value of the lateral wheel-rail force at crossing area become minimum. If the friction coefficient is 0.5, the fatigue damage and wear will cancel each other and the wheel-rail conditions will be optimal. Generally, when the Kalker weight coefficient at the crossing area is 1 and the friction coefficient is 0.5, the dynamic wheel-rail performance will be good. the wear and fatigue damage will cancel each other out and the wheel-rail

contact will be in a good state.

iv When the high-speed wheels pass through the closure panel, both the wheels and rail have good dynamic performance and the rail profile has a constant section. When the Kalker weight coefficient is 0.1, the maximum wear number of the closure panel will be closer to the lower limit of the second region and both the fatigue damage and wear are very low.

Generally this paper analyses the influence of Kalker weight and friction coefficients on the wear damage of high-speed turnouts based on the damage function model. In order to improve the wheel-rail dynamic performance and reduce the wheel-rail wear in the turnout area, the Kalker weight coefficient and friction coefficient suitable for the switch area and the frog area of the high speed turnout are put forward respectively. Therefore, the suitable creep curve is put forward, which provides a theoretical basis for developing friction modifiers suitable for turnout area.

FIELD INVESTIGATION ON THE HIGHER-ORDER POLYGON WEAR ON WHEEL OF HIGH SPEED TRAINS

Sheng Qu, Jianbin Wang, Dafu Zhang, Huailong Shi, Pingbo Wu & Huanyun Dai*

State-Key Laboratory of Traction Power, Southwest Jiaotong University, Chengdu, 610031, China

* E-mail: daihuanyun@163.com

Abstract: This study investigates the mechanism of high-order polygonization of wheel for high-speed trains. Analysis in the wheel roughness and vibration of axlebox shows that the wheel polygonization on one wheelset can be transmitted to another one of a bogie, which leads to a rapidly increasing in the uneven wear on tread by a quite short operation distance. The 3rd bending mode of rail has a constant frequency around 572 Hz regardless of its boundary conditions. A resonance occurs between the natural frequency of rail and the high-order polygonization induced frequency of wheel in case of running speed around 300 km/h.

Keywords: High-speed trains; polygonal wheel; wheel/rail interaction; modal analysis.

1. Introduction

There are more than 3,000 high-speed trainsets running on the high-speed railways everyday in China. A long-term field test has been conducted for the high-speed train with a continuous running speed of 300 km/h to evaluate the dynamics behaviour evolution with the traveling distance of vehicle [1]. It is found that the vibration and lateral hunting stability of bogie increases or deteriorates with the wheel wear increasing. Additionally, it has been found that the high-speed railway vehicles have encountered higher-order polygon wear on wheel after a certain operation distance. The order of polygon ranges from 17 to 20, in which the order is not a constant because of the track structure and wheel diameter. Wheel polygonization is critically harmful to the vehicle dynamics as well as the structure strength of bogie, and severe noise can be noticed [2-8]. In order to have a thorough understanding on the development of wheel polygonization for high-speed trains, some tests in field and laboratory have been carried out to show the effects of polygonization on the vehicle dynamics and its mechanism of development. A modal analysis of the rail segment supporting the bogie is also provided to explain the propagation of wheel propagation on one wheelset to another wheelset of bogie.

2. Field test of wheel polygonization

Wuguang high-speed railway has a total distance of 1069 km from Wuhan to Guangzhou in China, and the continuous operation speed is 300 km/h. The ballastless track CRTS-I (double block)is used with a sleeper span of 0.65 m, as shown in Fig 1.

Fig 1 *Wuguang (Wuhan-Guangzhou) CTRS-I(double block) ballastless track*

Fig 2 *Tested vehicle and accelerometers mounted on wheelsets*

The test region is from Guangzhou to Changsha with a distance of 707 km in the Wuguang high-speed railway line. The CRH380B series high-speed train has been tested, which is one of the mainly used high-speed trainsets in China. During the test, the four wheelsets of the third coach of one trainset were measured. Accelerometer was installed on the axlebox, as shown in Fig 2. A high sampling frequency of 5000 Hz was employed for the data acquisition system to record the high-frequency vibration excited by the high-order wheel polygonization. A total of three rounds of test on the Wuguang high-speed line was measured to record the uneven wear on wheel tread.

The location of the wheelsets and distance between them shows in Fig 3.

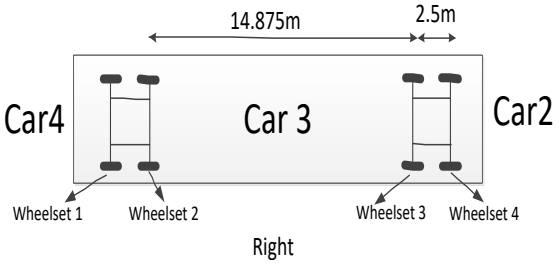

Fig 3 *The location and the distance between the wheelset*

2.1 Wheel roughness analysis

Before the test, the wheels of wheelsets 1, 2 and 4 in the test car were re-profiled, while the wheelset 3 has a serious high-order polygon wear on the wheel tread. This wheel polygonization leads to an initial excitation on vehicle. The surface roughness of wheel tread was measured by using the equipment Müller-BBM before and after the tests, and results are demonstrated in Tab.1. It shows that the polygonization amplitude of the wheel is 31.87 dB for the left wheel of wheelset 3 (3L) before the test, and the associated polar diagram and order diagram are plotted in Fig 4. This clearly shows that the wheel 3L experiences a severe out-of-roundness (OOR).

As shown in Tab.1, the polygonization state on wheel 3L increases from 31.87 dB to 34.24 dB with an order of 19 after three rounds of operation within a running distance of 2121 km. Similarly, the polygonization state on wheel 4L increases from -15.92 dB to 10.42 dB with an order of 18. In the contrast, the polygonization states on wheel 2L changes little within the traveling distance. This can be concluded that that the polygonization of wheel on one wheelset can be transited to the other one of bogie, which leads to a rapidly increasing in the uneven wear of wheel in a quite short operation distance.

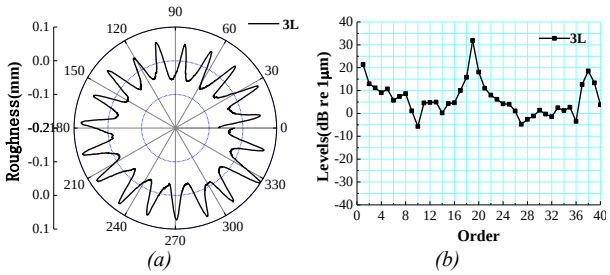

Fig 4 *Wheel tread roughness of the left wheel of wheelset 3, (a) polar diagram and (b) order diagram*

Tab 1 *Wheel polygonization states of the test wheelsets*

	Left wheel of wheelset 2		Left wheel of wheelset 3		Left wheel of wheelset 4	
Measured time	Polygonization order	Level dB/μm	Polygonization order	Level dB/μm	Polygonization order	Level dB/μm
Before test	—	—	19	31.87	18	-15.92
After the first round	—	—	19	32.82	18	-7.38
After the second round	20	-5.41	19	32.66	18	0.246
After the third round	20	-4.48	19	34.24	18	10.42

2.2 Vibration analysis of axlebox

Figure 5 demonstrates the vertical acceleration of axlebox on wheel 4L, which increases from 100 g to 400 g after three rounds of operation on track. It implies the vibration of wheelset has been significantly amplified, more than four times, after three rounds of operation on Wuguang highs-peed line in case of wheel polygonization. However, the acceleration amplitude of axlebox corresponds to wheel 2L changes little during the test as illustrated in Fig 6, and the maximum acceleration is around 100 g.

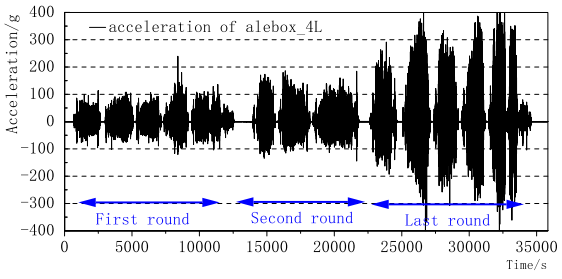

Fig 5 *Vertical acceleration of axlebox on wheel 4L*

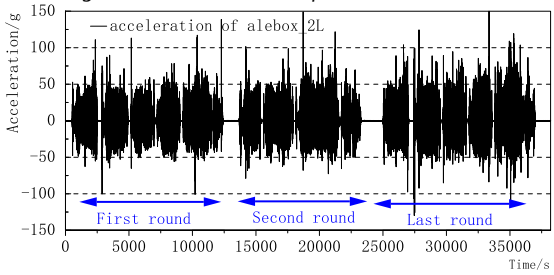

Fig 6 *Vertical acceleration of axlebox on wheel 2L*

Figures 7 and 8 demonstrates the frequency spectrums (Short-term Fourier Transform) of vertical acceleration on the axlebox of wheel 4L. In case of running speed of 300 km/h, the induced frequency of higher-order polygonization of wheel is 560 Hz with an amplitude of 16.5 g and 24.8 g for the first and last round of operation, respectively.

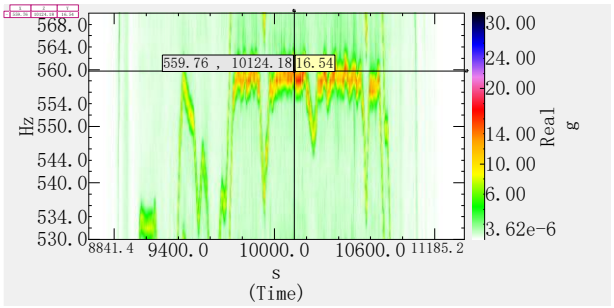

Fig 7 *Time-frequency spectrum of acceleration at the first round*

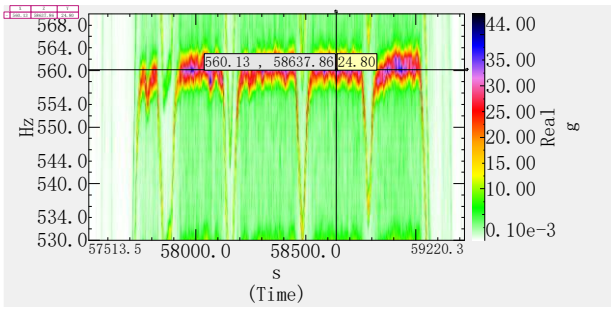

Fig 8 *Time-frequency spectrum of acceleration at the third round*

Figure 9 demonstrates the time history of acceleration for different axleboxes on wheel. It shows that the acceleration of wheels 3L and 4L are in the same phase, while the vibration of wheel 2L behaves randomly. This implies that the polygonization state of wheel 3L has an influence on the wheel 4L but little on wheel 2L, since

the wheels 3L and 4L are assembled in one bogie while wheel 2L locates on the other bogie.

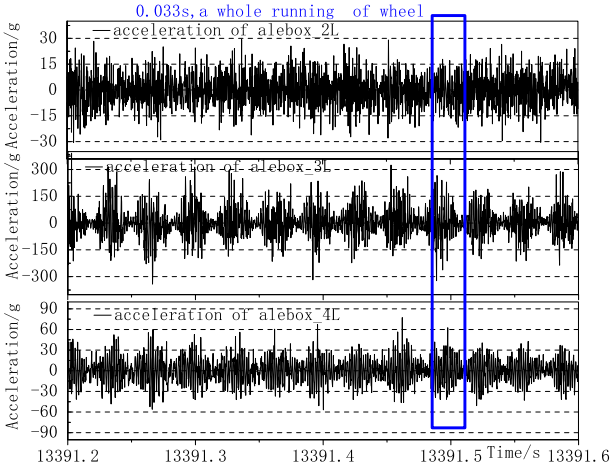

Fig 9 *Time history of vertical acceleration for various axleboxes*

3. Mechanism study of wheel polygonization

It is noticed that the polygonization state of wheel 3L has an effect on that of wheel 4L within one bogie, then modal tests for the rail were carried out both in the laboratory and on field to study this propagation mechanism of wheel polygonization among wheels.

3.1 Modal analysis of rail by lab tests

The mode shapes and frequencies of the rail segment supporting the bogie were tested in the laboratory. In this case, the two wheelsets within the bogie play the boundary of the rail segment. In addition, the concrete sleepers through rubber pads also constrain the rail segment, as shown in Fig 10.

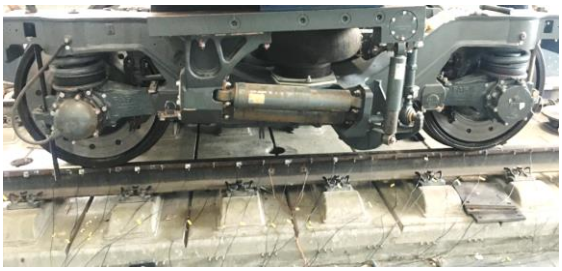

Fig 10 *Modal test of rail segment within one bogie*

A bogie was put on the track which has the same structure of that used in the Wuguang high-speed line, CRTS-I double block. The bogie is also the same type as used on the field operation, which has a wheelbase of 2.5 m. An array of accelerometers were mounted on the side rail with an interval of 15 cm along the track. In the modal testing, a hammer impact was used to excite the rail under the bogie. Then the 1st, 2nd and 3rd modes of the rail segment under the bogie can be evaluated, and the corresponding modes are illustrated in Fig 11. Table 2 lists the natural frequency and damping ratio, and it shows that the 3rd bending mode has the lowest damping.

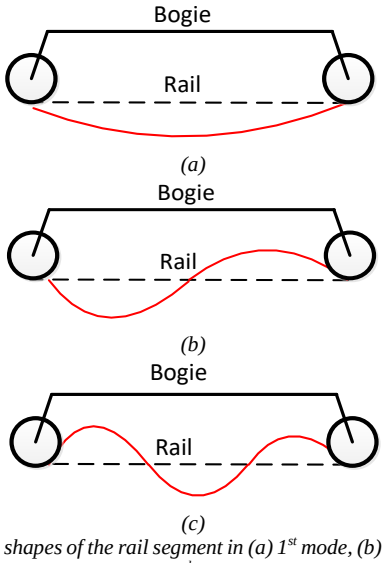

Fig 11 *Mode shapes of the rail segment in (a) 1st mode, (b) 2nd mode and (c) 3rd mode.*

Tab 2 *Natural frequency and damping ratio of the rail segment*

Order	*Natural frequency /Hz*	*Damping ratio*
1	*206*	*11.8%*
2	*352*	*4.1%*
3	*572*	*3.2%*

Additional tests have been performed to declare that the location of the bogie on rail has no effect on the 3rd order mode of the rail segment under the bogie. One case is that the two wheelsets were placed at the position of sleepers, since the distance between two sleepers is about 0.65 m which can be divided by the wheelbase 2.5 m. Another case is that the two wheelsets were placed at the mid-point between two sleepers. The corresponding results for these two cases are illustrated in Fig 12. It is found that the 3rd mode of the rail segment remains the same as that in Fig 11(c) no matter if the wheelsets are directly supported by the sleepers in these two cases. The frequency of the 3rd mode is about 572 Hz.

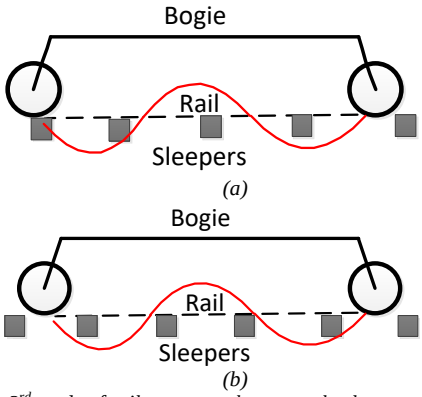

Fig 12 *The 3rd mode of rail segment when two wheelsets are placed (a) at the position of sleepers and (b) the mid-point between two sleepers*

It can be declared that the 3rd order modal of the rail segment is straightforwardly excited by the wheel/rail interaction. This can be proved by conducting another modal test. In this case, remove the wheel load on rail firstly by lifting one of wheel 10 mm above the rail surface by a jack, then release this lifting force suddenly to introduce an impact on rail. Similarly, the 3rd mode shape and natural frequency are still the same as they

shows in Fig 11(c) and Fig 12.

***Fig 13** modal test by a jack*

3.2 Resonance analysis of wheel and rail by field tests

The 3rd mode of the rail segment is 572 Hz, which is close to the induced frequency of vibration by the high-order polygon of wheels 3L and 4L. Since the damping ratio of the 3rd mode of rail is quite low, a significant resonance appears which can be clearly seen from the field test data. As demonstrated in Fig 14, the maximum acceleration on the axlebox of wheel 3L reaches to 600 g when the vehicle was running at a speed of 305 km/h. While the acceleration reduces to 100 g if the vehicle speed decreases to 290 km/h in case of passing neutral sections or arriving at a station when losing its traction power.

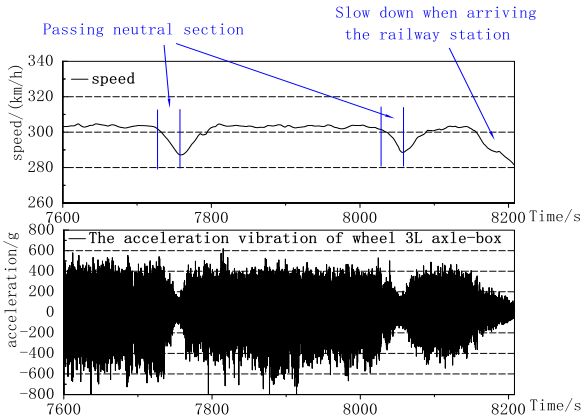

***Fig 14.** Time history of vehicle speed and acceleration on axlebox*

The associated frequency spectrum of Fig 14 is plotted in Fig 15, in which the main frequency was definitely induced by the polygonization on wheel 3L. In case of a lower speed with respect to 305 km/h, the energy or amplitude of vibration corresponds to the polygonization drops down significantly.

This can be explained as that a resonance occurs in case of a continuous running speed of 305 km/h between the polygonal induced frequency and the 3rd mode of rail segment within the bogie has wheel polygonization. Then a large vibration can be noticed on the axlebox of corresponding wheel 3L which experiences severe polygonization on tread. In case of lower speed than 305 km/h, the induced frequency by the polygonization decreases which is lower than the 3rd mode of rail, then there is no resonance happened in this case between the wheel and rail. That why the speed of vehicle changes a bit can lead to a great change in the vibration of axlebox.

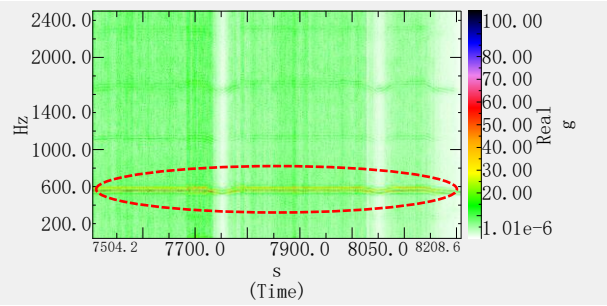

***Fig 15** Time-frequency spectrum of acceleration of wheel 3L*

3.3 Analysis of wheel polygonization propagation

In the field test, the wheel 3L experiences a serious polygonization condition at an initial state, which leads to resonance with the 3rd mode of rail. This resonance introduce large vibrations on the wheelset 3 which is in turn transited to the wheels of wheelset 4 through the rail segment supporting the bogie. As a consequence, this polygonization related vibration leads to uneven wheel-rail interaction and wear on wheel 4L. Then polygonization appears and increases rapidly on wheel 4L with respect to the wheels on the other bogie.

There are three types of ballastless track which are commonly used in the Chinese high-speed railways. A long-term field test has been conducted to investigate the wheel polygonization state on various types of track with the on-board data acquisition system of CRH380B series high-speed trains.

(1) **CRTS-I Plate**, has a sleeper span of 0.629 m, the frequency of 3rd mode of rail is 650 Hz.
(2) **CRTS-I Double Block**, has a sleeper span of 0.65 m, the frequency of 3rd mode of rail is 570 Hz.
(3) **CRTS-II**, has a sleeper span of 0.65 m, the frequency of 3rd mode of rail is 580 Hz.

In order to prove the mechanism of wheel polygonization propagation by the rail segment supporting the bogie, additional filed tests were carried out on Jinghu high-speed railway which starts from Beijing and ends at Shanghai with a total distance of 1318 km. In the high-speed line, most of it are equipped with CRTS-II track structure except on bridge, such as the bridges across the Yellow River and the Yangtze River use the CRTS-I Plate track.

Similarly, the test was again for the CRH380B series high-speed car, in which wheels on one bogie had serious polygonization. When the vehicle passes over the bridge, the acceleration on axlebox has the higher-order polygon on wheel decreases from 75g to 30g in case of a continuous running speed of 300 km/h, as depicted in Fig 16. As illustrated in Fig 17, the energy corresponding to the polygonal frequency shows great difference when the vehicle running from the track of CRTS-II to CRTS-I plate. This can be explained as that the polygonization induced resonance with the rail on a track type of CRTS-II disappeared when it matches with the rail on CRTS-I, because the frequency of the 3rd mode of rail changes from 570 Hz to 650 Hz.

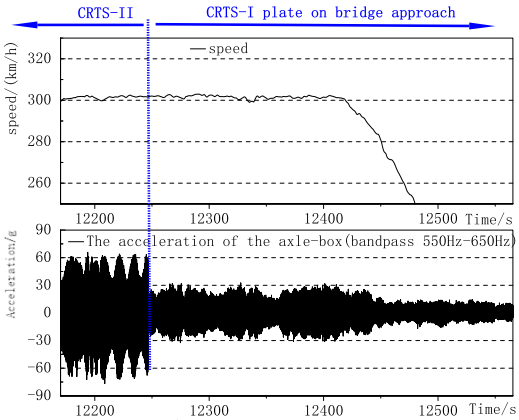

Fig 16 *Time history of acceleration on axlebox when the vehicle running from the track of CRTS-II to CRTS-I plate*

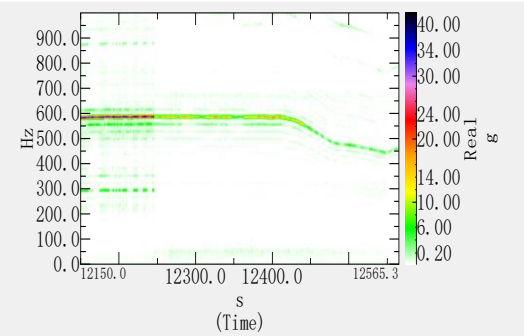

Fig 17 *Time-frequency spectrum of acceleration on axlebox when the vehicle running from the track of CRTS-II to CRTS-I plate*

Additionally, field tests were also carried out on Wuguang high-speed railway in the case that all wheels of one trainset were re-profiled before the test. This means that none of them has an initial polygonization. Figure 18 depicts the polar and order diagrams of the wheel 1L, which implies that the wheel has a good roundness in the initial state of test.

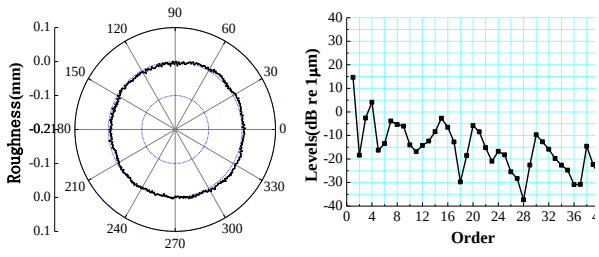

Fig 18 *Wheel tread roughness in (a) polar and (b) order diagrams*

Figure 19 shows the vertical acceleration on the axlebox, in which a zoomed plot is provided. It has many impacts with an amplitude of 50 ~ 150 g, while the nominal amplitude of acceleration is lower than 30 g when ignoring the impact signals as the zoomed plot shows. These impacts come from the rail joint passing, which has an interval of 1.21 s when the vehicle has an continuous operation speed of 300 km/h. This time interval corresponds a distance interval of 100 m. Clearly, the time interval is dependent on the vehicle speed. Generally, the rails are made by 100m for high-speed railway and welded together on field as shown in Fig 20. The rail joint through welding causes external excitations on vehicle and needed to be ground smoothly. Rail joints exists for the whole track line.

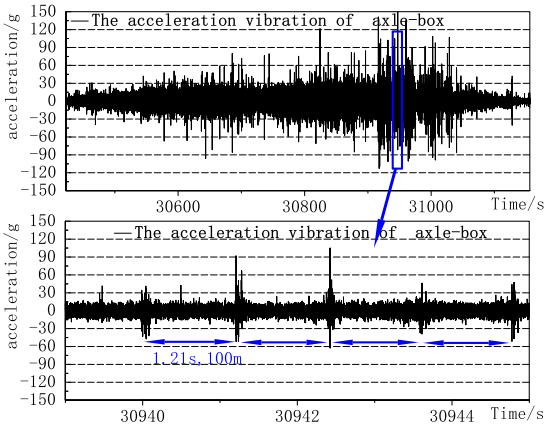

Fig 19 *Time history of vertical acceleration on axlebox*

Fig 20 *Rail grinding at a welding joint*

Although all wheels have been re-profiled before the field test, the main frequency at 580 Hz can be still noticed on the vertical acceleration on the axlebox as shown in Fig 21. It is because the impact forces lead by passing over rail joint can excite the vibrating of the 3rd mode of rail. It is why an impact force from the hammer impact on rail is used as the input for the rail modal testing in Section 3.1.

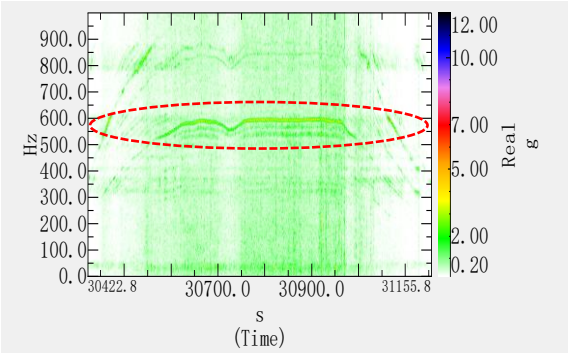

Fig 21 *Time-frequency spectrum of acceleration on axlebox*

As a consequence, the impact caused by rail joint, wheel flats or track irregularity can lead to the rail vibrating at the 3rd mode, then the wheel get polygonization easily in this situation. In recent two years, the track maintenance operator grind the rail frequently to reduce the impact and irregularity, and also strengthen the inspection of the wheel flats. Then the wheel polygonization has been greatly reduced compared with that in the previous years.

3.4 Wavelength of polygonal wear on wheel

The rail vibrates at the 3rd mode with a frequency of 570

~ 580 Hz for the case of CRH380B high-speed trains running on the track of CRTS-I double block or CRTS-II. The associated vibration period is T = 1/580 = 0.00172 s, and the wheel rotates a distance of 0.1434 m within one period when vehicle moving at 300 km/h. This distance equals to the wavelength of the polygonal wear on wheel.

4. Conclusions

Field tests were carried out on field and in laboratory to show the effects of polygonization on the vehicle dynamics and its mechanism of propagation. In this investigation, a modal analysis of the rail segment supporting the bogie is provided to investigate the propagation of vibration induced by the polygonal wear from one wheelset to the other wheelset.

It was found that if polygonization occurred on one wheelset, the other wheelset within one bogie shall be polygonised in a quite short travelling distance. This copy phenomenon from one wheelset to the other wheelset of bogie is transited by the rail segment supporting the bogie. Resonances occurs when the polygonization frequency at certain running speed matching with the 3rd mode of rail, and significantly amplifies the acceleration on the axleboxes of wheels with polygonal wear. The rail vibrates at the 3rd mode with a frequency of 570 ~ 580 Hz for the case of CRH380B series high-speed trains running on the track of CRTS-I double block or CRTS-II. The impact caused by rail joint, wheel flats or track irregularity can lead to the rail vibrating at the 3rd mode, which in turn leads to the wheel polygonization.

Abstract: Material properties were evaluated for the laser cladding of 410L grade stainless steel on a hypereutectoid steel rail substrate under two different heat treatment conditions. Miniature tensile test samples were produced to evaluate the mechanical properties of the clad layer and HAZ. The tensile properties, in particular ductility, were improved by a post-heating and slow cooling rate which resulted in a more favourable microstructure. Elongation values were increased by 423% and 186% for the clad layer and HAZ, respectively, compared to pre-heat treatment. The post-heat treatment also marginally increased the tensile strength in these regions.

Keywords: Laser cladding; hypereutectoid steel rail; miniature specimen; tensile properties; heat affected zone (HAZ)

1. Introduction

Laser cladding is one of the most advanced repair techniques in many applications such as tools [1, 2], turbine blades [3, 4] and internal combustion engine parts [5], as well as various components of a military nature [6, 7]. It has the ability to deposit a wide range of high strength, wear, and corrosion resistant materials without substantially changing the substrate material's properties. Clad layers with optimized laser cladding parameters [8-10] have been shown to exhibit superior microstructural and mechanical properties, which improves the mechanical performance and in-service product-life of the substrate material.

The applicability of laser cladding technique for repairing damaged railway components has also been studied by several research groups. Laser cladding on Grade 900A rail was investigated in the InfraStar project [11-13]. Hiensch et al. [11] showed the RCF was improved by cladding with two (Duroc 222 and Duroc 508) laser cladding materials. Ringsberg et al. [13] developed a fatigue evaluation model using shakedown theory to predict the fatigue life of laser cladded railway rails. For a given traction coefficient, the FEA results showed that thicker claddings increased the shakedown limit. Recommended cladding thickness varied with the load case, but typically were about 3–4 mm. Franklin et al. [12] conducted laboratory twin disc experiments under simulated rail-wheel contact conditions. They showed that laser cladded rail endured 200,000 cycles of water-lubricated twin-disc testing without crack formation whereas uncladed rail showed severe cracking after only 4,000 cycles. Field trial tests [12] also showed good agreement with the laboratory twin disc experiments. A similar investigation was conducted by Niederhauser and Karlsson [8] on B-82 grade steel, which was commonly used for railway wheels in Sweden. Cladding with Co-Cr alloys showed consistent and promising fatigue performance.

Robles Hernández et al [14] investigated the application of laser cladding to improve the batter performance of aluminothermic (thermite) welds under heavy haul conditions [14]. Jominy heat treatment protocols were used to determine the thermal processing conditions required to hinder or temper martensite and improve the toughness [14]. The combination of testing and materials design significantly improved the fatigue life for the laser cladded rail.

The tribology research group from Southwest Jiaotong University, China [15-17] performed laser cladding on U71Mn Chinese standard rail using a Co-based alloy. Their extensive research under different contact conditions and a lubricated environment showed significant improvement of wear and fatigue resistance of laser cladded rails. Further investigation of laser cladding on 260-grade rail was conducted by Lewis et al. [18, 19] using several stronger and harder cladding materials. The resistance to RCF initiation of all of the candidate materials was superior compared to the R260 grade material. More recently, microstructural analysis by Lai et al [20, 21] showed the potential for application of laser cladding repairing techniques on high strength rail steels used in Australian heavy haul conditions. A premium hypereutectoid grade rail (R400HT) was cladded with 410 grade stainless steel, which is a high strength, excellent abrasion and corrosion resistant material. These studies demonstrated the successful elimination of untempered martensite from the clad layer and HAZ by changing the cladding direction from rail transverse to

longitudinal and applying a post cladding heat treatment.

Previous research on laser cladding of rail to repair and extend the service life has mainly focused on the microstructure and the hardness evaluation of clad layers, and the assessment of wear and rolling contact fatigue behaviour using laboratory tests. Limited data, other than hardness measurements, is available on the mechanical properties of the cladding materials and the HAZs. Correlation of the mechanical properties with the laser cladding conditions, including associated heat treatment strategies, is challenging without knowing the basic properties, such as Young's modulus and yield strength, of the cladded rails. The current research aims to measure the mechanical properties of laser cladded rails directly by carrying out tensile tests. A high strength, hypereutectoid rail was used as a substrate, and clad with 410L grade stainless steel.

2. Methodology

2.1. Materials

The rail used as a substrate is a high strength, heat treated hypereutectoid rail. The mechanical properties and chemical compositions of the substrate rail comply with the rail grade R400HT of European Standard EN 13674. A martensitic stainless steel (410L) hard facing material was selected for cladding because of the excellent resistance to abrasion and corrosion, excellent fatigue properties and high compatibility with the laser cladding process.

2.2. Laser cladding process

The laser cladding material was used in a powder form with an average particle diameter of 150 µm. Laser cladding was conducted with a laser coaxial head comprising a 4 kW IPG fibre laser gun and a Sultzer-Metco twin-10 gas carrier powder feeder. For the deposition of the cladding material onto the substrate rail head, the constant laser cladding parameters were used as 3.2 kW laser power; 1000 mm/s scanning speed, 26.4 g/min powder feed rate and 5 mm spot size. A 500 mm long full-scale rail piece was used for depositing a 400 mm long clad layer, as shown in Figure 1. Two individual heat treatment conditions were applied in the laser cladding process; these were designated Group-A- (410L-A), with pre-heating the substrate to 350 °C only and normal air cooling, and Group-B- (410L-B), which involved pre-heating the substrate to 350 °C, post heating to 350 °C then slow cooling under a ceramic blanket.

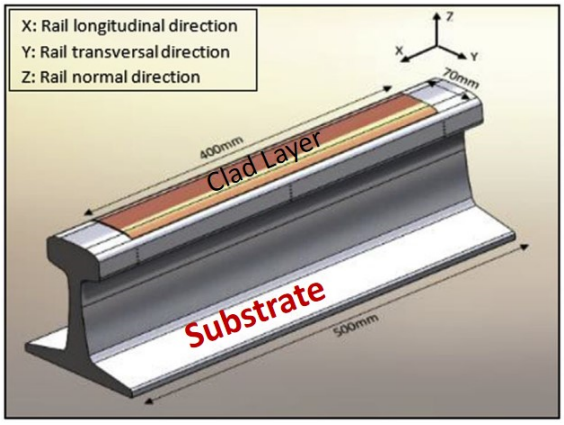

Figure 1 Schematic diagram of laser cladded rail.

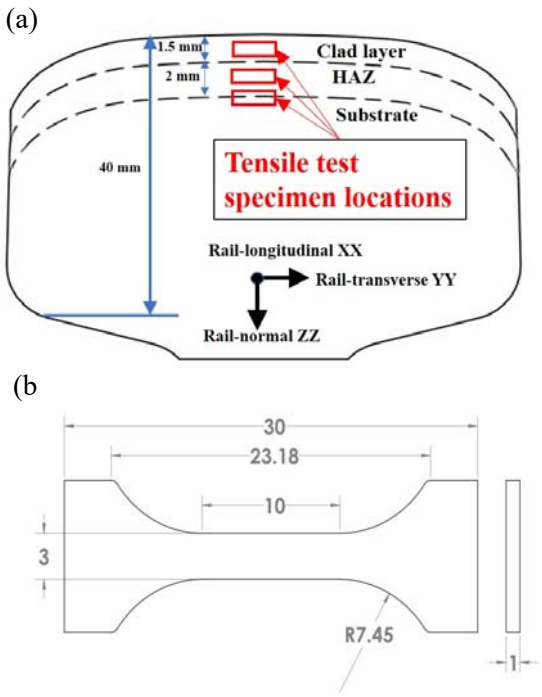

Figure 2 a) Schematic diagram of rail-longitudinal cross-sectional view of a representative cladded rail indicating the clad layer, HAZ, substrate and the locations of that tensile test specimens; b) schematic diagram of miniature tensile test specimen (dimensions are in mm).

2.3. Tensile testing

The thickness of the clad layer and heat affected zone (HAZ) of the laser cladded rail is about 1.5 mm and 2 mm, respectively, as shown in Figure 2(a). Conventional tensile techniques are not suited to evaluate the small-sized region of clad layer and heat affected zone (HAZ). Hence miniature tensile specimens were extracted from these critical regions by electro-discharge machining (EDM) process. Three parallel specimens were cut from each section of the clad layer, HAZ and substrate regions for each heat treatment condition. In total, nine specimens were produced from cladded rail with Group-A: pre-heat treatment and another nine specimens from heat treatment Group-B. The dimensions of the miniature specimen are shown in Figure 2(b).

In this study, an experimental setup has been modified to accommodate the miniature specimens. Monotonic tensile tests were performed to determine the elastic modulus, yield strength, tensile strength, and elongation from the stress-strain curves.

2.4. Microstructural analysis and hardness measurement

The cross-sectional surface of all specimens was ground and polished to a mirror finish for hardness measurements. Microhardness tests were conducted on a microhardness machine using a 2 kg-f load for 15 s. Microhardness measurements were made every 150 µm

apart from the edge of each specimen in a zig-zag line. After the tensile testing, the fracture surfaces were examined under scanning electron microscope (SEM).

3. Results and discussion

3.1. Microhardness

Figure 3 shows the hardness distribution of the 410L cladding materials with the two different heat-treated conditions. The specimen 410L-A represents the laser cladded rail with pre-heat treatment only, and 410L-B represents the laser cladded rail with pre-heating, post-heating then slow cooling. The hardness distribution is shown for the three distinctive regions identified in Figure 2(a).

The average hardness in the clad layer was 415 HV for 410L-B and 396 HV for 410L-A, i.e marginally higher in 410L-B. The higher hardness for the Group-B sample can be explained by the finer microstructure [22]. In the HAZ, the hardness variation between the two heat treatment conditions was not significant. For the substrate region, the average hardness value of 410L-B was about 3% higher than the hardness in 410L-A.

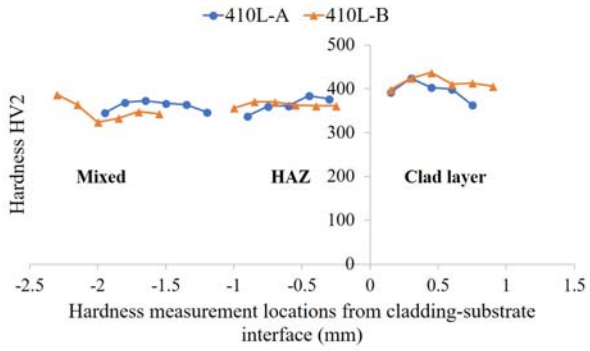

Figure 3 Hardness distribution of the tensile test specimens

3.2. Tensile testing

Figure 4 and Figure 5 show the stress-strain curves for the clad layer, HAZ and mixed specimens for 410L-A and 410L-B, respectively. Clearly, the clad layer material for both heat treatment conditions has a higher tensile strength, and the combined heat treatment (pre-heating and post-heating) process has significantly increased the elongation of clad layer and HAZ.

The tensile results are summarised and compared in Table 1. The 0.2% proof stresses of the clad layers were 1010 MPa and 950 MPa for 410L-A and 410L-B, respectively. This result shows that the post-heat treatment lowers the proof stress for the 410L cladded rail. In comparison, the post heat treat process increased the elongation of the clad material to 4.2 times that for the pre-heat-treated condition. Similarly, the post- heat treatment increased the ultimate tensile strength of the clad layer.

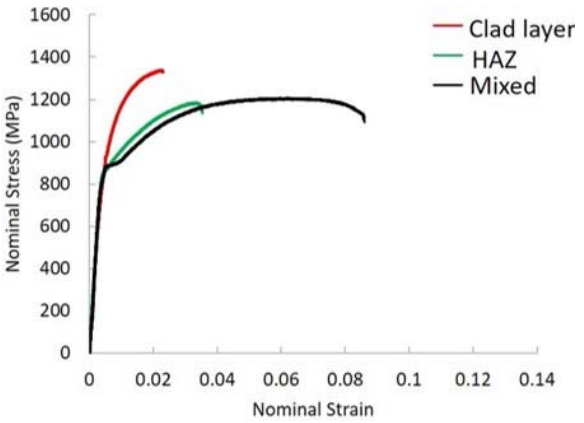

Figure 4 Stress-strain curves for 410L-A cladded rail

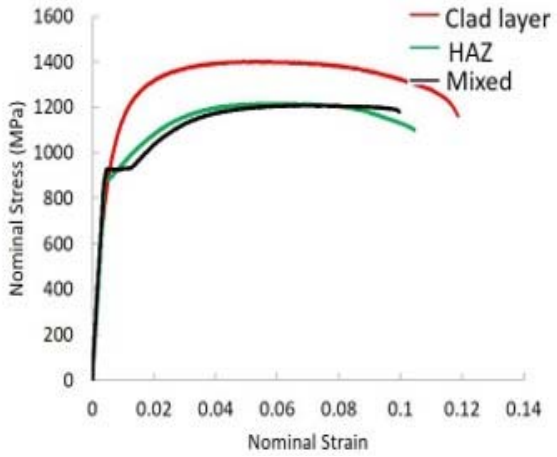

Figure 5 Stress-strain curves for 410L-B cladded rail

In the HAZ, the proof stress in the post- heat treated condition was marginally (2.4%) higher than for the preheated-only condition. Elongation and ultimate tensile strength were increased by 186% and 3%, respectively. For the mixed HAZ/substrate region, tensile properties were slightly higher in the post-heat treated condition, but the increase in elongation was not significant as that achieved in the clad and HAZ regions.

The low elongation in the pre-heat treated condition in the clad layer and HAZ can be attributed to martensite formation, as described in previous publications [20, 21]. The pre-heat treatment at 350^{o}C, over the length of 400 mm was insufficient to reduce the rapid cooling rate generated by the thermal mass of the substrate and prevent the formation of martensite [20]. Untempered martensitic microstructures typically exhibit lower ductility and higher sensitivity to cracking compared to other microstructural constituents for a given carbon content [21]. Therefore, the application of pre-heat treatment along with the post-heating and slow cooling was used to eliminate martensite from the cladding layer. Application of post heat treatment resulted in tempered martensite with finer dendritic structure, and subsequently improved the ductility as evidenced by the higher elongation of the clad layer and HAZ [23].

Table 1 Summary of tensile testing

410L	Clad layer			HAZ			Mixed		
	0.2% proof stress	Elongation (%)	UTS (MPa)	0.2% proof stress	Elongation (%)	UTS (MPa)	0.2% proof stress	Elongation (%)	UTS (MPa)
410L-At	1010	2.2	1340	879	3.5	1180	891	8.5	1205
410L-B	950	11.5	1402	900	10	1217	930	9.5	1212
Difference (%)	**-5.9**	**422.7**	**4.6**	**2.4**	**185.7**	**3.1**	**4.4**	**11.8**	**0.6**

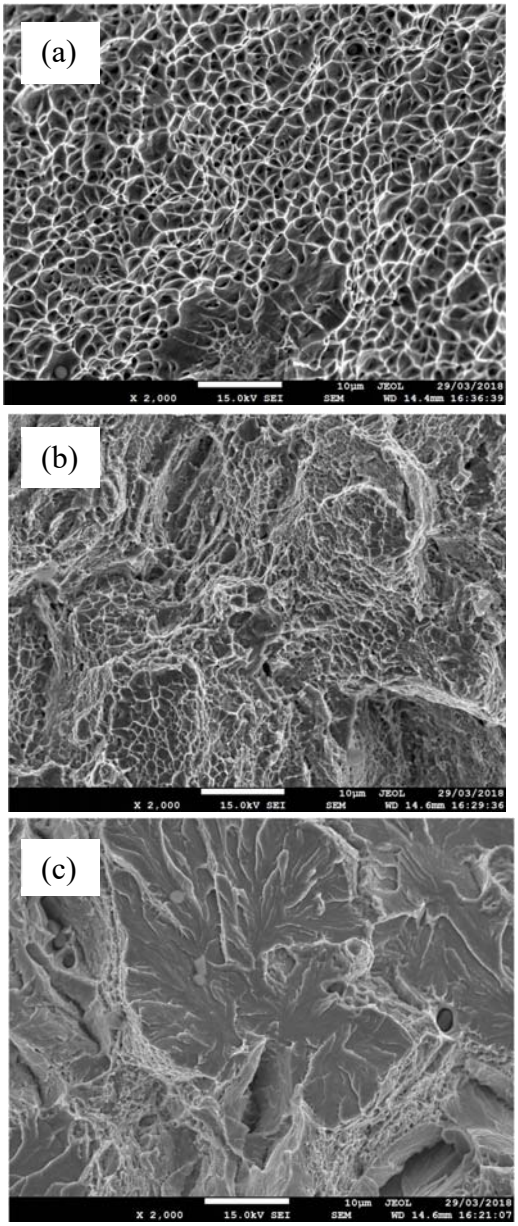

Figure 7 *SEM micrographs showing the fracture morphology of 410L-B cladded rail. a) Clad layer; b) HAZ and c) substrate material (mixed specimen)*

3.3. Fracture surfaces

The fracture surfaces of the three different sections of preheated cladded specimen (cladding, HAZ and mixed) are shown in Figure 6. Likewise, the fracture surfaces of the combination of pre-heat and post-heat treated specimens are shown in Figure 7. In Figure 6(a) and Figure 7(a), the fracture surfaces of the clad section for both heat treatment groups show similar fracture appearance. The fracture mode was predominantly micro-void coalescence. For most of the ductile material, micro-voids form in a parallel direction to the applied load, and coalesce as the load increases producing the

dimpled fracture surfaces. However, the clad section with the combination of pre-heat and post-heat treated specimens (Figure 7(a)) displayed a finer dimpled fracture surface compared with the pre-heat treated specimen (Figure 6(a)). The finer dimpling suggest that more energy is absorbed by the material and consequently displayed the higher ductility as shown in Figure 5.

The fracture surfaces of the HAZ sections appeared different from the clad sections. For the pre-heat treated condition, the fracture surface showed insignificant plastic deformation (Figure 6(b)). In the pre-heat treated condition, the appearance of the fracture surface was consistent with the low elongation, with little/no micro-void formation and dimpling (Figure 6(b)). However in the pre- and post-heat treated condition, regions of dimpling were evident on the fracture surface (Figure 7(b)), consistent with the higher elongation. The difference between the two conditions can be attributed to the presence of untempered martensite in the HAZ [20, 21, 23].

Figure 6(c) and Figure 7(c) show the fracture surfaces of the substrates for the pre-heat treated specimen, and the combined treated (pre-heat and post-heat) specimen respectively. Both fracture surfaces show mainly cleavage facets and river patterns. The cleavage facets were larger in the pre-heat-treated specimen, as shown in Figure 6(c). In case of the post-heat treated condition (Figure 7(c)) the cleavage facets were smaller, consistent with the slightly higher elongation.

Having the same tensile strength of a material, a higher ductility is beneficial in resisting the rolling contact fatigue damage such as spalling. In this study, the tensile results showed significant improvement in particular elongation of the materials with the heat treatment group-B (pre-, post-heating and slow cooling). So, laser cladding with heat treatment group-B was considered an appropriate technique to improve the material properties of laser cladded rail.

4. Conclusions

The following conclusions can be drawn from the mechanical tests performed on hypereutectoid rail steel laser cladded with 410L stainless steel.

- The tensile properties of three critical zones associated with the cladding process (cladding, HAZ and the HAZ/substrate boundary) were successfully evaluated using miniature tensile speciments.
- Application of a combined pre-heating and post-heating process followed by slow cooling was found to improve the tensile properties, in particular elongation.
- The improvement in tensile properties was associated with a more favourable microstructure, which resulted in more ductile facture behaviour in the clad layer and the HAZ

Abstract: In this paper, we present an analytical method of dynamic contact between wheel and rail, which is developed based on the three-dimensional large-scale parallel finite element method. We built the wheel/rail finite element models with wheel-flat over 1 million DOFs, and simulated wheel-rail rolling contact behavior using the program. We discuss the influence of the traveling speed on impact behavior, and the transition of the contact condition during impulsion between wheel flat and rail.

Keywords: FE method, Dynamic contact analysis, Rolling contact, Parallel computing, Wheel flat, Impact behavior.

1. Introduction

To clarify the initiation and development mechanisms of wheel/rail damage, such as wear and cracks, understanding the contact behavior between the wheel and rail is the fundamental issue. There are, however, few experimental techniques to grasp the contact behavior in detail under a running load. It becomes more difficult if there exist irregular geometries on the wheel surface which induce impact behavior.

Numerical simulation based on finite element analysis has been a promising approach for an improved understanding of the physical phenomena that occur inside the contact patch in detail [1, 2]. In addition, the numerical approaches that are carried out focus on the wheel flat [3, 4]. Many simulations of wheel/rail interaction are based on assumptions, such as the setting of the contact spring between wheel and rail, or a theoretical distribution about the contact force, because of the complicated calculations involved. In the case of a complex condition, such as the occurrence of a local deformation about the impulsion of the edge of the wheel flat, or two points contact during the rolling in the transition curve with the micro stick/slip condition, more direct approach about wheel/rail interaction with the solution of an equilibrium is useful.

This paper presents an analysis method of the dynamic rolling contact between the wheel and rail which was developed based on the three-dimensional finite element method, called "PaRC (parallel rolling contact simulator)". Here, "parallel" stands for parallel computing on distributed memory machines which enables the execution 3-D FE dynamics contact analysis using fine large-scale FE mesh models for both the wheel and rail. We built the wheel/rail FE model with a wheel-flat and simulated wheel-rail rolling contact behavior using PaRC.

2. Finite element solution model of PaRC

PaRC is developed with FrontISTR, the open source large-scale parallel FEM program for nonlinear structural analysis [5]. PaRC has been subject to some improvements to calculate a match faster and more stably.

2.1. Caterpillar mesh

A schematic of the analysis model is shown in Figure 1. The rail model is represented by a series of several rail blocks. After the wheel travelled one block length, the last block was placed into the front position. We called this function "caterpillar mesh". Using this function, the consecutive dynamic rolling motion was simulated to obtain the transient contact state with the fine large-scale FE model.

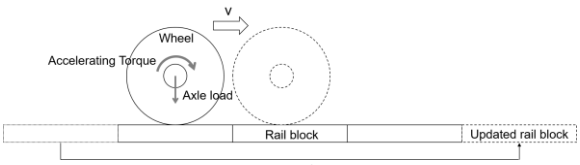

Figure 1 *Schematic of caterpillar mesh.*

2.2. Reflect-wave reduction boundary

When the high-frequency vibration, in the order of kilohertz, was estimated in the contact rolling analysis, the elastic wave, which spreads and reflects on the inside of a rail with limited length at the time of the rolling behavior of a wheel, affected the evaluation of a contact patch adverse negatively. As a consequence, the Rayleigh damping was given to some caterpillar rail blocks, shown in Figure 2. To avoid the occurrence of the reflected wave between a non-reflection element and reflection element, the power of the damping force became large as the edge of the rail drew nearer.

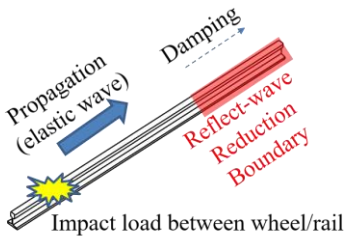

Figure 2 *Description of reflect-wave reduction boundary.*

2.3. Large-scale parallel computing

In the case of the fine large-scale FE model, the total mesh size became too large for one processor, a distributed memory machine, so a PC cluster was utilized to attempt to solve the probrem in parallel, based on the domain decomposition method. The whole system can be divided into several subdomains, and each subdomain was assigned to a process, as shown in Figure 3. The parallel process was executed; communicating the halo between neighbor processes when required by the message passing interface (MPI).

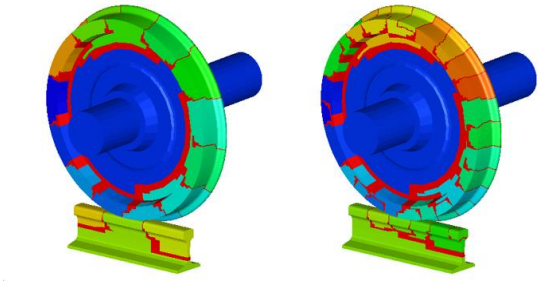

Figure 3 *Domain decomposed FE model for parallel computation: (a) 16 domains. (b) 32 domains.*

2.4. Solution procedure

PaRC employed the implicit Newmark time integration scheme. The mass matrix was handled as a lamped-mass in this program. Rayleigh damping can be used for any element groups.

Finally, in the sequence of the dynamic analysis, the contact state of the system under gravity and an axle load was firstly solved, and after the equilibrium state was reached, accelerating torque was loaded onto the axle nodes. The normal contact problem was solved using the Lagrange multiplier method and the tangential problem was solved using the penalty method; the normalized Coulomb friction model was employed. For each nonlinear iteration step, the linear equation of the system was solved using MUMPS [6], a distributed parallel direct solver. A flowchart of the analysis is shown in Figure 4.

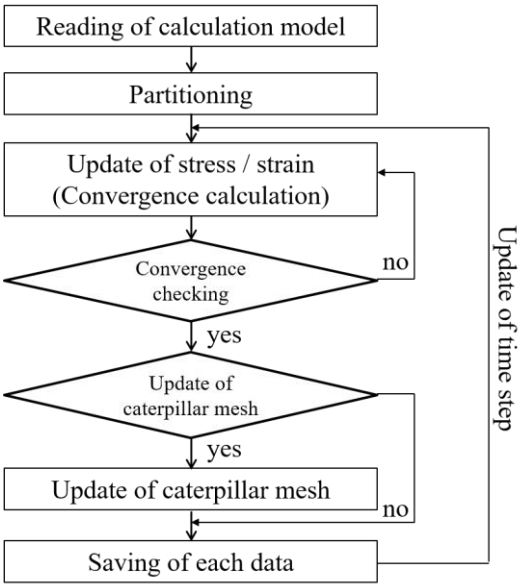

Figure 4 *Flow chart of the calculation.*

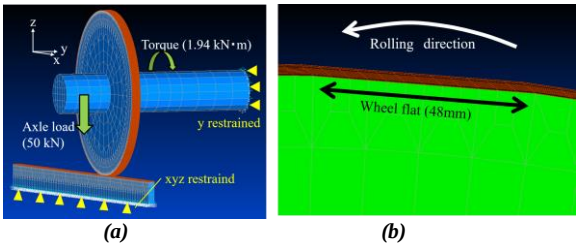
3. Simulation of impact behavior using wheel-flat model

In this paper, the impact behavior between the wheel and rail is discussed using two-types of FE model, the simple model and detailed model.

3.1. Models and analytical conditions

A description of the FE model is presented in Table 1. The wheel of the “simple model” was simplified by a disk without a flange, and the rail had a rectangular sectional shape. The wheel and rail shapes of the “detailed model” were of the standard of a Japanese conventional line; modified arc wheel profile and 50 kg N rail profile.

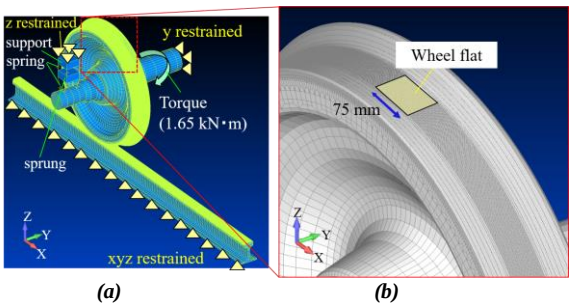
Table 1 *Model information.*



Model	Simple	Detailed
Nodes (Pcs.)	47,515	1,094,948
Elements (Pcs.)	36,368	959,678
Diameter of wheel (mm)	800	860
Diameter of wheel axle (mm)	194	165
Minimum mesh size of contact area (mm)	4	2
Length of wheel-flat	48	75

The specifications of the various parameters of each model are shown in Table 2. In this paper, all materials had elastic characteristics.

Table 2 *Parameters for calculation*



Parameters			Simple	Detailed
Young's modulus (MPa)			Wheel: 1.973×10^5 Rail: 2.098×10^5	
Poisson's ratio			Wheel: 0.30 Rail: 0.29	
Density (t / mm^3)			Wheel: 7.81×10^{-9} Rail: 7.81×10^{-9}	
Time increment (s)			5.0×10^{-4}	
Friction coefficient			0.3	
Tangential penalty			1.0×10^4	
Coefficient of Newmark β method		γ β	0.6 0.3025	0.53 0.265225
Sprung mass Element	Mass (kg)		—	5.37×10^3
Support element	Mass (kg)		—	3.81×10^{-3}
Spring / damper between axle - sprung	Spring stiffness (kN / m×pcs.)		—	X: $2.523 \times 10^5 \times 4$ Y: $2.523 \times 10^5 \times 4$
	Damper viscosity (kNs / m × pcs.)			X,Y: 0.0 ×4 Z: 5.6 ×4
Spring / damper between sprung - support	Spring stiffness (kN / m×pcs.)		—	X: $2.523 \times 10^5 \times 4$ Y: $2.523 \times 10^5 \times 4$
	Damper viscosity (kNs / m × pcs.)			X,Y: 0.0 ×4 Z: 5.6 ×4

The model shapes including the boundary conditions, are shown in Figures 5 and 6. Both models were taken as one axis/wheel, which has one wheel and a half of axles on one side rail. The wheel-flat shape of each model is plane and uniform. As a boundary condition, the axle load was given as a concentrated load at the center of the axle, and a concentrated load equivalent to the torque was added on the surface of the axle. The node of the symmetry plane of the axle was restrained at the longitudinal direction, and the node of the rail bottom was taken as the full restraint.

(a) *(b)*

Figure 5 *Overview of simple model:(a) Wheel / rail FE model and boundary condition. (b) Wheel flat*

(a) *(b)*

Figure 6 *Overview of detailed model:(a) Wheel / rail FE model and boundary condition. (b) Wheel flat*

Furthermore, in the case of the detailed model, a sprung element, with its density equivalent to the sprung mass, was set at the upper position of the axlebox. The bottom nodes of this element and some axle center nodes were connected by some Voigt model springs and dampers. In addition, a supportive element upper sprung element was set to avoid rolling of the sprung element. The upper nodes of the support element were restrained in the vertical direction. Some Voigt springs/dampers were used to connect the sprung element and the support element. The mass of the support element was set to an extremely small value. The vertical direction stiffness of the springs between the sprung-support elements were lower than the spring between the axle-sprung elements.

3.2. Calculation results of the simple model

Figures 7 to 10 show the calculation results from the simple model. Each graph indicates the travel speed of the wheel, the time history of the vertical acceleration at the axle center node, the vertical displacement of it, and the time enlarged graph of the displacement between 1.0 and 1.4 seconds, respectively. These graphs show the following results:

- Due to accelerating torque, the wheel gains its translation speed from static state up to 190 km/h. As the travel speed rises, the tangential gradient of the velocity tends to be small particularly over 4.0 second. This phenomenon would be due to energy loss with the elastic deformation between wheel and rail at the time of impulsions, or a slipping in the contact patch.
- Peak values of the acceleration and the displacement were between 1.0 and 1.5 seconds (from 30km/h to 50 km/h). The maximum values of the acceleration and displacement tended to decrease as the speed of the wheel increased. As shown in Figure 10, a small displacement in the negative direction appears first. Then, a large displacement in the plus direction occurs from the impulsion between the wheel and rail. The former indicates that a wheel whose speed becomes high enough, passes over without contacting the flat and the rail completely. Thus, the axle center did not fall to the depth of the flat and did not gain a large displacement.
- The simple model is too rough to evaluate the normal/tangential force distributions in detail.

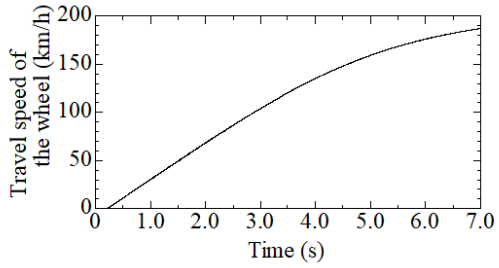


Figure 7 *Travel speed of the wjheel.*

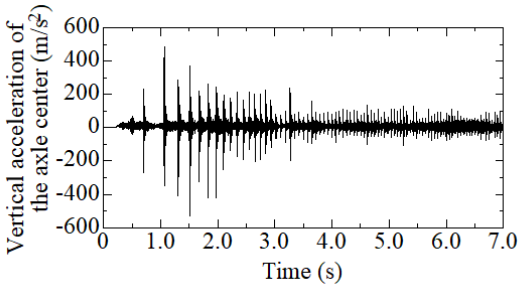

Figure 8 *Time history of the vertical acceleration at the axle center node.*

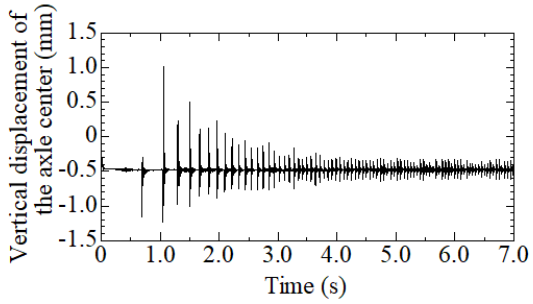

Figure 9 *Time history of the vertical displacement at the axle center node.*

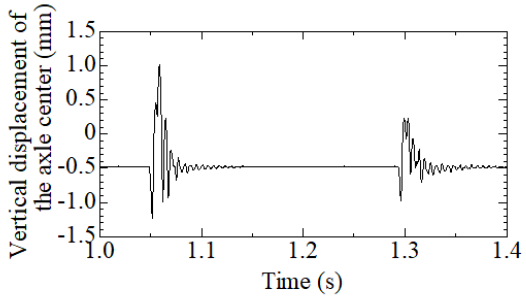

Figure 10 *Time enlarged graph of Figure 9.*

3.3. Calculation results of the detailed model

Figures 11 to 14 show the numerical simulation results from the detailed model. This case, also indicates the normal/tangential contact force in the contact patch. In this FE simulation, the reaction force is outputted from each node in the contact patch. For the normal direction vector of each surface of the rail mesh, that is positioned almost vertically toward the rail surface, the total reaction force represents the wheel load.

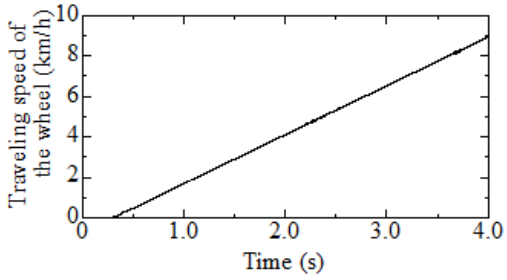

Figure 11 *Travel speed of the wheel.*

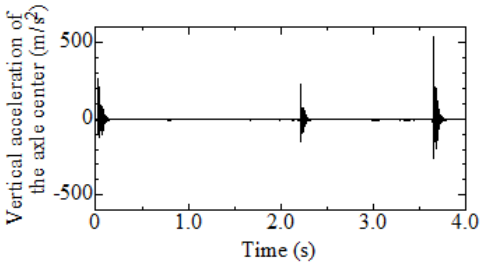

Figure 12 *Time history of the vertical acceleration at the axle center node.*

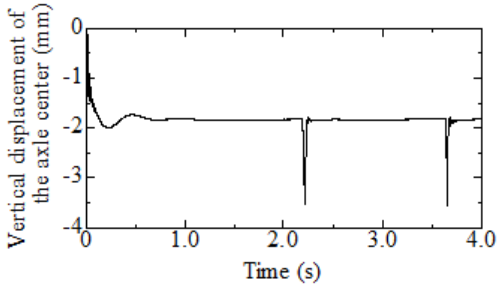

Figure 13 *Time history of the vertical displacement at the axle center node.*

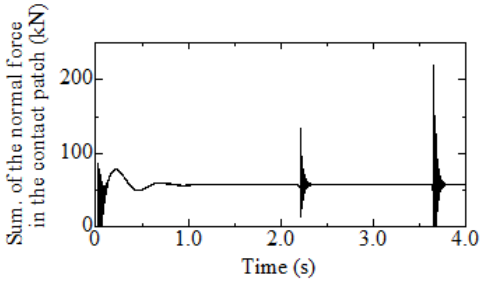

Figure 14 *Time history of the vertical displacement at the axle center node.*

From 0 to 0.25 second, no torque is accelerated in order to wait for the equilibrium state of the contact force to be reached. Because spring-damper model is adopted, a low-frequency vibration can be seen in Figures 13 and 14 before the equilibrium state is reached under acceleration. After about 2.2 seconds, the first impulsion between the flat and rail occurs. Then, second impulsion is caused at about 3.7 seconds. As shown in Figures 13 and 16, the axle center fell to the depth of the flat completely due to the low speed of the wheel.

As shown in Figures 15 to 17, the tendency of the waveform at the time of impulsion is similar to the simple model case. Contrarily, the displacement of the plus direction after impulsion between the flat and rail cannot be confirmed in the Figure 16. The reason could be due to the low speed of the wheel, or the effect of spring-damper model.

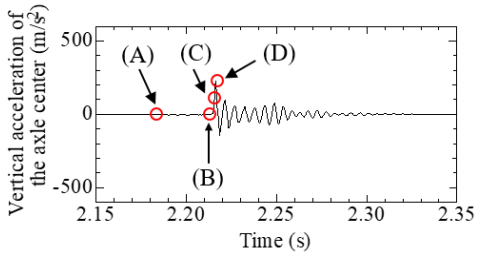

Figure 15 *Time enlarged graph of Figure 12: from 2.15s to 2.35s.*

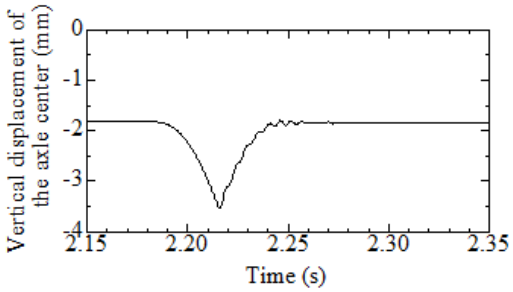

Figure 16 *Time enlarged graph of Figure 13: from 2.15s to 2.35s.*

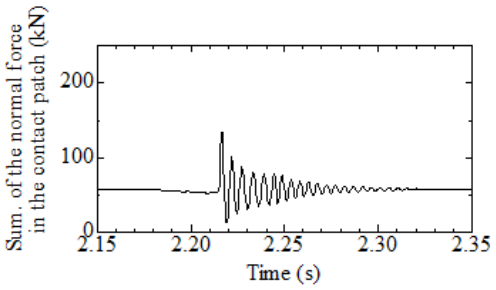

Figure 17 *Time enlarged graph of Figure 14: from 2.15s to 2.35s.*

To evaluate the impulsion behavior, the equivalent stress distribution throughout the model, the normal/tangential force, and the stick/slip condition in the contact patch were investigated near the time of the impulsion. Here, the analytical result near 2.2 seconds gives the first impulsion between the flat and rail is used for discussion. Figures 18 to 21 indicate the stress distribution and contact force distribution in the contact patch during flat impulsion (Fig. 15(A) the axle center begins to fall to the depth of the flat, (B) before the occurrence of the plus acceleration, (C) during the increase in plus acceleration, (D) the maximum acceleration value appears). In the contact force contour, the plot of the middle coating represents the stick condition, and the plot of the white space on a colored background indicates the slip condition. In these graphs of contact distribution, the stick/slip condition is defined as follows refer to the paper [2]:

$$CFt_{max} - CFt \leqq T_{tf} : Slip\ condtion \quad (1)$$

$$CFt_{max} = \mu \times CFn \quad (2)$$

where μ is the friction coefficient, CF_n and CF_t are the calculated contact forces in the normal and tangential directions. In this paper, the threshold between the stick/slip condition, T_{tf}, is set to 0.1% of the normal contact force that is analyzed in each contact node.

These figures are deduced as follows:

- When the wheel continues rolling after the contact between the front edge of the flat and the rail, the shapes of the contact patch become long and narrow (Figures 18 to 20). This is the reason the rail is curved on top, and the shape of the wheel flat is plane. At this time, the stress caused the impulsion to propagate into the wheel and rail (Figure 20(a)).
- In the process of moving the contact area from the front edge of the flat to the plane part of the flat, the contact node with a large tangential force and slip condition increased (Figure 20(c)).
- When the rear edge of the flat made contact with the rail, the vertical acceleration of the axle center indicates the maximum value with a large normal contact force at the rear edge of the flat. At this moment, the stress in the wheel and rail increased (Figures 21(a, b)).
- From the two figures, which have an approximately equal area of the contact patch, it is understood that the value of the local normal contact force around the rear edge of the flat is larger than that around the front edge of the flat (Figures 20(b), 21(b)).
- To investigate the influence of traveling speed of the wheel, it is necessary to calculate until high speed area in the analysis using the detailed model.

In this study, the underside of the rail is completely restrained in all models, so the vertical accelerations and contact forces could increase compared to the traveling on an actual track. Thus, in the future, a more detailed modelling of the underside of the rail, or execution of the elasto-plastic analysis should be carried out to reproduce more realistic phenomenon.

4. Conclusions

In this paper, the impulse behaviour between the wheel with the flat and the rail in the dynamic rolling condition is discussed and two types of numerical model were used: the simple model and detailed model. The knowledge from these analyses are as follows:

- As a result of the numerical simulation, used by a simple disk/bar model, the wheel gains its translation speed from the static state up to 190 km/h. The peak values of the acceleration and the displacement were from 30km/h to 50 km/h. The maximum values of the acceleration and displacement tended to decrease as the speed of the wheel increased. This indicates that the wheel whose speed becomes high enough, passes over without contacting the flat and the rail completely. Thus the axle center did not fall to the depth of the flat and did not gain large displacement.
- The detailed model, with the real shape of the wheel and rail, was constructed. Furthermore, a sprung element, with its density adjusted to be equivalent to the sprung mass, was set to the upper position of axlebox. The bottom nodes of this element and some axle center nodes were connected by some Voigt model springs and dampers.
- In the process of moving the contact area from the front edge of the flat to the plane part of the flat with the wheel rolling, the contact nodes with a large tangential force with the slip condition increased.
- When the rear edge of the flat made contact with the rail, the vertical acceleration of the axle center indicates the maximum value with a large normal contact force at the rear edge of the flat. At this moment, the stress in the wheel and the rail increased.
- It is understood that the value of the local normal contact force around the rear edge of the flat is larger than that around the front edge of the flat.
- To investigate the influence of traveling speed of the wheel, it is necessary to calculate until high speed area in the analysis using the detailed model.

Thus, PaRC enables analysis of the impact behavior while rolling the wheel with a flat. In addition, it can simultaneously grasp the changing contact force in detail in the contact patch. The local normal/tangential forces in the contact patch could have a close relationship to the damage phenomenon, such as wear and cracks that occur on the wheel and the rail. In the future, calculation precision can be improved by creating a fine mesh model that considers track structures, and execution of elasto-plastic analysis. PaRC will be adopted as the tool to evaluate the influence of the impact force on the bogie frame and track materials.

Abstract: Rolling Contact Fatigue (RCF) is a common failure mechanism in rails. Accelerated RCF tests were carried out on five rail materials. The aim was to evaluate the wear rates, and the depth and mean spacing between RCF cracks. Thickness and maximum hardness of surface layers were measured using micro-indentation. The results showed that for hard rails the wear rates are lower. For the pearlitic materials (R260, R350HT, and R400HT), there is a correlation between thickness of deformed layers and mass losses. Cracks were shallower for R400HT and deepest for standard rail material. Hardened rails had lower mean spacing between cracks.

Keywords: Rolling contact fatigue, hardened rails, Twin-disc tests

1. Introduction

Rolling Contact Fatigue (RCF) is a common failure mechanism in rails [1]. Typical testing of RCF has been done by performing dry twin-disc tests up to 800.000 cycles and monitoring the damage with the aid of an accelerometer. However, those tests are expensive and time consuming. Kaneta and Murakami studied experimentally [2] the effects of oil pressure on surface crack growth in rolling-sliding contacts by using transparent polycarbonate resin discs in a twin-disc machine and they found that hydraulic pressure applied repeatedly on the crack face induces fatigue crack growth. Bower [3] proposed three mechanisms of crack growth assisted by fluids. The mechanisms were based on experimental results and the author concluded that: i) cracks will propagate only if a fluid is applied to the surfaces in contact, ii) cracks always grow in the loading direction over the surface iii) if sliding occurs, the cracks will grow only in the driven surface. The pressurization mechanisms can be used to perform accelerated RCF tests in the laboratory.

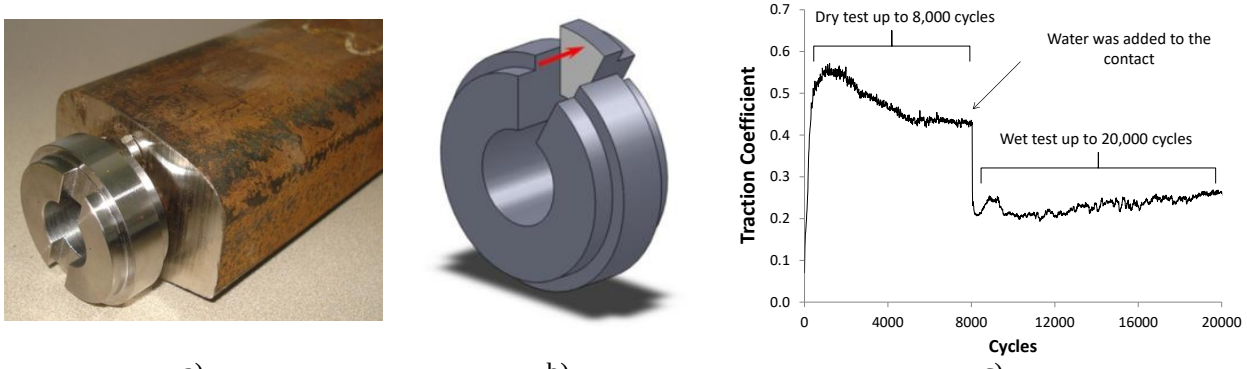
A short survey of different articles studying rolling contact fatigue is presented to identify different testing techniques. Several methods have been developed to study RCF including those by Kaneta *et al* [2], Tyfour, Beynon, and Kapoor [4], Fletcher and Beynon, [5], Liu, Jiang and Magel [6], and Eadie *et al* [7].

Fletcher and Beynon [5] studied the effect of friction modifiers using accelerated RCF tests. They used R260 rail and studied the effect of intermittent lubricant on fatigue. Initially, dry tests were performed, and after that, water and a friction modifier (FM) were added to the contact. They found that after a critical number of cycles (500 cycles for R260 rail) the fatigue life was reduced. In addition to that, they used eddy-current testing to identify the cracks and to stop the tests once the cracks reached a certain depth. The pressurization mechanism was used to accelerate the tests with the aid of the FM. Tyfour, Beynon, and Kapoor [4] studied the effect of several dry cycles on the RCF of pearlitic steel using a twin-disc machine. The authors demonstrated that the number of dry cycles had a significant effect on the rail life. The effect was thought to be caused by the accumulation of plastic deformation, and the surface becoming more sensitive to fluid entering the cracks. In addition, they found that there is an equilibrium between the crack growth rate and the wear rate in unlubricated tests. In those tests, the pressurization mechanism was used to accelerate the tests with the aid of the water.

In 2012, Liu, Jiang and Magel [6] studied the rolling contact damage function using twin-disc tests. They used extended dry tests, up to 800 thousand cycles, and detected damage using an accelerometer. They found that the severity of RCF is a function of the T-gamma parameter (energy per m entering the contact patch) and they proposed a new relationship between the number of cycles required to fail (Nf) and T-gamma. The authors performed long-term tests to evaluate RCF of materials.

The Association of American Railroads (AAR) specification [8] also uses long-term tests to evaluate the rolling contact fatigue of materials used for train wheels. In that specification, a shelling test is conducted using two discs with a contact pressure of 1.1 GPa and 0.3% slip. The duration of the tests is determined by using a vibration sensor. This test is sensitive to the later stage of fatigue when shells appear at the surface of the samples. However, the standard does not specify an acceleration value and the criterion for stopping the tests according to the vibration is subjective.

Eadie *et al* [7] studied the effect of using a friction modifier on wear and rolling contact fatigue on a full-scale test rig (FSR). The application of a friction modifier reduced the rail wear and the number of head checks (cracks) in the rail. They concluded that it is possible to simultaneously reduce RCF and wear by applying the FM to the rail surface on the same rail test rig. Additionally, the results also clearly indicate the advantages of the premium rail grade R350HT compared to the R260 grade in the areas of wear and RCF behavior. A maximum reduction in wear rate and RCF development propagation can be achieved by combining FM application with a premium rail grade. In this case, the FSR tests were long-term tests since the pressurization mechanism was not used to accelerate RCF.



Summarizing, rolling contact fatigue (RCF) of rail and wheel materials has been studied by several authors. Three different types of tests were identified: 1. Accelerated tests [4,5], 2. Long-term tests [6,8] and 3. Full-Scale-Rig tests [7]

Since RCF can be accelerated by using the pressurization mechanism, in this work accelerated tests were done to evaluate different rail materials. The aim was to evaluate the wear rates caused by fatigue, and the depth of the RCF cracks. The tests were done to evaluate different materials under fatigue conditions since some contradictory results were found in the field when cracks appeared at the surface of a hardened premium rail just a few months (8 MGTon) after installation [9]. The tests were done in a twin-disc machine using water to induce cracks by the pressurization mechanism. The tests will help to develop new rail materials with improved fatigue resistance and to understand the relationship between the microstructure and fatigue wear.

2. Method

RCF of different rail materials was studied in a twin-disc machine using water to accelerate the crack growth rate by the pressurization mechanism. The tests were performed in SUROS machine [10] using 1% of creepage and a maximum contact pressure of 1300 MPa. For the tests, discs were extracted from the head of different rail materials (see **Figure 1a**) and in all cases rolling-sliding tests were done using the same wheel discs extracted from E8 wheels kindly provided by Metro de Medellín. Five different rail materials were studied: R260, R350HT, R400HT, and two new rail materials: NRM1, and NRM2.

The first tests were done by performing a fixed number of dry cycles (8,000) for all the rails. The same methodology has been used before in the literature [10,11]. After stopping the tests, the samples were cut as shown in **Figure 1b** and polished before measuring the strain-hardened layers (thickness and maximum value) by micro-indentation (Vickers $HV_{100g,\ 10\ s}$). The hardness of the samples before testing had also been measured. Since the thickness of the deformed layer was different for all samples, the hardness at the end of the test was measured at the same depth, 20 µm from the surface, for all samples. The thickness of the deformed layer was evaluated by metallographic inspection, and by obtaining a microhardness profile from the surface. The microstructure near the surface was inspected and the end of the deformed layer was determined by observing the pearlite lamellas. The microhardness profiles were also used to determine the thickness of the layer.

a) b) c)

Figure 1. *Details of rail samples and tests. a) Extraction of samples b) Cut performed to observe deformed layers and cracks c) Friction during the tests*

In another set of tests with new samples the same number of dry cycles (8,000) was run in the twin-disc machine to accumulate surface fatigue. After that, the wet test commenced: 0.125 g per second of water was applied to the contact for a further 12,000 cycles (a total of 20,000 cycles) as shown in **Figure 1c**. At the end of the tests, the wear rates of different rail materials and the wheels were compared. In all cases deionized water was added to the contact to avoid corrosion. Three repeats for each material were performed and after the tests the crack parameters (mean spacing, angle, and depth) for every

rail were measured. The worn surfaces were also observed in a stereomicroscope, and in a Scanning Electron Microscope (SEM).

3. Results

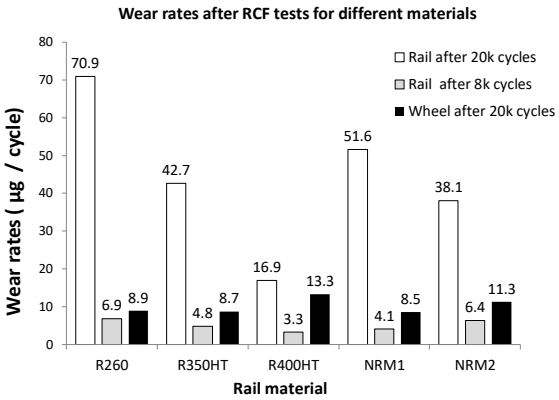
3.1. Wear rates

The average and the standard deviation of mass losses after wear tests performed up to 20 thousand (20k) cycles (8k dry cycles and 12k wet cycles) are shown in **Figure 2**. From the results, the lowest mass losses, when rolling contact fatigue is induced by pressurization using water, were found for the hardened rail. The highest mass losses were found for the standard R260 rail for which the wear rate was 4.1 times higher than the hardened rail. From **Figure 2** it can also be concluded that, for rail materials R260, R350HT, and R400HT, when the hardness of the rail is higher, the wear rates are lower. The correlation after wear tests for those rails is given by the equation: Wear rate after 20k cycles RCF = -0.1814 (Rail $\text{hardness}_{100g,10s}$) + 160.33 $R^2 = 0.9575$

The coefficient of friction for the test rails (not shown) were very similar for the tested conditions (1% of creepage and a contact pressure of 1.3 GPa); slightly lower values were found for the rails with the lower hardness. **Figure 2** also shows the wear rates under dry conditions (after 8k cycles). From the data the same trend (lower wear of the rail material for higher hardness) was observed, with the wear rate under dry conditions for the standard rail (R260) being 2.1 times higher than that for the hardest rail (R400HT).

Another issue that has been discussed by maintenance engineers is if the use of hardened rails will affect the behavior of train wheels and cause high wear rates in the wheels. It can be seen in **Figure 2** that the wear rates of wheels after the tests were higher when the hardened R400HT was used. The results obtained by the manufacturer of premium rails in FSR tests [12] showed that the wear rates of the wheels rolling against different rails were very similar. However, these results were obtained under dry rolling-sliding after 100k wheel passes (cycles). The damage caused by shelling in the twin disc test can affect the results since the debris from the rail (detached shells) can cause abrasion on the surface of the wheel samples: this does not represent the conditions in the field.

Figure 3 shows the worn surfaces of the samples after the tests. The damage is different for every rail and the largest flakes were found for the R260 rail. R400 HT and NRM2 showed fewer flakes at the surface. Even though the surface of NRM2 rail appears to be sound, the flakes caused by pressurization were removed during the tests and, as a consequence, high mass losses were found for this material.



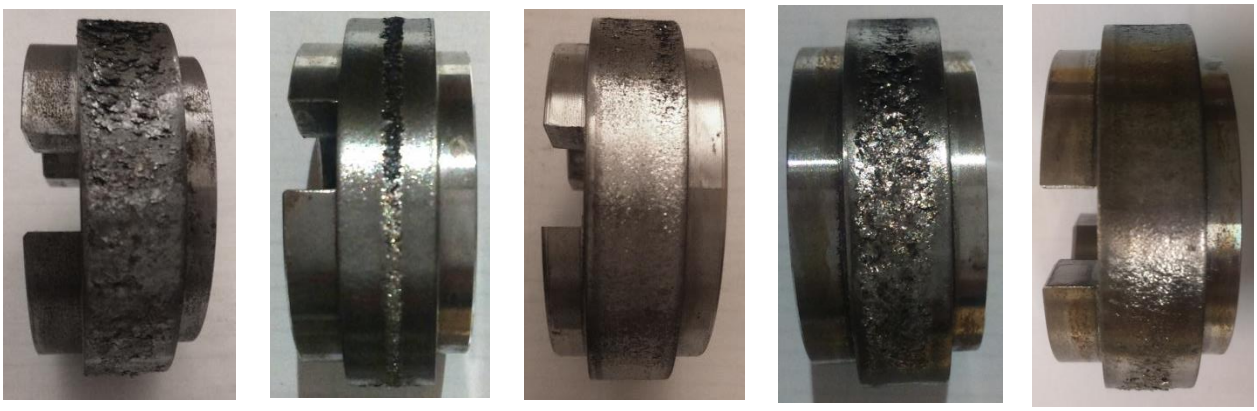


Figure 2. *Wear rates after dry and wet tests with different rail materials*

Figure 4 shows the deformed layers after rolling-sliding for 8k dry cycles. The white arrows at the bottom-right show the rolling-sliding directions. The thickness of the deformed layer varied from 60 to 255 µm for the different rail materials. The thickest deformed layer was found for the R260 rail, while the thinnest deformed layer was found for the R400HT rail. For the standard pearlitic materials (R260, R350HT and R400HT) there is a correlation between the thickness of deformed layer and the mass lost during the test. The correlation found is given by the equation Wear rates at 20k cycles RCF = 0.5367 (thickness of deformed layers, µm) - 16.444, R^2 = 0.9929. The analysis of the microstructure and chemical composition of the rails shows that there are significant differences in chemical composition and microstructure for the NRM2 and NRM1 rails (not shown in this paper). This explains the anomalous wear rates for these materials. For some rails, cracks appeared between deformed slithers after 8k cycles (see arrows in Figure 4a, d and e).

Figure 5 shows the initial and final hardness after 8k dry cycles, and the thickness of the deformed layer for all the rail materials. The difference between the final and initial hardness shows that even harden rails can be strain-hardened during rolling sliding tests.

a) R260 b) R350HT c) R400HT d) NRM1 e) NRM2

Figure 3. *Worn surfaces of the samples after the tests*

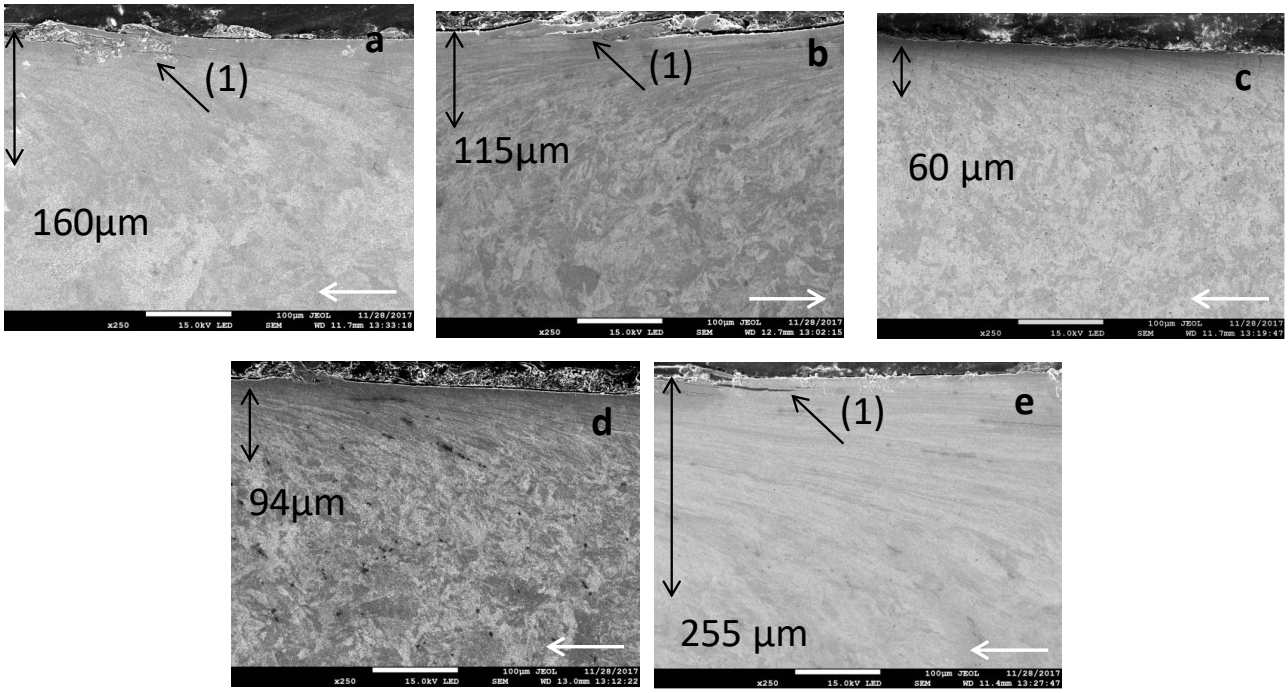

Figure 4. *Deformed layers in rail discs after 8k dry cycles, cracks indicated by (1) and an arrow: a) R260 b) R350HT c) R400HT d) NRM1 e) NRM2*

Figure 6 shows the results of the depth of the cracks for the different rail materials and the spacing between them. The cracks were shallower for the hardened rail (R400HT) and the deepest cracks were found for the standard rail material (R260). Even though the wear rates were high for the NRM1, the cracks were shallow.

Closer inspection of cracks after the full 20k cycles showed cracks with lengths ranging from 153 µm to 730 µm with mean angles from 8 to 23°. The analysis of cracks also revealed significant differences between the rails. The density of cracks was higher for the softer rail.

Another issue discussed in the literature [13] is the difference between the cracks in the standard and the hardened rail. In the field some authors [13] found that, for similar operating conditions, the mean distance between cracks is different for different rail materials. Typically, the number of cracks per unit length in hardened rail is higher than in standard rail. Accordingly, for this study the mean crack spacing in the samples was also measured and the grey bars in **Figure 6** show the results. It is observed that hardened rails have a lower mean crack spacing. The same trend was observed in the field [13]. However, even though there were more cracks per unit length, the cracks were shallow and consequently the removal of material induced by RCF is lower than that observed for standard, R260, rail. Typical images of the cracks in the discs made of standard R260 rail and hardened R400HT rail are shown in **Figures 7 a and b,** respectively.

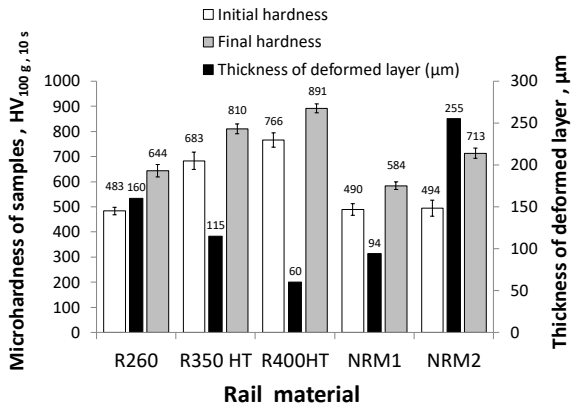

Figure 5. *Initial and final hardness after 8k dry cycles and thickness of the deformed layer.*

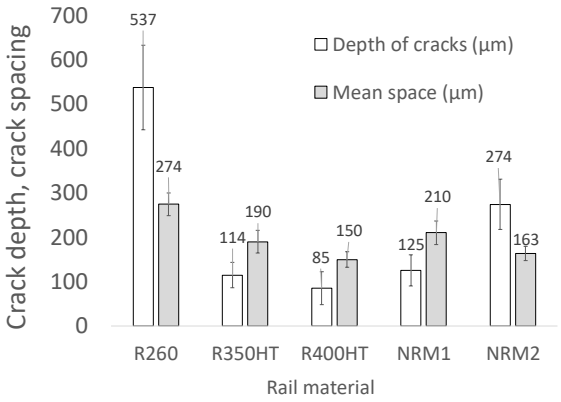

Figure 6. *Maximum cracks depth and mean space between cracks in the discs after 20k cycles*

4. Conclusions

Laboratory testing was performed to assess rolling contact fatigue of different rails with pre-existing RCF cracks. The results suggested that the application of water caused accelerated crack growth and the method allowed significant differences between different rail materials to be found.

The lowest mass losses when RCF is induced by pressurization using water were found for the hardened rail. The highest mass losses were found for standard, R260, rail. Higher hardness was associated with a lower wear rate.

The thickness of deformed layers was found to vary from 60 to 255 µm for the different rail materials. The thickest deformed layer was found for the R260 rail while the thinnest deformed layer was found for the R400 HT rail. For the standard pearlitic materials (R260, R350HT and R400HT) there was a correlation between the thickness of the deformed layer and the mass losses found during the tests. The difference between the final and initial hardness shows that even hardened rails can be strain-hardened during rolling sliding tests

Inspection of discs after the tests showed cracks with lengths ranging from 153 µm to 730 µm with a mean angle from 8 to 23°. The analysis of cracks also showed significant differences between the rails. The density of cracks was also higher for softer rails. The maximum crack density was found for R260 rail after dry tests.

TRI-AXIAL RESIDUAL STRESS ANALYSIS OF A RAILWAY RAIL USING TWO-DIMENSIONAL X-RAY DIFFRACTION METHOD

Toshihiko Sasaki [1,*]

[1] Kanazawa University, Kakuma-machi, Kanazawa, Ishikawa, 920-1192 Japan

[*] E-mail: sasakit@staff.kanazawa-u.ac.jp

Abstract: Tri-axial residual stress state of a rail head (used in service) with a 17-mm-long crack was analyzed by an X-ray diffraction method. X-ray stress measurement, the so-called modified cosα method, was applied to determine residual stresses. Shearing stresses, τ_{xz} and τ_{yz}, of the rail head as well as full width at half maximum (FWHM) were measured and mapped. The mapping results show the actual state on the rail head in terms of the formation of residual shearing stresses and white etching layers.

Keywords: Residual stress; Tri-axial stress state; X-ray diffraction; Diffraction ring; Modified cosα method; White etching layer; Full width at half maximum.

1. Introduction

The risk of rail failures generally depends on defects in the rail material. Such defects form and grow due to repeated loading of wheels of passing trains. The formation and growth of the defects are mainly influenced by bending stress, contact stress, thermal stress and residual stress [1-6]. Although residual stress in rails has been studied by X-ray and neutron methods [7-11], the effect of residual stress at the surface of the head of a rail ("rail head" hereafter) has not been revealed in detail. In this study, to analyse the residual stress at the rail head that had been used in service, the residual stress was measured by X-ray stress analysis.

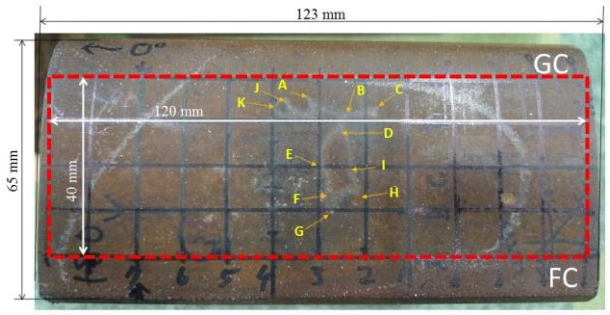
The damage on the rail head, known as "shelling", is associated with cracks originating from sub-surface defect or initiated at the running surface. To investigate the causes of the shelling, the surface changes caused by wheel loading should be analysed. Accordingly, in this study, X-ray stress analysis was applied for that purpose. The ordinary method for X-ray stress analysis, the so-called $\sin^2\psi$ method [12], is to measure a part of the diffraction ring (a Debye-Scherrer ring) with various incident angles and determine the stress from the relation between the diffraction data (Bragg angle or strain determined from the Bragg angle) and the orientation of the lattice plane contributing to the X-ray diffraction. The $\sin^2\psi$ method, however, requires an accurate setting of the X-ray equipment and long measurement time, so it is unsuitable for an effective study of rails. To overcome this difficulty, the authors used "the cosα method" which was proposed by Taira et al. in 1978 [13]. As for the cosα method, the plane stress state is analysed by measuring the whole X-ray diffraction ring at a time using a two-dimensional detector, and residual stresses are then calculated from the distortions of the diffraction ring. It is more effective to conduct the tri-axial stress analysis applying the modified cosα method proposed by Sasaki et al. in 1995 [14] and updated in 2009 [15]. In this study, the modified cosα method was used to determine two kinds of residual shearing stresses, τ_{xz} and τ_{yz} (where the x-axis is the running direction of the train and the y-axis is the width direction of the rail).

Diffraction rings were measured point by point over the whole head of a rail sample, which was used in service on a conventional line in Japan for about seven years. The white etching layer (hereafter WEL) was estimated from the full width at half maximum (hereafter FWHM) obtained from the diffraction ring.

2. Experiment

2.1. Sample rail

A photograph of the rail sample (which was cut to length of 123 mm) taken from a rail used in service on a conventional line in Japan for about seven years is shown in Fig. 1. As shown in Fig. 1 (b), a 17-mm-long crack (with 8 crack opening sections and 3 crack brunches) exists near the center of the rail head. The rail used was classified by the Japan Industrial Standard (JIS) as a 60-kg rail (with height of 174 mm and width of 65 mm). The rectangle in Fig. 1(b) shows the area measured by X-ray diffraction. The size of the measurement area was 120 mm long and 40 mm wide. X-ray diffraction rings were measured point by point at 2-mm intervals in both the transverse and longitudinal (running) directions. Total number of X-ray measurement points were 1,260 (i.e., 21 points across the rail's width 61 points along rail's length).



2.2. X-ray measurement

The X-ray equipment used in this study is shown in Fig. 2. It houses an image plate as a two-dimensional X-ray detector. X-ray measurement was performed under the condition that the X-ray incident angle was set normal to the surface of the rail head. The X-ray equipment was suspended from an X-Y stage, and mapping measurement was conducted automatically. It took about 1 min to measure a diffraction ring. It is possible to

determine two kinds of shearing stresses with respect to depth z, τ_{xz} and

Fig. 1. Sample rail, JIS 60 kg rail, and rail head measured by X-ray.

τ_{yz}, by analyzing the diffraction ring with the modified cosα method. The principle used in this study is described in the next section.

Full width at half maximums (FWHMs) were determined simultaneously with the shearing stresses from the diffraction ring (with 0.72° intervals) from each profile of X-ray diffraction intensity in the radius direction. Accordingly, a total number of 500 FWHM was obtained from each measurement point on the rail head. The mean value averaged over those 500 FWHMs was used as the representative value of each measurement point.

2.3. Determination of tri-axial residual stresses using the modified cosα method [14, 15]

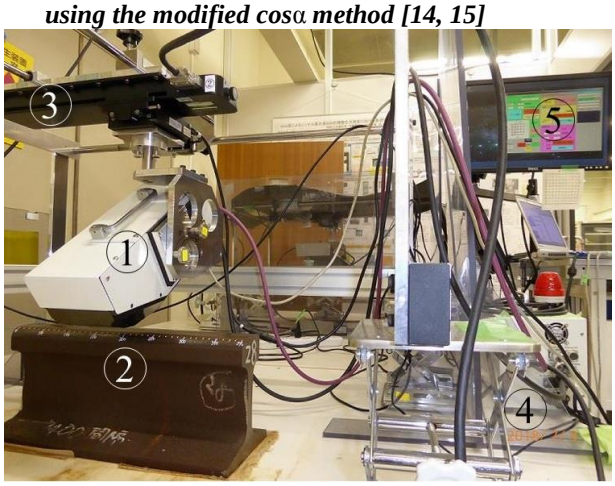

Fig. 2. X-ray equipment used in this study. (1: X-ray equipment for measuring residual stress, 2: sample measured, 3: X-Y stage for automatic mapping, 4: High-voltage power supply, 5: Computer.)

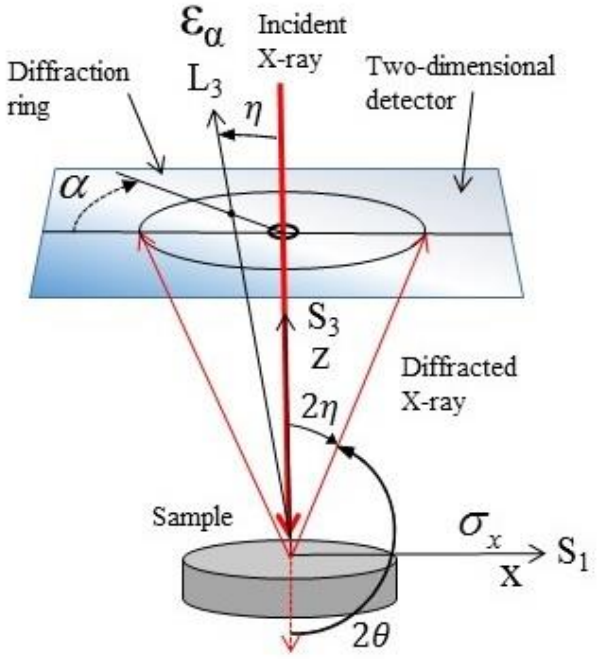
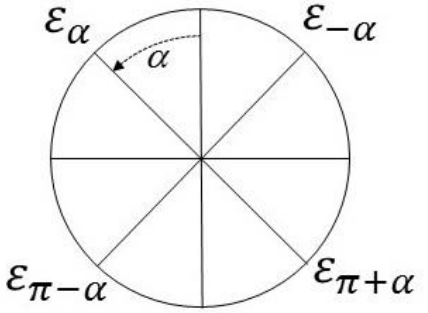
According to the Bragg's law, normal strain parallel to the center line between the incident and diffracted X-rays can be obtained from each radius on a diffraction ring (see Fig. 3 (a)). Since the angular interval of the diffraction ring was 0.72°, 500 normal strains were also obtained from each diffraction ring. These strains were analyzed to calculate stress by using the modified cosα method [15] (outlined in Fig. 3).

First, X-rays are diffracted from the rail when it is irradiated by the incident X-ray beam. The diffracted X-rays obey Bragg's law, given as [12]



$$2d\sin\theta = n\lambda \ , \qquad (1)$$

where d is lattice spacing, θ is Bragg angle, λ is the wavelength of the incident X-rays and n is diffraction order (n=1 is used in the following). Most industrial materials are polycrystalline aggregates having an infinite number of fine grains. In such cases, X-rays are diffracted in the form of a cone whose vertex marks the point irradiated by the X-rays (Fig. 1(a)). Accordingly, if a two-dimensional detector is placed perpendicular to the incident X-ray beam, an almost circular diffraction ring can be detected. As for the X-ray stress measurement by the standard $\sin^2\psi$ method [12], only one diffraction-intensity distribution with respect to the radial direction on a diffraction ring is measured, and θ of Eq. (1) is then obtained and used for calculating the stress. However, with a two-dimensional detector system, the whole diffraction ring can be measured an shown in Fig. 1, and a lot of θ values can be obtained from the whole diffraction ring as follows:



$$\theta = \frac{\pi}{2} - \frac{1}{2} tan^{-1}\left(\frac{R}{C_L}\right) \ , \qquad (2)$$

where R is the radius of the diffraction ring, C_L is the distance between the X-ray irradiated point and the detector. The relation of the normal strain of the lattice plane contributing to the diffraction and θ can be

obtained as follows by the differentiation of Eq. (1) [12]

(a) Measurement of diffraction ring by X-rays and symbols used in the text.

(b) Definition of four parameters of a diffraction ring used for calculating stress by the modified cosα method [14, 15] (view from sample side).

Fig. 3. Outline of X-ray residual-stress measurement used in this study.

$$\varepsilon = \frac{\Delta d}{d} = -\Delta\theta \cdot cot\theta \qquad (3)$$

where Δd is the change of d (i.e., d-d_0), where d_0 is the lattice spacing in the stress-free state, and $\Delta\theta$ is the change of θ (i.e., θ-θ_0), where θ_0 is Bragg angle in the stress-free state. Eq. (3) indicated that it is possible to obtain strain, ε, from θ and its change ($\Delta\theta$) only. The fact that ε is based on an extremely microscopic gauge length as lattice spacing is a remarkable characteristic of the X-ray method. Except in the case of a particular orientation (like almost parallel to the surface plane), strains in almost of all orientation can be obtained by using X-rays in the manner explained above.

A coordinate system, *S*, is defined on the sample, and strain in this coordinate system is expressed as ε^S_{ij}, where i, j=1, 2, 3. A laboratory coordinate system, *L*, is also defined as a direction perpendicular to the diffracting plane as the L_3-axis. Normal strain in the L_3 direction is denoted as ε^L_{33}; accordingly, the following equation representing corresponding strains in both coordinate systems can be obtained:

$$\varepsilon^L_{33} = \omega_{3i}\,\omega_{3j}\,\varepsilon^S_{33} \ , \qquad (4)$$

where ω_{3i} are the direction cosine from the *S*-system to the *L*-system. In case of the method using a two-dimensional detector as shown in Fig. 3 (a), ω_{3i} is given by the following equations [14-16]:

$$\begin{aligned} \omega_{31} &= sin\eta cos\alpha \\ \omega_{32} &= sin\eta sin\alpha \\ \omega_{33} &= cos\eta \end{aligned} \ , \qquad (5)$$

where η is a supplementary angle of θ, and α is the central angle of the diffraction ring. The origin of the *S*-system is set at the X-ray irradiated point on the sample, and the stress in the *S*-system is denoted as σ^S_{ij}.

Strain can be obtained from each portion of the diffraction ring by using Eq. (3). In the following, strain obtained from the position of central angle α of the diffraction ring is denoted as ε_α, which is related to stress as

$$\varepsilon_\alpha = \varepsilon^L_{33} = \frac{1+\nu}{E}\omega_{3i}\,\omega_{3j}\,\sigma^S_{ij} - \frac{\nu}{E}\sigma^S_{ij} \qquad (6)$$

Substituting Eqs. (5) and (6) into Eq. (4) and expressing stresses as $\sigma^S_{11}\rightarrow\sigma_x$, $\sigma^S_{22}\rightarrow\sigma_y$, $\sigma^S_{33}\rightarrow\sigma_z$, $\sigma^S_{12}\rightarrow\tau_{xy}$, $\sigma^S_{13}\rightarrow\tau_{xz}$ and $\sigma^S_{23}\rightarrow\tau_y$ gives the following equation [14-16]:

$$\begin{aligned} \varepsilon_\alpha = {} & \sigma_x \frac{1}{E}\{\omega_{31}^2 - \nu(\omega_{32}^2 + \omega_{33}^2)\} + \sigma_y \frac{1}{E}\{\omega_{32}^2 - \\ & \nu(\omega_{33}^2 + \omega_{31}^2)\} + \sigma_z \frac{1}{E}\{\omega_{33}^2 - \nu(\omega_{31}^2 + \omega_{32}^2)\} + \\ & \tau_{xy}\frac{2(1+\nu)}{E}\omega_{31}\,\omega_{32} + \tau_{yz}\frac{2(1+\nu)}{E}\omega_{32}\,\omega_{33} + \\ & \tau_{xz}\frac{2(1+\nu)}{E}\omega_{33}\,\omega_{31} \end{aligned} \ , \qquad (7)$$

where E is Young's modulus and ν is Poisson's ratio. Both elastic constants are the X-ray elastic constants [12]. If a diffraction ring is measured, a sufficient large number of independent strains (ε_α) for the stress calculation can be obtained from a whole diffraction ring.

X-ray strain, ε_α, usually indicates a nonlinear behavior against α. To use ε_α for practical stress measurement, it is necessary to obtain ε_α values with high accuracy by using high-precision equipment. However, if the modified cosα method is used, a simple linear relationship can be available for determining stress from the slope of a linear relation in the same manner as the conventional method of X-ray stress measurement [12]. As shown in Fig. 3 (b), four strains on the same diffraction ring are selected. Strain at α is denoted as ε_α; similarly strains at central angles (-α), (π+α), and (π-α) are denoted as $\varepsilon_{-\alpha}$, $\varepsilon_{\pi+\alpha}$, and $\varepsilon_{\pi-\alpha}$, respectively. Then, parameters a_1 and a_2 are introduced as follows [13]:

$$a_1 = \frac{1}{2}\{(\varepsilon_\alpha - \varepsilon_{\pi+\alpha}) + (\varepsilon_{-\alpha} - \varepsilon_{\pi-\alpha})\}$$
$$a_2 = \frac{1}{2}\{(\varepsilon_\alpha - \varepsilon_{\pi+\alpha}) - (\varepsilon_{-\alpha} - \varepsilon_{\pi-\alpha})\} \quad (8)$$

Substituting Eq. (7) into Eq. (8) gives the following equations [15, 16]:

$$\tau_{xz} = -\frac{E}{2(1+\nu)}\frac{1}{\sin 2\eta}\left(\frac{\partial a_1}{\partial \cos\alpha}\right), \quad (9)$$
$$\tau_{yz} = \frac{E}{2(1+\nu)}\frac{1}{\sin 2\eta}\left(\frac{\partial a_2}{\partial \sin\alpha}\right). \quad (10)$$

The parameters on the right-hand side, namely, ν, E, σ_x, and η can be treated as constants in practical. This treatment leads to the fact that a_1 becomes linear with respect to cosα and that a_2 becomes linear with respect to sinα. Accordingly, τ_{xz} can be determined from the slope of the relation between a_1 and cosα, and τ_{yz} can be determined from the slope of the relation between a_2 and sinα. Other tri-axial stress components, such as σ_x, σ_y, σ_z and τ_{xy} can also be obtained if other diffraction rings are measured with different incident X-ray angles. The details of that measurement are reported in ref. [14, 15].

3. Results

3.1 Diffraction rings

Representative diffraction rings obtained from the sample rail are shown in Fig2. 4 to 7. The location of each X-ray measurement is described in each caption, which is shown in Fig. 10 (d). The line x=20 (mm), the location selected in Fig. 4, crosses the WEL, and the diffraction ring of Fig. 4 (b) shows a larger FWHM than that of the other diffraction rings. A similar tendency is also seen in Fig. 7 (b), which was measured from the location x=110 (mm), where the WEL also existed near the center. It is clear from Figs. 4 (b) and 7 (b) that the WEL can be distinguished by measuring the diffraction ring.

Diffraction rings obtained from the line x=66 (mm), where a crack existed, are shown in Fig. 5. According to these results, change in diffraction intensity along the circumference of the diffraction ring is bigger than with those of the other rings (Figs. 4, 6 and 7). Because the intensity of the diffracted X-ray beam is related to the density of crystal orientation, this result suggests the formation of texture on the line.

3.2 Diffraction profiles

To check the influence of the WEL on the X-ray diffraction measurement in more detail, X-ray profiles with respect to the radius direction were plotted and compared in Fig. 8. In the figure, X-ray profiles at the central angle α=0 are plotted. The first number in the parentheses in the figure shows x-coordinate and the second one shows y-coordinate. According to these results, the X-ray profiles obtained from (20, 0), (20, 2), (110, 0), and (110, 2), where the WEL existed (see Fig. 10 (d)), have greater width and lower maximum intensity than the other profiles. It is therefore possibility to judge the presence of the WEL by the shape of the X-ray

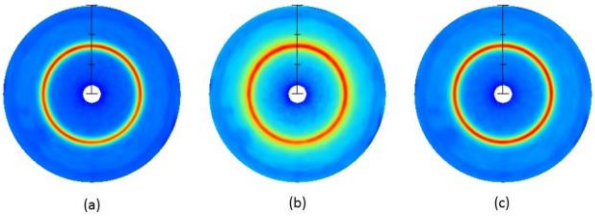


Fig. 4. Diffraction rings obtained from line x=20 mm on sample rail. (a) x=20, y=-10 (mm), (b) x=20, y=2 (mm), (c) x=20, y=-10 (mm).

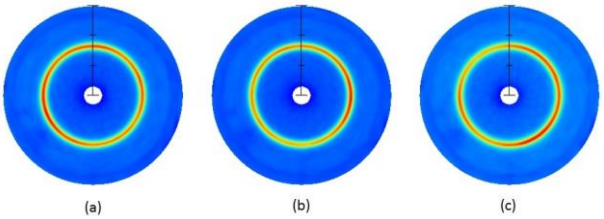

Fig. 5. Diffraction rings obtained from line x=66 mm on sample rail. (a) x=66, y=-10 (mm), (b) x=66, y=2 (mm), (c) x=66, y=-10 (mm).

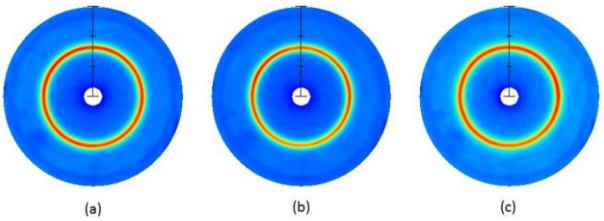

Fig. 6. Diffraction rings obtained from line x=94 mm on sample rail. (a) x=94, y=-10 (mm), (b) x=94, y=2 (mm), (c) x=94, y=-10 (mm).

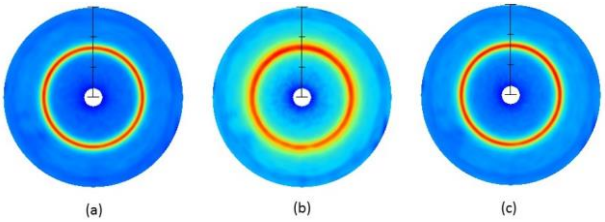

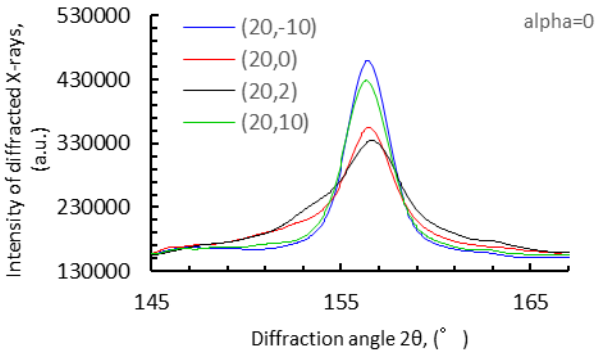

Fig. 7. Diffraction rings obtained from line x=110 mm on sample rail. (a) x=110, y=-10 (mm), (b) x=110, y=2 (mm), (c) x=110, y=-10 (mm).

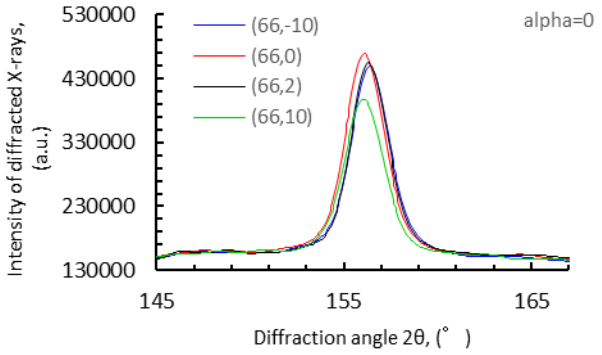
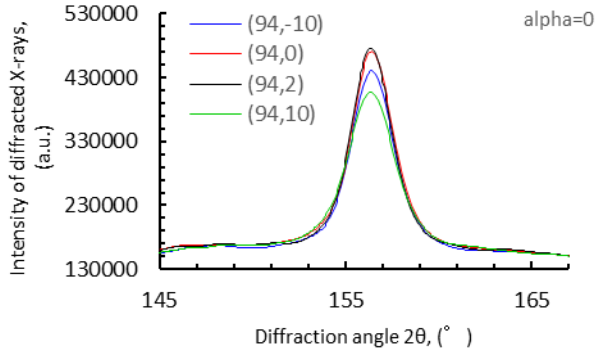
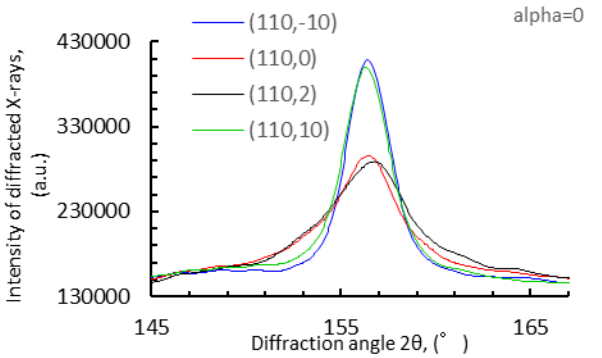


diffraction profile. Moreover, the shape of the X-ray profile obtained from location (20, 2) differs from that of a Gaussian distribution. It can thus be understood that the profile was generated by compositing the X-ray profile of the WEL and that of the ferritic steel of the sample rail, which was not transformed to the martensitic phase (showing larger FWHM), just beneath the WEL.

3.3 Stress determination by means of the modified cosα method

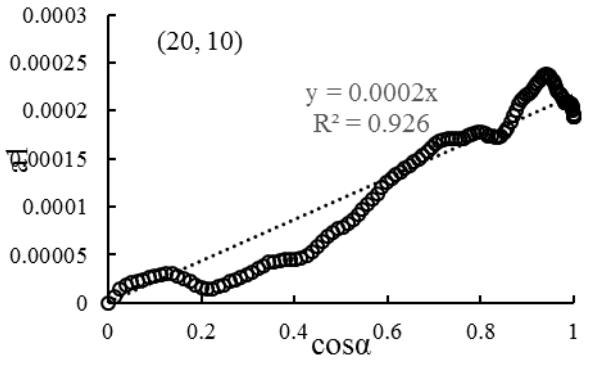


The obtained diffraction rings were used for determining stress by the modified cosα method. Example of the relation between a_1 and cosα (hereafter cosα plot) and that between a_2 and sinα (hereafter sinα plot) are shown in Fig. 9. Although oscillations appear in the cosα plot, roughly speaking, it can be said that it mostly has a straight-line tendency as expected from Eqs. (9) and (10). The cause

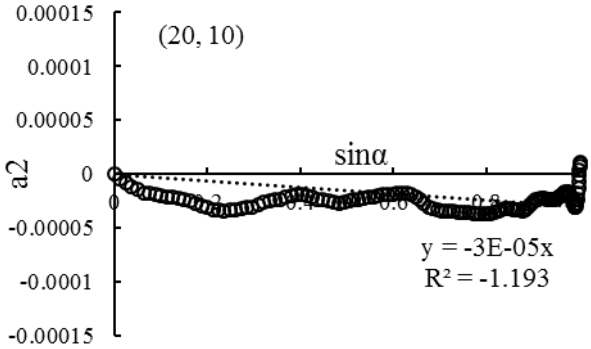


(a) x=20 (mm)

(c) x=66 (mm)



(c) x=94 (mm)



(c) x=110 (mm)

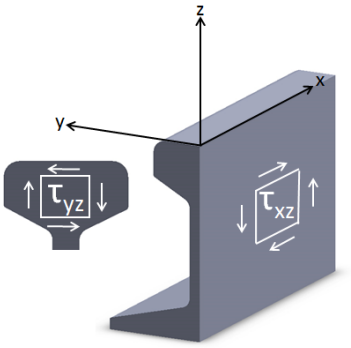
Fig. 8 Diffraction profiles obtained from line x=110 mm on sample rail. Central angle α=0.

of the nonlinear behavior seems to be the formation of texture, a steep stress gradient in the depth direction and coarse grains like a conventional method [17]. According to results obtained by the modified cosα method, the slope of the cosα plot is proportional to shearing stress,

(a) Relation between a_1 and cosα

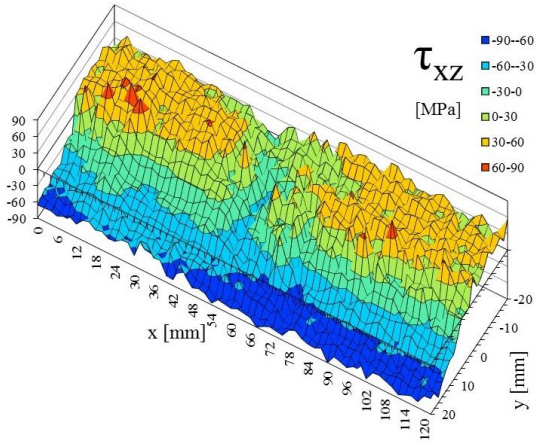
(b) Relation between a_2 and sinα

Fig. 9 Examples of results obtained by modified cosα method.



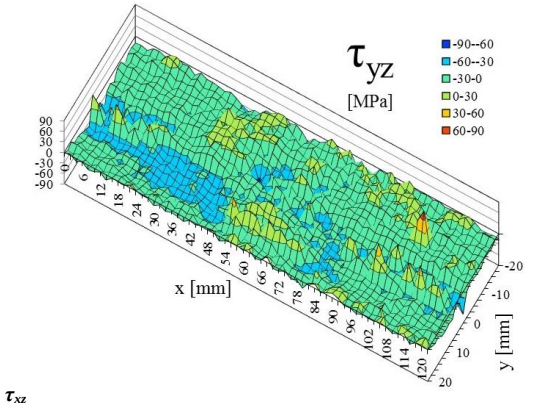
τ_{xz}, and that of the sinα plots is proportional to another shearing stress, τ_{yz}. Stress was determined in this manner for all diffraction rings. The result are presented in the following section.

3.4. Mapping of X-ray data (residual shearing stress and FWHM)



The x-, y-, and z-axes as well as a schematic action of the two kinds of shearing stresses are defined in Fig. 10(a). Mapping results on residual shearing stresses and FWHM obtained from the rail head are shown in Fig2. 10(b)-(d). According to these results, except for the center of the rail, shearing stress τ_{xz} shows a step-like distribution with respect to the transverse direction of the rail, and that distribution corresponds to the pattern of the plastic flaw formed at the subsurface of the rail head [17]. On the other hand, shearing stresses τ_{xz} show an almost zero-stress state around the center of the rail head, where a 17-mm long crack was generated. It is thus concluded that stress relaxation occurred because of the crack formation. On the contrary, the values of the other shearing stress, τ_{yz}, are small, and they do not show any distinguished characteristic pattern, as shown in Fig. 10 (c).

The FWHM, which is known to be related to dislocation density as well as to crystal size in the gage volume contributing to the X-ray diffraction is shown in Fig. 10(d). It can be clearly seen from the figure that very high values (hereafter "peaks") were obtained on both sides of the center line of the rail head. In consideration of the value of the FWHM (i.e., 4°~5°), it is concluded that the



martensitic transformation occurred at these peaks, and

(a) Residual shearing stresses of τ_{xz}

(b) Residual shearing stresses of τ_{xz}

(c) Full width at half maximum (FWHM)

Fig. 11. Line profiles of X-ray data: (a) Residual shearing stress τ_{xz}; (b) residual shearing stress of τ_{yz}; (c) full width at half maximum (FWHM) on rail head.

the WEL was formed. The causes of this transformation are thought to be high frictional heat and rapid cooling just after heating due to traction between the rail and wheels. On the other hand, the reason that the FWHM decreased at the center of the rail head, where the 17-mm long crack was generated, is a kind of softening phenomena occurring during the repeated passage of trains after the formation of the crack. Up until now, this softening phenomenon has only been observed in relatively hard materials with high FWHM.

In this study, it took about 1 min to measure two kinds of tri-axial shearing stresses, τ_{xz} and τ_{yz}, from each measurement point, and these stresses could be mapped automatically. However, it would take about one hour per point if a similar measurement was made using an ordinary method such as Dölle and Hauk's method [18]. Accordingly, this experimental procedure is useful for studies on mapping residual stress, especially in a tri-axial stress state.

3.5 Line profile of residual stress

Line profiles of residual shearing stress of τ_{xz} with respect to the width direction (y) on the rail head along the four lines x=20, 66, 94, and 110 (mm) are shown in Fig. 11(a). The left WEL shown in Fig. 10 (d) is crossed by line x=20 (mm), and the right one is crossed by line x=110 (mm). Line x=64 (mm) crosses the center of the crack, and line x=94 (mm) crosses the outer periphery of the crack part. As a result, the stress τ_{xz} is almost constant at points between $-20<y<0$ (mm), except those of the line x=66 (mm), and it decreases gradually to become compressive toward the gauge corner between $0<y<20$ (mm). Because line x=66 (mm) crosses the crack, it is possible that the stress is relaxed there.

As shown in Fig. 11(b), the other residual shearing stress, τ_{yz}, shows no clear features, except for some points included on line x=66 (mm). Because a crack exists on the line, the formation of the crack seems to have influenced the residual-stress state. The two erroneous points (indicated by "○" and "●") were obtained from the location where the WEL exists. The large FWHM of the WEL caused the scattering of stress because the determination of θ from the diffraction ring becomes difficult when FWHM is large.

Sharp peaks of FWHM can be seen in Fig. 11 (c). They occurred around y=2 (mm) on lines x=20 and 110 (mm), where the WEL existed. It is thus concluded that the peaks were caused by the WEL. According to Fig. 11 (d), the FWHMs, except for those on the WEL, differ in the cases of the gauge-corner side and the field-corner side. The FWHM for the gauge-corner side is slightly larger than that for the field-corner side. This difference in FWHM is thought to be caused by the difference between the plastic strains stimulated during repeated contact with wheels.

4. Conclusions

The tri-axial stress state on a rail head (used in service) with a 17-mm long crack was analyzed by X-ray diffraction. The modified cosα method was used to determine shearing stresses τ_{xz} and τ_{yz} simultaneously within 1 min. It was found that the present modified cosα method is more effective in saving measurement time than an ordinary method such as Dölle and Hauk's method (which usually takes more than one hour to conduct similar measurement). As a result of this analysis, the in-depth state of two kinds of shearing stress and full width at half maximum (FWHM) were determined as a two-dimensional mapping image. These patterns will contribute to evaluating rail damage more precisely than hitherto possible. The results of this study will contribute to establishing a new maintenance method for rails that is more effective than the conventional method.

Acknowledgments

The author is grateful to Toshio Mizukami, East Japan Railway Company, for preparing the rail sample used in this study. This work was partially supported by JSPS KAKENHI Grant Numbers JP16H02309, JP16H00946 and JP16K14145.

A short review of the rail rectification history reveals the enormous progress made with regard to rail maintenance technologies and their highly specialized applications. All sorts of rail surface irregularities and in particular Rolling Contact Fatigue (RCF) is today controlled by restorative, corrective and cyclic preventive activities. Nevertheless, these defects keep reappearing and - even more critical – new phenomena show up and trigger discussions. Questions are raised about the rectification processes, their limits or – similar to medicine – possible side effects.

Lessons learned so far are analysed by looking at the present reprofiling practices and specifications. Furthermore, a specific type of rail defect and its correct treatment will be discussed. The complexity of the rail-wheel system requires a comprehensive approach to successfully control RCF. Positive synergy effects of restorative, corrective and preventive measures have to be explored. Intervention thresholds, maintenance cycles and metal removal requirements need to be regularly challenged to adapt specifications. Only by considering these important aspects of the highly dynamic rail-wheel system it is possible to provide the appropriate maintenance strategy with best possible results..

INVESTIGATION ON THE MECHANISM OF RAIL CORRUGATIONS BY RATIONAL CONJECTURE AND TESTS

Gang SHEN , Huiming YAO [*], Meng WU

Tongji University

[*] E-mail: elsg163@163.com, huimingyao@126.com

Abstract: This paper tries to give a universal answer to the most types of rail corrugations according a conjecture and a series of related tests in the limited contact zoom. Regarding to the type of wear damage, It is concluded that all corrugations are caused by the coincidence with two essential ones, one is the tangential vibration due to unstable oscillation; the other one is the periodical change of the oscillation from stable to unstable due to normal load raised by certain initial corrugation.

Keywords: Mechanism of rail corrugation, rail corrugation, wheel rail system, wear, contact.

1. Introduction

The rail corrugation has become a tough problems in rail transportations not only on curved track but also on straight track. Many research has also been carried out for specific cases [1-8]. There are many types of rail corrugations which happened on heavy haul line, metro line and high-speed line etc. in the form of different wave lengths and different damage pattern including plastic and wear. Whatever the different types of rail corrugations, the damages to the rail and vehicles are serious with great impact force, noise and fatigue failures. This paper tries to investigate the mechanism of rail corrugations limited in the contact zone and to give a universal answer to the most types of rail corrugations.

2. The general mechanism of rail corrugations

Figure 1 shows a general corrugation mechanism comprising 'wavelength-fixing mechanism' and 'damage mechanism'. The initial roughness combined with traction, creep, friction characteristics, etc. excites the dynamic loads which cause the damages of some type. [4].

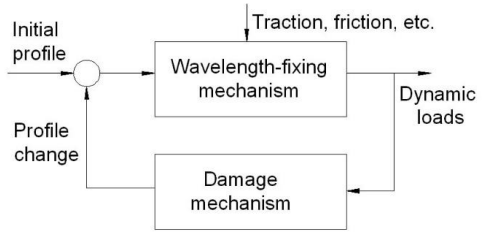

Figure 1 Corrugation mechanism

This general mechanism is based on a concept in which only the key features which are taken into account because of the complex track-vehicle system with many components, including rail pad, sleeper, track bed, unspring mass, primary suspensions, wheel/rail profiles, track curvatures, etc. Each component will affect the initiation and propagation of the rail corrugations. Only the common features taken in the consideration here are the contact area, normal force, tangential force, creep, friction characteristics, deformation and wear for the general purposes.

Two types of damages including wear by creep under normal force and plastic deformation under normal force are the essential factors to change rail profile but not always corrugation eventually. For the initiation of corrugation, the damage must be periodical alone the rail. It can be assumed that a certain mechanism should exist in the interface of wheel/rail, i.e. the damage will become larger in the troughs than on the peek. If any condition triggers this mechanism the rail corrugation will occurs.

3. The conjecture of the mechanism for wear type corrugation

Regarding the type of wear damage, the illustration of mechanism of corrugation shows in the Figure 2, which consists of two parts: left part is a sub-figure with creepage versus creep forces, the right part is the sub-figure with distance alone the rail versus normal forces (left part) and corrugation profile (right part) and creep forces (axis toward to the paper) together in the middle. There are two curves on the left sub-figure, the upper one is under higher contact normal load, the lower one is under lower contact normal load. ξ_0 is the current working point. On the right part of the figure the profile of corrugation is shown. It is easy to realize that the impact on the peek area will cause the larger contact forces. The variation of the impact force is between N_{min} to N_{max} around the mean level N_0, which related with upper and lower curves in the left sub-figure. The working point varies between A and B point. It is assumed that the slope at point A is positive, the slope at B is negative. The slope of the curves is related with stiffness between wheel/rail. The negative stiffness causes the wheelset oscillation so called stick-slip vibration. According to the right figure the impact force is lower at troughs area and higher at the peak area, so the oscillation more likely stronger at the depths of corrugation. This might be the micro mechanism of the propagation of the rail corrugation of wear type.

Clearly, there are two prerequisites for the propagation, one is the variation of normal contact load up to certain

amplitudes; another one is the working point of the creepage, it changes across the positive slope and negative slope with the varying normal contact load.

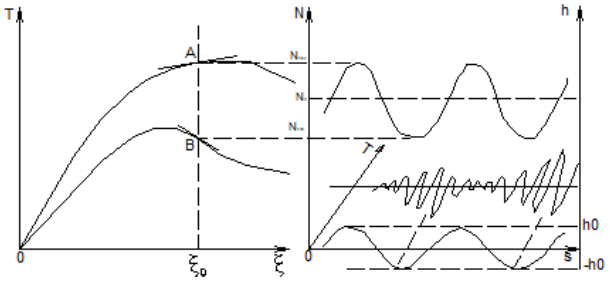

Figure 2 Illustration of conjecture of general mechanism for rail corrugation propagations

It is clear, if the creepage is higher enough with all negative slopes on the creep force versus creepage curves, there is no rail corrugation occurring, but together with heavy wear occurring. If the creepage is lower with all positive slopes on that curves, there is also no corrugation occurring with less wear on the rails. If the dynamic load has not yet reached the magnitude to cause the phenomenon of the jumping between positive and negative slope point, for example, at the beginning stage of service, there is no ready-made rail corrugation for propagation. However the rail roughness will growth with wear after certain passage of wheels, inevitably the dynamic load will reach the level with the mixed positive and negative slope at specific conditions.

In order to convince the conjecture, two clues are needed to be proved as following:

1) Weather does the negative sloop exists with large creepage? With the increasing of normal loading, will the peak point moves towards the direction of lateral axis of creepage?

2) Weather does the large tangential vibration happen if working point located on the negative sloop point as shown in the Figure 2?

Two tests are carried out as shown in the following sections.

4. The scaled down test rig and the preliminary results

In order to prove the first one, a scaled test rig has been built. The scheme of the test rig is shown in the Figure 3. The roller B is driven by a motor with adjustable speed. The roller A can be rotated with an angle ∅ an adjustable applied normal force N. The lateral creep force can be measured by a sensor mounted on the axle of roller B in series with axle. Figure 4 is the typical results of creep force vs angle under 3 different normal loads. The angle represents the lateral creepage. It can be seen that the peek point moves to right direction with the increase of normal load which match the assumption in the figure 2.

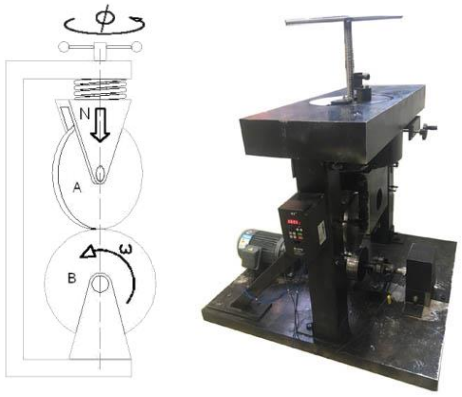

Figure 3 The scheme of the test rig and a photo on site

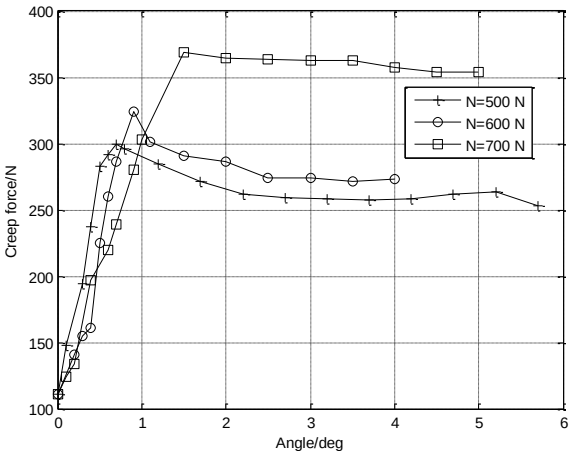

Figure 4 Typical results of creep curves under different loads

5. The site test and typical results

In order to prove the second one, a field test has been carried out on a curved track with 300 m radii and rail corrugation existing on the top of inner rail. The test layout is illustrated in the Figure 5. The train will pass through straight track section and then normal circular track section 1 and friction modified (FM) circular track section 2, the vertical/lateral acceleration sensors are all mounted on the rails for all three sections as shown in the Figure 6. The friction coefficient in the FM section is controlled around 0.3 with no negative sloop of creep force – creepage curves. The measured rail corrugation is shown in the Figure 7 with peak to peak value about 0.5-0.6 mm and wave length of 200 mm.

The typical results are shown in the Figure 8 with vertical and lateral accelerations for straight track section and the following circular track sections from top to bottom. It can be seen that the vertical accelerations on circular track section 1 and 2 are larger than that on straight track section because of the rail corrugation. The frequency of main contribution is around 70-90 Hz. For the lateral accelerations on the right column, there is no lateral on straight track section. There is large lateral vibration on the circular section 1 dominated on two frequencies, one is around 70-90 Hz, the other is 150 Hz. There is less lateral vibration on the circular track section 2 with FM compared with the above one on 150 Hz. That is clear the tangential vibration happened on the negative sloop with frequency of 150 Hz. It will become less if the negative

sloop modified by FM. The vibration with frequency between 70-90 Hz may be the lateral component of vertical vibration.

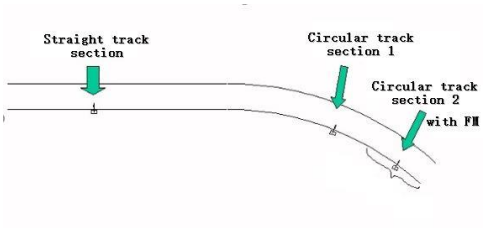

Figure 5 The layout of test

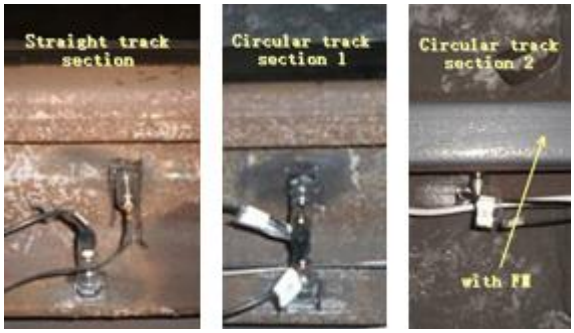

Figure 6 The layout of Sensors on three sections

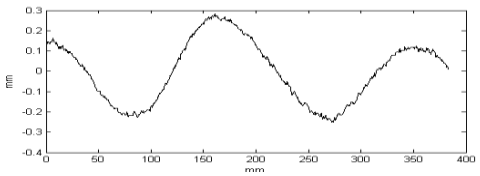

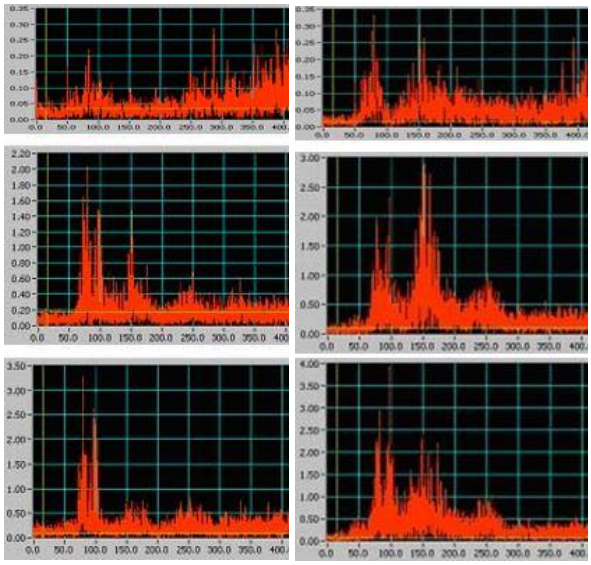

Figure 7 The measured rail corrugation

(a) *(b)*

Figure 8 The test result: (a) Vertical (b) Lateral

6. Conclusions

A rail corrugation mechanism has been conjectured and validated by a scaled down test rig and field test. All corrugations are caused by the coincidence with two essential ones, one is the tangential vibration due to unstable oscillation, for example, the negative sloop of creep force-creepage on working point; the other one is the periodical change of the oscillation from stable to unstable due to normal load raised by certain initial corrugation. According to the conjecture many actual appearances of rail corrugations can be clearly explained. For example, why does the softer support under the rail usually brings faster and heavy growth of rail corrugation compared with normal support of rail? That is because the vertical vibration force will be larger and easy to reach the mixed positive and negative slope state. Why does the corrugation usually appear on the curves with the curvature between 300-500 m? It is due to the creepage at these zones which matches the positive and negative slope. Why does the rail corrugations usually appear on one rail only (normally on inner rail) on the curved track? The reason is that on the curved track the wheelset oscillation usually happens on one wheel and the outer wheel contact on high rail is stronger than the inner wheel. Why does the rail corrugation appear on the straight line? That is because the certain oscillation happens on the section (longitudinal creep on both sides) or a depth initiated on the rail to make the P2 impact force.

The reference papers are just an example from so large volume of valuable research work on the rail corrugation research and the author apologized to those work not listed in the references.

Abstract: The abnormal vibration of a tram in China occurred during operation. To investigate the cause of abnormal vibration, field tests were carried out on the wheel out-of-roughness (OOR) and vibration of car body. By comparing the vibration acceleration level and polygon features of the car body before and after re-profiling, it is found that the vehicle with abnormal vibration has serious eccentric and low-order polygonalization on the wheel. After re-profiling, the wheel out-of-roundness is obviously improved, and the abnormal vibration of the car body corresponding to the frequency is reduced. The results show that the wheel with eccentric and low order polygonalization is one cause for the abnormal vibration of the tram, which can be solved by wheel re-profiling. In this paper, the wheel polygonal characteristics of a tram are summarized and analyzed, and an algorithm for evaluating the wheel out of roundness is given. At the same time, the influence of the wheel polygonalization on the vibration of the tram is also analyzed, but the mechanism and development of wheel polygonalization need to be further explored.

Keywords: Out-of-round of train wheels; Vehicle vibration; Field test; Tram

1. Introduction

At present, the phenomenon of out-of-round wheel has been commonly found in all kinds of rolling stocks such as the high-speed trains, metro cars and trams due to different reasons. And the wheel polygonization is a special form of out-of- roundness (OOR). The wheel polygon will aggravate the vertical vibration of railway vehicles and decrease the quality of operation. Besides, it will also affect the operation safety, ride stability of train vehicle as well as cause serious damage of rail [1]. Therefore, it is becoming more and more important to measure and analyze the wheel out-of-roundness, which is not only significant to monitor the development of wheel polygonal wear but provide useful strategies to re-profile and maintain the wheels. In 2006, Anders Johansson introduced the assessment of out-of-round of train wheels [2]. Until now, scholars worldwide have studied the mechanism of wheel roundness, [3-5] which mainly focus on the wheel out-of-roundness of high-speed trains and subway vehicles. [6-7] At the same time, the influence of wheel polygon on vehicle dynamic performance has been obtained by simulation. [8-10] In this paper, the lateral profile of the roundness of a trolley in China was analyzed based on a portable measuring instrument of out-of-roundness developed by Shen[11]. Furthermore, an algorithm for the analysis of wheel roundness was developed based on MATLAB. The magnitudes and wavelength contents of measured wheel roughness as well as the amplitudes and harmonic orders of the polygonal wear were obtained. Until now, researchers worldwide mainly focus on the simulation and prediction of out-of-round wheels. There was less research on field test of wheel polygonization. In view of the serious wear and abnormal vibration condition of a trolley in China, a field-test program has been carried out to acquire the polygonal wear profile and the spectrum of vertical vibration of car body before and after wheel re-profiling. The acceleration spectrum level and the characteristics of the wheel polygon were obtained, and the influence of the wheel polygon on the vehicle vibration was analyzed.

2. Measurement and analysis of wheel OOR

2.1. Measurement of wheel OOR

In order to find possible cause of abnormal vibration, an extensive wheel measurement campaign was therefore launched to obtain the representative indication of OOR. The radial deviation of eighty wheels on trams in China was measured, including seven different kinds of motor and trailer cars. Both wheels before and after re-profiling were investigated. Number A, C and D indicate that the vehicles are motor cars, while B is trailer car. Each vehicle was tested with four wheels, in which Number One and Three are left wheels while Two and Four represents right wheels. The tram wheels of this measurement campaign were independent and a summary of properties of the wheels measured in the campaign were shown in Table 1.

Table 1 *Summary of properties of the wheels measured*

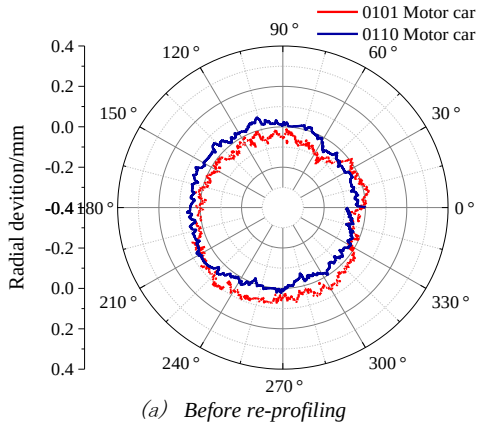
Re-profiling Condition		Before	After
Bogie type		Motor	Trailer
Wheel	Before re-profiling	0101ACD、0104AC、0105AD、0110A	0124B、0117B、0101B 0104B、0105B、0110B
	After re-profiling	0101ACD	0101B、0107B、0110B
Bogie type		Motor	Trailer
Mass of a assembled wheelset/t		0.72	0.875
Running speed		60	

(km/h)	
Brake type	Disc brake
Nominal diameter/mm	600

Figure 1 reflects the situation of measurement. The measured data were obtained by using mechanical contact measurement method with the portable wheel OOR measuring instrument developed by Shen [11]. Wheel raw data of OOR were measured at the nominal contact position. During the measurement, the brake devices were unlocked and wheels could be automatically rotated around the axles. Furthermore, the sampling frequency was 40Hz, and the accuracy of the instrument was 0.02mm.

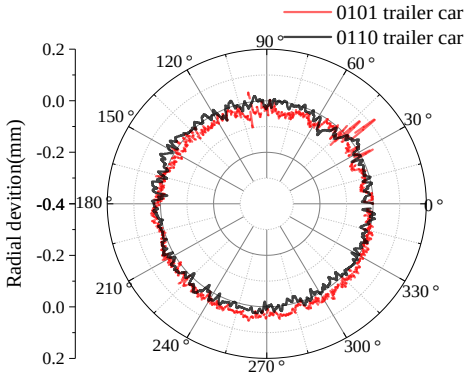
Figure 1 *Field test of OOR*

The measurement data of wheel roundness shapes are acquired through sensors. According to the assessment of wheel roundness presented by Anders Johansson,[12] an algorithm for the analysis of wheel roundness was developed based on MATLAB. The radial deviation, magnitudes and wavelength contents of measured wheel roughness level as well as the amplitudes and harmonic orders of the polygonal wear were obtained.



2.2. The radial deviation

The deviation [12]:of wheel roundness is defined as Eq(1):



$$r(x) = R(x) - R_0 \qquad (1)$$

where $r(x)$ is wheel irregularity/roughness profile(m), $R(x)$ is the wheel radius as function of circumferential coordinate (m), R_0 is the average radius (m), x is the circumferential coordinate (m).

Since all test data contain 6th-order polygon information with the amplitude about 0.01mm, which is mainly caused by the measurement accuracy of the instrument itself. Therefore, it is adopted the corresponding low-pass filter to filter 6th-order wheel polygon, and the cut-off wavelength (the minimum wavelength of spectral analysis) is set to 0.005m. The diameter of new wheel is 600 mm and circumference is 1885 mm. The relationships between radial deviation of the 0101 trains before and after re-profiling in the polar coordinates are shown in Fig. 2.

(a) Before re-profiling

(b) After re-profiling

Figure.2 *Radial deviation of the 0101 train before and after re-profiling in the polar coordinates*

Figure 2 shows that the wheel eccentricity and low-order polygonalization (mainly 3rd order) exist in motor and trailer cars of the same train before re-profiling. After re-profiling, the wheel out-of-roundness condition is obviously improved, which there is only a slight eccentricity. Besides, the radial deviation values of the motor and trailer cars tend to be same.

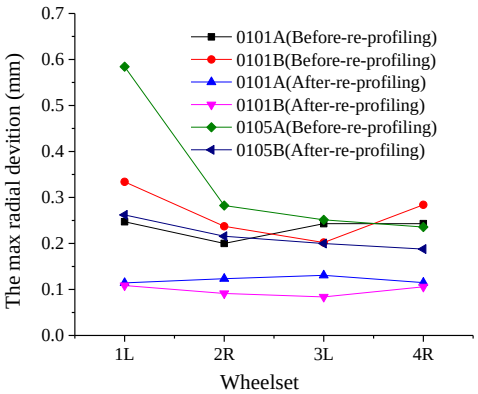


Figure.3 *The max radial deviation of wheel roundness*

Analysing all test data, the maximum radial deviation value of four wheels in different vehicles are counted, just as shown in Fig. 3. It can be found that 0101 motor and trailer cars and 0105 motor car have obvious wheel roughness before re-profiling, which the radial deviation value is 0.2-0.4mm. Besides, the radial deviation of the 0101 and 0105 trailer car is smaller than the motor car with the amplitude about 0.15-0.25mm. In addition, the radial deviation after re-profiling is relatively reduced

and the roughness is mainly kept below 0.1 mm. The result shows that the wheel re-profiling can effectively improve the wheel out-of-round phenomenon of the tram.

2.3. Roughness level

According to the definition of roughness：

$$L_r^k = 20\log 10\frac{\tilde{r}_k}{r_{ref}} \qquad (2)$$

where $\tilde{r}_k$ is the amplitude with different wavelength in one-third octave band. The evaluation of $\tilde{r}_k$ is based on the Welch algorithm. Compared with the direct method, this method has greatly improved both in the resolution and variance performance. [13] The self-power spectral density function of a discrete random signal sequence is calculated with signal overlap segmentation, windowing function and FFT algorithm. By using the *periodogram* function in the MATLAB Software, the PSD function $Grr(f)$ of radial deviation $r(x)$ is evaluated. The root mean square values is $\tilde{r}_k$ in one-third octave band with central wavelength, which is shown in the Eq.(3) :

$$\tilde{r}_k = \sqrt{\sum_{fl}^{fu} Grr(f)\frac{fs\cdot m}{N}} \qquad (3)$$

$$fl = \frac{100v}{\lambda}\cdot\frac{1}{2^{1/6}} \qquad (4)$$

$$fu = \frac{100v}{\lambda}\cdot 2^{1/6} \qquad (5)$$

The r_{ref} is the reference value of wheel roughness with r_{ref} =1um , the fs is the sampling frequency, N is the total number of sampling point, m is the number of sequences contained in the signal in one-third octave band, λ is the central wavelength of the one-third octave band, v is the velocity of wheel, fl is the lower limit frequency in one-third octave band, fu is the max limit frequency in one-third octave band, according to the Eq.(4) and (5).

According to the Standard ISO3095, the roughness limit values with different wavelength are shown in the Fig.4. To compare the wheel roughness of the field test with the values in standard, the upper limit of harmonic order is 20th order and the corresponding wavelength range of wheel roundness is 95 to 1885mm. There is some superposition of irregularity spectrum and roughness spectrum in some sections. Thus the roughness spectrum is obtained by accumulating the irregularity spectrum with different wavelengths within each one-third octave band. The central wavelength range of wheel is 5 to 315mm.

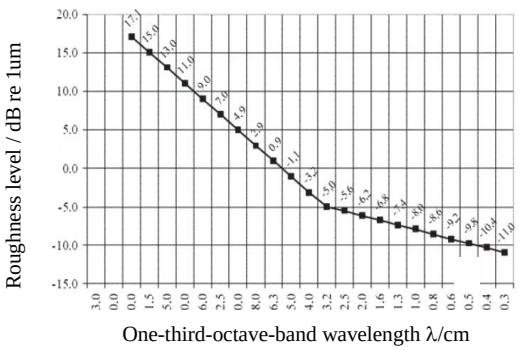

Figure.4 *The limit value of roughness in Standard ISO3095*

In the roughness level spectrum, the roughness level corresponding to roughness value with 10μm is 20dB, while the roughness level corresponding to roughness value with 1μm is 0dB.

2.4. Harmonic Order

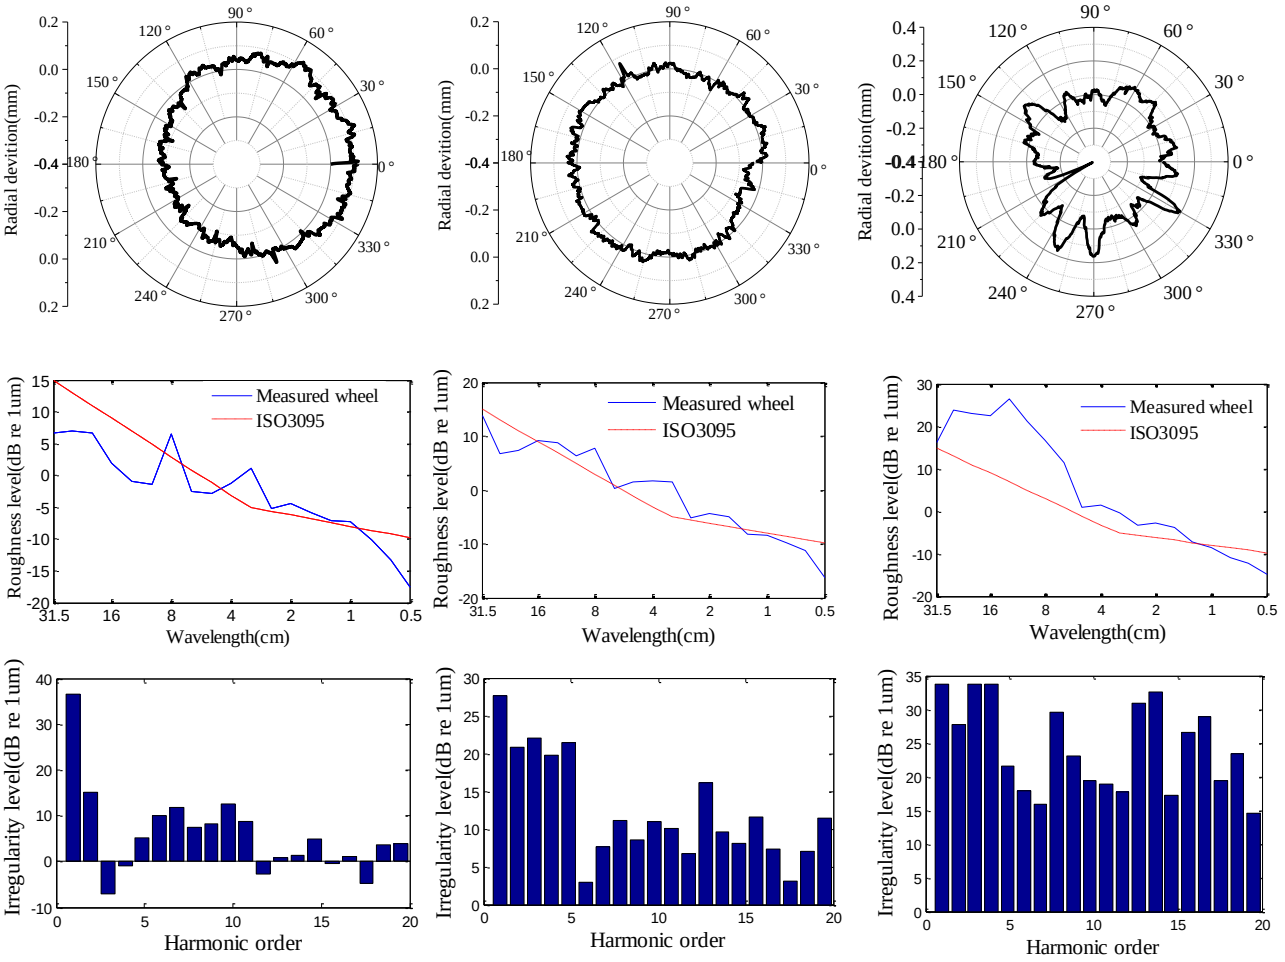
$z(f)$ is performed by Discrete Fourier transform on radial deviation sequence $r(x)$, which is shown in the Eq. (6).

$$z(f) = FFT[r(x)] \qquad (6)$$

$$A_k = \frac{|z(f)|}{N/2} \qquad (7)$$

where A_k the amplitude of different wavelength, as shown in Eq.(7). The N is the total number of sampling point, $|z_k|$ is the module value obtained by discrete Fourier transform. The order of wheel polygonalization is obtained by Eq.(8),

$$f_k = n\cdot fs/N^* \qquad (8)$$



The n is integer (n=0, 1, 2…, 20), fs is the sampling frequency, $N^*=fs+1$. The highest order of the OOR is 20th order, and the highest level of amplitude spectrum is 40dB 1um. Making the rounded operation on f_k then the order of wheel polygonalization can be obtained, the corresponding level of irregularity amplitude is $\bar{L}_r^k$, which is shown in Eq. (9).

$$\bar{L}_r^k = 20\log 10\frac{A_k}{r_{ref}},\ r_{ref}=1\text{um} \qquad (9)$$

2.5. Analysis of OOR

According to the analysis of OOR wheels, Fig.5 shows the three typical types of OOR wheels. The roughness spectrum and polygonal level spectrum of polygonal wheels are obtained and compared with the Standard ISO3095. Fig.5 (a) shows the wheel of 0124 trailer car before re-profiling, which mainly presents the eccentricity. The part of eccentricity has a high proportion according to the amplitude level spectrum, whose amplitude is close to 40dB re 1um. According to the roughness spectrum, the amplitude in the range of 10 to 80mm of central wavelength of one-third octave band exceeds the limit value in the Standard ISO3095, which shows that the roughness of the wheel surface is large. Fig.5 (b) shows the motor car wheel before re-profiling, which presents low orders from 1st order to 5th order. The roughness in the range of 105 to 160mm of central

wavelength exceeds the limit value in the Standard ISO3095. Fig.5(c) shows the wheel of 0105 motor car, whose roughness almost exceeds the Standard ISO3095. Except the low orders from 1st order to 5th order, there are low-wavelength discrete defects on 0105 wheel and the roughness level corresponding to the wavelength range from 50 to 350mm severely exceeds the Standard ISO3095. The field investigation shows the wheel scratch on the motor car wheel of the tram, which is rare in the whole measured wheels.

(a) Eccentricity *(b) Low order Polygonalization* *(c)low-wavelength discrete defect*

Figure.5 *The OOR wheels of tram*

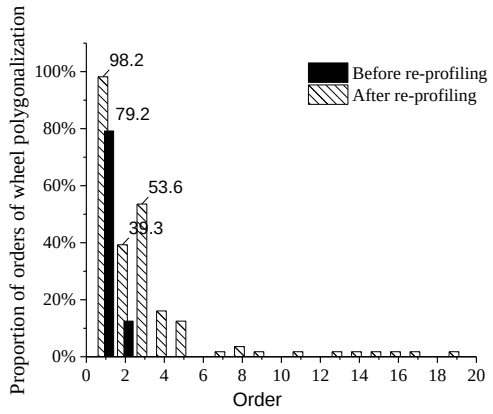


Figure.6 *Proportion of orders of wheel polygonalization*

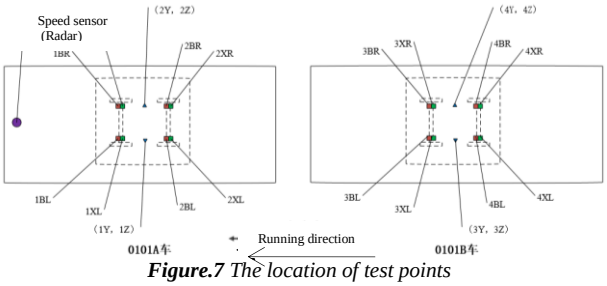
According to statistics of all wheels in the test, the main order of wheel polygonalization before and after re-profiling are obtained. The Fig.6 shows that almost all wheels have the eccentricity (1st order) before and after the wheel re-profiling, which is related to the machining accuracy and mass eccentricity. More than 50% of the wheels before re-profiling have slight the 3rd order polygonalization. Besides, the low order irregularity is mainly focused on the 2nd order to 5th order. According to the reference paper [14], the new wheel in the initial state, the polygonalization is mainly caused by the fixation on the three claw chuck. After re-profiling, there is mainly eccentricity on the wheel, which the radial deviation is below 0.1mm and the roughness is within the limit value of Standard ISO3095.

3. Vibration test of tram

To investigate the influence of out-of-round wheel on car body vibration, the vibration test is carried on the tram in China. In AWO condition, the maximum speed of the test is 56km/h. There is a speed radar installed at the front of train body for real-time measurement and record of the train speed. The vertical acceleration of the car body, bogie frame and axle boxes of motor and trailer cars of train 0101 before and after the wheel re-profiling are

tested, and the location of test points is shown as Fig.7.



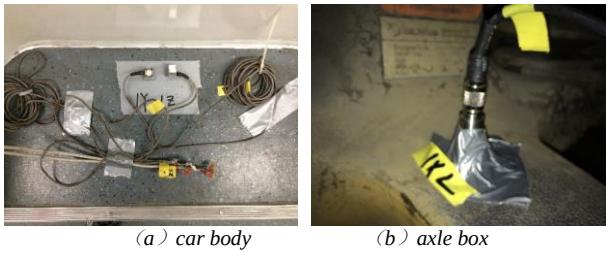


Figure.7 *The location of test points*

The acceleration sensors on the car body and axle box are shown in the Fig.8. The sampling frequency is 1024Hz, and the cut-off frequency of the low pass filter is 100Hz.The acceleration data is processed in the LabVIEW. The riding quality index, the root mean square value and spectrum analysis are obtained. The wheel OOR mainly influences the vertical vibration of car body. Therefore, this paper is mainly focused on the influence of wheel OOR on the train tram operation. The frequency spectrum analysis is carried on tested vibration acceleration of car body. Then the vibration acceleration level is obtained, whose reference value is $1m/s^2$ and the range of spectrum analysis is based on four speed levels, 34±2km/h, 41±2km/h, 48±2km/h and 54±2km/h. The sampling time is 5s.

（a）car body *（b）axle box*

Figure.8 *Acceleration sensors*

4. Influence of wheel OOR on vibration

The vertical acceleration signal of car body before and after wheel re-profiling is analysed by spectrum analysis, which the 40Hz frequency band is selected and transformed in the vibration level/dB [15]. Tab.2 shows the vibration of car body. To verify whether the abnormal vibration of car body is caused by the wheel OOR, the vibration of car body before and after re-profiling is analyzed. Fig.9 shows the vibration level of the motor and trailer cars at each speed level.

Table.2 *Vibration level of car body*

Speed/（km/h）	Acceleration amplitude level/dB			
	Before re-profiling		After re-profiling	
	Motor car	Trailer car	Motor car	Trailer car
34	-13.9	-6.9	-15.1	-12.1
41	-11.4	-9.4	-13.9	-10.9
48	-7.5	-3.3	-13.4	-7.5
54	-6.9	7.9	-10.9	-10.4

According to the Tab.2, it is found that the vibration level of trail car of train 0101 before and after wheel re-profiling is higher than the motor car of train 0101 l at each speed level. As for the kind of vehicle, the vertical vibration level is obviously lower after wheel re-profiling, which shows that the wheel re-profiling can efficiently improve the vibration level.

To investigate the relationship between the wheel OOR and the vehicle vibration, the acceleration amplitude level spectrum and wheel OOR spectrum of the motor car of train 0101 before and after wheel re-profiling are obtained, as shown in Fig.9.

f_0 is the excitation frequency due to the wheel polygonalization, which is evaluated according to Eq. (10).

$$f_0 = \frac{nv}{3.6\pi d \times 10^{-3}} \qquad (10)$$

where v (m/s)is the running speed of the vehicle, n is the order of the wheel OOR, d is the radius of wheel.

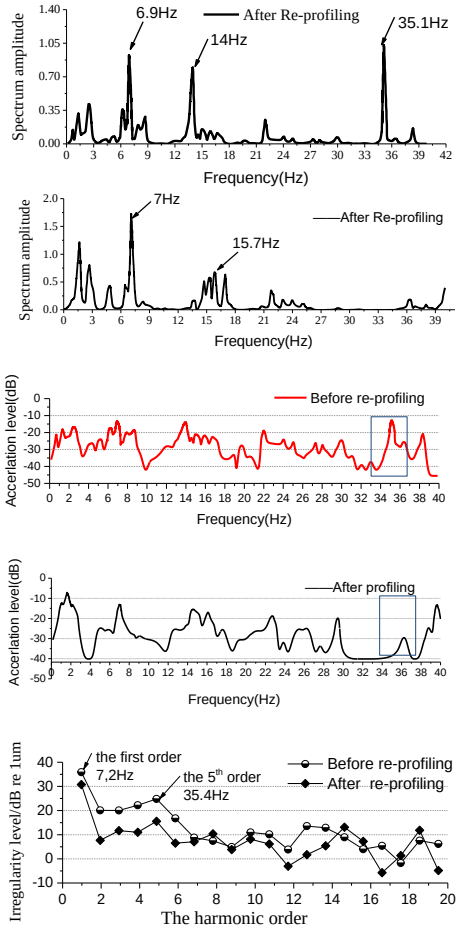

Figure.9 *The acceleration amplitude level Spectrum and wheel OOR spectrum before and after wheel re-profiling*

According to Fig.9, there is a corresponding relationship between the wheel OOR and the car body vibration, there are mainly 7~8Hz, 12~15 Hz and 34~35Hz ranges of car body abnormal vibration before the wheel re-profiling, which are corresponding to the frequency 7.2Hz of 1st order(eccentricity), 3rd order and 35.4Hz of 5th order of wheel polygonalization. After wheel re-profiling, the overall level of wheel OOR is improved, and vibration corresponding to the main frequency range 34~35Hz is lowered obviously. The wheel is still eccentric after wheel re-profiling, and the vibration corresponding to frequency range of 7~8Hz is not improved efficiently.

Overall, serious wheel OOR will aggravate the vibration level, it will be worse when the order of wheel polygonalization is in the resonance range of car body.
According to vibration spectrum of the wheel, there are vibration with frequency range 34~35Hz in most of the wheels, some wheels have vibration with frequency range 8~9Hz, which are not caused by wheel OOR. According to the reference, the modes of car body of train 0101A on AW0 conditions are shown in Tab.3.

Table.3 *The modes of car body of train 0101A on AW0 conditions*

No	Frequency(Hz)	Amplitude（mm）	Mode
1	8.80	0.91	Lateral deviation+Torsion
2	9.89	1.90	Vertical bending
3	12.77	1.31	Torsion

The frequency of first torsion mode of car body of train 0101A on AW0 condition is 12.77HZ, the vibration frequency of car body is approximately12~14Hz, which is close to the torsion mode. It is considered that the abnormal vibration frequency of the car body within 12~14Hz is aroused by the torsion of the car body. Besides, it is found that the abnormal vibration frequency within 8~9Hz is related to the coupling of vertical bending and lateral torsion mode of car body.

5. Conclusion

(1) Analysis of wheel OOR of a tram, including the radial deviation, roughness level and amplitude level. It is found that there are eccentricity (1st order) and low-order polygonalization (2^{th}-4^{th}) on the wheel before re-profiling. Even some wheels have wheel scratch. There is still eccentricity on the wheel after re-profiling. The radial deviation is reduced with 0.1mm and the roughness level is basically conformed to the StandardISO3095.

(2) The field test on the wheel OOR and vehicle vibration of a tram is carried out. It is found that the abnormal vibration of car body with ranges of 7~8Hz,12~15 Hz and 34~35Hz ranges are related to the 1^{st} and 5^{th} orders of wheel polygonalization at the running speed of 54km/h. Among these orders, the vibration level of vehicle becomes higher. After re-profiling, the wheel OOR is improved and the vibration level will be lowered.

(3) The vibration of car body with 12~15Hz is close to the frequency of torsion mode of car body, so this kind of frequency range can also arise the abnormal vibration of the vehicle.

[*] E-mail: s.shrestha@cqu.edu.au

Abstract: Information about the adhesion condition in wheel-rail contact during railway operations is required to characterise the braking and traction which are key factors in railway performance and safety issues. Adhesion estimation is a methodical process which requires mathematical models of crucial processes. As a part of this development, the wheel-rail interface process needs to be modelled at the initial stage. A real-time multipoint wheel-rail contact model is developed in the Matlab software environment using a modular approach. Additionally, a simplified friction condition estimation algorithm is implemented to determine friction condition between wheels and rails. The friction condition information is further implemented in a Matlab contact model to determine the actual adhesion coefficient. Finally, a bogie test rig is developed in the Gensys multibody simulation tool to validate the Matlab contact model. The contact model gives realistic results during numerical investigations. The friction condition algorithm is able to handle the change in slip under varying friction conditions which indicates the robustness of the algorithm.

Keywords: wheel-rail contact; adhesion estimation; real-time; inverse model; slip.

1. Introduction

Adhesion estimation at the wheel-rail contact interface is a multifaceted process because it is dependent on several operational factors such as processes at the wheel-rail nonlinear contact interface, distribution of load conditions acting on small contact patches, speed of the vehicle; operational rail self-cleaning mechanism, track irregularities and axle load distributions. Moreover, environmental factors also have a significant influence on the adhesion estimation. Some of these are unintentionally spilled contaminations, deliberately used friction modifiers, weather condition and contact surface temperature. Hence, adhesion is dependent on many parameters and the analytical dependency on some of them may not be easy to define. Moreover, adhesion estimation requires carefully selected methodological processes and a wheel-rail interface process is one of them, which is modelled in this work.

For the adhesion estimation process, several model-based methods have been implemented. The first is based on the inverse method as described in the patent [1]. In this method, the wheel-rail contact forces are predicted from vehicle dynamic behaviour without incorporating the wheel-rail contact algorithm [2,3]. The result may not be sufficiently accurate in some cases as explained in paper [4]. Different Kalman filter methods have been used in adhesion estimation. In [5,6], an Extended Kalman Filter is used in the online estimation of low adhesion condition by using vehicle response to lateral track irregularities in normal (no traction or braking) running condition. In [7], the Kalman-Bucy filter is used to detect lateral creep force for local adhesion condition determination. Multiple Kalman filters are used in [8] based on wheelset dynamics and a fuzzy logic observer to identify the operating condition of the wheelset at the wheel-rail interface. Recently, a multiple model approach based on swarm intelligence to estimate friction at the wheel-rail interface was proposed in [9]. The artificial neural network method was also used to predict wheel-rail contact force [10] and to estimate adhesion condition [11]. However, these approaches do not consider many significant parameters such as wheel and rail profile change, friction conditions, etc. In this case, it is better to use classical wheel-rail contact algorithms [12] that are used for multi-body software packages which provide results with good accuracy.

However, the classical contact models become impracticable for implementation in real-time due to the low computational speed. To achieve real-time simulation by satisfying the requirements mentioned in literature [13], the fast approximation model seems to produce reasonable accuracy, however, it is unable to consider contact profile change and requires user-defined coefficients in models. In [14,15], the real-time model is implemented in field-programmable gate array (FPGA) hardware including Hertz and Fastsim modules to describe contact laws between wheels and rails. The contact geometry, creepages and normal forces are extracted from a precalculated lookup table. Furthermore, a real-time contact model for a scaled test rig has been developed at Politecnico di Torino, Italy [16,17] which considers single point contact.

This paper presents a methodological development of a multipoint wheel-rail contact model for the purpose of real-time adhesion estimation. The model has potential to consider multiple wheel-rail contact points.

2. Contact model in MATLAB

The proposed model considers multiple point wheel-rail contact. It is created in the MATLAB platform. The model consists of the following modules:

2.1. Profile generation module

In this work, the S1002 new (unworn) wheel profile and UIC60 new rail profile are used. The profiles for both right and left side wheel and rail are initialised separately by loading stored prm-files as ASCII data to ensure a modular approach.

Since it is a two dimensional (2D) contact model, the profiles can be defined on the x-plane (profile in y and z coordinates) to their local reference. To define the wheel and rail surface in a global reference system, a rotary-translation subroutine is defined based on the 2D rotational matrix algorithm. The wheel profile is first translated in the lateral direction of wheelset (y). A rotary translation is then performed in the vertical direction (z) and along the roll angle (θ) to achieve the defined contact condition in an iterative process.

$$\begin{Bmatrix} y' \\ z' \end{Bmatrix} = \begin{bmatrix} cos\theta & sin\theta \\ -sin\theta & cos\theta \end{bmatrix} \begin{Bmatrix} y \\ z \end{Bmatrix} + \begin{Bmatrix} y_0 \\ z_0 \end{Bmatrix} \quad (1)$$

For faster execution, it considers only that part of the wheel profile z_w which has a projection of rail profile z_r on a horizontal plane and interpolates using the common abscissa y to calculate distance function $d_z(y)$ between the two profiles as shown in **Figure 1**.

$$d_z(y) = z_w(y) - z_r(y) \quad (2)$$

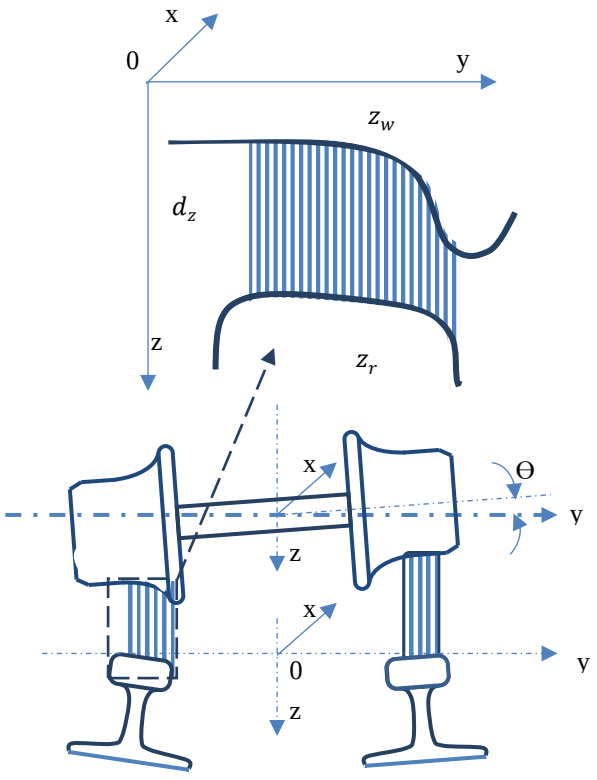

Figure 1 *Interpolation for wheel-rail contact geometry*

2.2. Geometrical module

It is possible to determine the entire area in which there is interpenetration between wheel and rail profiles and the point of contact corresponds to the point in that area that has the maximum penetration value. If the penetration is greater than a specified tolerance value ε, or in the case of no contact, rotary translation is applied to the wheelset to reach the desired value. Relatively more iterative process is required in the case of non-linear profiles (i.e. $y, z, \theta_w \neq 0, \theta_r \neq 0, \psi \neq 0$) as compared to a linear profile (i.e. $y, z, \theta_w = 0, \theta_r = 0, \psi = 0$). Here θ_w is wheel roll angle, θ_r is rail roll angle and ψ is yaw angle.

For at least single contact point detection on both sides of the wheel and rail interaction, the requirements specified in Equation (3) need to be fulfilled.

$$\frac{d(z_w)}{dy} - \frac{d(z_r)}{dy} = \Delta Z < 0 \quad (3)$$
$$length(\Delta Z) \geq 3$$
$$\left(\left| d_{zmin_l} \right| \leq \varepsilon \ and \ \left| d_{zmin_r} \right| \leq \varepsilon \right.$$

where d_{zmin_l} is the interpolated distance between wheel and rail profiles on the left side and d_{zmin_r} is the interpolated distance between wheel and rail profiles on right side. The suggested penetration for a 50 kN wheel load is in the order of 10^{-2} mm approximately, hence a specified tolerance value ε of 10^{-4} mm is used here to meet the accuracy requirements.

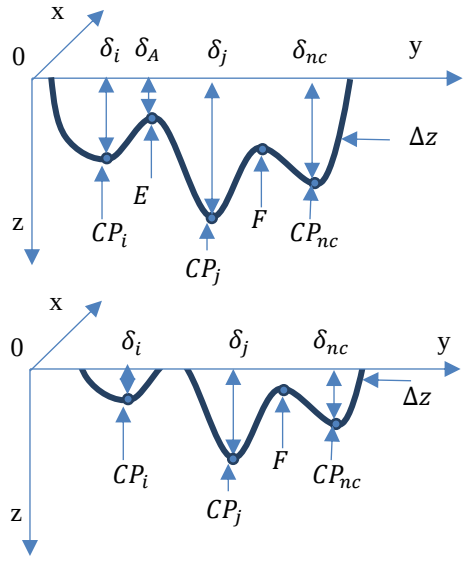

Figure 2 *Penetrated sections after interpolation- collinear contact points (top), non-collinear contact points (bottom)*

To determine if there is multi-point contact, the requirements specified in Equation (3) need to be fulfilled first. If the requirements are satisfied, there exists one or more contact point(s). In **Figure 2**, there are five extreme points which satisfy the requirements, however, E and F are not probable contact points. An additional essential condition for multi-point contact is that each independent contact point must be adequately far from each other and

separated by at least one extreme point (such as E or F in **Figure 2**) as specified in Equation (4).

$$\begin{cases} \delta_i > \delta_A \\ \delta_j > \delta_A \\ y(\delta_i) < y(\delta_A) < y(\delta_j) \end{cases} \quad (4)$$

where δ is the penetration depth of the potential contact point. The number of probable contact point(s) is n_c. If $n_c > 1$, multi-point contact exists and if $n_c = 1$, single point contact occurs.

Figure 3 shows one case of the wheel-rail profiles not in contact. In this case, the vertical distance of the wheel is lower by dz and rotated clockwise by θ_w. The value of dz differs on the right and left sides which is calculated as in Equation (5). The value of θ_w is calculated as in Equation (6) - (9).

$$dz = |d_{min}| + |\varepsilon| \quad (5)$$

$$z = z \pm dz$$

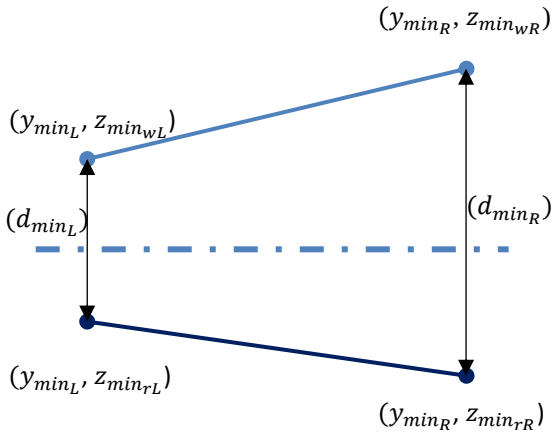

Figure 3 *Potential contact points on both sides of the wheel-rail profiles*

$$m1 = \frac{(z_{min_{wL}} \pm dz) - (z_{min_{wR}} \pm dz)}{y_{min_L} - y_{min_R}} \quad (6)$$

$$m2 = \frac{z_{min_{rL}} - z_{min_{rR}}}{y_{min_L} - y_{min_R}} \quad (7)$$

$$\Delta\theta_w = \tan^{-1}(m1) - \tan^{-1}(m2) \quad (8)$$

$$\theta_w = \theta_w \pm |\Delta\theta_w \quad (9)$$

Here $m1, m2$ are slopes of the lines connecting potential contact points on wheel and rail respectively. $Subscripts_{R,L}$ denote right and left sides of wheelset respectively. $Subscripts_{r,w}$ denote rail/roller and wheelset respectively. The radii of curvature is calculated using the Frenet formula, which requires first and second derivatives of contact points. The contact angle is the arctangent of the first derivative at the point of contact.

2.3. Vertical force calculation

The vertical force acting on the bogie was evaluated based on the simplified inverse modelling presented in the study by Sun et al. [18]. The following simplified expressions were used, assuming constant train acceleration/deceleration and tangent track.

$$F_{z\,Bogie} = \frac{M_c}{2}(g + a) \quad (10)$$

$$F_{z\,ws} = \frac{F_{z\,Bogie}}{2} + \left(\frac{M_b}{2} + M_a\right) * (g + a) \quad (11)$$

where, $F_{z\,Bogie}$ is vertical force acting on bogie, $F_{z\,ws}$ is vertical force acting on each wheelset, M_c is carbody mass, M_b is bogie mass, M_a is axle mass, a is train acceleration, g is acceleration due to gravity.

2.4. Normal task module

The normal problem is solved by using the theory of Hertz [19]. For faster calculation, an approximation function reported by Ayasse and Chollet [20] is implemented in this work. Suppose that each body has two principal rolling radii, one in the y-z plane ($Rx1, Rx2$) and the other in the x-z plane ($Ry1, Ry2$). The separation for this case can be written in terms of coefficients C and D,

$$z(x, y) = Cx^2 + Dy^2 \quad (12)$$

where

$$C = \frac{1}{2}\left(\frac{1}{Rx1} + \frac{1}{Rx2}\right)$$
$$D = \frac{1}{2}\left(\frac{1}{Ry1} + \frac{1}{Ry2}\right)$$

m and n are non-dimensional coefficients tabulated as a function of the ratio $g =$ n/m or the angle θ. When 0 < g <∞, in all the cases, $g =$ b/a = n/m. Hence, the Hertz table can be rewritten as **Table 1**. C/D can be used directly as the input to the table, instead of $cos\theta$ [20]. The coefficient m is determined from the Piecewise Cubic Hermite Interpolating Polynomial (PCHIP) method [21].

$$m = f\left(\frac{C}{D}\right) \quad (13)$$

$$\frac{b}{a} = \frac{n}{m} = \left(\frac{C}{D}\right)^{0.63} \quad (14)$$

$$ab = mn\left(\frac{3}{2}N\frac{1-\nu^2}{E}\frac{1}{C+D}\right)^{\frac{2}{3}} N^{\frac{2}{3}} \quad (15)$$

where N normal load at the point of contact is, E is Young's Modulus and ν is Poisson's Ratio.

Table 1 *Hertz Coefficients for θ=0 to 180 degrees.*

Θ	0	5	10	30	60	90	120	150	170	175	180
C/D	0	0.002	0.01	0.07	0.333	1	3	13.93	130.6	524.6	Inf
m	Inf	11.24	6.61	2.73	1.486	1	0.72	0.493	0.311	0.238	0

2.5. Creepage module

In this module the longitudinal s_x, lateral s_y, and spin φ creepages are calculated.

$$s_{xi} = \frac{\dot{u}}{V_n} + \frac{\dot{\chi} r_0}{V_n} \tag{16}$$

$$s_{yi} = -\psi + \frac{1 + A_0(r_i + \alpha_i a_i)}{V_n} \dot{V} \tag{17}$$

$$\varphi_i = \pm \frac{\alpha_i}{r_0} \tag{18}$$

where $i = 1,2$ for the right wheel and left wheel respectively; $\dot{u}$ is the longitudinal translation velocity; V_n is the nominal velocity in the longitudinal direction; $\dot{\chi}$ is the nominal spin velocity; r_0 is the nominal radius of a wheel for the central position of a wheelset; ψ is the yaw angle of a wheelset; A_0 is a geometrical parameter based on the contact patch dimensions; r_i is the actual rolling radius; α_i is the contact angle; a_i is the actual distance from the centreline of the track to the wheel contact point in the lateral direction; $\dot{V}$ is the velocity of a wheelset in the lateral direction.

2.6. Tangential task module

This module is used to calculate the value of creep force based on the Polach algorithm [22] which is described as:

$$F = \frac{2\mu Q}{\pi}\left(\frac{k_A e}{1 + (k_A e)^2} + \arctan(k_S e)\right), \quad k_S \le k_A \le 1 \tag{19}$$

$$e = \frac{2\pi a^2 b C}{3\mu Q} s \tag{20}$$

$$s = \sqrt{s_x^2 + s_y^2} \tag{21}$$

$$F_x = F\frac{s_x}{s} \tag{22}$$

$$\mu = \mu_0\left((1 - A)e^{-B\lambda} + A\right) \tag{23}$$

where Q is wheel load, C is proportionality coefficient characterising the contact shear stiffness, a and b are the semi-axes of the elliptic contact patch, s_x and s_y are longitudinal and lateral creepages, F_x is the longitudinal creepage force and μ_0, k_A, k_S, A, B are model parameters for different friction conditions which are defined in **Table 2**.

Table 2 *Creep force model parameters*

Parameters	Dry	Wet	Low
μ_0	0.47	0.25	0.1
A	0.44	0.40	0.40
B	0.60	0.20	0.20
k_A	1.0	1.0	0.6
k_S	0.4	0.4	0.2

3. Adhesion coefficient detection algorithm

The algorithm is based on the approach presented in [23]. First, the adhesion-slip curve is created to define the relationship between the adhesion in dry, wet and low conditions with respect to slip. The adhesion coefficient is calculated for the longitudinal slip range from zero to one at step size of 0.001.

$$[c] = \min(abs(\mu_i - \hat{\mu}_c)) \tag{24}$$

where μ_i represents the probable adhesion coefficients in all conditions for a given slip value, $\hat{\mu}_c$ is preliminary estimated adhesion coefficient and c is friction condition represented numerically (i.e., $c = 1, 2, 3$ for dry, wet and low). The schematic of the algorithm is presented in **Figure 4**. The predicted adhesion condition is provided to the real-time contact model to determine the actual adhesion coefficient as shown in **Figure 5**.

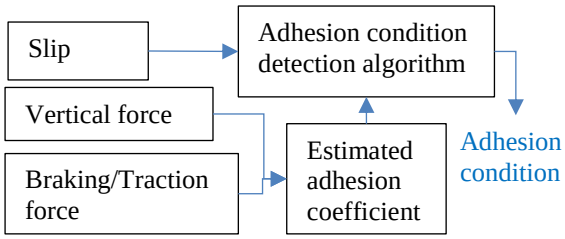

Figure 4 *Schematic diagram of adhesion condition detection algorithm [23].*

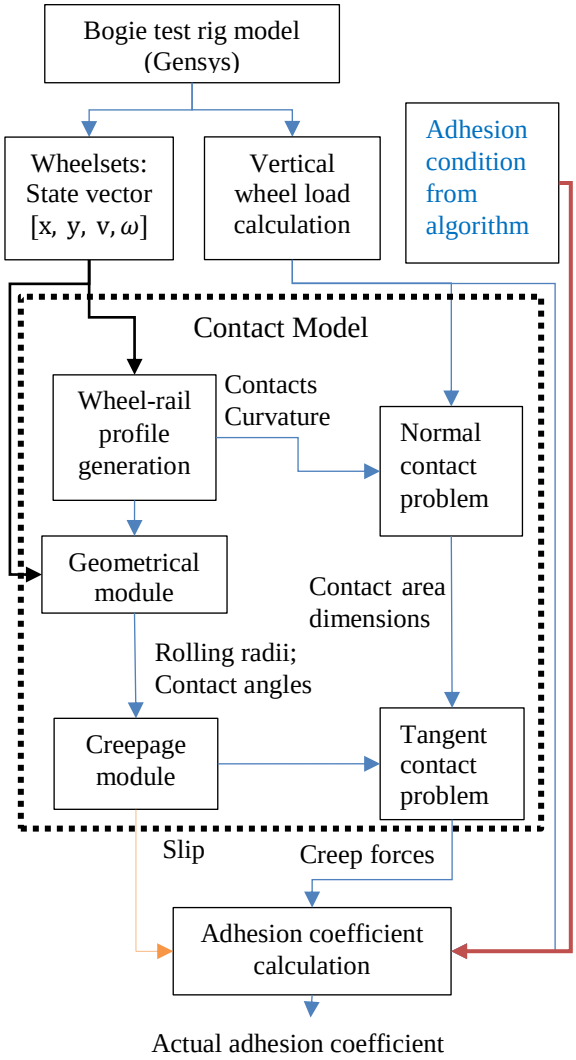

Figure 5 *Adhesion coefficient calculation from contact model*

4. Bogie test rig model in Gensys

For the simulation process, the two axle wagon bogie test rig model as shown in **Figure 6** is designed based on the model provided from the real-time bogie test rig model [24]. It uses the new ENS1002 wheel on new UIC60 roller profiles identical to the profiles used in Matlab contact model. The car body is modelled as a single mass with six degrees of freedom (DOFs) considering longitudinal, roll and pitch DOFs as zero. The bogie frame consists of two side frames and a bolster each with four DOFs. The connection between masses is shown in **Figure 7** with the relevant number of DOFs.

The connection between car body and bolster include 10 couplings;

- two vertical coil springs with longitudinal, lateral and vertical stiffness;
- one anti-roll stiffness element, two lateral bump stops, one lateral damper, two vertical viscous dampers;
- one damping element and one stiffness element working in parallel in the longitudinal direction for the traction rod.

The connection between bolster and side frames includes:

- 14 couplings;
- six damper and six stiffness elements for longitudinal, lateral and vertical directions;
- two yaw dampers.

Each wheelset is modelled as a single mass with six DOFs. The connection between the bogie side frames and each wheelset includes:

- 24 couplings;
- twenty-four stiffness and damping elements for longitudinal, lateral and vertical directions;
- four vertical and four lateral bump stops.

The bogie masses and inertia are shown in **Table 3**.

5. Simulation and results

5.1. Validation of the contact model

Both the Gensys bogie test rig model and the contact model consider the same wheel and roller profiles. In order to validate the geometrical and normal problem, results provided by Gensys [25] are compared. Results can be seen for variation in the contact patch semi-axes ratio due to lateral wheelset displacement in **Figure 8**. A significant discrepancy between results is seen in the area of contact switching from wheel tread to the flange and in the flange region because the yaw angle is not taken into account in the contact model. To validate the tangent module of the contact model, the Polach creep force model [22] is used in both models. The state vectors from the Gensys model were used in the contact model. The comparisons of the results from the Gensys bogie model against the real-time contact model are presented in **Figure 9**.

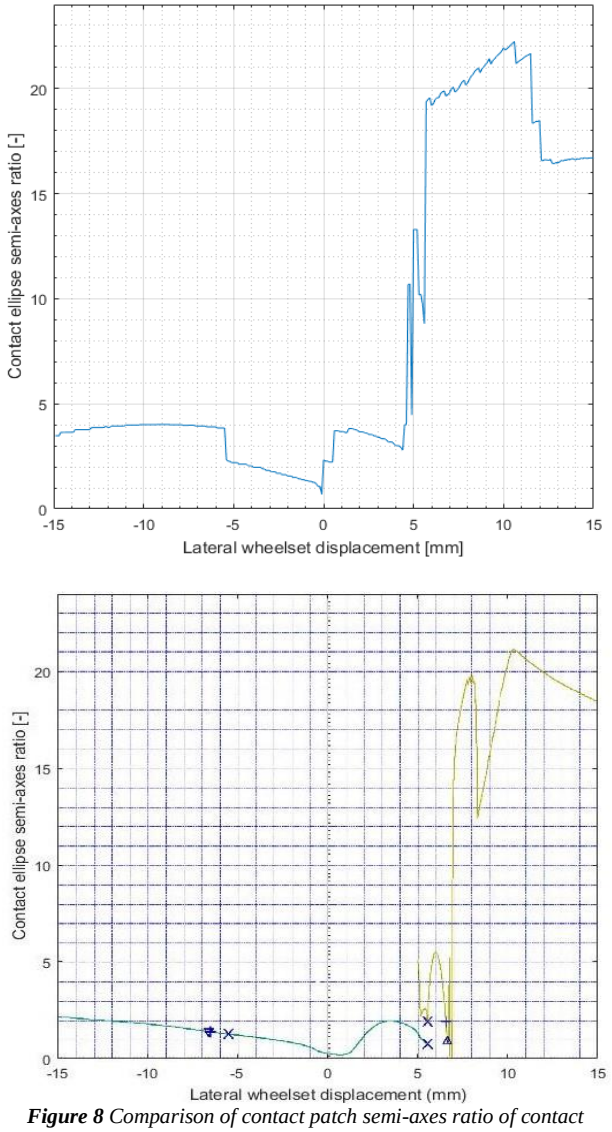

Figure 8 *Comparison of contact patch semi-axes ratio of contact model (top) and Gensys model (bottom) from* [25]

5.2. Cases

Two simulation cases are performed in this study. The first case is required to validate the real-time contact model and friction condition detection algorithm. In this case, the longitudinal slip value has been adjusted for each friction condition, namely 'dry', 'wet' and 'low', by means of a simple traction controller. Each condition remains for 5 seconds in an order of dry-low-wet. The bogie model was run on the roller rig under varying friction conditions with a constant speed of 20km/h.

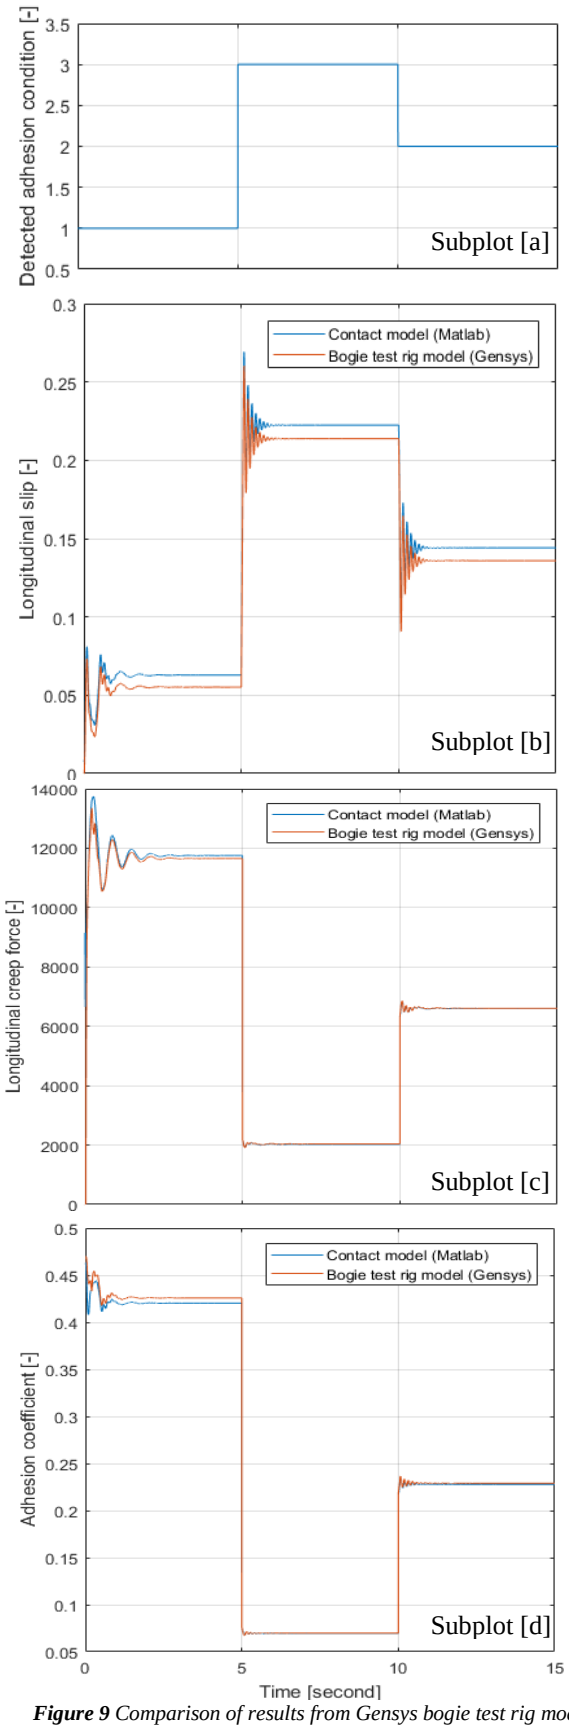

Figure 9 *Comparison of results from Gensys bogie test rig model (orange line) and real-time wheel-rail contact model (blue line)*

The second case is required to validate the friction condition detection in a braking mode. In this case, the friction condition is 'wet' for the first 30 seconds, 'low' for the next 30 seconds and then remains 'dry' until the test rig stops. The initial braking speed is 90km/h.

The result of the first case simulation is presented in **Figure 9**. The adhesion condition detected from the algorithm is displayed in subplot [a]. The longitudinal creepage obtained by the contact model is slightly higher as compared to the Gensys bogie test rig model which can be seen in subplot [b]. The longitudinal creep force is marginally higher and adhesion coefficient is slightly lower in the contact model in a dry condition which can be seen in subplots [c] and [d] respectively. The algorithm is able to handle the change in slip under variations of friction condition, which shows that the algorithm is robust.

The results for the second case simulation are presented in **Figure 10**. The speed of the roller and wheel are presented in subplot [a]. The slope gradient between 30 to 60 seconds is the lowest among all, which indicates the 'low' friction condition. The estimated slip value has highest fluctuation when the friction condition is changed which is noticeable in subplot [b].

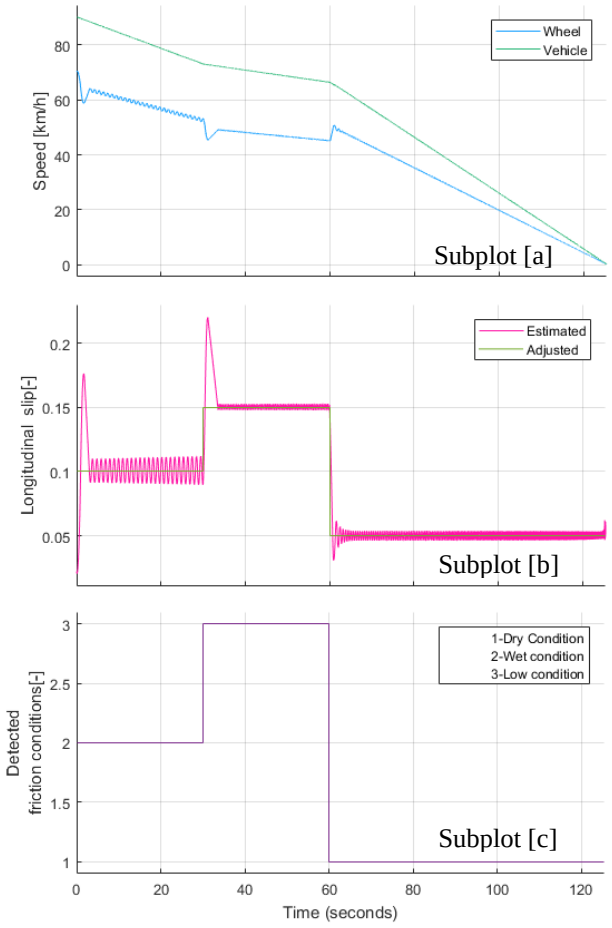

Figure 10 *Results for friction condition detection in braking mode*

Based on these simulation results, the contact model gives realistic results during numerical investigations. Moreover, the adhesion estimation algorithm provides the anticipated result in both traction and braking conditions which indicates the robustness of the algorithm.

6. Conclusion

At this stage, the algorithm uses a simplified adhesion estimation method which will be further advanced by using dedicated input observers. In the next stage, the contact model and the adhesion estimation algorithm will be experimentally validated using test rig data. In this study, vertical force and braking/traction force are used to determine the preliminary results. To achieve more realistic initial results, an approach such as rolling noise analysis [26] could be used in combination.

Abstract: Model validations are essential for the development of simulation programs. Several wheel/rail (W/R) related benchmarking exercises have been conducted since 1999 to assess the suitability of various software packages for simulation of vehicle and track dynamics. Most of these benchmark exercises were limited to comparisons among simulation packages, and could not conclude calculations were accurate because of a need for experimental data. This paper presents the validation of NUCARS®[1] W/R contact model by using measurement data from TTCI's Rolling Contact Fatigue Simulator (RCFS), a full-scale test rig for W/R interaction mechanism study. A discussion of observed creep force transition phenomena is also included.

Keywords: Wheel-rail contact model; model validation; contact geometry; creep force; transient to steady state rolling; test.

1. Introduction

Transportation Technology Center, Inc., in Pueblo, CO, has acquired a Rolling Contact Fatigue Simulator for the investigation of the root causes of rolling contact fatigue (RCF) at the W/R interface under various conditions. It comprises a full-scale railway wheelset rolling on a reciprocating track under controlled vertical loading, as well as controlled lateral displacements (shifts) and angles-of-attack (AOA) relative to the track. The wheelset has one degree of freedom (DOF)—spin, and the table has six DOFs. The attitude control systems of the wheelset on the track and the force measurement systems of the RCFS provide acceptable data to validate W/R contact forces and RCF models for differing W/R forces, contact patch geometries and locations, third body conditions, wear rates and life cycles.

The research program is co-funded by the Strategic Research Initiatives (SRI) program of the Association of American Railroads (AAR) as well as the Office of Research and Development of the Federal Railroad Administration (FRA). Thus far, the research program has focused on the effect of wheel and rail profiles and contact geometry on W/R contact forces and RCF. This paper presents the comparison of measured and predicted W/R contact geometry and forces under varying contact conditions.

2. Full-scale W/R contact tests

A base-case test using AAR1B wheel and AREMA 136RE rail profile combinations was conducted in September 2017. Tests were performed on the RCFS using a full-size instrumented wheelset (IWS) on a full-size pair of rails under 36-ton axle load and dry surface conditions. The load environment and contact conditions were controlled by adjusting the RCFS table's position and orientation. Three different angles-of-attack were applied: 0, 5, and 10 mrad. The lateral position of the wheelset was changed in increments of 0.05-inch from 0 to 0.7-inch whereupon wheel flange contact begins. After flange contact, the table was displaced an additional 0.1-0.2-inch to test flange-rise contact conditions.

Static tests were conducted with vertical loads to generate W/R contact patch imprints. Dynamic tests were conducted to measure W/R contact forces. The maximum table reciprocating speed is approximately 60 inch/s or 3.5 mph. The following data sets were recorded during testing:

- Wheel and rail profiles, surface hardness and roughness before and after each test.
- Wheel and rail contact patch imprints with 0.1-inch lateral shift increment.
- Longitudinal, lateral and vertical wheel and rail contact forces.
- Table displacements and rotation.
- Wheelset angular position.

3. Modeling and test results comparison

Multibody dynamic simulation programs are used in the railroad industry to help system design, optimization and other investigations. Several W/R-related benchmarking exercises [1~4] have been conducted since 1999 to allow assessment of the suitability of the various software packages for simulation of vehicle and track dynamics. Most of these benchmark exercises were limited to

[1] NUCARS® is a registered trademark of TTCI

comparisons among participated simulation packages, and could not conclude that calculations were accurate because of a need for experimental data.

Benchmarking modelling results against on-track measurement were used for model development [5] and validation [4]. However, on-track measurement data may not be used directly to validate model because not all dynamic movements and parameters in the field can be measured easily. Most laboratory contact/friction experimental devices, such as twin disks and roller rigs, are scaled in dimensions and can only control longitudinal creepages, with little control on lateral and spin creepages. The advantages of the RCFS at TTCI include use of full-scale wheels and rails and also accurate control of the creepages between wheel and rail.

The NUCARS® vehicle and track multibody dynamic simulation program was used to simulate the RCFS dynamic movements and W/R interactions. The NUCARS W/R penetration contact model [5] was used to simulate the W/R contact geometry and forces; the NUCARS double rail model [6] was used to simulate the RCFS table movements including prescribed rail lateral, vertical displacements and rail rotations.

3.1. Static W/R contact test

The wheel load for static contact imprint tests was about 36 kips on both wheels; the vertical load was applied to wheel statically. The rail surfaces were painted before testing. For each test, the wheel was spun about 5 degrees and the rails were shifted longitudinally with the table to allow contact imprints to be distributed discretely along the surfaces.

The test wheelset used for the base case was an instrumented wheelset (IWS, ID No. 59). The IWS was re-trued and calibrated in 2015. The purpose of using IWS for the base case tests was to

- Measure the W/R contact forces accurately;
- Benchmark the RCFS force measurement accuracy during tests.

Figures 1 and 2 show the W/R contact regions on the low rails; the imprint shapes from 0 mrad AOA tests were similar to that with 10 mrad AOA, the effect of AOA on low rail contact geometry was negligible.

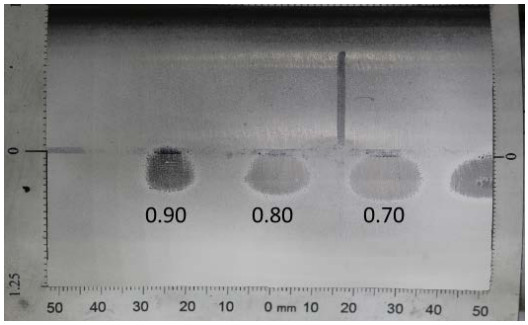

Figure 1 *Contact imprints on low rail, AOA: 0 mrad lateral shift: 0.7-0.9 inch*

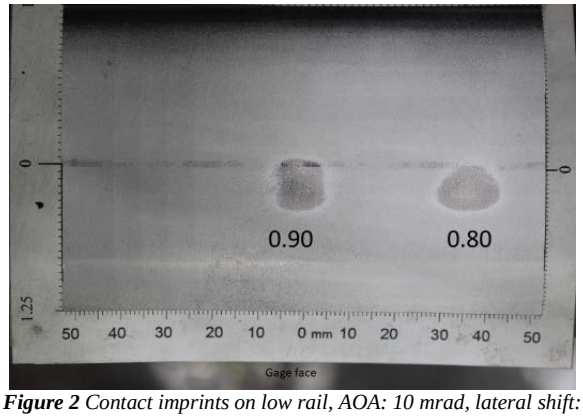

Figure 2 *Contact imprints on low rail, AOA: 10 mrad, lateral shift: 0.8-0.9 inch*

Imprints in Figures 3- 5 show the AOA has significant effect on high rail W/R contact. The wheel began flange contact on the rail at 0.70-inch lateral displacment at 0 mrad AOA, while the flange contact occured at 0.65-inch lateral displacment at 10 mrad AOA because of the relative position changes between wheel and rail caused by AOA. Not only did flange contact occur at less lateral shift for tests with 10 mrad AOA, but also the contact position on the flange was shifted longitudinally about 15mm along the rail.

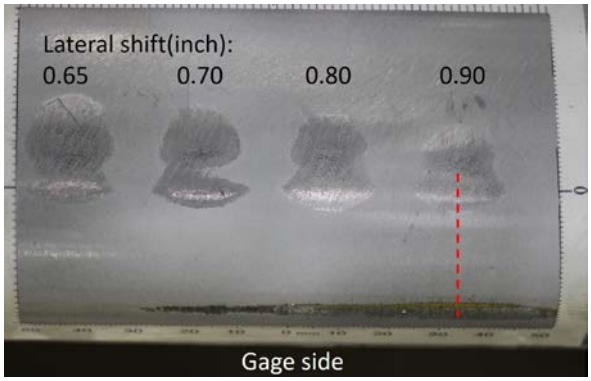

Figure 3 *Contact imprints on high rail, AOA: 0 mrad, lateral shift: 0.65-0.9 inch, red dotted line shows 0 mrad*

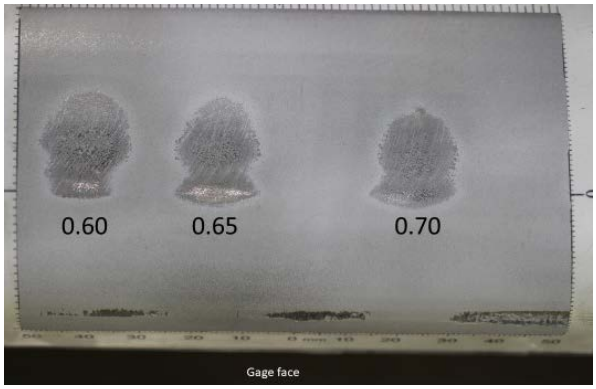

Figure 4 *Contact imprints on high rail, AOA: 10 mrad lateral shift: 0.6-0.7 inch*

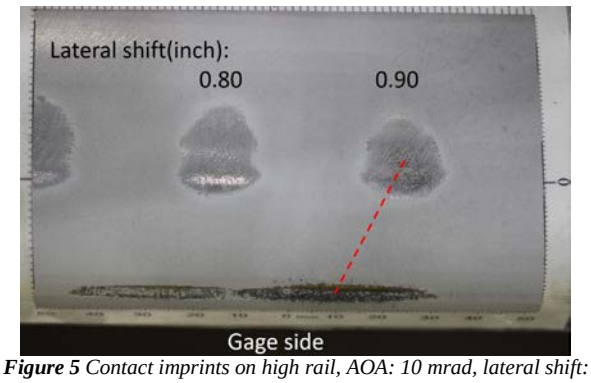

Figure 5 *Contact imprints on high rail, AOA: 10 mrad, lateral shift: 0.8-0.9 inch red dotted line shows 10 mrad*

To benchmark the W/R contact geometry in a manner consistent with the imprints that were observed, a series of quasi-static W/R contact simulations were conducted by using NUCARS.® The measured W/R profiles were used in the simulation, the axle running speed was 5 km/h, and the W/R friction coefficient used in the simulation was 1.0E-5 to eliminate the creep force effect for comparing with static imprints. Figures 6 and 7 show the simulated contact patches on two rails for the test with 0.9-inch lateral shift (toward to high rail) and 10 mrad AOA generally match the measured imprints (Figures 5 and 2) in terms of shapes, sizes and the longitudinal shift distance on flange.

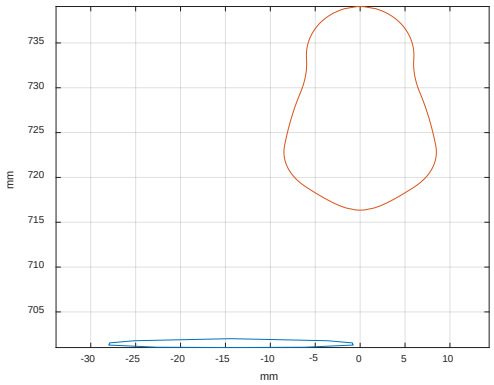

Figure 6 *NUCARS® predicted contact patches on high rail, AOA: 10 mrad, lateral shift: 0.9 inch*

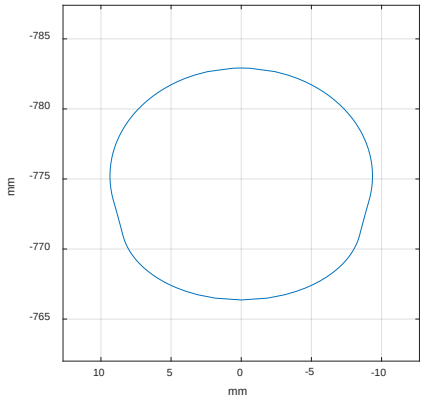

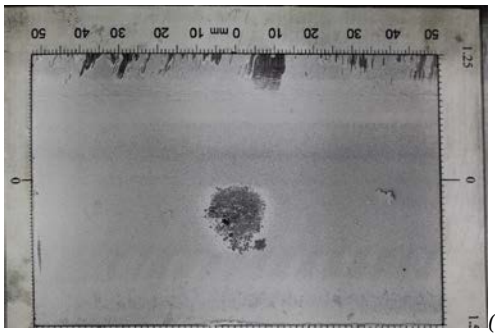

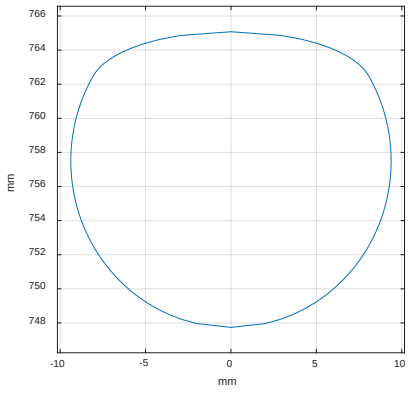

Figure 7 *NUCARS Predicted contact patches on low rail, AOA: 10 mrad, lateral shift: 0.9 inch*

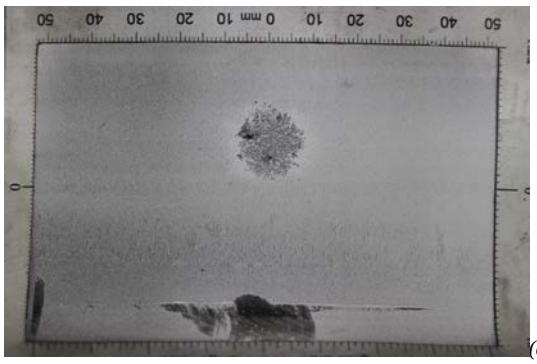
Further comparisons were performed by using measurements from a RCF test in which the wheel and rail wore into conformal contact after 60,000 cycles. Figures 8- 13 show the comparison of contact patches at the beginning of the test, after 12.5k and 50k test cycles.



The contact band became wider as the wheel and rail became more coformal. NUCARS® simulation generally matches the measured imprints for conformal contact situations. However, the imprints show mutiple pressure centers seperated during the test process, while the simulated contact patches always appeared to merge. The discrepency might be explained by local hardening of the contact surfaces, which was neglected in the simulation.

3.2. Quasi static W/R contact tests

The RCFS rails are attached to a table which moves in the longitudinal direction. Figure 14 shows the table movements with a sine wave shape. The table's longitudinal velocity is approximately constant (quasi static) within a 10-inch range near the middle of the track; the velocity ramped up (accelerating) and down (deaccelerating) beyond this range, where the table was in transient movements.

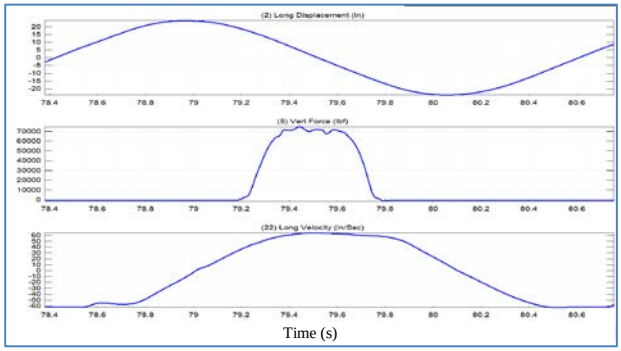

Figure 14 *RCFS table longitudinal movements and vertical loading*

Figure 15 shows the measured quasi static W/R forces in longitudinal, lateral and vertical directions at different W/R lateral displacement and AOA conditions.

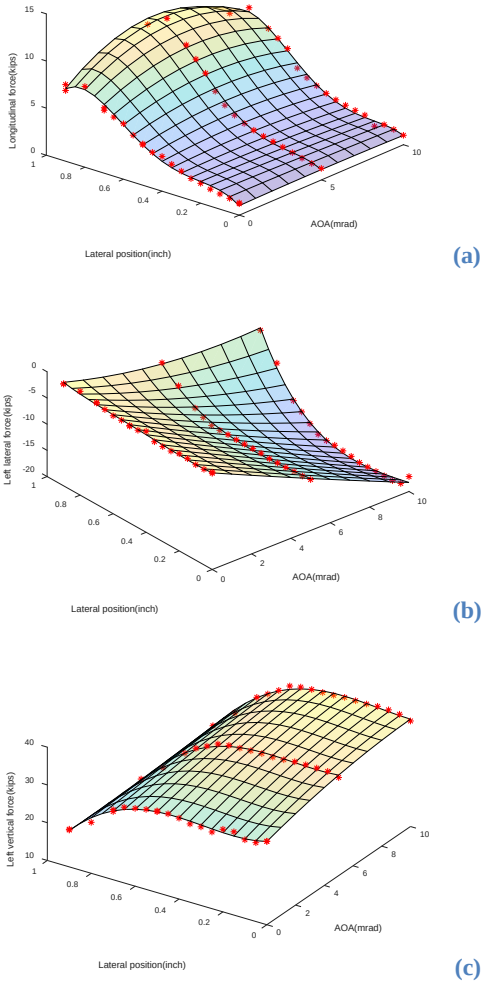

Figure 15 *Measured wheel forces (a) longitudinal; (b) lateral; (c) vertical*

Figures 16 and 17 compare the NUCARS simulated forces along with measured forces from RCFS testing. The modelling results were generally consistent with test results up until flange contact. The discrepancy at flange contact could be caused by the rail flexibility which was not modelled. In that case, it is possible that the NUCARS® flexible track model could be used to improve the simulation, but the parameters for simulating a 4-foot track with special boundary conditions needs to be investigated further.

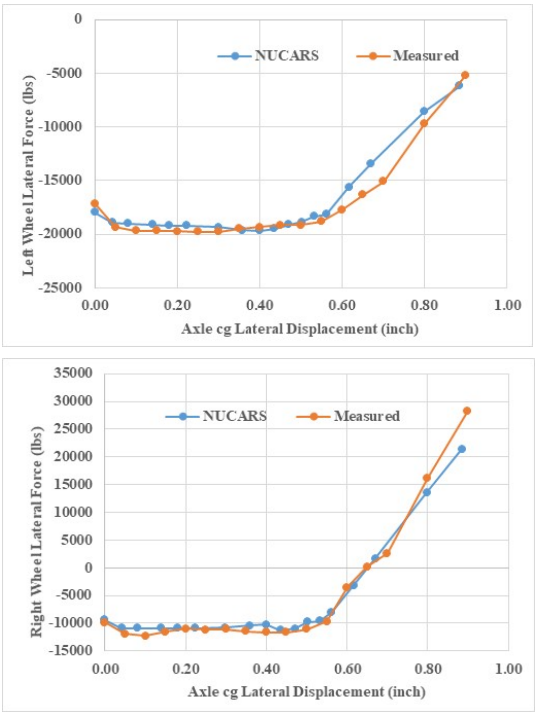

Figure 16 *Measured and NUCARS® predicted wheel lateral forces*

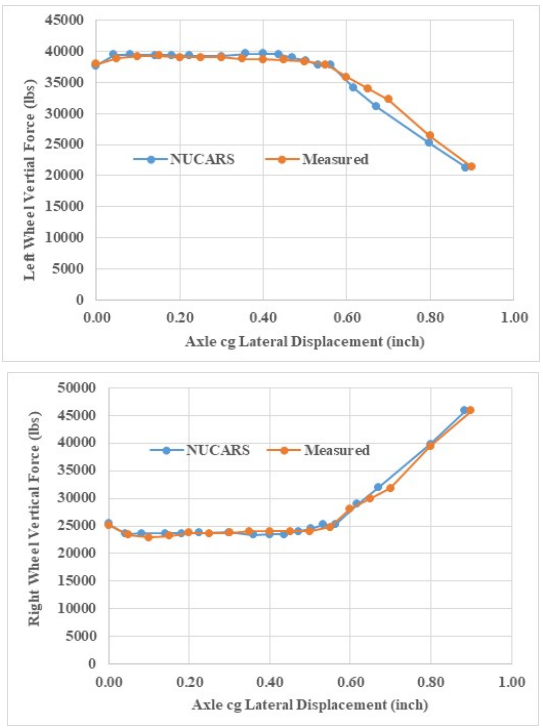

Figure 17 *Measured and NUCARS® predicted wheel vertical forces*

3.3. Transient W/R contact tests

Figure 18 compares the calculated and measured W/R contact forces during the whole loading cycle period, including table acceleration and deceleration. The comparisons show that the calculated lateral forces using Kalker's creep force look-up table [7] match the forces measured by the Instrumented Wheelset (IWS) near 88.5 seconds when the axle was in quasi static movement. However, the amplitude and gradient of the calculated lateral force during transient movements were significantly different from that of the measured forces.

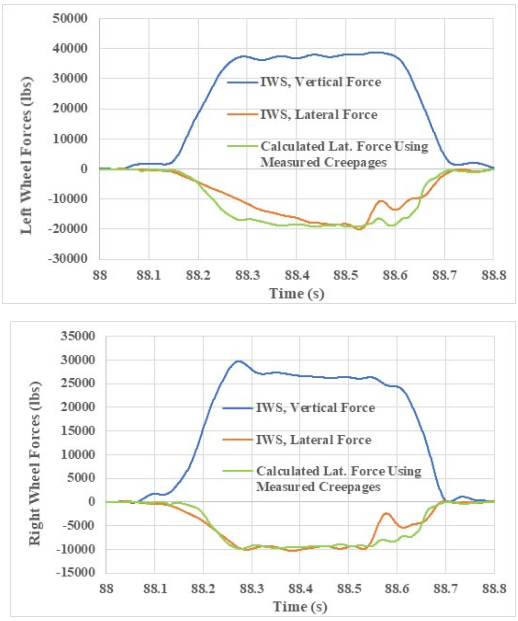

Figure 18 *Measured and calculated wheel forces (based on Kalker's contact creep force theory), low rail (a), high rail (b)*

It can be understood that Kalker's creep force law (look-up table) [7] only can be used for steady state (quasi-static) contact conditions. The difference between measured and calculated lateral forces could be caused by the differences between transient and steady-state dynamic movement. An interesting phenomenon observed was that the lateral force on the left rail (low rail) kept increasing when the vertical load, axle and rail/table movements were almost constant (quasi static) from 88.4 to 88.5 seconds, as Figure 18 shows. The slope of the measured lateral force (from instrumented rail) was steep at lower AOAs, but decreased with the increase of AOAs, and turned to flat at 15mrad (0.85 degree) AOA, as Figure 19 shows.

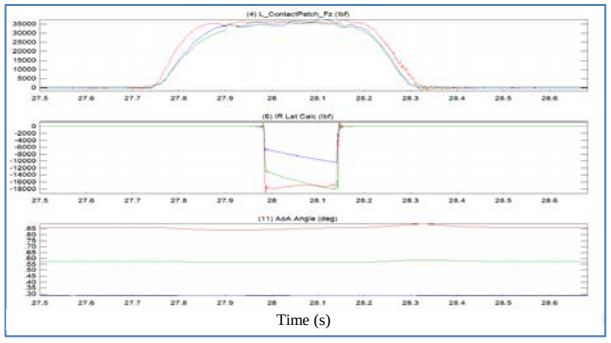

Figure 19 *Effect of AOA on Wheel Lateral Forces*

To investigate the rail flexibility effects, four rigid brackets were installed on the low rail field side. Figure 20 shows that rail flexibility does affect the lateral force magnitude (about 10 percent), but not the slope; the difference of rail head lateral displacement is less than 0.1mm, as measured by laser transducer.

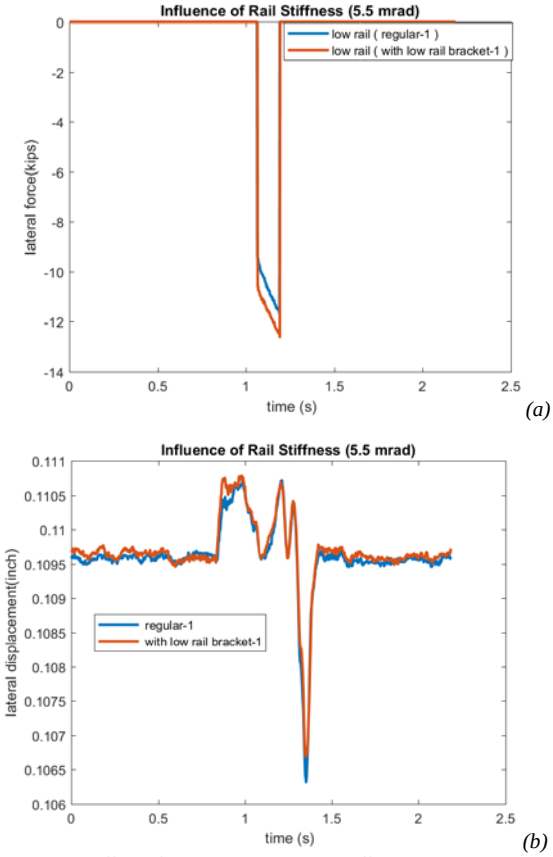

Figure 20 *Effect of rail lateral and roll stiffness on wheel lateral forces (a) and displacements (b)*

The lateral force on the low rail came from the lateral creep force and the normal force on the contact patch. The normal force projection on lateral direction was almost constant because the contact angle on the low rail kept about 3 degrees regardless of AOAs. If the W/R movement was in quasi-static condition, the lateral force variation (slope) may be caused by the lateral creep force itself.

A series of tests with different combinations of lateral shift position (to control longitudinal creepages) and AOA (to control lateral creepages), as Table 1 shows, was conducted to prove this assumption.

Table 1 *Test cases and conditions*

Cases	*Lateral Position (inch)*	*AOA (mrad)*	*Contact Condition*
1	*0*	*5*	*dry*
5	*0*	*15*	*dry*
7	*0.2*	*10*	*dry*
2	*0*	*5*	*lube*
12	*0*	*15*	*lube*
14	*0.2*	*10*	*lube*

Figure 21 shows the two loading cycles lateral forces and the ratios of the total tangential creep force ($T = \sqrt{T_x^2 + T_y^2}$) to normal force from three different test cases.

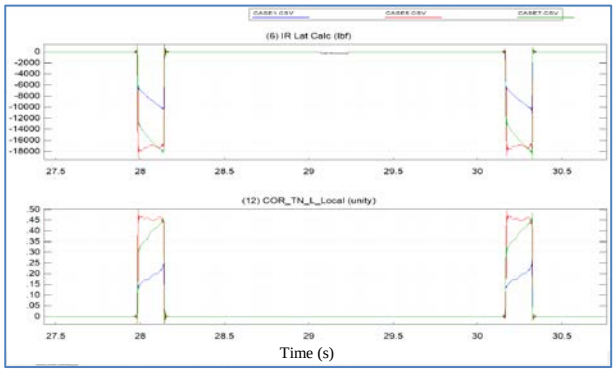

Figure 21 *Effect of AOA on wheel lateral forces and T/N ratios*

Figure 21 shows the lateral creep force was building up during the transition from transient to steady state condition, until the total tangential creep force reached saturation. These tests were performed under dry contact conditions and the calculated W/R friction coefficient was about 0.45.

The same tests under dry conditions were conducted again except that lubricants were applied between the wheel and the low rail. Figures 22-24 show the lateral force shapes for all test cases became flat after lubricant was applied; the difference of measured wheel and rail movements and vertical loads between dry and lubricated conditions were small compared to the change of the lateral force magnitude and slope. The approximate constant lateral forces under lubricated conditions may indicate that creep forces reached saturation easily without building up transition under a low friction coefficient.'

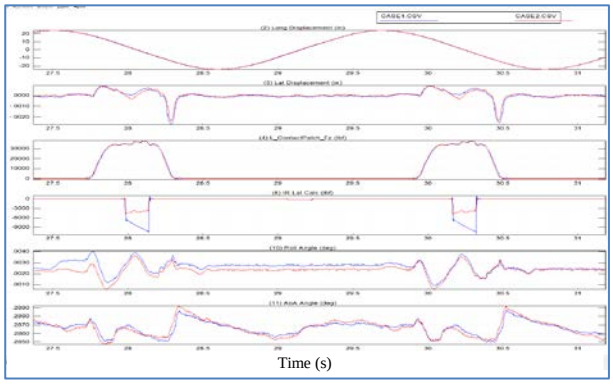

Figure 22 *Effect of lubrication on wheel lateral forces, case 1, 2 (AOA: 5mrad)*

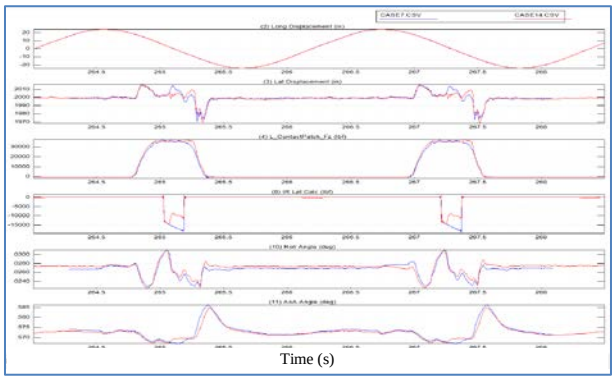

Figure 23 *Effect of lubrication on wheel lateral forces, case 7, 14 (AOA: 10mrad)*

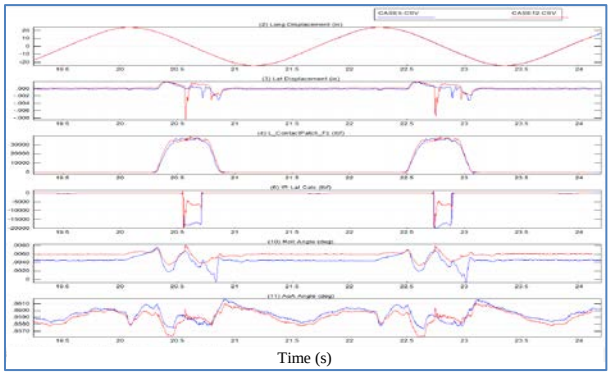

Figure 24 *Effect of lubrication on wheel lateral forces, case 5, 12 (AOA: 15mrad)*

According to Kalker's CONTACT simulation results [8], the transition from transient to steady state rolling was quick; it took about one contact patch diameter distance from Cattaneo shift to steady state rolling (Transition from Cattaneo to Carter), and 2 contact patch diameter distance from Spence compression to steady state rolling, much shorter than the distance measured from IWS and instrumented rail on RCFS. It should be noted that Kalker's simulation cases didn't include lateral and spin creepages which may increase the transition time from transient to steady state rolling, especially under dry conditions. The creep force transition phenomena needs to be investigated further.

4. Conclusions

The predicted W/R forces and contact patches in static and quasi-static movements from NUCARS® modeling generally were consistent with those measured from RCFS testing. However, comparisons showed discrepancies between measured and calculated lateral forces during the transition from transient to steady state rolling. The lateral and spin creepages may increase the transition time. The creep force transition phenomena needs to be investigated further.

The full-scale RCFS provides an ideal experiment platform for W/R contact mechanics studies.

Acknowledgments

The research described in this paper was funded jointly by the Federal Railroad Administration Research and

Development program, and the Association of American Railroads Strategic Research Initiatives program.

The test rails were provided by EVRAZ North America, Pueblo, CO, USA.

Abstract:
In this work a methodology is presented to assess running gears with respect to wheel and rail rolling contact fatigue (RCF). This assessment is based on wheel/rail contact data for different wheel profile wear states taken from a wheel profile prediction methodology. The approach allows e.g. the assessment of rail RCF in different curve radii in a cumulative way (sum of damage over lifetime of wheel profiles). Furthermore, RCF assessments can be done at different wear states of the wheel profiles to get insight how the contribution to wheel and rail RCF varies depending on the evolution of the wheel profiles. The presented methodology is exemplary applied to two bogie types, the UIC-Y25 standard bogie and the so called FR8RAIL bogie with a mechanical wheelset steering device. The presented methodology is a helpful tool e.g. to optimize vehicles already in an early stage of the development process.

Keywords: Rolling contact fatigue; wear; rail; wheel; running gear; bogie; freight wagon.

1. Introduction

Rolling Contact Fatigue (RCF) driven damage patterns developing in the wheel/rail interface cause high maintenance costs [1], [2]. It is well known that the severity of RCF depends on the following factors: the infrastructure (track curvature, rail profiles, track irregularities, rail material, etc.), operational conditions (speed profile, cant deficiency in curves, etc.) and adhesion conditions in the contact between wheels and rails (climate/environmental conditions, lubrication, etc.). Furthermore, the type of vehicle plays an important role. In this context the traction and braking systems are relevant subsystems as well as the curving friendliness of the used running gears. The latter one is strongly influenced by the combination of the wheel base, the longitudinal guiding stiffness of the wheelsets in the primary suspension and the wheel profiles. This work is focussing on a stochastic simulation-based assessment methodology for running gears with respect to their curving friendliness in the sense of wheel and rail RCF.
Exemplary, two vehicles are analysed and their response to long-term RCF evolution is compared. The first vehicle is a freight wagon with UIC-Y25 standard bogie which is used as a reference vehicle, and the second one is a modified UIC-Y25 bogie vehicle with double Lenoir links and braced side-frames. The latter bogie design has been developed by TATRAVAGONKA a.s. Poprad, hereafter it is called FR8RAIL bogie. To further study the effects of various design parameters in long-term evolution of wheel and rail damages, a parameter study is carried out on longitudinal clearance between the spring-holder and axle-box and the bogie wheel-base. The two mentioned parameters are believed to have a great significance on dynamics behaviour of the bogie regarding curving performance and stability.
Before describing the damage calculation methodologies, a section on vehicle parameters and modelling issues is presented in this study. Moreover, two distinct methodologies are used to predict cracks on wheels and rails respectively. However, both methodologies are based on the same multi-body-system (MBS) simulation results. Since both methodologies consider long term evolution of RCF cracks, it is important to consider the evolution of wheel and rail profiles due to wear. For the rails, five pairs of measured profiles are used in nine track sections as a function of curve radii in which the tightest curves have the most worn rail profiles and the straight line has the nominal profiles cf. Section 4. However, for the wheels, an iterative methodology based on Archard formula is used cf. Section 3.

2. Vehicles and variations

The Y25 running gear (UIC bogie) is a widely used running gear in Europe. Over the years, several variants of the standard model have been studied to improve track friendliness, curving performance, etc, mainly by design optimisation of the primary suspension, see [3] and [4]. Carrying the work forward on similar lines in the Shift2Rail project, FR8RAIL [5], a new bogie design developed by TATRAVAGONKA a.s. Poprad is presented, modelled in this work (FR8RAIL bogie) and compared with the standard UIC-Y25 variant.

2.1. Construction

The UIC-Y25 running gear consists of two steel long-beams on each side welded together to a bolster beam in the middle. The loading aspect of the running gear calls for load-dependent primary suspension characteristics. This is achieved using two coils of helical springs and friction damping using a Lenoir-link as seen in Figure 1.

The inner springs come into contact when the vehicle is loaded beyond 4 t of axle load. The load-dependent friction damping is provided by the normal force, generated by the Lenoir-link because of its inclination, acting on friction surfaces on both sides of the axle box.

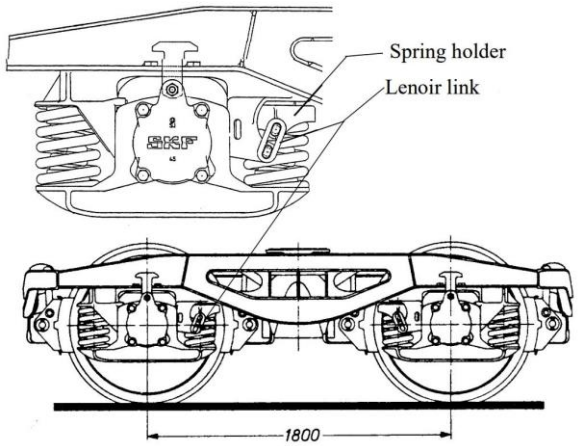

Figure 1: UIC-Y25 bogie [6].

One of the key disadvantages of the standard UIC-Y25 running gear however, is its stiff horizontal primary suspension, which leads to high damage to wheel and rail while curving. The FR8RAIL wagon incorporates some additional components and variations in key suspension parameters with the intention to improve the curving performance while not compromising the stability of the running gear at higher speeds. Table 1 lists the values of some important parameters of the UIC-Y25 running gear and the FR8RAIL bogie for comparison. Note that the studied parameters in the FR8RAIL bogie design are show in red. Some of the key differences are:

- Presence of double Lenoir-links in FR8RAIL design (see Figure 2),
- Clearance in primary suspension in the longitudinal direction,
- Presence of cross-bracing links and
- Side-bearer clearance.

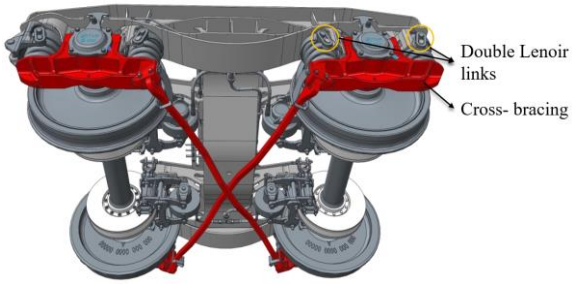

Figure 2: FR8RAIL bogie.

2.2. Modelling

A lot has been done in the development of a three-dimensional MBS simulation model for the standard UIC-Y25 running gear as seen in [7]-[10]. Jendel's model [7], validated according to the Manchester Benchmarks [10] has been used in the current work. The FR8RAIL bogie is modelled by modifying the primary and secondary suspensions in this model.

A comprehensive review of the running gear and modelling of the suspension components can be seen in [6] and [11] respectively. The modelling methodology of the key variations listed out in the previous section follow the same and is described in brief in this subsection.

Table 1: Key design parameters and their variations for the running gear(s).

Parameter	UIC-Y25	FR8RAIL
Bogie pivot distance [m]	7.38	7.38
Wheel base [mm]	1800	1800, 2000
Wheel radius [mm]	460	460
Primary suspension, clearance in longitudinal direction (Δx_{max}) [mm]	4	8, 12
Side-bearer spring clearance in longitudinal direction [mm]	1	-
Axle-load [t]	22.5, 30.0	22.5, 30.0
Cross bracing element mass [kg]	-	35

Primary suspension:

Lenoir links (refer Figure 1) connect the outer springs at the spring holder with the bogie frame such that downward movement of the bogie-frame pulls the spring holder down, resulting in a transfer of normal force. The normal force acting on the friction surface provides the damping. The Lenoir link in addition to providing frictional damping also contributes to the stiffness coupled in the vertical (Z) and longitudinal (X) directions due to its orientation. Jendel calculates the stiffness matrix as:

$$\begin{pmatrix} F_x \\ F_z \end{pmatrix} = \begin{bmatrix} k_z tan^2\alpha & k_z tan\alpha \\ k_z tan\alpha & k_z \end{bmatrix} \begin{pmatrix} \Delta x \\ \Delta z \end{pmatrix} \qquad (1)$$

with k_z referring to the stiffness of the outer spring coil, α to the inclination of the Lenoir link in the x-z plane and Δx and Δz to relative displacement of the coil in longitudinal and vertical directions respectively. With the introduction of double Lenoir links, the maximum allowable clearance in the longitudinal direction is doubled as is the case for the FR8RAIL bogie (refer Table 1). Beyond a maximum value (Δx_{max}), a metallic stop is encountered, modelled by a force element with high stiffness. One can infer here that allowing more clearance in the longitudinal direction softens the primary suspension.

The *cross-bracing* links are modelled as high stiffness elements connecting the wheels diagonally as seen in Figure 2. A clearance at the connecting points of maximum 1 mm at the wheels were provided as well.

Secondary suspension:

The secondary suspension consists of a centre-plate in the middle with two side bearers on either side of the bogie. The centre-plate consists of a spherical pivot on the bogie frame upon which the carbody rests.

Side-bearers consist of horizontal friction plates mounted on twin vertical coil springs. In the standard UIC-Y25 model, the vertical springs also shear longitudinally up to 1 mm in either direction before encountering a metallic stop, modelled with a high stiffness element. This clearance provides for the softening of the secondary suspension in the longitudinal direction. For the FR8RAIL bogie design, this clearance is not included and modelled with a very small value (10-5 mm) to avoid computational issues. The simulation model was constructed using the modelling principles described

using the MBS software, GENSYS [12].

3. RCF assessment methodology

The proposed RCF assessment methodology is based on a wheel profile prediction methodology which is able to account for the stochastic nature of railway operation. Wheel/rail contact data for different wheel profile wear states are used to assess the development of wheel and rail RCF. This is important especially if someone wants to assess different running gear concepts with respect to their impact on wheel and rail RCF because wheels change their profiles due to wear dependent on the investigated running gear technology itself. Thus, using measured wheel profiles from other vehicles is not sufficient in this context.

To consider wear on wheel profiles, a long-term wear calculation methodology is used. The methodology is based on Archard wear calculation theory [13]. According to Archard, the depth of the material removal due to wear (W) is proportional to quotient of pressure (p) and the hardness (H) of the softer material multiplied by sliding velocity S.

$$W = k' \cdot \left(\frac{p}{H}\right) \cdot S \qquad (2)$$

The proportionality factor (k') depends on the governing wear mechanisms. One way to evaluate k' is to use Olofsson and Telliskivi's laboratory test results where, the wear coefficients depends on sliding velocity and contact pressure cf. Figure 3.

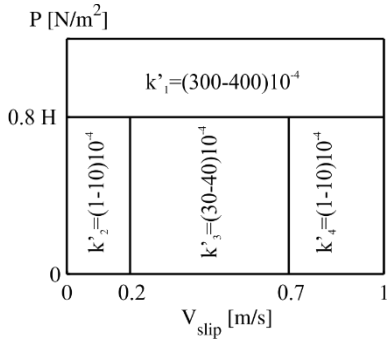

Figure 3, Wear map for wheel and rail steel; H is the hardness of the material.

To follow the methodology, first, a set of dynamic time-domain simulations representing the train, line geometry and the operational conditions should be prepared. The simulation outputs used for the wear calculations include creepages, creep forces, normal force, moment, contact size and locations on wheel and rail and wheel/rail friction level. Usually, in MBS software, Hertz theory and FASTSIM algorithm are used to solve the normal and tangential contact problems respectively. It is shown that to estimate the forces, FASTSIM provides relatively acceptable amount of error; however, this may have considerable defects in estimating the level of shear stresses in the contact patch (more than 33% at the point of contact and close to infinity at the contact edges) [14]. This is more pronounced in the cases with high spin values. To overcome the issue by using the MBS outputs, the wear code calculates the shear stresses by FaStrip algorithm which is shown to be precise and fast [15]. The methodology also considers the contribution of the elastic strain in the sliding velocity assessment as it is previously done by Enblom [16]. After calculating wear in each contact patch at each wheel revolution, the wear depths will be summed up along the simulated track line (cf. Figure 4) and the accumulated wear depth will be applied on the wheel profiles to be used for the next iteration of wear calculation process which is called a *wear-step*.

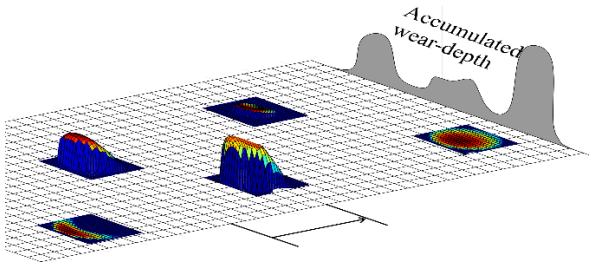

Figure 4, Summation of the wear per strip at each wheel revolution to give total wear depth.

The wear calculation methodology is summarised in Figure 5. As mentioned at the beginning of this section, wheel/rail contact data for different wheel wear states are used to assess RCF on wheels and rails in a cumulative way.

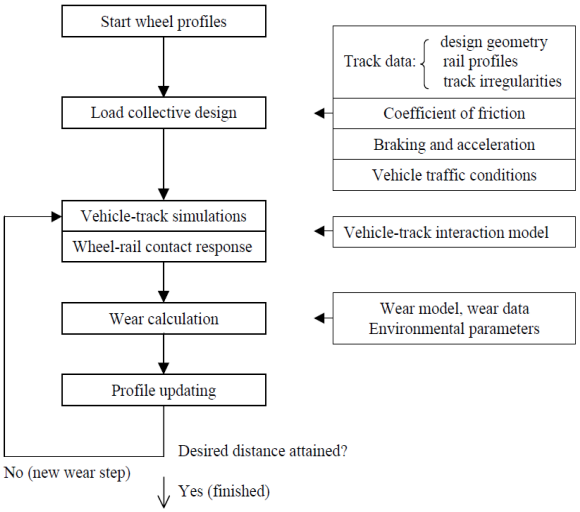

Figure 5, Methodology of wheel wear prediction developed by Jendel [17].

4. Simulation setups and variations

For the current study the Swedish Iron-Ore track line (Malmbanan) is used. The line is around 500 km long which connects the ports Luleå in the north of Sweden and Narvik in the north of Norway. More than half of the line is located above the Arctic Circle. For each wear-step, according to the line geometry data (with some minor modifications: track section with 200 m radius is added), and based on engineering experiences, nine classes of simulation cases are chosen, see [18]. The details of the track design geometries for the simulation cases are listed in Table 2.

Moreover, the wheel/rail friction level for each simulation case is randomly chosen with the probability of normal distribution around 0.4, maximum of 0.5 and minimum of 0.15. Flange lubrication is applied on the wheels in which the friction coefficient at the flange area drops to 0.15. Furthermore, the vehicle speed for each simulation is calculated in a way to result in a random

cant deficiency with a probability of normal distribution around 20%. The distribution of wheel/rail friction level and the vehicle speed after 200k km of simulated running distance are shown in Figure 6 and Figure 7 respectively.

Table 2, Details of the track design geometries for each simulation case according to Malmbanan.

Radius Interval [m]	Length [m]	Gauge [mm]	Super elevation [mm]	Contribution to the total line length [%]	Rail profile
200	510	1444	68	1	Worn 4
300	450	1443	61	3.5	Worn 4
400	340	1448	66	1	Worn 3
450	427	1447	51	1.5	Worn 3
600	410	1445	46	14	Worn 2
800	400	1444	37	16.1	Worn 2
1000	410	1443	33	7.9	Worn 1
1500	390	1440	28	5	Worn 1
Straight	500	1435	0	50	Nominal

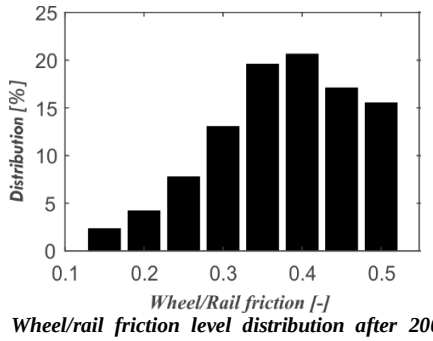

Figure 6, Wheel/rail friction level distribution after 200k km of simulated running distance.

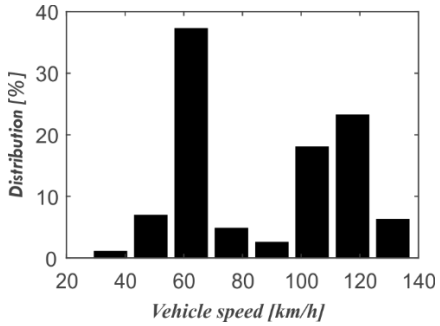

Figure 7 Vehicle speed distribution after 200k km of simulated running distance.

As it is mentioned in the introductory section, five distinct pairs of measured rail profiles are used in the simulation setups. They are listed in Table 2 from the most worn profile (Worn 4) in the tightest curve to the least worn profile in the widest curve (Worn 1) and finally nominal profiles in the straight section. These rail profiles are shown in Figure 8. The starting wheel profile for all the simulations carried out in this study is EU standard S1002 wheel profile.

When performing dynamics simulation of freight trains, it is very important to include track irregularities. This is since often freight bogies are equipped with frictional damping elements. Track irregularities provide excitation which trigger sliding of the rigid bodies in contact and prevent them to stick. Thus, for the current study, a somewhat low amplitude track irregularities are used in vertical, lateral, super-elevation and gauge formats. Based on UIC518 standard, around 70% of the chosen track sections are with QN<1 and 30% are with 1<QN<2 track irregularities. According to the standard, the second class of the irregularities (i.e. 1<QN<2) should consist of less than 40% of the line. This classification is defined based on the maximum and standard deviation of the lateral and vertical track irregularities in every 100 m of the track. Figure 9 shows the lateral and vertical track irregularities along 600 m of the line.

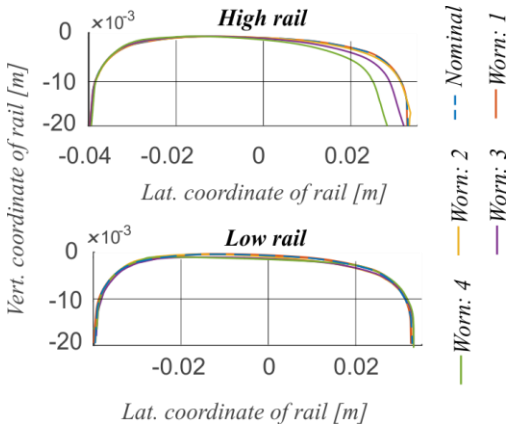

Figure 8, Used measured rail profiles.

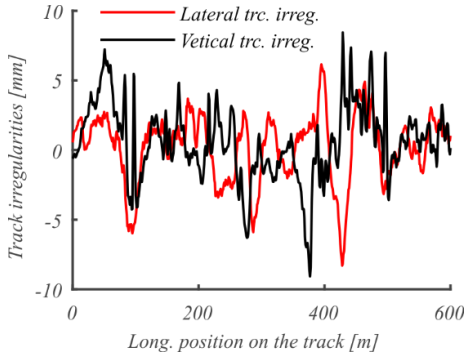

Figure 9, Lateral and vertical track irregularities.

To simulate the operational loading conditions, wagons change their load every full run (i.e. 500 km) from empty to loaded and vice versa. Two axle loads are investigated in this study. The first one is the standard loading condition for UIC-Y25 bogies 22.5 t and an extreme case of 30 t. This is since the current wagons operating in Malmbanan are with three-piece bogies with 30 t of axle load. Thus, the outcomes of this study can be compared with the already published measurement and simulation results of the line e.g. [19].

5. RCF assessment

5.1. RCF assessment on wheels

According to Johnson [20], considering assumptions like steady-state rolling and plane-strain and in the presence of residual stresses, material flow starts at the surface of the wheel when the shear stress values at friction level higher than ≈ 0.3 reaches the yield limit in shear of the material (i.e. Tresca yield criterion). Note that the normal contact problem i.e. pressure distribution and contact geometry are solved by Hertz theory and the shear

stresses are calculated using the FaStrip algorithm from the MBS results. Any of the contact patch mesh elements in which the yield limit is reached is considered as a location imposed by RCF. It is possible to count the number of wheel cycles with the risk of RCF throughout the entire simulated running distance (RCF number). This gives a good indication of where on the wheel profile, the RCF cracks are expected to appear.

To consider the effect of wear on RCF, it is assumed that the energy dissipation at the patch is related to the fatigue life of the wheels (i.e. Burstow model [21])

$$E_i = \frac{\nu_i \cdot A}{2\sqrt{3}} \left(\sigma_y + \sigma_U\right), \text{for } i = 1,2 \qquad (3)$$

In Equation (3), E_i is the thresholds for dissipated energy, ν_i is the total creepage for 0.3% and 1% respectively, A is the contact area, σ_y is yield strength and σ_U is the ultimate tensile strength of the wheel material.

If the calculated energy values are less than E_1, then the frictional energy is transformed into initiation and opening of the RCF cracks, and therefore the corresponding RCF number will be unchanged. However, for energy values between E_1 and E_2, the amount of energy consumed for material removal due to wear starts to dominate, and thus the RCF number is decreased proportionally, meaning that more wheel cycles are needed to initiate the cracks. Finally, if the calculated energy dissipation is higher than E_2, it is assumed that wear is completely governing the situation and there are no cracks to propagate. The energy dissipation for each mesh of the contact patch is calculated as Equation (4).

$$E(x,y) = q_x(x,y) \cdot (\nu_x - \phi \cdot y) + q_y(x,y) \cdot \left(\nu_y + \phi \cdot x\right), \qquad (4)$$

where, x and y are the wheel profile coordinates, q_x and q_y are the shear stresses in longitudinal and lateral directions respectively, and ν_x, ν_y and ϕ are the longitudinal, lateral and spin creepages. Finally, it is assumed that if the total energy dissipation in the contact patch is greater than the global E_2, all RCF number values in both the slip and stick area will be discarded and equated to zero.

5.2. RCF and wear assessment on rails

As described in Section 5.1 for wheels, the typically occurring high contact stresses in the interface between wheels and rails can also cause material flow in the near-surface layers of rails. Such usually severe plastic deformations lead to changes of the microstructure in the sense of an alignment of grains. This alignment causes material ansisotropy resulting in variations of the crack growth resistance dependent on the orientation relative to the alignment. Depending on the amount of shear deformation, the crack resistance can vary significantly, ending up in preferred crack paths parallel to the alignment of the microstructure.

This phenomenon is considered in the so-called wedge model [22], [23]. The model predicts RCF crack initiation dependent on the distribution of the plastic shear strain in a thin layer near the rail surface (crack initiation layer). Based on this approach, four different cases can be distinguished: case A with low plastic deformations without a preferred crack growth direction (wear only), case B with high plastic deformations with a preferred crack growth direction parallel to the surface with a high probability that micro-cracks break out (wear only), case C with medium plastic deformations again with a preferred crack growth direction but in this case with an oblique angle to the surface forcing microscopic cracks to grow quickly away from the surface resulting in macroscopic cracks (wear and RCF). There is a fourth case D again with severe plastic deformations causing wear and RCF despite a preferred crack growth direction parallel to the surface. In this case RCF crack initiation occurs mainly due to the very high contact stresses with low influence from changes in the microstructure.

The model consists of a plasticity module predicting the plastic shear deformation distribution within the crack initiation layer dependent on the normal and tangential contact stresses and creepages.

To assess the contribution of severe plastic shear deformations to RCF crack initiation the distribution of the plastic shear deformation near the surface (in the crack initiation layer) is compared to a reference distribution which is assumed to be favorable for crack initiation by calculating a so-called similarity parameter A_α. The reference plastic shear deformation distribution has been established based on rail specimens from railway operation and from test rig experiments previously.

The calculated similarity parameter A_α goes into the fatigue module of the wedge model. The fatigue life calculation is based on the so-called effective stress σ_A which is calculated from this similarity parameter A_α, the maximum (tensile) principal stress σ^* during the load cycle, and the parameter f_t (quantifying the influence of traction and braking) [22]:

$$\sigma_A = \max(\sigma^*(t)) \cdot (1 + k_A \cdot A_\alpha) \cdot f_t \qquad (2)$$

The constant k_A and the constant in the parameter f_t have been determined by wheel/rail test rig experiments [22], [23]. The effective stress σ_A is then used with Basquin's equation and linear damage accumulation to estimate the damage D with respect to RCF initiation [22].

After calculating the damage D some of the damaged material is removed from the surface to account for the wear process in the model. Similar to the approach described in Section 3 for the wheel wear, this is done based on the dissipated energy within the contact. Due to this removal of damaged material from the rail surface, undamaged material moves into the crack initiation layer. If the contact conditions do not change, this leads to a kind of shake down in the sense that the damage increment and the removal of damaged material due to wear per cycle are in equilibrium.

After calibrating the wedge model by wheel/rail test rig experiments, the model has been applied to heavy haul operation for further validation [24]. The investigations showed a good qualitative agreement with observations from the field.

5.3. Discussion of wheel and rail RCF models

In this section the used methodologies to assess wheel RCF (see Section 5.1) and rail RCF (see Section 5.2) are compared and discussed.

Qualitatively both approaches show the same general model behavior. Cases with wear only and cases with wear and RCF at the same time are distinguished. However, the model view behind the two methodologies is quite different. While in the wheel RCF assessment methodology the distinction between the wear only and wear-RCF cases is mainly based on the local stress situation and the dissipated energy (removal of initiated cracks due to wear), in the rail RCF assessment methodology (wedge model) the initiation of RCF cracks and wear are more or less two independent processes even though the wear continuously removes some of the damaged rail material on the surface. Whether RCF cracks get initiated on the rail surface or not (wear only or wear and RCF) is, beside the stress situation, mainly determined by the distribution of the plastic shear deformation within the crack initiation layer – which of course depends again on the local stress situation – to account for effects from changes in the material microstructure and the according developing material anisotropy. Although the thinking behind the two approaches is significantly different, the qualitative behavior of the two models is similar. While the rail RCF assessment methodology tries to account more for the physical phenomena behind RCF crack initiation by the cost of increased calculation times but with reduced effort for calibration and validation (wider range of applicability), the wheel RCF assessment methodology is a more phenomenological approach which needs more effort for calibration and validation for certain operation conditions but with benefits regarding calculation time.

6. Results

6.1. Wheel wear

All the simulation cases in this section are with 30 t axle load, when fully loaded, and the simulated running distance is around 200k km. The vertical wear depth is calculated for various simulation cases and it is shown in Figure 10. As the figure shows there is a significant difference between the FR8RAIL and UIC-Y25 vehicle when it comes to wear of the wagon wheels. The differences are more pronounced in the flange area. This is due to better curving performance of the FR8RAIL bogie. Comparing the results with measured data on Iron-Ore line (see [17]) for the wagons running with three-piece bogies shows that while the standard UIC-Y25 bogie performs slightly better (less wear), the FR8RAIL bogie results in almost 4 times less wear after 200k km running distance.

6.2. Wheel RCF

For the same simulation cases, the RCF calculation results for wheels are presented in this section. The results are the RCF-numbers (cf. Section 5.1) as function of wheel coordinates after about 200k km simulated running distance, see Figure 11.

As the figure shows, changing the wheel-base distance and longitudinal clearance between the spring-holder at the FR8RAIL bogie does not have any considerable effects in the long run. However, the FR8RAIL bogie significantly reduces the RCF risk compared to UIC-Y25 standard bogie.

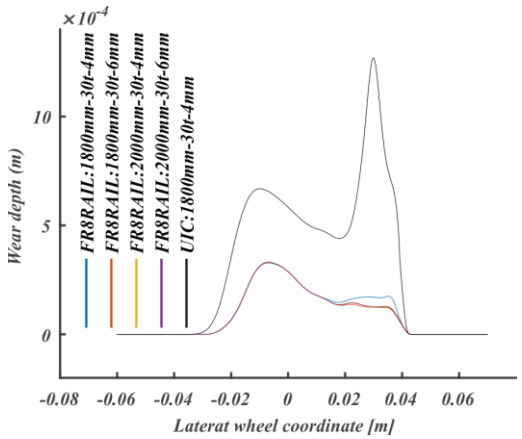

Figure 10, Vertical wear depth for various simulation cases after 200k km simulated running distance. The flange area starts at lateral coordinates above 0.02 m.

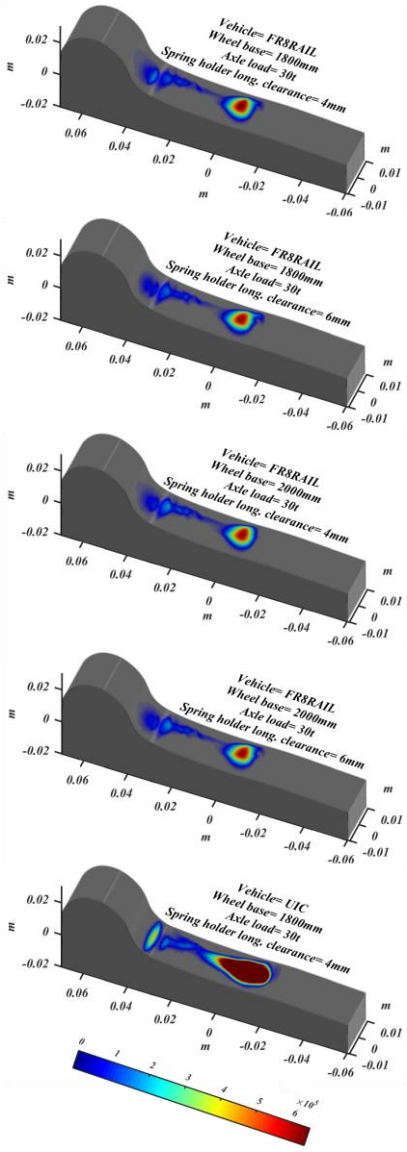

Figure 11, RCF results for various simulation cases after 200k km simulated running distance.

RCF-numbers are counted in each wheel revolution which means, after 200k km of running distance, the UIC-Y25 vehicle has run around 14 times more (~12k km) with RCF condition (i.e. the shear stresses above the shear strength at the surface) compared to the FR8RAIL bogie.

Moreover, most of the RCF cracks are located at the vicinity of the nominal rolling radius, this is in contrast with the observed data in the Iron-Ore line where the cracks are more shifted to the field side (between -0.02 to -0.04 according to [25]). The main reason to this could be the different wheel and rail profiles used in Iron-Ore line compared to the ones used in this study, apart from the differences in dynamic behaviour of three-piece and UIC-Y25 bogies.

6.3. Rail RCF

For different wear steps of the wheel profiles (10k km, 100k km, 190k km) wheel/rail contact data have been taken from the according MBS simulation runs for the UIC-Y25 and FR8RAIL (1.8 m wheel base, 4 mm longitudinal clearance between the spring-holder) running gears in 200, 400, 600 and 1000 m curves. These data have been used to access the RCF initiation on the surfaces of the high and the low rail according to the methodology described in Section 5.2. It must be mentioned again, that because of the stochastic approach some of the vehicle model parameters are not constant in the chosen simulation samples, as for example the coefficient of friction or the speed (see Section 4). The chosen simulation samples include only cases where the vehicle is fully laden (according to 30 t axle load).

Figure 12 shows a qualitative comparison between the UIC-Y25 and FR8RAIL bogie regarding the predicted RCF damage for a randomly chosen position on the track within the constant curve. The maximum cumulated normalised RCF damage (*max(log(D/max(D)))*) for the high and the low rail is plotted over the curve radius. As expected, generally higher damage values are predicted on the high rail compared to the low rail. In most of the cases the FR8RAIL bogie results in an improvement regarding rail RCF compared to the UIC-Y25 bogie. However, in some cases the FR8RAIL bogie shows slightly increased damage values as for example in the 600 m curve at the high rail. The same is true for the low rail in a 200 m curve even though the damage values are still very low compared to the high rail. Further detailed investigations are needed and will be done to fine-tune adaptable bogie parameters further.

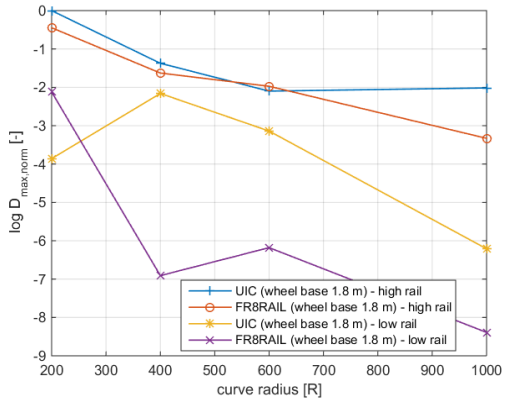

Figure 12, Maximum cumulated normalised RCF damage (max(log(D/max(D)))) for three simulation cases (10k km, 100k km, 190k km running distance) on the high and low rail for the fully laden UIC-Y25 and FR8RAIL wagon dependent on curve radius.

Figure 13 shows the according maximum cumulated normalised wear depth results (*max(Δz/max(Δz))*). The FR8RAIL bogie shows a significant improvement compared to the UIC-Y25 bogie in all investigated cases on both, the high and the low rail.

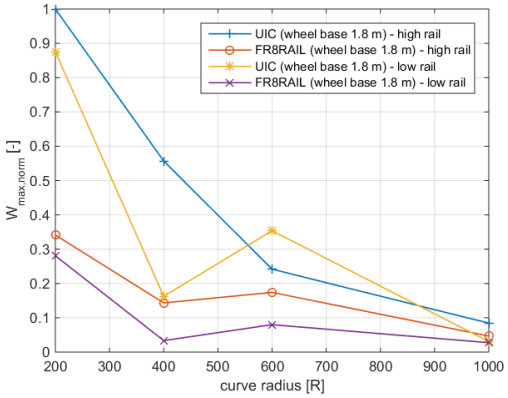

Figure 13, Maximum cumulated normalised wear depth (max(Δz/max(Δz))) for three simulation cases (10k km, 100k km, 190k km running distance) on the high and low rail for the fully laden UIC-Y25 and FR8RAIL wagon dependent on curve radius.

7. Conclusions

The assessment of running gears with respect to wheel and rail RCF already during their development process is a complex task. The basis therefore are reliable vehicle dynamics, RCF and wear models. Furthermore, the interaction between the vehicle and the track must be considered in a sufficient way e.g. by accounting for the stochastic nature of adhesion in the wheel/rail interface and the variations in operating conditions. One of the main issues in this context is the fact, that for such investigations realistic wheel and rail profiles should be considered because they have a high impact e.g. on the steering behaviour of the considered running gears and therewith on the loading conditions in the wheel/rail interface. In the case of rail profiles, using measured profiles is a practicable approach. But in the case of the wheel profiles, this approach fails because the development of the profiles due to wear depends on the investigated running gear technology itself. Thus, using measured wheel profiles from other vehicles is not sufficient.

In this work an integrated approach is presented. Based on a wheel profile prediction methodology which accounts for the stochastic nature of railway operation in the MBS simulations behind, wheel/rail contact data for different wheel profile wear states are used to assess the development of wheel and rail RCF. This approach allows e.g. for the assessment of rail RCF in different curve radii in a cumulative way (sum of damage over lifetime of wheel profiles). Furthermore, RCF assessments can be done at different wear states of the wheel profiles to get insight how the contribution to wheel and rail RCF varies depending on the evolution of the wheel profiles.

The presented methodology is exemplary applied to two freight wagon bogie types, the UIC-Y25 standard bogie and the so called FR8RAIL bogie with a mechanical wheelset steering device to improve the curving behaviour of the vehicle (developed by TATRAVAGONKA a.s. Poprad). The initial results show a significant improvement with respect to wear (wear depth) and RCF on wheels for the FR8RAIL bogie

compared to the UIC-Y25 bogie. When looking on wear on rails (wear depth) also a significant improvement in the investigated cases is predicted. The same is true for rail RCF in most of the investigated cases. However, in certain scenarios (curve radii) a slight increase of RCF on the high and the low rail is predicted for the FR8RAIL bogie. Further detailed investigations are needed and will be done to fine-tune adaptable bogie parameters further.
The presented methodology is a promising tool to optimize vehicles already in an early stage of the development process. Furthermore, it might have significant benefits in service, as for example when thinking about improvements regarding vehicle and track maintenance by application of friction management products. It could be used to assess the impact of lubrication and friction modifier devices on the development of wheel/rail wear and RCF.

Abstract: Low adhesion between a train's wheel and the rail can cause performance and safety issues; in the rail industry this is mitigated by sanding. This paper outlines a particle characterisation framework and applies it to three types of silica sand. It was found that the size of the sand particles differed with sand type but all other measured characteristics were relatively similar. Tribological tests were then conducted under realistic contact pressures to study the sands' influence on traction under varying adhesion conditions. All sands increased traction in low adhesion contacts. Further work will investigate extending the range of particles.

Keywords: traction enhancement; sanding; particle characterisation; tribological testing; adhesion materials.

1. INTRODUCTION

Low adhesion between train wheels and the rail is estimated to cost the UK industry £345m per annum [1] with the majority of this cost coming during Autumn when weather conditions are sub-optimal. Low adhesion in the wheel/rail contact leads to costly delays [2] as well as safety issues due to the loss of traction when braking, potentially leading to SPADs (signals passed at danger) and in the worst case collisions [3]. Low adhesion becomes a major problem when the coefficient of traction between wheel and rail drops below 0.2 for acceleration and 0.09 for braking [2]. Low adhesion conditions can exist in the wheel/rail contact when a third body layer is present, such as: water [4], water and oxides [5], and leaves on the line which bond tightly to the rail [6].

As the cost of low adhesion is so high it is imperative that the rails should be cleaned of third body layers to increase adhesion within the contact, one of the methods for achieving this is sanding which has been in use for many years. Sanding is a train-borne system that activates whenever low adhesion is detected; the sand particles are discharged into the wheel/rail contact from a hopper via a hose directed at the contact in the opposite direction of the train's travel.

In a literature review [7] looking at the effect of sand characteristics on adhesion restoration it was found that previous research primarily focussed on the grain size of the sand [8]–[12]. Some research has also been conducted looking at the effect of particle hardness on restoring adhesion [13]. These studies suggested that larger particle sizes were more effective at restoring traction/braking, but there did seem to be an upper limit at which larger particles were not being effectively entrained into the contact. There was also some evidence to suggest harder particles were more effective, but this relationship plateaued after the hardness went above that of quartz on the Mohs scale.

This paper aims to define a particle characterisation framework for sand particles and assess the effect of these particles in restoring traction using a small scale tribological test. This framework will allow future particle systems to be identified for possible use in future sanding applications.

Previous studies have largely ignored the particle's geometry, mineralogy, and physical properties all of which may have an effect on the adhesion recovery in the wheel/rail contact and on the particle's entrainment into said contact. This paper proposes a series of tests to assess these properties for different rail sands.

Application of sand can be studied by breaking up the sanding process into separate stages; the flow of the sand from the hopper and through the hose, the bounce of the particle when it first hits the wheel or rail , and the entrainment into the wheel/rail contact. The first two stages have been modelled as small scale tests and included in the characterisation framework.

Lastly, this paper uses a small scale test to assess the coefficient of traction of the rail sands in dry, wet and sycamore leaf extract contaminated conditions to assess their traction restoring capability.

2. METHODOLOGY

2.1. Particle Characterisation Methods

The particle characteristics were split into four groups; geometry, mineralogy, physical properties, and application. Within these groups characteristics were categorised and assigned a test method based on either a current standard or from adapting a test method used in literature. A summary of this is included in Table 1, and the methodologies will be detailed in the following section. For all tests a representative sample of sand was produced using a chute splitter (As outlined in ASTM C702 [14]) which reduces the maximum error due to variations in the sand particles to <5% [15].

Table 1 *Characteristic with corresponding test method.*

Particle Characteristic		Testing Method	Standard/Example Paper
Geometry	Size	Sieving/Image Analysis	BS 1377-2:1990 [16]/ ASTM E2651-13 [17]
	Shape	Image Analysis	ASTM E2651-13 [17]
Mineralogy		X-Ray Diffraction	Lafuente et al. [18]
Physical Properties	Density	Pycnometry	BS 1377-2:1990 [16]
	Hardness	Nanoindentation	Oliver & Pharr [19]
	Fracture Toughness	Microindentation	ASTM E2546-15 [20]
Application	Angle of Repose	Tilting Cylinder	Geldart et al. [21]
	Coefficient of Restitution	Recording of Bounce with High Speed Camera	Hastie [22]

2.1.1. Particle Geometry

2.1.1.1. Sieve Analysis

Sieving was carried out to assess particle size distribution as it is a simple, cost effective way of comparing different sand samples, the method used for sieving follows the method for sieving fine grained soils set out in BS1377-2:1990 [23]. The sieve apertures ranged from 2mm to 63μm. All the sieves were placed, in order from largest to smallest, onto a sieve shaker for 20 minutes to ensure the sand had been adequately sieved.

2.1.1.2. Image Analysis

The image analysis was carried out using the Morphologi G3S, an optical microscope with pre-programmed stage movements allowing multiple images to be taken of a large number of particles. The sand being tested was dispersed onto a sample plate using high pressures to separate particles and the image analysis machine scanned the area that particles were dispersed over. The captured images of the particles were subsequently binarized which allowed measurements to be taken of each individual particle. The circle equivalent diameter has been used in this study to characterise sand size. The circular equivalent diameter is the diameter of a circle with the same area as the measured particle.

In addition to particle size, particle shape measurements were taken from the image analysis as well. The measurements taken included:

- *Circularity;* the ratio between the perimeter of a circle of equivalent area to the particle and the actual perimeter of the particle. Circularity can take a value between 0-1 with 1 denoting a perfectly circular particle.
- *Convexity;* the ratio between the convex hull perimeter of the particle shape and its actual perimeter. The convex hull can be thought of as the shape an elastic band would take if put onto the 2D particle shape [24].

2.1.2. Mineralogy

X-ray diffraction (XRD) measurements of each sand were used to find the major constituent minerals for each sand. The measurements were carried out using a Siemens D5000 x-ray diffractometer and were scanned using Cu Kα1 radiation between slit angles of 5-80°. The data was then assessed using ICDD PDF-4+ 2018 software to identify and match characteristic peaks to elements in the software's database.

2.1.3. Physical Properties

2.1.3.1. Pycnometry

The density of each sand was measured using the small pycnometer method outlined in BS 1377-2:1990 [23]. A small change was made so that three specimens were measured at a time instead of just two, therefore giving more confidence in the validity of the results.

2.1.3.2. Indentation

Both nano and micro indentation was conducted on each specimen, partly to compare the methods' efficacies for measuring hardness on sand particles and also microindentation was needed to measure the fracture toughness of the particles.

The sand samples were prepared by cold mounting particles in an epoxy resin system and subsequently grinding a polishing the surface of the particles to achieve a suitable surface for indentation techniques.

Nanoindentation was carried out on a Hysitron TI Premier from Bruker using a Berkovich indenter and a 10,000 μN load. Nine indentations were performed on >5 particles for each specimen. The raw load vs displacement data was then analysed using the Oliver-Pharr method [19] to produce hardness results.

Microindentation was carried out on a Durascan -70 G5 from Struers using a HV0.3 loading conditions. The indentation was measured optically to produce a hardness value and the cracks at each corner were subsequently measured to find a value for fracture toughness from a formula derived by Antis et al. [25]:

$$K_C = \alpha \left(\frac{E}{H}\right)^{0.5} \left(\frac{P}{c^{\frac{3}{2}}}\right) \quad (1)$$

where K_C is fracture toughness, α is an empirical constant varying with tip indenter geometry (α =0.032 in this case), E is the Youngs modulus (obtained from the Oliver-Pharr nanoindentation method [19]), P is the load and c is the crack length. Daphalapurkar et al. [26] found this produced data that could be used to characterise sand at the granular level but is ineffective for bulk characterisation, something which is less of a problem in this case where the sand does not act as a bulk material when discharged from the sanding hose.

2.1.4. Application Characteristics

2.1.4.1. Angle of Repose Test

The angle of repose can be used as a quick and simple test for assessing the flowability of a powder system

[21], in this case the angle of repose was tested using a rotating cylinder method. The cylinder was rotated gradually until sliding occurs on the surface of the sand, after which the angle was measured, a diagram of this is included in Figure 1. The tests were run in dry conditions and with 0.2%wt and 3%wt moisture contents to assess the effect of moisture content on flowability, these values were chosen as they have been found to cause problems with sand flow in the hopper [13]. 400g of sand was dried for each test with the moisture being added afterwards by a pipette. Each test condition was run 5 times for each sand.

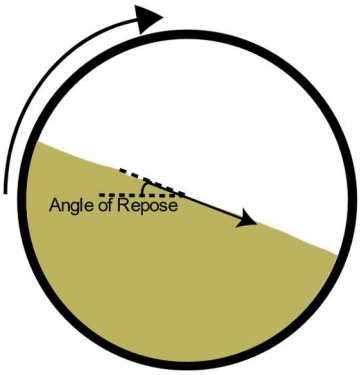

Figure 1 *Revolving Cylinder Method Diagram.*

2.1.4.2. Coefficient of Restitution Test

The coefficient of restitution was tested by carefully pushing a sand particle off of a platform and onto a rail with a high speed camera recording the particle bouncing on the rail; 20 particles from each sand were tested. A set of lights and white background were used to ensure sufficient contrast in order to clearly see the particle, a schematic of this set-up is included in Figure 2.

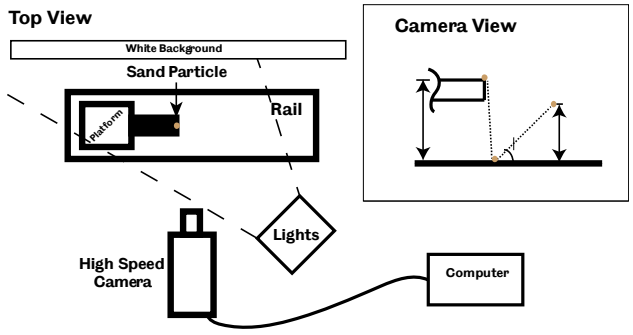

Figure 2 *Coefficient of Restitution Test Set-up.*

Taking the height of the platform as the particle's initial height and measuring the bounce height of the particle and the angle from where it bounced to its maximum bounce height, the coefficient of restitution (CoR) could be calculated:

$$CoR = \frac{Velocity\ After\ Collision}{Velocity\ Before\ Collision} \quad (2)$$

It has been found that particles that bounce lower tend to be more easily entrained into the wheel/rail contact [27], therefore identifying particles with lower CoR's, or even just characterising particle behaviour when keeping low, may help improve understanding of how to improve entrainment.

2.2. Tribology Test Method

Pin-on-disc tests have been used in the past to study friction at high contact pressures (as seen in the wheel/rail contact), however due to the small contact area used in these tests granular materials are not appropriate to be studied as third body materials as a single particle may completely dominate the contact area, leading to unrealistic results. The high pressure torsion (HPT) rig is capable of achieving high contact pressures whilst also maintaining a large enough contact area for the particles not to dominate.

HPT rigs have been used as a workbench test of the wheel/rail contact with traction gels [28] and sand [29] as third body layers in the contact. These experimental methods were adapted for the testing conducted in this paper.

The HPT rig compresses a bottom specimen (made of R260 grade rail) together with a top specimen (made of R8T wheel) to create an annulus contact. A torque is applied to the bottom specimen until it has moved through a set sweep length at a low speed (<1 mm/s), a schematic of this action is included in Figure 3. Initially the surface deforms elastically until part of the surface plastically deforms and the contact enters slip.

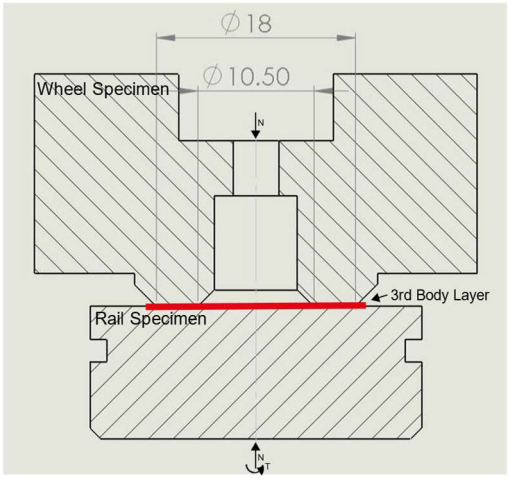

Figure 3 *Schematic of HPT Interface.*

The specimens were run together to fully shakedown the surfaces and the third body material was then added to the contact. For liquid contaminants 100µL was added using a pipette whilst 0.025g of sand was hand placed in sanded tests, an example of this sand placement has been included in Figure 4.

Figure 4 *Sand Placement on HPT Sample.*

Each sand type was tested in dry, wet, and leaf extract contaminated conditions for three runs. The annulus contact has an inner diameter of 10.5mm and an outer diameter of 18mm; a contact pressure of 900 MPa was used for all tests, with the maximum attainable torque being 1000 Nm.

2.3. Specimens

Three different sands have been studied in this paper:

- Garside 10/18 Sand; the current industry standard for sand used by the UK rail industry. Garside meets all the current UK sanding standards as set out in GMRT2461 [30].
- Central European (CE) Rail Sand; a representative sand currently being used in central European sanding operations.
- Youlgreave 110 Sand; currently sold commercially as an "anti-skid" sand. This sand was obtained from Derbyshire Aggregates.

3. RESULTS

3.1. Particle Characterisation

A summary of the particle characterisation results have been included in Table 2. This following section will describe the results included in this table in more detail.

In addition to the results listed in Table 2, images taken using a optical microscope have been included in Figure 5. These images are a representation of each sand which allows the reader to understand how the sands visually differ.

Table 2 *Particle Characterisation Results.*

Particle	Garside 10/18 Sand		Central European Rail Sand		Youlgreave 110 Sand	
Size (mm)	Sieve Analysis D_{50}: 1.30 Uniformity Coefficient: 1.34	Image Analysis Circle Equivalent Diameter D_{50}: 1.53	Sieve Analysis D_{50}: 0.92 Uniformity Coefficient: 1.49	Image Analysis Circle Equivalent Diameter D_{50}: 0.95	Sieve Analysis D_{50}: 0.55 Uniformity Coefficient: 1.56	Image Analysis Circle Equivalent Diameter D_{50}: 0.72

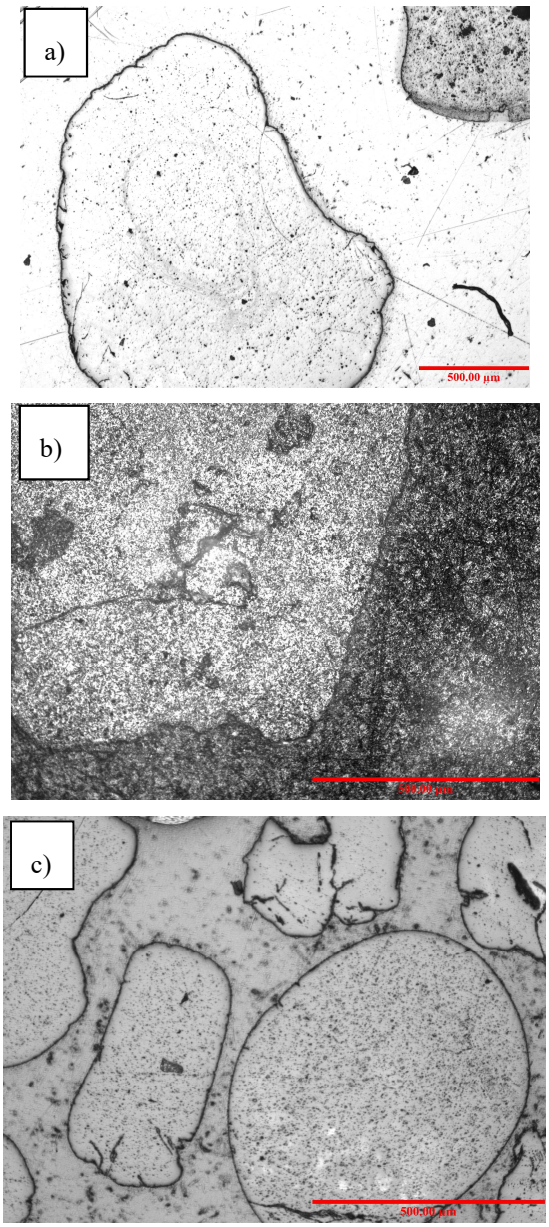

Figure 5 *(a) Garside Particles; (b) CE Rail Particles ; (c) Youlgreave Particles.*

3.1.1. Geometry

3.1.1.1. Sieve Analysis

The full sieve analysis has been included in Figure 6, where a cumulative volume graph shows the relative amount of sand passing through each sieve aperture. The median particle size (D_{50}) and the uniformity coefficient values were included in Table 2. Youlgreave sand was found to be the smallest sand as well as the least uniform, with Garside sand being the largest and most uniform.

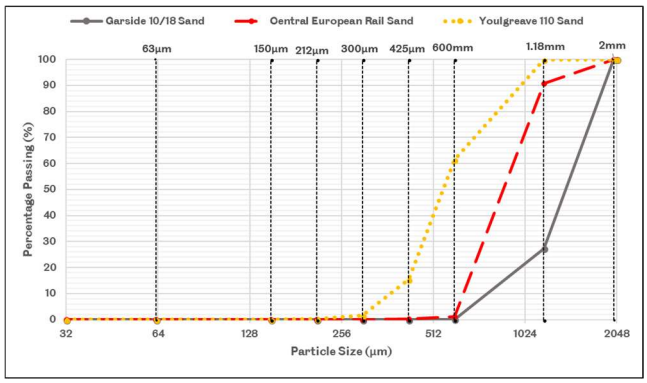

Figure 6 *Cumulative Volumes from Sieve Analysis Data.*

3.1.1.2. Image Analysis

As with the sieve analysis data, the data from the image analyses are presented as cumulative volume graphs with their median values included in Table 2. Circle equivalent diameter, circularity, and convexity have been plotted in Figure 7, Figure 8, and Figure 9 respectively. The Garside sand was the largest, with Youlgreave being the smallest sand. All sands were both relatively circular and non-convex though Garside sand was found to be very circular in comparison to the other two sands.

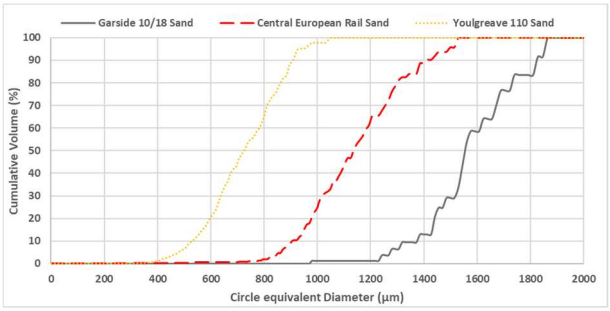

Figure 7 *Circle Equivalent Cumulative Volumes.*

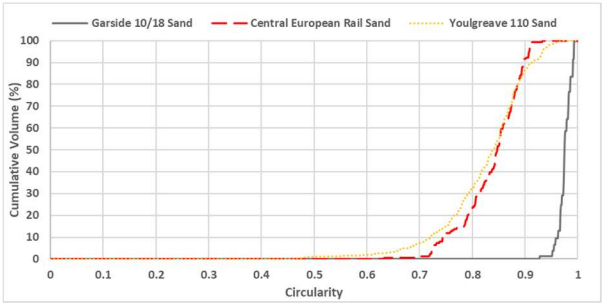

Figure 8 *Circularity Cumulative Volumes.*

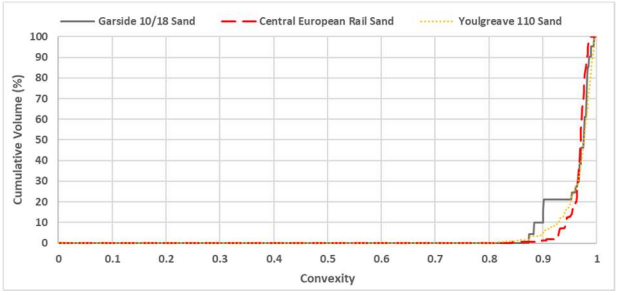

Figure 9 *Convexity Cumulative Volumes.*

3.1.2. Mineralogy

The mineral content for both the CE sand and the Youlgreave sand was found to be 100% silica. The Garside sand had ~5% titania content with <2% calcium also being present, the Garside sand was still >90% silica.

3.1.3. Physical

All the relevant data obtained from the physical tests has been included in Table 2. An example microindentation has been included in Figure 10, where the area of the indent was used to calculate hardness and the crack length was used to calculate fracture toughness.

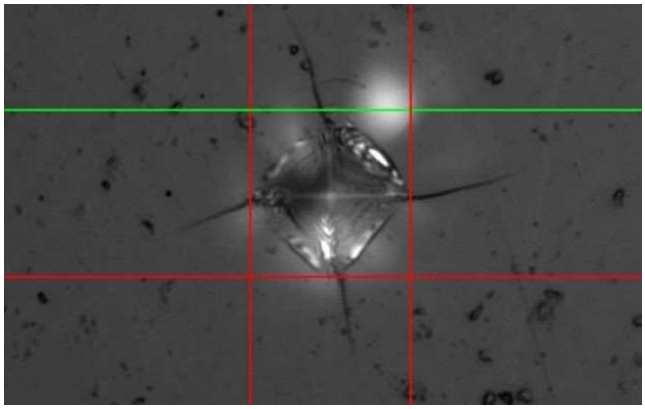

Figure 10 *Example Measurement of Microindentation Hardness.*

3.1.4. Application

3.1.4.1. Angle of Repose Test

There seemed to be very little effect on the angle of repose when 0.2% of moisture was added to all tested sands, this is readily apparent in Figure 11. At little to no moisture all the sands seem to have roughly the same angle of repose at 30-35°. However, when 3% moisture was added the angle of repose increased markedly for all sands. There was little difference between the Garside and the CE sand at 3%, with their angle of repose being ~45°, whereas the Youlgreave sand was affected by the moisture even more with a mean value of 65° being measured.

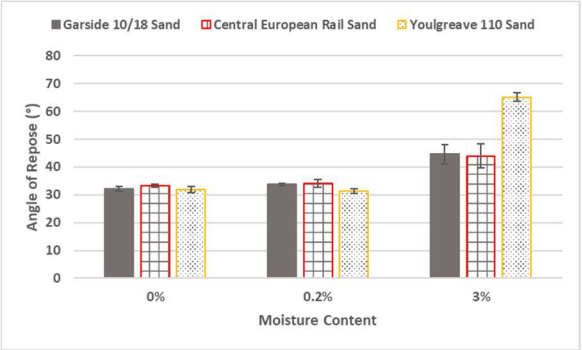

Figure 11 *The Effect of Changing Moisture Content on Angle of Repose for all Rail Sands.*

3.1.4.2. Coefficient of Restitution Test

The coefficient of restitution measurements have been summarised in Figure 12. Whilst the coefficients are all roughly the same, between 0.44-0.49, the variance in results means a single value for each sand is a very unreliable way of comparing. The best way of analysing the data will be to characterise what different bounce behaviour is occurring between low and high coefficients.

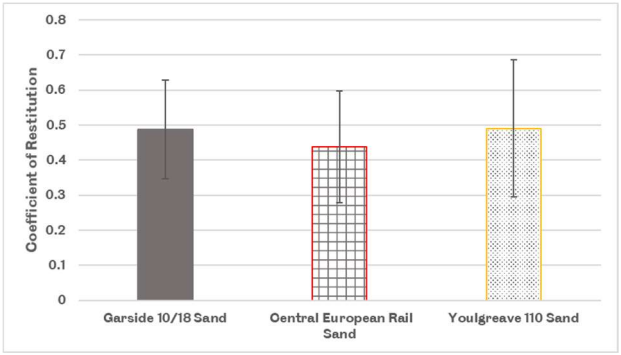

Figure 12 *Coefficient of Restitution of All Sand Samples.*

The best way to interpret the coefficient of restitution results is by characterising the different bounce behaviours of particles. From analysis of the videos it was observed that particles that kept low bounced sideways with a low angle relative to the rail, and had a lot of spin imparted onto them by the surface, whereas high bouncing particles showed little spin and went straight up, stills of these behaviours have been included in Figure 13. Similar results have been found in previous work on the CoR of irregular particles [22].

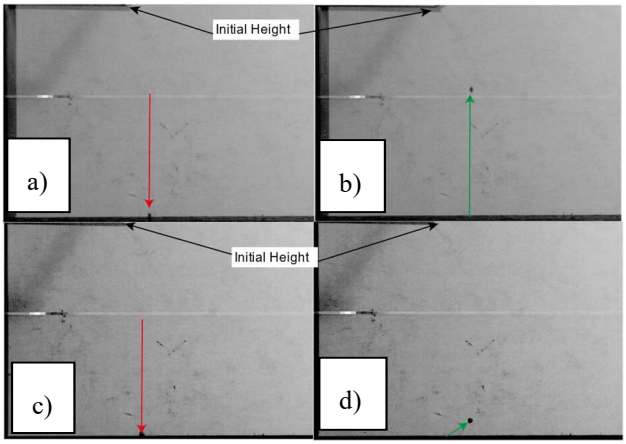

Figure 13 *High CoR Behaviour: (a) Point of Contact, (b) Maximum Height Obtained; Low CoR Behaviour: (c) Point of Contact, (d) Maximum Height Obtained.*

3.2. Tribological Testing

The contact conditions that produced the highest coefficient of traction were when the contact was dry, producing a coefficient of traction of ~0.8. When sand was added to a dry contact it lowered the coefficient of traction marginally to 0.7-0.8, with all the sands performing very similarly in both the stick and slip events.. The change in coefficient of traction throughout the test sweep has been included in Figure 14.

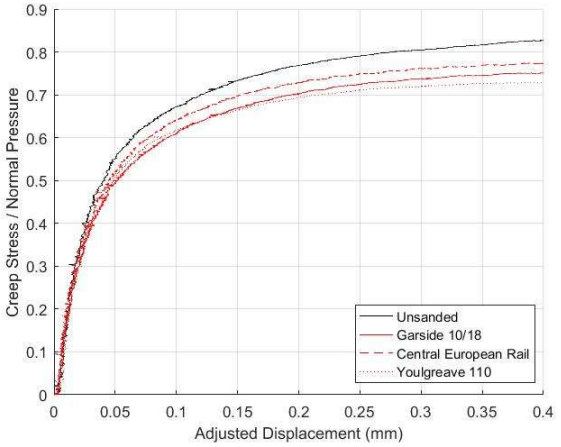

Figure 14 *Effect of Sand on Dry HPT Interface.*

When water was added to the contact the coefficient of traction dropped to just above 0.2 with a maximum coefficient of traction of 0.36 before the slip occurred, as can be seen in Figure 15. The Garside and CE sand both increased the coefficient of traction in the wet contact to above 0.5, though the Garside did this much more slowly than the CE sand which reached a maximum peak of just under 0.6, giving a similar curve shape to the wet unsanded contact. The Youlgreave sand was less effective, with the coefficient of traction only getting up to 0.4-0.5, as with the CE sand the coefficient of traction reached a peak before full sliding commenced.

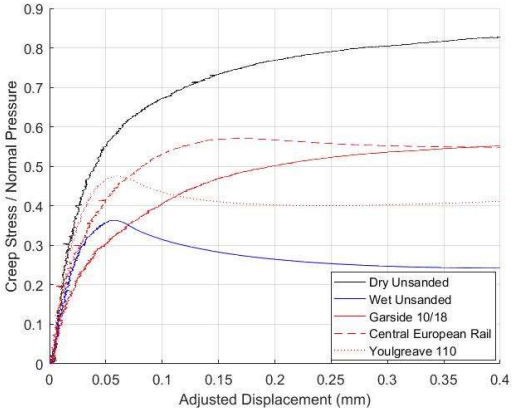

Figure 15 *Effect of Sand on Wet HPT Interface.*

The effect of the leaf extract on the contact was a lowered coefficient of traction, reducing to just above 0.2 thereby exhibiting the lowest tested coefficient of traction for all test conditions, this is apparent in Figure 16. Similar to the wet contact, peak traction was reached just before the onset of sliding. The Garside sand performed as it did in the wet test with traction being restored to above 0.5. The CE sand was less effective than it was in the wet contact, with the coefficient of traction peaking at just above 0.4. The Youlgreave sand was also less effective than in wet tests, only recovering traction to just above 0.3.

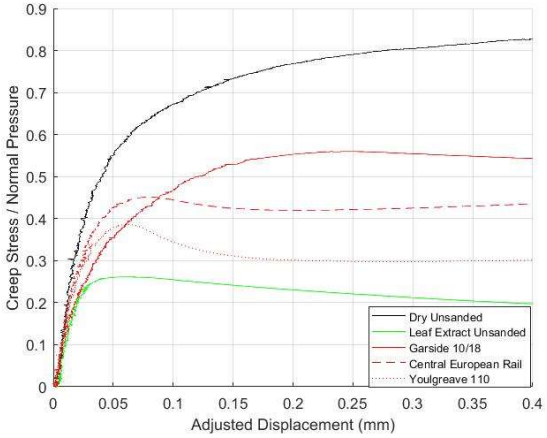

Figure 16 *Effect of Sand on Leaf Contaminated Interface.*

4. DISCUSSION

4.1. Comparing Sands

Both the Garside and CE sand were found to be of acceptable size according to the sand size criteria for braking (>90% sand between 0.71-2.8mm) as set out in the GMRT2461 sanding standards [30]; the Youlgreave sand was found to be smaller than currently acceptable. All tested sands were found to be fairly circular and non-convex which fits with the requirement for braking sand to be rounded and irregular.

The mechanical properties for Garside and Youlgreave sands were very similar perhaps unsurprising as they had similar mineral contents; mostly silica. The relatively large range of hardness, stiffness, and fracture toughness values was in large part due to the variation from one particle to the next; for Garside particles slightly differing mineralogy affected the particle structure which can be seen in Figure 5 where different particle types are evident. Both particles exhibited areas of hardness stratification with hardness values as low as 4-6 GPa in some areas, these are possibly due to small areas being affected by nearby pores lowering the measured hardness, evidence of the porous nature of both particles can also be seen in Figure 5. Microindentation was less affected by these small pores and therefore gave more consistent results. The German rail sand was found to be very porous (evidence of this can be seen in Figure 5), therefore the same indentation process could not be conducted upon it without improvements to the current preparation system.

With regards to the angle of repose tests, the dry values for all sands was found to be in line with literature findings [31]. All tested sands can be defined as free-flowing according to the Carr classification mentioned in a paper by Beakawi Al-Hashemi and Baghabra Al-Amoudi [32]. The large jump in the measured angle of repose when 3% moisture was added will be due to the water surface tension reducing flowability; this seemed to be especially pronounced for the Youlgreave sand, possibly due to its smaller size meaning it has a larger surface volume to mass ratio and therefore giving more sand surface for the water to stick upon.

4.2. Sieve Analysis vs Image Analysis

Whilst both image analysis and sieve analysis put the sands in the same order they both produced different values for sand size. This is due to the analyses measuring different dimensions and therefore not being directly comparable; image analysis measures the circle equivalent diameter, whereas the sieve analysis measures the second smallest dimension of a particle as the smallest aperture a 3D shape can fit through will be based on its smallest 2d projection which is dependent on its second smallest dimension.

The image analysis method used in this paper will generally overestimate the size of the sand; as the sand is lying on a 2D surface it will settle on its most stable base, generally its largest surface, leading to an image being taken of this surface. For more informative measurements future research should try to take a 3D image of the particle using x-ray tomography methods [33], [34].

4.3. Interpreting Coefficient of Restitution Results

The best way to interpret the coefficient of restitution results is by characterising the different bounce behaviours of particles. From analysis of the videos it was observed that particles that kept low bounced sideways with a low angle relative to the rail, and had a lot of spin imparted onto them by the surface, whereas high bouncing particles showed little spin and went straight up; these results are similar to previous work into the CoR of irregular particles [22]. The most likely cause for these different behaviours is due to the shape of a particle. In Figure 17 two particles are shown, the left particle's point of contact is directly below its centre of mass (CoM) thus the only forces acting on the sand (R) are straight up; the right particle has contacted the surface at a point away from its centre of mass creating a force couple which will cause the particle to spin and move sideways. A perfectly circular particle will always contact a flat surface at a point below its centre of mass, therefore the less circular a particle the higher chance of it bouncing low. To further examine this behaviour future work should measure the shape of individual particles and examine this effect on bounce behaviour.

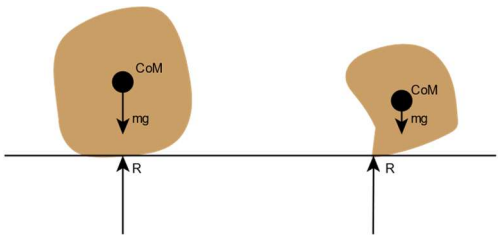

***Figure 17** Diagram of Sand Bounce Behaviour.*

4.4. Efficacy of Sands for Restoring Traction

The Garside rail sand was more than twice the size of the Youlgreave sand, bearing in mind larger particles have been shown to be more effective at restoring traction in a wheel/rail contact [8], [10] this may explain the Garside's better performance in HPT tests with the CE sand being the second largest size sand and also the second best performer.

From visual inspections of the surface after testing it was apparent that not much was staying in the contact during the compression portion of the test, though there did seem to be more sand staying in the contact under wet conditions which was also an observation from a study by Lewis and Masing [35]. The sand that did stay in the contact was ground down to a fine powder by the large contact pressures in the interface.

None of the contact conditions went below the minimum coefficient of traction needed on UK railways (<0.2) [2], though the leaf extract contact came very close. Therefore, it is hard to say for certain whether all the tested sand would be effective in very low adhesion conditions. Future work will need to find a way of reducing friction further to truly test a sand's efficacy in low adhesion conditions.

5. CONCLUSIONS

Garside 10/18 sand was found to be the largest sand and the Youlgreave 110 sand was the smallest whilst the CE rail sand was in the middle, these results were the same for both sieve analysis and image analysis. The image analysis also found that all sands were fairly circular and non-convex with the Garside sand being very circular. According to previous work, the larger sand would be expected to give larger coefficients of traction in a tribological test, something which was found in the high pressure torsion tests in this paper.

Whilst all non-geometric characteristics were very similar for all types of sand, work will be undertaken characterising dissimilar particles as a part of future work. These particles characterised will include those used in current commercial traction enhancing products as well as particles used in industries other than rail for their anti-skid properties.

Three different baseline conditions were used for tribological testing: dry conditions, wet conditions, and sycamore leaf extract contaminated conditions. When sand was added to the baseline tests the contact produced coefficients of traction that are deemed acceptable on the UK rail network (>0.2) and showed significant increase in traction compared to wet and leaf extract conditions. Future testing should reduce the traction in baseline low friction tests to below 0.1 thereby testing the efficacy of sand in very low adhesion conditions.

The characterisation and tribological experiments performed in this paper outline a method for assessing future particles and investigating whether particles with particular characteristics are more effective at restoring traction in a wheel/rail contact. As well as characterising more particles, future work should focus on:

- The use of a particle's 3D shape when conducting image analysis.
- Investigate the relationship with particle shape and bounce behaviour.

- Conducting high pressure torsion tests under very low adhesion conditions.
- Assessing the impact of sand on wheel/rail surface wear and train detection.

Abstract: The interaction between rail and wheel leads among other effects to corrugation of tracks. Although a number of preventing, mitigating and corrective measures already are applied in operations, the implementation of effective strategies on design and maintenance of the wheel-rail-system requires still research on vehicle behaviour. Therefore, the wheel-rail-interaction was simulated by multi-body simulation based on analytical equations describing the contact situation. Main result of this research was the fact that not the velocity dominates safety, but the geometric factors, determining the number of contact points between rail and wheel.

Keywords: Rail corrugation; Light Rail; Multi-Body Simulation; Ride quality; Economy of Transport; Track maintenance planning.

1. Motivation

Corrugation of rail tracks is a common phenomenon in rail bound traffic, which influences the quality of services as well as life cycle costs of the rail system as a whole. This worn state of the infrastructure leads to oscillations of rail vehicles. They result finally in riding comfort losses for passengers and, in freight traffic, may cause dangerous situations with goods not being safely loaded and starting to move by the vibrations. In addition, corrugation has been a recurrent and still increasing problem regarding the wellbeing of people living close to the tracks due to the noise emitted by the bouncing wheels. Not less important, maintenance costs for both, tracks and wheelsets, will raise as they need to be re-profiled more often or even exchanged. Wear of rails and wheels highly accelerate the damage of track and vehicle components [5, 6].

The occurrence of corrugation on tracks in general can be partly prevented by construction elements like track design (e.g. lower cant in curves), mitigated during operation by application of antifriction elements or at last eliminated during maintenance by actions like head rail grinding. Nevertheless, as it may not always be possible to apply sufficient constructional or operational measures the phenomenon appears in a significant range. Thus, it is important to quantify its effects on ride quality in passenger systems. In light rail systems, the conditions for corrugation development are different from conventional railways. This paper seeks to determine the riding quality of a light rail system through simulation and numeric methods. Therefore, the limits in which corrugation affects ride comfort for passengers and compromises the safety of operation are explored. Even though vibration and noise originating from interaction of the vehicle with the corrugated track are an important issue, this study does not yet include their analysis. The focus lies rather on the vital influences of corrugation on vehicle's behaviour.

In [1], corrugation is described as a type of plastic flow represented by quasi-sinusoidal irregularities of less than a meter wavelength that generate high-frequency forces on the track. Grassie points out that all kinds of corrugation detected up to date are essentially constant frequency phenomena [2]. It is further explained that corrugation emerges from wavelength fixing and damage mechanisms. The wavelength fixing mechanism represents the dynamic behaviour of vehicles as a response to the longitudinal irregularities on the rail (e.g. "pinned-pinned" resonance). According to [2], this mechanism is responsible for the dimension of the wavelength and the position of corrugation along the track. The damage mechanism is the one that changes the profile of a rail's surface, such as the development of plastic flow, plastic bending, rolling contact fatigue and wear as the most prevalent, as reported in [3]. The so-called long-pitch corrugation (i.e. wavelengths between *8* and *30 cm*) is common in homogeneous traffic lines according to [4]. This is in accordance with light rail traffic, which uses vehicles having the same or similar properties, such as mass, axle-centre distance, centre of mass, length, etc. However, also other corrugation wavelengths are covered by this theoretical study to show the impact of the entire spectrum.

Following Grassie, the most common type of corrugation for "light axle load" traffic (i.e. $< 20\ t$) is the pinned-pinned resonance, which causes plastic flow as damage mechanism. This occurs on straight tracks and outer rails in large radii curves. This type of corrugation displays a frequency band of *400 - 1200 Hz* [2]. Another recurrent type of corrugation in urban systems (i.e. metro) is the so-

called rutting occurring on curved tacks, which display a frequency band of *250 - 400 Hz*.

One aim of the study is to identify the influence that corrugation has on dynamic loads, which may increase due to the over-vibration of vehicle-track systems. The publication on hand focusses on this topic. However, improvements of vehicle construction or adaptation of material characteristics will be further outputs of the ongoing research in this field.

2. Multi-Body Simulation: Basics and Modelling

For simulation of track corrugation and its impact on vehicle behaviour, a multi-body simulation (MBS) model is used in this study. As MBS is a method to simulate the mechanical behaviour of a body being connected to more than one other bodies, for example by joints or force elements, it is well established to represent reality and to obtain information about the vehicle's mechanical behaviour without any complex measurement equipment or test runs before building a prototype. Furthermore, simulations are less expensive than performing test runs. If the model is validated, MBS may even be used for vehicle authorization.

Car-body excitations are mainly caused by the combination of wheel and rail profile considering their contact conditions and contact forces as well as the impact of corrugation. To measure accelerations in the car-body, six sensors are placed at representative positions according to the riding comfort standard EN 12299 [7]. The sensors record accelerations in *x*-, *y*- and *z*-direction (for directions see Figure 2) during the simulation. The data generated is used to assess a comfort level value. EN 12299 proposes an evaluation method for ride comfort which is mandatory for conventional rail vehicles. To assess the comfort level for light rail vehicles the standard can be used voluntarily [7].

For the research on hand, a DT 8.10 Light Rail Vehicle of the Stuttgart Tramways corporation (Stuttgarter Straßenbahnen AG, SSB) was shaped from data provided by SSB. The vehicle consists of two car-bodies and eight driven wheelsets placed in four bogies. Wheelsets, bogie frames, car-bodies and other components are realized through rigid bodies, connected by different types of spring-damper force elements, joints or constraints. Using rigid bodies instead of flexible bodies is tolerable since the benefit of elastic modelling would only be minor, whereas the calculation effort would increase significantly. Figure 1 exemplarily shows the model of the bogie.

The data provided by SSB made it possible to create and verify the model through the analysis of the vibration performance. More than 100 simulations were performed on a standard gauge corrugated tangent track with a rail profile S49. Corrugation was applied to the track as a harmonic sine function according to [1], allowing an easy way to adjust wavelength as well as amplitude.

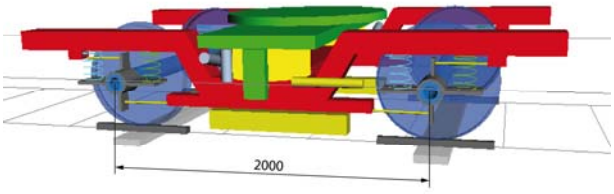

Figure 1 *Bogie as MBS model*

To analyze a wide spectrum, amplitudes from *0.001* to *10 mm* and wavelengths from *0.001* to *2000 mm* (axle-centre distance within a bogie, see Figure 1) were examined at typical velocities, being *10*, *40*, *60* and *80 km/h*. This allows to identify the specific vehicle's response without the necessity of real measured data. Nevertheless, it does only partly represent the real shape of corrugation, which is a superposition of numerous wavelengths and amplitudes at the same time. The simulation method represents a theoretical, scientific approach that is independent from factors like track shape, curve radius or cant. The main parameters considered to determine the limits of acceptable corrugation levels are velocity, wavelength and amplitude.

During simulation, warnings and errors occurred for several wavelengths and amplitudes. The assumption is that the algorithm is not able to cope with two or more contact points per wheel along the track. Based on this, the relationship between error occurrence and physical dimensions were investigated further in a theoretical study. This was done in order to predict the simulation behaviour based on corrugation wavelength and amplitude as well as wheel radius as presented in the following chapter.

3. Prediction of simulation behaviour based on physical dimensions

The algorithm presented under this section reduces complex wheel and rail geometries to a two-dimensional plain in the x-z-direction. The description of the wheel-corrugation-contact is based on an ideal formed wheel rolling on an ideal "sine-waved" rail. Hence, both the wheel *W(x)* and the rail *R(x)* can be described by the analytical functions,

$$W(x) = -\sqrt{R^2 - x^2} + R + H \qquad (1)$$

and

$$R(x) = A \cdot \left(1 - cos\left(\frac{2 \cdot \pi \cdot x}{L}\right)\right) \qquad (2)$$

whilst *R* describes the wheel radius, *H* the elevation of the wheel above the rail head, *A* the corrugation amplitude and *L* the corrugation wavelength. *x* is used as the control variable in the longitudinal track direction. Figures 2, 3 and 4 show the geometries described.

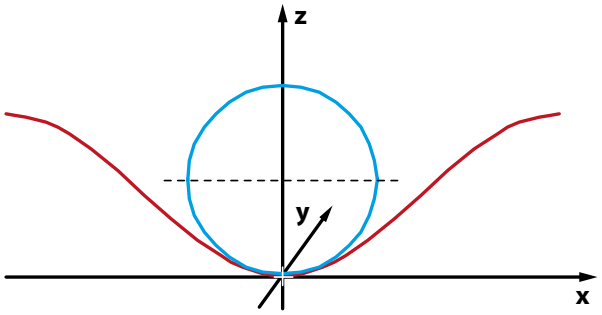

Figure 2 *Axis directions and one-point-contact*

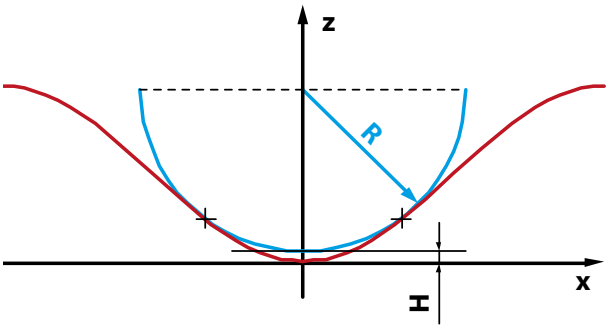

Figure 3 *Mathematical definition of the Wheel and two-point-contact*

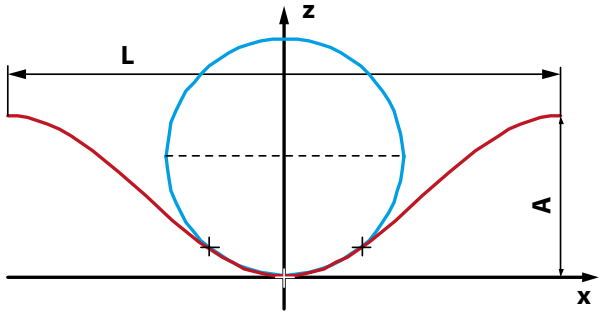

Figure 4 *Mathematical definition of the Rail and three-point-contact*

The wheel radius R is initially treated as a constant value according to the DT 8.10 wheel dimensions. The "sine-waved" rail is described by the two variables amplitude *A* and wavelength *L*. Depending on the relationship between *A* and *L*, one, two or three contact points can be found. For example, two contact points are shown in Figure 2, one contact point in Figure 3 and three contact points in Figure 4. In case of one contact point, the trajectory of the wheel is described through the sine function and the height *H*, which is zero. Hence, for this case study, *H* is assumed to be zero. An array of curves for different *A* and *L* values is produced according to the process shown in Figure 5. First, logarithmically spaced vectors for wavelength and amplitude are created in reasonable ranges. The variable *x* is chosen symmetrically from the origin with a length of R in each direction. Using these values, three-dimensional matrices for the wheel and the rail are calculated. Next, the relationship between wheel and rail height is found.

L steps = logspace from 10^{-2} to 10^{3} mm
A steps = logspace from 10^{-3} to 10^{1} mm
(logspace = creation of logarithmically spaced vectors with 100 steps)

Variable **x** = -R ... R

Calculate Matrices for **L** and **R**

$$W_{Result} = [W(x, A_{steps}, L_{steps})]$$
$$R_{Result} = [R(x, A_{steps}, L_{steps})]$$

Figure 5 *Wheel and Rail Matrix calculation*

If the difference between *W(x)* and *R(x)* is greater or equal to zero $\forall\, x$, only one contact point exists. A difference smaller than zero leads to the conclusion that there must be more than one contact point. This is represented by the matrix M_{Result}:

$$M_{Result} = W_{Result}(x, A_{steps}, L_{steps}) - R_{Result}(x, A_{steps}, L_{steps}) \tag{3}$$

To figure this out, results are compared and written into a two-dimensional M_{Sign} matrix as 0 (one contact point) or 1 (more than one contact point). As a result, a diagonal line in the matrix can be noticed, see Equation (5). Above this line, every element is 0 and below this line every element is 1. Therefore, it is later called "0 to 1 transition line". When using the *A* and *L* vectors as indices, information about the contact shape is represented in this matrix for different values of *A* and *L*.

$$M_{Sign} = \begin{cases} 0 & for\ M_{Result}(\forall\, x, A_{steps}, L_{steps}) \geq 0 \\ 1 & for\ M_{Result}(\forall\, x, A_{steps}, L_{steps}) < 0 \end{cases} \tag{4}$$

$$M_{Sign}(A_{steps}, L_{steps}) = \begin{bmatrix} 0 & \dots & 0 \\ 1 & \ddots & \vdots \\ \vdots & \ddots & 0 \\ 1 & \dots & 1 \end{bmatrix} \tag{5}$$

The 0 to 1 transition diagonal is used for the case study. The wavelengths and amplitudes represented by the diagonal are plotted in Figures 6 and 7.

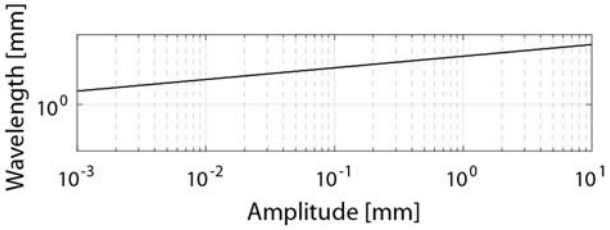

Figure 6 *Result plot*

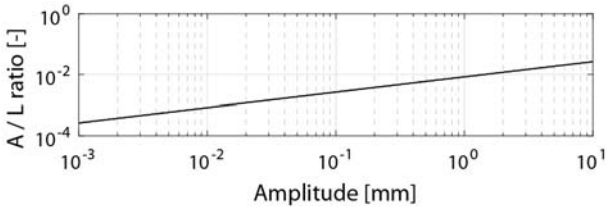

Figure 7 *Result plot for A/L ratio*

The algorithm is examined for different values of *R* to find an approximate description for the occurrence of one or two contact points. Based on experience, a root function is used (see Figures 6 and 7), leading to a coefficient of determination of 0.9998.

Variation of R, curve fitting and parameter estimation

Application of Algorithm on different Radii
R = 100 ... 1 500 mm

do **curve fit** for each Radius and find coefficients

$$L(A,R) = a(A,R) \cdot x^{b(A,R)}$$

$$a(\forall\,(A,R)) = const = 2 \cdot \pi$$

$$b(\forall\,(A,R)) = const = 0.5$$

$$x(A,R) = A \cdot R$$

$$L(A,R) \geq 2 \cdot \pi \cdot \sqrt{A \cdot R}$$

Figure 8 *Variation of wheel radius and cure fitting*

The relationship between corrugation amplitude, wavelength and wheel radius is determined as

$$L \geq 2 \cdot \pi \cdot \sqrt{A \cdot R} \qquad (6)$$

In chapter 4, this finding is compared to the simulation results.

4. Simulation and evaluation

The data used for simulation based on vertical excitations is applied to the MBS represented by a sine function as mentioned before. Comfort is evaluated in accordance to the mean comfort evaluation presented in EN 12299 [7]. The measured accelerations are filtered using weighting curves. Then, *5 s rms* (root mean square) values are taken. Finally, the 95th percentile value for a duration of *300 s* are evaluated and combined to the N_{MV} value, which combines results for all three dimensions. This process is shown in Figure 9.

However, by experience, *300 s* of simulation time are not necessary for this application, because the harmonic excitations are continuous. Thus, simulation time is shortened to *10 s*. This is a reasonable compromise between sufficiently converging results and saving both, simulation time and storage.

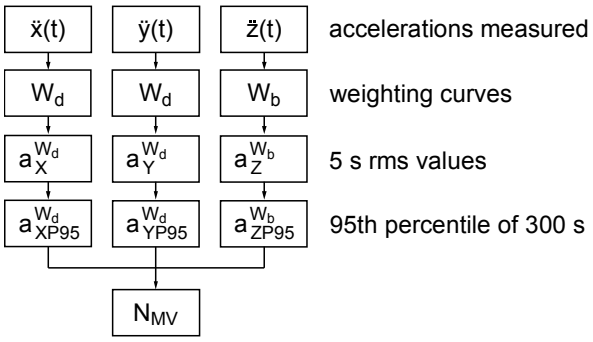

Figure 9 *Mean comfort calculation according to EN 12299*

In EN 12299, mean comfort values up to *2.5* are representative for a comfortable ride quality [7]. Since this evaluation only covers corrugation, the results represent a deterioration of comfort that can be added to the predominant comfort level caused by other track irregularities. Hereinafter, this effect based on corrugation is mentioned as comfort deterioration. To show the influence of wavelength and amplitude on comfort deterioration, graphics of the simulation results are presented in Figure 10.

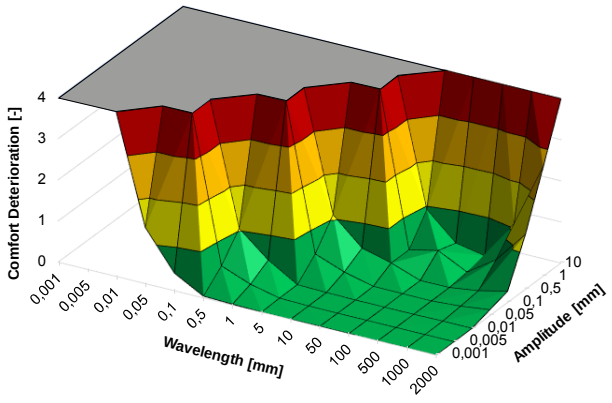

Figure 10 *Simulation results*

The comfort deterioration increases rapidly from zero to four. The green surface in Figure 10 shows the range of acceptable comfort. Severe deterioration can be observed above *1.0*, thus above the green surface. Starting from the red range, sporadic derailments are observed. Above *4.0*, derailment is most likely to occur.

An important finding of this study is that comfort deterioration does not depend on the velocity of the vehicle considering the constraints of simulation. The deterioration is mostly dependant on the corrugation's wavelength and amplitude. Therefore, the simulation results shown here represent all considered velocities. This is due to the geometric relationship presented in chapter 3 that has the most influence on the observed behaviour.

Issues with the simulation were observed at or around the 0 to 1 transition line, which resulted in warnings or fatal errors. However, those warnings and errors did not occur exclusively at the 0 to 1 transition line, which was

attributed to the fact that the numerical simulation does not account for a dynamic wheel-rail interaction based on more than one contact point. As seen in Figure 11, the simulation problems occur within a range below and above from the transition line. The difference observed was found to originate in the loss of contact between wheel and rail during simulation. The loss of contact in general states a safety issue, regardless whether the derailment coefficient (*Y/Q*) stays below *0.8* or *1.2*, which represent the limits of derailment prescribed in standard EN 14363 [8]. Hence, from the calculations in chapter 3, even a limit related to safety could be derived. For amplitudes between *0.5 mm* and *1.0 mm* and wavelengths above between *50 mm* and *100 mm*, several *Y/Q* values significantly exceeded the limit value *1.2* of the derailment coefficient. This is due to the very low wheel load *Q* that increases the ratio *Y/Q*.

As it can be seen in Figure 11, simulation results (orange line) and calculated results (blue line) are not the same for most of the spectrum. They cross at approximately *120 mm* wavelength and *1 mm* amplitude. Simulations performed on wavelength and amplitude combinations below the intersection point (i.e. lower wavelengths and amplitudes) resulted in a loss of contact between wheel and rail along and above the orange line. Conversely, simulations above the intersection (i.e. longer wavelengths and higher amplitudes) resulted in warnings and fatal errors at and around the 0 to 1 transition line (blue line). These results are in accordance with Equation (1). In this configuration, the crossing represents the change from the geometrical influence on the dynamic influence; however, it is also the point where the highest derailment coefficient value *Y/Q* was observed.

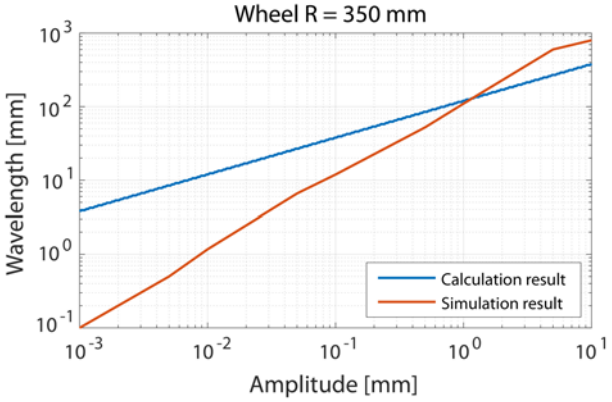

Figure 11 *Result of Calculation and Simulation*

In the graph, the orange line represents a boundary of contact loss and the blue line represents a problem with the number of contact points between the wheel and the rail. The gap between both lines can be explained by the mathematical approach not accounting for dynamic influences like wheel load changes due to vehicle suspension or the influence of the contact patch, whilst the simulation does.

A limit boundary representing track issues mathematically and dynamically can be formed by both lines, the orange and the blue one exceeding the point of intersection.

In summary, it must be stated that the simulation algorithm does not perform well for more than one contact point.

5. Application Example: Dynamical Vehicle Behaviour

Regarding the dynamic vehicle behaviour, there are different vehicle responses depending on the excitation caused by rail. When using MBS, the excitation varies for each parameter (i.e. driving velocity, wavelength, amplitude) and thus the vehicle response consists of an indefinite number of solutions. Therefore, a representative example at one specific velocity and one specific amplitude is given here to demonstrate how the vehicle behaves dependent on different corrugation wavelengths. The vehicle response is represented by comfort deterioration values determined as mentioned above.

Figure 12 shows mean values of the comfort deterioration N_{MV} for different wavelengths. The velocity is kept constant at *80 km/h* and the excitation amplitude is always *0.46 mm*. This value's origin is based on Equation (6) when wheel radius is *350 mm* and the minimum reference wavelength for long-pitch corrugation is used (*8 cm*, see chapter 1). Nevertheless, the shortest wavelengths are chosen at lower values (starting from *25 mm*) to see how the vehicle behaves. The maximum wavelength is *3 m*, dependent on the factor *1.5* of the axle-centre distance of *2 m*. The mean value is used to smooth the curve. It is calculated using in total five values including the reference value (the actual wavelength), meaning that the two values before and the two after are used.

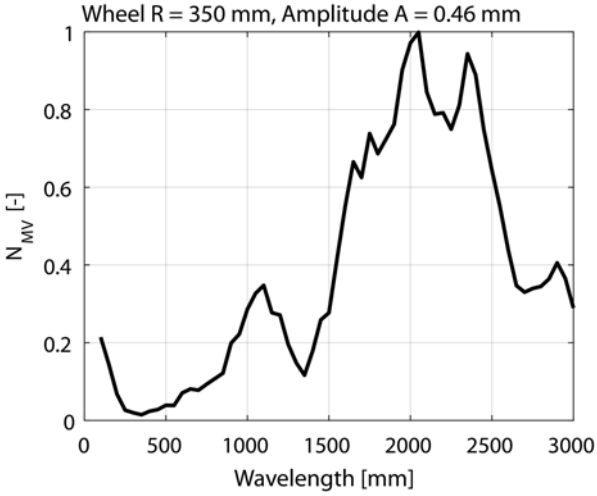

Figure 12: *Mean Values of Comfort Deterioration for different Wavelengths*

It is evident that N_{MV} never exceeds *1*. In most cases, it is even lower than *0.5* what would represent a very comfortable ride when concerning track quality. But there are some wavelengths leading to significantly high values: short wavelengths lead to *0.8*, which is an increase of factor *4* compared to a reference value *0.2*. This reference corresponds to *80 mm*, which is the lowest wavelength possible according to Equation (6). Those

wavelengths near to the axle-centre distance result in even higher comfort deterioration values of *1* compared to the reference value (factor *5*). Also, for multiples of this distance, similar effects are observed, but on lower values.

The increase for short wavelengths is based on disturbances in the simulation as explained in chapter 3: the wavelength is too short to simulate an exact one-point-contact, see Equation (6), what leads to vertical shocks and thus to high comfort deterioration values. The increase for wavelengths about the axle-centre distance is caused by a maximum amplitude addition so that both wheelsets "see" the same displacement in z-direction, which is independent of velocity.

6. Conclusion

Although several measures and design actions to reduce the potential of corrugation formation are in place already, it is still necessary to quantify corrugation to assess the vehicle's reaction regarding comfort and safety. Thus, maintenance and design strategies can be optimised in the frame of comfort and safety for both, passengers as well as goods, on the one hand and life cycle costs on the other hand.

This research study shows the effects of corrugation on vehicle behaviour using multi-body simulation as well as the boundaries of simulation. The model applied contains the real characteristics of light rail vehicles operating in Stuttgart, Germany. Corrugation is realized by synthetic sine curves. The results are analyzed to demonstrate the influence of corrugation on the ride comfort, called comfort deterioration. Ride comfort is evaluated for periods of ten seconds according to mean value evaluation EN 12999 [7]. One of the main findings of the study is that velocity does not play a role on the comfort deterioration. A limiting curve was created mathematically representing the area where more than one contact point between the wheel and the track occur. So this curve represents a limitation for both, simulation capability and running behaviour in matter of vertical raise of the wheel. An additional problem was determined based on warnings or fatal errors in the simulation caused by more than one contact point per wheel in longitudinal direction.

Within the scope of this study, derailments were no common issue. Only a few derailments were observed above the 0 to 1 transition line (see Figure 11, blue line). It was further observed that shorter wavelengths in combination with higher amplitudes result in higher accelerations, which does not only mean a more uncomfortable ride, but also a higher risk of derailment. This is due to the steeper slope formed by the short wavelength and the higher amplitude.

Furthermore, comfort deterioration results are compared for a representative constant velocity and amplitude. It was found that also in this case the result of the mathematical approach can be applied to simulation as can be seen from a significantly high comfort deterioration for wavelengths lower than allowed by Equation (6). Also, a relationship between the axle-centre distance and comfort deterioration is visible when using wavelengths in the range of this distance. This fact is based on bogie geometry and therefore independent of the driving velocity.

Since only driving velocity, corrugation's wavelength and amplitude were considered, further studies should investigate the influences of other parameters as well. For example, curve radius and cant of a curved track have a high influence on the formation of corrugation. To get more detailed results, also real measured data must be used in proceeding simulations.

Finally, the possibility to simulate with more than one contact point in longitudinal direction must be covered by further research, i.e. development of algorithms or substitution models. This additional use must be brought not only to light-rail systems, but to the entire railroad sector. Working on this topic is a good example for rewarding theoretical research and how future work will enable to quantify and predict corrugation better. This will help to mitigate one of the biggest cost drivers in terms of rail maintenance significantly.

Abstract: The application of a multidisciplinary methodology for the prediction of rail damage in railway crossings is demonstrated. Two rail steel grades are compared: R350HT and rolled Mn13. Based on a load sequence designed by Latin hypercube sampling considering the variation in traffic conditions, the results include the calculated plastic deformation and wear after a load collective corresponding to 0.8 MGT of traffic. The methodology has been introduced in earlier work but is here improved in terms of computational efficiency. Wheel–rail normal contact is solved using a Hertzian-based metamodel accounting for the inelastic material response. It is shown that the rolled Mn13 crossing experiences more ratchetting strain than the R350HT counterpart.

Keywords: switches & crossings; S&C; FE method; plastic deformation; wear.

1. Introduction

Railway crossings represent a structural and geometrical irregularity in the railway track that induces a severe load environment. As a result, frequent maintenance of crossings is required due to damage in the forms of wear, plastic deformation and breaking out of material caused by surface or subsurface initiated rolling contact fatigue cracking. The dynamic wheel–rail interaction in the crossing panel typically results in an impact load on the crossing nose (traffic in facing move) or on the wing rail (trailing move). The magnitudes of these impact loads depend on system dynamics, vehicle speed, axle load and on the impact angle, which is the difference in inclination between the vertical wheel trajectories on the wing rail and crossing nose. Furthermore, worn wheels contribute to the increase in impact load. If the rail profiles are not corrected in time, the deteriorated profiles will magnify the impact loads.

For a given traffic situation, at least three different approaches can be identified as means of reducing the wheel–rail contact forces and damage in the crossing panel by design. These are the optimisations of: 1) crossing and wing rail profiles (geometry); 2) stiffness of the resilient elements in the crossing, such as rail pads, baseplate pads and implementation of under sleeper pads; and 3) material. A methodology for the optimisation of the shape of the profiles along the length of the crossing nose was described in [1,2]. Both studies emphasise that the results of the optimisation are only relevant for the traffic conditions considered. The effect of rail pad stiffness on different damage modes was presented in [3].

In the present study, the influence of material selection is explored. Common materials used in crossings include austenitic steels (such as the explosively depth hardened manganese steel Mn13), bainitic steels (B360) and high strength pearlitic rail steels (such as the fine-pearlitic rail steel grade R350HT). Based on field experience, each of the materials has different advantages in terms of resistance to the various types of damage. For example, the manganese steel, which is predominant in the Swedish rail network since the 1990s, has a higher rate of plastic deformation during the initial load cycles but at the same time a better adaptability of rail profile to meet the variation of worn wheel profiles in traffic. Choosing a material that for given traffic conditions is stable in geometry and resistant to fatigue cracking can reduce damage and therefore the maintenance costs. Hence, for a cost-efficient and safe optimisation of material selection in railway crossings, it is integral to predict and compare the long-term damage and performance of different steel grades by simulations.

A literature survey on the modelling of surface plasticity and wear in railway applications was performed by Enblom [4]. It was concluded that most studies of wheel/rail damage focus on one of several damage modes and that models where wear and plastic deformation are integrated are needed. Such a study was conducted using a multidisciplinary simulation methodology developed by Johansson et al. in [5]. It is comprised of the following steps that are repeated in an iterative process:

I. For a given traffic situation, simulation of wheel–rail contact forces, contact positions and creepages using a multibody simulation (MBS) software;
II. For each contact position, calculation of contact stresses and contact patch size using a 3D finite element (FE) model with non-linear material properties;

III. Calculation of accumulated plastic deformation using a non-linear 2D FE model, and wear based on Archard's model for sliding wear [6];
IV. Smoothing of the summed accumulated profile change, which is used as input in the next iteration, etc.

To capture the various contact load conditions that the studied switch and crossing (S&C) are subjected to in the field, the methodology operates on statistical input distributions of simulation parameters (wheel profile, vehicle speed and friction coefficient). A validation of the methodology has previously been performed by comparing predicted rail profiles with those measured at Härad (Sweden) [5] and Haste (Germany) [7]. Since the methodology is computationally expensive, another aim of the current work is to improve the methodology in terms of robustness and computational efficiency.

2. Multibody simulations

As described above, the first step of the methodology involves simulations of vehicle–track dynamic interaction. The model and the results of the simulations in this section are adopted from [8] and summarised here for the convenience of the reader. The study considers a passenger vehicle travelling in the through route of the crossing panel of a 60E1-1:15-R760 turnout in the facing move. The vehicle–track interaction was modelled in SIMPACK 2017.

The used vehicle is the Manchester benchmarks passenger vehicle model [9] with standard vehicle configuration, except for the axle load that is increased to 19.1 tonnes by adjusting the car body mass.

The track model is a planar system of rigid masses, springs and dampers running with each wheelset. It is depicted in Figure 1.
The track model has nine degrees of freedom in total, which are distributed as follows: each rail has one vertical and one lateral degree of freedom; the sleeper body has one vertical, one lateral and one in-plane rotational degree of freedom; each ballast mass has one vertical degree of freedom. The crossing rail geometry is taken from [1]. In total, 90 rail profiles are used to represent the crossing.

For each simulation, a unique combination of vehicle speed, wheel–rail friction coefficient and wheel profile is generated using Latin hypercube sampling. This allows to mimic the traffic environment that a crossing would experience in the field. This is achieved using a sample of 276 measured wheel profiles from Bombardier Regina passenger trains [10] to represent the variation in wheel profile geometry, while the vehicle speed and wheel–rail friction coefficients are assumed to be normally distributed with means 160 km/h and 0.35, and standard deviations 5 km/h and 0.07, respectively.

Depending on the direction of traffic, a wheel travelling over a crossing generally induces an impact load on the crossing rail or on the wing rail.

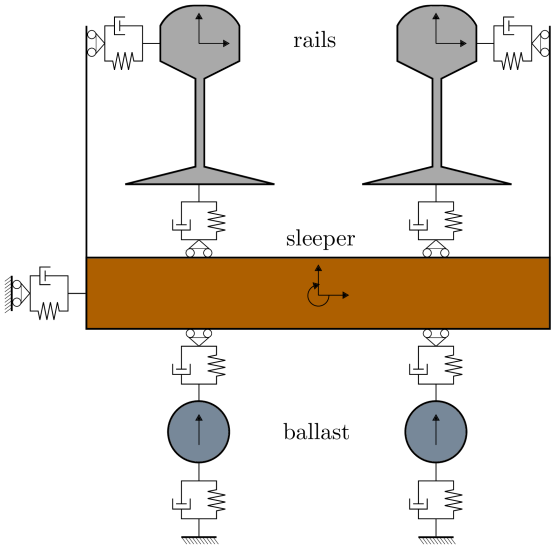

Figure 1 *Track model. Arrows denote degrees of freedom.*

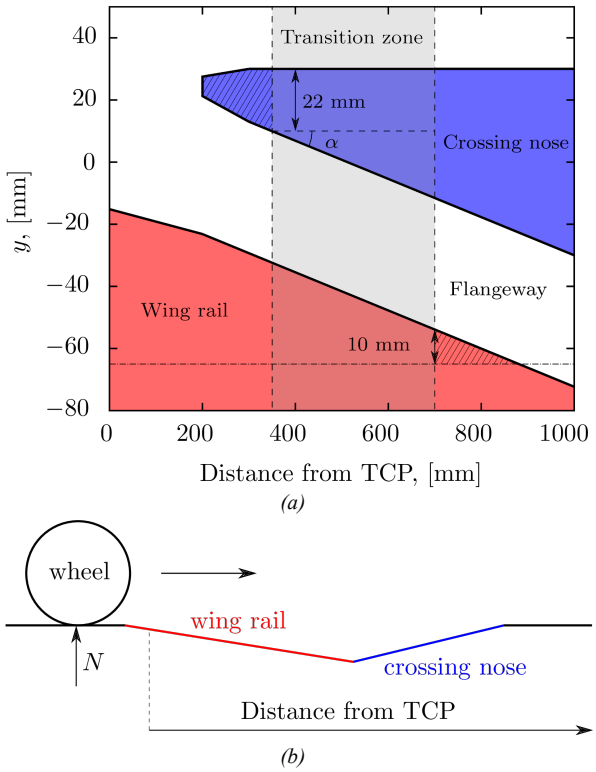

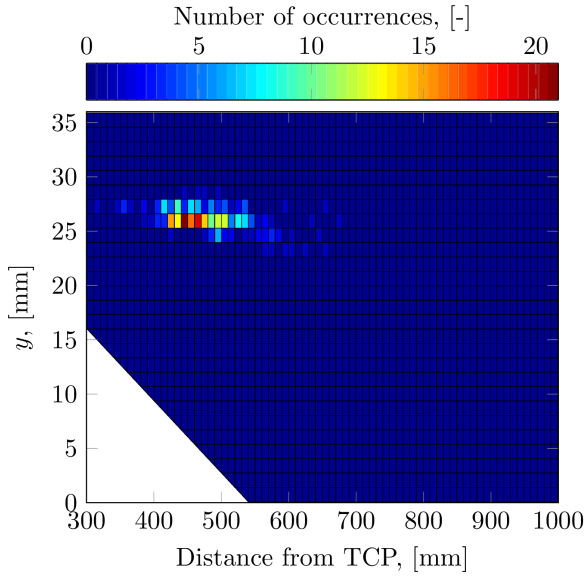

Figure 2 *Crossing views: (a) top view, and (b) side view. TCP stands for theoretical crossing point.*

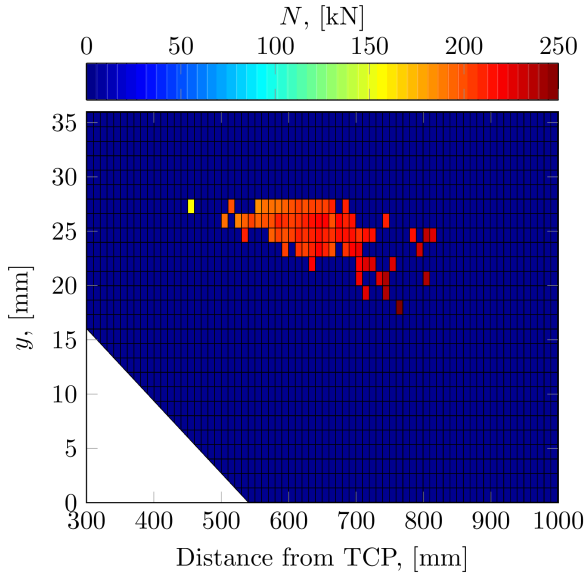

The impact load is caused by the downwards-upwards motion experienced by the wheel as it rolls along the wing rail and over to the crossing rail or vice versa, see Figure 2. On the wing rail, the vertical motion is caused by the conicity of the wheel and the significant change in lateral wheel–rail contact position that occurs due to the lateral deviation of the wing rail in the running direction. On the crossing rail, the lateral contact position is relatively constant but the crossing rail has a vertical inclination in the traffic direction.

The simulations of dynamic vehicle–track interaction provide the positions and magnitudes of the wheel–rail contact forces that are needed to solve the contact problem in step II of the methodology. This allows to

generate contact maps as shown in Figure 3. Figure 3(a) serves as a heat map for the first contact points on the crossing rail and gives insight about their locations. It is worth noting that the rail geometry change between subsequent wheel passages is not considered at this stage. The location of the maximum normal contact force of each wheel passage is illustrated in Figure 3(b). For the considered load sequence, it is evident that the largest contact force appears between 700 and 800 mm after the TCP.

(a)

(b)

Figure 3 *Contact maps: (a) first contact point occurrence, and (b) maximum normal contact force.*

3. Wheel–rail contact

In the second step of the original methodology described in the introduction, the wheel–rail normal contact was solved using the finite element method (FEM) under the assumption of constant local curvature for the two bodies in contact. Unlike the contact theory of Hertz [11] or Kalker's variational method [12], FEM is not restricted to elastic material behaviour only, and as Kalker's method, it supports arbitrary geometries. However, FEM is computationally very expensive. This is why, in [13], it was replaced in the methodology with a metamodel. Doing this allows to save about 15 minutes per contact simulation on a computer equipped with a "haswell" CPU and 3 GB of RAM.

The metamodel is inspired by the Hertzian theory of contact and therefore provides a solution for elliptic contact, but it is augmented to support elasto-plastic material response. Figure 4 shows how the maximum von Mises stress in the rail estimated by the metamodel relates to the FE solution. The red crosses mark the metamodel results. The closer the crosses are to the blue line, the better the agreement with FEM. To quantify the observed results, a coefficient of determination R^2 is used. It shows how much (as a fraction of a unit) of variability in the data is accounted for by the metamodel.

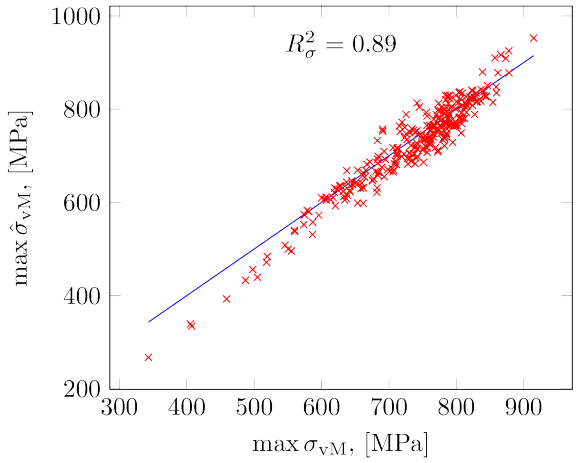

Figure 4 *Evaluation of metamodel for R350HT in terms of maximum von Mises stress. $\hat{\boldsymbol{\sigma}}$ with symbol ^ denotes output from metamodel, while $\boldsymbol{\sigma}$ without ^ denotes FE output.*

3.1. Material modelling

Since the intention is to capture the inelastic material response during contact for different materials, a material model or at least a set of model parameter values is required for each material. To this end, an appropriate material model needs to be selected and the model parameters need to be chosen accordingly. For this it is necessary to use material test data. Figure 5 shows results from uniaxial cyclic stress-controlled experiments for R350HT and rolled Mn13 from Schilke et al [14]. It is evident that both materials accumulate a net strain during each load cycle, i.e. they both exhibit a ratchetting behaviour. The model by Ohno and Wang [15] is employed in this study as it is an example of a model capable of addressing this behaviour. The model parameters were calibrated (see [8] for more details) to minimise the discrepancy between simulations and experiments. The calibrated model will also be used in step III of the methodology to simulate plastic deformation.

By examining the experimental data, it can also be seen that the rolled Mn13 is softer than the R350HT. For example, the rolled Mn13 accumulates more ratchetting

strain after the first load cycle than the R350HT after 25 cycles. Also, the Mn13 undergoes considerable plastic deformation during the initial cycle. During subsequent cycles the rolled Mn13 approaches elastic shakedown, whereby the strain rate slows down and the net strain becomes nearly constant. Conversely, the R350HT has a pronounced ratchetting with noticeable strain accumulation in each cycle.

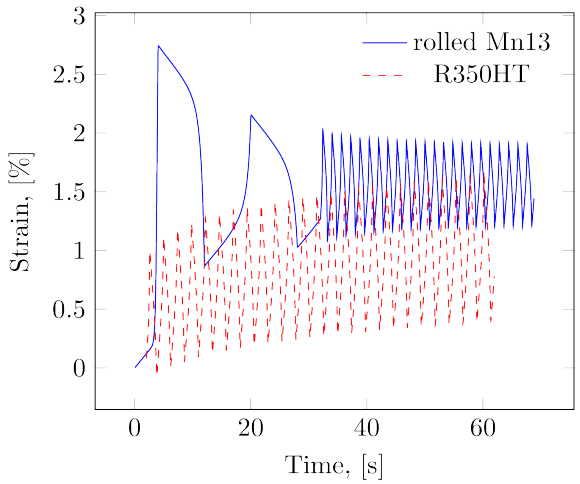

Figure 5 *Experiments for 25 load cycles for rail grades rolled Mn13 (solid line) and R350HT (dashed line).*

3.2. Metamodel results

Based on the calibrated material model for each of the two materials, it is possible to tune the metamodel parameters (this procedure is described in [13]) and compare the results. Figure 6 illustrates types of output from the metamodel for all wheel passages evaluated at the cross-section that is associated with the highest impact load (750 mm after TCP, see Figure 3(b)). The first plot shows the histogram that compares contact patch areas for the two materials. As could be anticipated from the discussion in the previous subsection, the softer rolled Mn13 steel results in contact patches with larger areas. It can be noted that there is a considerable spread in the magnitudes, between 0.5 and 3 cm^2. Figures 6(b) and 6(c) present comparisons in terms of maximum contact pressure and maximum von Mises stress. In both cases, it is evident that the higher values are obtained for the crossing made of R350HT. The interval of values for the rolled Mn13 is narrower than for the R350HT because of the lower strain hardening.

4. Damage in crossings

A review of common damage mechanisms in S&C is given in [16]. The mechanical damage is divided into three categories:

1. Plastic deformation.
2. Wear.
3. Fatigue.

The results in this section concern the first two categories.

Plastic (permanent) deformation develops as the result of dislocation movements in the grains of the material due to wheel–rail contact stresses exceeding the yield limit. Plasticity in metals can lead to undesirable residual stresses and is often a precursor to crack propagation.

Wear is the loss of material from a surface in contact. In the context of wheel–rail contact, two situations that induce wear are identified: sliding and rolling. Sliding is more detrimental in terms of wear rate and it is common for wear models to relate the amount of wear to the sliding distance (see e.g. [6]). Even though the rolling motion is mainly associated with the fatigue driven wear mechanisms, some micro-sliding may occur as well.

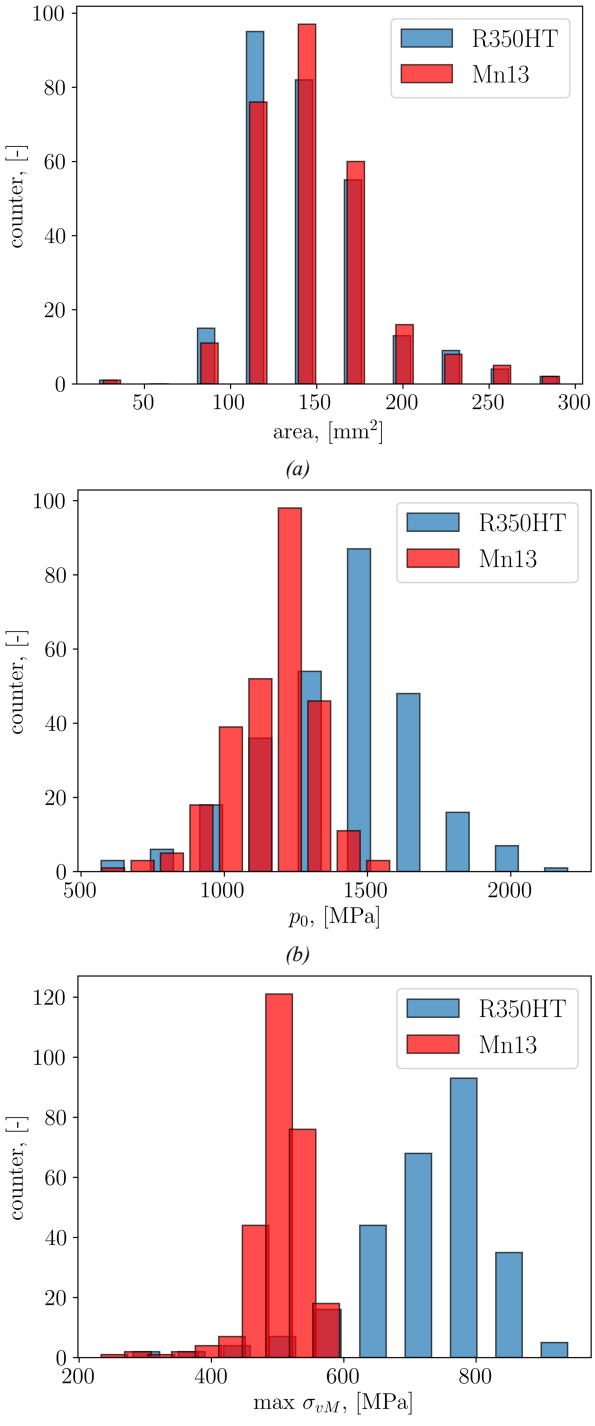

Figure 6 *Comparison of responses from metamodels for two rail steel grades: (a) contact patch area, (b) maximum contact pressure and (c) maximum von Mises stress.*

4.1. Plastic deformation

The solution of each wheel–rail contact becomes the input for step III of the methodology, which deals with the predictions of plastic deformation and wear.

Nowadays, non-linear FE analysis is the standard tool for the simulation of plasticity. However, it is associated with large computational expenses when dealing with the 3D geometry of the crossing. To reduce the computational effort in the methodology, the plastic deformation is computed only for selected rail cross-sections. Since the input is given for a 3D case, special care needs to be taken for the conversion to a 2D problem, which is done here by adjusting the applied load to match the same maximum von Mises stress level as provided by the metamodel.

Plastic deformation is simulated for a load collective of 150 load sequences, i.e. the loads from 276 unique wheel passages are repeated 150 times, which is equivalent to 0.8 MGT of traffic. Damage is generated by leading wheelsets accounting for one contact point. Full slip is assumed in the contact patch with the same friction coefficient as defined by the load cases in the load sequence. Therefore, the tangential traction has the same spatial distribution as the normal pressure.

The results of the simulations for both materials are given in Figure 7. The cross-section of the rolled Mn13 crossing is subjected to a larger shape change. More results from simulations of plastic deformation are available in [8].

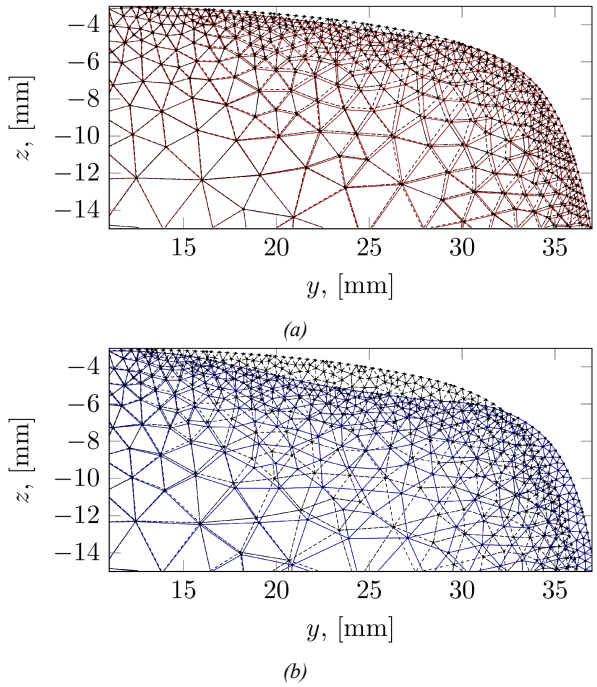

Figure 7 *Unscaled accumulated plastic deformation (solid lines) after 0.8 MGT of traffic for two rail steel grades: (a) R350HT and (b) rolled Mn13.*

4.2. Wear

The Archard's model [6] is used to simulate wear due to sliding. The model suggests that the volume of material being worn is proportional to the normal force N and the sliding distance s, and inversely proportional to the hardness of the softer material H:

$$V = \frac{k}{H} N s, \tag{1}$$

where k is a non-dimensional wear coefficient.

The wear rate depends on the wear regime that can be specified by k using a wear map, see e.g. [17]. Unfortunately, the wear map data available in the literature are scarce. In the present work, the average wear rate of 140 mm^3/MGT measured for an explosively depth hardened Mn13 crossing at Niklasdorf in Austria [18] is used. This wear rate has been used to calibrate the ratio k/H in Equation (1). One load sequence was considered in the simulation and the wear was scaled to correspond to 1 MGT of traffic. The calibrated value of k/H for explosively depth hardened Mn13 is 8.7×10^{-14} m^2/N. Unfortunately, a corresponding tuning of the ratio k/H for R350HT has not yet been possible as no such turnouts were included in the field test campaign in Austria.

Based on the calibrated wear model for explosively depth hardened Mn13, the calculated wear depth distribution after 150 load sequences is illustrated in Figure 9. Damage is generated by potential two contact points from all four wheels in the vehicle model. The maximum wear depth is 157 µm and positioned at 0.53 m from the TCP, which is in the region where most transitions from the wing rail to the crossing nose take place. Due to the large spread in worn wheel profiles, the accumulated wear is distributed over a band that is increasing in width along the crossing nose. At 0.75 m from the TCP, the maximum accumulated wear depth is 39 µm. This corresponds to around 2% of the maximum plastic deformation.

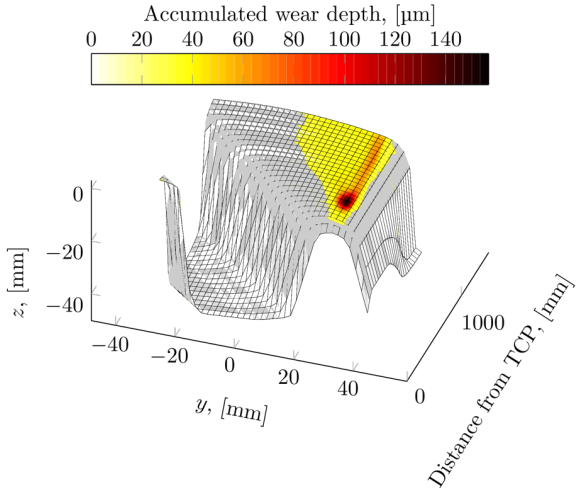

Figure 9 *Distribution of accumulated wear for Mn13 after 150 load sequences.*

5. Conclusions

Results of the updated multidisciplinary simulation methodology have been presented for two rail steel grades: R350HT and rolled Mn13. Based on the solution of a wheel–rail normal contact problem, provided by an elasto-plastic Hertzian-based metamodel, plastic deformation was computed for a loading equivalent to 0.8

MGT of traffic (41400 wheel passages). For the same amount of traffic, wear was estimated using Archard's equation. The loading accounts for the spread in traffic conditions by means of three random variables: vehicle speed, worn wheel profile and wheel–rail friction coefficient.

The comparison revealed that after 0.8 MGT, which corresponds to about two weeks of traffic for an average crossing in Sweden, the overall change of profile and the amount of ratchetting strain were smaller for the crossing made of R350HT. This situation might alter if more load cycles are considered, since the stabilised ratchetting rate is higher for the R350HT as compared with the stabilised ratchetting rate for the rolled Mn13.

In terms of sliding wear, the simulations suggest that the maximum wear occurs soon after the transition from the wing rail to the crossing nose. For the rolled Mn13, it was observed that the predicted wear after the initial 41400 wheel passages was 2% of the predicted maximum plastic deformation. The wear model for R350HT needs to be calibrated once wear map data are available.

Acknowledgments
The performed work is part of the activities of the Centre of Excellence CHARMEC (CHAlmers Railway MEChanics). It is partly financed within the European Horizon 2020450 Joint Technology Initiative Shift2Rail through contract no. 730841. The authors would like to thank voestalpine VAE GmbH and the Swedish Transport Administration (Trafikverket) for their support. The simulations were performed on resources at Chalmers Centre for Computational Science and Engineering (C3SE) provided by the Swedish National Infrastructure for Computing (SNIC).

HYPEREUCTECTOID NON HEAT TREATED RAIL PERFORMANCE IN HEAVY HAUL

Dr Lindsey Smith

British Steel, Rail Technologies, Brigg Road, Scunthorpe, Lincolnshire, DN16 1BP

* E-mail: lindsey.smith@britishsteel.co.uk

Abstract: A hypereutectoid rail steel, HP335, has been monitored on a heavy haul site within a tight radius over a three year period. This paper describes the current findings and results of extending the potential operating window of HP335 grade rails into heavy haul locations.

Keywords: Hypereutectoid rail, rolling contact fatigue, site inspection, heavy haul, HP335, plastic flow

1 Introduction

Improved wear and fatigue resistance has been a driver for a step change in rail steel performance over the past decade due to the increase in traffic loading, reduction in maintenance time and hence a goal of longer track life. Historically the trend to improve the wear resistance of railway steels has been through an improvement in hardness, which is traditionally delivered through heat treatment methods.

In order to combat wear and Rolling Contact Fatigue (RCF), British Steel has developed a novel hypereutectoid steel, HP335 (also known as HPrail®). Unlike other rail grades that are designed to mitigate wear and rolling contact fatigue through heat treatment, HP335 is an as-rolled rail. HP335 was metallurgically engineered to have improved wear resistance, but also an improved resistance to RCF.

The chemical composition of HP335 is shown in Table 1 and mechanical properties in Table 2 compared that of R260 and R350HT.

	Grade		
	R260	HP335	R350HT
C	0.60 – 0.82	0.87-0.97	0.72 – 0.82
Si	0.13 – 0.60	0.75-1.00	0.13 – 0.60
Mn	0.65 – 1.25	0.75-1.00	0.65 – 1.25
P	≤0.030	≤0.020	≤0.025
S	≤0.030	0.008 – 0.020	≤0.030
Cr	≤0.15	≤ 0.10	≤0.15
Al	≤0.004	≤ 0.004	≤0.004
V	≤0.030	0.09 – 0.13	≤0.030

Table 1: Chemical composition comparison (%wt. Solid) of different rail grades. HP335 composition is British Steel specification

	Mechanical properties		
	R260	HP335	R350HT
Rm (MPA)	≥880	≥1150	≥1175
Elongation (%)	≥10	≥7	≥9
BHN hardness (centre line)	260 - 300	335 - 375	350 - 390

Table 2: Mechanical properties of different rail grades compared to HP335

To date, over 1000km of HP335 has been installed in locations with a range of curve radii experiencing a range of the key degradation mechanisms (wear, rolling contact fatigue, plastic flow, corrugation). HP335 makes up approximately 15% of UK rail demand.

HP335 was introduced into service in 2010 and has been extensively monitored for in excess of five years in the UK. In total eight sites were monitored closely with sites being inspected approximately every three months. Seven of the monitoring sites were installed on national rail infrastructure , and the eighth on a light rail network. Site locations were chosen based on historical degradation mechanisms to ensure that the rail was installed in some of the most harshest environments found within the UK. At one particular site, Hett Mill, the national operator (Network Rail) reported that a saving of around £250,000 GBP [1] had been achieved in a five year period when compared to the previous standard rail grade on a single track curve.

The extensive real-life track experience concluded HP335 was very good at resisting plastic deformation and RCF delivering similar if not superior performance to common heat treated rail grades such as R350HT. Sites inspected retained a very good crown profile, despite historically being prone to plastic flow on traditional non heat treated rail grades.

Given the conclusions from the monitoring sites, it was decided to monitor a ninth site on a heavy haul freight line within the UK. This paper will discuss the performance of HP335 at this heavy haul trial site.

2 Site background

The HP335 heavy haul trial site has been installed at Drax Power Station near to Selby, UK. The rail has been installed in a 200m radius curve, the operation speed is low (max 15mph /~24km/h). The rail profile installed is 56E1 and previously R260 grade rails were installed. Historic rail performance at the site was poor with both plastic flow and rolling contact fatigue limiting rail life,

in particular spalling on the low rail preventing ultrasonic testing.

HP335 was installed on both high and low rails on the arrival and departure curve routes. The arrivals curve (installed in July 2015), is subject to the UK maximum tonnage of 25 tonnes per axle. The vehicles traversing the departure curve (installed October 2014) are a mixture of loaded/unloaded wagons. This paper will primarily discuss the arrivals curve, as the departure curve since installation as remained in as new condition with little wear or signs of damage.

An example of the conditions found at the site on the arrivals line are shown in Figure 1 and Figure 2. In Figure 1 plastic flow can be seen to the field side of the low rail. This is caused in part due to vehicle tonnage and the track design. Depending on signal priorities, often vehicles must wait on the curve prior to entering the main power station facility, hence the bulk of the vehicle load will be placed upon the low rail.

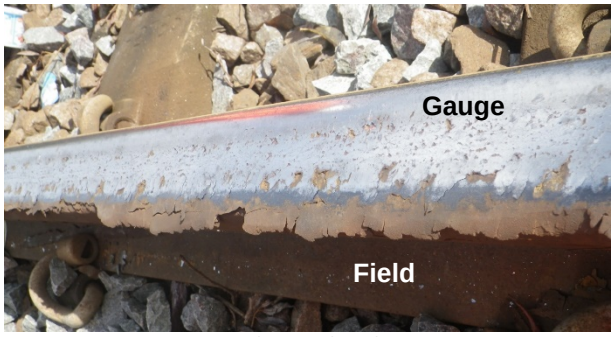

Figure 1: Typical example of plastic field flow on the arrivals low rail on the R260 rail.

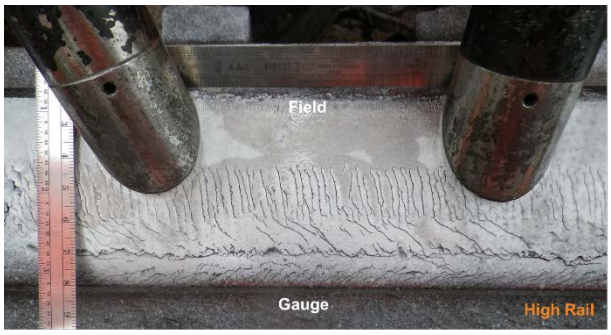

Figure 2: Typical example of RCF on the arrivals high rail on the R260 rail

Another damage mechanism on the arrivals curve low rail was spalling of the rail head. The rail would develop a 'snake skin' effect of shallow cracks that would join and cause the rail head to spall (Figure 1). It is this spalling that makes rail ultrasonically untestable, as the spalling on top may hide a crack below thus allowing it to propagate to failure (see Figure 4).

Figure 3: Example of spalling of the rail head on the R260 prior to replacement ~ 35MGT

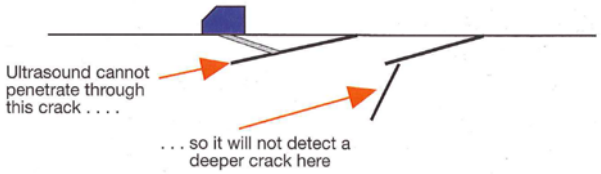

Figure 4: Schematic showing how cracks can be masked from the ultrasonic probe

Prior to the HP335 installation, the R260 was inspected. The installation date of the R260 was not precisely known, but visually inspection determined that the rail was manufactured in 2012 and 2013. Although the manufacturing date does not indicate when the rail was actually installed it is estimated that the service life of R260 was approximately two years old.

A site diagram can be seen in Figure 5. The circle prior to the overbridge denotes the signal where vehicles commonly must stop prior to entry to the site. A more detailed view of the arrivals curve is shown in Figure 6. As the trial has progressed the remaining R260 panels detailed in the schematic have been replaced with HP335 (although not monitored) due to the improved performance of the rails measured during this trial.

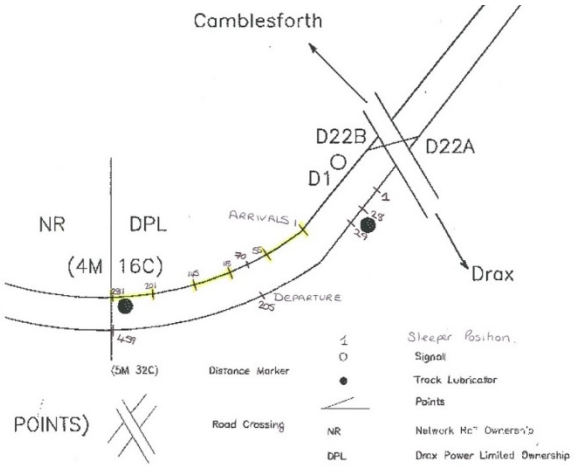

Figure 5: Site layout diagram

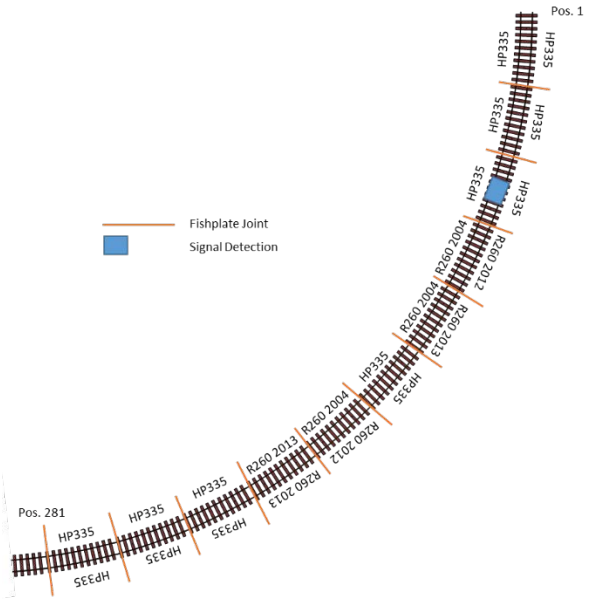

Figure 6:Detailed schematic of the HP335 installation on the arrivals curve.

3 In-service behaviour

The trial site has been monitored approximately every three months from installation. Visual inspection has been undertaken, with characterisation of rail surface damage including Magnetic Particle Inspection (MPI) and photographic records.

Rail profile measurements have been taken using a MiniProf device. The MiniProf device records the full transverse profile of the rail head. It produces a 2-D trace that can be compared to the reference profile to establish the amount of rail wear. A reference profile of the rail was taken post-installation to eliminate any manufacturing tolerance variations and all subsequent measurements have been compared to these.

3.1 Arrivals

Whilst undertaking the first inspection post reference (five months post installation) it was discovered that the arrivals curve had been ground erroneously by the national rail operator up to the signal detection magnet (see Figure 6). From the traffic data this is calculated to have been 6 MGT (million gross tonnes) of traffic after installation.

3.1.1 Low Rail

Figure 7 - Figure 14 denote a timeline of pictures taken looking down onto the rail head at sleeper position 255. At the 12 MGT (Figure 8) some low rail contact fatigue had started to develop towards the rail crown. The visual inspection also identified a number of shiny visible patches on the rail head and it is thought this have been caused through the rail experiencing high lateral shear stress. By 23 MGT at this position some clear distinctive RCF could be seen and this is shown in Figure 9. The direction of the cracks have been highlighted in Figure 10. There are three bands of cracks that can be visually seen, longitudinal, transverse and 45° to the transverse.

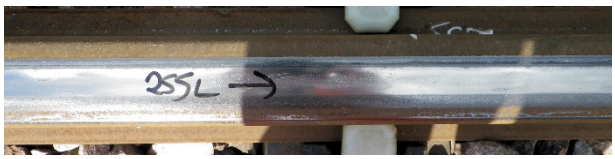

Figure 7: Arrivals curve - Low rail, Sleeper position 255. ~2 MGT

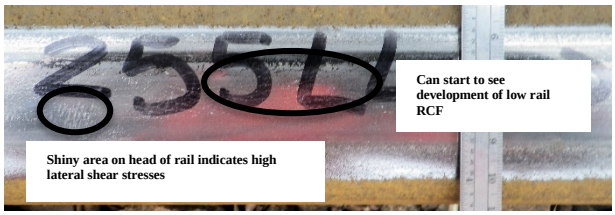

Figure 8: Arrivals curve - Low rail. Sleeper position 255. ~15 MGT

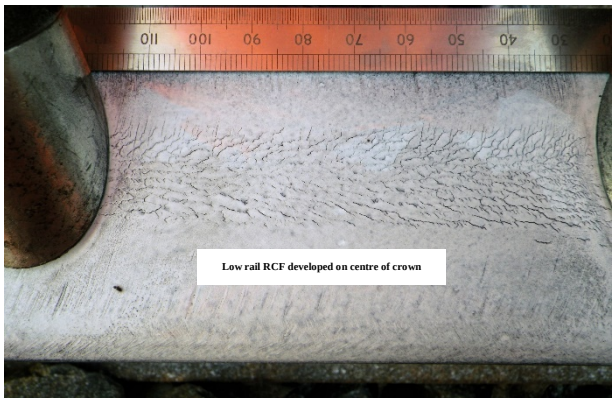

Figure 9: Arrivals curve - Low rail. Sleeper position 255. ~23 MGT

A preventative grinding regime was recommended to Drax Power to ensure that the maximum life could be achieved from their HP335 and that the rail would remain ultrasonically testable. A corrective yearly grinding schedule has been introduced. The HP335 rail was first ground at ~26MGT, Figure 10 and Figure 11 show photographs taken at sleeper position 255 before and after grinding. Figure 12 shows the rail profile measurement taken pre and post grinding at ~ 26 MGT. 0.7mm was removed from the centre of the crown.

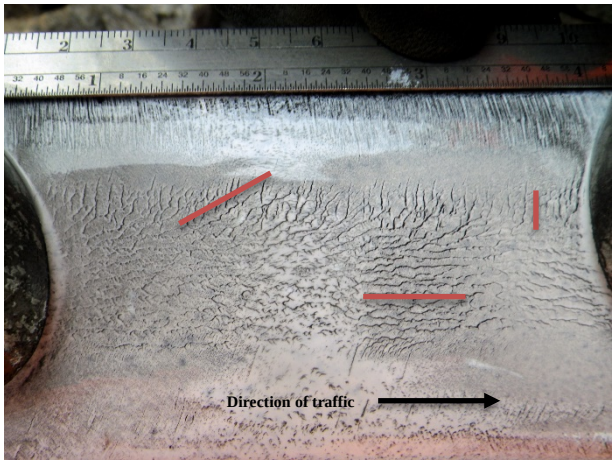

Figure 10: Arrivals curve - Low rail. Sleeper position 255. ~26 MGT – pre grinding. Picture shows magnetic particle inspection (MPI). Red lines highlight different direction of crack growth.

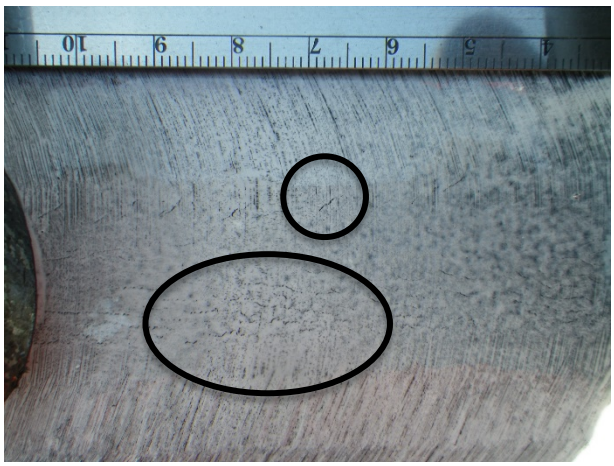

Figure 11: Arrivals curve - Low rail. Sleeper position 255. ~26 MGT – post grinding. Picture shows magnetic particle inspection (MPI). Black lines denote areas of remaining RCF.

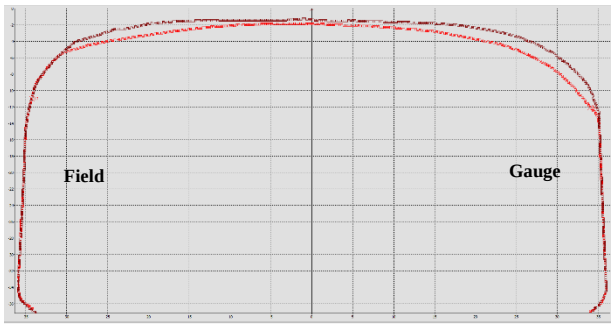

Figure 12: Rail profile measurement of pre and post grinding on the arrivals curve (low rail) at ~26 MGT. ~0.5mm removed from the centre of the crown.

Figure 13 shows the development of the cracks on the low rail at ~ 4 MGT post grinding. The grinding marks on the gauge corner were still visible. At ~ 38 MGT the cracks have again grown to a similar length of that at ~26 MGT (see Figure 14). The rails were ground again in April 2018 (38 MGT).

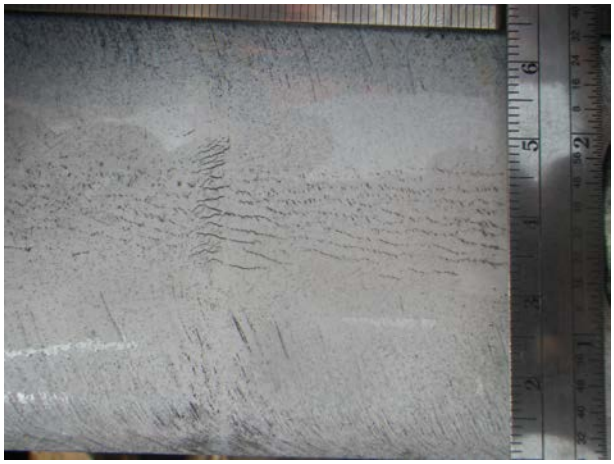

Figure 13: Arrivals curve - Low rail. Sleeper position 255. ~30 MGT. Picture shows the development of cracks since grinding at ~26 MGT.

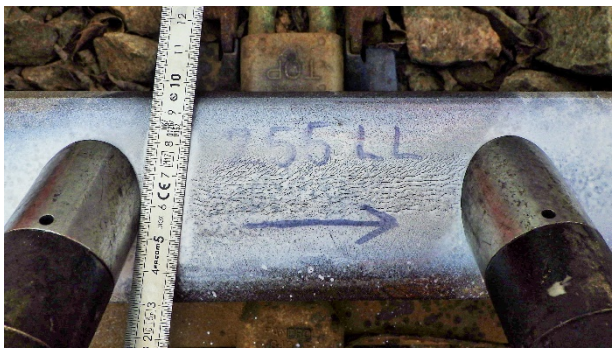

Figure 14: Arrivals curve - Low rail. Sleeper position 255. 33 months post installation.

Whilst, rolling contact fatigue cracks are still present within the HP335,their reduced growth combined with suitable grinding has prevented the rails from spalling and thus they still remain ultrasonically testable unlike the R260.

Where the HP335 has excelled in this trial on the low rail is the prevention of plastic flow. Figure 15 and Figure 16 compare a rail profile measurement trace of the HP335 and R260 at similar tonnage and position. On the R260 (Figure 16) the plastic deformation on the field side can be seen, whilst the HP335 (Figure 15) retains its crown profile. Headwear on the HP335 (2mm) has also halved in comparison to the R260 (4.3mm) even inclusive of the additional artificial wear through grinding.

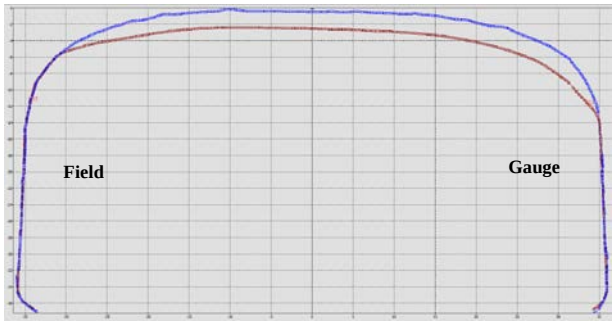

Figure 15: Arrivals curve - Low rail. Sleeper position 255. ~35 MGT (Pre-grinding). Rail profile measurement trace compared to reference. No plastic deformation. Blue: Ref, Red: Measured. Headwear:2.2mm

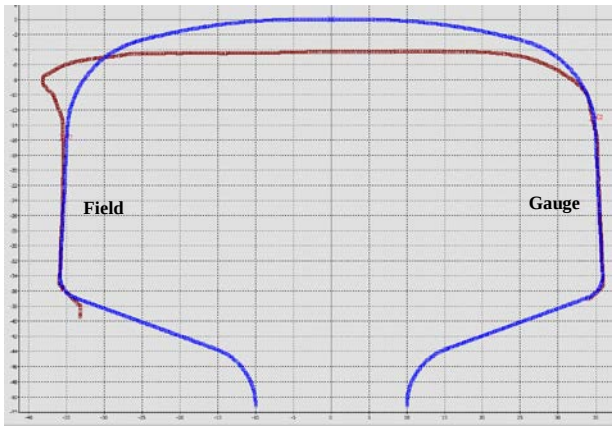

Figure 16:An example of a R260 rail profile pre-installation on the R260 low rail. ~35 MGT. Rail profile measurement compared to nominal. Vertical wear and plastic deformation. Headwear 4.3mm.

3.1.2 High Rail

The high rail inspection history follows a similar theme to that of the low rail. Rolling contact fatigue was present on the R260 rail prior to replacement. On the high rail that was inspected multiple patches of RCF were exhibited and a typical example is shown in Figure 17. The R260 rail also experienced side wear and a rail profile measurement is shown in Figure 18. The measurement was taken just before renewal at ~35 MGT.

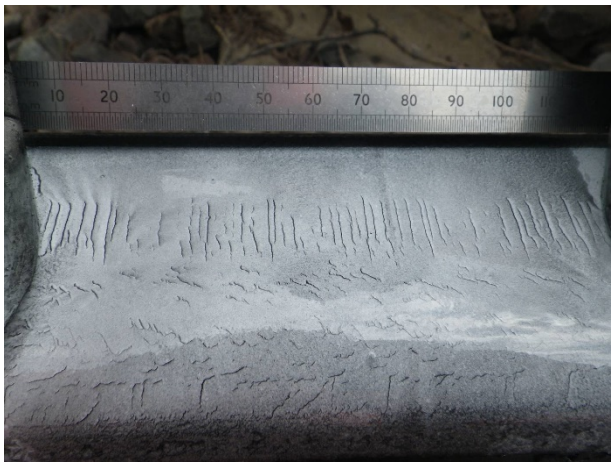

Figure 17: R260 Arrivals curve - High Rail.~35 MGT.

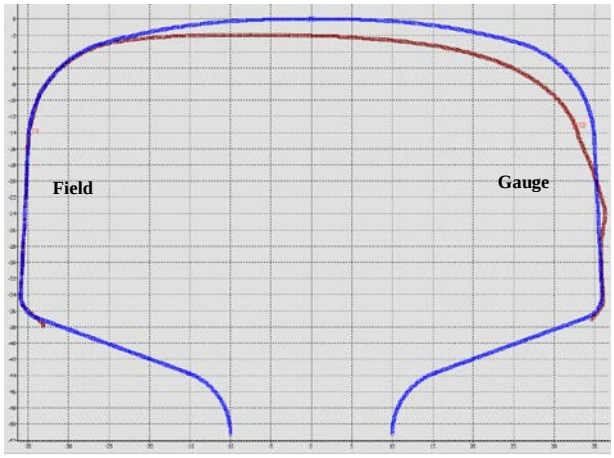

Figure 18: R260 Arrivals curve - High Rail ~ 35 MGT. Typical example. Note sidewear on the gauge corner

Whilst it is difficult to compare R260 vs HP335 because the rail has been ground on the HP335, Figure 19 shows a photograph of the HP335 at a similar position to the R260 (Figure 17) prior to grinding at ~ 26MGT.

Corrective grinding has been undertaken twice since HP335 was installed (and one erroneous on part of the trial site). Figure 20 shows a photograph taken after the second corrective grind at ~38 MGT. Not all the surface cracks were removed, as can be seen in the highlighted section.

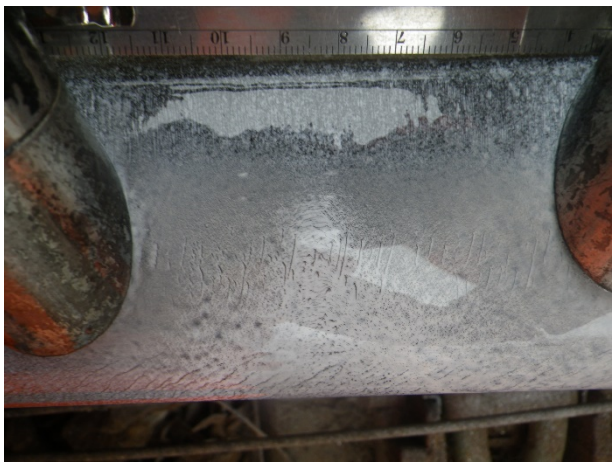

Figure 19: HP335 Arrivals curve - High Rail. Sleeper position 118 ~26 MGT.

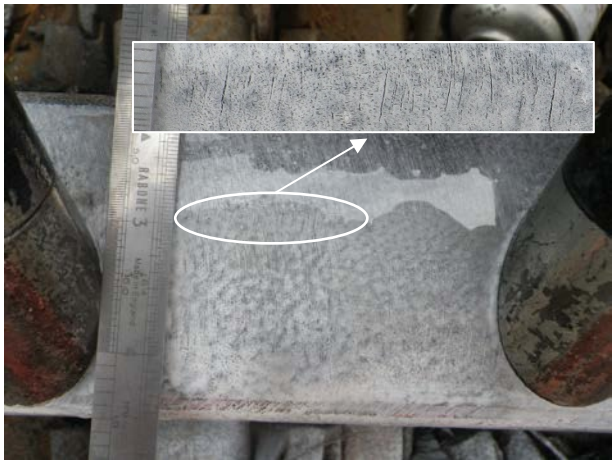

Figure 20: HP335 Arrivals curve - High Rail. Sleeper position 118. 33 months post install. Picture taken after corrective grinding.

Month since install	~ MGT	Headwear (mm)
21 (Pre-Grind)	26	0.7
21 (Post Grind)	26	1.4
33 (Pre Grind)	38	1.6
33 (Post Grind)	38	2.3

Table 3: Headwear measurements pre and post grinding (high rail).

4 Discussion

The HP335 installed on the low rail of the arrivals curve has demonstrated the superior crown profile retention/plastic flow resistance that the rail grade has compared to the previous R260. The HP335 rail grade has a combined high yield strength and low elongation. It is this combination that is believed to offer the superior plastic flow resistance.

The life of the HP335 hypereutectoid rail has already exceeded the lifetime of the R260 rail. With an appropriate preventative grinding maintenance plan in place the life of the HP335 rail on the low rail will last multiple lifetimes compared to that of the R260. If the current grinding schedule is maintained then it is predicted that the rail will last 14 years in service based on current traffic (Figure 21) compared with two years for the R260.

Table 4 summarise the mm of head wear per million gross tonnes between the R260 and HP335 for both the low and high rail.. For purposes of comparison the artificial wear from grinding has been removed. If grinding is excluded for a like for like comparison then the wear rate has been reduced by a two-thirds on the low rail and a quarter on the high rail.

	~ MGT	Headwear mm/MGT
R260 low rail	35	0.12
HP335 low rail (grinding excluded)	33	0.04
HP335 low rail (grinding included)	33	0.06
R260 high rail	35	0.04
HP335 low rail (grinding excluded)	33	0.03
HP335 low rail (grinding included)	33	0.04

Table 4: Head wear measurements comparison between R260 and HP335 per million gross tonnes.

The performance of the high rail is better than the R260 although the gains are not as high as that seen on the low rail. With the corrective grinding now in place the rail is now predicted to last 16 years in service based on current grinding and traffic (Figure 21) compared to the previous two year rail life for R260.

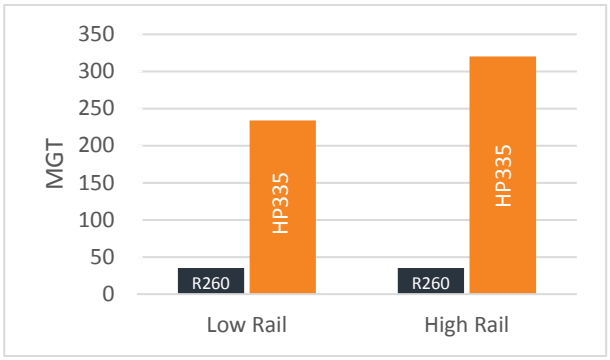

Figure 21: Predicted lifetime of the HP335 compared to R260 (wear to 14mm Headwear, UK standard)

Lifecycle costing has been calculated for the low rail at Drax (Figure 22). R260 based on historical performance requires replacement every 35MGT. With the current grinding regime HP335 life is predicted at 234 MGT. Figure 22 shows that if you are looking in the short-term (less than 35MGT) then R260 would be the most cost effective. However, if your outlook is beyond 35GMT the most efficient long term solution is to use HP335 with significant cost savings by avoiding the cost of disruption of six rail renewals.

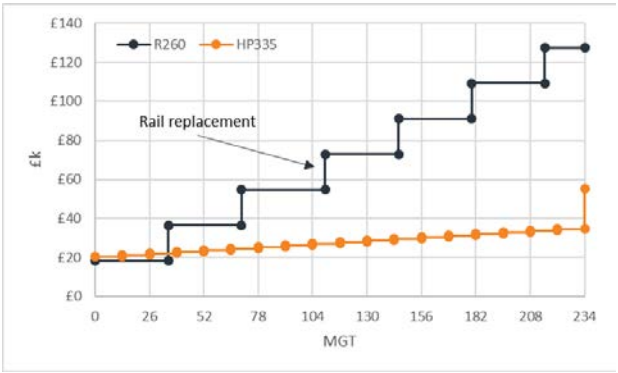

Figure 22: Lifecycle costing(low rail)

5 Conclusions

A hypereutectoid rail - HP335 - has been installed on a heavy haul site and monitored over a period of three years. The site has seen favourable results for the HP335 in particular on the low rail where plastic deformation on the field side has been eliminated. Combined with a suitable grinding plan the rail is now expected to last seven times as long compared to the previous R260. This equates to a predicted cost saving of £92,000 for the low rail on this single curve. Observed site performance has resulted in further installations of HP335 on this site.

Abstract:
To understand the effect of locomotive dynamic behaviour on track damage, a great number of train operational parameters should be considered in the analysis. Two of the critical parameters are based on the introduction of friction-creep curves and in-train forces in the locomotive models. Due to the high costs of locomotive field testing programs, this paper proposes a methodology that focuses on the introduction of friction measurements, performed with an experimental tribometer, and estimates in-train forces from locomotive/track multibody simulations. Two implementation cases, dry and lubricated friction conditions, are presented in this paper.

Keywords: friction, adhesion, traction, measurement, modelling, locomotive, track damage

1. Introduction

This case study is part of a heavy haul project initiated by the Australasian Centre for Rail Innovation and its industry partners. This project seeks to provide a new systematic approach to evaluate track damage (wear, RCF, etc.) for rails and track infrastructure under various train operational and wheel/rail contact characteristics.

The implementation of modern AC locomotives on heavy haul networks [1] provides a number of benefits for railway operators that allow significantly increasing train hauling performance. This leads to the realisation that high adhesion forces at the wheel-rail interface may cause more intensive track damage, which could significantly reduce the life cycle of wheelsets and rails. In spite of a large number of investigations on this topic, the existing numerical modelling approaches cannot precisely replicate the creep force characteristics at the wheel-rail interface without field test measurements being performed on locomotives under traction or braking [2-4]. All such field test measurement programs are associated with high costs and disruption to commercial train operations. Therefore, other approaches should be considered in order to deliver actual creep force characteristics at the wheel-rail interface without field test measurements. One existing alternative that allows measurements on rails in the field is the application of recent developments in creep force scaled measurement techniques using experimental tribometers [5-6].

In this paper, a special methodology with the application of the HO Tribo tribometer [7] is described. In addition, the methodology developed in this paper allows track damage simulations to be carried out for locomotives operating on specifically defined heavy haul routes. These simulations use selected wheel and rail profiles and provides indicative rates of wear and recommendations on limitations of traction and braking forces.

2. Methodology

The track damage model is based on a general concept described in [8] and shown in Figure 1.

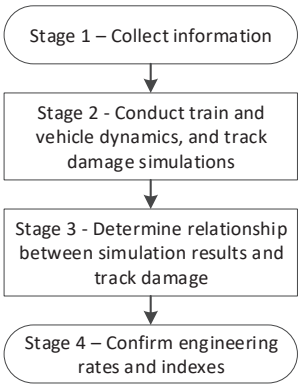

Figure 1 *Methodology to estimate infrastructure damage costs for different train types [8].*

At Stage 1, rail track and rolling stock owners should identify the sections of track and rolling stock types to be assessed and it should also highlight areas of track that show the effects of high adhesion and in-train forces, which may be in the form of rail or track geometry defects. Stage 2 includes train and vehicle dynamic simulations for the identification of rail wear and RCF derived from train and rail vehicle simulations, taking into account train configurations and journey information. Stage 3 is focused on the relationship determination between simulation results and track damage. The latter is judged by force effects derived from train simulations. Stage 4 is needed to confirm results and conduct a sensitivity study. The confirmation of results is done by testing the expected range of configuration

values found on train and track assets to determine the validity of cost and degradation models.

In this paper, further improvements were implemented in Stage 2 using the Extended Contact algorithm [4], and the simulation methodology for this stage has been delivered as shown in Figure 2. The problematic parts in this simulation methodology are:

- delivering of initial parameters for the modelling of friction at the wheel-rail contact interface using Extended Contact;
- implementation of the Extended Contact algorithm in a multibody software package for the modelling of different friction conditions at each contact point at the interface.

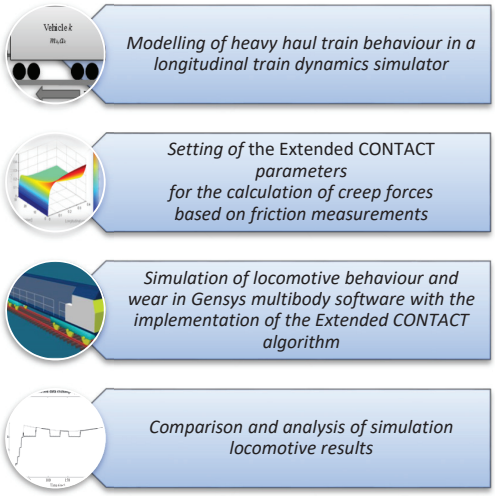

Figure 2 *Simulation methodology for locomotive track damage studies.*

2.1. Acquisition of friction data and its processing

As the interface is subject to various environmental and operational conditions (surface contaminants, lubrication, friction modifiers, wheel vertical load, roughness etc.), its friction coefficient vs slip/creep can vary significantly due to changes in contact conditions on actual track routes. These can be caused by a presence of a third body layer (surface contaminants, lubrication, friction modifiers etc.), operational parameters (speed, wheel vertical load), maintenance parameters (wheel and rail profiles, roughness etc.) and weather conditions (humidity, rain, snow etc.). A mobile scaled tribometer measures the rail friction conditions, as shown in Figure 3, at the many places on rail network(s) selected in Stage 1. It is necessary to measure and replicate the existing operational conditions from the actual rail line.

The acquisition process requires the application of the 5 steps shown in Figure 4. The first step requires performing simulations of locomotive behaviour under traction/braking operational scenarios on the actual track parameters. During the simulation process in a multibody software package, the main task is to detect possible contact points at the wheel-rail interface and to calculate contact stresses with the Extended Contact add-on at each contact point. The second step requires performing simulations for a tribometer with a variety of vertical forces and tribometer wheel profiles for the same rail profile. The outputs are contact stresses which are also calculated with the Extended Contact add-on. The third step is focused on the analysis of multi-body vs tribometer simulation results in order to deliver similar contact stresses at each contact point on the rail. Based on this analysis, a choice of vertical load(s) and profile(s) for field tests should be determined. The fourth step is commonly represented by a set of experimental tests with predefined parameters. The fifth step requires post-processing of measured field data in order to deliver friction-creep curves and model parameters for further locomotive track damage studies. An example of this is shown in Figure 5.

Figure 3 *Friction measurements with a scaled tribometer on a heavy haul railway line.*

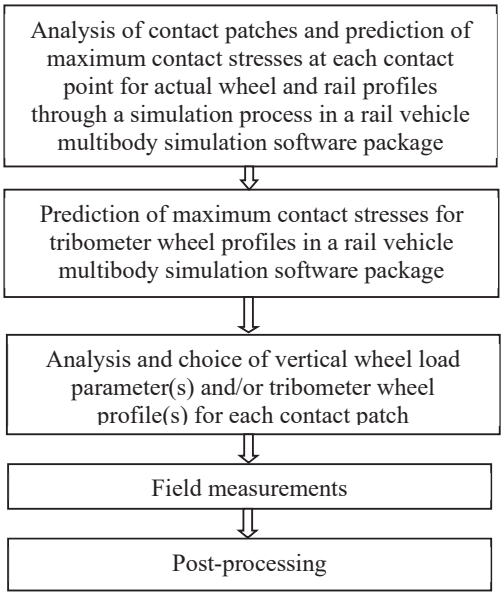

Figure 4 *Simulation methodology for a friction measurement process.*

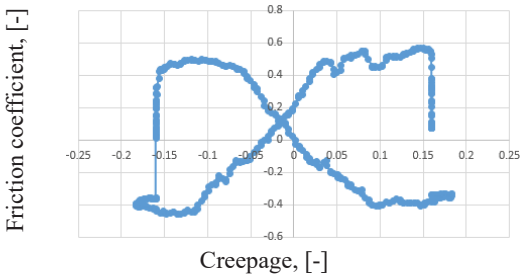

Figure 5 *Processed data – friction coefficient vs creepage delivered on a dry heavy haul rail.*

When the friction characteristics between wheel and rail are obtained from field measurements, a set of numerical experiments in Matlab are run to deliver parameters for a relationship between the friction/adhesion coefficient, applied load, velocity and longitudinal creepage (slip) in the Extended Contact algorithm. Finally, these parameters should be inserted in wheel-rail couplings of a locomotive model in a rail vehicle multibody dynamics simulation package. The full flowchart for delivering numerical parameters of friction characteristics is shown in Figure 6.

2.2. Implementation in a multibody software package

A modification of the concept used in heavy locomotive studies described in [9] is required in order to provide an adequate solution for rail wear estimation processes. The new wheel/rail coupling subroutine 'creep_contact_2' has been developed in Gensys based on the principle that the creep forces are modelled with the Extended Contact algorithm [4] and the wear model is based on Archard's wear formulation [10].

The developed wheel/rail coupling allows modelling up to nine possible contact points at the wheel/rail interface and modifying the friction coefficient and third body parameters as well as the rail profile along the track distance. The basic concept of the wheel/rail coupling is shown in Figure 7.

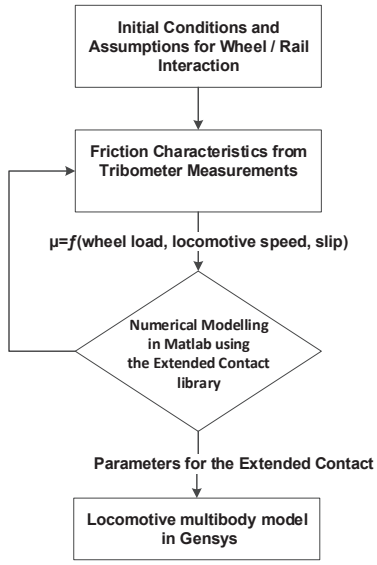

Figure 6 *Flowchart of the process for delivering numerical parameters of friction characteristics implemented in Step 5: Post-processing.*

A contact coordinate system is created in the centre of each possible contact patch, with its X-axis pointing forward along the track and its Z-axis normal to the contact patch and pointing into the rail. When wheel-rail contact is found to exist, then a mesh is generated containing the perpendicular distances between wheel and rail. The same step is performed for each possible contact patch. If a positive distance between wheel and rail is detected, it indicates a gap. In the case of a negative distance, it means that the undeformed wheel and rail profiles have penetrated each other. However, after analysis with the Extended Contact algorithm, the surfaces will not penetrate each other, because the deformation of wheel and rail surfaces are considered. From the theoretical penetration, Extended Contact calculates the shape and size of the contact patch and contact forces.

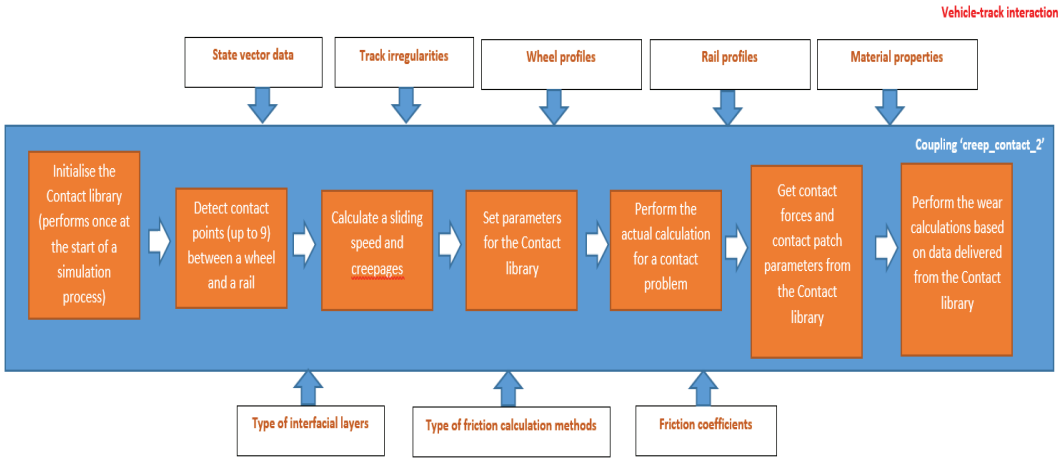

Figure 7 *Modelling approach for one wheel with the implementation of Extended Contact in Gensys.*

The current implementation of the Extended Contact algorithm in 'creep_contact_2', does not allow use of numerical integration methods with a back step to calculate creep forces at the wheel-rail interface. Therefore, the recommended integrator for this approach is an explicit Runge-Kutta method with a fixed time step.

The main difference with the advanced Archard's model [10] used in this study is that it predicts wear volume rates using m^3/s instead of wear volume using m^3. The model is expressed as:

$$V_{wear} = k\frac{Nv_{slip}}{H} \quad (1)$$

where V_{wear} is the wear volume rate; k is the coefficient; N is the normal force; v_{slip} is the slip velocity of the wear rail contact; H is the hardness of the material. Comparing with the original Archard's model, it can be seen that the extended version replaces the sliding distance by sliding velocity. Therefore, the extended version does not need integration to obtain the sliding distance, which makes the model simpler and faster.

3. Simulation scenario

This paper investigated two simulation cases that considered the third leading high adhesion locomotive (134 tonne) in a heavy haul train configuration. The track consists of a 240 m radius curve, standard gauge track with a cant of 15 mm, FRA Class 5 track irregularities, constant speed of 20 km/h, and maximum tractive effort. In Case 1, high and low rails both have a dry friction condition. However, in Case 2, the high rail has lubrication applied and the low rail has a dry friction condition.

Tribometer measurements taken on operational tracks were used to deliver initial parameters for setting of the Extended Contact friction model parameters in Matlab. Further calculation of creep forces in Gensys multibody software have been performed in this study with new ANZR1 wheel and new AS60 rail profiles. The friction-creep characteristics delivered are shown in Figures 8 and 9. The values of friction model parameters for the Extended Contact are presented in Table 1.

Table 1 *Parameters for the contact models used in this study.*

Model parameters	Dry friction condition	Lubricated friction condition
V (m/s)	0.14	0.14
μ_S	0.36	0.26
A	0.4	0.4
B (s/m)	0.34	0.34
$h^{(3)}$ ***(μm)***	0.45	0.75
$G^{(3)}$ ***(N/mm²)***	840	1200

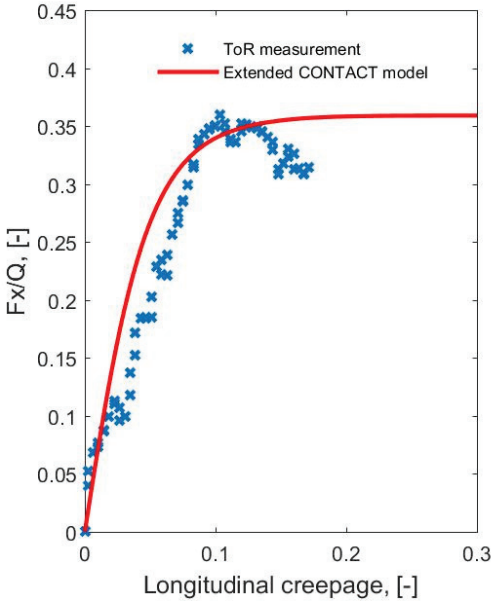

Figure 8 *Friction-creep curve measured for a dry friction condition.*

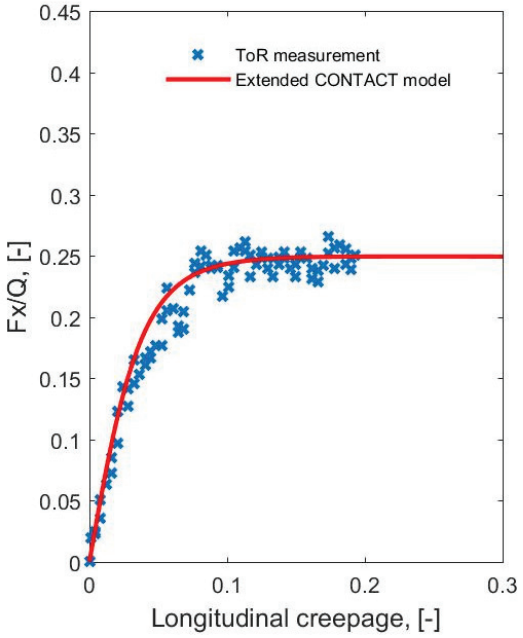

Figure 9 *Friction-creep curve measured for a lubricated friction condition at gauge corner contact.*

The hypothetical train consist includes 3 leading high adhesion locomotives arranged at the front and hauling 55 identical wagons [1]. To focus on the third locomotive, the coupler forces are required before conducting any simulation cases. These forces may be obtained from a separate longitudinal train dynamics simulation. The approach for the application of longitudinal train dynamics in heavy haul locomotive dynamics behaviour is also described in [1]. The lateral coupler force results were approximated for the third locomotive as 48 kN at the front coupler and 124 kN at the rear coupler.

The locomotive model developed in Gensys for this study is similar to the models published in [11-13]. The locomotive has two bogies with six traction axles, that are each equipped with an AC motor. The multibody locomotive models consist of nine rigid masses: one car-body, two bogie frames and six wheelsets. The traction motor masses and moments of inertia are incorporated into neighbouring bodies; one third of each is added to the relevant axle whist the remaining two thirds is incorporated into the bogie frame.
The full traction control system of a locomotive has been integrated in the Gensys locomotive model as a shared library, generated by means of Simulink Code Generation [14-16]. The slip threshold for the traction control system is set to 0.04 as for a conventional traction system [1,17].

4. Simulation results

The results show that the tractive effort achieved by the locomotive in Case 2 is 420 kN and is slightly less than the 424 kN achieved in Case 1 due to the presence of lubricant on the gauge corner of the high rail in Case 2.

Analysing wear indices, which are calculated on the 240 metre radius curve for both cases, and are also considered as track damage indicators, we can see that it only causes redistribution of wear on the high rail for a first axle as shown in Figure 10. In the case of a comparison of results calculated for wear volumes, as shown in Figure 11, no difference in results can be observed.

Figure 12 shows that there is a redistribution of contact forces between wheels of the locomotive caused by the traction control system and the response of the locomotive suspension system in the direction of locomotive movement. In addition, in-train forces result in the re-distribution of higher wheel loads onto low rails in the curve for the third locomotive when travelling at the slow speed of 20km/h. The latter confirms that the accurate introduction of friction conditions at the wheel rail interface and locomotive/train operational data is very important for track damage studies because any variation in wheel-rail dynamic forces can change the locomotive's behaviour and its deliverables significantly.

5. Discussion

This paper shows that the developed approach proposed in this paper is fully workable for studying the influence of high adhesion locomotive impact on railway track. However, the results presented in this paper should be considered as an example only because an actual operational train scenario (for example, differences in wheel-rail contact conditions that may occur between the first and subsequent wheel positions in a locomotive etc.) can lead to a different locomotive dynamic behaviour. Therefore, the obtained results should only be considered as a workability proof for the developed methodology and all data should be interpreted carefully.

6. Conclusion

A methodology based on frictional measurement results and a numerical experiment was developed in this study. The new wheel/rail coupling based on the Extended Contact algorithm and developed in Gensys was used to calculate track damage indicators.
Future work includes the continuation of further improvements on the introduction of friction measurement results from a tribometer. This should include an increased number of cyclic tests, in order to deliver a relationship for the numerical definition of friction coefficients under the rail cleaning effect. The calculated wear indices results should be correlated with actual wear data from field and maintenance measurements.

[*] E-mail: M.J.M.M.Steenbergen@tudelft.nl

Abstract: Rail maintenance occurs irrespective of its performance regime. However, the scope is profile restoration in the case of wear and 'resetting' of the surface fatigue life for RCF, which is essentially different. The latter requires not only surface roughness limitations, but a properly 'tuned' surface finishing process with respect to three input energy dissipation mechanisms: removal of surface material, thermally driven transformation of remaining surface material and mechanically driven deformation of subsurface material. Fundamental research into the relationship between post-treatment surface parameters, via contact loading conditions and failure mechanisms to lifecycle performance appears crucial, with this paper discussing its basis.

Keywords: Rolling contact fatigue (RCF); rail grinding; rail milling; white etching layer (WEL); friction-induced martensite (FIM); wheel-rail contact.

1. Introduction and context

Rolling Contact Fatigue (RCF) is a critical, lifetime-governing degradation mechanism for rails that do not exhibit sufficient wear under train operation. This absence of sufficient 'natural' wear may be due to either material factors such as inappropriate hardness of the rail or mechanical factors such as the distribution and history of 3D contact stresses exerted by rolling stock over the railhead profile.

Conventional RCF may lead to surface cracking within the entire running band, either on the gauge corner of the rail (head-checking) or on top the railhead (squats) (see Fig. 1). Both defect types occur due to specific and different mechanical aspects of wheel-rail interaction, but they have a common origin in a plastic ratchetting strain response of the contact surface under cyclic tangential loading.

Whereas a few decades ago the vast majority of rails worldwide performed in the wear regime, the share of rails performing in the RCF regime has steadily increased over the past years, necessitating increased monitoring efforts to guarantee safe train operation. This shift is due to a number of factors. From the side of the rolling stock there are factors such as an increased wheel reprofiling frequency (along with improved wheel monitoring) – at least for passenger trains, leading to 'monoculture' of the running band, and increased tractive power transmitted by driven wheels along with optimisation of traction efficiency. From the side of the infrastructure, the main development is the increased application of premium pearlitic rails with respect to standard carbon grades, especially in curved track.

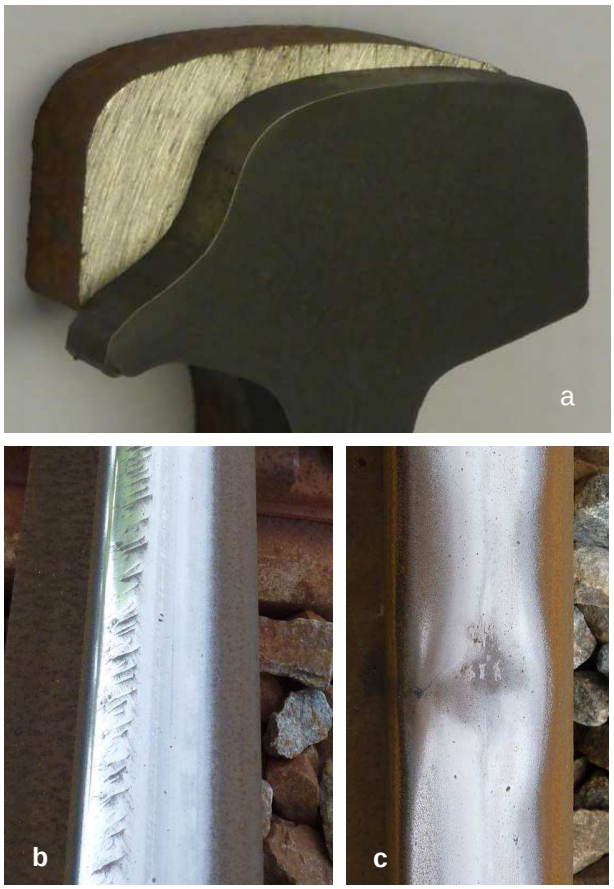

Figure 1 *Rail degradation regimes: wear and plasticity (a) versus RCF (gauge fatigue/headchecking (b) and crown fatigue/squat (c)); gauge faces at the left.*

Premium rail grades, obtained by thermal head-hardening and/or by alloying, have been developed with the objective of an increased resistance against both wear and RCF-initiation. Typically, though not exclusively, such an improved performance is tested and established under uniform laboratory conditions, assuming a constant wear type/regime; an example of widely referenced testing in the framework of the Innotrack research program is shown in Fig. 2. The basis of this figure is given by a set of laboratory measurement results from ref. [1] for different pearlitic rail grades as specified in the European norm [2] and in use worldwide. It is important to underline that this is a

specific set of measurements, and that the results depend on a number of testing parameters; however, in the framework of this paper this set is sufficient for illustration purposes.

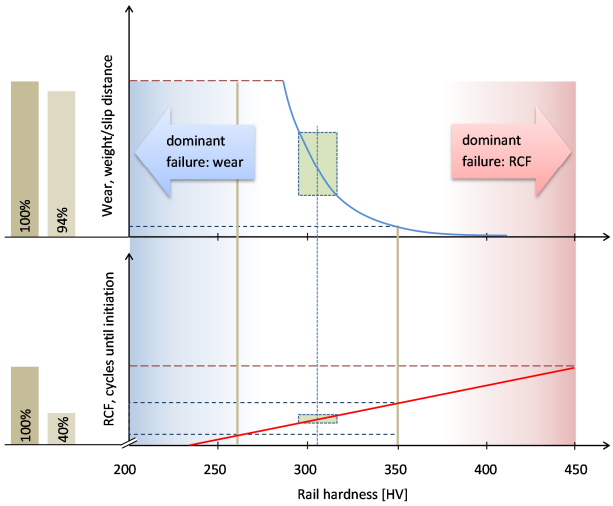

Figure 2 *Rail grade hardness design: increased wear and RCF resistance in laboratory testing (graphs from Innotrack report [1]) and consequences of 'hardness sampling' adopted by the norm [2].*

The horizontal axes in Fig. 2 show the rail hardness, with values of interest typically ranging from about 200 to 400 HV. The vertical axes show, respectively, the wear and the number of load cycles until RCF crack initiation. Since the aim of the figure is to compare the relative wear and RCF behaviour as a function of rail hardness, values are not important and both vertical axes have been normalised. It is obvious from Fig. 2 that for hardness values close to 200 HV wear is dominant with respect to RCF; the wear rate is so high that eventual cracks cannot develop. For hardness values in the area of 400 HV, wear has almost disappeared and RCF is the dominant surface failure mechanism. In the area between both hardness values, wear and RCF are competing mechanisms, with one striking effect: the variation of wear with hardness is relatively much stronger as compared to that of RCF. Within this area, two grades have particular relevance as they are most used in practice; these are grades R260 (predominantly on tangent track) and R350HT (predominantly in curves). The R350HT grade is basically a heat-treated version of the R260 pearlitic grade.

Fig. 2 now demonstrates the consequence of the corresponding 'sampling distance' on the hardness axis that is adopted by the norm [2] and applied on rail networks worldwide: increasing the rail hardness from 260 HV to the next value, 350 HV, 'uses' at least 94 percent of the entire available wear 'window' between 200 and 450 HV, whereas only about 40 percent of the available RCF window is used. As has been said, exact numbers depend on the specific test setup; what matters is the order of magnitude, and this shows a very considerable divergence. Clearly, there is room for optimisation. This divergence has an important practical implication: it is often problematic to adjust the rail grade to operational conditions in the field in such a way that RCF is avoided whereas wear is minimised, even in an approximate manner. As a consequence, as stated above, the share of rails performing in the RCF-regime increases.

The previous paragraphs addressed the design stage of railway track. Design choices however have significant consequences for the life-cycle performance and therefore for the rail maintenance. Wear basically leads to a loss of volume in the cross-sectional profile (Fig. 1a), which is important for the running performance of trains. Therefore, the traditional form of maintenance consists of *reprofiling* of the railhead by means of grinding. Over the service life of the rail, this takes the form of periodic rail grinding (Fig. 4) with specially equipped trains: a common practice throughout many networks worldwide. Also longitudinal rail profile correction (such as mitigation of corrugation) is done this way. It can be said therefore that from a historical perspective the exact condition of the finished rail surface itself, in terms of geometry/roughness and material properties (or local variations therein), has been of limited importance: this surface was to be worn off in any case soon after taking the rail again into service. What mattered was restoration of the cross-sectional profile. This is clear also from the scope of the European norm NEN-EN 13231-3 [3], which focuses almost exclusively on the finished surface in terms of geometry/roughness and does not provide any regulations as to the finishing process itself and the treated material.

RCF of rails, as the problem expanded, was mitigated by exactly the same method: cyclic grinding of the affected and cracked surface. Preventive grinding is generally single-pass; corrective grinding may involve multiple passes. Corrective rail milling was and is used too, however on a much smaller scale to mitigate RCF propagated until greater depths, where the take-off is considered too large to be realised by grinding. These methods are normally subject to the same specifications, focusing on surface geometry/roughness left behind. However, in the case of RCF the scope is changed from *profile restoration* to removal of the work-hardened surface layer with crack initiations, thereby creating a fresh contact surface and *'resetting' the fatigue life*.

An earlier study [4] as well as other recent work [5] have shown the critical effect of aggressive surface grinding on the surface conditions and the lifecycle of rails performing in the RCF regime: critical combinations of material phase, parent material hardness, residual stress and roughness may arise. However, objective criteria for which grinding can be assessed as 'aggressive' and which grinding as 'benign' (if the latter exists), are not available. The more general and fundamental underlying question for academic research therefore is whether and to what extent surface finishing processes 'reset' the RCF lifecycle, both in theory and in practice; a second question would be how to control this operationally. Fig. 3 illustrates how partial resetting will lead to early rail damage along with a strongly reduced maintenance cycle.

Where rail grinding in itself and its optimisation with respect to several aspects (such as acoustics) have received substantial interest in the scientific literature within the railway engineering domain, this is not true

for the research question as mentioned, apart from some recent work [4-6] and an older study that implicitly also addresses this subject [7].

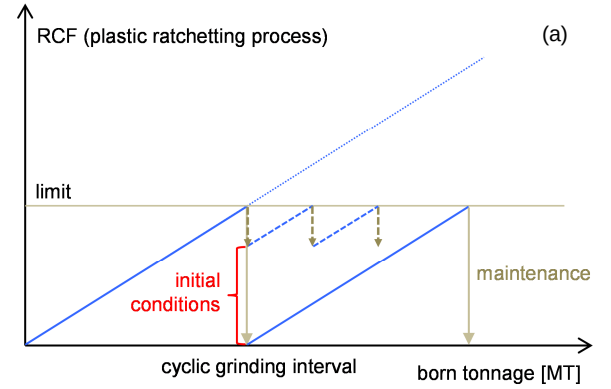

Figure 3 *Cyclic grinding and RCF: entirely versus partial 'resetting' of rail service life initial conditions (a) and consequences of incorrect 'resetting' with substantial loss of lifecycle (b).*

The present study cannot provide 'the' full answer to this fundamental question, which involves an extended research effort. It is therefore of a preliminary nature and considers, in response to this more general question, concisely both theoretical and practical aspects of rail surface finishing that need to be addressed and investigated. It establishes the crucial importance of the initial conditions on the service life of those rails situated in network parts performing in the RCF regime.

2. The tribological wheel-rail contact pair: surface conditions at both sides of the interface.

The wheel-rail system is a special case of a tribological contact pair, due to its open character and the difference in dimensions of both sides of the interface, with the resulting difference in contact cycles over a duration of time experienced by a material point at both sides. The rail typically has a length-scale which is orders of magnitude larger than the wheel circumference. Still, they form a tribological pair with surface conditions that govern the stress response at both sides, and therefore implicitly also the maintenance cycle. From this point of view it would be strange to not even compare – let alone adjust – the surface conditions and the criteria governing these conditions at both sides of the contact.

Treated rails will experience their first contact cycles with worn wheels in majority. Contact between a freshly ground rail and turned wheel (Fig. 4) may occur, but only on an incidental basis. Worn wheels in general have roughness values that decrease rapidly over the first few thousands of kilometers after turning. Therefore, the contact of a freshly ground rail and a freshly turned wheel can be considered as a worst-case scenario, at least when considering roughness scales that play a role locally – within the contact area itself.

Figure 4 *Comparison of both sides of the tribological wheel-rail pair: a freshly field-ground rail surface with facets satisfying the European norm [2] and a freshly turned wheel.*

Comparing the surface conditions at both sides, a first difference consists in the treatment method itself: wheels are turned, whereas rails are commonly ground. Both techniques result in significant differences with respect to the surface conditions that affect the metallurgy and the RCF life, as established in the scientific literature [8-10], with turning generally being in the advantage. The involved parameters will be mentioned and discussed further in this paper.

When comparing the geometrical requirements ([2] for rails and [11] for wheels (delivery condition)), for rails a maximum R_a value is required of 10µm, whereas this value equals 6.3 or 12.5 µm (depending on the category) for wheel rims and treads. These values are in a comparable order of magnitude. However, as has been stated this is a worst-case scenario; the wheel roughness rapidly decreases and generally the wheel surface may

be assumed much smoother as compared to the treated rail surface (Fig. 4). The rail roughness therefore will dominate the local stress distribution within the contact zone and the sub-surface stress response within the rail over the first part of its life- or maintenance cycle. This is especially true for premium rails, since wheel material commonly does not exceed the hardness of standard pearlitic rail (grade R260 according to [2]).
It is noted here that roughness values (such as R_a) seem insufficient to describe the surface quality (and therefore the initial conditions with respect to the lifecycle) in the framework of RCF; the two longitudinal rail profiles in Fig. 5 are geometrically identical but would have a completely different response to contact loading. Fig. 5 is also apt to show that individual surface-describing parameters are not critical; the best way to assess the resistance of a treated surface against cyclic contact loading therefore consists of parameter combinations that take into account the entire surface topology.

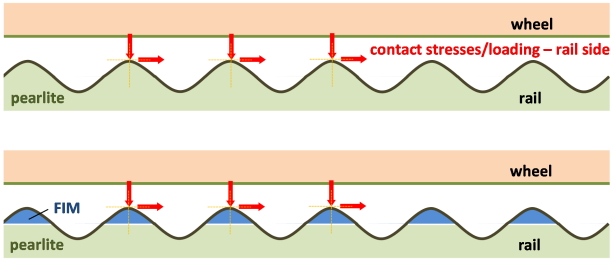

Figure 5 *Conceptual wheel and rail surfaces in loaded contact with relative motion: equal geometry but different subsurface response to contact loading and therefore different lifecycle.*

3. Surface finishing techniques: energy flux and stratification of surface properties

Basically, each surface finishing process needs – controlled by its settings – a specific energy input per surface area unit. The objective of this input is the removal (either by friction/abrasion or cutting) of a predefined layer of surface material. The energy transfer is however not consumed exclusively in this process; it is dissipated in the rail by three different 'mechanisms', of which only the first one is intended explicitly and both other ones are implicit 'by-products':

i. removal of surface material;
ii. thermally driven phase transformation of the surface layer over a certain depth;
iii. mechanically driven plastic deformation of the subsurface granular matrix.

These three 'mechanisms' are illustrated in Fig. 6. Their occurrence generally leads to a stratification in the finished surface/subsurface properties.
Fig. 6 shows a case with a uniform presence along the surface of all three mechanisms; this is not always the case, as will be discussed in more detail in section 4. In practice, for rails performing in the wear regime an exclusive focus on *i* is sufficient. For rails performing in the RCF regime, the 'balance' between mechanisms *i* through *iii* must be optimised by an appropriate tuning of the parameters of the finishing process (such as power; working speed; pressure; grinding tool composition and roughness for grinding and insert/tool material and geometry including nose radius; depth of cut; entering arc; power, feed rate and cutting speed; eventual application of cutting fluid and/or coolant for milling) for given material properties, whereas a unique focus on *i* here may lead to a reduction of the RCF lifecycle and early damage [4].

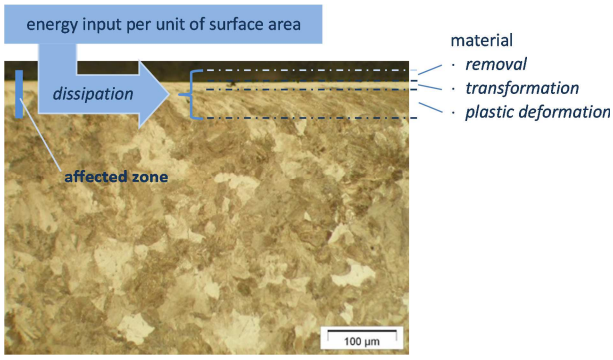

Figure 6 *Conceptual model: the energy flux in rail surface finishing leading to stratification of surface properties.*

4. Surface effects in relation to damage

This section addresses a number of parameters that are linked to one or more of the three 'dissipation' mechanisms discussed in the previous section and that need to be taken into account when optimising the initial conditions of the contact surface.

4.1. The white etching surface layer: general

Although the phenomenon of a white etching rail surface layer (WEL) has been known for a long time and to a certain extent also documented in the literature (see an overview in earlier work [12] and more recent contributions such as [13]), this mainly focuses on the origin and nature of the WEL as such. There is no unanimous view on the harmfulness versus profit of such a layer. On one hand a WEL may protect against wear; on the other hand the layer is relatively brittle and often related to RCF damage. Even if earlier work [12] distinguished between the WEL with a thermal origin (consisting of phase-transformed martensite) and the WEL with a mechanical origin (consisting of an amorphous nano-structure), it seems that further differentiation and research is needed. On the relation between specific WEL properties (this section will address a number of them) and damage initiation mechanisms much less research has been performed.
The WEL may be present on the rail surface at the moment of treatment and interact with its settings, but it may also be induced by the treatment itself (dissipation mechanism *ii*). In the latter case, its properties are more uniquely defined. The layer consists of martensite and is also called friction-induced martensite or FIM. The spatial properties of the FIM layer (uniformity versus non-uniformity and configuration over the railhead) have a significant effect on the stress response under wheel-rail contact loading. Even when this response is not dynamic in the time domain, it has a transient nature and may therefore easily trigger local fatigue, also when immediate failure does not occur. These spatial properties are a function of the treatment control parameters and therefore need to be closely examined. The next paragraph discusses this aspect in more detail.

4.2. Discrete versus continuous character of the WEL

Aggressive or coarse grinding, inducing substantial roughness, may typically give rise to the formation of grinding grooves with locally accumulated FIM deposits along the edges of these grooves, such as visible in the cross-sections in Fig. 7.

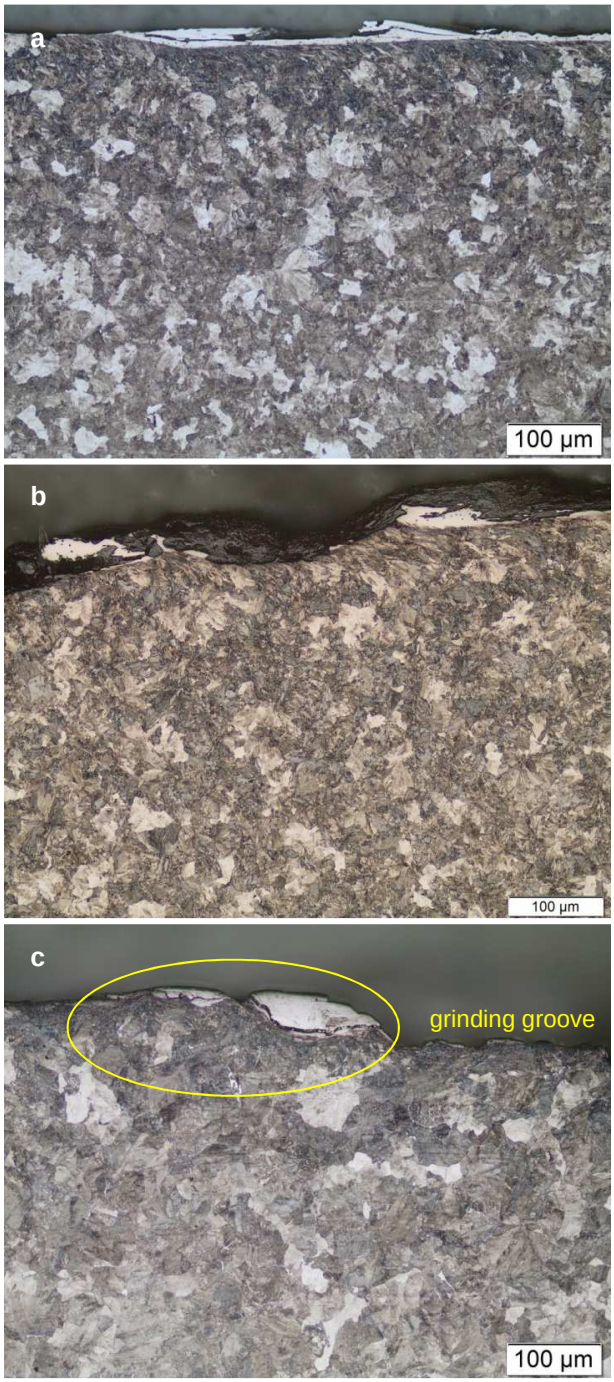

Figure 7 *Cross-sections over individual superficial grinding grooves for two different processes on premium grade R370crHT; FIM deposits and subsurface deformation (a,b) and FIM deposit at the edge of a grinding groove on R260Mn.*

This may lead to a surface morphology with 'white etching crests' with a differential and increased hardness. The earlier mentioned specific study [4] proved a critical effect under normal train operation especially on head-hardened grades: they cannot accommodate the imprint of hard FIM portions/deposits in an elastic mode, leading to material failure and substantial crack initiation. Another recent study [5] also claims harmful effects for standard grades. It can be added that the orientation of the harder 'crests' and the grooves with respect to the tangential stress directivity is a second decisive factor with respect to surface failure and crack growth. In this sense, grinding grooves aligned perpendicular to the rail axis can be assumed as particularly unfavorable, since the longitudinal component of the tangential stress field generally exceeds the transversal one for driven wheels on tangent track, and therefore, for the majority of rails in a network.

When a comparison is made between grinding and milling with respect to the aspect discussed in this paragraph, the latter process is clearly in advantage (Fig. 8), milling being a cutting process covering the entire surface in a similar way, also on a microscale.

Figure 8 *Uniform surface of milled R350HT.*

4.3. Thickness of the WEL

Any proper assessment of the effect of the thickness of - eventually stratified [14] - surface layers with distinct constitutive properties as compared to the parent material cannot consider this thickness in an absolute sense but needs to account for the properties of the base material itself. A proper way can be to consider the average grain size of the parent material as a reference. A 2D uniform WEL with a thickness significantly smaller than the average grain size can be expected to both generate lower shear stresses at the interface and be more subject to fracture – due to its reduced capability of stress spreading – as compared to a relatively thick layer (Fig. 9). A discrete portion of WEL with a seize that is much smaller than the average grain size can do only limited damage upon penetration into the granular matrix as compared to a relative substantial portion. This aspect may also contribute to an explanation of the relatively higher susceptibility of head-hardened/fine-grained materials to crack initiation from WEL (typically developing in the form of spalling defects or 'studs' [15]) as compared to standard grades.

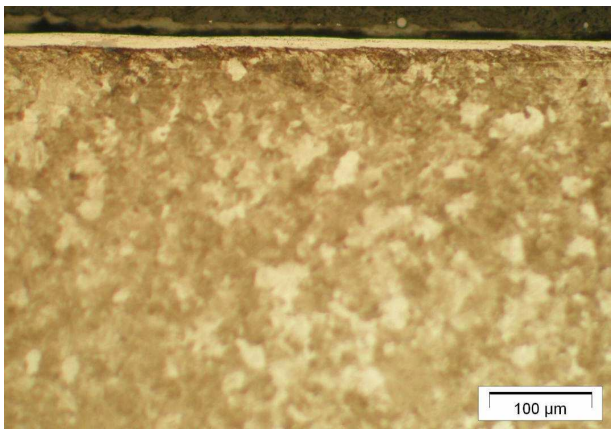

Figure 9 *Relatively thick, uniform WEL (FIM) layer on ground R370crHT*

4.4. Internal uniformity of WEL properties

White etching layers with uniform properties along the surface can be expected to perform differently under contact loading (both normal and tangential) as compared to layers containing discontinuities. Any edge of a white etching region at the surface represents a discontinuity, but discontinuity may also occur internally. Fig. 10 shows a relatively thin white etching surface layer with discontinuities at the grain boundaries, where the pro-eutectoid ferritic phase permeates the layer until the free surface. It is known that this free ferrite has inferior strength as compared to the basis material, and that these locations will therefore be preferred sites for crack initiation upon exposure of such a surface to contact loading. The same is valid for external edges of layers, which will act as stress concentrators.

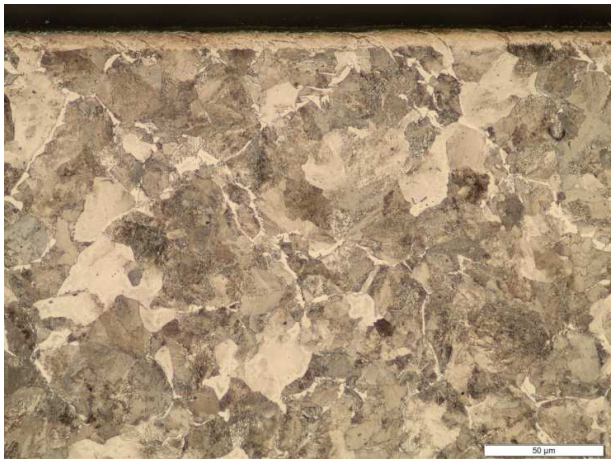

Figure 10 *Intergranular pro-eutectoid ferrite permeating a WEL on a smoothly ground surface of grade R350HT.*

4.5. Nature of the WEL; constitutive properties as compared to parent material

The constitutive properties of a surface layer govern its strain response to contact stresses, and therefore also its failure behaviour. As mentioned, a white etching surface layer can be formed thermally, i.e. by phase transformation of the parent material, or mechanically. Both cases lead to different constitutive properties. In the first case, a martensitic structure arises with strongly increased hardness (in the order of 600 to 800 HV) as compared to the pearlitic parent material (200 to 400 HV). In the second case, plasticity – often cyclic – of confined material under high compressive and/or shear stress leads to a surface layer with a nanocrystalline composition. Such layers have even significantly higher hardness values (in the order of 1000-1200 HV), and therefore also a higher strength.

4.6. Degree of bonding of the WEL with parent material

In general, a mechanically formed layer has good bonding properties with the subsurface parent material, also because the grain refinement toward the surface is gradual. In the case of a phase transformed layer, the transition is abrupt, with a discrete interface between two phases. As will be discussed in paragraph 4.8, this interface may concentrate high shear stresses, depending on the extension of a continuous layer over the surface. Therefore, delamination along the interface may occur in the case of thermally formed layers, resulting in unbound portions of WEL along the surface. Fig. 11 shows examples of thermal layers both with good bonding and delamination, for different material grades.

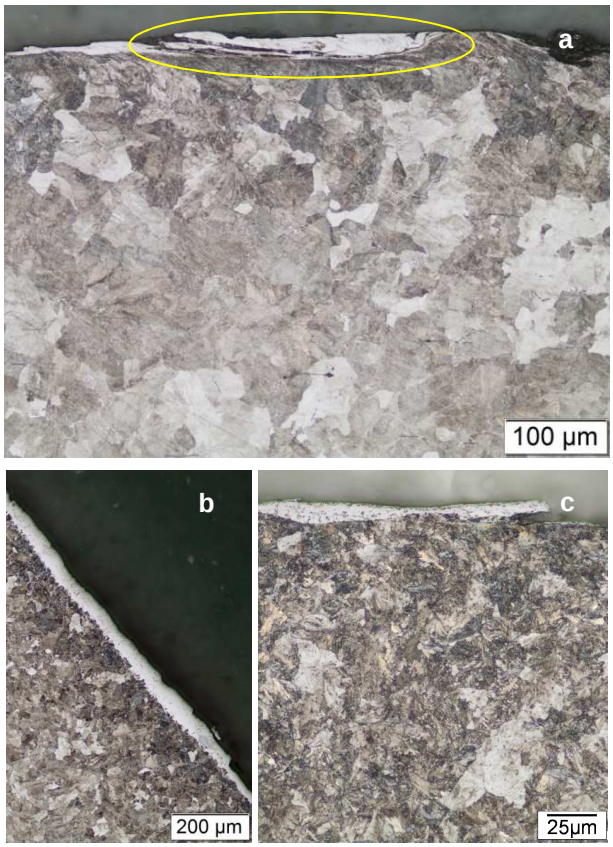

Figure 11 *Delamination versus bonding of thermally formed WEL due to grinding (a,b: R260Mn, c: R370crHT)*

4.7. Subsurface plasticity

All surface treatment processes, from grinding to milling and cross-forms, induce subsurface plasticity (dissipation mechanism *iii*) to some degree. This is due to the fact that an infinitely sharp and infinitely rigid cutting element does not exist; any contact between an individual grain of a grinding stone (Fig. 7) or tip of a cutting tool (Fig. 8) will cause deformation with an

order of magnitude exceeding the grain size of the material of the treated surface, and therefore plasticity. Plasticity may have a positive side-effect: without plasticity, residual stresses cannot be introduced. If these stresses, at least at a depth in the surface layer that is relevant under contact loading, are compressive, they may protect from crack initiation or growth. They may provide 'shielding' of the subsurface. These residual stresses will be discussed in an individual paragraph. Plastic deformation may also have a less favorable effect; severe plasticity directionally coinciding with that induced by successive contact loading may shorten the fatigue life. The direction of treatment-induced plastic deformation is therefore important.

4.8. Residual stresses

Both mechanisms (*ii*) and (*iii*) lead to the introduction of residual stresses, although of a different nature. In (*ii*), the heat generated in the contact as a result of friction and subsequent rapid cooling leads to a pearlite-martensite transformation. As discussed, FIM may be present in the form of discrete portions, typically accompanied with roughness, and as a more or less uniform surface layer. The volumetric expansion that accompanies this phase transformation leads to substantial shear stresses at the interface between FIM and pearlitic parent material, concentrating at the edges of the FIM layers or portions (Fig. 12).

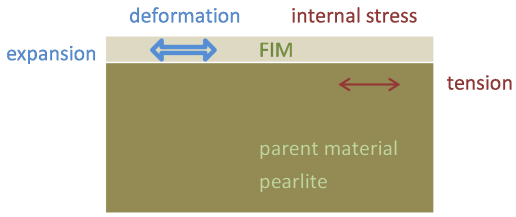

Figure 12 *Mechanism of residual stress profile generation by formation of FIM at the surface.*

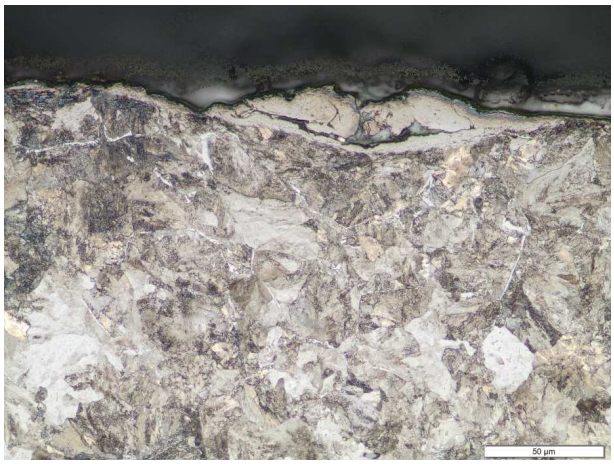

Figure 13 *Delamination of a relatively brittle FIM deposit from the pearlitic parent material.*

It is clear from the way these stresses are generated that they are very localized as concerns their position in depth. As a consequence, these layers often have a tendency to delaminate from the parent material, such as exemplified in Fig. 13. Due to the stress concentration at the extremities, this process often starts at the surface contours. The tendency to delamination, which appears (from field evidence) to be favored by cyclic contact stresses under train operation, is beneficial to the rail life, FIM layers being very prone to fracture and crack initiation due to their increased hardness and brittleness.

Also mechanism (*iii*) leads to residual stresses, albeit of a different nature as compared to (*ii*). These stresses may be either benign or detrimental. They are associated to the strain hardening of the subsurface material and therefore not localized but extended over the depth, limited by the depth of plastic deformation. They may be either compressive or tensile, in the first case protecting against and in the latter case favoring crack propagation and eventually surface spalling damage [15]. Especially in this domain, milling or turning techniques are promising and have a clear advantage with respect to grinding, as they may introduce compressive stresses both with a larger magnitude and to a larger depth [8-10].

Figure 14 *Heat-treated pearlitic rail with a workshop-milled surface; effect of tool cutting edge and sharpness on depth profile of plasticity and residual stress.*

Fig. 14 shows two examples of pearlitic rail (grade R350HT) with a factory-based milled surface. Both have a significantly different depth of subsurface work hardening, related to different operating conditions in terms of cutting edge and tool sharpness. In both cases a subsurface residual stress field is generated, which extends to a different depth and probably also with a different magnitude. An 'infinitely' sharp cutting tool

would avoid any subsurface deformation; however, this would also mean that no benign residual compressive stress field is generated. A blunt tool on the contrary generates significant frictional heat and a white etching layer. It remains to be investigated which condition is optimal in view of the RCF lifetime.

4.9. Surface geometry/roughness

Both grinding and milling generate typical micro-roughness patterns that are inherent to the process. Longitudinal production grinding is not possible without grooves; longitudinal production milling not without the orbits (typically with a honeycomb configuration on a flat surface, Fig. 15) yielding the removed chips. But also on a larger scale the generated roughness patterns are typical for the treatment process; for grinding this macro-pattern is controlled by the rotational axis and diameter of the grinding disc, together with the working speed and the local circumferential speed.

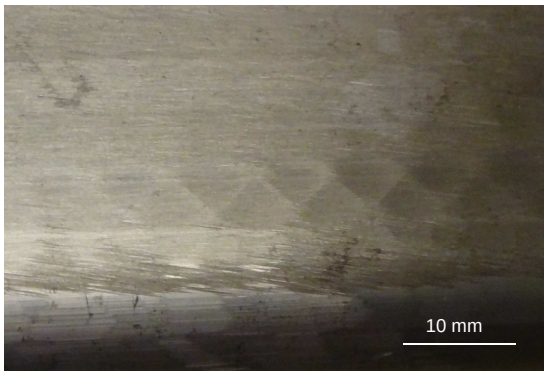

Figure 15 *Milled (and abrasively post-treated) rail surface; the honeycomb configuration of the surface contours of the orbits described by the cutting nose remains visible.*

The roughness of the surface is a critical aspect from two different points of view. The background is the composition of the contact zone, according to frictional contact mechanics, of two distinct areas: one with adhesion - without relative sliding, but with elastic deformation, and one with microslip - relative sliding. That means that both 'stress transfer' and 'slip' need to be considered as regimes the contact surface is exposed to and has to deal with. This is even more true since the entire contact zone may shift to the macroslip regime for certain wheels of bogies under particular conditions. In both cases, the term 'roughness' refers the micro-roughness of the surface, 'seen' by the wheel-rail contact and therefore with a length-scale smaller than the size of the contact patch.

It has been discussed that roughness peaks of a ground surface typically coincide with martensitic (FIM) deposits bordering grinding grooves. As a result, stress redistribution occurs within the nominal contact patch, with roughness peaks concentrating both tangential and normal loading in the wheel-rail contact. It has been mentioned that the relatively hard portions are pressed in the pearlitic matrix under high shear loading, which causes crack initiation especially on head-hardened rails. The quantitative relationship between the roughness level and the sensitivity to this failure mechanism remains to be investigated, in coherence with the other aspects discussed in this section.

A second and equally important aspect, not studied before, concerns the interaction between surface roughness and micro- or macroslip in moving contacts with creepage. When one of the surfaces of the contact pair is relatively much smoother than the other (as discussed in chapter 2 for the combination of turned/worn wheels and ground rails), asperities concentrate the contact stresses, whereas at the same time the contact surface is strongly decreased. This may cause slip, especially for zones in the contact with low normal stresses and a high relative tangential velocity. This may, on its turn, generate heating of the asperities and phase transformation resulting in martensite. Field observations of this phenomenon for different rail grades are shown in Fig. 16, in all cases accompanied with defect initiation and subsurface propagation.

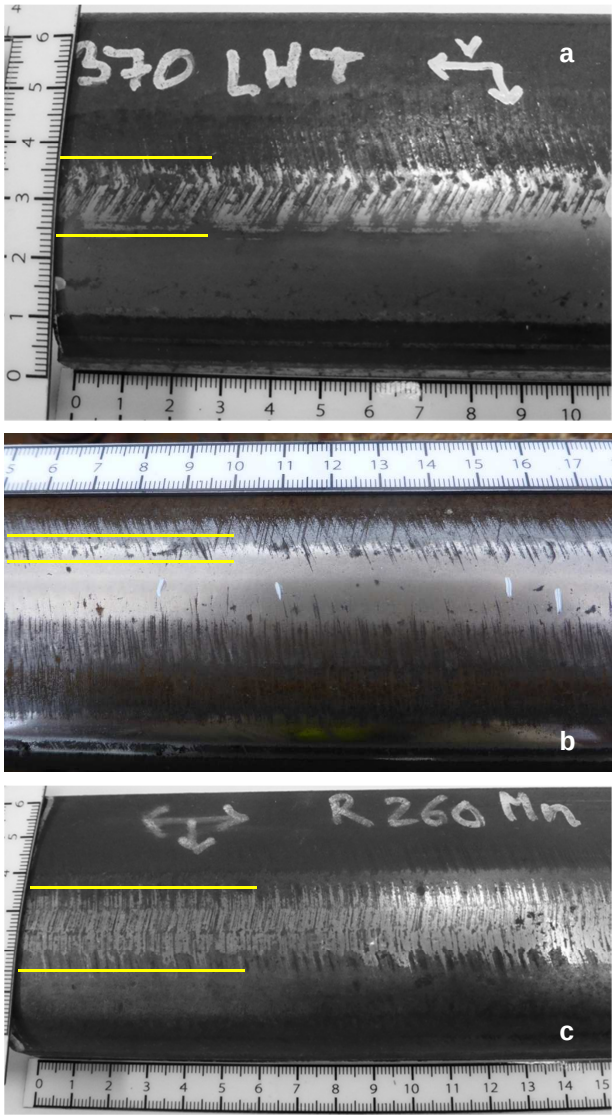

Figure 16 *Three cases of white etching material, generated by interaction of contact slip and surface roughness at the gauge side of the running band: R260Mn (a), R350HT (high leg of a curve) (b) and R370crHT (c). All cases are associated with crack initiation.*

Fig 16a shows the presence of a particular band within the running band and at the gauge side of R370crHT rail, with significant roughness and covered with white

etching material. Fig. 16b shows a similar effect but with a smaller width, on grade R350HT. The effects in Figs. 16a,b are likely caused by spin slip at the gauge side extremity of a relatively wide contact patch. Such a wide contact patch, with high spin magnitudes, typically results from high profile conformality. Especially in case (b) the width of the band is only a few millimeters, which is too small to be caused by macroslip. Fig. 16c shows a third example on standard grade R260Mn. In this case, the entire running band suffers from WEL formation (along with substantial cracking) following the roughness contours. This is an indication that macroslip of passing wheels is responsible in this case, likely due to imperfections in the driving system of motorised bogies with multiple driven axles.

It requires further research to determine which roughness levels are acceptable to prevent damage initiation; these levels will depend also on other parameters such as wheel-rail profile matching and may very well be different for both discussed mechanisms in this section.

When grinding and milling (Figs. 4 and 17) are compared, milling typically may give a lower roughness in that part of the spectrum containing wavelengths 'seen' within the wheel-rail contact, with the exact content depending on the applied process and its parameters. The opposite is the case for somewhat longer wavelengths, with length-scales comparable to the dimensions of the contact zone; this is the reason why freshly milled rails are often post-treated with an abrasive technique within the same process (Figs. 15, 17).

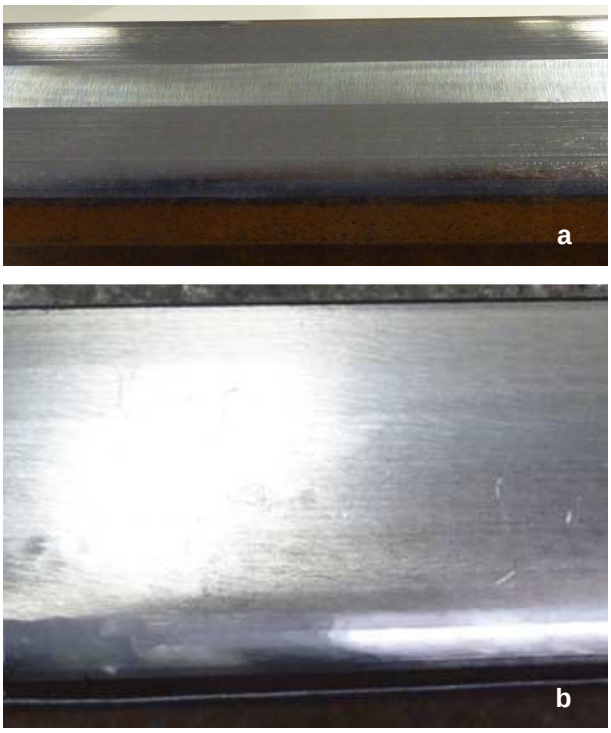

Figure 17 *Milled rail surface; factory (a) and field (b, with abrasive post-treatment) production.*

5. Conclusions

Due to operational conditions and design choices concerning the rail infrastructure, the share of rails performing in the RCF regime has steadily increased over the past decades. Maintenance of rails by cyclic grinding is performed irrespective of the regime in which the rail surface is performing: wear or RCF. The scope however is different in both cases: profile restoration in the case of wear and resetting of the fatigue life of the top layer in the case of RCF. The latter requires a properly 'tuned' surface finishing process with respect to three mechanisms: removal of surface material, thermally driven transformation of remaining surface material and mechanically driven deformation of subsurface material. Both last mechanisms are associated with residual stress generation, tensile (or detrimental) in the first and generally compressive (or benign) in the second case. Whereas aggressive grinding appears on one side of the spectrum, with excessively negative consequences for the lifetime in terms of phase-transformed material, residual stresses and roughness, milling appears on the other side of the spectrum as at least a technically promising – but largely unexplored – method to achieve an extended RCF service life. It appears of crucial importance to set up fundamental research into the relationship between rail surface parameters resulting from treatment, via contact loading conditions and failure mechanisms to surface lifecycle performance. This paper has discussed a number of important aspects and the reasons why they need to be included in such research. In view of the special situation (scale) of the wheel-rail contact among other tribological assets, feasibility needs to be taken into account here as well. Based on the outcomes of such research, infra owners can develop adequate rail maintenance specifications with the explicit scope of mitigation of both wear and RCF.

[1] KTH Royal Institute of Technology, Stockholm, Sweden

[*] E-mail: stichel@kth.se

To investigate the general dynamic behaviour of a rail vehicle like ride comfort and running stability it is usually sufficient to use the Hertz solution for the normal contact and Kalker's Fastsim algorithm for the tangential contact as most multibody simulation tools do today. If the aim is to study more complex phenomena, such as the prediction of long-term wear behaviour or the RCF risk of a wheel, it is more doubtful whether these simplified contact theories provide results that are accurate enough. An elliptic contact patch might indicate contact, and in turn contact pressure and tangential deformation, where there would not be contact at all with a more realistic non-elliptical contact patch. On the other side of the spectrum, much more accurate codes like CONTACT still are numerically too costly to perform a long-time wear prediction where the dynamic simulations have to be repeated many times. In the lecture the methodologies for wear and RCF prediction will be introduced shortly and results achieved with simplified respectively more accurate contact theories will be presented, and the balance between computational efficiency and accuracy will be discussed.

Abstract: Squats/Studs are rail surface damage patterns which cause high maintenance costs and can lead to safety issues when not treaded appropriately. The mechanisms behind their formation are manifold and complex and still not fully understood. It is agreed that it represents a system level problem, where the chosen maintenance technology represents one part of the system. Based on a simulation tool chain and experiments it is shown that rail milling can produce high quality rail surfaces ensuring that existing Squat/Stud are removed and that the risk of generating additional potential initiation points by the milling process itself is very low.

Keywords: Squats, WEL, Martensite, Rail Maintenance, Rail Grinding, Rail Milling, Milling Simulation.

1. Introduction

Rolling contact fatigue (RCF) defects (Head Checks, spalling, shelling, Belgrospies, corrugation etc.) and other railway operation related defects (wheel burns, imprints, dipped welds etc.) represent a major challenge for infrastructure owners globally. Especially during the last 15-20 years, the defect type Squat has started to re-appear on an extensive and almost epidemic scale. Research activities with respect to this defect type focus on prevention of initiation and growth but also on maintenance technologies to remove existing defects in a sustainable way that Squats will not re-appear in the same location.

2. A historical view on Squats

Squat research was started in the 1950s and 1960s by Japanese railways to overcome a “dark spot” and “shelling” problem on conventional lines as well as the Shinkansen high speed lines [1]. The name Squat for this type of defect was introduced in the 1970s and 1980s in England [2]. According to UIC [3], a Squat is characterised as “a widening and a depression of the rail-wheel contact band, accompanied by a dark spot containing cracks with a circular arc and/or V shape” (see Figure 1).

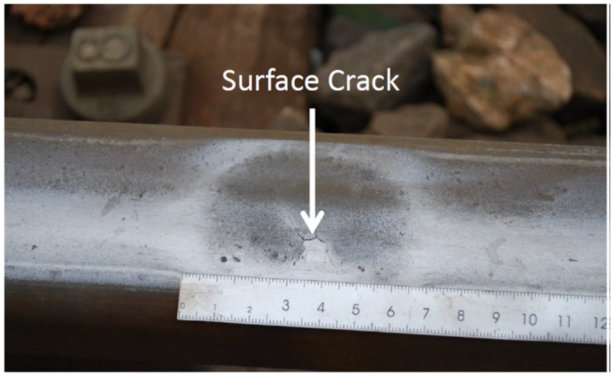

Figure 1: Photography of a Squat defect on a rail surface [4]

The British Rail Research [2] indicated that such a defect would develop from surface imperfections in highly deformed material structure of the rails within approx. 100-150 MGT (milling gross tons) of traffic load. The main damage mechanism was identified as ratchetting (continuous cyclic plastic deformation and subsequent crack initiation) with some indication for fluid assisted crack growth. The high shear deformation of the rail surface was associated with high traction forces caused by driven railway wheels. Typical rail grades at this time had a carbon content around 0.4-0.6% (R200, R220) resulting in a microstructure of proeutectoid ferrite (inter-granular) and pearlite. This type of microstructure had a reduced resistance against plastic deformation and ratchetting. Initiated Squat cracks could grow with low resistance along the heavily sheared inter-granular ferrite phases into the railhead. If these defects were not treated, they would result in a transverse fracture of the rail. Finally, Squat defects became of lesser importance with the introduction of rail grinding at optimised cyclic intervals (to remove initiated cracks at an early stage) and by the introduction of rail grades with purely pearlitic microstructure (like R260) that had a higher resistance against plastic deformation and crack initiation by ratchetting compared to the previously used rail grades (R200, R220).

3. Actual Squats, Squat type defects and Studs

After having this problem presumably under control, the defect started to re-appear in the late 1990s on a large scale in Australia [5] and Europe [6]. Besides mainline

infrastructure owners, also multiple urban train networks started to suffer from widespread Squat-reappearance at the same time.

In the Netherlands, extensive research efforts were put into the topic of Squat initiation and growth [6][7][8]. It was found that stiffness and tamping characteristics of the track (and presumably vehicle stiffness characteristics) play a role. Furthermore it was found that several types of surface irregularities can act as a starting / initiation point for Squats like indentations, vertical track misalignment, welds, short pitch corrugation, wheel burns etc… Especially, short pitch corrugation is seen as a major initiation source for Squats in the Dutch railway network. The high dynamic stresses in corrugation areas can result in local exhaustion of rail material ductility and deformation capability resulting in the formation of micro cracks. The growth of these micro cracks will result in small depression areas on the rail surface. There seems to be a similarity to a defect called Belgrospi [9] however, this will not be further analysed in this paper. It is also postulated that a certain initial size of these depression areas is required in order to develop into a Squat (under the given conditions). Besides Squats can also result in secondary corrugation patterns (Squat induced corrugation) due to dynamic behaviour that will promote additional Squat development and growth. As indicated above the initial defect might not only be caused by corrugation but also by other initiation points resulting directly or indirectly in the same critically sized initial defect area. In addition, the Dutch researches supported their track observations also with according simulation models and tools.

Other researches [10][11][12] found that most of the Squats observed in Europe and Australia during the last 15-20 years show deviating characteristics compared to Squats in the 1970s and 1980s although sharing superficial similarities. For this reason, the name Squat type defect or “Stud” was introduced to provide better differentiation. Key differentiating factors for Studs include:

- Studs can form in as little as 10 MGT or less.
- Non or little plastic deformation is found in Stud affected rails suggesting that ratchetting is not the cause for Stud initiation. There is also no evidence for fluid assisted crack growth.
- Cracks will grow through the almost un-deformed pearlitic structure (inter- and trans-crystalline crack growth)
- Stud defects can reach significant depths without causing transverse defects (TDs). TDs are only observed if Studs have formed in the vicinity of other RCF defects like head checks. In this case the TD will originate at the RCF defect due to dynamic overloading by the nearby Stud defect.
- White etching layers (WEL) are always found in Stud areas. There is some evidence that WELs can contribute to Stud formation and growth.
- AC traction systems can reliably and controlled operate at high slip values (compared to the previously used DC traction systems). High traction forces and slip values can result in mechanical and thermal damage of the rail surface.
- Low rail wear environment will favour the formation of Studs.

Many of the above-mentioned findings coincide very well with the observations in [8]. Another way of combining the findings of different researchers and of indicating the complexity of the actual Squat / Stud problem is summarized in the Squat staircase concept [13] (see Figure 2).

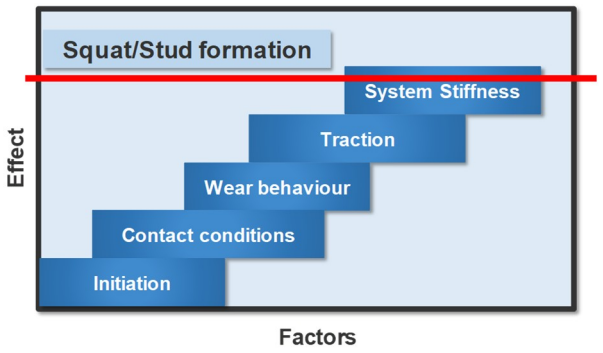

Figure 2: *Modified version of the Squat staircase concept for Squat/Stud formation as presented in [13]*

This concept lists the key factors / key conditions that have to be present in the rail wheel contact in order for Squats/Studs. As the authors of this concept did not differentiate between Squats and Studs the term Squat/Stud is used below.

- Initiation point: as listed above there are a number of possible initiation points for the defect. In principal, any kind of deviation on the rail surface (or even track) in the right order of magnitude / dimension can act as an indirect or direct initiation point for Squats/Studs.
- Contact conditions: in order for Squats/Studs to form, unfavourable, high stress contact conditions need to be present in the wheel rail contact. The shape of rail and wheel profiles have a significant impact on this point.
- Wear behaviour: Squats/Studs preferably form in a low wear environment. Possible initiation points and high stress contact conditions will remain for a longer time on the rail surface in the case of low wear environment.
- Traction: Squats/Studs do form in areas where high traction forces are acting on the rail surface. These traction forces can result from actively driven wheels. They might also result out of unfavourable geometric conditions between wheel and rail during curving. Resulting slip marks and wheel burns can also act as possible initiation points.
- System stiffness: As indicated above sufficiently stiff rail/wheel systems will favour the formation of Squats/Studs. Both track stiffness and vehicle stiffness can contribute to

Squat/Stud formation by increased dynamic system response.

Although each individual factor alone will not result in Squat/Stud initiation, the "right" combination of these factors can result in Squat formation and growth. Together with the resulting stress condition in the rails (indicated by simulations), the authors in [13] define this as the "Squat condition of rail materials". This condition needs to be present in order for Squats/Studs to form and grow.

However, it is to date difficult to quantify the necessary magnitude of the each individual factor. Each railway system will require a different combination of magnitudes of each "step" of the Squat staircase and some of the factors might be very difficult to measure/determine. The Squat staircase concept and the findings by the other research clearly indicate that Squats/Studs are results of a general rail/wheel system level problem and can only be resolved by optimising the system as a whole. Tweaking only individual system components might not resolve the problem and/or might even impact the wheel/rail system negatively with respect to other unintended side effects.

The multi-level view described above matches also with the ideas presented in [14][15]. There, the initiation and propagation processes are systematically analysed with respect to contact mechanic aspects. A required initiation point can be an initial local geometric deviation on the rail surface or a local material inhomogeneity generated in service (e.g. a WEL caused by wheel slips). At this initiation point, a Squat/Stud can start to grow. This propagation mechanism is mainly driven by local variations in the running band and the according contact stresses causing locally varying wear, crack initiation and crack propagation. This can result in the worst case in a fully grown Squat/Stud.

4. Maintenance Technologies

The paper will analyse how rail maintenance technologies and especially rail milling can contribute to a system level solution for Squat/Stud mitigation.

The most commonly used technology is rail grinding. Grinding stones rotating around the vertical axis are moved along the rail at variable angles to remove a defined amount of material. This results in an adjustment of the transversal and longitudinal rail profile. This highly flexible process can achieve low to medium metal removal per pass dependent on machine size (number of stones). Typically, rail grinding is applied for a preventive or medium-corrective maintenance strategy. The weaknesses of grinding are formation of sparks and dust as well as high energy input into the rail surface that can result in unwanted material transformation of surface layers. In order to achieve high metal removal rates, multiple passes of a grinding train are required, resulting in a clearly reduced production rate (finished meters per shift).

Rail milling is a spark free rotational cutting process resulting in the formation of metal chips to be cut out of the rail surface. Rail milling achieves medium to high metal removal rates in one milling pass. The process heat mostly transfers into the metal chips and the milling tool. The metal chips are collected on board the milling machine and can be recycled afterwards complementing the process with an environmental added value. In order to produce a noise-optimised surface finish a polishing unit (completely enclosed longitudinal grinding wheel with a small off-set angle) is included in the machine immediately followed to the milling unit. Compared to rail grinding, rail milling is a slower process. However, the slower process speed can be compensated by higher one-pass metal removal capabilities, especially when applied for corrective or regenerative maintenance strategies.

5. Milling Technology Analysis

In order to optimise the application of rail milling and to get a detailed numerical analyse of the process itself, the Materials Center Leoben (MCL) in Austria developed a simulation toolset of the rail milling process in close collaboration with LINMAG [16]. By using the finite element program Abaqus/Explicit and an Arbitrary-Lagrangian-Eulerian (ALE) method, a 2D model including one milling insert and a small region of a rail head next to the milling area is set up. A set of well-chosen boundary conditions and defined mesh regions in the model allow simulating accurately a high dynamic machining process like rail milling without numerical instabilities [17]. One of the special features of the model is the assumption of a starting chip geometry with an Eulerian boundary condition to allow a material outflow at the top surface of the chip outside the chip-tool contact zone. Figure 3 shows the milling wheel on a rail head and below a result plot of the model during milling. Depicted is the strain rate $\dot{\varepsilon}$ in the rail workpiece. The material is deforming mainly in the visible and marked primary shear zone. The rail material is shearing and flows away from the rail into the chip. Rail milling can be seen as a continuous forming process. The material separation between remaining rail and chip is a result of plastic deformation without development of cracks. The simulation shows that the produced process heat flows mainly into the chip (up to 800° Celsius), the milling insert (up to 900° Celsius) and the tool holder. Some few microns at the top of the maintained rail are influenced by work hardening and a raised temperature of up to 300° Celsius. The detailed results can be found in [17]. In contrast, simulations of a conventional grinding process, shown in [18], clearly indicate that rail surface temperatures can rise multiple times above the pearlite-austenite transition temperature during one pass of a 24 stone grinding vehicle.

In the next chapter, this paper will further analyse the impact of the rail milling process on the metallographic structure and behaviour of the rail surface based on experiments.

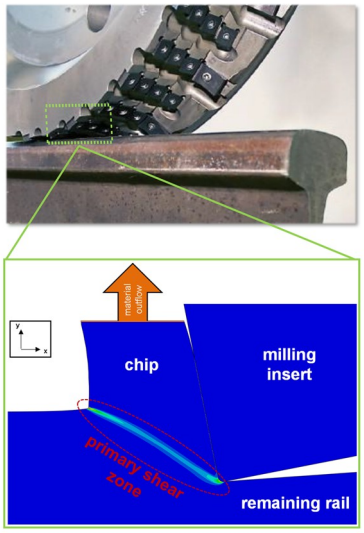

Figure 3: *A milling wheel on a rail head and a close-up view of the 2D milling simulation. The result plot of the strain rate ε˙ is shown during milling.*

6. Milling Tests

To better understand the influence of the rail milling process with respect to the rolling/slipping contact behaviour of a rail surface several investigations were performed and some results of these tests are presented here. Two milling test programs were executed, one in the factory track at LINSINGER and LINMAG in Austria and another one in the track of a European infrastructure owner.

6.1. Test Set Up

For the first test program, newly installed rails (previously used and refurbished, grade R260) at the factory track in Austria were milled with typical rail milling parameters. A milling machine type SF02W-FS applied a 60E2 profile to the rail. About 1.0mm of metal was removed in the center of the rail head during one milling pass.

The second test was part of a regular rail milling program in the network of Irish Rail. Two adjoining track segments (test segment 1 and test segment 2) were milled with the same milling machine type as mentioned above. Also for this test common milling parameters were used in order to completely remove the damage from the rail surface and to restore the rail according to the target profile of 54E1. On average about 2.0 mm of rail material was removed from the rail surface (measured at the center of the railhead) in two milling passes to ensure a crack free rail surface. Each milled track segment consisted of 4 parts (Figure 4):

- Part one (ramp in – start of rail milling)
- Part two (full rail milling process)
- Part three (ramp out – end of rail milling)
- Part four (worn – not maintained, reference)

All analysed rail samples were taken out of part two and/or part four of each test segment as these two parts represent stable test conditions.

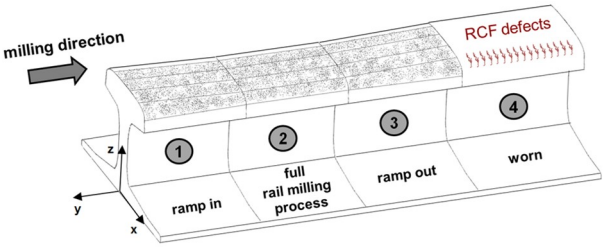

Figure 4: *typical milling test segment consisting of 4 parts. Part 2 and Part 4 represent stable conditions and were used for further analysis*

Test segment 1 was removed from track only after 11 days of train service which corresponds to an approximate load of 0.12 MGT (million gross tons). The second segment was kept in track for about 7 months (approx. 2.3 MGT) and was recently removed. Together with the samples from the factory track four different rail conditions were available for analysis:

- In-service rail with given surface damage, reference sample – condition 0
- A newly milled rail surface without any traffic – condition 1
- A milled rail service after 11 days of light traffic – condition 2
- A milled rail surface after 7 months of light traffic – condition 3

Different measurement methods (Rail surface roughness, eddy current, ultrasonic depth gauge and transversal profile measurement with a DQM device) were performed in order to characterise the rail surface condition in longitudinal and transverse direction before and after milling for the four different rail conditions.

6.2. Metallographic examinations

Each analysed rail sample was sectioned in longitudinal and transversal direction to characterise the condition of the microstructure. The untreated rail surface of test program 1 (factory track) was not used for this analyse as there were many uncertainties with respect to this refurbished (second hand) rail. Both the loading history as well as the refurbishing methodology were unknown. Eddy current measurements of the factory track rails indicated a mostly crack free rail with some sporadic indications of crack depths of 0.5mm or below.

The condition 0 rail sample was taken out of part 4 of test segment 1 (test program 2 – Irish Rail). The metallographic analysis both in transversal and longitudinal direction clearly show approx. 1.5mm deep cracks growing through the deformed microstructure of this R220 rail material (see Figure 5). At this test segment no Squats or white etching layers were found on the rail surface. The predominant damage at this segment consisted of Head Check defects (periodic cracks at the gauge corner of the rail).

The micrographs of rail condition 1 (newly milled rail surface without any traffic) show no visible damage and a visually very smooth rail surface (see Figure 6). No white etching layers were found at the analysed sample positions. It is worth mentioning that the original rail condition was also mostly crack free (see above)as this sample was taken from the refurbished rail (test program 1) installed in the factory track.

The rail samples of condition 2 are shown in Figure 7. The rail damage was completely removed and no residual cracks were found. This was also confirmed by eddy current measurements that were conducted as part of the rail milling operation (on board measurement device). Furthermore, no white etching layers were detected at the analysed positions. After 11 days of traffic the rail surface is still quite smooth however in some areas material has been removed from the rail surface due to wear.

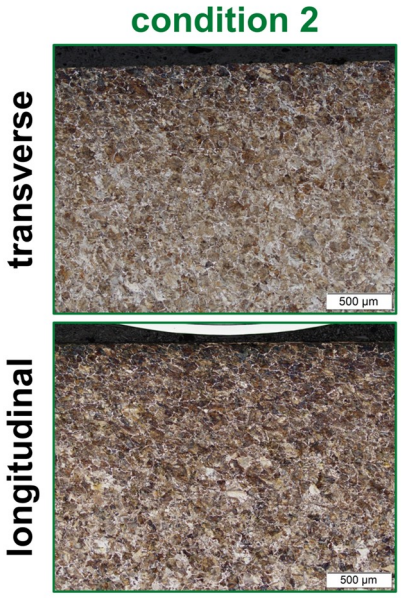

Figure 7: *Rail microstructure at the rail surface (50x magnification) of the milled and loaded rail head (11 days of light traffic, condition 2) in transverse and longitudinal direction.*

7. Rail maintenance and Squat Mitigation

Rail maintenance can be used in two ways to contribute to Squat mitigation. A preventive maintenance strategy can help to keep the rail surface free of any defects or Squat/Stud initiation points and if Squats/Studs have formed a regenerative rail maintenance strategy can be used to completely remove Squats and prevent premature rail exchange.

Conventional rail grinding can result in heat induced material transformation of the rail surface (WEL) due to the nature of the process [18]. There is some evidence that WEL can contribute to the formation of Squats / Studs (initiation point) as discussed in Section 3. However not every WEL (introduced by rail grinding, locomotive traction power, etc.) will generate a Squat. More research effort needs to be carried out on this topic to better quantify potentially critical properties of a WEL with respect to Squat/Stud formation.

In reference to the Squat staircase concept, rail milling can contribute to Squat mitigation in multiple ways:

- Rail milling can regenerate the rail surface by completely removing existing (Squat / Stud) damage. The process can be precisely controlled to introduce exactly the required amount of wear to a rail surface.
- The process will generate a very precise transversal rail profile thereby helping to reliably reduce the contact stresses between wheel and rail.
- Finally rail milling will result in a defect free and (longitudinally) smooth rail surface. This will ensure that all possible initiation points are removed. Furthermore, this maintenance process will not introduce additional / potential / new initiation pointes (e.g. WEL, surface irregularities, etc.) for Squats/Studs.

8. Conclusions

Global research activities have shown that there is a clear differentiation between Squats before the 1990s and Squats/Squat like defects/Studs experienced today. Formation and growth of these defects are a result of a very complex system and depend on several interacting and overlapping factors. The Squat staircase concept demonstrated in [13] presents a very good indication of this problem complexity.

Rail maintenance and especially rail milling can contribute to Squat mitigation if applied correctly. A simulation tool chain for the milling process was developed to better understand various aspects of this technology. Together with a series of milling track tests it was shown that rail milling represents a gentle rail treatment technology capable of applying a curative rail maintenance strategy. Therefore, rail milling can contribute to Squat/Stud mitigation by addressing several steps in the Squat/Stud staircase concept. However, in order to achieve a sustainable solution for the Squat/Stud problem a comprehensive approach needs to be chosen, that does not only consider some of the contributing factors (steps) but solves this problem on the system level.

Abstract: The ratcheting performance of heavy haul rails in curved tracks under different in-service loading conditions was numerically evaluated by using a recently developed approach. The wheel-high rail cyclic rolling contact was simulated by translating the non-Hertzian contact pressure distribution and the estimated longitudinal tangential traction repeatedly on the running surface of the high rail. The maximum ratcheting strain rate of the rail target section was obtained in each loading cycle. Based on the known ductility limit of the rail steel and the obtained maximum stabilized ratcheting strain rate, the crack initiation life of the rail was predicted in each case. The results indicate that the crack initiation life for all the three rail steels investigated decreases with the increase of the normalized tangential traction, the friction coefficient, the ratio of lateral/axle load and the axle load. The hypereutectoid steel with a lower carbon content always shows the best ratcheting performance and is likely to be the best choice for the high rails in curved tracks. The results can provide valuable information to assist rail operators in the selection of rail steel grades and the development of rail maintenance strategies.

Keywords: curved tracks; two-point cyclic rolling contact; ratcheting performance; crack initiation life; finite element analysis.

1. Introduction

As a train passes a curved track, the vehicle is subjected to the centrifugal force and may shift transversely towards the high rail. Under such situation, and depending on the wheel and rail profiles in use, two-point contact between wheel and high rail may occur as the wheel flange can touch the rail gauge [1, 2]. The area of wheel tread/flange–rail gauge contact can be smaller than that under wheel tread–rail crown contact in tangent tracks, so the high rail surface can be subjected to cyclic rolling and sliding condition with higher contact stresses. It has been found that if the rail stress level resulted from the wheel-rail cyclic rolling contact is above the plastic shakedown limit, new plastic deformation will generate and accumulate in each loading cycle, which is known as plastic ratcheting. The increment of plastic deformation in one cycle may be small, but it can accumulate to large values after many cycles [3]. Initiation of rail degradation, such as rolling contact fatigue (RCF) or wear, will occur where the ratcheting strain reaches the limiting ductility of the rail material [4, 5]. Throughout the past few decades, the introduction of higher axle loads and annual haulage rates has placed more emphasis on the performance of the curved tracks. In view of these reasons, it is essential to evaluate the ratcheting performance of high rails in curved tracks under different in service loading conditions.

A comprehensive approach for numerically evaluating the ratcheting behaviour of the rails under in-service cyclic rolling loading has been developed by Pun et al. [6]. Different wheel–rail cyclic rolling contact conditions, i.e. free rolling, partial slip and full slip conditions, different friction coefficients and different axle loads were investigated under single-point contact in tangent rails [6]. The wheel–rail cyclic rolling contact was simulated by repeatedly translating a non-Hertzian contact pressure distribution obtained from a separate quasi-static finite element (FE) analysis, and a longitudinal tangential traction predicted from Carter's theory [7]. A constitutive cyclic plasticity model was developed and applied to simulate the ratcheting behaviour of the three rail steels [8]. The results indicated that the increase of the normalized tangential traction, the friction coefficient and the axle load can reduce the crack initiation life. The hypereutectoid rail steel grade with a lower carbon content showed the best ratcheting performance among the three rail steels investigated. These outcomes can provide useful information to assist in the selection of rail steel grades and the development of improving rail maintenance strategies.

In the current study, the same procedure developed by Pun et al. [6] is applied to numerically evaluate the ratcheting performance of the three rail steel grades for the high rails in curved tracks under cyclic rolling contact. Different axle loads, different ratios of lateral/axle loads, different values of normalized tangential traction and different friction coefficients will be considered. The results obtained can be useful to predict the crack initiation life of the curved rail and such information can further improve rail maintenance strategies. The comprehensive approach is briefly outlined in Section 2, followed by numerical results and discussion presented in Section 3. Conclusions are provided in Section 4.

2. Methodology

The comprehensive approach developed by Pun et al. [6] was updated for cyclic rolling contact of high rails in curved tracks. The research methodology is illustrated in the flowchart as shown in Figure. 1.

2.1. Material properties

The wheel and rail materials applied in the current study are identical to those used in Pun et al. [6]. The wheel grade corresponds to AAR Class C with the yield strength of 855 MPa [9]. Its properties are described by an elastic-plastic constitutive model combined with the isotropic hardening rule. Three types of pearlitic rail steel grades considered include a low-alloy heat-treated (LAHT) rail steel with 0.8% carbon content and two hypereutectoid rail steels (HE1 & HE2) with 1% and 0.85% carbon content, respectively. The development of the constitutive cyclic plasticity model for these rail steels can be found in Pun et al. [8].

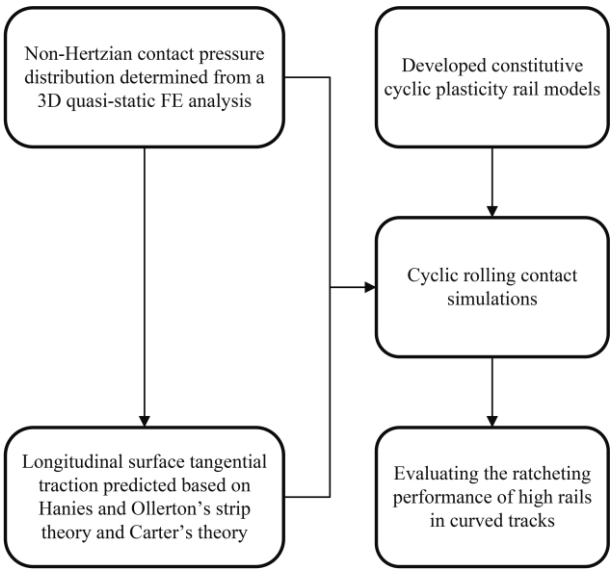
2.2. Finite element model

To simulate the cyclic rolling contact problems, the distributions of normal pressure and tangential traction were applied on the rail surface.

Johnson [10] indicated that only a minor loss of accuracy occurs if the normal contact pressure distribution is determined with the assumption that the contact pressure distribution is independent of the friction and shear forces for two bodies with similar elastic properties. Therefore, the non-Hertzian contact pressure was first obtained from a separate frictionless quasi-static FE analysis.

A half three-dimensional wheel-high rail model was generated in Abaqus 6.14-1 as shown in Figure. As the length of the rail in the FE model is very short (390 mm) comparing to the radius of the curvature applied in railway systems, a straight rail segment can be fairly used to simulate a real curved one. Both vertical force, which represents the axle load, and lateral force were simultaneously applied at the wheel centre.

The rail profile considered was an as-rolled 68 kg/m flat-bottom rail [11], while the wheel profile corresponded to an M-107/M-208 wheel with standard wide flange contour (AAR Type D-38) as specified in [9]. Both rail and wheel profiles considered in this study were in new condition. The geometrical parameters of the rail profile include rail height of 186 mm; rail width of 74 mm; crown radius of 254 mm; and gauge radius of 32 mm. Rail cant of 1:40 was applied. The geometrical parameters of the wheel profile include flange radius of 16 mm, wheel width of 145 mm and diameter of 965 mm. The fine mesh region with 0.8 mm element size was designed to capture the high stress and its gradient near the initial contact points in Figure 2b. The value of contact pressure of each element on the rail surface was represented by the average of the corresponding nodal pressure values.



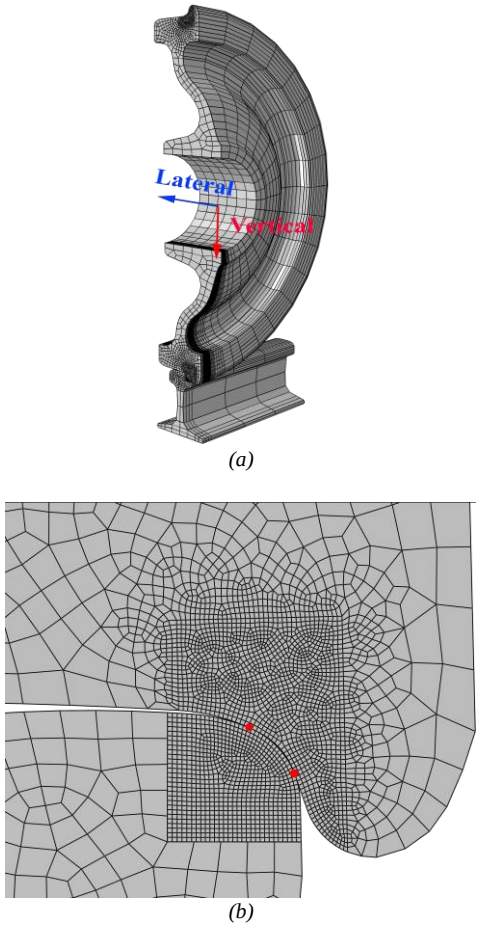


***Figure 1**. Flowchart of the research methodology to evaluate the ratcheting performance of the rails in curved tracks.*

(a)

(b)

***Figure 2**. Illustration of the FE wheel-high rail model for quasi-static analysis: (a) the whole model; (b) fine mesh region near the initial contact points (red dots).*

Based on the obtained numerical results of non-Hertzian contact pressure, the Haines and Ollerton's strip theory [12] was then applied to identify the slip and stick zones along the rolling direction in the contact area, and the surface tangential traction was estimated by applying Carter's theory [7]. Johnson stated that the estimated results obtained from these theories have almost no

difference to the results obtained from Kalker's theory [13]. It should be noted that the attack of angle is zero in current study. As an example, Figure 3(a) illustrates the contact pressure distribution obtained from the FE analysis for the LAHT steel in high rails when the applied axle load L is 35 t and the ratio of lateral/axle load η is 0.3. The determined longitudinal tangential traction distributions with the normalized tangential traction of ξ = 0.25, 0.5 & 0.75 and friction coefficient *f* of 0.4 are shown in Figures 3b-d.

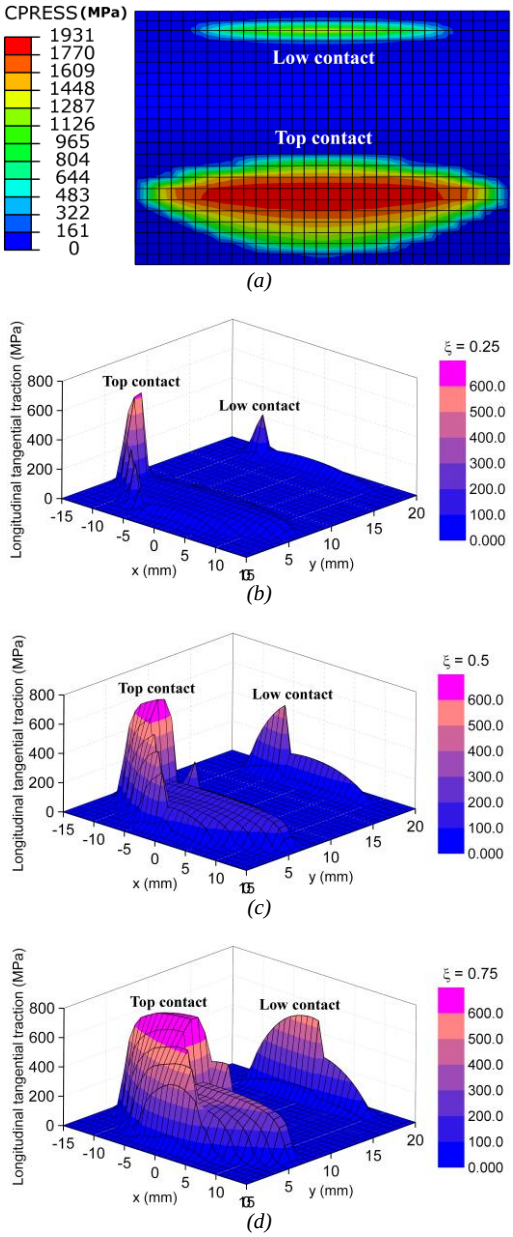

***Figure 3**. Contact pressure distribution (a) and longitudinal tangential traction distribution with different values of normalized tangential traction: ξ=0.25 (b); ξ=0.5 (c); ξ=0.75 (d), for LAHT steels in high rails with axle load of $L = 35\ t$, ratio of lateral/axle load $\eta = 0.3$ and friction coefficient of $f = 0.4$.*

The FE model for cyclic loading is shown in Figure 4(a). The element size and the fine mesh zone are identical to those used in the quasi-static wheel–rail model, but the length of the rail is double. A target section which covers all the corresponding fine elements below its top surface was set in the middle of the fine mesh region to output the plastic strain components shown in Figures 4b-c.

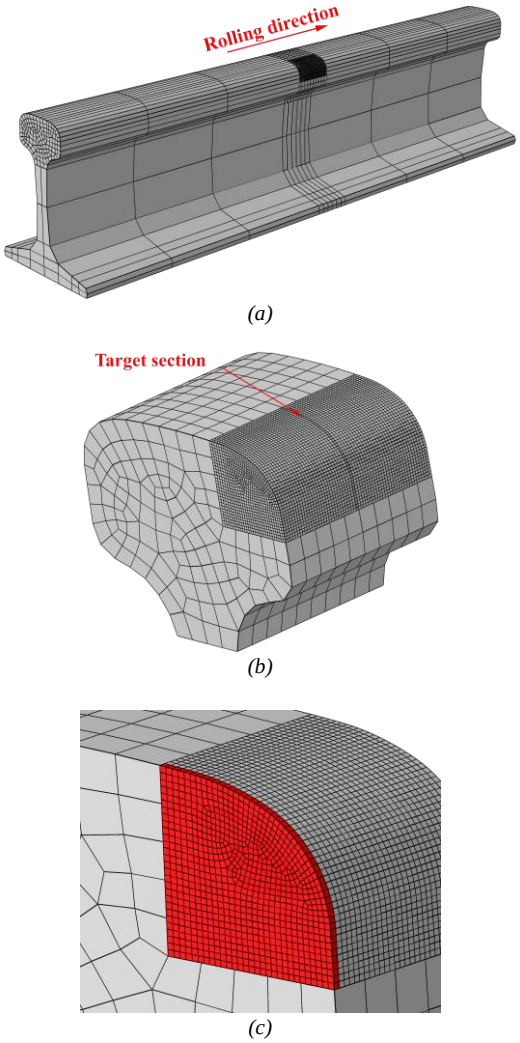

***Figure 4**. Illustration of the FE model for cyclic loading: (a) the full rail model; (b) and (c) Fine mesh region with the target section.*

Figure 5 illustrates the process of cyclic loading simulation on the rail surface. The obtained normal contact pressure distribution and the estimated surface tangential traction distribution were translated repeatedly from left to right on the top surface of the fine mesh zone. All the nodes located at the bottom of the rail were fixed in all directions throughout the whole simulation.

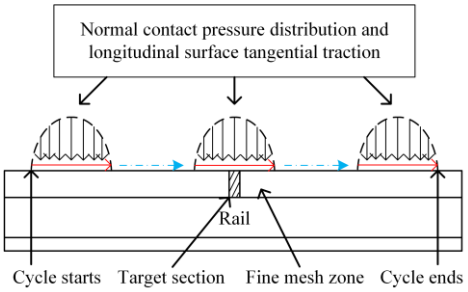

***Figure 5**. Illustration of the process of cyclic loading simulation.*

2.3. Evaluation of ratcheting performance

The approach to evaluate the ratcheting performance of rails under different loading conditions is presented in

Pun et al. [6]. The cyclic loading simulation can provide both normal and shear components of plastic strain, and then the effective plastic strain ε_{eff}^{p} can be applied to obtain the ratcheting strain ε_r which is the maximum value of effective plastic strain $(\varepsilon_{eff}^{p})_{max}$ of the rail steel in each loading cycle. It can be determined from the following equation:

$$\varepsilon_r = \left(\varepsilon_{eff}^{p}\right)_{\max} = \left(\sqrt{\frac{2}{3}\boldsymbol{\varepsilon}^{p} : \boldsymbol{\varepsilon}^{p}}\right)_{\max} \quad (1)$$

where $\boldsymbol{\varepsilon^p}$ is the plastic strain tensor. Then the ratcheting strain rate $d\varepsilon_r/dN$ in each loading cycle can be obtained which is applied to predict the crack initiation life N_i of the rail. As mentioned in Section 1, the local rail material may fail where the ratcheting strain reaches its ductility limit. Therefore, the crack initiation life N_i can be predicted from the stabilized maximum ratcheting strain rate $(d\varepsilon_r/dN)_{max,sta}$ of the target section under different cyclic rolling contact conditions. The following equation is applied to judge cyclically stable state:

$$\left|\frac{\left(d\varepsilon_r/dN\right)_{\max,N} - \left(d\varepsilon_r/dN\right)_{\max,N-1}}{\left(d\varepsilon_r/dN\right)_{\max,N-1}}\right| < 0.5\% \quad (2)$$

where $(d\varepsilon_r/dN)_{max,N}$ is the maximum ratcheting strain rate in the current loading cycle and $(d\varepsilon_r/dN)_{max,N-1}$ is the maximum ratcheting strain rate in the previous loading cycle. If Eq. (2) is satisfied in five continuous cycles, the position with the maximum ratcheting strain rate reaches a cyclically steady state. Knowing the ductility limit D of each rail steel as given in [6], the crack initiation life N_i under different loading conditions can be predicted by,

$$N_i = \frac{D}{\left(d\varepsilon_r/dN\right)_{\max,sta}} \quad (3)$$

3. Numerical results and discussion

With the existing approach and the developed FE model for cyclic rolling contact simulations, several case studies have been conducted on the ratcheting performance of the three rail steel grades for high rails within curves under various loading conditions in service. Different axle loads, different ratios of lateral/axle load, different values of normalized tangential traction and different friction coefficients. The number of cycles considered in each case depended on the number of cycles required for the location with the maximum ratcheting strain rate to reach the cyclically steady state which is judged by Eq. (2). For all the cases considered as shown in Figures 6, 9, 12 & 15, the stabilized maximum ratcheting strain rate is non-zero. This means that the net plastic deformation will accumulate continuously in each following loading cycle even if its value may be very small. As mentioned in Section 1, crack initiation will occur when the ratcheting strain reaches the limiting ductility of the rail materials.

3.1. Influence of normalized tangential traction

Figure 6 demonstrates the maximum ratcheting strain rate $(d\varepsilon_r/dN)_{max}$ versus the number of loading cycles N under different values of normalized tangential traction ξ for all the three steels. It is shown that the maximum ratcheting strain rate decreases with the increasing number of loading cycle but increases with the normalized tangential traction. The stabilized maximum ratcheting strain rate is around 10^{-6} when the normalized tangential traction is less than or equal to 0.5. When the normalized tangential traction increases to 0.75, HE2 steel has the lowest stabilized maximum ratcheting strain rate of 1.14×10^{-5} while it is 7.2×10^{-5} and 9.71×10^{-5} for LAHT and HE1 steels, respectively. In addition, the number of loading cycles required for the rail steels to become cyclically stable increases with the normalized tangential traction.

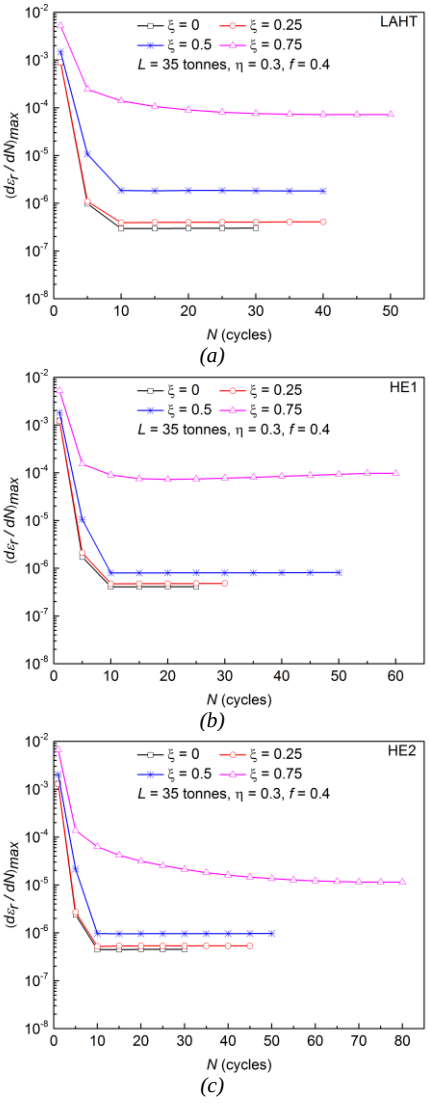

***Figure 6**. Maximum ratcheting strain rate $(d\varepsilon_r/dN)_{max}$ versus number of loading cycle N under different values of normalized tangential traction ξ for (a) LAHT; (b) HE1; (c) HE2, with axle load of $L = 35$ t, ratio of lateral/axle load $\eta = 0.3$ and friction coefficient of $f = 0.4$.*

Figure 7 shows the influence of the normalized tangential traction ξ on the stabilized maximum ratcheting strain rate $(d\varepsilon_r/dN)_{max,sta}$ for each rail steel. The results illustrate that the stabilized maximum ratcheting strain rate almost keeps constant when the normalized tangential traction is less than or equal to 0.25. A minor increase on the stabilized maximum ratcheting strain rate

is observed when the normalized tangential traction increases to 0.5. As the normalized tangential traction is greater than 0.5, the stabilized maximum ratcheting strain rate for both LAHT and HE1 steels increases dramatically while a slight increase is observed on HE2 steel which give the lowest value.

Based on the obtained stabilized maximum ratcheting strain rate, the known ductility limit listed in [6] and Eq. (3), the crack initiation life under different values of the normalized tangential traction for each rail steel can be predicted. Figure 8 demonstrates the relationship between the crack initiation life N_i and the normalized tangential traction ξ. It is found that the crack initiation life decreases as the normalized tangential traction increases. The crack initiation life of LAHT steel is up to 1.5 million cycles under the free rolling condition, while it is 0.39 million cycles and 1.1 million cycles for HE1 and HE2 steels, respectively. When the normalized tangential traction increases to 0.75, the crack initiation life of HE2 steel is reduced to 4×10^4 cycles, which is the longest among all the three steels. The results also indicate that under mild tangential traction conditions, i,e. $\xi \leq 0.25$, LAHT steel shows the best ratcheting performance while HE2 steels show the best one under severe tangential traction conditions, i,e. $\xi \geq 0.5$. Additionally, HE1 steel always has the shortest crack initiation life among all the three steels although its reduction is not as dramatic as the other two steels.

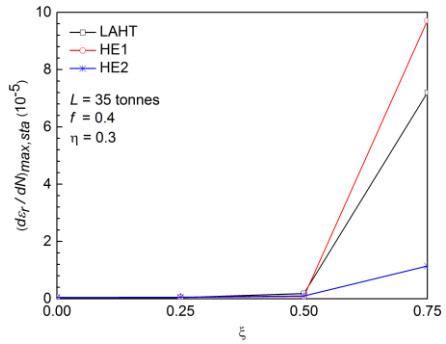

***Figure 7**. Stabilized maximum ratcheting strain rate $(d\varepsilon_r/dN)_{max,sta}$ versus the normalized tangential traction ξ for all the three rail steels with axle load of $L = 35\ t$, ratio of lateral/axle load $\eta = 0.3$ and friction coefficient of $f = 0.4$.*

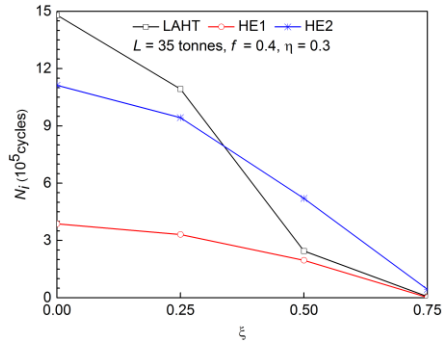

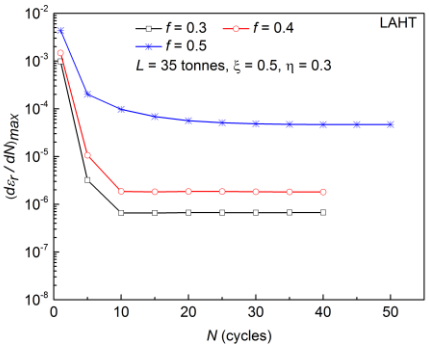

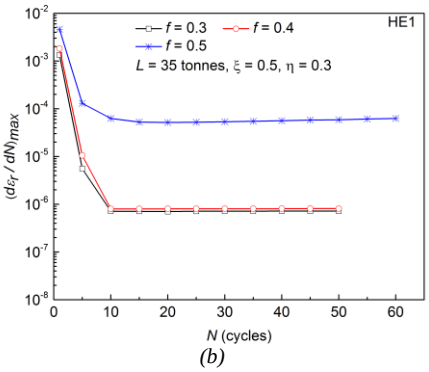

***Figure 8**. Estimated crack initiation life N_i versus the normalized tangential traction ξ for all the three rail steels with axle load of $L = 35\ t$, ratio of lateral/axle load $\eta = 0.3$ and friction coefficient of $f = 0.4$.*

3.2. Influence of friction coefficient

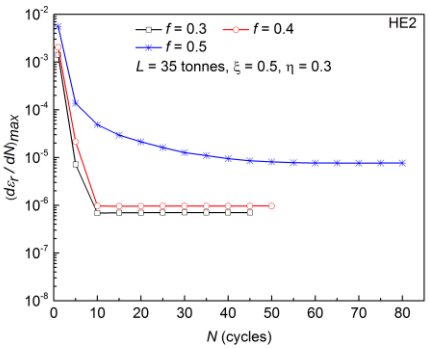

Figure 9 illustrates the maximum ratcheting strain rate $(d\varepsilon_r/dN)_{max}$ versus the number of loading cycles N under different values of the friction coefficient f for all the three steels. The results demonstrate that the maximum ratcheting strain rate decreases with the increasing number of loading cycles but increases with the friction coefficient. The stabilized maximum ratcheting strain rate for all the three steels is around 10^{-6} when the friction coefficient is less than or equal to 0.4. When the friction coefficient increases to 0.5, the stabilized maximum ratcheting strain rate for HE2 steel only increases to 7.64×10^{-6} while the one for both LAHT and HE1 steels increases to the range of 10^{-5}. It is also shown that higher friction coefficient results in the position with the maximum ratcheting strain rate requiring more loading cycles to reach cyclically steady state.

(a)

(b)

(c)

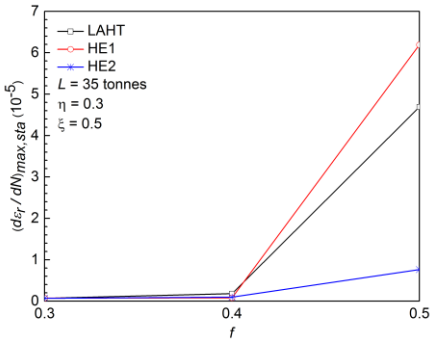

***Figure 9**. Maximum ratcheting strain rate $(d\varepsilon_r/dN)_{max}$ versus number of loading cycle N under different values of friction coefficient f for (a) LAHT; (b) HE1; (c) HE2, with axle load of $L = 35\ t$, ratio of lateral/axle load $\eta = 0.3$ and normalized tangential traction of $\xi = 0.5$.*

The influence of the friction coefficient f on the stabilized maximum ratcheting strain rate $(d\varepsilon_r/dN)_{max,sta}$ for all the three steels is presented in Figure 10. It is apparent that there is no significant change in the stabilized maximum ratcheting strain rate when the friction coefficient increases from 0.3 to 0.4. As the friction coefficient further increases to 0.5, the stabilized maximum ratcheting strain rate increases slightly for HE2 steel whereas it increases rapidly for both LAHT and HE1 steels.

Figure 11 summarizes the influence of the friction coefficient f on the crack initiation life N_i for each rail steel. The results clearly indicate that an increase of the friction coefficient can cause a decrease of the crack initiation life. It is also found that HE1 steels always have the shortest crack initiation life while HE2 steel has the longest one among all the three steels. When the friction coefficient is 0.5, the crack initiation life of HE2 steel is 6.57×10^4 cycles while it is less than 10^4 cycles for both LAHT and HE1 steels. It is worth noting that when the friction coefficient increases from 0.3 to 0.5, the crack initiation life is reduced by 98% and 91% for LAHT and HE2 steels, respectively. However, the crack initiation life of HE1 steel shows a relatively slight decrease when the friction coefficient is greater than 0.4. This information indicates that the performance of LAHT and HE2 steels is more sensitive to the friction coefficient than HE1 steel and the application of effective lubrication is required.

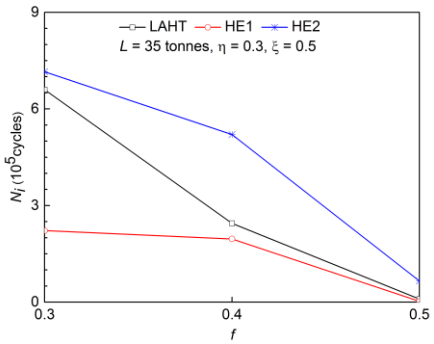

***Figure 10**. Stabilized maximum ratcheting strain rate $(d\varepsilon_r/dN)_{max,sta}$ versus the friction coefficient f for all the three rail steels with axle load of $L = 35\ t$, ratio of lateral/axle load $\eta = 0.3$ and normalized tangential traction of $\xi = 0.5$.*

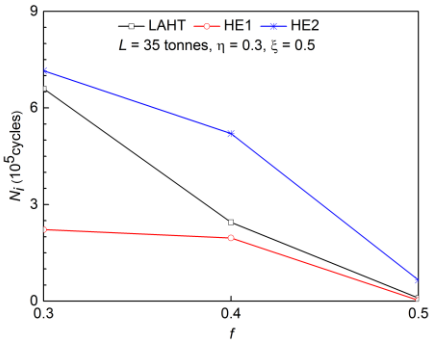

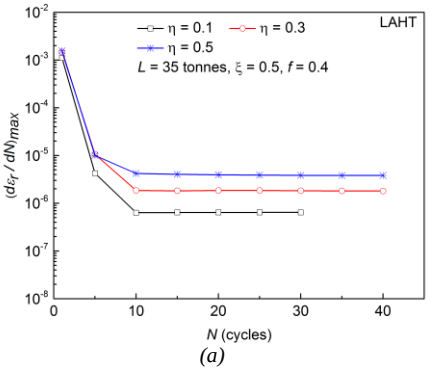

***Figure 11**. Estimated crack initiation life N_i versus the friction coefficient f for all the three rail steels with axle load of $L = 35\ t$, ratio of lateral /axle load $\eta = 0.3$ and normalized tangential traction of $\xi = 0.5$.*

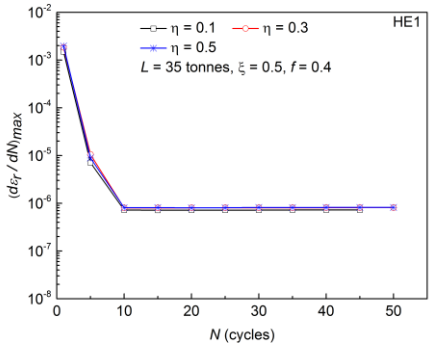

3.3. Influence of lateral/axle load ratio

In Australian heavy haul railways for iron ore haulage, the radius of the sharpest curves in the mainline can be less than 400 m and the maximum operating speed can be up to 85 km/h. Under such conditions, the high rails can be subjected to large lateral load from the wheelset and hence it is necessary to understand the ratcheting performance of the rail steels under different lateral loading conditions. In the present study, the ratios of lateral/axle load η: 0.1, 0.3 and 0.5 were selected.

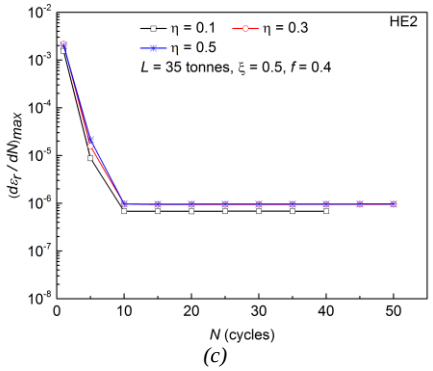

Figure 12 shows the maximum ratcheting strain rate $(d\varepsilon_r/dN)_{max}$ versus the number of loading cycles N under different values of the ratio of lateral/axle load η for all the three steels. Similar to the influence of friction-related parameters: ξ and f, the maximum ratcheting strain rate decreases as the number of loading cycle increases. For LAHT steel, the stabilized maximum ratcheting strain rate increases from 6.42×10^{-7} to 3.81×10^{-6} when the ratio of lateral/axle load increases from 0.1 to 0.5. In contrast, the influence of the ratio of lateral/axle load on the stabilized maximum ratcheting strain rate for both hyper-eutectoid steels is insignificant. All the results of the stabilized maximum ratcheting strain rate lie between 6.5×10^{-7} and 9×10^{-7}.

(a)

(b)

(c)

***Figure 12**. Maximum ratcheting strain rate $(d\varepsilon_r/dN)_{max}$ versus number of loading cycle N under different values of the ratio of lateral/axle load η for (a) LAHT; (b) HE1; (c) HE2, with axle load of $L = 35\ t$, friction coefficient of $f = 0.4$ and normalized tangential traction of $\xi = 0.5$.*

Figure 13 further illustrates the relationship between the ratio of lateral/axle load η and the stabilized maximum ratcheting strain rate $(d\varepsilon_r/dN)_{max,sta}$ for each rail steel. It is found that the stabilized maximum ratcheting strain rate is almost identical for all the three steels when the ratio of lateral/axle load is 0.1. However, the stabilized maximum ratcheting strain rate for LAHT steel increases rapidly with the increase of the ratio of lateral/axle load. In comparison, the one for both hyper-eutectoid steels is almost constant, although there is a minor increase for HE2 steel when the ratio of lateral/axle load increases from 0.1 to 0.3.

The influence of the ratio of lateral/axle load η on the crack initiation life N_i for all the three steels is demonstrated in Figure 14. It is clearly shown that when the ratio of lateral/axle load is 0.1, HE1 steel has the shortest crack initiation life which is around 0.2 million cycles. As the ratio of lateral/axle load increases to 0.5, the crack initiation life of HE1 steel keeps almost constant, while the one of LAHT steel decreases rapidly from 0.7 million cycles to 0.1 million cycles and becomes the shortest among all the three steels. These results reveal that both LAHT and HE1 steels are likely to be maintained frequently if installed in the high rails with sharp curve or high allowable speed of the rolling stock. In addition, HE2 steel always shows the best ratcheting performance among all the three steels even though a significant reduction of the crack initiation life is observed as the ratio of lateral/axle load increases from 0.1to 0.3.

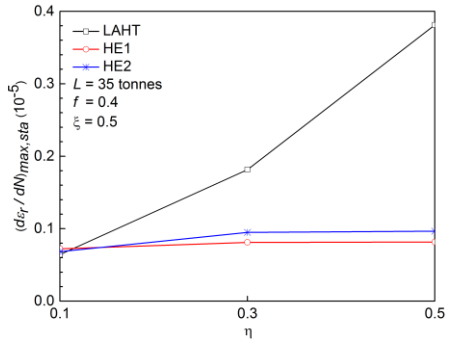

***Figure 13**. Stabilized maximum ratcheting strain rate $(d\varepsilon_r/dN)_{max,sta}$ versus the ratio of lateral/axle load η for all the three rail steels with axle load of $L = 35\ t$, friction coefficient of $f = 0.4$ and normalized tangential traction of $\xi = 0.5$.*

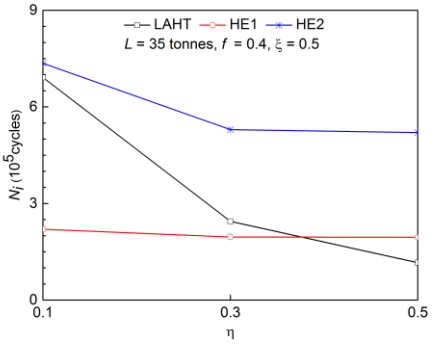

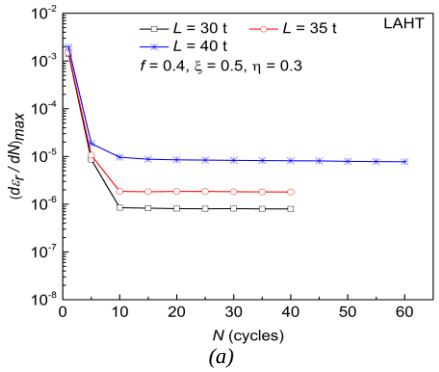

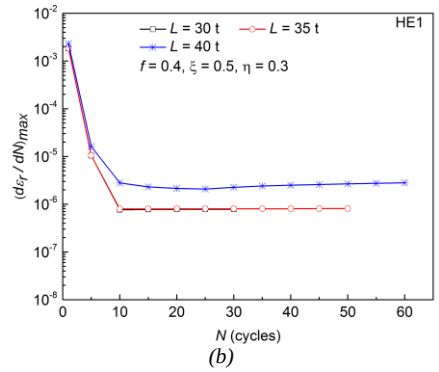

***Figure 14**. Estimated crack initiation life N_i versus the ratio of lateral/axle load η for all the three rail steels with axle load of $L = 35\ t$, friction coefficient of $f = 0.4$ and normalized tangential traction of $\xi = 0.5$.*

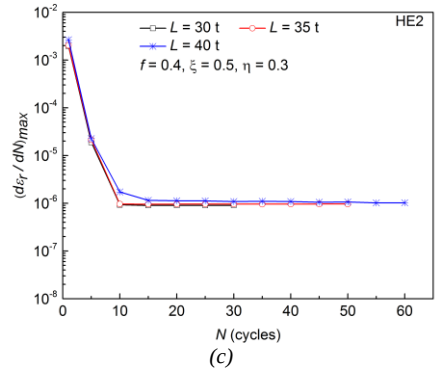
3.4. Influence of axle load



The axle load applied in Australian heavy haul railways for iron ore haulage is typically in the range of 30-40 t. Therefore, it is also essential to evaluate the ratcheting performance of the rail steels under different axle loading conditions. Figure 15 shows the maximum ratcheting strain rate $(d\varepsilon_r/dN)_{max}$ versus the number of loading cycles N under different values of axle load L for all the three steels. The results demonstrate that the maximum ratcheting strain rate decreases with the increasing number of loading cycle. The stabilized maximum ratcheting strain rate for LAHT steel increases from 8×10^{-7} to 7.76×10^{-6} as the axle load increases from 30 t to 40 t. With regard to HE1 steel, the stabilized maximum ratcheting strain rate is almost constant when the axle load is less than or equal to 35 t. When the axle load further increases to 40 t, the stabilized maximum ratcheting strain rate increases to 2.82×10^{-6}. In comparison, the influence of the axle load on the stabilized maximum ratcheting strain rate for HE2 steel is minor. All the results of the stabilized maximum ratcheting strain rate are approximately 10^{-6}.

(a)

(b)

(c)

***Figure 15**. Maximum ratcheting strain rate $(d\varepsilon_r/dN)_{max}$ versus number of loading cycle N under different values of axle load L for (a) LAHT; (b) HE1; (c) HE2, with ratio of lateral/axle load $\eta = 0.3$, friction coefficient of $f = 0.4$ and normalized tangential traction of ξ = 0.5.*

Figure 16 summarizes the influence of the axle load L on the stabilized maximum ratcheting strain rate $(d\varepsilon_r/dN)_{max,sta}$ for all the three steels. The results indicate that when the axle load is 30 t, the stabilized maximum ratcheting strain rate for all the three steels is almost identical. As the axle load increases to 40 t, the stabilized maximum ratcheting strain rate for LAHT steel increases dramatically and becomes the highest value among all the three steels whereas HE2 steel gives the lowest one which almost keeps constant. For HE1 steel, an increase in the stabilized maximum ratcheting strain rate is observed when the axle load is larger than 35 t.

The relationship between the crack initiation life N_i and the axle load L for each rail steel is demonstrated in Figure 17. It is clearly shown that the crack initiation life decreases with the increase of the axle load although there is almost no change for HE1 steel when the axle load increases from 30 t to 35 t. In addition, HE2 steel always provides the longest crack initiation life even though it is reduced gradually with the increase of the axle load. In contrast, HE1 steel always has the shortest crack initiation life among all the three steels. It is noteworthy that LAHT steel is more sensitive to the axle load as the crack initiation life is reduced by almost 90% with the axle load increasing from 30 t to 40 t. These results reveal that both LAHT and HE1 steels may require more frequent maintenance.

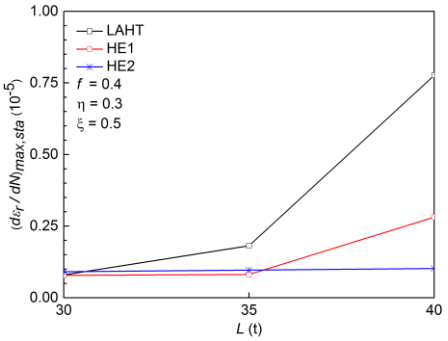


***Figure 16**. Stabilized maximum ratcheting strain rate $(d\varepsilon_r/dN)_{max,sta}$ versus the axle load L for all the three rail steels with ratio of lateral/axle load $\eta = 0.3$, friction coefficient of $f = 0.4$ and normalized tangential traction of ξ = 0.5.*

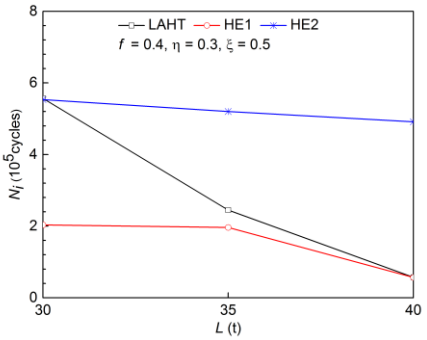

***Figure 17**. Estimated crack initiation life N_i versus the axle load L for all the three rail steels with ratio of lateral/axle load $\eta = 0.3$, friction coefficient of $f = 0.4$ and normalized tangential traction of ξ = 0.5.*

3.5. Discussion

As shown in Figures 8, 11, 14 & 17, HE1 steel always shows a shorter crack initiation life when compared with HE2 steel, even though HE1 steel has a lower stabilized maximum ratcheting strain rate in some cases, i.e. $\eta \geq 0.3$. The reason is that HE1 steel has lower ductility limit which decreases with the increase of carbon content for hyper-eutectoid steels [6, 14]. Additionally, HE2 steel always has the best ratcheting performance among all the three steels, particularly under more severe rolling contact conditions, i.e. $\xi \geq 0.5$, $f \geq 0.4$, $\eta \geq 0.3$ and $L \geq 35$ t. With regard to LAHT steel, the crack initiation life is same as or even longer than HE2 steel under mild loading conditions, i.e. $\xi \leq 0.25$. However, as the loading conditions become severe, the stabilized maximum ratcheting strain rate increases and the corresponding crack initiation life decreases more significantly than both hyper-eutectoid steels. The reason is that the LAHT steel has the smallest interlamellar spacing of the three rail steels, which means that the LAHT steel is most sensitive to cyclic softening and is likely to suffer higher deformation [15, 16]. Szablewski et al. [17] conducted

the RCF tests for LAHT and HE2 steels on a curved track with 350 m radius. The results show that LAHT steel has more severe wear than that of HE2 steel after a traffic of 81.1 million gross tonnes. Such information indicates that HE2 steel has the most reliable resistance to ratcheting and are the best choice to be applied in high rails particularly installed in the sharper curved tracks, for Australian heavy haul operations.

As illustrated in Section 2.3, the crack initiation life of the rail steels can be predicted from the stabilized maximum ratcheting strain rate. Therefore, the possible location of crack initiation should correspond to the location of the stabilized maximum ratcheting strain rate. Based on the numerical results obtained from the current study, the stabilized maximum ratcheting strain rate or the crack initiation in curved tracks is always located around 1 mm beneath from the top initial contact point. When the traction conditions become more severe, i.e. $\xi \geq 0.5$, $f \geq 0.4$, the location of crack initiation may shift from the sub-surface to the running surface as shown in Figure 18. Generally, RCF defects occurring at high rails, such as gauge corner checking, shelling and flaking, are originated from the rail surface or around 3 mm under the gauge corner of the rail head [18]. This indicates that the numerical results provide a reasonable agreement with the practical situation and can be useful to improve the maintenance of curved tracks.

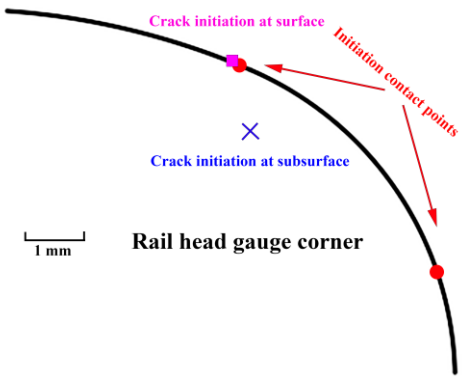

Figure 18*. Crack initiation locations at surface and subsurface of the rail head gauge corner.*

So far, the approach developed by Pun et al. [6] has been successfully applied to evaluate the ratcheting performance of the steels for tangent rails and high rails in curved tracks under new rail and wheel profiles. Practically, the profiles should be modified and implemented in rail systems with the aim of avoiding hazardous contact situations, i.e. the rail profile for heavy haul operations is ground to improve more resistance to gauge corner damage by spreading the contact load on the high rails in curved tracks [18, 19]. The near-conformal or conformal contact formed between the rail gauge and the wheel flange is able to ensure a larger contact area and hence reduces the normal stress [20]. This approach can also be applied to evaluate the ratcheting performance of the rail steels under such situations. The results can then assist rail operators in developing cost-effective maintenance strategies and optimizing the rail performance for special situations.

4. Conclusion

The present work investigated the ratcheting performance of three premium high strength rail steels in curved tracks under different in-service heavy haul loading conditions based on a previous approach developed by Pun et al. [5]. The numerical results obtained for high rails indicate that the stabilized maximum ratcheting strain rate for all the three steels increases with the normalized tangent traction, the friction coefficient, the ratio of lateral/axle load and the axle load, and the corresponding crack initiation life shows a decreasing trend. Among all the three steels, the HE2 steel always has the longest crack initiation life and is the best choice to be installed in high rails, particularly under severe rolling contact conditions, i.e. $\xi \geq 0.5$, $f \geq 0.4$, $\eta \geq 0.3$ and $L \geq 35\,\mathrm{t}$, due to its highest ductility limit and relatively better resistance to ratcheting. Additionally, both LAHT and HE1 steels are more prone to suffering rail degradation when installed in high rails even though the ratcheting performance of the LAHT steel is better or almost the same as the one of HE2 steel under mild cyclic rolling contact conditions i.e. $\xi \leq 0.25$, $f = 0.3$, $\eta = 0.1$ and $L = 30\,\mathrm{t}$. These outcomes can further supply useful information about the application of rail maintenance strategies, such as rail grinding and friction modification, to the track owners and operators.

Abstract: Combined with the optimal control theory, wheel rail creep theory and Kalman filtering method, this paper established a wheel-rail contact force identification model. Firstly, the identification problem was converted into the design issues using optimal control strategy, an optimal acceleration state tracker was developed by using the state space equation of the vehicle system. Secondly, the design issues was inversely solved using Singular Value Decomposition (SVD) technique, the evolution history of contact forces were obtained. The predicted contact forces were positively updated using Kalman Fliting method. Finally, the relation between contact forces and wheelset displacement were updated by using the wheel-rail Creep Theory, therefore the ill-posedness problem was solved and independent left/right lateral forces can be obtained. The identification results were validated by the numerical simulation and the inspection data.

Derailment coefficient and wheel lift can both be identified by Identification Model above. Using a comprehensive evaluation index based on the derailment coefficient and the vertical displacement of wheel, the safety of the rail-vehicle system is evaluated and the evaluation results show that comprehensive evaluation can reduce risks of mistake and miscalculation while maintaining safety.

Keywords: Optimal Control Theory; Kalman Method; Wheel/rail Creep Theory; Holographic Identification Model.

1. Introduction

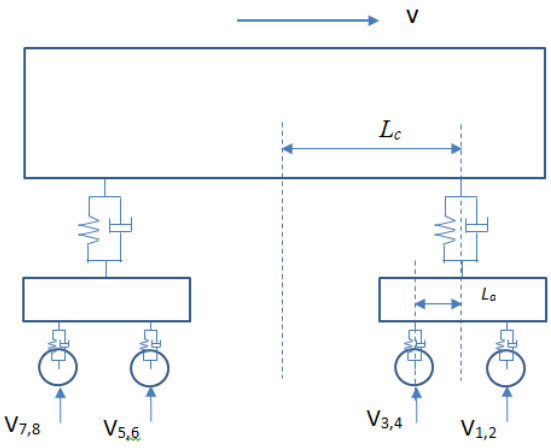
Wheel rail contact force is an important indicator to evaluate railway safety. Therefore, it is very important to monitor the wheel rail contact force and to evaluate the safety of track-vehicle system by using the monitoring data acquired during high speed railway operation.

Given economic reasons and maintenance complexities, Indirect measuring methods for wheel rail contact force based on the responses from vehicles are necessary, and it provides great theoretical significances and practical value[1][2][3].

Forward Problem and the second kind of Inverse Problem in structural dynamics can be taken into consideration for indirect wheel/rail contact force measurements. Forward Problem which is also called dynamic simulation in the field of rail transportation is in a mature phase of development. It utilizes track irregularities as input to obtain the wheel/rail contact force. The results of the Forward Problem rely deeply on track structure parameters such as track stiffness and damping. Track structure parameters are mainly selected according to past experiences, so there are some limitations when the Forward Problem is applied to obtain the wheel / rail contact force[4][5][6].

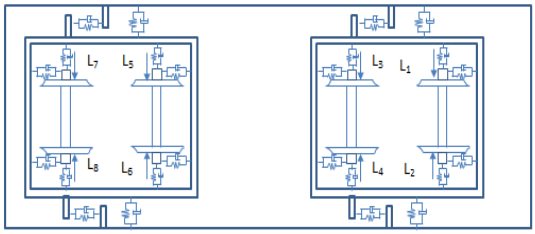
The second kind of Inverse Problem in structural dynamics is called load identification. To obtain the wheel/rail contact force, with the help of load identification, the disadvantage of high price, maintenance complexities and the experience dependence mentioned above can be avoided. However, load identification is an inverse problem of structural vibration, and its solution is usually ill-posed, as a result, it is not a widely used method in practice. With the development of load identification theory and computation technique, load identification is gradually becoming an increasingly viable option for wheel/rail contact force indirect measurements[7][8][9].

From the perspective of railway safety, given the features of the track-vehicle system, this paper established a wheel/rail contact force identification model of track-vehicle system, and studied its application on railway safety evaluation[10].



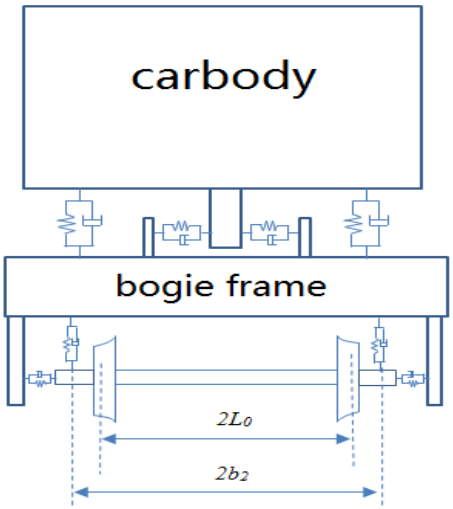
2. WHEEL/RAIL CONTACT FORCE IDENTIFICATION MODEL

2.1. State Space Equation of Vehicle System



The vehicle dynamics model is shown in Figure 1. Where L_C is half-length between bogie centers, L_0 is half distance between left and right rolling contact circle. $L_{1,2...8}$ are lateral forces, $V_{1,2...8}$ are vertical forces. So the dynamic equation of the vehicle system is as follows.

$$M\ddot{y} + C\dot{y} + Ky = F \qquad (1)$$



Where M 、 C 、 K are damp, stiffness and mass matrices of the system.

(a)

(b)

(c)

Fig 1 *Dynamic model of the vehicle system: (a) Elevation view. (b) Top view. (c)Side view*

Let $x_{i+1} = \begin{bmatrix} y_{i+1} \\ \dot{y}_{i+1} \\ \ddot{y}_{i+1} \end{bmatrix}$, using the Newmark method, Equation 1 can be discretized as follows:

$$x_{i+1} = Ax_i + Bf_i \tag{2}$$

where:

$$A = \begin{bmatrix} I & 0 & -\beta\Delta t^2 I \\ 0 & I & -\gamma\Delta t I \\ K & C & M \end{bmatrix}^{-1} \begin{bmatrix} I & \Delta t I & (\frac{1}{2}-\beta)\Delta t^2 I \\ 0 & I & (1-\gamma)\Delta t I \\ 0 & 0 & 0 \end{bmatrix} \tag{3}$$

$$B = \begin{bmatrix} I & 0 & -\beta\Delta t^2 I \\ 0 & I & -\gamma\Delta t I \\ K & C & M \end{bmatrix}^{-1} \begin{bmatrix} 0 \\ 0 \\ I \end{bmatrix} \tag{4}$$

2.2. Identification of Vertical Contact Force And Total Lateral Force Applied on the Wheelset

1）Reverse Prediction

Let observation $z_i = Hx_i$.

The tracking error $e(t)$:

$$e_k = \hat{z}_k - z_k \tag{5}$$

Optimal performance index:

$$J = \frac{1}{2} e_N^T P_N e_N + \frac{1}{2}\left[\sum_{k=0}^{N-1} (e_k^T Q e_k + u_k^T R f_k)\right] \tag{6}$$

R、Q、P_0、P_N are weight matrices of J.

Construct Hamiltonian Functions:

$$\begin{aligned} T &= \frac{1}{2} e_k^T Q e_k + \frac{1}{2} u_k^T R u_k + \lambda^T{}_{k+1}(AX_k + Bf_k) \\ &= \frac{1}{2}(\hat{z}_k - Hx_k)_k^T Q(\hat{z}_k - Hx_k) + \\ &\frac{1}{2} u_k^T R u_k + \lambda^T{}_{k+1}(AX_k + Bu_k) \\ &= \frac{1}{2} \hat{z}_k{}^T Q \hat{z}_k - x_k{}^T H^T Q \hat{z}_k \\ &+ \frac{1}{2} X_k{}^T H^T Q H X_k + \frac{1}{2} u_k^T R u_k \\ &+ \lambda^T{}_{k+1}(AX_k + Bu_k) \end{aligned} \tag{7}$$

Combined with the regular equation and the cross equation, the following equation can be derived:

$$f_k = -\left[I + R^{-1}B^T D_{k+1} B\right]^{-1} R^{-1} B^T (D_{k+1} A x_i + g_{k+1}) \tag{8}$$

where:

$$D_k - H^T Q H - A^T D_{k+1}\left[I + BR^{-1}B^T D_{k+1}\right]^{-1} A = 0 \tag{9}$$

$$\begin{aligned} &- g_k - H^T Q \hat{z}_N \\ &- A^T D_{k+1}\left[I + BR^{-1}B^T D_{k+1}\right]^{-1} BR^{-1}B^T g_{k+1} \\ &+ A^T g_{k+1} = 0 \end{aligned} \tag{10}$$

Combined with boundary equations:

$$D_N = H^T P_N H \tag{11}$$

$$g_N = -H^T P_N \hat{z}_N \tag{12}$$

Vertical contact force and total lateral force applied on the wheelset can be predicted inversely using SVD technique[11].

2）positive correction

Vertical contact force and total lateral force applied on the wheelset can be corrected positively using Kalman method.

Based on the inspection acceleration data and the predicted force above, using recursive formula of Kalman Filte, the optimal estimation contact forces including vertical contact forces and total lateral force applied on the wheelset can be obtained[12].

2.3. Left and Right Lateral Force Identification

However, Wheel/rail lateral contact force identification in two-dimensional space is an ill-posed problem, because there are 4 forces to be identified with only 3 dynamic equations. Rolling contact theory can be introduced as an additional constraint to solve the ill-posed problem. Based on the relationship between lateral/vertical force and creep/normal force, with the help from rolling contact theory, 4 forces (i.e. left/right lateral/vertical force) can be expressed as the function of 3 variables in total, that is, left/right normal force and the lateral relative displacement of the wheelset with respect to the track. Then there are 3 variables to be identified by 3 dynamic equations, thus, the ill-posed problem is solved. Based on the ideas above, according to Creep Theory and Dynamic Theory, a new model called Identification Model Based on Rolling Contact (RC Model) can be built. The model is discretized by Newark method and is solved by Chord Intercept method. Then the lateral contact force is identified.

The Force Diagram of the wheel-sets is shown in figure 4.

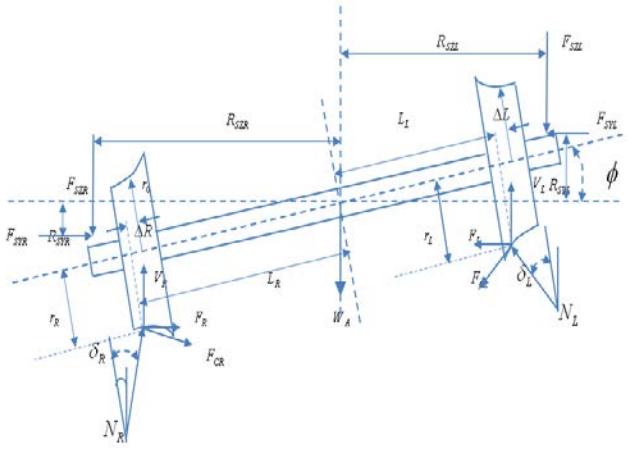


Fig.2 Sketch of forces applied on one pair of wheels

The equations of motion are as follows:

Vertical equation:

$$m(\frac{\ddot{z}_L+\ddot{z}_R}{2})+C_{ZL,R}(\dot{z}_L+\dot{z}_R)+K_{ZL,\ R}(z_L+z_R)-W_A=V_L+V_R \quad (13)$$

Lateral equation:

$$m(\frac{\ddot{y}_L+\ddot{y}_R}{2})+C_{YL,R}(\dot{y}_L+\dot{y}_R)+K_{YL,\ R}(y_L+y_R)=F_L+F_R \quad (14)$$

Roll equation:

$$\begin{aligned} &I_{wx}(\frac{\ddot{z}_R-\ddot{z}_L}{R_{Ly}+R_{Ry}})+C_{ZL,\ R}R_{SZL,R}\cos\varphi(\dot{z}_R-\dot{z}_L)\\ &+K_{ZL,\ R}z_L R_{SZL,R}\cos\varphi(z_R-z_L)\\ &=R_{L,Ry}(V_R-V_L)+R_{L,Rz}(F_L+F_R) \end{aligned} \quad (15)$$

where:

m	The mass of the wheelset
w_A	The weight of the wheelset
$\ddot{z}_L$, $\dot{z}_L$, z_L	The left vertical acceleration, velocity,displacement of the axle box
$\ddot{z}_R$, $\dot{z}_R$, z_R	The right vertical acceleration, velocity,displacement of the axle box
$\ddot{y}_L$, $\dot{y}_L$, y_L	The left lateral acceleration, velocity,displacement
$\ddot{y}_R$, $\dot{y}_R$, y_R	The right lateral acceleration, velocity,displacement
$K_{ZL,\ R}$	The vertical stiffness of Left/right primary suspention
$C_{ZL,R}$	The vertical damping of Left/right primary suspention
$K_{YL,\ R}$	The lateral stiffness of Left/right primary suspention
$C_{YL,R}$	The lateral damping of Left/right primary suspention
F_L, F_R	The left/right lateral force
V_L, V_R	The left/right vertical force
r_L, r_R	The left/right contact radius
ϕ	roll
δ_L, δ_R	The left/right contact angel
N_L, N_R	The left/right normal contact force
$F_{CLx,y}$, $F_{CRx,y}$	The left/right creep force
$R_{SZL,R}$	The arm of vertical left/right primary suspension force

The relationship between lateral/vertical forces and normal/creep forces is as follows:

$$V_L=N_L\cos(\delta_L+\phi)+F_{CL}\sin(\delta_L+\phi) \quad (16)$$

$$V_R=N_R\cos(\delta_R-\phi)+F_{CR}\sin(\delta_R-\phi) \quad (17)$$

$$\begin{aligned} F_L&=N_L\sin(\delta_L+\phi)\sin\varphi+\\ &F_{CLx}\cos\varphi+F_{CLy}\cos(\delta_L+\phi)\sin\varphi \end{aligned} \quad (18)$$

$$\begin{aligned} F_R&=-N_R\sin(\delta_R-\phi)\sin\varphi+\\ &F_{CRx}\cos\varphi-F_{CRy}\cos(\delta_R-\phi)\sin\varphi \end{aligned} \quad (19)$$

Formula （18）can be added with（19）:

$$
\begin{aligned}
&F_L + F_R = N_L \sin(\delta_L + \phi)\sin\varphi \\
&+ F_{CLx}\cos\varphi + F_{CLy}\cos(\delta_L + \phi)\sin\varphi \\
&- N_R \sin(\delta_R - \phi)\sin\varphi + F_{CRx}\cos\varphi \\
&- F_{CRy}\cos(\delta_R - \phi)\sin\varphi
\end{aligned} \tag{20}
$$

Using Kalker theory[19], the creep forces can be expressed as creepage:

$$F_{CLy} = -f_{11}\xi'_{yL} - f_{12}\xi'_{spL} \tag{21}$$

$$F_{CRy} = -f_{11}\xi'_{yR} - f_{12}\xi'_{spR}$$

$$F_{CLx} = -f_{33}\xi'_{Lx} \tag{22}$$

$$F_{CRx} = -f_{33}\xi'_{Rx}$$

Creepage can be written as follows:

Left:

$$
\begin{aligned}
\xi'_{Lx} &= \left(1/v\right)\left\{v\left[1 - r_L/r_0\right] - a\dot{\varphi}\right\} \\
\xi'_{Ly} &= \left(1/v\right)\left[\dot{y} + r_L\dot{\phi} - v\varphi\right] \\
\xi'_{spL} &= \left(1/v\right)\left[\dot{\varphi} - \Omega\delta_L\right]
\end{aligned} \tag{23}
$$

Right:

$$
\begin{aligned}
\xi'_{Rx} &= \left(1/v\right)\left\{v\left[1 - r_R/r_0\right] + a\dot{\varphi}\right\} \\
\xi'_{Ry} &= \left(1/v\right)\left[\dot{y} + r_R\dot{\phi} - v\varphi\right] \\
\xi'_{spR} &= \left(1/v\right)\left[\dot{\varphi} + \Omega\delta_R\right]
\end{aligned} \tag{24}
$$

Where a is half gauge, Ω is nominal angular velocity, v is the velocity of the wheelset.

The relationship between Ω and v is as follows:

$$\Omega = \frac{v}{r_0} \tag{25}$$

Where r_0 is the nominal rolling radius of the wheelset.

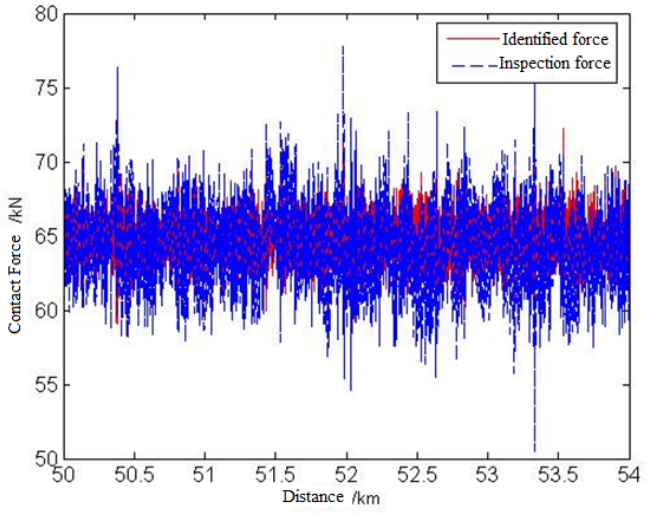
f_{11}、f_{12}、f_{22}、f_{33} is creep coefficient, which is the fuction of the normal contact force. Rolling radius r_L、r_R and roll angle ϕ are also the function of the lateral wheelset displacement y'''.

Substituting formula (21), (22), (23), (24) into Equation (20), we can get a new formula as follows:

$$F_L + F_R = f(N_L, N_R, y''') \tag{26}$$

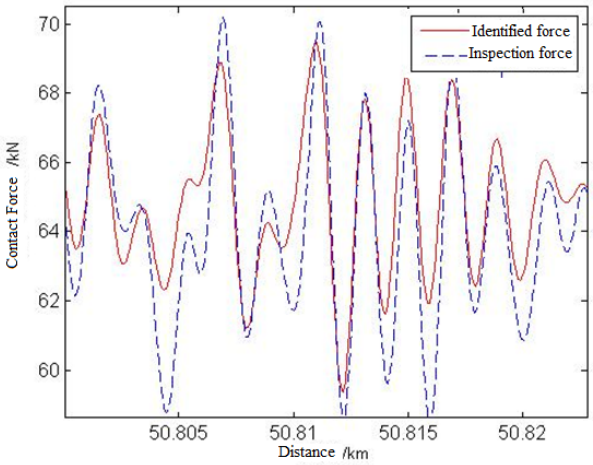
Formula (26) has no detail function form for the relationship between variables is very complicated. Using the normal force and total lateral force applied on the wheelset identified in section 2.1, 2.2, formula (26) can be solved using nonlinear equation solving methods.

Variables in formula (26) cannot be expressed by function, and they have no derivative, so formula (26) is solved using secant method.



Finally, the lateral wheelset displacement y''' can be obtained, and lateral left/right contact forces can also be obtained using creep theory.

2.4. MODEL VALIDATION



Model validation is necessary, and a validated model can correctly describe the characteristic of a system. Good model calculation results must be close to conclusions from experiments[13] [14]. In this paper, the identification results were compared with the numerical simulation and the experimental finding, and it showed that the correlation coefficient of identification lateral force/vertical force and simulation forces were 0.69/0.8, and the correlation coefficient of identification lateral force/vertical force and verification forces were 0.51/0.69.

3. SAFETY EVALUATION FOR TRACK-VEHICLE SYSTEM BASED ON IDENTIFICATION MODEL

Safety evaluation methods for track-vehicle system can be divided into three types: safety evaluation methods for track systems based on track geometry irregularity, safety evaluation methods for vehicle systems based on vehicle responses, and comprehensive safety evaluation methods for track-vehicle systems. Comprehensive evaluation using multivariate index is expected to be the trend.

This paper tries to evaluate track-vehicle safety by using comprehensive evaluation index of derailment coefficient and wheel lift. Derailment coefficient and wheel lift can be identified by Identification Model. So, a comprehensive evaluation index based on the derailment coefficient and the vertical displacement of wheel is proposed. And finally, the safety of the rail-vehicle system is evaluated by the index proposed above. Evaluation results show that comprehensive evaluation can reduce risks of mistake and miscalculation while maintaining safety.

4. CONCLUSIONS

The holographic wheel/rail contact force identification model using vehicle accelerations was established. It can solve the ill-posed problems of deficiency of equation and lack of inspection data.

The holographic wheel/rail contact force identification model is precise, and suitable for real time wheel/rail contact force identification. The correlation coefficient of identification lateral force/vertical force and simulation forces were 0.69/0.8，and the correlation coefficient of identification lateral force/vertical force and verification forces were 0.51/0.69.

A comprehensive safety evaluation index for vehicle/track system is proposed, and evaluation results show that comprehensive evaluation can reduce risks of mistake and miscalculation while maintaining safety.

Abstract: To investigate the rail damage due to wheel-rail dynamic interactions, a new method is introduced which uses a parallel co-simulation technique to link a detailed in-house track model developed by using FORTRAN code with a detailed rail vehicle model using GENSYS. The co-simulation method can be applied to understand the dynamic performance characteristics of high axleload wagons to provide an accurate evaluation and assessment of rail damage based on existing rail damage modelling. The case studies due to ballast voids show that, besides the wheel-rail contact, the effect of rail bending to the rail damage is significant.

Keywords: Rail vehicle-track interaction; wheel-rail contact performance; rail damage modelling; parallel co-simulation.

1. Introduction

A few of years ago, the longest and heaviest heavy haul train in the world was operating in Western Australia. Two or three locomotives provided traction for a train with each loaded 250wagons. The train was 2.7km long and weighed around 40,000 tonnes, with a payload of 35,000 tonnes. The 40-tonne axleload which was used at that time was then the highest in the world, and was subsequently increased to 42 tonnes, and it is now said that up to 43.5tonne axleload wagons are operating. It is suggested that 45tonne or even 50tonne axleload wagons will be developed to meet the demand from Australian heavy haul railways in the future [1].The ongoing growth in demand for iron ore and other bulk products continues to push the technical boundaries of heavy haul railways.

The higher axleload being applied on the track could cause more frequent damage to both the rail vehicle and track components. The fine checking and shelling on rail gauge corner and running surface defects might be commenced by the high shear stresses at the wheel-rail contact patch when such stresses exceed the allowable limits. Gradually, they may develop various rolling contact fatigue (RCF) defects.

In our investigations on the track damage due to wheel-rail dynamic interactions in Australian heavy haul railways, a new method is developed which uses a two-way co-simulation technique to link a detailed in-house track model software package that is developed using the FORTRAN code with a detailed rail vehicle model that is generated by using the GENSYS software package. As the rail vehicle and track models can run separately, the simulation speed can be improved as well as the model integration process can be simplified by applying a parallel computing technique. The main purposes are: (1) to understand the dynamic performance characteristics of high axleload wagons, (2) to give an accurate evaluation and assessment of track damage due to the operation of high axleload wagons, and (3) to allow maintenance management strategies and appropriate operational decisions to be implemented based on reliable simulation results.

2. Rail damages due to wheel-rail dynamic interactions

The life of rails in heavy haul tracks is dependent primarily upon:

- Wear, which happens mostly on the gauge face of the high rail in curved tracks due to wheel flanging contact. Some wear also appears on the running surfaces of all rails on both straight and curved tracks due to wheel-rail interaction.
- Plastic flow, which is often observed in heavy haul tracks and happens on both low and high rails on curved tracks subjected to higher axleloads than 20 tonnes. Plastic flow is mainly due to the wheel-rail contact stresses, which exceed the strength of the rail material.
- Defects, which can be observed in all rails because of a lot of various reasons. If a RCF crack defect is not detected in time, it can propagate and possibly cause rail to totally break, which would result in expensive rail maintenance.

The cyclic dynamic loading on the wheel and rail has frustrated railway transport operators for a long time. Plastic deformation, shakedown and fatigue crack initiation and propagation may occur [2], which depend on the wheel load, wheel-rail contact stress distribution and traction coefficient. The initiation of fatigue cracks in rail material is a threshold phenomenon. The different mechanisms of deterioration would manifest themselves through a number of damage patterns. It was stated [3] that uncontrolled operation-related wheel and rail damage primarily included thermal cracks, skidded wheels (wheel flats), wheel-burns and wheel tread metal build-up, and skid mark deformation of the rail surface.

The rail defects at welds and insulated joints can be reckoned the plastic deformation induced rail defects, which are relevant to dynamic loads which typically lead to high bending and contact stresses [4]. The most important dynamic loads could be the well-known P_1 and P_2 force modes of wheel-rail impact force vibration. P_1 force mode involves the wheel and rail moving out of phase to compress contact stiffness while P_2 force mode does the wheel and rail moving in phase to compress track infrastructure stiffness. Many factors influence the magnitudes of these dynamic loads [5], and the most important one among them is the unsprung mass of the wheelset. The unsprung mass can be a limiting factor for the maximum operational speed without subjecting the rail to an excessive load spectrum for a given amplitude of rail defect.

Besides wheel-rail contact normal forces, creep forces can also increase rolling contact fatigue (RCF) stresses [6]. When the traction level (T/N, T - creep force and N - normal force) reaches a level of approximately 0.3, the maximum shear stress increases and its location moves closer to the wheel-rail contact surface. This then makes surface initiated RCF cracks such as head checks and rail squats more prevalent. Depending on the contact conditions, the surface cracks can develop into either wear or RCF defects [7]. Tangential creep and normal forces, contact pressure, creepage and the presence of fluid are important factors in determining the amount of wear and RCF damage.

Investigations on RCF defects in freight wagon wheels, namely wheel spalling, shelling and tread checking [8], indicated that the increase in the coefficient of adhesion would result in an increase of the stick zone at the wheel-rail contact patch, an increase in the maximum shear stress, the shift of plastic flow zone from subsurface to surface (from the traction coefficient of 0.3), and an increase in tensile stress with maximum value at the boundary of the contact patch opposite the direction of movement. The vehicle dynamic simulations undertaken at some rail RCF sites has confirmed [9] that the major causes of RCF damage are large tangential creep forces and creepages, mainly in the longitudinal traction direction along the railhead. It was shown that the energy dissipation in the wheel-rail contact patch, which was measured by $T\gamma$ - the product of creep forces and creepages, is the best indicator of the risk of RCF initiation and the good indicator of the surface crack development. Reduction in RCF could potentially be achieved [10] by installing active steering systems. Another technique with potential resistance to RCF is the development of bainitic rail steels [11]. It was pointed out that the bainitic steel rails could have significantly better RCF performance compared to the pearlitic rails.

3. Rail stresses & RCF damage modelling

In rail transport systems, rails directly support rail vehicle wheels and are subjected to very high static and dynamic loads and harsh environmental conditions. It is indicated [12] that the most important loading components included wheel-rail rolling contact stress, shear stress and bending stress due to the wheel loads, thermal stresses as a result of restrained elongation of continuously welded rails, and residual stresses due to manufacturing in the factory and welding in the field.

3.1 Rail contact stresses

Wheel–rail contact stresses are generally created by the dynamic forces in the wheel-rail contact interface. The well-known Hertzian non-linear theory has been widely used to produce the calculation model, which can illustrate the local stresses with excellent accuracy for the most general wheel–rail contact problems. Assumptions that are made include linear elastic materials for both wheel and rail, smaller wheel-rail contact areas compared to the radii at the wheel-rail contact points and to other dimensions, and smooth surfaces. Another assumption is that both wheel and rail have the same material parameters, including the elastic modulus E and Poisson's ratio v. This means that locally equal stress fields will be generated in wheel and rail. Generally, the coordinate system is usually selected to have its origin at the centre of the wheel-rail contact patch whose shape would be elliptical with semi-axes a and b in the longitudinal and lateral (x, y) directions. The contact pressure distribution [13] becomes:

$$p_z(x,y) = p_0\sqrt{1-\frac{(x-x_1)^2}{a^2}-\frac{(y-y_1)^2}{b^2}} \qquad (1)$$

where x_1 and y_1 are locations of the point load relative to the centre of the Hertz ellipse; the maximum pressure p_0 is related to the total contact force F_z as:

$$p_0 = \frac{3F_z}{2\pi ab} \qquad (2)$$

All nine stress components at any point for Hertzian pressure can be written:

$$\sigma_{ij} = p_0\int_{-b}^{b}\int_{-a}^{a}\left[\frac{\sigma'_{ijN}}{P_N}+\frac{\mu_x\sigma'_{ijTx}}{P_{Tx}}+\frac{\mu_y\sigma'_{ijTy}}{P_{Ty}}\right]\sqrt{1-\frac{x^2}{a^2}-\frac{(y-y_1)^2}{b^2}}\,dxdy \qquad (3)$$

The σ_{ij} subscripts i and j imply $\sigma_{11}, \sigma_{12}, \sigma_{13}, \sigma_{21}, \ldots, \sigma_{33}$, where $\sigma_{11}=\sigma_x$, $\sigma_{12}=\tau_{xy}$, $\sigma_{13}=\tau_{xz}$, $\sigma_{21}=\tau_{yx}$, …, $\sigma_{33}=\sigma_z$; μ_x and μ_y are the effective coefficients of friction acting longitudinally or laterally to the wheel-rail interface; for concentrated loads $P_N = p_z dxdy$, $P_{Tx} = \mu_x p_z dxdy$ and $P_{Ty} = \mu_y p_z dxdy$; the stress expressions of σ'_{ijN}, σ'_{ijTx} and σ'_{ijTy} are given [13].

It is known that the rail plastification is an essential material reaction to wheel-rail contact loading, it is of interest to examine the induced effective stress. Therefore, the von Mises effective stresses is chosen:

$$\sigma_{vM} = \left[\sigma_x^2+\sigma_y^2+\sigma_z^2-\sigma_x\sigma_y-\sigma_y\sigma_z-\sigma_z\sigma_x+3\tau_{xy}^2+3\tau_{yz}^2+3\tau_{zx}^2\right]^{1/2} \qquad (4)$$

The von Mises yield criterion indicates that plastification would not occur if the von Mises stress $\sigma_{vM} < \sigma_Y$, where σ_Y is the yield stress in uniaxial testing of the material.

If the maximum stresses that happen at $y = 0$ are concerned, the two-dimensional contact model of an infinite cylinder (called line contact), subjected to normal and tangential loading, can be often used for a simplified

wheel-rail contact analysis [14]. Usually, in the wheel-rail contact the lateral semi-axe b of the ellipse is larger than the longitudinal semi-axe a, and the changes of wheel-rail contact pressure near the ellipse centre are only slight with y. In this case, the two-dimensional contact model can provide an excellent approximation, but in wheel flange contact the model should not be used because of $a \geq b$ in this situation. In the condition of full sliding, the ratio of T/N (T - the tangential force and N - the normal load) is assumed to be constant within the contact area and equal to the coefficient of friction μ. Therefore, the stresses at the wheel-rail contact patch due to both the pressure and the tangential traction could be written as:

$$\sigma_x = p_0\sqrt{1-\frac{x^2}{a^2}} \pm 2\mu\frac{x}{a};\ \sigma_z = p_0\sqrt{1-\frac{x^2}{a^2}}$$

$$\text{and } \tau_{zx} = \pm\mu p_0\sqrt{1-\frac{x^2}{a^2}} \qquad (5)$$

The rail material yielding starts when the equivalent stress such as von Mises stress is equal to the yield limit σ_Y. Here, the von Mises expressed in Eq. (4) can be simplified as:

$$\sigma_{vM} = \frac{1}{\sqrt{2}}\left[\left(\sigma_x-\sigma_y\right)^2+\left(\sigma_y-\sigma_z\right)^2+(\sigma_z-\sigma_x)^2+6\tau_{xz}^2\right]^{1/2} \qquad (6)$$

3.2 Rail bending stresses

Rails have been widely modelled using the Winkler model in studies on rail fatigue life. For a given rail type and wheel load, the magnitude of the rail bending moments and bending stresses can result from the rail displacement and the track infrastructural stiffness (track modulus). In the Winkler model the rail is considered to be an infinite beam on a continuous elastic foundation. The vertical rail deflection $w(x)$ and the bending moment $M(x)$ at distance x from a single wheel load (P) can be calculated and expressed in the following equations:

$$w(x) = \frac{P\beta e^{-\beta x}}{2K}(cos\beta x + sin\beta x);\qquad M(x) = \frac{P\beta e^{-\beta x}}{2\beta}(cos\beta x - sin\beta x) \qquad (7)$$

where K is the track modulus and β is the stiffness ratio equal to $(k/4EI)^{0.25}$ with EI being the rail bending stiffness. Therefore, the bending stress on the top of rail head is:

$$\sigma_b = \frac{M(x)\cdot z}{I} = \frac{P\beta e^{-\beta x_z}}{2\beta I}(cos\beta x - sin\beta x) \qquad (8)$$

Here, I is the moment of inertia, z is the distance from the neutral axis to the top of rail head.

3.3 RCF damage modelling

Many theoretical studies and experiments have been undertaken to investigate the mechanisms behind rail damage RCF defects. The studies on the rail damage have conducted detailed site investigations combined with comprehensive vehicle-track interactive dynamics simulations to compare simulated wheel-rail interactive forces at experimental locations of rail surface damage. A number of similar investigations have increased understanding of the dynamic forces and mechanisms responsible for different forms of rail RCF damage and resulted in the development of several models to predict RCF. To assess possible rail RCF damage, two assessment modelling methods are introduced. One is the wheel-rail surface fatigue index - FI_{surf} based on the shakedown map, which is defined by Ekberg et al. [15] ~ [17]. Figure 1 shows the shakedown map which illustrates the relationship between T/N and p_0/k in which $f = T/N$ is the traction coefficient, k is the yield stress in pure shear and p_0 is the maximum contact stress.

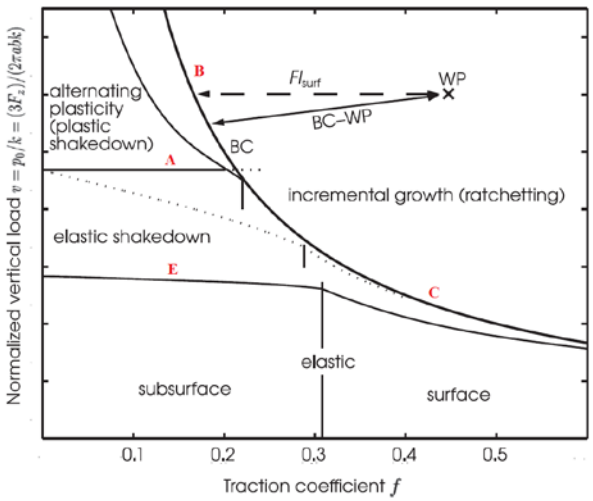

Figure 1 Shakedown map [17]. (A) Upper bound to elastic shakedown limit against alternating plasticity, (B) Upper bound to plastic shakedown limit against incremental growth, (C) Upper bound to elastic shakedown limit against incremental growth of surface strain, (E) Elastic limit, and (….) lower bound to elastic limit.

The fatigue index $FI_{surf} = T/N - k/p_0$ (or $f - \frac{2\pi abk}{3F_z}$) is shown with work points to the right of the bold drawing in Figure 1 corresponding to positive magnitudes. Here, $FI_{surf}>0$ is supposed to correspond to surface plasticity that leads to surface initiated RCF. For f > 0.3, the initial yielding happens at the surface with an even smaller maximum contact stress as the traction coefficient increases. It should be noted that a shakedown map cannot be used to predict a limited fatigue life, however, it can show that, for instance, surface flow will happen, in which case surface fatigue is also possible to happen. Further, the shakedown map is derived under the assumption of full slip.

The second method involves examining the shape of the damage function [18], which considers the competing damage mechanisms of wear and crack growth because of the forces in the wheel-rail contact patch. The rail fatigue damage is described as the proportion of the fatigue life of the rail material for the specific wheel-rail contact condition. For each wheel-rail contact position, the rail damage can be summed and RCF will happen when unity is reached for the total rail damage. Figure 2 shows this model in terms of the relationship between fatigue damage and wear number T_γ. The model also reflects on the influence of wear, e.g., the negative slope shown in Figure 2. At low levels of T_γ <15 no damage develops. In the range 15 < T_γ < 65, the RCF cracks can be formed through a ratchetting process. For higher T_γ

values (T_γ> 65), the wear starts to dominate and for T_γ>175, the wear rate is much higher than the crack growth, causing no RCF damage at all. The fundamental drawback of this RCF damage model is its empirical characteristic and the recalibration need is required for new applications.

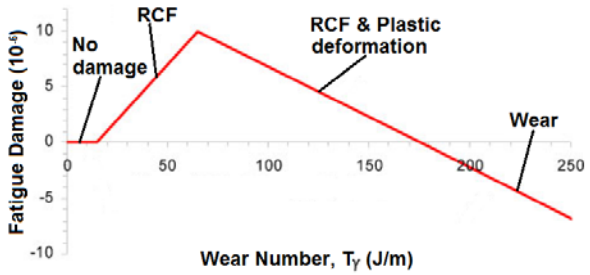

Figure 2 Shape of the damage function [18]

4. Co-simulation approaches

For this study, the full model is needed to divide into two submodels – one is an advanced track model, and the other a rail vehicle (locomotive or wagon) model. The advanced track model is based on an in-house software package, written in FORTRAN codes, which will be briefly introduced in the next section. The rail vehicle model is carried out in the Gensys multibody software package. It is crucial for this package to have a client-server architecture, which allows the data communication between two computers or two software packages through a Transmission Control Protocol/Internet Protocol (TCP/IP) interface [19] ~ [20]. Figure 3 just shows this architecture for the developed co-simulation approach.

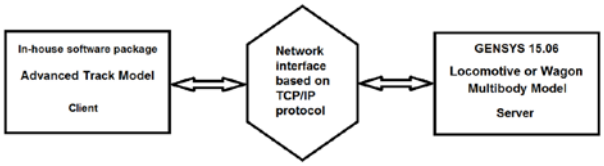

Figure 3 Co-simulation approach

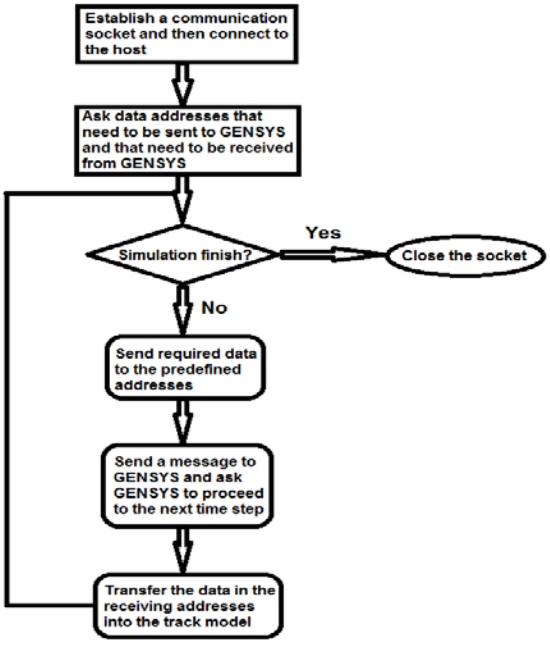
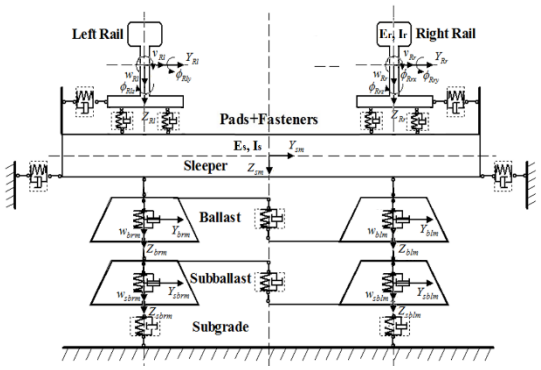
4.1TCP/IP protocol

The platform for data exchange used for the co-simulation process is independent and the interface is provided by using TCP/IP. A co-simulation technique in the studies of dynamic behaviour of rail vehicles can provide the data exchange processes between two software packages, with a predefined time step. The Gensys multibody software package has been used to model the mechanical system of a heavy haul locomotive or wagon. Since the development of version 10.10 of Gensys software, this package includes a server co-simulation interface, which allows the creation of the client interface in the advanced track model software environment. The co-simulation approach between Gensys model and the advanced track model has been created based on the data exchange between these software tools by means of TCP/IP, taking into consideration that Gensys runs on a 64-bit Linux platform and the advanced track model runs in a 64-bit Windows environment. With regard to the existing capabilities provided by Gensys, the co-simulation is executed by the tsim script of the CALC program. In this case, this program is a server, which can be called 'server_tsim'. The existing interface works under TCP/IP protocol version 4. The developed interface can work in both uni- or bi-directional data exchange modes. The communication process flowchart for the track model is shown in Figure 4.





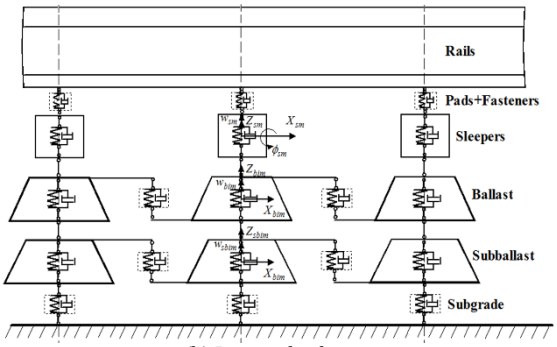


Figure4 Communication process flowchart

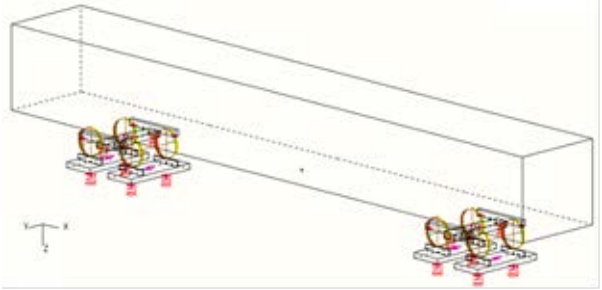
4.2 Advanced track modelling

The cross-sectional and longitudinal views of the model used in the description of the track subsystem are schematically shown in Figure 5. The model consists of four layers as shown in that figure, namely the rails and their pads and fastener assemblies, the sleepers, the ballast, and the sub-ballast resting on the subgrade. The rails are modelled as continuous Timoshenko beams that are discretely held on the sleepers through fasteners and pads modelled as linear spring and damping elements enclosed within a dashed-line box which indicates that the mass of the pads and fasteners are omitted. The sleepers are modelled with mass and viscoelastic properties by springs and dampers enclosed within a solid-line box which indicates the mass being included. The ballast and sub-ballast blocks are modelled as pyramids for calculating their effective mass, stiffness and damping coefficients. In the lateral and longitudinal directions the viscoelastic dampers and linear springs connecting one pyramid to the other imitate the continuity of the ballast and the sub-ballast. The subgrade is represented as viscoelastic elements without mass connecting the sub-ballast blocks to the ground. The coordinate system and degrees of freedom (DoFs) of each track component are also shown in Figure 5.

(a) Cross-sectional view

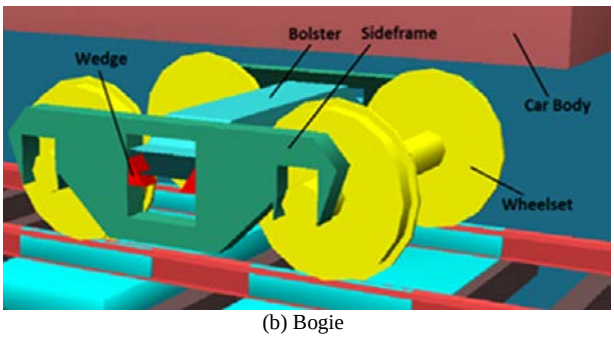
(b) Longitudinal view

Figure 5 Schematic diagram of the track model



The track model has been published, and detailed modelling descriptions can be found in [21] ~ [25]. Finally, the governing dynamic equilibrium equations for track modelling are expressed as:

$$[M_T]\{\ddot{q}_T\} + [C_T]\{\dot{q}_T\} + [K_T]\{q_T\} = \{\tilde{F}_{WT}\} \quad (11)$$



where M_T, $C_T$and $K_T$are the mass, damping and stiffness matrices of the track system. The vector $q_T$contains displacement of the track system that includes the modal and physical displacements, and $\tilde{F}_{WT}$ is the combined wheel-rail interface force vector.Equation (11) is solved using a modified Newmark-β method.

4.3 Rail vehicle modelling

Atypical rail wagon widely used in heavy haul transportation in Australia is selected to create a model using the Gensys software package [26] ~ [27], as shown in Figure 6 (a) and (b).

(a) Wagon Model

(b) Bogie

Figure 6Modelling of a typical heavy haul wagon in GENSYS

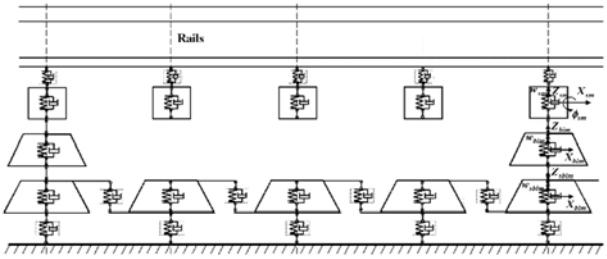
In the wagon model, shown in Figure 6 (b), there are 11 masses. Among them, the connections include the connection between wagon car body and two bogies; the connection of side bearer between wagon car body and bolster; the secondary suspensions (including spring nests and friction edges) between bolster and sideframes; and the primary suspensions between sideframes and wheelsets. For wheel-rail contact, a standard function in [28] has been used for the modelling of a wheel/rail contact interaction. Three springs represent three contact points, namely top of rail (cp1), gauge corner (cp2) and gauge face (cp3) contacts. These three different contact points can be in contact simultaneously. The calculations of creep forces are made in a lookup table calculated by Fasim.

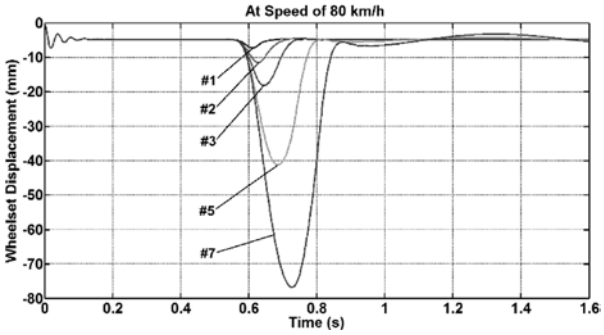
5. Case study

The special case study focuses on the ballast void simulation [29]. Sleepers could become suspended from two rails without ballast support due to several reasons, including local subgrade sinking, ballast washed away by heavy rain, and big gaps forming between sleepers and ballast due to ballast permanent deformation, etc. Therefore, the ballast void modelling can be expressed by:

$$F_{sbi} = \begin{cases} K_{bi}[w_{si}(t) - w_{bi}(t) - \delta_{zi}] & w_{si}(t) - w_{bi}(t) - \delta_{zi} > 0 \\ 0 & w_{si}(t) - w_{bi}(t) - \delta_{zi} \le 0 \end{cases} \quad (12)$$

where F_{sbi} is the vertical force between the ith sleeper and the ith ballast block, K_{bi} is the stiffness of the ith ballast block, w_{si} and w_{bi} are the vertical displacements of the ith sleeper and the ith ballast block respectively, δ_{zi} is the gap between the ith sleeper and the ith ballast block in the vertical direction. In the following simulations, the gap δzi is considered to be large enough to make $F_{sbi} = 0$. In this situation, it is assumed that $K_{bi} = 0$. Figure 7 shows the specific case of $K_{bi} = K_{b(i+1)} = K_{b(i+2)} = 0$ (three consecutive sleepers with ballast voids under them).





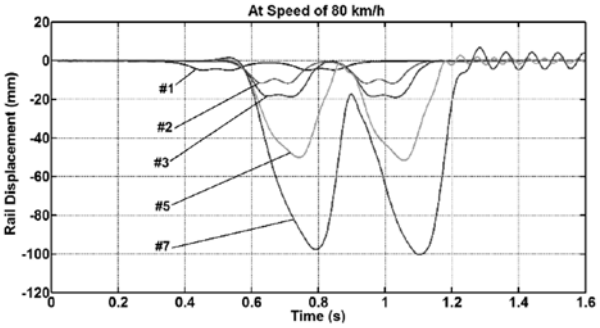


Figure 7 Ballast void case - three sleepers without ballast support

5.1Rail dynamic responses

Simulations were carried out for a wagon running at the speed of 80 km/h to pass over the locations with one, two, three, five or seven consecutive sleepers without support respectively.

(a) Wheelset displacement

(b) Rail displacement

Figure 8 Rail dynamic responses at the ith sleeper position

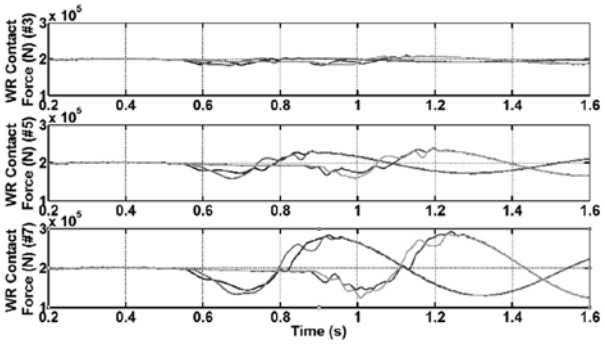

Figure 8 (a) shows the leading wheelset vertical displacement, in which the numbers against the graph plots represent the number of consecutive sleepers without support due to ballast voids. It can be seen that the ballast voids will cause a noticeable dynamic dip, the size of which will depend on the number of sleepers without support, the rail properties, wheel load and wagon speed, etc. For the example of five sleepers without support, the dip size will be 4.44 m long and about 50 mm in depth. The vertical displacement of the rail central point over the range of sleepers without support is shown in Figure 8 (b). For the situation of seven sleepers without support, the maximum displacement is about 100 mm.

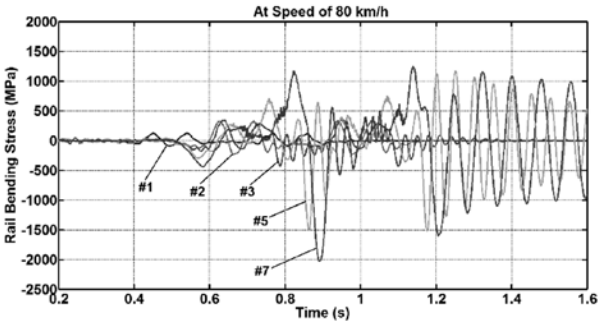
5.2Rail bending analysis



Based on basic beam theory, the bending moment and the bending stress can be expressed by:

$$M = -EI\frac{d^2w}{dx^2}\ ,\ \ \sigma = \frac{Mz}{I} = -zE\frac{d^2w}{dx^2} \qquad (13)$$

As the wagon is running at a constant speed V, the distance x can be expressed as $x = V{\times}t$ and $(d^2w)/(dx^2) = (d^2w)/(V^2{\times}dt^2) = (d^2w)/(dt^2)/V^2$. For the 60 kg/m rail, E = 200 GPa is considered, and the bottom of the rail's cross-section is z = -79.1 mm from the neutral axis while the top is z = 90.9 mm. The height of the cross-section is 170 mm. Based on Equation (13), if the vertical acceleration (d^2w/dt^2) of rail at the middle of location of sleepers without support is output, the bending stresses can be obtained.

(a) Wheel-rail normal contact forces

(b) Rail bending stress

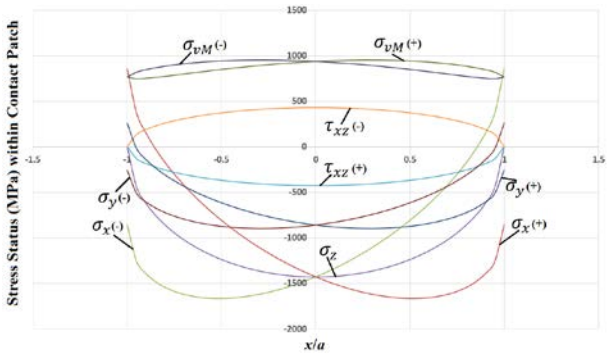


Figure 9 Dynamic responses

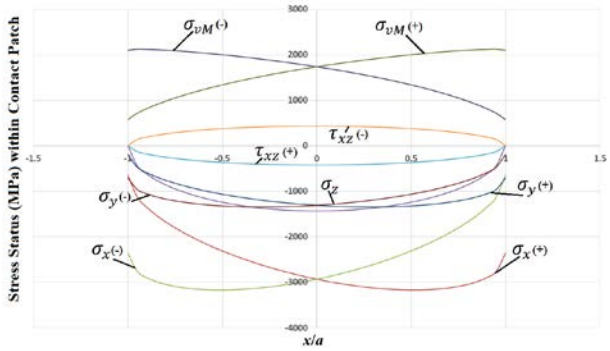
Figure 9 (a) shows the wheel-rail normal contact forces for the cases of three, five and seven sleepers without support. In the cases of five and seven sleepers without support, the wheel-rail contact force has a large low frequency wave, and a higher frequency force component is superimposed on it. For all five cases, the maximum contact forces are 202.3 kN, 205.6 kN, 210 kN, 238 kN and 290.1 kN while the minimum forces are 190 kN, 187.5 kN, 183 kN, 159 kN and 125 kN respectively. It can be seen that the increase of the number of consecutive multiple ballast voids results in the increase of the maximum contact forces in the form of a second-degree polynomial. The bending stresses on the middle point of the rail top surface at the rail central position over the range of sleepers without support are shown in Figure 9 (b). The maximum bending tensile stresses are 130 MPa, 340 MPa, 350 MPa, 1150 MPa and 1250 MPa while the maximum bending compressive stresses are 90 MPa, 230 MPa, 420 MPa, 1500 MPa and 2000 MPa respectively. It can be seen that the bending stress is in the allowable range only for the case of one sleeper without ballast support. The increase of the numbers of sleepers without support results in a dramatic increase in the maximum bending stress.



5.3 Rail stress analysis

The stress status within the wheel-rail contact patch for the case of five sleepers without support is further analysed. From Figure 9 (a), the static wheel load is about 200 kN (the wagon axleload of 40 ton is selected), and the maximum wheel load is about 238 kN. Based on Eqns

(5) and (6), the stress status without and with considering the bending stress for this case are shown in Figure 10 (a) and (b) respectively.

(a) Wheel-rail contact stresses

(b) Combined wheel-rail contact stresses and bending stress
Figure 10 Wheel-rail contact stress status.

At almost the same position as the maximum wheel-rail contact forces on the leading bogie, the maximum bending compressive stresses of 1500 MPa on the top surface of the rail is found in the longitudinal direction due to the wagon passing. The longitudinal resultant stress should be the sum of this bending stress andσ_x. From Figure 10, it can be seen that, due to the effect of bending stress, the von Mises stress on the rail top surface is more than doubled.

6. Conclusions

This paper presented a co-simulation method to study wheel-rail interactions under Australian heavy haul transportation scenarios. Due to the introduction of very high axleload wagons, more rail damage can be expected and has been observed. A more accurate and reliable simulation method for the wheel-rail dynamic interactions would be a better way to determine the reasons for the rail damage based on the existing rail damage modelling. Meanwhile, the investigation on the wheel-rail dynamic interactions will be beneficial to new track component design and the implementation of appropriate track maintenance strategies.
