ISSN: 2590-0609.

Preface

Welcome to the 11th International Conference on Contact Mechanics and Wear of Rail/Wheel Systems (CM2018) held in Delft, The Netherlands, from September 24-27, 2018. The ever increasing demands for higher speed, capacity, efficiency and safety of railway systems impose increasing demands on the small contact patch between wheel and rail in terms of bearing capability, reliability and durability. Railways are increasingly demanding better and predictive performance from the train-track systems which are affected by rail-wheel contact. These can only be achieved through an improved understanding of the behaviour and mechanisms of rail-wheel contact by fundamental scientific research and innovative engineering, operation and maintenance.

With CM2018 organized in Delft, by members of the university of Prof. J.J. Kalker, we continue with the long tradition of the conferences: CM1982 Vancouver (Canada), CM1986 Kingston (RI, USA), CM1990 Cambridge (UK), CM1994 Vancouver (Canada), CM2000 Tokyo (Japan), CM2003 Gothenburg (Sweden), CM2006 Brisbane (Australia), CM2009 Florence (Italy), CM2012 Chengdu (China) and CM2015 Colorado Springs (USA). During CM2018 we remember the contributions of Prof. K.L. Johnson who passed away in 2015.

For the 2018 edition of the conference there were 216 abstract submissions. Each abstract submission was reviewed by at least 2 International Committee members or additional reviewer. Many thanks to both the International Committee members and to the additional reviewers: Andrea Bracciali, Hua Chen, Werner Daves, Irina Goryacheva, Roger Lundén, Eric Magel, Peter Mutton, Jens C.O. Nielsen, Oldrich Polach, and Wolfgang Schoech. Based on the revisions, 162 abstracts were accepted. Out of environmental consideration, the proceedings will not be printed, but authors are provided with digital copies. Moreover, some presentations will be video recorded and they will be available online.

We would like to express our sincere appreciation for the work performed by the local organizing committee and all the persons involved during the conference. Finally, we wish a great success of the conference.

Abstract: The vertical dynamic interaction between vehicle and railway track is simulated in the time domain using an extended state space vector approach. The track model includes a transition zone between slab track on a bridge and ballasted track on an embankment. By considering a multi-objective optimisation problem, solved using a genetic algorithm, selected vehicle and track responses are simultaneously minimised by optimising the distributions of rail pad stiffness and sleeper spacing in the transition zone. It is shown that the magnitudes of the maximum dynamic loads in the optimised transition zone can be reduced to be similar as the magnitudes far away from the transition zone.

Keywords: Transition zone; slab track; vehicle–track interaction; railway track transitions; optimisation; genetic algorithm.

1. Introduction

In high-speed railway lines, different types of transition zones between different track forms are frequently occurring [1]. Examples include transitions between different types of superstructures, such as from slab track to ballasted track, or between different properties of the substructure, such as from an embankment to a bridge or a tunnel structure. In this study, a model of dynamic vehicle–track interaction is used to describe a transition zone between a ballasted track on an embankment and a slab track on a bridge. The applied simulation methodology was originally developed for a ballasted track by Nielsen and Igeland [2], and was recently extended to consider different designs of slab tracks [3].

At transitions, there is a structural discontinuity leading to an abrupt variation in track stiffness, increased dynamic wheel–rail contact forces and an increased pressure between sleeper/panel and foundation. The increased dynamic loads may lead to accumulated damage of the components in the superstructure, differential settlement of ballast/subgrade and irregularities in track geometry (longitudinal level). In this paper, both vehicle and track responses are minimised by optimising the variation of vertical track stiffness along the transition zone. The considered design variables include the sleeper spacings and the stiffness of the rail pads within the transition zone, but an extension of the model to account for auxiliary rails, transition slab, under sleeper pads (USP) and variations in slab and sleeper dimensions is straight-forward.

2. Track and vehicle models

The complete track and vehicle models are illustrated in Figure 1. The rail, sleepers and panel are modelled using finite elements based on Rayleigh–Timoshenko beam theory, whereas the vehicle is modelled as a multibody system. In this paper, the transition zone where the optimisation will be carried out spans over 39 rail seat distances and is centred around the transition. Further, the loading from the vehicle is assumed to be symmetrically distributed between the two rails, and therefore only half of the sleepers/panel and one rail need to be considered. Only vehicle–track interaction in the vertical direction is studied. For more information about the vehicle–track interaction model, see [2–4]. In Appendix A, all parameter values for the track and vehicle models are presented. The track parameter values were taken from [4], whereas the vehicle parameter values were collected from [5] (except the mass of the car body, which was modified such that an axle load of 17 tonnes was achieved).

To reduce the simulation time and allow for an efficient optimisation, it has been a priority to limit the number of degrees-of-freedom of the track model. Therefore, the embankment is modelled as a distribution of non-interacting springs and viscous dampers (Winkler foundation). Furthermore, the bridge deck is assumed to be fully rigid since the main part of the track stiffness for slab track systems is governed by the rail pads. Also, the scope of the present paper is the stiffness variation in the transition zone, excluding the effects related to bending of the bridge deck. The number of degrees-of-freedom is further reduced by employing a complex-valued modal superposition technique for the track model and only using modes which have an eigenfrequency below a threshold value. In this paper, the threshold value is set to 1500 Hz, and it has been verified that the influence of the truncated modes is negligible.

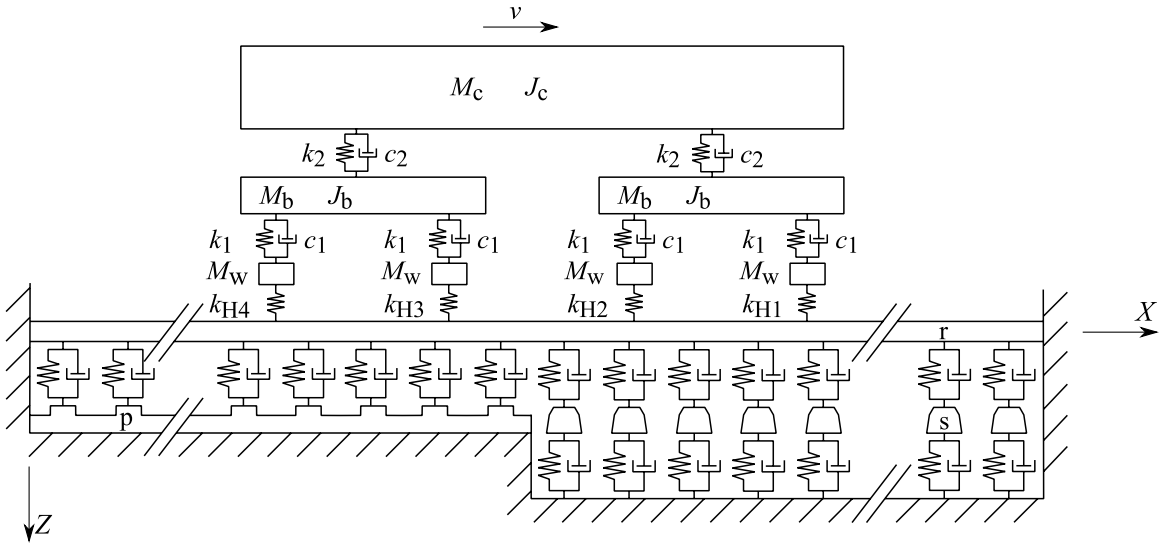

Figure 1 *Sketch of vehicle and track models in a transition zone between slab track on a bridge and ballasted track on an embankment. The bridge is assumed to be significantly stiffer than the embankment and is here modelled as a rigid foundation.*

In many situations, the complete vehicle model shown in Figure 1 can be simplified to a bogie model in which the influence of the car body is simplified to a static point force acting at the centroid of the bogie [4]. For the track responses considered in this paper, it has been confirmed that the difference between using the bogie model or the complete vehicle model is negligible. For the calculated vehicle response (here vertical bogie acceleration), it was found that there are some minor differences between the two vehicle models. It has, however, been verified that minimising the vertical bogie acceleration when using the bogie model in the optimisation problem also reduces the vertical bogie acceleration significantly when the complete vehicle model is considered in an evaluation of the optimised transition zone. Therefore, the simplified vehicle model is used in the upcoming optimisation procedure. By using the bogie model, the required track length is reduced, which is crucial in order to reach convergence of the optimisation methodology at a reasonable computational cost.

3. Optimisation methodology

In this work, both vehicle and track responses are simultaneously minimised. By minimising these responses, the ride comfort is increased and the track degradation mitigated. In particular, the risk of rail damage and differential settlement is reduced, which may reduce the required maintenance work and increase the service life of the transition zone.

Let $F(\boldsymbol{x})$ consist of all the considered track and/or vehicle responses and let $\boldsymbol{x}$ denote all design variables that will be used to optimise the transition zone. A multi-objective optimisation problem can then be formulated as

$$\min_{\boldsymbol{x}\in S} \boldsymbol{F}(\boldsymbol{x}) = \big(f_1(\boldsymbol{x}), \dots, f_n(\boldsymbol{x})\big), \qquad (1)$$

where $f_1(\boldsymbol{x}), \dots, f_n(\boldsymbol{x})$ are the considered track and/or vehicle responses, n is the number of objective functions and S is the design space. In this paper, the following objective functions are considered: the maximum wheel–rail contact force at any of the wheelsets, the maximum pressure between sleeper/panel and foundation, and the maximum vertical acceleration at the bogie centroid. Let $F_i(t)$, $i = \{1,2\}$, denote the wheel–rail contact force of the i^{th} wheelset in the bogie model as a function of time. The first objective function can then be formulated as

$$f_1(\boldsymbol{x}) = \max_{i\in\{1,2\}} \Big(\max_{t\in[t_\text{L}\ t_\text{U}]} [F_i(t)] \Big), \qquad (2)$$

where t_L is a time before the vehicle has entered the transition zone and t_U is a time after the vehicle has passed the transition zone. Further, let X denote the longitudinal track position, Y the lateral track position and $P(X,Y,t)$ the pressure between sleeper/panel and foundation. The second objective function can then be formulated as

$$f_2(\boldsymbol{x}) = \max_{X\in[X_\text{L}\ X_\text{U}]} \Big(\max_{Y\in[Y_\text{L}\ Y_\text{U}]} \Big[\max_{t\in[t_\text{L}\ t_\text{U}]} \big(P(X,Y,t)\big) \Big] \Big), \qquad (3)$$

where X_L is a longitudinal track position before the transition zone and X_U is a longitudinal track position after the transition zone, whereas Y_L is the lateral coordinate at the end of the sleepers and Y_U is the lateral coordinate at the middle of the sleepers. In this paper, X_L is set to the longitudinal coordinate corresponding to ten rail seat distances before the transition zone starts and X_U is set to the longitudinal coordinate corresponding to ten rail seat distances after the transition zone ends. Moreover, t_L and t_U are calculated as $t_\text{L} = X_\text{L}/v$ and $t_\text{U} = X_\text{U}/v$, where v is the speed of the vehicle. Finally, by letting a_b denote the vertical acceleration at the bogie centroid, the third objective function is defined as

$$f_3(\boldsymbol{x}) = \max_{t\in[t_\text{L}\ t_\text{U}]} (a_\text{b}). \qquad (4)$$

As design variables, the stiffness of 40 rail pads (20 on slab track and 20 on ballasted track) and 20 sleeper spacings are considered. To increase the convergence speed of the genetic algorithm, the rail pads and sleeper spacings are collected in stacks of five. Within one stack

of rail pads, the stiffness of the rail pads must be equal, and within one stack of sleeper spacings, all distances must be equal. Note that by using stacks of the same rail pad stiffness and sleeper spacing, the transition zone is probably a more practically relevant design.

By using the objective functions in Equations (2–4) and the described design variables, the generic optimisation problem given in Equation (1) is reduced to

$$\min_{\boldsymbol{k}\in S^{\mathrm{k}},\ \boldsymbol{d}\in S^{\mathrm{d}}} \boldsymbol{F}(\boldsymbol{k},\boldsymbol{d}) = \left(f_1(\boldsymbol{k},\boldsymbol{d}), f_2(\boldsymbol{k},\boldsymbol{d}), f_3(\boldsymbol{k},\boldsymbol{d})\right), \quad (5)$$

where $\boldsymbol{k}$ and $\boldsymbol{d}$ are vectors containing the rail pad stiffness and the sleeper spacing of each stack in the transition zone. By letting k_{L} and k_{U} denote the lower and upper constraints of the rail pad stiffness, and d_{L} and d_{U} the lower and upper constraints of the sleeper spacing, the design spaces S^{k} and S^{d} are defined as

$$S^{\mathrm{k}} = \{\boldsymbol{k} \in \mathbb{R}^{n_{\mathrm{k}}} : k_i \in [k_{\mathrm{L}}\ k_{\mathrm{U}}]\ \forall\ i = 1,2,3\ldots, n_{\mathrm{k}}\}, \quad (6a)$$

$$S^{\mathrm{d}} = \{\boldsymbol{d} \in \mathbb{R}^{n_{\mathrm{d}}} : d_i \in [d_{\mathrm{L}}\ d_{\mathrm{U}}]\ \forall\ i = 1,2,3,\ldots, n_{\mathrm{d}}\}, \quad (6b)$$

where n_{k} and n_{d} are the numbers of rail pad stacks and sleeper spacing stacks. The multi-objective optimisation problem given in Equation (5) is now well-defined and can be solved using the Non-dominated Sorting Genetic Algorithm II (NSGA-II) [6]. The algorithm consists of a non-dominated sorting approach that calculates non-dominated fronts of a parent population and an offspring population. The best fronts are used to build up the next generation until all seats in the generation are occupied. Regarding the final front, which is used to fill the last seats in the next generation, all members in the front will not fit and a crowding distance control function is used to preserve diversity among the solutions.

4. Numerical example

In this section, an optimal transition zone is developed by solving the multi-objective optimisation problem presented in Section 3. The design variables are constrained by k_{L} = 25 kN/mm, k_{U} = 120 kN/mm, d_{L} = 45 cm and d_{U} = 75 cm and the nominal sleeper spacing is set to 60 cm. The considered vehicle speed is 320 km/h and no rail irregularities are considered in the optimisation procedure. Note that the robustness of the optimised transition zone to rail irregularities (compared to the nominal transition zone) can be assessed in a post-processing stage [4].

Depending on the direction of traffic, the non-dominated front (the set of optimal solutions in the objective function space) varies. In this paper, three different traffic conditions are considered including single-direction traffic from slab track to ballasted track, single-direction traffic direction from ballasted track to slab track and mixed traffic directions. When the mixed traffic directions case is considered, the objective functions defined in Section 3 are calculated for both traffic directions, and the maximum values are used as objective functions.

In this paper, 50 iterations and a population size of 200 is used in the genetic algorithm. From the final iteration of the genetic algorithm, the associated non-dominated front is calculated. The non-dominated front contains the set of optimal solutions in the objective function space where no solution outperforms another solution in terms of all objective functions. Figure 2 shows the non-dominated fronts for the three different types of traffic conditions. Figure 2(a) shows a 3D view, while Figures 2(b)–(d) show the non-dominated fronts in three different 2D views. The vertical and horizontal lines indicate the level of the track and vehicle responses on nominal track evaluated far away from the transition zone. Hence, the solutions in the non-dominated fronts are bounded by the vertical and horizontal lines since the design variables do not affect the track and vehicle responses far away from the transition zone. Note that the line which indicates the maximum wheel–rail contact force on nominal track is higher than the static wheel–rail contact force since the parametric excitation induced by the discrete rail seats causes a dynamic contribution to the wheel–rail contact force. Moreover, it can be seen from Figures 2(b) and 2(d) that the maximum pressure between sleeper/panel and foundation in the transition zone is close to the maximum pressure far away from the transition zone. Hence, the maximum pressure between sleeper/panel and foundation cannot be reduced further even if more design variables were to be added. Note that the results for all three traffic conditions are similar. Hence, using different transition zones for different traffic directions, which may be cumbersome to implement in field, seems to be unnecessary.

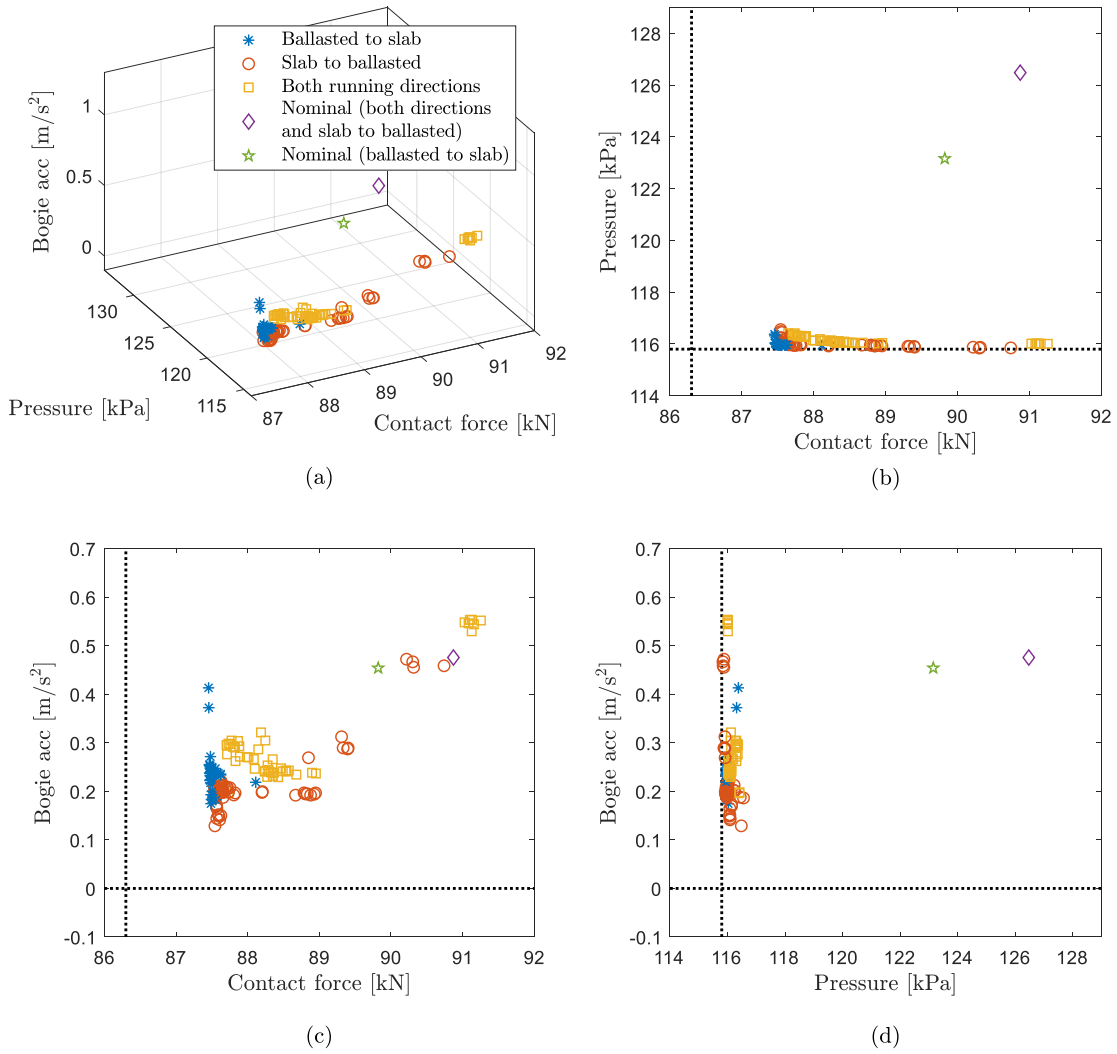

Figure 2 *Non-dominated fronts when minimising the maximum wheel–rail contact force, the maximum pressure between sleeper/panel and foundation and the maximum vertical bogie acceleration. Figure 2(a) shows a 3D view, while Figures 2(b)–(d) show the non-dominated fronts in three different 2D views. The vertical and horizontal lines indicate the levels of the associated responses far away from the transition zone.*

In the following figures, results are only presented for the optimised transition zones where mixed traffic directions were accounted for in the optimisation. Figure 3 shows the stiffness at the rail level for the nominal and optimised transition zones. The optimised transition zones consist of the extreme solutions in the non-dominated front giving the lowest response in terms of each objective function. From the figure, it is noted that the extreme solutions that give the lowest maximum wheel–rail contact force and lowest maximum vertical bogie acceleration have a similar stiffness at the rail level, while the stiffness at the rail level differs significantly when the maximum pressure between sleeper/panel and foundation is minimised. This substantial difference in stiffness at the rail level occurs since the pressure between sleeper and foundation is always higher than the pressure between panel and foundation. Hence, the stiffness increase at the rail level on the slab track does not increase the maximum pressure between sleeper/panel and foundation. Note that the stiffness at the rail level that minimises the maximum pressure between sleeper/panel and foundation is not a good solution in terms of the other objective functions, see Figure 2. Moreover, the difference in magnitude of the maximum pressure between sleeper/panel and foundation is small for all solutions in the non-dominated front. Hence, a solution that minimises the maximum wheel–rail contact force or the maximum vertical bogie acceleration can be selected without increasing the maximum pressure between sleeper/panel and foundation significantly. In order to define one optimal transition zone, a weighting factor for each objective function has to be determined.

The stiffness at the rail level is changed by both the stiffness of the rail pads and sleeper spacings. In Figure 4, the settings of the design variables for the nominal and optimised transition zones are presented. It is noted that the sleeper spacings are similar for all setups, while the stiffness of the rail pads is higher when the maximum pressure between sleeper/panel and foundation is minimised. For all optimised designs, the highest pressure between sleeper/panel and foundation occurs at the end of the transition zone. Hence, the fact that the stiffness at the rail level is very high on the slab track

close to the transition when the maximum pressure between sleeper/panel and foundation is minimised has no influence on the maximum pressure between sleeper/panel and foundation.

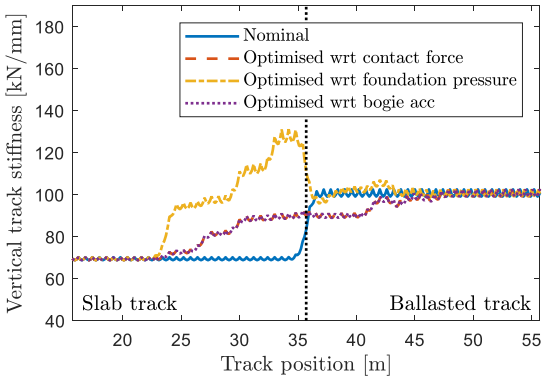

Figure 3 *Stiffness at the rail level for the nominal and optimised transition zones when both traffic directions are considered. The vertical line indicates the position of the transition.*

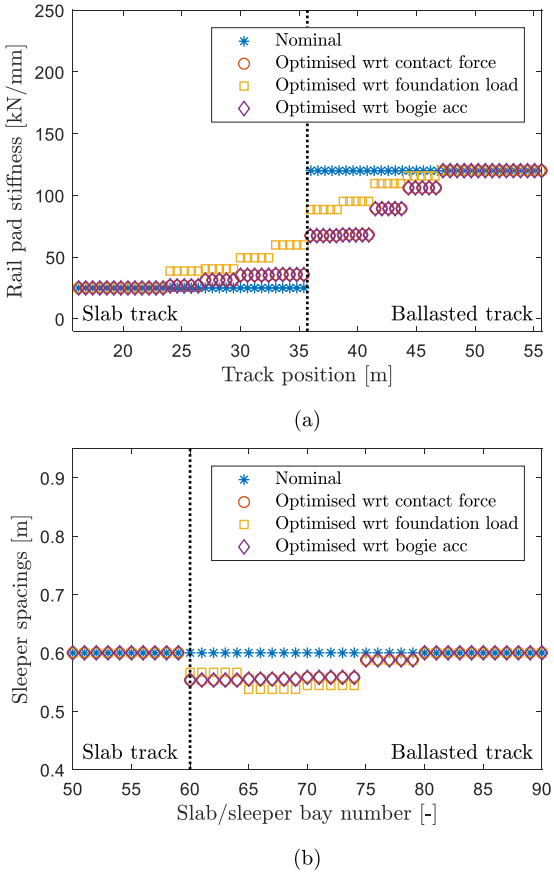

Figure 4 *Settings of (a) rail pad stiffness and (b) sleeper spacing for the nominal and optimised transition zones when both traffic directions are considered. The vertical line indicates the position of the transition.*

In Figure 5, the time history of the vertical bogie acceleration is shown for both traffic directions and for both the nominal transition zone and the transition zone where the maximum vertical acceleration of the bogie has been minimised. It is observed that the maximum bogie acceleration is similar for both traffic directions. When comparing the nominal and optimised transition zones, the maximum acceleration is reduced from 0.48 m/s^2 to 0.19 m/s^2.

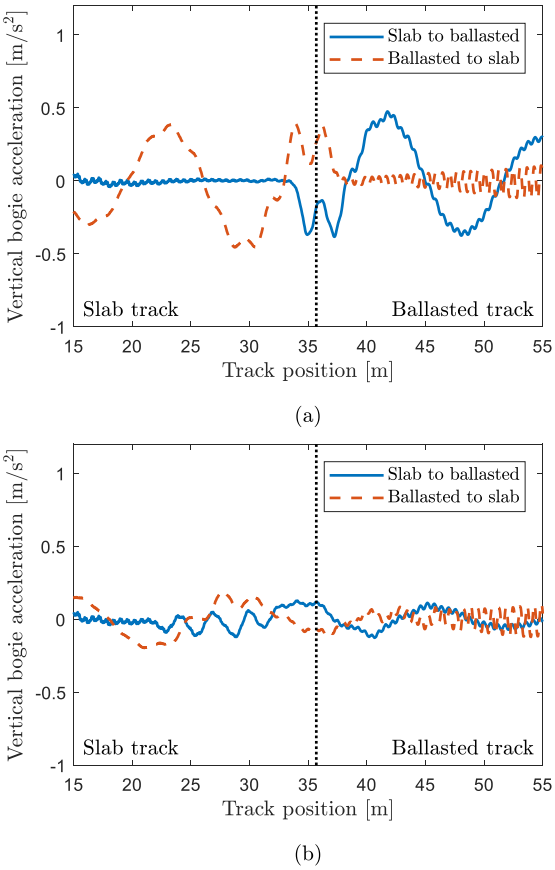

Figure 5 *Vertical acceleration of the bogie for (a) the nominal transition zone and (b) the transition zone where the vertical acceleration of the bogie has been minimised when both traffic directions are considered. The vertical line indicates the position of the transition.*

5. Conclusions

A transition zone between slab track on a bridge and ballasted track on an embankment has been analysed by considering the coupled vertical dynamic vehicle–track interaction problem. By considering a multi-objective optimisation problem, solved using a genetic algorithm, both track and vehicle responses have been minimised simultaneously. From the solution of the optimisation problem, it was found that a similar non-dominated front could be achieved for all considered traffic conditions, which means that the same transition zone can be used independently of the direction of travel. From the non-dominated front, one optimal transition zone can be determined if a weighting factor for each objective function is defined. Further, it was shown that the magnitudes of the maximum dynamic loads in the optimised transition zone become similar as the maximum loads on nominal track far away from the transition zone. Hence, adding more design variables would not improve the performance of the transition zone in terms of the considered track responses.

Appendix A. Track and vehicle parameter values

The applied track parameter values shown in Tables 1–3 were collected from [4]. In Table 1, the dimensions of the concrete panel and sleepers are given. In this study, the cross-section of the panel is invariant along the slab, whereas the sleepers have slightly varying dimensions. The material properties of the beam elements are presented in Table 2. Subscripts `r', `s' and `p' denote rail, sleeper and panel, and each layer of beam elements has bending stiffness EI_A[1], shear stiffness kGA_A, mass m_A per unit beam length, rotatory inertia $m_A r_A^2$ per unit beam length, width b_A and height h_A that may vary along the beam axis (longitudinal direction for rail and panel and lateral direction for sleepers). Further, the stiffness k and the viscous damping c of the resilient layers in the track are presented in Table 3. The subscript `e' denotes embankment, while the subscripts `rs' and `rp' denote the coupling between rail–sleeper and rail–panel, respectively.

The parameter values for the full vehicle model presented in Table 4 were collected from [5]. When the bogie model is considered, the same parameter values as for the full vehicle model are used. M_c, M_b and M_w denote the mass of the car body, bogie and wheelset, whereas J_c and J_b denote the pitch inertia of the car body and bogie. Moreover, k_1, k_2, c_1 and c_2 denote the stiffness and viscous damping of the primary and secondary suspensions. Finally, L_1 denotes the longitudinal wheelset spacing in a bogie, while L_2 denotes the longitudinal distance between the two bogies.

[1] Replace A with the label of the considered layer (r, s or p). As an example, the bending stiffness of the rail is denoted EI_r.

NUMERICAL SIMULATION MODEL FOR THE COMPETITION BETWEEN SHORT CRACK PROPAGATION AND WEAR IN THE WHEEL TREAD

Makoto AKAMA*, Takafumi KIMATA

Abstract: A numerical model is developed to simulate the competition between RCF-initiated short crack propagation and wear in a wheel tread. The model is shown to operate properly when applied to the results of unidirectional twin disc tests. When an outward route comprising a 1000 km straight run is simulated based on the Shinkansen routes, it is found that the tread is hardly damaged. The results obtained from the rolling reversal fatigue tests show that if the rolling direction of the wheel is reversed, the delamination wear becomes dominant.

Keywords: Wheel tread; rolling contact fatigue; short crack; wear; Hobson model; Archard model; FE analysis.

1. Introduction

Railway systems involve contact between rolling wheels and rail. The demand for higher train speed and greater wheel loads have led to increased contact pressure and tangential traction between the wheel and the rail. Under a cyclic wheel passage, these lead to the perpetual initiation of cracks known as "rolling contact fatigue" (RCF), and wear in both surfaces and these are major damages for wheels and rails. For example, the railway wheel turning data [1] indicated that the majority of wheels were turned due to RCF or tread/flange wear.

In the initiation and early propagation stages of cracks, crack propagation competes with wear [2]. The mechanism that initiates cracks depends on factors such as the geometry of the rail and the wheel, properties of their steels, type of traffic, and lubrication. At the same time, wear changes the shape of both surfaces, thereby altering the wheel–rail contact region and associated contact stresses. Both crack propagation and wear are driven by stress, strain, and traction, which are all related to the forces in the contact region. When the wear rate is much greater than the crack growth rate, cracks cannot propagate and, in some cases, are eliminated. In contrast, very low wear rates have negligible influence on crack growth. Consequently, wear rate must be considered to estimate the net crack growth rate.

The pioneering research on the competition between RCF crack propagation and wear in a wheel/rail system was carried out by Franklin et al. [3–5], who developed a "brick model" that employs a formulation based on the incremental plasticity by ratcheting within a number of sections (or bricks) within a cross section through a rail. If the bricks reach their critical shear strain, they are considered to fail and are marked as weak. Franklin et al. designed many patterns of weak and non-failed healthy bricks as scenarios in which a brick might be removed. Doing so can indicate situations in which bricks either are removed at the surface as wear debris or form crack-like defects inside the rail.

Burstow [6–8] developed a "whole life rail model" that considers the competition between RCF crack propagation and wear in a rail. In this model, he proposed a "damage function" that describes the relationship between the wear number $T\gamma$ and the RCF crack initiation fatigue damage, where T is the shear force and γ is the creepage at the wheel–rail interface. The damage function comprises four regions: (i) a threshold below which RCF damage does not occur, (ii) a region where RCF damage linearly increases, (iii) the amount of damage falls as wear increases, and (iv) a region where damaged material is entirely removed by wear.

Mazzù [9–11] proposed an integrated model that considers multiple interacting damage mechanisms in railway wheels. The procedure is based on models for wear, cyclic plasticity, and surface and subsurface fatigue cracks, all integrated in an algorithm that exchanges input and output data between each failure model. The wear is assessed by means of the Archard model of adhesive wear. The cracks are evaluated by means of linear elastic fracture mechanics (LEFM) terms such as stress intensity factors (SIFs), threshold SIFs, and a Paris-type law.

Karttunen et al. [12,13] provided an engineering "meta-model" to predict gauge corner and flange root degradation concerning RCF and wear from measured rail, wheel, and track geometries. The RCF impact is quantified by a shakedown based dimensionless "fatigue index" (FI) [14]. Deterioration due to wear is quantified using $T\gamma$.

Dirks and Enblom [15] introduced a model that can predict both wear and RCF of railway wheels and rails. Two existing RCF prediction models were analyzed and compared in a parametric study, the first being an FI model and the other being a "damage function" model. For the wear model, the Archard model was applied.

Bevan et al. [16] developed a damage model to predict the deterioration rate of a wheel tread in terms of wear and RCF damage. This model uses a description of a fleet's route diagram to characterize the duty cycle of the vehicle. Using this duty cycle and a combination of the Archard and $T\gamma$ damage models, many vehicle dynamics simulations were conducted to calculate the wheel and

rail contact forces and predict the formation of wear and RCF damage.

Brouzoulis [17] presented a two-dimensional (2D) finite element (FE) model to simulate the growth of a single RCF crack in a rail. This model accounts for wear and allows crack curving. The Archard wear model was adopted along with a Paris-type crack propagation law whose crack driving force is based on the concept of material forces.

Jun et al. [18] studied the minimum size at which a crack would grow in a rail, which being defined as the size of the smallest crack that grew fast enough to stay ahead of removal by wear and periodic grinding. They used the Archard wear model and the "2.5D" fatigue crack growth model developed by Fletcher and Kapoor [19].

Trummer et al. [20] developed a predictive model for RCF crack initiation at the surface of rails and wheels, referred to as the "wedge model." In this "wedge model", both surface RCF crack initiation and delamination wear are deemed to be governed by the growth of the microscopic cracks in a severely shear deformed layer near the surface.

Hiensch and Steenbergen [21] extended the concept of a "damage function" from a conventional rail to a premium pearlite rail. This was done both by simulating the dynamic train–track interaction and by using field observations. Values of the RCF damage index were established for the rails, describing the behavior of the associated "damage function."

With reference to the aforementioned models, this study develops an accurate numerical simulation model to study the competition between RCF-initiated short crack propagation (including initiation) and wear in a railway wheel tread. First, the model is applied to the results of twin disc fatigue tests to assess its capabilities and accuracy. Next, it is applied to the stress, strain, and slip velocity states associated with the wheel tread. Finally, how reversing the wheel rolling direction affects the crack propagation and wear is studied by means of twin disc fatigue tests.

This paper extends the study by Akama et al. [22] in that the methodology and model have been applied to the competition between short cracks and wear in a railhead.

2. Numerical simulation model

This section details the model developed to simulate the competition between RCF crack propagation and wear.

2.1. Short cracks

An RCF crack begins life as a short crack. When the crack size becomes comparable to the scale of the characteristic microstructural dimension (i.e. grain size or less), obstacles such as grain boundaries, particle inclusions or phase changes hinder further growth. These obstacles are called "barriers" to crack propagation and retard or even arrest crack growth. In such cases, the crack is called a "microstructurally short crack" (MSC). After overcoming these microstructural barriers, the crack may be long enough to grow by continuum-mechanics mechanisms, whereby the crack length and applied stress or strain determine the crack growth rate. However, crack growth may occur within plastic regions, which invalidate LEFM analyses; the growth rate is greater than that predicted by LEFM. Such a crack is called a "physically small crack" (PSC) [23]. While treating the early stages of crack growth, such short-crack characteristics must be taken into account.

To model the initial stages of crack growth, we consider the entire crack in a three-dimensional (3D) microstructure. However, the growth details for a short 3D crack are not yet well understood. Franklin et al. [24] used a model based not on the physical process, but only on how small 3D cracks depend on the geometry or morphology of the steel microstructure. Therefore, this study considers short crack propagation in a 2D microstructural area within an arbitrary cross section of a material.

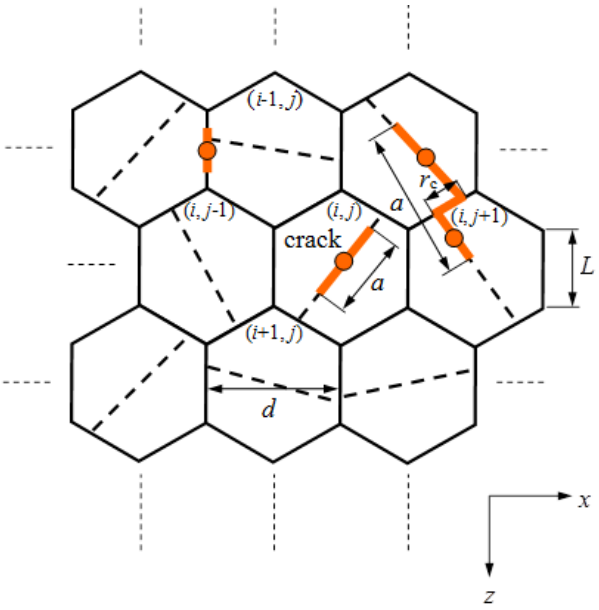

Figure 1 *A hexagonal network of ferrite plates and pearlite grains. Crack length a and the origin, slip line directions in the case of ferrite plates or lamellae directions in the case of pearlite grains (broken lines), side length L, diameter d of the grain, and the critical distance for the crack coalescence r_c are shown.*

2.1.1 Microstructure

The microstructure of general steel consists of pearlite grains bordered by the regions of PE ferrite and a few ferrite plates. A pearlite grain consists of pearlite colonies characterized by the joint arrangement of thin layers of ferrite and cementite. The orientation of the lamellae varies from colony to colony. The microstructure is modeled as a 2D area by using equilateral hexagons with a side length L and diameter d as an initial shape for the individual grains (Fig. 1).

The original shape of each hexagon is deformed randomly to represent a more realistic microstructure. All apices of the hexagon are moved from their initial positions within a limited circle by using a series of uniform random numbers so that the resultant hexagon shape remains convex [25]. Multiple slip systems are active in each ferrite plate with a randomized crystallographic orientation. The orientation of the pearlite colony is also determined randomly.

2.1.2 Initiation

Franklin and Kapoor [3–5] proposed a criterion based on ratcheting to predict crack initiation life. Here, we follow

Franklin and Kapoor's study and apply this criterion to predict crack initiation.

The point at which a crack initiates is determined randomly in a region of PE ferrite, ferrite plates or ferrite of the lamellar structure in pearlite grains. The geometry of the given crack seed is a point, so the initial crack length is zero. The initial crack points are given at the beginning of the simulation. The crack is assumed to initiate when the total accumulated plastic shear strain $\gamma^{ij}{}_n$ in the region reaches the critical shear strain γ_c. The strain increment $\Delta\gamma^{ij}$ is calculated for each load cycle and for each grain (i, j) in row j and column i (Fig. 1) by using the maximum value $\tau_{zx}{}^{j}{}_{(max)}$ of the orthogonal shear stress at each depth and the effective shear yield stress $k_{eff}{}^{ij}$ for each grain.

$$\gamma_n^{ij} = \gamma_{n-1}^{ij} + \Delta\gamma^{ij} \tag{1}$$

$$\Delta\gamma^{ij} = C\left[\left(\frac{\tau_{zx(max)}^{j}}{k_{eff}^{ij}}\right) - 1\right] \tag{2}$$

where n is the number of load cycles and C the ratcheting rate parameter.

The effective shear yield stress increases as the plastic shear strain accumulates. A modified Voce equation is used to calculate the new value:

$$k_{eff}^{ij} = k_0 \max\left(1,\ \beta_s\sqrt{1-e^{-\gamma_n^{ij}}}\right) \tag{3}$$

where k_0 is the initial shear yield stress and β_s the strain hardening ratio.

In addition, we consider initiation at a ductile inclusion. Garnham et al. [26] used scanning electron microscopy (SEM) to examine the microstructural detail of the used service rails taken from the high rails of curves together with that of rail discs from the twin disc tests. They found that, near the gauge corner surface, MnS ductile inclusions became flattened both longitudinally and transversely due to the accumulated cyclic stressing. They concluded that these strain-flattened MnS inclusions could be a source of surface and near-surface crack initiation with the wheel–rail contact. They also investigated spatial distribution in some rail steels of inclusions within certain size ranges. Nanohardness tests were also conducted to determine the difference in hardness between MnS inclusions and the pearlite and PE ferrite constituents of the matrix.

In this study, MnS inclusions are randomly located within the regions of PE ferrite, ferrite plates and ferrite of the lamellar structure in the pearlite colonies. A crack is assumed to initiate at the inclusion where the cumulated shear strain of the inclusion reaches a critical value. To date, the detailed behavior and mechanical properties of MnS inclusions have not been clarified; however, this simple treatment allows such inclusion "weak spots" to be represented in the microstructure.

2.1.3 Propagation

In this study, crack growth is modeled based on Hobson et al.'s [27] study because of the simplicity of the model. The Hobson model requires only a few material constants, which may be determined by standard experiments, and has been used extensively.

The MSC crack growth equation describes the propagation of cracks within the first few ferrite plates, PE ferrite and ferrite of the lamellae structure in the pearlite colonies (stage I). We assume that such cracks are driven by cyclic shear stress range on the slip planes, on the grain boundaries, or on the planes parallel to the lamellae structure, depending on the point of crack initiation. The crack growth rate is influenced by the distance between the crack tip and the dominant microstructural barriers. At a grain boundary, a pearlite banded colony is encountered. The strength of the pearlite phase makes it a major microstructural barrier to crack propagation. The crack-growth rate in stage I is described by

$$\frac{da}{dn} = A\Delta\tau_{\omega}^{\alpha}\cdot(d-a) \tag{4}$$

where A and α are material constants, a the crack length and $\Delta\tau_{\omega}$ is the cyclic shear stress range on the slip planes.

When the orientation of the lamellae is close to the crack growth direction, cracks can propagate into pearlite and across ferrite along a grain boundary. Therefore, we assume that cracks can propagate when oriented between −10° and +10° with respect to the lamellae direction. Otherwise, the crack is arrested by the grain boundary barrier.

When a crack is sufficiently long to permit a crack tip to open, PSC crack propagation occurs (stage II). In stage II, the influence of the microstructure is not considered, and crack growth is described by continuum mechanics in the form

$$\frac{da}{dn} = B\Delta\varepsilon_t{}^{\beta}a - D \tag{5}$$

where $\Delta\varepsilon_t$ is the total normal strain perpendicular to the crack faces, and B, β and D the experimentally determined material constants.

In the transition from stage I to II, the crack length is introduced in terms of the number of grains, and in the present simulation, is assumed to be three grain diameters. In this transition stage, crack growth is calculated by using the larger of the values calculated by Eqs. (4) and (5).

2.1.4 Coalescence

During the crack propagation stage, a sudden extension of crack length must be considered because cracks may link together. Crack coalescence is represented by assuming that linking occurs when crack length reaches a critical length l_c and the tip-to-tip distance between the cracks is less than a critical distance r_c (Fig. 1). After coalescence, crack length is defined by the length of the straight line between both crack tips. If a crack is formed by linking several cracks, the overall crack length is taken to be the greatest separation between the tips of the cracks involved.

2.1.5 Surface roughness

Crack growth near the surface can be strongly influenced by surface roughness, which locally modifies the pressure distribution of the contact. In this study, we use

Seabra and Berthe's [28] approach, in which surface roughness causes pressure peaks with amplitudes that depend mainly on the perturbation amplitude A_{mp} and wavelength λ. The pressure concentration effect is defined as the ratio of pressure peak P_{max} to nominal maximum contact pressure P_0:

$$\mathrm{PCF} = \frac{P_{\max}}{P_0} = C_1 \left(\frac{\lambda}{A_{\mathrm{mp}}}\right)^{\alpha_p} \left(\frac{b}{R_e}\right)^{\beta_p} \left(\frac{\lambda}{b}\right)^{\gamma_p} \quad (6)$$

where b is the contact area half width, R_e the equivalent radius of the contacting bodies, C_1 = 4.3884, α_p = −0.4234, β_p = −0.4204, and γ_p = −0.0155, respectively.

2.2. Wear

Franklin and Kapoor [4] considered that wear and RCF are two consequences of the same damage mechanism. Cracks and voids form near the contact surfaces and then join together by growth of voids, crack propagation and the plastic shear deformation of the material. Finally, the surface material spalls off as wear debris, a process well known as "delamination theory" [29]. The theory was first proposed to explain the adhesive wear against Archard model, however considering the mechanism, this theory may be applicable to fatigue wear. In this study, wear is considered an independent phenomenon, and its interaction with crack formation and propagation is included.

When modeling wear in the contact region, the Archard model for adhesive wear has been used and has provided results that are consistent with the measured data. Thus, the simulation in the present study is based on the Archard wear model, which is given by

$$V = K\frac{Nd_s}{H} \quad (7)$$

where V is the wear volume, K the wear coefficient, N the normal force, d_s the sliding distance, and H the penetration hardness of the surface that is wearing away. In the wheel–rail contact region, we use n_x points in the longitudinal direction (i.e. running direction) of the train, which is defined as the x-direction, and n_y points in the transverse direction (y-direction). The intervals Δx and Δy between the points are constant. For a single point, the wear-depth increment Δz is

$$\Delta z(x,y) = \frac{Kp(x,y)}{H}\sqrt{s_x(x,y)^2 + s_y(x,y)^2}\,\frac{\Delta x}{V_t} \quad (8)$$

where $p(x,y)$ is the normal pressure distribution, $s_x(x,y)$ and $s_y(x,y)$ are the slip velocities in the x-and y-directions, respectively, and V_t is the train velocity. All contributions in the longitudinal array of the points sum to obtain

$$\Delta z_l = \frac{K}{H}\frac{\Delta x_l}{V_t}\sum_{k=1}^{nx} p(x_{kl},y_{kl})\sqrt{s_x(x_{kl},y_{kl})^2 + s_y(x_{kl},y_{kl})^2} \quad (9)$$

where (x_{kl}, y_{kl}) is the point inside a contact region, as shown in Fig. 2.

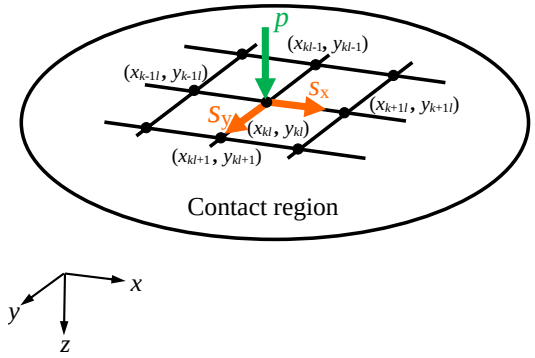

Figure 2 *Normal pressure p, s_x and s_y at point (x_{kl}, y_{kl}) inside a contact region.*

3. Application of the model to twin disc fatigue tests

To investigate the capabilities and validity of the model described above, unidirectional rolling fatigue tests are performed on a Nishihara type twin disc wear testing machine.

3.1. Test procedure

Wheel discs are machined from the cross section of a standard wheel rim and run against rail discs from the railhead. Both discs are 12 mm thick and have a diameter of 30 mm. The chemical compositions and material properties of the constituent steels are given in Tables 1 and 2, respectively.

Table 1 *Chemical compositions (wt. %).*

Material	C	Si	Mn	P	S
Wheel steel	0.65	0.26	0.73	0.016	0.01
Rail steel	0.68	0.26	0.93	0.016	0.01

Table 2 *Mechanical properties.*

Material	Ultimate tensile strength (MPa)	Proof stress (MPa)	Elongation (%)
Wheel steel	981～1030	470	8～12
Rail steel	934	508	≧10

All tests were conducted at 1% creepage with the wheel disc at faster speed. The maximum Hertzian contact pressure was 1100 MPa and the rotational speed of the wheel disc was 1000 rpm. To prevent corrosion, the contact area was lubricated with water containing 5 % cutting oil (product name: MI cool X510) using a gravity drip system that supplied one drip per second approximately. After each predetermined number of cycles, the discs were removed and weighed. At the end of each test, all discs were sectioned and photographed for the optical metallography of their crack morphologies and microstructural changes.

3.2. Test results

The details of the tests will be reported in a future; only those results that are relevant to model verification are shown herein.

It was confirmed that a number of cracks initiated and propagated on the contact surface of the rail disc,

whereas cracks were rarely found on the contact surface of the wheel disc even after around 1×10^6 cycles. Figure 3 shows an example of each section. Significant shearing plastic flow is evident near the surfaces of both discs. Wear particles are clearly present near the surface of the wheel disc. To observe the morphology of these wear particles, the discs were not cleaned up. Therefore, the mass of a disc sometimes increased because of wear particles being transferred from the mating disc.

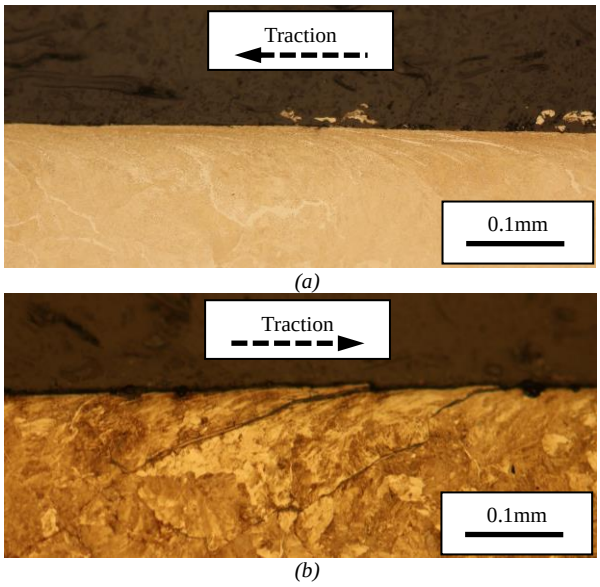

Figure 3 *Circumferential sections of wheel and rail discs after 9.5 × 10^5 cycles: (a) wheel disc. (b) rail disc.*

3.3. FE analysis of the twin disc fatigue test

FE analysis of the twin disc fatigue test was conducted using the general-purpose FE code MARC to obtain the stresses and strains in the discs, and the contact pressure and slip velocity in the contact region. The discs were modeled with first-order plane strain elements, and the numbers of elements and nodes were 24,600 and 25,622, respectively.

This study used a model that combines a nonlinear kinematic hardening rule with the isotropic hardening rule developed by Chaboche and Lemaitre [30] for the rail disc material, namely

$$ {}^{t_i+\Delta t_i}\sigma_y = {}^{0}\sigma_y + Q\left\{1-\exp\left(-B_c\,{}^{t_i+\Delta t_i}\bar{e}^{\,p}\right)\right\} \tag{10}$$

$$ \mathrm{d}\alpha = \frac{2}{3}h\mathrm{d}e^{p} - \zeta\alpha\mathrm{d}\bar{e}^{\,p} \tag{11}$$

where ${}^{t_i+\Delta t_i}\sigma_y$ is the updated yield stress at time $t_i+\Delta t_i$, ${}^{0}\sigma_y$ is the initial yield stress (namely 508 MPa), Q and B_c are material constants, ${}^{t_i+\Delta t_i}\bar{e}^{\,p}$ is the accumulated effective plastic strain at $t_i+\Delta t_i$, α is the shift of the center of the yield surface, e^p is the plastic strain, h and ζ are material constants, and d implies an increment in the variable following it. The material constants were determined as follows by means of strain controlled uniaxial fatigue experiments using normal rail steel:

Q = –208MPa, B_c = 24.2, h = 85,248 MPa, ζ =193. Young's modulus is E = 183,008 MPa and Poisson's ratio is ν = 0.3, respectively.

Meanwhile, bilinear plasticity is used for the wheel disc material because of the lack of detailed data: ${}^{0}\sigma_y$ = 470 MPa, tangent modulus E_0 = 1973 MPa, E = 197,300 MPa and ν = 0.3.

A Coulomb type friction law is presumed, and the friction coefficient between the discs is set to 0.1. At each disc center, a pilot node is connected to the nodes at the inner circumference of the disc using a multipoint constraint. All the external loading and boundary conditions are applied on the pilot nodes. As an example of the analytical results, Fig. 4 shows the in-plane shear stress distribution after 10 cycles. In the ratcheting state, the incremental strain becomes stable after receiving some load repeatedly. Therefore, stress, strain, contact pressure, and slip velocity were evaluated based on the results after 10 cycles.

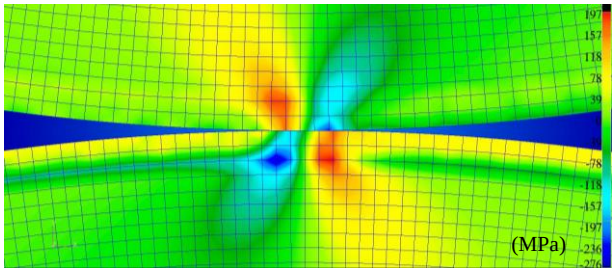

Figure 4 In-plane shear stress distribution near the contact region.

3.4. Competition between short crack propagation and wear in rail disc

The area in which the competition between short crack propagation and wear is simulated is a rectangular area of 0.9 mm (x) × 0.3 mm (z) in the rail disc whose center is 0.15 mm below the surface and an upper edge coincides with the surface. Various parameters are determined as follows.

The volume fraction of ferrite is 0.02 as estimated from the carbon content, and the thickness of grain boundary ferrite is set to 0.2 μm.

Regarding crack initiation, k_0 and β_s for the ferrite are 190 MPa and 1.41, respectively, and those for pearlite are 320 MPa and 1.41, respectively, with γ_c = 11 for both ferrite and pearlite. These were obtained from nanohardness measurements and microscopic observations of the discs used in the tests. It is difficult to obtain C, and therefore, the value of BS 11 rail steel determined by Tyfour et al.[31] is used, namely 0.00237.

The volume fraction of MnS is set to 0.002. The initial shape is assumed to be a square and the average length of a side is set to 2.5 μm. The distribution density is 5 mm^{-2} on average, as per Garnham et al. [26]. k_0 of MnS is 19 MPa [32] and strain hardening is not considered, namely β_s = 0. Also in this case, γ_c is set to 11.

Regarding crack propagation, d = 31.8 μm from the microscopic observations, $A = 1.85 \times 10^{-31}$, α = 11.14 with reference to Hobson et al. [27], and B = 0.504, β = 1.466, and $D = 3.57 \times 10^{-3}$ μm as obtained from the fatigue tests conducted independently using relevant rail steel.

In the present simulation, crack coalescence is assumed to occur when the crack length reaches 75% of d ($l_c = 0.75 \times d$) and r_c is less than 50 % of d.

The parameters for PCF are as follows:

A_{mp} = 0.5 μm, λ = 150 μm, b = 0.28 mm, and R_e = 15 mm.

Regarding wear, H = 3494 MPa, and considering the test condition as a boundary lubrication, K is set to 1 × 10^{-7} [33].

$\tau^j_{zx\,(max)}$, $\Delta\tau_\omega$, $\Delta\varepsilon_t$, p_z (x_{ij}, y_{ij}), s_x (x_{ij}, y_{ij}), s_y (x_{ij}, y_{ij}), and Δx_j were obtained from the aforementioned FE analysis.

Hereinafter, these values are referred as a "standard case" of the twin disc fatigue test to use for comparison hereafter.

The simulation was conducted for a maximum of 1 × 10^6 cycles, and the results are shown in Fig. 5. The plastic flow near the surface was already remarkable and many stage I cracks were propagating at 5 × 10^5 cycles. At 1 × 10^6 cycles, these cracks coalesced to form several stage II cracks. The wear from the surface can also be seen clearly.

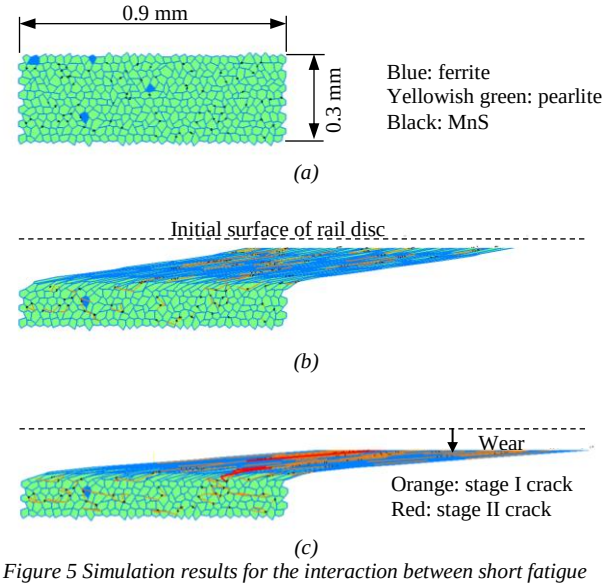

Figure 5 Simulation results for the interaction between short fatigue crack growth and wear for the standard case: (a) initial (n = 0); (b) after 5 × 10^5 cycles; (c) after 1 × 10^6 cycles.

3.5. Influence of various factors

To assess how the various factors influence the results, a series of simulations was performed.

3.5.1 Thickness of grain boundary ferrite

Figure 6(a) shows the result at 1 × 10^6 cycles, when the thickness of the grain boundary ferrite was changed to 0.1 μm, which is half of that in the standard case. In this case, the cracks did not progress to stage II ones eventually, and the plastic flow was low compared to that in the standard case. This is because fewer cracks were initiated from the grain boundary ferrite as the thickness decreased. As the hardness increased because of the decreased amount of low hardness ferrite, the plastic flow also decreased.

3.5.2 Volume fraction of non-metallic inclusion

The result obtained by changing the volume fraction of MnS from 0.002 to 0.001 is shown in Fig. 6(b). Compared to the standard case, no cracks progressed to stage II ones. This is because the cracks are less prone to initiate because the number of MnS inclusion is reduced, which are the initiating points of the crack.

3.5.3 Wear coefficient

The result of changing the wear coefficient from 1 × 10^{-7} to 2.5 × 10^{-7} is shown in Fig. 6(c). Compared with the standard case, the initiated cracks and plastic flow near the surface are completely scraped off. That is, wear has become dominant over crack propagation.

The above analysis results confirm that the developed simulation model can operate correctly.

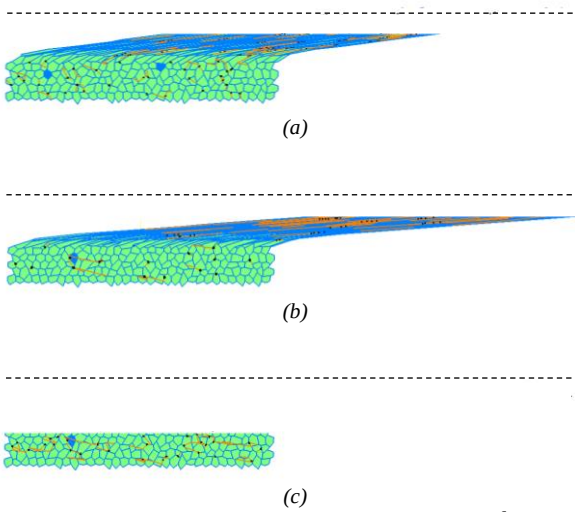

Figure 6 Influence of various factors on the results at 1 × 10^6 cycles: (a) thickness of grain boundary ferrite (0.2μm → 0.1μm); (b) volume fraction of non-metallic inclusion (0.002 → 0.001); (c) wear coefficient (1 × 10^{-7} →2.5 × 10^{-7}).

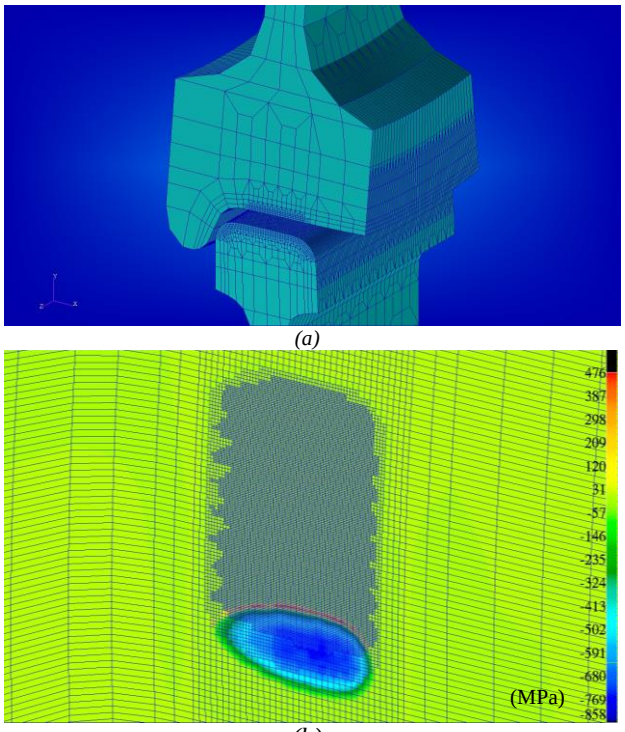
4. Application of the model to the wheel tread

Next, the model is applied to the stress, strain, and slip velocity associated with the wheel tread by using FE analyses together with the variables for microstructure, crack initiation, propagation, and wear.

4.1. FE analysis of wheel/rail contact



A 3D FE model of a wheel and a rail is shown in Fig. 7(a). The wheel shape is that for newly manufactured Shinkansen vehicles, and the diameter and configuration of the tread surface are 860 mm and a modified arc, respectively. The shape of the railhead is that of a new normal 60 kg rail. The symmetry in the lateral direction of the wheel and the rail is utilized, implying that the wheel is rolling on the center line of the rail in a straight section. The modeled parts are large enough to neglect boundary effects and consume an insignificant amount of computational resources. Regions close to the contact area are meshed with the first-order brick elements. The smallest element sizes close to the contact area are roughly 0.2 mm, thanks to the adaptive remeshing, and the final numbers of elements and nodes are 536,488 and 632,784, respectively. The constitutive models for the rail and wheel materials are the same as those used in Section 3.3.

To rotate the wheel on the rail surface, an axle is modeled by elastic straight beam elements. The beams have the same diameter and elastic modulus as those of the axle and are connected to the wheel by rigid elements [34]. The wheel rotates on the rail in a pure rolling condition macroscopically.

The wheel load is set to 98 kN as a dynamic force considering the traveling train though an additional dynamic factor. Thermal damages due to tread braking are not considered because in this study, disc braked

vehicles are considered. The friction coefficient between the wheel and the rail is set to 0.3. Only one wheel passage is analyzed because of the large computational time due to the high mesh density and the demand of small time steps.

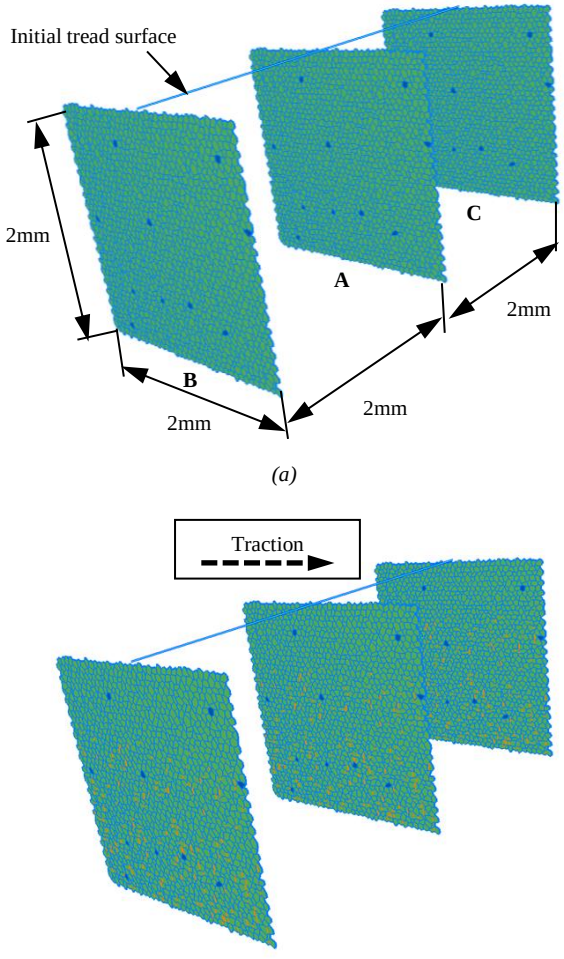
Figure 7(b) shows part of the results, namely the radial stress distribution on the wheel tread in the middle of the wheel negotiation.

(a)

(b)

Figure 7 (a) An FE mesh for the wheel-rail contact problem. (b) Radial stress distribution on the wheel tread.

4.2. Competition between short crack propagation and wear in the wheel tread



The simulation region may be taken from the FE analysis region by selecting arbitrary positions and sizes. As an example, simulations are conducted for a square region **A** with sides of length 2 mm, and with an upper edge that coincides with the tread surface, which is in the plane parallel to the circumferential direction of the wheel. In the transverse direction, the center of gravity of the region is at the center of the wheel, which is 65 mm away from the outer surface of the flange. In addition, we consider two regions **B** and **C**, which are located roughly 2.0 mm away from region **A** in the positive and negative transverse directions, respectively. Region **B** is closer to the flange side, whereas region **C** is closer to the anti-flange side. All regions are under the wheel–rail contact patch.

Unfortunately, certain parameters of the wheel steel that are necessary for simulating the competition between short crack and wear, such as k_0, β_s and γ_c for crack initiation, A, α, B, β and D for crack propagation are not available. However, the chemical compositions and mechanical properties of wheel steel and normal rail steel are similar so the missing wheel steel parameters are taken as those of rail steel as given in Section 3.3. The value of K is set to 1×10^{-4}, which is the typical value for the contact between the wheel tread and the rail top surface in dry conditions [35]. The parameters for PCF are as follows:

A_{mp} = 1.0 μm, λ = 1 mm, b = 5.0 mm, R_e = 430 mm.

$\tau^j_{zx\,(max)}$, $\Delta\tau_\omega$, $\Delta\varepsilon_t$, p_z (x_{ij}, y_{ij}), s_x (x_{ij}, y_{ij}), s_y (x_{ij}, y_{ij}), and Δx_j were obtained from the FE analysis as discussed in Section 4.1. Hereafter, these values are referred to as a "standard case" of the wheel tread.

With reference to the Shinkansen routes, the train travels a distance of 1000 km at an average speed of 200 km/h. Shinkansen routes are mostly straight sections; any curved section has a sufficiently large radius not to require consideration. Only the outward route run was simulated.

(a)

(b)

Figure 8 (a) Initial, and (b) simulation result near surface of the wheel tread in the standard case (Blue: ferrite; Yellowish green: pearlite; Orange: stage I crack).

One set of simulation results is shown in Fig. 8(b). Under these conditions, the stress and strain generated near the tread surface were so small that almost no macroscopic plastic flow occurred. No cracks progressed to stage II ones. Because the conditions were straight running with pure rolling macroscopically, the maximum shear stress related to crack initiation occurred roughly 0.5 mm beneath the surface. Many stage I cracks developed below that depth. Because there was almost no slip, there was very little wear of the tread surface.

4.3. Influence of various factors

To assess how various factors influenced the results, a series of simulations was performed.

The factors whose values were changed were the macroscopic slip ratio (0% to 1%), the wheel load (P = 98 kN to 118 kN) and the wear coefficient ($K = 1 \times 10^{-4}$ to 1×10^{-3}). Only in the case in which the slip ratio was set to 1 % did the crack initiation and stage I crack propagation move toward the surface. In all cases, stage II crack propagation was not seen and there was very little wear, namely almost the same as in the standard case.

5. Tests involving reversal of rolling direction

Generally, trains operate as a shuttle service. When a train arrives at the terminal station, its direction of travel is reversed, and therefore so is the rolling direction of the wheels. It is therefore important to investigate how the crack morphology, propagation, and wear are changed by reversing the rolling direction.

Tyfour and Beynon [36,37] studied how the rolling direction reversal affected the fatigue crack morphology, propagation, RCF life, and wear rate of pearlitic rail steel. Considering a single line supporting a two-directional traffic, they used a twin disc fatigue machine to simulate the conditions, reversing the rail discs every predetermined number of cycles. They reported a beneficial effect on both RCF life and wear rate.

At present, the model for the competition between crack propagation and wear does not allow the wheel rolling direction to be reversed. This is because it is yet to be clarified how the crack propagation and wear near the wheel tread behave under such circumstances. The results obtained by Tyfour and Beynon [36,37] cannot be referred to because the direction of relative slip and the inclinations of the generated propagating cracks differ completely between the wheel and the rail. This is why we did not simulate the return route in Section 4.2.

To elucidate how reversing the rolling direction of the wheel affects crack initiation and wear, a series of tests was conducted using a Nishihara type twin disc wear testing machine.

5.1. Test procedure

The rolling direction was reversed by inverting the wheel disc after a certain number of rolling cycles. That number was determined as that after which cracks were definitely initiated in the wheel discs as obtained in the previously performed unidirectional tests. Other items such as the machine and materials used and testing conditions were the same as those presented in Section 3.1.

5.2. Test results

The test details will be reported in the near future; only those results that are relevant to improving the model are presented here.

The unidirectional tests confirmed that cracks were initiated and propagated near the contact surface of the wheel disc after 1.2×10^6 cycles, so the disc was reversed after that number of cycles. Figure 9(a) shows a crack in the wheel disc when it was run for 1.2×10^6 cycles, and Fig. 9(b) shows a crack in the wheel disc when it was run for 3.0×10^5 cycles after having been reversed after 1.2×10^6 cycles. To capture entire image of the cracks, low magnification micrographs of the same disc are presented in Fig. 10. The cracks clearly tended to propagate parallel to the surface when the disc was reversed, and the resulting long and thin wear sheets delaminated. There was no plastic flow near the surface where the wear sheets were peeled off.

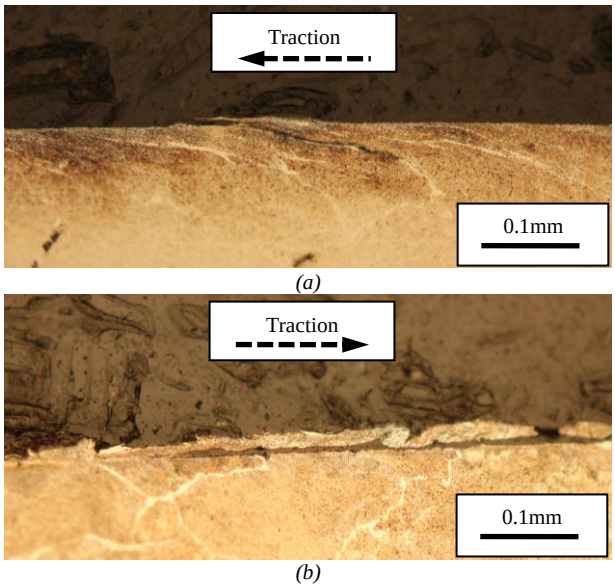


Figure 9 Circumferential section through the detected crack zone of a wheel disc. (a) After 1.2×10^6 cycles run unidirectionally. (b) After 3.0×10^5 cycles reversed after 1.2×10^6 cycles.

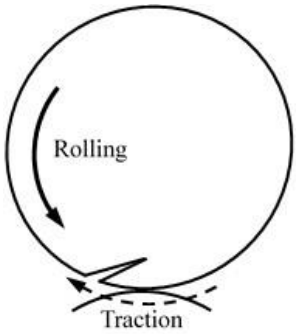
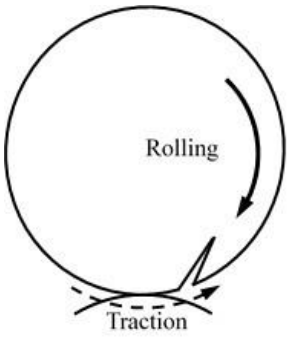
6. Discussion

A numerical model was developed to simulate the competition between short crack propagation and wear in a wheel tread. First, unidirectional rolling fatigue tests were performed, and the model was validated using the experimental results of crack initiation and propagation in a rail disc. A series of sensitivity analyses indicated that the present simulation model can operate properly at least qualitatively. However, the values used for the variables concerning microstructure, crack initiation, propagation, and wear were often uncertain and some were merely tentative. To achieve quantitative accuracy, these values should be made certain by situation-specific experimental results.



In these tests, infinitesimal wear particles as shown in Fig. 3(a) were frequently observed near the surfaces of the discs. These are inferred to be either wear particles that have grown as a result of combining the transfer particles that were previously proposed by Sasada [38] in the adhesive wear theory or delaminated sheets broken into small pieces by entrapment between the contacting surfaces. In the former case, it is reasonable to use the Archard model while changing the wear coefficient to approximate values. If these particles are fragments of delaminated sheets, applying the model is questionable. These particles must be investigated in more detail.

Next, the model was applied to the situations in the wheel tread considering the actual operation of Shinkansen vehicles. Simulations were conducted for three square regions under the contact patch with sides of length 2 mm and with an upper edge that coincides with the tread surface. Only a straight outward route of 1000 km was simulated, changing the various factors within their practical ranges. In that case, no stage II crack propagation was seen, and very little wear occurred. It is necessary to simulate a return route by adding a function to analyze the situation in which the rolling direction of the wheel is reversed, also considering other crack initiation criteria. However, as long as normal operation is simulated, and disc braked vehicles are considered, it seems that no stage II crack propagation occurs, whereas wear progresses definitely as the mileage increases. Under such circumstances, the phenomenon known as wheel flat becomes important. When a flat is generated on the tread, high tensile stresses remain around the martensite structure, and fatigue cracks initiate and propagate under the interaction of RCF with these residual stresses. Few of the articles reviewed in Section 1 considered wheel flat explicitly. For reliable analysis of the competition between cracks and wear on the wheel tread, this phenomenon should be considered.



Rolling direction reversal tests were performed using a twin disc machine and it was found that when the rolling direction of the wheel disc was reversed, long and thin wear sheets were apt to delaminate. The phenomenon was never observed in the unidirectional tests. The mechanism behind the formation of such sheets is considered as follows.

Figure 11 (a) is a schematic of a state in which a crack initiated and propagated slightly along the direction of shear plastic flow of the wheel disc in the unidirectional test. In this case, the crack tip enters the contact zone between the two disks before the mouth. Therefore, no fluid is expected to be trapped because the crack is closed starting from the tip, while the mouth remains open. Because the presence of fluid in the crack is known to be essential for RCF cracking, it is difficult for the crack to continue to propagate.

By contrast, Fig. 11(b) shows a state in which the disc is reversed after a crack has initiated on its surface. The crack is filled with fluid just before its mouth reaches the contact area, whereupon the mouth is sealed. In this case, the fluid is trapped in the crack and acts as a lubricant to either reduce the friction coefficient or pressurize the crack faces. With either mechanism, cracks tend to propagate easily.

(a)

(b)

Figure 11 Schematic representation of the directions of rolling and traction for a wheel disc in rolling–sliding contact: (a) during a unidirectional test; (b) after the rolling direction was reversed.

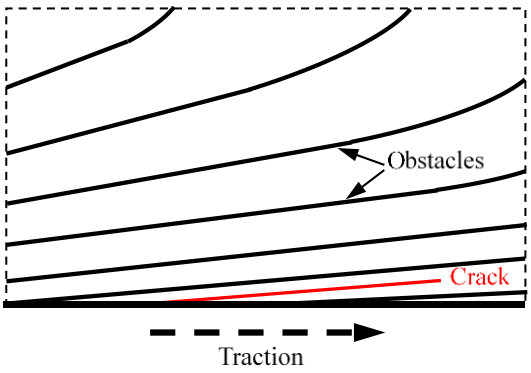


Figure 12 Schematic representation of a lamellar structure formed near the contact surface of the wheel disc.

During unidirectional rolling–sliding contact, the microstructure near the surface of the wheel disc deforms in such a way that the carbide plate in the pearlite lamellae and the grain boundaries are aligned almost parallel to the surface as shown in Fig. 9(a). These become obstacles to the crack propagation. In this case, once a crack initiates between these obstacles, it propagates easily along them because there are no obstacles in that direction, as shown schematically in Fig. 12. Therefore, the thin and long wear sheets shown in Fig. 10 are likely to form and then delaminate.

In these ways, when short cracks are present on the wheel tread, reversing the rolling direction seems to make delamination wear dominant. Therefore in future work, we will add to a present model a function that can simulate delamination wear by devising the mechanisms properly, considering also the crack initiation and propagation caused by a wheel flat.

7. Conclusions

A numerical model was developed to simulate the competition between RCF-initiated short crack propagation and wear in a wheel tread. The simulation model assumes that the wheel materials are polycrystalline ferrite and pearlite and that RCF crack initiation is determined by the total accumulated plastic shear strain. The growth of RCF cracks is calculated using the Hobson model and the Archard model is used to calculate wear.

First, the model was applied to the results of the twin disc fatigue tests. We used parametric studies to investigate how the various factors influence the competition between cracks and wear. It was shown that the present simulation model can operate properly.

Next, the model was applied to the situations in the wheel tread by using the stresses, strains and relative sliding velocities obtained from FE analyses together with the variables for microstructure, crack initiation, propagation and wear. When a straight outward route of 1000 km was simulated based on the Shinkansen routes, it was found that the tread was hardly damaged.

Finally, how reversing the rolling direction of the wheel affected crack propagation and wear was studied using the twin disc fatigue tests. It was shown that reversing the rolling direction makes delamination wear dominant.

Abstract: Brittle White Etching Layers on in-service rail steels initiate surface cracking which can progress to cause squats. Ex-service damaged rails containing both WELs and squats were investigated using electron microscopy and synchrotron diffraction. In heavy breaking rail regions, WEL containing martensite and retained austenite was observed, alongside undeformed pearlite at the interface layer between the WEL and the base rail head. It was concluded that this type of WEL, referred as TP-WEL, is induced by temperature and pressure changes. In contrast, in low braking utilisation regions where the traffic speed is steady, WEL caused by rolling contact fatigue deformation contained nanocrystalline martensite and a region of severe plastic deformation immediately below the WEL. This type of WEL is termed as SD-WEL. Microstructural observations suggest that both WELs types play significant roles in crack initiation and squat formation.

Keywords: White Etching Layer; Martensite; Retained Austenite; Transmission Electron Microscopy (TEM), Focused Ion Beam (FIB); Synchrotron Diffraction.

1. Introduction

White Etching Layers (WELs) are a microstructural phenomenon associated with surface damage of steels induced by wear such as that involving by rolling contact fatigue. When occurring on the surface of on the surface of rails, it is characterised by hard, brittle thin layer with thickness about 10 μm -100 μm. It appears to have structureless features revealing white colour under light microscopy after being etching by 2% Nital. WELs can cause rail surface damage and are considered as an important cause of crack initiation [1-6]. Rail surface defects including squats are possibly linked to WELs [7]. The formation mechanics and root causes, as well as structural nature of WELs, are still matter of controversy [8-11]. Theoretical research hypothesised that WELs are the result of either mechanical and/or thermal processes. WELs, which are composed of nanocrystalline ferrite and cementite [12], are believed to be mechanically induced by severe plastic deformation [13]. However, the presence of retained austenite in martensitic microstructure indicates that WELs are generated by a thermally induced phase transformation [14-16]. Reaching the austenization temperature means that the rail steel needs to be heated up to a flash temperature of 727 °C and then rapidly cooled to form martensite. However, under high contact pressures, the transformation into austenite, and then martensite, can be achieved at slightly lower temperature [15, 17]. Recently, WELs were proposed to be formed by a combination of both thermal and mechanical processes [17, 18].

In the present work, WELs obtained from two different ex-service damaged rails were investigated. Structural and microstructural analyses for WELs were discussed and the characteristic features of both WELs were compared. Correlation with the cracks initiation and squat formation on the rail surface was measured.

2. Methodology

Two ex-service damaged rails were cut from different re-railing sites. Rail A was removed from the area where the train approaches the station (high braking utilisation, likely loss of traction and wheel slip) while Rail B was cut form track section where the vehicles speed is steady (low braking utilisation but heavy repeated use). Rail A was taken from low rail, curved track (1598 m raduis) and Rail B was taken from high rail, curved track with approximately 1000 m radius. Samples containing WELs were obtained from the top surface layer of both rails, prepared by the metallographic procedure and then observed by optical and scanning electron microscopy. Thin WELs lamellas were prepared for Transmission Electron Microscopy (TEM) by Focus Ion Beam (FIB) milling using FEI Helios NanoLab G3 CX instrument. Two lamellas; one from the topmost region and another from transition zone were taken from WEL sample of Rail A as shown in Figure 1(a). Whereas only one lamella that includes both WEL and transition area was lifted out from WEL sample of Rail B as indicated in Figure 1(b). TEM observation was performed using JEOL JEM-ARM200F with accelerating voltage of 200 kV. The crystallographic structure of WELs was examined by high resolution synchrotron X-ray diffraction using the Power Diffraction (PD) beamline. The beamline was used in glancing incidence geometry with a monochromic X-ray beam of energy 15 keV

(λ=0.8265 Å). The experiments were performed at the Australian Synchrotron, Victoria, Australia.

3. Results and discussion

3.1 Optical metallography

Optical micrographs in Figure 2 show the surfaces of the Rails A and B, respectively. Observation was carried out along the longitudinal sections of the rail samples. As indicated in the figure, the rolling direction is from the right to the left. White Etching Layers with a bright featureless contrast was found to be sitting on the top surface layer of the rails. For rail sample A, WEL has formed with a thickness about 50 µm. Underneath WEL, a sharp transition zone is characterized by undeformed pearlite structure. For rail Sample B, the WEL has much less thickness (about 10 µm). Underneath the WEL, the structure at the transition zone is characterised by heavily deformed pearlite grains, confirming the presence of plastic deformation.

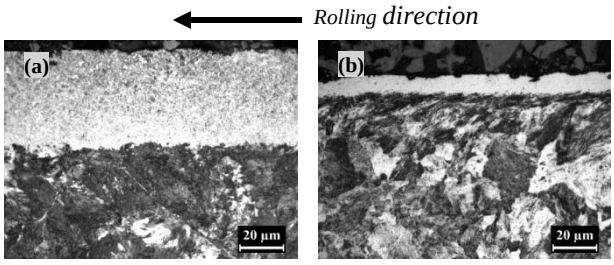

Figure 2 *Reflected light micrographs* ***of*** *White Etching Layer (WEL) of (a) Rail sample A; (b) Rail sample B.*

3.2 TEM observations

Figures 3 a and b show bright (BF) and dark field (DF) TEM micrographs obtained at the interface transition zone of Sample A. At the WEL region, the lamalle of ferrite and cementite could not be observed, indicating that the cementite layers, appearing brighter in the dark field image, have fully dissolved and very fine plate like martensite structure was formed. But, at transition zone underneath WEL, a typical undeformed pearlite structure, with an average interlamellar spacing about 50-100 nm, depending on the grain origination, was recognized. It is interesting to note there is a very small proportion of different crystal structure within pearlite structure at transition zone, showing that the cementite lamellas have partially dissolved to form fine lath martensite. At the interface boundary, dislocation in the ferrite lamella can be clearly observed, as well as some cementite particles remained undissolved.

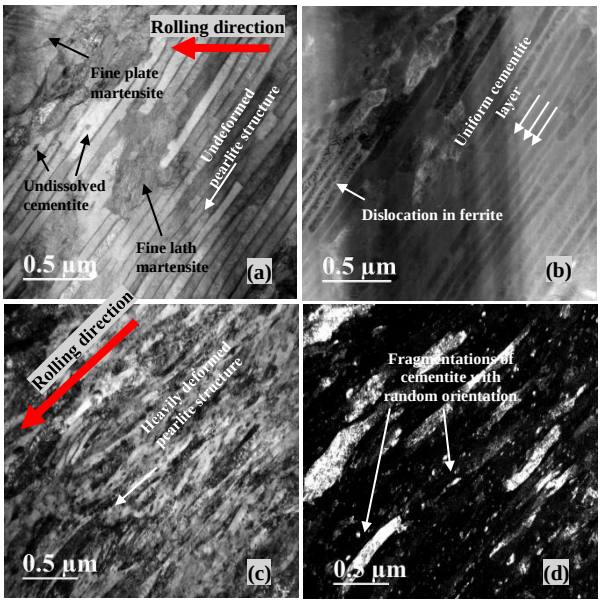

Figure 3 *Bright and dark field TEM image showing the characterisation of the transition zone of (a) BF (b) DF of Rail sample A using cementite and α' reflections; (c) BF and (d) DF of Rail sample B using cementite and α' reflections.*

Figure 3 c and d shows the microstructure characterization of Sample B obtained at the transition region. In the bright field image (Figure 3c), the structure is characterised by heavily deformed pearlite regions, confirming the presence of severe plastic deformation underneath the WEL. The dark field image (Figure 3d, using α' and Fe3C reflections) indicates fragmented and near randomly oriented nano-sized cementite and heavily deformed α' or α grains.

Figure 4 shows the TEM image and the corresponding diffraction pattern, obtained from the topmost WEL region of rail samples A and B, receptively. The microstructures of the two WELs reveal different morphologies and amounts of grain refinement. In Figure 4a, WEL, which was associated with an absence of plastic deformation in the underlying pearlite structure, is characterised by the presence of martensite and retained austenite (Also confirmed by Synchrotron XRD; Sect 4.3). Plate-like crystals of martensite (PM) can be recognized at the middle and bottom of the image. Regions of retained austenite (RA) were found parallel to the nearby regions of plate martensite, indicating an orientation relationship present between martensite and parent retained austenite. The selected area electron diffraction (SAED) pattern taken over plate martensite and adjacent region (indicating by red circle in the TEM image, Figure 4a) shows a martensite orientation close to [001] bcc zone axis and (111) fcc zone axis of austenite. In addition, diffraction spots

associated with twins were identified (indicated in yellow) in conjugation with the bcc matrix, as indicated by dashed circle and the fine twin contrast within the region. A splitting of the [002/200 planes was also observed in the diffraction pattern consistent with martensite with a tetragonal structure.

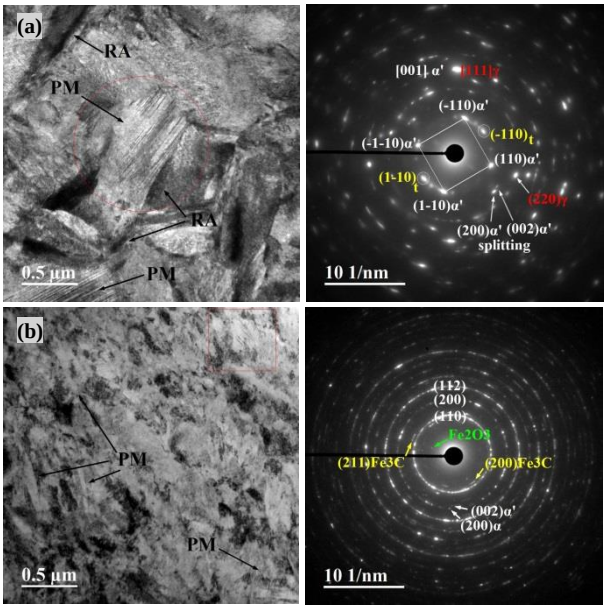

Figure 4 *TEM images with corresponding indexed diffraction patterns showing WEL structure at the topmost regions of (a) Rail sample A; (b) Rail sample B. The finer nanostructure of B is indicated by both the bright-field and selected area diffractions patterns*

Figure 4(b) shows TEM image and diffraction pattern from WEL that was correlated with the presence of severe plastic deformation near the transition region between the martensite and the deformed pearlite. The microstructure of WEL of very fine polycrystalline structure, containing ultra-fine plate like martensite, a few lath shaped crystals believed to be martensite, as well as very fine fragmented particles consistent with the Fe3C dark field imaged in Fig 3(d). The SAED pattern covering whole TEM image of Figure 4(b) shows diffraction ring pattern with concentric ring of spots, indicating a very fine nano-grain size and the occurrences of high-angle of misorientations between the grains. The diffraction spots associated with cementite are present, clearly visible either side of the diffraction ring of (011)bcc. There was no evidence of austenite in this microstructure.

Figure 5 shows a high magnification bright field (BF) and dark field (DF) TEM image with corresponding diffraction patterns obtained from the region indicated by the square in the Figure 4(b). In this region, a fine twined structure was found inside the plate martensite, and is believed to have been induced by severe plastic deformation. From SAED, cementite particles with (101) Fe_3C and (202) Fe_3C were found in the diffraction pattern, confirming that nano-fragmentations of carbide is embedded within plate martensite. The diffraction spots of cementite in the diffraction pattern indicate that cementite particles were not fully decomposed. Splitting of spots was found in the SAED pattern, indicating two overlapping peaks of the (002) α' and the (200) α, confirming the tetragonal distortion of the martensite induced in this WEL structure.

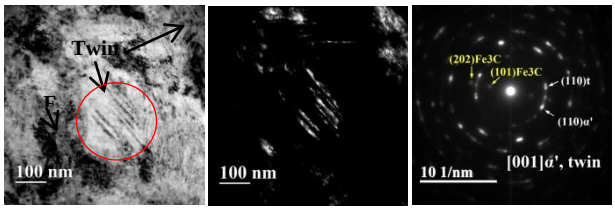

Figure 5 *Rail Sample B, TEM Bright- and Dark-Field Image (α' and α' twin reflections) and corresponding diffraction pattern. The region corresponds to the WEL region indicated by red square in Figure 4 b.*

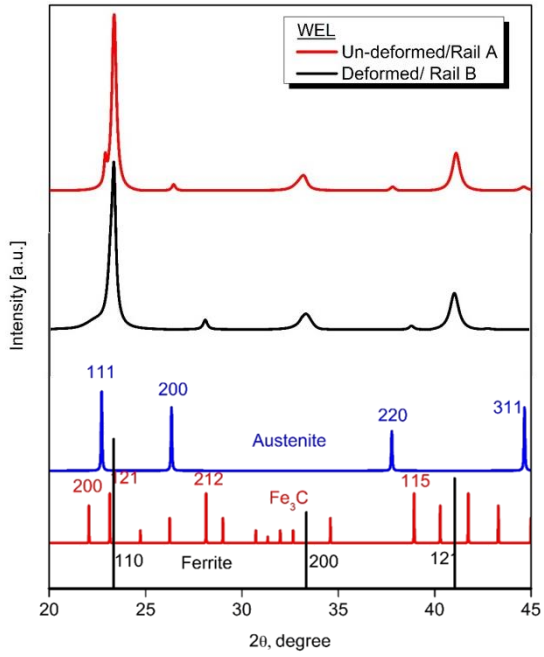

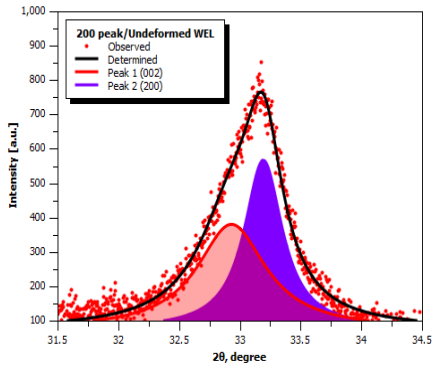

Figure 6 *XRD patterns obtained from the two WELs types; rail Sample A and B.*

3.3 Synchrotron X-ray analyses

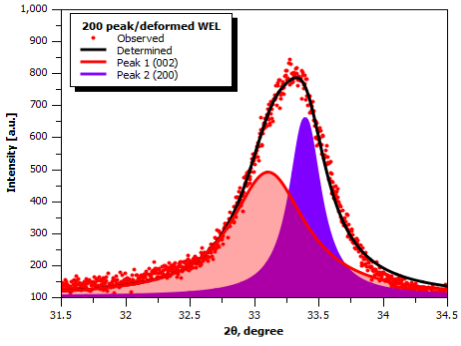

Figure 6 shows XRD patterns obtained from the two WELs types (undeformed and deformed substructure layer), obtained from the top surfaces of rail samples A and B. The results reveal a significant variation in the crystal structure between the WELs. The (111), (200) and (220) peaks of austenite are clearly visible in the profile of WEL that is associated with Sample A and the undeformed transition region while these peaks are absent in the profile of WEL that is associated with the deformed transition region (Sample B). Cementite peaks (200), (212) and (115) are clearly observed in the deformed-type WEL. However, these peaks are barely visible in the undeformed-type WEL. The diffraction pattern of both WELs types confirms the martensitic structure nature of WELs while the presence of cementite in Sample B indicates that this phase has only partially decomposed. The presence of austenite peaks in the diffraction pattern of Sample A indicates a temperature induced transformation to the higher carbon containing phase. The applied pressure on the rail surface by wheels can reduce the transformation temperature needed to form austenite. In contrast, based on the both the TEM and Synchrotron Diffraction

evidence, it appears that WEL associated with the presence of severe plastic deformation at the transition zone is more likely to be mechanically induced, resulting from the partial dissolution of decomposition of Fe_3C and formation of a nanocrystalline product containing martensite with high defect densities.

Figure 7 shows the diffraction pattern near the (200) reflection of the ferrite phase (body centred cubic, BCC) for the two WELs types. The peak was chosen because it can indicate either ferritic or ferritic/martensitic phases. It can be clearly observed that the peak profile of both WELs has an asymmetric shape which indicates that a separation of the (200) α to the different crystal planes (002) α' / (220) α' of martensite associated with the distortion of the ferrite into tetragonal martensite. The peak in the deformed- type WEL reflection were found to be slightly broadened compared to undeformed – type WEL, which is related to grain size refinement. In contrast, the peak of undeformed type WEL shifted toward the low angle direction indicating a high microstrain existence in the lattice, confirming the TEM results.

(from Rail A)

(From rail B)

Figure 7 *200 reflection profiles obtained from the two WEL types, from Rails A and B.*

The lattice parameter, c/a, of the tetragonal crystal structure of the WELs was quantitatively calculated based on Bragg's law. The c/a ratio of martensite reaches 1.011 and 1.009 for undeformed and deformed WELs, respectively, indicating the formation of supersaturated Fe-C alloy. The c/a ratio of martensite is a function of carbon content in the structure. Based on the liner correlation between c/a ratio and the percentage of carbon content (wt%), the solute carbon content of both WELs was calculated. It was found the maximum amount of carbon content reaches up to 0.26% wt and 0.2% wt on undeformed and deformed type WELs regions. It means that about one-third of the carbon concentration content of the steel material was dissolved in the WELs.

The volume fraction of retained austenite was determined by calculating the integrated intensities of the austenite peaks to the ferrite/ martensite peaks in the diffraction pattern. The quantity of retained austenite was about 17% on the structure of WEL that is associated with the undeformed underlying region. On the other hand, the retained austenite was not detected on the structure of WEL that is correlated with deformed pearlite structure underneath WEL.

4. Discussion

4.1 White Etching Layer, structure and formation mechanics

The structural and microstructural investigation has shown that there are two distinct types of WEL formed on the rail track surface. Each type contains different microstructural features. The subsurface layer underneath WEL (Transition zones) was also confirmed to have different structures: undeformed pearlite (Sample A) and deformed pearlite (Sample B). The topmost surface of the WEL of Sample A comprised a relatively coarse grained plate martensite and retained austenite. The deformed-type WEL (Sample B) was characterised by ultra-fine plate like martensite, few deformed ferrite layers as well as very fine fragmented carbide particles. Retained austenite was not confirmed to be a part of deformed-type WEL structure. The synchrotron XRD results also revealed the existence of austenite peaks in the diffraction pattern of undeformed-type WEL and the absence of these reflections in the diffraction pattern of the deformed-type WEL. In addition, the tetragonality in the nanocrystals structure of both WELs was confirmed by showing asymmetric shape profile of the 200 peaks which indicates the distortion of the lattice structure causing a splitting the 200 α of ferrite into 002/200 α' tetragonal martensite. The results showed that the asymmetry shape of the 200 reflection of deformed WEL was a relatively higher than the undeformed- type WEL, indicating high distortion induced in the lattice structure due to severe plastic deformation. In addition, the peak shows a slight more broadening which is related to grain size refinement and microstrain induced between the lattice structures. In contrast, the 200 peak profile of the undeformed WEL was found to be shifted toward the low angle direction compared to the other WEL. This can be related to the compressive stress induced at the grain boundaries due to formation the other phase structure (Austenite).

A formation mechanism is suggested based on the structure of WELs and previous literature. WEL containing martensite and austenite phase structure appears more likely to be the result of martensitic phase transformation of the top rail surface material caused by thermal and/or thermomechanical (pressure/temperature) induced process. This type of

WEL is termed as TP-WEL. This finding is further evidenced by observations of an undeformed structure at the interface between the WEL and bulk material. In contrast, a WEL structure characterised by very fine nanocrystalline martensite, some deformed ferrite and fine fragmented cementite is observed in Sample B and is associated with severe plastic deformation at the transition zone. This result is consistent with WEL being induced by severe plastic deformation (a mechanical induced process) and so it is referred as SD-WEL. Thus, it was concluded that the rail surface layer contains two different types of WEL and each type is caused by different actions on the contact zone between wheel and rail.

The nature of WEL structure as well as the mechanism of its formation has been reported in several studies. A laboratory simulated WEL by mechanical processes was found to contain nano-crystalline martensite and ferrite and an absence of austenite and fragmented cementite [19]. Martensite and retained austenite WEL has also been formed in the lab by thermomechanical processes [15]. However, in a separate investigation, only ferrite and cementite were observed in a separate investigation of WEL induced in the lab by severe plastic deformation, while thermally induced WEL contained martensite, austenite and cementite was produced via a different method [20]. WEL obtained from trade of U71Mn rail was found to consist of martensite, austenite and ultra-fine undissolved cementite, and it is mainly attributed to thermal action [21]. The tetragonal crystal lattice distortion of martensite (bct) accompanied with ferrite crystal structure (bcc) was identified in the WEL by synchrotron X-ray diffraction experiments, suggesting that it represents a thermally induced by phase transformation [3, 16]. However, perlite after severe plastic deformation reveals similar characteristics to WEL, with nanocrystalline structure and decomposition behaviour, consistent with that WEL caused by severe plastic deformation [4, 22].

4.2 Correlation between WELs and squat formation

The formation of WEL on the surface of the rail can be a significant problem as it is considered as one of the main causes of crack initiation. WELs are often linked with rail surface damage such as squats [5-9]. Microstructural observations confirmed a possible relationship between WEL existence and squat occurrence [10]. Indeed, WEL is characterised by a high levels of hardness and brittleness compared to the bulk rail head. This layer represents a critical location for the occurrence of cracks. Formation of micro-cracks may extend from WEL down into the rail and subsequently the cracks are driven by fatigue crack propagation. Microstructural evolution below the WEL plays an important role in propagation of rolling contact fatigue induced defects [9, 11]. In addition, the existence of WEL on the rail surface can reduce the wear rate due to high hardness level [12-14].

In order to determine the state of the WELs and whether they have played role in crack formation, samples containing WELs, obtained from the vicinity of squats region were examined. These samples were cut from the top surface layer of Rails A and B, which means that each sample contained similar WEL types as observed in Figure 2, but they were taken from a different location (a cracked area). The microscopic analysis for the longitudinal sections of Rail samples A and B are shown in Figure 8(a) and (b). The WELs appear to have fragmented, spalling and formed cracks. The cracks were seen to have initiated in the location where the part of WEL has missed and broken away from the layer. The cracks then extended down from WELs into the rail bulk material. It appears that the crack initiation directions were related to the structure of the transition zone underneath the WEL. For TP-WEL type, the enlarged image, Figure 8(a) shows two cracks, the large crack initiated vertically and the small crack formed in the direction opposite to rolling direction. Whereas, for the SD-WEL that is correlated with the presence of plastic deformation at the transition zone, the crack initiated down the material and followed the deformation texture, as seen in the enlarged image of Figure 8(b). These microstructural observations suggest that both WELs types play significant roles in crack initiation and squat formation.

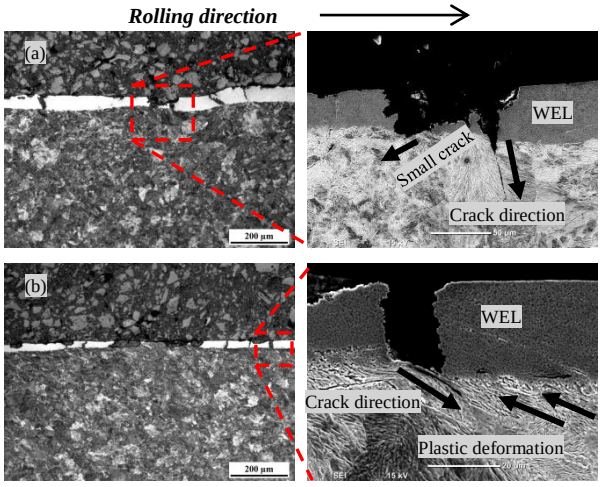

Figure 8 *Microstructural observations of WELs obtained from a squat region, showing a crack initiated from the WEL and extending down into the surface of the rail. (a) shows Optical and SEM images of WEL associated with the undeformed substructure layer, obtained from Rail A, (b) shows WEL associated with the deformed pearlite structure at the transition zone, obtained from Rail B.*

5. Conclusions

Structural and microstructural characterization of the two types of WELs associated with the operation condition that the rail samples were taken from is strongly evident that there are two distinct type of WELs.

One WEL type, TP-WEL is characterised by coarse martensite, retained austenite and an undeformed texture of pearlite sub-structure and is thermally and pressure induced. It is associated with regions of track where wheel slip is likely.

The other WEL type SD-WEL contains ultra-fine martensite, fine ferrite and fine fragmented cementite and is also characterized by the presence of severe plastic deformation beneath the surface. It is associated with regions of track subjected to severe rolling contact fatigue and the martensite present is believed to be induced by severe plastic deformation.

The microstructural observations suggest that both WELs types play significant roles in crack initiation and squat formation.

Acknowledgments
The authors would like to acknowledge the Sydney Trains (ST) to provide financial support and rail samples for investigation. In addition, the authors also acknowledge the allocation of experimental beam time at the Powder Diffraction beamline of the Australian Synchrotron, part of ANSTO. The authors acknowledge the assistance of Dr Mitchell Nancarrow and Dr. Gilberto Casillas from the UOW Electron Microscopy Centre. Abstract: A periodic out-of-round wheel generates a range of excitation frequencies that may approach to the fundamental resonance of the track and vehicle. Detecting these defects by current condition monitoring systems is challenging. This paper focuses on the polygonal defect detection. VI-Rail is used to model the wheel-rail interaction to generate required data. A fusion algorithm reconstructs the defect signals in the space domain. The comparisons between the reconstructed defect signals and the wheel defects present a great potential for defect type identification. The results show that different polygonal defects can be correctly recognized and the dominant harmonics can be successfully decomposed.

Keywords: Wheel; defect; polygonal; periodic out-of-roundness; condition monitoring; signal reconstruction; detection.

1. Introduction

A polygonal defect is a periodic radial deviation from the nominal railway wheel radius around the wheel circumference. Polygonal defects are caused in different phases for a variety of reasons that can be explained by inhomogeneous properties, misaligned axle hole during the manufacturing process, misalignment in the re-profiling and maintenance process, or by polygonal wear during the operation [1]. These defects can be a pure sinusoidal wave with a long wavelength that covers the wheel circumference or a combination of multiple waves with different harmonics. The amplitude of these waves have been reported from 0.3 mm [2] to 1 mm [1], [3].

Several condition monitoring systems have been developed to detect the defective wheels [4]. Wheel defects normally change the wheel-rail contact force and can be detected by Wheel Impact Load Detectors (WILD). For the polygonal defects, the change in the contact force is in the order of 100 kN [5], that is much lower than the alarm and warning thresholds, 240 and 425 kN respectively [6]. In addition, detection of these defects during visual inspection is not easy [5].

Generally, the contact force of a defective wheel is changed by variation of train velocity [7]. According to the wavelengths of the polygonal defects, a range of excitation frequencies is generated that is changed by variation of the train velocity. The excitation frequency may approach to the fundamental resonance of the track and vehicle [8] that leads to high impact force, high-frequency vibration, noise and reducing the passenger comfort [9]. For example, a wheel flat generates one impact on each turn of the wheel. When the wheel circumference is about 3 m, the main frequency of defect will be between 1-33 Hz for the velocity between 10 – 360 km/h. Since the first resonant frequency of a wheelset is around 72 Hz [8], the main frequency of a non-periodic defect such as wheel flat is lower than the resonant frequency. A third order polygonal defect has the frequency between 3-100 Hz for that range of velocity that covers the first resonant frequency of the wheelset. Therefore, while the polygonal defects are generally safe, they can be detrimental in some specific velocities. Hence, detection of these defects is vital especially for high-speed trains. In-service detection of polygonal defects is an open issue that is tackled in this paper.

WILDs are commercial devices that estimate the wheel-rail contact force [10]. They use the dynamic force to estimate the wheel out of roundness. Wheel defects have a geometric pattern along the wheel circumference that is replicated in every wheel revolution. Previously, a multi-sensor fusion method has been developed to generate the defect signal from the partial data collected by the multiple sensors [11]. This method transfers the partial data from the time domain to the space domain and maps them along the wheel circumferential coordinate. This fusion method provides a circumferential pattern from the data collected using the space relation of the sensors, sample intervals, and the wheel circumference.

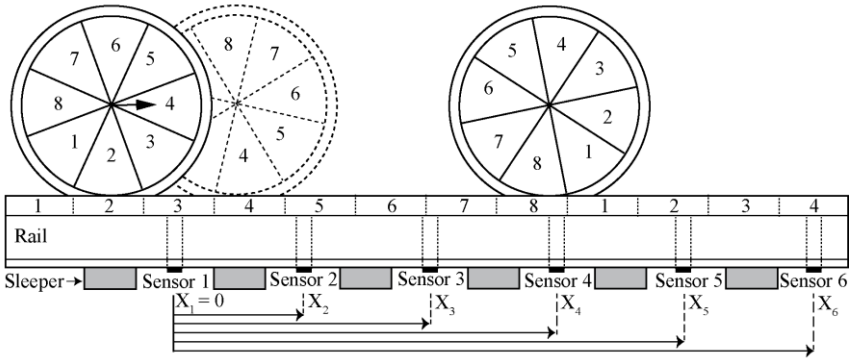

Figure 1 *The schematic view of a track and the configuration of the wheel portions with respect to the sensors*

The reconstructed signal represents the wheel defect. The purpose of monitoring is detecting and identifying the defects, but train velocity and load change the reconstructed signals. To response to this challenge, prior research [12] exploited pattern recognition tools to classify the signals reconstructed from four wheels into four classes.

This paper aims to focus on polygonal defects detection. The polygonal defects are periodic and it is expected that the reconstructed signals represent the feature of these periodic defects. This paper investigates the polygonal defects and presents meaningful features to identify these defects using the reconstructed signals. To achieve this purpose, VI-Rail is used to model the wheel-rail interaction and to simulate the data collected by the wayside sensors. Then, the fusion algorithm developed in [11], is exploited to reconstruct the defect signals from the signals measured by multiple sensors. Then, the reconstructed defect signals are transferred into the frequency domain to investigate the similarity between the harmonics of the polygonal defects and the reconstructed signals.

The paper is structured as follows. Section 2 presents an overview on the multi-sensor fusion algorithm. Section 3 explains the simulation procedure to generate data by VI-rail. Section 4 discussed the results obtained from signal reconstruction and decomposition. Finally, section 5 draws the main conclusions.

2. Multi-sensor data fusion model

Wheel and rail have contact in a very small area. Wheel defect changes the contact patch and consequently pressure profile that lead to high pressure and dynamic contact force. Wheel Impact Load Detectors (WILDs) are common wayside wheel monitoring systems that measure the rail response to the contact force using strain [13] or vibration [14] sensors to estimate the condition of the in-service wheels. This measurement depends on the position of the defect with respect to the sensors. Therefore, the results of the field measurements presented considerable variation even when the axle load, train velocity, and the defects were kept constant in different experiments [7].

Figure 1 presents a schematic view of the configuration of wheel, rail, sleepers, and sensors. In this Figure, the wheel circumference has been divided into eight portions. These portions have different contact positions with respect to the sensors.

According to Figure 1, each sensor is sampling from limited portion of the wheel. Figure 2 illustrates a schematic view of the outputs of the sensors. Each sensor has an effective zone in which the wheel is on top of the sensors.

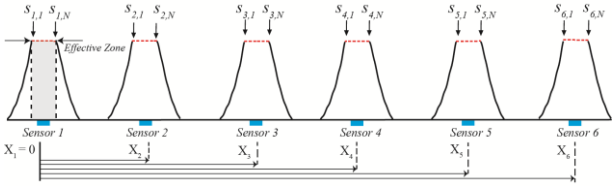

Figure 2 *The multiple sensors collecting multiple samples in their effective zone.*

Each sensor collects multiple samples in its effective zones. The sensors are identical and measuring with similar sampling frequency. Therefore, M sensors collect identical number of samples (N samples) in their effective zones. These samples generate a dataset as follows:

$$S_{m,n} = \begin{bmatrix} S_{1,1} & S_{1,2} \dots & S_{1,N-1} & S_{1N} \\ S_{2,1} & S_{2,2} \dots & S_{2,N-1} & S_{2,N} \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ S_{M-1,1} & S_{M-1,2} \dots & S_{M-1,N-1} & S_{M-1,N} \\ S_{M,1} & S_{M,2} \dots & S_{M,N-1} & S_{M,N} \end{bmatrix} \quad (1)$$

In this dataset, each row represents the effective zone samples of a sensor. The locations of the sensors are known and are presented with vector X. The portion of the wheel that is measured by each sensor can be related to the sensor location using the circumference of the wheel. This relation is presented as follows [11]:

$$Y_{m,1} = X_m - \left(L_w \times \left\lfloor \frac{X_m}{L_w} \right\rfloor \right) \quad (2)$$

In this equation, X_m is the position vector of the sensors, L_w is the wheel circumference, $\lfloor \ \rfloor$ is the round operator toward the nearest integer less than or equal to the element, and $Y_{m,1}$ is the position vector of the first samples of the sensors (first column of dataset) over the circumferential coordinate. This fusion method associates the samples collected by different sensors to each other and generates a signals over the circumferential coordinate in the space domain. The wheel velocity (V) and the sampling frequency of the sensors (f_t) influence the intervals of the samples in the space domain. Therefore, the samples of the other columns of the dataset should be positioned using these parameters as follows:

$$Y_{m,n} = Y_{m,1} + \left((n-1) \times \lambda\right) \quad (3)$$

in this equation $Y_{m,1}$ is the positions of the first sample of each sensor, n is the number of samples, and λ is space interval between the samples that is defined as follows:

$$\lambda = \frac{V}{f_t} \quad (4)$$

This fusion method associates the samples collected by different sensors to each other and generates a signals over the circumferential coordinate. This reconstructed signal represents the features of the wheel defects. Therefore, by investigating the features of the reconstructed signals, the wheel defect can be identified. To find more detailed explanation of the fusion method refer [11]. Next section simulates data for the fusion method.

3. Generation of data by VI-rail

VI-Rail as a commercial multi-body dynamics software is used to model the wheel-rail interaction to generate the required data. This software considers the track and vehicle subsystems such as car body, sleepers, rail pads, wheelsets, primary and secondary suspensions, dampers, and anti-roll bars.

Figure 3 presents the procedure of the data generation by VI-Rail. In the first step, the defect model generates the required defect on the wheel. Then, the operational parameters presented in Table 1 are fed into VI-Rail. Other parameters of the vehicle and track are based on the Manchester Benchmarks [15]. Using these parameters, VI-Rail models the wheel-rail interaction and generates some outputs.

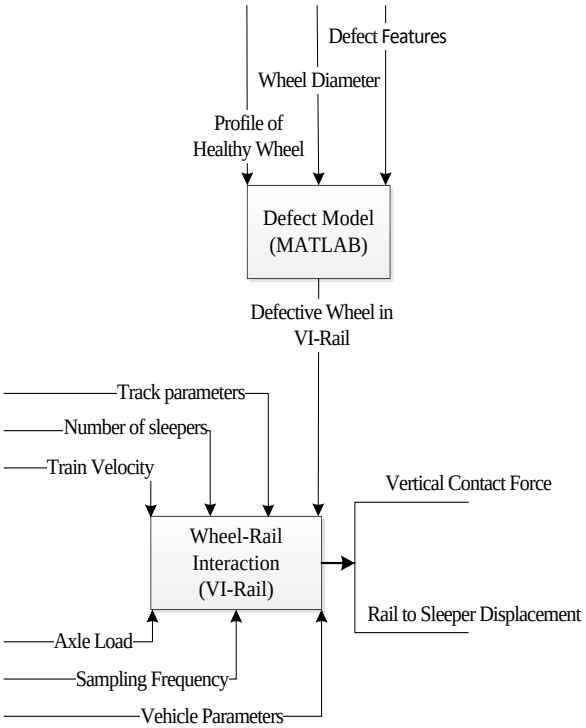

Figure 3 *The procedure of the data generation by VI-Rail.*

This paper considers six different defective wheels including four polygonal wheels and two flat wheels, but the focus is on polygonal defects. Three polygonal defects are pure periodic defects including 1st order, 3rd order, and 4th order polygonal with 0.3 mm amplitude. Another polygonal defect is combination of multiple waves while third harmonic is dominate with average amplitude of 0.2 mm [1]. Two other defects are flats with 40 and 60 mm length and 0.4 mm and 1 mm depth respectively. Figure 4 presents the radial deviation of these six defective wheels in addition to a healthy wheel. These defects are the inputs of the VI-Rail model.

Table 1 *Operational parameters of VI-Rail model.*

Parameter	Value
Number of sensors (Sleepers)	59
Sensor interval (Sleeper interval)	600 mm
Train velocity	40 m/s
Train axle load	11120 kg
Sensor sampling frequency	10 kHz
Wheel diameter	850 mm

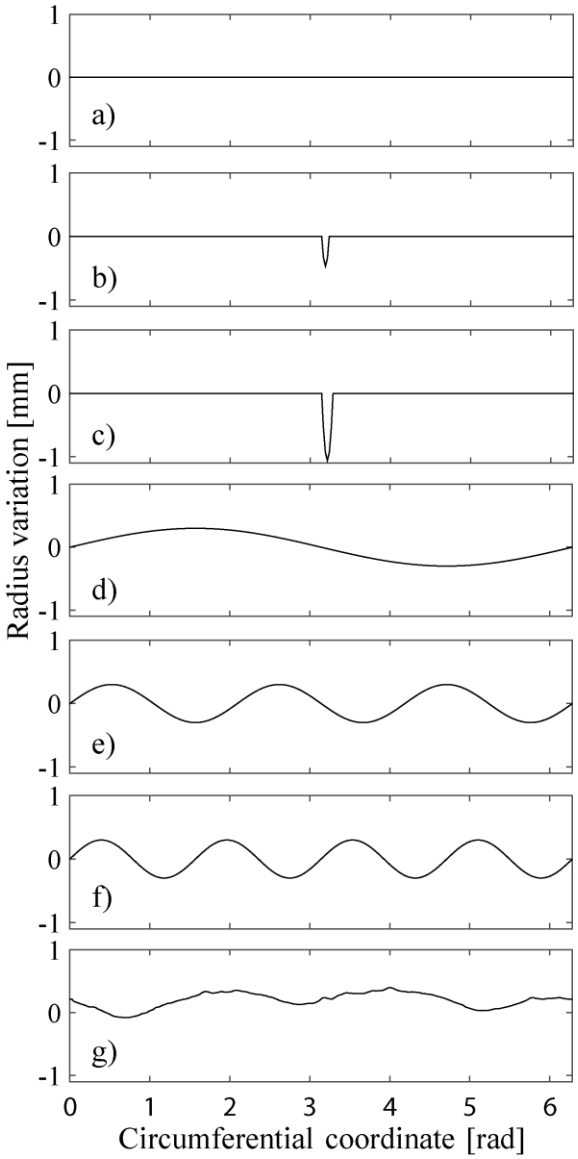

Figure 4 *The radial deviation of the wheels over the circumference for a) healthy wheel, b) 40 mm flat, c) 60 mm flat, d) first order polygonal, e) third order polygonal, f) forth order polygonal, and g) a combined polygonal wheel presented in [1].*

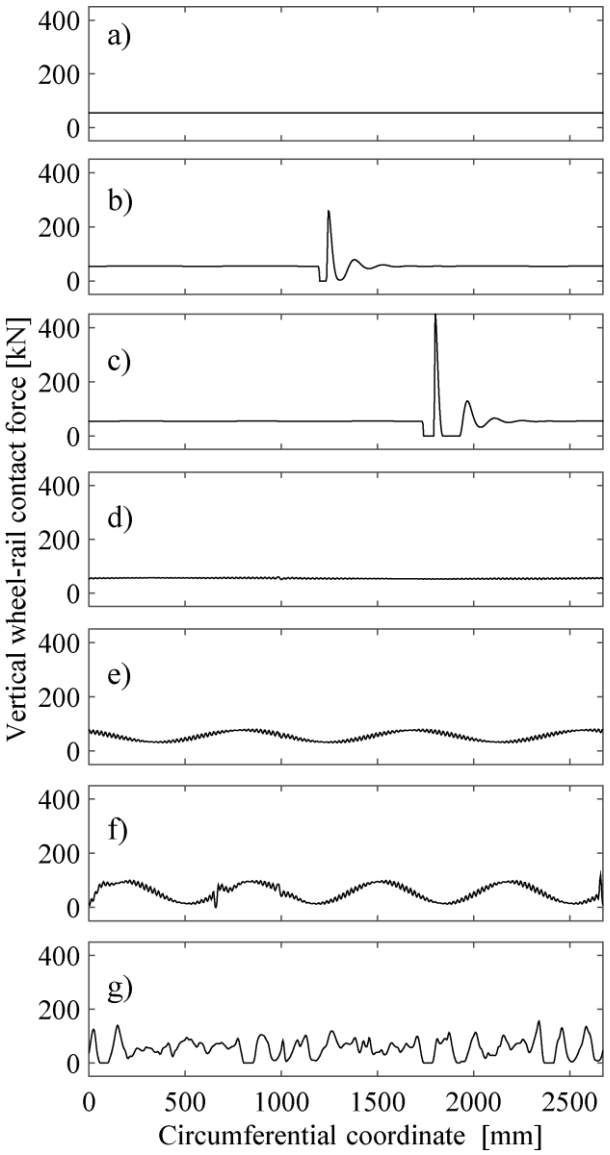

Figure 5 *The vertical wheel-rail contact forces generated by a) healthy wheel, b) 40 mm flat, c) 60 mm flat, d) first order polygonal, e) third order polygonal, f) forth order polygonal, and g) a combined polygonal wheel presented in [1].*

One output of the VI-Rail model is vertical wheel-rail contact force. This force is calculated using the contact features. Figure 5 presents the vertical wheel-rail contact forces generated by different wheels. Each wheel depending on its condition generates a unique contact force pattern. This contact force is transferred into track and vehicle and causes some responses. Wayside monitoring systems measure these responses to estimate the wheel condition.

VI-Rail provides rail to sleeper displacement signals. These signals are used as the required outputs that simulate the rail response to the contact force. Therefore, each sleeper is used as a sensor that converts the contact force to an output signal that is here the rail to sleeper displacement signal.

4. Results and discussion

This research uses 59 sleepers as the required sensors. The rail to sleeper displacement signals are fused by the developed data fusion method to reconstruct a signal over the wheel circumference [11]. Figure 6 presents the reconstructed signals generated by fusing 59 rail to sleeper displacement signals for different wheels.

The reconstructed signal represents the features of the wheel defect and is called the defect signal. Using the features of the defect signals the condition of the passing wheels can be estimated.

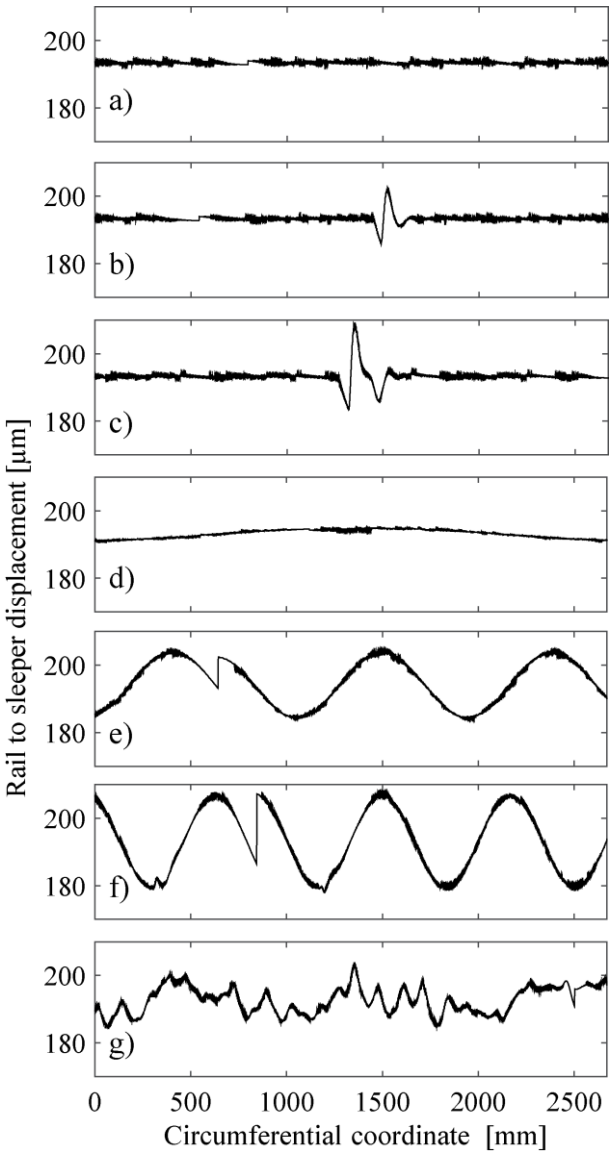

Figure 6 *The reconstructed defect signals for a) healthy wheel, b) 40 mm flat, c) 60 mm flat, d) first order polygonal, e) third order polygonal, f) forth order polygonal, and g) a combined polygonal wheel presented in [1].*

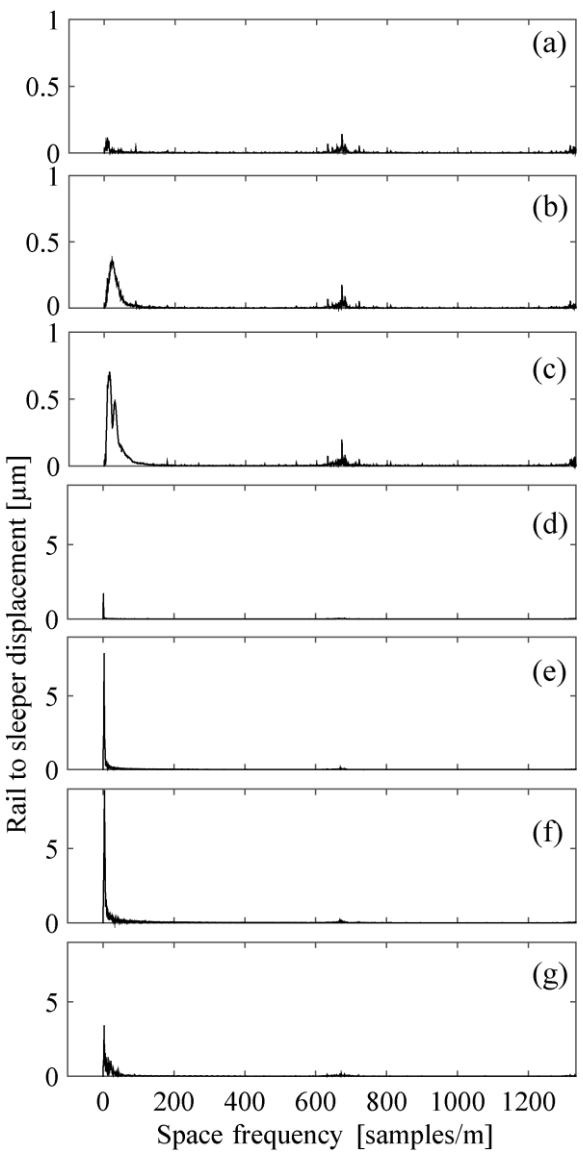

Figure 7 *The frequency representation of the reconstructed defect signals for a) healthy wheel, b) 40 mm flat, c) 60 mm flat, d) first order polygonal, e) third order polygonal, f) forth order polygonal, and g) a combined polygonal wheel presented in [1].*

Figure 7 presents the frequency representation of the reconstructed defect signals (note that vertical axes have different scales). Since the signal reconstructed over the circumference of the wheel in the space domain, the frequency representation has the unit of samples/m. The signals have noise with the frequency between 600-800 samples/m that is observable in Figures 7(a), (b), and (c). The frequency spectral of flat defects in Figures 7(b) and (c) has a range between 0-100 samples/m. Figures 7(d), (e), (f), and (g) present very narrow low frequencies that reflect the nature of the polygonal periodic defects.

Figure 8 presents the magnified view of the frequency spectral for the polygonal defects presented in Figures 7(d), (e), (f), and (g). Figure 8(a) corresponds to the 1st order polygonal wheels and the frequency spectral shows the first harmonic as the dominant harmonic. Figure 8(b) presents the third harmonic and Figure 8(c) presents the forth harmonic as the dominant harmonics. Figure 8(d) depicts that the dominant frequency is third harmonic that is matched by the defect feature of the wheel.

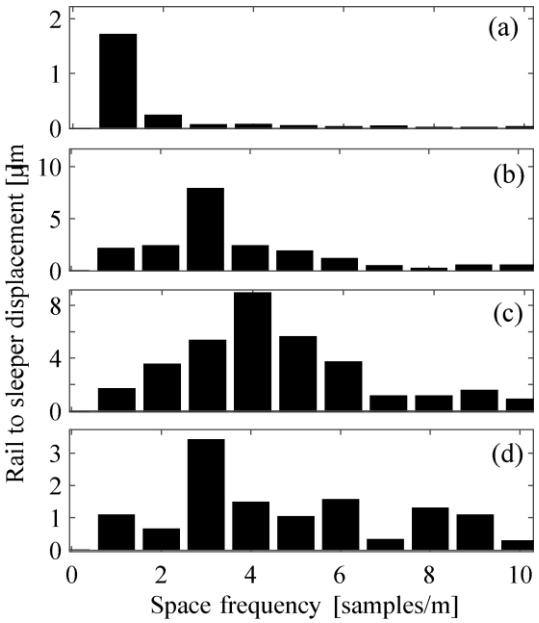

Figure 8 *The magnified view of the frequency representation of the reconstructed defect signals for a) first order polygonal, b) third order polygonal, c) forth order polygonal, and d) a combined polygonal wheel presented in [1].*

5. Conclusions

This paper aimed to exploit multi-sensor data fusion method to detect polygonal defects. The results show that different polygonal defects can be correctly recognized and the dominant harmonics can be successfully decomposed. This method can be used to detect the defective wheels with periodic out of roundness to reduce the noise and enhance the comfort of the passenger.

Abstract: This work presents the initial steps given in order to obtain a comprehensive physical model for the specific case of wheel rail contact, which would be able to relate contact conditions, material properties and wear rates. The main advantage of a physical damage wear model is that wheelset an rail manufacturers can perform simulations in order to improve and optimize material properties for different operational cases. The initial work has focused on delaminative wear, starting with the importance and modelling of rough contact, and a comparison against classic smooth contact models.

Keywords: physical damage model; delaminative wear; surface roughness; rough contact; contact surface topography; normal contact problem.

1. Introduction

The accurate prediction of wheel and rail profiles evolution is one of upmost interest for the railway industry. The profiles of both the wheels and rails have a direct influence on most of the problems related to vehicle dynamics: hunting motion, safety against derailment, comfort, rail displacements due to excessive lateral forces, flange climbing, etc.) Due to that, wheel and rail profiles are monitored at periodic intervals in order to assure that the profiles parameters are within certain limits.

The capacity to know in advance how the profiles will evolve is very important since it would allow the wheel profiles to be optimized in order to reduce the wear and increase the time periods between wheel reprofilings. Moreover, a detailed knowledge of profile evolution would ease the scheduling of re-profiling activities of the different vehicles or sections of the track reducing in this way, the cost of maintenance of vehicles and tracks.

Due to that during the last years different research projects have been conducted in order to develop methodologies that allow the wheel profiles evolution to be predicted. Among the different works carried out in this field it is worth mentioning the ones developed within Roll2Rail [1], where wheel and rail wear was identified as one of the most important influencing factors of the developed Universal Cost Model [2], [3].

Due to the importance of the problematic, a scheme of the different steps to carry out wear calculations was proposed. The main steps identified were the followings:

- Development of a validated computational model of the railway vehicle to perform dynamic simulations in different scenarios. This vehicle model must be validated in order to assure the trustworthiness of the results.
- Analysis of track layout and vehicle mission profile in order to define the simulations to be carried out in order to estimate the wear form the obtained results. Different methodologies can be followed with different computational costs and accuracy characteristics.
- Dynamic simulations in the different scenarios in order to calculate the contact conditions at different instants of time during the circulation of the vehicle. The variables that are usually sought are the wheel rail contact forces, the relative slip between the wheel and the rail, the pressure and tangential stress distribution between the bodies in contact, the dissipated power, etc.
- Relate the contact conditions with the amount of material removed from the bodies in contact. At this point two main wear laws were proposed: the Tγ law and the Archard Law. Both relationships are empirical in nature and their applications to a specific case depend on tuning of certain parameters. The adjustment of these parameters is, nowadays, dependant on experimental data obtained in the site and therefore, the capacity of forecasting the parameters in a new site where no measurements are available is very limited; that is, if predictions are sought in cases where no data are available the uncertainty of the parameters will be very high.
- The profiles must be updated with the results of removed material obtained in the previous step. The dynamic simulations must be carried out again since the profiles have a direct influence on the results and, this way, the process is repeated.

The profiles' evolution is calculated as a function of travelled length. From these data, all the parameters related to vehicle profiles can be calculated: equivalent conicity, flange height, etc. and the dynamic characteristics of the vehicle can be evaluated assuring, this way, the safety margin when evaluating different critical situations.

During the Roll2Rail project as assessment of the different methodologies was performed from both the infrastructure and railway manager point of view. One of the main conclusions about the wear module was the big uncertainty when choosing the law and parameters relating contact conditions to removed material; that is, the obtained results when applying the wear module were very dependent on what low and what parameters were used. These results cast doubts on the predictive capacity of the models to obtain accurate results with new vehicle.

Due to these uncertainties, one of the objectives of the FR8RRAIL is to gain knowledge in this problem. For this, a detailed analysis of one of the most important types of railway wear will be analysed from a physical point of view, trying to determine the mechanisms that have a role in this type of wear. The idea is to extend in the future the work carried out within this project in order to cover other types of wear obtaining, in this way, a comprehensive physical wear map for wheel and rail wear.

2. Delaminative wear

Delaminative wear is caused by crack nucleation and propagation due to high strain and stresses caused by the wheel rail contact. An extensive analysis of the available experimental surface condition, debris morphology…) data has been conducted (in order to determine the different phenomena that must be taken into account in order to study the problem in detail.

As a result of this analysis, it was concluded that the following topics must be addressed in

- Wheel rail contact problem solution taking into account rough surfaces. The crack nucleation is very dependent on the actual stresses and strain. Therefore the contact must be solved in such a way that these parameters be obtained with accuracy enough.
- Crack nucleation process taking into account number and distribution of soft inclusions.
- Crack propagation taking into account the elastoplastic behaviour of the material under successive passes of asperities.
- Debris generation process.

In the following sections the models developed to analyse each of this parts will be briefly explained.

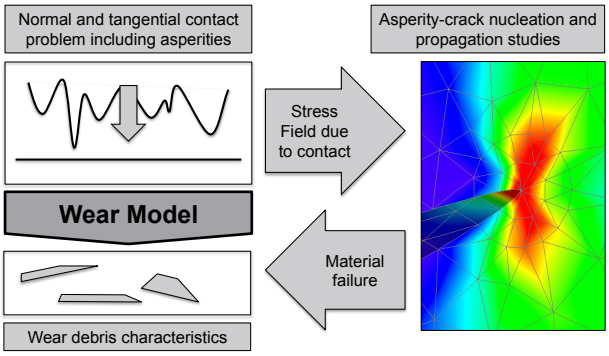

Figure 1 *Schematic of the proposed delaminative wear model.*

3. Wheel rail contact taking into account rough surfaces

When performing dynamic simulations it is commonly assumed that the surfaces of both the wheel and the rail are smooth. This is valid as only the total transmitted forces are sought as an input for generating the dynamic equations. In cases where the strain and stresses distributions are needed this approach is no longer valid and the influence on the surface roughness has to be taken into account.

In order to solve the contact between rough surfaces different approaches have been followed:

- Stochastic methods [4]–[6] based on the statistical characterisation of the surface by means of three parameters: root mean square value of the height of the roughness, surface density of the roughness and average curvature radius of the roughness.
- Methods based on the fractal characterisation of the rough surfaces [7]–[9].
- Numeric methods based on the application of numeric methods with a sufficiently fine mesh of the contact surfaces in order to model the geometry of the roughness [10], [11].

The stochastic method proposed by Greenwood allows statistical information of the contact characteristics to be obtained in a straightforward way. This method is based on the following characterization of the roughness:

- All the deformations are elastic.
- The roughness peaks are spherical shaped. Also, all the roughness peaks have the same curvature radii.
- The roughness profile height has a normal distribution.

Based on these hypotheses a model to solve the normal contact problem with rough surfaces was proposed. The most important results obtained when solving the roughness normal problem are as follows:

- Real contact area. For smooth surfaces, contact occurs in a well determined and continuous area. However, for rough surfaces, contact occurs in an infinity of small contact areas.

- Apparent distribution of normal pressures. This is the relationship between the total force transmitted via a surface differential and the value of the surface differential.
- Statistical information of the Pressure distribution at each contact area.

The standard way to obtain the input parameters of the method is the use of a profilometer. However, different analyses [12] have shown that the results obtained with this method are dependent on the precision of the profilometer and therefore, an alternative way based on three-dimensional characterization of contact surface must be used.

In this work a preliminary analysis of a worn wheel surface has been conducted in order to calculate the parameters needed to solve the normal contact problem and to check the hypothesis of the Greenwood method for rough contact. The methodology used to carry out this analysis is the so-called optical interferometry. *Figure 2* shows an example of the results obtained when analysing a real wheel surface:

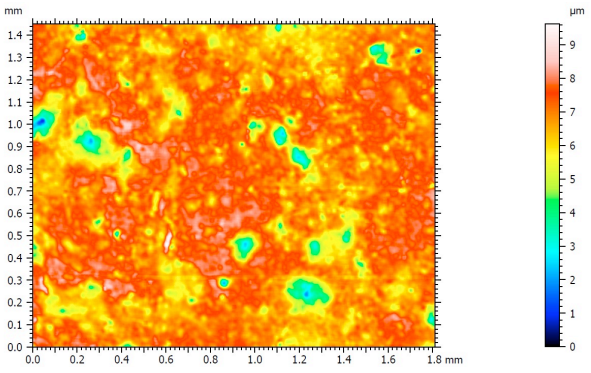

Figure 2 *Measured wheel surface topography.*

As it can be seen, the three dimensional topography of the surfaces in contact can be obtained with this methodology. With this information, all the data related to peak distribution can be calculated.

3.1. Peaks in contact density

One of the most important parameters when applying the Theory of Greenwood to solve the normal contact problem is the determination of the number of peaks in contact as a function of the vertical displacements of the surfaces in contact. In order to characterize this phenomenon, it is supposed that there is a constant density of peaks whose heights follow a normal distribution. Therefore two parameters are required:

- Density of points
- Standard deviation of the normal distribution representing the asperities' height distribution.

The mean value of the normal distribution is not strictly required since it is compensated with the approach of the bodies in contact.

In the case that a three-dimensional representation of the surface is available, the number of contact points in contact as a function of the approach can be calculated directly numerically. It has been analysed how much this distribution differs from the Greenwood Hypothesis. For that this distribution has been approximated by a normal distribution of heights with a constant density of peaks, see *Figure 3*.

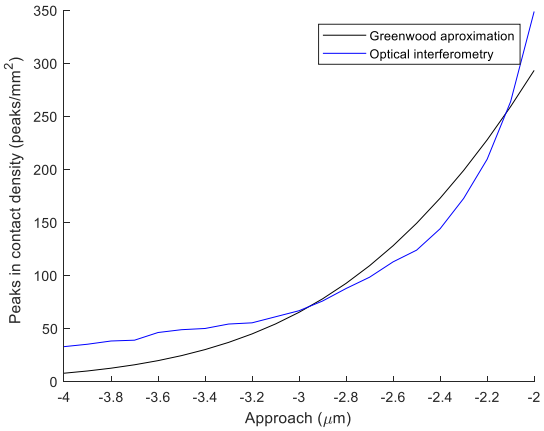

Figure 3 *Comparison between the Greenwood approximation (black) and the experimental results (blue)*

In order to obtain the Greenwood approximation the following parameters have been used:

- μ(mean value of the normal distribution) $= -0.998\mu m$.
- σ(standard deviation) $= 1.169\mu m$.
- ρ(density) $= 1497$ peaks/mm^2

As it can be seen, the experimental results cannot be perfectly fitted using the curves proposed by Greenwood. The influence of this deviation should be checked latter when solving the contact problem.

3.2. Peaks shape

The other surface parameter that is required to solve the contact problems by means of Greenwood theory is the asperity radius. This parameter gives info about the shape of the asperities and relates the interpenetration at each peak with the contact area created. Greenwood assumes that the peaks have a spherical form and therefore only one parameter is required.

In this work and following the idea of Greenwood, the different peaks shape will be approximated to a sphere and the sphere radius will be calculated for each peak. *Figure 4*shows the cumulative distribution function for for an approach of -1.5μm.

As it can be seen, in this case 80% of the peaks have radii between 1.4·10-6 and 1.40·10-5; that is, around one order of magnitude. If a different approach, i.e. -4μm is used, the curve radii are significantly lower that in the previous case, around one order of magnitude. Therefore, it seems that the approach has a direct influence on the curve radius distribution. The influence

of this effect must be checked later when solving the normal contact problem.

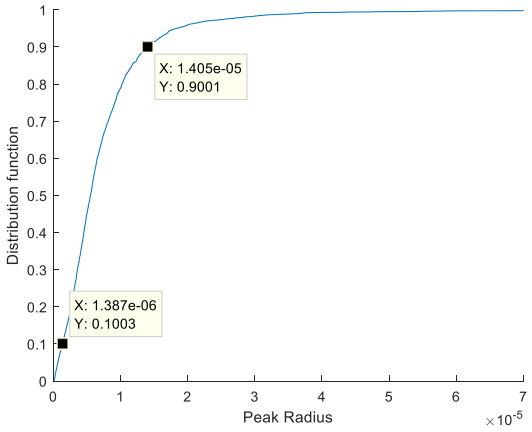

Figure 4 *Cummulative distribution function of the peak radii*

4. Normal problem solution

Once the surface topography of the bodies in contact has been characterized, the solution of the normal contact problem can be addressed.

Usually, the objective when solving the normal contact problem is to obtain the normal contact area and the pressure distribution. When performing dynamic simulations it is commonly assumed that the surfaces of both the wheel and the rail are smooth. This is valid as only the total transmitted forces are sought as an input for generating the dynamic equations. In cases where the strain and stresses distributions are needed this approach is no longer valid and the influence on the surface roughness has to be taken into account.

4.1. Algorithm to solve rough problems

Within this project, a program to solve the normal contact problem between wheel and rail taking into account the roughness has been developed. This program allows overcoming the main restrictions of the Greenwood method and, therefore, general wheel rail contact surfaces topographies can be considered. Subsequently, the main points of the program are explained:

- The height of the asperities can have a generic distribution
- The Radius distribution is dependent on the height
- The real amount of asperities obtained with the optical interferometer is used.
- The bulk deformation of the bodies is considered elastic. However the deformation of the peaks can be considered in a general way (elastoplastic deformation)

The solution of the contact problem is done using an iterative method:

- The feasible contact area is divided into $N_x \cdot N_y$ rectangular elements.
- An initial guess of the apparent pressure distribution is assumed

$$P_i^0;\ i = 1..N_xN_y \quad (1)$$

- Each of the pressures causes a surface displacement in the same element u_(i,i) and in the rest of the elements $u_{i,j}; j = 1..N_xN_y, j \neq i$
- The deflection calculation u_(i,j) is simplified using the criteria of Saint-Venant "... the difference between the effects of two different but statically equivalent loads becomes very small at sufficiently large distances from load." Therefore, in order to calculate the deflections out of the element Love equations are used (the pressure is assumed to be uniformly distributed within the element).
- The direct deformation can be calculated using the following formula:

$$u_D = \eta \int_{-Lx/2}^{Lx/2}\int_{-Ly/2}^{Ly/2}\int_{d}^{\infty}\int_{-\infty}^{-\infty} f_u\left(z - d, \beta, \sqrt{x^2+y^2}\right)\phi(z,\beta)\ d\beta\ dz\ dx\ dy \quad (2)$$

  Where
  - $\phi(z,\beta)$ is the density function of asperities (it is assumed that it depends on two variables: height (z) and radius (β))
  - $f_u(z - d, \beta, \sqrt{x^2+y^2})$ is a function that gives the deflection generated by an asperity at a distance $\sqrt{x^2+y^2}$ as a function of the interpenetration and the asperity radius.
- The interpenetration distance (that will cause the local deformation of asperities) will be calculated in the following way:

$$u_{LDi} = q - d_i - u_{i,i} - \sum_{j=1,i\neq j}^{N} u_{i,j} \quad (3)$$

- With this distance, the number of asperities, their areas and the forces transmitted can be calculated within each element.
- An approximation to the apparent pressure P_i^i can be calculated using the parameters calculated in the previous step P_i^0.
- The process continues until the difference of the pressure distribution calculated in the steps is under a certain limit.

The method has been programmed in Matlab®. Several problems where hertzian hypothesis were fulfilled were solved and compared with Hertz solution in order to check the accuracy of the results provided by the program. All the results obtained in the different cases were completely satisfactory.

4.2. Solution of the normal contact problem using Greenwood assumptions

Once the program is validated, it will be used in order to obtain conclusion when solving the normal contact problem taking into account rough surfaces The first problem that will be analysed consist of one fulfilling the greenwood hypothesis and using the following parameters to characterize the roughness:

- $\mu(\sigma(\text{standard deviation of height}) = 1.169\mu m$.
- $\rho(\text{peaks density}) = 1497 \text{peaks/mm2}$.
- $R(\text{peak radius}) = 20 \cdot 10^6$ m

Figure X shows the apparent pressure within the contact area. The apparent pressure is calculated summing up all the forces transmitted through an element and dividing it between the element area.

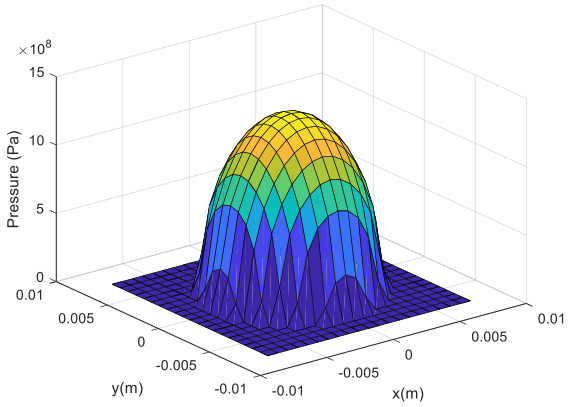

Figure 5 *Apparent pressure within the contact area when using Greenwood's assumptions*

As it can be seen, the apparent pressure follows a ellipsoidal shape. In fact, if it is compared to the Hertz solution it can be seen that both the Hertzian pressure and apparent pressure calculated taking into account the rugosity are very similar. For example, the maximum pressure calculated with Hertz Theory is 1.37GPa while the maximum apparent pressure is 1.31GPa.

The area of the contact path is also very similar. The semi-axis obtained with Hertz Theory is 5.67mm and the apparent contact area has a semi-axis of 5.71mm.

As a conclusion of this analysis it can be said that both the apparent contact area and the apparent pressure distribution are very similar to the results calculated with Hertz Theory. This result is also stated in [13].

Analysing the obtained results the following comments can be made:

- The density of asperities in contact in the central area of the contact path is of the order of 1000 peaks/mm2. Therefore around 70% of the total peaks are in contact.
- In this region the ratio between real contact area and apparent contact area is of the order of 8%.
- The real pressures in the central part of the area are around 10 times higher than the values predicted by the Theory of Kalker.

5. Use of rough contact results for physical damage calculation

As stated in the introduction, the analysis of rough contact is meant to provide accurate peak pressures in the contact patch so that a realistic debris detachment analysis can be carried out. The steps in these areas are preliminary, so in this section the exploratory steps will be described.

Plastic shear deformation is induced due to that the surface traction is utilized by the harder asperities on the softer surface. This plastic deformation accumulates with repeated loading.

As a result of the continuous subsurface deformation due to the plastic shear deformation introduced by surface traction cracks nucleate below the surface. Additional loading after nucleation causes cracks to extend and propagate, usually parallel to the surface, until they finally shear to the surface, generating a wear chip.

5.1. Crack initiation

According to metallurgical studies, the debris has a crack growth pattern that starts in some sort of irregularity or inclusion in the metal matrix. In order to determine if a stress peak will generate a crack, the maximal subsurface stresses need to be cross-correlated to the location of the inclusions, as only then will the crack nucleate and grow.

For this analysis is important to know not only the average values of the stresses, but even more so the peak stresses and their position. For instance, *Figure 6* shows the cumulative pressure values in the previously analysed contact patch. As it can be seen, around 90% of the peaks have a normal pressure lower than 10GPa. In the rest of the peaks a higher pressure is obtained, because a fully elastic model has been used to solve the problem. If elasto-plastic model is used, the maximum pressures would be reduced.

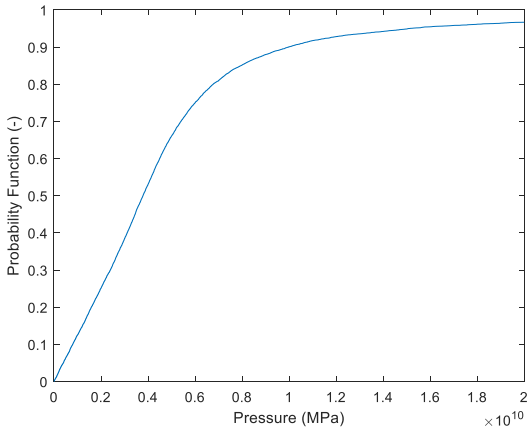

Figure 6 *Cummulated maximum pressure occurrences in the contact patch asperities.*

5.2. Crack propagation and breakup

Considering a practical approach, for a specific crack nucleation situation the easiest way of analysing crack growth and breakup is the use of FEM software.

Commercial FEM software like Abaqus have in-built implementations of XFEM models that include fracture mechanics. Knowing the load distribution and size and

position of the inclusions, it is straightforward to generate models that calculate crack propagation speed for certain cyclic-loads. However, exploratory analyses have shown that simulating microscopic crack growth is far from direct, so future efforts for developing the model need to focus on this topic.

6. Conclusions

In this paper the first stages of a physical delaminative wear model have been described, specifically the analysis of the contact between rough surfaces, where the following conclusions have been drawn:

- The apparent contact area and the apparent contact pressures obtained when taking into account the rough surfaces are similar to those obtained under the assumption of smooth surfaces.
- Although the apparent distributions are similar, a series of micro-contact are obtained when solving the problem considering the rough surfaces (instead of a continuous distribution). In this micro-contact the pressures are much higher than those obtained when solving the problem using Hertz. The differences can reach one order of magnitude.
- The optical interference allows detailed information about the surface topography to be obtained. This information permits to check the validity of Greenwood hypothesis; i.e., the peak height distribution and the peak radius.
- It has been check that solving the normal contact using the real information topography infor problem allows us to obtain more accurate results regarding number of contact, size and pressure distribution within the micro-contacts. It has been checked that the average pressure is lower in this case that that obtained with using the Greenwood hypothesis.
- The accurate knowledge about number of contact points, size and pressure distribution is of upmost importance when analysing the crack nucleation and propagation. Therefore the use of this information can be very valuable to adjust wear models.

After this study, there is still work to be done both within the rough contact analysis and the crack nucleation and propagation analysis. For the rough contact, a variability analysis needs to be performed in order to assess the influence of different variables in the final normal and tangential pressure distribution, contact area, etc. For the crack nucleation, propagation and breakup there is still work to be done both regarding the correlation between stress peaks and material inclusions, and the modelling of crack growth and breakup of the wear chips. The final challenge is to be able to couple all the different submodels into a realistic wear model that, being material based, would be extremely useful for wheel and rail manufacturers, allowing them to optimise material properties targeting wear or RCF.

Abstract: The WILAC low adhesion creep force model has been integrated into the LABRADOR train braking model to enable an improved simulation of braking in low adhesion conditions. Trial runs were carried out using a class 158 2 car unit. The Inclusion of the WILAC model improves the capability of the LABRADOR model, but some limitations are still to be overcome.

Keywords: Low adhesion creep force model; brake model, brake scenario predictions.

1. Introduction

Low adhesion in the wheel/rail interface can cause both safety and performance issues. In braking it can lead to station overruns and signals passed at danger (SPADs) and in traction it can lead to costly delays. Low adhesion can result from a number of causes including "wet-rail" syndrome, where a mixture of a small amount of water and oxide causes friction to lower; leaves, oil, etc. A lot of attention has been paid to understanding and mitigating against leaf problems, "wet-rail", however, has received less attention. In a recent RSSB project (T1077) though, a validated creep force model (Water Induced Low Adhesion Creep Force model (WILAC) was developed for predicting the effects on adhesion of small amounts of water in the wheel/rail interface [1]. The aim of this work was to implement the WILAC model in the recently developed train braking model (Low Adhesion Braking Dynamic Optimisation for Rolling stock model (LABRADOR)) to improve the low adhesion input and therefore braking predictions for a "wet-rail" scenario.

2. LABRADOR

The LABRADOR model has been developed in MATLAB/Simulink software. The model has been developed to represent the complex behaviour of modern multiple unit passenger trains braking in normal and low adhesion conditions. It is modular to allow easy specification of vehicle, bogie and wheelset subsystems. Figure 1 shows a block diagram of the LABRADOR model in which the train module interacts with the environment model and driver brake demand model as inputs. In LABRADOR's modular structure the train module contains one, two, three, or four functionally identical vehicle modules, each vehicle module contains a number of functionally identical wheelset modules. Within the wheelset module, WSP& friction braking, sanding, dynamic braking, and wheel and contact patch subsystems exist. The contact patch module contains the contact patch temperature, contact patch dimension and adhesion creep curve modules.

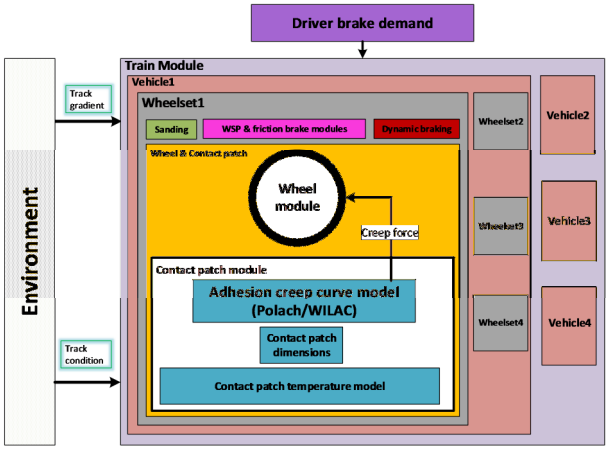

Figure 1 *LABRADOR model architecture for 4 car train.*

The modular structure of LABRADOR provides the easiest way to exploit the duplicated systems within real, long trains. For example, changing how the WSP system works for every vehicle in a 4 car train only involves changing the WSP module which is then replicated many times within the model structure for a long train. Figure 2 illustrates the functions within the simulation tool. One to four car trains can be constructed with configurable brake arrangements. More details of the LABRADOR simulation tool can be found in [2] and [3].

Integrating the WILAC model into LABRADOR offers the possibility of significantly improving the modelling of low adhesion in the presence of water and offers the potential for improved understanding of the response of modern braking systems under such conditions.

Figure 3 shows LABRADOR output compared against measurements for a Class 158 DMU in dry conditions

[5] [6]. In this prediction a Polach approach was used for the creep force relationship.

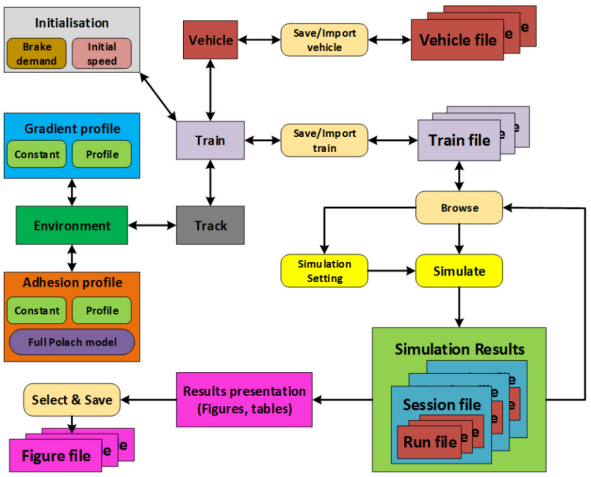

Figure 2 *Schematic diagrams of the FE model: (a) Front view. (b) Side view.*

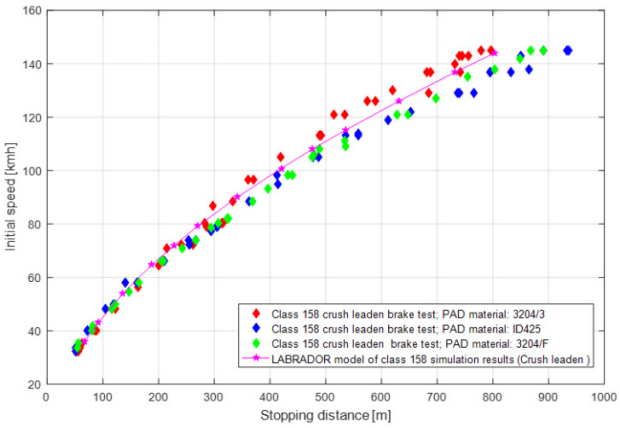

Figure 3 *Class 158 full service brake application (notch 3) – experimental and LABRADOR simulation data* ***[5] [6].***

3. WILAC

The WILAC model was developed to predict adhesion/creep forces in a rolling contact in the presence of water [1]. The model covers the whole range of conditions from dry to damp to wet rail. Special emphasis has been put on low amounts of water in the contact, conditions which may be encountered at the onset of rain for example. The model has been parameterized based on experimental results from a full-scale tram wheel test rig. These results show that adhesion changes with the water flow rate in a complex way. Adhesion values as low as 0.06 have been observed in the experiments at high creep (see Figure 4) with only wear debris and small amounts of water present in the contact. The model results also agree with experimental data from locomotive tests [7] (recorded at high normal contact force) in dry and wet conditions (see Figure 5). The model may be implemented in multibody software or in braking models to study train performance and braking strategies, especially in damp conditions.

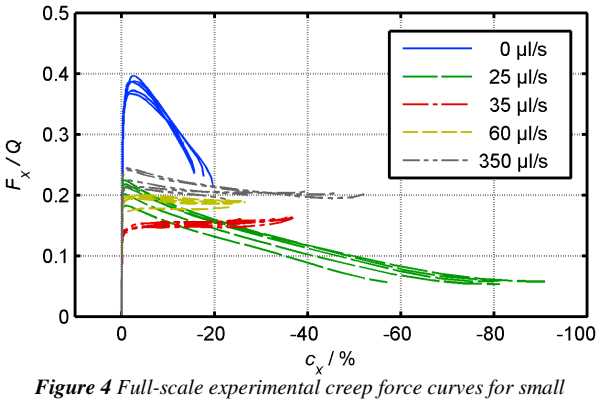

Figure 4 *Full-scale experimental creep force curves for small amounts of applied water* ***[1].***

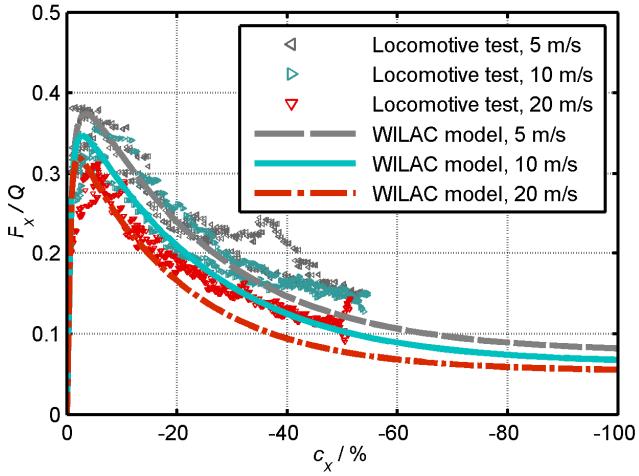

Figure 5 *WILAC predictions for wet and dry conditions compared to locomotive test data (from* ***[7]****)* ***[1].***

4. Implementation of WILAC in LABRADOR

4.1 Approach

Figure *6* shows how the WILAC model has been integrated in the contact patch module of LABRADOR. The integration approach was to keep the modularity of the LABRADOR model and add the WILAC model as a user selectable option. The original Polach model was retained in the contact patch module. A selection functionality has been added so the user can select which model is activated during the simulation. The operation of the WILAC model inside the contact patch module can be summarised as follows:

1. The normal load Q and vehicle speed v are fed to the four predefined contact condition blocks (Dry, Damp2, Damp1, and Wet).
2. Each block applies multiple linear regression algorithms to calculate the Polach model parameters $K_A, K_S, A, B,$ and μ_0.
3. The Polach parameters from each contact condition block are sent then to a Polach model to calculate the creep force for each set of parameters. Hence, four creep forces are generated from the Polach model blocks, which are $F_{x,Dry}$, $F_{x,Damp2}$, $F_{x,Damp1}$, and $F_{x,Wet}$ for Dry, Damp2, Damp1 and Wet condition respectively.

4. The generated creep forces are then passed to the blending process. The blending process uses the amount of water as input to calculate the weights $(f_{Dry}, f_{damp2}, f_{damp1}, f_{Wet})$ that are applied to each of the four contact conditions. The resulting creep force is then calculated based on:

$$F_x = F_{x,Dry} \cdot f_{Dry} + F_{x,Damp2} \cdot f_{damp2} \\ F_{x,Damp1} \cdot f_{damp1} + F_{x,Wet} \cdot f_{Wet} \quad (1)$$

5. The resulting creep force is then output and passed to the wheel module.

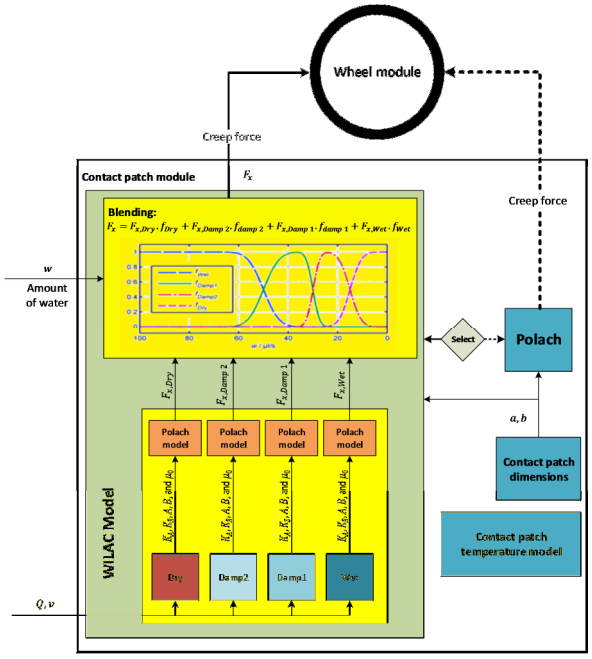

Figure 6 *WILAC model integrated into the contact patch module of LABRADOR.*

4.2 Trial runs

This section presents some simulation results which demonstrate the main differences between the LABRADOR and LABRADOR-WILAC models. All the examples presented below use a 2-car model of a class 158 diesel multiple unit as shown in Figure 7. Masses and centre of gravity heights of this train are given in Table 1. Bogie wheelbase is 2.6m, pivot spacing 16m and inter-vehicle pivot spacing 7.208m.

Figure 7 *Schematic diagram of a 2-car class 158 unit (DMS-DMS).*

Table 1 *Class 158 masses and CoG height.*

Item	**Tare**	
	Mass /kg	CG height /m
Car body 1 DMS(A) 57748	26437	1.519
Car body 2 DMS(B) 52748	26677	1.519
Trailer bogie 1	2192	0.56
Motor bogie 2	2005	0.56
Wheelset 1 & 2 trailer	1528	0.42
Wheelset 3 & 4 driven	1925	0.42

The initial speed of train is 20 m/s $(45\ mile/h)$ and the driver brake demand is 9% g (notch 3). The case studies cover two rail conditions; dry and damp with 35 $\mu l/s$ of water (Damp1). These conditions represent two of the WILAC experimentally validated conditions as shown in Figure 4.

The level of adhesion that is shown in Figure 4 cannot be considered as low adhesion as it remains higher than 0.09 for most creepages. However, the Damp2 condition (25 $\mu l/s$ of water) shows a low adhesion level at high value of creepage (e.g. $c_x > 50\%$), but this amount of the creepage will not occur in normal operation and the same condition gives sufficient adhesion for normal brake demands at lower creepage. A scaling factor is therefore introduced to scale the adhesion curve, in order that sufficiently low adhesion conditions can be generated. The scaling factor is selected to be 0.44 for all cases presented.

The scaling can be justified by the fact that in the experimental work used to develop the creep curves illustrated in Figure 4 at the start of the tests no oxide was present and friction was governed by the presence of water only. In an actual wheel/rail interface the oxide would be present, either on the rail head or within the contact, and it could anticipated that the friction would be lower.

Dry condition:

The LABRADOR class 158 model was firstly configured to use the Polach model with a high value of the maximum adhesion profile ($\mu_0 = 0.3$). In the second run the WILAC model with dry rail condition was used in LABRADOR. The simulation results show that the LABRADOR gives the same results whether the Polach model or the WILAC is selected to generate the creep force. For example, Figure 8 shows the train speed against the braking distance for both cases and it can be seen that the results are identical. The stopping distance is 202 m in both cases.

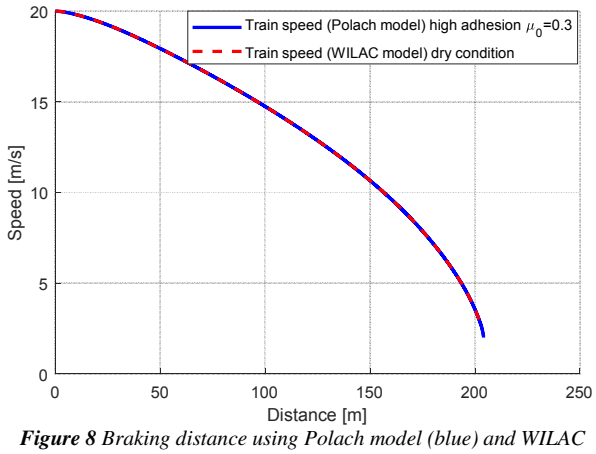

Figure 8 *Braking distance using Polach model (blue) and WILAC model (red) for high adhesion/dry condition.*

Damp1 condition:

The aim of this case is to generate a low adhesion condition and compare the model behaviour when using the Polach model and WILAC models.

WILAC model configuration: A scaled version (scaled

by 0.44) of the WILAC adhesion curve of the Damp1 condition is shown in Figure 9 (magenta line). The scaling factor is selected to make the maximum adhesion value equal to 0.07 which is below the adhesion required to sustain a brake demand of $9\%g$. The LABRADOR model was configured so that the water flow rate on the rail is constant at 35 $\mu l/s$.

Polach model configuration: The default values of the Polach model parameters for low adhesion conditions are given in Table 2.

Table 2 *Polach model parameters in low adhesion condition.*

Polach model Parameter	K_A	K_S	μ_0	A	B
Value	0.30	0.10	0.07	0.40	0.20

This configuration produced adhesion curve shown in Figure 9 (green line). It can be seen that the Polach adhesion curve (green) decreases dramatically to about 0.03 at 30% of creepage while the WILAC adhesion curve just dropped by 0.01 at the same creepage value. The parameter 'A' of the Polach model represents the ratio between the minimum and maximum adhesion value and therefore controls the drop of the adhesion curve beyond the low creepage peak. The red and blue lines in Figure 9 show the adhesion curves that are generated when the parameter 'A' changed to 0.9 and 0.8 respectively from which it can be seen that the bigger the parameter 'A' the lower the amount of the drop in adhesion curve. The changes in the adhesion-creep curve due to the change of the Polach model parameter shows the sensitivity of the Polach model to the parameter change, which, of course, will be reflected in the LABRADOR behaviour as will be seen in the simulation results below.

These four configurations (WILAC Damp1 and the Polach model with the three configurations of the parameter 'A'), which have the same maximum adhesion level, were simulated in LABRADOR. Figure 10 shows the train speed against the distance for these four configurations. As can be seen, there are significant differences between the four curves. For example, the stopping distance when the WILAC model is used is 354 m while it goes up to 520m with the Polach model default configuration (i.e., A=0.4). However, the stopping distance is reduced when the 'A' parameter increased to 0.8 and reduced further when A=0.9.

These differences in the stopping distances are due to the levels of the adhesion that seen by the wheelsets at different configurations that given in Figure 9. Figure 11 shows the adhesion level at wheelset 1 in Vehicle 1 for the stated configurations. It can be seen that there are clear differences in the shape\behaviour and value of wheelset 1's adhesion for different cases. For example, the adhesion value drops to about 0.03 and remains there for a long distances when the Polach model was used with its default parameters (i.e., A=0.4), the green line in Figure 11. However, increasing the A parameter to 0.8 and 0.9 will change the adhesion shape\behaviour dramatically (blue and red lines). In case of using WILAC model wheelset 1's adhesion level (magenta line) drops slightly for shorter distances. The drop in the adhesion value at higher creepages means smaller wheel-rail force hence slower rotation of the wheelset which further increases the creepage value which in turn activates the WSP system that acts to restore the wheelset rotation and decrease the creepage by releasing the brake force on the wheelset. The activity of the WSP system (and hence the overall braking distance in each case) is also governed by the WSP system model that has been used in LABRADOR and its configuration, thus different WSP models (e.g., more advanced WSP model) or different WSP model configuration will give different results.

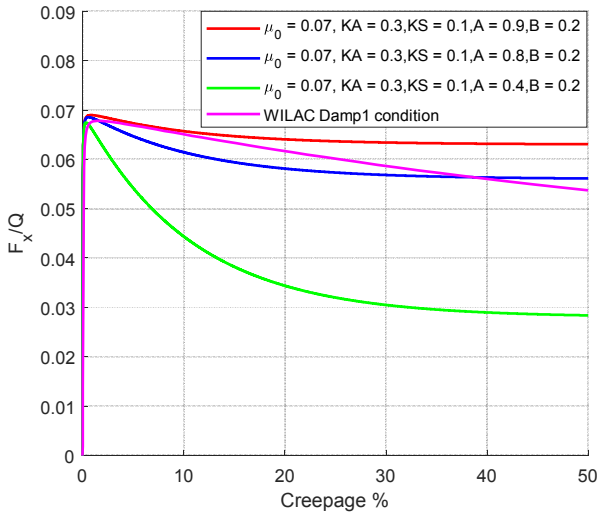

Figure 9 *Adhesion creep curve for low adhesion condition using Polach model with different value of the parameter A (red, green and blue) and the WILAC adhesion curve for Damp1 condition (magenta).*

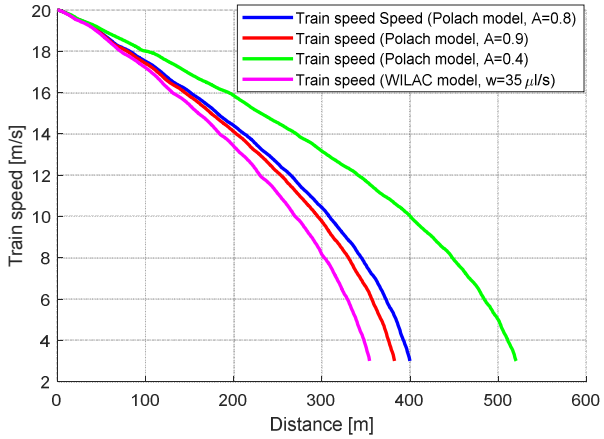

Figure 10 *Train speed at low adhesion condition using: Polach model with different parameter A (green, blue, red); WILAC model (magenta).*

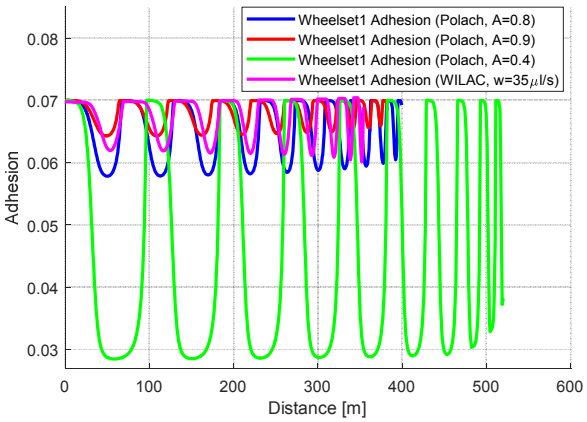

Figure 11 *Wheelset1 adhesion at low adhesion condition using: Polach model with different parameter A (green, blue, red); WILAC model (magenta).*

The wheel-rail forces are the main variable that effects the train's stopping distance directly. Figure 12 shows the wheel-rail force for wheelset 1 for the different adhesion configurations. The WILAC model gives the maximum value of the wheel-rail force while the Polach model (A=0.4) gives the minimum wheel-rail force which drops to zero in many occasions. This explains why using the WILAC model results in a shorter stopping distance than using Polach model.

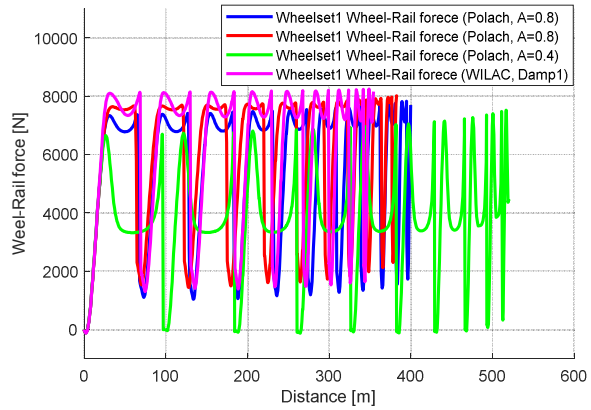

Figure 12 *Wheelset 1 wheel-rail force at low adhesion condition using: Polach model with different parameter A (green, blue, red); WILAC model (magenta).*

In order to investigate the effect of the Polach model sensitivity to its parameters on the LABRADOR stopping distance results, additional simulation runs were carried out using the Polach model with different sets of parameters. Table 3 shows the train stopping distance for ten different parameter configurations of the Polach model (the colours of the cells that give the stopping distance are selected to match those in Figure 13).

The adhesion creep curves for these configurations are shown in Figure 13 where it can be seen that configuration 3 (solid green line), which gives the shortest stopping distance, has the maximum peak value and has the maximum average adhesion value over the creepage range, in contrast configuration 10 (dashed cyan line), which gives the longest stopping distance, has a slightly lower peak, but it decreases sharply to give the lowest value of the adhesion at higher creepages (i.e. it has the lowest average value of the adhesion over the creepage range).

Table 3 *Train stopping distances for different Polach model configurations.*

Con-fig.	Polach model parameters					Stopping distance [m]
	μ_0	A	B	K_A	K_s	
1	0.07	0.54	0.06	0.43	0.35	388
2	0.085					323
3	0.09					299
4		0.2				309
5			0.13			423
6			0.2			510
7	0.087					511
8			0.13			453
9	0.083		0.06			358
10			0.2			543

As can be seen the stopping distance differs significantly as the parameters are changed. For example, the difference between the stopping distance for configuration 3 and configuration 10 is about 245 m.

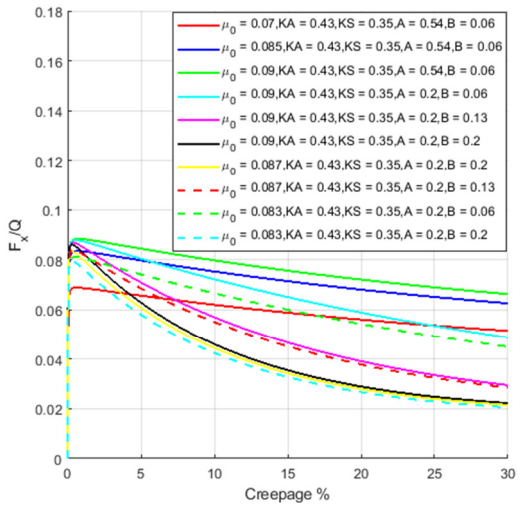

Figure 13 *Adhesion creep curves for different Polach parameters configurations.*

The simulation results show that the LABRADOR model behaves differently with different configurations of the adhesion curve model and imply that the same variation in contact conditions would lead to significant differences in stopping distance in real life too. Using the Polach model to produce the adhesion-creep curve and hence the wheel-rail force, means that LABRADOR will inherit the Polach model sensitivity to its parameters. This means that selecting the wrong (or imprecise) parameters will lead to incorrect results. Also the current LABRADOR model assumes that the Polach model parameters are constant, which is not the case as the WILAC model shows. For example, Figure 14 shows how the Polach model parameters for the Damp1, Damp2, Wet and Dry conditions in the WILAC model vary with as the speed varies. The WILAC model tunes the Polach model parameters dynamically depending on the speed and load, then blends the resulting adhesion creep curves based on the wheel-rail conditions to generate the wheel-rail force. This feature means that users do not have to tune the adhesion model parameters for each condition, instead they only give the rail wetting profile as input and the WILAC model makes

the calculation and produces the corresponding adhesion and wheel-rail force based on the train speed, wheel speed, load and the rail condition.

4.3 Limitations and Future Work

The main limitations of the WILAC model as implemented in LABRADOR are that:

1. WILAC represents the rail adhesion condition by the water flow rate into the contact in l/s. However, water flow rate has limited meaning outside laboratory test conditions and so, an intermediate stage is needed to interpret the users required adhesion input, which could be a linguistic expression of the rail condition into the WILAC water flow rate input.

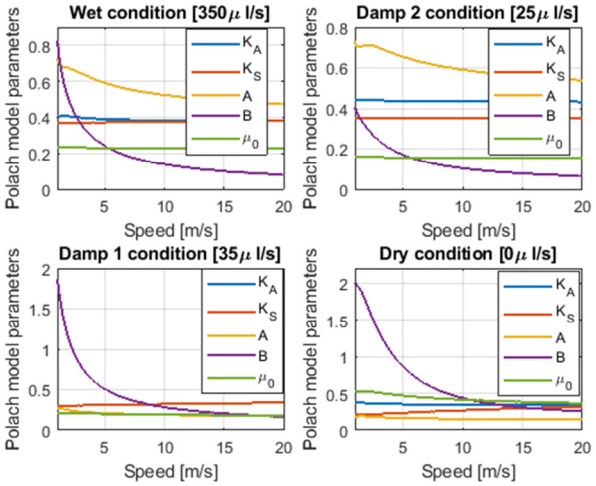

Figure 14 *Wet, Damp1, Damp 2 and Dry contact patch conditions' Polach parameter changing during simulation as a function of the train speed.*

2. 'Low adhesion conditions', where the adhesion level is less than 0.09 for notch 3 (9%g) brake demand or less than 0.06 for service brake demand notch 2 (6%g), are generated in the WILAC model by introducing a scaling factor. The WILAC adhesion-creep curves are multiplied by the scaling factor to reduce them to the low adhesion levels required. However, this only resizes the adhesion curve without affecting its shape/behaviour (i.e. the adhesion-creep curve peak position, the slopes of the curve and the position of minimum adhesion value). However, the experimental results presented in [8] and [9] show that the adhesion creep curve shape/behaviour is dramatically changed when the rail condition is changed. It is recommended that the WILAC model be extended to include low adhesion conditions produced by different environmental factors (e.g. leaf film, grease and lubricant). This would enhance the ability of the WILAC model to represent low adhesion model whilst exploiting the current WILAC methodology using linear regression to produce the Polach model parameters and blending techniques to calculate the wheel-rail force.

5. Conclusions

The LABRADOR model has been successfully modified to incorporate the WILAC model and give the user the ability to easily configure and run WILAC within a LABRADOR simulation. The main advantages of using WILAC model in LABRADOR can be summarised as follows:

- The original LABRADOR model depended on the Polach model for calculation of adhesion - creep curves, which needs a predefined set of parameters. These parameters remained constant during simulation runs. In contrast, the Polach model parameters generated by the WILAC model are a function of speed and load.
- In the original LABRADOR model, the condition of the rail has been categorised in two levels; high adhesion and low adhesion, with each having a set of predefined Polach parameters to generate the adhesion creep curves. However, WILAC provides four models (*dry*, *damp1*, *damp2* and *wet*) that generate four sets of Polach model parameters, based on the speed and load, and by blending these four curves, depending on the rail condition (i.e., water flow rate), the wheel-rail force is calculated.
- It has been found that the Polach model is very sensitive to the model parameters which is reflected in the stopping distances simulated in LABRADOR. However, in WILAC the model itself calculates the Polach model parameters and tunes them depending on the speed and load.
- Any further improvements to WILAC can be integrated easily in LABRADOR due to its modular structure.

Abstract: Rail weld deterioration in heavy haul track has been a main concern since increasing maintenance cost. To gain a better understanding of its deterioration, a dynamic finite element model is developed to solve wheel-rail rolling contact at rail weld. This model integrates vehicle-track dynamics and wheel-rail contact for every step online calculation, thus avoiding the contact stiffness difference. The advantage of this model is to drop basic assumptions adopted in classic contact theory, and transient behavior and elastic-plastic material can be considered. Through introducing measured evolutionary rail welds, detailed evolution of dynamic force, stick-slip distribution and normal pressure are obtained.

Keywords: Contact mechanics; rail-wheel systems; elastic-plastic contact; explicit FE method; rail weld

1. Introduction

Rails of standard length can be welded into rails of required length in the continuous welded track to eliminate the joint gaps. This method can improve the continuity and integrity of the track structure, provide a good riding performance, extend service life of rails and decrease labour in maintenance, which has been widely accepted in the railway. However, the difference between welding materials and base metals can easily exist due to the limitation of the welding process and the improper operation. Irregularity of material properties can cause irregular plastic deformation and wear under some certain conditions of wheel rolling over, and then local short-wave irregularity can initiate and develop as shown in Fig. 1.

Initiation and development of this irregularity can be a high-frequency excitation which finally loses their energy by dissipation in the form of plastic deformation, wear and other processes related to the growth of track damage. In this field, scholars have finished many meaningful works. Mutton [1] carried out a detailed microstructural examination of the characteristics associated with flashbutt welds in the new condition and after exposure to service conditions which resulted in gauge corner cracking. Xiao [2] developed a 3D vehicle-track coupling dynamics model and investigated the influence of weld defects on the wheel/rail force, and then proposed safety limits based on dynamic amplification factor. Steenbergen and Esveld [3] put forward a QI method to evaluate the quality of the rail welds, which can be used for any weld geometric forms. Related standards were determined based on numerical calculation and engineering experience. Wen [4] proposed an approach combined with vehicle-track coupling dynamics model and finite element model to solve plastic deformation induced by impact at rail weld. This approach was extended to curving track by Li [5], whose research further considered tangential interaction of wheel and rail through employing Kalker's FASTSIM algorithm.

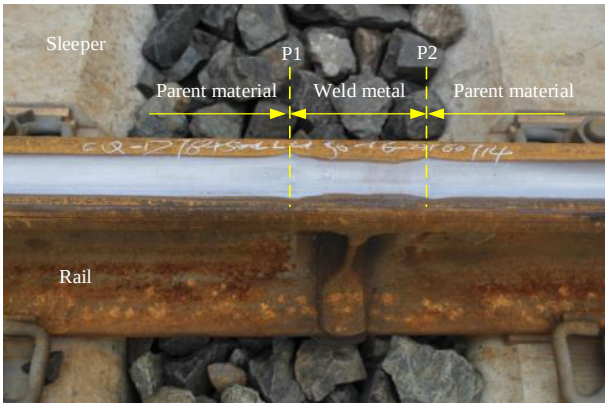

Figure 1 *Rail weld observed in heavy haul track (P1 and P2 means heat affecting zones)*

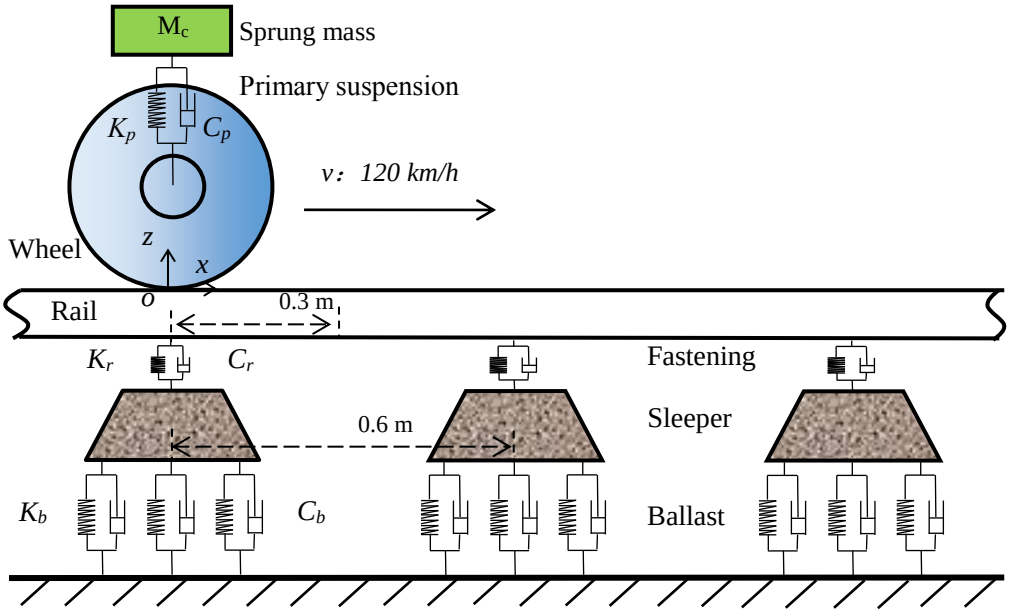
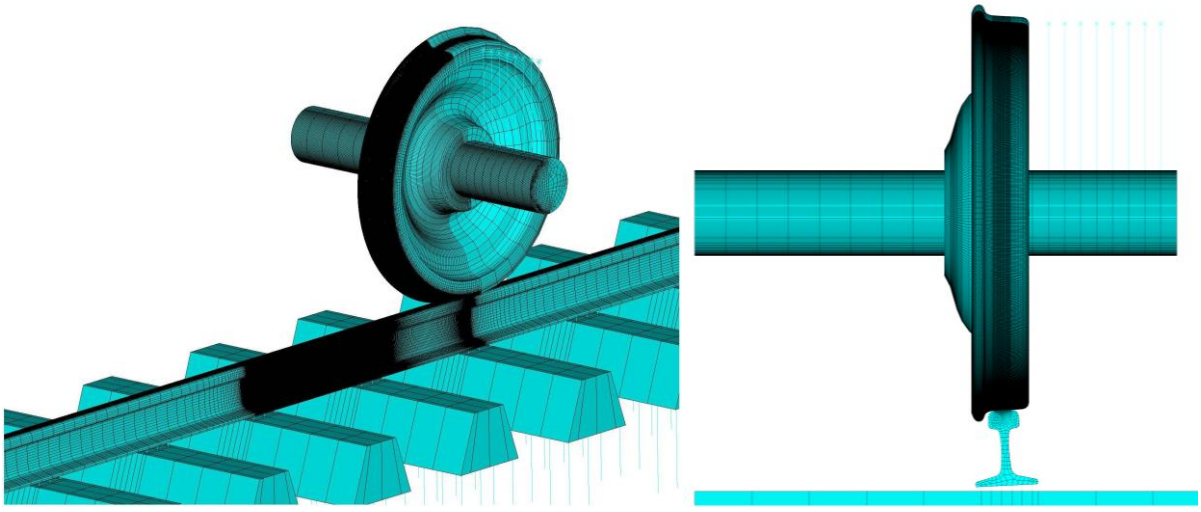


Although many meaningful works have been conducted, transient wheel-rail rolling contact at rail weld during the life cycle has been rarely reported, and thus the evolution of rail weld irregularity remain not clearly understood. To solve this transient problem, classic contact methods are unappropriated due to the limitation of their three basic assumptions (i.e. elastic material, half-space and steady rolling). Recently, explicit rolling contact finite element models established by Li et al. [6], Zhao et al. [7] and Zong et al. [8] provide a powerful tool for such problems, which will be employed in this paper. The focus of this paper is to present transient wheel-rail rolling contact solution at the measured evolutionary rail weld.

2. Numerical model



2.1. Dynamic wheel/rail rolling contact finite element model in 3D

2.1.1 Finite element modelling

In Fig. 2, it shows the developed 3D elastic-plastic wheel/rail rolling contact finite element model and simulates vehicle-track system on the heavy haul line. Only half a wheelset and track are simulated since longitudinal and vertical plane of vehicle-track system are symmetric. All components above primary suspension of a vehicle are simplified as mass points and connected with wheels through primary suspension. LM-CHN75 wheel-rail profiles are employed in this paper. The wheel, rail and sleepers are all meshed using 3D solid elements with the consideration of their actual geometries. The track is ballast track, containing rails, fasteners, sleeper and ballast. The fastening system and ballast only includes support stiffness and damping that are relevant to the dynamic behaviour. Parameters of this model is obtained from our previous paper [9], while the rail in this paper is further modelled in elasto-plasticity as described in section 2.2.2.

(a) schematic diagram

(b) the mesh

***Fig. 2** Dynamic FE model of wheel/rail rolling contact*

2.1.2 Simulation process

Implicit-explicit analysis as shown in Fig. 3 was adopted in the simulation to treat the wheel-rail rolling contact behavior. It firstly adopts implicit algorithm to solve the static contact in the initial position A, and then initialize the explicit algorithm with the vehicle rolling forwards at a constant speed *v*. Boundary conditions imposed in the model include: constraint of lateral movement on the front of the wheel axle and sleepers, as well as the longitudinal ends of rail; fixed the bottom of ballast, and only vertical movement is allowed for the primary suspension, fastening and ballast.

The traction coefficient μ defined by Eq. (1) is 0.3 for a traction case, and the friction coefficient f is 0.5 for the typical case of wheel-rail contact in dry condition. Note that no force is applied in the lateral direction.

$$\mu = F_L / F_N \le f \tag{1}$$

Here, F_N is the normal contact load in the contact patch and F_L is the traction force transmitted in the longitudinal direction.

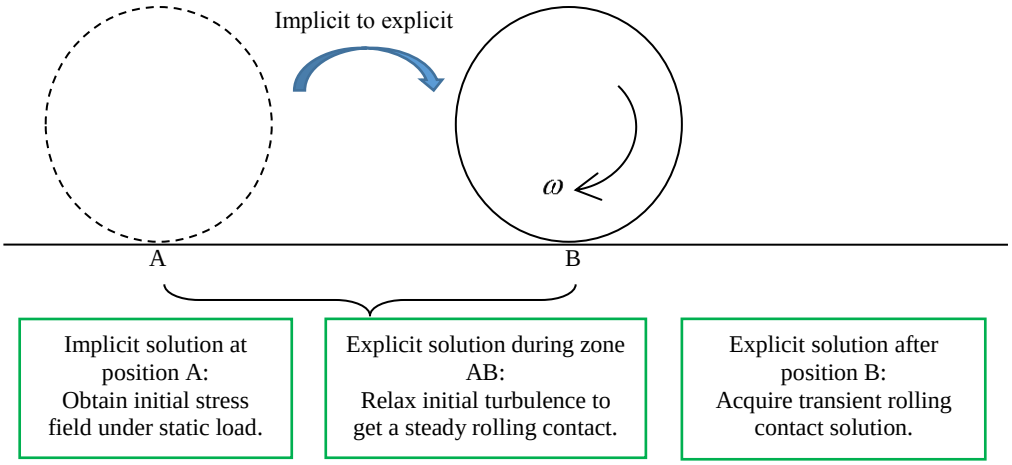


Fig. 3 *Schematic diagram of simulation process*

2.1.3 Validation of this model

The FE modelling approach employed in this study origins from Li & Zhao [6]. This approach has been validated by Li & Molodova for high frequency vehicle-track interaction at squats [10], and Zhao & An for local rolling contact fatigue occurring on high-speed wheel tread [7]. Recently, An [11,12] successfully apply this model on prediction of dynamic force with axle box acceleration and geometrical gradient at rail weld.

2.2. Measured rail weld and elastic-plastic material

2.2.1 Measured evolutionary rail weld

Fig. 4 shows the evolution process of a measured rail weld in the heavy haul track [13]. The measured data is obtained from the center line of rail top, including results of 9 times measurement at interval of one month. It can be found initial irregularity exists for the first measurement, and it becomes steady in the next four months. An obvious phenomenon is 'w' shape irregularity can easily form at heat affecting zones P1 and P2 due to wear and plastic deformation. In the sixth month, the irregularity becomes relative smooth after grinding. However, in the following three months, the irregularity develops fast especially for the last time. This work aims at investigating transient wheel/rail rolling contact at such an evolutionary rail weld.

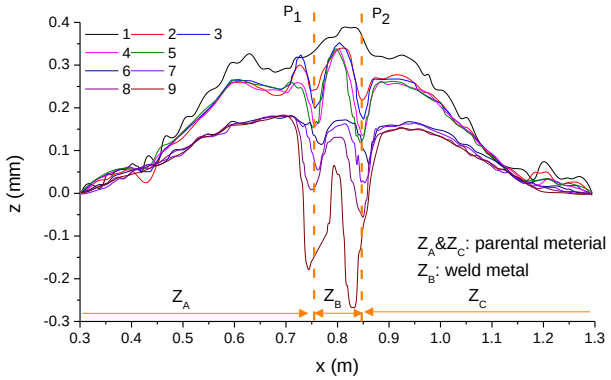

Fig. 4 *A typical evolution process of the rail weld in heavy haul track*

With smooth wheel/rail surface upon mesh generation, the 3D geometry irregularity at rail welds in the calculated area is applying through changing coordinate of related nodes on the surface by self-compiled program. Therefore, rail surface irregularity can be fully considered in this FE model. For example, Fig. 5 plots 3D geometry of rail weld at 9th measurement, i.e. RW9. Its longitudinal geometry D along x- direction (rolling direction) can be found in Fig. 4, and irregularity depth d distribution across the transverse direction at any longitudinal location x_L is assumed to be parabolic (2)

$$d = [1-(y/w)^2] \cdot D_{x=x_L} \qquad (2)$$

Here, w is half the width of the weld and 15 mm is selected in this paper according to field observation.

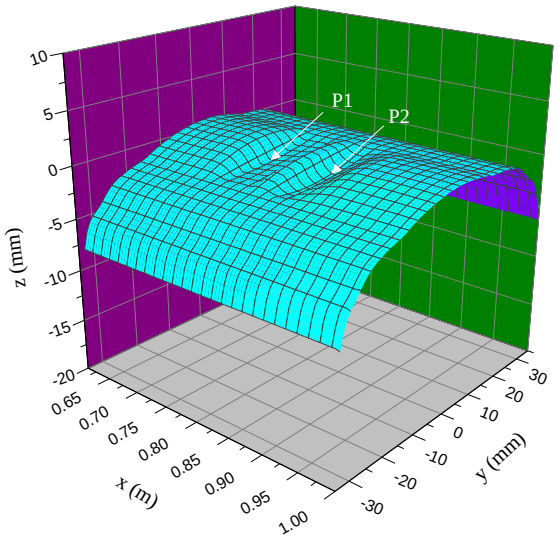

Fig. 5 *The rail weld of RW9 in 3D (depth is amplitude by 5 times)*

2.2.2 Elastic-plastic material

It is well known that there is a difference among heat affected zones, welding zone and parent material due to material softening. Three elastic-plastic material with different yield stress are selected to represent such difference. The yield stresses of the parental material,

weld material and HAZ is 526 MPa, 463 MPa and 421 MPa according to [5]. The location of three materials can be found in Fig. 4, and each width of hear affected zones are 30 mm.

3. Results and analysis

3.1. Dynamic force

Fig. 6 shows the change of wheel-rail contact force with running distance for RW1, 5 and 9. Before 0.65 m, the normal and tangential wheel-rail contact force keep nearly the same for these three cases though they have different irregularity, which means the long-wavelength irregularity can hardly excite obvious impact force. Then during *x* distance ranging from 0.7 to 1.0 m, two obvious impact appears corresponding to P1 and P2 in Fig. 4 and tends to be stronger with rail weld's evolution. The vibration excited by impact can easily disappears since energy dissipation by the first suspension and fastening. It is noted that tangential force only dissipates its energy by damper of rail and cannot become steady quickly. This continued vibration may be the cause of many damages like rail corrugation while it can also provide a beneficial signal for health monitoring.

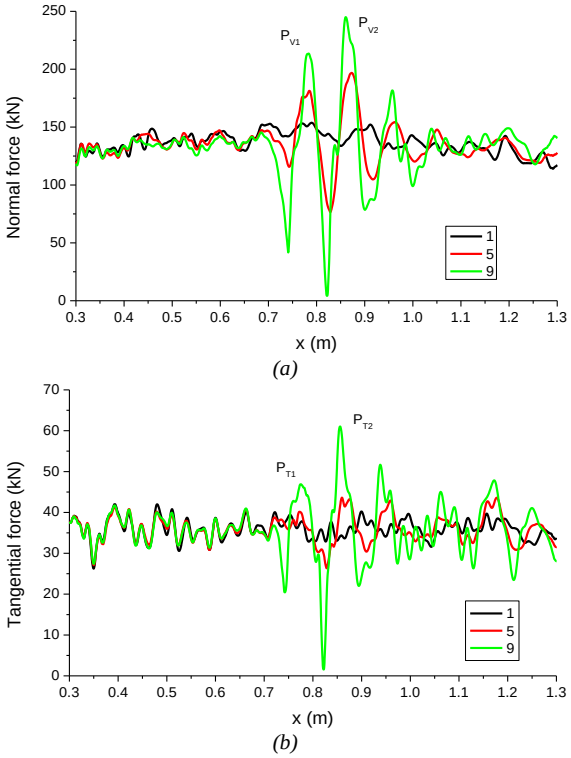

Fig. 6 *Wheel/rail force in (a) normal and (b) tangential direction*

The change of maximum normal and tangential dynamics in Fig. 6 during the evolution of rail weld are presented in Fig. 7. For normal force, the value increases from153.7 kN to 190.8 kN till the fifthth month, and then the force decreases to 160 kN, but finally increases sharply to 245 kN, about 2 times of the static wheel load. In terms of tangential force, its variation is relatively steady except for the last time.

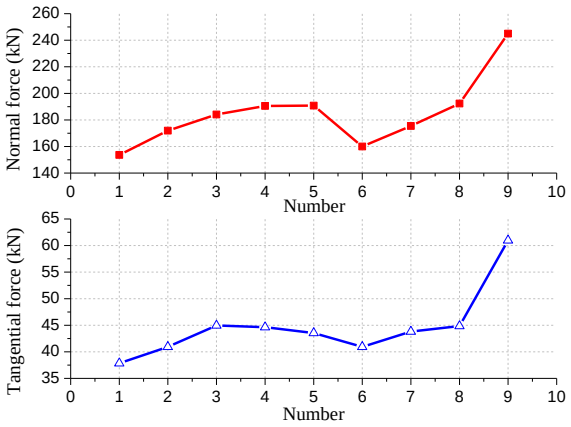

Fig. 7 *Evolution of maximum dynamic force*

3.2. Contact stress

In Fig. 8, it presents the transient process of wheel-rail contact patch and stick-slip distribution for RW1 and 9. Results of 10 instants are included in this picture, and the lateral coordinates of them are modified for a clear presentation. For RW1, the shape of contact patch and ratio of stick-slip zones keep steady during the whole process. However, contact patch and stick-slip distribution changes dramatically since strong impact and out-sync change of normal and tangential force. It is noted that nearly full slip appears on the second and sixth instants corresponding to the heat affecting zones, which means material can be easily wearied out in these two zones as observed in Fig. 3.

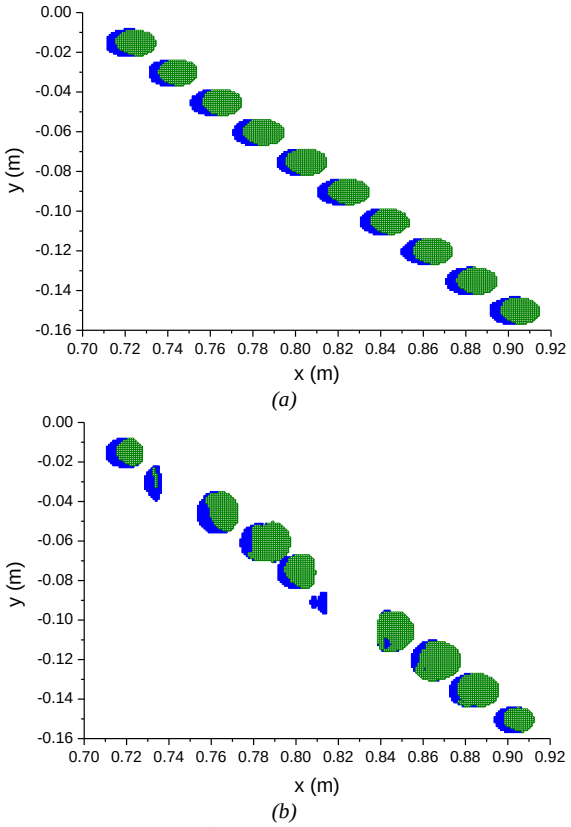

Fig. 8 *Transient change of contact patch and stick-slip distribution at (a) RW1 and (b) RW9*

The maximum pressure for different positions during the whole process of a wheel passing is plotted in Fig. 9, and it also shows their evolution for all rail welds. Two

obvious peaks of pressure can be found with the evolution of rail weld, and the change trend of maximum pressure is like that of contact force. It is observed that the maximum appears in the first peak for RW5 and 9, and it is opposite with contact force in Fig. 7. This is because the pressure not only depends on normal force but also contact geometry and that is why we choose such a FE model to simulate the transit rolling contact solution at short-wavelength irregularity.

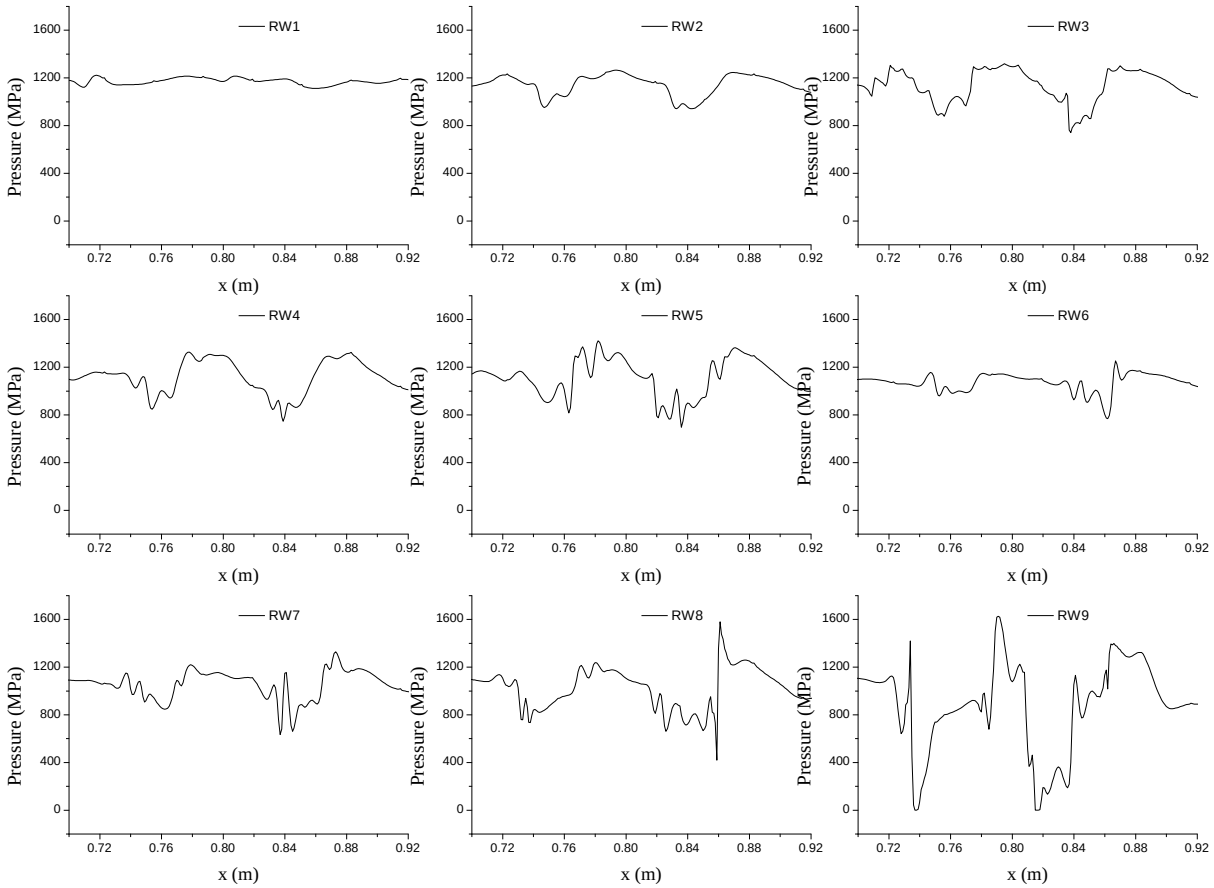

Fig. 9 *Evolution of maximum pressure at different positions for all rail welds*

4. Conclusions

In the present work, a wheel/rail FE model is developed with consideration of measured evolutionary rail weld irregularities and material inhomogeneity. Implicit-explicit integration is employed to treat transient wheel-rail rolling contact and impact. Through initial analysis of transient behaviour at measured rail welds, we show the evolution of dynamic force, stick-slip distribution and normal pressure. Dynamic force increases at initial stages and then sharply since the irregularity becomes concave shape and deteriorates more seriously. The contact patch changes obviously especially in the soften zones, and full slip phenomena is observed which may mean a serious wear damage. The normal pressure shows a similar tendency with contact force. However, it also depends on local contact geometry, and thus a different position of maximum pressure and contact force can appear. More detailed results of creepage, plastic deformation and frictional work will be presented in the future, and the main deterioration mechanism may be achieved.

Abstract: In this paper, a mechanism of inner rail corrugation was examined. A measurement was focused on rail fastening devices of the track structure. It was conducted for the rail with two different modulus fastening devices in the curve section. From the result of measurement, we investigated the occurrence of inner rail corrugation focused on bogie behaviour, rail tilts and rail lateral vibration acceleration frequency. We found that the occurrence of inner rail corrugation is caused by the lateral creep force and specific lateral vibration acceleration frequency.

Keywords: Inner rail corrugation; fastening device; bogie behavior; rail tilts; vibration acceleration frequency.

1. Introduction

1.1. Background

Tokyo Metro owns many sharp curved lines of subway route because most subway route is constructed under the roads in urban areas. In such sharp curves, lateral forces while train passing can generate rail corrugation. Inner rail corrugation is a major problem to us for safe rail transport, which causes large vibration amplitudes and noise.

Until today, we tried to restrain the generation of inner rail corrugation by installing vibration proof rail structure, oil application devices, and so on. However, they didn't solve the problem completely.

To solve this problem substantially, we have been researching mechanism of inner rail corrugation by focusing on the rail fastening devices of the track structure.

1.2. Research

It is known that inner rail corrugation varies by difference of track structure. We laid two types of fastening devices in the specific curve section to estimate the effect of restraining inner rail corrugation. One fastening device appeared to contribute to suppress inner rail corrugation and other one didn't.

To compare the characteristics of each fastening device, we measured bogie behaviour, rail tilts and rail lateral vibration acceleration frequency under train passing in the section. Based on the results, we examined mechanism of inner rail corrugation concerning with fastening devices.

2. Measurement

2.1. Conditions

2.1.1 Researching curve section

Geometrical elements and measurement points in the researched section are shown in Figure 1. The circular curve length of this section is 107 m, and the radius of this curve is 150 m. There is 54 m transition curve for both beginning and end of this curve. In this section, rail is installed on a concrete bed. Oil coating units are installed at the beginning of transition curve to lubricate wheels and rails. The average train running speed in this section is 35 km/h. Rail grinding machine grinded the rail in this section about 1 year before starting the research. In addition, rail grinding was conducted during the research to compare the force and vibration of the rail before and after rail grinding. Hereinafter we call "grinding during the research" as "grinding".

Two types of fastening devices were laid in this section for both inner rail and outer rail. One is double modulus fastening devise called PL5. Spring constant of PL5 is 50 MN/m. Other one is suppressing rail corrugation fastening device called KD2, which is installed low modulus material both under rail and under tie plate. Spring constant of modulus material under rail and under tie plate are both 50 MN/m. These composite spring constant is 25 MN/m. However, it took about 25 years from KD2 installation. Therefore, ten KD2 samples were selected in this section at random to estimate the actual spring constant. The average of composite spring constant of these samples was about 30 MN/m. As shown in Figure 1, KD2 section is near oil coating units.

There are 2 measurement points for each section. In these points, lateral force (Y) and wheel load (Q) on rail were measured. Table 1 shows measurement condition on these measurement points. The investigation focuses on Q, Y value, bogie behavior, rail tilts and vibration acceleration frequency both PL5 section and KD2 section. Figure 2 shows the outline of PL5 and KD2. In Figure 3, pictures show the circumstances of a laying site. That

pictures also show the difference of modulus of PL5 and KD2.

2.1.2 Situation of inner rail corrugation

At the start of the research, inner rail corrugation was observed in PL5 section, which is 80 to 90 mm length and about 0.1 mm average height. That corrugation appeared from at 2.1 m away to the end of KD2 section. This rail corrugation was large enough to observe visually. On the other hand, in KD2 section, we couldn't observe large inner rail corrugation, and average height of that corrugation was about 0.02 mm. From these results, there was clear difference between PL5 section and KD2 section in terms of generation of inner rail corrugation. That difference occurred around boundary between two sections clearly. Circumstances of rail corrugation is shown in Figure 4 for each section.

Circumstance after rail grinding in PL5 section is shown in Figure 5. In Figure 5, that rail corrugation in PL5 section was completely removed.

(a) (b)

Figure 5 *Circumstance after rail grinding of PL5 section*

2.2. Measurements and results

2.2.1 Inner rail YQ

We investigate the difference between PL5 section and KD2 section in terms of Y and Q. Where, Y is a lateral force and Q is a wheel load. Each value is measured at measurement points in researching section shown in Figure 1. These values were measured by strain gauge. Situation of setting gauges shown in Figure 6.

First, Y and Q were measured before grinding. For both PL5 section and KD2 section structure, maximum outer rail Y/Q values were about 0.6. These values were below the safety limit in the case of flange angle equals to 70 degrees, and there were no clear differences between PL5 section and KD2 section. On the other hand, inner rail Y/Q values were 0.4 to 0.8 in PL5 section, and 0.2 to 0.6 in KD2 section. Therefore, inner rail Y/Q value in KD2 section was slightly lower than PL5 section.

After grinding, Y and Q was conducted again and showed the same result as before and after rail grinding.

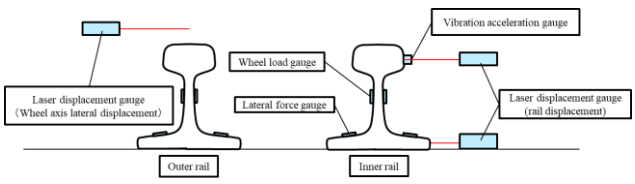

Figure 6 *Situation of setting gauges*

2.2.2 Wheelset displacement and wheelset attack angle

In terms of wheelset lateral displacement before grinding, outside wheel of the leading axis touched flange, and the trailing wheelset keeps its neutral position. Therefore, as shown in Figure 7, the leading axis has both flange force and lateral creep force, and the trailing axis has two longitudinal creep forces to different direction. From these results, we considered that bogie behaviour wasn't affected from the structure of fastening devices.

From the result of lateral wheelset displacement, the attack angle could be calculated. Bogie behaviour is shown in Figure 7. Both PL5 section and KD2 section structure, the wheelset attack angle was 10 to 15 mrad of the leading axis, and 0 mrad of the trailing axis.

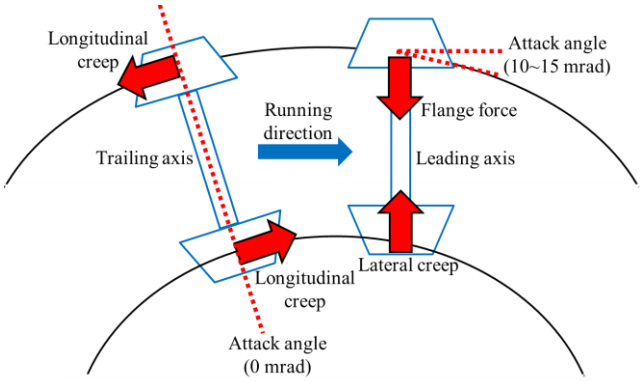

Figure 7 *Bogie behaviour*

2.2.3 Rail lateral displacement and rail tilt angle

As shown in Figure 6, the lateral wheelset displacement and the lateral rail displacement was measured by contactless displacement gauge. In the case of lateral wheelset displacement, contactless gauge was put to measure at rail head. In addition, for the lateral rail displacement, contactless gauge was put on the concrete bed. That gauge measured displacement from the center of rail head to the center of rail base.

Before grinding, we measured the lateral rail displacement to investigate the angle of rail tilts and the distance from center point of rail tilts to rail base by unit lateral force.

We assumed that there is a relationship between inner rail lateral force and rail tilts. For the lateral force, the angle of rail tilts and constant of proportionality relating rail head and rail base, we consider relationship θ/Y:

$$\theta/Y = (\alpha - \beta)/a \qquad (1)$$

Where θ is the angle of rail tilts, Y is the lateral force, α is constant of proportionality relating the rail head, β is constant of proportionality relating the rail base, and a is the distance from measured points at rail head to rail base (=143.5 mm).

Then, we consider the distance from center point of rail tilts to rail base L:

$$L = \beta \times a/(\alpha - \beta) \qquad (2)$$

Where, L is the distance from center point of rail tilts to rail base.

From the result of rail lateral displacement, rail tilt angle was investigated before grinding. Under the same lateral force, the angle of rail tilts in KD2 section was about 1.2 times as large as that angle in PL5 section. In addition, the distance from center point of rail tilts to rail base was 9.9 mm for PL5 section, and 35.9 mm for KD2 section. This result shown in Table 2 and Figure 8. This result shows that the structure of fastening device affects characteristics of rail tilts. However, the difference of the angle of rail tilts were not so large in comparison to the difference of distance from center point of rail tilts. The difference of rail tilts between PL5 section and KD2 section derive from the difference of low modulus material. Namely, PL5 section has a low modulus material only under its rail, but KD2 section has low modulus materials both under its rail and under the tie plate.

Table 2 *The result of characteristics of rail tilts.*

	α, β		θ/Q (mrad/kN)	L(mm)	L (mm, from rail base)
PL5	α	0.045	0.282	15.9	9.9
	β	0.0045			
KD2	α	0.062	0.334	41.9	35.9
	β	0.014			

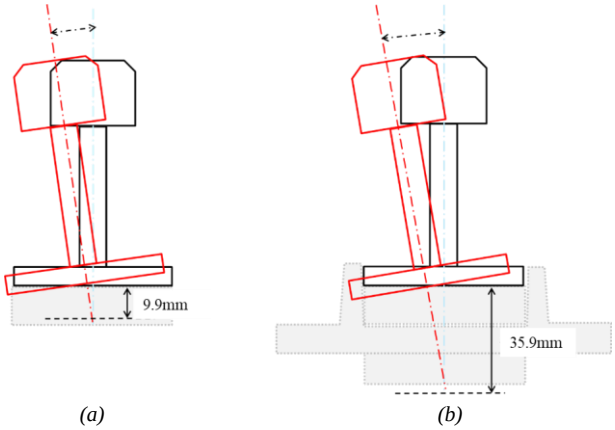

Figure 8 *Characteristics of rail tilts: (a) PL5. (b) KD2.*

2.2.4 Inner rail lateral vibration acceleration frequency

First, inner rail lateral vibration acceleration frequency was measured before grinding. The dominant frequency of inner rail lateral vibration acceleration in PL5 section when train passing was 120 Hz of the leading axis, and 250 Hz of the trailing axis while train passing. On the other hand, in the case of KD2 section, such lateral vibration acceleration frequency was 450 Hz in both the leading and the trailing axis. These results are shown in Figure 9 for PL5 section and Figure 10 for KD2 section.

Power spectral density function (PSD) analysis for inner rail lateral vibration acceleration through 10 trains set passing was also calculated. The peak of PSD value for PL5 was near 120 Hz shown in Figure 11. On the other hand, in the case of KD2, there was no clear peak near 120 Hz. However, large PSD value was observed near 450 Hz shown in Figure 12. The result of vibration

acceleration frequency was markedly differed by the structure of fastening devices.

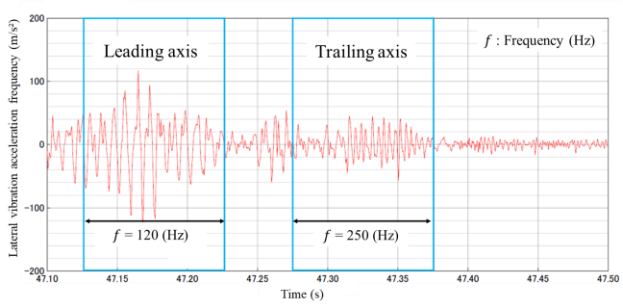

Figure 9 *Inner rail lateral vibration acceleration frequency in PL5 section*

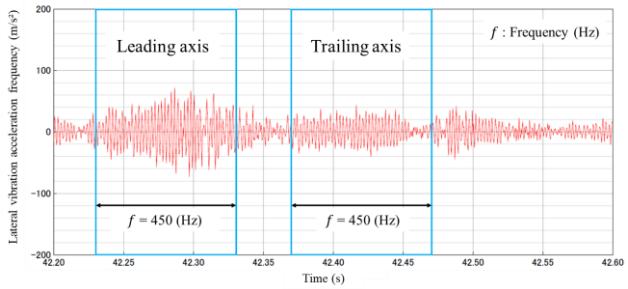

Figure 10 *Inner rail lateral vibration acceleration frequency in KD2 section*

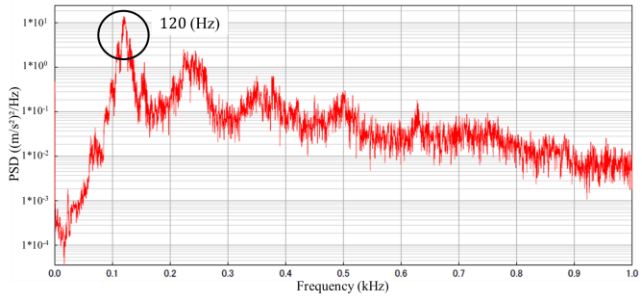

Figure 11 *PSD value in PL5 section before rail grinding*

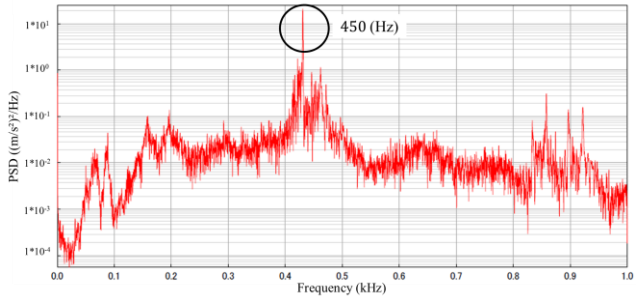

Figure 12 *PSD value in KD2 section before rail grinding*

From the result of inner rail lateral vibration acceleration frequency and PSD value, the wave length of inner rail corrugation could be calculated. We consider the relationship between lateral vibration acceleration frequency and the average of train running speed in researched section to caluculate the wave length of inner rail corrugation λ:

$$\lambda = v/f \qquad (3)$$

where λ (m) is the wave length of inner rail corrugation, v (m/s) is the average train running speed and f (Hz) is the inner rail lateral vibration acceleration frequency.

The average train running speed in these section is 35 km/h. The inner rail lateral vibration acceleration frequency in PL5 section when train passing was 120 Hz of the leading axis. So, from equation (3), λ equals to about 81 mm in PL5 section in the case of leading axis. In PL5 section, 80 to 90 mm rail corrugation was observed. Therefore, calculated result almost matches observed wave length. On the other hand, the inner rail lateral vibration acceleration frequency in this section was 250 Hz of the trailing axis. Accordingly, from equation (3), λ equals to about 39 mm in PL5 section in the case of trailing axis.

In the case of KD2 section, the inner rail lateral vibration acceleration frequency when train passing was 450 Hz in both the leading axis and the trailing axis. From equation (3), λ equals to about 22 mm. However, any large inner rail corrugation couldn't be observed in KD2 section. Therefore, for KD2 section, calculated result didn't match observed wave length.

Lateral vibration acceleration frequency after grinding was also measured. Rail grinding is conducted to meet within 0.1 mm irregularity standard. PSD value in PL5 section after rail grinding shown in Figure 13. Compared to the result of before grinding shown in Figure 11 and Figure 13, the peak PSD value near 120 Hz was decreased, and PSD value decreased in all acceleration frequency. That result shows that after rail grinding, alteration of PSD value was measured. However, the lateral vibration was still occurred.

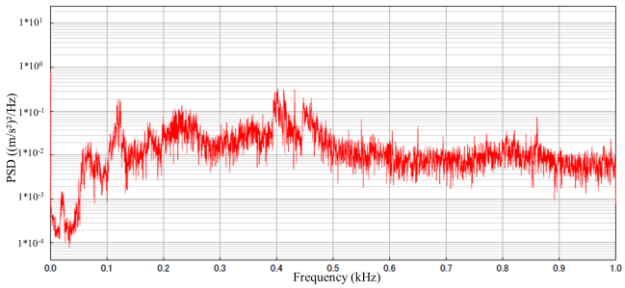

Figure 13 *PSD value in PL5 section after rail grinding*

3. Considerations

3.1. The cause of inner rail corrugation

The calculation result of the wave length of inner rail corrugation for the leading axis in PL5 section matches observed wave length. However, in the case of trailing axis, it isn't. Therefore, we considered that the cause of inner rail corrugation is the lateral creep of the leading axis. The lateral creep from the attack angle of leading axis lead to stick and slip vibration, and it generates inner rail corrugation.

Even after rail corrugation removed by rail grinding, lateral vibration acceleration frequency still measured in PL5 section. That lateral vibration acceleration frequency related to the wave length of inner rail corrugation in PL5 section. Therefore, we consider that the cause of inner rail

corrugation is specific lateral vibration acceleration frequency.

3.2. Suppressing inner rail corrugation

In the case of KD2 section, the inner rail lateral vibration acceleration frequency when train passing was 450 Hz in both the leading axis and the trailing axis. And calculated wave length by vibration acceleration frequency was about 22 mm. However, any large rail corrugation couldn't be observed. Even lateral vibration occurred in KD2 section like PL5 section, the circumstance of inner rail corrugation was quite different. The difference between PL5 section and KD2 section was the value of the inner rail lateral vibration acceleration frequency.

There are oil coating devices near KD2 section, but that devices didn't bring influence in terms of inner rail corrugation because the difference occurred at the boundary between two sections clearly.

From the result of wheelset attack angle and wheelset lateral displacement of wheelset, there are not so large difference of bogie behaviour between PL5 section and KD2 section. But the angle of rail tilts for unit lateral force and the distance from center point of rail tilts was different for each fastening device section. That difference of the characteristics of rail tilts create the difference of inner rail lateral vibration acceleration frequency. From the result of PL5 section, around 120 Hz inner rail lateral vibration acceleration frequency became a critical cause of inner rail corrugation. In the case of KD2 section, we could change the peak of inner rail lateral vibration acceleration frequency to around 450 Hz for both the leading axis and the trailing axis. That inner rail lateral vibration acceleration frequency value didn't become a cause of inner rail corrugation.

Figure 14 shows the relationship between PSD value and Y/Q at specific lateral vibration acceleration frequency equals to 116 Hz in both PL5 section and KD2 section. This lateral vibration acceleration frequency near the peak of that in PL5 section. Black plots in this figure shows results in PL5 section, and red plots are KD2 section. From the result of Figure 14, PSD values quite different between PL5 section and KD2 section.

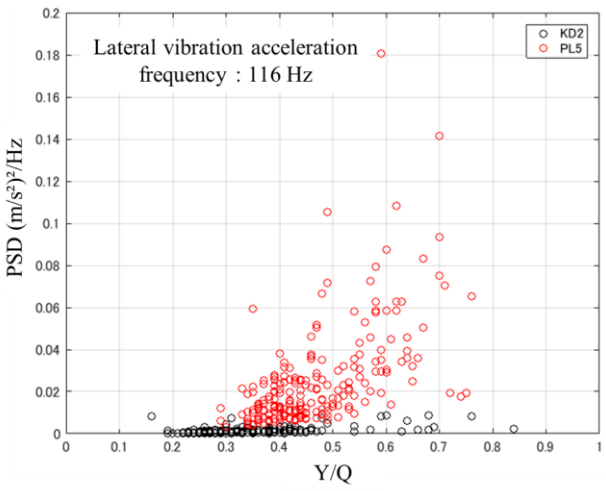

Figure 14 *The relationship between PSD value and Y/Q at specific lateral vibration acceleration frequency (116 Hz)*

Figure 15 and Figure 16 also shows the relationship between PSD value and Y/Q at specific lateral vibration acceleration frequency equals to 124 Hz and 132 Hz. As the result of Figure 14, PSD value of PL5 section is higher than KD2 section in Figure 15 and Figure 16. In the result of lateral vibration acceleration frequency equals to 132 Hz, PSD value of KD2 section increased as Y/Q increasing. However, in the range of Y/Q until 0.5, PSD value of KD2 section is very low. Therefore, even in the case of lateral vibration acceleration frequency equals to 124 Hz and 132 Hz, there are clear difference between PL5 section and KD2 section.

From the result of ground Y/Q measurement, inner rail Y/Q values were 0.4 to 0.8 in PL5 section, and 0.2 to 0.6 in KD2 section. Therefore, in terms of creation of inner rail corrugation while train passing, such Y/Q value range 0.4 to 0.8 is very important. In a range 0.4 to 0.8 of Y/Q, PSD value of PL5 section is higher than that value of KD2 section for several patterns of lateral vibration acceleration frequency in the case of 116 Hz, 124 Hz, and 132 Hz. In addition, in the case of lateral vibration acceleration frequency almost equals to the peak in PL5 section, around 120 Hz, PSD value of KD2 section is almost equals to 0 $(m/s^2)^2/Hz$.

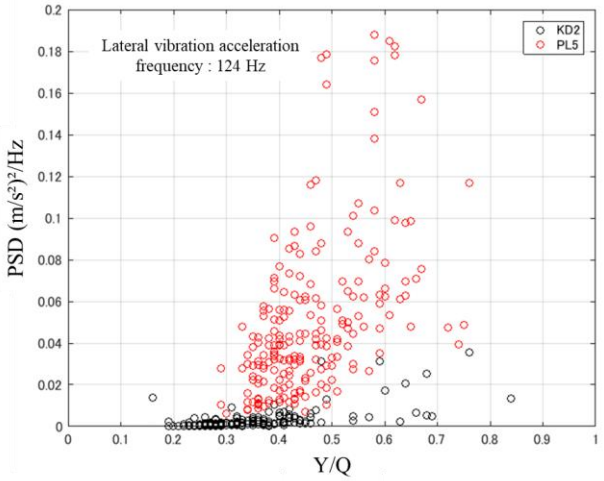

Figure 15 *The relationship between PSD value and Y/Q at specific lateral vibration acceleration frequency (124 Hz)*

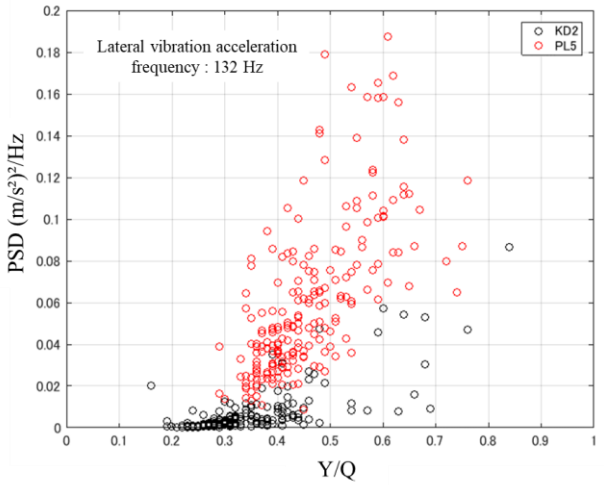

Figure 16 *The relationship between PSD value and Y/Q at specific lateral vibration acceleration frequency (132 Hz)*

In PL5 section, with the increasing of Y/Q, PSD value also increased. However, in KD2 section, PSD value equals to almost 0 $(m/s^2)^2$/Hz in 0.3 to 0.5 of Y/Q. We consider that around 120 Hz of lateral vibration acceleration frequency creates inner rail corrugation. Therefore, the results of figure 14 are also closely related to corrugation. High PSD value in PL5 section lead to inner rail corrugation. And very low PSD value in KD2 section shows the effect of supressing inner rail corrugation. This result also shows the difference between PL5 section and KD2 section in terms of the difference of fastening device clearly.

3.3. Future perspective

We will conduct measurement again by using PL5 and KD2 or other fastening devices to confirm the reproducibility. In addition, we will conduct further measurement to confirm a series of sign, generation and extension of inner rail corrugation.

The inner rail corrugation in researched section caused by lateral creep of the attack angle of the leading axis. In Tokyo Metro subway line, there are some inner rail corrugation caused by longitudinal creep from the trailing axis. And the inner rail lateral vibration acceleration frequency of that section is around 250 Hz. However, rail fastening device of track structure is different from PL5 section and KD2 section. We will investigate these detail situations. For example, we will research about other track structure in terms of alignment, inner rail Y/Q values, vibration acceleration frequency and characteristics of rail tilts.

4. Conclusions

From the result of measurement, we found that the occurrence of inner rail corrugation is caused by the lateral creep force and specific lateral vibration acceleration frequency due to the wheelset attack angle of the leading axis. In addition, we found that the function to suppress inner rail corrugation is related to the difference in rail lateral vibration acceleration frequency and rail tilt characteristics of each fastening devices. We considered that the difference between PL5 section and KD2 section in terms of lateral vibration acceleration frequency and rail tilts derive from the difference of modulus material in fastening device. A future task is to inspect a mechanism of the generation of inner rail corrugation deeply, and to create rail maintenance method focused on inner rail lateral vibration acceleration frequency. We will also investigate a relationship between lateral vibration acceleration frequency and other parameters around the track structure.

Abstract: In this work, formation mechanisms of squats were investigated based on field and laboratory measurements, full-scale wheel-rail test rig experiments and a new developed simulation tool. Wheel-rail contact conditions were found, which can lead to cracks in or to outbreaks of a white etching layer (WEL) on a rail surface. According to the simulation results, geometrical deviations of the rail surface - as for example outbreaks of WELs - can remain on the rail surface and grow up to a size comparable to that of squats. Furthermore, the crack initiation potential of permanent geometrical deviations can be increased.
This work summarizes parts of the doctoral thesis [1] which is written in German.

Keywords: squats; squat model; squat simulation; white etching layers (WEL); local defects

1. Introduction

Squats are rail defects whose formation is not yet clarified despite its observation for a long time. Reportedly (compare [2]), squats derive their name from their characteristic outer appearance in the shape of two lobes of similar size. The two lobes look like that they are caused by a very heavy gnome who squatted on the rail. Due to the fact that gnomes squatting on rails were never observed by field studies, further investigations concerning the formation of squats had to be carried out.

A more realistic idea of the origin of squats was presented by Clayton and Allery [3] in 1982. Their work is mainly based on field investigations and photographic documentation of the squat development. In their work [3], Clayton and Allery described two different initiation mechanisms of squats: the initiation by small circular indentations of the rail surface or the initiation by cracks which first appeared at the gauge corner of the rail.
Clayton and Allery found several small circular indentations at rail surfaces of an investigated line. The indentations had a diameter of 5 mm and depths up to 2 mm. The indentations were found more or less periodically every 3 m at the rail surface which roughly corresponds to the circumference of a wheel. Because of the correlation between a wheel circumference and the distance between the indentations, Clayton und Allery assume that the indentations were caused by a very hard object which was sticking on a wheel tread. Some of the indentations propagated into squats. Clayton and Allery explained the further development as follows: The loads caused by the traffic flattened the indentations and lead to a flow of the material of the edges towards to the centre of the indentations. At regions with the highest shear of the material cracks can be initiated. Some of the cracks propagate further into the rail. Consequently, the material above these cracks is not supported anymore, resulting in a depression of the rail surface up to 1 mm deep. [3]
Cracks which first appeared at the gauge corner of the investigated line lead to squat formation process comparable to the formation process caused by indentations. The cracks propagated into the rail material. Again, the material above these cracks is unsupported which results in a depression of the rail surface. [3]
The initiation of squats on rails due to a geometrical deviation of the rail surface was also observed by the working group around Li and Zhao [4], [5], [14]. Li and Zhao describe the further squat propagation due to the dynamic contact forces caused by the initial geometrical deviation at the rail surface. The dynamic contact forces lead to a second geometrical deviation immediately after the first initial one.
Additional to squat initiation caused by an initial geometrical deviation of the rail surface or by gauge corner cracks there are some evidences that squats can be initiated by material inhomogeneities known as white etching layer (WEL) or weldings [2] [8] [10] [11] [12] [13] [18] [19] [20]. WEL is a material layer which appears white after etching it with Nital. The exact material structure of WEL is not known, although, in literature partly associated with martensite. Basically, WEL is caused on the rail surface during the operational use of the rails. Effects during operation, which can be the cause of WEL (e.g. effects in the wheel-rail contact) are “uncontrolled”, resulting in an inhomogeneous and not precisely classifiable material structure of the WEL. However, in literature it is assumed that at zones with WEL and at the transition zones between WEL and

normal rail material cracks can be initiated which can further develop into squats.
According to other works [21] [22] squats can be caused on all types of rail steels. Furthermore, WEL seems not to be necessary for the development of squats. However, a necessary condition seems to be a constant and permanent overloading of the running band.
Since 2000s, a further distinction has been made between squats and squat-like defects, called studs. Both defects are similar in its outer appearance, a lung like shaped deviation at the rail surface where a visible v-shaped crack can exist at the surface [4], [5], [8]. Because of the similar outer appearance, the study at hand does not distinct between squats and squat like defects. Basically, all types of permanent geometrical deviations at a rail surface which are in the geometrical size of squats and squat-like defects are called squats in this paper.

2. Investigations on squats from the field

The study at hand involves the analysing of squats which were located in a station area. The investigations were carried out on-site and in laboratory.
In average the squats had lengths of 60 mm - 80 mm, widths of 50 mm - 60 mm and depths up to 0.3 mm. Alternating regions with and without WEL were found on the rail surface by etching the rail with Nital (see Figure 1). The regions of WEL had a distance of 15 mm – 30 mm to each other. The WEL had a hardness of up to 900 HV 0.2.

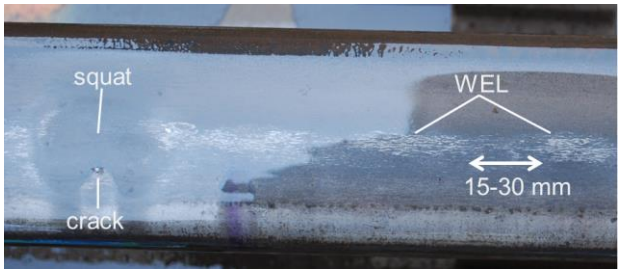

Figure 1: *Rail surface etched with Nital. A squat and rail surface regions with WEL are visible. The WEL spots are spaced with a distance of 15-30 mm.*

Another test should reveal the wheel-rail contact behaviour around the squats. For this purpose, the rail surface was painted with white colour. The colour was partly removed by passing wheels of a train, revealing the running band. The geometrical deviation at the rail surface leads to variations in the running band (see Figure 2).
In laboratory, the rail surface geometries of nine squats from the station area have been quantified by a 3D Alicona optical measurement system. Figure 3 shows a typical measurement result of this investigation. The surface geometry of the squat is comparable with a local valley. Hills are not found in the surrounding of the squat. Such hills would indicate massive plastic deformations out of the valley of the squat to its surroundings during the squat formation. Because of that, it can be concluded that the surface geometry of the squat is caused by local wear-variations. However, small local plastic deformations followed by removal of the material due to wear cannot be excluded.

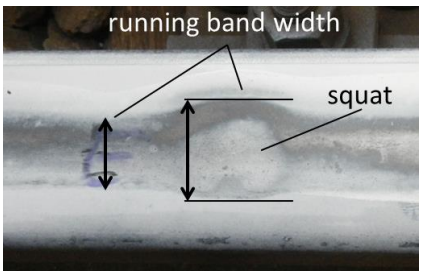

Figure 2: *Rail surface painted with white colour. The passing wheels of a train removed the colour. The variations of the actual running band (widening, no contact of the deeper regions of the squat) are caused by the deviation of the rail surface geometry at the squat.*

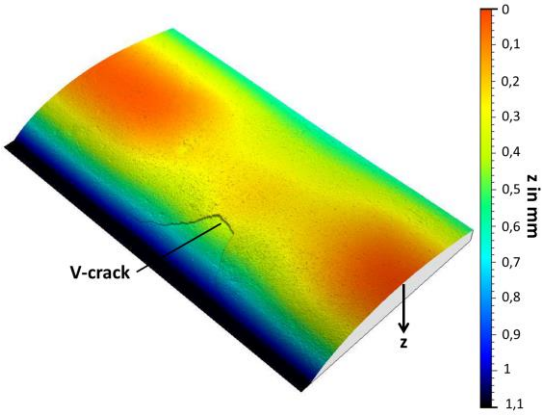

Figure 3: *3D geometry measurement of a squat. The colour represents the vertical level of the rail surface.*

3. Origin hypotheses and objectives

The structure presented in Figure 4 is proposed to depict the formation process of squats schematically in a systematic way. Squats are rail defects which are limited in their geometrical extent (length $<\approx 100$ mm). Thus, the initiation mechanism must lead to local variations of the wheel-rail contact conditions which cause a locally different development of the rail.

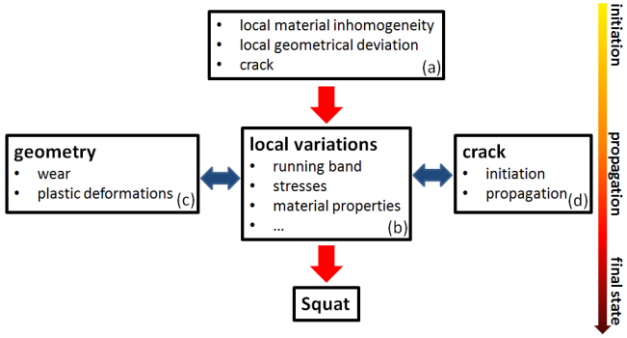

Figure 4: *Schematic representation of the hypotheses for the initiation and propagation process of squats.*

According to literature, squats can be initiated by local discontinuities, as for example local initial deviations of the rail surface geometry, cracks or material inhomogeneities such as WEL or weldings (see Figure 4 (a)). It is assumed that such local discontinuities are causing initial variations of the running band (see Figure 2), of the stress distribution, and of material properties (see Figure 4 (b)). Subsequently, at such positions the rail surface geometry evolves differently compared to the geometries before and behind the discontinuity due

to locally varying wear and/or local plastic deformation (see Figure 4 (c)). Furthermore, cracks can be initiated locally, and existing cracks can grow due to the existing local conditions (see Figure 4 (d)).
The work at hand focusses on the role of WEL for squat initiation and propagation. It will be investigated whether WEL can lead to first geometrical deviations of the rail surface (e.g. outbreaks of the surface) or to first cracks. Furthermore, the behaviour of initial geometrical deviations at the rail surface will be investigated. It is to be examined whether initial geometrical deviations remain at the rail surface and can propagate into squats or not.

4. Investigations concerning WEL

In a recently published article [17], the results of three different full-scale wheel-rail experiments (carried out by voestalpine Schienen GmbH, Austria) accompanied by temperature-simulations were presented. The investigations showed that significantly increased temperatures caused by high wheel-rail contact creepage rates are causing WEL on the rail surface. Each experiment was carried out with a new rail (VI60E1 profile). A cylindrical wheel was used, and the normal load was $F_N = 110\,kN$. The experiments started with one thousand cyclic loads of the three rails, respectively. These cyclic loads were done with a relative velocity of $v_{rel} = 0{,}002\,m/s$ at a defined rolling speed of $v_{roll} = 2\,m/s$, resulting in rail surfaces which are more or less in elastic shakedown. After that, each rail was loaded one time with the following relative velocities but the same rolling speed of $v_{roll} = 0.1\,m/s$: $v_{rel} = 0.02\,m/s$ (*rail A*), $v_{rel} = 0.3\,m/s$ (*rail B*) and $v_{rel} = 3\,m/s$ (*rail C*).
The following examination of the rails revealed WEL on the surfaces of *rail B* and *rail C*. The accompanied simulations done with the parameters from the experiment revealed temperatures above 700 °C (austenitization temperature of steel ≈ 720 °C) down to a depth which corresponds to the observed maximum thickness of the WELs. In contrast, according to the simulations the wheel-rail contact temperatures reached by the experiment with *rail A* were far below 700 °C. However, cracks in the WEL or outbreaks of the WEL were not found.
In the following, wheel-rail contact conditions which - accordingly to the simulations [17] - can lead to temperatures above the austenitization temperature are named *WEL-conditions*.

4.1. Cyclic loads experiments

Two further experiments carried out at the same full-scale test rig should reveal the behaviour of WEL under further cyclic loads. In the experiments, loading conditions should be found which can lead to cracks or outbreaks of the WEL.
The experiments were carried out with a normal load of $F_N = 110\,kN$ and the wheel profile was cylindrical again, if not stated otherwise. Both experiments started with a new rail (VI60E1 profile). The rails were cyclic loaded with a relative velocity $v_{rel} = 0{,}002\,m/s$ by a defined rolling speed of $v_{roll} = 2\,m/s$ to get rail surfaces which are more or less in elastic shakedown. Both experiments differ in the subsequent loading cycles:

- **1st experiment (*rail A1*):** The rail was cyclic loaded one time with a defined rolling speed of $v_{roll} = 0.1\,m/s$ and a relative velocity of $v_{rel} = 0.3\ m/s$ (*WEL-conditions*) followed by for a total of 143 thousand load cycles with and without relative velocity between wheel and rail.

- **2nd experiment (*rail A2*):** The rail was cyclically loaded five times with a defined rolling speed of $v_{roll} = 0.1\,m/s$ and a relative velocity of $v_{rel} = 0.3\,m/s$ (*WEL-conditions*). Subsequently, the initially cylindrically wheel profile was modified to a non-cylindrical wheel profile to get a less wide running band. With the new wheel profile, another 600 thousand cyclic loads of the rail were carried out.
  The first 200 thousand cyclic loads were done without relative velocity. All other cyclic loads were carried out with relative velocity between wheel and rail.

After the cyclic loads the rails were cross sectioned (Figure 5 to Figure 7).
The cross section of the rail *A1* (Figure 5) reveals a flaky opening with a crack parallel to the surface in the WEL. No cracks can be found in the base material of the rail.

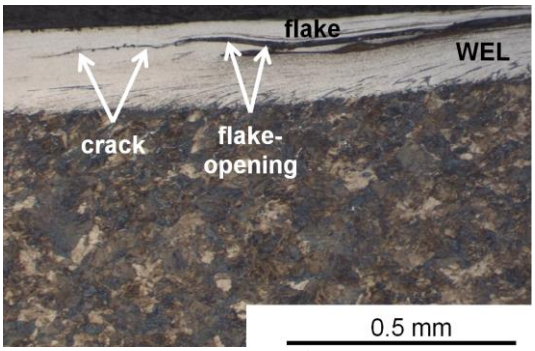

Figure 5: *Longitudinal cross section of the rail A1.*

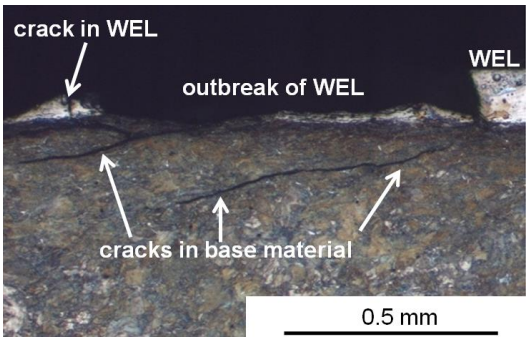

Figure 6: *Longitudinal cross section of the rail A2.*

In contrast, the cross sections of the rail *A2* (Figure 6 and Figure 7) reveal cracks in the WEL and in the base material of the rail. Some of the cracks, especially those in the WEL, are not parallel to the surface but perpendicular to it. Additional to these cracks, an outbreak of the WEL (see Figure 6) and an indentation

of the WEL into the base material were found at rail *A2* (see Figure 7).

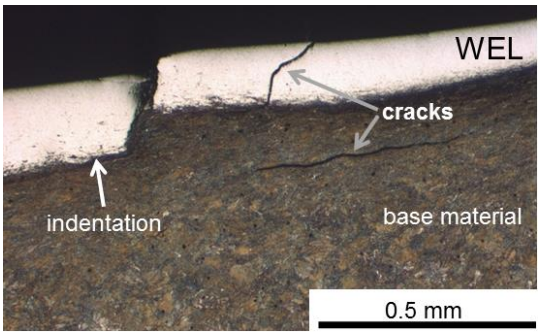

Figure 7: *Lateral cross section of the rail A2.*

4.1.1. Discussion

Cyclic loads of rails with a WEL on the surface can lead to cracks in the WEL and to outbreaks of parts of the WEL. The different alignment of the cracks within the WELs observed on *rails A1* and *A2* can have several reasons:

- The different alignment of the cracks within the WELs can be explained by the different mechanical loads during the cyclic loads. In contrast to the 1st experiment (*rail A1*) the cyclic loads of the 2nd experiment (*rail A2*) was done with a non-cylindrical wheel.
- An investigation [23] showed that multiple heating and cooling events of a rail surface during the operation can lead to changed residual stresses in the rail. The study [23] assumes that a WEL on a rail surface has partly a martensite structure. An additional heating event of the rail surface would lead to differences between the thermal expansion of the martensite structure of the WEL and the ferritic-pearlitic structure of the base material. Both material structures contracts comparable during the cooling process. Overall, the entire dilatation of both material structures is different after multiple heating and cooling events, resulting in tensile stresses in the WEL. Basically, tensile stresses caused by multiple heating and cooling events of the *rail A2* (*rail A2* was heated up five times to austenitization temperature according to temperature simulations) may lead to the vertical cracks found in the WEL of the *rail A2*.

The vertical cracks (*rail A2*) lead to a segmentation of the WEL which may makes the layer less resistant against further loads compared to a continuous WEL. An outbreak of a WEL segment or the indentation of a WEL segment into the base can be a consequence. It was not investigated whether the horizontal cracks in the WEL of *rail A1* change their growing direction in the case the 1st experiment would have been continued without changing the testing parameters. However, it is unlikely that horizontal cracks lead to a segmentation of the WEL, resulting in outbreaks or indentations.
Although a fully developed squat was not found on the rail surfaces both, outbreaks and indentations are local geometrical deviations at the rail surface which may propagate into squats.

5. Squat simulation tool

Basically, initial geometrical deviations at the rail surface can be e.g. outbreaks of a WEL on a rail surface (compare chapter 4.1) or indentations of the rail surface caused by hard objects (compare chapter 1). To investigate the long-term development of an initial geometrical deviation at the rail surface including a large number of cyclic loads a new simulation tool was developed.
Figure 8 shows a schematic representation of the squat-model algorithm. The wheel and rail surface are discretised. Both, the wheel and the initial rail profile can be selected as required. The initial geometrical deviation at the rail surface is specified by an algebraic surface. The normal contact problem is solved with Contact [25] which is based on Kalker's theory for non-Hertzian contact problems for elastic bodies [24]. Due to the geometrical deviation at the rail surface, non-Hertzian wheel-rail contacts are to be expected.
The relative velocities in the wheel-rail contact are calculated according to equation 1, based on the assumptions of rigid bodies creepage distribution [24],[25]:

$$\vec{s}(x,y) = \begin{pmatrix} c_x - \omega \cdot \Delta r \cdot \frac{1}{v_w} \\ c_y - \omega \cdot \sin\varphi(y) \cdot x' \cdot \frac{1}{v_w} \end{pmatrix} \qquad (1)$$

where v_w is the translatory speed of the wheel over the rail (equal to vehicle speed), c_x and c_y are the creepages in the contact point if the wheel and the rail are seen as rigid bodies caused by accelerating ($c_x < 0$), by braking ($c_x > 0$) or by driving through railway curves ($c_y \neq 0$). The angular speed of the wheel is determined by ω, Δr represents the rolling radius differences of the wheel and the influence of the lateral contact patch inclination is represented by the inclination angle $\varphi(y)$. The influence of the longitudinal expansion of the contact patch is considered by x'. x' is measured from contact point of the wheel and rail if both are seen as rigid bodies.
The tangential stress $\tau(x,y)$ and the frictional power $\dot{q}(x,y)$ distributions are calculated by the ECF model [26], [27]. The ECF model is capable to estimate the adhesion coefficient between wheel and rail taking into account the 3rd body layer between these bodies. The 3rd body layer includes e.g. wear debris or sand and furthermore all kind of irregularities of the near surface layer of the wheel and the rail e.g. roughness or micro-cracks. Wheel and rail are assumed to be elastic bodies whereas the 3rd body layer behaviour is described by an elastic-plastic material law according to Voce.
The material parameters of the 3rd body layer depend on contact normal stresses $p_n(x,y)$ and surface temperatures $T(x,y)$ and were parametrised by laboratory and vehicle tests. In contrast to the normal stress distribution $p_n(x,y)$ which is calculated externally by Contact, the temperature distribution, which depends on the frictional power $\dot{q}(x,y)$, is

calculated by the ECF model iteratively. All in all, the consideration of these complex interactions enables a reliable and realistic estimation of the adhesion coefficient between wheel and rail.

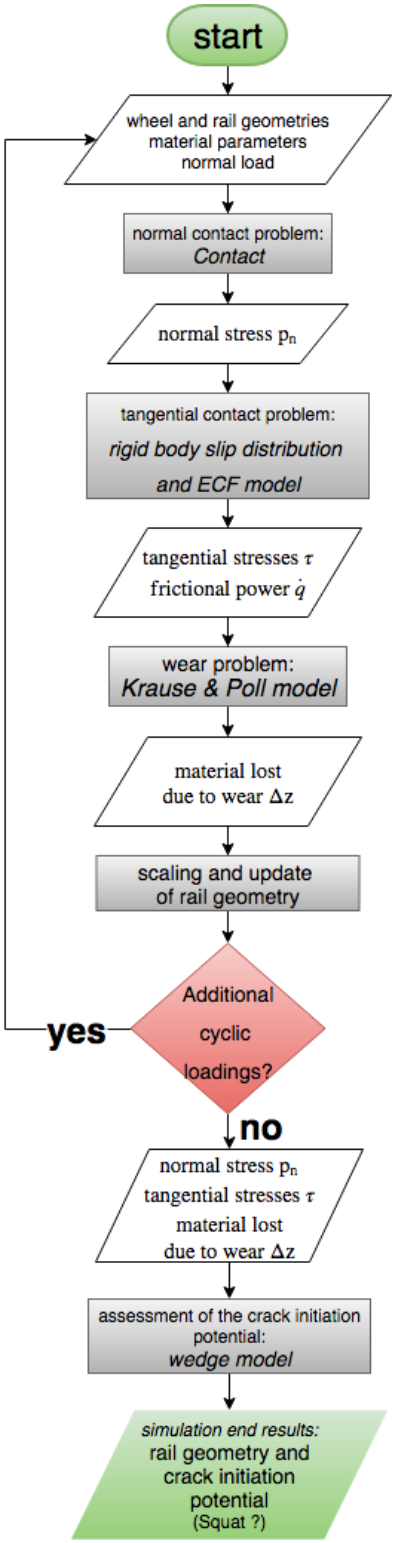

Figure 8: *Schematic representation of the squat-model algorithm.*

The loss of material due to wear $\Delta z(x, y)$ is calculated according to the wear model of Krause and Poll [28]:

$$\Delta z(x, y, t) = \frac{1}{\rho} \cdot k(\dot{q}(x, y, t)) \cdot \dot{q}(x, y, t) \cdot \Delta t \qquad (2)$$

where k is a proportional factor, ρ is the density of the rail steel and Δt the time of one time step of the simulation. According to Krause and Poll [28], the proportional factor k is influenced by the materials and the temperatures of the contacting bodies and the environmental conditions. The influence of the temperature is considered by the dependency of the factor k on the frictional power $\dot{q}(x, y)$ (see table 1).

Table 1: Assumed values for the factor k, depending on frictional power $\dot{q}$ and the material.

	$\dot{q} \leq 4\frac{W}{mm^2}$	$\dot{q} > 4\frac{W}{mm^2}$
k for zones without WEL	$2 \cdot 10^{15}\frac{kg}{Nm}$	$2 \cdot 10^{14}\frac{kg}{Nm}$
k for zones with WEL	$4 \cdot 10^{15}\frac{kg}{Nm}$	$4 \cdot 10^{14}\frac{kg}{Nm}$

Before updating the rail geometry, the loss of material due to wear of one load cycle is scaled for calculation time reasons. The scaling factor is chosen that the maximum material loss due to wear does not exceed $2\ \mu m$.

In the simulation tool, it is assumed that the development of the rail geometry is not influenced by the damage in terms of crack initiation. Due to that, the assessment of the crack initiation potential is done as a post processing step but using the results of every calculated load cycle. The investigation of the damage potential is done with the wedge model [26], [29], [30]. Basically, the wedge model was parameterised for RCF cracks at the gauge corner of rails in curves and not for squats. Therefore, in the context of this work the results of the wedge model should be seen qualitatively.

According to the delamination theory [29], [32], the alignment of the material microstructure due to severe plastic deformation has a high impact on the crack development. Cracks prefer to grow parallel to this alignment due to the related reduced crack growth resistance. Microscopic cracks in this layer can lead to the formation of flakes which are likely to break off the surface under contact loads or remain in the material growing into deeper regions resulting in macroscopic fatigue cracks. Which mechanism dominates depends on the microstructure alignment (shear deformation) distribution within the near-surface material layer.

The wedge model [26], [29], [30] takes into account the shear deformation of the near-surface layer (crack initiation layer) caused by the contact stresses p_n and τ on a cyclic basis. Furthermore, the wedge model considers the partly removal of the near-surface layer because of the loss of material due to wear. The fatigue life to crack initiation is estimated based on the effective stresses σ_A which are calculated by the maximum principle stresses during the load cycles modified by the influence of the shear deformation of the near-surface layer (crack initiation layer) and the influence of the direction of the contact stresses.

Due to the fact that the wedge model is not parameterised for squats the results in this work are given in relation to the maximum damage of a reference rail cross section, which is subjected to the same loads but is not “disturbed” by a geometrical deviation at the rail surface. The results are indicated by means of a colour scale: yellow means that the damage potential is

smaller, green that the damage potential is up to compared with the damage potential of the reference rail cross section.

6. Simulation results

The simulations are based on the following assumptions: no accelerating or braking of the wheel (longitudinal creepage of the rigid contact point $c_x = 0$), no angle of attack of the wheel (lateral creepage of the rigid contact point $c_y = 0$), constant normal load ($F_N = 110\,kN$) and constant rolling speed ($v_w = 10\,m/s$). The wheel profile corresponds to the norm S1002 and is not updated during the simulations. The initial rail profile corresponds to VI60E1 and the rail inclination is 1/40. In all simulation cases the rails have an initial geometrical deviation at the surface. An exception is the rail of the simulation case presented in chapter 6.2.

6.1. Development of the rail surfaces with initial geometrical deviations due to cyclic loads

Three simulations were carried out which should show the development of three different initial geometrical deviations at rail surfaces under further cyclic loads. The geometrical deviations differ in their initial size: the geometrical deviation *small* has an initial length and width of 6 mm, the geometrical deviation *intermediate* has an initial length and width of 20 mm and the geometrical deviation *large* has an initial length and width of 40 mm. In all three cases, the geometrical deviations have an initial depth of 0.15 mm. The lateral positions of the centers of the geometrical deviations correspond to the position of the rolling line ($c_x = s_x = 0$). They are located at $y = -13\,mm$. The rails were cyclic loaded around 900 thousand times.

Figure 9 to Figure 11 show the initial and the end state of the rail surfaces for all three simulation cases. The variation of the running band, which reflects the variation of the contact patch width during the load cycle, is indicated by the visualization of the material loss due to wear Δz. It can be seen that the *small* geometrical deviation (see Figure 9) does not lead to variations in the running band. Furthermore, the material loss due to wear is only slightly disturbed by the geometrical deviation. At the end of the simulation (after ≈ 900 thousand cycles), no geometrical deviation can be found on the rail surface.

In contrast, the *intermediate* (see Figure 10) and *large* (Figure 11) geometrical deviations cause variations of the running band. In these cases, the material loss due to wear Δz is not constant. The material loss due to wear Δz is significantly increased before and after the geometrical deviation in the case of a *large deviation*. Both, geometrical deviation *intermediate* and *large* are growing in length and width under the cyclic loads. At the end of the simulations, the geometrical deviation *intermediate* and *large* have a length of 70 mm and 100 mm, respectively. Both geometrical deviations have a width of about 45 mm. The depth of the *intermediate* geometrical deviation decreases to 0,025 mm and of the large one to 0,08 mm during cyclic loads. All these values kept more or less constant towards the end of the simulations so that no further changes in the geometrical deviations are to be expected under further cyclic loads.

Figure 12 shows the results of the assessment of the crack initiation potential of the (a) *small*, (b) *intermediate* and (c) *large* geometrical deviations for 300 thousand cyclic loads. The geometrical deviation *small* does not lead to an increased crack initiation potential. In contrast, the geometrical deviations *intermediate* and *large* lead to an increased crack initiation potential. The crack initiation potential of the *intermediate* geometrical deviation is increased over a wide area of the rail surface.

6.1.1. Discussion

The simulations reveal both, the geometrical development of rail surfaces and the crack initiation potential of rails with an initial geometrical deviation at the rail surface under cyclic loads. Three different cases were investigated: a *small*, an *intermediate* and a *large* initial geometrical deviation. Each rail was cyclic loaded for 900 thousand times.

In Figure 9**,** it can be seen that the geometrical deviation *small* has a negligible influence on the running band. Therefore, it can be assumed that the contact stresses are not strongly influenced by this geometrical deviation of the rail surface. Overall, the material loss due to wear is relatively constant in longitudinal direction of the rail, resulting in a rail surface without a geometrical deviation at the end of the simulation.

In contrast, Figure 10 and Figure 11 reveal variations of the running band and thus variations of the contact patch shape, caused by the geometrical deviations *intermediate* (Figure 10) and *large* (Figure 11).

Different contact patch shapes are leading to different normal stress distributions within the contact patches. Furthermore, the rigid body creepage distributions are changed. An increased width of the contact patch leads to larger rolling radius differences Δr within the contact patch and an expansion in length of the contact patch leads to increased values of x'. Both Δr and x' are influencing the rigid body creepage distribution based on equation 1. The normal stress distribution and the rigid body creepage distribution are used in the ECF model to calculate the frictional power distribution $\dot{q}$ which is used for the calculation of the material loss due to wear Δz (see equation 2). Furthermore, in the ECF model the local traction coefficient depends on the material properties of the 3rd body layer. The material properties are influenced by the temperatures and normal stresses. Basically, the calculation of the tangential stresses and temperature is therefore an iterative process.

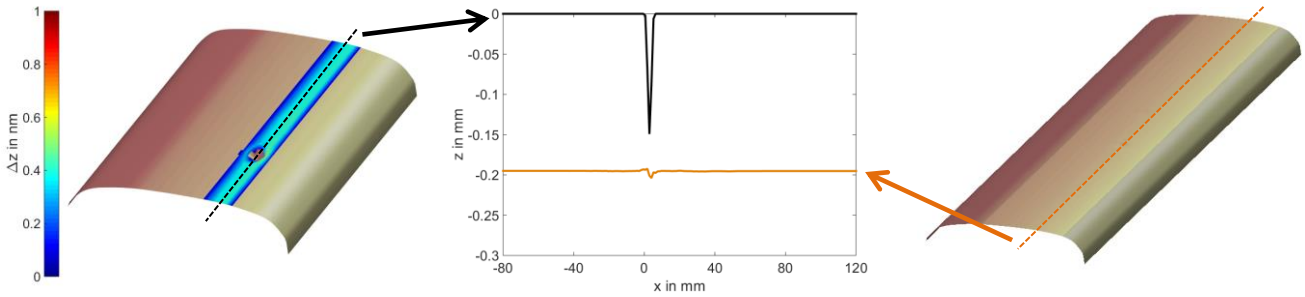

Figure 9:*The left picture shows the initial state including information of material loss due to wear of the first load cycle, the right picture shows the end state (after ≈900 thousand cycles) of the rail surface and the picture in the middle shows the longitudinal cross sections of both, the initial and end state. The material loss due to wear is not increased at the geometrical deviation. (geometrical deviation small)*

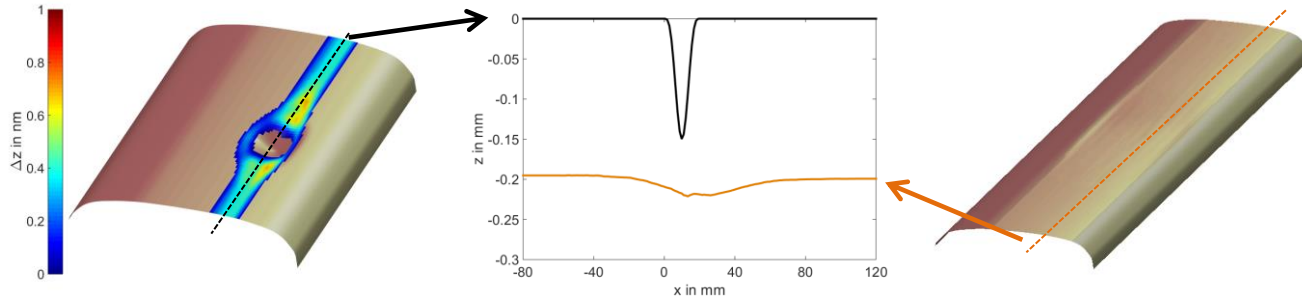

Figure 10:*The left picture shows the initial state including information of material loss due to wear of the first load cycle, the right picture shows the end state (after ≈900 thousand cycles) of the rail surface and the picture in the middle shows the longitudinal cross sections of both, the initial and end state. At the geometrical deviation the material loss due to wear* **Δz** *is partly increased. (geometrical deviation intermediate)*

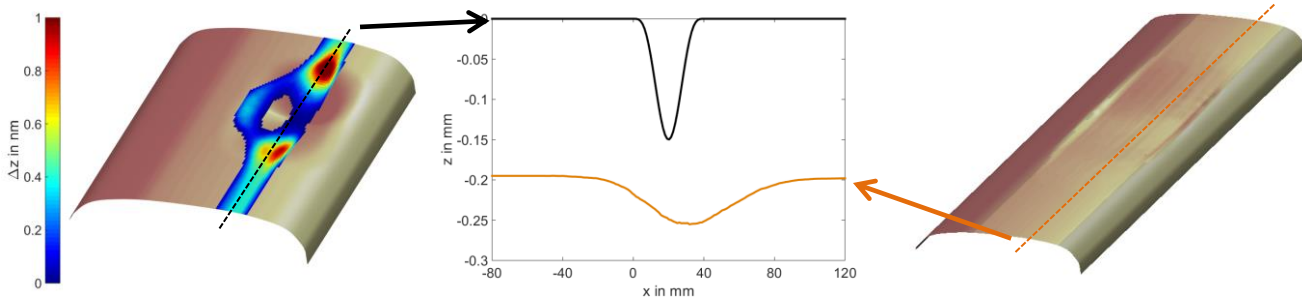

Figure 11:*The left picture shows the initial state including information of material loss due to wear of the first load cycle, the right picture shows the end state (after ≈900 thousand cycles) of the rail surface and the picture in the middle shows the longitudinal cross sections of both, the initial and end state. At the geometrical deviation the material loss due to wear* **Δz** *is partly significantly increased. (geometrical deviation large)*

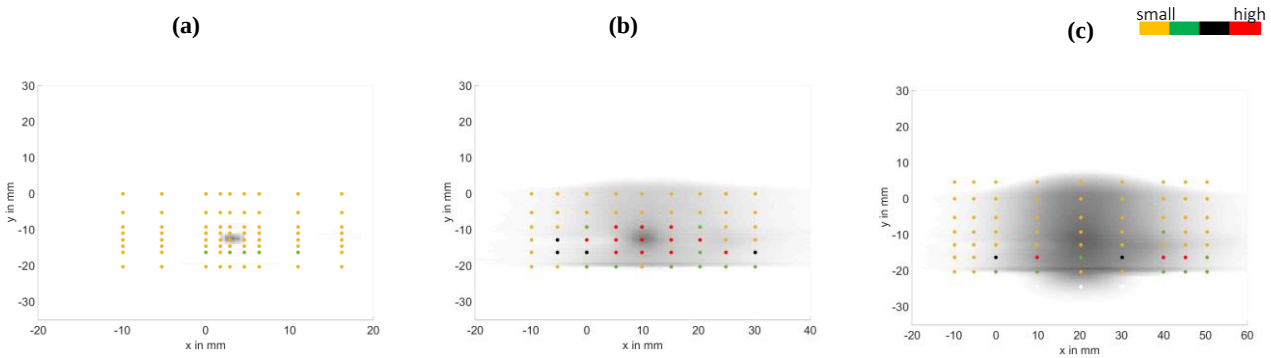

Figure 12: *Assessment of the crack initiation potential done for ≈300 thousand cycles. Geometrical deviations: (a) small (b) intermediate (c) large.*

To sum up, a change of the contact patch shape and thus a change of the normal stress distribution and the rigid body creepage distribution within the contact lead to local changes of the material loss due to wear (Δz).Both, the *intermediate* and the *large* geometrical deviation remain on the rail surface under cyclic loads (see Figure *10* and Figure 11). Because of the locally changed wear behaviour around the geometrical deviations, both, the *intermediate* and the *large* increased in length and width and decreased in depth. This process continued until the wheel-rail contact is not influenced by the geometrical deviations anymore.

In contrast to the case *small* and *intermediate*, the wheel touches the rail surface in deeper regions (around the centre) in the case of the *large* geometrical deviation already from the beginning (compare Figure 10 and Figure 11). Due to that, material loss due to wear occurs in this area from the beginning. For this reason, the geometrical deviation *large* remains permanently deeper on the rail surface compared to the geometrical deviation *intermediate*.

For all three cases the assessment of the crack initiation potential is done for 300 thousand cyclic loads (see Figure 12). The geometrical deviations *intermediate* and *large* show an increased crack initiation potential (see Figure 12 (b) and (c)). Furthermore, the *intermediate* one shows increased crack initiation potential over a larger area of the rail surface. In contrast, the geometrical deviation *small* does not show significantly increased crack initiation potential (see Figure 12 (a)). The assessment of the crack initiation potential was done with the wedge model. The wedge model uses the contact stresses of each load cycle to estimate the shear deformation distribution of the near-surface layer of the rail. Furthermore, the model considers the wear of the near-surface layer. The fatigue life to crack initiation is estimated based on the effective stresses σ_A which are calculated by the maximum principle stresses during the load cycles modified by the influence of the shear deformation distribution of the near-surface layer (crack initiation layer) and the influence of the direction of the contact stresses. The variations of the contact stresses seem preferably lead to a higher crack initiation potential. Overall, the crack initiation potential seems to decrease at relatively large geometrical deviations at the rail surface (see Figure 12 (c)). In this case the wheel can contact the deep area of the geometrical deviation from the first load cycle on, recognizable on the branch of the running band through the centre of the geometrical deviation (see Figure 11). In contrast, the wheel is not able to contact the deep area of the geometrical deviation in the intermediate case (see Figure 10) which leads to higher values of effective stresses σ_A and thus to a higher crack initiation potential.

6.2. Development of the rail surface with zones of WEL due to cyclic loads

The examination of a rail revealed alternated regions with and without WEL on the rail surface (see chapter 2). The regions with WEL showed a longitudinal distance of approximately 15-30 mm between each other and had a higher hardness compared with the regions without WEL. Basically, a study [31] based on the investigation of a rail segment with and without WEL revealed that surface regions with an "undamaged" WEL can have a locally deviating wear behaviour with reduced material removal compared to regions without WEL. In this section the situation described above is tried to be simulated. Basically, the rail surface does not have an initial geometrical deviation. It is assumed that regions with WEL are "undamaged" (no cracks, no outbreaks) and that they have a locally deviating wear behaviour with reduced material removal compared to the regions without WEL. This assumption results in alternating wear-resistances of the rail surface represented by different k values in equation 2 for regions with and without WEL, respectively (see table 1).

The left picture of Figure 13 shows the initial state of the rail surface. Corresponding to the observed situation in the field, a longitudinal distance of 30 mm was chosen between the regions with WEL. The WEL had an initial width of 10 mm on the surface whereby the WEL width decreases linearly to 0 at a depth of 0.1 mm. The rail has been cyclic loaded for ≈1.2 million times. The right picture of Figure 13 shows the end state of the rail with a noticeable geometrical deviation on the surface.

The cross sections of the initial and end state of the rail surface (see middle picture in Figure 13) reveals a length of ≈ 90 mm and depth of ≈ 0.07 mm of the developed geometrical deviation.

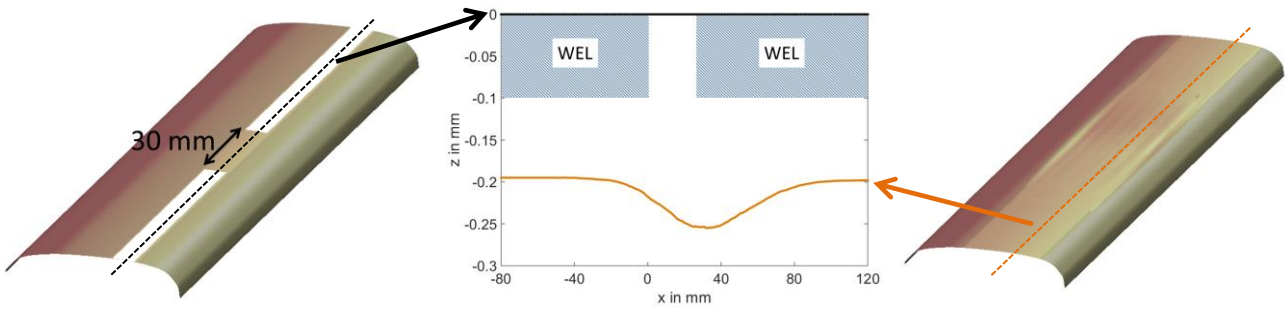

Figure 13:*The left picture shows the initial state and the right picture the end state (after ≈1 million cycles) of the rail surface. The picture in the middle shows the longitudinal cross sections of both, the initial and end state. At the beginning, the rail has no geometrical deviation but areas with WEL with a distance of 30 mm to each other. Originally, the WEL has a depth of 0,1 mm and a width of 10 mm.*

6.2.1. Discussion

The simulations showed that alternating wear-resistances because of regions with and without WEL on the rail surface can be the cause for the development of geometrical deviations on the rail surface. According to a study [31], WEL should have a locally deviating wear behaviour with reduced material removal compared to other surface regions if the WEL is undamaged (no cracks, no outbreaks). Experiments [17] at a full-scale test rig showed that an undamaged WEL can be generated due to the one-time occurrence of increased temperatures in the wheel-rail contact. Further experiments (see chapter 4.1) showed, that further cyclic loads can lead to outbreaks and cracks in the WEL.

Basically, it can be assumed that WEL shows cracks or outbreaks in real operation due to further cyclic loads after its formation. Therewith, it can be assumed that WEL in real operation does not have a reduced material removal compared to other surface regions.

However, the simulations showed that alternating wear-resistances on the rail surface can be the cause for the development of a geometrical deviation at the rail surface.

7. Summary and conclusion

In this work, the formation mechanisms of squats were investigated. Squats can be categorised as local rail defects due to their limited geometrical size (length $<\approx 100\ mm$).

Based on a literature review, a structure was proposed to depict the development process of squats in a systematic way (see Figure 4). In literature, material inhomogeneities such as WEL or weldings, cracks and initial indentations on the rail surface caused by hard objects are mentioned to cause squats. Overall, all these causes can lead to local discontinuities of the running band, of the contact stresses or of the material properties which can lead to different local development of the rail under further cyclic loads.

An investigation of a rail from the field with squats revealed alternated regions with and without WEL on the rail surface. The regions with WEL showed a higher hardness compared to the regions without WEL. A 3D optical measurement of the rail surface geometry was done in laboratory. Due to the fact that no hills were found near the squats, it was concluded that massive plastic deformation of the rail surface is not the main development mechanism of squats. However, small local plastic deformations followed by removal of the material due to wear cannot be excluded.

Previous experiments [17] showed that WEL on a rail surface can be caused by significant increased wheel-rail contact temperatures ($\approx 700\ °C$). Such temperatures can be induced by increased creepage rates (relative velocity between wheel and rail). Two further experiments done at a full-scale wheel-rail test rig revealed the behaviour of WELs under cyclic loads. For every experiment a separate rail was used. The first rail was loaded one time with increased creepages to produce WEL again. The second rail was cycled five-times with the same increased creepages as the first rail. Subsequently, both rails were cyclically loaded by several thousand wheel passes with a low creepage rate and partly without additional creepage. Only the second rail showed outbreaks of the WEL on the surface.

A new simulation tool (3D wheel and rail geometries) was developed to show how different sized geometrical deviations like outbreaks of the rail surface evolve under further cyclic loads. The results achieved with this new simulation tool reveal that initial geometrical deviations of different size evolve unequally. Small initial geometrical deviations at the rail surface with a diameter up to about ≈6 mm on the surface are worn out. On the contrary, medium sized or large initial geometrical deviations lead to a permanent geometrical deviation at the surface which is consistent with field observations [3] [4] [14]. Furthermore, the crack initiation potential is increased over a wide area on the rail surface around medium sized deviations of the rail surface.

An additional simulation should reveal the geometrical development of a rail surface without an initial geometrical deviation but with alternating wear-resistances. Alternating wear-resistances can be caused by e.g. alternating regions with and without WEL on the rail surface [31]. Corresponding to the investigations on a squat taken out from service, in the simulation the regions with WEL had a distance of about 30 mm to each other. The rail was cyclic loaded 1.2 million times. After the simulation, the rail surface showed a geometrical deviation.

Based on these results no black or white statement about squat development can be given. The investigations showed how an initial geometrical deviation of the rail surface can come into existence and how it subsequently behaves both geometrically and with respect to crack initiation potential under further cyclic loads.

Overall, a simulation result in the form of a permanent geometrical deviation at the rail surface in connection with an increased crack initiation potential can be interpreted as an indication for a possible squat development. Further validation of the model is necessary.

Acknowledgments

This work has been partly financed within the European Horizon 2020 Joint Technology Initiative Shift2Rail through contract n° 730841 (IN2TRACK).

This work was accomplished at the VIRTUAL VEHICLE Research Center in Graz, Austria. The authors would like to acknowledge the financial support of the COMET K2 - Competence Centers for Excellent Technologies Programme of the Austrian Federal Ministry for Transport, Innovation and Technology (bmvit), the Austrian Federal Ministry of Science, Research and Economy (bmwfw), the Austrian Research Promotion Agency (FFG), the Province of Styria and the Styrian Business Promotion Agency (SFG).

Abstract: A vision-based experimental methodology was developed for monitoring the surface state evolution of specimens during bi-disc rolling contact tests, aimed at providing information for identifying the damage phenomena. The system is based on a high-speed camera and three laser pointers for illuminating the specimen surface. Images of the specimen surface are acquired and processed, allowing the definition of synthetic surface state indexes, as well as the 3D reconstruction of the damaged surface topology. The vision system was applied to alternated dry-wet rolling-sliding contact tests on railway wheel steel specimens, highlighting its effectiveness in the damage evaluation.

Keywords: Online monitoring; image processing; rolling contact fatigue; wear; damage assessment.

1. Introduction

Bi-disc tests are an effective method for characterizing the material response to rolling-sliding contact, as they are able to reproduce the damage phenomena of real components at a laboratory scale in controlled working conditions. These testing procedures have been widely used to characterize materials for bearings, gears, railway wheels and rails (see some examples in [1]~[5]). In bi-disc rolling contact tests different damage mechanism can interact and affect each other, such as wear, Rolling Contact Fatigue (RCF), strain hardening, ratcheting, etc., as presented in [6]~[8]. Recognizing and monitoring all these phenomena is a key issue for material characterization.

Monitoring of surface damage in rolling contact tests is usually performed by means of online indirect measurements, such as the coefficient of friction or vibrations. The direct evaluation is usually obtained by means of destructive measurements at the end of the test, including microscope observation and micro-hardness measurement on sectioned specimens. In [3], a correlation between direct and indirect measurements was attempted, obtaining a methodology for estimating the evolution of damage during the tests. However, the indirect measurements can be affected by the different damage mechanisms even in competition with each other, therefore the online damage monitoring requires the combination of various measurement techniques for having a complete information. A deeper knowledge of the temporal evolution of the surface topology can provide additional key information for identifying damage phenomena, even providing clues of what is happening under the contact surface.

In the present study, a dedicated vision-based measurement system was applied to a bi-disc test bench. A technique of image analysis is proposed for obtaining synthetic parameters able to provide information about the surface state evolution [9]. This approach was applied to rolling contact tests in alternated sessions of wet and dry condition on a railway wheel steel. Indeed, according to the experience of the authors ([5], [10], [11]), the alternation of dry and wet contact is a severe condition for railway wheels. During the dry phase surface cracks nucleate due to unidirectional plastic flow; subsequently, in the wet phase such cracks propagate under the action of the water, which is entrapped inside the cracks and pressurized by the passing load. This testing procedure was therefore considered particularly indicated for trying the new vision system, as the contact surface was expected to evolute through very different states.

2. Testing procedure

The tests were carried out by means of the bi-disc testing machine shown in Figure 1, whose detailed description is provided in [8].

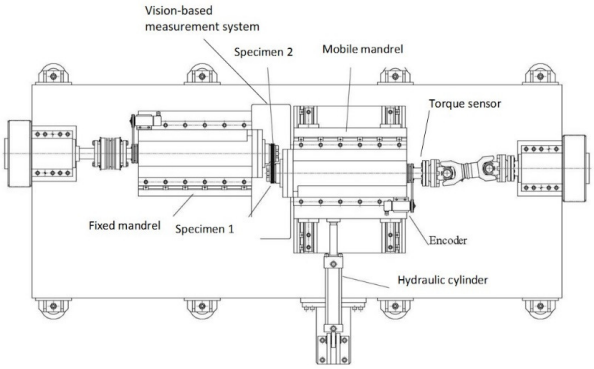

Figure 1 *Schematic of the bi-disc test bench.*

It is bi-disc machine where specimens are positioned onto independent shafts. One of them can be displaced orthogonally to the shaft axis by a hydraulic cylinder that applies the imposed contact load as well. The rolling speed of each shaft, and therefore of each

specimen, is measured by encoders, and a load cell located at the piston head measures the contact load between specimens. The bench is also equipped with a torque sensor positioned on the displaceable shaft, which can continuously acquire torque values at a synchronous sampling frequency of 5 kHz. The measured torque signal is then elaborated to obtain the friction coefficient between specimens by Equation (1):

$$f = \frac{T}{rF} \quad (1)$$

where T is the torque measured by the torque sensor, r is the radius of the specimen and F is the contact load acted on the specimens. Piezo-accelerometers are mounted on each mandrel support, one in vertical and the other in horizontal direction, both normal to the rotation axis. The used transducers are Wilcoxon 736 IEPE accelerometers, with nominal sensitivity 0.98 V/(m/s^2), full scale 5 m/s^2, linear bandwidth within the range 5-20 kHz.

Rolling-sliding tests in dry and wet contact were carried out on specimens in 0.7%C steel with fine pearlite structure, with hardness HV330. All of the tests were conducted with the same maximum contact pressure (0.9 GPa), rolling speed (500 rpm) and sliding/rolling ratio (0.5%). Wet contact was realized by means of a jet of water with the addition of 10% glycol for prevention of test bench corrosion. In two tests (identified as T1 and T2) dry and wet contact phases of 50 kcycle each were alternately applied, starting with dry contact. In the third test (identified as T3) 600 kcyles in dry contact were applied, subsequently wet contact was applied. In the fourth test (identified as T4) 1 Mcycle in dry contact was applied, subsequently wet contact was applied. The tests were stopped when severe damage occurred on the surface: this condition was identified by a severe increment of the vibrations of the mobile mandrel, as detailed below in the results section.
A summary of the applied test conditions in terms of sequence of dry and wet sessions is shown in Table 1.

Table 1 *Summary of the applied test conditions.*

Test ID	Dry-wet sequence
T1	50.000 dry + 50.000 wet + 50.000 dry + 50.000 wet + … up to failure
T2	50.000 dry + 50.000 wet + 50.000 dry + 50.000 wet + … up to failure
T3	600.000 dry + *n* wet up to failure
T4	1.000.000 dry + *n* wet up to failure

Figure 2 shows the vision-based measurement system integrated with the test bench. The vision system performs measurements on the fixed wheel specimen (Specimen 2 in Figure 1). With reference to Figure 2, C is a high-speed camera (PROMON 501; AOS Technologies AG), L1a and L1b are two laser pointers suitably defocused to illuminate the specimen surface. L2 is a dedicated laser stripe, to perform 3D measurements, and L3 is a laser stripe for the measurement of the angular position of the specimens during the tests, allowing for the synchronism between images and angular position. A f/50 mm-lens is used.

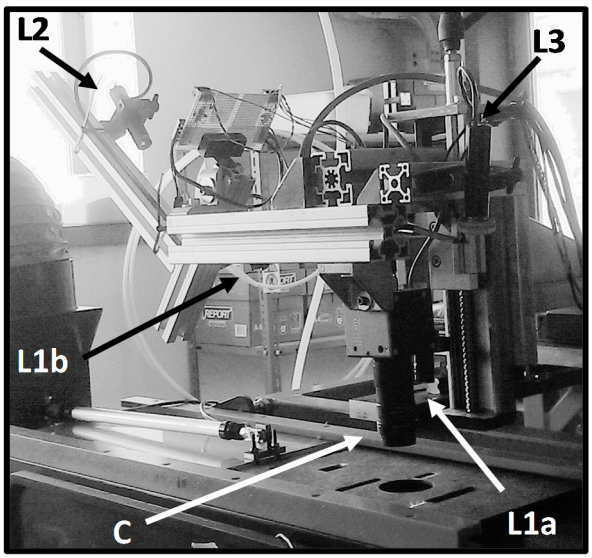

Figure 2 *Vision system integrated into the RCF test bench*

To measure the angular position of the rolling specimen, a purposely-designed encoder is used. This component, shown in Figure 3, is an axial cam, with external diameter of 50 mm and internal diameter of 44 mm; the height of the region with the maximum diameter varies linearly along the circumference from 3 mm to 8 mm. Since the encoder is fixed on a disk screwed onto the specimen, encoder and specimen roll coaxially. Every time the specimen is disassembled and reassembled, the zero position of the encoder always coincides with the same portion of specimen. The camera acquires images with dimensions (1280 px × 240 px), with a bit depth of 8 bit, and the resulting field of view (FOV) is (265 mm × 6.5 mm) with spatial resolution equal to 0.021 mm/px, in both X and Y directions, as defined in Figure 3.

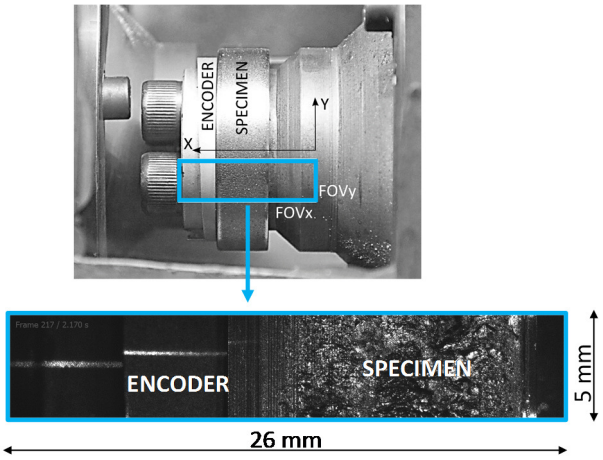

Figure 3 *Analogic, linear encoder fixed on a disk coaxially screwed on the specimen. Definition of the X and Y directions*

During the dry tests, images of the surface of the wheel specimens are continuously acquired at a frequency of 377 fps. They are acquired with a gain of 24 and an exposure time of 40 µs. In the performed tests, surface images of rolling wheel specimens are acquired every 10 seconds, each acquisition having a duration of 2

seconds. Acquisitions are also performed at the beginning and at the end of each step, with the mandrel rotating a the reduced speed of 5 rpm. In these cases, the acquisition frequency of the vision-based measurement system is 100 fps and the duration of the acquisition is 1 min.

3. Image processing

To quantify surface damage, images of the surface of the specimen undergo simple and fast image processing, allowing the definition and assessment of the synthetic indexes. Three regions of interest (ROI) were defined, shown in Figure 4. ROI1 includes the surface illuminated by the defocused lasers L1a and L1b; ROI2 includes the region illuminated by laser blade L2; ROI3 includes the region illuminated by laser blade L3.

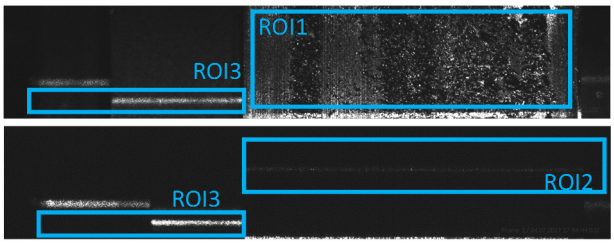

Figure 4 *Definition of the regions of interest (ROI)*

3.1. Angular position measurement

Laser L3 projects a stripe on the encoder, and the corresponding acquired image of this projection is shown in Figure 4, completely included in ROI3. While specimen and encoder are rolling together, the height of the encoder profile linearly varies, therefore its measurement in each image allows the determination of the angular position of the specimen. Being the L3 laser stripe included in each current image, the angular position measurement results synchronous with the image itself.

ROI3 is univocally defined on the image before the image processing starts, so that it only contains the projected laser stripe. The portion of image contained in ROI3 undergoes a thresholding at a level of grey of 62.7, i.e. the value of pixels with a grey level lower than 62.7 are put equal to zero, and the value of pixels with a grey level greater than 62.7 are put equal to one, therefore the resulting image is a binary one. Such thresholding was chosen to eliminate the grey levels corresponding to the grey level of a not damaged surface. Details about this procedure are given in [12]. For each column c, the position r_G of the center of mass of the grey levels is calculated, so that a center-of mass array $\{r_G\}$ is available. The difference between the first and the last element of the array is the encoder length.

3.2. Diffused light image analysis

Lasers L1a and L1b project a diffused light, which results in a scattered light pattern on the specimen surface, whose images exhibit bright areas having number, dimension, position, shape and orientation that can be correlated to the formation of small dips and crests during wear and RCF processes. In fact, in [12] it is shown that the brighter areas correspond to the bottom of surface pits. To analyze such non-texturized discrete defects, blob analysis is used. Considering an image, a blob is each pixel group within a closed line: in the presented work, blobs correspond to bright areas, and to highlight them, each image underwent firstly the same thresholding process.

Blob analysis allows us to derive a number of parameters, such as the number of blobs, their area, and their linear dimensions, i.e., height and width of the rectangles that circumscribe the blobs [9]. In this work the most significant parameter is the R_B, defined as follows:

$$R_B = \frac{A_B}{A_{ROI1}} \tag{2}$$

where A_B is the sum of the areas of the blobs found in the region ROI1, averaged over the whole specimen surface, and A_{ROI1} is the total area of ROI1.

3.3. 3D profile measurements

The 3D profile of the contact surface were obtained by elaboration of the laser blade track acquired during the tests, with a precision of 0.018 mm. A scheme of the elaboration procedure is shown in Figure 5. In particular, Figure 5a shows the image of the laser blade deformed by the surface asperities; Figure 5b shows the measurement of the contact surface profile on a radial plane, obtained by a calibration of the deformed laser blade, as detailed in [9]. Figure 5c shows the combination of different profiles acquired at a short distance between each other, which allows reconstructing the 3D profile of the damaged surface.

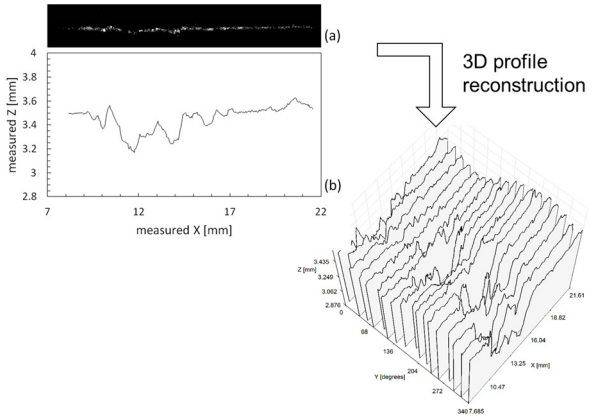

Figure 5 *Scheme of laser blade elaboration and 3D surface reconstruction*

4. Results

The total test durations and the total dry and wet cycles performed are summarized in Table 2.

Table 2 *Dry, wet and total cycles performed in the tests.*

Test ID	Total dry cycles	Total wet cycles	Total cycles
T1	500.000	450.000	950.000
T2	600.000	550.000	1.150.000
T3	600.000	550.000	1.150.000
T4	1.000.000	287.360	1.287.360

Each test was stopped when the surface was severely damaged; this condition was identified by a significant increment of the vibrations of the mobile mandrel, as shown in diagrams from Figure 6 to Figure 9, which shows the accelerations of the two mandrels during the tests. The accelerometer mounted on the mobile mandrel is particularly useful for having information about what happens in the tests. In the alternated dry-wet tests (T1 and T2) the acceleration of this mandrel kept approximately constant until about the last 100 kcycles, when they started to ramp up to 2 m/s^2. In the third test (T3), the acceleration had a sudden increase in the very last cycles. In the fourth test, acceleration started to ramp in the dry phase, and continued to ramp with steeper slope in the wet phase.

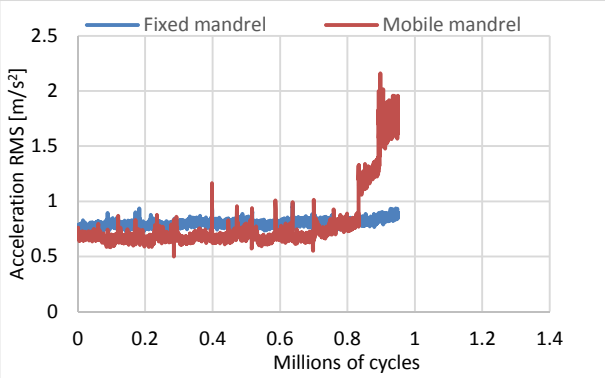

Figure 6 *Accelerations of fixed and mobile mandrels during test T1.*

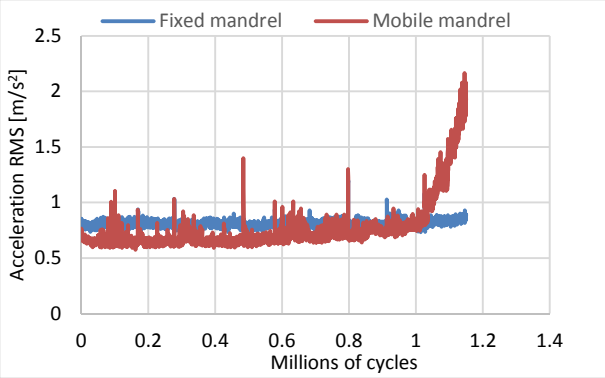

Figure 7 *Accelerations of fixed and mobile mandrels during test T2.*

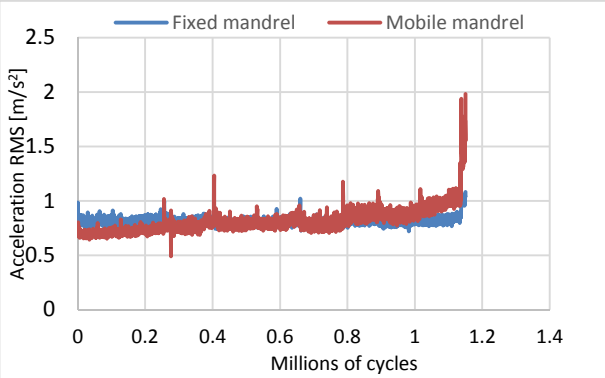

Figure 8 *Accelerations of fixed and mobile mandrels during test T3.*

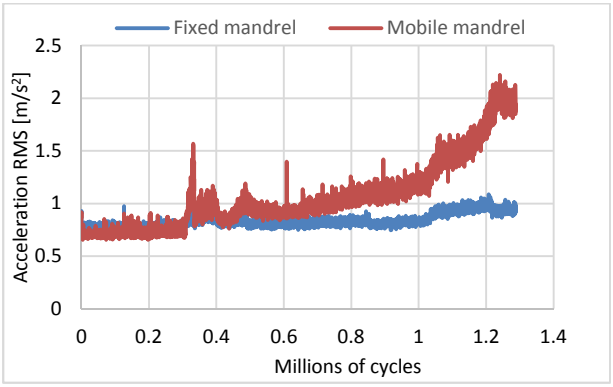

Figure 9 *Accelerations of fixed and mobile mandrels during test T4.*

Figure 10 shows the coefficient of friction in the four tests. In the alternated dry-wet tests T1 and T2 it oscillated in the range 0.2-0.3, with higher values during dry phases and lower values in the wet phases. In the T3 test it oscillates around 0.2, decreasing in the wet phase. In the T4 test, after an initial increase, it stabilizes between 0.25 and 0.3 in most of the dry phase, decreasing below 0.2 in the wet phase.

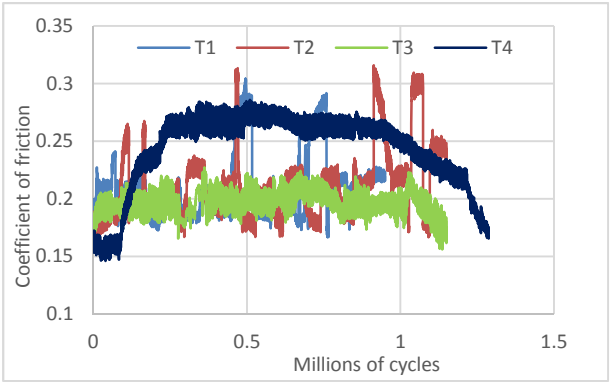

Figure 10 *Coefficient of friction during tests.*

4.1. 2D image analysis

Figure 11 to Figure 14 show the R_B parameter for the T1, T2, T3 and T4 tests. Blue triangles refer to the measurements after the dry phase, red dots after the wet one. In the T1 and T2 tests initially the R_B parameter is higher after the dry phases, but this tendency is inverted after about 750-800 kcycles. In the T3 and T4 tests the R_B parameter after the wet and dry phases tends to be equivalent.

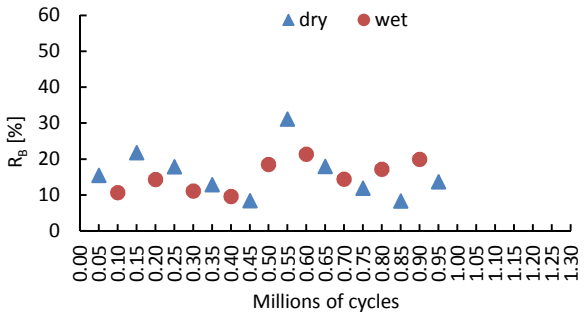

Figure 11 *R_B parameter in test T1 after dry and wet phases.*

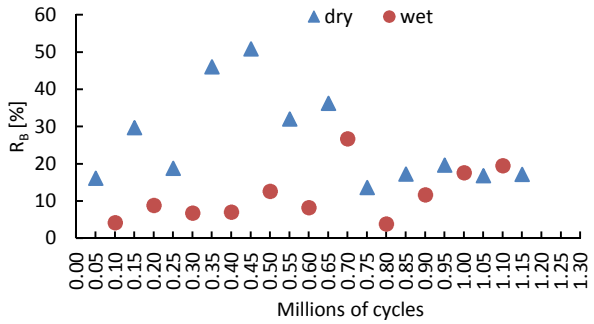

Figure 12 *R_B parameter in test T2 after dry and wet phases.*

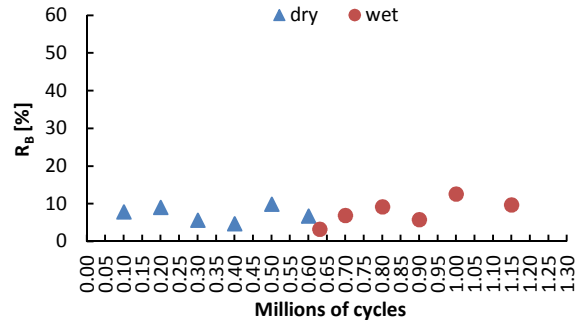

Figure 13 *R_B parameter in test T3 after dry and wet phases.*

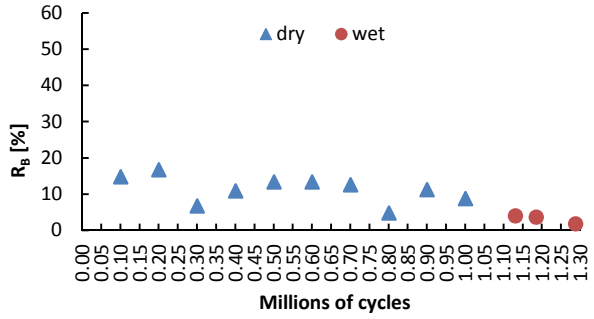

Figure 14 *R_B parameter in test T4 after dry and wet phases.*

4.2. 3D image analysis

Considering the T3 specimen, the laser stripe detects the beginning of a rolling contact fatigue crack, at 630k cycles, as visible in Figure 15. The incipient crack is revealed by a deviation of the stripe.

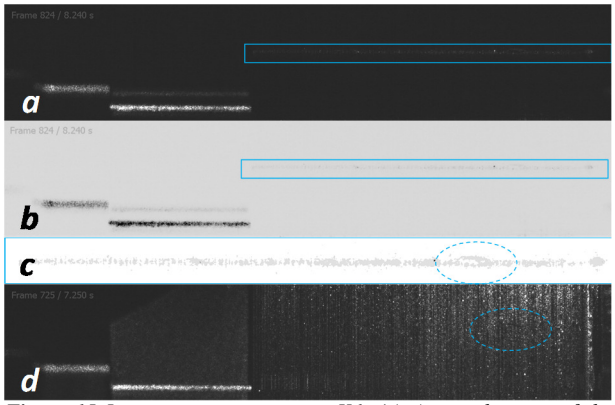

Figure 15 *Image acquisition in test K6. (a) Acquired image of the laser stripe. (b) Acquired image of the laser stripe with inverted colors. (c) Zoom of the acquired laser stripe. (d) Corresponding surface of the specimen.*

Figure 16 shows the damage evolution of the surface of the specimen. The incipient crack observed at 630k cycles in Figure 15 is in the right part of the specimen surface. Figure 16a shows the surface, in the crack position, at 700k cycles, and Figure 16b shows the same surface after 1150k cycles. In both the images is clear that the damage appears and propagates in the right part of the surface of the specimen, in accordance with the position of the incipient crack.

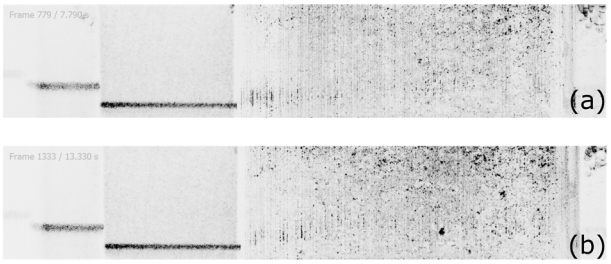

Figure 16 *Surface damage evolution. (a) Damaged surface after 700k cycles. (b) Damaged surface after 1150k cycles. (Colours are inverted to highlight damaged areas).*

In the following analysis the T4 specimen is considered after the end of the test. In order to provide a validation of the 3D measurement system, the specimen was mounted on a rotor and its 3D profile was measured by both the proposed vision system and a commercial 2D/3D sensor (Wenglor MLWL 132) (see Figure 17).

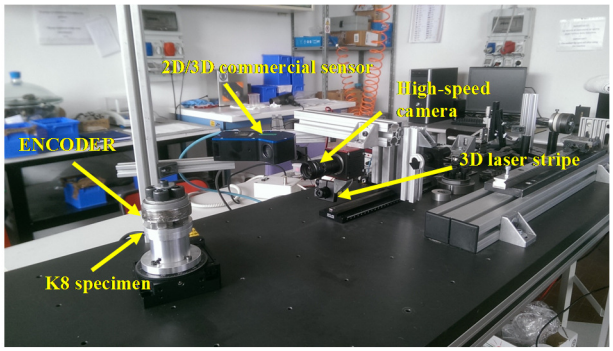

Figure 17 *Experimental set-up to compare the 3D measurement of the vision system to the 3d measurement of a commercial 3D sensor.*

Figure 18 shows an example of the image of a considered surface portion, the laser stripe of the vision system, the laser stripe of the commercial sensor. Figure 19 shows, for 3 different positions of the wheel specimen, the comparison between the measurements obtained with the two systems. It shows the substantial agreement between the two measures, validating the presented prototypal system. Its advantage with respect to the commercial system is that the acquisition is made from a much higher distance, therefore it is more flexible and suitable to be mounted on test benches. The analysis of the 3D lines allows estimating the size and the depth of the RCF damages on the contact surface.

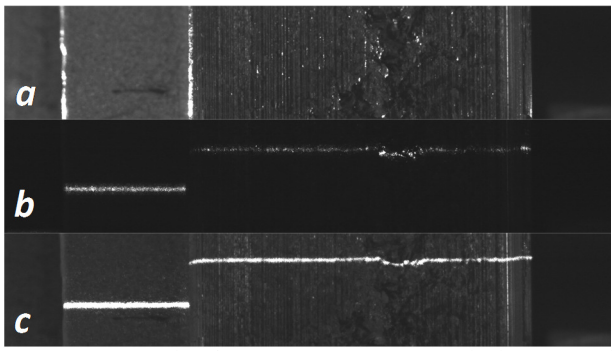

Figure 18 *Example of 3D image acquisition with the presented prototypal system and a commercial system. (a) 2D image of a considered surface portion. (b) Laser stripe of the presented vision system. (c) Laser stripe of the commercial sensor.*

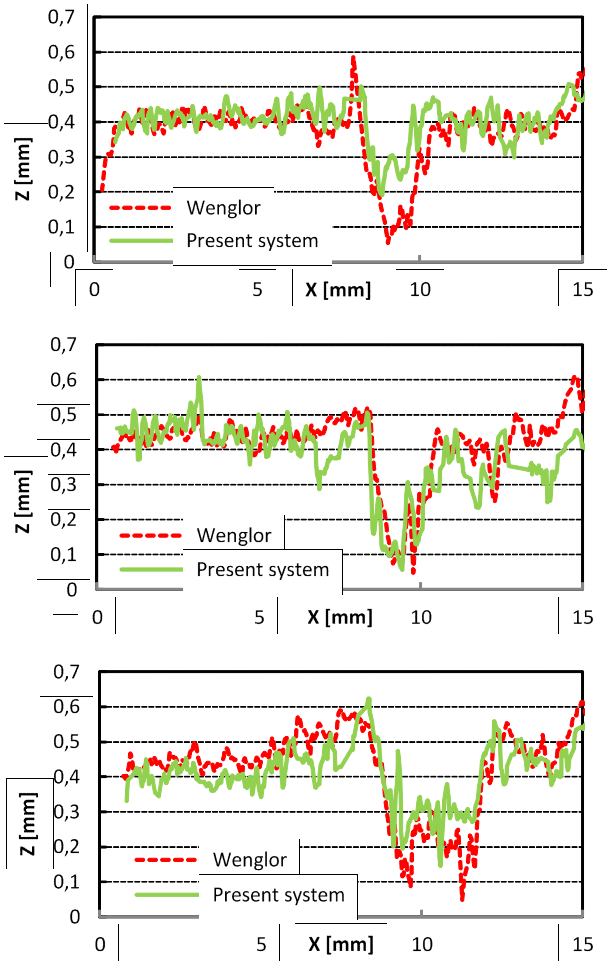

Figure 19 *Comparison of the profile measurements obtained by the proposed prototypal vision system and the commercial Wenglor system.*

5. Discussion

The general information that can be derived from T1 and T2 tests is that until about 650-700 kcycles the dry phases generate more severe damage than the wet ones, as the R_B parameter is higher. However, after such number of cycles is exceeded, the R_B parameter after dry and wet phases first becomes approximately equal, than R_B after the wet sessions is higher. This can be correlated to a switch of the surface damage typology. In the early cycles, due to higher friction, ratcheting and wear prevail, with a probable formation of surface non-propagating cracks. The following wet phases provide a surface smoothing (likely due to asperity crests removal) without inducing new damage due to low coefficient of friction. However, when ratcheting has proceeded enough and sufficiently long surface cracks have been generated, it can be hypothesized that the application of fluid induces crack propagation by means of the entrapped fluid pressurization mechanism, and rolling contact fatigue begins to prevail. The final failure, which is detected by the increment of vibrations of the mobile mandrel, becomes evident just in the final cycles; however, the analysis of the R_B parameter suggests that the phenomenon of fluid driven rolling contact fatigue starts earlier, becoming instable just in the final cycles. Indeed, vibrations are sensitive to the overall contact elasticity, which changes significantly only when the damage becomes severe and diffused over the whole specimen surface. On the contrary, R_B is sensitive to the surface state, and is able to capture changes even when the damage involves a small depth below the surface.

The results of the T3 test show that the R_B parameter in pure dry contact tends to stabilize within the range 8%-10%. In the subsequent wet phase, first it falls down to about 2%, then it raises up exceeding the value of the dry phase. This seems to confirm the tendency of the previous tests. Again, in the initial wet cycles there is a surface smoothing likely due to crests removal; subsequently, fluid driven fatigue starts to be effective increasing the surface damage. Even in this case, looking at the R_B variation, fluid driven fatigue seems to start well earlier than it is detected by the vibration measurement system.

In test T4 the final failure occurred very rapidly after the application of the liquid. Looking at the vibration profile, the damage appears more progressive than in the other cases, starting since the last part of the dry phase. Indeed, the coefficient of friction during the dry phase was significantly higher than in other cases: probably, fatigue cracks started to propagate since the dry phase, having an acceleration in the wet one. The R_B parameter did not change significantly from the dry to the wet phase, meaning that the surface damage was rather severe even in the dry phase.

A further consideration can be obtained comparing the data of Table 2 relative to tests T1, T2 and T3: it can be seen that the total dry cycles necessary to induce the final failure is approximately the same, despite in the first two cases they are alternated with wet tests and in the third one they are applied continuously. This suggests that the number of cycles necessary for allowing nucleation of surface cracks which are able to propagate in wet contact depends only on the total dry cycles applied. In test T4, where a higher number of dry cycles was applied before the wet phase, the final failure occurred more rapidly. In other words, wet contact seems to influence only crack propagation, not nucleation. Such aspect is worth to be investigated more in depth.

The system for acquiring the 3D profile of the contact surface was shown to be able to detect incipient cracks, therefore it can be used as a diagnostic system for early damage detection. Furthermore, the analysis of the 3D profiles allows measuring the size and depth of surface damage such as pits or spalls, giving quantitative information about the damage severity.

6. Conclusions

A vision based system was set up for monitoring the evolution of the specimen surface during rolling contact tests. It provides information by means of 2D analysis of images of the specimen surface acquired under defocused laser illumination, and by 3D analysis of the images of a laser blade deformed by surface asperities. Synthetic indexes were defined for quantifying the damage obtained by the 2D analysis. This system was applied to alternated dry-wet tests on railway wheel steels.

The 2D image analysis was shown to be able to provide information about the starting of fluid driven rolling contact fatigue; the 3D analysis was shown to be able to provide a quantitative estimation of the damage depth. Overall, the vision system appears a useful tool for providing quantitative information about the damage evolution in rolling contact tests, being able to identify different damage mechanisms and to localize in the space and in the time their occurrence.

Abstract: Heavy haul operating conditions in Australia are some of the most severe in the world, resulting in large contact stresses and eventual failure of the rail. A common flaw type with limited research focus are rail foot flaws. Given the physical obstruction for any contact method detection of these flaws, a non-contact method is required. Infrared thermography for this purpose has been proposed as a research topic. This paper explores rail surface temperature and presents details of field trials undertaken for development of a rail heat transfer model and a thermography based detection technique.

Keywords: tribometer, wheel-rail friction, surface temperature, rail heat transfer, infrared thermography

1. Introduction

Australia's heavy haul rail operating conditions are some of the most severe in the world, with axle loads exceeding 40t and ambient temperatures reaching nearly 50°C. The resulting stresses on the rail due to this dual effect are great and it is common for both Rolling Contact Fatigue (RCF) and rail foot flaws to occur. RCF detection techniques are now quite refined; however, the detection of rail foot flaws presents significant issues to operators as they currently have no reliable rail foot flaw detection technique available in the market place.

A valid question in the context of contact mechanics is what roll the wheel-rail contact interface could possibly contribute towards the detection of rail foot flaw faults. There are three key rolling stock sources identified that contribute to heat flow in the rail. These are rail bending, longitudinal sleeper-rail friction and wheel-rail running surface temperature. Of these three, the frictional heating and conduction due to the wheel-rail contact interface have been shown through laboratory experiments to exhibit the greatest heating effect in the rail. Perhaps this rail heat transfer can be used in the detection of cracks in the rail foot.

The rail foot environment presents some unique challenges for a condition monitoring device in comparison to the head of the rail. Unlike the head, ballast fouling and rail fasteners prevent contact based detection methodologies such as conventional ultrasonics and a non-contact approach is therefore required. A common practical detection methodology in Non-Destructive Testing is Infrared Thermography (IRT) and it has been chosen for a research project into non-contact rail foot flaw detection.

IRT is the process whereby an infrared sensor captures the emissions of an object and analyses the imagery for temperature differentials that may be indicative of a fault. There are two types of IRT, passive and active. The passive approach requires the object under test to be naturally at a different temperature to its surrounds, whereas, active excitation requires some form of excitation applied either internally or externally to generate a heat flux in the object. Any flaw in the object creates a disturbance in heat flow, causing a hot spot to appear.

Within the scope of the proposed project, this active excitation may be generated by the passage of rolling stock on the track. The key question to be answered is whether the heat sources caused by rolling stock generate a significant heat flow in the rail to cause a disturbance around a foot flaw that can be detected by IRT.

There is currently limited rail heat transfer theory with respect to the rail foot and the purpose of the research is to establish initial theory in this area. This paper shall focus on the wheel-rail running surface temperature, the data acquisition process and analysis of field results, and initial approaches to the development of a heat transfer model. The field tests were performed on a live heavy haul network in Australia.

2. Methodology

The comparison of the field recorded temperatures against simulated results is a multi-step method. The general process is described in the dot points below:

1. Analysis of expected wheel-rail contact parameters and tribometer modifications to match these expected field conditions as closely as practical.
2. Selection of a site suitable for measuring friction and temperature.
3. Measurement of rail profiles, friction values and surface roughness.
4. Development of a rail heat transfer model with surface running temperature as its boundary condition.

At this point the methodology branches according to the desired outcome.

5. The first approach is to derive the surface running temperature based on remote temperature measurement on the rail, i.e., cannot directly measure surface temperature. This will be referred to as the inverse model.
6. The second approach is to use output parameters such as contact stresses, sliding velocity and friction to mathematically model the surface temperature as the boundary condition to the rail heat transfer model.

This paper will focus on the process for measuring field data parameters described in steps 1 – 3, discuss an initial approach to rail heat transfer modelling with a surface running temperature boundary condition and conclude with an inverse model for deriving steady state surface running temperature from measured data. The mathematical modelling of surface running temperature in step 6 will be described in future publications.

2.1. Tribometer modification

The accurate modelling of the wheel-rail contact interface for a train passage in practice requires a thorough understanding of a number of different parameters, including friction, wheel/rail profiles and surface roughness. In this case we will start with friction. Is the friction constant in the contact area or does it vary between top of rail and the flange and, if lubrication is present, what part does it play? The other factor to consider is the mean and maximum contact stresses expected at the site in practice and how these compare to those generated by a tribometer.

To measure the rail frictions, the Hand Operated (HO) tribometer from International Engineering is used [1]. This tribometer can measure 12 different rail head locations from top of rail through to flange. Its contact stress capabilities will be described in greater detail below.

Although this tribometer is not able to capture changes in friction due to temperature variation in sliding velocity, it provides sufficient understanding of the underlying conditions present at the rail site. In particular, macroscopic variations such as those observed in lubricated gauge corners where the top of the rail has a high coefficient of friction and the flange is low, indicating dry and lubricated conditions respectively. For a recent survey on wheel-rail friction measurement devices both in the field and laboratory, refer to the FRA report by Magel [2].

Prior to the field measurements being conducted, an analysis of the mean and maximum contact stresses generated by the tribometer in comparison to those experienced in practice are required. *Table 1* shows a number of different rollingstock/track combinations and the resultant mean and max contact stresses for Hertzian contact assuming new rail and wheel profiles. It should be understood that these present the worst case scenario as the location of max contact stresses will undergo plastic deformation of both the wheel and rail, eventually resulting in a convergence towards a conformal contact between wheel and rail. This results in lower max and mean contact stresses.

Table 1 *Contact stresses for Heavy Haul Rollingstock in Australia.*

Wheel Load (N)	Wheel Radius (mm)	Rail Size (kg/m)	Top of Rail Radius (mm)	Mean Contact Stress (GPa)	Max Contact Stress (GPa)
107910	533.5	54	305	0.81	1.21
129982	435	60	190	1.09	1.63
147150	435	60	190	1.13	1.7
163434	533.5	68	254	0.99	1.49
208462	485	68	254	1.11	1.66

The standard configuration for the tribometer is a loading wheel radius R_x = 100mm and a lateral radius of contact with the rail head R_y = 25.4mm. *Table 2* shows the mean and max contact stresses for the tribometer and the comparative values with a proposed R_y of 6.35mm when configured with the maximum stable load possible of 88N (20lbf). These values are calculated assuming top of rail running for the tribometer.

Table 2 *Comparison of R_y = 25.4m and R_y = 6.35mm.*

Top of Rail Radius (mm)	Ry = 25.4mm		Ry = 6.35mm	
	Mean Contact Stress (GPa)	Max Contact Stress (GPa)	Mean Contact Stress (GPa)	Max Contact Stress (GPa)
190	0.39	0.58	0.68	1.02
254	0.38	0.58	0.68	1.02
305	0.38	0.57	0.67	1.02

Although the mean and max contact stresses for R_y = 6.35mm are still less than what is experienced in the field, they are almost double that of the 25.4mm wheel. It is also known in advance that the rail conditions at the field measurement sites are quite worn which will result in a variation from those presented in *Table 1*. To achieve directly comparative results to the worst case, field results would require an R_y = 6.35mm and load of nearly 300N, which is not achievable with the current device and difficult to achieve in practice with any hand operated device.

2.2. Field measurements

The overall project focused on measurements of 5 track locations for temperature, friction, rail profiles and surface roughness. The sites were selected based on analysis of driver log/GPS synchronised Longitudinal Train Simulation for the rail corridor with each site selected for its different relationship between curvature, traction and lateral operation.

For this paper, only one site shall be considered and this is site 5. *Figure 2* shows the 2 points where friction is measured on the rail head. The high and low rail profiles are measured using the NextSense Calipri C40 [3]. The Calipri is a non-contact laser measurement device capable of comparing the measured profile to the cross section design standard and provide percentage of wear.

The measured profiles can also be exported as Cartesian coordinates.

The temperature measurement system comprises sensors installed on the head, web and foot on the outside of the rail for both the left and right rail as shown in *Figure 2*. For redundancy, each location contains 2 sensors that are spliced across two separate loggers.

One of the key requirements to installing on a live network is that the sensor system can be easily installed and removed and does not cause electrical issues at track circuited sites. To achieve this, a magnetically attached sensor "shell" was developed with a thermally conductive, but electrically insulated, contact pad. The sensor shell is shown in *Figure 1*.

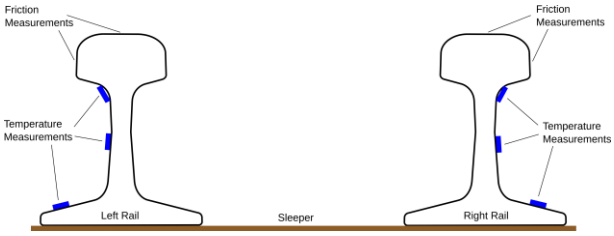

Figure 1 *Friction and temperature measurement locations.*

The LM35 temperature sensors are the TO-220 package variety and are attached internally within the shell to a short metal bar that also houses the magnet. As these components all form a thermally conductive pathway, the side effect is a significant increase in the time constant (τ) of the temperature measurement response.

Laboratory experimentation shows that τ for the LM35 with conductive paste is approximately 2s, and with thermally conductive silicon adhesive, 2.5 to 4s (dependent on quantity of paste used) and for the field system configuration approximately 85s. This response must be taken into account when comparing model results with field recorded data and translating into the field results space can be done with a first order filter. The filter cut-off frequency for a first order system is defined in (1):

$$f_{cutoff} = \frac{1}{2\pi\tau} \qquad (1)$$

For τ of 85s, this results in a cut-off frequency of 1.87 x 10^{-3}Hz. This can be used in Octave or Matlab to calculate the *a* and *b* coefficients for a 1 Pole Butterworth filter. Other general parameters describing the collection of field temperature results are shown in *Table 3*.

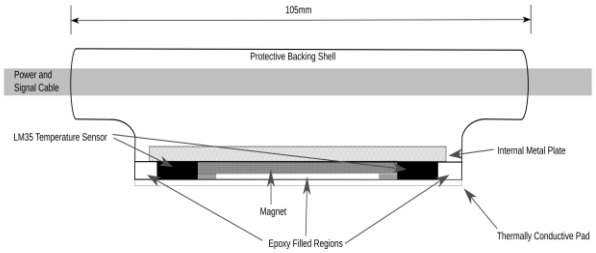

Figure 2 *Sensor shell that houses the LM35 temperature sensors.*

Table 3 *Temperature measurement system parameters.*

Field Test Parameter	Unit	Value/range
Oversampling data acquisition rate	KHz	10
Recording Rate	S/s	1
Temperature Range	°C	0 to 85
Operating Time	Hrs	48
Sensor Types		Texas Instruments LM35
Sensor Precision	°C	< 0.1

2.3. Track

The specific parameters at the measurement site are a 240m radius curve of total length 435m, cant 15mm, and gradient of 1.51%. The instrumentation was installed just prior to the exit transition of the curve. The 5km of approach track and 2km of departure track is shown in *Figure 3*. It is important to observe the track both before and after the site as train control scenarios required there will influence the track temperature at the given location. For example, if a train auto-brake application is required before the site, all the wheels may be at a slightly elevated temperature due to tread braking.

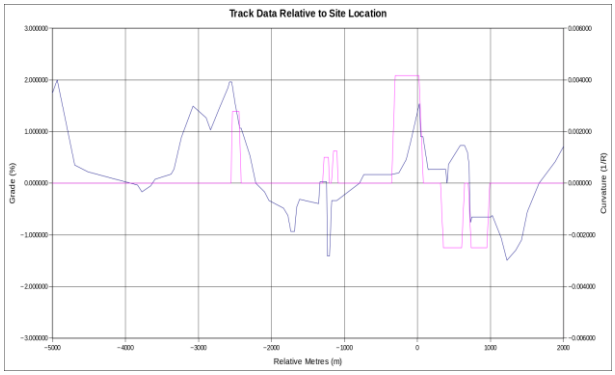

Figure 3 *Track data relative to the site location.*

2.4. Train operation

Two types of trains operate on the standard gauge track network where the testing was conducted, a fuel train and an iron ore train. Due to its short length of approximately 20-30 cars, the fuel train is not being considered for this paper and the focus shall instead be on the iron ore train. The standard consist for this train is 2 x Locomotives (G43ACi, GT46C), 106 x wagons, 2 x Locomotives (C43ACi/C43ACi) and 54 x wagons. The wagons are all 23TAL/4 axle vehicles. The performance characteristics for the locomotives are shown in *Table 4* and the wagon parameters are set out in
Table 5.

Table 4 *Locomotive Characteristics.*

Parameter	GT46C	C43ACi
Length (m)	20.836	22.00
Weight (Kg)	133500	134000
Max Starting TE (kN)	620	535
Continuous TE	408	453
Max DB	270	310

Table 5 *Iron ore wagon parameters.*

Parameter	Unit	Value
Gross Mass	Kg	14025
Tare mass	Kg	2925
Average Length	m	1792

Simulation of the train via longitudinal train dynamics through the site region shows very differing tractive effort requirements from 25 to 200kN depending on the speed profile requirements. The performance of the train can vary on a daily basis due to temporary speed restrictions, degradation in train performance due to locomotive failures and overloading of the wagons.

2.5. Rail heat transfer

Initial laboratory results have shown that the majority of heat transfer in the rail is due to effects in the wheel-rail contact area, as opposed to bending or sleeper-rail friction. These wheel-rail components can be split into frictional heating and conduction through the contact patch. A brief description of the single wheel roller rig used to perform the laboratory experiments is now provided. The rig has horizontal and vertical actuators with vertical actuation weight up to 55t @ 1Hz and horizontal longitudinal motion of +/-100m @ 1Hz. A thorough description of the rig is provided by Boyd et al [4].

The laboratory temperature measurements were conducted with an array of 12 LM35 temperature sensors attached to the rail using thermally conductive silicone adhesive and spaced equally between the head and foot at four locations.

To isolate any conduction between wheel and rail, the initial test was performed at temperature equilibrium and a 1.5°C increase in head temperature and resultant 0.5°C increase in foot temperature was observed after 500 horizontal cycles with a constant normal load of 20t applied. In contrast, the bending test, where the actuator roles were reversed, resulting in oscillatory vertical motion between 1 to 25t and no horizontal movement, showed < 0.1°C variation in temperature throughout the rail. Given the near pure elastic nature of rail bending within normal operating conditions, this is a somewhat expected result. At this stage no testing has been conducted to measure conduction through the contact patch; this is the focus of future research.

With these results in mind, the development of a rail heat transfer modelling approach will primarily be driven by a surface temperature model that serves as the boundary condition at the rail head. A recent review by Srivastava et al [5] captures the work in this area and, with respect to analytical solutions, can be broken down into two approaches.

The first approach attempts to capture the microscopic effects of flash temperature calculation by modelling asperities and calculating the temperature due to plastic deformation at the tips of these asperities [6~8]. This, along with other material properties and interfacial layer modelling, can be used to derive expected friction conditions and resultant flash temperature.

The second approach comes more from the macroscopic viewpoint and assumes there exists information about the friction conditions at the location. The friction, along with contact stress and creepage parameters, are then used directly to calculate temperature [9,10]. The additional source of heat due to conduction is also accounted for in the modelling.

With respect to the comparison of measured track temperatures, the latter modelling approach is likely to be the best solution given the variability of track in the field. Comparisons can only be made on a macroscopic scale with assumptions and some local track knowledge such as friction conditions required. The measurement of friction in itself incorporates the effect of surface roughness to some extent.

The proposed surface temperature model that shall be used as the wheel-rail boundary condition of the rail heat transfer model was first developed by Spiryagin et al [11] and is shown in (2) below.

$$T = \frac{2q\sqrt{t}}{\sqrt{\lambda c \rho}} \qquad (2)$$

where q is the heat input at the surface of the contact, t is the contact time between wheel and rail, λ is the thermal conductivity, c the specific heat and ρ is the material density. The next phase of work will model the wheel-rail contact using CONTACT with measured wheel/rail profiles and friction interpolated from the top of rail to flange. The CONTACT output parameters must be extracted at a per element context as inputs to the model.

The rail heat transfer model is a time and distance series temperature prediction for a given x position on the track. From the viewpoint of the proposed problem, this will be at the site where the temperature measurement occurred. The influence of each wheel at the track point is a function of the train speed at that time, and the wheel spacing for the respective passing vehicle. In between the passage of wheels, the surface of the rail is subject to a cooling effect due to convection and radiation components. Heat transfer vertically downward through the rail will also be subject to convection and radiation through the side of the rail. All of these effects are shown in *Figure 4*.

The heat equation with losses due to convection is shown in (3). This equation assumes the surrounding temperature is the reference temperature centred at zero and heat is lost through all surfaces.

$$\frac{\partial u}{\partial t} = \kappa \frac{\partial^2 u}{\partial x^2} - \nu u \qquad (3)$$

where $\kappa = \frac{\lambda}{c\rho}$ and $\nu = \frac{Hp}{c\rho\omega}$.

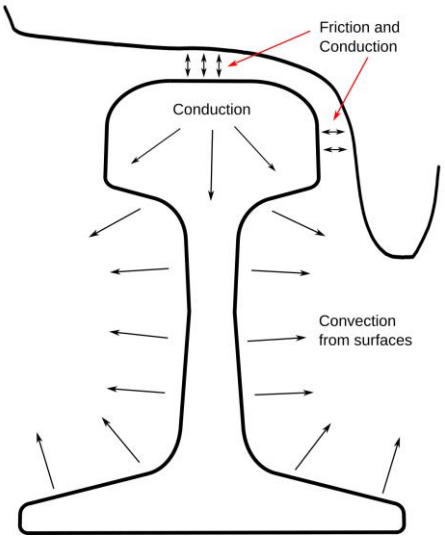

Figure 4 *Rail heat transfer components.*

The proposed initial approximation for vertical heat transfer is a finite rod described by $0 < x < l$ with cross section ω and perimeter p. The initial temperature condition is $f(x)$ with no flow of heat at x = 0 and x = l at temperature $\phi(t)$.

$$u = \frac{2}{l}\sum_{n=0}^{\infty} e^{-\nu t-\kappa\beta_n^2 t}\cos\beta_n x\{\alpha+\varphi\}$$

$$\alpha = \kappa\beta_n(-1)^n\int_0^t e^{(\kappa\beta_n^2+\nu)\eta}\phi(\eta)\,d\eta \qquad (4)$$

$$\varphi = \int_0^l f(x')\cos\beta_n x'\,dx'$$

where $\beta_n = (2n+1)\frac{\pi}{2l}$ and l is the length of the rod. The coordinate system convention in this case is x = 0 at the base of the rail and x = l at the top most surface of the head. In the case of the evaluated site, the rail is at equilibrium with its surrounds before the temperature measurement and, therefore, $f(x) = 0$ which results in $\varphi = 0$ and simplifies the analytical solution by dropping its last term.

A brief note on the calculation of H, the convective heat transfer coefficient. The calculation of this coefficient is typically done empirically with an equation like the one shown in (5). To reduce the potential sources of error for the comparison the temperature, measurement selected for further analysis later in the paper is at early morning before sunrise with calm conditions. These were measured by a nearby weather station. With v = 0m/s, H = 10.45.

$$H = 10.45 - v + 10\sqrt{v} \qquad (5)$$

While it is expected that the homogenous finite rod approximation will not be sufficient over the entire height of the rail, it should bear a reasonable approximation at the head and top of web. It is expected to provide a reasonable initial indication of the performance of the wheel-rail boundary conditions. Further development is required with the proposed next step using the differential equation for a finite non-homogenous rod as shown in (6) where ω and p are a function of displacement. This is highly dependent on a suitable function in x describing the surface of the rail from head to foot. Beyond this, a further approach may be a lumped capacitance model.

$$\frac{\partial u}{\partial t} = \frac{\kappa}{\omega}\frac{\partial}{\partial x}\left(\omega\frac{\partial u}{\partial x}\right) - \frac{H}{\rho c}\cdot\frac{p}{\omega}(v - v_0) \qquad (6)$$

2.6. Inverse model

An interesting approach that shall be considered for the remainder of the paper is to deduce the surface temperature through an inverse approach of using a measured rail temperature at a location some distance from the surface. In this scenario we use the temperature measurement at *u(x, t)* to solve the boundary condition at $x = l$ and at time t.

To demonstrate the idea it is assumed the boundary condition is steady state. For the temperature measurement system employed, this assumption is quite reasonable given τ = 85s, as any transient temperatures will be lost through the filter. However, this does still assume that the contribution of every wheel-rail contact is equivalent. With this in mind, the boundary condition at x = l can be described as $\phi(t) = \gamma$ and the solution in (4) once computing the definite integral becomes:

$$u = \frac{2}{l}\sum_{n=0}^{\infty} e^{-\nu t-\kappa\beta_n^2 t}\cos\beta_n x\left\{\gamma\frac{e^{(\kappa\beta_n^2+\nu)t}-1}{(\kappa\beta_n^2+\nu)}\right\} \qquad (7)$$

To find a solution for γ, a binary search of temperature solutions is conducted that match as closely as possible the temperatures measured at the head and web of the rail. An example solution to the binary search for the steady state surface running temperature is shown in the results.

3. Results

The results in this section show the field installation for the temperature measurement system and site recorded rail profiles in Figures 5 and 6 respectively. A measured locomotive profile that will be used in future surface temperature modelling is shown in Figure 7 and is included for completeness.

Figure 8 shows a comparison between the measured temperature at the three locations, rail, head and web, with the inverse model using a steady state temperature for the high rail of 17°C and for the low rail, 27°C. The time series of the graphs are currently limited to the approximate train passage time of 200s, assuming 30kph average speed. The reason for this will be described further in the discussion. For the comparison in Figure 8, the inverse model results are filtered according to the frequency cut-off of 1.87 x 10^{-3}Hz as described by the sensors response, τ = 85s.

Figure 5 *Temperature sensors installed in the field.*

Figure 7 *Locomotive worn wheel profile.*

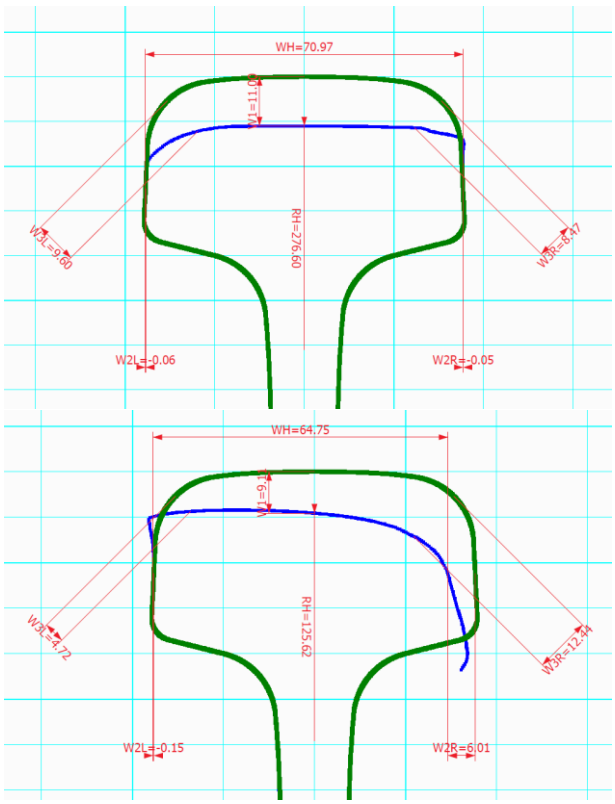

Figure 6 *High (top) and Low (bottom) rail profiles measured at the site with NextSense Calipri.*

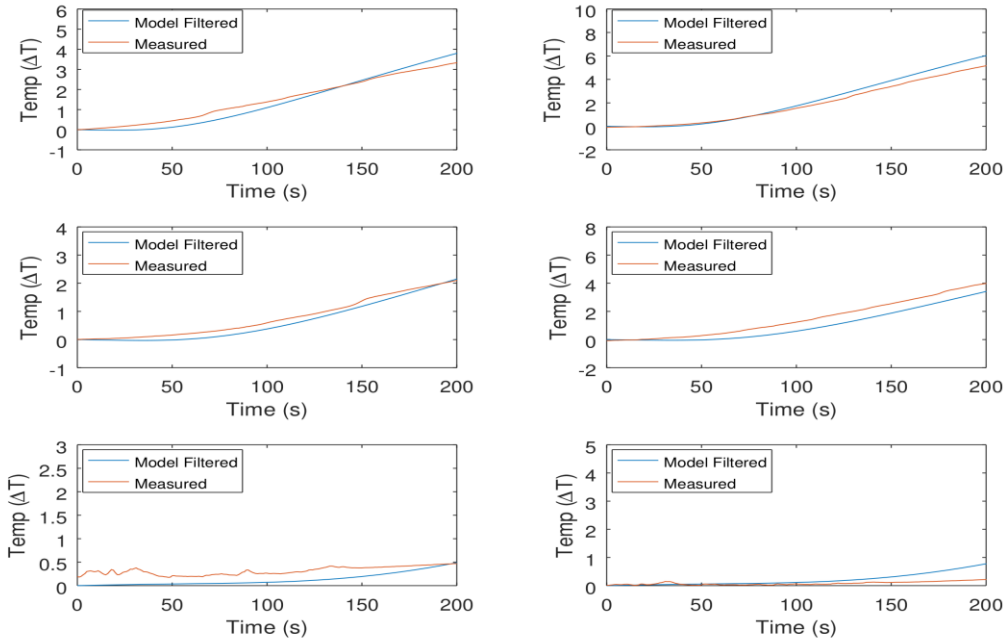

Figure 6 *Graphs in column major format - High Rail Head, Low Rail Head, High Rail Web, Low Rail Web, High Rail Foot, Low Rail Foot.*

4. Discussion

The steady state surface temperature derived through a binary search of boundary condition temperature has shown reasonable approximation for the head and web during the train passage phase. The foot on the other hand, due to its significant variation in characteristics from the homogenous model does not correlate well. In the real rail cross-section, the ratio of surface area to volume is much higher in the foot allowing for a greater quantity of heat to be lost due to convection and this

effect is clearly seen in the bottom right graph of *Figure 6*.

While there is correlation in the upper sections of the rail, it certainly does not discount the possibility of multiple solutions to this problem, especially given the response of the sensors used. Therefore, making any firm judgements at this stage of development should be taken with caution.

Further understanding and improvements to an inverse modelling approach will be gleaned upon the introduction of the bulk cooling that occurs when the train has passed. Currently the modelling can only assume the steady state heating aspect of the train passage. When the train has passed, $\phi(t) = \gamma$ no longer holds and the boundary condition must be allowed to cool. This will require a piece-wise evaluation of the rail with the boundary condition cooling captured by the usual Newtonian bulk cooling function, $\phi(t) = e^{-kt}$.

As mentioned earlier in the paper, approach and departure track characteristics and train control requirements will affect the site temperature measurements. In the case of the approach track, this may affect the temperature of the wheels and the conduction through the contact patch. This remains the greatest unknown with any simulation approach and respective comparison against measured track data.

The next phase of work involves modelling and simulation of surface running characteristics based on further development of equation (2) and utilising the field program data presented in the results. This will be conducted using a whole of train co-simulation approach using Gensys and the Centre for Railway Engineering Longitudinal Train Simulation software. A model capturing the average running temperature of the wheel will also be required.

With regards to conduction of heat into the foot region, it can be seen in *Figure 6* that the measured data does show some heat flow into the foot area. Given the response of the sensors, the actual temperature of the foot during the train passage will be greater than this.

5. Conclusion

This paper has presented the results for a field test program acquiring friction for top of rail and flange, surface roughness and temperature measurement at the head/web/foot. Rail heat transfer was discussed with a focus on the surface temperature boundary condition. An inverse model utilising measured temperature data showed correlation in the head and web for a steady state temperature input at the surface of the rail, with further work to explore the mathematical modelling of the surface temperature and resultant transfer in the rail.

TRACK FRIENDLINESS OF AN INNOVATIVE FREIGHT BOGIE

Andrea Bracciali*, Gianluca Megna

Dipartimento di Ingegneria Industriale, Università di Firenze, via Santa Marta 3, 50139 Firenze, Italy

* E-mail: andrea.bracciali@unifi.it

Abstract: The design of freight running gear has always been a rather steady field. Due to the very demanding tasks as the high ratio between laden and tare weight (up to 5:1), the low cost production and the necessity of easy maintenance procedures, many potential innovations have never found application in the freight wagon market. The design of the Y25 bogie does not allow speed higher than 100 km/h in laden conditions and adequate track friendliness. The paper introduces a new concept of bogie for freight wagons, focusing the attention on the dynamic behaviour of the vehicle and its interaction with the track.

Keywords: freight bogie, track friendliness, inboard frame bogies, railhead damage, Tgamma, Variable Usage Charge.

1. Introduction

The current practice for freight operation follows two main directions: trains with high axle-load (30÷35 t/axle) that run at low speed (60 km/h) and trains with lower axle-load (20÷25 t/axle) running at higher speed (100÷120 km/h).

The first case is related to "heavy haul" operations that are very common in countries where very long distances have to be covered especially to carry raw materials. For this kind of operation, lines are almost fully dedicated to the operation of these heavy trains, and therefore a "homogeneous operation" traffic is generated. Dedicated lines are nevertheless not a very common option for transportation of generic goods. In this case, freight trains have to run on the same lines of conventional passenger trains, generating a mixed and "heterogeneous operations" traffic.

To allow freight trains running in between passenger trains, it is therefore requested a higher maximum speed and a better track friendliness. The current design of freight wagons is not able to guarantee a track friendliness comparable to modern passenger vehicles, whose running dynamics is in continuous improvement, noticeably reducing track maintenance costs.

It is commonly agreed that it is nearly impossible to increase the freight transport efficiency with the current solutions used for freight bogies [1]. The most common bogie for freight wagon in Europe, the Y25 bogie that was released in 1967, does not allow a safe running at speeds over 120 km/h. The maximum axle load is currently bound to increase from 22.5 t/axle to 25 t/axle but the original Y25 concept was never changed and the limitations of this bogie are now evident.

In this paper, an innovative bogie architecture for freight wagons is introduced. The new architecture is designed to allow a straightforward replacement of the Y25 bogie, while the main drawbacks of the current design are avoided introducing new concepts for the primary suspension, the friction damping and the bogie frame. The bogie is designed with the aim to be stable in tangent track at least at a speed of 140 km/h and to increase the track friendliness in curved track. Comparison with Y25 and other freight bogies are presented in terms of $T\gamma$ (or *Tgamma*, i.e. "wear number") and vertical forces at the maximum speed. Finally, an evaluation of the Variable Usage Charge is shown, in order to estimate the track access charge according to UK specifications.

2. Description of an innovative freight bogie

While developing a new bogie for freight vehicles the designer has to take into account a number of demanding and often contradictory constraints, from the very high ratio between empty and laden axle load to running safety on twisted track and to the structural strength of the bogie frame.

However, recent innovations in bogie frames for passenger vehicles may be implemented also in freight bogie technology without increasing the production and maintenance costs, e.g. inboard bearings bogies (or inside frame bogies). Even if an inboard bearings bogie for freight wagons has been already proposed in the past, today this technology is strongly consolidated and it can be used without major problems. The main advantage of this kind of bogie is the lower mass and the reduction of the yaw moment of inertia. When applied to passenger bogies, this brings in many cases to a lower wheelbase increasing the track friendliness of the vehicle.

The 1.8 m wheelbase of Y25 is sufficiently low, but the mass is mainly concentrated far from the bogie centre (i.e. in the axleboxes), raising up the moment of inertia.

Figure 1 shows how the proposed innovative bogie, with inside frame architecture, can reduce the overall dimensions with respect to a conventional Y25 bogie introducing interesting new features like:

- the *AIR Wheelset* technology [2] or conventional inboard bearings wheelsets;
- wheel web mounted brake discs;

- horizontal coil springs with progressive stiffness (two springs *per bogie*).

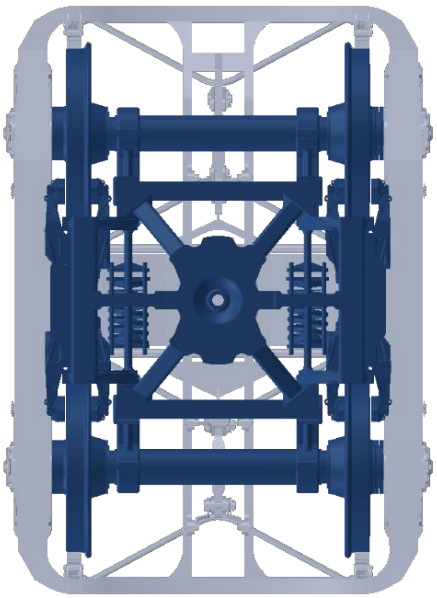

Figure 1 *Schematic representation of the overall dimensions of an Y25Ls(s) bogie (grey), compared with the innovative inside frame bogie (blue).*

The bogie is designed with a conventional centre bowl and two side bearers, in order to guarantee a straightforward replacement on standard wagons. As shown in Figure 2, the main difference is the primary suspension arrangement, where one progressive coil spring is used to replace the eight springs used on each side of an Y25 bogie.

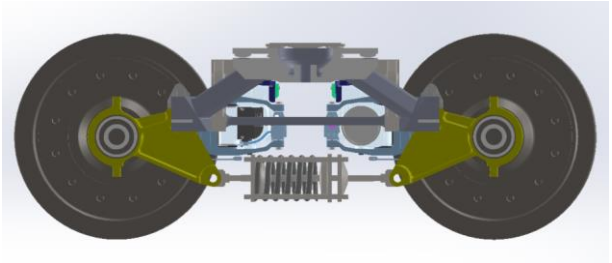

Figure 2 *Primary suspension arrangement of the modified bogie from an inside view. One progressive coil spring is used on each side.*

The primary suspension acts in longitudinal direction as already done in other kinds of bogies, with the difference that each spring connects the two arms on one side and therefore the two wheelsets. Load dependent friction damping is provided by the cylindrical pin connection between the arm and the frame.

The final characteristics of the bogie are described in Table 1 and compared with a conventional Y25 bogie. It is worth to highlight how the mass is reduced even if brake disks are introduced.

Table 1 *Main characteristics of the two bogies.*

	New bogie	Y25	Difference
M [kg]	4058	4750	-15%
Ixx [kgm^2]	3001	4667	-36%
Iyy [kgm^2]	3853	5610	-31%
Izz [kgm^2]	4564	6631	-31%

3. Vehicle and track dynamic models

A multibody model was developed with the VI-Rail software package [3] to investigate the dynamic behaviour of the new bogie. Both empty and laden wagon conditions were evaluated, resulting in the vehicle characteristics described in Table 2. The model represents a Sgnss 60' intermodal wagon, generally equipped with Y25Ls(s) bogies.

Table 2 *Main data used for the models*

	Empty	Laden
Axle load [t]	4.25	22.5
Total mass [kg]	17000	90000
Wheelbase $2a^+$ [m]	1.8	
Vehicle pitch $2a^*$ [m]	14.2	

The bogie model includes a flexible body, representing the bogie frame, whose flexibility is central to guarantee the needed vertical force equalization over twisted track. In fact, due to the primary suspension arrangement and the low static load when empty, the spring flexibility is not sufficient to obtain $\Delta Q/Q$ values lower than 0.6. The model was tuned through *FEM* simulations, resulting in a total wheel unloading of $\Delta Q/Q$=0.51 when considering both bogie and carbody twists.

The friction damping on the centre bowl and the side bearers was set to comply with the requirements of [4], where the yaw resistance of the bogie (*X factor*) shall be lower than 0.16 for the empty wagon and 0.1 for the laden wagon. The *X factor* is calculated as:

$$X = \frac{M_z}{2a^+ * P_0}$$

where P_0 is the nominal axle load in kN.

The total value of the yaw moment resistance M_z is shown in Figure 3 for both empty and laden condition, resulting in an *X factor* equal to 0.13 and 0.06 respectively.

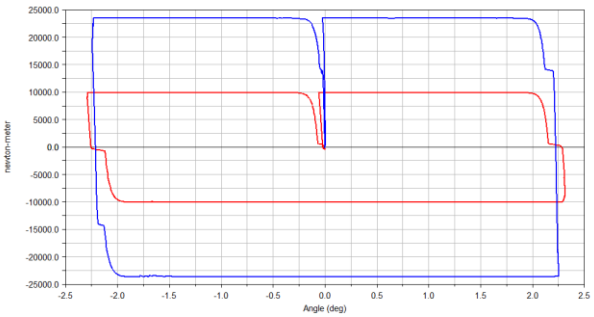

Figure 3 *Yaw resistance vs. the yaw angle of the bogie for an empty wagon (red) and for a laden wagon (blue).*

All running dynamics simulations were performed with S1002 wheel profile, coupled with 60E1 rail profile inclined of 1:40, in order to avoid double contact and to generate a medium to high value of equivalent conicity (γ_{eq}=0.17 at 3 mm of lateral displacement). The wheel-rail friction coefficient was set to f=0.4 in all simulations.

Track flexibility was considered according to [5] and lateral and vertical irregularities (i.e. alignment and longitudinal level defects) were added to the track geometry. Two different kind of irregularities are used:

- irregularities sampled from measurements on an Italian regional line, where running dynamics homologations tests are usually performed;
- *ERRI High level* irregularities generated according to [11].

The PSD function of these irregularities are plotted in Figure 4. The first kind is used for running dynamic simulations (i.e. according to the requirements of [4]), while the second kind is used to investigate the response of the bogie in terms of railhead damage.

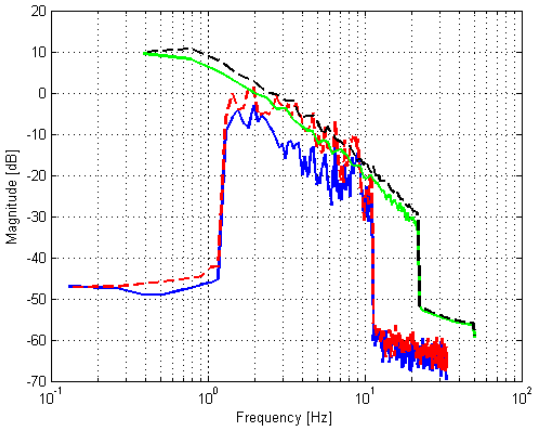

Figure 4 *PSD distribution of lateral (alignment, solid blue) and vertical (longitudinal level, dashed red) for measured defects and the corresponding ERRI "High Level" irregularities lateral (solid green) and vertical (dashed black).*

4. Dynamic behaviour of the bogie

4.1. Lateral dynamics

The frequency response of the vehicle was evaluated by simulations on straight track at a speed of 148 km/h. The frequency of lateral wheel forces has then been calculated for both empty and laden conditions (Figure 5).

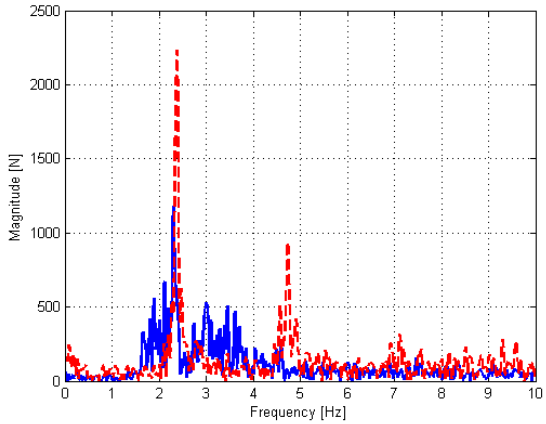

Figure 5 *Lateral frequency response for empty (dashed red) and laden (solid blue) conditions*

The main lateral frequency of the vehicle is about f_0= 2.3 Hz. This value is used to investigate the stability of the vehicle according to [4], where the maximum *RMS* value of the sum of guiding forces ΣY on left and right wheel (filtered in the range of the critical frequency $f_0 \pm 2$ Hz) is compared with half of the Prud'Homme limit, i.e.

$$\Sigma Y_{lim} = k_1(10 + \frac{P_0}{3})/2$$

where k_1=0.85 for freight vehicles and P_0 [kN] is the axle load. The stability assessment values are therefore calculated and shown in Table 3.

Table 3 *Assessment values for stability evaluation*

	Empty	**Laden**
Axle load [kN]	41.69	220.73
Limit value [kN]	10.16	35.52

The maximum *RMS* value over runs of 300 m of the last wheelset of the wagon model is plotted in Figure 6 as the percentage of the limit value vs. the running speed for both loading conditions.

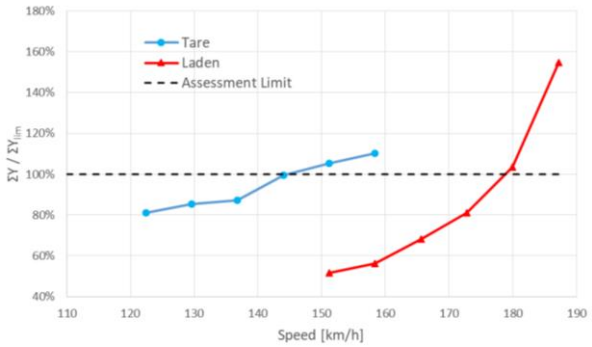

Figure 6 *Stability assessment in tare condition and laden condition.*

The limit value is reached for a speed of about 145 km/h for the empty wagon and for a speed of 180 km/h for the laden wagon. However, for the laden wagon, a maximum speed of 160 km/h is considered sufficient to perform the evaluations that are the object of this paper.

4.2. Vertical dynamics

The frequency spectrum of vertical wheel force is plotted in Figure 7. A bad vertical dynamics of the bogie is one of the main causes of railhead damage accumulation.

Without considering singular track defects like joints or welding, which are responsible of high frequency impact forces where unsprung masses and track stiffness are dominant, the characteristic of the primary suspension is a relevant factor for random distributed vertical irregularities [6].

One of the main advantages introduced by the new suspension arrangements is a better response of the bogie to random vertical irregularities. This is particularly true for such irregularities with wavelengths lower than the bogie wheelbase, for example short pitch corrugation, due to the lower stiffness (half of the nominal) "seen" during the passage over the defect. However, this kind of irregularities have to be considered separately from the longer irregularities which are taken into account in this paper. Therefore, a future paper will specifically describe in detail the response of the suspension "short-circuit effect" on short irregularities compared to a conventional suspension.

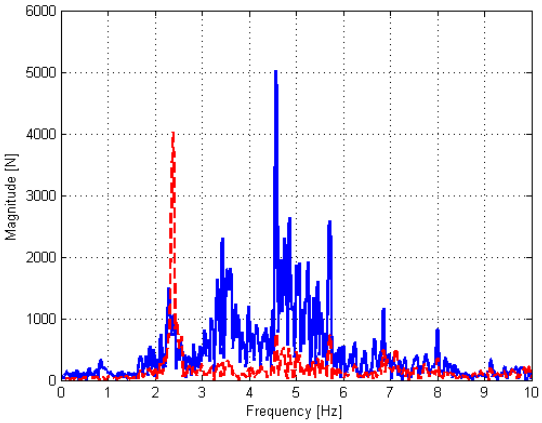

Figure 7 *Vertical frequency response for empty (dashed red) and laden (solid blue) conditions*

In this paper a more general evaluation of the vertical dynamics is described. A part of the *Track Access Charge* (*TAC*) for freight vehicle in *UK* is due to the vertical wheel dynamic force produced by the wagon. In particular, the parameter used to evaluate the performances of a bogie is the *Ride Force Count* (*RFC*). The *RFC* is a metric of the vertical dynamic force which assesses the track friendliness of freight bogies and their suspension system. From this index a *Suspension Discount Factor* is then calculated which scales the final *Variable Usage Charge* (*VUC*) paid by the operator. The *Discount Factor* is defined as a function of *RFC* by a curve (or discrete bands).

RFC values are calculated by means of dynamic simulations on specific track, named *Track for Banding* (*TfB*) and evaluating the correlation between the standard deviation of the vertical track irregularities and the standard deviation of the dynamic vertical force, calculated for 200 m-long track sections. By means of a linear interpolation of the data, it is possible to derive the *Ride Force Coefficient* (gradient of the trend line in kN/mm) and the *Ride Force Constant* (intersection of the trend line with the *y-axis*). Then, these parameters supply the *Suspension Discount Factor* (SDF) evaluating the distribution of the standard deviation of the vertical irregularities. An explanation of this process can be found in [7].

This method was therefore chosen to evaluate the vertical performance of the new primary suspension arrangement. To compare the results with those from other freight wagons, data available from [8] and [9] were used, in which a four axle *Y-series* flat 60' wagon represents the reference for another innovative freight bogie developed for the six-axle *Spectrum* vehicle project. To permit a fair comparison, the vertical forces (low pass filtered at 20 Hz) are initially normalized by the axle load. The simulation speed is set to 120 km/h, 145 km/h, 160 km/h. The axle load of the reference vehicles is summarized in Table 4.

Table 4 *Axle load of reference vehicles*

Vehicle	Tare axle load [t]	Laden axle load [t]
Y-series reference	5.75	22.25
Spectrum reference	5.31	15.8

It is worth to highlight that the *TfB* used for the *RFC* calculation has a specific track irregularities distribution, which was not available to the authors. However, the ERRI defects, which are normally used to model track irregularities in multibody simulations, show higher values of standard deviations compared to the measured ones. This can be explained (see Figure 4) by considering that the measured values are filtered in the *D1* wavelength range (3÷25 m) according to [4] and [10], while the others are numerically synthesized for a broader wavelength range (2÷100 m). Filtering for example the *ERRI High Level* defect in the *D1* range, it is possible to see how the distribution shifts to lower values of standard deviation. This is shown in Figure 9, where a track divided in 100 m long sections was simulated. In these conditions the original high level defects distribution is very close to *TfB* and therefore it can be used for the *RFC* calculations.

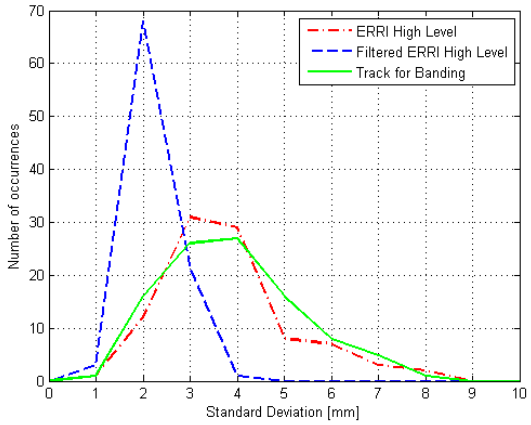

Figure 8 *Number of occurrences of the standard deviation of vertical ERRI High Level defects as generated (red), filtered in the D1 wavelength (blue) and the Track for Banding distribution (green).*

The evaluation is shown in Figure 10. While the *Ride Force Coefficient* and the *Ride Force Constant* will be used with the aim to perform *VUC* calculation, the most relevant and directly usable parameter is the mean value over the track sections. Table 5 shows the comparison between the vehicles.

Table 5 *Dynamic vertical force comparison between bogies*

Vehicle		Mean value (tare)	Mean value (laden)
Y-series reference (120 km/h)		0.238	0.102
New bogie	**120 km/h**	0.127	0.052
	145 km/h	0.162	0.072
	160 km/h	-	0.085
Spectrum reference (160 km/h)		0.148	0.083

The results show that the mean dynamic vertical force *per unit of axle load* are low for the new bogie even at high speeds. At the maximum speed, the values are only slightly higher than those of the Spectrum vehicle.

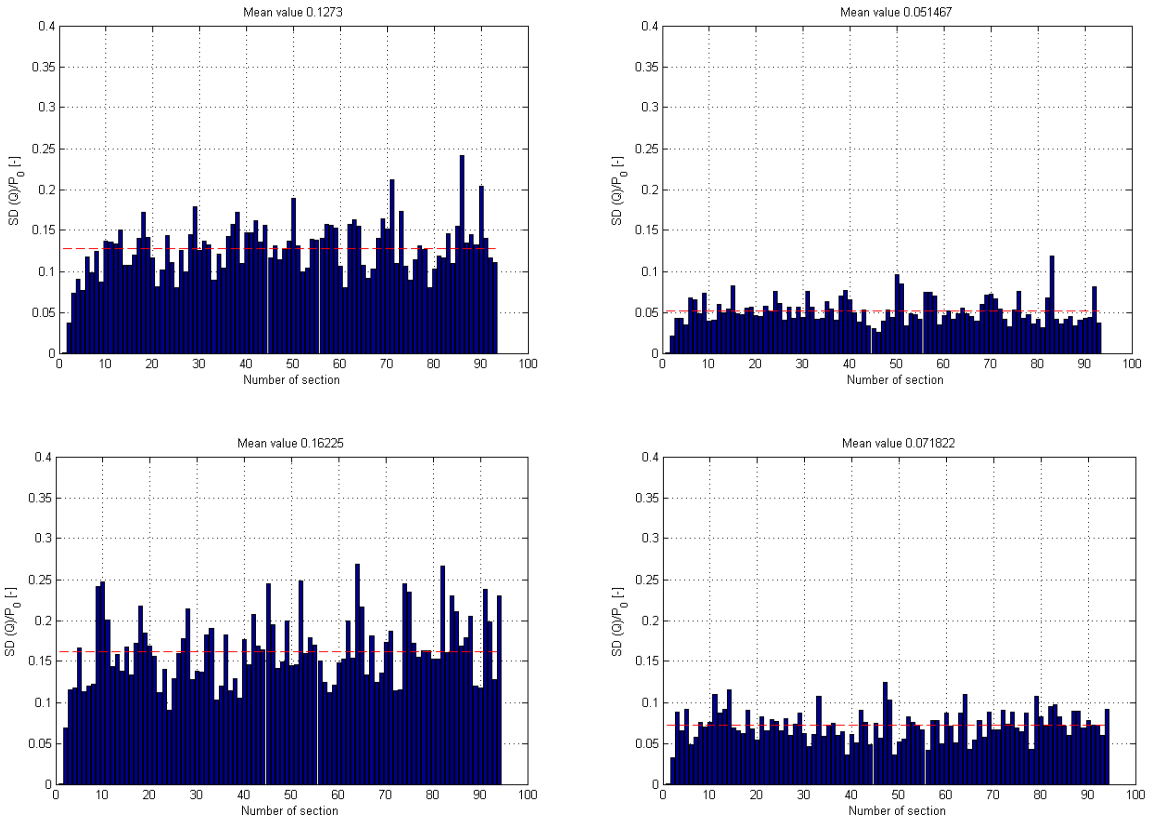

Figure 9 *Standard deviation of the vertical dynamic force over 100 m long track sections for the empty wagon (left) and for the laden wagon (right) at the speed of 120 km/h (above) and of 145 km/h (below). Dashed red line represent mean values.*

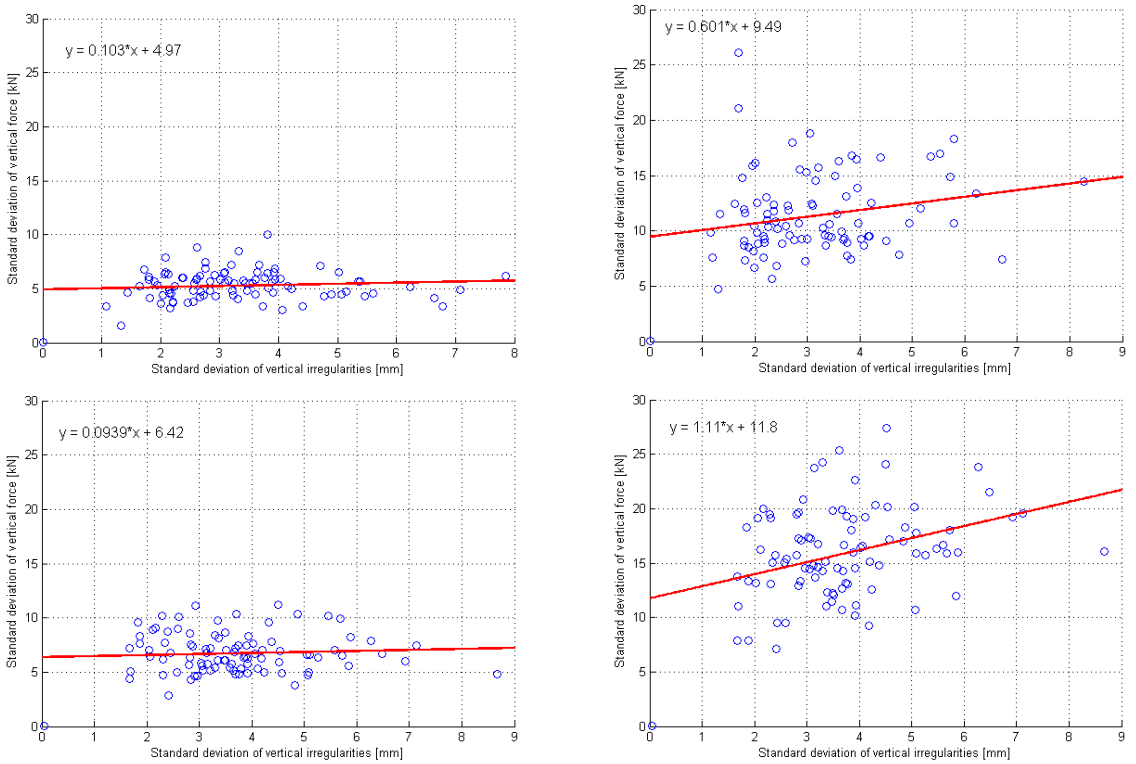

Figure 10 *Standard deviation of the vertical dynamic force over 100 m long track sections for the empty wagon (left) and for the laden wagon (right) plotted against the standard deviation of vertical irregularities at the speed of 120 km/h (above) and of 145 km/h (below). Red lines are the best fit linear regressions.*

With the aim to perform a *VUC* calculation for the freight wagons, the suspension discount factor was evaluated. This value is obtained separately for the tare and laden conditions from the RFC value, obtained as

$$RFC = \sum_{i=1}^{n} (SD(i) * P1 + P2) * N(i)$$

where *SD* is the standard deviation class (1 mm each) of vertical irregularities, *P*1 is the Ride Force Coefficient [kN/mm], *P*2 is the Ride Force Constant [kN] and *N* is the number of occurrences for the *i-th* class of standard deviation.

The results in terms of *Suspension Discount Factor* are shown in Table 6 and Table 7. The values are derived from seven bands (from 0.858 to 1.098), where each band corresponds to a particular range of *RFC*, different for tare and laden conditions.

Table 6 *Suspension Discount Factor comparison in empty condition*

Vehicle		*RFC*	Band	Discount factor
Y-series reference		680-715	2	1.058
New bogie	120 km/h	489	6	0.898
	145 km/h	631	4	0.978
Spectrum reference		465-564	6	0.898

Table 7 *Suspension Discount Factor comparison in laden condition*

Vehicle		*RFC*	Band	Discount factor
Y-series reference		>1650	1	1.098
New bogie	120 km/h	1029	6	0.898
	145 km/h	1438	4	0.978
	160 km/h	1689	1	1.098
Spectrum reference		>1650	1	1.098

Even at *v*=145 km/h the new bogie remains in the bands for which the discount factor is *SDF*<1.

5. Steady state curving behaviour

5.1. T-gamma and Rail Surface Damage

The track friendliness of a vehicle, and therefore of a bogie, is often evaluated by using the $T\gamma$ value. The product of the tangential force *T* and the tangential creepage γ is a measure (in J/m) of the energy dissipated at the contact of each wheel and it can be used to assess both track friendliness and the steering ability of a bogie. The lower the $T\gamma$ is, the lower the damage introduced by the wheels to the rails is. In [15], this parameter was used to compare different kind of freight bogies considering their effect on rolling contact fatigue.

The importance of $T\gamma$ as a parameter to evaluate the track access charge of a vehicle is confirmed by its introduction in the track deterioration models ([12], [13]).

Figure 11 describes the relationship between $T\gamma$ and the damage introduced by an axle of the vehicle. In the evaluation, only $T\gamma$ from high rail is taken into account. The total rail surface damage (and the related maintenance cost) is therefore the result of the combination of the two damage rates, as explained in Table 8.

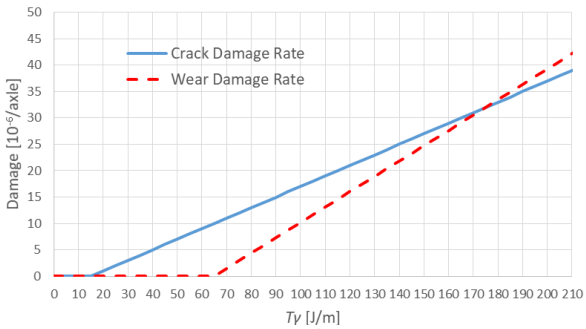

Figure 11 *Assumed damage rate for wear and crack growth as function of $T\gamma$ in the Rail Surface Damage (RSD) model.*

Table 8 *Range of $T\gamma$, effects on rail damage and fixing actions*

$T\gamma$ [J/m]	**Kind of damage**	**Action**
0-15	No damage	-
16-65	Crack growth	Rail grinding
66-175	Crack growth > Wear	Rail grinding (wear contributes to remove cracks)
>175	Crack growth < Wear	Rail renewal

In the *Variable Usage Charge*, 85% of the charge is assigned to track maintenance and renewal, 70% of which linked to vertical rail forces and 30% to horizontal rail forces. While the first is only a function of axle load, operating speed and unsprung mass, the second depends on the steady state curving behaviour of the vehicle and therefore on $T\gamma$. The model prescribes a number of simulations in curves of different radius to generate a $T\gamma$ table used to calculate the charge for freight or passenger operators.

An automatic tool was developed and included in VI-Rail that generates the fifteen curves (from 200 m to 10000 m) with the conditions described in [16]. The curving behaviour is evaluated with the following values of cant deficiency:

- h_d=40 mm for passenger vehicles;
- h_d=0 for freight vehicles with v_{max}= 100 km/h.

Therefore, freight vehicles simulations are performed at the equilibrium speed. Contact conditions shall be modelled considering the lubrication of the gauge face of the high rail (*f*=0.2).

A comparison between $T\gamma$ values from the external wheels (high rail) of the new bogie and the Spectrum bogie is shown in Figure 12. Values are related to the leading bogie whose $T\gamma$ values are greater than the trailing bogie.

Unfortunately, due to the lack of information, a direct comparison in laden conditions or with a wagon equipped with Y25 is not possible. An indirect comparison will be given in the next paragraph with the *VUC* calculations.

It is worth to highlight that at the moment of writing the tool was in the finalization stage and the wheel and rail profiles used for the new bogie are not the ones (measured semi-worn profiles) required in [16]. However, for low radius curves it is assumed that conicity has only a slight effect on the curving behaviour of a bogie.

The aforementioned assumption of h_d=0 is seen as particularly conservative as running faster is one of the main goals of freight operation. Higher cant deficiency values are therefore investigated.

Due to the roll angle of the wagon and the increase of the load of the external wheels, the suspension arrangement of the new bogie generates a better steering performance as it allows the wheelset to align radially when the vehicle runs with h_d>0 (a_{nc}>0). In such case the external suspension arms rotate more than the internal ones, generating an outer wheelbase greater than the internal one.

As the effect of cant deficiency was found not relevant for the empty vehicle, $T\gamma$ values and angle-of-attack for the laden condition only are shown in Figure 13 for h_d=0, 40, 92, 153 mm. These values correspond to a_{nc}=0, 0.26, 0.6 (typical for freight traffic) and 1.0 (typical for passenger traffic) m/s^2.

While for very low radius curves (200 m) the steering ability is quite poor in all the investigated situation, the effect of increasing cant deficiency is clearly beneficial for mild curve radii (R=600÷800 m) where at the equilibrium speed the transition between wheel and rail flange contact to tread contact occurs. This transition shifts towards lower curve radii when the cant deficiency increases, as the angle of attack tends to zero more rapidly.

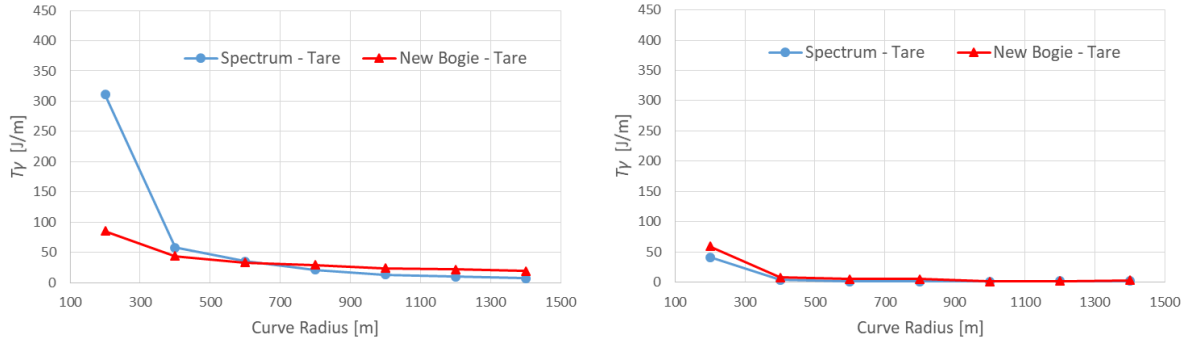

Figure 12 *Front wheelset (left) and rear wheelset (right) Tγ comparison of leading bogie of the spectrum vehicle (from [9]) with the new bogie (tare condition, zero cant deficiency).*

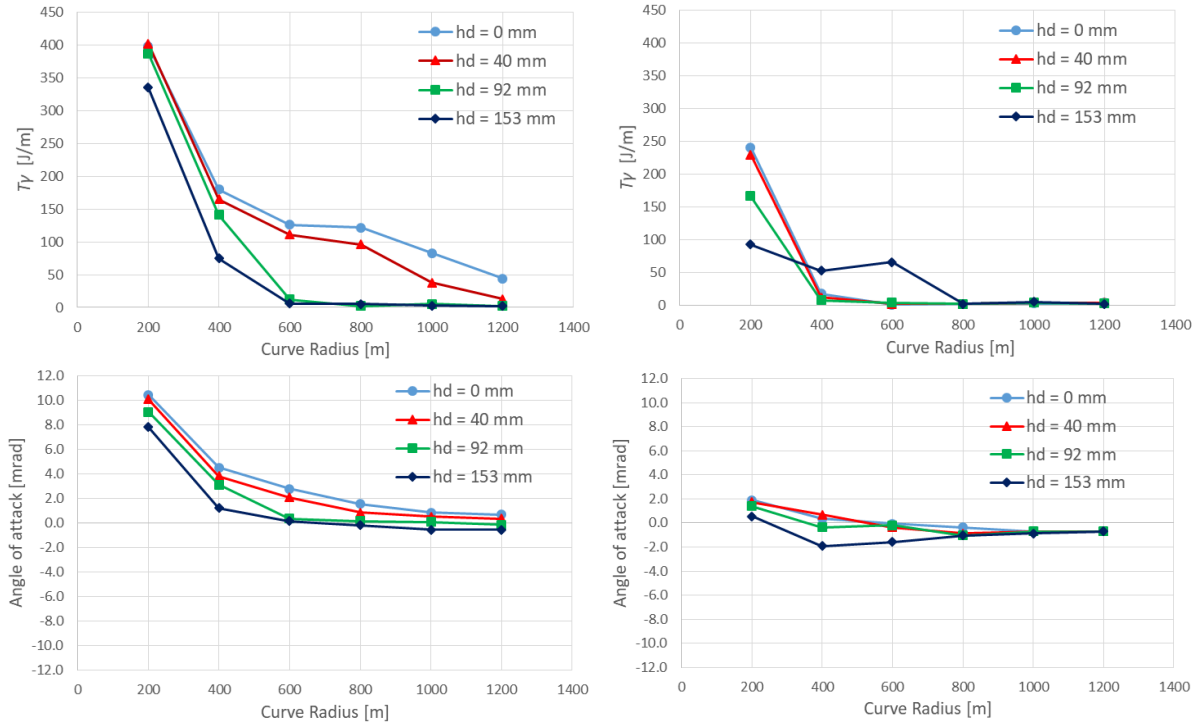

Figure 13 *Tγ (top) and angle of attack (bottom) of front axle (left) and rear axle (right) of the leading bogie for different curve radii and cant deficiency values for the new bogie in laden condition.*

5.2. Variable Usage Charge calculation

Wear damage (*WD*) and *crack damage* (*CD*) according to [14] were calculated from the steady state calculated $T\gamma$ values. Track maintenance and renewal costs (in £/km*axle) are then obtained by weighing *WD* and *CD* with the distribution of curves over the UK network as follows:

$C = 14500 * CD - 2000 * WD$ if $T\gamma < 175$ J/m
$C = 12500 * WD$ if $T\gamma > 175$ J/m

in which multipliers are derived through the parameters listed in Table 9. A spreadsheet that allows to perform the calculation procedure is freely available on the Network Rail website [16]. The other costs that generate the final charge, such as signalling costs (5%) and civil costs (10%), are not relevant for the scope of this paper.

Table 9 *Parameters used to correlate RSD to maintenance and renewal costs [14]*

Grinding cost	2000 £/km
Renewal cost	250000 £/km
Depth ground	0.5 mm/grinding cycle
Side wear limit	10 mm

Taking into account that for freight vehicle the previously calculated *Suspension Discount Factor* is applied, Table 10 shows the final charge in £/kGTM (kGTM=million gross tonne miles) for the empty case. Table 11 shows both £/kGTM and the charge of carrying payload (i.e. the cost for kNTM= million net tonne miles) for the laden case compared with the two reference wagons.

As shown in previous paragraph, h_d>0 has a considerable effect on the curving behaviour for the laden case. Therefore, the comparison is made for both the cases of 0 mm, 40 mm and 92 mm of cant deficiency.

$$VUC_{net} = VUC * \frac{Laden\ weigth}{Laden\ weigth - Tare\ weigth}$$

Table 10 *VUC comparison in empty condition*

Vehicle	*VUC* [£/kGTM]
Y-series reference	1.5242
New bogie	1.1046
Spectrum reference	1.3585

Table 11 *VUC comparison in laden condition*

Vehicle		*VUC* [£/kGTM]	VUC_{net} [£/kNTM]
Y-series reference		3.1745	4.275
New bogie	h_d=0	3.3072	4.077
	h_d=40 mm	3.0788	3.796
	h_d=92 mm	2.7366	3.374
Spectrum reference		2.3847	3.595

Charges at the equilibrium speed for the new bogie are comparable with Y25 bogies, lower in empty conditions (-27%) and slightly higher in laden condition (+4%).

While the reference vehicle had a tare of 23 t, the wagon equipped with new bogies has a tare of 17 t resulting in a lower charge *per unit of payload*.

The comparison with the Spectrum reference is nevertheless quite unfavourable especially for the laden wagon, although laden axle loads are very different (Spectrum = 15.8 t/axle, new bogie = 22.5 t/axle). This gap reduces when running at h_d=92 mm, resulting in a 20% *VUC* decrease, thanks to the radial aligning of the wheelsets.

6. Conclusions

In the last years, the necessity of improvements related to bogie technology for freight wagons is becoming a crucial topic inside railway transportation system. Greater operating speed and better track friendliness are needed to increase freight efficiency and the conventional architecture (Y25 for example) are not suitable for different services respect to the current ones.

In this paper a novel bogie architecture with inside frame, brake discs and progressive coil springs is presented and applied to a freight wagon. Multibody simulations were performed to investigate the dynamic behaviour of the vehicle. Critical speed over defective track were calculated showing that maximum speed over 140 km/h is reachable. At the maximum speed, vertical dynamic forces over defective track are still lower than the ones generated by a wagon equipped with Y25 bogie, generating a lower impact on railhead damages. This is due to the innovative arrangement of the primary suspension, which at same time allows to reduce the number on components (two springs per bogie) and to improve the vertical response to distributed irregularities. The horizontal spring arrangement, together with the lower yaw moment of inertia, has shown good results also in curving behaviour resulting in lower $T\gamma$ values especially for mild radius curves (R=600÷800 m).

The comparison with other freight bogies in terms of *VUC* calculations according to Network Rail specifications has shown comparable charge both in empty and laden conditions, with advantages due to the lower weight of the bogie and therefore of the tare weight of the simulated wagon. However, the effect of the cant deficiency is not included in the current analysis methods, resulting, in the authors opinion, in a too conservative costs evaluation.

Even if further investigations are scheduled for future papers, the innovative design has shown favourable features in terms of track friendliness.

TRACTION AND CURVING OF VEHICLES EQUIPPED WITH GUIDED INDEPENDENTLY ROTATING WHEELS

Andrea Bracciali, Gianluca Megna*

Dipartimento di Ingegneria Industriale, Università di Firenze, via Santa Marta 3, 50139 Firenze, Italy

* E-mail: gianluca.megna@unifi.it

Abstract: Modern advances in permanent magnet electric motors allow designing vehicles with gearless driven guided independently rotating wheels (GDGIRW). High precision controls allow to define simple and effective different strategies in straight track and in curves, such that the wheels belonging to the same "axle" are virtually coupled in straight track while torque control (with different angular speed) can be easily achieved in curves as train location in metros with ATO systems is constantly known. The paper discusses the advantages of a metro vehicle equipped with the GDGIRW architecture over a conventional architecture with bogies in terms of performances and track friendliness.

Keywords: Independently rotating wheels; driven guided IRW; motor wheels; traction; curving; adhesion; creep forces.

1. Introduction

Longitudinal and lateral creepages that inevitably arise during sharp curve negotiations of a vehicle equipped with bogies are responsible for rail gauge face wear and corrugation. Wheels, on their side, may show abnormally high flange wear and periodic out-of-roundness (polygonization). This is due to both the constraint of equal angular speed of the wheels of a wheelset and the necessity to keep the wheelsets parallel in order to run stably at the maximum speed.

The behaviour of a bogie is, as known from the literature [1, 2], strongly influenced by traction. A low primary yaw stiffness improves steering in coasting while it worsen the kinematic asset of the bogie (angle of attack, wheel-rail forces) during traction. Moreover, stability at high speeds in critical conditions (empty vehicle, worn wheel profiles, high adhesion) requires typically a high yaw stiffness.

This situation is the inevitable results of the never-ending conflict between guidance and stability that is intrinsic in all vehicles with rigid connection of the wheelsets to the carbody or to the bogie frame.

In this paper, the architecture of a vehicle with gearless driven guided independently rotating wheels (GDGIRW) is presented. Although Independently Rotating Wheels (IRW) are widely used in low-floor trams [3], to the authors' knowledge there are no application of self-propelled vehicles equipped with driven guided IRW. It will be shown that the proposed architecture, together with a simple and well-established philosophy of traction, may virtually eliminate lateral creep allowing the maximum traction in all situations.

A case study for a metro vehicle running through a very demanding section (track slope and curvature) is presented, comparing the results with a conventional metro vehicle.

The implications of the use of the adoption of GDGIRW technology are extremely relevant, impacting on carbody manufacturing, the number of doors per meter, the position of the auxiliary equipment as well as power electronics, HVAC and so on. This paper is focused on contact mechanics aspects, so modifications and advantages potentially introduced by the use of new concept vehicles using the DGIRW technology will be discusses in a future paper. It can be said that the vehicle architecture is modular and that has its perfect application in driverless metros where performances may be critical in steep and sharp curves situations.

2. The GDGIRW technology

Trying to prevent high lateral creep forces arising while negotiating sharp curves in all vehicles with conventional bogies, a number of self- or assisted-steering bogies were proposed in the past to reduce the angle-of-attack (AOA) of the wheelsets. Unfortunately, these techniques are not as widespread as one could expect. Bogies actively steered with actuators, known as "mechatronics bogies", suffer high costs and low reliability and maintainability, justifying the reluctance of system integrators and of final customers to embrace such solutions. Passively steered wheelsets / bogies had more success, but the various strategies (bracing, linking) introduce some degree of complication that is often not justified for conventional operations.

A way to remove longitudinal creep forces is the adoption of IRW technology. This is simply the way the wheels of any cart are connected to the vehicle structure, so this looks the natural choice also for railways. As longitudinal forces vanish, there are no stability problems and this led in the 1960's to several studies about the application of IRW to high speed trains to avoid hunting. When running

dynamics became better known they were readily abandoned.

In fact, the "differential effect" offered by the wheelset made of an axle and two rigidly connected tapered wheels ensures self-centring and, to some extent, also curving without the intervention of wheel flanges. Bogies equipped with IRWs, where the kinematic constraint of equal angular speed of the wheels is absent, are infamous for the absence of centring in straight track that leads to premature flange wear as one or more flanges within a bogie run in constant contact with the rail gauge face.

The Spanish company Talgo developed in the 1940's the Guided IRW (GIRW) architecture, which proved to be a successful application of IRW. It consists on a set of "triangular structures" supported by single – axis portal bogie (named *rodal* by the company) equipped with IRW. The *rodal* is driven by linkages connected to the carbodies and therefore runs centred, as it has no freedom around the vertical axis (Figure 1). One of the more interesting applications of the Talgo trains is the use of a passive tilting layout, where the secondary suspension is located above the centre of gravity of the carbody. This allows "Talgo Pendular" to run through curves at higher speeds offering the same comfort given by conventional slower trains.

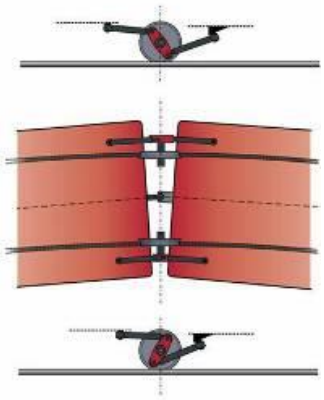

Figure 1 *Mechanism to steer IRW developed by the Spanish company Talgo.*

To the author's knowledge, Talgo manufactured trains made of conventional (with bogies) locomotives and hauled passenger cars equipped with *rodal*. Modern technology makes available driving chains that allow conceiving an architecture in which GIRW are driven, thereby adopting the concept of EMU (Electrical Multiple Unit) that is more and more widespread in railways and is the standard in metros since the application of electrification. The concept of gearless driven guided independently rotating wheels (GDGIRW) is therefore introduced in this paper.

3. Direct drive (gearless) motor wheels

Central to the technology of GDGIRW is the availability of electric motors that can be installed as close as possible to each wheel.

In recent years, the development of permanent magnet (PM) synchronous AC brushless motors for automotive application has been vertiginous. This kind of motors has a fixed hub (stator) with windings and a rotating part (rotor) equipped with permanent magnets. They were developed to drive electric and hybrid cars and are therefore "hidden" in the wheel web with a maximum external diameter of 17"-19" (Figure 2).

Figure 2 *In-wheel electric motors (left) and a motor wheel (right) for automotive applications.*

Typical performances offered by in-wheel motors for the automotive industry are far from the specifications of a modern metro vehicle, that require a typical specific power of 55÷60 kW/wheel and a starting torque of 3000 Nm/wheel. The greatest advantage in metro applications with web-mounted brake discs is that the motor does not have to fit in the wheel web, that the diameter can be increased and that the axial width is not strictly limited by the low-floor architecture of trams.

By applying the usual electric motor equations, it was estimated that a maximum starting torque of around 4500 Nm/wheel can be obtained. The direct coupling results in a gearless vehicle, so all gearbox maintenance operations are eliminated. Moreover, with PM brushless motors both speed and torque controls can be easily implemented as well as a precise position control down to stop. This means that electric braking is sufficient to stop and to hold the vehicles in all conditions and that the braking system is so lowly used that it can be downsized consistently. PM motors, in fact, guarantee dynamic braking when are not fed. In case of absence of power, the train comes to a stop automatically. A sketch of the volume occupied by a rotor supplying approximately 4500 Nm at the start is shown in Figure 3.

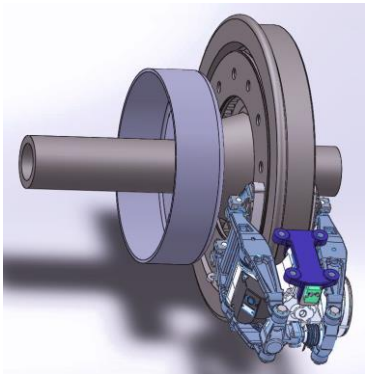

Figure 3 *Sketch of a wheel with a direct drive motor and a brake disc installed on the web. Starting estimated torque is 4500 Nm.*

4. Traction, curving and rail damage comparison of conventional and GDGIRW architectures in sharp curves

4.1. Vehicle description

In order to compare the behavior of conventional (A) and GDGIRW (B) vehicles, a simulation with the multibody code VI-Rail [4] was set up. The vehicles considered are typical of a metro application, and their characteristics are shown in Table 1. Although not many details can be provided here for space reasons, it can be seen that the vehicles have the same length and carry approximately the same number of passengers. The number of cars for the GDGIRW solution is clearly higher, resulting in smaller overthrows and therefore lower gauging problems. Loaded mass and lengths are slightly lower for the GDGIRW metro, resulting nevertheless in the same axleload. All the axles are driven, identifying this application as one to be used in very demanding operations in terms of resistance to motion.

Table 1 *Simulated vehicles.*

Vehicle name	A	B
Architecture	Conventional (bogies)	GDIGRW (*rodals*)
Number of cars	6	19
Car length	18 m	5.65 m
Number of bogies	12	N/A
Number of axles	24	20
Overall length	108 m	108 m
Total # of passengers	1208	1143
Axleload / wheel load	12 t / 6 t	12 t / 6 t
Number of driven axles	24	20
Fully loaded mass	288 t	240 t

In order to avoid misalignments of the end *rodals* of vehicle B, they were connected to the nearest *rodal* through a classical cross-bracing architecture. It should be remembered that this arrangement gives the desired results in constant radius curves, while in transitions the guidance may result not perfect. A sketch of the two vehicles is shown in Figure 4.

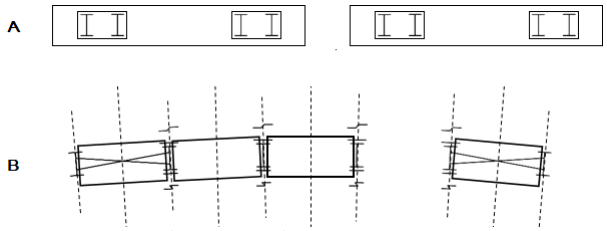

Figure 4 *Sketch of the layout of the conventional vehicle A (six cars) and of the DGIRW vehicle B (19 cars). End axles of vehicle B are guided by a classical cross-bracing mechanism driven by adjacent rodals.*

4.2. Adhesion considerations

An adhesion coefficient of f=0.4 was used to be consistent with all classical running dynamics conditions. It is nevertheless well known that in many case adhesion can be as high as f= 0.6, especially in dry, hot, long metro tunnels. The results shown in the following are therefore to be considered as conservative, in the sense that wear and tear will be amplified in more "sticky" conditions.

The full Kalker model implemented in the software package allows to define a saturation of the traction curve according to the maximum longitudinal creep until the adhesion force is passed. Simulations where conducted with a (piecewise defined) saturation curve that has a maximum of f=0.4 for a longitudinal creep γ_x=1.65% while it drops down to f=0.01 when the creep becomes γ_x=1.70%. This approximation tends to mimic the behavior of anti-spin systems installed in all normal vehicles. Traction control ramps up torque until the speed of all the axles is the same, leaving some room for the inevitable difference in the various wheels diameter. As an example, a locomotive tolerates a maximum difference on 25 mm in the diameter of nominal D=1100 mm, corresponding to a difference in speed of ±0.0116 = ± 1.16%. Speed differences larger than this are perceived by the control as spin or skid, interrupting traction or braking.

The simulations therefore resulted in a maximum torque for which the vehicle was not able to re-start once stopped. This is not fully true in the real life, as the traction control will try to exploit the full traction conditions again and again until the vehicle (hopefully) starts. A deeper description of traction controllers lays out of the scope of the present paper.

4.3. Simulated scenarios

As a general rule, *wear numbers* $W = T\gamma = T_x\gamma_x + T_y\gamma_y$ for both vehicles were calculated but only the results of the front bogie of vehicle A are shown, as the carbody-bogie frame torque is zero and the two bogies exhibit exactly the same behaviour. Selected profiles were S1002 for wheels and 60E1 laid 1:40 for rails to avoid double contact problems. For the sake of simplicity, the simulation of vehicle B was initially limited to a 5-cars symmetrical trainset.

As it is expected that the GDGIRW solution has no or little advantage vs. the conventional solution in flat straight track (see par. 5), a set of simulations were performed to investigate the differences in a "difficult" situation. The track chosen in all the following cases was therefore selected as a constant radius curve with R=200 m. This is nevertheless representative of a wide variety of situations that can be found in metros.

It is anticipated that a summary of the results obtained for both the front bogie of vehicle A (axles 1+2) and for the reduced formation of vehicle B (five cars, axles 1+2+3+4+5+6) is shown in Table 2. A graphical representation of the wear numbers limited to the front bogie of vehicle A is shown in Figure 5.

The AOAs for the first axle of both vehicle A and B are shown in Table 3, amply justifying the outcomes in terms of wear numbers.

The overall damage introduced in the rails by a full six-cars formation of vehicle A (24 axles) and by a full 19 cars formation of vehicle B (20 axles) is shown in Table 4. Beyond the wear number for specific wheels, this can well represent the advantage offered by the GDGIRW architecture.

Case # 1: starting in high-canted steep track
The track used for starting conditions has a slope of i=50‰ = 5% and a cant of h=160 mm (cant deficiency h_d=-160 mm). This track conditions can be found e.g. in ref. [5] and may be present in limited but significant line stretches worldwide.

The simulation was conducted starting with a small torque on a flat, straight track, then the vehicle started curving and climbing on a transition until it stopped in the steep, circular curve as the torque was insufficient to climb up the line. When the speed zeroed, a predetermined torque was applied *per axle*.

For vehicle A this results in different longitudinal (traction) forces depending on local contact conditions which are obviously different between the right and the left wheels, while for vehicle B (on which torque control is applied) the longitudinal forces are exactly the same as the wheels are independently driven.

The torque was increased stepwise until wheel slip was detected on vehicle A. This resulted in a maximum torque of 4500 Nm per axle (4500*24/288=375 Nm/t) and in an acceleration of 0.33 m/s^2.

The same torque was applied on each *rodal*, resulting in the same specific torque (4500*20/240=375 Nm/t). The fact that vehicle B has a lower resistance to motion leads to a slightly higher acceleration of 0.35 m/s^2.

Case # 2: starting in flat steep track
The same torques were applied in a similar scenario, i.e. starting on a track with the same slope of 50 ‰ but without cant.

In this case the damage introduced by vehicle B is negligible, while vehicle A exhibits wear number values similar to the canted case, confirming that cant is not related to damage in case of high cant excess.

Case # 3: coasting at 153 mm cant excess
The "natural" behavior of the two solutions was compared in coasting on canted track h=160 mm.

The simulation requested a programming trick to keep the vehicles running after one full circle. The software does not allow in fact to design tracks that intersect. The solution was found by designing a helical track with a helix pitch of –1 mm, resulting in a negligible artificial slope.

Starting speed in tangent track was set to 3.1 m/s as this is the speed that results in h_d=-153 mm (or a_{nc}=- 1 m/s^2 non-compensated acceleration). Vehicle A, due to slightly higher resistances during the approach, negotiated the circular curve at 2.5 m/s, with a negligible difference.

As the wheels rotate freely for vehicle B, no slip results in this direction and the damage is limited to the one given by lateral forces/creepages. Vehicle A keeps going on showing high wear number for the front wheelset, while the rear wheelset runs centered compensating for the track curvature introducing nearly no damage on the rails. Wear numbers are not negligible for vehicle A, and also vehicle B introduces minor damage in the rails.

Case # 4: coasting at balance speed
Increasing the initial speed to 14.5 m/s leads to balance in the curve (h_d=0, a_{nc}=0). As before, Vehicle A, due to slightly higher resistances during the approach, negotiated the circular curve at 14.38 m/s, with a negligible difference.

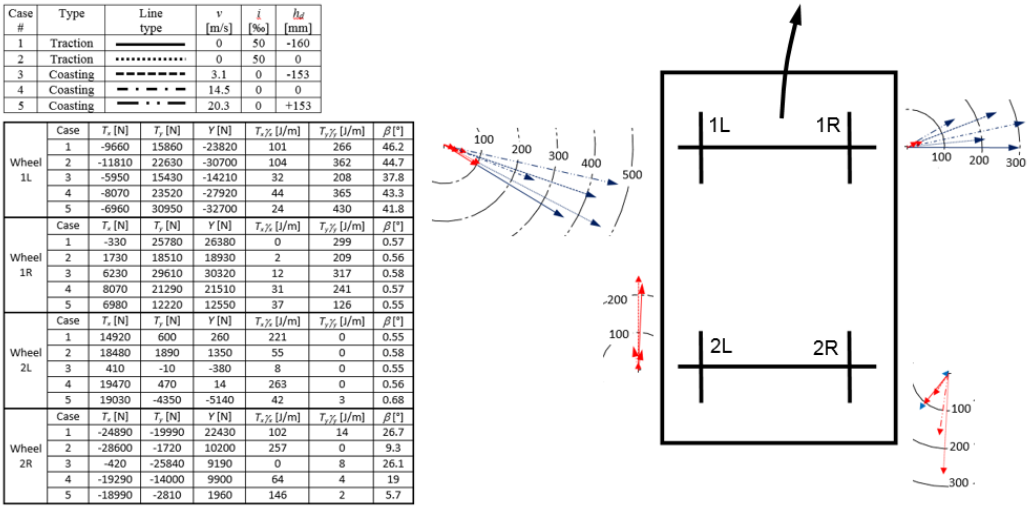
Regardless of the kinematic balance, wear numbers for vehicle A remain significant, while they vanish in practice for vehicle B.

Case # 5: coasting at 153 mm cant deficiency
Increasing further the initial speed to 20.3 m/s leads to h_d=+153 mm (or a_{nc}= + 1 m/s^2 non-compensated acceleration).

Due to the rotation of the bogie around the vertical axis given by centrifugal forces that are supported by the flange of the outer wheel of the first wheelset, wear numbers for vehicle A decrease with respect to the balance conditions. The same lateral forces generate more wear on vehicle B.

This case should be typical case for conventional railway lines with mixed traffic, in which freight trains negotiate curves run typically at a_{nc}= 0.6 m/s^2 while passenger trains run at a_{nc}= 1 m/s^2 on the same curves.

This is not the case for metros, for which the speed profiles is fixed (especially with ATO operation) and the tendency is to design cant in order to result in balance conditions that maximize passenger comfort. Anyway, also in this case, which is favourable for vehicle A and unfavourable for vehicle B, confirms that vehicle B is less damaging the low rail.



4.4. Comparison of vehicles A and B
Curving attitude is normally evaluated by considering the AOA of the wheelsets of the first bogie. Table 3 compares AOA the said axles of vehicle A to the first *rodal* of vehicle B.

It can be observed that AOA of the first wheelset of vehicle A are always larger than those of vehicle B, while the second wheelset of the vehicle A runs almost radially. This justifies the different wear numbers (Table 4).

The superiority of vehicle B on vehicle A in terms of rail damage is overwhelming. In the worst case vehicle B is less damaging of vehicle A by a factor 4, in the best case by a factor 400.

Table 2 *Wear numbers for the front bogie of vehicle A and for all the axles of a six cars train formation of vehicles B in the five simulated scenarios. Numbers in the cells are $T_x\gamma_x$ and $T_y\gamma_y$, while the bold values are the total wear number $T= T_x\gamma_x + T_y\gamma_y$.*

What is expected (and confirmed by the results) is the negligible damage introduced by vehicle B running in "near balance" conditions (i.e. cases 2 and 4). In the same cases vehicle A exhibits high wear numbers, that explain the extensive damages observed even if the vehicle runs in apparently favourable kinematic conditions.

Also in the cases of high cant excess (i.e. cases 1 and 3) vehicle B is superior. It can be concluded that the damage introduced in the rail by vehicle B is due only to traction forces at balance speed and that also in high-canted track wear numbers are relatively limited despite high gravitational forces.

Although rail damage is central in this paper, safety against derailment must be checked in all situations. It can be seen (Table 5) that vehicle B has derailment

coefficients *Y/Q* lower than vehicle A. In any case, estimated values are much lower than the maximum values allowed by running dynamics standard EN 14363 [6].

Table 5 *Y/Q derailment ratio for all the simulated cases*

5. Rail damage in mild curves

As aforementioned, the convenience of the GDGIRW technology tends to vanish when the curvature of the line decreases, i.e. when the curves tend to become mild.

A large number of simulations was conducted with or without traction, slope, cant deficiency and so on. In the following the behavior of vehicles A and B is compared, for clarity, only during coasting with two levels of non-compensated acceleration (a_{nc}= 0 and a_{nc}= 1 m/s^2, corresponding to h_d=0 and h_d=153 mm), for five different curvatures (ρ=1/R=1, $\sqrt{2}$, 2, 3 and 5 km^{-1}) corresponding to R=1000, 707, 500, 333 and 200 m respectively.

The results are shown in Figure 6 for the balance speed case and in Figure 7 for the h_d=153 mm case.

As expected, the vehicle B with GDGIRW architecture introduces no damage at all in the rail at balance speed, while vehicle A seems to be not track friendly at all for R<400 m, a value typical for metros.

When cant deficiency increases, bogie rotation due to centrifugal effects makes vehicle A more friendly than in the balance case. In any case, the advantage offered by the adoption of the GDGIRW architecture is relevant or, at least, neutral.

To highlight the effect of traction, two simulations were conducted at v=22.9 m/s on an R=1000 m, h=80 mm curve (h_d=0) with and without the maximum torque of 4500 Nm per axle used above.

For vehicle A, the wear number for the front outer wheel raised from 71 J/m to 103 J/m passing from coasting to full traction. For vehicle B, wear numbers remained very low, changing from 1÷2 J/m to 3 J/m even with the maximum traction.

This has important consequences on rail damage in mild curves. Models developed by Burstow [7] and Öberg [8] identify the range of $T\gamma$ for which RCF damage is dominant over wear (Figure 8). It can be seen that vehicle A results in wear numbers in a range for which RCF damage is dominant, while vehicle B is constantly below the threshold of 15 J/m for which no damage is introduced in the rail. It results therefore that a conventional vehicle is able to damage the high rail regardless of the fact that it is coasting or in traction; on the opposite, vehicle B *never damages* the rail for any operating condition.

6. Development of the GDGIRW technology

As already described, preliminary analyses show that permanent magnet (PM) "motor wheels" with a continuous torque of 3500 Nm and a starting torque of 4500 Nm can be designed in the larger spaces normally available for wheelsets compared to car wheels. Some problems are nevertheless foreseeable in the application of PM motors on GDGIRW vehicles.

First, service factors for a metro vehicle are particularly severe and a liquid cooling would probably be necessary. Compared to AC asynchronous motor, PM motors are known to be "cool" as there are no currents circulating in the rotor (equipped with permanent magnets) while the "hot" part of the motor is stationary (the stator) and can be cooled relatively efficiently.

Second, PM motors would work in a very hard conditions in terms of accelerations and shocks that are of a at least one order of magnitude higher than those experienced by motors mounted on cars equipped with rubber tyres.

It is not the intention of the authors to hide the technological problems linked to such new and promising technology, promoted by the vertiginous development of micro- and power electronics, but, once solved, it would offer distinct advantages as follows.

A further simulation was in fact performed with the best scenario of a starting torque of 4500 Nm *per wheel*, i.e. 9000 Nm per *rodal*. Conditions chosen for this analysis were the most critical ones already observed: starting on an i=5% slope in a curve with R=200 m and cant h=160 mm.

It is worth reminding that vehicle A started slipping at 4500 Nm *per axle*, with wear numbers as high as 7000 J/m on the high rail and 5000 J/m on the low rail.

Simulations on vehicle B led to an astonishing acceleration of 1.16 m/s^2 with wear numbers of 800 J/m of the high rail and 1390 J/m on the low rail. These figures show that the performances of a GDGIRW vehicles can be massively superior compared to a conventional vehicle. Moreover, to obtain the usual performances that are requested in purchasing tenders, the GDGIRW vehicle can be equipped with less than 100% of driven wheels saving consistent money and complications.

7. Conclusions

The distinct advantage of the GDGIRW architecture is the ability of aligning the "wheel axis" (the axle does not exist) always radially. These conditions eliminate virtually all creepages in a trailed *rodal*: longitudinal creepage is zero as wheels are freely rotating, while lateral creepage is zero as the *rodal* is guided by the carbodies and the angle of attack vanishes. The latter condition is obviously possible when the trainset runs in a constant radius curve, while during transitions the behaviour of the end axles must be properly managed.

With the GDGIRW layout, maximum accelerating and braking efforts can be obtained. Adhesion is partly "wasted" during negotiation of a conventional bogie due to longitudinal and lateral creepages. Both these phenomena dissipate energy and damage the surfaces in contact. This requires bigger motors installed on the vehicles and leads to undesired wheel and rail wear, tear and associated costs.

The paper has compared the behaviour of a conventional metro to that of a trainset built with the GDGIRW technology respecting the basic requirements in terms of axleload, number of passengers, acceleration, braking and so on. In particular, several scenarios to highlight the advantage that can be obtained in full and partial traction compared to conventional vehicles were simulated.

Although several complex control strategies are available for mechatronic bogies, the one used in this research is particularly simple and effective, consisting in a speed control in straight track and a torque control in curves managed, for example, by ATO system.

Wear numbers highlight that the damage introduced in the wheel-rail contact is minimum, avoiding lateral wear and longitudinal corrugation at the best. The GDGIRW architecture has the highest possible track friendliness and is virtually capable to avoid as well any damage due to Rolling Contact Fatigue.

The GDGIRW looks very promising in terms of both simplicity and performance once technological problems linked to cooling and vibrations are solved.

Abstract: Two of the main problems in railway systems, both dynamically (safety, comfort, etc..) and economically (planning of maintenance interventions maintenance, reduction of wheel and rail lifetime, etc..) are represented by the wear of wheel and rail profiles and by the rolling contact fatigue. For this reasons, nowadays the prediction of wear and crack growth at the wheel-rail interface is a fundamental problem in the railway field, directly correlated to the maintenance planning. Hence, the authors present the development of a tool, suitable to different scenarios, that combines a wear model to evaluate the wheel and rail profile evolution and a RCF crack prediction model in connection with multibody dynamics simulations.

Keywords: Rail-wheel contact; Rolling contact fatigue; Wear; Multibody simulation, Rail-wheel contact; Rail and wheel damage.

1. Introduction

Two main factors reduce the life of wheels and rails: intensive wear and the rolling contact fatigue (RCF). The prediction of wear and crack growth at the wheel-rail interface is a fundamental problem in the railway and tramway field, directly correlated to the maintenance planning, vehicle dynamic behaviour and safety. Therefore, the wheel and rail profiles need to be re-established periodically in order to keep assuring vehicle stability and running safety. Because of all these reasons, in this work an efficient but accurate procedure to simultaneously estimate the evolution of wheel and rail profiles due to wear and of RCF crack depth and length will be presented, to obtain, together with multibody dynamics simulations, a powerful tool to manage wheel and rail damage.

2. Model layout

The general layout of the wear and RCF model is made up of two main parts: the dynamic system and the wear model (see Figure 1). The dynamic block consists of the multibody model of the benchmark vehicle, built in Simpack Rail environment, and of the global contact model, implemented in C/C++ that, during the dynamical simulation, interact online creating a loop. Generally, the resolution of wheel-rail contact is divided in three phases: the contact points detection, the normal problem to calculate the normal pressure distribution and the tangential problem for tangential pressures calculation. Simpack Rail software already includes several wheel-rail contact models but in this work a 3D global contact model developed in the previous years by the Authors [13][14] is adopted to achieve better accuracy and reliability. After contact points detection, the model calculates, for each contact points, the contact forces (normal and tangential) and the global creepages on the contact patch through Hertz's and Kalker's global theories [16][17]. The global contact variables are then passed to the multibody model in order to carry on the simulation of the vehicle dynamics. The track and the multibody model of the considered vehicle are the main inputs of the dynamic block. More particularly, in this research activity, the track is represented by the real whole Tram Line 1 of the city of Florence that connects the railway station Santa Maria Novella to the suburban area of Florence. The wear model consists in three distinct phases: the local contact model, the wear evaluation and the profile update. The local contact model (based both on Hertz's local theory and on simplified Kalker's algorithm FASTSIM [16][17]), starting from the global contact variables (outputs of multibody simulation), evaluates the local contact variables (contact pressures and local creepages within every discretization point of the contact patch) and divides the contact patch into adhesion area and creep area. Then, the distribution of removed material is calculated on the wheel and rail surface only within the creep area using an experimental law between the removal material and the energy dissipated by friction at the contact interface [8]. Finally, the wheel and rail worn profiles are derived from the original ones through an appropriate innovative update strategy. The new updated wheel and rail profiles are then fed back as inputs to the vehicle model and the whole model architecture can proceed towards the next discrete step. The whole model is therefore based on a discrete process: each discrete step consists in one dynamic simulation and one profile update by means of the wear model while, within the discrete step, the profiles are supposed to be constant. The choice of an appropriate step is fundamental in terms of accuracy and computational load. Moreover the different time scales characterizing the wheel and rail wear evolution require the development of a suitable strategy for the profiles update, as it will be clarified in the following. More in

detail, the wheel profile update strategy proposed by the Authors is based on the total distance travelled by the considered vehicle, while the rail profile update strategy is based on the total tonnage burden on the track. In such a way, the removal of the material is carried out considering the different time scales of wheel and rail wear evolution.

The RCF model is implemented in parallel with the wear model (see Figure 1), allowing to simultaneously evaluate the removed material due to wear and the crack growth, in terms of length and depth, both for the wheel and for the rail. Contact stresses, slips and calculated wear are the only inputs for the crack model and the influence of wear on crack growth can be taken into account at the end of each calculation step. In fact, wear and RCF are deeply connected: wear changes wheel and rail profiles impacting on stresses magnitude in the wheel–rail contact and leading to more or less RCF damage. In presence of high wear rate short cracks may also be worn off.

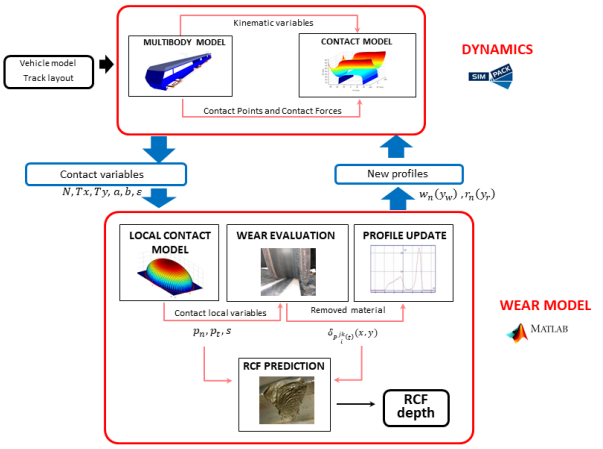

Figure 1 *Model layout*

3. Wear and RCF damage estimation

As regards the wear estimation, the model developed by the Authors is based on a local contact model (in this case the Kalker's FASTSIM algorithm [16]) and on an experimental relationship for the calculation of the removed material [8]. Also the RCF model is based on a local contact model and on a relationship between the shear in the wheel-rail contact and the crack length. This model also takes into account the wear influence on cracks propagation: when the wear rate is high, short cracks may also be worn off, leading to a lower RCF damage. The RCF model proposed by the Authors is an improvement of the theory proposed by Dirks, Enblom, Ekberg and Berg [6][7] capable to evaluate the distribution of RCF damage along the wheel and rail profile and its evolution respectively as a function of the mileage travelled by the vehicle and the tonnage burden on the track, respectively.

3.1. The wear model

The wear model consists in three phases: the local contact model, the evaluation of the amount of removed material and the wheel and rail profile update. For a complete description of the wear model refer to [1][2].

3.1.1. The local contact model

The local contact model, based on Hertz's local theory and on simplified but efficient version of Kalker's theory (FASTSIM algorithm) [16], starting from the global contact variables (contact forces and global creepages, outputs of multibody simulation), evaluates the corresponding local contact variables. The contact patch is discretized in a grid of points in which the local normal contact pressures p_n, the local tangential pressure $\mathbf{p}_t$ and the local creepages $\mathbf{s}$ are evaluated in order to divide the contact patch in adhesion and slip zone (according to Coulomb's adhesion law), necessary to evaluate the volume removed by wear that will be calculated only in the slip zone. One refers to literature for a more detailed description of the FASTSIM algorithm [16].

3.1.2. The wear evaluation

Starting from the local contact variables estimated in every points of the contact patch grid according to the contact model, it is possible to evaluate the specific volume of removed material on wheel and rail (expressed in $mm^3/(m \cdot mm^2)$): $\delta_{P_{wi}^j(t)}(x,y)$ and $\delta_{P_{ri}^j(t)}(x,y)$ (where x and y indicate the coordinates of a generic point of the contact patch) related to the i-th contact points $P_{wi}^j(t)$ and $P_{ri}^j(t)$ on the j-th wheel and rail pair for unit of distance travelled by the vehicle (expressed in m) and for unit of surface (expressed in mm^2). For this purpose an experimental relationship between the volume of removed material and the frictional work has been used. Knowing the local contact stresses $\mathbf{p}_t$ and creepages $\mathbf{s}$ the wear index I_W (expressed in N/mm^2), which represents the frictional power generated by the tangential contact pressures, can be evaluated:

$$I_W = \mathbf{p}_t \bullet \mathbf{s} / V \tag{1}$$

where V is the longitudinal velocity speed. This index is correlated with the wear rate K_W, that represents the mass of removed material (expressed in $\mu g/(m \cdot mm^2)$) for unit of distance travelled by the vehicle and for unit of surface. The two index are correlated by means of a law, available in literature [8][4], based on experimental wear tests carried out in the case of metal to metal contact with dry surfaces using a twin disc test arrangement. The experimental relationship between K_W and I_W adopted for the wear model described in this work is the following:

$$K_W(I_W) = \begin{cases} 5.3 * I_w & I_W < 10.4 \\ 55.1 & 10.4 < I_W < 77.2 \\ 61.9 * I_W - 4778.7 & I_W > 77.2 \end{cases} \tag{2}$$

After obtaining the same wear rate $K_W(I_W)$ both for the wheel and for the rail, the specific volume of removed material respectively on the wheel and on the rail can be calculated:

$$\delta_{P_{wi}^{j}(t)}(x,y) = K_W(I_W)\frac{1}{\rho}$$
$$\delta_{P_{ri}^{j}(t)}(x,y) = K_W(I_W)\frac{1}{\rho} \quad (3)$$

expressed in $mm^3/(m \cdot mm^2)$ and where ρ is the material density.

3.1.3. Profiles update

In this subparagraph a summary of the profile update strategy will be provided. For a full description of the approach refer to the works available in literature [1][2]. After obtaining the amount of worn material, wheel and rail profiles need to be updated to be used as inputs for the next step of the iterative process through a specific update strategy. The update strategy requires some integration and average operations in order to remove numerical noise that affect the distributions $\delta_{P_i^j(t)}(x,y)$ and to calculate the average quantities of removed material due to wear $\bar{\Delta}^{w}(s_w)$, $\bar{\Delta}^{r}(s_r)$ (expressed in mm): sum in the longitudinal direction of all the wear contributes inside the contact patch and averages over the whole longitudinal development of the wheel and of the rail, sum of all the wear contributes coming from the dynamic simulation and of each contact points, average on the wheels of each wheelset (if a single mean profile for the wheel of each wheelset is required), sum on all vehicle wheels and average on the left and right side for the rail (if a single mean profile of the rail is required). Moreover, to have a better accuracy in the calculation of the worn profiles, the natural abscissas s_w and s_r of the wheel and rail curves $w(y_w)$ and $r(y_r)$ have been introduced.

Since normally travelled distance of thousands kilometres are needed to obtain measurable wear effects, an appropriate scaling procedure that amplify the removed material during the dynamic simulations is necessary to reduce the simulated track length with a consequent limitation of the computational effort. The complete scaling procedure which leads to obtain the quantities $\bar{\Delta}^{wsc}(s_w)$ and $\bar{\Delta}^{rsc}(s_r)$ is described in [1][2].

Finally, after a smoothing process on the removed material function, necessary to reduce the numerical noise, the new profiles $w_n(s_w) = w_n(y_w)$ and $r_n(s_r) = \tilde{r}_n(y_r)$ are obtained removing the worn material in the normal direction to the wheel and rail old profile ($w_o(s_w) = w_o(y_w)$ and $r_o(s_r) = \tilde{r}_o(y_r)$). Since the removal of material occurs in the normal direction to the profiles (n_w^r and n_r^r are the outgoing unit vector for the wheel and rail profile respectively), once removed the quantities $\bar{\Delta}^{wsc}_{sm}(s_w)$ and $\bar{\Delta}^{rsc}_{sm}(s_r)$ (where the subscript *sm* indicates that the profiles have been smoothed), a re-parameterization of the profiles is needed in order to obtain again curves parameterized by means of the curvilinear abscissa:

$$\begin{pmatrix} y_w(s_w) \\ w_o(s_w) \end{pmatrix} - \bar{\Delta}^{wsc}_{sm}(s_w)\mathbf{n}_w^r \Rightarrow \begin{pmatrix} y_w(s_w) \\ w_n(s_w) \end{pmatrix}$$
$$\begin{pmatrix} y_r(s_r) \\ r_o(s_r) \end{pmatrix} - \bar{\Delta}^{rsc}_{sm}(s_r)\mathbf{n}_r^r \Rightarrow \begin{pmatrix} y_r(s_r) \\ r_n(s_r) \end{pmatrix} \quad (4)$$

3.2. The RCF model

The rolling contact fatigue is a damage caused by repeated cyclic loading and unloading together with creep forces from curving, traction and braking that leads to cracks initiation and propagation. Cracks may grow until wheel or rail failure increasing the maintenance costs, broken rails and derailments. Many previous studies [9][10][11] have shown as shear stresses and forces (resulting from sliding caused by nominal radius difference between inner and outer wheels and by yaw angle of the wheelset when a train is running through a curve) are the main cause of cracks initiation and propagation. The RCF analysis is based on an improved version of the model developed by Dirks, Enblom, Ekberg and Berg [6][7] that gives the possibility of evaluating the RCF damage distribution along the wheel and rail profile. The Dirks, Enblom, Ekberg and Berg has been chosen as main reference because it is able to predict RCF damage in terms of crack depth and length starting from the same inputs of the wear model.

The proposed RCF model is implemented in parallel with the evaluation of the material removed by wear (see Figure 1). Contact stresses, slips and calculated wear are the only inputs for the crack model and the influence of wear on crack growth can be taken into account at the end of each calculation step. More specifically, the two models do not interact during the simulations but they run in parallel and interact at the end of each process step, combining the depth of removed material and the crack depth in order to consider the effect of wear rate on crack growth and propagation. In this work the crack propagation model developed by Dirks, Enblom, Ekberg and Berg has been used and, in particular, the relationship between the predicted crack length $c_{plP_i^j(t)}$ (where the subscript *pl* indicates the predicted length, i.e. the length calculated by means the RCF model) and the stress magnitude $\sigma_t(y)$ for each time step t (the index i is referred to the generic contact points $P_{wi}^j(t)$ and $P_{ri}^j(t)$ on the j-th wheel and rail pair):

$$c_{plP_i^j(t)}(y) = \frac{1}{\alpha(\sigma_t(y))^{\beta'}} \quad (5)$$

where α and β are calibrated parameters (different for the rail and the wheel). Such relation is based on five years rail crack measurements campaign and on fifteen months wheel crack measurements campaign [6][7]. To determine the stress magnitude $\sigma_t(y)$ in equation (5) the stress index $SI(x,y)$, evaluated in each cell of the discretized contact patch, is used:

$$SI(x,y) = \sqrt{\mathbf{p}_{tx}(x,y)^2 + \mathbf{p}_{ty}(x,y)^2} - k \quad (6)$$

where $\mathbf{p}_{tx}(x,y)$ and $\mathbf{p}_{ty}(x,y)$ are the tangential pressures (the same used in the wear model) and k is the yield limit in shear of the material. For the wheel a $k_w = 240$ MPa is assumed while, for the rail, a 260 Mn grade rail with $k_r = 400$ MPa is considered. Damage only occurs at $SI(x,y) > 0$ (N/m^2). Then, the maximum values in the longitudinal running direction (x direction) were determined and the maximum value of $SI(y)$ distribution is taken as stress magnitude $\sigma_t(y)$. After obtaining the stress magnitude $\sigma_t(y)$ for each wheel-rail contact, the same procedure used in the wear model for the wheel and rail profiles update [1][2] has been applied to calculate an average value of the crack length. In particular the procedure consists of the following steps:

- Average on wheel and rail longitudinal development

The predicted crack length is averaged over the whole longitudinal development of the wheel and of the rail by means of the factors $1/2\pi w\left(y_{wi}^j\right)$ and $1/l_{curve}$:

$$\frac{1}{2\pi w\left(y_{wi}^j\right)} c_{plP_i^j(t)}(y) = c_{plP_{wi}^j(t)}(y)$$
$$\frac{1}{l_{curve}} c_{plP_i^j(t)}(y) = c_{plP_{ri}^j(t)}(y) \quad (7)$$

where $w\left(y_{wi}^j\right)$ is the wheel radius evaluated in y_{wi}^j and l_{curve} is the length of the simulated track. It is equivalent to the complete track length if the whole length of the railway/tramway network is considered or to the length of a curved track if the study is focused on single specific curves.

- Track integration

The track integration sums all the contributes to the crack length coming from the dynamic simulation (integration on the whole track length l_{track} for the wheel and on the considered track section l_{curve} for the rail) allowing to accumulate damage with the increase of the load cycles:

$$\int_{T_{in}}^{T_{end}} c_{plP_{wi}^j(t)}(y)V(t)dt \approx \int_{T_{in}}^{T_{end}} c_{plP_{wi}^j(t)}(\mathrm{s}_w - \mathrm{s}_{wi}^{cj}(\mathrm{t}))V(t)dt = C_{plP_{wi}^j}(\mathrm{s}_w)$$
$$\int_{T_{in}}^{T_{end}} c_{plP_{ri}^j(t)}(y)V(t)dt \approx \int_{T_{in}}^{T_{end}} c_{plP_{ri}^j(t)}(\mathrm{s}_r - \mathrm{s}_{ri}^{cj}(\mathrm{t}))V(t)dt = C_{plP_{ri}^j}(\mathrm{s}_r) \quad (8)$$

where s_w and s_r are the natural abscissas of the curves $w(y_w)$ and $\tilde{r}(y_r)$ while s_{wi}^{cj} and s_{ri}^{cj} the natural abscissa of the contact points.

- Sum on the contact points

All the RCF contributes of each contact points are summed as follows:

$$\sum_{i=1}^{N_{PDC}} C_{plP_{wi}^j}(\mathrm{s}_w) = C_{pl_w^j}(\mathrm{s}_w)$$
$$\sum_{i=1}^{N_{PDC}} C_{plP_{ri}^j}(\mathrm{s}_r) = C_{pl_r^j}(\mathrm{s}_r) \quad (9)$$

- Average on the vehicle wheels

A different value of crack length for each wheel of each wheelset as output of the RCF model is obtained. Since the vehicle makes a round trip the average on the wheels of each k-th wheelset is calculated as follows:

$$\sum_{j \in \text{k-th wheelset}} \frac{C_{pl_w^j}(\mathrm{s}_w)}{2} = \overline{C_{L\,k}}^{w}(\mathrm{s}_w) \quad (10)$$

Instead for the rail, since all the wheels contribute to rail RCF damage, the sum over the number of vehicle wheels is calculated obtaining the total crack length for the right and left rail side (subscript r/l).

$$\sum_{j \in \text{right/left side}} C_{pl_r^j}(\mathrm{s}_r) = \overline{C_{L\,r/l}}^{r}(\mathrm{s}_r) \quad (11)$$

Then, as for the wheel, the average crack length between right and left rail is evaluated.

Once the average crack length is calculated, the crack depth depends on the experimental relationship between the measured crack surface length ρ and the crack depth h that is assumed to be linear:

$$\rho = f \cdot h \quad (12)$$

where the value of the scaling factor, experimentally evaluated [6], is approximately $f = 8$. Considering this experimental relationship, it is now possible to calculate the predicted crack depth $\overline{C_D}$ in mm both for the wheel and for the rail:

$$\overline{C_{D\,k}}^{w}(s_w) = \overline{C_{L\,k}}^{w}(\mathrm{s}_w) / f$$
$$\overline{C_{D\,r/l}}^{r}(s_r) = \overline{C_{L\,r/l}}^{r}(s_r) / f \quad (13)$$

- Scaling

The same scaling procedure introduced in the wear model [1][2] is used to reduce the simulated track length and the consequent computational effort and time.

$$\overline{C_{D\,k}}^{w}(s_w)\frac{km_{step}}{l_{track}} = \overline{C_{D\,k}}^{wsc}(s_w)$$
$$\overline{C_{D\,r/l}}^{r}(s_r) * N_{step} = \overline{C_{D\,r/l}}^{rsc}(s_r) \quad (14)$$

where km_{step} is the travelled distance inside a wheel discrete steps in which the total mileage travelled km_{tot} is subdivided and N_{step} is the vehicle number moving in a rail discrete step (see Figure 2 and Figure 3). Both km_{step} and N_{step} are calculated in adaptive way

imposing a threshold values on the maximum of the removed material quantity on the wheel at each discrete step (refer to previous works [1][2] for the adaptive step approach description). Therefore, when the removed material reaches this quantity, a discrete step finishes and the whole procedure passes to the following discrete step

Figure 2 *Discretization of the total mileage*

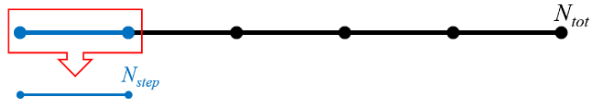

Figure 3 *Discretization of the total vehicle number*

- Effect of wear

Finally, after a smoothing process (the subscript *sm* indicates that the crack depth has been smoothed), to include the effect of wear, the difference between crack and wear depth is calculated. The cracks are considered worn off where this difference assumes negative values:

$$C_{Dk}^{\ w}(s_w) = \overline{C}_{D_{sm}\,k}^{\ wsc}(s_w) - \overline{\Delta}_{sm}^{\ wsc}(s_w)$$

$$C_{Dr/l}^{\ r}(s_r) = \overline{C}_{D_{sm}\,r/l}^{\ rsc}(s_r) - \overline{\Delta}_{sm}^{\ rsc}(s_r) \quad (15)$$

Contrary to the wear model, where the new worn wheel profiles are fed back as inputs to the vehicle model, the RCF damage is not considered in the simulation of the following discrete step; the accumulated crack depth at the end of the whole iterative process is calculated adding up the crack depths obtained for each discrete step of the procedure:

$$C_{TOT\,k}^{\ w}(s_w) = \sum_{i=1}^{ns_w} C_{Dki}^{\ w}(s_w)$$

$$C_{TOT\,r/l}^{\ r}(s_r) = \sum_{i=1}^{ns_r} C_{Dr/li}^{\ r}(s_r) \quad (16)$$

where ns_w and ns_r are respectively the number of discrete wheel and rail steps of the procedure according to profile update strategy.

4. Wear – RCF model preliminary validation

In this chapter, according to the different scheduled steps of the research project, a preliminary wear model validation will be carried out comparing the wheel measured reference parameters to the numerically evaluated ones (flange height Hb, flange thickness Lbe and flange steepness Qr – see Figure 4). The reference quotas allow to estimate the wheel profile evolution without necessarily knowing the whole profile shape and then to establish when the worn wheel profile has to be re-profiled because it does not guarantee the dynamical stability of the vehicle anymore. The reference quotas for the Florence Tram Line are defined as follows (see Figure 4): the reference point C which defines the nominal rolling circumference is evaluated on the profile at 44 mm from the internal vertical face of the wheel, the flange height Hb is the vertical distance between C and the flange vertex, the flange thickness Lbe is the horizontal distance between the internal vertical face and the point on the flange identified by the line 10 mm above the point C, the flange steepness Qr is the horizontal distance between the points defined in the previous bullet point and the point 2 mm under the flange vertex.

The wear model validation is performed considering as track layout the whole real Florence Tram line 1 that connects the railway station Santa Maria Novella to the suburban area of Florence. The tramway is characterized by an approximate length of 7.4 km with 14 intermediate stops and it is equipped with the standard track gauge (1435 mm). The vehicle which provides passenger service in the city of Florence is a tramway vehicle, designed by Hitachi Rail Italy. It is an independent wheels and articulated tram, built on Sirio platform and it is equipped with 3 bogies (two motor and the central one trailer) and five coaches (two motor with cabin, one trailer and two hanging).

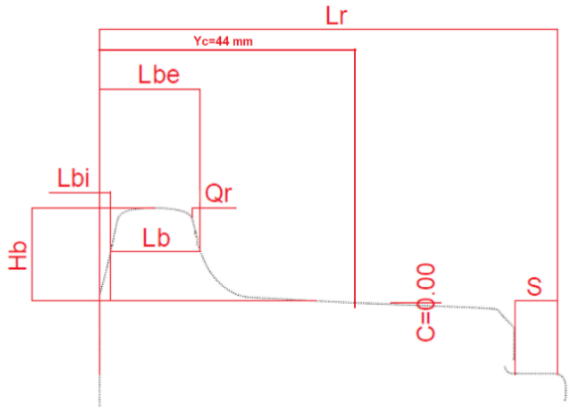

Figure 4 *Tram wheel reference parameters*

Figure 5 *Tram vehicle Sirio*

The experimental data, provided by Hitachi Rail Italy, come from tests conducted from March 2012 to November 2016 on the Sirio Firenze vehicles and are related only to the wheel wear control parameters measured as function of mileage travelled by the vehicle. The vehicle is equipped with 84 mm wide wheel with UNI3332 profile running on 60R2 rail profile. The data are related to all the wheels of the entire fleet (17 vehicles) and it was necessary to make a selection to consider only the measurements of the reference parameters evaluated in a period between two turnings during which the profiles are not re-established. For the sake of simplicity, according to this strategy, the experimental reference parameters related to a leading axle of a single vehicle has been presented for the preliminary model validation (see Table 1 for the left wheel and Table 2 for the right one).

Concerning RCF model validation a comparison with wheel experimental data related to other previous works available in literature [6][7] is considered.

Table 1 *Experimental left wheel wear parameters*

Mileage [km]	Hb [mm]	Lbe [mm]	Qr [mm]
0	18.83	20.43	1.76
15 684	18.71	20.08	1.78
35 387	18.57	19.92	1.64
52 386	18.52	19.88	1.74
70 156	18.39	19.87	1.82

Table 2 *Experimental right wheel wear parameters*

Mileage [km]	Hb [mm]	Lbe [mm]	Qr [mm]
0	18.84	20.68	1.78
15 684	18.63	20.41	1.61
35 387	18.47	20.31	1.55
52 386	18.40	20.45	1.59
70 156	18.26	20.17	1.68

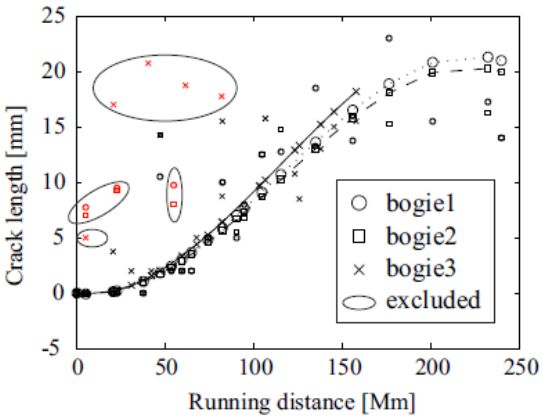

Figure 6 *Experimental crack length development [6]*

In particular the Authors consider the work carried out by Dirks, Enblom and Berg [6][7] who developed and verified their RCF model against wheel measurements related to a period of 15 months of three bogies at the front of three different units of a commuter train. In Figure 6 the measured crack lengths of the three bogies of the considered trains versus the running distance are shown. From the experimental data, it could be noticed that the maximum crack length is approximately 20 mm after about 240.000 km.

4.1. Wear model validation

In this first phase of the research project the study is focused on the wheel wear evolution while the validation against rail experimental data acquired on test rigs and directly on field is scheduled as next step.

The evolution of wheel wear control parameters obtained from the dynamic simulations after 5 steps (after which the simulated mileage is as close as possible to the real distance travelled by the vehicle between two turnings) of the iterative process at the first rail step (new rail profile) is then compared with the experimental data.

Although the wear model is capable to consider separately the wear evolution of the wheels of a same axle, in the present work, a symmetrical wear evolution between left and right wheel is considered because of the operating conditions of the vehicle (the tram is periodically turned during the service). Then, as output, a single wheel profile is obtained for each wheelset.

The Hb quota progress is represented in Figure 8 as a function of the mileage and shows how the flange height decreases due to the flange tip running motion and the low wear rate on wheel tread. Contrary to a railway applications, a tram vehicle has a particular behavior when it runs on switches and crossings, called flange tip running (Figure 7). The groove of the rail is filled to a certain level and the wheel runs on the flange tip over the crossing gap without any contact between wheel tread and the rail. Once the crossing gap is passed, the groove is gradually deepen back to its normal depth. The main consequence is a flange tip wear that is not present in a conventional train wheel.

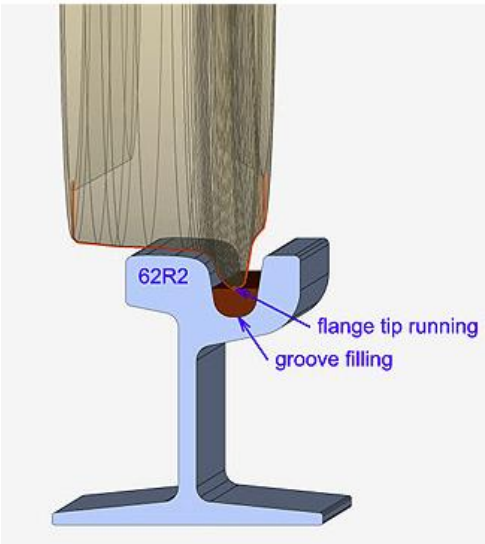

Figure 7 *Flange tip contact*

The progress of Lbe dimension is shown in Figure 9 while in the Figure 10 is shown the Qr factor trend. The comparison shows a good agreement between the outputs of the wear model (continuous blue lines) and the experimental data (red and black dots, one for the right wheel and one for the left wheel), both for the flange dimension (Hb, Lbe) and for the conicity (Qr). The Figure 11 shows the evolution of wheel profile (related to the reference parameters described in the previous figures) due to wear of the leading wheelset obtained as output of the wear model: the removed material is mainly localized on the flange zone due to the presence of several narrow curves typical of a tramway scenario. The flange tip wear, as already said, is caused by the flange tip running motion that occurs when the tram vehicle runs over switches and crossings.

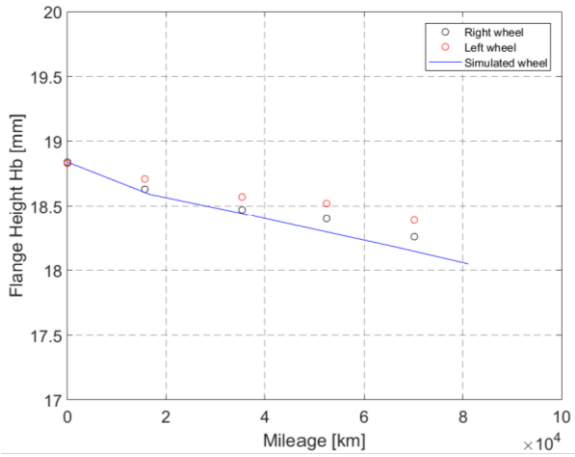

Figure 8 *Hb dimension comparison at first rail step - leading wheelset*

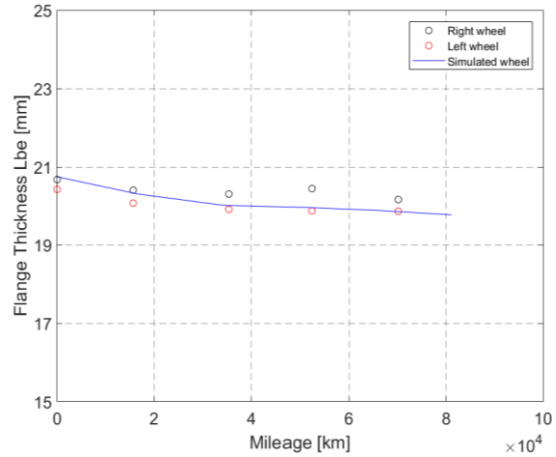

Figure 9 *Lbe dimension comparison at first rail step - leading wheelset*

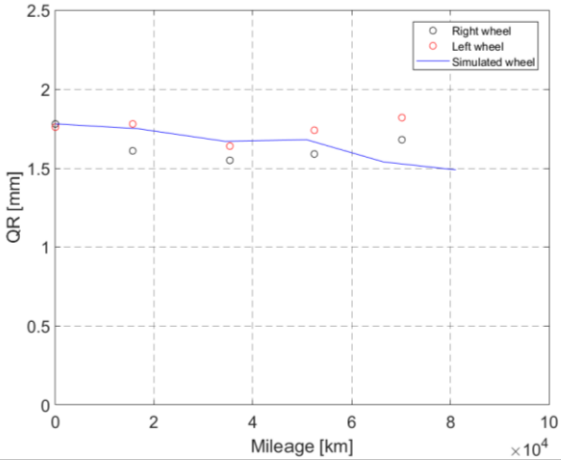

Figure 10 *Qr dimension comparison at first rail step - leading wheelset*

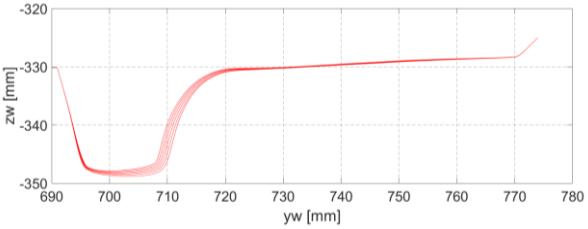

Figure 11 *Simulated wheel profile evolution at first rail step - leading wheelset*

The RCF model allows to have as outputs of each discrete step of the iterative process the crack depth distribution along the lateral wheel profile. More in details, for each point of the wheel profile in lateral direction, the model is able to predict if the crack initiates and its eventual length and depth. In Figure 12, the cumulative RCF crack depth on wheel for a running distance equal to 81,088 km is presented. This distance is obtained after 5 wheel steps of the iterative process and at first rail step (the rail profile is unworn). The last blue profile is the total amount of crack depth calculated adding up the crack depths obtained of each discrete step of the procedure. The crack length and depth for each discrete step, are evaluated considering the effect of wear on cracks: if the wear rate is high, the crack may be also worn off. To include the effect of wear, the difference between crack and wear depth is calculated. The cracks are considered worn off where this difference assumes negative values (see Equation (15)).
In Figure 13 the crack depth on wheel at first rail step plotted as a function of the distance travelled by the vehicle is presented while in Table 3 the experimental [6] and simulated maximum crack length and depth (the latter calculated by means Equation
(13)) are summarized. The predicted maximum crack depth after 81,088 km is 0.73 mm while, considering the experimental value of crack length as a function of the travelled mileage given by Dirks, Enblom and Berg (20 mm crack length in 240,000 km) and taking into account the relationship between crack length and depth (see Equation
(13)), the measured crack depth is about 2.5 mm. From Figure 6, it is possible to obtain the experimental crack length corresponding to a distance of 81,088 km and approximately equal to 6.25 mm in order to compare this value (named “Experimental scaled” in Table 3) with those numerically obtained at the same mileage. This way, a scaled experimental crack depth equal to about 0.78 mm is gotten. In conclusion, the comparison of these values has shown that the results obtained from simulations are comparable to those found in literature [6][7], confirming the goodness of the experimental law.
Finally, to show an example of the RCF model output concerning the rail, in Figure 12 the simulated crack depth evolution for all simulated rail steps and related to the curve with 25 m radius is presented.

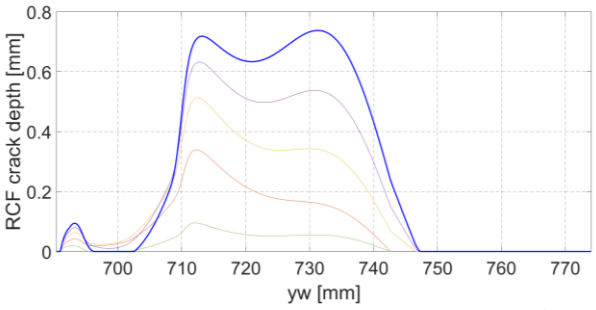

Figure 12 *Simulated RCF crack depth evolution on wheel of the leading wheelset*

4.2. RCF model outputs

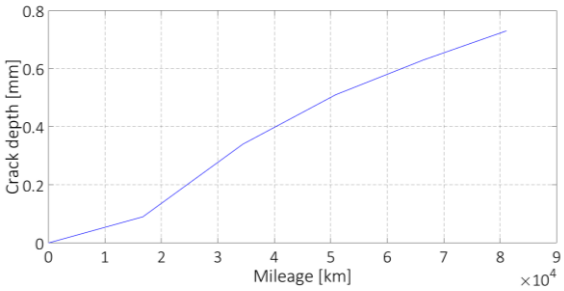

Figure 13 *Simulated crack depth against the mileage*

Table 3 *Experimental data vs simulated data*

DATA	Mileage [km]	Crack length [mm]	Crack depth [mm]
Experimental	240,000	20	2.5
Simulated [6]	81,088	5.84	0.73
Experimental scaled	81,088	6.25	0.78

5. Conclusions

In this work the Authors presented a complete model for the wheel and rail wear prediction properly combined to a RCF crack prediction model, specifically developed for tramway and railway applications. The main feature of the proposed model is the capability of simultaneously evaluating wear evolution and RCF crack growth (crack length and depth), both on wheel and on rail. The good compromise between numerical efficiency and accuracy reached by this new approach, allows the wear-RCF model to be implemented into complex multibody models of railway and tramway vehicles to be used for long and time-consuming simulations.

The whole model is made up of two main parts: the first one evaluates the vehicle dynamics by means of the vehicle multibody model implemented in Simpack Rail and a global wheel–rail contact model for the calculation of the contact points and of the contact forces. The second part is the wear model which, starting from the outputs of the multibody simulations, evaluates the amount of material to be removed. The estimation of wheel and rail wear is a discrete process and, for this reason, the evolution of the wheel and rail is described through several intermediate profiles. Also the different time scales in wheel and rail wear evolution has been taken into account through a suitable update algorithm based on the distance travelled by the vehicle and the tonnage burden on the track.

The RCF model has been implemented in parallel to the wear model and its main inputs are contact stresses, slips and calculated wear. The influence of wear on crack growth (high wear rate may wear off short cracks) has been considered at the end of each calculation step.

The necessary technical and experimental data for a preliminary wear - RCF model validation have been provided by Hitachi Rail Italy and Gest SpA. The considered test case is the Florence tramway line characterized by very sharp curves and on which the Sirio vehicle, built by Hitachi Rail Italy, circulates.

At this preliminary stage of the research, the Authors have considered the wheel damage evolution comparing the proposed wheel-rail prediction tool against wheel wear measurements: particularly, the numerically obtained wear results have been validated considering experimental data acquired on field while the RCF results have been compared to data available in other works presented in literature. A model validation against rail wear - RCF experimental data acquired on test rigs or directly on field has already been scheduled for the next project step.

As regards the wheel wear, the results obtained from the comparison are good in terms of wheel reference parameters. The wear model provided also the evolution of wheel profile, highlighting how the wear is mainly localized on the wheel flange and in particular on the flange top because the flange top running motion typical of a tramway line.

As regards wheel RCF, the numerical results concerning the crack growth as a function of the travelled distance showed to be comparable to the measured values found in literature highlighting, the goodness of the experimental law proposed by Dirks, Enblom and Berg [6][7].

As a future development, further model validations considering different vehicles and scenarios will be considered, focusing especially on the rail. Moreover, other wear mechanisms in addition to abrasive wear and RCF as plastic wear, pitting wear etc. will be implemented within the wear model. Furthermore, the conformal contact, that may become quite important especially under worn conditions (in particular on the wheel flange) and that cannot be neglected if an accurate wear assessment is required, will be considered together with a code optimization to further reduce the computational times.

Acknowledgments

Authors would like to thank Hitachi Rail Italy for providing all the technical data related to the vehicle and the Florence tramway line manager, Gest SpA (especially Engg. G.Zumbo) for giving us all the data related to wheel wear evolution.

Abstract: In order to study the mechanism of high order wheel polygonal wear, a long-term wear iteration model is established, in which a coupled vehicle/track dynamic model together with a wheel/rail wear model is included. Combined with experimental and simulation results, it suggests that the "constant-frequency" mechanism leads to the formation of high order wheel polygonalization. The third-order rail vertical bending resonance between the front and rear wheels of the bogie causes the periodic fluctuation of wheel rail forces at around 550-600 Hz and further leads to the periodic wear around the wheel circumferences, consequently, the high order polygonalization forms.

Keywords: wheel polygonalization; coupled vehicle/track dynamic model; flexible track; Archard wear model; wear prediction.

1. Introduction

Wheel polygonal is defined as a periodic irregularity around the wheel circumference from the mean wheel radius[1], which is one of most concerns in the railway vehicles. A vast number of researchers have done much work in the mechanism of the polygonal wear. Pallgen [2] compared the order of wheel polygonalization in different types of wheels in ICE trains and found that the third harmonic dominates for solid steel wheels while the dominating order of the rubber sprung wheel was second. According to Rode's [3] research, the initial third-order wheel polygonal may be caused by the three-jaw chuck during the wheel re-profiling. Kaper [4] and Dings [5] presented that the hot spots and hardening effects between cast-iron block and wheel tread could be the main contributor to the wheel polygonalization in Netherlands Intercity train. Johansson [6] gave a detailed overview of wheel polygonalization occurring in different types of train traffic in Sweden, it was shown that high eccentricity levels exist on most of the wheels, and the wheel irregularity with wavelengths in approximate range 30-80mm dominates on freight train and powered high-speed train wheels, which is also caused by the tread braking using cast-iron brake blocks. With a coupled vehicle/track dynamic model and a long-term wear model, Johansson and Andersson's [7] research indicated the vertical track anti resonance and the P2 resonance may cause the development of out-of-round. In recent years, great quantity of polygonal wear wheels were found in different type trains in China, including the metro train [8], the electric locomotive [9] and the high speed EMU [10]. Jin [8] carried out a detailed investigation into the mechanism of ninth-order polygonal wear in the LIM metro trains, the experiments show that the root causes of the ninth-order polygonal wear are attributed to the first bending resonance of the wheelset. Tao [9] presented the similar results that the polygonal wear of electric locomotive was related to the first bending mode of the wheelset axle and the lateral bending mode of wheel disc. High-order polygonal wear wheels were widely observed in Chinese high-speed EMU train, the wheels show the presence of 18-20th order polygonalization when the operating speed is 300 km/h[11, 12], while for the vehicle of 250 km/h speed, the dominating order becomes 23-24th[10]. The high order wheel polygonal in high-speed trains would lead to extremely large acceleration on axlebox and wheel/rail impact forces [12], and further reduce the residual lifetime of wheelset axle [11]. Besides, the wheel polygonalization also brings about serious wheel/rail noise and interior noise [13]. Thus, in order to control the development of high order wheel polygonalization from the root, it is necessary to get insight into the formation mechanism of wheel polygonalization.

In this study, the measured high order wheel polygonalization is analyzed firstly. Then a coupled vehicle/track dynamic model together with a wheel/rail wear model is established, in which a long flexible track model is taken into account. Prior to the wear prediction, the harmonic behaviour of the rail/wheel interaction is carried out to identify the possible contributor of the polygonal wear. Finally, using the long-term wear iteration model, the evolution of polygonal wear is investigated considering different parameters.

2. Experimental analysis

2.1. *Measured high order wheel polygonalization*

Large quantity of polygonal wear wheels were measured in China's high speed train. Fig. 1(a) (b) (c) illustrated the typical 18th, 19th and 20th order polygonalization obtained in the 300km/h train, the corresponding radii are 0.42m (18th order), 0.4375m (19th order) and 0.46m (20th order), respectively. Fig. 1(d) is the 23th order polygonalization on the wheel of 0.43m radius at speed 250km/h. The excitation frequency of those polygonalization is:

$$f_{oor} = \frac{V}{\lambda} = 550 \sim 600 Hz \quad (1)$$

This phenomenon shows a coincidence that dominating frequency of these different wheel polygonalizations are

all at the range of 550 ~ 600Hz regardless of speed and radius, which demonstrates that the "constant-frequency" mechanism is the cause of the high-order polygonal wear.

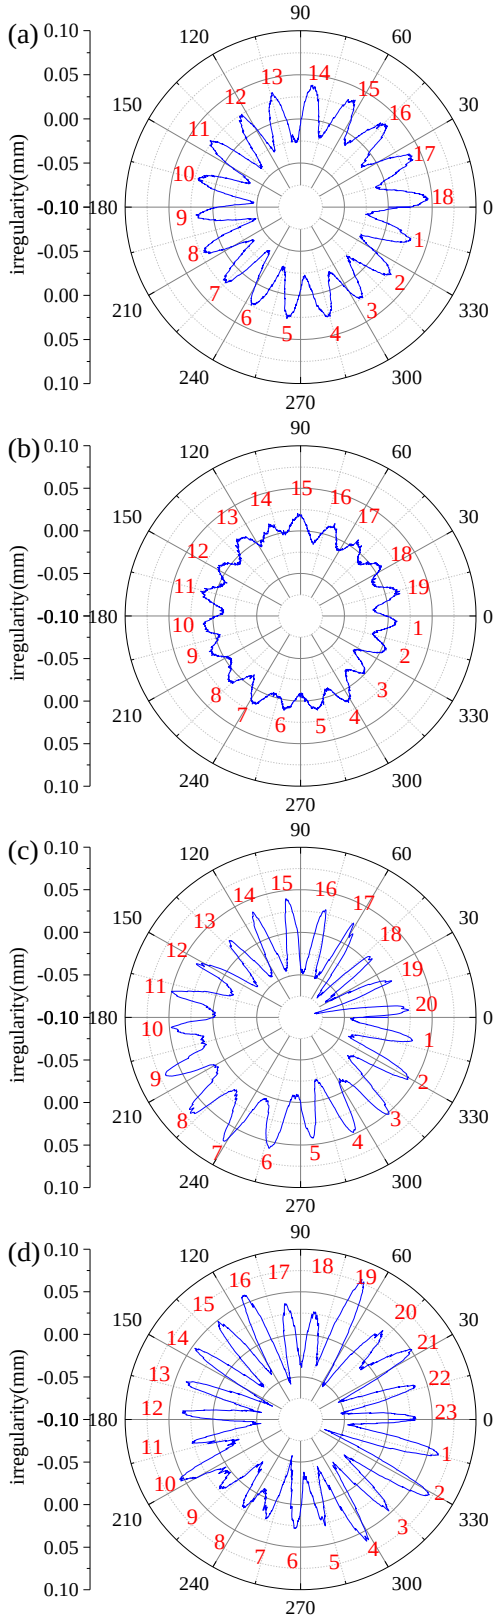

Figure 1 *Measured typical wheel polygonal wear in High-speed train, (a): 18th order wheel polygonalization (speed=300km/h, radius=0.42m), (b): 19th order wheel polygonalization (speed=300km/h, radius=0.4375m), (c): 20th order wheel polygonalization(speed=300km/h, radius=0.46m), (d): 23th order wheel polygonalization(speed=250km/h, radius=0.43m).*

2.2. Measured vehicle vibration

Once the wheel polygonalization has formed, the vehicle/track system would be in the condition of forced vibration. In order to take away the influence of the forced vibration caused by the formed wheel polygonalization and identify the root cause of the initial formation stage of wheel polygonalization, the accelerations of the vehicle right after the wheel re-profiling are measured in operation. Fig. 2 shows the vertical accelerations of the axlebox obtained from two different type's high speed right after the wheel re-profiling, one EMU's operation speed level is 300km/h, the other one is 250 km/h. As it is can be seen, in spite of different types of vehicles and different operation speeds, the frequency spectral of vertical accelerations obtained from the axlebox presents the similar peaks at about 45 Hz and 550~650 Hz. The first peak at about 45 Hz is related to the P2 resonance. The second peak at around 550~650 Hz is coincident with the excitation frequency of the high order polygonalization. In other words, the dominating frequency of the axlebox acceleration still locates at high order polygonalization excitation frequency even though the high order polygonalization has been removed. Therefore, it is indicated that resonance at 550~600 Hz exists in the vehicle/track system which induces the periodic oscillation in the wheel/rail interface, consequently, leads to the periodic wear around the wheel circumference. In order to identify where the resonance exactly comes from, detailed simulation would be carried out in later section.

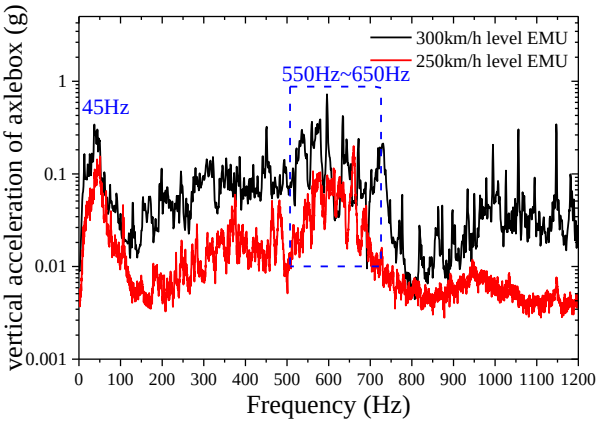

Figure 2 *Spectral of vertical acceleration of axlebox at different speeds right after the wheel re-profiling*

3. Coupled vehicle/track dynamic model

To account for the high frequency vibration, a coupled dynamic model incorporating with a flexible slab track model is established, as the Fig.3 shown.

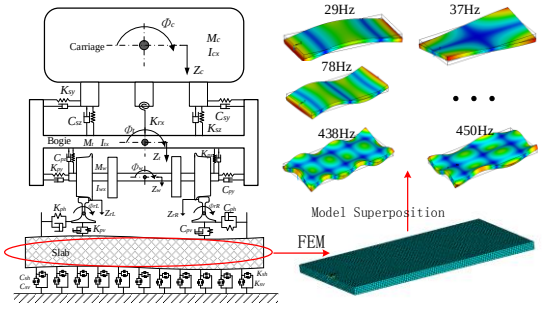

Figure 3 *Coupled vehicle/track dynamic model*

The vehicle is treated as a carbody seated on two bogies

through the secondary suspensions. Each bogie consists of two wheelsets and a bogie frame, the wheelsets are coupled to the bogie frame via first suspensions. Each component has six rigid body degrees of freedom (DoF), including three translation motion and three rotation motion respect to vertical, lateral, longitudinal directions. The conventional motion equations of the vehicle can refer to [14].

As for the track subsystem, the rail is described by a Timoshenko beam discretely supported on slabs through the rail fasteners, where the fasteners are represented by periodic discrete viscoelastic elements. The slab is formulated using the finite element method, and the displacement of the slab can be described by the modal superposition principle [15],

$$x = \sum_{i=1}^{N_{\text{mode}}} \{\phi\}_n X_n \qquad (2)$$

where $\{\phi\}_n$ is the nth modal shape vector, X_n represents the generalized modal coordinates of the slab, which can be solved through,

$$M_n \ddot{X}_n + C_n \dot{X}_n + K_n X_n = P_n \qquad n = 1 \sim N_{\text{mode}} \qquad (3)$$

in which, M_n, C_n, K_n and P_n are the generalized mass, damping, stiffness matrix and load vector for mode n, which could be obtained from the FEM software ANSYS.

The coupled vehicle/track dynamic model is further dealt with by a 'sliding window' method [16, 17], as shown in Fig.4. In this method, the vehicle initially locates at the left side of centre region of the track regarded as the initial position. After the running distance of *L_m* on the track, the vehicle reaches the right side of centre region of the track system regarded as the end position. Subsequently, the vehicle together with its dynamic state in a specific window is manipulated to the initial position from the end position. The least square criterion is used to eliminate the artificial disturbances caused by the window sliding. By repeating this procedure, this method permits us simulating the vehicle running on an infinite long track smoothly.

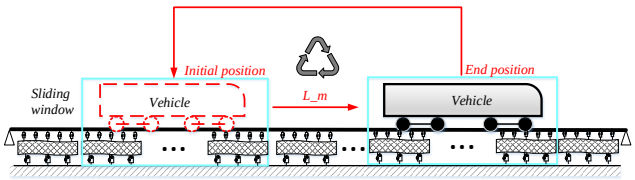

***Figure* 4** *A simulation scheme of the vehicle travelling on an infinite long track.*

The coupled vehicle/track dynamic model is validated through comparing its dynamic response to the measured one. The vertical acceleration of the axlebox is tested when the vehicle operates at the speed of 250 km/h on the Guizhou-Guangzhou high-speed line. The wheels are just after re-profiling and the track irregularities on Guizhou-Guangzhou line with wavelength at the range of 20-300 mm are measured using CAT system. Both measured wheel initial polygonalization and track irregularities are input to the simulation model. Fig. 5 presents the discrete Fourier transform of the tested vertical acceleration of the axlebox and the simulation results, it can be seen that the simulation has a good agreement with the field test in the frequency domain, the crest at 45 Hz and 105 Hz are the P2 resonance and sleeper passing frequency [18] respectively. It is expected that the peaks at the range of 300-400 Hz and 550-650 Hz are associated with the formation of high order polygonalization.

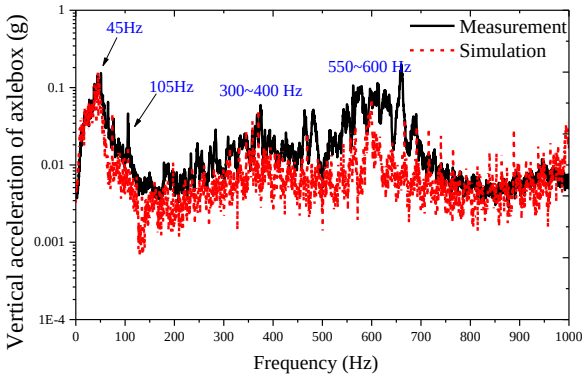

Figure 5 *Validation* of the coupled vehicle/track dynamic model

4. Harmonic behavior of the wheel/rail interface

In order to identify the possible contributor of polygonal wear in the coupled vehicle/track system, a sinusoidal excitation is applied at the wheel/rail interface, the frequency sweep range is from 10~1300 Hz, the amplitude is 0.01 mm. Two scenarios are first considered in the simulation, one is for single wheelset model, and the other is the single bogie model (wheelbase=2.5m), as shown in Fig. 6. For the single bogie model, the excitation is applied only at the rear wheel and the response of forces at the rear wheel is evaluated. The harmonic responses of the wheel/rail normal forces obtained from the two models are illustrated in Fig. 7, both models show a crest at 45 Hz, which is caused by the P2 resonance. However, for the single bogie model, the contact forces have other four more peaks in the frequency of around 180 Hz, 400 Hz, 650 Hz and 960 Hz.

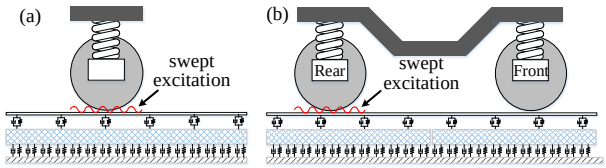

Figure 6 *Harmonic response of the wheel/rail contact: (a) single wheelset model (b) single bogie model*

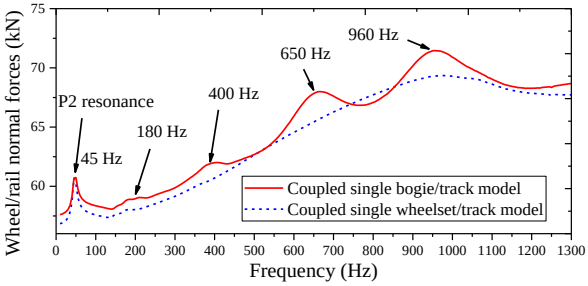

Figure 7 *Comparison of harmonic responses of the wheel/rail normal forces between the single wheelset model and single bogie model.*

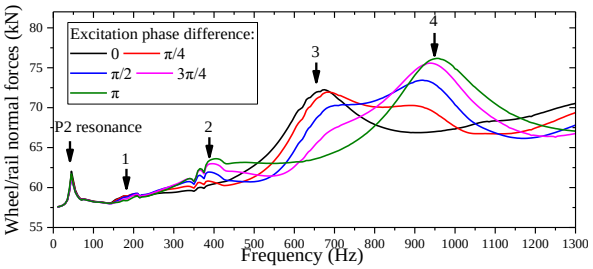

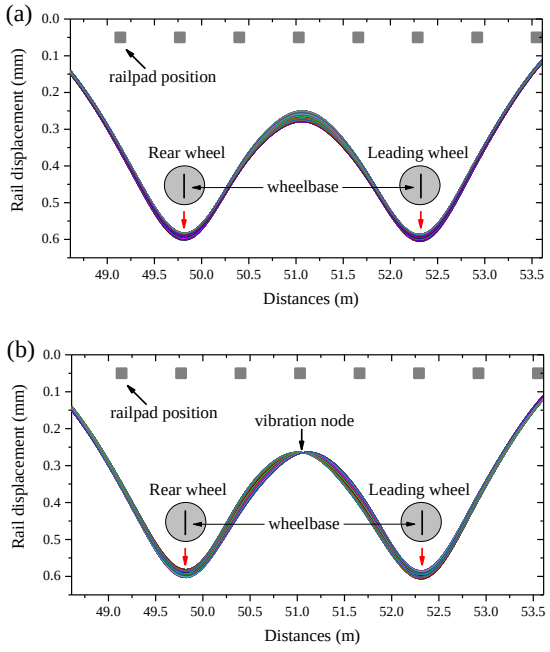

Figure 8 *Harmonic responses of the wheel/rail normal forces with different excitation phase differences between front and rear wheelset.*

Detailed calculation is carried out to find out where the four peaks comes from in the coupled single bogie/track model: sinusoidal excitation is applied at the front and rear wheels at the same time considering different phase differences, the responses of the wheel/rail normal forces are illustrated in Fig. 8, it is found from Fig. 8 that peak 1 (180Hz) and peak 3 (650Hz) reach the maximum when the excitations are at the same phase, while peak 2 (400Hz) and peak 4 (960Hz) become the most prominent when the excitations are at the anti-phase. According to the previous research[19], these four peaks could be caused by the rail wave reflections between the front and rear wheels, the peaks at 180 Hz, 400 Hz, 650 Hz and 960 Hz are relate to the first-order, second-order, third-order and fourth-order vertical rail bending mode between the front and rear wheels of bogie, respectively. For further verification, the rail displacements vibration near the two wheels at different frequencies are plotted in Fig. 9. As it can be seen, the two wheels play a role of constraints to the rail, and the rail vibrates locally between the constraints. Furthermore, the rail has zero, one, two and three vibration nodes respectively when the excitation frequency is 180 Hz, 400 Hz, 650 Hz and 960 Hz, which coincides with the properties of first-order, second-order, third-order and fourth-order bending mode.

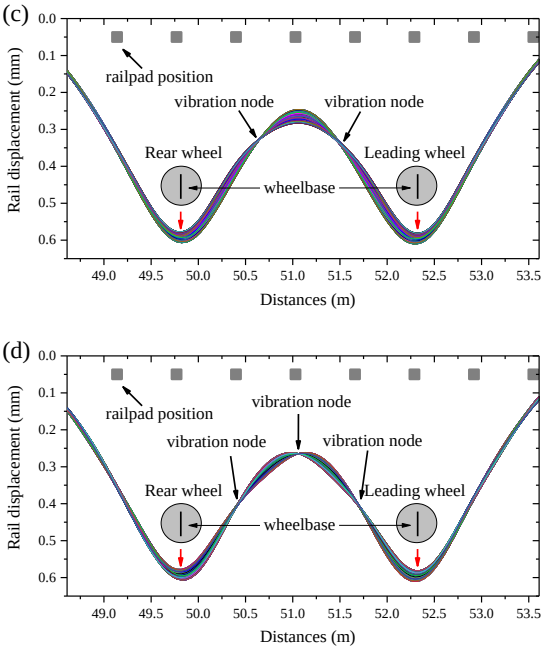

Figure 9 *Vibration shapes of rails under different frequency excitation: (a) excitation at 180 Hz, have no vibration node; (b) excitation at 400 Hz, hove one vibration node; (c) excitation at 650 Hz, hove two vibration node; (d) excitation at 960 Hz, hove three vibration node;*

From the harmonic response results, the second-order and third-order rail local bending mode frequencies are close to the peak frequencies of the axlebox acceleration (cf. Fig. 5), and the high order polygonalization characteristic frequencies. It is, thus, believed that rail local bending modes could be the main contributor to the high order wheel polygonalization.

5. Prediction of the wheel polygonal wear

5.1. *Wear model*

There are many different wear hypothesis in the prediction of wheel/rail wear [20], the Archard model is widely used due to its good accuracy. The volume of worn material V_{wear} (m^3) is assumed as follows,

$$V_{wear} = k_w \frac{Nd}{H} \tag{4}$$

in which, k_w is the wear coefficient, and the value is dependent on the contact normal pressure and the slip velocity. H is the hardness of the softer material. N denotes the normal force (N) and d represents the sliding distance (m).

Based on the FASTSIM algorism, the wear depth in each element at each instant can be solved by [21],

$$\Delta z = \frac{3Nk_w}{2\pi abH}\sqrt{1-\left(\frac{x}{a}\right)^2-\left(\frac{y}{a}\right)^2}\sqrt{{s_x}^2+{s_y}^2}\frac{\Delta x}{v_c} \tag{5}$$

In the present work, only the tangent track is simulated and the wheel/rail sliding is relatively small, it is thus assumed wear coefficient simply has the constant value $k_w = 1\times10^{-4}$, and the hardness of wheel tread is chosen to be $H = 3.2\text{Gpa}$ according to [21]. And only the wear of wheel is calculated.

5.2. *Long-term wear iteration scheme*

Based on the coupled vehicle/track dynamic model and Archard wear model, the long-term wear iteration

scheme is given in Fig. 10. At the beginning, the initial wheel polygonalization is input into the coupled vehicle/track dynamic model. Short-term dynamic simulation is carried out to obtain the time history of the wheel/rail normal forces, creepage and contact patch size, the total running distance is only 15 wheel revolutions, in which the first 5 revolutions are excluded to minimize the influence of the initial transient response. Subsequently, the wear depth corresponding to the valid 10 wheel revolutions is calculated by the Archard model and summed around the wheel circumference. The short-term wear depth are further scaled by a large factor (20852) associated to a longer travelled distance (550 km).The scaled wear depth will be added around the wheel circumference, as the last step of each iteration, for updating the wheel polygonalization. Then, based on the updated wheel polygonalization, such process is performed once again. In order to simulate more realistic operating condition, the running direction of the vehicle changes from one iterative step to another, and the wheels are rotated a random angle before each dynamic simulation. By repeating the long-term iteration, the wheel polygonalization evolution is expected to be obtained.

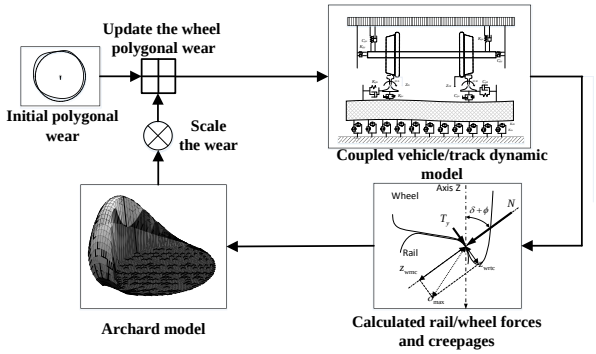

Figure 10 *Flow chart of the tong-term wear iteration.*

5.3. Prediction of the wheel polygonal wear

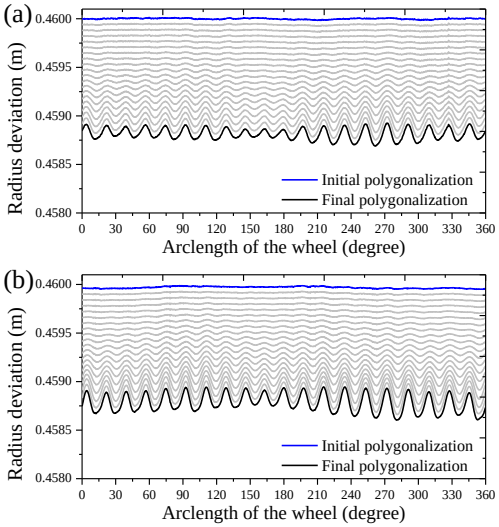
Using the long-term wear iteration model, the polygonal wear progress is predicted. The measured re-profiled wheel irregularity is taken as the initial irregularity at the beginning of the wear prediction. The vehicle speed is 300 km/h in the simulation. The nominal value of parameters of the vehicle and track system are listed in Table 1.

Table 1 *Value of parameters*

Notation	Parameters	Value
Track subsystem		
$E(N/m^2)$	Young's modulus of rail	2.059×10^{11}
$G\ (N/m^2)$	Shear modulus of rail	7.9×10^{10}
$\rho(kg/m^3)$	Density of rail	7860
$A\ (m^2)$	Cross-sectional area	7.745×10^{-3}
$I_y(m^4)$	Bending moment about y-axis	3.217×10^{-5}
$I_z(m^4)$	Bending moment about z-axis	5.26×10^{-6}
$I_0(m^4)$	Polar moment of inertia	3.741×10^{-5}
κ_y	Lateral shear coefficient	0.4570
κ_z	Vertical shear coefficient	0.5329
$\rho_s(kg/m^3)$	Density of slab	2800
$E_s(N/m^2)$	Young's modulus of slab	3.6×10^{10}
$K_{pv}(MN/m)$	Rail pad vertical stiffness	40
$C_{pv}(kN.s/m)$	Rail pad vertical damping	30
$l_0(m)$	Sleeper spacing	0.63
Vehicle subsystem		
Speed(km/h)	Vehicle speed	300
$M_c(kg)$	Carbody mass	44039
$M_t(kg)$	Bogie mass	2439
$M_w(kg)$	Wheelset mass	1881
$K_{sz}(MN/m)$	Vertical stiffness of secondary suspension	0.24
$C_{sz}(kN.s/m)$	Vertical damping of secondary suspension	25
$K_{pz}(MN/m)$	Vertical stiffness of primary suspension	9
$C_{pz}(kN.s/m)$	Vertical damping of primary suspension	10.5
$R_w(m)$	Wheel radius	0.46
$L_c(m)$	Distance between two bogie frames	8.9
$L_t(m)$	wheelbase	2.5

After 40 iteration steps (22 000 km), Fig. 11 and Fig. 12 show the evolution of the polygonal wear of two wheels in the left side of bogie described by the Cartesian coordinate system and spatial spectrum. As it can be seen, the wheel stochastic irregularities develop into high-order polygonalization gradually. The dominating harmonic order of the final polygonalization is 20th order for both wheels, the roughness level of the 20th order polygonalization grows from around -10 dB to 35 dB. The polygonalization evolution in the right side of the bogie is similar to the left one, which is not listed here. These results show a good agreement with the polygonal wear measured on the 300 km/h EMUs.

Fig 13 presents the polygonalization evolution when using the single wheelset model. Comparing to the single bogie model, the 20th order wheel polygonalization does not form in the single wheelset model. Combined with the aforementioned results of the harmonic behavior of the wheel/rail forces, it can be inferred that the third-order rail vertical bending resonance between the wheels of bogie is the main contributor to the periodic fluctuation of wheel rail forces at around 550-600 Hz and further lead to the periodic wear around the wheel circumferences, consequently, the 20th high order polygonalization forms.



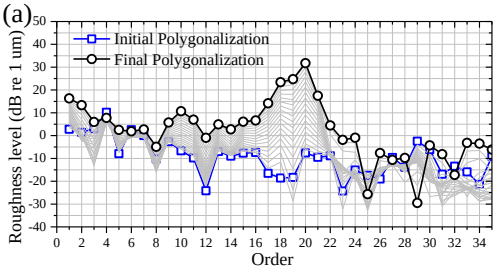


Figure 11 *Evolution of the wheel polygonalization in the left side of a bogie described in Cartesian coordinate system: (a) front wheel; (b) rear wheel.*

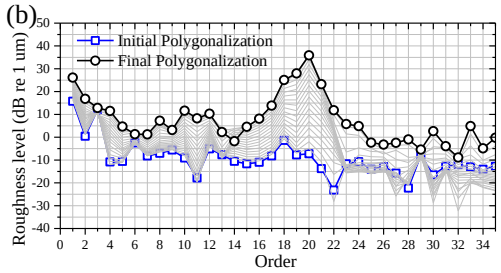

Figure 12 *Evolution of the wheel polygonalization in the left side of a bogie described by harmonic order levels: (a) front wheel; (b) rear wheel.*

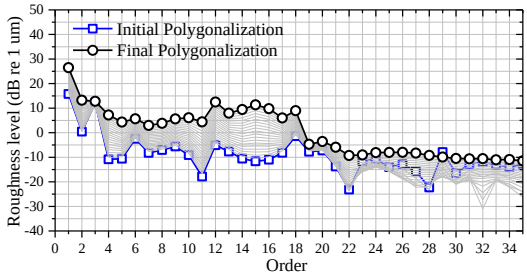

Figure 13 *Evolution of the wheel polygonalization when using a single wheelset model.*

5.4. Parametric studies

In order to get insight into the mechanism of the high-order polygonalization and put forward the mitigation measures, comprehensive parametric studies of the evolution of polygonalization have be carried out considering different operating speeds, wheelbases, railpad vertical stiffness and railpad vertical damping. Fig 13 indicates the effect of different operating speeds on the formation of the wheel polygonalization, the final polygonalizations at 200 km/h, 250 km/h, 300 km/h and 350 km/h speeds are in the presence of 30th order, 24th order, 20th order and 15th order, respectively. Through calculating, the passing frequencies of these wheel polygonalizations are all at the range of 550 ~ 600Hz, which is quite comparable to that measured on the China high speed train and further proves the "constant-frequency" mechanism. Therefore, it is expected that changing speed, instead of constant speed operating, would violate the formation law of wheel polygonalization and suppress the growth rates of polygonal wear.

Obviously, with the increase of the wheelbases, the vertical bending frequency of the rail would decrease. Fig 14 illustrates the formation process of wheel polygonalization when the wheelbases are 2 m, 2.5 m, 2.7 m and 3 m. The wheel with wheelbases of 2.5 m, 2.7 m and 3 m grows to 20th order, 18th order and 15th order polygonal wear respectively, whose passing frequency are 577 Hz, 519 Hz and 432 Hz. It is due to that the third-order rail vertical bending frequency between the wheels of bogie descends as the increase of wheelbases. However, the difference is that the wheel polygonalization with wheelbase of 2 m develops into 16th order finally (461 Hz), which is not in accordance with the third-order rail vertical bending frequency. Further results in Fig 15 show that the wheel polygonalization with wheelbase of 2 m is more likely attributed to the second-order rail vertical bending resonance between the front and rear wheels rather than third-order one. Fig 15 presents the final polygonalization on front wheel and rear wheel of bogie, it is found that the phase of front and rear wheel polygonalization with wheelbase of 2 m is opposite, while the others' are in phase, which are corresponding to the excitation characteristics of the second-order and third-order rail bending mode.

The influences of the railpad vertical stiffness are shown in Fig 16, the dominating order of the polygonalization change little (20th order) when the rail pad stiffness is under 100 MN/m. However, the 2nd order wheel polygonalization (58 Hz) becomes dominated when the stiffness increased to 100 MN/m, it is because the large railpad stiffness aggravates the response of P2 resonance , the P2 resonance becomes the main cause of lower order polygonalization instead of the rail local bending mode.

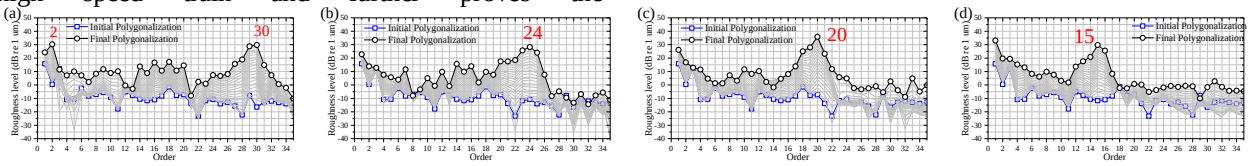

Figure 13 *Effect of the vehicle operating speeds on the evolution of the wheel polygonalization: (a) 200 km/h; (b) 250 km/h; (c) 300 km/h; (d) 350 km/h;*

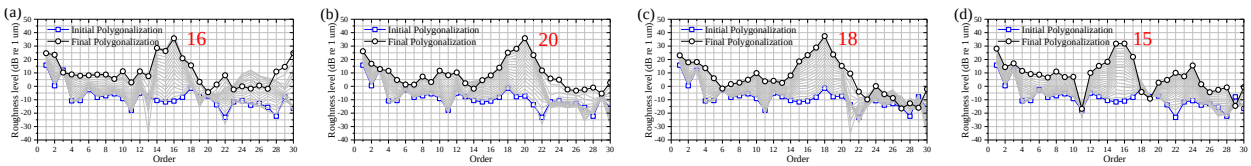

Figure 14 *Effect of the wheelbases on the evolution of the wheel polygonalization: (a) 2 m; (b) 2.5 m; (c) 2.7 m; (d) 3 m;*

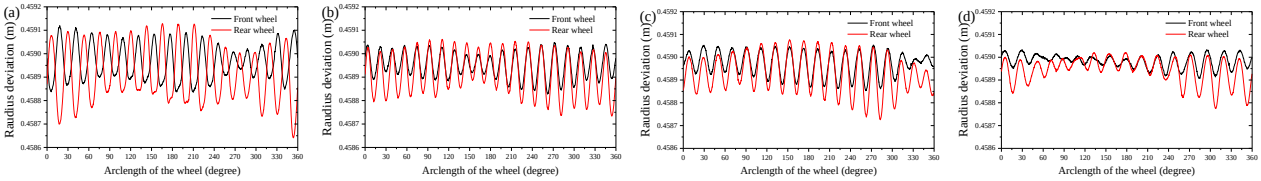

Figure 15 *Effect of the wheelbases on the polygonalization phase differences between the front and rear wheels: (a) 2 m; (b) 2.5 m; (c) 2.7 m; (d) 3 m;*

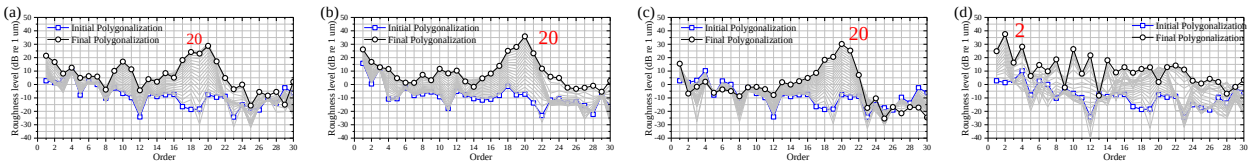

Figure 16 *Effect of the railpad vertical stiffness on the evolution of the wheel polygonalization: (a) 20 MN/m; (b) 40 MN/m; (c) 80 MN/m; (d) 100 MN/m;*

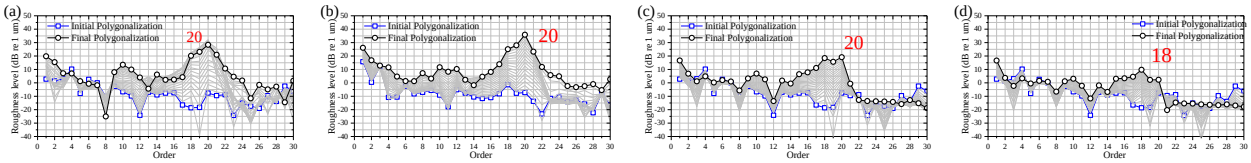

Figure 17 *Effect of the railpad vertical damping on the evolution of the wheel polygonalization: (a) 10 kN.s/m; (b) 30 kN.s/m; (c) 40 kN.s/m; (d) 50 kN.s/m;*

Fig 17 illustrates the effect of the railpad damping on the formation of wheel polygonalization, the increase of railpad damping would suppress the dynamic responses of rail local bending resonance and further reduce the growth rate of the wheel polygonalization.

6. Conclusions

The high-order wheel polygonal wear is a tricky problem in the China's high speed railway, the mechanism is still being debated. This paper gives some typical polygonalization measured on wheels with different radius and different vehicle operating speeds firstly. Then a long-term polygonal wear iteration scheme is modelled, in which a coupled vehicle/track dynamic model and Archard wear model are considered. Prior to the wear prediction, the harmonic behavior of the rail/wheel interaction are carried out to identify the possible contributor of the polygonal wear. Finally, the evolution of the wheel polygonalization is predict considering different speeds, wheelbases, railpad stiffness and damping. The conclusions are as follows,

1. The passing frequency of the high order wheel polygonalization in China's high speed railway is mainly in the frequency range of 550~600Hz regardless of the operating speed and wheel radius, which means that they are induced by the "constant-frequency" mechanism.
2. The rail vertical bending mode between the front and rear wheels of bogie plays an important role in the dynamic response of the wheel/rail forces. The frequencies of first-order, second-order, third-order and fourth-order rail local bending mode are 180 Hz, 400 Hz, 650 Hz and 960 Hz, respectively.
3. Combined the results obtained from harmonic response and long-term polygonal wear iteration, it is concluded that the third-order rail vertical bending resonance between the wheels would cause the periodic fluctuation of wheel rail forces at around 550-600 Hz and further lead to the periodic wear around the wheel circumferences, consequently, the 20th high order polygonalization forms.
4. Increasing the operating speed would shift the high dominating order of the wheel polygonalization to lower. Changing speed, instead of long-time constant speed operating, could violate the law of formation of wheel polygonalization and suppress the growth rate of polygonal wear.
5. With different wheelbases, the wheel would grow to different order polygonalization according to its dominating rail local bending resonance frequency. The dominating order of the polygonalization changes little when the railpad stiffness is under 100 MN/m, while the P2 resonance-induced polygonalization become dominated when the railpad stiffness increased up to 100 MN/m. The increase of railpad damping would reduce the growth rate of the wheel polygonalization.

Abstract: Adhesion in the wheel-rail contact is a key factor determining stable running conditions and safety during train driving and braking. The wheel-rail abrasion of EMUs often occurs when the adhesion force is insufficient. This paper presents experiments performed on the high-speed full-scale roller rig of wheel-rail interface to simulate the low adhesion problem of high-speed wheel-rail adhesion in wet condition. Tests were conducted to study the adhesion characteristic at high speed under water lubrication. The influential factors on the high-speed wheel-rail adhesion coefficient are investigated, which include water spray amount, roughness of wheel-rail contact surface, running speed, water spray temperature and axle load. In the adhesion tests, water was sprayed on the wheel-rail contact interface by 0 to 250ml/min, the roughness of the wheel-rail contact surface Ra was set within 0.30 to 1.1μm, the test running speed range was 40 to 400km/h, the temperature of water changed from 0 to 80℃ to simulate the effect of temperature on the adhesion coefficient, the axle load was set within 8 to 16t respectively. The law of influence on wheel-rail adhesion characteristic curves at high speed was revealed and explained based on the test results, which can be helpful to the design and optimization of the brake anti-slip control and traction wheel rotation/slip control device of EMUs.

Keywords: wheel-rail interface; rolling contact; adhesion characteristic curve; water spray amount; surface roughness; axle load; temperature.

1. Introduction

Wheel-rail adhesion characteristics have direct influence on the traction and braking performance and the quality of operation of high-speed trains. The starting, acceleration, deceleration and parking of the train are all directly related to the wheel-rail adhesion. There are many factors affecting wheel-rail adhesion, such as speed, axle load, angle of attack, and the status of wheel-rail contact surface. When the wheel-rail adhesion is insufficient, wheel slipping would take place during train operation, leading to the failure in the train to drive, start up and accelerate, while brakes would cause the wheel to slide and the train to go beyond the limited braking distance. At the same time, both the slipping and sliding would definitely cause surface abrasions on the wheel and the rail, which would not only affect the running quality of the operation of the high-speed train, but also aggravate the damage of the wheel and the rail, increase the maintenance cost and endanger the safety of high-speed railway.

Theoretical simulation, rig test and line test constitute the main methods of testing wheel-rail adhesion. The numerical model of wheel-rail adhesion mainly includes Carter's two-dimensional rolling contact theory [1], Vermeulen P.J. and Johnson K.L's elliptic contact theory[2], Kalker J.J.'s three dimensional linear law of creep rate/force and its simplified theory[3-5], CONTACT program, ALE finite element wheel-rail rolling model[6-8], and the mixed lubrication theoretical model[9-12]. As these models do not include the influence of high frequency vibration and the "third medium" of wheel-rail interface on wheel-rail adhesion, it is difficult to accurately simulate the adhesion process between high-speed wheel and rail. Currently, small-scale wheel-rail test rigs are still used in many research institutions to study the wheel-rail adhesion characteristics [13-16], based on the similarity theory of Hertz contact. Due to existence of nonlinear characteristics in the wheel-rail rolling contact relationship, it is impossible to accurately predict the operation status of real line by the small-scale test rigs based on the general similarity theory. This is the fundamental deficiency of small-scale test rigs. Also, it is difficult to obtain the high-speed wheel-rail adhesion law out of the tests carried out on the small-scale low-speed wheel-rail test rig. On the other hand, the line test is a good way to study the wheel-rail adhesion coefficient, but the downside of it includes high cost of carrying out the test and rail abrasion, which is easy to occur. In 1990, Ohyama[17] tested the Shinkansen 200 Series, Class 951 electric trainsets with water sprayed on the rail surface, and obtained the adhesion coefficient distribution in the speed range of 30-270km/h and 60-210km/h.

Not only does the adhesion test taken on the full-scale high-speed wheel-rail interface test rig avoid the shortcomings of the general similarity relation on the

low-speed small-scale test rig, but it also overcomes the disadvantage of high cost of carrying the adhesion test on real lines in operation. Besides, all influence factors can be controlled, thus it is possible to measure the influence of a single factor on the high-speed wheel-rail adhesion. In this experimental study, researchers used a full-scale high-speed wheel-rail interface test rig to research high-speed wheel-rail adhesion characteristics in wet condition, and the influence of variance in the amount of water spray, roughness of the wheel-rail contact surface, running speed, temperature of water spray and axle load on the high-speed wheel-rail adhesion coefficient under water medium conditions.

2. High-speed wheel-rail interface test rig

The full-scale high-speed wheel-rail interface test rig of China Academy of Railway Sciences is technically advanced, with perfect measuring and testing functions and the maximum testing speed of 500km/h. It can be used for fundamental, forward-looking study of basic application technologies, simulated integrated test of wheel-rail products with an aim to improve the design and reliability of the products. With it, we have dramatically improved the tests and theoretical studies of high-speed wheel-rail interface in China.

The test rig consists of rail-wheel system, wheelset system, hydraulic excitation system, environment simulation system for track contact interface, numerically controlled rail-wheel profile lathing device, high-pressure hydraulic supply unit, lubrication unit, calibrator, electrical equipment, measurement and data acquisition system, control system and other parts. Figure 1 shows the test rig's outfit for adhesion test, while Table 1 shows the main technical parameters of the test rig. The rig can simulate dry, wet and oily wheel-rail interface environment and measure wheelset(adhesion wheel) rotation speed, Track wheel rotation speed, wheel-rail contact force, wheelset lateral displacement, wheelset attack angle, hydraulic excitation force, motor torque, braking torque and other parameters. It can be used to carry out tests of high-speed wheel-rail adhesion, creep, derailment, wear, fatigue, braking, noise, etc. It can also be used for dynamic calibration tests of instrumented wheelsets and the tests for matching and optimization test of wheel-rail geometry and material properties.

3. Methods of wheel-rail adhesion test on HS wheel-rail test rig

(1) Mathematical definition of wheel-rail adhesion characteristic curve

Wheel-rail adhesion characteristic is normally expressed with the longitudinal adhesion coefficient and the longitudinal creep rate curve. In the rig test, the traction coefficient is defined as

$$\mu_x = \frac{F_x}{N} \tag{1}$$

Where F_x refers to the wheel-rail traction force, and N the wheel-rail normal contact.

And the longitudinal creep rate can be obtained with the following equation:

$$\xi_x = \frac{R_w N_w - R_r N_r}{(R_w N_w + R_r N_r)/2} \tag{2}$$

Where R_w and R_r refer to the radiuses of the adhesion wheel and the track wheel at the contact point respectively, while N_w and N_r refer to the rotation speeds of the adhesion wheel and the track wheel respectively.

(2) Preparations before the test

To remove the pollution on the wheel-rail contact surface, the surface of the adhesion wheel and the track wheel shall be cleaned with alcohol or rust before the test to keep the rolling surface clean and dry. The diameters of the wheel and track wheel shall be measured before the test. The profiles of the wheel and the track rail shall be measured with Miniprof. The hardness of the tread of the wheel and track wheel shall be measured with the sclerometer, and the roughness of the contact surfaces of the wheel and the track wheel shall be measured with the roughness meter. The vertical load, the lateral load, speed and the relative lateral displacement and the attack angle of the wheel and the track wheel shall be set, and the position on the gearbox shall be set on the test rig. The environmental condition shall be dry and clean, with water or oil added. The ambient temperature shall be controlled to stay within the range 0 to 40℃ and the ambient humidity at 60%RH , and both shall be measured during the test.

(3) Procedures of the test

1) The vertical exciter above the wheel applies vertical load, another vertical exciter controls displacement (and the equilibrium position of the guide frame), and the lateral exciter controls the wheel so that the lateral displacement of the wheel is 0mm.

2) Start the drive motor to rotate the track wheel, and the adhesion wheel should start rotating due to the wheel-rail friction, following the track wheel. Wait until the speed of the contact point of the track wheel and the adhesion wheel reaches the specified test speed.

3) According to the wheel-rail interface, select a suitable test condition: clean and dry, wet or oily, and begin apply the environmental simulation condition.

4) Gradually increase the rotation speed of the adhesion wheel so that the track wheel rotation remains constant. Gradually increase the wheel-rail longitudinal creep rate from zero to 1%, and then gradually decrease it to zero.

5) Stop applying the environmental simulation condition, and use the drive motor to gradually decrease speed of the track wheel and the wheel to zero.

4. Experimental study of wheel-rail adhesion characteristics and law of influence in wet condition

In the wheel-rail adhesion test, the wheel material was ER8, the tread profile was S1002CN, and the hardness of the wheel tread around the rolling circle ranged from 260HB to 320HB; the track wheel material was U71MnK, the profile was TB60, and the hardness of the track wheel top around the rolling circle ranged from 320HB to 380HB. The roughness of the wheel tread of the high-speed EMU train in field was monitored, showing that after wheel tread lathing operation of 20,000km, Ra, the roughness of the wheel tread around the rolling circle, was between 0.4μm and 0.6μm.

4.1. Influence of variance in amount of water spray on HS wheel-rail adhesion characteristics

(1) Test conditions

The test speed was 250km/h, there was no lateral displacement of the wheelset in relation to the track wheel, and the wheelset had no attack angle. A 70kN testing vertical constant load (equivalent to an axle load of 14T) was applied, the roughness of the wheel contact surface Ra ranged from 0.45 to 0.55μm, and the roughness of the contact surface of the track wheel Ra ranged from 0.2 to 0.3μm. During the test, the amount of water sprayed per unit of time on the wheel-rail contact interface was adjustable (and the difference in the amount of water sprayed per unit of time was big enough to simulate that between heavy and light rains). Thus, the wheel-rail interface was preconditioned to be clean and dry, the amount of water sprayed per unit of time be 50ml/min, 100ml/min, 150ml/min, 200ml/min and 250ml/min respectively, and the ambient temperature and the water temperature were both room temperature.

(2) Test analysis

When the wheel-rail contact surface is clean and dry, the amount of water sprayed was 50ml/min, 100ml/min, 150ml/min, 200ml/min and 250ml/min (room temperature) respectively and the speed was 250km/h, the function of tractive force/wheel load (coefficient of tractive force) versus time is shown in Figure 2. It shows that, under the clean and dry condition, after the tractive force/wheel load of the wheel-rail contact surface reached its highest point, it fluctuated slightly; with the amount of water spray being 50ml/min, after the tractive force/wheel load reaches its highest point, it fluctuated most vehemently; then, with the amount of water spray increasing, after the tractive force/wheel load reached its highest point, it gradually fluctuated less; and when the amount of water spray being 200ml/min, after the tractive force/wheel load reached its highest point, the fluctuation basically disappeared. This phenomenon may have something to do with the water-film condition of the wheel-rail contact surface made by the increasing amount of water spray. When the amount was low, due to the unstable time-related distribution of dryness and wetness on the wheel-rail contact surface, as when the surface was dry the wheel-rail friction coefficient was higher, and when it was wet the coefficient became lower, hence the fluctuation of the wheel-rail tractive force. Whereas when the amount of water spray was increased to 200ml/min, the water film on the wheel-rail contact surface became completely and stably distributed, thus the disappearance of the fluctuation of the wheel-rail tractive force.

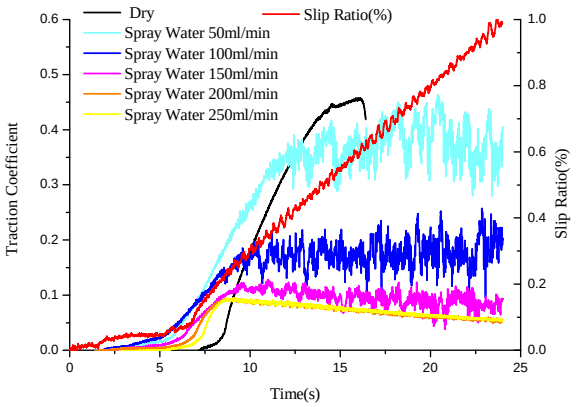

Figure 2 *Tractive force/wheel load versus time with different amount of water spray at the speed of 250km/h*

The traction adhesion characteristic curve with different amount of water spray is shown in Figure 3. The figure shows the basic features of the wheel-rail traction adhesion characteristic curve with the wheel-rail contact surface being dry and clean and with different amount of water spray. When the contact surface was dry, the longitudinal creep rate at the saturation point of the adhesion characteristic curve was 4.5‰, and gradually decreased with the increase of water spray. When the amount of water spray was increased to 200ml/min, the longitudinal creep rate at the saturation point of the

adhesive characteristic curve was 2.2‰. Figure 4 shows the wheel-rail adhesion coefficient as it changes with the amount of water spray. The test results show that the wheel-rail adhesion coefficient decreased gradually with the increase of amount of water spray. When water spray amount reached 200ml/min, the adhesion coefficient no longer decreased with the increase of water spray amount (it stayed unchanged). The adhesion coefficient at 250km/h gradually decreased from 0.46 when it was dry to 0.09 with the increase of water spray, a drop by 80%.

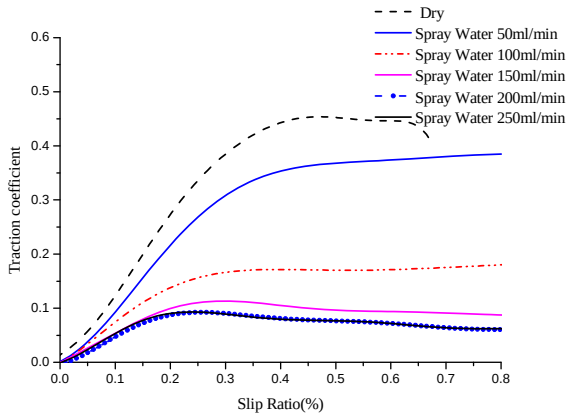

Figure 3 *The wheel-rail adhesion characteristic curve at the speed of 250km/h with different amount of water spray*

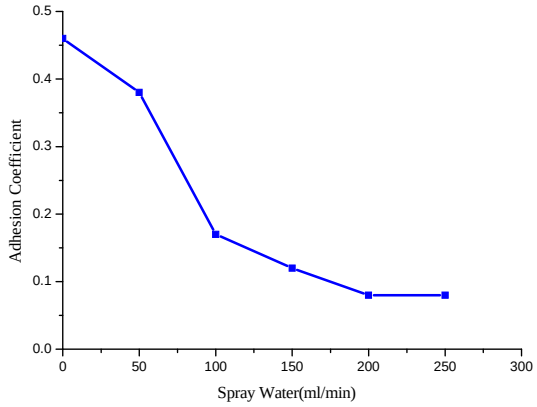

Figure 4 *Adhesion coefficient versus amount of water spray at the speed of 250km/h*

4.2. Influence of variance in roughness of the wheel-rail contact surface on HS wheel-rail adhesion characteristics

(1) Test conditions

The roughness of wheel-rail surface, as an important component of the wheel-rail interface, exerts an unneglectable influence on the wheel-tail adhesion when the wheel-rail contact is wet. In the above-mentioned study, the high-speed wheel-rail interface test rig was used to study the influence of the water spray amount on the wheel-rail adhesion. As it shows, the wheel-rail adhesion coefficient reduced gradually with the increase of the amount of water spray; and when the water spray amount reached 200ml/min, the wheel-rail adhesion coefficient no longer reduced with the increase of the amount of water spray (it stayed unchanged). Therefore, in the study of the influence of the roughness of the wheel-rail contact surface on the HS wheel-rail adhesion characteristics, the amount of water sprayed on the wheel-rail contact interface was set to 200ml/min (room temperature).

The test speed was 100km/h and 250km/h respectively, there was no lateral displacement of the wheelset in relation to the track wheel, and the wheelset had no attack angle. A 70kN testing vertical constant load (equivalent to an axle load of 14t) was applied, the roughness of the wheel tread contact surface Ra ranged from 0.30 to 0.40μm, from 0.45 to 0.55μm, from 0.7 to 0.8μm, and from 1.0 to 1.1μm, respectively. And the roughness of the contact surface of the track wheel top Ra ranged from 0.20 to 0.30μm.

(2) Test analysis

With the test speed being 100km/h, the wheel-rail adhesion characteristic curve with different roughness is shown in Figure 5. The figure shows that with the adhesion characteristic curve, the tractive force/wheel load kept increasing linearly as the longitudinal creep rate ranged from 0 to the saturation point; Roughness Ra affected the maximum value of the tractive force/wheel load (adhesion coefficient), and the adhesion coefficient increased with the increase of roughness; when the wheel tread roughness was within the range of Ra0.7-1.1μm and the longitudinal creep rate was beyond the tractive force/wheel load saturation point, the tractive force/wheel load decreased slowly with the increase of the longitudinal creep rate.

At the test speed of 250km/h, the wheel-rail adhesion characteristic curve with different roughness is shown in Figure 6. It can be seen from Figure 6 that that with the adhesion characteristic curve, the tractive force/wheel load kept increasing linearly as the longitudinal creep rate ranged from 0 to the saturation point; Roughness Ra affected the linear slope, as the higher the roughness Ra is, the higher the slope became. Roughness Ra affected the maximum value of the tractive force/wheel load (adhesion coefficient), and the adhesion coefficient increased with the increase of roughness; when the wheel tread roughness ranged from Ra0.3 to 0.4μm and from Ra0.45 to 0.55μm, the wheel-rail adhesion characteristic curves were relatively close.

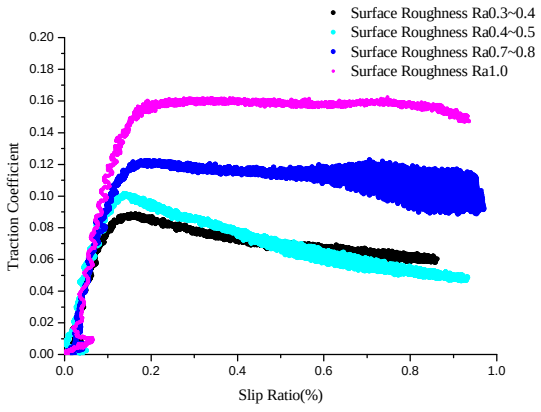

Figure 5 *Wheel-rail adhesion characteristic curves at the speed of 100km/h and with different roughness.*

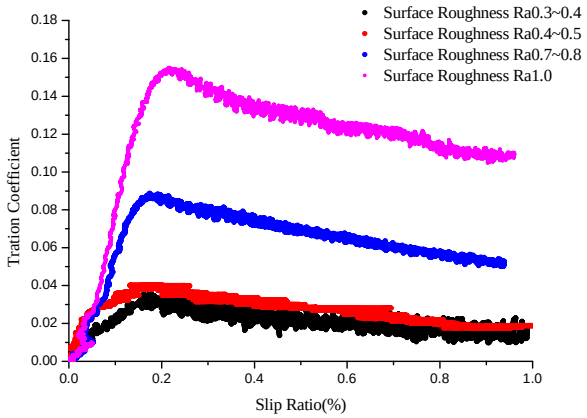

Figure 6 *Wheel-rail adhesion characteristic curves at the speed of 250km/h and with different roughness.*

When the wheel-rail contact interface was in wet condition, and the test speed was 100km/h and 250km/h, the function of wheel-rail adhesion coefficient versus wheel roughness is shown in Figure 7. It shows that the wheel-rail adhesion coefficient increased with the increase of roughness in wet condition; at the speed of 100km/h, the adhesion coefficient increased from 0.088, when the Ra ranged from 0.30 to 0.40μm, to 0.16, when the Ra ranged from 1.0 to 1.1μm, a growth of 82%; at the speed of 250km/h, the adhesion coefficient increased from 0.032, when the Ra ranged from 0.30 to 0.40μm, to 0.155, when the Ra ranged from 1.0 to 1.1μm, a growth of 384%, higher than at 100km/h; with different roughness, the influence of the speed on the wheel-rail adhesion coefficient differed; when the roughness Ra ranged from 0.30 to 0.40μm, a relatively low range, the influence of the speed on the wheel-rail adhesion coefficient was relatively big. As the roughness increased, the influence gradually decreased; when the roughness Ra ranged from 1.0 to 1.1μm, a relatively high range, the influence of the speed on the wheel-rail adhesion coefficient was very small.

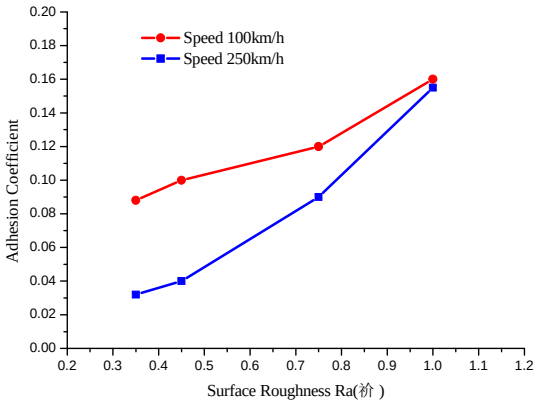

Figure 7 *Adhesion coefficient versus different roughness at 100km/h and 250km/h*

4.3. Influence of variance in water temperature on HS wheel-rail adhesion characteristics

(1) Test conditions

The test speed were 100km/h and 250km/h respectively, there was no lateral displacement of the wheelset in relation to the track wheel, and the wheelset had no attack angle. A 70kN testing vertical constant load (equivalent to an axle load of 14T) was applied, the roughness of the wheel contact surface Ra ranged from 0.45 to 0.55μm, and the roughness of the contact surface of the track wheel top Ra ranged from 0.2 to 0.3μm. During the test, the amount of water sprayed on the wheel-rail contact interface was 200ml/min, and the water temperature were 0℃, 20℃, 40℃ and 60℃ respectively, to simulate the influence of variance in water temperature on adhesion coefficient.

(2) Test analysis

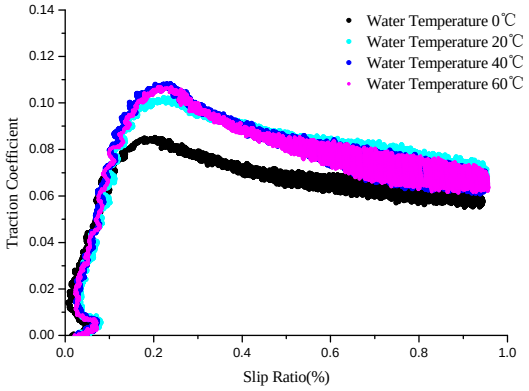

Figure 8 *Influence of different water temperatures on the wheel-rail adhesion characteristic curve at 100km/h*

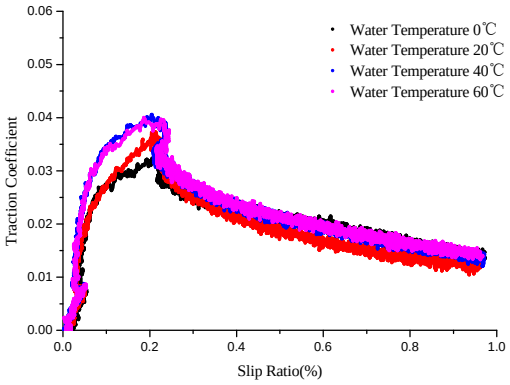

Figure 9 *Influence of different water temperatures on the wheel-rail adhesion characteristic curve at 250km/h*

The wheel-rail adhesion characteristic curves under different water temperatures at 100km/h and 250km/h are shown in Figure 8 and Figure 9. It can be seen from the figures that the temperature of water spray mainly influenced the adhesion coefficient. How the adhesion coefficient of the wheel-rail contact interface in wet condition changed with the variance in the temperature of water pray can be seen in Figure 10, which shows that in wet condition, the wheel-rail adhesion coefficient increased with the increase of the temperature of water spray. Under the speed of 100km/h, the adhesion coefficient grew from 0.085 when the water spray temperature was 0℃ to 0.11 when the water spray temperature was 60℃, an increase of 29%; Under the

speed of 250km/h, the adhesion coefficient grew from 0.032 when the water spray temperature was 0℃ to 0.04 when the water spray temperature was 60℃, a relatively slow increase of 20%; the influence of the water spray temperature on the adhesion efficient was higher in high-speed section than in low-speed one. From another perspective, at the speed of 100km/h, the adhesion coefficient was 0.10 when the water spray was in room temperature (20℃), and was 0.085 when the water spray was in snow temperature (0℃), hence a drop of 15% in adhesion coefficient when the temperature dropped from room temperature to 0℃(snow temperature); while at the speed of 250km/h, the adhesion coefficient was 0.036 when the water spray was in room temperature (20℃), and was 0.032 when the water spray was in snow temperature (0℃), hence a drop of 11% in adhesion coefficient when the temperature dropped from room temperature to 0℃(snow temperature).

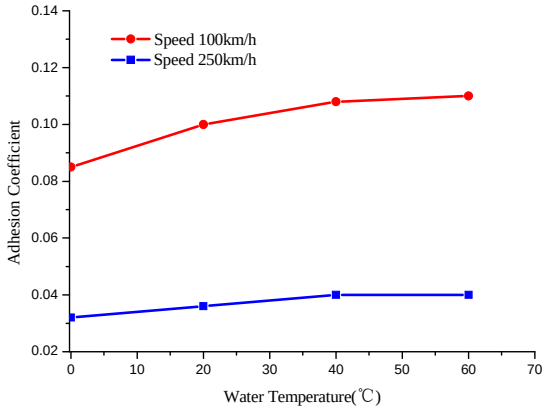

Figure 10 *Adhesion coefficient versus water temperature*

4.4. Influence of variance in axle load on HS wheel-rail adhesion characteristics

(1) Test conditions

The test speed were 100km/h, there was no lateral displacement of the wheelset in relation to the track wheel, and the wheelset had no attack angle, the roughness of the contact surface of the track wheel top Ra ranged from 0.20 to 0.30μm, and testing vertical constant loads of 40kN (equivalent to an axle load of 8t), 50kN (equivalent to an axle load of 10t), 60kN (equivalent to an axle load of 12t), 70kN (equivalent to an axle load of 14t) and 80kN (equivalent to an axle load of 16t) were applied respectively. During the test, the amount of water sprayed (room temperature) on the wheel-rail contact interface was 200ml/min.

(2) Test analysis

The wheel-rail adhesion characteristic curves with different wheel loads are shown in Figure 11, which shows that at the speed of 100km/h, and when the longitudinal creep rate ranged from 0 to 1.5‰, tractive force/wheel load kept increasing linearly, and in the range from 1.5‰ to the saturation point, tractive force/wheel load showed a non-linear increase; the wheel load affected the maximum value of the tractive force/wheel load (adhesion coefficient), and the adhesion coefficient decreased while the increase of the wheel load.

The function of the wheel-rail adhesion coefficient of the wheel-rail contact interface versus the wheel load in wet condition at 100km/h is shown in Figure 12, which shows that the wheel-rail adhesion coefficient in wet condition generally decreased with the increase of the wheel load; the coefficient decreased from 0.1255 when the wheel load was 40kN to 0.106 when the wheel load was 50kN, a decrease rate of 0.0195/10kN and a relatively fast decrease; and it further decreased from 0.106 when the wheel load was 50kN to 0.101 when the wheel load was 70kN, a decrease rate of 0.00025/10kN and a relatively slow decrease; and it decreased further still from 0.101 when the wheel load was 70kN to 0.0915 when the wheel load was 80kN, a decrease rate of 0.0095/10kN and a relatively fast decrease. In the axle load range of 10t-16t, a regular one for EMUs, from the adhesion coefficient of 0.106 when the axle load was 10t to 0.0915 when the axle load was 16t, the influence of the axle load on the adhesion coefficient was relative small, only about 10%.

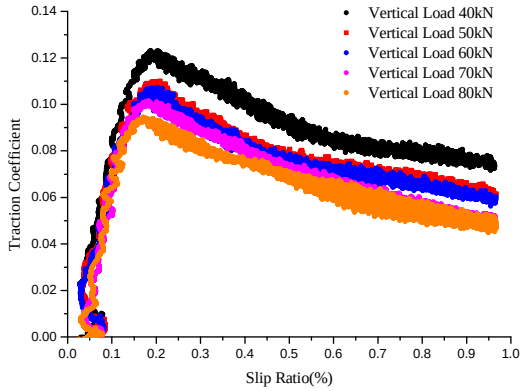

Figure 11 *Wheel-rail adhesion characteristic curves with different axle loads at 100km/h*

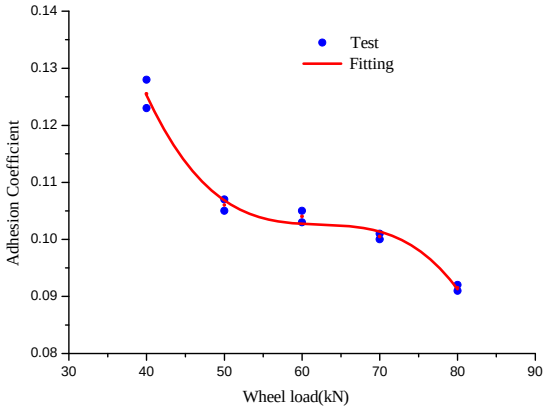

Figure 12 *Adhesion coefficient versus wheel load at 100km/h*

4.5. Influence of variance in running speed on HS wheel-rail adhesion characteristics

(1) Test conditions

In the test, the roughness of the wheel contact surface ranged from Ra0.45 to 0.55μm, the roughness of the

contact surface of the track wheel top ranged from Ra0.20~0.30μm, there was no lateral displacement of the wheelset in relation to the track wheel, and the wheelset had no attack angle, and a testing vertical constant load of 70kN (equivalent to an axle load of 14t) was applied. The test speed ranged from 40km/h to 400km/h. The amount of water sprayed (room temperature) on the wheel-rail contact interface was 200ml/min.

(2) Test analysis

The wheel-rail adhesion characteristic curves in wet condition at different speeds were shown in Figure 13, which shows that the adhesion coefficient decreased with the increase of the speed, the speed not only affected the adhesion coefficient, but also the slope of the linear growth of the tractive force/wheel load while the longitudinal creep rate of the adhesion characteristic curve ranged from 0% to the saturation point. The higher the speed, the smaller the slope became. In addition, the speed affected the location of the longitudinal creep rate of the saturation point of the adhesion characteristic curve. For example, at 40km/h the longitudinal creep rate of the saturation point of the adhesion characteristic curve stood at 2.6‰, as the speed increased, the rate gradually decreased; at 380km, it was 1.4‰.

The function of the wheel-rail adhesion coefficient of wheel-rail contact interface in wet condition versus the speed is shown in Figure 14, which shows that the wheel-rail adhesion coefficient in wet condition generally decreased with the increase of the speed; the coefficient decreased from 0.226 at 40km/h to 0.054 at 200km/h, a relatively fast decrease; the coefficient then decreased further from 0.054 at 200km/h to 0.038 at 400km/h, a relatively slow decrease. Based on the test results, the function of adhesion coefficient versus speed can be expressed as:

$$\mu = 5.71v^{-0.864} \tag{3}$$

where μ stands for the adhesion coefficient, v is the speed in km/h.

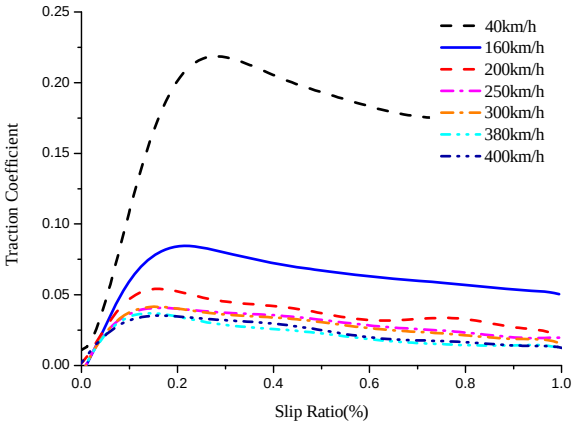

Figure 13 *Traction adhesion characteristic curves at different speeds*

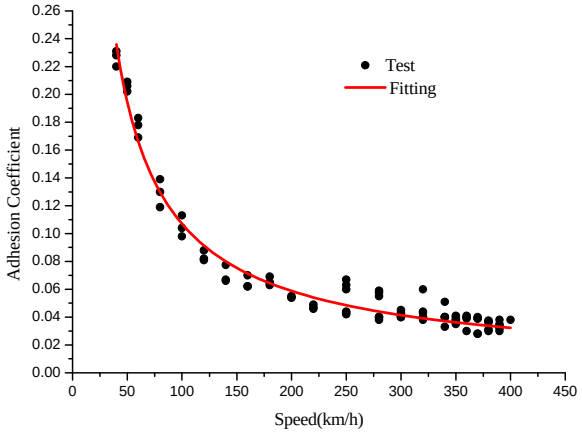

Figure 14 *Wheel-rail traction adhesion coefficient versus speed*

5. Conclusion

1) The wheel-rail adhesion coefficient gradually decreased with the increase of the amount of water spray, and after the water spray amount reached 200ml/min, the adhesion coefficient did not decrease any more with the increase of the water spray amount (it stayed the same). At 250km/h, the adhesion coefficient dropped 80% from 0.46 in dry condition to 0.09 under a large amount of water spray.

2) The wheel-rail adhesion coefficient increased with the growth of the roughness in wet condition; the influence of the roughness on the adhesion coefficient in different speed sections was different, higher in high-speed section than in low-speed one; With different roughness, the influence of the speed on the wheel-rail adhesion coefficient differed, as when the roughness was relatively low, at Ra0.30 to 0.40μm, the influence of the speed on the coefficient was relatively large, but as the roughness grew, the influence gradually dwindled, and became very small when the roughness was relatively high, at Ra1.0 to 1.1μm.

3) The wheel-rail adhesion coefficient increased with the increase of the temperature of the water spray. In the regular temperature range 0℃ to 20℃, The influence of the water temperature on the adhesion coefficient was relatively small, about only 10%.

4) The wheel-rail adhesion coefficient decreased with the increase of the axle load in wet condition. In the regular axle load range 10t to 16t, the influence of the axle load on the adhesion coefficient was relatively small, about only 10%.

5) In wet condition, the wheel-rail adhesion coefficient generally decreased with the increase of the speed. The adhesion coefficient dropped relatively fast from 0.226 at 40km/h to 0.054 at 200km/h, and relatively slowly from 0.054 at 200km/h to 0.038 at 400km/h.

6) The water spray amount, roughness of the wheel-rail contact surface and running speed influenced relatively heavily the adhesion coefficient in wet condition, while

the water spray temperature and axle load influenced it relatively lightly. Therefore, increasing the roughness of the wheel-rail contact surface can effectively raise the wheel-rail adhesion coefficient.

[*] E-mail:chendilai@163.com

Abstract: In view of the excessive contact stress and severe wear of rail in the switch panel of turnout, a method of backward designing the rail profile by the curvature radius of the rail is proposed. At the same time, the target profile of rail grinding is obtained. The method is based on the wheel-rail contact theory, aiming directly at reducing wheel-rail contact stress. The optimization results show that there is a better "conformality" of the optimized wheel-rail interface, which can significantly improve the wheel-rail contact stress, which can effectively reduce the wheel-rail wear, and wheel-rail contact points distribution after optimization is more uniform, with less jump of the contact points.

Keywords: profile optimization; contact stress; wheel-rail contact; rail grinding; switch panel;

1. Introduction

Turnout is an essential element of railway infrastructure. It makes it possible for railway vehicles to run from one track to another at a railway junction[1].The most mechanically stressed parts of a railway turnout are the switch panel and the crossing panel. As a result of the variation of rail profiles in the switch and crossing panels, increases in dynamic wheel–rail contact forces, wear of rail and rolling contact fatigue are observed. Railway turnouts (switches and crossings) require more maintenance than other parts of railway network[2].

According to maintenance databases, turnouts stand for the largest contribution of reported track faults and thereby, require high maintenance costs[3].The design of rail and wheel profiles is a fundamental problem, and various approaches were developed to obtain a satisfactory combination of wheel and rail[4]. The main idea in optimizing rail and wheel profiles of ordinary tracks is based on wheel-rail contact characteristics such as rolling radius difference (RRD) [5-6]of wheelset. To improve the dynamic performance of turnout crossings, Wan et al. [7] proposed a numerical optimization method to minimize RCF damage and wear in the crossing panel by varying the nose rail shape. For the switch panel of railway turnout, because of serious abrasion and stronger contact stress between vehicle wheels and tracks, the service life of rail and running safety of train will be sharply effected.

In this paper, the optimal design method of rail profile is proposed, which directly uses the wheel-rail contact stress as the optimization objective function. It design the rail profile backward by the radius of curvature of the rail. The depth and width of the profile is easy to control in this case, with the guarantee of smooth optimized rail profile. This optimization method is used to optimize the design of a key section of No.12 turnout in China before, the target grinding profile matching the given wheel is obtained.

2. Algorithm description

The main steps of the method are as follows:

(1) Given the wheel tread profile, the rail profile of turnout to be optimized and the related wheel- rail contact parameters, the maximum wheel-rail contact stress, under the condition of different lateral wheelset displacement, is calculated by using Hertz contact and wheel-rail geometry matching calculation. The maximum contact stress between wheel and rail is regarded as the direct optimization object.

(2) The contact points position of the rail and wheel profile are determined based on the maximum contact stress $P_{\max}$, and the curvature radius of the contact points between the rail and the wheel can be obtained. The expected value of the contact stress $P_{\exp}$ is set based on the maximum value of the contact stress $P_{\max}$. According to the expected contact stress, the optimization interval of the rail profile is determined. It's shown in Figure 1.

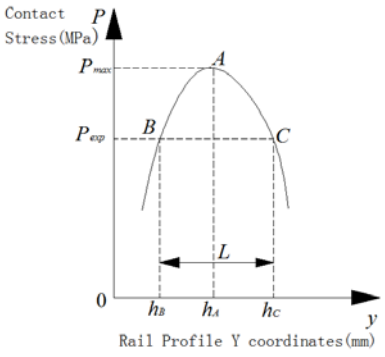

Figure 1. *Schematic diagram of rail optimum width*

(3) Assuming that the position of the contact point on the wheel does not change, with the only change of the curvature radius of the contact points, the maximum value of the contact stress $P = Hetze(R_r)$ under the condition of different radius of curvature can be obtained by the Hertz contact theory. Then the expected curvature radius at the contact point can be obtained by the utilization of $P_{\exp}$ and $P = Hetze(R_r)$. It's shown in Figure 2.

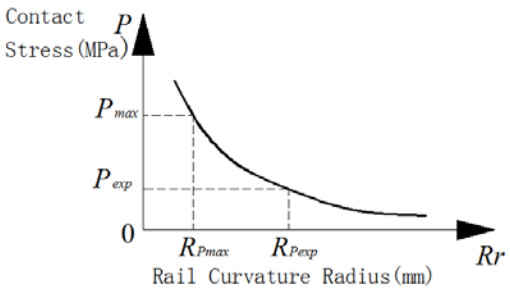

Figure 2. *Curvature radius variation before and after optimization*

(4) Rail profile can be backward designed according to the expected curvature radius:

$$y_{i+1} = y_i + Rr_i \times (-\sin(\theta_i) + \sin(\theta_i + l_i / Rr_i)) \quad (1)$$

$$z_{i+1} = z_i + Rr_i \times (\cos(\theta_i) - \cos(\theta_i + l_i / Rr_i)) \quad (2)$$

Where (y_i, z_i) and (y_{i+1}, z_{i+1}) are the position of i and $i+1$ point on the rail respectively. Rr_i is the curvature radius of the point i, θ_i is the angle of the point i on the arc of radius Rr_i; l_i is the displacement between point i and point $i+1$.

(5) The wheel-rail geometry matching calculation is performed on the designed profile of the rail, and the maximum value of the actual wheel-rail contact stress is obtained. And compare it with the original maximum value, if the actual maximum contact stress is less than the original maximum value but greater than the convergence tolerance, then adjust the expected maximum contact stress and the optimization interval, and then perform step(3). If the actual maximum contact stress is greater than the original contact stress, then the expected maximum contact stress and the optimization interval are also required to be adjusted, and then perform step (3). If the actual maximum contact stress is less than the original maximum and less than the convergence tolerance, then optimize the design for the next peak point and perform step (2). Until all peak points are optimized, the program ends and outputs the optimized rail profile.

(6) Constraint conditions of rail profile in the turnout:
①The rail profile in the turnout is a strictly convex curve in geometry. The intrinsic convex curve characteristic of the rail profile determines that the slope of the data points of the rail profile from left to right has a monotonically decreasing state. Based on this, the constraint equation for the rail profile optimization is: $k_i < k_{i+1}$

Where k_i indicates the slope of two adjacent points on the rail profile at the i-th data point.

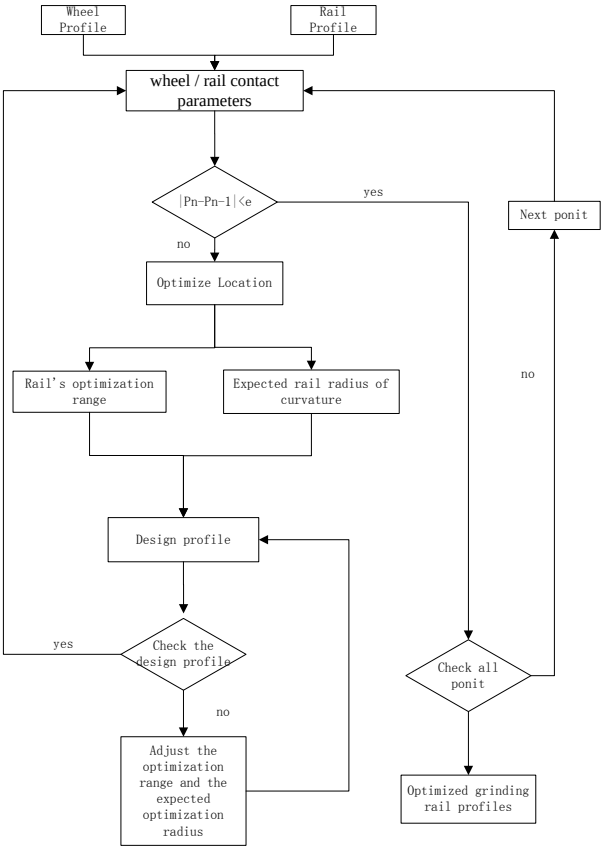
②The designed rail grinding target profile should be below the original profile. The vertical coordinate z_i of the rail profile should meet the constraints of the upper and lower boundaries: $m_i \le z_i \le n_i$.

Where n_i is the vertical coordinate of the original profile; m_i is the maximum grinding amount of the rail.

According to the optimization objectives and constraints of the rail profile, a mathematical model for the optimization of the rail profile can be obtained, which is shown as follows:

$$\begin{cases} \min P = \sum_{i=1}^{n} w_i P_i \left(i = 1, 2, 3, ..., n\right) \\ P = Hetze(R_r) \\ y_{i+1} = y_i + Rr_i \times (-\sin(\theta_i) + \sin(\theta_i + l_i / Rr_i)) \\ z_{i+1} = z_i + Rr_i \times (\cos(\theta_i) - \cos(\theta_i + l_i / Rr_i)) \\ k_i < k_{i+1} \\ m_i \le z_i \le n_i \end{cases}$$

The flow diagram of the method is shown in Figure 3.



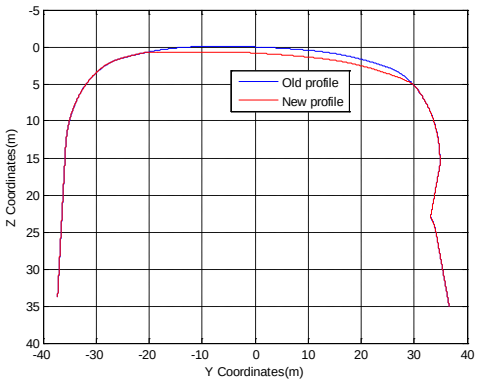


Figure 3. *Flow diagram of the rail profile design process*

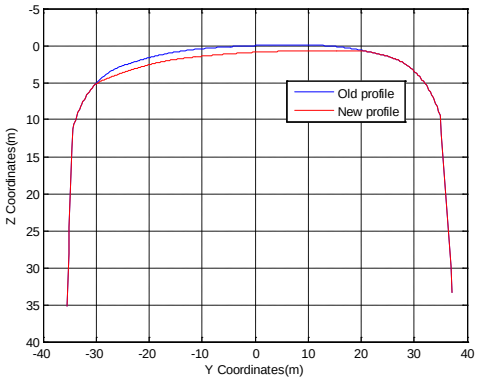
3. Design example



Taking the LM wheel tread and the No. 12 turnout as an example, the key section of the switch panel of turnout is selected for optimization design. The parameters are as follows: the width of the switch blades are 0 mm, 30 mm, 50 mm respectively. The rail gauge is 1435 mm, the nominal rolling circle radius of the wheel is 420 mm, and the axle weight is 20 t.

3.1. *Switch Blades with width of 0mm*

When the width of switch blades is 0 mm, rail profiles before and after optimization are shown in Figure.4. As we can see from the figure, the main optimization range is from the rail top to the side of gauge angle, and the maximum grinding amount of the left and right rails is around 1 mm. The change of the contact stress before and after optimization is shown in Fig. 5. When the lateral wheelset displacement varies in the range of -5mm to 5mm, the contact stress between the wheel and rail is significantly reduced, the maximum reduction percent is 51%. The distribution of the wheel-rail contact points before and after optimization is shown in Figures 6 and 7. As is shown in the figure, the optimized wheel-rail contact points are more evenly distributed and jumps of the wheel-rail contact points are reduced.

3.2. Switch Blades with width of 0mm

When the width of switch blades is 30 mm, the section includes the stock rail and the switch rail. In this case, it's necessary to optimize the design of the stock rail and the switch rail respectively. The contour curves of rail before and after optimization are shown in Fig.8. The curve of the contact stress before and after optimization is shown in Fig.9. When the lateral wheel displacement varies in the range of -5mm to 5mm, the contact stress between the wheel and rail is significantly reduced, the maximum reduction percent is 58%. The contact points distribution before and after optimization is shown in Figures.10 and Figures.11. The optimized wheel-rail contact points are more evenly distributed and jumps of the wheel-rail contact points are reduced.

3.3. Switch Blades with width of 0mm

When the width of switch blades is 50 mm, only the switch rail is included in this section. And only the switch rail needs optimal design. The contour curves of rail before and after optimization are shown in Fig. 12. The curves of the contact stress before and after optimization are shown in Fig. 13. When the lateral wheelset displacement varies in the range of -5 mm to 5mm, the contact stress is significantly reduced, the maximum reduction percent is 43%. The distribution of the wheel-rail contact points before and after optimization is shown in Figures.14and Figures.15. The optimized wheel-rail contact points are more evenly distributed and jumps of the wheel-rail contact points are reduced.

4. Conclusions

Rail grinding is an important approach to ameliorate the relationship between wheel and rail. In this paper, the rail profile optimal design method, with wheel-rail contact stress as the direct optimization target, is established for the case of excessive wheel-rail contact stress in the turnout. The optimized rail grinding profile significantly reduces the wheel-rail contact stress and improves the "wheel-rail conformality", thus effectively reducing the wheel-rail wear and rolling contact fatigue damage, prolonging the service life of the rail, making the contact points position more uniform than before.

Abstract: In a field test, three corrugation profiles of rails and their corresponding vibrations were measured. The wavelengths and frequencies of rail corrugations were obtained. In the corrugation prediction, finite element models of the self-excited vibrations corresponding to three different wheelset-track systems were established. The corrugation frequencies of these models were predicted. A comparison between the measured corrugation frequencies and the predicted corrugation frequencies shows that they are in good agreement. It can be concluded that self-excited vibration of a wheelset-track system can cause rail corrugation. A benchmark condition for the validation of rail corrugation models is proposed.

Keywords: Rail corrugation; undulant wear; rail-wheel interaction; friction-induced self-excited vibration

1. Introduction

Nowadays, rail corrugation has been seldom reported in Chinese main-line railway tracks. It may be attributed to the application of worn-type tread profiles and the adoption of the minimum curved track radius of 500-600 m. However, rail corrugation is still an elusive problem in metro tracks all over the world. Almost all low rails on the tight curved tracks whose radii are less than 350 m in China suffer from rail corrugation. The length of corrugated rails occurring on the low rails of tight curved tracks makes up more than 80% of the total length of all corrugated rails. In the early 1900s, railway administrators and researchers have paid attention to rail corrugation. Over the years, many experimental and theoretical studies have led to good understandings of the generation mechanism for rail corrugation [1-4]. It is generally accepted that rail corrugation depends on the wavelength fixing mechanism and material removal mechanism [1]. Now the most widely accepted prediction model of rail corrugation is based on the wheel-rail interaction due to rail surface roughness. In the model, the rail surface roughness causes vibration of the wheel-rail system, which leads to a fluctuation of the friction power of the wheel-rail contact interface. According to a known fact that the fluctuation of the friction power leads to undulant wear, the rail work surface subsequently suffers from corrugation [5-15]. Stick-slip motion of wheel-rail systems as a possible mechanism for rail corrugation was also studied [16-19]. Experimental studies have accumulated a lot of information about the nature of rail corrugation and validated several prediction models [20-25].

Unfortunately, up to date the occurrence probability of rail corrugation on the low rail of the tight curved track is still close to 100%. The authors think that this is attributed to a lack of the understandings of some generation mechanisms for rail corrugation. In the research field of rail corrugation, there is a very common and deterministic phenomenon of rail corrugation (CD phenomenon of rail corrugation): almost all low rails on the tight curved tracks whose radii are less than 350 m in China suffer from rail corrugation but high rails on the same curved track rarely suffer from rail corrugation. The left and right rails on smooth curved tracks whose radii are larger than 650-800 m or on straight tracks rarely and uncertainly suffer from rail corrugation. The relevant literature does not indicate why almost all low rails on the tight curved track suffer from rail corrugation but high rails on the same curved track rarely suffer from rail corrugation. It is also unknown why the left and right rails on smooth curved tracks or on straight tracks rarely and uncertainly suffer from rail corrugation, either. Because of these flaws in the existing rail corrugation theories, several researchers proposed improved rail corrugation models to better understand the generation mechanism for rail corrugation. In these improved models, Vila et al. [26] and Baeza et al. [27] proposed models which include rotating flexible wheelset coupled with a flexible track model and a non-Hertzian/ non-steady contact. Jin et al. [28] took a complicated wheel-rail contact wear model for corrugation evaluation into account. Bellette et al. [29] studied the influence of the contact wear filter on rail corrugation. Alternatively, Chen, one of the authors of this paper, and other co-authors proposed the friction-induced self-excited vibration of a wheelset-track system as a possible mechanism for rail corrugation in 2010 [30]. Later on, Chen and his colleagues carried out further work and found that their model could succeed in reproducing most of rail corrugation phenomena including the above-mentioned CD phenomenon of rail corrugation [31-32]. Omar [33] applied a similar method to study rail corrugation in his master degree dissertation.

Several reviewers have expressed their concerns about the validation of the authors' models in reviewing the authors' manuscripts on the friction-induced self-excited vibration of a wheelset-track system as a possible mechanism for rail corrugation. In the authors' viewpoint, the friction-induced self-excited vibration of a wheelset-track system belongs to the category of the stick-slip motion. It is generally accepted that the stick-slip motion of a wheel-rail system is a possible mechanism for rail corrugation. Unfortunately, there are very few publications that deal with the validation of the stick-slip motion causing rail corrugation in the literature. The authors spent 2-3 years to reflect on the validation of the authors' model. This paper presents our work on the validation of the authors' model. Before introducing our work, it is necessary to review the the validation of rail corrugation models.

In the literature, there are two methods available to validate rail corrugation models. One method consists of the following procedure [20, 21, 25]: (1) measure a profile of the rail working surface without rail corrugation along the longitudinal direction of the rail. (2) measure several different profiles of the rail working surface with rail corrugation along the longitudinal direction of the rail to obtain the evolution of rail corrugation with time. (3) establish a rail corrugation model and perform a numerical analysis of the model to obtain the evolution of rail corrugation with time. (4) compare the measured result and the numerical result of rail corrugation and draw a conclusion. The other method consists of the following procedure [34]: (1) make a field measurement of rail corrugation to obtain the profile of rail corrugation, track and vehicle parameters. (2) establish a rail corrugation model and perform a numerical analysis of the model to obtain the evolution of rail corrugation with time. (3) compare the measured result and the numerical result of rail corrugation and draw a conclusion. Several researchers reported that they had successfully validated their models [20, 21, 25, 34].

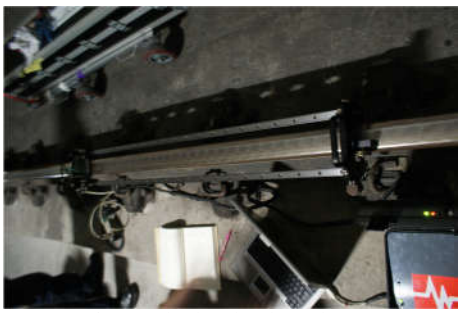
The aim of the present work is to present a comparison study between the field test result and the prediction result. The existing validation methods of rail corrugation models are discussed. A benchmark condition for the validation of rail corrugation models is proposed.

2. Field test measurement

In Beijing metro line 4, the designers used 5 types of sleepers or track structures to suppress vibration and noise due to the wheel-rail interaction, which include a short sleeper, a booted short sleeper, a Cologne-egg damping fastener, a ladder sleeper track and a floating slab track. Contrary to the expectation, however, the vibration and noise get worse. Further field investigations show that the strong vibration and noise are due to rail corrugation. To better understand the generation mechanism for rail corrugation, the authors made field test measurements of rail corrugation profiles, track parameters and rail vibration when metro trains passed through.

2.1. Rail corrugation profile measurement

The total length of Beijing metro line 4 is about 28 km. All low rails of tight curved tracks whose radii are less than or equal to 350 m are subjected to corrugation. The low rail of a tight curved track of radius 450 m is also subjected to corrugation. Two rails of a tangential track equipped with Cologne-egg damping fasteners are also subjected to corrugation. An ODS wheel and rail roughness measuring system was used to measure rail corrugation profiles, as shown in Figure 1.



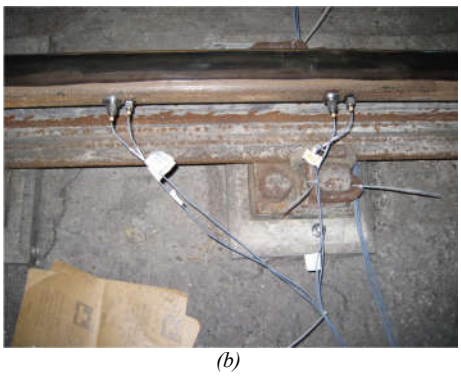


Figure 1 *Picture of ODS wheel and rail roughness measuring system.*

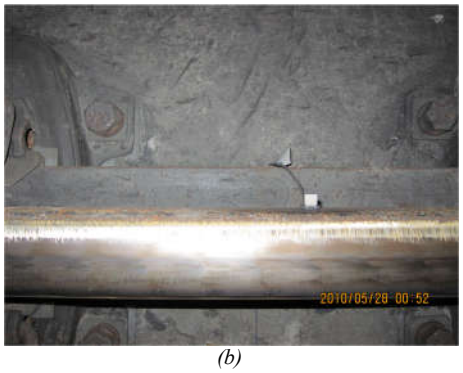
2.2. Rail vibration measurement

Accelerometers were used to measure vibrations of rails and sleepers. The vertical and lateral vibrations of the rail positions at the central point between two sleepers and above a sleeper, and the vertical vibration of the sleeper were measured simultaneously. Figures 2-4 show the positions of the accelerometers on rails and sleepers.

(a)



(b)

Figure 4 *Positions of accelerometers on rails and sleepers: (a) High rail. (b) Low rail.*

2.3. Fastener stiffness and damping measurement

Fastener stiffness and damping were measured by the authors' colleagues in laboratory. The measurement data are presented as follows.

(1) DTVI2-type fastener: the vertical stiffness of the fastener k_v=40.73 kN/mm, the vertical damping coefficient of the fastener c_v=9898.70 Ns/m, the lateral stiffness of the fastener k_l=8.79 kN/mm, and the lateral damping coefficient of the fastener c_l=1927.96 Ns/m.

(2) Elastic bar II separated fastener: k_v=18.28 kN/mm, c_v=6361.29 Ns/m, k_l=9.00 kN/mm, c_l=1830.22Ns/m.

(3) Cologne-egg damping fastener: k_v=12.07 kN/mm, c_v=1361.12 Ns/m, k_l=7.58 kN/mm, c_l=974.27 Ns/m.

3. Modeling of rail corrugation

Combining the knowledge of the friction-induced vibration and the knowledge of the vehicle system dynamics, Chen and other co-authors proposed the friction-induced self-excited vibration of a wheelset-track system as a possible mechanism for rail corrugation [30]. In a tight curved track, the creep force between the wheel and rail is approximately equal to the friction force, that is, the normal force times the coefficient of friction. The motion equation of the wheelset-track system can be written as follows [30]:

$$\mathbf{M_r}\ddot{\boldsymbol{x}}+\mathbf{C_r}\dot{\boldsymbol{x}}+\mathbf{K_r}\boldsymbol{x}=0 \quad (1)$$

where $\mathbf{M_r}$, $\mathbf{C_r}$ and $\mathbf{K_r}$ are asymmetric matrices due to friction. The eigenavlue equation of Eq (1) is presented in the following form:

$$(\mathbf{M_r}\boldsymbol{\lambda}^2 + \mathbf{C_r}\boldsymbol{\lambda} + \mathbf{K_r})\boldsymbol{\phi}=0 \quad (2)$$

The general solution of Eq (1) is written as follows:

$$\boldsymbol{x}(\boldsymbol{t}) = \sum \boldsymbol{\phi}_\mathbf{i}\mathbf{exp}(\boldsymbol{\lambda}_\mathbf{i}\,\boldsymbol{t}) = \sum \boldsymbol{\phi}_\mathbf{i}\,\mathbf{exp}((\boldsymbol{\alpha}_\mathbf{i} + \mathbf{j}\boldsymbol{\omega}_\mathbf{i})\boldsymbol{t}) \quad (3)$$

where $\boldsymbol{\phi}_\mathbf{i}$ is the ith eigenvector of Eq (2) and $\boldsymbol{\lambda}_\mathbf{i} = \boldsymbol{\alpha}_\mathbf{i} + \mathbf{j}\boldsymbol{\omega}_\mathbf{i}$ is the ith eigenvalue of Eq (2), j is the imaginary unit. From Eq (3), it is seen that when a real part of eigenvalues is larger than zero, the displacement will increase with time, that is, the vibration of the system becomes unstable.

Figures 5-7 show finite element models of three metro wheelset-track systems, which correspond to those wheelset-track systems in the field test measurement. In the model shown in Figure 5, the radius of the curved track is 350 m, the superelevation of the track is 120 mm. The whole curved track is supported by two types of sleepers. Half of the sleepers are short sleepers with elastic bar II separated fasteners. Another half of the sleepers are booted short sleepers with elastic bar II separated fasteners. In the model shown in Figure 6, the track is a tangential track equipped with Cologne-egg fasteners. In the model shown in Figure 7, the radius of the curved track is 350 m, the superelevation of the track is 120 mm. The whole curved track is supported a type of ladder sleepers. Half of the ladder sleepers are equipped with DTVI2-type fasteners. Another half the ladder sleepers are equipped with elastic bar II separated fasteners.

4. Results

4.1. Rail corrugation profile measurement

Figures 8-13 show measured rail surface profiles and their wavelength analyses. From Figure 8, it is seen that the low rail is subjected to a clear corrugation with an amplitude of 0.236 mm but the corrugation of the high rail is invisible to the eye. From Figure 9, it is seen that the main wavelength of the low rail corrugation is about 125 mm. From Figure 10, it is found that the left and right rails of the tangential track are subjected to severe corrugations whose amplitude is about 0.05 mm. From Figure 11, it is found that the main wavelength of rail corrugation is about 40 mm and sub-wavelength is about 20 mm. From Figure 12, it is seen that the low rail is subjected to an obvious corrugation with an amplitude of 0.124 mm but the corrugation of the high rail is invisible to the eye. From Figure 13, it is found that the main wavelength of rail corrugation is about 100 mm.

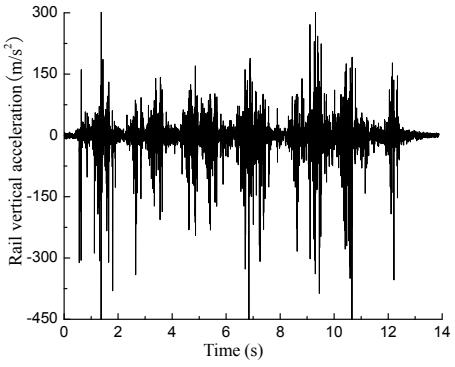
4.2. Rail vibration measurement

Figures 14-19 show measurement results of the rail vibrations and their frequency analyses. Comparing Figure 14a with Figure 14b and Figure 14c with Figure 14d, it is seen that the vibration of the low rail is 5-6 times as big as that of the high rail. From Figure 15a and Figure 15c, it is found that the main vibration frequency is about 77-80 Hz. From Figure 16, it is seen that the vibration of the left rail is approximate to that of the right rail in amplitude. From Figure 17, it is found that the vibration frequencies of the left and right rails are all about 320 Hz. In Figure 18, only the vibration of the low rail is presented since other measurement sensors were broken.



From Figure 19, it is found that the main vibration frequency is about 134 Hz.

4.3. Rail corrugation prediction

Figures 20-22 show three prediction results obtained by using the models shown in Figures 5-7. From Figure 20a, it is seen that the miminum frequency of the self-excited vibration of the wheelset-track system is about 108.59 Hz. The corresponding mode shape is shown in Figure 20b. From the mode shape, it is seen that only the low rail and the wheel are subjected to self-excited vibration. It suggests that only the low rail is subjected to rail corrugation. From Figure 21a, it is seen that the miminum effective damping ratio corresponds to a self-excited vibration of frequency 291.76 Hz. The corresponding mode shape is shown in Figure 21b. From the mode shape, it is seen that two rails and two wheels are subjected to self-excited vibrations. It suggests that the left and right rails are subjected to rail corrugation in that case. From Figure 22a, it is seen that the miminum frequency of the self-excited vibration of the wheelset-track system is about 167.38 Hz. The corresponding mode shape is shown in Figure 22b. From the mode shape, it is seen that only the low rail and the wheel are subjected to self-excited vibration. It suggests that only the low rail suffers from rail corrugation in that case.

5. Discussion

Several researchers reported that they had successfully validated their models [20, 21, 25, 34]. Their works are of significance. However, the authors have a question why these validated models are difficult to satisfactorily reproduce the CD phenomenon of rail corrugation. These models can satisfactorily predict corrugation of the low rail of tight curved track but cannot satisfactorily predict rail corrugation of smooth curved tracks and tangential tracks. This is because these models can always predict corrugation of high rails of tight curved tracks, and rail corrugation of smooth curved tracks and tangential tracks. That is to say, whether the track is a tight curved track or a smooth curved track or a tangential track, these models can predict rail corrugation of the track without a significant difference. In fact, two rails on a smooth curved track or a tangential track is rarely subjected to corrugation. Obviously, the prediction results are not consistent with the CD phenomenon of rail corrugation.

The authors think that the reason why these validated models are difficult to satisfactorily reproduce the CD phenomenon of rail corrugation may be attributed to a flaw in the methods for the validation of rail corrugation models. As mentioned in Section 1, there are two methods available to validate rail corrugation models in the literature. The authors think that in these two validation methods, the identification of the vibration which can lead to rail corrugation has been neglected. That is to say, the vibration evolution with time before corrugation occurs is neglected. Chen, one of the authors of the present paper, and other co-authors studied the rail vibration evolution before rail corrugation occurred [35]. They found that there are several rail vibrations with different frequencies before rail corrugation occurred and not all vibrations can lead to rail corrugation. These

several vibrations were considered to be excited by the rail surface roughness or the friction coupling. Then, the authors also measured vibrations of two rails on a main-line tangential track when trains passed through and found that there were always some vibrations in these two rails when trains passed through, but these vibrations could not cause rail corrugation because these two rails have not suffered from corrugation for a pass decade. As mentioned in Section 1, the generally adopted validation procedure for rail corrugation models mainly consists of the following four steps: (1) measure a profile of the rail working surface without rail corrugation along the longitudinal direction of the rail. (2) measure several different profiles of the rail working surface with rail corrugation along the longitudinal direction of the rail to obtain the evolution of rail corrugation with time. (3) establish a rail corrugation model and perform a numerical analysis of the model to obtain the evolution of rail corrugation with time. (4) compare the measured result and the numerical result of rail corrugation and draw a conclusion. After seriously thinking about, the authors think that the rail surface roughness measured in Step 1 is not the necessary and sufficient condition for rail corrugation generation. That is because a random roughness has also led to rail corrugation [27]. If a new rail is laid as the low rail of the tight curved track, the probability of the rail suffering from corrugation is close to 100%. If the new rail is laid as a rail of a tangential track, however, the probability of the rail suffering from corrugation is close to zero. This fact supports the conclusion that the rail surface roughness is not the necessary and sufficient condition for rail corrugation generation. The authors think that the measured corrugation evolution in Step 2 can validate the well-known conclusion that the wear of the rail is proportional to the friction power.

The authors notice that the above motioned researchers generally used the low rail corrugation of a tight curved track to validate their models [20, 21, 25]. Since the occurrence probability of the low rail corrugation of the tight curved track is close to 100%, the effectiveness of these validation methods is questionable. Fortunately, the CD phenomenon of rail corrugation is observed all over the world. Therefore, the authors proposed the CD phenomenon of rail corrugation as a benchmark condition for the validation of rail corrugation models. If the prediction result of a model is consistent with the CD phenomenon of rail corrugation, the rail corrugation model is considered to be validated.

In the field tests, the measured corrugation frequencies are 80 Hz for the wheelset-track system shown in Figure 2, 320 Hz for the wheelset-track system shown in Figure 3 and 132 Hz for the wheelset-track system shown in Figure 4, respectively. In the prediction of rail corrugation, the predicted corrugation frequencies are 108.59 Hz for the wheelset-track system shown in Figure 2, 291.76 Hz for the wheelset-track system shown in Figure 3 and 167.38 Hz for the wheelset-track system shown in Figure 4, respectively. The relative errors are 26.33%, 9.68% and 21.14%, respectively. The models can predict that the low rail of the tight curved track suffers from corrugation but the high rail does not. The models can also predict that rail corrugation rarely occurs on smooth curved tracks and tangential tracks. This is because the creep forces are not saturated in these cases, therefore, friction-induced self-excited vibration of the wheelset-track systems does not occur. Hence one can see that the models established by the authors can predict the CD phenomenon of rail corrugation.

It deserves to be mentioned that the modeling procedure for the prediction model established by the authors is stationary, which mainly was based on the finite element method. Man behaviors are restrained. The source code of the prediction model is open for public [33]. Chen, one of the authors, also provided the ABAQUS source code of a prediction model for an engineer worked in PERMAS, a finite element package developed in Europe. The engineer used the ABAQUS source code to make a comparative analysis with PERMAS. The calculation results from ABAQUS and PERMAS are in good agreement.

6. Conclusions

In the paper, the field test measurement results of rail corrugation and prediction results were presented. A comparison between the test measurement results and prediction results was performed. Further discussion is made. The following conclusions can be drawn:

1. The relative errors between the test measurement results and the prediction results are 26.33%, 9.68% and 21.14%, respectively. The prediction results are consistent with the CD phenomenon of rail corrugation. Therefore, the model established by the authors can used to predict rail corrugation.
2. The authors proposed the CD phenomenon of rail corrugation as a benchmark condition for the validation of rail corrugation models. If the prediction result of a model is consistent with the CD phenomenon of rail corrugation, the rail corrugation model is considered to be validated.

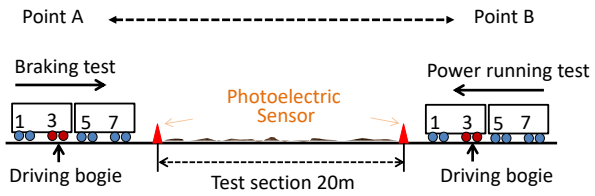
Abstract: In the slope section of a train service line located in mountainous area, idling and sliding of the wheels caused by fallen leaves in autumn often occurs, which hinders the scheduled operation of the train. Although sand and ceramic particles are sprayed onto the contact zone of wheel/rail as its countermeasures, the effect is not sufficient. In order to find more effective countermeasures, it is necessary to clarify the mechanism of a decrease in adhesion between the wheel and the rail by fallen leaves. The authors conducted vehicle running tests on the test track and investigated the influence of leaves on the adhesion of wheel/rail for the purpose of acquiring knowledge useful for the practical use of countermeasures. This paper introduces the characteristics of adhesion during driving and braking as well as the reason for the decrease of adhesion by fallen leaves.

Keywords: wheel/rail, adhesion, wheel slipping, wheel sliding, leave, wet condition

1. Introduction

A train can accelerate and decelerate thanks to the so-called "adhesive force" that is a tangential force which acts on the point on which the wheel and the rail contacts in the longitudinal direction (running direction of the train). On the other hand, when the driving force or the braking force of the train exceeds the adhesive force during acceleration or deceleration, the wheel slips in the case of power running and skids in the case of braking. As a result, the accelerating distance and the braking distance increase, which affect punctuality. Furthermore, significant slipping and skidding might cause wheel burn on the rail and flat spots on the wheel.

In railway sections in a mountainous area, leaves of trees along the line frequently fall on the track from late autumn to early winter. The leaves on the track are pressed by the wheels of passing trains and adhere to the rail surface. The leaves accumulate as trains pass over the section repeatedly and as time elapses, they are altered to black accretion.1) In past studies, it was found that slipping occurs frequently in the first train of the day in the line and the train was not only delayed but also unable to advance in some cases. It is said that slipping in the trains that run in early morning such as the first train of the day in the line is due to wet rail surfaces. 1-3) Wet rail surfaces are considered to be caused by condensation in early morning due to the significant fluctuation of temperature in the cold season. Although there have been studies that analyze the conditions under which the leaves cause slipping/skidding of the wheel 1-3) and that are related to countermeasures for control or prevent slipping and skidding, a very small number of studies have been conducted to investigate in detail the relation between the adhesive force and the leaves, which is a significant factor in the slipping and skidding. 4-8)

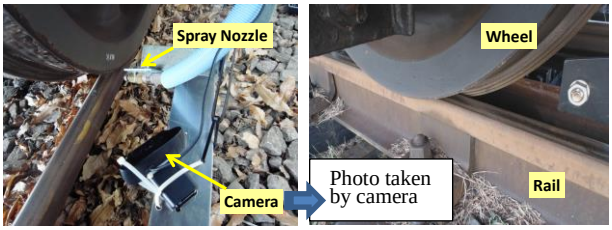


In this study, we simulated the situation of the rail surface of a section in a mountainous area during cold season from late autumn to early winter in an in-house test track to conduct the power running test and the braking test using a test car to check the condition of the slipping wheel and evaluate the adhesion coefficient of the rail surface on which slipping/skidding of wheel frequently occurs. In addition, we measured the traction coefficient on the test rings that run on accumulated leaves of which the condition continuously changes between dry, wet, and with accumulated leaves (the maximum traction coefficient is considered to be the adhesion coefficient) and observed the influence of the leaves in various rail surface conditions. The following describe the details of this study and its results.

2. Vehicle running test conditions

2.1 Overview of the test

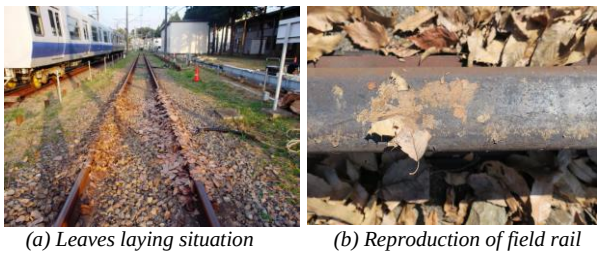
As shown in Fig. 1 (a) and (b), we configured a test section of approximately 20 m in the straight track section of the test line of RTRI (Railway Technical Research Institute) and we adopted an R291 series electric train (2-car train set with 0.5M and 1.5T) in which an anti-skid valve is installed for each axle of the M-car bogie as the test vehicle. In this test, only the electric brake in the M-car bogie is used and the air brake in the T car bogie is not operated. A camera was installed on the bogie frame to allow observing the condition of the contact between the left and right wheels of the driving axles and the rail while the vehicle is running and the state of the slipping wheel. A water spray nozzle was installed on the bogie frame to spray water for simulating rail wet conditions (see Fig. 1(c)).



The power running test was conducted when the train ran from point A to B; and the braking test was conducted when the train ran from point B to A. That is to say, the power running test and the braking test were conducted alternately while the train was operated in a round trip between point A and B (see Fig. 1(a)). Table 1 lists the running control conditions.

(a) Test track section (20m)

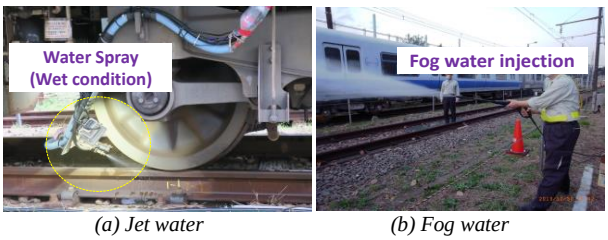
(b) Test car



(c) Camera and water spring nozzle installed on bogie

Fig. 1 Overview of the test

Table 1 Running control conditions



Power running test	
Notch	3 - 4
Slip detection	Enabled
Re-adhesion control	Enabled
Braking test	
Deceleration (km/h/s)	1.1 - 1.3
Brake control	Electric control
Slide detection	Enabled
Re-adhesion control	Enabled

Before conducting the running test, we spread leaves prepared by mixing those of various species on the rail surface and simulated the state of a section in a mountainous area by running the train repeatedly while providing the appropriate environmental condition (see Fig. 2). The wet rail surface was realized by two methods, one is to spray water onto the contact zone of wheel and rail by the nozzle as shown in Fig.1 (a); the other is to spray mist water on the rail surface using a high-pressure sprinkler (see Fig.3). In addition, we also conducted a running test under rain condition because it rained for a day during the test period.

(a) Leaves laying situation *(b) Reproduction of field rail*

Fig.2 Reproduction of rail surface in the track section in mountainous area

(a) Jet water *(b) Fog water*

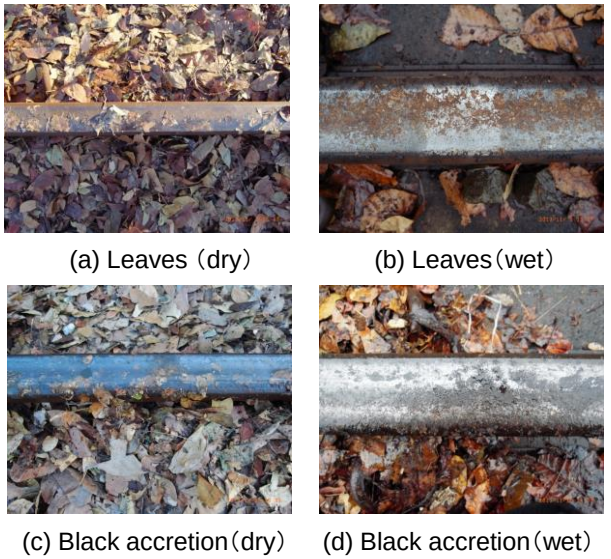


Fig.3 The method to simulate wet conditions

For the power running and braking sections, the axle speed of the driving bogie and the running speed of the train were measured. In addition, the value corresponding to the traction coefficient for the driving bogie (the 3rd axle) was determined based on the total weight of the vehicle and the command values for the excitation current in the driving motor and of the torque current. In the field test, the traction coefficient at the time when the wheel begins to slip is regarded as the adhesion coefficient.

2.2 Rail conditions

For the running test, as shown in Fig. 4, we reproduced two types of rail surface conditions, that is to say, a rail surface on which pressed leaves exist (Fig. 4(a)) and that on which black accretion exists (Fig. 4(c)). In addition, we simulated dry and wet conditions (Fig. 4(b) and (d), respectively) for the rail surface states described above. The condition in Fig. 4(a) was reproduced by spreading leaves on the rail surface in the test section and then running the train on the rail to make the leaves adhere to the surface. The condition in Fig. 4(c) was reproduced by spreading leaves on the rail surface in the test section and then running the train and spraying (atomized) water on the rail alternatively to generate a black accretion film on the rail surface.

Because the speed limit of the test track is 35 km/h at the maximum, the speed of the train when entering the test section (the initial speed for the power running and the braking) was set to 30 km/h.

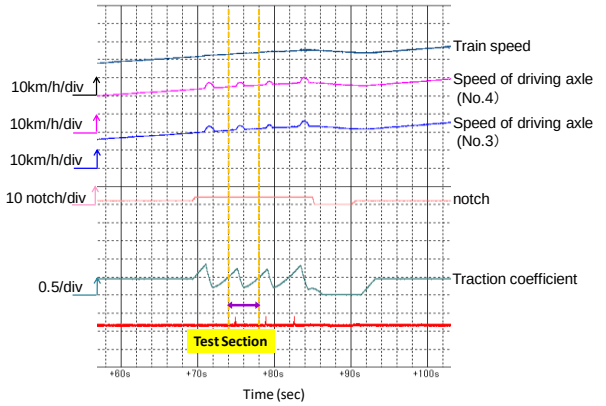
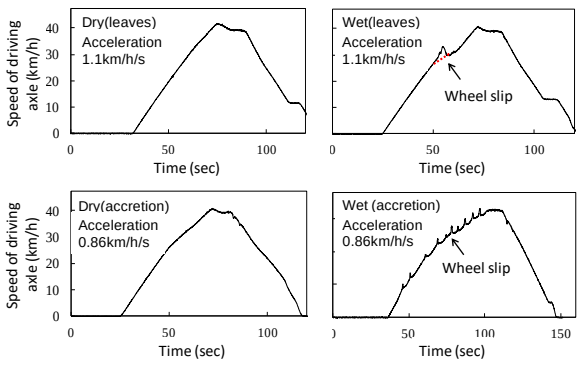
Fig. 4 Rail surface conditions for the running test

2.3 Observation of wheel slip

Figure 5 shows an example of the results of running test. This is the measurement result in the power running test for the case when wet leaves exist on the rail surface. It is indicated that the wheel of driving axle slips within the test section (pink and blue lines). Also, the traction coefficient fluctuates because re-adhesion control is applied due to slipping of the wheel (green line).





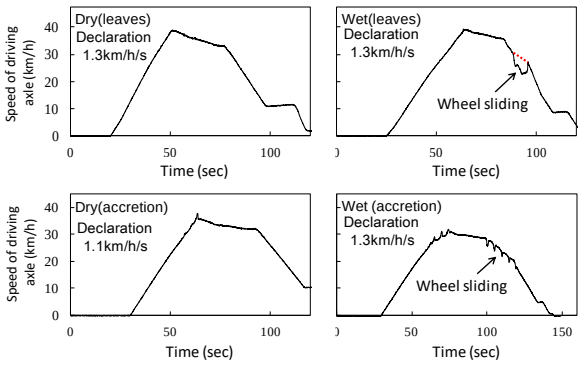


Fig. 5 An example of running test results (in case of leaves (wet), power running test)

Figure 6 shows the relation between the rail surface condition and the slipping state of the wheel in driving axle that is observed on the results of the power running test (see Fig.6 (a)) and the braking test (see Fig.6 (b)). The test results indicate that although significant wheel slipping does not occur under dry conditions even if there are leaves or black accretion film on the rail surface, a situation that causes significant wheel slipping is generated under wet conditions. In addition, the wheel frequently slips when the black accretion film on the rail surface is wet and wheel slipping occurs not only in the test section (20 m) but also in the running section before and after the test section. The reason is considered to be as follows: When the test car passes the test section for the first time, the black accretion film in wet conditions (in a paste form) is transferred from the rail surface to the wheel tread. After the train has passed the test section, the black accretion film on the wheel tread is transferred to the rail surface outside the test section due to the rolling motion of the wheel. It is considered that wheel slipping outside the test section occurs due to the decrease of adhesion coefficient on the wheel of the following car that passes that point.

(a) Power running test

(b) Braking test

Fig. 6 Occurrence of wheel slipping and sliding

Figure 7 shows the condition of transfer of the black accretion film due to a running test car. We developed the black accretion film on the rail surface in the test section and ground a part of the surface with abrasive paper to expose the base metal. After running the test car on that part, it was found that the black accretion film was transferred on the ground rail surface. According to the result of the observation for the rail surface of the whole section on which the test car ran, it was found that the black accretion film was transferred to a fairly wide range outside the test section. Based on this result, it is considered that wheel sliding and wheel slipping can occur not only in a section in a mountainous area where leaves fall on the rail surface, but also in a point before or after such a section.

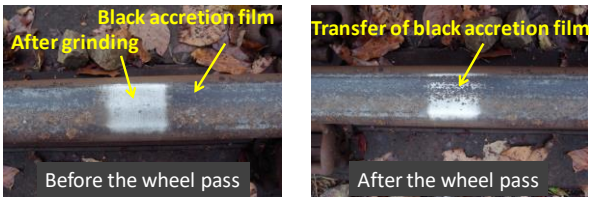

Fig. 7 Transfer of black accretion film on rail surface due to running trains

3. Evaluation of adhesion coefficient

3. 1 Overview of the test

Because it is found that the black accretion film on the rail surface is a significant factor that causes wheel sliding and wheel slipping as shown in Fig. 6, we focused on the black accretion film generated on the rail surface and conducted an evaluation test for its influence on the adhesion coefficient between the wheel and the rail in wet and dry conditions.

The test was conducted in the same method as the power running and braking tests described in Subsection 2.1. We defined the value corresponding to the maximum traction coefficient just before wheel slipping occurs as the adhesion coefficient.

3. 2 Rail conditions

To compare the adhesion coefficients for dry and wet conditions, it is required to make the thickness of the black accretion films on the rail surface that are to be

compared as uniform as possible. Because it is difficult to prepare the black accretion film with a uniform thickness with the same method as indicated in Fig. 2(c), we crushed leaves to make it in a paste form and uniformly applied 10 ml of the paste on the top of rail surface in one meter of track length in the test section (20 m) (see Fig. 8). Then, we sprayed water on the rail surface and ran the test car alternately to prepare the black accretion film as shown in Fig. 9.

Fig.8 Treatment of leaf paste on rail

Fig. 9 Reproduction of black accretion film on rail surface

For the test conditions, we conducted a running test under rain in addition to the tests for wet and dry conditions because it rained for a day during the test period.

When observing the state of the rail surface before running the test car with naked eyes, the black accretion film strongly adheres to the rail surface under the dry condition, and the black accretion film becomes pasty under the wet condition. Also, in the case of drizzle, the black accretion film is floating on the rail surface, and in rainy weather the black accretion film is flowing from the rail surface.

During the running test, the running speed when the test car entered the test section (the initial speed of the power running and the braking operations) was set to 30 km/h, however, in the case of drizzle, the test car entered the test section at a speed slower than 30 km/h in consideration of the expected stopping distance in the braking operation.

3.3 Test results

Figure 10 shows the maximum adhesion coefficient with black accretion film during the power running and braking tests under the conditions of dry, wet, drizzle and mid rain. The magnitude of the adhesion coefficient decreases in order of drying, wetting, middle rain and drizzle. The reason why adhesion coefficient under wet condition becomes smaller than mid rain is because the black accretion film on the rail surface under mid rain conditions was drained by rain and the rail surface was clean. In the case of drizzle, the adhesion coefficient is the smallest because the black accretion film is floating on the rail surface.

Figure 11 shows the average adhesion coefficient with black accretion films in dry, wet conditions, as well as without black accretion films in dry, wet and rainy (includes drizzle and mid rain) conditions obtained during the power running and braking tests. These average values indicate a slight difference in the adhesion coefficient between power running and braking, but there was almost no change in the adhesion coefficient in dry conditions regardless of the presence or absence of the black accretion film (Shorthand notation: BCF). The average adhesion coefficient in wet and rainy conditions however decreased significantly compared with the dry condition.

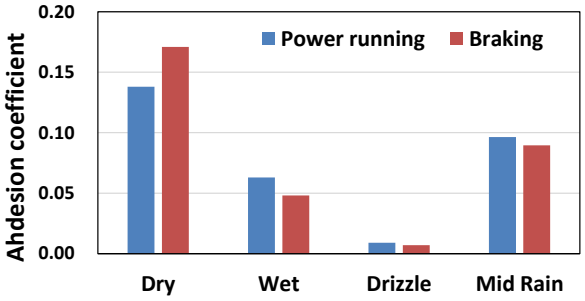

Fig.10 Maximum adhesion coefficient with black accretion film under different conditions

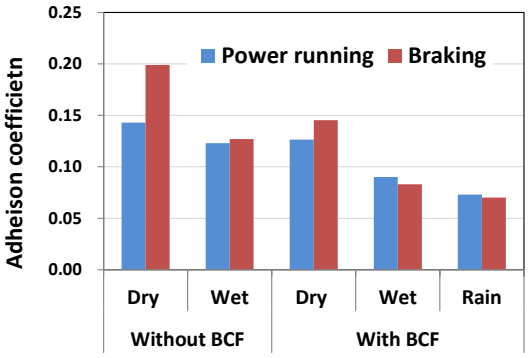

Fig. 11 Estimated average adhesion coefficients under various conditions

From the result indicated in Figs. 10 and 11, it can be grasped that the wheel tends to easily slip in a section in a mountainous area when the black accretion film on the rail surface is wet due to morning dew, frost, and drizzle. Although it is impossible to make quantitative comparison because different measurement devices and methods are used, the adhesion coefficients between the wheel and rail obtained in this test for dry and wet conditions indicated almost the same tendency as the coefficient of friction for the black accretion film on the rail surface that was measured under the same condition by using a simple measurement method in a line in the mountainous area in Tohoku region [1)], therefore it is considered that this test reproduced the actual condition of the commercially-operated line well.

4. Laboratory experiments

4.1 Overview of the test

To understand the adhesion behavior before a black accretion film is generated on the rail surface, i.e. when the wheel presses fallen leaves on the rail surface in normal wet or dry conditions, a "rolling - sliding friction test rig" shown in Fig. 12 was used to simulate the contact between the wheel and rail. The rig was used to

measure the traction coefficient (the maximum traction coefficient is considered to be the adhesion coefficient) in different conditions: dry, wet, and with accumulated leaves.

The rig consisted of test rings with a diameter of 30 mm reproduce the wheel (wheel ring) and rail (rail ring) respectively. To reproduce the contact pressure between an actual wheel and rail, the tread surface of the wheel ring was flat while tread of the rail ring was arched with a curvature radius of 600 mm. Both rings were made of the same material as the part they imitated, i.e. they were cut from actual wheels and rails.

Regarding operating conditions, the rig was set with a load of 245 N (contact pressure was approximately 800 MPa), the rotational speed of the wheel ring was 800 rpm (circumferential velocity was approximately 4.5 km/h), with a slip ratio of 5% (slipping speed was approximately 0.2 km/h).

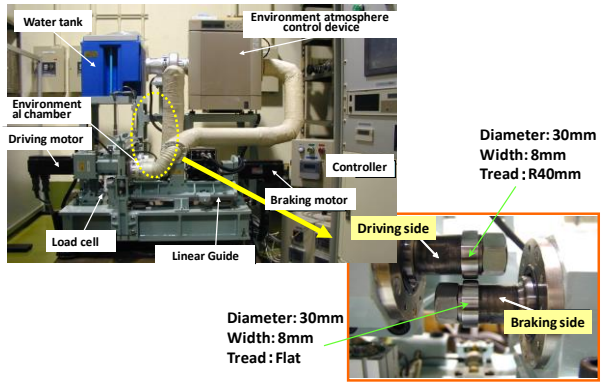

Fig. 12 Rolling - sliding friction test rig

4.2 Test conditions and method

The laboratory test was conducted by inserting leaves between the wheel and the rail rings while alternating the state of the test rings from dry to wet continuously. The test condition was changed as described in items a) to d) below while the rings were being rotated, rather than maintaining it in a constant state. The condition indicated in item a) simulates green leaves blown onto the rail by a typhoon to compare this case with withered leaves falling on the rail. Wet conditions were obtained by spraying water between the wheel and the rail rings with a garden spray.

a) With green leaves (simulating fresh leaves blown onto the rail by a typhoon)

b) With withered leaves (simulating leaves falling in autumn and winter)

c) Transition from dry to wet conditions, and then adding leaves (simulating condensation appearing on the rail surface, withered leaves falling on the rail, followed by a passing train)

d) Transition from dry conditions to presence of leaves, and then to wet conditions (simulating withered leaves falling on the rail, condensation occurring on the rail surface, followed by a passing train)

4.3 Test results

Figures 13 and 14 show the traction coefficient when fresh and withered leaves exist between the wheel and the rail rings respectively. Results show that the traction coefficient was 0.2 - 0.3 in the case of fresh leaves on the contact surface (Fig. 13), while it decreased significantly to less than 0.1 when the leaves were crushed and the pith squeezed out. This is even lower than the coefficient found when the contact surface is covered in a common type of oil. In the presence of withered leaves the traction coefficient was 0.2 - 0.3 (Fig. 14). However, when withered leaves where inserted between the wheel and the rail rings they were discharged from the contact zone without being crushed as the test rings rotated. The traction coefficients obtained therefore is considered to be the values corresponding to when the old leaves are actually sandwiched between the wheel and the rail rings.

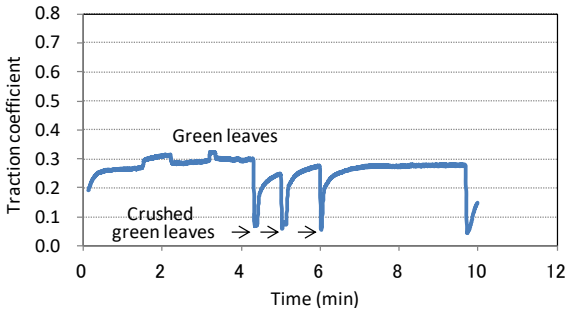

Fig. 13 Traction coefficient with fresh leaves

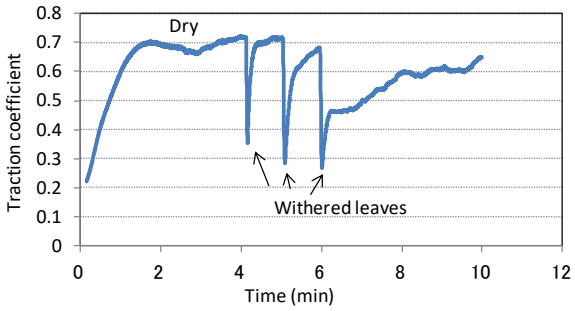

Fig. 14 Traction coefficient with withered leaves

Figure 15 shows the traction coefficient on the contact surface of the test rings as it transitioned continuously from dry to wet, and then with withered leaves. The test simulated conditions where a rail surface in a mountainous area first becomes wet and then has leaves crushed on it under the wheel, forming a layer on the rail surface. As in Fig. 15, the traction coefficient in wet conditions was half of that found in dry conditions. When withered leaves were added the traction coefficient decreased further to approximately one tenth and one fourth of the value obtained in dry and wet conditions respectively.

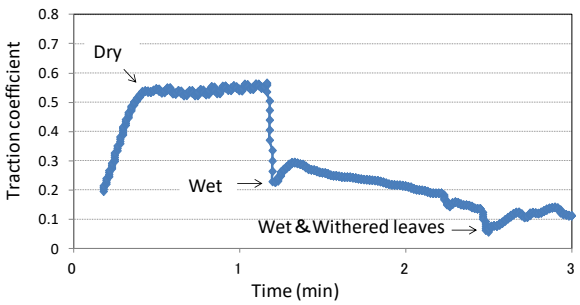

Fig. 15 Traction coefficient when transitioning from dry to wet conditions, and then with the addition of withered leaves

Figure 16 shows the traction coefficient when the contact surface of the test rings transitioned continuously from dry to the addition of withered leaves, and then to wet conditions. The test simulated the falling of leaves on a rail surface in a mountainous area which are crushed by the wheels, and then moistened. As in Fig. 16, the traction coefficient decreased by two thirds when withered leaves were added, compared to dry conditions. When water was applied, the traction coefficient recovered slightly and increased. The reason is thought the crushed leaves slightly flown down by spraying water.

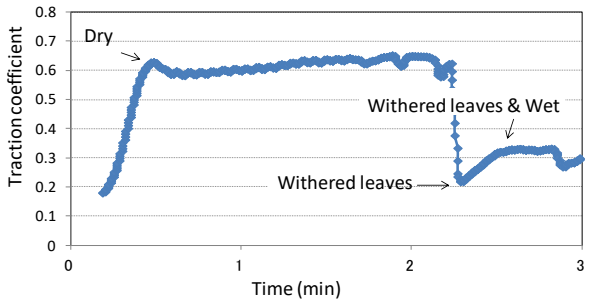

Fig. 16 Traction coefficient transitioning from dry conditions to addition of withered leaves, then to wet conditions

Laboratory test results indicated that the behavior of the traction coefficient when leaves were present on the rail surface varied between dry and wet conditions. It is posited that the adhesion coefficient decreases, creating conditions where wheels can slip easily, when leaves fall on an already wet rail surface and are then pressed by a wheel.

Figure 17 shows that the black accretion film adhered to the test rings tread surfaces after the test using fresh leaves (the condition a)). In addition, Fig. 18 (b) shows that the black accretion film was also found on the surface of the test rings after tests under condition c). This black accretion film was similar to the one generated on the rail surface in mountainous areas.

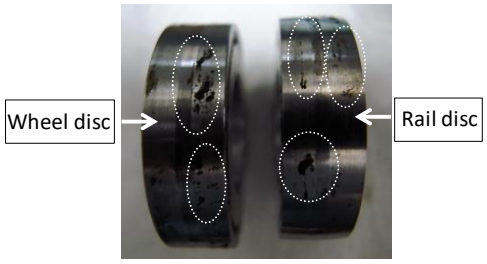

Fig. 17 Tread surface after tests with fresh leaves (test condition a))

(a) During the test *(b) After the test*

Fig. 18 Tread surface after tests with withered leaves (test condition c))

5. Discussion

The results from the power running and braking tests conducted on the RTRI test track show that the adhesion coefficient decreased significantly and that wheels tended to slip or slid when the black accretion film on the rail surface became wet in mountainous areas. The reasons for this are considered to be as follows: in mountainous areas in autumn, leaves are crushed by the wheel of passing trains and the leaves adhere to the top surface of the rail. The rail surface becomes moist from condensation forming at night and/or early morning due to changes in temperature. Repetition of this process over several days creates a black accretion film on the rail surface which gets thicker over time. This black accretion film then forms a paste with the addition of rain and/or early morning condensation leading to wheel slipping or sliding as trains pass over it.

Nevertheless, results from tests to measure the traction coefficient when the contact surface between the test rings was covered with withered leaves and when transitioning continuously from dry to wet conditions demonstrated that the adhesion coefficient would decrease with wet leaves on the rail surface in mountainous areas. Furthermore, the adhesion coefficient was lower when leaves fell on an already wet rail surface and were then crushed by a passing wheel than when leaves first fell on a dry rail that only became wet afterwards and were then crushed by the passing wheel. These results therefore lead to the conclusion that wheel slipping and sliding tend to occur more easily in mountainous areas where trains pass over leaves fallen on an already wet rail surface due to morning dew and/or frost.

6. Conclusions

Power running and braking tests were conducted on the RTRI test track under conditions simulating a rail surface a mountainous area, and the occurrences of wheel slipping and sliding were investigated. Furthermore, traction coefficient was measured on a rolling - sliding friction test rig in laboratory conditions simulating the time of year when leaves begin to fall in autumn. The results of the study produced the following conclusions:

1. The adhesion coefficient decreases significantly and wheels tend to slip or slid when a black accretion film made from crushed leaves adheres to the rail surface and gets wet.
2. A black accretion film is created from the repeated crushing of leaves by the train wheels on the rail surface and the rail surface repeatedly changing from dry (daytime) to wet (condensation forming at night and/or early morning due to changes in temperature) conditions.
3. The black accretion film generated on rails in sections surrounded by many trees is transferred by the train wheels to other section along the line.
4. When leaves are pressed by the wheel on an already wet rail surface the adhesion coefficient decreases significantly causing frequent wheel slipping and/or sliding.

* E-mail: wmzhai@swjtu.edu.cn

Abstract: A new method is presented to simulate the vertical high-speed vehicle-track-subgrade dynamic interaction based on the Green function method. It is applied to investigate the influence of wheel polygonal wear on the dynamic responses of the vehicle-track-subgrade system. Results show that the high orders of polygon will induce high-frequency wheel-rail interactions, intensifying the wheel and rail vibrations, but hardly affect the car body accelerations. The wheel-rail vertical forces and fastener forces are significantly exacerbated by the increased polygon order, and the dynamic responses of the slab-subgrade system are mainly affected by the low orders of polygon.

Keywords: Vehicle-track-subgrade interaction; wheel polygonal wear; the Green function method; polygon order; dynamic stress.

1. Introduction

In recent years, the development of high-speed railway in China has made great achievements. Meanwhile, in order to meet the requirements of the high speed and the heavy haul, some engineering problems have gradually been exposed [1]. The wheel polygonal wear is one of the most serious problems nowadays, which is a phenomenon of uneven compound harmonic wear in the circumferential direction of railway vehicle. With the formation of wheel polygonal wear, the dynamic interaction between wheel and rail is obviously increased, which severely threatens the running safety. Nielsen and Johansson [2] presented a detail review of different types of deficient wheels and discussed their influence on the dynamic responses of the vehicle, which mainly focuses on the problem of the 1^{st}~5^{th} wheel polygon order. However, as the in-depth development of the high-speed railway in China, wheel polygonal wears with high orders ranging from 17^{th} to 25^{th} order have been detected. The impact loads induced by wheel polygonal wear with high orders will raise the fatigue problems of railway components [3] and excite the resonance of wheel set axle [4]. The effects of wheel-rail impact loads caused by wheel polygonal wear on the vehicle dynamics have been of particular concern to a number of scholars, in which the track structure is usually assumed to be a rigid base. It is defective to reflect real responses under the excitation of mid- and high-frequencies. Therefore the detailed as well as elastic track model should be took into account. In addition, vibrations of the vehicle and elastic track system can be influenced mutually, so the effects of wheel polygonal wear on the track system are essential to investigate.

However there is a little literature considering the influence of wheel polygonal wear on the track system. Liu and Zhai [5] adopted a vertical vehicle-track coupled dynamics model to systemically investigate the dynamic performance of the vehicle system and the ballast track system under the excitation of wheel polygonal wear. Results illustrated that for the vehicle system, wheel polygonal wears mainly affect the wheelset vibration. The short-wavelength components of the wheel polygonal wear will lead high-frequency vibrations of the track system, especially considerably enhance the high frequency oscillations of rails and sleepers. However currently, the influences of wheel polygonal wear on the ballstless track and subgrade are not quite clear.

In traditional railway vehicle-track dynamics simulation, track system is mainly modelled by the modal superposition method [6] and the finite element method [7]. The calculational accuracy of the modal superposition method is affected by the form of assumed modes and the number of cut-off modes. The finite element method is capable to describe the track system in detail but generating a large number of motion equations which are time-consuming to be solved. Recently, the time-domain Green function method [8-11] has gained plenty of attentions in the research on vehicle-track coupled dynamics. The method is based on the time-domain Green functions of the wheel and rail, which represent the unit impulse-induced responses of the wheel and rail. In the existing Green function method, the structure under the rail is always simplified, resulting in a lack of reality in reflecting high-frequency vibrations of track system. Additionally, the Green function of the rail is related to the running speed of the vehicle, which gives rise to low universality in calculating the responses at different speeds.

In this paper, a new method is proposed to investigate the influence of wheel polygonal wear on the high-speed vehicle-track-subgrade interaction. A traditional vehicle subsystem modelled as a 10-degree-of-freedom multi-rigid-body is coupled with the rail beam, which is

discretely supported by a series of rail pads. As for the substructure, a non-ballasted track and subgrade system is described as a finite element model. The differential dynamic equations of the vehicle-rail system and the integral dynamic equations of the slab-subgrade system are linked through fastener forces. The validity of the proposed method is demonstrated by comparing the simulation results with the finite element method. Finally, the effects of the measured wheel polygonal wear and main parameters of wheel polygonal wear on the vehicle-track-subgrade system are studied.

2. Vehicle-track-subgrade dynamic interaction model

A vertical vehicle-track-subgrade dynamic interaction model considering wheel polygonal wear is established to obtain the system dynamic responses when the vehicle moves on the elastic track, as shown in Figure 1. This interaction model consists of three sections: the vehicle-rail subsystem, slab-subgrade subsystem, and the fasteners connection. The interactions between the vehicle and rail are characterized by the wheel-rail contacts, and the interactions between the vehicle-rail subsystem and slab-subgrade subsystem are transferred by the fasteners connection.

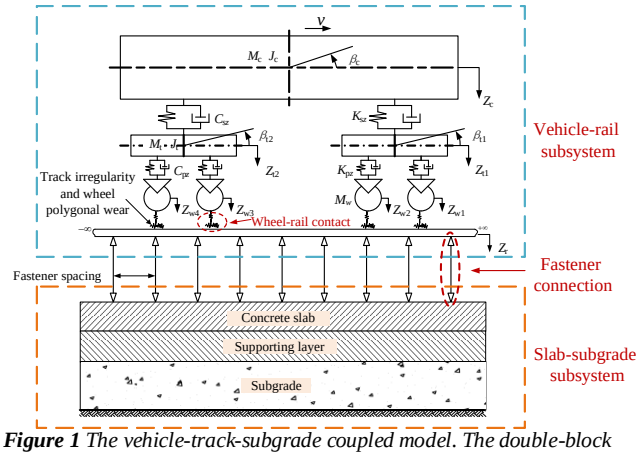

Figure 1 *The vehicle-track-subgrade coupled model. The double-block ballastless track is used in this model.*

2.1. Vehicle-rail dynamic model

Based on the vehicle-track coupled dynamics theory [12], the vehicle is treated as a multi-rigid-body system, which has a total of 10 degrees of freedom, including vertical motion and pitch rotation of a car body and two bogie frames, and vertical motion of four wheelsets. The vehicle moves at a constant speed in the longitudinal direction. The rail is treated as a continuous Bernoulli-Euler beam discretely supported by rail pads.

The motion equations of the vehicle system can be easily described in the form of a second-order differential equation, and the motion equations of the rail can be also given in the form of the second-order differential equations based on the Ritz's method. The coupling of the vehicle and rail is performed by the wheel-rail vertical contact force which can be solved by the simplified Hertz non-linear elastic contact theory. A simple fast time integration method proposed by Zhai [13] is utilized to solve the high dimensional differential equations of the vehicle-rail system. A detailed description of the vehicle-rail model has been presented in Refs. [6].

2.2. Slab-subgrade dynamic model

A three-dimensional finite element model of the typical double block ballastless track and subgrade system is built based on the commercial software ANSYS. The model is constructed by a multi-layer structure with different components, i.e., concrete slab, supporting layer, and subgrade. The system responses caused by a unit impulse excitation which is applied to a fastener position on the concrete slab can be obtained, namely the Green functions of the system. Therefore, based on the obtained Green functions of the system, the responses of the slab-subgrade system induced by the fastener forces can be expressed by the Duhamel integral as follows:

$$W(x,y,z,t)=\sum_{j=-\infty}^{+\infty}\int_0^t G(x,y,z,x_j,y_p,z_p,t-\tau)F_{rsj}(\tau)d\tau \quad (1)$$

where (x, y, z) is the coordinate at any position of the system, (x_j, y_p, z_p) is the coordinate of the j^{th} fastener, $G(x,y,z,x_j,y_p,z_p,t-\tau)$ denotes the Green function which indicates the response at the position (x,y,z) and the time $t-\tau$, when a unit impulse excitation is applied to the j^{th} fastener at time $t=0$, $F_{rsj}(t)$ denotes the j^{th} fastener force at the $t-\tau$ moment.

The convolution integral $\int_0^t G(t-\tau)F_{rs}(\tau)d\tau$ can be solved using the numerical method proposed by Mazilu [7]. Assuming that in the time interval $[t_{i-1}, t_i]$, the Green functions $G(t-\tau)$ and the fastener forces $F_{rs}(\tau)$ have a linear variation. Then the convolution integral at the m^{th} integral step can be written as

$$\begin{aligned}&\int_0^{t_m} G(t_m-\tau)F_{rs}(\tau)d\tau\\&=\Delta t\sum_{k=1}^{m}\left\{\frac{G(t_m-t_{k-1})F_{rs}(t_k)+G(t_m-t_k)F_{rs}(t_{k-1})}{2}\right.\\&\left.+\frac{[G(t_m-t_k)-G(t_m-t_{k-1})][F_{rs}(t_k)-F_{rs}(t_{k-1})]}{3}\right\}\end{aligned} \quad (2)$$

where Δt is integral step.

2.3. Rail-slab interaction model

The rail-slab interaction model is the essential element that couples the vehicle-rail subsystem with the slab-subgrade subsystem at the rail-slab interfaces. The interactions between two subsystems are transferred by the fastener forces. From Section 2.1 and Section 2.2, the displacement and velocity responses of the rail and the concrete slab can be obtained. Thus, the fastener force of the i^{th} fastener at the m^{th} integral step can be expressed by

$$F_{rsi}(t_m)=k_p\left[Z_{ri}(t_m)-Z_{pi}(t_m)\right]+c_p\left[V_{ri}(t_m)-V_{pi}(t_m)\right] \quad (3)$$

where k_p and c_p are the stiffness and damping of the fasteners in the vertical direction, Z_r and V_r are the displacement and velocity of the rail, Z_p and V_p are the displacement and velocity of the concrete slab, respectively.

2.4. Procedure of the proposed method

The method is presented to perform the vehicle-track-subgrade dynamic interaction. Calculation process of this method is as follows:

Step 1 Establish the finite element model of the slab-subgrade system to obtain the Green functions of the system by applying a unit impulse excitation to a fastener position on the concrete slab. The Green functions include two components: $h(t)$ denoting the responses of the displacement and velocity at fastener positions on the concrete slab, and $g(t)$ denoting the responses at other positions which are required to be analyzed.

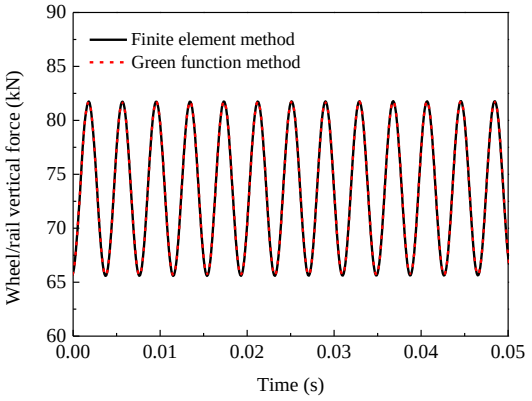
Step 2 Establish the dynamic model of the vehicle-rail system. Set the initial condition of the dynamic differential equations of the vehicle-rail system.

Step 3 Solve the displacement and velocity responses of the vehicle-rail system at the m^{th} step using Zhai method [13].

Step 4 Solve the displacement and the velocity at the fastener positions on the concrete slab at the m^{th} step excited by fastener forces using the Duhamel integral equation, based on the obtained Green functions $h(t)$ and the fastener forces before the $(m\text{-}1)^{th}$ step.

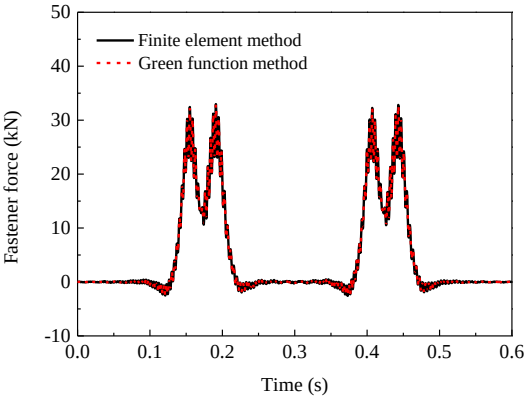
Step 5 Solve the fastener forces at the m^{th} step combining the displacement and the velocity at the fastener positions of the rail and the concrete slab.

Step 6 Solve the acceleration responses of the vehicle-rail system at the m^{th} step combining the displacement and velocity responses of the vehicle-rail system and fastener forces at the m^{th} step.



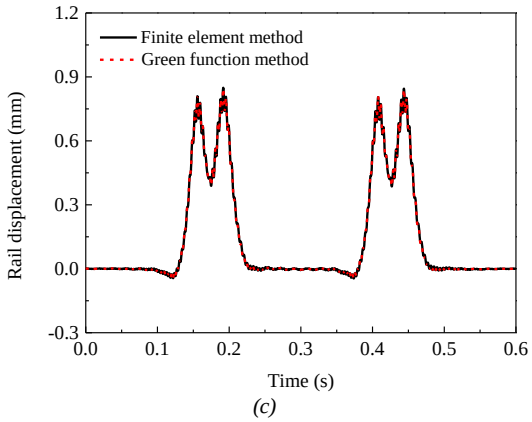
Step 7 Set the final step M. If $m=M$, the solving process is finished. In such a cyclic calculation from step 3 to step 6, the time history responses of the vehicle-rail system and fastener forces $F_{rs}(t)$ can be obtained.

Step 8 Solve the dynamic responses of the slab-subgrade system at other positions by employing the Duhamel integral equation based on the obtained Green functions $g(t)$ and $F_{rs}(t)$.



3. Method verification

The validation of the proposed method is carried out by comparing the dynamic responses derived from the Green function method with the results calculated by the finite element method [13]. As the finite element method is widely used and track model can be described in detail, it can be employed as a reference for evaluating the accuracy of the dynamics simulation results. The parameters of the Chinese high-speed vehicle CRH3 and the double-block ballastless track are adopted here. The vehicle speed is 300 km/h. The harmonic irregularity which the wavelength is 0.27m and wavedepth is 0.1mm, is taken as the excitation between the surface of the wheel and rail



The dynamic responses acquired with two methods under the excitation of the harmonic irregularity are displayed in Figure 2. It can be concluded that the dynamic responses show a pretty good consistency between the Green function method developed in this paper and the finite element method. That is, the presented method is validity for simulating the vertical vehicle-track-subgrade coupled dynamics. Furthermore, compared with the finite element method, the Green function method attributes to improve the computational efficiency. In case of 1s simulation time, the central processing unit times for the Green function method and the finite element method are 16.20 minutes and 12.67 hours on a conventional desktop with the processor Intel Core i7-7770, 3.6 GHz, indicating that the computational time of the finite element method is about 47 times more than that of the Green function method.

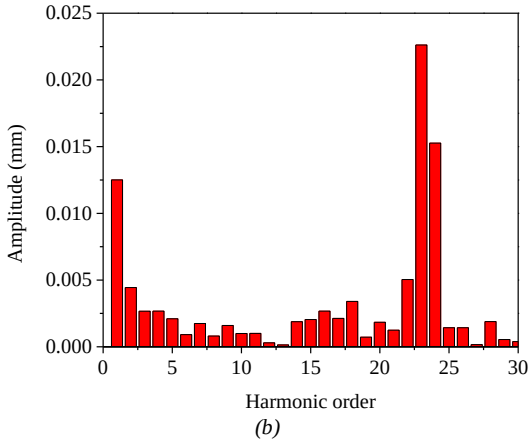
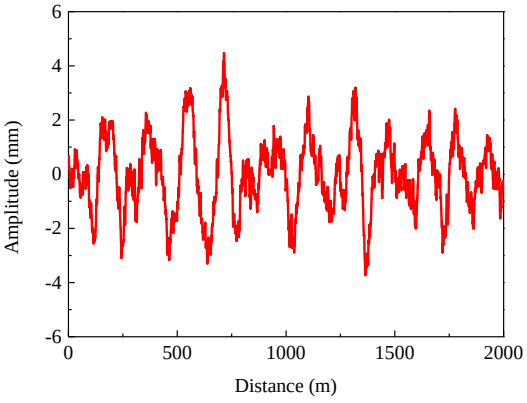
4. Effect of wheel polygonal wear on the vehicle-track-subgrade interaction



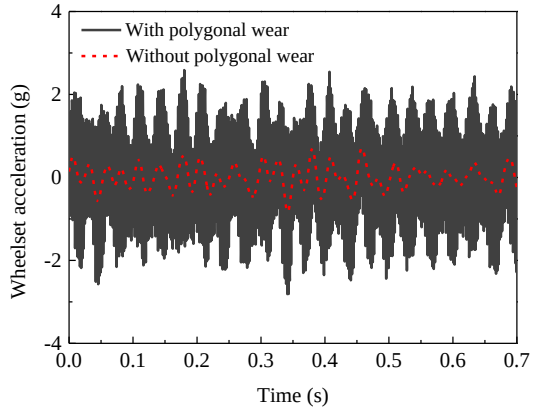
To investigate the effects of wheel polygonal wear on the dynamic performance in the actual conditions, the analysis is performed by considering the measured wheel polygonal wear. Besides, the wheel polygonal wear which is treated as simply harmonic model is also employed to analyze the effects of main parameters of polygon wear. The parameters of the Chinese high-speed vehicle CRH2 and double-block ballastless track are adopted in this paper, and the vehicle running speed is 250 km/h.

4.1. Effect of the measured wheel polygonal wear on the vehicle-rail system

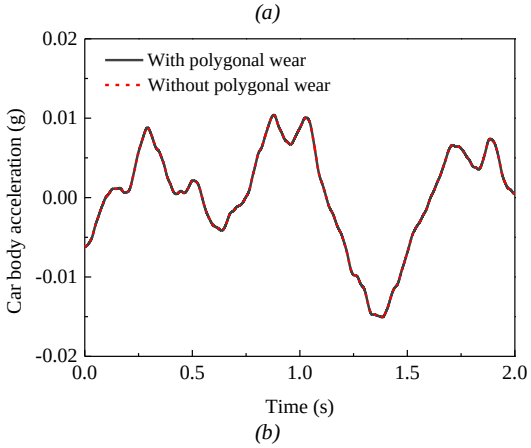


For the purpose of analyzing the influence of wheel polygonal wear during the running process, the measured wheel polygonal wear (Figure 3(a), 3(b)) as well as the Chinese high-speed ballastless track random irregularity (Figure 3(c)) are superimposed as the excitation between the surface of the wheel and rail. The wavelength of the track random irregularity ranges from 2m~200m. The measured polygonal wear can be treated as a superimposed wave with different orders, different phases, and different wave depths. It can be seen from Figure 3(b) that the amplitudes of order 23th and 24th are obviously larger than other orders, which indicates the amplitude of the measured wheel polygonal wear is mainly dominated by this two orders.

(a)



(b)



(c)

Figure 3 *The measured wheel polygonal wear: (a) Polar coordinates. (b) Cylindrical coordinates. Track random irregularity: (c).*

The acceleration responses of the wheelset and car body are shown in Figure 4. It can be observed that, due to the vibration isolation effect of the both primary and secondary suspension structures, the vibration acceleration amplitude of the wheelset and car body are sequentially reduced. Under the excitation of the measured wheel polygonal wear, the wheelset vibrates extremely, however the car body vibrates in small amplitude. The acceleration amplitude of the wheelset is about 3g (g=9.8m/s^2), while the car body drops below 0.02g.That is to say, the irregularities of the measured wheel polygonal wear have an obvious effect on the wheelset vibration, whereas little effect on the vibration of the car body.

(a)

(b)

Figure 4 *Vertical acceleration: (a) Wheelset. (b) Car body.*

Figure 5 shows the responses of the wheel-rail vertical force in both time and frequency domains with and

without the excitation of the measured wheel polygonal wear. It can be seen from the time-domain results that the quite noticeable vibrations are induced by the short-wavelength components stemmed from the measured wheel polygonal wear. The maximum value of the wheel-rail vertical force with and without the excitation of the measured wheel polygonal wear are 131kN and 80kN, respectively. Consequently, it is indicated that the wheel-rail dynamic interaction is obviously enhanced under the excitation of the measured wheel polygonal wear. The response of the wheel-rail vertical force in frequency domain is shown in Figure 5(b). In the absence of the measured wheel polygonal wear, the frequency characteristics of the wheel-rail vertical force are dominated by low frequency. However, under the excitation of the measured wheel polygonal wear, the frequency characteristics of the wheel-rail vertical force are changed clearly, where the frequencies dominated by the high-frequency interactions are 591Hz and 616Hz, respectively. Due to the amplitudes of the measured wheel polygonal wear are dominated by 23th and 24th orders, the frequencies induced by these components correspond to 591Hz and 616Hz, under the running speed of 250km/h, accordingly giving rise to remarkable contribution in the vibration.

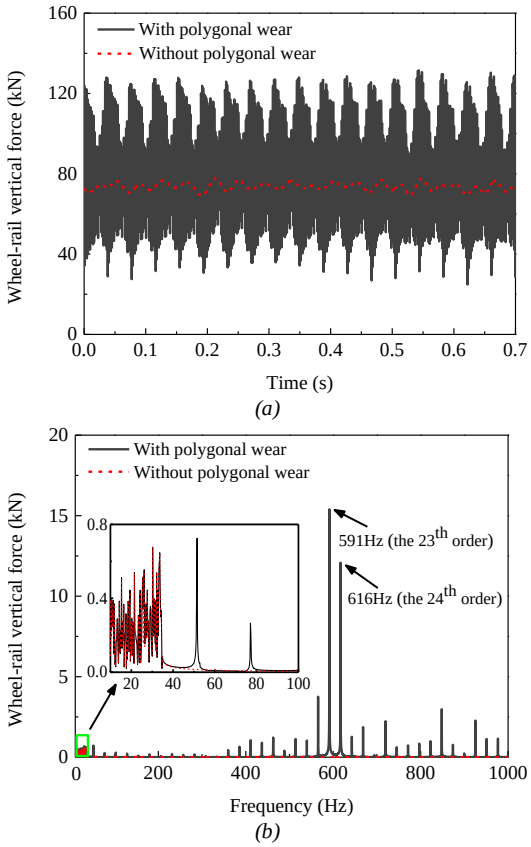


Figure 5 *Wheel-rail vertical force: (a) Time domain. (b) Frequency domain.*

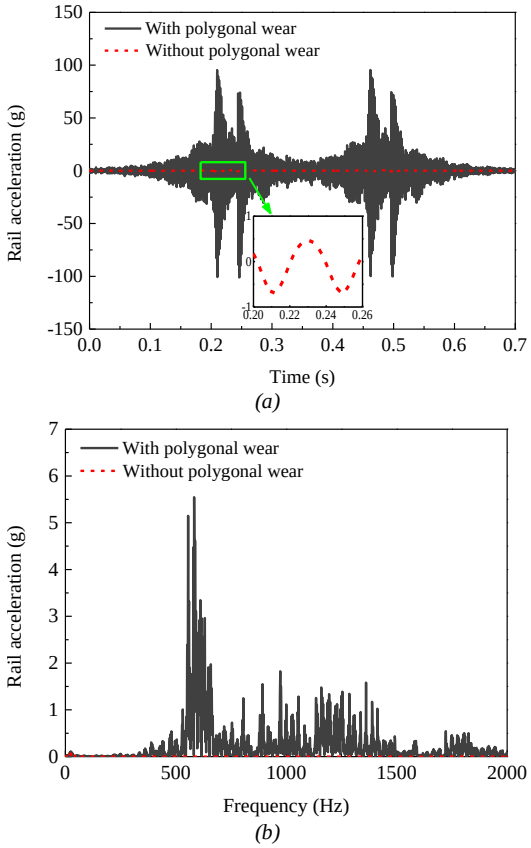
The short-wave irregularity attached to the measured wheel polygonal wear will exasperate the wheel-rail interactions and intensify the rail vibrations. Figure 6 displays the simulation results of the rail acceleration with and without the measured wheel polygonal wear. It can be seen that the maximum value of the rail acceleration under the excitation of the measured polygonal wear is about 100g. It indicates that in contrast with only the track random irregularity, the rail acceleration caused by the measured polygonal wear shows a distinct increase. It should be noted that the rail acceleration caused by the only the track random irregularity shows a relatively very small value, which is attributed to lack short-wave irregularity component. As illustrated in Figure 6(b), the frequency spectrum of the rail acceleration shows that the 22th, 23th, and 24th order (corresponding with 565Hz, 591Hz, 616Hz components) contribute a lot to the responses.



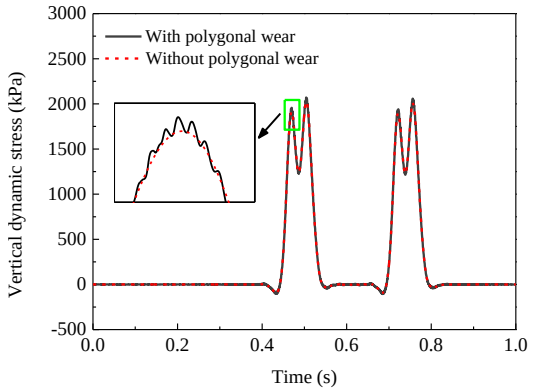


Figure 6 *Rail acceleration: (a) Time domain. (b) Frequency domain.*

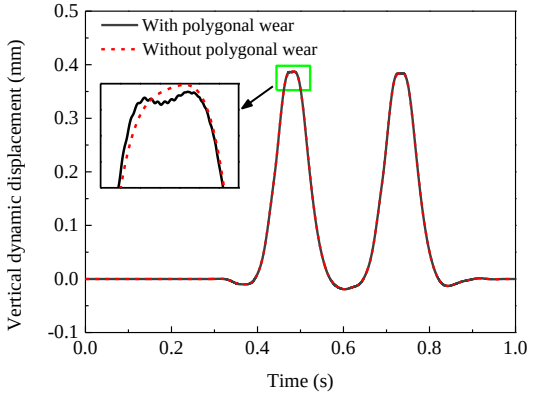

4.2. Effect of the measured polygonal wear on the slab-subgrade system

The high frequency wheel-rail interaction generated by the measured wheel polygonal wear continuously acts on the track, consequently the structure under the rail will be suffered from high frequency stresses, which may results in excessive subgrade deformation and failures. Responses of the vertical dynamic stress and displacement on the concrete slab upper layer are shown in Figure 7. It can be observed that the concrete slab appears the high-frequency vibrations under the measured wheel polygonal wear, which indicates that the high-frequency wheel-rail interaction is propagated from the wheel-rail interface to the structure under the rail. However the amplitudes of the vibrations change slightly compared with only the track random irregularity, illustrating that the high-frequency wheel-rail interaction only affects the vibration shape of the concrete slab and has a little effect on the vibration amplitude. Likewise, responses of the vertical dynamic stress and displacement on the subgrade upper layer are shown in Figure 8. It also

illustrates that the high frequency wheel-rail interaction caused by the measured wheel polygonal wear has a little effect on the dynamic displacement and stress of the subgrade system.

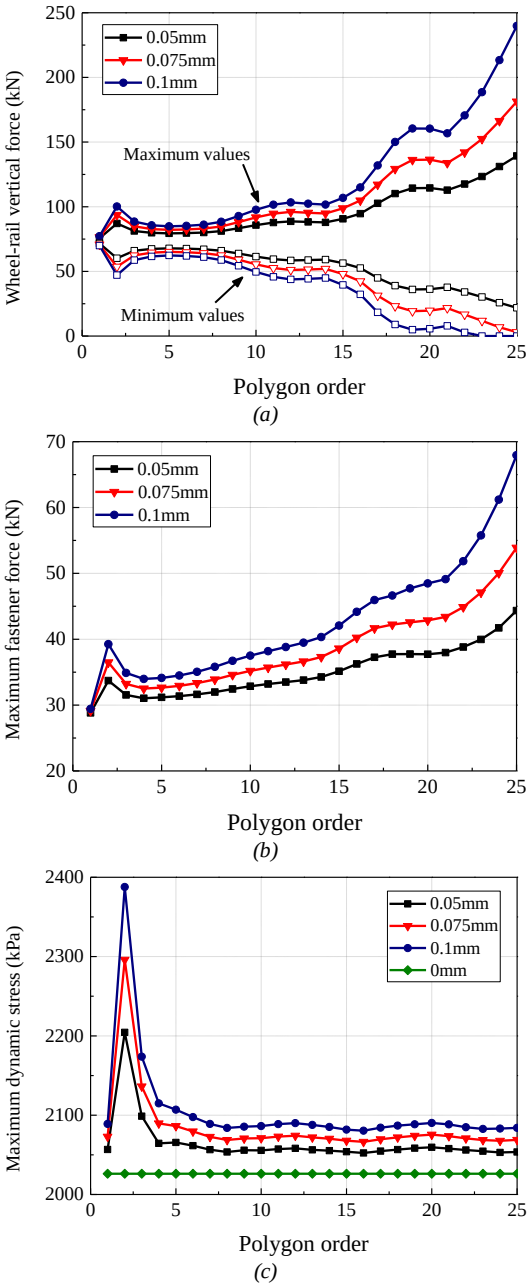
Figure 8 *Dynamic responses on the subgrade upper layer: (a)Vertical dynamic stress. (b) Vertical dynamic displacement.*

4.3. Influence of main parameters of wheel polygonal wear

In the description of the wheel polygonal wear, the main characteristic parameters are wave depth, order number, phase difference, etc. The order indicates the wavelength of the wave which relates to the vibration frequency of the wheel-rail system. The wave depth denotes the degree of wheel polygonal wear along the circumferential direction, namely the amplitude of wheel polygon. In order to investigate the vertical dynamic performance caused by wave depth and order of wheel polygonal wear, a single harmonic model is applied here and the simple harmonic component is treated as the excitation of the wheel-rail interface.

The amplitude of wheel polygonal wear $Z(t)$ can be expressed as Fourier series:



$$Z(t) = \sum_{N=1}^{\infty} A_N \sin\left(\frac{VN}{R}t + \varphi_N\right) \quad (4)$$

where N is harmonic order of the polygon; A_N is the amplitude of N^{th} order and φ_N is corresponding phase; V is running speed of vehicle; R is wheel radius.

Results of the wheel-rail vertical force, fastener force, the vertical dynamic stress and displacement excited by simple harmonics with different orders and different wave depths at the running speed of 250km/h are shown in Figure 9. It is evident from the Figure 9(a) that, with the increased polygon order and wave depth, the maximum values of wheel-rail vertical forces increase significantly, and the minimum values of wheel-rail vertical forces decrease. The phenomenon that the wheel-rail separation appears under the condition of 23th order and 0.1mm wave depth. It indicates that with the increase of polygon order and wave depth, the wheel-rail interactions behave higher frequency and higher amplitude, posing threats to running safety. Note that a local peak of the wheel-rail vertical force can be found at the 2th order, corresponding to 51Hz at the speed of 250km/h, which is probably attributed to the frequency getting close to the resonance of the first vertical mode of vibration of the track coupled to the wheelset [14]. Figure 9(b) shows that the maximum values of the fastener forces increase notably with increased polygon order and wave depth as well. Due to the influence of high order and high wavedepth of wheel polygonal wear, the phenomenon of fasteners fatigue is likely to be caused by the increased amplitudes and frequencies of fastener force.

However, Figure 9(c) shows that the wave depth of wheel polygonal wear has slightly influence on the maximum values of dynamic stresses on the concrete slab, while the high order plays an insignificant role. As the polygon order getting higher, the maximum values of dynamic stresses remains comparably stable. Similarly, Figure 9(d) shows that polygon orders and wave depths have little influence on the maximum values of dynamic displacements on the concrete slab. After 5th order, the

maximum values of dynamic displacements are close to the dynamic displacement amplitude without harmonic irregularity, indicating that the higher orders have negligible influence on the dynamic displacement. The main reason is that the high-frequency wheel-rail interactions are easily absorbed by the fasteners and subgrade system, resulting in the slab-subgrade system shows the low-frequency vibration. Thereby, it can be concluded that the dynamic stress and displacement of the slab-subgrade system are mainly effected by lower orders.

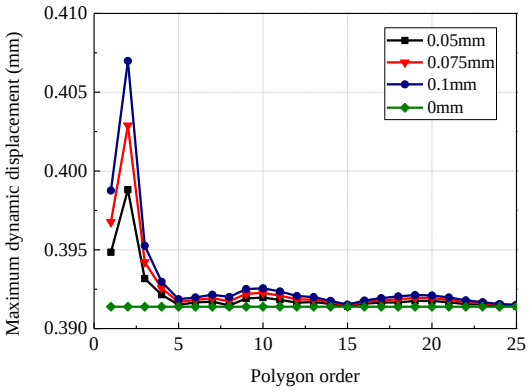


Figure 9 *The effects of polygon order and wave depth on the dynamic responses. (a) wheel-rail vertical force; (b) fastener force; (c) concrete slab vertical dynamic stress; (d) concrete slab vertical dynamic displacement.*

5. Conclusions

In this paper, a new method is presented to simulate the vertical vehicle-track-subgrade dynamic interaction. A hybrid model is established in which the vehicle-rail subsystem are described using the differential equations and the slab-subgrade subsystem are described using the integral equations. The interaction of two subsystems are characterized through fastener forces. The proposed method is then validated to be efficient and accurate through a detailed numerical simulation comparison with the finite element method. On this basis, the dynamic effects of the wheel polygonal wear on the vehicle-track-subgrade system are discussed. The following conclusions can be drawn.

(1) For the vehicle-rail system, short-wave components of the measured wheel polygonal wear will induce the high-frequency wheel-rail interactions. Accordingly the vibration of the wheel and rail are enhanced obviously compared with the results of without polygonal wear. The frequency characteristics of the wheel-rail vertical force are dominated by the 23th and 24th orders which contribute to high amplitudes in the measured wheel polygonal wear. With the increased polygon order and wave depth, the maximum values of the wheel-rail forces and fastener forces increase distinctly, which may bring running safety and fastener failure problems. However high orders of polygon have little influence on the vibration of the car body due to the high-frequency interactions are weakened by the first and second suspension structures.

(2) For the slab-subgrade system, the vertical dynamic stress and displacement are insensitive to the high-frequency interactions caused by the measured wheel polygonal wear. The maximum values of the vertical dynamic stress and displacement show a slight increase in low orders of polygon, whereas gradually level off as the polygon order becomes higher. It indicates that the slab-subgrade system is mainly affected by the low orders of polygon.

Abstract: The hollow wear is a typical type of wheel profile evolution in high-speed railway, causing special contact characteristics in turnout. Focused on wheel profile evolution differed from operating mileages, simulations of vehicle-turnout dynamic interaction considering the wheelset flexibility by SIMPACK software, wheel-rail contact behaviour by CONTACT program, damage evaluation with the wear index and accumulated surface-initiated rolling contact fatigue (RCF) are carried out. Results indicate that the wheel profile evolution decreases the wheel-rail force in crossing panel and the accumulated surface-initiated RCF, but worsens the ride comfort significantly. The wear index reaches the peak with medium hollow wear.

Keywords: High-speed railway turnout; wheel profile evolution; hollow wear; dynamic interaction; accumulated rolling contact fatigue.

1. Introduction

Turnouts (switches and crossings) are critical track equipment that provide flexibility for traffic operation. Cross-sections varied longitudinally cause inherent structural irregularities in turnout. When the wheel transfers between stock (wing) rail and switch (nose) rail, multi-point contact and significant vehicle-turnout dynamic interaction are usually found, resulting in complex wheel-rail relationship and severe impact. As a result, turnout is the weak link of high-speed railway and maintenance key points. In addition, evolution of wheel profiles are found under the long-term service, resulting in the wheel diameter difference, high-order polygonal wheel wear as well as the hollow wear. A hollow shape is one where the profile at the centre of the tread lies below the profile at the end of the tread. It deviates from the standard wheel-rail contact design and affects the vehicle running behaviour as well as contact damage mechanism in turnout zone.

The hollow wheel phenomenon has attracted attention of researchers. X. Jin et al. [1] summarized the transverse wear of Chinese high-speed railway, including its characteristics, the formation mechanism, its effect on running stability of high-speed train and measures against such wear pattern, of which the hollow wear is the most typical. R. Fröhling et al. [2] carried out dynamic curving behaviours with hollow wheels. After considering the contact configuration based on the FE-simulation, effect of hollow wheels on the risk for surface initiated rolling contact fatigue was analysed. K. Sawley et al. [3~5] examined the effect of hollow wheels on wheel/rail contact geometry and vehicle stability, indicating that the small diameter difference in wheelset is one of the formation factors of the hollow wheel wear. Based on the hollow wear value, the criterion of the wheel re-profiling for heavy haul railway in operation condition was suggested. D. Cui et al. [6] studied the detrimental influences of different wear forms on the vehicle dynamic behaviours, including hollow wear as well as the wheel diameter difference. The common standpoint of these studies is that hollow wear has great influence on the vehicle dynamic behaviour. But studies above mainly focused on both the straight and curve route in interval line, without consideration of the interaction of vertical and lateral track irregularity, such as the turnout zone.

On the other hand, considering the interaction of repeated loading, temperature variation and foundation deformation, effect of the service performance evolution of turnout structure on vehicle running behaviour and damage has been investigated. T. Kuminek et al. [7] measured the tram frogs profile and discussed the wheel-rail contact characteristics with the finite element model. J. Xu et al. [8] proposed a numerical procedure to predict the effect of track gauge, rail inclination and friction coefficient on the wear of railway turnouts. Based on the Latin hypercube sampling, A. Johansson et al. [9] simulated the random dynamic load with train passing through turnout. The dynamic interaction was obtained by GENSYS and damage evaluation including wear, plastic deformation as well as rolling contact fatigue (RCF) were studied. Focused on the conformal contact and two-point contact, N. Burgelman et al. [10] developed the CONTACT program and put forward the WEAR algorithm, which would apply in the analysis of RCF in turnouts. M. Pletz [11] investigated the rolling/sliding behaviour and multiple contacts with a wheel passing through the crossing nose by finite element model. Z. Wei [12] developed a contact model capable of simulating wheel–

rail impact at crossing panels using the finite element method. The simulated dynamic response was verified through comparisons with in situ axle box acceleration measurements. As mentioned above, the existing research findings focused on the standard wheel profile, without consideration of the wheel profile evolution.

With continued demand for high-speed operations, it is essential to build better understanding of the wheel-turnout rail dynamic interaction and contact damage mechanism with the growth of wheel hollow wear. In this study, a vehicle-turnout coupled dynamic model is formulated by multi body dynamics software SIMPACK and the dynamic response of a high-speed vehicle passing through turnout is obtained. The model incorporates flexibilities of the wheelset to account for the precise wheel-rail contact position and creepages. Then, the wear index is applied to compare the rail wear. Finally, having obtained the normal and tangential wheel-rail rolling contact behaviour by the CONTACT program, the accumulated surface-initiated RCF damage is compared under hollow wear profile in variation of operation mileages.

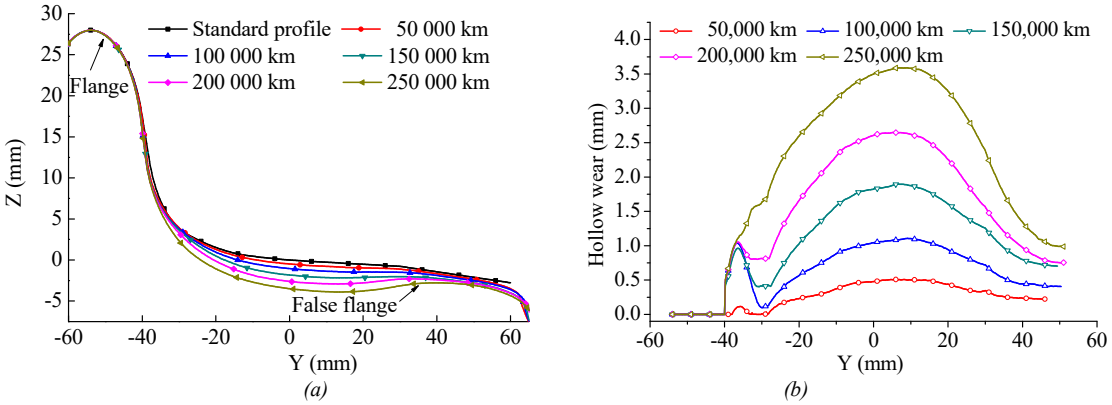

Figure 1 *Field measured wheel profiles: (a) Profile with respect to mileage. (b) Hollow wear of wheel profiles with respect to mileage.*

The curvature of the hollow bottom on the wheel is smaller than that of the rail head, so the hollow zone on the wheel cannot contact with the rail head. As a result, contact points are located around the edge of the hollow zone and may keep jumping on the wheel tread. The outside edge of hollow area is defined as the false flange.

2.2. Vehicle model

Taking the Chinese CRH2 high-speed railway vehicle as the prototype, the vehicle is modelled as a multi-body dynamic system consisting of a car body supported on two bogie frames via air springs. The force elements provided by the bump-stop, lateral damper and yaw damper are modelled either. Each wheelset is coupled to the bogie frame via coil springs in the vertical direction, and the vertical damper and axle box constraint force are included in the primary suspension force. The parameter values of the vehicle model are referred to Ref. [13].

The wheelsets are modelled as flexible bodies and the displacement at any given point $\mathbf{d}(\mathbf{c}, t)$ on the wheelset can be expressed as follows:

$$\mathbf{d}(\mathbf{c}, t) = \mathbf{c} + \mathbf{u}(\mathbf{c}, t) \quad (1)$$

where $\mathbf{c}$ is the position vector of the same point in the undeformed state, and $\mathbf{u}(\mathbf{c}, t)$ is the elastic deformation at the given point, which is obtained using the modal superposition approach:

$$\mathbf{u}(\mathbf{c},t) = \mathbf{\Phi} \cdot \mathbf{q}_w(t) \quad (2)$$

where $\mathbf{q}_w(t)$ denotes the generalized coordinate vector and $\mathbf{\Phi}$ is the modal matrix of the wheelset. The modal matrix for the wheelset is obtained in the finite-element platform using 136,079 solid 45 elements as shown in Fig. 2. A total of 311 master nodes located on 11 cross-sections of the wheelset along the axle direction are selected.

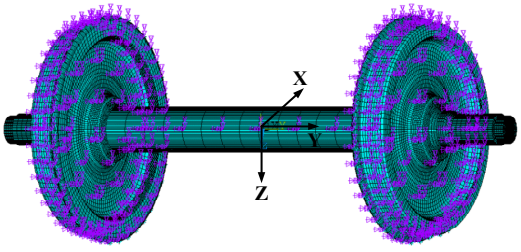

Figure 2 *Finite element model of the wheelset*

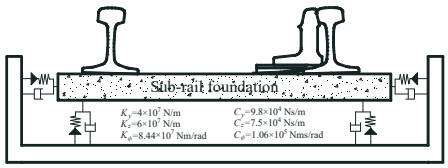
After obtaining the free-free modal based on the finite element method, the flexible wheelset is employed in the vehicle model via the FEMBS interface. Considering that the wheelset is subject to revolute constraint imposed by the axle box and primary suspension, the eigenfrequency of the vehicle-wheelset coupled model are evaluated in the SIMPACK software. According to

2 Vehicle-turnout coupled model

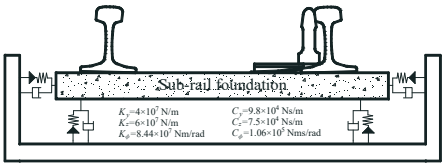
The vehicle-turnout simulation model integrates the dynamic model of a high-speed CRH2 vehicle coupled with the 350 km/h CN60-1100-1:18 turnout model via wheel-rail contact model. Field measured wheel profiles with hollow wear are applied in the model.

2.1. Field measurements of hollow-worn wheel



In order to characterize the development of wheel-rail wear, the wheel tread shapes in different mileages were measured on CRH2 electric multiple units (EMU), as shown in Fig. 1a. The intersection of nominal rolling circle and standard LMA wheel tread is considered as the origin of the coordinate system. The hollow degree develops with the added operation mileage among the abscissa of -30 ~ 40 mm. Fig. 1b shows the value of hollow wear as the difference between the depth point of measured profile and high point of standard profile. When the operation mileage reaches 250 thousand kilometres, the hollow wear exceeds 3.5mm.

the field measurement by Z. Ren [14], a vehicle passing through turnout can give rise to fundamental excitation frequency above 600Hz in axle boxes for a nominal speed of about 300 km/h. The wheel/rail contact forces at such high frequencies may excite some higher vibration modals. As a result, the modal approach is used to account for 29 free-free deformation modals up to 1778 Hz, while the coupled modal frequency is below 1398 Hz.



2.3. Turnout model

The simulated turnout model is based on the Chinese CN60-1100-1:18 turnout with a movable nose rail of the passenger dedicated line. The varied rail profiles are realized by sampling the composite cross-sections combined with stock (wing) rails and switch (nose) rails at certain longitudinal positions. Based on the linear interpolation between discrete points of adjacent sampling sections, cross-sections with 1 mm intervals of the head width are obtained. This ensures the linear variation of the head width and height reduction value for the switch rail and nose rail. Then, taking the arranged turnout sections according to mileages as inputs, the variable profiles of the turnout are interpolated by means of Bézier curves along the longitudinal direction.

To highlight the superiority of computational efficiency for multi-body dynamics, the rails are simulated with massless elements and simplified to be fixed on sleeper and ballast, which ignores the characteristics of the fastener system. Then, the sub-rail foundational elements, including the sleeper and ballast, are simulated with a rigid mass together of three DOFs, namely lateral movement, vertical movement, and roll (Fig. 3). The spring-damping elements with stiffness K_y, K_z, K_ϕ and damping C_y, C_z, C_ϕ in the lateral, vertical, and rolling directions are applied to create the transitions from subgrade to sub-rail foundation. Finally, joints are set to ensure the foundations follow the track at the position of the wheelset.

(a)

(b)

Figure 3 *Turnout model: (a) Switch panel. (b) Crossing panel.*

2.4. Wheel-rail contact model

For each combination of wheel profile and rail cross-section, the wheel-rail contact geometry problem is solved in advance using the discrete elastic wheel-rail contact algorithm. This method deals with the subject of the semi-Hertzian contact and splits the profiles into a number of longitudinal slices with constant width. The contact search is performed in each slice in the local normal direction of the rail profile. Further, the normal forces are determined via the Hertz contact theory, while the tangential forces and moments are evaluated using the FASTSIM algorithm. The model considers the multi-point contact situations, and time histories of normal and tangential forces, creepages and positions for each wheel-rail contact are calculated with the sampling frequency of 2 kHz.

3. Contact damage analysis method

The output of the multi-body dynamic model mainly focuses on the wheel-turnout rail dynamic interaction, including the wheel-rail contact force, the lateral displacement, roll angle and yaw angle of wheelset, tangential and spin creepages. Based on the subsequent CONTACT program, these dynamic outputs are used as inputs to calculate the microcosmic behaviour of wheel-rail ronglling contact in turnout zone, including the normal and tangential contact stress distributions. Finally, the accumulated surface-initiated RCF is compared based on the surface RCF index.

3.1. Wear index

The wear volume is dependent on the wheel-rail normal force and relative sliding. Based on the calculated energy dissipation, wear can be assessed by the wear index that is the sum of force/moment and corresponding creepage/spin in each wheel-rail contact patch. The wear index W_i at the i^{th} integration step is calculated with the time history by summing the dynamic response of each possible contact point (j=1, 2, 3):

$$W_i = \sum_{j=1}^{3} T_{x,j}\gamma_{x,j} + T_{y,j}\gamma_{y,j} + M_j\varphi_j \tag{3}$$

where $T_{x,j}$ and $T_{y,j}$ are the creep forces at the j^{th} contact point in the longitudinal and lateral directions respectively; M_j refers to the creep torque at the j^{th} contact point; $\gamma_{x,j}$ and $\gamma_{y,j}$ are the associated creepages; φ_j is the spin creepage.

3.2. Surface-initiated rolling contact fatigue

The surface-initiated rolling contact fatigue is caused by the plastic deformation and low circle fatigue. Based on the shakedown theory [15], when the material status is in the ratcheting area, the material doesn't fracture and crack until the plastic deformation accumulates to a certain extent. To identify wheel-rail contact situations that could lead to initiation of surface-initiated RCF, the index FI_{surf} was proposed in Ref. [16]. It is defined as:

$$FI_{\text{surf}} = f - \frac{2\pi abk}{3N} \tag{4}$$

where f is the traction coefficient given by the ratio of the magnitude of tangential force and normal contact force; a and b are the semi-axes of the Hertzian contact patch and N is the normal contact force; k is the yield stress in shear for the work-hardened material and is taken as k=350MPa. When the FI_{surf} is above 0, the initiated RCF is predicted to occur.

This method is based on three assumptions including

elastic condition, Hertzian wheel-rail contact and full slip. For the first one, the CONTACT program features on elastic wheel and rail material (elasticity modulus 210 GPa and Poisson's ratio 0.28). In order to meet the second assumption facing with the non-Hertzian rolling contact problem, the wheel-rail contact patch can be divided into n strips. Besides, it is thought that the wheel-rail contact in the central of strip meets the Hertzian contact assumption. As a result, the application of equation (4) has been expanded to the non-Hertzian as follows [17]:

$$FI_{\text{surf}}(x,y)=f(x,y)-\frac{k}{p_z(x,y)} \tag{5}$$

$$f(x,y)=\frac{\sqrt{(p_x(x,y))^2+(p_y(x,y))^2}}{p_z(x,y)} \tag{6}$$

where $FI_{\text{surf}}(x, y)$ means the local RCF index in each element; $p_z(x, y)$, $p_x(x, y)$ and $p_y(x, y)$ refers to the normal contact stress, tangential contact stresses in the longitudinal and lateral directions respectively. Outputs in the discretization contact area from the CONTACT program can be adopted to analyze the local RCF index.

The severe wheel-rail friction leads to the wear of surface materials, thus inhibiting the occurrence of RCF and extending the fatigue life. For the third assumption, an alternative approach to predict RCF on rails under more general partial slip conditions is relating the RCF index with the wear index. The wear index is shown in Eq. (3) but neglects the spin influence. Ref. [18] put forward a damage model considering the interaction of RCF and wear. It shows that the fatigue damage will not be weakened as the wear index is below 100N, while the wear dominates the damage and no RCF occurs as the wear index is above 265N. As a result, a penalty function $p_f(W_i)$ should be multiplied with the RCF index to consider the wear effect:

$$p_f(W_i)=\begin{cases}1, & W_i \le 100N\\ 53/33-W_i/165, & 100\text{N}<W_i<265\text{N}\\ 0, & W_i \ge 265N\end{cases} \tag{7}$$

3.3. Accumulated surface-initiated RCF on rails

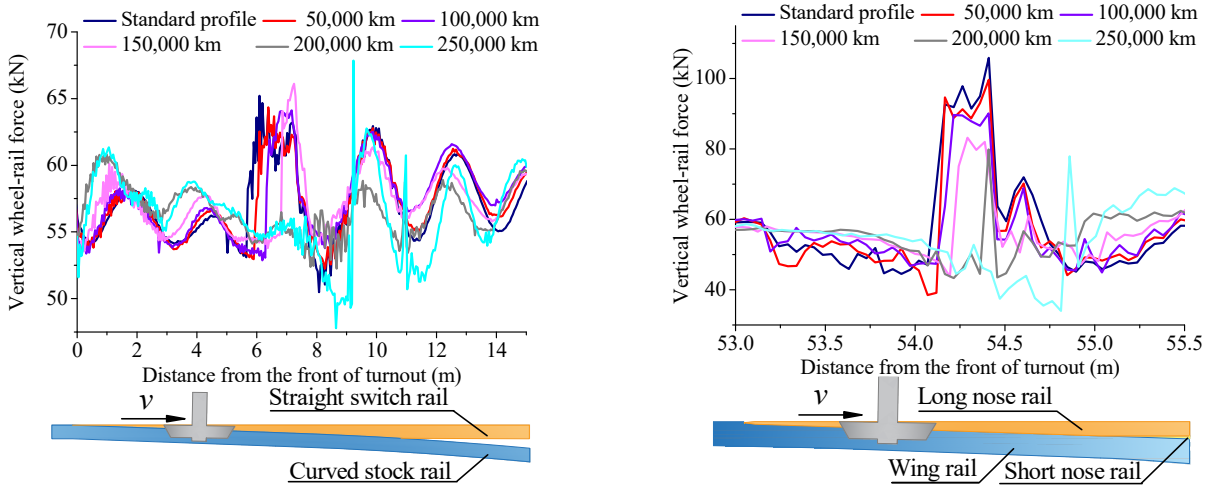
The wheel-rail contact patches vary with the wheel rolling through the specified cross-section. However, the simulation is simplified assuming that the contact information is constant. According to the strip method, the maximum surface RCF index among the longitudinal strip is taken as the maximum damage during the contact patch traversal [19]. The distribution transversely of surface RCF on specified contact patch $FI_{\text{surf}}^{\text{patch}}(y)$ can be expressed as:

$$FI_{\text{surf}}^{\text{patch}}(y)=\max_x[p_f(W_i)\cdot FI_{\text{surf}}(x,y)],\quad \forall\, FI_{\text{surf}}(x,y)>0 \tag{8}$$

Fatigue damage $D_k(y)$ after one wheel passage can be approximated, see Ref. [20], as

$$D_k(y)=\frac{(FI_{\text{surf}}^{\text{patch}}(y))^{\delta}}{\varepsilon},\ \forall FI_{\text{surf}}^{\text{patch}}(y)>0 \tag{9}$$

where, the δ and ε are the best fit value obtained by curve-fitting of results from three bench experiments, including the double discs friction test, wheel rail friction test and linear test. The best fit value is set as δ=4 and ε=10. The fatigue damage at any cross-sections caused by N wheels rolling through the turnout rails can be predicted by the Palmgren-Miner rule as:



$$D(y)=\sum_{k=1}^{N}D_k(y) \tag{10}$$

4 Simulation results

In this section, simulations of vehicle passing through turnout in the straight route of facing move with speed of 350 km/h are carried out. To completely understand the damage mechanism with profile evolution, the wheel-turnout rail dynamic response should be analysed as follows.

4.1. Wheel-rail dynamic interaction

As shown in Fig. 4, compared with the dynamic response in switch panel, the values of maximum vertical wheel-rail force in crossing panel decrease significantly with the added operating mileages. In detail, when the standard wheel profile changed to hollow wear profile with 250,000 km operation mileage, the maximum vertical wheel-rail force decreases from 105.90 kN to 77.92 kN by 26.42%. Besides, the position of maximum vertical wheel-rail force is shifted backward.

(a) *(b)*

Figure 4 *Vertical wheel-rail force at the straight switch rail side: (a) Switch panel. (b) Crossing panel.*

Fig. 5 shows the lateral displacement of wheelset in turnout. The positive value means the wheelset moves towards the straight switch rail and curved stock rail side. With the operation mileage increases from 0 to 100,000 km, the maximum lateral displacement of wheelset increases in switch panel and the oscillation is aggravated. As the operation mileage reaches 150,000 km, the amplitude of lateral displacement of wheelset is close to zero. On the contrary, as the operation mileage is up to 200,000 km, the wheelset moves in the opposite direction laterally in switch panel.

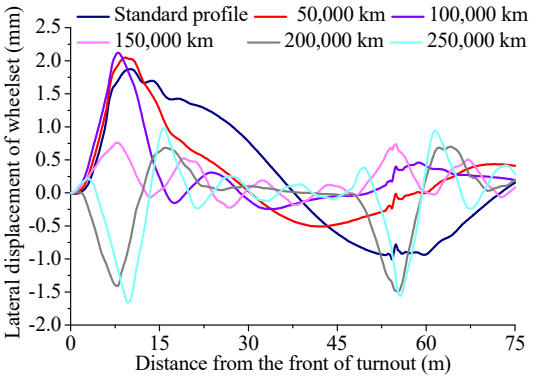


Figure 5 *Lateral displacement of wheelset*

In order to find out the causes of dynamic response in turnout, the lateral contact position on wheels at the straight switch rail side are compared. Before the wheel transition, the contact point moves with the curved stock rail and wing rail bent outward. The position of full transition of wheel from the curved stock (wing) rail to straight switch (long nose) rail is expressed as the abrupt change of the first contact point position.

Firstly, with wheel profile evolution, the wheel transition position is shifted backward to the stronger cross-sections of switch rails and nose rails, leading to the decreased maximum vertical wheel-rail force. However, the variation of lateral contact position increases, resulting in the enlarged amplitude and aggravated vibration of lateral wheelset displacements as the operating mileage is below 100,000 km. Meanwhile, it is observed that after wheel transition, the contact positions are concentrated in the edge of hollow wear and get closer to the wheel flange gradually with wheel profile evolution.

For wheel profiles with operating mileage above 150,000 km, when the wheel enters the switch and crossing panel, the contact point moves to the outside of the wheel tread that is more far away from the wheel flange and locates near the false flange. This is corresponding to the lateral movement of wheelset in the opposite direction. In addition, with wheel profile evolution, it is found that the two-point contact area is enlarged after the full transition of wheel. The contact points keep jumping near the edge of hollow wear.

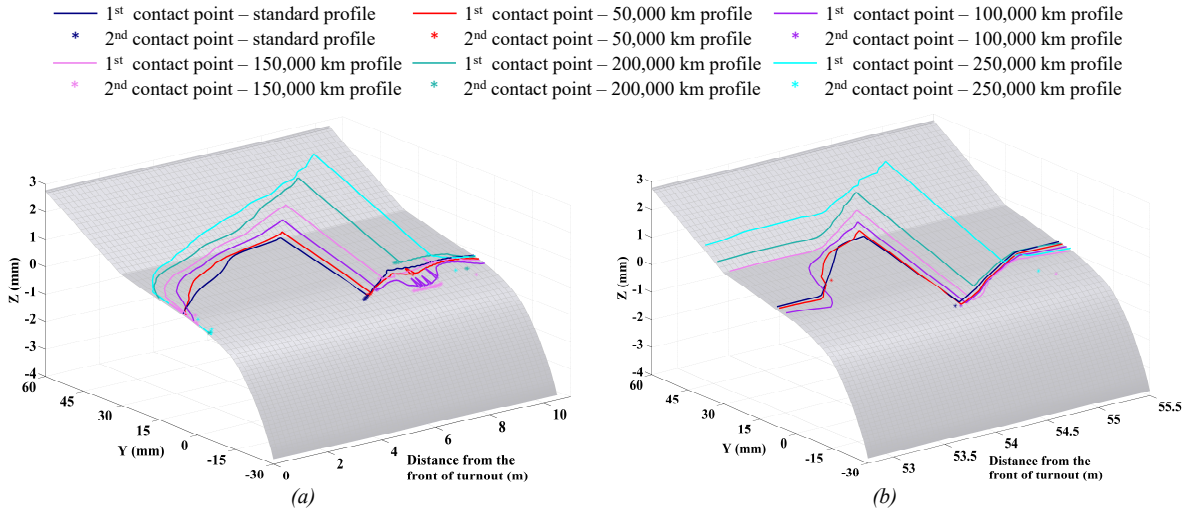

Figure 6 *Lateral contact positions on wheel at the straight switch rail side: (a) Switch panel. (b) Crossing panel.*

4.2. Ride Comfort

Fig. 7 depicts the lateral accelerations measured at three points of the carbody. As the simulation doesn't consider the track irregularity in turnout area, the amplitude of evaluating indicators is a bit low but is suitable for the relative comparison. The maximum lateral acceleration obtained by 250,000 km wheel profile is much greater than that calculated by the standard profile. But it is found that there is a valley value when the mileage is 150,000 km as its maximum wheelset displacement is low. To comprehensively reflect the ride comfort with wheel profile evolution, the Sperling comfort indices [21] are illustrated as well. When the operating mileage of wheel reaches 250,000 km, the frontal Sperling index is above 2.5, which is 45% higher than that with standard wheel profile. With the wheel profile evolution, the wheel transition position is shifted backward, causing the increased lateral contact irregularity in turnout and worse ride comfort.

4.3. Wear index

As the high-speed vehicle passes through turnout in the straight direction, the phenomena of flange contact is so few that the maximum wear index is low. It can be found that effect of wheel profile evolution on maximum wear index is more obvious in crossing panel than that in switch panel. When the operating mileage is in the range of 50,000 km to 150,000 km, the maximum wear indices reach the peak and are nearly 2 times larger than that of

standard wheel profile. With the continued development of hollow wear, the maximum wear index decreases.

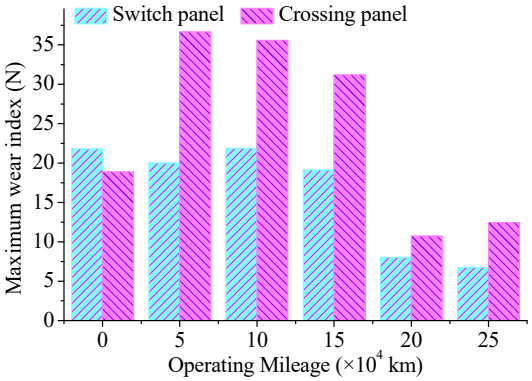

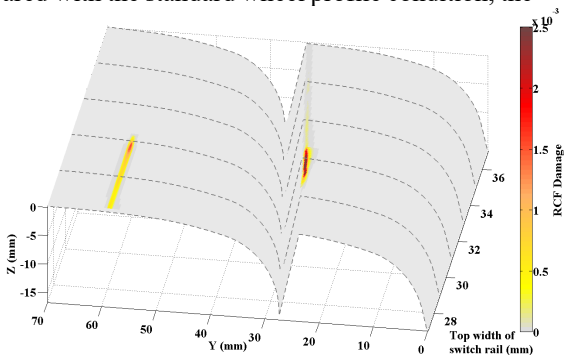

Figure 8 *Maximum wear index at the straight switch rail side*

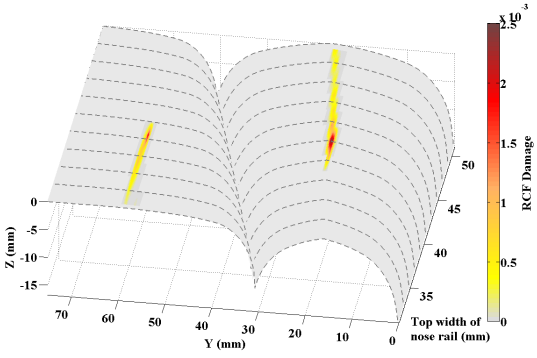
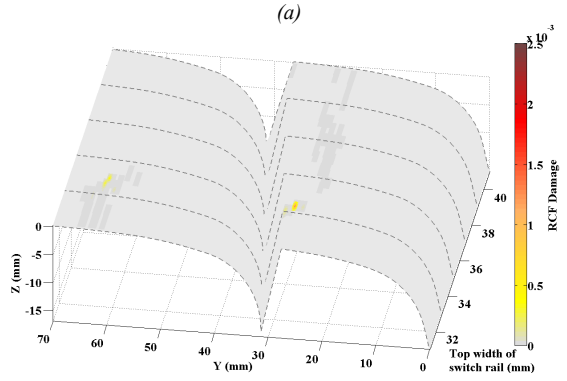


4.4. Surface-initiated RCF

After one vehicle passage (four wheels), the corresponding distributions of accumulated surface-initiated RCF damage on the outer curved stock (wing) rail and inner straight switch (long nose) rail among the wheel transition range are compared in Fig. 9. In order to improve resolution of trajectory and RCF distribution, the maximum values of the colour bars are unified. It is observed that the maximum RCF is concentrated in the two contact patches area. For the standard LMA wheel profile, the RCF distributions on switch and nose rails are near the non-working edges and on the top of rails. Running bands with high RCF value has long and narrow distribution. With wheel profile evolution, several wider RCF bands are found not only on the top of switch (nose) rails but also near the gauge corner.



Compared with the standard wheel profile condition, the maximum damage value obtained from profile with 250,000 km mileages decreased from 0.0034 to 0.0005 in switch panel and 0.0025 to 0.0005 in crossing panel, corresponding to a reduction by 85% and 80% respectively. Taking the accumulated surface-initiated RCF in switch panel as example, for wheel profiles with different operating mileages, these figures are respectively found to be 0.0013 for 100,000 km as well as 0.0007 for 150,000 km, and the corresponding decreased magnitude is respectively 62% and 79%. It is concluded that the accumulated surface-initiated RCF significantly reduced as the hollow wear are formed. The wheel profile evolution improves the wheel-rail conformal contact that increases the contact patches and reduces the contact stress. Further, wheel transition positions are shifted backward to strong cross-sections, resulting in the decreased wheel-rail impact.

5. Conclusions

Taking hollow wear of wheel profile as the typical factor, effect of wheel profile evolution on wheel-rail dynamic interaction and contact damage mechanism in turnout area are investigated. Considering hollow-worn wheel profile with the operating mileage from 0 to 250 thousand kilometres, simulations of vehicle–turnout dynamic interaction considering the flexibility of wheelset, normal and tangential contact behaviour by CONTACT program, the evaluation of wear index as well as surface-initiated RCF index are carried out.

It can be summarized that the wheel profile evolution shifted the wheel transition position to the stronger turnout cross-sections, leading to the significantly decreased vertical wheel-rail force by an amplitude of 26.42% in the crossing panel. Then, the lateral contact position on wheel moves towards the false flange before wheel transition. Two-point contact and jumping of contact points at the edge of hollow zone after the wheel transition are found, causing lateral displacement of wheelset in opposite direction and worse ride comfort. Therefore, the Sperling index is above 2.5 with severe hollow wear profile, which is 45% higher than that with standard wheel profile. Meanwhile, larger wear index is found in medium hollow wear with operating mileage range of 50,000 km to 150,000 km. Finally, the wheel profile evolution results in reduced surface-initiated RCF due to the conformal contact and decreased wheel-rail force.

To develop the simulation method, conformal contact, such as two-point rolling contact analysis should be improved. What's more, considering the constraint in variation of switch (nose) rails and stock (wing) rails, the relative motion of rails in turnout should be involved. In the future, combined with centrifugal force and flange contact, effect of wheel profile evolution on contact damage in the diverging route of turnouts will be studied.

Abstract: A wheel wear model that considers the effects of temperature during tread breaking was established on the basis of Archard wear model. In the model, the temperature field of wheel tread was calculated using a numerical algorithm based on finite element method and the influences of temperature on the size of contact patch, division of adhesion/slip zone and wear depth are studied taking the effects of temperature rising on wheel material properties in consideration. The results show that the area of contact patch, wear depth and worn area increase with the temperature rising cause by tread braking.

Keywords: Tread braking; Temperature effect; Contact patch; Division of adhesion/slip zone; Wear coefficient; Wear depth.

1. Introduction

Wheel/rail wear is one of the focuses of the researchers in the railway industry. Wheel/rail wear not only takes up railway maintenance cost, but also changes the original wheel-rail contact geometry relationship, threatening running safety seriously [1]. On freight trains and subway trains, tread braking is widely used and the physical process of turning vehicle kinetic energy into heat by the friction between wheel tread and brake shoes causes a significant temperature rising on wheel tread. The high temperature may not only cause wheel tread damages but also has a possibility of influencing wheel wear due to the change of coefficient of friction, elastic modulus or other material and contact properties at high temperature. Therefore, study on the influence of temperature rising on wheel wear contributes to the understanding of wear and damage on wheel tread and helps to the efforts of wheel/rail wear reduction.

Although there are hundreds of papers published on wheel wear, only a few discuss the mechanism of the effects of braking on wheel wear. The influence of disc breaking on wheel wear was studied by Enblom and Berg [2]. They included braking in vehicle dynamics modelling and the results show that breaking influences wheel wear by changing creepage and contact position. However, the effects of tread temperature rising on wheel wear was not studied partially due to the fact that, in disc braking, the tread temperature caused by wheel/rail contact in disc braking is much lower than that in tread braking. The abnormal wear on wheel tread of metro vehicles with tread braking are discussed by Qiao [3]. Research results indicated that the change of mechanical properties of brake shoes, due to the high temperature rising, lead to the friction property of brake shoes changes. However, only a simple qualitative analysis to the influence of tread braking to wheel/rail wear was presented in this paper and the influences of the temperature rising due to braking to wheel/rail contact condition and wear were not considered. Chen et al. studied the effects of temperature on wheel wear taking hardness as a function of temperature and found that the wear depth increases 22.5% when the temperature effects are considered [4]. However, in ref [4] the effects of temperature on wheel tread wear was studied without considering temperature effects on wheel material properties and wheel/rail contact condition.

In this study, the temperature field of wheel tread was calculated using a numerical algorithm based on finite element method, and a wheel wear model that considers temperature effects was established according to the relation between material properties and temperature. In the model, the influences of temperature on the size of the contact patch and the division of adhesion/slip zone are considered. Wear depth was studied taking parameters such as hardness, relative sliding velocity and wear coefficient into consideration. Besides, the influence of braking temperature on the distribution of wear coefficient in the contact patch are studied according to hardness, contact pressure and relative sliding velocity.

2. Wheel tread temperature

Numerical methods for the wheel tread temperature are established through finite element method, calculating the wheel tread temperature during emergency braking. In the model, the wheel actual geometrical sizes were considered. The condition of heat flux boundary replaces the frictional heat flux, depended on the loads, wheel diameter, wheel rim width, running speed and acceleration, between wheel tread and brake shoes. And the condition of convection boundary takes in place of the heat change between wheel and surroundings.

2.1. The finite element models

Taking into consideration the symmetry of the wheel structure, a single wheel finite element model was modelled. In the model, the wheel diameter is 840 millimeters, the wheel type is LM, and the material

properties are shown in Table 1. The number of nodes and the minimum mesh size are 341900 and 0.4 millimeters, respectively. In order to guarantee accuracy and improve the efficiency, a local mesh encryption of wheel surface and subsurface is used (Fig. 1). The condition of heat flux and convention boundary are shown in Fig. 2.

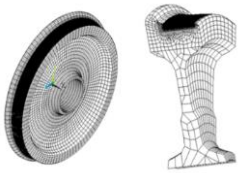

Figure 1 *The wheel finite element model*

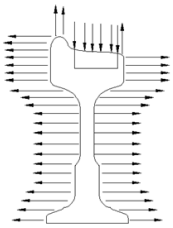

Figure 2 *The boundary conditions*

Table 1 *The material factors.*

quantity	value
Density (kg/m3)	7800
Specific heat capacity (J/(kg • ℃))	470
Pyroconductivity (W/(m • ℃))	50
Environment temperature (℃)	40

2.1.1. The condition of heat flux boundary

Heat flux density is the total flow-in per unit surface heat in per unit time. Based on principle of conservation of energy, the loss of kinetic energy will transform into friction heat, which most of are transported to the wheel and a very few is absorbed by brake shoes. As a result, the partition coefficient of heat flux between wheel and shoe is introduced. The heat flux can be determined as follows [5]:

$$q(t)=\eta\frac{\dfrac{d\left(\frac{1}{2}mv_0^2-\frac{1}{2}mv^2(t)\right)}{d(t)}}{S}=\eta\frac{am(v_0-at)}{S} \tag{1}$$

where v_0 is the running speed(m/s); m the total mass of a roll stock(kg); a the deceleration of braking(m/s^2); S the contact area between brake shoe and wheel tread(m^2); the partition coefficient of heat flux. According to the material properties of wheel and brake shoes, in general, the value of partition coefficient of heat flux is 0.91[6].

The contact surfaces between wheel and brake shoes constantly change, due to the relative movement each other during tread braking. As a result, the position of wheel tread applied heat flux is continuous variable in process of simulation.

(1) The perimeter of wheel is *Sc*, averagely divided by n parts. Then, the relative distance between wheel and brake shoes along the circumference can be confirmed as follows:

$$\Delta l=\frac{S_c}{n} \tag{2}$$

(2) The interval(△t) of time passing the distance △l is be wrote as:

$$\Delta t_i=\frac{2\Delta l}{(v_i+v_{i-1})},(i=1,2,3\cdots,m) \tag{3}$$

where v_i is the peripheral speed at current load step, i = 1,2, 3…, m; m the total load steps, $m=\frac{s}{\Delta l}$, s the braking distance.

(3) *L/Sc* of tread surfaces are applied heat flux boundary, and another are applied heat convention boundary during wheel rolling process, assumption that the wheel rim length is *L*. The heat flux density can be calculated by the Eq. (1).

(4) The input surfaces of heat flux move the interval(Δl) of the distance along the circumference in every load step. To ensure continuity of simulation result, the interval of the distance must be less than the half of the wheel rim length. Meanwhile taking account of calculative efficiency, we set the interval(Δl) of the distance equal to the half of the wheel rim length(*L/2*).

2.1.2 The condition of heat convention boundary

The running speed is the most principal factor of heat convention coefficient, with the simpler structure and higher rate rotate speed of wheel. The heat convention coefficient $h(t)$ is obtained according to experimental results [7].

$$h(t)=0.3828+14.39v(t) \tag{4}$$

2.2. Emergency braking

The wheel tread temperature during emergency braking can be obtained by means of finite element model of heavy haul trains. The initial running speed is chosen to be 80 km/h, and the deceleration of braking is chosen to be 1.2 m/s^2.

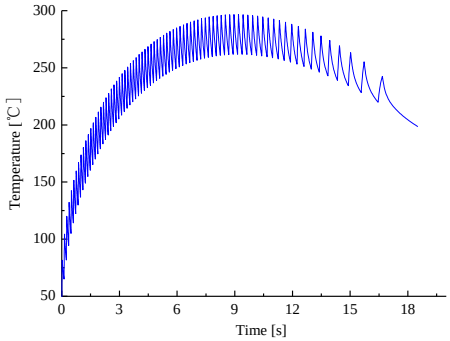

Figure 3 *Wheel tread temperature during emergency braking*

Fig. 3 shows the change rule of the tread temperature along with time during emergency braking. The temperature can be seen to be a trend of increased and decreased after a period of time, due to a decrease of kinetic energy used for translating into friction heat along with reduction of the running speed. The wheel tread temperature reaches the maximum 300℃ when braking 8.9 seconds. Besides, the fluctuations of temperature rising reflect the physical phenomenon that alternate contact and non-contact between wheel and brake shoes.

3. Material properties

The microscopic theory of metallic quality indicates that the material properties such as elastic modulus and tensile strength reduce as the temperature rises [8]. Besides, the deterioration of wheel material properties will lead to the decrease of wheel surface abrasion resistance, which increases wheel-rail wear.

3.1. Elastic modulus

Although elastic modulus of metallic material is an insensitive mechanical performance index to structure, the factors affected the bonding strength have impacts on the elastic modulus, such as binding mode, crystal structure, microstructure and temperature. The functional relations between elastic modulus and temperature can be obtained as Eq. (5), based on a simple model and classical methods [9]:

$$E = E_0\left(1-25\alpha T\right)\frac{1}{1+\frac{\Omega b\rho_m \upsilon_c}{C}e^{-\Delta F/kT}} \tag{5}$$

where E_0 is the elastic modulus at 0 degrees Kelvin; α the linear expansion coefficient of material at normal temperature; Ω the orientation factor of slip plane; ρ_m the movable dislocation density; b the size of the dislocation berg vector; υ_c the speed of sound in metals; k Boltzmanns constant; ΔF the energy required for dislocation to overcome barriers; C the constant. In the Eq. (5), the parameters of Ω, b, ρ_m, υ_c are physical parameters, not influenced by temperature. And the parameter of ΔF is not influenced by temperature. As a result, the Eq. (5) can be simplified as follows:

$$\begin{aligned} E &= E_0\left(1-25\alpha T\right)\beta \\ \beta &= \frac{1}{1+Ae^{-\Delta F/kT}} \\ A &= \Omega b\rho_m \upsilon_c / C \end{aligned} \tag{6}$$

The experimental results of the wheel-rail steel elastic modulus are shown in table 2. The total parameters of the Eq (6) can be calculated by fitting the experimental data. Therefore, the functional relations between elastic modulus and temperature can be obtained as follows:

$$E = \frac{E_0 - 25E_0\alpha T}{1+Ae^{-\Delta F/kT}} = \frac{234948.74-88.106T}{1+18.021e^{-3403.56/T}} \tag{7}$$

Table 2 *The relationship between temperature and elastic modulus [9]*

Temperature (℃)	Experimental value (MPa)	Calculated value (MPa)	Relative errors (%)
25	208680	208638	0.02
100	204750	201674	1.50
400	157500	157554	0.03
700	96600	96539	0.06

The results indicated that the simulation results by Eq. (7) is fairly identical with result measured, which the maximum error of within 1.5%. Compared with normal temperature, the elastic modulus reduced to 176080 MPa, when wheel tread temperature reaches the maximum 300℃, declined by 15.6 %.

3.2. Tensile strength

The experimental study on a comparison of the results by transient and steady tests on Q345 cold-formed steel at elevated temperatures was done by Wei chen et al using a MTS810 system, according to GB/T443-2006 *Standard Test Methods for Elevated Temperature Tension Tests of Metallic Materials* [10]. The trend of reduction of tensile strength, the ratio of tensile strength at current temperature to normal temperature, with temperature is shown as Fig. 4. The results show that the reduction of tensile strength almost decreases linearly with increasing temperature below 450 degrees Celsius. The reduction of tensile strength declines sharply, when temperature reach 450 degrees Celsius. And the decline rate will be slowed when temperature overpass 600 degrees Celsius. The tests of mechanical behavior of structural steel at high temperature show that the strength decreases slowly with the increasing temperature below 400 degrees Celsius. But, the reduction of strength declines sharply when temperature reach the critical temperature [11]. Therefore, an assumption that the relationship between tensile strength and temperature is linear during braking is acceptable, due to the maximum temperature rising (300℃) less than the critical temperature (400℃).

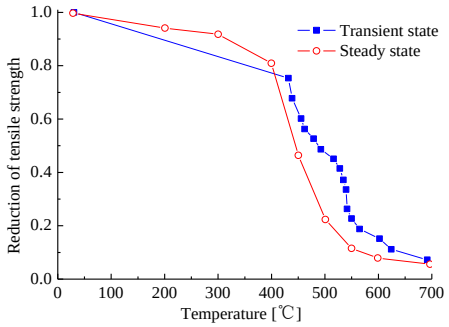

Figure 4 *The reduction of tensile strength [10]*

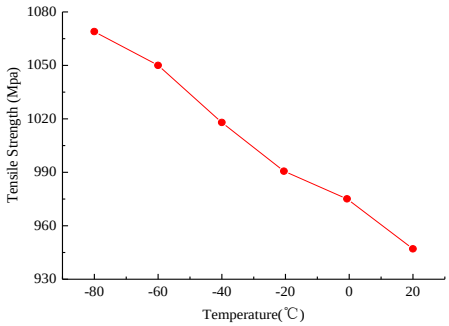

Figure 5 *The tensile strength of wheel steel [11]*

The tensile test of wheel steel was done in the temperature range from -80℃ to 20℃ by Xuechong Ren, according to GB/T443-2006 *Metallic Materials-Tensile Testing at Low Temperature* [12]. The results (Fig. 5) indicate that the impact toughness and fracture toughness decreased with decreasing temperature in the range from -80℃ to 20℃, which was in the ductile-brittle transition region. These experimental dates are selected for linear fitting, whose temperatures range from -40℃ to 20℃ for accuracy of the result, because -40℃ is the critical temperature. Therefore, the function relation between tensile strength and temperature can be wrote as follows. Compared with normal temperature, the tensile strength declines by 25%, when wheel tread temperature reaches the maximum.

$$\sigma_b = -1.105T + 1205 \tag{8}$$

3.3. Friction coefficient

Processes occurring in a surface layer of solids in friction are simulated by the method of movable cellular automata by Popov et al [13]. The friction coefficient can be expressed as a function of material parameters (yield stress, fracture stress, elastic modulus, viscosity, density) and loading parameters (sliding velocity and normal pressure) as Eq. (9):

$$\mu = 0.15 + 102\frac{\sigma_0}{E} + 2.0\times10^5\left(\frac{\sigma_0}{E}\right)^2 - 1.6\times10^4\left(\frac{\sigma_0}{E}\right)^2 \ln\left(2.5\times10^5 + 1590\frac{E}{\sigma_0}\right) \quad (9)$$

where E is the elastic modulus; σ_0 the tensile stress.

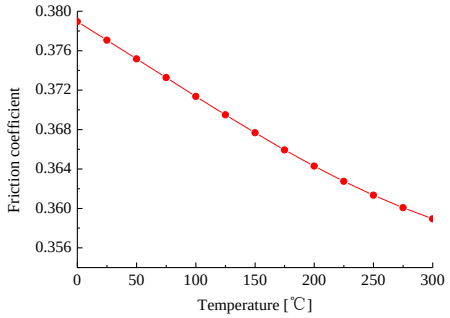

Figure 6 *Friction coefficient value at different temperature*

Bringing the Eq. (7) and (8) into the Eq. (9), and then the function relation between friction coefficient and temperature as follows:

$$\mu = 0.15 + 102 f(T) - 1.6\times10^6 f^2(T)\ln\left[1 + \frac{0.00636}{f(T)}\right]$$
$$f(T) = \frac{(-1.105T + 1205)\left(1 + 18.021e^{-3403.56/T}\right)}{234948.74 - 88.106T} \quad (10)$$

Fig. 6 shows the trend of friction coefficient with temperature. The results indicate that friction coefficient decreases with increasing temperature. And compared with normal temperature, friction coefficient declines by 4.8%, when wheel tread temperature reaches the maximum.

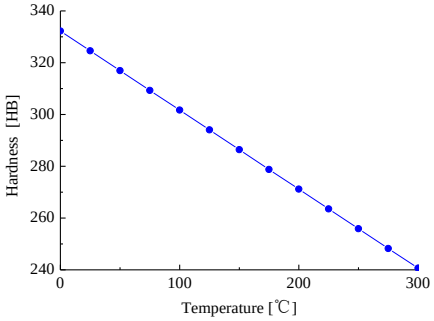

Figure 7 *The hardness value at different temperature*

3.4. Hardness

The function relation of hardness with temperature can be wrote as Eq. (11), according to the conversion tables of hardness values and tensile strength values of ISO 18265:2003. Besides, the wheel hardness value (320 HB) in normal temperature (25℃) is considered.

$$HB = k_1 T + c = -0.3T + 320 \quad (11)$$

Fig. 7 shows the trend of hardness with temperature. Compared with normal temperature, the hardness declines by 26%, when wheel tread temperature reaches the maximum.

4. The calculation models

The wheel tread temperature rises sharply and reach a very high level in tread braking. The high temperature may not only affect wheel-rail contact but also influence wheel wear due to the change of material properties, such as elastic modulus, friction coefficient and other material properties. In this study, a wheel wear prediction model that considers temperature effects was established to calculate wheel wear. In the simulation process, the tread temperature was first calculated under the assumption of constant deceleration braking through finite element method. Then, wheel-rail contact conditions were calculated using Kalker simplified theory, with the material properties parameters under different temperatures. At last, wheel wear depth was thus predicted using the wear model in the slip zone.

4.1. Contact model

4.1.1 Size of the contact patch

The ellipse semi-axes a, and b is calculated based on Hertz' theory as follows [14]:

$$a = m\left[\frac{3}{2}\times\frac{G^*}{2(A+B)}N\right]^{1/3}$$
$$b = n\left[\frac{3}{2}\times\frac{G^*}{2(A+B)}N\right]^{1/3} \quad (12)$$

where N is the normal contact force; G^* a function of elastic modulus and Poisson ratio, $G^* = \frac{1-\upsilon_1^2}{E_1} + \frac{1-\upsilon_2^2}{E_2}$, E_i the elastic modulus of the wheel and rail material, i = 1,2; υ_j the Poisson ratio of the wheel and rail material, j =1,2; A and B the coefficient of normal gap between wheel and rail, a function of radius of curvature on the contact point.

4.1.2 The division of adhesion/slip zone

Coulomb's friction law is introduced to divide the contact area into regions of adhesion and slip, $p_t(x,y) > fp_z(x,y)$. That is, the actual point is in the slip zone, if the local stress magnitude exceeds the traction bound. In the Fastsim algorithm the tangential stress distribution is calculated by numerical integration over the contact patch area. In the longitudinal integration loop the tangential stress are determined as follows [15]:

$$p_x(x,y) = p_x(x-dx,y) - \left(\frac{\xi_x}{L_x} - \frac{y\xi_\varphi}{L_\varphi}\right)dx$$
$$p_y(x,y) = p_y(x-dx,y) - \left(\frac{\xi_y}{L_y} + \frac{x\xi_\varphi}{L_\varphi}\right)dx \quad (13)$$
$$\mathbf{p}(x,y) = [p_x(x,y), p_y(x,y)]$$

where p_i is the tangential stress component, i = x, y; ξ_i the rigid body creepage and spin creepage; i = x, y, ϕ; L_i the tangential flexibility parameters, i = x, y, ϕ; dx the grid spacing; x and y the contact patch co-ordinates, origin at the center. Besides, the tangential flexibility parameters can be obtained as follows: $L_x = \frac{8a}{3GC_{11}}$, $L_y = \frac{8a}{3GC_{22}}$, $L_\varphi = \frac{\pi a\sqrt{a/b}}{4GC_{23}}$

where G is the modulus of rigidity; L_{ij} the creepage coefficient of the linear theory, i, j = *1, 2, 3*.

The normal pressure distributions are determined according to the Hertz' theory as follows:

$$p_z(x,y)=\frac{2N}{\pi ab}\sqrt{1-\left(\frac{x}{a}\right)^2-\left(\frac{y}{b}\right)^2} \tag{14}$$

The actual point in the contact patch exists only two cases:

(1) If the local stress magnitude exceeds the traction bound, the actual point is in the slip zone and the stress is reduced accordingly:

$$\mathbf{p}_s(x,y)=\frac{\mathbf{p}(x,y)}{|\mathbf{p}(x,y)|}fp_z(x,y) \tag{15}$$

where $\mathbf{P}_s$ is the tangential stress in the slip zone. The relative sliding velocity $\mathbf{s}$ (x, y) is calculated according to steady state rolling.

$$\mathbf{s}(x,y)=v_0\begin{Bmatrix}\xi_x-y\xi_\varphi\\ \xi_y+x\xi_\varphi\end{Bmatrix}-\frac{\partial\mathbf{u}(x,y)}{\partial x} \tag{16}$$

where $\partial\mathbf{u}(x,y)$ is the elastic deformation.

(2) Otherwise, the actual point is in the adhesion zone, and the relative sliding velocity is zero. And the tangential stress in the adhesion can be wrote as follows:

$$\mathbf{p}_a(x,y)=\mathbf{p}(x,y) \tag{17}$$

4.2. Wear model

Archard's wear model states the volume V of material worn away is proportional to the sliding distance s, contact force N, and inversely proportional to the hardness H of the worn material according to Eq. (25) [16]:

$$V_{wear}=k_w\frac{Nd}{H} \tag{18}$$

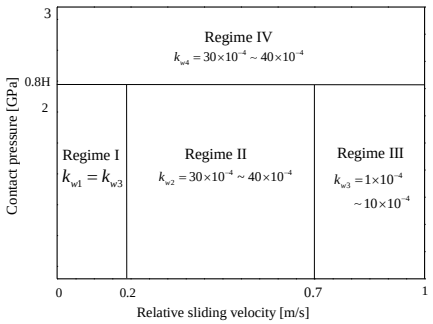

Figure 8 *Wear map*

where the wear coefficient k_w is a physical quantity depends on the contact pressure, hardness and relative sliding velocity. Based on available test results for relevant material combinations a wear map for dry conditions has been defined as Fig. 8. In the wear map, the characteristic of regime I is mid wear due to a lower relative sliding velocity. The regime II, between 0.2 and 0.7 m/s, is a severe wear regime. The large slip may occur at poor adhesion conditions in the regime III. And the regime IV implies the devastating wear due to the higher contact pressure, which exceed the limit value (0.8 H) [17].

The normal pressure, hardness and relative sliding velocity will vary with the change of the temperature. As a result, the impact of temperature on the wear coefficient is very complex. The value of wear coefficient is more likely to keep in the regime IV due to the declined by 26% of hardness, which leads to increasing wheel wear and abnormal wear.

The contact ellipse in the present implementation of the Fastsim algorithm is divided into 80 × 80 elements to provide smooth wear distributions. The wear depth in an element can be calculated according to Eq. (26):

$$\Delta z(x,y)=k_w\frac{p_z(x,y)\Delta d}{H} \tag{19}$$

where $p_z(x,y)$ is the contact pressure, N; Δd the sliding distance, calculated according to Eq. (27):

$$\Delta d=s\times\Delta t=\sqrt{s_x^{\,2}+s_y^{\,2}}\frac{\Delta x}{v_x} \tag{20}$$

where s is the relative sliding velocity, m/s, s_i the relative sliding velocity component, $i = x, y$, m/s; v_x the speed passing the contact patch, m/s; Δx the length of the elements, m.

Bring Eq. (14) and (20) into Eq. (19), and then the wear depth in an element is determined as follows:

$$\Delta z(x,y)=\frac{2Nk_w}{\pi abH}\sqrt{1-(\frac{x}{a})^2-(\frac{y}{b})^2}\sqrt{s_x^{\,2}+s_y^{\,2}}\frac{\Delta x}{v_x} \tag{21}$$

The wear depth is further simplified as Eq. (29), with the assumption that the speed passing the contact patch equals to the running speed of roll stock due to microslip during rolling.

$$\Delta z(x,y)=\frac{2Nk_w\Delta x}{\pi abH}\sqrt{1-(\frac{x}{a})^2-(\frac{y}{b})^2}\sqrt{\left(\xi_x-y\xi_\varphi-\frac{\partial u_x}{\partial x}\right)^2+\left(\xi_y+x\xi_\varphi-\frac{\partial u_y}{\partial x}\right)^2} \tag{22}$$

5. Results and discussion

The emergency braking of the heavy haul strains, the initial running speed of 80 km/h, at the deceleration of 1.2 m/s^2 until the trains stopping is simulated in this study. The contact patches and wear depths are calculated at different temperature, according to the wheel wear model considering temperature effect presented in this study, to study the influence of temperature rising due to tread braking on wheel wear.

Table 3 *Parameters of kinetics*

quantity	value
Density (kg/m^3)	7800
Displacement (mm)	0
Yaw	0
Normal force (kN)	125
Longitudinal creepage (%)	0.15
Lateral creepage (%)	0.05
Spin creepage	0.3

In the simulation, the total time for braking is 18.51 seconds, and the total running distance is 205 meters. The change rule of the tread temperature along with time during emergency braking is shown as Fig. 3. The input data are shown in Table 3 to calculate the contact patches and wear depths at different temperature, such as 25, 50, 100, 150, 200, 250 and 300 degrees Celsius.

5.1. Material properties

The material properties are calculated at different temperature according to the third part of this paper. Table 4 shows that the material properties such as elastic modulus, friction and hardness decrease with the increasing temperature. Especially, the elastic modulus and hardness declined by 15.6 % and 26 %, respectively, when wheel tread temperature reaches the maximum.

Table 4 *Material properties at different temperatures*

Temperature （℃）	Elastic modulus （MPa）	Friction coefficient (--)	Hardness （HB）
25	208638	0.38	320
50	206378	0.38	312
100	201674	0.37	297
150	196529	0.37	282
200	190678	0.36	267
250	183902	0.36	252
300	176084	0.36	237

5.2. Contact patch

The reduction of elastic modulus due to the increasing temperature leads to the reduction ability of material to resist deformation, resulting in the increasing of contact patch areas and the decreasing of normal pressure. The results of contact patch condition at different temperature is shown as Table 5. Compared with the result at normal temperature, the size of semi-axes of ellipse increases by 5.8%, and the area of contact patch increases by 12%, when wheel tread temperature reaches the maximum. At the same time, the maximum contact pressure declines by 10.7% as Fig.9. The comparison of contact patch condition at the maximum temperature and normal temperature is shown as Fig. 10, respectively.

Table 5 *The results of contact patch*

Temperature (℃)	Semi-axes of ellipse a (mm)	Semi-axes of ellipse b (mm)	Area of contact ellipse (mm^2)	Area of slip zone (mm^2)
25	7.93	4.65	115.83	66.49
50	7.96	4.67	116.68	67.03
100	8.02	4.71	118.49	68.28
150	8.09	4.75	120.55	69.68
200	8.17	4.80	123.00	70.97
250	8.27	4.85	126.00	72.33
300	8.39	4.92	129.70	73.99

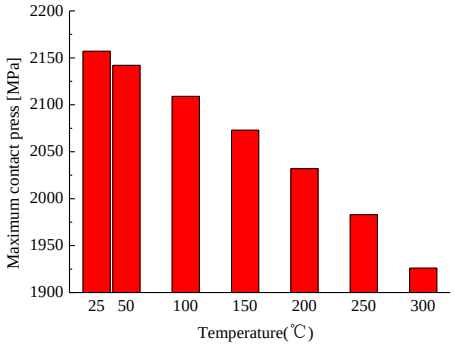

Figure 9 *The maximum contact pressure at different temperature.*

The contact ellipse is divided into 80 × 80 elements to divide the contact area into regions of adhesion and slip, according to the Coulomb's friction law. The traction bound is declined as a result of the reduction of the friction coefficient and normal pressure due to temperature rising. Besides, the local stress magnitude is declined with the temperature rising due to the reduction of the elastic modulus. Therefore, the impact of temperature rising on the division of adhesion/slip zone is very complex.

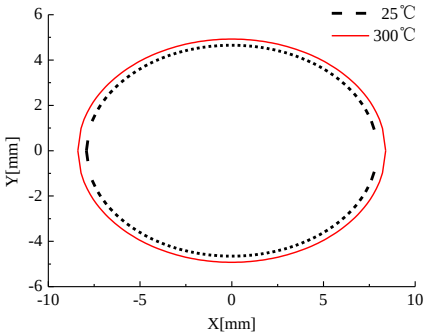

Figure 10 *The comparison of contact patch*

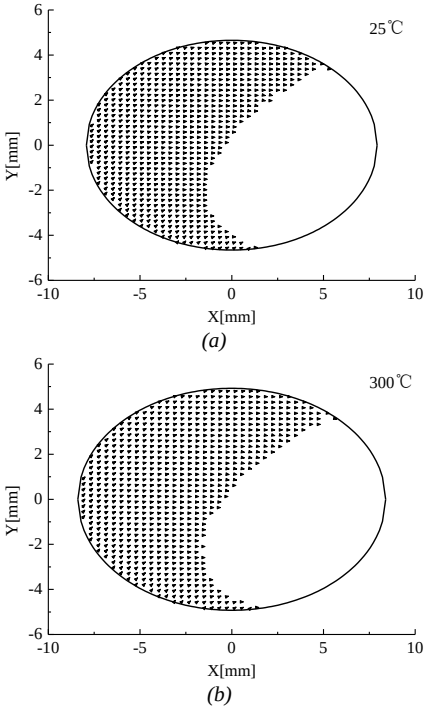
The results of the slip zone at different temperatures indicated that the area of slip zone increases with the temperature rising. And compared with the results of normal temperature, the area of the slip zone increases by 11%, when wheel tread temperature reaches the maximum as Fig. 11.



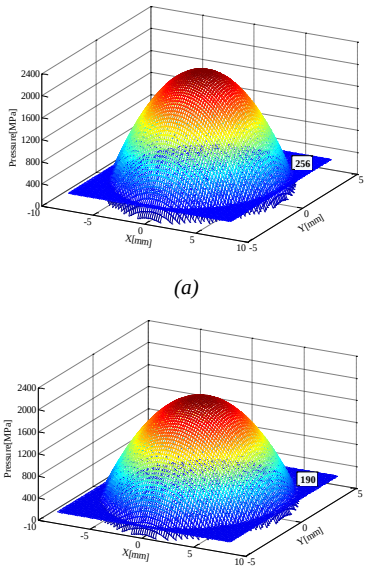


Figure 11 *The comparison of the division of adhesion/slip zone: (a) Normal temperature 25 ℃. (b) Maximum temperature 300 ℃*

5.3. Wheel wear

Wear coefficient depends on the contact pressure, hardness and relative sliding velocity. The hardness decreases with the increasing temperature according to Eq (11). The area of contact patch increases due to the reduction of ability of material to resist deformation with the increasing temperature, leading to the reduction of contact pressure. Besides, the relative sliding velocity decreases with the increasing temperature due to the reduction of the elastic modulus.

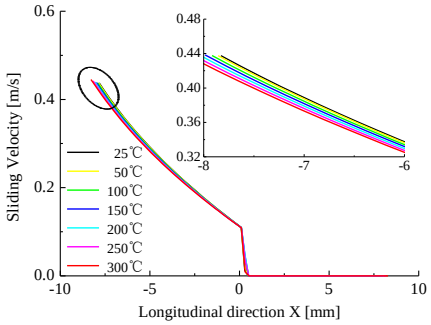
The comparison of contact pressure and pressure bound distribution at normal temperature and maximum temperature as Fig. 12 indicates that more elements' wear coefficients will locate in the regime IV, because the drop of the pressure bound 26% is greater than one of contact pressure 10.7%. The corresponding relative sliding velocity distribution along the contact patch center line at different temperatures is shown as Fig. 13. Results

indicates that the closer to the trailing edge of slip zone, the larger the relative sliding velocity is. And the relative sliding velocity decreases with the increasing temperature, with the maximum drop only of 4% during braking.

(a)

(b)

Figure 12 *Comparison of contact pressure and pressure bound distribution at different temperatures of adhesion and slip: (a) Normal temperature 25 ℃. (b) Maximum temperature 300 ℃*



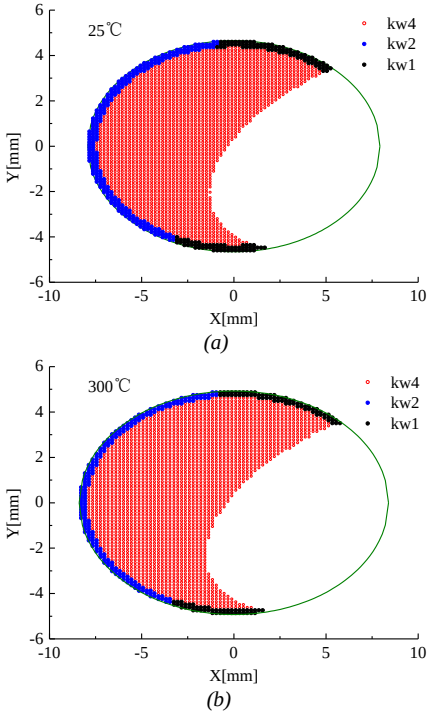


Figure 13 *Comparison of relativity sliding velocity along the contact patch center line at different temperatures*

The wear coefficient distribution in contact patch is refined at different temperatures, according to the magnitude of the contact pressure, pressure bound and relative sliding velocity. The comparison of wear coefficient distribution at normal temperature and maximum temperature is shown as Fig. 14. The contact pressure in the edge of contact patch don't exceed the pressure bound, and the relative sliding velocity at the leading edge of the slip zone is less than 0.2 m/s. As a result, the wear coefficient at the leading edge of the slip zone is located in regime I. The relative sliding velocity at the trailing edge of the slip zone is between 0.2 and 0.7 m/s, lead to the wear coefficient locating in regime II. The wear coefficient in the other positions of the slip zone is in regime IV, because the contact pressure exceeds the pressure bound. It is can be seen from Fig. 13 that the percentages of regime IV at maximum temperature is significantly more than one of normal temperature. The percentages of different regimes such regime I, II, III and IV are calculated as Table 6. The percentages of regime III are zero at all temperatures, due to the maximum relative sliding velocity less than 0.7 m/s. It is can be seen that the percentage of regime IV increases with the increasing temperature, leading to aggravating wheel wear.

(a)

(b)

Figure 14 *Comparison of wear coefficient distribution at different temperatures: (a) Normal temperature 25 ℃. (b) Maximum temperature 300 ℃*

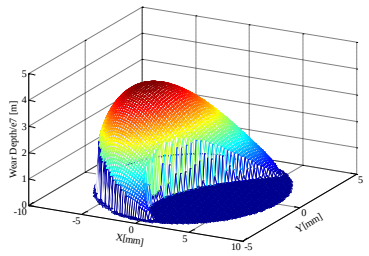

Table 6 *The percentages of different wear coefficient*

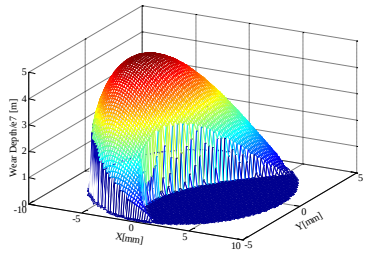
Temperature (℃)	Percentage of regime I (%)	Percentage of regime II (%)	Percentage of regime III (%)	Percentage of regime IV (%)
25	4.9	8.5	0	86.6
50	4.7	8.2	0	87.1
100	4.5	7.9	0	87.6
150	4.4	7.7	0	88.9
200	4.2	7.4	0	88.4
250	4	7.0	0	89.0
300	4	7.0	0	89.0



The wear depth of every element in the contact patch is calculated according to Eq (22), and the maximum wear depth is shown as Table 7. Calculation results show that the changes of physical quantities to calculate wear, such as hardness and wear coefficient increasing, influence the wear depth. Compared with the result at normal temperature, the maximum wear depth of contact patch increases by 28%, when wheel tread reaches the maximum temperature. The comparison of wear depth distribution in a contact patch at normal temperature and maximum temperature is shown as Fig. 15.

Table 7 *Maximum wear depth*

Temperature (℃)	Maximum wear depth ($\times 10^{-7}$m)
25	3.52
50	3.59
100	3.74
150	3.91
200	4.09
250	4.29
300	4.58

(a)

(b)

Figure 15 *Comparison of wear depth distribution in a contact patch: (a) Normal temperature 25 ℃. (b) Maximum temperature 300 ℃*

The wear profile in lateral direction after rolling over a contact patch is calculated by summing up wear depth at each wheel lateral position along longitudinal direction. The comparison on wear after rolling a contact patch at different temperatures is shown as Fig. 16. Results indicates that the wear depth and wear range increase with the increasing temperature. Compared with the results at normal temperature, the wear depth increases by 25%, when wheel tread temperature reaches the maximum. At the same time, the wear range of wheel lateral increases by 5.8%.

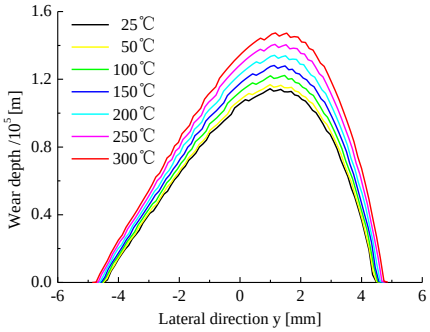


Figure 16 *Comparison of wear profile in lateral direction after rolling over a contact patch at different temperatures*

6. Conclusion and future work

The temperature field of wheel tread during tread braking was calculated using a numerical algorithm based on finite element method. Wheel wear model that considers temperature effects was established based on Archard wear model and according to the relationship between material properties and temperature. The contact patch condition and wear depth are calculated and compared at different temperatures to analyze the impact of braking temperature on wheel wear. Results indicated that：

(1) The area of contact patch and slip zone increase with the increasing temperature due to the reduction of the wheel material's ability to resist deformation caused by the negative correlation between elastic modulus and temperature of wheel material. Compared with the result at normal temperature, the area of slip zone increases by 11% when wheel tread temperature reaches the maximum.

(2) According to existing experiments and theory, the hardness, wear coefficient and relative sliding velocity vary as the change of temperature, which influences the wear depth on the wheel. Compared with the maximum wear depth at normal temperature, the maximum wear depth of contact patch increases by 28% when wheel tread reaches the maximum temperature in tread braking.

(3) Contact area with its wear coefficient dropped in the devastating wear regime on the wear map may be dozens of times larger when the temperature increases from room temperature to maximum temperature in tread braking, leading to an aggravated wheel wear. The change of hardness, contact pressure and relative sliding velocity is the main reason that causes the wear coefficient moves from mild wear regime to devastating wear regime on wear map.

(4) The wear profile in lateral direction after rolling over a contact patch increases due to the increasing wear coefficient in a contact patch and area of slip zone. At the same time, the wear range increases as the increasing in the area of contact patch. Compared with the result at room temperature, the maximum depth in the lateral wear profile and wear range increase by 25% and 5.8%, respectively, when the wheel tread temperature reaches the maximum during braking.

The tread wear introduced by the braking shoes is not considered in this study because it is another wear source and significantly different from the wear from the wheel/rail contact. A more comprehensive wear model that includes wear from different sources should be established in future work.

BENCHMARKING OF PREMIUM RAIL MATERIAL WEAR

Abstract: Railway steel that offers a greater quality and extended life is described by the industry as premium rail. Premium rail is mainly used on areas of rail networks where accelerated wear, RCF or other rail related damage phenomena prevail. However, little performance data exists for these materials and where it does it is limited to one set of contact conditions. The aim of this work was therefore to map premium rail performance across a range of $T\gamma$ contact conditions to benchmark against standard grade R260 rail. Laboratory tests using a twin disc machine were performed to determine the wear performance of four premium rail grades against R8 wheel material, at various slip conditions of 1-20%. The results are shown in terms of $T\gamma$ and cyclic wear rate for both the rail and wheel discs. The purpose of this work is to understand the likelihood of wear in different wheel/rail contact conditions and to produce enough wear information for the premium rail that could be used in prediction tools for comparison with other materials and contact conditions.

Keywords: Wear; RCF; rolling-sliding; laser cladding; twin disc; hardness; premium rail.

1. Introduction

The demand for faster and safer railways promotes the development of railway steel with greater quality and extended life. Such steel is described by the industry as premium rail and is mainly used on areas of rail networks where accelerated wear, RCF (rolling contact fatigue) or other rail related damage phenomena prevail. It is important to evaluate new materials used for rail since its performance may affect the other component of the interface, the wheel. Different types of wheel material and dimensions/profiles are being used on railways with a combination of varying loads and conditions. Wear mapping of materials is common practice in research [1, 2] and enables tribologists to identify material wear behaviour for example by mapping wear rate against $T\gamma/A$ or using an Archard wear coefficient approach [3]. This provides a standalone tool for understanding the likelihood of wear in different wheel/rail contact conditions. In combination with data from dynamic simulations, the wear data can also be used in prediction tools for comparison with other materials and contact conditions. Currently there is a lot of data available for standard grade materials [2], but not so much on premium grades, making the prediction of their performance in the field difficult.

In this work the wear performance of four premium rail grades against R8 wheel material was measured in a laboratory environment. Twin disc testing was performed using the SUROS (Sheffield University ROlling Sliding) machine. Material loss from wheel and rail discs was measured as well as friction in order to document the relationship of wear to $T\gamma/A$ curves. Conditions for testing were constant, with the exception of slip, which enabled variation of $T\gamma/A$ so that a benchmark wear map for a range of slip ratios could be established. Not all premium rail grades can be disclosed for this publication so rather than results specific to individual steels we focus on higher level conclusions relevant to premium grades in comparison to standard grade. The premium materials are referred to as R350HT, A, B and C. Comparison R260 rail material laser clad with a layer of MSS from [4] was made as a further benchmark.

Standard rail material R260 is the basis against which the premium material is compared. R260 and one of the premium materials (R350HT) are designed in accordance with EN 13674-1:2011+A1:2017, which specifies Vignole rails of 46kg/m linear mass and with a hardness range of 200-440HBW. The rest of the premium materials are based on the manufacturers' own standard. All premium materials in this study are designed for 40-60kg/m linear mass for conventional and high speed railway track. Material R350HT has mainly wear resistant properties and it is designed for use on curved and heavy haul tracks. Material A is designed to be wear and RCF resistant in comparison to similar steel grade, commonly used in curved track and high duty areas, while material B is designed to be the most wear resistant grade with exceptional resistance to RCF, aimed for tightly curved and heavy haul tracks. Material C is mainly designed for RCF resistance and for use in critical areas such as switch blades.

2. Background

Rail steel comes in many grades which have been developed over the years by the industry, aiming at achieving certain properties and focusing in achieving some of these properties on the head of the rail where the contact with the wheel is taking place. Rail steel grades are normally categorised by the head hardness where in most cases the grade naming designation contains the hardness value in Vickers. Premium rails are made with a target to increase wear resistance or RCF resistance or both.

However, there is a trade-off between these two properties as they are competing with each other depending on the operating conditions. Wear is the predominant damage mechanism that exists at different levels, in most loading cases and conditions. Rolling contact fatigue on the other hand only initiates when the cyclic loading level exceeds the material fatigue limit. This is when individual loading cycles have resulted in accumulation of plastic strain to the point that the material's resistance to further plastic strain is exhausted. At low $T\gamma/A$ values the most likely failure mechanism is RCF crack initiation and growth which at its worst, if unchecked, could lead to cracks turning down and causing a rail break. As the $T\gamma/A$ value increases, the wear rate in the system rises which removes material from the surface, thus removing any RCF cracks that may have initiated. At high $T\gamma/A$ failure will be by wear which is less catastrophic. This is encapsulated in the Whole Life Rail Model [5] that looks at wear and RCF interactions for standard grade rail. A $T\gamma$ damage curve is utilised that was developed based on field data and twin disc laboratory measurements. Hiensch and Steenbergen recently extended this type of approach to map this behaviour for other rail grades. This is limited in its application though as the same wear rate was assumed for all materials, which further emphasises the point made earlier about a lack of wear data for premium rail materials [6].

Some data is available though. Studies to characterise the wear and RCF behaviour of pearlitic and bainitic rail steels have been made by Stock and Pippan [7, 8]. The results indicated a reduction in wear, plastic deformation and the formation and growth of head checks (RCF) with increasing hardness and strength of five pearlitic rail steels, which were tested in a laboratory full-scale rig and also compared to track data. With regards to bainitic rail, tests indicated a lower wear resistance than the high hardness pearlitic rails, however, the potential of an improved RCF resistance was highlighted [8].

Past studies investigated the wear and RCF performance of rail materials for limited contact conditions, such as contact pressure (900-1,500MPa) or low slip ratio (creep) of around 0-6% [9, 10]. Bolton and Clayton tested at higher slip ratios but with lower contact pressure of 1,300MPa [11]. Under such conditions the mechanical energy that dissipates in the wheel-rail contact patch is not representative of the overall mix of loads that exist in the field. Heavy haul trains and multiple size wheels made of different steel grades affect the contact patch but also the environmental conditions, track geometry, friction modifiers as well as the driving behaviour of train drivers leads to increasing slip between the wheel and rail. Such increase in slip takes place at certain sections of the track, at tight curves or in braking and accelerating sections, and repetitive occurrence can be damaging for both the rail and wheel. As part of this study the contact pressure was maintained constant, but the slip ratios were tested at 1% as well as 10% and 20%. This caused an increase in the $T\gamma/A$ value and allowed direct comparison to damaging conditions that occur in the field.

Some of the issues with testing at the same contact conditions at small scale is the dissipation of heat generated. In the field the large mass of the wheel and rail aids in dissipating heat, in combination with the airflow around the system while the train is moving. To compensate for this in the twin-disc tests, compressed air was supplied to each wheel to aid in dissipating heat but also the duration of the tests was kept short with increasing slip, for example 10,000 cycles for 10% and 1,000 cycles for 20%. In addition, the compressed air was a way of removing the generated debris from the test machine, ensuring that the debris was not sticking to the discs.

The main characteristic of premium rail grades is their increased hardness, for example the higher the rail head hardness the more hard wearing the rail is expected to be. However, standard rail, for example R260, work hardens in the field and can eventually achieve similar surface hardness as some premium rail. That does not mean that it will perform the same as premium rail or rail with higher hardness, in terms of wear or RCF resistance and this can be seen from this comparable study. Superficial hardness may not be as effective as through thickness hardness, since it can be re-worked during operation and the rail head may experience multiple phases of plastic deformation, ratchetting and hardness fluctuations in comparison to materials designed for high wear resistance. Other methods to increase the hardness/wear resistant properties of the rail head is with the use of laser cladding. These methods are of interest due to the thicker coatings that can be produced in relation to more traditional coating techniques (μm versus mm). Figure 1 is a hardness profile of R260 material, the four premium materials and a laser clad R260 with a coating of MSS steel of a 1mm depth. The hardness measurements were taken after the samples were tested at 1% slip for 30,000 cycles from the edge of the disc contact surface in a linear trajectory towards the centre of the disc up to 2mm into the depth of the material. It is clear that all materials have had some sort of work hardening, affecting the material at about 300μm below the surface while the R260 material has had a much greater hardness change of all of them to a depth of about 800μm. In comparison to the MSS Clad it can be observed that the higher hardness of the clad material runs to a depth of just over 1mm from the surface and this highlights the possible benefits of using thicker coatings.

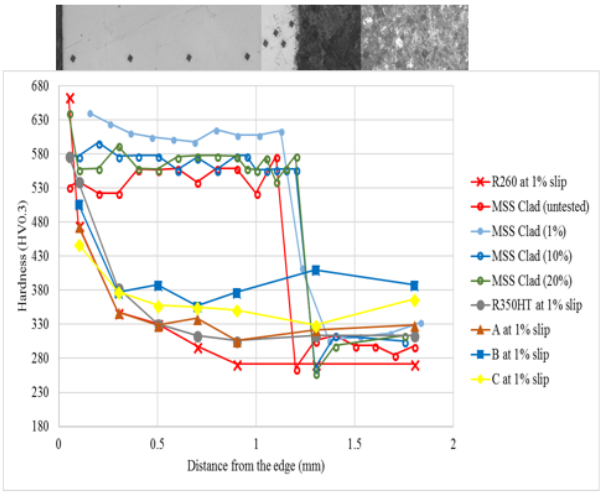

Figure 1 *Hardness profile through the thickness of sectioned samples and stitched image of untested MSS Clad (using Struers DuraScan at 20HV0.3).*

The laser clad material is a form of Martensitic Stainless Steel. A chemical analysis was obtained using an optical emission spectroscopy method on the surface of the disc, which indicated the quantities of elements as listed in table 1.

Table 1 *Chemical analysis of the R260 laser clad disc.*

C [%]	Si [%]	Mn [%]	S [%]	P [%]	Cu [%]	Ni [%]

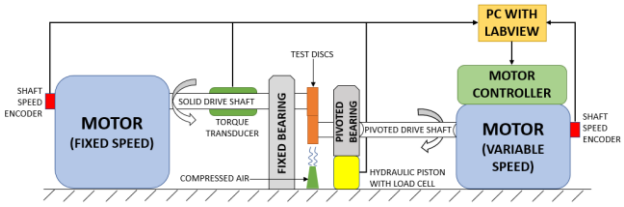
9.53	0.24	0.27	1.22	0.46	84.75	

3. Materials and test method

Laboratory tests were the preferred method of evaluating the wear performance of the premium rails because it is an economical way which allows to obtain results much quicker than in the field. In addition, the use of a small scale twin-disc tester allows for replication of the tests under the same conditions, which can be difficult to achieve with field trials. Tests were planned in line with the good practice as described by Lewis et al. [4]. The SUROS twin disc machine [4] (see figure 2) was set-up at a maximum Hertzian contact pressure of 1500MPa and a rail disc rotational speed of 400rpm. The slip between the wheel and the rail discs was controlled by increasing the wheel disc rotational speed by the appropriate percentage of 1%, 10% and 20% of the rail disc's rotational speed, thereby representing a driving wheel. A torque transducer positioned on the rail disc drive shaft was used to measure torque and enabled calculation of the tractive force and therefore the $T\gamma$ for each test. Tests were performed in dry conditions for varying numbers of cycles (1,000 cycles for 20% and up to 30,000 cycles for 1% slip). The discs have a contact width of 10mm and a diameter of 47mm (see figure 3a). The room temperature was varied between 22ºC-28ºC and the humidity in the room between 30%-60%.



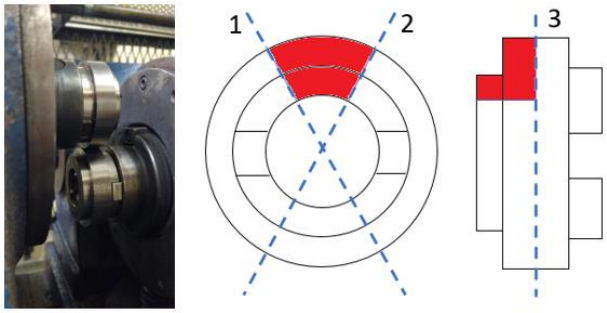


Figure 2 *Schematic diagram of the SUROS twin disc testing machine.*

The specimens were cut from the rail head of each material and machined into SUROS discs. The hardness in each rail head may vary, since some premium rail grades are designed to have an increasing hardness towards the rail head. Also, due to inconsistencies in the manufacturing process, the hardness may vary in different parts of the rail head and through the thickness of the standard rail. This means that the hardness of the disc samples may vary slightly around the contacting face with the opposing disc (wheel). Similarly, the wheel was machined from the outer rim of an R8 wheel which complies with BS 5892:3. Typically such wheels have a harder running face which is softer towards the centre of the wheel. The samples used for the test were taken at random from different batches, tested in no particular order and the tests took place over a ten-month period.

Before commencing a test, the specimen discs were dipped in acetone and cleaned in an ultrasonic bath for two minutes. The weight of each disc was recorded using the Adam AAA-300L weighing balance with an output of four decimal points (0.1mg precision). For the 1% slip, the test was interrupted every 5k cycles up to 30k, in order to record the wear of each disc. Before measuring the wear, the discs were cleaned again in ultrasonic bath as at the beginning of the test. For the 10% slip, the test was interrupted at 1k, 2k, 3k, 4k and 10k cycles. Finally, for the 20% slip, the test was interrupted at 500 cycles and 1k cycles.

After the tests were completed, the discs were sectioned in three cutting planes in order to expose an internal face of the disc in the middle of the outer rim (see figure 3b). The sectioned pieces were mounted and polished for further analysis including hardness testing. Micro-hardness testing took place with a load of 0.3kg in multiple locations from the outer rim of the disc towards the centre in the section in order to observe any work hardening effects occurring near the running area of the disc (figure 1). Surface images were also taken.

(a) *(b)*

Figure 3 *(a) Image of test discs mounted on the SUROS tester. (b) Locations of the three section cuts (sample highlighted in red).*

For the corresponding wear rate, the mass loss was divided by the number of cycles in order to calculate the wear rate per cycle. The contact patch area was multiplied by the circumference of the disc to produce a figure that represents the area covered per one cycle. The final wear rate is mass lost over one cycle over a given area and is represented in micrograms per metre per millimetre squared.

$$\frac{\frac{\mu g}{m}}{\frac{}{mm^2}} = \frac{\frac{m}{n}}{\frac{}{\pi d A}} \quad (1)$$

where m is the mass loss (g), n is the duration of the test in numbers of cycles, d is the diameter of the disc (m) and A is the contact patch area (m^2). In equation 2 the $T\gamma$ energy in the contact patch is calculated and re-arranged to represent the corresponding energy dissipated over an area. This enables correlation to the wear rate calculation in equation 1. The friction used in the equation is calculated by the measured toque and force. The average torque measurement is used to calculate the traction force, by dividing it by the radius of the disc. The average friction is then calculated by dividing the calculated traction force by the average normal force applied during the test.

$$\frac{T\gamma}{A} = \frac{\mu P l \lambda}{A} \quad (2)$$

where μ is the friction as calculated from the twin disc machine, P is the normal force applied (N), l is the length of the cylindrical contact area (m), A is the contact patch area (m^2) and λ is the slip ratio between the two discs (%).

4. Results

The results are presented in terms of wear rate for the rail (figures 4) and for the wheel (figure 5). In terms of wear rate over $T\gamma/A$ for the rail (figure 6) and lastly in terms of system wear which includes the wheel and rail (figure 7). In figure 4 the wear rates are represented for the three slip ratios tested, split into three graphs. For the 1% slip the measurements taken every 5,000 cycles up to 30,000 cycles. This test approach was adopted from [2] and used to monitor the wear evolution of the different materials.

In the same graph data from other tests of laser clad rail performed under the same conditions [12] have been added (MSS Clad) for comparison with the R260 baseline and premium materials. For calculating the wear rate for the 10% and 20% tests, the overall mass loss was divided by the number of overall cycles to produce a wear rate figure of mass loss per cycle while for the 1% slip tests, only the mass loss in the last 5,000 cycles was used for calculating the wear rate, since it takes about 20-25,000 cycles for the wear rate to reach steady state when testing at 1%.

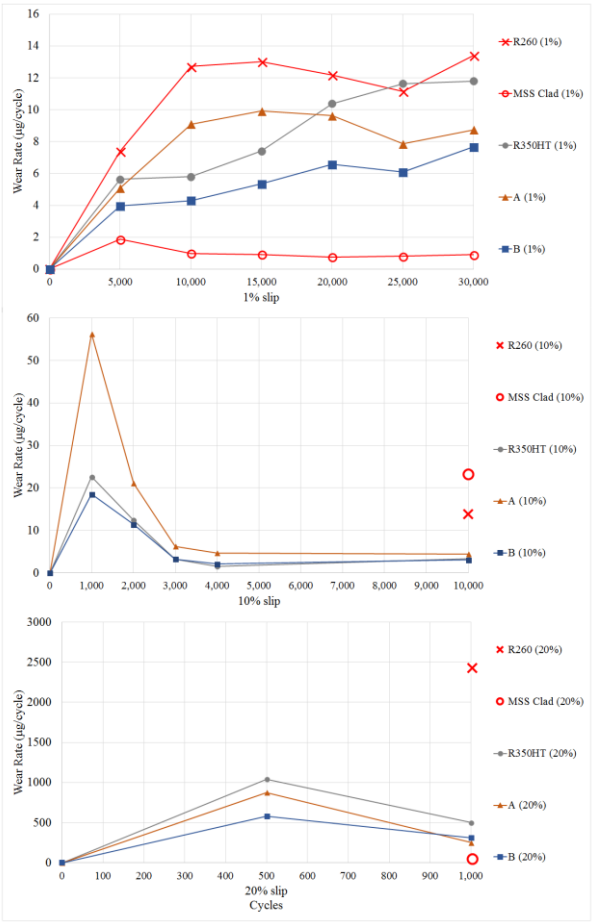

Figure 4 *Rail wear rate per cycle at 1%, 10% and 20% with 1500MPa contact pressure and 400 rpm primary rotational speed.*

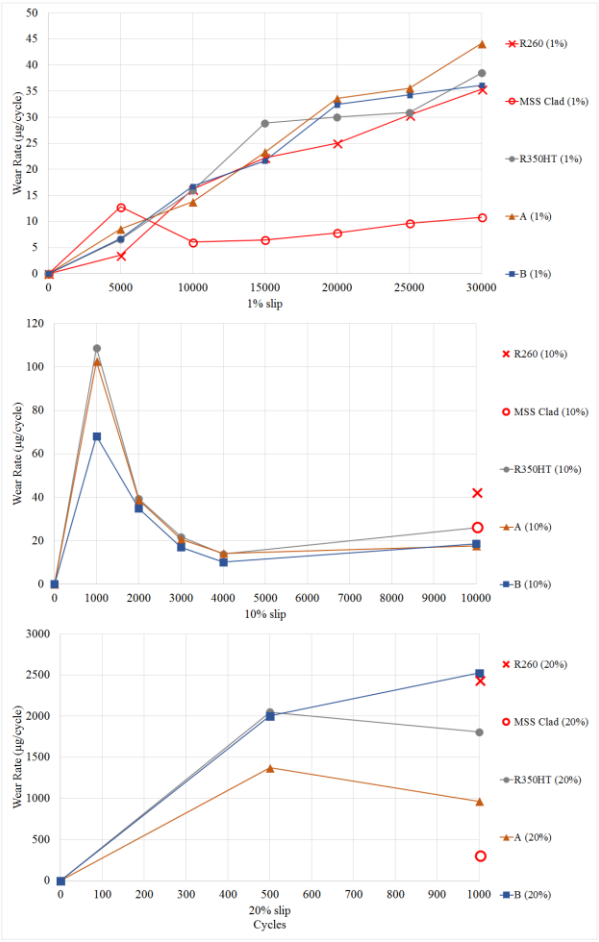

Figure 5 *Wheel wear rate per cycle at 1%, 10% and 20% with 1500MPa contact pressure and 400 rpm primary rotational speed.*

In some repeat tests the wear rate was only measured at the beginning and at the end of the test, so it was preferable to indicate the overall wear rate for comparison, including a "run in" period. The "run in" period varies depending on the material and slip ratio.

Material C showed poor wear resistance in comparison to the other materials at 1% and an extremely high wear at 10% and 20%. In addition, the shape of the material C disc has turned from cylindrical into a polygonal shape, while the wheel disc has remained cylindrical. Material C is aimed at improved RCF resistance rather than improved wear resistance and it is difficult to say why the rail disc has taken this form without further investigation and testing. For this reason, the results for material C for 10% and 20% have been omitted from the graphs in this section.

Figure 6 is put together using the calculations from equation 1 and equation 2, where the contact energy over 1mm^2 area ($T\gamma/A$) is plotted against the wear rate (µg/m/mm^2). The data points are forming three distinct areas on the graph, which resemble the three wear regimes of "Type I-Mild", "Type II-Severe" and "Type III-Catastrophic" [2, 11, 13]. A Schematic of this typical relationship of pearlitic steel indicating a predicted path for the data points is shown in figure 16. This path on the graph is verified in figure 6 and highlighted with the exception of material C.

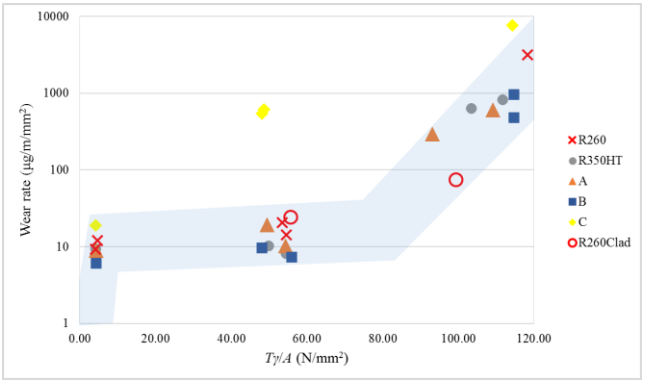

Figure 6 *Rail wear vs Tγ/A.*

A way to describe how much wear damage is attributed to the wheel and how much to the rail, figure 7 was put together. The overall wear in µg for the wheel and rail is shown in for each slip condition, with the exception of material C.

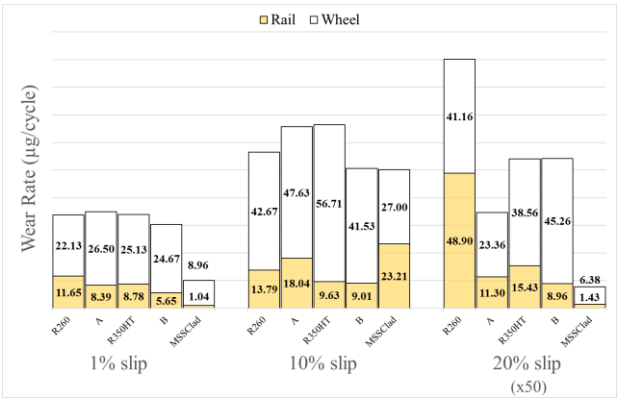

Figure 7 *Cumulative System wear (20% is shown on a different scale).*

Etched images from an optical microscope are shown in figures 8-12 with a 5x objective lens magnification. In some images the hardness diamond indentation is still visible after etching. The rolling direction indicates the direction the axis of the disc would be displaced, if the opposing disc was a flat surface.

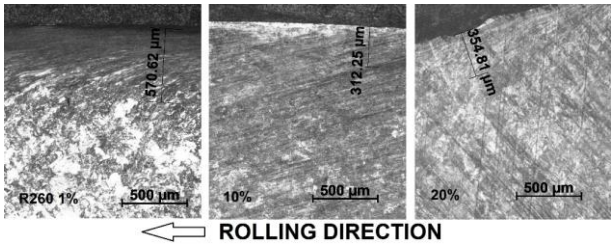

Figure 8 *Optical microscope images of R260 (1%, 10%, 20% slip).*

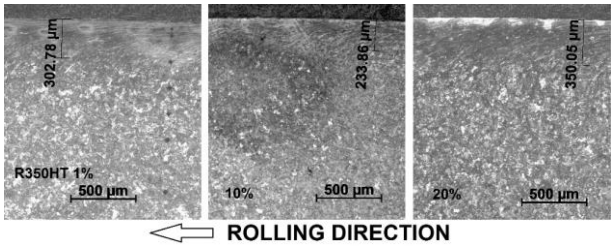

Figure 9 *Optical microscope images of R350HT (1%, 10%, 20% slip).*

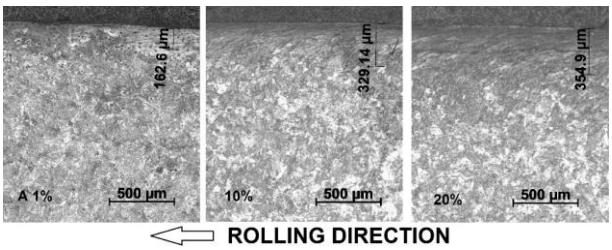

Figure 10 *Optical microscope images of A (1%, 10%, 20% slip).*

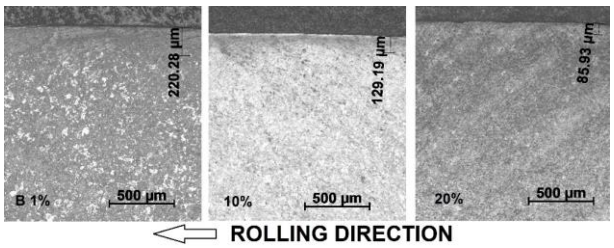

Figure 11 *Optical microscope images of B (1%, 10%, 20% slip).*

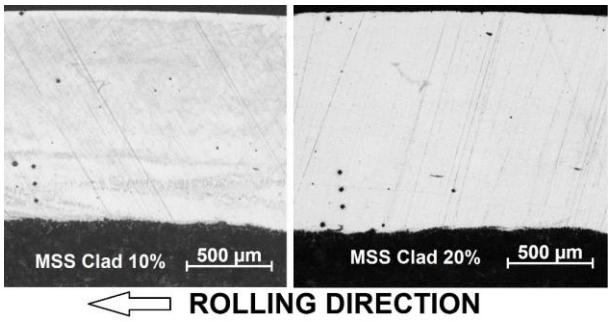

Figure 12 *Optical microscope images of material R260 with MSS clad, from 10% and 20% slip etched samples - Very small plastic deformation.*

Finally figure 13 shows pairs of rail and wheel discs for the 20% slip test, while figure 14 shows images of the etched samples taken from the 20% slip test of the R8 wheel material. The notation on the images indicates the rail discs material reference, R260, R350HT, A and B. There is a peculiar phenomenon of plastic deformation which differs in each material combination and rolling conditions.

Figure 13 *Image of wheel and rail discs after testing at 20% slip.*

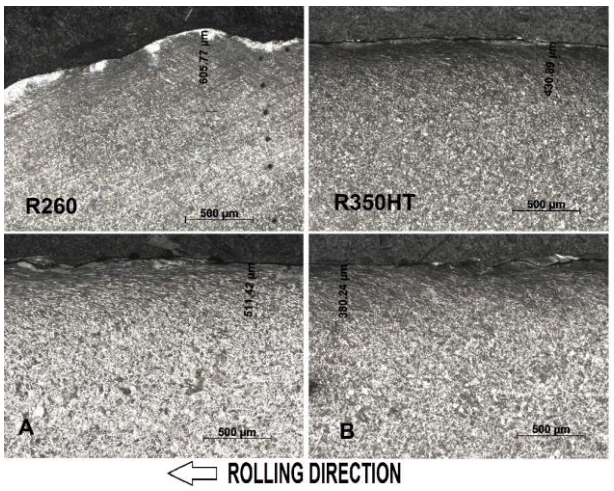

Figure 14 *Optical microscope images of wheel material R8, rolled against R260, R350HT, A and B rail discs, taken from 20% slip etched samples.*

For the material A test, the wheel exhibits short flat areas which did not form on the rail material. This is similar to the material B tests, where the rail has been plastically formed into a polygonal shape, while the wheel has remained round. In magnification the plastic deformation near the surface exhibits a wave pattern, as shown in figure 15.

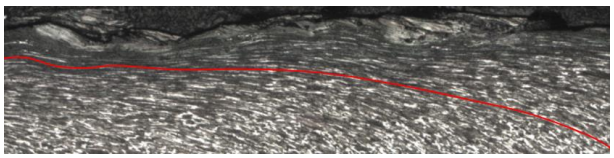

Figure 15 *Image of wheel disc (Material B-tested at 20% slip) indicating the waviness of plastic deformation near the surface.*

For the material R350HT test, the wear patterns on both the wheel and rail are similar to the lower slip tests while for the material C test extreme wear and plastic damage is shown on both the wheel and rail. The R260 test has shown another peculiar phenomenon where both the wheel and rail discs have formed a matching pattern between them that resembles a helical gear. This is visible in figure 13, where the edge of the disc is sloping and where material has been removed as well as plastically deformed. This phenomenon could be induced by many things such as high temperatures in the contact zone and the plastic deformation attributed to the work hardening properties of R260.

5. Discussion

The rail wear rate for all materials at 1% slip, increases until a steady state is reached before 30k cycles, see figure 4, while for the laser clad material it decreases to a steady value. Blau [14] explains that the wearing behaviour during testing happens in stages, depending on the type of wear. Transitions from one stage to the next can be induced by external changes (Type 1) or they can occur naturally (Type 2), for example running-in, wear of coating and thermally-induced from the build-up of heat. An oxide layer on the surface of the specimens contributed to the initial running-in stage.

The measurement of the mass loss was made periodically and the frequency of stopping can be detrimental in capturing different stages. The initial measurement was made at 5,000 cycles (1%), 1,000 cycles (10%) and 500 cycles (20%). The initial stage, for example an incubation period before the wear-in period, followed by a sudden acceleration in wear was missed and two stages can be seen, of acceleration in wear and a terminal stage. For this reason, the wear data used for the calculation of $T\gamma/A$ are normalised. In some cases, for example at 10% slip, the wear rate generally starts at a high rate and decreases until it reaches a steady state at around 10k cycles. Four transition stages were captured here, the acceleration, maximum rate, deceleration and terminal stages. Similarly, at 20% slip the deceleration stage can be identified from the three data points, as it is decreasing between the 500 and 1,000 cycles data points. This clearly describes the extreme damage which is happening at higher slip and which wears the material at a higher rate until a steady state is reached as opposing to the low slip case where the wear rate is increasing slowly. Figure 5 is showing data for the wheel of the same material as tested against the different rails as shown in the legend. The wheel is behaving in a similar way, however, it seems that the wear rate at 1% has not reached a steady state, but it is still increasing. For the 10% and 20%, the change in wheel wear rate has a similar profile to the rail but at different levels.

Figure 6 is a typical representation of wear rate over $T\gamma/A$ and most data points seem to follow the observations of Lewis et al. [13] as explained in the previous section and described by figure 14. The wear rate is expected to increase with more traction in the interface and this is achieved with each increase of the slip ratio. Three groups can be observed, representing the 1%, 10% and 20% slip, each with a calculated $T\gamma/A$ value, with 1% at $T\gamma/A$ values below 10N/mm^2, 10% at values in the region of 50N/mm^2 and 20% at values over 90N/mm^2. The standard rail R260 showed the worst wear resistance at higher $T\gamma$ levels along with material C which was wearing significantly more in all slip cases and it is outside the expected wear zone, as highlighted in the graph. The R260 repeat test at 20% slip was omitted from this graph as the test was not comparable to the other data due to the large plastic deformation that cause the helical gear patterns as shown in figure 13. Due to this matching shape on both wheels, the friction in the system was increased to more than 0.5, resulting in high $T\gamma$ values outside of the scale of figure 6 and subsequent very high wear under non rolling sliding conditions.

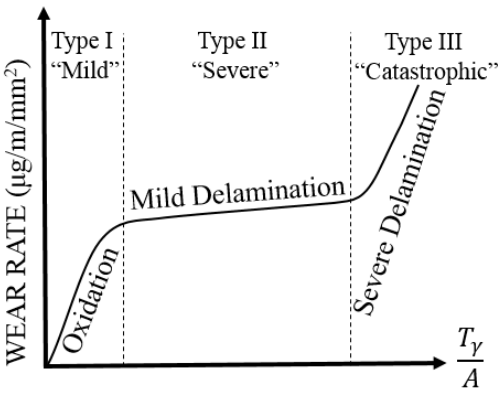

Figure 16 *Schematic diagram of wear regimes (adapted from Lewis et al. [13]).*

Materials A and R350HT are designed for wear resistance and they have a similar performance at all slip conditions. There is a difference in system wear though which indicates that at 20% slip material R350HT is wearing the wheel more than material A.

Material B is designed to be the most wear resistant grade and it seems to stand out as a lower wearing material in all cases. Even though the data points at 20% indicate higher wear, these are at much higher $T\gamma$, at harsher conditions. However, the system wear (figure 7) for material B is worse than the other materials at 20% and this is due to the wheel wearing more at high creepage. Material C is mainly designed for RCF resistance and during these tests it showed poor wear resistance with unwanted plastic deformation at all slip ratios and outside of the expected wear performance in comparison to the other rail materials. An R260 laser clad with MSS was tested to provide another point of reference of a non-commercial rail material. Although the laser clad material exhibits higher wear than the other rail materials at 10%, it is performing much better at 20% slip, with much lower wear than the other rail materials. However, in all cases for the laser clad material, the system wear is significantly low, and this is because the wheel is wearing less in all cases when the laser clad material is used. This observation highlights the importance of considering the wheel wear when comparing different rail materials and perhaps the selection of premium rail should be conducted as a system wear methodology.

The balance between rail wear and wheel wear varies for each material at 1% slip, and this can be seen in figure 7. The overall system wear is more or less the same for all materials with the exception of material B which is slightly lower and the laser clad material which is significantly lower. This is an indication, that despite the various materials with various hardness levels, the system is wearing in such a way that it always wears out the same amount for these set conditions, either from the wheel or the rail. It is only for material B and for the laser clad material that the system wear is reduced. Figure 7 illustrates that in both of these cases the wheel is wearing significantly more than the rail, but still the overall system wear is lower than the other cases.

The difference in wear between the different rail materials as well as the wheel materials is attributable to the intrinsic mechanical properties of the materials which are different since all the materials tested do not have the same chemical composition or post manufacture processing such as heat treatment. In some cases, for example at low slip, most of the premium materials behave similarly, while at high slip some of the material characteristics help reduce wear. From the initial test results it was observed that the wheel is wearing more than the rail in all slip cases. The difference in wear rate between wheel and rail is small at low slip ratio, for example at 1% slip it is in the region of 5μg/m/mm^2. For the 20% slip the difference in wear rate between wheel and rail has increased and it is in the region of 2000μg/m/mm^2.

To bring the amount of wear into perspective, let's assume that one of the wheels of a typical train has a contact patch area of 70mm^2 then if the rail was made of R260, for every km of rail that the wheel is passing, the rail would wear by 0.7g (10μg/m/mm^2 at 1% slip, and around 4N/mm^2-$T\gamma/A$), while if the rail was made of material B it would wear by 0.42g (6μg/m/mm^2 at same conditions) and this is calculated by multiplying by 1,000 metres and by the square patch. From this comparison we can see that if this particular kilometre of R260 rail was to be replaced by material B, it would probably increase the service life by 40%. In reality the overall traffic must be calculated for different sections of railway, so the wear rate must be multiplied by the number of wheels for each train and the number of trains that will run over a certain period of time based on a schedule. It is more complicated to estimate total rail wear as the traffic and rolling conditions change continuously, so the results from this study can only be used for direct comparison between the different materials, unless they can be used with more sophisticated simulation and prediction software.

Further tests will be performed for accelerating the crack growth under rolling contact fatigue damage in order to evaluate the RCF performance of the premium material, as previously tested for R260 rail by Hardwick et al. [15]. Some rail materials are designed to have greater wear resistance and others to have greater RCF resistance, making it very difficult to optimise both. It has been discovered from premium rail trials in the field that the use of premium rail has unexpectedly changed the damage mechanism in particular locations from wear to RCF. This has identified a need for developing a new damage function describing the wear-RCF relationship with $T\gamma$ for the premium rails, going beyond the well-known damage function for standard rail [16].

6. Conclusions

Currently, wear coefficients have been utilised in mapping and predicting wear and RCF. This new data will be useful to make the required improvements to modelling tools based on wear coefficients and material properties [13]. This will eliminate the process of deriving wear coefficients from twin disc testing which is laborious and costly when it comes to exploring different scenarios with various loading conditions. Wear coefficients are limited to a single load, while mapping with dissipated energy $T\gamma$ the data can be extrapolated to various loading conditions. The purpose of this work is to provide a benchmark for comparison with other technologies such as laser cladding of alloys on wheels and rails, and to evaluate their performance. Previous work by Lewis et al. [12] on testing the wear of laser clad rail material has been very promising. In addition, this work will contribute to a database of information for wear prediction tools of premium material as well as laser clad material. Wear of wheel and rail discs for R260, four premium rails and a laser clad rail was measured in order to document its relationship to $T\gamma$ curves for three slip conditions of 1%, 10% and 20%. The wear resistance performance of these materials at high creepage and harsher conditions is of interest, as the premium materials are generally designed for high axle loads and tight curves. The wear rates produced in figure 6 correlate with the three wear regimes as identified by Lewis et al. [17] as mild, severe and catastrophic. At low slip tests, the premium materials are wearing at similar values and results can be inconclusive when the mass loss is low, without extensive and repeatable tests to produce a statistical analysis of multiple tests. At high slip tests of 10% and 20% the premium rails showed improved wear resistance over the standard rail, with material B to perform better, in line with the design intend of material B. Material C is designed for increased RCF resistance rather than wear and although at low slip the wear was moderately high, at high slip it exhibited high wear, outside of the other material's wear range.

The wheel wear differs depending on the rail material and it is always higher than the rail wear due to the lower hardness of the wheel. Overall the ratio of wheel wear and rail wear varies with premium rail, showing more wheel wear with premium rail in comparison to standard rail, however the overall system wear may be reduced at low slip ratios but especially at high slip ratios, for example 20% (figure 7), which can be found in critical areas such as switches and crossings and tight curve track sections. R8 wheel material was used for all the tests. Different wheel material is in use by several train operators and future rail performance and comparison should include other wheel material, for comprehensive understanding of the in-service wear.

Further work on high slip would be of benefit to verify the performance of this early study, with focus on both the rail and wheel wear performance and preferably in full scale testing to eliminate the limitation of small scale testing. In a study where a large number of samples can be tested, separating the results into initiation phase (newly installed, work hardening phase) and steady state would make it clearer how each material performs. The RCF performance of the rail has not been evaluated in this study and it is important that future work investigates the RCF performance in combination with the wear performance. In addition, work hardening effects of the different rails need to be considered when selecting premium rails.

The combination of the above data can be of benefit to the industry when selecting rail material for various sections of railway.

Abstract: Twin-disc tests were carried out with E8 wheel and premium R400HT rail samples in testing machines installed at the University of Sheffield, UK, and Universidad Nacional de Colombia, Colombia. The wear rate and friction coefficient were correlated with the frictional work spent at the contact interface. The wear rates of both wheel and rail samples were consistently lower than those reported in the literature for other contacting pairs in which the rail material studied is softer than R400HT. Also, the energy needed for the transition from moderate to severe wear regime significantly increased with the use of the hardened rail.

Keywords: Twin disc testing; Premium rail; Tgamma approach; Wear rate; Slip ratio.

1. Introduction

This paper outlines a study of the friction and wear behaviour of specimens extracted from wheels and rails of the commercial railway system of the Metro de Medellín in Colombia when tested under controlled rolling-sliding conditions in twin-disc testing machines in laboratories. Wheel and rail materials play a very important role in the optimization of the management of wheel-rail contacts. The choice of rail material used, for example, can determine whether wear, or fatigue processes are dominant. Therefore, studying the tribological behaviour of a pair of materials under diverse contact conditions is key to understanding the transitions between different wear regimes. Hiensch and Steenberger [1], for instance, used data from the field to show that premium R370CrHT grade rail offers better resistance to Rolling Contact Fatigue (RCF) than conventional R260Mn grade, mainly because the fatigue crack initiation limit value of the harder rail is higher. Therefore, a mild wear regime is favoured, i.e. the transition to a severe wear regime needs harsher contact conditions.

Laboratory studies have also been carried out to identify wear transitions in materials for wheels [2,3], and rails [4-7]. Pin-on-disc, twin-disc, and full-scale rigs have been used for this purpose with reasonable success in terms of transferring the results from the laboratory to the field. Pioneering works from Danks and Clayton [8], McEwen and Harvey [9], and Bolton and Clayton [10] established correlations between laboratory tests and field data for specific operation conditions; they proposed basic theoretical models to predict wear of rails in service. Ma et al [11] tested E9 wheel – U71Mn rail pairs in a twin-disc machine with different slip ratios up to 10% and found that the transition from mild to severe wear regime occurred at around 3.8% slip. The transition was also linked to changes in the main mechanisms of damage of the contact surfaces. In the mild regime, cracks propagated mainly parallel to the contact surface, while in the severe regime, the angle with respect to the surface increased, and detachment of material from the surface became more frequent.

In most cases, the Tgamma approach has been implemented to model the behaviour of the materials as a function of the contact conditions. According to this approach [12], it is assumed that the wear rate (expressed in $\mu g/(m.mm^2)$) is related to frictional work done at the wheel/rail contact, i.e. to the amount of energy available at the contact interface.

This work presents the results of twin-disc tests carried out independently at two laboratories with samples extracted from E8 wheels and premium R400HT rails. The purpose of the experiments was to identify the wear regime transitions and to compare the behavior of the premium rail with that of softer materials already reported in the literature.

2. Materials and Methods

Work was carried out to produce wear rate and coefficient of friction (COF) curves under different slip ratios for hardened rail material (R400HT) in contact with standard wheel material (E8). The chemical compositions

measured by optical emission spectroscopy is shown in Table 1.

Table 1. Chemical composition of rail and wheel samples (wt %)

Element	R400HT	E8
C	0.931	0.542
Si	0.251	0.253
Mn	1.269	0.734
P	0.0095	0.011
S	0.022	0.006
Cr	0.275	0.141
Mo	0.068	0.006
Al	<0.0002	0.027
V	0.0035	0.006
Cu	0.017	0.165
Ti	0.0024	0.002

Twin disc tests were performed at the National University of Colombia and at the University of Sheffield, UK under identical conditions to evaluate the reliability of inter-laboratory testing as well as its limitations for practical purposes. All the tests were conducted in dry conditions with a 1300 MPa contact pressure and 400 rpm rotational speed. The tangential force between the discs was measured during the tests to calculate the energy dissipated in the contact per unit area (Tγ/A) (Tgamma approach). Ten different slip ratios varying from 0 to 20% were used. Four tests were performed for each slip value: 2 in the UK, and 2 in Colombia, except for the tests with slip ratios of 15% and 20%, which were carried out in the UK only.

Cylindrical specimens were extracted from actual wheels and rails by cutting and turning on a lathe. The rail specimens were extracted from the rail's head (Fig. 1). Both rail and wheel specimens had the same dimensions: a diameter of 47 mm, and a width of 10 mm.

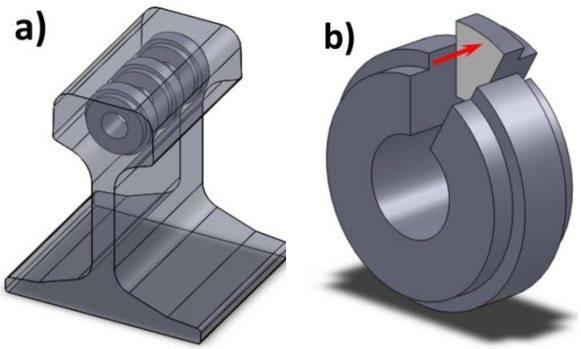

Fig. 1*. a) Extraction of the rail samples for tribological tests, b) cutting scheme for subsurface analysis.*

3. Results and discussion

3.1. *Variation of COF and wear rate with slip ratio*

In Figure 2 the wear rate of wheel and rail samples is plotted against the wear index Tγ/A, where T refers to the tangential force at the contact interface in Newtons, γ is the dimensionless slip ratio, and A is the contact area in mm². The wear rate for the wheel was about one order of magnitude higher than that for the rail for a wide range of slip values. Also, no clear dependence of the wear rate on the wear index was seen when the wear index was between about 25 and 80 N/mm². When the slip ratio was increased to 20%, Tγ/A reaches about 90 N/mm² and the wear rate jumped to more than twice the mean value observed when the wear index was between about 25 and 80 N/mm²; this indicates a transition from a severe to a catastrophic wear regime.

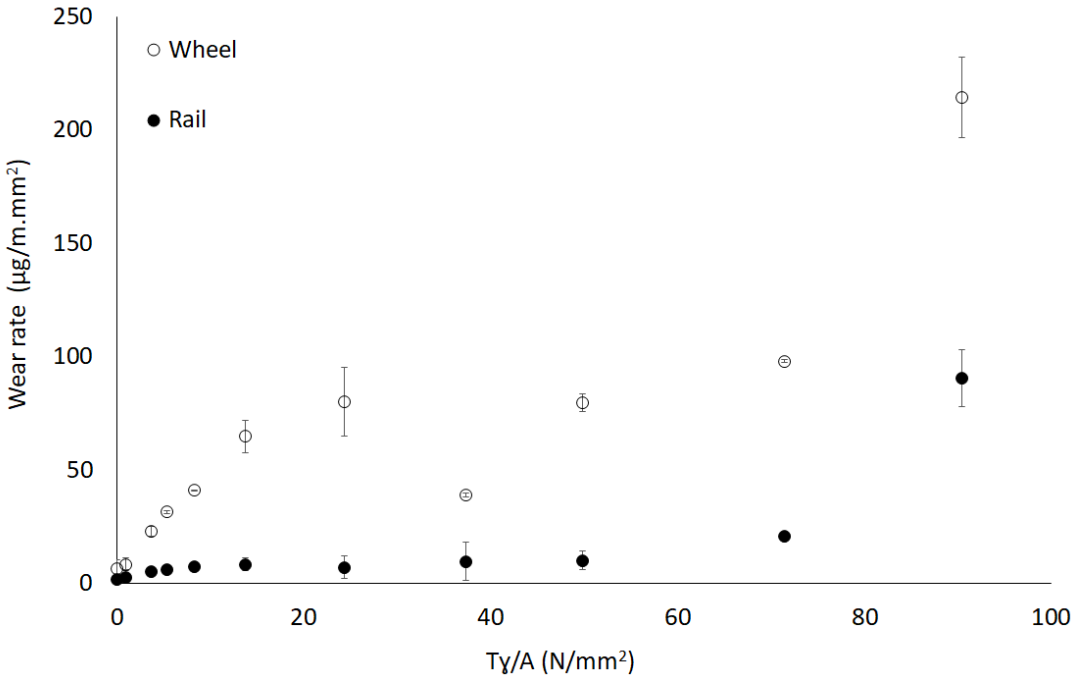

Fig. 2 *Average wear rates for R400HT rails rolling-sliding against E8 wheels for different slip ratios from 0 to 20%*

The detail of the results for wear indices between 0 and 25 N/mm² is shown in Figure 3, where two features become evident: a) for low slip values, a linear relationship between the wear rate and the wear index Tγ/A can be established for both wheel and rail samples, and b) different Tγ/A thresholds can be defined for the wheel and rail samples to mark the end of the linearly dependent region; this is in concordance with previous reports by Lewis & Olofsson [2]. The wear rate of the rail samples does not exceed 100 µg/(m.mm^2) even under the very harsh conditions imposed using a slip ratio of 20%. On the other hand, under such aggressive conditions, the wear rate of the wheel samples significantly increased, as did the magnitude of the surface damage observed at the end of the tests.

Figure 4 shows the COF and the wear rates of wheel and rail samples versus the percentage of slip. The COF initially increases with slip, and then stabilizes around a value of 0.5 for slip values higher than about 7%. For very high slip percentages there is a slight decrease in COF; a value of 0.4 was measured in the tests performed with a slip percentage of 20%.

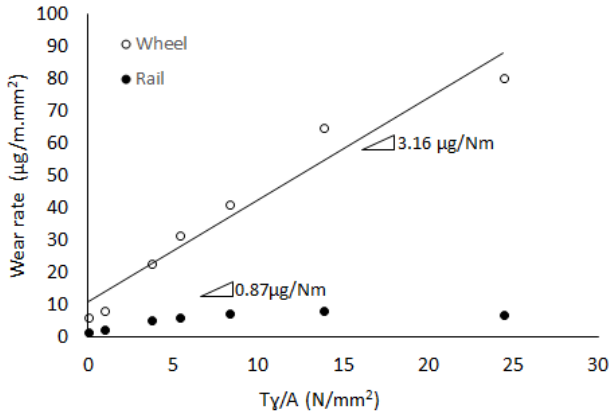

Fig 3 Detail Average wear rates for R400HT rails rolling-sliding against E8 wheels for wear index < 25 N/mm²

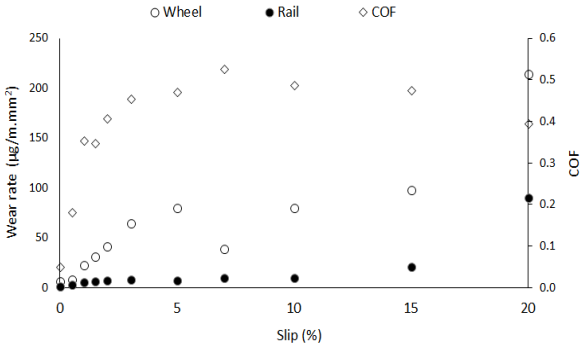

***Fig. 4** COF and wear rates versus slip for R400HT rail rolling-sliding against E8 wheels for different slip ratios*

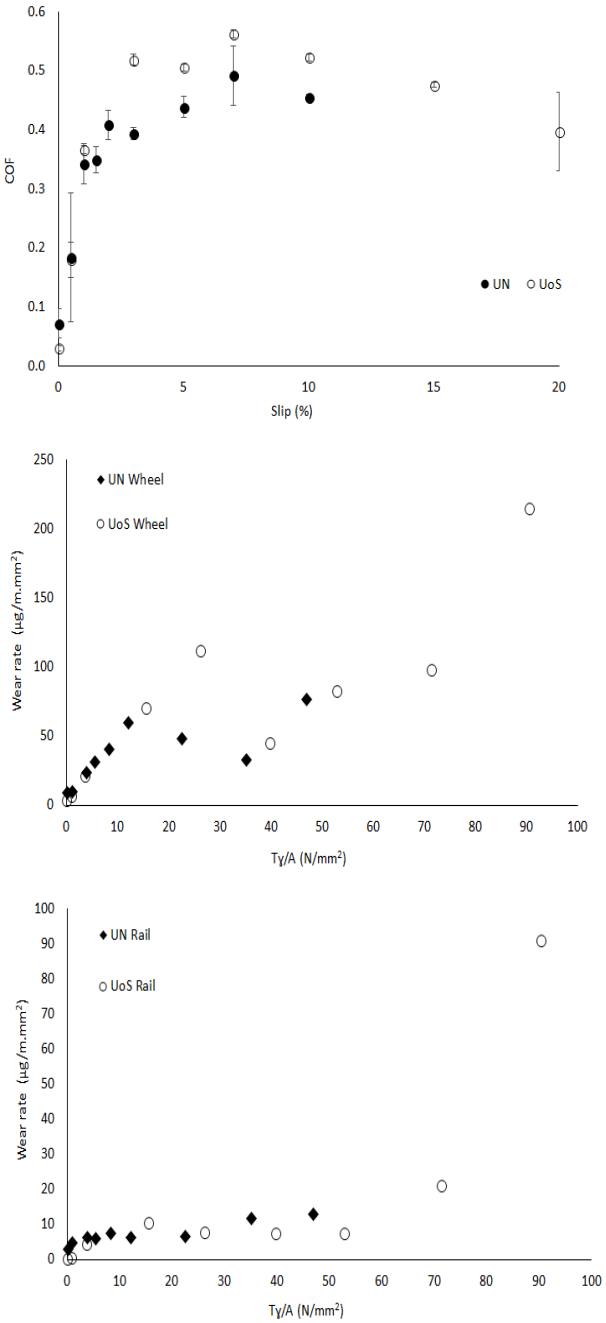
3.2. *Comparison of testing machines*

The results shown in Figures 2 to 4 correspond to the average values of wear rate and COF obtained in similar testing machines installed at the University of Sheffield and Universidad Nacional de Colombia. A comparison between the results obtained from each testing machine is given in Figure 5.



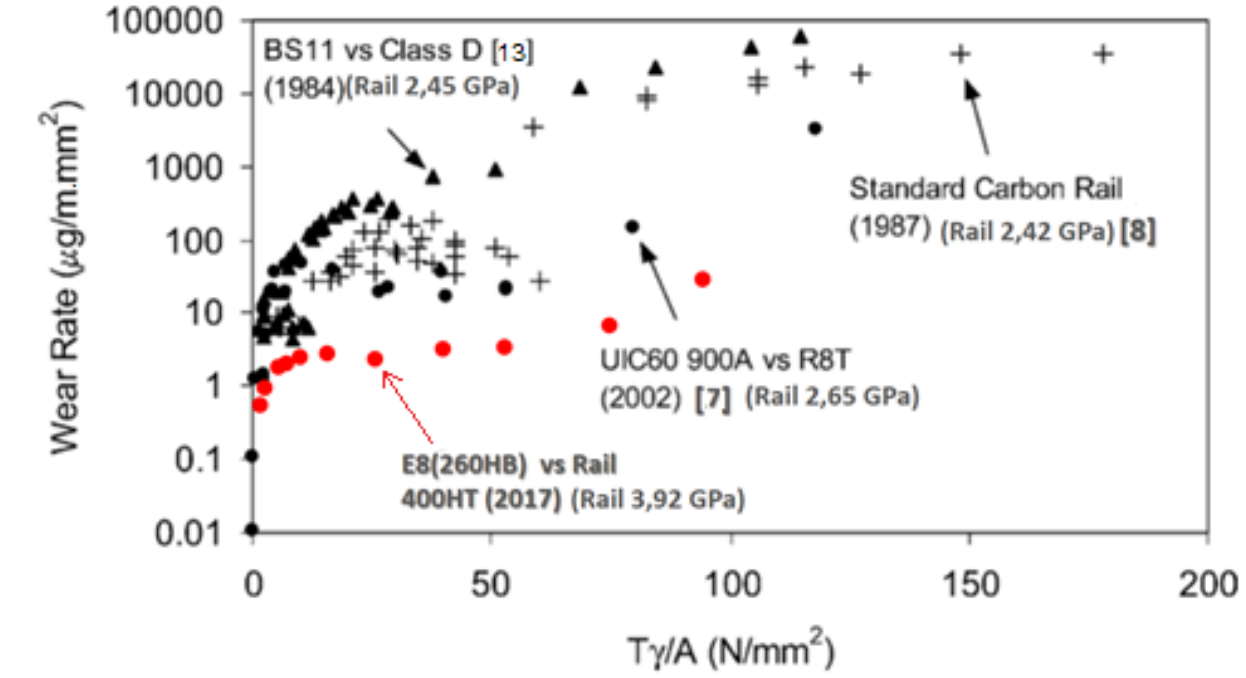


***Fig. 5**. Comparison of wear rates and COF measured in UK (UoS) and Colombia (UN)*

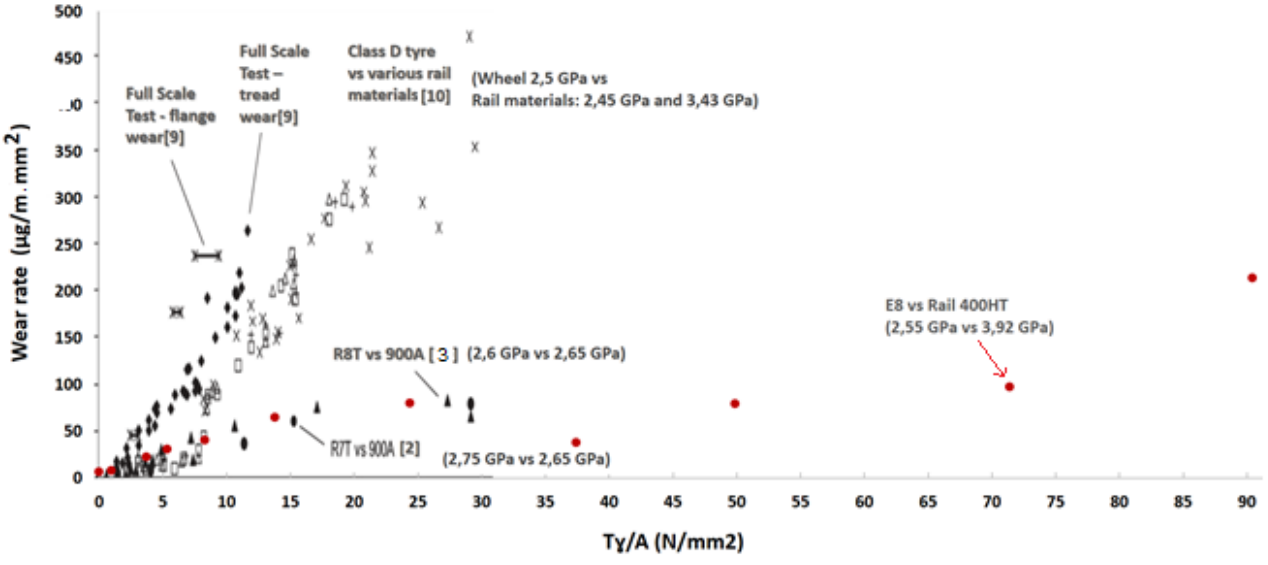

Fig. 5 shows that for slip ratios lower than 3% (wear indexes lower than 15 µg/m.mm^2) the differences between the results obtained in the two twin-disc machines were negligible. As the slip ratio increases the machine installed at Universidad Nacional de Colombia delivered lower friction coefficients (and consequently lower Tγ/A values). Since this deviation depended on the magnitude of the slip ratio it could have been related to the dynamical range of the torque meter used to measure the frictional force at the contact interface, and/or to the stiffness of the sample holders. In any case, the differences are small and the authors consider that the tests performed at both universities are equivalent in terms of their effectiveness to discriminate mild wear regimes from severe and catastrophic wear regimes.

3.3. *Behaviour of premium R400HT rail*

Figure 6 compares the wear rates of R400HT rail (a) and wheel E8 (b) tested in this work to the wear rates reported in the literature for other rail and wheel materials [2,3,7-9,10,13]. Generally speaking, the wear rates for the pair with the R400HT rail material are significantly lower than those for most other contacting pairs for virtually all the Tγ/A values studied. Comparison with the results obtained after tests with Class D wheel material are of particular interest since it has hardness and microstructure similar to the E8 steel studied in this investigation, so the differences in the behaviour of the pairs is mostly associated with the characteristics of the rail materials. It is worth noticing that the measured wear rates for R400HT rail samples were always below 50 μg/(m.mm²) regardless of the value of Tγ/A with the sole exception of the case when Tγ/A was extremely high, about 90 N/mm², while, for instance, the BS11 rail material shows wear rates higher than 50 μg/(m.mm²) even for Tγ//A values as low as 10 N/mm².

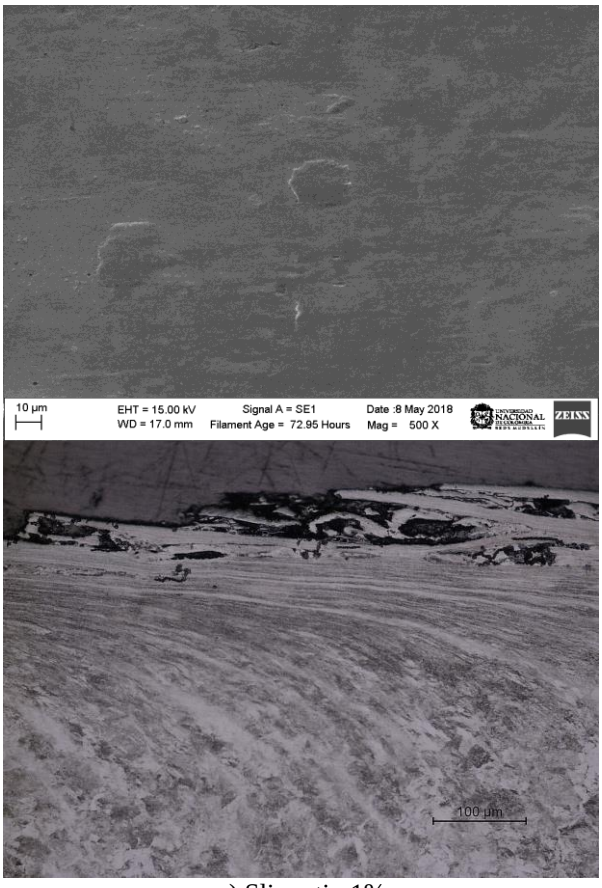
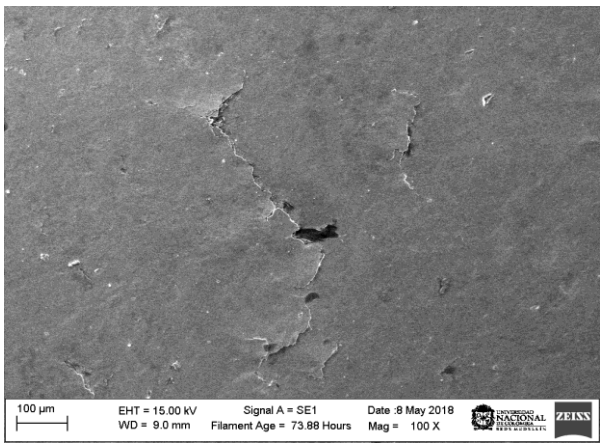
3.4. Damage processes

Fig. 7 shows the typical aspect of the worn surface of rail and wheel samples after the twin-disc tests with 1%, 5% and 10%. Damage in rail samples proceeds mainly by ratchetting and surface cracking, while in wheel samples spalling and adhesive wear are the predominant mechanisms.

a) 1% slip ratio



b) 5% slip ratio



c) 10% slip ratio

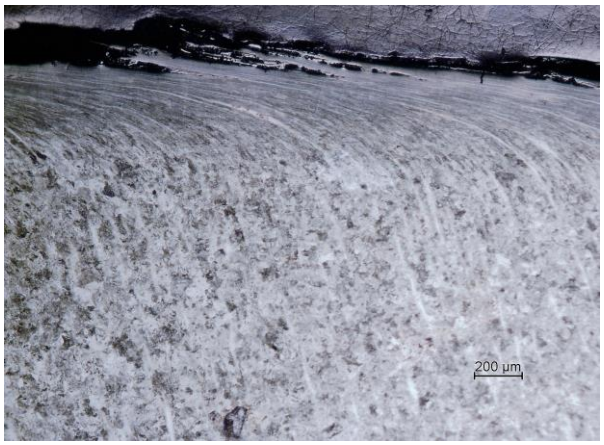


Fig. 7. *Aspect of the worn surface of wheel and rail samples after twin-disc tests with different slip ratios.*

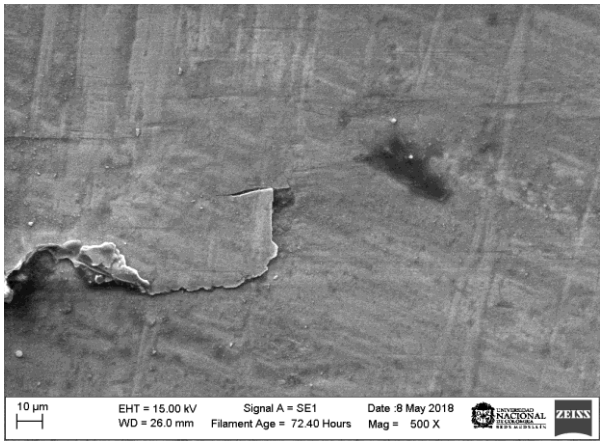
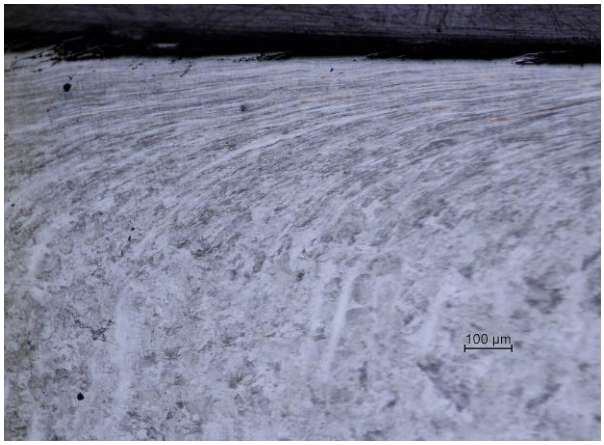
Figure 8 presents SEM images of the worn surface and LOM images of the cross section of rail samples after tests with slip ratios of 1%, 5%, and 10%. Ratchetting marks and small surface cracks are evident in samples tested with 1% slip ratio, in which the mean angle of propagation of the cracks with respect to the surface is circa 5º. After the tests with 5% slip ratio the ratchetting marks become larger and the overall damage of the surface is more intense, while for 10% slip ratio the amount and size of the wear marks reduce again and the surface is somehow similar to that observed after the tests with 1% slip ratio. The crack angle increases with the slip ratio to a value around 12 º for slip ratio 10% as shown in Figure 9, in which can also be seen that the depth of the deformed layer reaches a maximum of 365 µm at 5% slip ratio and then decreases to circa one third of that value at 20% slip ratio. These results are consistent with the observed variation of microhardness with the distance from the surface as illustrated in Figure 10. Changing the slip ratio from 1% to 5% causes a significant increase in the hardness near the contact surface as well as and in the depth of the hardened layer. On the other hand, when the slip ratio increases to 10% the depth of the hardened layer is just slightly larger than that observed for slip ratio 1%. Further increases in slip ratio lead to a softer surface despite the strain hardening process being more intense for larger slip ratios. This is caused by the removal of external, harder layers, of material due to sliding friction, leaving sub-surface, softer layers, as “new” surfaces.





a) Slip ratio 1%

b) Slip ratio 5%

c) Slip ratio 10%

Fig. 8. *Aspect of the worn surface and cross section of premium R400HT rail after twin-disc tests with different slip ratios.*

If the frictional force at the surface increases, the angle of the cracks also increases, which is in accordance with the theoretical model of slip lines associated with plastic deformation due to the contact stresses. On the other hand, the depth of the plastically deformed layer decreases with the slip ratio because of the increasing effect of sliding wear with greater friction forces, similar to what is observed in many cases in the field, where the right amount of sliding wear accounts for partial removal of damaged material from the surface and helps prevent the unsafe growth of cracks. In the laboratory tests, however, this effect prevailed only when the slip ratio was larger than 5%.

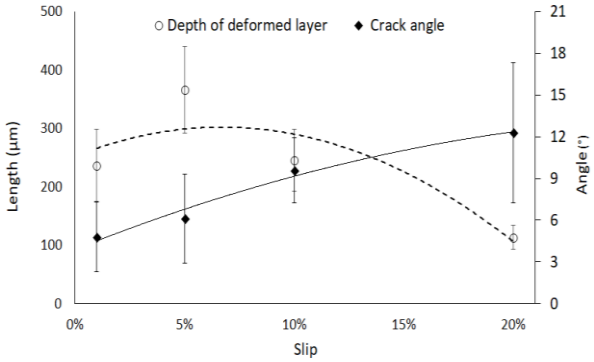


Fig. 9. *Variation of mean crack angle with respect to the surface and depth of deformed layer as a function of the slip ratio for premium R400HT rail.*

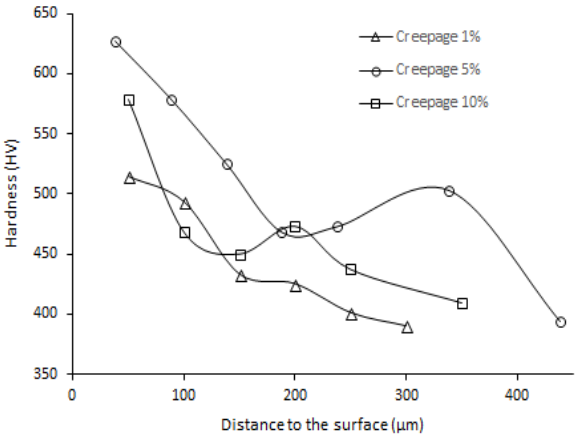

Fig. 10. *Variation of microhardness of premium R400HT rail as a function of the distance from the worn surface for three different slip ratios.*

In terms of the dominant wear mechanisms, the size and amount of ratchetting marks clearly increase with the slip ratio, and the variations of surface finishing parameters can be used as indicators of the magnitude of the damage experienced by the worn surface. Fig. 11 shows the variation of several roughness parameters due to the contact conditions imposed by the twin-disc tests.

The roughness parameters that showed significant changes after the tests for different slip ratios were Rq (Root mean square deviation of the assessed profile), Rku (Kurtosis of the assessed profile), Rp (Maximum profile peak height of the assessed profile), Rv (Maximum profile valley depth of the assessed profile) and Rpc (Linear density of peaks of the assessed profile). Before

the tribological tests Rq, Rku, Rp and Rv were small (below 12 µm) and the surfaces were homogeneous with a high Rpc.

Cracking and spalling can be related to the increase of Rv, Rp and Rku and the decrease of RPc (especially in the transverse direction). This is in accordance with other studies of damage accumulation and crack initiation detection, such as the work of Hiensch and Steenberger [1], who demonstrated that the number of peaks and valleys decrease as the sliding percentage increases, and that the effect can be appreciated by the naked eye if the slip ratio is high enough. The results of the present work indicate that the rate of variation of Rv and Rp with slip ratio is higher than that of Ra and Rq, which means that average descriptors are less sensitive to the changes imposed to the surface by the contact conditions.

It is worth noticing that Kurtosis increased significantly in both directions of measurement for slip ratios up to 3% and then decreased. According to Ghosh and Sadeghi [14] this informs about changes in the real area of contact during the tests since it is larger for surfaces with low kurtosis values and becomes smaller as the roughness profile begins to show more extreme deviations with respect to the mean descriptors. After the tests, the roughness measurements taken transversal to the rolling-sliding direction provided less information since the variations were normally very small. On the other hand, the measurements in the rolling-sliding direction revealed a significant variation of all the parameters, which is consistent with the fact that typical RCF marks, such as ratchetting marks, appear distributed uniformly across the width of the samples but present significant variations of height in the direction of rolling.

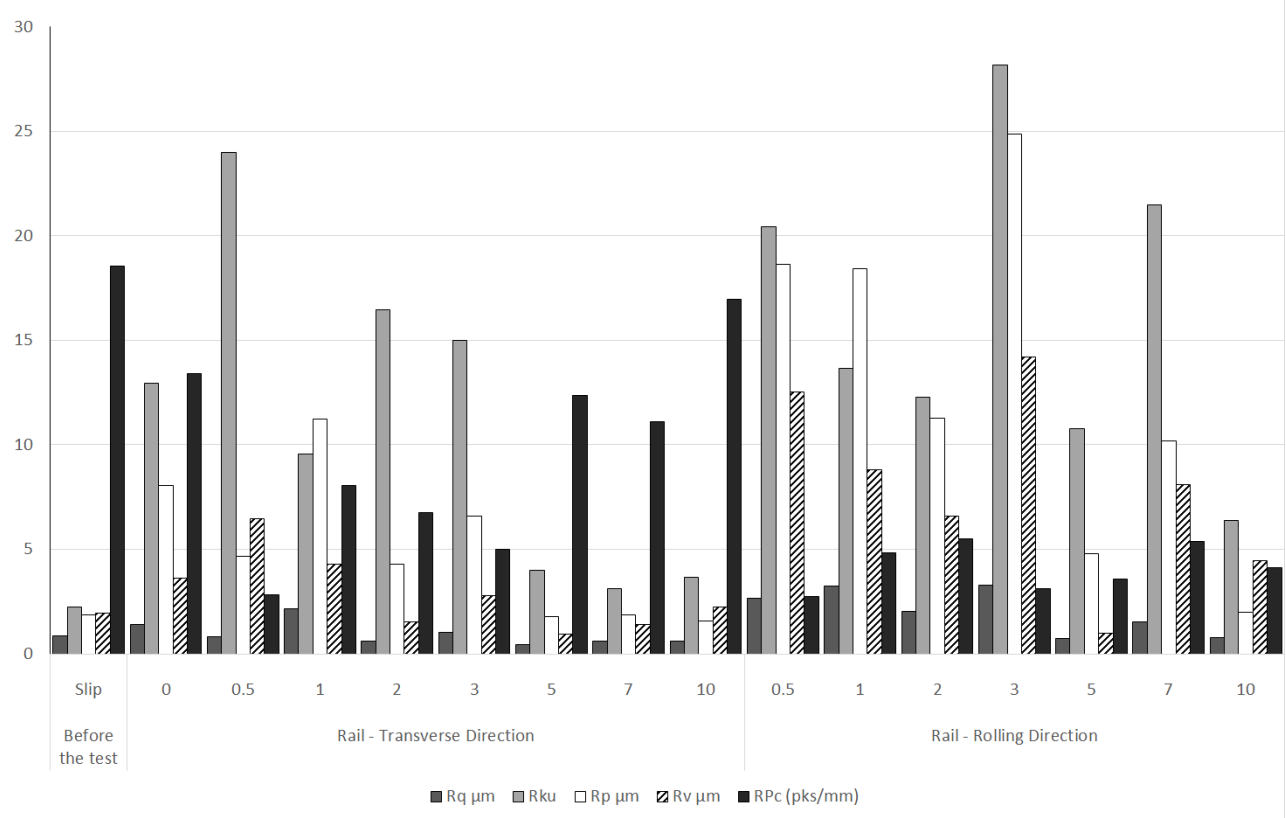

Fig 11.*Variation of roughness parameters of premium R400HT rail with twin-disc tests.*

4. Conclusions

The wear rates of premium R400HT rail and E8 wheel samples were determined as a function of the energy provided to the contact interface in laboratory twin-disc tests. An initial contact regime was observed in which the wear rate increased linearly with the wear index $T\gamma/A$ for both wheel and rail samples. A second stage, characterized by the independence of the wear rate and wear index, was also easily identified, with a stable wear rate for the rail samples approximately one order of magnitude lower than that of the wheel samples. For very high slip values, considerable damage at the surfaces was observed, which is consistent with a second regime transition to a catastrophic condition.

The wear rates of both R400HT rail, and E8 wheel materials measured in twin-disc tests were systematically lower than those reported by other researchers in tests performed with softer rail materials. The threshold values of the wear index $T\gamma/A$ related to wear regime transitions were also lower when the hardened rail material was used.

Comparison between testing machines in the UK and Colombia showed that the results were completely interchangeable for slip ratios lower than 3%. For higher slip ratios, the results were still comparable but there was

a trend for the machine installed in Colombia to produce friction values lower than those obtained in the UK.

The COF reached stable values of around 0.5 in twin-disc tests of the pair R400HT rail versus E8 wheel after 6-7% slip. When the slip was very high (20%), however, a slight reduction of friction was observed.

Abstract: Chinese high-speed train's wheel tends to encounter higher-order polygon wear in the circumference direction after several operation mileages. The wheel higher-order polygon wear intensifies wheel/rail dynamic interaction, resulting in parts failure of rails and bogies, deteriorating ride comfort of the vehicle. The issue of high speed train wheel polygonization needs to be solved urgently. this paper explores the wheel polygonal formation mechanism of the high-speed train. The rail system dynamics simulation model has been established, which illustrates how about wheel polygonization frequency generate from the rail. With the large number of dynamic test and wheel roughness level measurement carried on Chinese high-speed trains, the wheel OOR formation and evaluation were obtained.

Keywords: Wheel polygonization; Cutting process; Self-excited vibration; Modal analysis; Polygon frequency; Formation mechanism.

1. Introduction

With the number of the high-speed railway lines increasing, the high-speed train wheel tends to encounter higher-order polygon wear in the circumference direction after several operation mileages. The wheel higher-order polygon wear intensifies wheel/rail dynamic interaction, generates wheel/rail impact vibrations with high frequency, resulting in parts failure of rails and bogies and deteriorating ride comfort of the vehicle. As we see, wheel polygonization has aroused more and more concern of the railway departments, the issue of high speed train wheel polygon needs to be solved urgently.

Currently, research home and abroad mainly focuses on the problem of the wheel 1~5 order polygon [1]-[9]. At present there is no effective measures to fundamentally solve the problem.

Based on the existing research home and abroad on wheel polygonization in the fields, like railway, automobile, mechanical processing, this paper explores the wheel polygonal formation mechanism of the high-speed train. Specifically, considering wheel polygonization, the rail system dynamics simulation model has been established, which illustrates how about wheel polygonization frequency generate. With the large number of dynamic test and wheel roughness level measurement carried on Chinese high-speed trains, the wheel OOR formation and evaluation were obtained.

2. Wheel higher-order out-of-round roughness and wear formation mechanism

Considering the formation of cutting marks in cutting progress, as Fig.1.

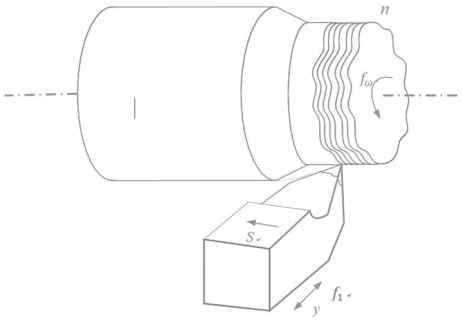

Figure 1 *Cutting progress*

In the conventional theory, the mechanism of cutting marks formation in metal cutting vibration has been treated as a sample reproduction of tool-work vibration. Therefore, the number of cut marks on the surface of the workpiece which are caused by the frequency of the relative vibration can be obtained by the relative vibration frequency dividing by the workpiece rolling speed. The number of marks is given by the followed equation:

$$n = \frac{f_1}{f_\omega}$$

where f_1 reference the vibration frequency between tool and workpiece, and f_ω means the rotation frequency of the workpiece.

Taking example by cut marks formation mechanism, the edge number of wheel higher-order polygon is approximately equal to the ratio of the excitation frequency caused by the wheel/rail vibration system and the rolling frequency of the wheel. It can be considered the high-speed train wheel polygon is caused by self-excited vibration between wheel and rail system.

Wheel polygon is the sample reproduction of wheel/rail vibration.

A wheel-rail contact simplification system was established to analysis the wheel polygonization

formation process. We call it the illustrated wheel-rail contact regeneration flutter system. If the system is stable, the system will be automatically restored to the initial equilibrium state after the system is subjected to external shocks or its own regenerative effect is too large to jump out of flutter. At this time, even if the excitation frequency between wheel and rail cannot be divisible by the rolling frequency of wheel, but the remainder is small, after a limited number of cycles the wheel and rail contact normal force back to the initial position, and the cumulative phase difference will be reset. As we see, the wheel-rail contact force is always close to a large or minimum value in a same phase, perform as the wheel tread wear, that is, wheel polygon wear.

After that, the vibration cause by wheel polygonization was considered into the system. Compared with the machine cutting chatter. This model satisfies two typical characteristics of machine cutting chatter model.

After the wheel polygon wear generated, the vibration of axle box will produce wheel frequency multiplier components. This high-order multiplier is the result of the interaction between the bogie wheel and the rail. In response to the axle box, the corresponding frequency is also disturbed in the rail structure itself, which acts as a forced harmonic excitation on the rail. As we know, the high frequency vibration component of the axle box caused by the polygonal wear is very close to the third order vertical bending mode frequency of the rail. At this time, it can be considered that wheel-rail contact system locates in the damping control region, as well the resonance area, the vibration amplitude will be significantly amplificated, resulting in the rapid development of wheel polygonal wear.

2.1. Wheel high order out of round roughness frequency statistics

Aiming at explaining the difference of the polygonal frequency of the common vehicles in the high-speed railway system of China, a large number of dynamic test and wheel roughness level measurement were carried out by Traction Power State Key Laboratory of SWJTU.

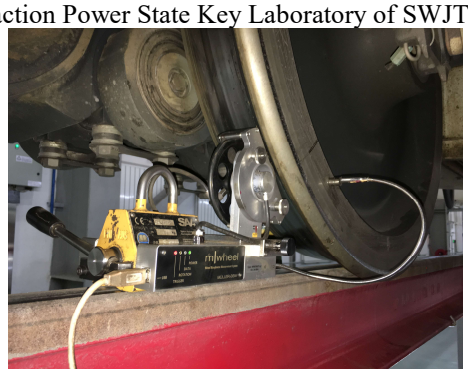

Figure 2 *Wheel OOR Measuring and test device*

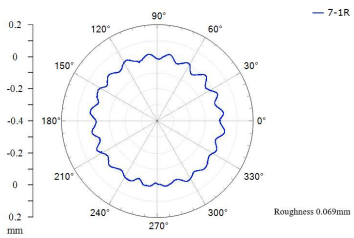

Figure 3 *Measured Roughness of wheel with typical polygon.*

Figure 4 *Roughness Level of wheel with typical polygon.*

The measuring device and a typical wheel polygonization are illustrated in Figure 2-Figure 4.We have already measured wheel roughness level in almost all high-speed train in China high speed railway system.

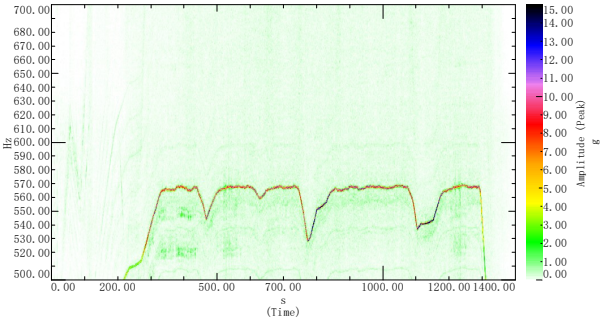

Figure 5 *Short time Fourier translation of an axlebox acceleration with typical wheel polygonization*

Figure 5 shows a short time Fourier translation of axlebox acceleration, in the whole frequency band, the vertical vibration of the axlebox has the dominant frequency of 560-580Hz, which is change with the speed and acted as multiple of the wheel rotation frequency.

Through a large number of wheel roughness and bogie dynamic data analysis, as

Table 1 shows.

Taking the CRH3C and CRH380BG as an example, the suspension parameter and structure of CRH380BG is close to the CRH3C, and the bogie is almost the same. The running speed of the CRH380BG and CRH3C also the same, 300km/h, but the wheel polygonization frequency is very different. When CRH3C running on Wuhan-Guangzhou high speed railway the wheel polygonization frequency of is close to 580Hz, the polygon frequency of CRH380BG on Haerbin-Dalian high-speed railway is close to 630Hz, which is significantly larger than CRH3C's. For the CHR5 running on the Lanzhou- Urumqi High speed railway and the CRH380D running in the Chengdu-Chongqing high speed railway, the bogie has the same wheelbase, 2.7m, and both two railway's unballasted track structure is the CRTS-1 double block with the sleeper span of 650mm. As the running speed of these two train is very different, but the wheel polygonization frequency are close, around 540Hz, respectively, for its of 27 times and 18 times the wheel rotation frequency.

Although wheel polygonization of different types EMU have different wavelengths and frequency, there are some common features determined by wheelbase of bogie and type of unballasted track, with the following characteristics:

- Wheel polygonization frequency is closely related to unballasted track type (sleeper span)
- Wheel polygonization and the speed of the

vehicle has little relationship

- Wheel polygonization is closely related to bogie wheelbase.

Table 1 *Wheel high order out of round roughness frequency statistics*

High speed Railways	Unballasted track type	Sleeper span mm	Wheelbase m	Velocity km/h	Polygon frequency Hz
Haerbin-Dalian	CRTS-I Plate	629	2.5	300	650
			2.5	300	643

Shanghai-Kunming	CRTS-I Double Block	650	2.5	300	550
Lanzhou-Urumqi	CRTS-I Double Block	650	2.7	200	557
Chengdu-Chongqing	CRTS-I Double Block	650	2.7	300	530

In terms of the dynamic test of bogie with wheel higher order OOR, it can be estimated there is about 500-650 Hz excitation vibration from elastic modal of wheels or rails. Namely, the vibration frequency may be caused by the wheelset, rail and wheel- rail coupling vibration.
Combined with the above statistical characteristics, we tend to consider the wheel vibration frequency generated form the rail, as two totally different bogie, with different wheel diameter, different bogie structure, different suspension parameter on a same high-speed railway acted the same wheel polygonization frequency. However, while the type of unballasted track is different, the wheel polygonization frequency is different, too.

2.2. The reasons of wheel/rail 500-650 Hz band harmonic

As Figure 6 shows, a rail between the bogie wheel base is considered as a Timoshenko continuous beam of length L and with 5 intermediate flexible supports. The elastic support, the rubber pad and rail fastener under the rail are unified as the support stiffness of the rail.

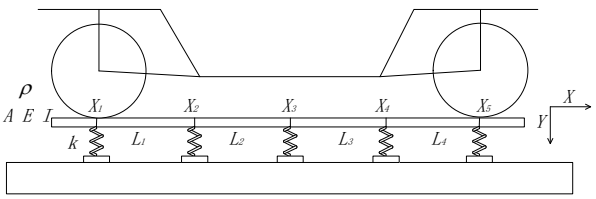

Figure 6 *rail between the bogie wheel base is considered as a Timoshenko beam*

The rail is divided by 3 support point and the length of each segment is L_i, absolutely, the total length of 4 segment equal to the wheelbase of the bogie.
According to the Timoshenko theory, for each segment, we have the following equation:

$$EI\frac{\partial^4 Y_i(X,T)}{\partial X^4}+\rho A\frac{\partial^2 Y_i(X,T)}{\partial T^2}-\rho I\left(1+\frac{E}{\kappa G}\right)\frac{\partial^4 Y_i(X,T)}{\partial X^2\partial T^2}+\frac{\rho^2 I}{\kappa G}\frac{\partial^4 Y_i(X,T)}{\partial T^4}=0 \quad (1)$$

$$EI\frac{\partial^4 \Phi_i(X,T)}{\partial X^4}+\rho A\frac{\partial^2 \Phi_i(X,T)}{\partial T^2}-\rho I\left(1+\frac{E}{\kappa G}\right)\frac{\partial^4 \Phi_i(X,T)}{\partial X^2\partial T^2}+\frac{\rho^2 I}{\kappa G}\frac{\partial^4 \Phi_i(X,T)}{\partial T^4}=0 \quad (2)$$

Where E and ρ are the Young's modulus and the density of rail material. G is the shear modulus of the material, A is the rail cross section area, I is the moment of inertia of the CHN60 rail section, κ is the Timoshenko shear coefficient which is a function of the rail cross-section and Poisson's ratio v.
For the contact point of wheel and rail, we considered it as a contact spring, and we considered the constraint on

the ends section of the rail as the symmetric constraint. For simplified situation, we regard the boundary condition as simply supported [9]:

$$Y(0,T) = Y(L,T) = 0 \quad (3)$$

$$\Phi'(0,T) = \Phi'(L,T) = 0 \quad (4)$$

The compatibility conditions between each segment beam are:

$$Y_i(X_i^-,T) = Y_{i+1}(X_i^+,T) \quad (5)$$

$$Y_i'(X_i^-,T) = Y_{i+1}'(X_i^+,T) \quad (6)$$

$$EI\Phi_i'(X_i^-,T) = EI\Phi_{i+1}'(X_i^+,T) \quad (7)$$

$$\kappa GA[Y_i'(X_i^-,T) - \Phi_i(X_i^-,T)] = \kappa GA[Y_{i+1}'(X_i^-,T) - \Phi_{i+1}(X_i^-,T) - SY_i(X_i,T) \quad (8)$$

We used the matrix transformation method[10]错误!未找到引用源。 to solve the modal, which has the following form of solution:

$$y_i(x,t) = [A_i\cosh(\lambda_1(x-x_{i-1})) + B_i\sinh(\lambda_1(x-x_{i-1})) + C_i\cos(\lambda_2(x-x_{i-1})) + D_i\sin(\lambda_2(x-x_{i-1}))]\,e^{j\omega t} \quad (9)$$

$$\phi_i(x,t) = [B_iq_1\cosh(\lambda_1(x-x_{i-1})) + A_iq_1\sinh(\lambda_1(x-x_{i-1})) - D_iq_2\cos(\lambda_2(x-x_{i-1})) + C_iq_2\sin(\lambda_2(x-x_{i-1}))]\,e^{j\omega t} \quad (10)$$

So, we have the frequency equation:

$$\det\begin{bmatrix} r_{12}(\omega) & r_{14}(\omega) \\ r_{22}(\omega) & r_{24}(\omega) \end{bmatrix} = 0 \quad (11)$$

Take CRH3 running on the track type CRTS-II in Chinese highspeed railway as an example. The sleeper span is 650mm, and the wheelbase is 2500mm. For a simplified situation, $L_1 = L_4 = 600mm$, $L_2 = L_3 = 650mm$. Take these parameters into the equation (1)-(11), First five-order vertical bending mode frequency of the rail between the bogie wheelbase are presented in Table 2.

In Table 2, the 4th order mode frequency corresponding to the vertical Pined-Pined modal of the rail, and we noticed the 3rd order mode frequency is really close to the wheel polygonization frequency of Chinese high-speed railway train on the CRTS-II rail track.

Table 2 *First five-order vertical bending mode frequency of the rail*

Support Stiffness	Frequency (Hz)				
	1st	2nd	3rd	4th	5th
20 MN/m	140.46	318.15	592.26	914.3	1217.41

Figure 7 shows the first five-order vertical bending modal shape of the rail, the amplitude normalization processing was made for contrast in that data. The 3rd order modal corresponding to the 592.26Hz contain one and a half sine wave between the bogie wheelbase.

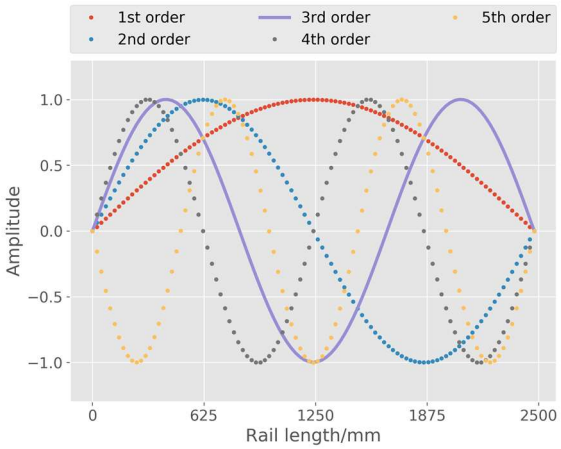

Figure 7 *First five-order vertical bending modal shape of the rail*

2.3. Field Measurement verification

As a continuous body, the rail is discretely supported on the fastener and the rubber mat; there are various modal frequencies exist in both the vertical and horizontal directions. First, for the common 60kg/m rail on CRTS-II unballasted tracks, we tested its free modal response without any vehicle on it. As Figure 8 shows, the rail is subjected to vertical impact as there is no vehicle load, and there are modal frequencies of about 385Hz, 502Hz, and 615 Hz, but no frequency around 580 Hz.

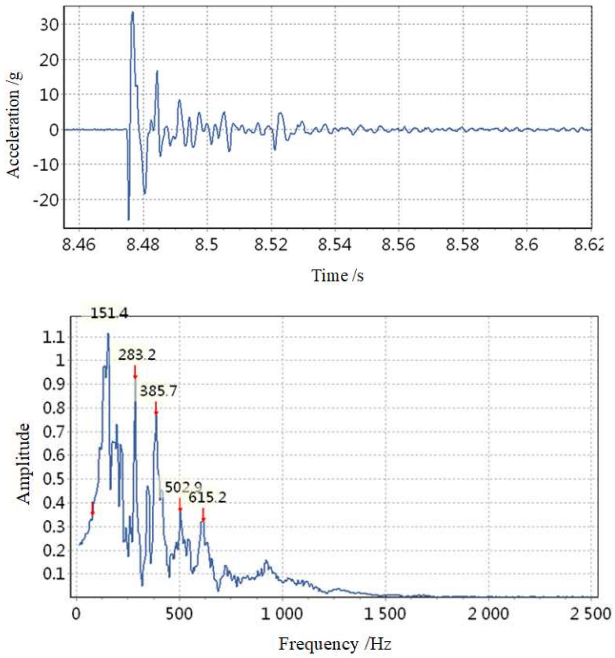

Figure 8 *Time domain and frequency domain response of free rail*

The vibration is transmitted in rail at speed 1700m/s, and the damping ratio of 3%.

After that, we put two bogies on the rail and tested the vibration characteristics of rails between adjacent wheelsets of two bogies. As Figure 9 shows.

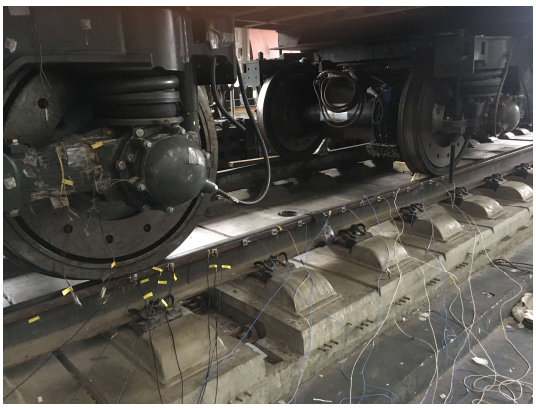

Figure 9 *vibration characteristics of rails between wheelsets*

In order to simulate the difference of the vibration characteristics of the rail when the wheelbase of the bogie is different, we moved 2 bogies to vary the spacing of two adjacent wheelsets from 2200mm to 3000mm. We used the PloyMAX method to calculate the rail modes .
Figure 10 illustrates the third-order modal frequency between the rails decreases with the increase of the wheelbase of the bogie.

Table 3 *The relationship between wheelbase and the first three-order vertical bending mode frequency of rail*

Wheelbase mm	1st order Hz	2nd order Hz	3rd order Hz
2350	222	408	660
2500	216	339	591
2700	213	331	530
2850	190	298	500
3000	180	287	488

The third-order modal damping ratio of 2500mm wheelbase is 3.21%.

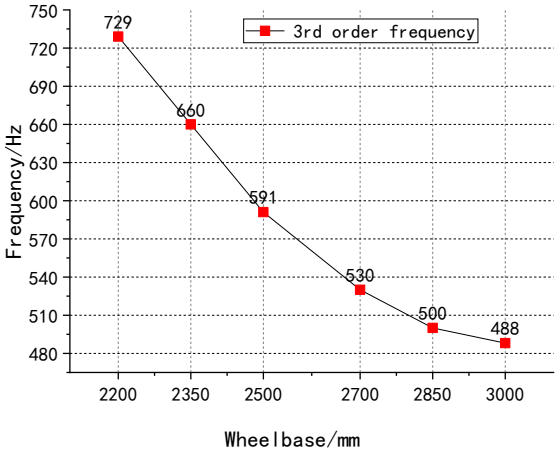

Figure 10 *The relationship between wheelbase and the third-order vertical bending mode frequency of rail*

It is worth noting that at the 2500mm wheelbase, the third-order vertical bending modal frequency of the rail is 591Hz, which is consistent with the wheel polygonization frequency when the 2500mm wheelbase bogie is running on the CRTS-II unballasted track.

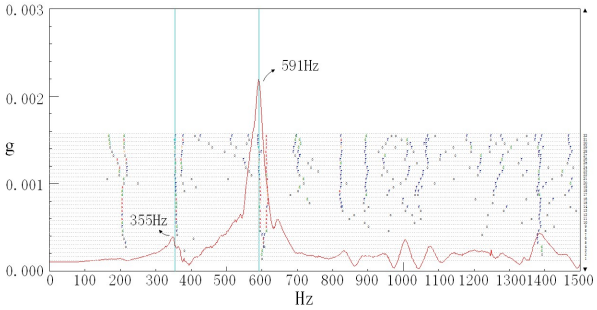

Figure 11 *cross power spectrum density of rail*

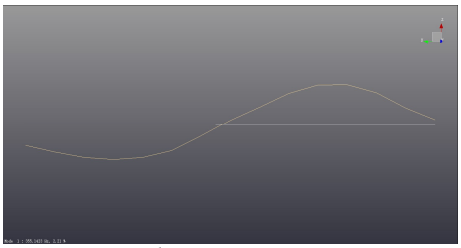

Figure 12 *2nd order vertical bending modal*

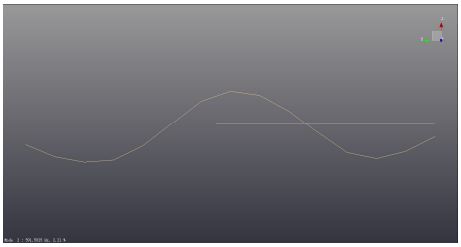

Figure 13 *3rd order vertical bending modal*

Figure 10 to Figure 12 illustrate the cross-power spectrum density, second and third order vertical bending modal shape of the rail between the wheelbase.
It can be found form the modal test that the third-order vertical bending frequency of the rail is 591 Hz, which corresponds to the largest amplitude in the cross-power spectrum.
The 591 Hz is consistent with the above mentioned theoretical calculation of the Timoshenko continuous beam, and is also consistent with the third-order bending frequency of the rail under the 2500 mm wheelbase.

3. Formation and evolution of wheel polygonization

3.1. Initial wheel polygonization formation

According to the formation mechanism of the wheel polygon, the high frequency around 580 Hz vibration between the wheel and rail causes the vertical force change between the wheel and rail, and the wave wear is formed on the wheel tread. The wavelength can be calculated by:

$$L = \frac{v}{f}$$

Where v stands for the running speed in $\mathrm{m/s}$ and f is the vertical vibration frequency between wheel and rail in Hz.
When the wheel tread has initial defects such as scratches, each time the defect impacts the rail, the rail mode will be excited, and the wheel tread worn in the relative fixed

position ($n \times L$, where n stands for the number of waves corresponding to the vibration attenuation to 2/3 of initial). As the rail vibration continues to decay, the farther the position from the initial defect, the less wear on the wheel tread.

The 3rd order modal vibration of the rail affects both wheels on the same side of the bogie. In the same way, rail vibration is transmitted to the wheels of adjacent bogies. Figure 14 illustrates how the wheel polygonization affects adjacent wheelsets. The vibration of four axlebox occur beat vibration as there are minor difference in the polygonization frequency of two wheelsets due to the difference of wheel diameter. It means that the vibration of the first axle has a transmitted to the second axle via rail.

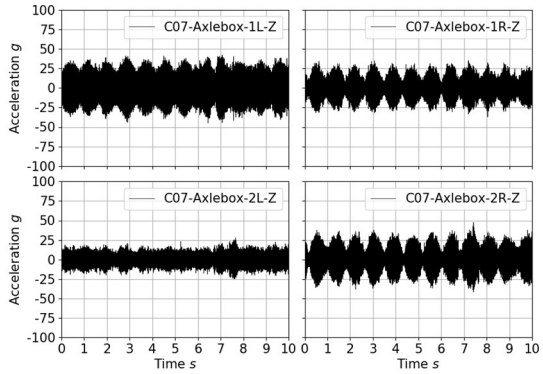

Figure 14 *Beat vibration of 4 axlebox on a same bogie.*

This is why the wheel on the same side of the bogie always have the same level of roughness of wheel OOR, and there is difference in the roughness level of wheels in a same wheelset.

As the running mileage increases, the wavy wear of the wheel tread increases, the new wavy wear continuously enlarges the vibration between wheel and rail, and continues to extend forward and backward, gradually forming a continues wavy wear in a wheel circle when the wheel circumference is an integer multiple of the polygon wavelength. In this situation, the wavy wear will be connected end to end, creating an initial regular polygon wear.

When the wheel circumference is not an integer multiple of the wear wavelength, the initial polygon wear is not a complete polygon, the wear position of the wheel in each turn is inconsistent, the wear shape is not a regular polygon. This is why polygon wear is not common under certain wheel diameters.

Figure 15 illustrates a typical wheel polygonization caused by initial tread flat.

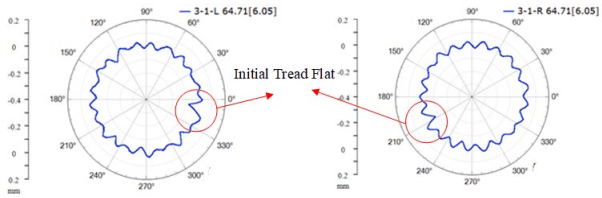

Figure 15 *Initial tread flat and wheel polygonization*

3.2. evolution of wheel polygonization

After the wheel regular polygon wear is formed, the wheel polygonization causes the rail vibration, and the regenerative vibration occurs. The wheel-rail system resonates near the third-order bending frequency of wheel, and the polygon wear is accelerated. As the mileage increases, the wheel roughness level grows continuously. When the amplitude reaches a certain level, the wheel-rail impact vibration occurs. The wheel-rail impact excites the larger wheel-rail vibration. The wheel polygon grows exponentially and rapidly, and the wheel and rail vibrate violently. The intense resonance will lead to structure damage of rail and bogie.

Figure 16 illustrates the evolution of axlebox at 300-850Hz between a wheel reprofiling interval. The test sensor was assembled on the axlebox of a CRH380CL motor bogie, which mainly running on the Beijing-Shanghai high speed railway at 300km/h. As long as the vehicle is operating normally, the test data will remain sampled. Through statistical processes from daily accumulated running data, the mean maximum and root mean square of vertical acceleration of the axlebox keep stable before day index 56, after that, the statics of axlebox acceleration is abrupt increase at 300-850Hz. Figure 16 illustrates the mean max acceleration of axle box increase from 5g to 15g. Other than this, the wheel roughness measurement indicates the wheel tread of the dynamic test vehicle appear wheel polygonization form day index 56.

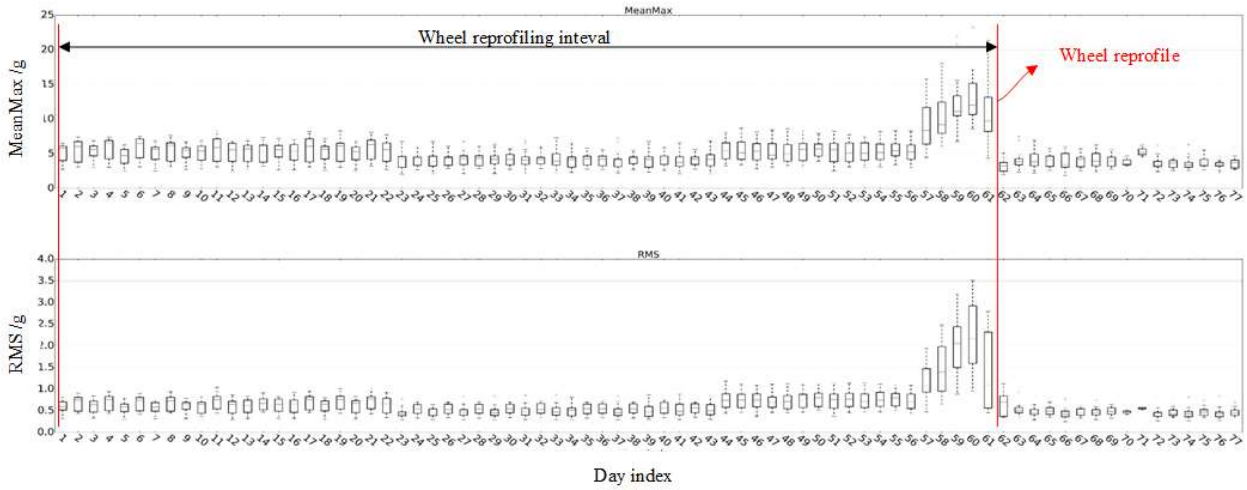

Figure 16 *Axlebox acceleration evolution at 300-800Hz*

4. Conclusions

Based on the calculation of rail modal vibration response, wheel polygonization measurement, and the field measurement verification. This paper explores the wheel polygonal formation mechanism of the high-speed train, illustrates the high order wheel polygonization frequency generate for the 3rd vertical bending modal of rail between bogie wheelbase. Based on the long-term dynamic test, the wheel OOR formation and evaluation were obtained.

Abstract: Rail wheel contact at switches and crossings (S&Cs) induces impact stresses along with normal and shear contact stresses, resulting in plastic deformation and eventually crack formation. A damaged and deformed wing rail of a manganese steel crossing is studied. This includes a characterization of the microstructure, hardness and 3D crack network. The surface of the rail receives the maximum deformation resulting in a hardened top layer. The deformation is manifested in a high density of twins in the microstructure. A complex crack network is revealed in high resolution by X-ray tomography.

Keywords: Switches and crossings (S&Cs); deformation; 3D X-Ray tomography; 2D & 3D crack network; rolling contact fatigue (RCF); rail steel grades

1. Introduction

Switches and crossings (S&Cs) are more susceptible to damage compared to normal tracks because of their moving parts and complex geometry. Therefore, poorly maintained switches and crossings encounter frequent failures and large maintenance cost. The direction of traffic plays an important role in the damage evolving at the crossing. When the wheel passes from nose to wing rail or vice versa, the wing rail suffers from high impact stresses as well as normal and rolling contact stresses causing severe damage like fatigue cracks and spallation if not maintained in time [1]. In this work, the damage and deformation of a manganese steel crossing has been investigated, focusing on the wing rail of the crossing. For this crossing, most of the traffic was from the nose to the wing rail and hence the wing rail was severely damaged with cracks.

Manganese steel has been the preferred choice for crossing because of its good mechanical properties like work hardening ability, large stress intensity factor, suitable strength, high toughness and good wear resistance. The surface of the crossing gets hardened due to repeated wheel passage and then eventually fatigue cracks develop within the material which may extend to several millimetres below the running surface. There has been limited research on the damage and deformation of railway crossings made of manganese steels published in the open literature. Non homogeneous deformation of austenite grains with variations in the deformation microstructure within the same grains has been reported [2]. In another study, a dynamic discontinuous recrystallized layer was observed on the worn surface of a manganese crossing [3]. Deformation of the crossings is dependent on many factors like the nature and direction of loading, the initial microstructure, grain size and crystallographic orientation as well as local substructure. There is no doubt the loading on a crossing is much more severe compared to normal track. Previous studies [4-8] on load assessment on a crossing indicate that the stresses developed and the equivalent plastic strain in the crossing is very sensitive to train speed as well as track conditions and the contact stresses can reach at least two to four times that of the static wheel load. Eventually with repeated transient loading and impact, defects like cracking and spallation evolve.

In the literature various studies [9-11] about crack formation and propagation in rail steel can be found, but these studies mostly focus on the pearlitic rail steel grade used in normal tracks. Numerical studies of different rail conditions indicate that load state condition, residual stress, friction conditions/modifiers and fracture mechanics parameters have a strong influence on rolling contact fatigue crack growth path [12-14]. Also the microstructure plays a key role. Cracks generally follow the direction of least resistance (minimum energy), which depends on the properties and microstructure in front of the crack tip [15]. Cracks generally develop from the running surface. However, in some cases sub surface cracks can also be found. Cracks with shallow angles to the surface typically propagate back to surface causing spallation whereas deeper cracks move downwards causing rail breakage. [16].

Previous studies mapping the crack network in 3D have been done by destructive techniques of multiple slicing followed by repeated grinding and polishing and then imaging of the cross section. Schilke [9] et al studied the crack growth in normal pearlitic grade R350HT rail steel by this technique. Garnham et al [17] made schematic representations of the crack geometries in rails by same destructive slicing. Non-destructive 3D tomography has been used in recent years to map crack networks within the rail. Casey et al [10] and Zhou et al [11] have used 3D X-Ray tomography to study the squats and head checks in normal grade pearlitic steels respectively.

Crack propagation studies on a wing rail from a manganese steel crossing have however not been done before, to the best of the authors' knowledge. The microstructure of manganese steel is quite different from the pearlitic grade and also the loading scenarios are far more severe in a crossing compared to straight track. This is likely to significantly influence the damage and deformation as well as the cracking mechanism in the material. In this paper, the deformation and damage caused by rolling contact fatigue as well as impact, when wheel passes over a wing rail of a manganese steel crossing has been characterized with the help of optical microscopy and hardness measurements. The crack network within the material was studied using 3D X-ray tomography measurements.

2. Experimental Procedure

The wing rail of a manganese steel crossing which had been in service in the Danish rail network for ten years was studied. Although nowadays most of the manganese steel crossings are explosion hardened for better mechanical properties, this one was not explosion hardened. The wing rail was heavily deformed and damaged which was evident from visual inspection. A part of the crossing is shown in Figure 1. Small samples were cut from the damaged part of the wing rail for investigation. The micro hardness measurements on the transverse surface of the wing rail were conducted using a Vickers hardness measurement tester with a load of 1 kg and dwell time of 20 seconds. The hardness map was constructed from a series of measurements which were done at an interval of 0.3 mm from the rail wheel contact surface throughout the transverse cut till a depth of 12 mm.

The deformed microstructure of the wing rail was studied using an optical microscope (OM). The samples were ground with Si-C paper ranging from grain 220 to 4000 and then polished by using diamond paste down to 1 µm and etched with Nital.

The crack network developed in the wing rail was studied with the help of X-Ray computerized tomography. For these measurements, a small sample having a cross section of 10 mm by 10 mm width and 40 mm length was cut out from the wing rail. A Zeiss Xradia Versa 520 was used for the measurements. A polychromatic X-ray energy was used with energies ranging up to 160 kV from a tungsten target. A total of 1601 projections were acquired during a full sample rotation. 3D maps were reconstructed by a standard filtered back-projection method to 2k×2k×2k voxel volumes with each voxel of 10 µm size. The crack network was segmented and visualized by using the Avizo 3D software.

3. Results

3.1 Hardness

Figure 2a -e shows the hardness maps of the wing rails at different locations. The figures show that the hardness gradient is different at different locations due to the difference in rail wheel contact at those places. In figures (b), (d) and (e), the deformation hardening is most severe at the top layer showing a high hardness of more than 600 Hv. The hardness maps from locations (a) and (c) show that these locations are comparatively less deformed than the others. As we move down below the contact surface the hardness values decrease indicating less deformation here. The undeformed region has a base hardness of around 220 Hv. Cracks are mostly found near region (b) of the wing rail although the hardness as well as depth of hardening is comparatively small at this point. No cracks are found in regions (d) and (e) in spite the most severe deformation i.e. high hardness is observed at these points. High deformation is not the only reason for crack formation in switches and crossings. It is the impact from the wheel when there is a change of plane as it switches from nose to wing or vice versa which may be the reason for crack formation.

Region (a) has the least deformation and hence maintains the original rail profile shape. In the other cases, the rail profile changes with deformation. With increased deformation, the depression of the surface profile (as in figures b, d and e) compared to the original profile gets more severe. The work hardened layer is observed to extend to 12 mm below the surface. The depth of hardening is significantly higher in manganese grade crossings as compared to normal pearlite grade. In literature it has been reported that in pearlitic grade the depth of hardening extends to upto only 3-5 mm from the contact surface [9, 18-19]. The extra work hardening capacity of manganese steels makes it a suitable choice for the railway crossing material which endures severe impact loadings and damages associated with it.

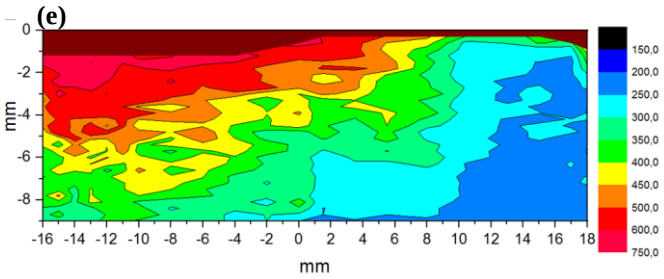

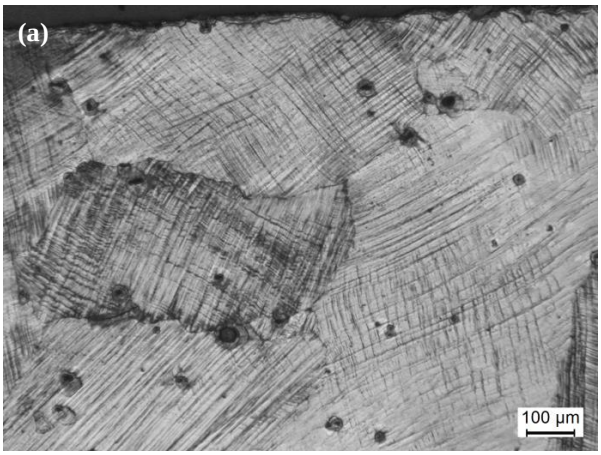

Figure 2 *Hardness contour maps of the wing rail of the manganese crossing at different locations: (a) Wing rail 1(position a). (b) Wing rail 2 (position b). (c) Wing rail 1 (position c). (d) Wing rail 1(position d). (e) Wing rail 2 (position e).*

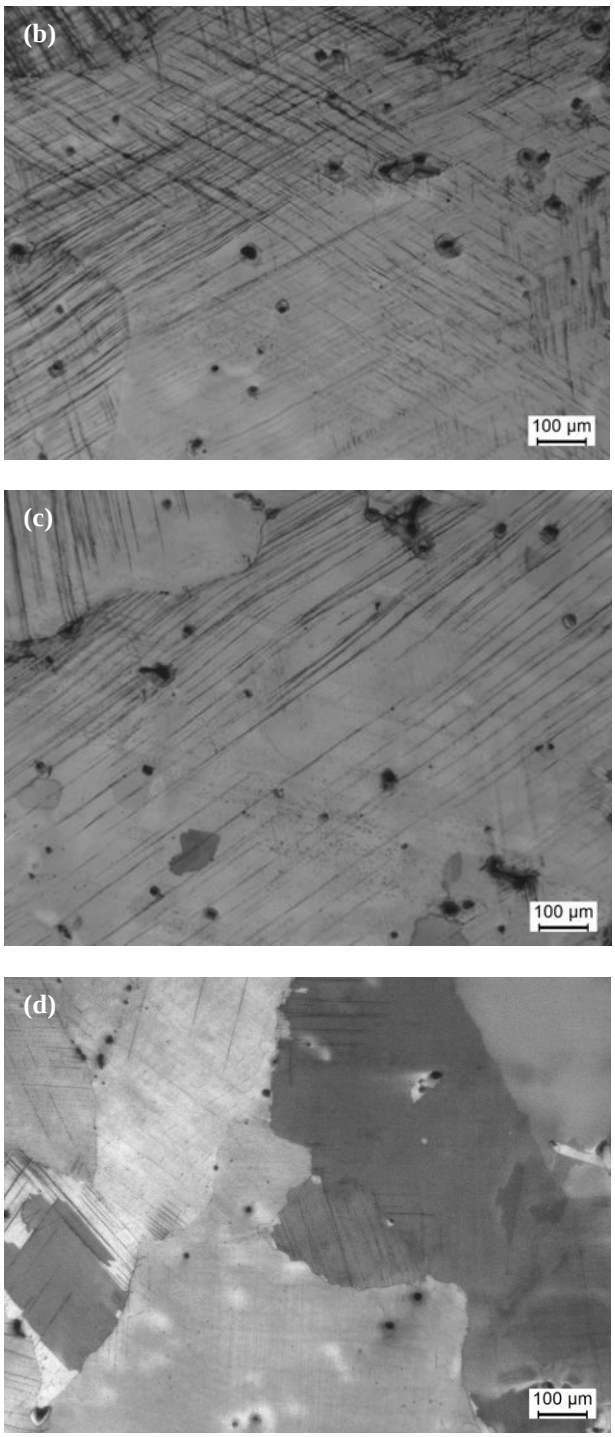
3.2 Microstructure

The microstructure is austenitic in manganese steel. The grain size is coarse, up to 500 µm, and the grains do not seem to deform as in normal pearlitic rails. Figure 3(a-d) shows the optical micrographs of the deformed wing rail at different depths from the wheel running surface. At the rolling contact surface, Figure 3a, a large number of bands can be seen crossing each other within the grains. The deformation in manganese steels is manifested in the form of these bands and not in the formation of elongated grains. The surface receives the maximum deformation and hence the density of these bands is higher at the surface and decreases with depth from the surface. As we move down from the surface, Figures 3b-3c the structure changes in terms of the density of the bands and finally we reach the base material in Figure 3d free from deformation where there are no bands. Most of the deformation bands are inhomogeneous with a wavy appearance. The orientation and the direction of the bands vary from one grain to another. Optical microcopy is not capable to distinguish whether the deformation bands are mechanical twins formed due to deformation or dislocation boundaries. Twinning is a favorable mode of deformation in austenitic steels. In some austenitic steel martensitic transformation also occurs due to deformation. However, no martensite was found in this steel.



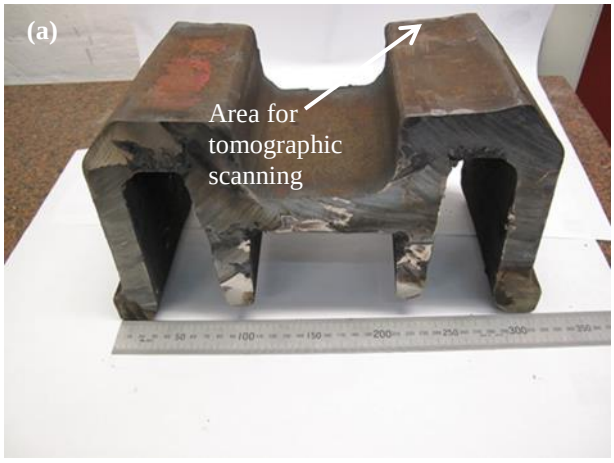


Figure 3 *Optical Microscope (OM) images of the transverse surface of deformed manganese steel wing rail: (a) At the rolling contact surface. (b) At 6 mm depth from the surface. (c) At 10 mm from the surface. (d) At 12 mm from the rolling surface which is the base of the wing without deformation.*

3.3 X-ray Computerized Tomography

Figure 4(a-d) shows the 2D slices from one of the 3D tomographic reconstructions. Based on the concept of density difference contrast, X-Ray tomography allows detection of even small cracks due to differences in density. With the application of an intensity threshold, cracks could be identified in 3D along with a detailed overview of the entire crack surface. The 2D images suggest the presence of very long subsurface cracks running across the cross section of the material. However the 3D reconstruction also suggests the presence of cracks originating from the surface. While most of the cracks run parallel to the running surface, the crack network is extensive and continuous.

Figure 5(a-b) shows the 3-D tomography images of another crack network. In this figure, the steel is represented as transparent and the blue colored area is the air which makes the crack visible. The white box represents the area of the piece of the wing rail which has been scanned. The crack surface has a rough and wavy appearance with ridges which are quite similar to crack surfaces formed due to rolling contact fatigue. It also indicates the crack network spreads quite deep within the material up to several millimetres. The propagation of crack appears quite random. Most of it moves parallel to the running surface while also branching down towards the deeper layers is observed which may cause rail break in the long run. Thus the wing rail contains both surface and sub surface cracks, where some are interconnected and some propagate individually.

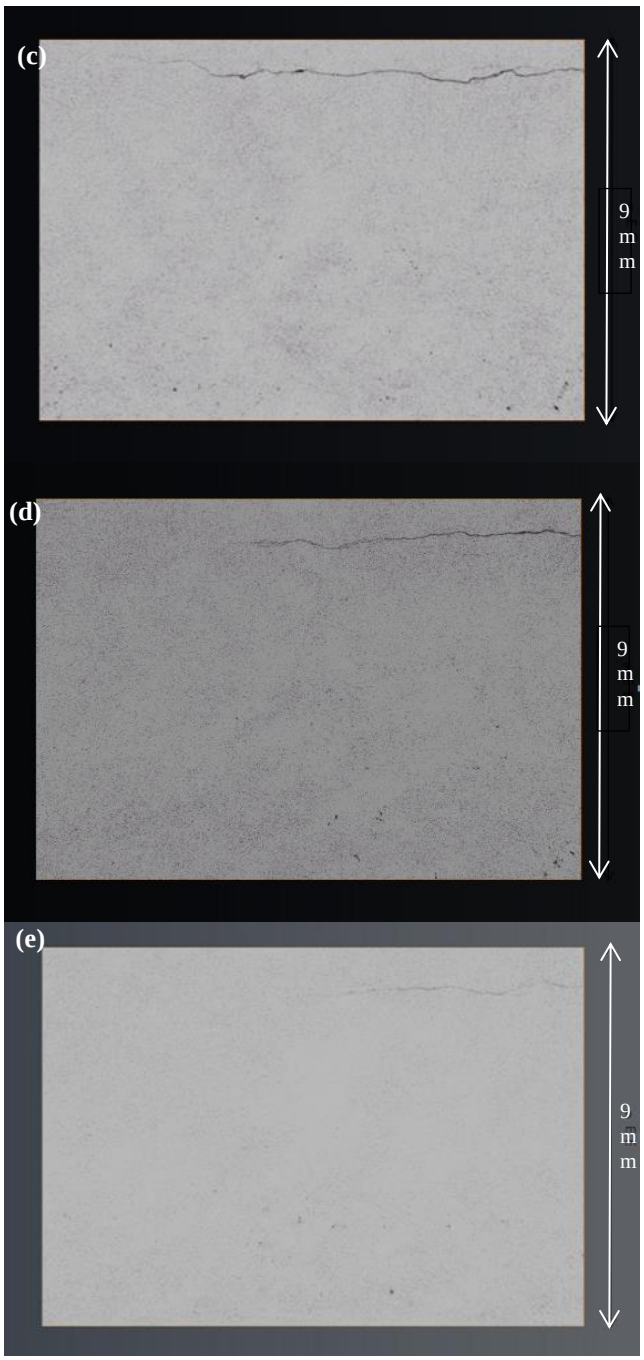

Figure 4 *2D crack network within the wing rail of the crossing at different locations along the rolling direction: (a) Area of the wing rail selected for tomographic scanning (b) At the surface of the trasverse cut (0 mm) . (c) 10 mm position from the trasverse cut. (d) 18mm position from the trasverse cut. (e) 29 mm from trasverse cut.*

4. Discussion

Rail wheel interaction induces both normal and shear contact stresses when a train moves over a crossing. The change of rolling planes from wing rail to nose or vice versa introduces high impact stresses as well. When the stresses are higher than the fatigue limit of the material, defects arise in the material; the most frequent ones are spalling, head checks, squats and cracks which in the long run can lead to failure of the material.

The damage and deformation in a manganese crossing is quite different from a pearlitic grade rail. In case of pearlitic grade deformation causes the grain to elongate in the direction of shear whereas in case of manganese steel the grains are not elongated but deformation induced twins and dislocation boundaries can be seen. Plastic deformation is caused by slip in pearlitic grade without twinning. However in case of manganese steel twinning can occur at quite early stage of deformation, so deformation is by both dislocation motion as well as twinning.

The work hardening behaviour is often related to the strain hardening exponent (n) value. Tensile tests done on both type of steels revealed that the manganese steel have higher strain hardening than the pearlitic grade. As manganese steel has a low stacking fault energy, twinning is favourable in this material [20-21]. Lower

stacking fault energy can also influence the distance between partial dislocations which in turn will have an effect on the mechanism of cross slip and dislocation pile up [22]. When twinning occurs, the shift of the carbon atoms from the octahedral interstitial sites to tetrahedral sites in the twinned region imparts an extra hardening which contributes to the high work hardening rate of the manganese steel [20]. Another theory suggests that reorientation of C atoms in C–Mn clusters in the cores of dislocations introduces additional hardening [23]. All these mechanisms are in competition with each other and improve the mechanical properties of the manganese steel. The extra ordinary work hardening of the manganese steel can thus be a cumulative effect of interactions between slip on different slip systems, dislocations and twins [24], interstitial carbon atoms and dislocations [20,23], and interactions between twins on different planes [24-25].

The two phase microstructure in a pearlite grade material consisting of ferrite and cementite affects the deformation mechanism and eventually the crack initiation and propagation. Earlier studies [19, 26] on effects of microstructure on crack growth of pearlitic rail steel indicated rolling contact fatigue cracks initiated mostly at the pro eutectoid ferrite grain boundaries. Cracks tend to follow the weakest link in the microstructure which causes the waviness in the crack path. Figure 6 shows a rolling contact fatigue crack in pearlite grade steel from a straight track. The crack passes through several grains at around 45 degree angle to the surface and it has a wavy propagation. In case of manganese steel, the microstructure is single phase austenite. Mostly MnS inclusions are present within the material which acts as defects and weak links within the material. Figure 7 shows an optical micrograph of a subsurface crack in the wing rail of the manganese crossing. The crack was confined in the plastically deformed layer. It has a wavy appearance intersecting several grains and having branches. Although the mechanism of plastic deformation is different in the two types of material owing to their different microstructure, the crack network developed in both of them seems to be comparable.

5. Conclusions

The deformation and degradation of the wing rail of damaged non explosion hardened manganese steel crossing, which has been in service in the Danish rail network, was studied. Most of the traffic through this crossing was from the nose to the wing rail and hence the wing rail is severely damaged with cracks and other defects. The deformation is evident with the formation of a high density of twins and deformation bands. The material work hardens due to deformation and the depth of hardening reaches to around 12 mm from the contact surface. The rail contact surface has a very high hardness of around 600 Hv and gradually drops to a base hardness of 220 Hv. The nondestructive 3D mapping of the crack network using 3D X-ray tomography reveal a complete crack network and its minute branches with very high accuracy. The presence of both surface and sub surface cracks is evident. Though, the material and the deformation mechanism of the manganese steel is quite different from that of normal pearlitic grade steel, the crack network seems to be similar to rolling contact fatigue cracks found in pearlitic grade steel used in normal straight tracks. The cracks tend to be concentrated mostly within the plastically deformed layer and have a wavy surface appearance which is common for rolling contact fatigue cracks.

Abstract: The 11,118 wheel profiles of Chinese railway freight cars were collected, of which 770 wheels had become hollow worn and the maximum hollow worn depth was 3.78 mm. Taking C70 freight cars as an example; the vehicle dynamics model has been established. Four wheels with different hollow worn depths were selected to analyze the influence of wear on the wheel/rail contact position, the critical hunting speed, the derailment coefficient, the lateral force of the wheelset, the vibration acceleration of the carbody and the RCF (Rolling Contact Fatigue) of the rail. The results showed that a hollow worn wheel had a large influence on the stability and safety of the vehicle.

Keywords: Wheel hollow wear; freight vehicle; dynamic performance; RCF.

1. Introduction

With an increase in vehicle speed and axle load, a worn wheel becomes more serious. For railway freight cars, because of their poor operating environment and the poor performance of freight car bogies, the wear of their wheels is more serious than that of passenger cars. The wear of the wheels of railway freight cars is mainly divided into flange wear and tread wear. However, abnormal tread wear will lead to hollow wear. A hollow shape is one where the profile at the center of the tread lies below the profile at the end-of-tread.

A survey of approximately 6,800 wheel profiles in the North American freight service concluded that 14.9% of wheels had a hollowing of greater than 2 mm, while 6.2% had more than a 3mm hollow [1]. In the past, there were a large number of small radius curves in the Chinese railway network, and the main wheel wear of freight cars was flange wear. However with the continuous improvement of the line grades in recent years, the number of small radius curves is decreasing. As a result, wheel wear has been gradually dominated by tread wear, resulting in hollow wear.

A hollow wheel shape impairs the ability of a bogie to steer, causing increased rolling resistance and lateral wheel/rail forces, and the optimum economic removal criterion for North America is when wheels have reached 3mm hollow wear [2]. Hollow wheels do not promote hunting, but can produce lateral vehicle accelerations approaching those caused by hunting [3].

In this paper, taking the hollow worn wheel selected in the field as an example, the influence of different hollow wear depths on the dynamic performance of freight cars and the RCF of rail has been analyzed.

2. Definition and Statistics of a hollow Wheel

A hollow shape is one where the profile at the center of the tread lies below the profile at the end-of-tread. The maximum depth of the hollow has been labeled as H, and the material at the end of the tread is said to be a false flange, as shown in Fig. 1.

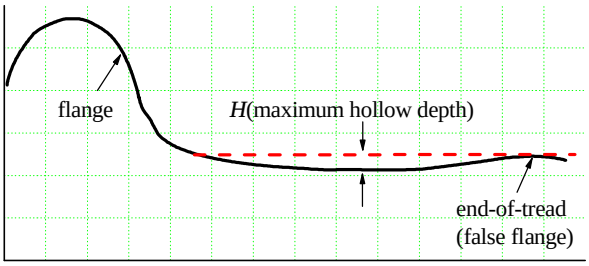

Figure 1. *Illustration of a hollow wheel shape and the hollow depth*

From 2014-2017, profiles were measured on 11,118 wheels on a wide range of freight vehicles by using a MiniProf machine. In the 11,118 wheel profiles, 770 wheel profiles were hollow worn and the ratio was about 6.9 %. The distribution of the hollow worn depths has been shown in Table 1, and the maximum hollow worn depth was 3.78mm (shown in Fig. 2), the mean hollow worn depth was 0.75 mm.

Table 1. *Distribution of hollow worn depths*

H/mm	0-0.5	0.5-1.0	1.0-1.5	1.5-2.0
Number of wheels	347	218	97	61

3. Influence of hollow wheel wear depth on the dynamic performance of the vehicle

3.1 Multi-body dynamic simulation model

In order to analyse the influence of the wheel's wear depth on the vehicle dynamic performance of wagons, a Chinese railway main freight car C70 was taken as an example to establish a multi-body dynamic simulation model in the SIMPACK software, shown in Fig. 3. In the multi-body models, the car-bodies, bolsters, frames and wheelsets were all considered rigid bodies, with primary and secondary suspensions represented through linear and non-linear viscoelastic elements. In order to obtain more accurate results from the dynamic simulation, track irregularity was considered in the multi-body models. The rails adopted the CHN60 rail profile, including new rails and worn rails, as shown in Fig. 4.

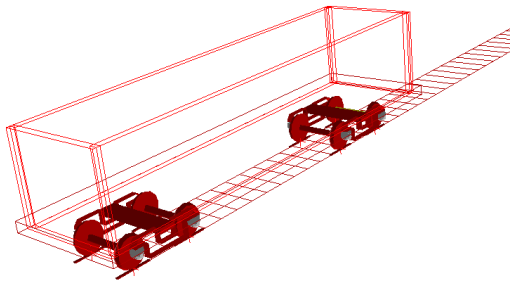

Figure 3. *Multi-body dynamic model in SIMPACK*

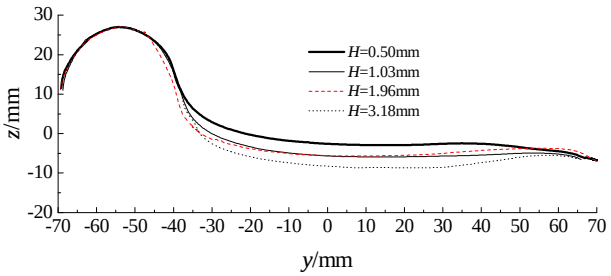
Figure 4. *New/worn wheel profiles*

In order to analyse the influence of the hollow worn depth on vehicle dynamic performance, some wheel profiles with different hollow worn depths were selected in this article and have been shown in Fig. 5.



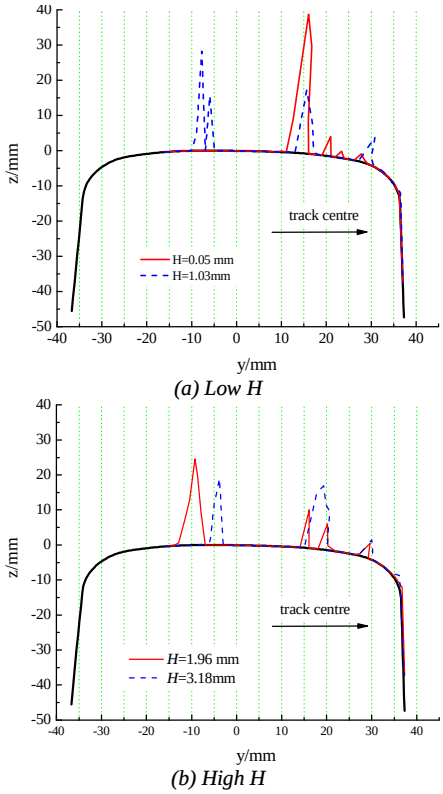


Figure 5.*Wheel profiles with different hollow worn depths*

3.2 Influence of hollow worn wheels on the wheel/rail contact positions

For hollow worn wheels running on a straight track, the distribution frequencies of the wheel/rail contact positions have been shown in Fig. 6.

(a) Low H

(b) High H

Figure 6. *Distribution frequencies of the wheel/rail contact positions*

When the wheel's hollow worn depth was 0.05mm, the wheel/rail contact positions were mainly distributed inside the center of the rail, and the distribution range was +10mm~+30mm. As the depth of the hollow wear of the wheel increased, the wheel/rail contact positions gradually moved to the outside of the center of the rail. The greater the depth of the wear, the greater the probability of the distribution being outside the center of the rail became. When the wheel's hollow worn depth was 3.18mm, the wheel/rail contact positions were distributed from -15 mm to +30 mm, which is 25 mm larger than 0.05 mm.

3.3 Influence of the wheel's hollow wear on vehicle stability

As the equivalent taper of the wheel/rail changes greatly with the increase of the hollow worn depth, it will inevitably have a large impact on the vehicle's stability.

The C70 freight car has two load conditions: empty and heavy. The load is 70 tons when the freight car is in the heavy condition. For different hollow worn wheels, the critical hunting speed under various loads has been shown in Table 2.

Table 2. *Critical hunting speed（km/h）*

Rail profile	Conditions	*H*/mm			
		0.50	1.03	1.96	3.18
New	empty	130	138	125	125
	heavy	135	140	130	127
Worn	empty	125	124	115	75
	heavy	130	128	118	78

Under the condition of new rails, the critical hunting speed instability of empty and heavy vehicles first increased and then decreased with the increase of the hollow worn depth, as seen in Table 2. The maximum critical hunting speed instability occurred when the hollow worn depth was 1.03 mm. Under the condition of worn rails, the critical hunting speed instability of the empty and heavy vehicles decreased with the increase of the hollow worn depth. When the worn depth reached 3.18mm, the critical hunting speed instability was even lower than 80km/h which is the maximum operating speed of this vehicle.

3.4 The influence of the wheel's hollow wear on the safety of freight car operation

For the safety of freight cars, the derailment coefficient and the lateral force of the wheelset have been mainly analyzed. In the simulation calculation, the vehicle ran at a constant speed of 80km/h in a straight line, while the track irregularity used was the AAR5 line spectrum of the US. In order to reflect the trend of dynamic performance more accurately, the RMS (Root Mean Square) value was taken for the derailment coefficient and the lateral force of the wheelset.

3.4.1 Derailment coefficient

The RMS value of the derailment coefficient of the C70 freight car under various working conditions varied with the wheel's hollow wear, as shown in Table 3.

It can be seen from Table 3 that, under the condition of the new rail, the change in the RMS value of the derailment coefficient of the empty and heavy vehicle was not obvious when the wheel's hollow wear depth was increased from 0.50mm to 3.18mm. When the rail was worn, the RMS value of the derailment coefficient of the empty and heavy vehicles increased sharply with the increase of the hollow wear depth of the wheel.

Table 3. *The RMS value of the derailment coefficient*

Rail profile	Conditions	*H*/mm			
		0.50	1.03	1.96	3.18
New	empty	0.10	0.07	0.10	0.12
	heavy	0.09	0.05	0.06	0.08
Worn	empty	0.07	0.13	0.31	0.36
	heavy	0.04	0.09	0.23	0.22

3.4.2 Lateral force of the wheelset

The RMS value of the lateral force of the wheelset of the C70 freight car under various working conditions varied with the wheel's hollow wear, as shown in Table 4.

Table 4. *The RMS value of the lateral force of the wheelset (kN)*

Rail profile	Conditions	*H*/mm			
		0.50	1.03	1.96	3.18
New	empty	2.97	3.92	4.42	6.28
	heavy	8.28	11.88	14.51	16.98
Worn	empty	2.38	3.26	5.75	7.07
	heavy	6.49	8.26	12.71	14.11

It can be seen from Table 4, that the RMS value of the lateral force of the wheelset of both the empty and the heavy freight car increased with the increase of the wheel's hollow wear depth, whether it was a new rail or a worn rail. When the wheel's hollow worn depth increased from 0.50mm to 3.18 mm, the RMS value of the lateral force of the wheelset was almost doubled.

3.5 The influence of the wheel's hollow wear on the vibration of the carbody

Considering that the wheel profile mainly affects the lateral vibration of the vehicles, only the lateral vibration acceleration and the Sperling lateral ride index were analyzed. The variation of the lateral vibration acceleration RMS value of the C70 freight car under various working conditions, as shown by the change of the hollow wear of the wheel has been shown in Table 5, and the Sperling lateral ride index has been shown in Table 6.

Overall, although the wheel had hollow wear, the RMS value of the lateral vibration acceleration and the lateral ride index of the carbody did not change much. The main reason is that the vibration caused by the change of the contact relationship of the wheel and rail had not been transferred to the body after the isolation of the primary and secondary suspensions.

Table 5. *Lateral vibration acceleration of the carbody*（g）

Rail profile	Conditions	*H*/mm			
		0.50	1.03	1.96	3.18
New	empty	0.04	0.03	0.03	0.04
	heavy	0.07	0.07	0.07	0.08
Worn	empty	0.02	0.03	0.05	0.05
	heavy	0.06	0.07	0.08	0.08

Table 6. *Lateral ride index of the carbody*

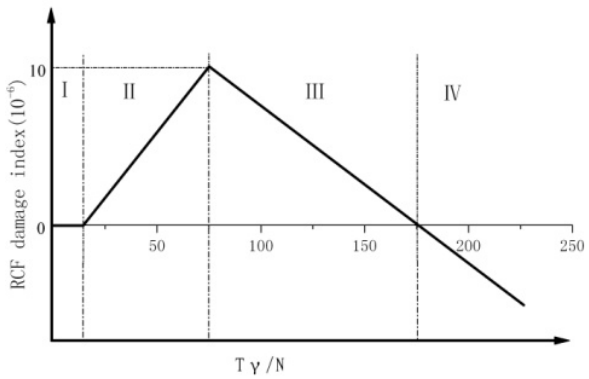
Rail profile	Conditions	*H*/mm			
		0.50	1.03	1.96	3.18
New	empty	2.19	2.22	2.23	2.23
	heavy	3.13	3.24	3.20	3.21
Worn	empty	2.21	2.50	2.87	2.89
	heavy	3.26	3.30	3.42	3.41

4. Influence of hollow wheel wear on the rail RCF

4.1 RCF damage model

The RCF damage function [4-5] was used to predict the RCF of different rail profiles. In this model, Tγ represented the energy dissipation in the wheel/rail contact patch and relates to the RCF damage index, in which T is the tangential force and γ is the wheel/rail creepage. The RCF damage function has been shown in Fig. 7.

The RCF damage function can be divided into 4 regions according to Tγ. In region I (Tγ<15N), the loads were below the shakedown limit and the material would not show RCF damage. In region II (15N≤Tγ<75N) and region III (75N≤Tγ<175N), the RCF damage rates were higher than the wear rates, and the RCF damage index reached the maximum value when Tγ =75N. In region IV (Tγ≥175N), the RCF damage would be removed by serious wear.



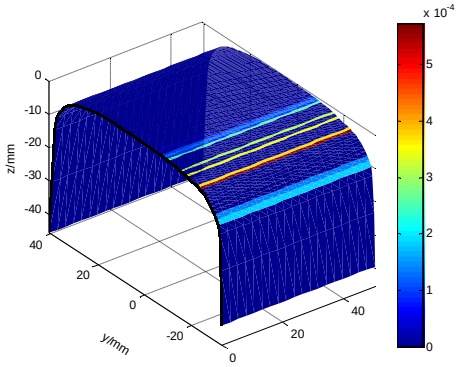


***Figure 7**. RCF Damage function related to T_γ[4-5]*

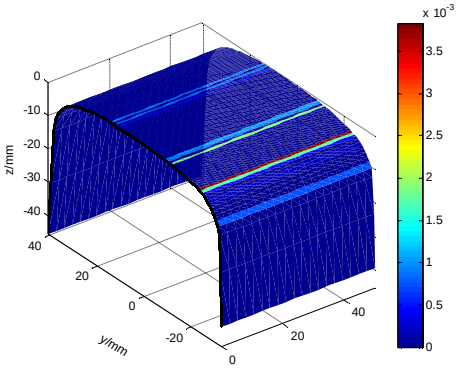
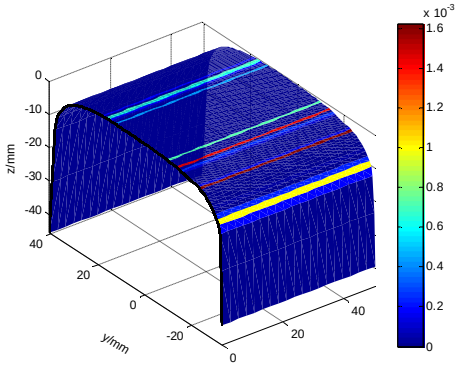
4.2 The influence of the wheel's hollow wear on the vibration of the carbody

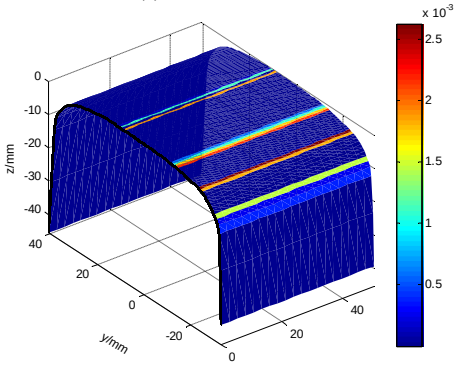


According to the vehicle's dynamic simulation results, when the total train weight was 10,000 tons, the cumulative RCF damage indices of the new rail profiles were calculated and mapped to the rail surface, as shown in Fig. 8. The maximum cumulative RCF damage indices have been shown in Table 7.

***Table 7**. The maximum cumulative RCF damage indices (10^{-4})*



H/mm	0.5	1.03	1.96	3.18
RCF damage indices	9.6	38.0	16.0	26.0



(a)H=0.50 mm

(b)H=1.03 mm

(c)H =1.96 mm

(d)H=3.18 mm

***Figure 8.** The cumulative RCF damage index distribution*

According to the calculation results, the cumulative RCF damage index first increased and then decreased with the increase of the hollow worn depth, and the maximum value occurred when the hollow worn depth was 1.03 mm. At the same time, the distribution ranges of the RCF on the rail were quite different, but the most serious damage was mainly at the shoulder position.

5. Conclusion

- The wheel profiles of 11,118 Chinese railway freight cars were measured and statistics, about 6.9% of the wheels had hollow wear and the maximum hollow worn depth was 3.78mm.
- With the increase of the hollow worn depth, the wheel/rail contact positions gradually moved to the outside of the center of the rail. When the hollow worn depth was 3.18mm, the distribution range of the wheel-rail contact position was increased by 25mm compared with that for 0.05mm.
- When the hollow worn depth reached 3.18mm, the critical hunting speed instability was even lower than the maximum running speed of 80km/h.
- When the rail was worn, the RMS value of the rail derailment coefficient of the empty and heavy vehicles increased sharply with the increase of the wheel's hollow worn depth. At the same time, the RMS value of the lateral force of the wheelset increased with the increase of the wheel's hollow worn depth. When the hollow worn depth of the wheel was increased from 0.50mm to 3.18mm, the RMS value of the lateral force of the wheelset almost doubled.

- The RMS value of the lateral vibration acceleration and the lateral ride index of the carbody did not change much with the hollow wear of the wheel.
- The RCF first increased and then decreased with the increase of the wheel's hollow worn depth, and at the same time, the most serious damage was mainly at the shoulder position.

Abstract: We present results of field tests of a new Hand Operated (HO) Tribometer that measures friction /creepage conditions on rail. Friction/creepage relationships (creep curve) are shown for a variety of conditions, including different cases of lubrication and friction management, temperature, and humidity. Effects of Hertzian stress and rail surface condition are discussed. Comparisons are made between the measurements by the HO Tribometer, a traditional Push Tribometer, and an Instrumented Wheelset (IWS). Third Body composition (iron oxides) is reported for different conditions and compared to corresponding traction creepage relationships. Lower friction seemed to be associated with iron oxy-hydroxides.

Keywords: friction, traction, third body, tribometer, creepage, iron oxides, X-Ray diffraction.

1. Introduction

1.1. Background

Characterizing wheel/rail friction is central in understanding many aspects of wheel/rail performance [1]. High friction levels promote damage mechanisms such as wear, rolling contact fatigue and corrugations. Low friction can lead to train operational issues such as wheel slip. In traction it is a performance issue and in braking it affects safety. It is well established that wheel/rail friction force strongly depends on creepage; i.e. normalized relative sliding velocity between the surfaces (creep curve). Friction is also understood to be influenced by parameters such as Hertzian contact pressure, wheel and rail roughness, Third Body (interfacial layer) shear strength, and other factors.

The shape of the traction creepage curve plays an important role in generation of stick-slip oscillations that can initiate corrugations and curve noise. A negative slope of the creepage curve (falling friction) may cause wheel slide. For these and other reasons, modern vehicle dynamic simulations incorporate non-linear friction / creepage relationships instead of using a single value for friction as was common in the past [2].

It has become increasingly common to introduce friction modifiers and lubricants that alter the shape of the creepage curve to minimize wheel/rail tangential forces, reduce wear and alter vehicle traction and steering characteristics ([3] and references therein). However, measuring and obtaining friction/creepage relationships under various conditions has largely been limited to instrumented locomotives, or to laboratory twin disc/ twin roller machines. Both have significant limitations.

Wheel/rail adhesion can be determined directly from on-board measurements. However, for track maintenance personnel this information is rarely available in a timely manner, such as to address low adhesion resulting from leaf fall.

Manual tribometers of various types have been used to measure the friction between a measuring head and the rail. The most widely used of these to date is the Salient Systems Push Tribometer developed by one of the authors [4, 5]. Another author has reported on the use of a pendulum rig for measuring rail adhesion [6]. Japanese researchers have also developed a rail tribometer [7].The original Push Tribometer, the new OnTrak HO Tribometer and the pendulum rig are commercially available today. The numbers from the Salient device have become familiar to many technical personnel in the industry, but are not equivalent to those obtained directly from on board tractive effort/adhesion measurements. The key limitations of the original Salient Push Tribometer are: 1) low Hertzian stress levels (approximately 400 MPa, typical of passenger coaches and lightly loaded freight wagons), and 2) unknown creep levels at the instant of measurement. Creepage has a profound influence on the measured friction, and Hertzian stress is also a significant variable. Values of friction coefficient from the Salient Tribometer range between 0.2 for heavily lubricated rail to 0.8 for very dry rail (high temperature and low humidity). The creepage at the point of measurement for the Salient Tribometer is close to 100% due to encoder stoppage being the only reliable capture point. There is no ability to determine friction/creep relationships in this or other tribometers referenced.

The work of Kalousek et al. [8], showed that wheel/rail friction can vary over a wide range depending on the presence and concentration of various materials that make up the Third Body interfacial layer. The Third Body refers to the interfacial layer between the wheel and rail that is always present, comprised of wear particles, iron oxides, moisture, other contaminants (such as leaves), as well as friction control materials deliberately introduced. Wheel/rail friction is understood to be fundamentally related to the shear strength of the third Body Layer, and thus to the composition of the layer. However, the type of iron oxides present under various conditions has received relatively little attention. Japanese researchers have studied the different forms of iron oxide present on the rail under different conditions [9, 10]. This work has shown that the identity of iron oxides present under different conditions is complex but important for understanding rail friction.

1.2. Characteristics of the OnTrak HO Tribometer

A new hand operated tribometer shown in Figure 1 (HO Tribometer) developed by one of the authors was described at CM 2015 [11]. This instrument takes a different approach to inferring rail friction; lateral creepage is induced by setting an angle of attack (AOA) between the measuring wheel and the rail. This angle is variable over a wide range (1–150 mrad), covering a corresponding range of lateral creepage from 0.1% to

Figure 1. *HO Tribometer in operation*

15%. The measuring wheel moves along a 30 cm length in both forward and reverse directions. The 97th percentile of the results from the two directions are averaged to provide the coefficient of friction, approximated as the ratio between lateral load on the wheel.

The HO Tribometer was developed to allow variation of normal force and transverse curvature of the measuring wheel rim, such that the Hertzian contact stresses could be varied. The normal force can vary over a 6:1 range and the rim transverse curvature over a 4:1 range yielding about a 5:1 range of Hertzian stresses. Lateral position on the rail can be automatically varied, covering from the top centre of rail to the bottom of the gauge corner.

One of the original goals in developing the HO Tribometer was to be able to measure creepage curve by continuously varying wheel angle of attack during one pass. Some users have had success using that feature, but currently, doing a stepwise sequence from 0.1% to 15% has proven to be more reliable.

These features change the capability of defining rail friction compared with previously available instrumentation. In particular, determining a traction creepage curve under different conditions in the field has not previously been possible. Hertzian contact pressures can be adjusted to a value appropriate for the system under evaluation. Finally, the new tribometer is much lighter and more portable than the previous instrument, making practical field measurements easier.

1.3. Objectives

The goals of the work reported herein are to evaluate the HO tribometer for generation of friction / creepage relationships under a variety of rail conditions. These include dry rail at different temperature and humidity conditions, tangent and curve locations, and with rail friction modified using various friction adjusting materials. We also set out to compare tribometer friction values with wheel/rail forces determined with an IWS T/N results in sharp curves. Finally, we wished to relate friction / creepage under different conditions with the presence and composition of Third Body components, primarily different forms of iron oxide.

The overall objectives are to add to the body of wheel/ rail tribological knowledge by:

- Establishing the utility of the new tribometer to identify the traction creepage relationship for a variety of rail frictional conditions.
- Determining the value of the new tribometer to understand performance of friction modifying materials.
- Comparing the results of the tribometer with IWS values of T/N and the prior push tribometer.
- Comparing friction creepage values with Third Body composition.

2. Test Design and Experimental Conditions

2.1. Test Site 1

This test site is on BC Rail Port Subdivision, a North American freight railway. Mixed freight traffic consists primarily of loaded coal trains and empty intermodal (double stack) traffic westbound, empty coal trains and loaded intermodal in the eastbound direction. Traffic is about 18 trains per day operating bi-directionally, and

annual tonnage is estimated at 25 million gross tonnes. The site measurement locations are shown in Figure 2. Measurements were made on tangent track (Location A), in the spiral of the 308 m radius curve, length 320 m (Location B) and in the body of the curve (Location C).

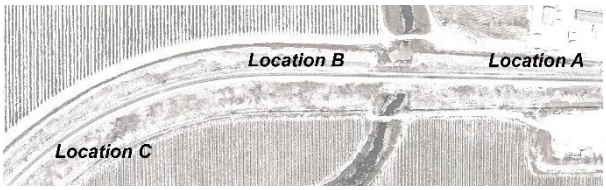

Figure 2. *BC Rail, Test Site 1*

Pronounced RCF damage on the top of the low rail at Location C prevented tribometer measurements at this location. A trackside lubricator was present at approximately 60 m west of Location A which provided very moderate amounts of lubrication to the gauge face of the high rail. There was no evidence of grease contamination on the top of rail from this unit at any of the measurement locations.

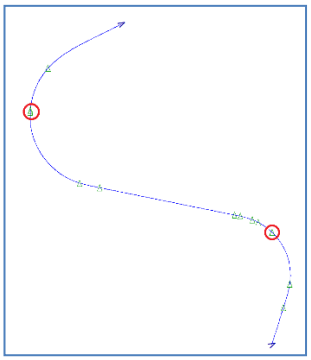

Figure 3. *Reverse curve at WRM Loop, Test Site 2*

2.2. Test Site 2

Testing under hot, dry conditions was carried out on the Wheel Rail Mechanism (WRM) loop at the Transportation Technology Center (TTC) in Pueblo, Colorado. This 5.4-km closed loop is used for curving performance tests, and includes curves ranging from 582 to 145 m radius. Figure 3 shows the locations for tribometer measurements in 145 m and 175 m radius reverse curves. The test consist in sequence was: locomotive, instrumentation coach, and loaded covered hopper wagon (measured gross weight 129.94 tonnes). The IWS was the leading wheelset of the leading bogie of the hopper. This is a 3-piece bogie with longitudinal clearances between bearing adapters and pedestal jaws filled with shims to increase the AOA of the leading wheelset and thus produce higher creepages. The IWS had static loads of 15.905 tonnes (left wheel) and 15.985 tonnes (right wheel), with 91-cm wheel diameter and AAR1B wide flange profiles [12]. The train operated at 39 km/h (balance speed for the two noted curves).

The method of estimating wheel/rail friction coefficients from IWS measurements is based on estimating the ratio of tangential to normal force at the wheel/rail contact patch (T/N ratio, traction ratio, or adhesion ratio) [13]. The contact patch of interest is between the inner rail in a curve and the tread of the wheel of the leading wheelset of a non-steerable bogie. When a bogie negotiates a sufficiently sharp curve, the creepage condition in this contact patch approaches saturation, and the traction ratio approaches the wheel/rail friction coefficient (μ).

2.3. Friction adjusting materials

A series of friction adjusting materials were applied to the top of rail at Site 1 (Location A or C) at recommended application rates, using a drench gun to deposit small drops of material, followed by rolling the material out using a paint roller.

1. KELTRACK® Manual water based Top of Rail friction modifier [3,14]
2. INFINITRACK™ oil based top of rail lubricant [3,14,15]
3. Alleviate™ traction enhancer [16].

Twin disc studies of the water based friction modifier have previously shown a positive friction creepage relationship over the full range of creepage examined. [17, 18]. The TOR lubricant has been shown to provide a flat friction/creepage relationship over a wide creepage range [19].

The traction enhancer is a water based suspension of sand particles designed for wayside application during leaf fall season.

2.4. Rail swab procedure

A methodology developed by the University of Sheffield was used to obtain samples of the Third Body layer from the railhead surface at Test Site 1. Two different types of filter paper [20, 21] were drawn along the rail for about 40 cm, against the direction of loaded traffic. The best results were obtained with filter paper made from glass micro-fibres. Air and rail temperatures and ambient humidity were recorded with both hand-held sensors and data logging equipment.

2.5. Third body materials analysis

A PANalytical X'Pert-3 powder X-Ray diffractometer mounted in reflection geometry and equipped with a Cu anode was used to analyse the swabs. Swabs were trimmed to size and mounted on zero background diffraction plates exposing the collected material. Continuous scans of each sample were performed between 2θ angles of 20 to 65 degrees using a step size of 0.013 degrees. Forty-minute scans were performed for each sample and in some cases for two hours to increase the signal and facilitate analysis. Spectra from the scans are compared against a scan of a blank swab to identify peaks from the material collected on the surface. The positions and relative intensities of these peaks are then matched to the peaks of known compounds to identify the contaminants collected on the swab [22].

3. Results

3.1. Dry conditions: creepage curve, tangent and curved track

As discussed in Section 2.1, there were three zones at Test Site 1 where individual tests were performed: 1) tangent (A), 2) mid-spiral (B), and 3) high rail (C) in body of the curve. For each location and for each site

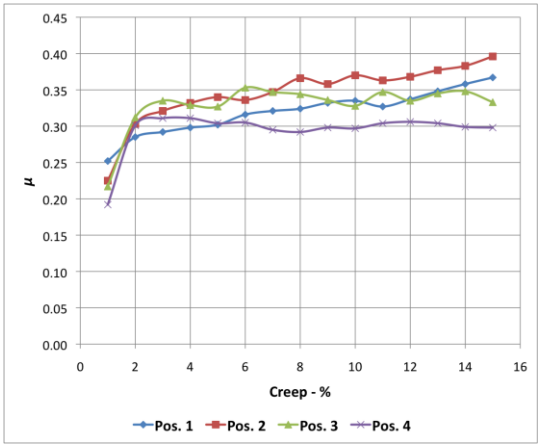

***Figure 4**. Typical dry values across running surface at tangent location*

visit baseline dry condition runs were made. Figure 4 shows a typical set of runs at different positions across the running band at low Hertzian stress (700 MPa). As shown in Figure 5, the running band region is designated in the HO Tribometer by the Positions 1 – 4 while 5 – 7 are the top, middle and bottom of the gauge corner. During data collection, it is up to the operator to select the specific position that best matches the running band at that location. (Field side positions can be acquired by flipping the Tribometer around and indexing against the field side of the rail.)

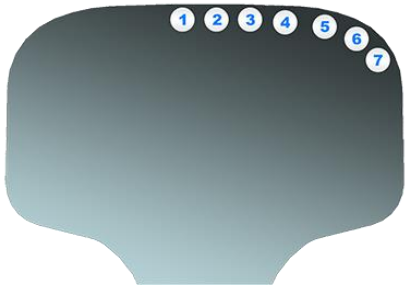

***Figure 5.** Position designations for HO Tribometer*

3.2. Reproducibility and wheel Cleaning

Nearly every test performed with the HO Tribometer

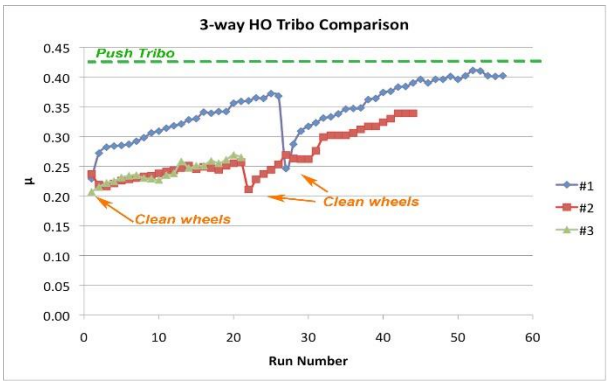

***Figure 6.** Three HO Tribometer vs. Push Tribometer comparison*

begins with the cleaning of the measurement rim. The question often asked is: "what is the effect of cleaning?" In general, any test run produces a small amount of wear product that affects subsequent runs. The black residue removed when cleaned is possibly haematite and magnetite (Fe_2O_3 and Fe_3O_4, respectively), whose accumulation increases the subsequent friction levels. Other Third Body materials may also be scrubbed off the surface of the rail and can alter the friction. Figure 6 shows a series of tests at TTC undertaken in the summer of 2017 on a rail with a fairly heavy build-up of surface oxides burnished in by infrequent, light traffic.

The three sets of sequential runs were from three different HO Tribometers at a single yaw angle (50 mrad). Each set of runs started with a clean wheel in addition to the noted re-cleaning. The rail locations of each HO Tribometer were adjacent on the same rail and all were fixed at the same lateral position on the top of rail (Position 1). The steady rise in value for each run is consistent with the slight build-up of iron oxides on the wheel except for the cleaning steps noted. The rapid increase of the readings in the first five or six runs after cleaning the wheels mid-sequence was due to transfer of Third Body material from the rail surface (which was not cleaned) to the wheel surface. We believe the difference in the readings of one of the tribometers (blue trace) may be caused by additional pre-conditioning runs on this machine.

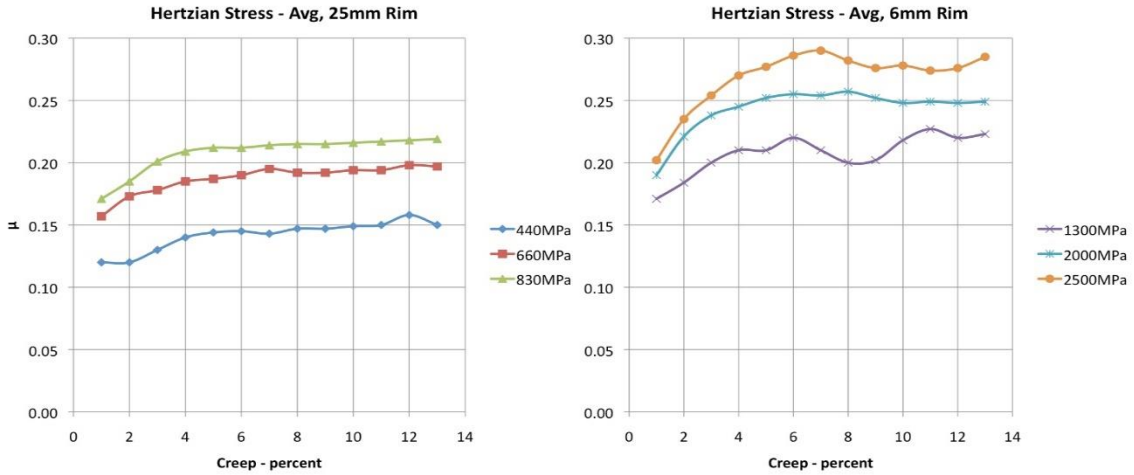

***Figure 7.** Effect of Hertzian stress on dry polished hard rail*

3.3. Effect of Hertzian contact pressure

The ability to vary the Hertzian stress was evaluated on a test rail under laboratory conditions. Figure 7 shows a series of runs on polished hard rail with curves produced from a lower contact pressure of 440 MPa to a maximum of 2.5 GPa.

A first glance indicates a rather monotonic increase in μ with Hertzian stress. However, there is some additional effect that is more evident in Figure 8 indicating an additional factor, possibly due to ellipticity differences between the two test rims resulting from differences in transverse radii (25 mm vs. 6 mm).

Often, during the field tests when only a couple of runs can be made, a change in the test rim transverse radius is a quick way to produce a 3:1 change in Hertzian stress. A brief evaluation in the field of different rim radii showed relatively small differences in μ. The delta of values produced under those conditions is often small enough that they cannot readily be seen as a separate effect. However, any comparative tests looking at external conditions are obviously done with a common rim and normal force. As with some other effects, the secondary influence of hardness, roughness, and other factors produce differences without clear delineation as to a specific consequential effect.

3.4. Effect of TOR FM materials: friction modifier, lubricant, adhesion enhancer

The tests to evaluate the behaviour of top of rail friction modifiers (TOR FM) were performed over two different visits to Test Site 1. On each visit, baseline (dry) measurements were performed before applying the TOR materials to the top of both rails. On the first visit, we measured friction one train passage after FM application in the spiral of the curve (Location B). On the third visit, traffic was not readily accommodating, so we applied material at the end of a long track maintenance period during the day. Overnight about 18 trains had passed (~10,000 axles). We first measured and then later reapplied TOR material before two consecutive trains passed (~1,100 axles).

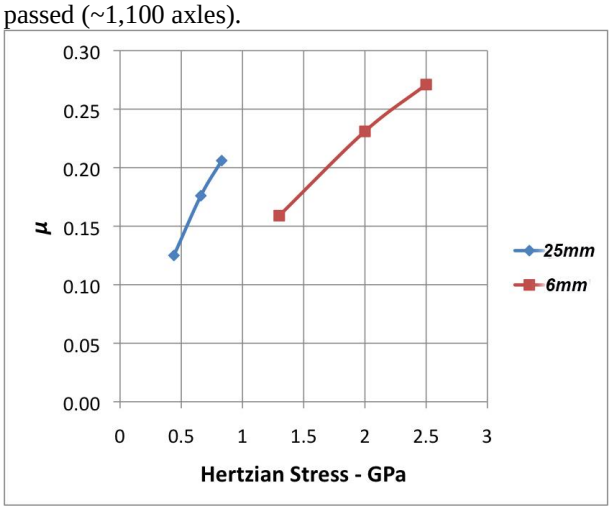

Figure 8. *Secondary effect of wheel rim geometry*

Figure 9 provides some critical insights into the behaviour of the FM material with increasing number of axle passes:

1. After 500 axle passes, the friction level is lower on the top of the high rail than on the low rail. The greater degradation of the Third Body film as shown by friction increase on the low rail reflects the higher creep forces experienced on the top of the low rail versus on the high rail.
2. On the top of the high rail, even after 10,000 axle passes, the friction at all creep levels is still lower than dry conditions, indicating the persistence of the FM film under these conditions.
3. The low rail data shows differential rates of FM degradation at different creep levels. At low creep levels ($\leq$ 2%) friction has returned to close to dry conditions after 1,100 axles, but at $\geq$ 2% creep the FM film is still effective at 1,100 and even 10,000 axles.

Point 3 is very significant. It has long been puzzling why the effective "carry distance" of wayside FM materials has been dramatically different depending on

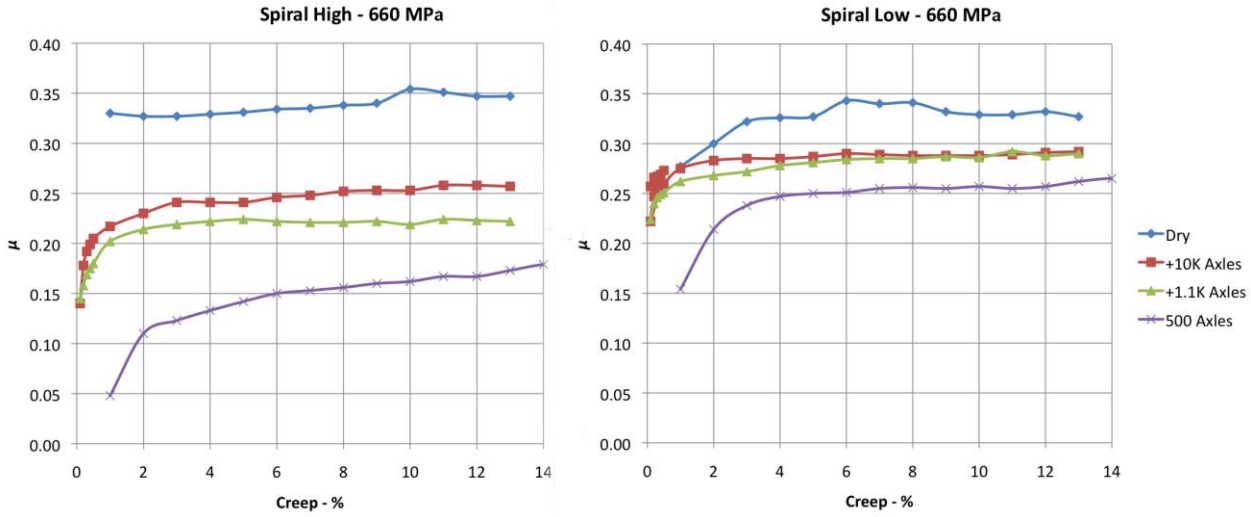

Figure 9. *Durability of TOR FM film on both rails of the test spiral*

the targeted function of the FM. Control of curve squeal by TOR-FM is typically limited to one or at most two curves after the point of application, for a total distance of perhaps 250 m maximum. On the other hand, for reduction of lateral forces and L/V ratios, wayside FM application is effective over continuously curved territory for multiple km distance from the point of application. One typical example in [15] shows lateral force reduction for curves 3.5 km from the point of application. It could be speculated that the behaviour of the FM material at low creep is the critical area for influencing curve squeal, whereas lateral force reduction is more influenced by friction at higher creep levels. This also suggests opportunities for development of new FM materials tuned to film durability at different points of the creep curve.

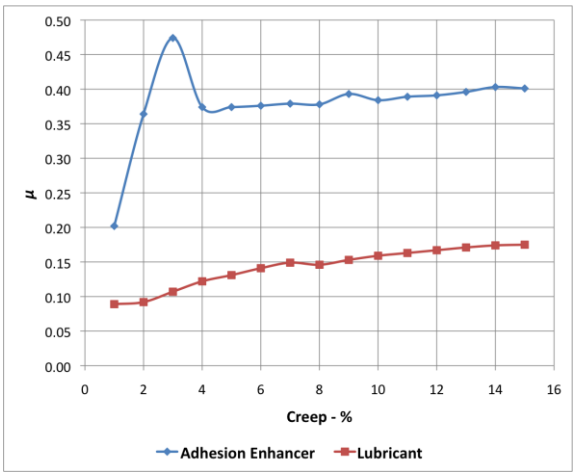

Figure 10. *Durability of adhesion enhancer and lubricant after one train pass*

Two other materials were tested, but with somewhat less opportunity to explore this behaviour. Application of the adhesion enhancer at the tangent track location followed by one train passage is shown in the upper trace of Figure 10, showing high values of μ around 0.40, as well as a single spike of 0.47. Repeats of this test were not able to be run so it was not possible to explore whether this was either a unique localized condition, or nominally a part of the expected response. Interesting results were also obtained with a lubricant applied to TOR in the body of the curve before a westbound train carried it away from the tangent location. Subsequently, an eastbound train carried the remaining oil east for nearly 400 m over the tangent location where the very low results shown in the lower trace in Figure 10 were produced. The oil-based lubricant provides markedly lower friction than the water based FM (compare Figure 9 with Figure 10) as expected from the fundamental properties, and as seen in twin disc studies [19]. However, the shape of the curve for the oil treated rail is not fundamentally different from that of the FM material, showing monotonic increase in friction with creepage. It was expected from twin disc studies that the oil film might show a flat friction creepage behaviour, with the FM showing "positive" friction or rising friction with creep.

3.5. Comparison with IWS Results

Figure 11 shows box plots of apparent friction coefficient μ measured by the HO Tribometer and the IWS throughout the two curves in the WRM loop (Test Site 2). The boxes designate Quartiles 1 through 3, and whiskers show 1st and 99th percentile of μ. The first two box plots show μ measured during the forward and reverse sweeps of a HO Tribometer at a 150 mrad angle of attack (15% creep); the next three plots show the traction ratio measured with IWS throughout the body of the curve. Readings of the Push Tribometer are shown as a line, since it only reports a single number.
The HO Tribometer tended to measure μ on the order of 0.15 below the IWS and the push Tribometer read on the order of 0.10 higher than IWS. This is consistent with some previous tests.

There have been numerous discussions over recent years

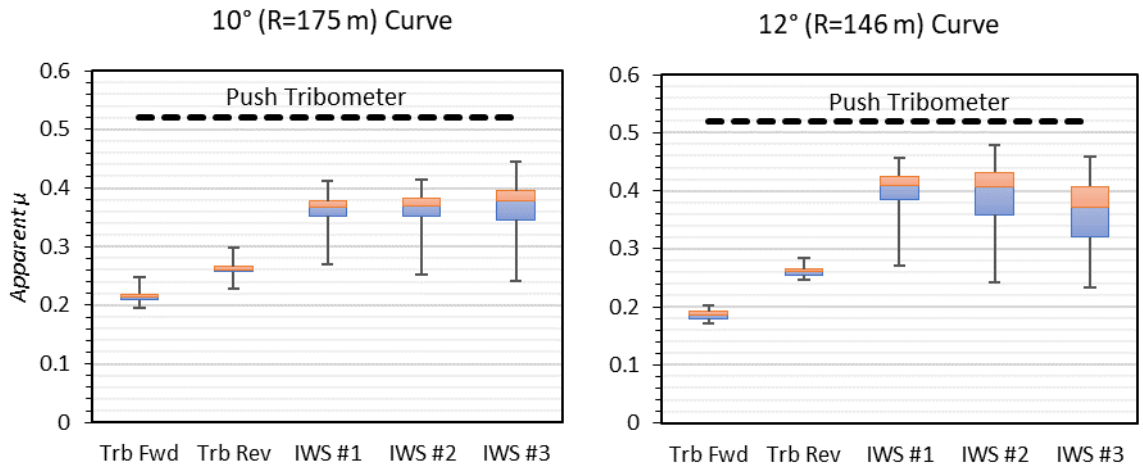

Figure 11. *Comparison of apparent friction coefficient values obtained with HO Tribometer, Push Tribometer, and IWS*

about the causes of fairly consistent difference in these readings between the three modes of measurement. Hertzian stress levels were always one of the factors considered, particularly given the research done by one of the authors. [23] However, recent tests show an increase of saturation limits with an increase in Hertzian stresses as seen in Figure 7 in Section 3.3.

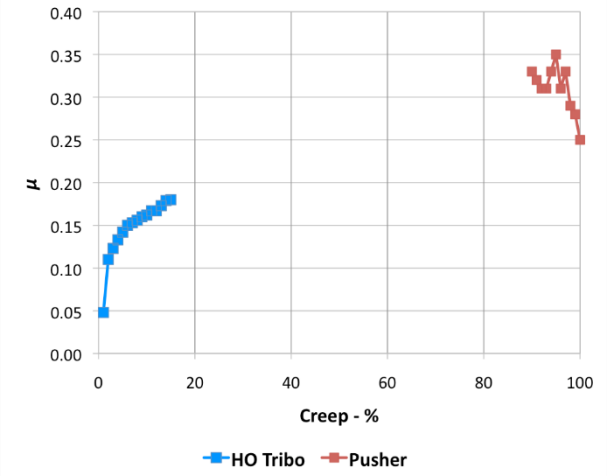

***Figure 12**. Comparison of HO and Push Tribometer*

Additionally, the creep regime may have a much larger effect. Figure 12 represents an example from the BCR tests where the two Tribometers are plotted on a common scale. This is a somewhat artificial construct in that the Push Tribometer cannot control its creep condition. It measures the effective T/N ratio continuously until the measuring wheel stalls and begins to slide. Once the encoder stops it then averages the last few readings and displays that averaged reading. For most cases this represents a 100% slip condition, but in some cases of a falling creep curve this maximum traction value reported may have been measured at less than 100% slip. So, to allow a comparison, a series of readings manually acquired from the Push Tribometer were collected in the area of the HO Tribometer, and to show the variability of its readings, a slip percentage was assigned manually to 100 minus the number of previous readings in the series. This still implies in many cases a rising rate that may not be factual, but it gives a much better sense of how the two devices operate in different domains.

3.6 Analysis of rail swabs

Table 1 lists different iron oxides detected in top of rail swabs on three different sampling dates at Location A (Site 1) and taken over a range of ambient conditions. Figure 13 shows a representative powder X-Ray Diffraction scan of one sample (GF01, Table 1). Peaks corresponding to different components can be clearly seen: metallic iron (wear particles), iron oxides: haematite (Fe_2O_3), maghemite (ΥFe_2O_3), akaganeite (an iron oxide-hydroxide, β-FeO(OH) and magnetite (Fe_3O_4). In the samples examined, the following iron oxides were specifically not detected, but were recorded by one of the authors at a test site in the UK using the same methodology: wustite, lepidocrocite and goethite.

The first sample date with relatively low temperatures showed the highest railhead oxide amounts. More material was picked up than on later dates, including iron particles. Spectral peaks were observed associated with iron-oxy-hydroxide materials. This suggests low temperature weathering in moderate to high humidity is the result of oxide contamination. The identification of maghemite likely formed from the dehydration and transformation of iron-oxy-hydroxides supports this hypothesis.

The second data set is for a day with warm and very dry conditions. The spectrum is dominated by the presence of iron, magnetite and haematite consistent with these conditions. It is expected that this type of Third Body component will increase the friction on the railhead.

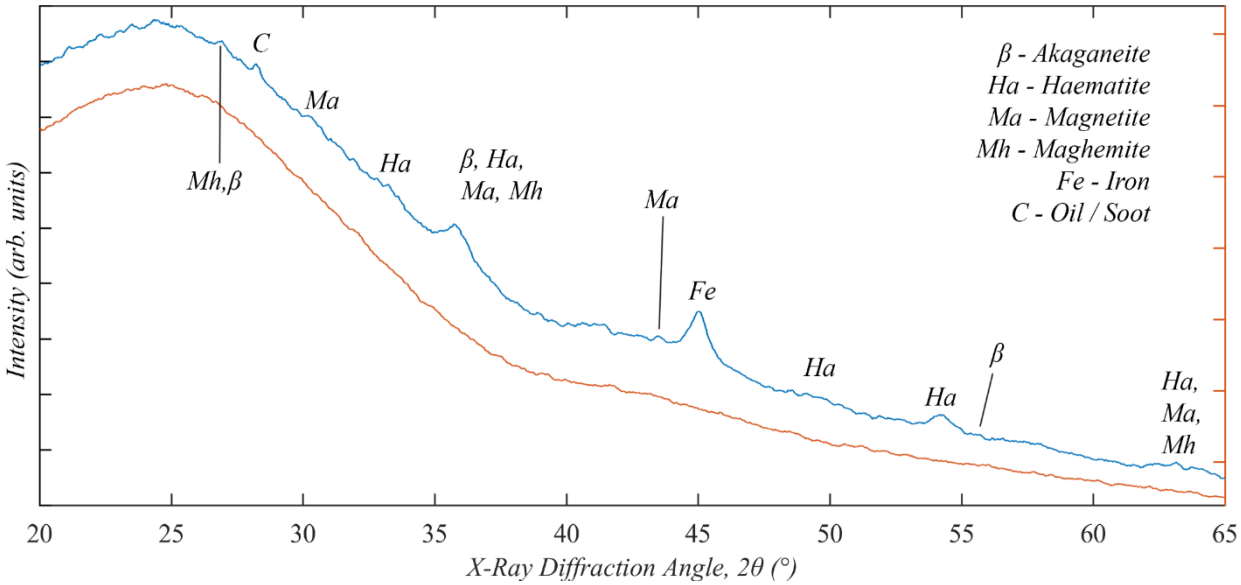

***Figure 13.** X-ray diffraction scan of a rail swab*

Table 1. *Swab composition: y is confirmed presence, m is probable presence*

Date	Sample ID	Rail Temp, C	Air Temp., C	Humidity, %	Oil / Soot	Maghemite	Magnetite	Haematite	Akaganeite	Iron
13-Feb-18	GF01	12.0	6	54	y	y	y	m	m	y
26-Apr-18	FP11	45.0	30	15	m			y		m
20-Jun-18	GF14	36.7	24.4	54.8		m		m	m	

The third data set (moderate temperature and humidity) proved difficult to get much material to transfer to the swabs, likely due to the railhead being in a relatively clean condition. The main spectral peak was the iron oxide haematite as well as elemental iron suggesting relatively dry conditions beforehand. Some iron-oxide-hydroxide peaks were also observed.

Figure 14 shows the corresponding friction/curves for the three samples tested. The plot 2_13 (February 13) is for the first sample (Table 1), April 16 the second sample, and June 20 the third. Friction levels were highest on the April 26, likely resulting from very low humidity and were lowest on June 20 when the analysis suggested the railhead was cleanest. The results show

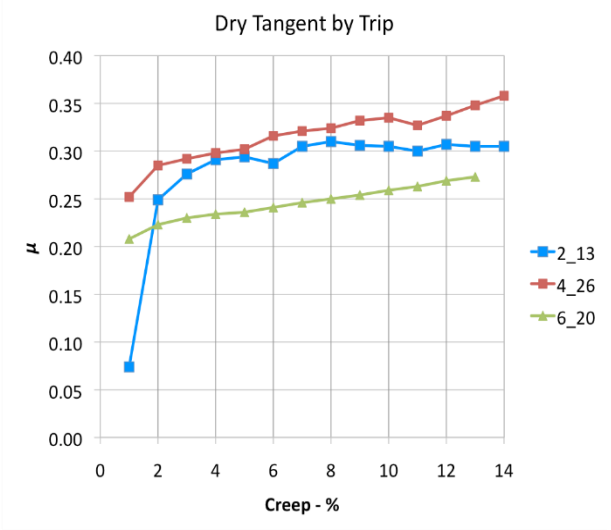

Figure 14. *Friction Creepage curves, dry, three site visits*

that under dry conditions, friction levels are highest with greater levels of oxidation and lower humidity. Under more humid conditions the oxide composition observed on February 13th had the highest degree of railhead oxidation and presence of iron-oxide-hydroxides. This may lead to the lowest friction conditions due to the properties of the oxides; however, this is yet to be tested. Further exploration relating the composition of the Third Body layer and environmental conditions to friction properties is needed.

4. Discussion and Conclusions

One of the original goals in developing the HO Tribometer was to be able to measure a creepage curve by continuously varying wheel angle of attack during one pass. This feature has had limited success. However, doing a stepwise measurement sequence from 0.1% to 15% creepage has proven to be more reliable, such as illustrated in figures 9, 10 and 12. More testing is needed to validate the accuracy and repeatability of measurements at creepages below 1%.

The HO Tribometer's ability to measure creepage, as contrasted to the previous widely used Push Tribometer, provides opportunities to further explore the friction interface between the wheel and rail. Like many new developments in other fields of engineering, this ability also reveals some effects that are puzzling and/or contradictory to previous expectations:

- There are substantial differences between maximum μ values measured with HO Tribometer, Push Tribometer, and the IWS. As previously discussed, the exact creepages at which IWS and Push Tribometer make their measurements are unknown, making a direct comparison difficult. The Push Tribometer, as normally used, typically is pushed along while noting the trend of the single values updated every few seconds. Instinctively, the operator waits until the readings stabilize. Recognizing this normal habit, our study logged all readings from the Push Tribometer immediately after cleaning. The result produced a spread of values that typically showed an increase in μ similar the HO Tribometer, but almost always at a much higher reading (Figure 12). Other factors, such as roughness and hardness of wheel surface, size of the contact patch and creepage regime (longitudinal vs. lateral creepage) may play a role.

- The HO Tribometer shows an increase in maximum μ values associated with increased Hertzian stress. This contrasts to previous experiments by one of the authors, which showed a clear inverse relationship between contact pressure and friction coefficient in a laboratory environment [23].

- Falling friction, i.e. decrease in friction force at high creepages, has not been consistently observed with the HO Tribometer under neither dry nor friction modified conditions. One possible cause is that the HO Tribometer operates at low longitudinal, high lateral creepage, in contrast with many other machines, which produce high longitudinal creepage. This may change the way Third Body layer is transferred from rail to wheel surface. Low sliding speed between wheel and rail may also play a role (it is lower than what is typical for trains and twin disc machines). Nevertheless, falling friction effects are not always detected with twin disc machines either, for unclear reasons [18, 19].

- The HO Tribometer has revealed very promising capabilities for understanding in more detail the behaviour of friction modifying materials, in particular differences in "retentivity" (the ability of the FM film to withstand creep forces from wheel passages) at different creep levels. This could explain the different behaviour of carry down effects for different targets (e.g. curve squeal, lateral forces).

5. Future Work

The work to date has not explored all potential applications of the HO Tribometer. In particular, we have not yet used the machine to study gauge face / gauge corner lubrication. Assessing the effectiveness of gauge face lubrication is one of the most common uses for the older Push Tribometer. The Push Tribometer usually gives values of around 0.25 for rail that appear well protected by lubrication. That range of values is higher than seems sensible from a tribological standpoint. Performance of the HO Tribometer under different gauge face / gauge corner lubrication conditions should provide valuable insights. The HO Tribometer also has clear potential for exploring other important aspects of friction, for example low adhesion problems related to moisture or leaf fall.

The insights derived from TOR FM performance have provided valuable output for this paper. Initial results reported need to be further explored under different conditions, e.g. curvature, effect of gradient (train braking), different FM materials, etc. The behavior of different types of FM materials [3] as revealed by the HO Tribometer may allow development of new FM materials tailored for optimal performance for different objectives (curve noise, corrugation, lateral force reduction, etc.).

The results reported on rail head composition and friction/creep behavior are rather preliminary and more research is needed to understand the fundamental Third Body material properties influence on friction. Additional results from the present work are also available but were outside the scope of this paper; analysis will continue and be reported later.

Overall, the HO Tribometer shows promise for improving field measurements of wheel/rail friction conditions. More work will be required to demonstrate its repeatability and accuracy. Understanding repeatability of friction measurements on rail in the field with any instrument has to deal with changing Third Body conditions. For example, it has been noted that the measurements of the Salient push tribometer on the same rail can vary by more than 0.2 on the same day simply due to changing temperature and humidity affecting Third Body composition and shear strength [24, 25]. A better understanding of why the HO tribometer reports lower values than benchmarks such as the IWS and the Push Tribometer, would be helpful to broaden acceptance within the railroad industry.

Future work should include further controlled experiments to evaluate its capability to repeatably measure creep force-creepage curve under both field and laboratory conditions for a wider range of materials and environmental conditions.

Acknowledgments

Partial funding for this project was provided by the Federal Railroad Administration (USA) administered through the National Research Council of Canada (E. Magel). Partial funding for the development of the HO Tribometer has been provided by Transportation Technology Center, Inc. (TTCI). We thank M. Santoro, M. Yu, P. Xia, L. Stanlake and C.-K. Luk (LB Foster Rail Technologies) for test materials, application support, and Push Tribometer measurements at Site 1.

Abstract

Squats and studs are defects in railheads that share features, but have different causes. This paper examined four squat and stud samples from three different traffic environments to compare features using μ-CT X-ray scans, surface and subsurface inspection. All defects contain similar superficial features but the depth of subsurface damage varies. Some of the studs show branching of cracks that could continue to grow into transverse defects, breaking the rail. The three defects that were scanned would all be classed as studs, but their crack morphology varies, possibly because they are all from different traffic environments.

1. Introduction

A great deal of research has been conducted in the area of squats, as they cause the need for expensive rail replacement by railway operators [1]–[3]. In the UK, between 4,000 and 10,000 new squats are detected in railway lines every year [4]. Despite growing knowledge in this area, the causes for the initiation of the squats and the reasons for some of the defects to develop transversely (causing the crack to travel down into the rail eventually breaking the railhead) are still unclear. Squats, also known as taches noirs (black spots) and shells, are a defect found on the running surface of the railhead. Squats have some typical features such as the black spots on the running surface and the v-shaped crack that branches towards the gauge corner (Figure 1), but they can vary due to extensive variation in traffic and layout conditions that a rail can experience. They typically comprise of a combination of plastic deformation and a subsurface crack network that may break the surface. Squats usually result in shelling of the upper surface of the rail but in some situations, the cracks can develop into a transverse defect, leading to a rail break.

Studs are a squat type defect that develop faster than squats [5]. They are caused by sudden heat flux in the running band due to excessive slip, i.e, wheel spin or wheel lock. While they develop faster than squats, they are not believed to break rails like squats can. They do not require plastic deformation of the surface material to form, are not linked with lubricant assisted crack growth [6], do not have the plastic deformation seen in squats and form in the running band rather than towards the gauge corner [5].

Studs arise from high slip leading to thermal damage of the rail. The thermal damage causes residual stress to become locked into the rail surface. There are two residual stress build-up mechanisms; from the temporary expansion and then contraction of the steel due to thermal input and then because of the lattice structure change from pearlitic base-centred cubic (BCC) through austenitic face-centred cubic (FCC) then cooling into martensitic base-centred tetragonal (BCT), which has a different volume to pearlite [7]. A tensile residual stress within the defect would pull cracks open, increasing the stress intensity factor at the crack tip. This results in a crack structure that ultrasonically looks similar to squats, but there are marked differences in their development as summarised by Grassie et al [5].

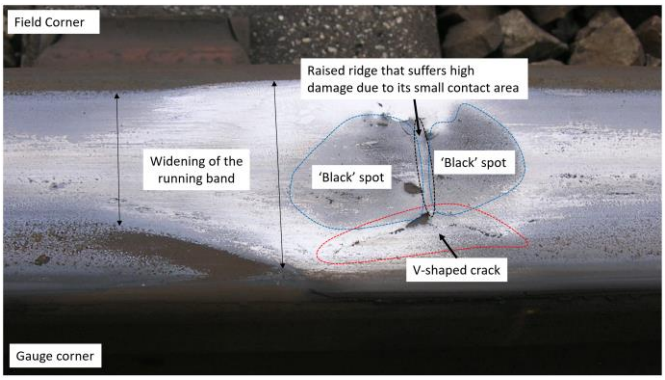

Figure 1: *An example of a squat defect. Original image courtesy of British Steel.*

Work carried out in Australia on squats refers to running band squats and gauge corner squats, so it could be that the running band squats were indeed studs, considering they are remarked as "often mistaken for wheelburn defects" [8]. These running band or rail crown squats are

considered to be similar in nature, but not in degree to wheelburns, are associated with a thick "White Etching Layer" (WEL) and can appear as multiple defects over a short distance [9]. Studs and squats share a similar subsurface crack network once the defect develops and they both have an association with WEL. Only a few samples have been presented as studs [5], so further comparisons between squats and studs would be beneficial to enhance the understanding as to what constitutes a stud and what should be identified as a squat.

The microstructural analysis and comparison of different squat samples should; give clues as to how they initiate, identify differences in any WEL present, show how the different traffic environments affect crack development and provide insight as to why some defects develop into transverse defects whilst others do not. In conjunction with traditional sample preparation techniques, this work utilises the use of X-ray micro-computed tomography (µ-CT) scanning as a non-destructive volumetric inspection tool [10]. This allows accurate targeting of regions of interest within the defect for closer inspection prior to any destructive sample preparations. µ-CT scanning has been used previously to successfully investigate the form of squats by Naeimi et al [11], who also gives good justifications for why CT scanning is a powerful NDT tool that maximises the information that can be retrieved from a sample. This work builds on this by expanding the scan to the entire defect, which required a 450kV µ-CT scanner.

2. Rail Samples

The samples were sourced from metro, mainline and high speed track in the UK and France. The samples have been characterised using 3D microscope mapping, X-ray µ-CT, optical imaging and scanning electron microscopy (SEM) in order to provide a comparison between them. The characterisation techniques also allow the identification of any samples that are squat type unidentified defects (studs). As a simple comparison, studs do not have the heavily deformed layer on the surface like squats do. Squats take much longer to form than studs: ~100MGTs of traffic to ultrasonic detection as opposed to ~30MGTs for a stud [5]. The samples analysed are shown in Table 1:

Table 1: *List of samples examined*

Sample number	Location removed from	Traffic type	Grade
1	France	Metro	R260
2	UK	Metro	R260
3	France	Mixed	R260
4	UK	High speed	R260

The samples were subjected to a variety of tests to assess and capture the characteristics of the defect. The tests are shown in Figure *2*, although not all samples went through every stage. Surface analysis was carried out to document the surface of the sample and choose points of interest on the sample. It was also used to compare the surface of the samples to each other. µ-CT scanning was not conducted on sample three as the surface had already shelled. All samples were sectioned, prepared and analysed optically with the most interesting regions being inspected using SEM.

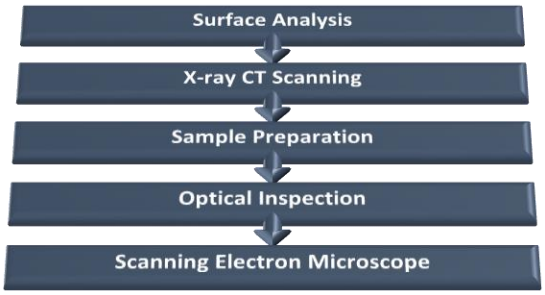

Figure 2: *The sequence of tests conducted on the squat samples.*

2.1. Sample 1

Not much is known about the track location and traffic experienced by sample one other than it was from an inclined track near a station on a metro line. Sample 1 is shown in Figure 3a. It shows signs of sliding surface damage and the dark spots are quite well developed. It contains a lot of surface damage including four obvious surface cracks, streaks of what is assumed to be white etching layer (WEL), a pit in one of the cracks, what seems to be 'snakeskin' damage just outside the widened running band. 'Snakeskin' is also known as running surface checking or flaking and is a precursor to spalling of the rail surface [12]. There is also the very common V-shaped crack that squats are known to exhibit, although the angle within the v in this crack is more obtuse than expected. There is also a faint series of small cracks along a ridge that extends from the apex of the V-shaped crack out between the two lobes which is often observed as squats develop [13]. On initial inspection, the presence of some lipping on the gauge corner of the sample combined with the typical black spots and v-shaped cracks, make this sample likely to be a squat.

2.2. Sample 2

This sample was taken from the high rail of a uni-directional rail in a gentle curve just over 1km along a 3.2km distance between two stations. This track has relatively high line speeds and is very busy regarding passenger trains compared to other lines on the same network. However, this sample came from a fairly rural overground section near the end of the line so the train volume may be less.

Sample two is shown in Figure 3b, and is post MPI (magnetic particle inspection): a non-destructive test that uses magnetic ink on a white contrasting background to highlight defects in the surface. The long crack seen on the left of Figure 3b, seems to be a combination of the long cracks found at the edge of the running band in samples 1 and 4 (Figure 3a and d respectively) and the expected V-shaped crack typically

seen in a classic squat. The crack also has sharp edges unlike the embedded cracks found on the other samples, possibly a sign that the crack is very recent. Sample two also has significant discreet material removal. These look like corrosion pits, but are more likely localised delamination and flaking characteristic of "ratchetting" [14]. Ratchetting is incremental plastic deformation of the upper surface of the rail material due to cyclic strain build-up. Unique features in sample two are possibly because of traction control being used by the rolling stock on this line. Traction control has been linked to squat development, or more specifically, thermal damage of the rail [15].

With just under 11MGT of traffic, initial thoughts were that it is very likely a stud rather than a squat. Studs are detectable from ~10MGT whereas squats are detectable from ~40MGT, the surface is also smooth to touch unlike squats, which are rough to touch in one direction due to the accumulated strain [5]. There was also no noticeable corrugation on the 1m section of rail, which would add to the dynamic loading and is often found in the vicinity of squats. However, the V-shaped crack can be made out and there is a crack along where the ridge should be.

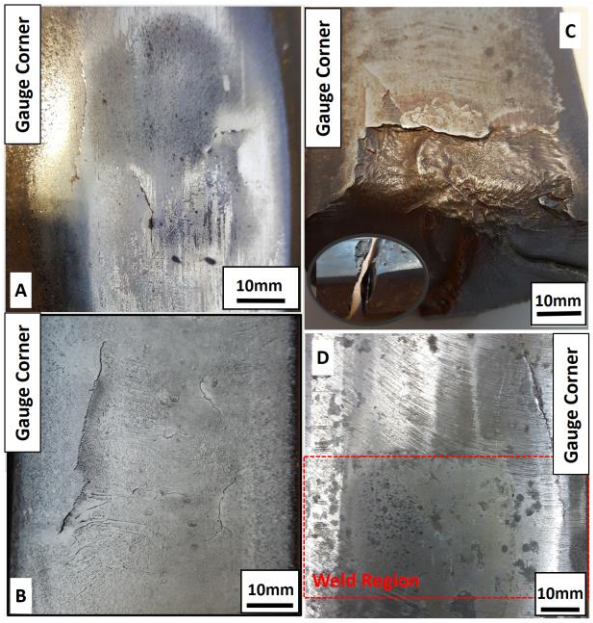

Figure 3: *Images of the samples, all of which are a full rail width (~75mm wide) a) Sample one b) Sample two covered in white paint to contrast the black ink in the cracks during a magnetic particle inspection c) Sample three with the other half of the defect inset d) Sample four with the weld region highlighted in red*

2.3. Sample 3

Sample three is a broken rail of unknown MGT, which failed due to a transverse defect, within a squat defect, shown in Figure 3c. Most of the squat was damaged in the break, removing any surface evidence of the expected V-shaped crack. There was not much information to be gained from the shelled lobe either. However, the unbroken lobe of the squat was still available to view. The second lobe was very close to shelling and so presented the opportunity to remove the almost separated plate of surface material from the top of the defect. This allows the inspection of the crack plane below the squat. This plane was covered in oxide but the presence of water may have come from the cutting process due to the coolant flooding the sample. The plane was dry ice blasted to remove the oxide. The plastic flow shown by the folded material right next to the shelled section makes this most likely to be a squat.

2.4. Sample 4

Sample four, shown in Figure 3d, was initially identified as a squat on a weld and following an ultrasound test, was believed to be a combination of a squat interacting with a weld defect. The longitudinal crack that runs along the edge of the sample shows that the squat is slightly elongated, possibly linked to the higher train speeds [16]. The lack of deformation in the squat and the traffic total of ~28MGT makes it highly likely that this is in fact a stud, and not a squat.

As with samples one and two, sample four has a large crack on the gauge corner side, but not the v-shaped crack that is usually expected of a squat. The sample showed extensive grinding marks across the surface, not including the depressed region of the defect, which was in the weld region. Grinding marks were more extensive than the other samples but this could simply be because grinding had occurred more recently. Grinding marks and other features that increase the roughness of a surface, such as crack mouths and the pits seen in sample two, can increase the subsurface stress by a factor of eight compared to smooth surface contact [17].

3. Analytical techniques

3.1. Alicona Infinite Focus SL 3D Microscope

The infinite focus (IF) microscope is capable of capturing both the form and the roughness of surfaces. It uses a reference point and coordinate system that maps a surface area and can measure surfaces up to 87º , so some features cannot be captured and appear as white regions within the bulk image (areas of no data). The microscope was used with IF-MeasureSuite Version 5.1 software.

In order to create the images in this work, two points needed to be specified in the volume of interest. These points had to contain the lowest x, y and z value and the highest x, y, and z value that the volume of interest occupied. By specifying 'two corners' of the volume the system then breaks the volume into a 3D grid and takes multiple images at various focal lengths across the entire x-y plane. The software then identifies the regions in each image that are in focus, and knowing these focused positions, stitches them together to provide a 3D model of the surface that can be manipulated by the user.

3.2. X-ray Micro-Computed Tomography (µ-CT) Scanning

Micro-focus cone beam X-ray CT (µ-CT) is a non-destructive volumetric imaging method, which works by acquiring a series (thousands) of 2D projection radiograph images based on X-ray photon absorption, as the specimen is rotated around a single axis, usually through 360º. The 2D projection images are then

reconstructed into a 3D volumetric dataset using mathematical tomographic reconstruction algorithms, commonly based upon Filtered Back Projection (FBP)[10]. The voxel intensity (grey scale value) in the reconstructed volume slice images, reflects a combined function of the variation in X-ray absorption, (which is a function of the specimen's physical and radio-density), and CT artefacts from the acquisition and reconstruction process[10], [18]. Therefore it can be inferred for the reconstructed images in this work, that the brighter voxels represent the dense metallic material, and the darker pixels represent less dense materials, i.e. air, cracks or voids in the sample. Care must be taken when interpreting images as artefacts can provide distorted images [18].

3.2.1. Data analysis

Avizo 9.3 (FEI SAS, Thermo Fisher Scientific, USA) is a 3D materials characterisation software that allows the visualisation and analysis of large data sets. The user can segment volume data to form colour coded models, i.e. grey scale voxels are labelled with colours corresponding to different structures identified within the specimen, such as different materials and features such as cracks and pores.

For this work Avizo was primarily used to map out the planar crack network of the defects within the rail samples. In the orthoslices of the scan the image was changed from greyscale to green and black to make the cracks more visible by eye. A touch screen pad and stylus connected to the computer were used to manually draw in the cracks for each 2D slide, first longitudinally then cross sectional. The model is then improved from a mesh structure into a smoother planar structure using linear interpolation between two known points. The two known points are the lines that have been drawn into the orthoslice.

VGStudio MAX (Volume Graphics GmbH, Germany) is a voxel based software that was used to view the orthoslices and take measurements of features within the µ-CT volume data. Fiji/ImageJ is an open source image processing software (National Institutes for Health, USA).

3.3. Microscopy

Before micro-preparation, the large rail samples were cut using industrial band saws. Sample one is an exception as it was received already cut to approximately 80x100x20mm. Micro-preparation involved the processing of the relatively large rail samples from the size of the defect down to etched and polished samples that would show the pearlitic microstructure under a microscope.

The samples were cut using an abrasive disc cutter, mounted in 32mm Bakelite discs, ground and polished down to a 1 micron diamond suspension finish. The samples were then etched in 2% nital (2% nitric acid and 98% ethanol) as is typical for steel: this reveals the microstructure. Once revealed the microstructure was inspected and documented using a Nikon Eclipse LV150 optical microscope with Buehler Omnimet software and Zeiss Axio Imager.A2m optical microscope with AxioVision4 software.

4. Methodology

4.1. Surface analysis

The surface was mapped from optical images of the samples and using the IF microscope. Attention was focused around surface breaking cracks and vertical irregularities such as grinding marks and pits. The region of interest was identified by specifying a 3D volume and the number of scanned points were reduced by using the 'decimate' function until the file size was manageable (the software gave a warning if it was too large). The 'decimate' function was always used once, twice for relatively large areas but never three times.

4.2. CT scans

The CT scans were conducted on samples one, two and four at the µ-VIS X-ray Imaging Centre (University of Southampton, UK) using a custom built, dual source 225/450 kV walk in room (Nikon Metrology, UK). The scans were acquired using a micro-focus 450kV source fitted with a tungsten reflection target together with a Perkin Elmer XRD 1621 CN03 HS detector.

The samples were made as small as possible without cutting into the defect. The smaller the sample could be made, the better the images would be. The sizes of the samples varied slightly depending on the size of the discernible defect. Sample four was reduced in size slightly after an initial quick scan allowed a more accurate idea of where the crack network was to be found. At its full size, sample three was approximately 8 cm wide, 10.5cm long and 3cm deep and the scan was able to identify the crack network clearly enough to trim the sample. The final size of the samples scanned are shown in Table 2. The width was taken along the bottom of the sample rather than over the curved surface.

Table 2: *Dimensions of samples that were µ-CT scanned*

Sample	Width (mm)	Length (mm)	Depth (mm)
1	70	55	15
2	74	85	15
4	66	65	26

Each sample was mounted within a 3mm thick Perspex tube in a vertical orientation, so as to minimise X-ray photon penetration path length. The source to object distance was set to 235 mm, and the source to detector distance was set to 800 mm, achieving a reconstructed voxel (cubic pixel) resolution of 50 µm. 4 mm of copper pre-filtration was used in addition to the aluminium window that forms part of the target housing on the X-ray gun. Each µ-CT scan was performed at 400 kVp (peak voltage) and 248 µA, using a 177ms image exposure time; 2801, 3142 and 2601 projection images were acquired during a full 360º rotation, with 32, 16 and 32 frames averaged per projection, for samples one, two and four, respectively. The projection images were

reconstructed into 2000x2000x2000 voxel 32 bit volumes using the FBP algorithms implemented within X-TEK CTPro 3D and CTAgent software packages (Nikon Metrology, UK).
Two scans were used to cover the full height of sample two, and the reconstructed volumes were concatenated using Fiji/ImageJ. Each sample's volume was converted to 8 bit in Fiji/ImageJ to reduce the computation time for analysis, and saved as a raw volume for review in VGStudio MAX. The results were viewed as three windows of orthogonal slices through the rail, providing a longitudinal, cross section and aerial view of the rail in orthoslices. The data was also investigated using Avizo, mentioned in section 4.3, building a 3D crack model. Cracks were highlighted every five orthoslices and added to the model, then the planar interpolation feature was used to interpret where the crack was most likely to be between the five slices. The built in crack detection software struggled to identify the cracks accurately if at all, hence the manual segmentation method. This was done for both the longitudinal and cross sectional slices.

4.3 Scan verification

The presence of CT artefacts in the volume images, from effects within the scanning and reconstruction process such as photon scatter, partial volume effect, image noise and beam hardening, could lead to spurious features within the reconstructed volume. A visible artefact when viewing some slides is the apparent 'shadows' that cracks can cast when they get very close to each other (streaking artefacts), this can make it look like there is a small void in the material. In order to be sure that what the scan shows is real it needed to be compared to micrographs of the scanned segment. Shadows that occur along a crack in were of particular interest as they may hold clues as to why the crack plane develops in certain directions.
Measurements were taken using the VGStudio Max software caliper tool and then the sample was marked up with cutting lines in preparation for physically cutting the sample to expose some of the interesting features found in the scans. The samples were prepared as described in section 3.3 and then compared to the slices to see how accurate the scans were.

5. Results

5.1. Sample one

On sample one there were quite a few differences in surface finish, such as the shiny running surface next to the dark corroded region of the black spots, as well as the cracked 'snakeskin' region. There are four obvious cracks on the surface that are identified in Figure 4 and the scanned images of them are in Figure 5. The longitudinal and obtuse V-shaped crack are found in the other samples, but the L-shaped and Y-shaped cracks are not (shown in Figure 4). The Y-shaped crack has been seen before in a squat sample reported on previously by Tata Steel [19] along with the 'snakeskin' surface damage (see Figure 6). In the Tata Steel report the snakeskin was also found on an area of the rail that did not contain a squat. The dark spot within the V-shaped crack is believed to be a spalled piece of snakeskin as the snakeskin can be faintly seen close to the crack (bottom left corner of Figure 5).
Figure 6 shows the Y-shaped cracks in sample one and the Tata Steel report as surface and subsurface defects. As the Y-shaped crack was the only surface crack in the Tata Steel report it can be assumed that this crack forms first. The shallow depth of the defect in the report compared to sample one also suggests that sample one is much more developed. Both samples are believed to be from the same metro network.

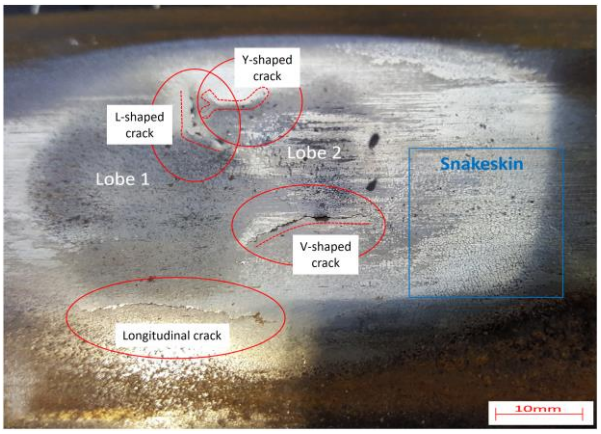

Figure 4: *Sample one with the cracks marked in red and the snakeskin marked in blue*

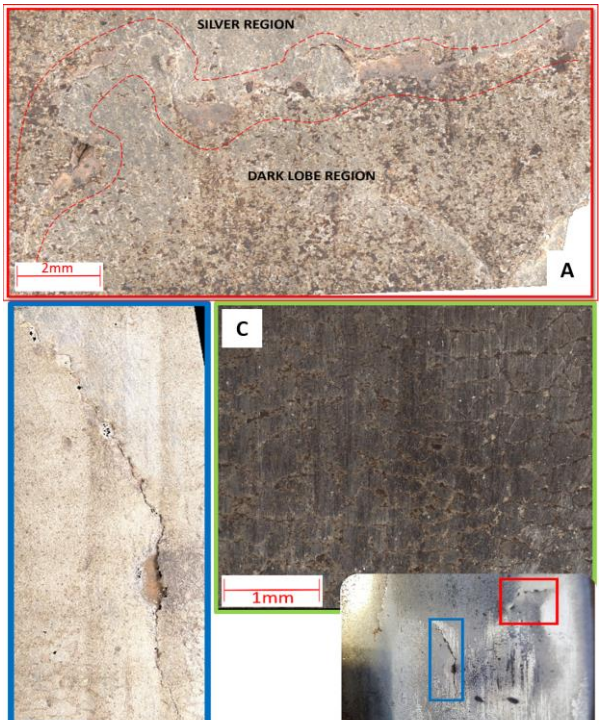

Figure 5: *Some of the surface features imaged from sample one a) The L-shaped crack with 'islands' that appear pink in the scan b) The V-shaped crack with a pit that penetrates into the substructure c) A colour coded overview showing where the images are taken from d) 'Snakeskin' microcracks across the surface of the rail just beyond the defect*

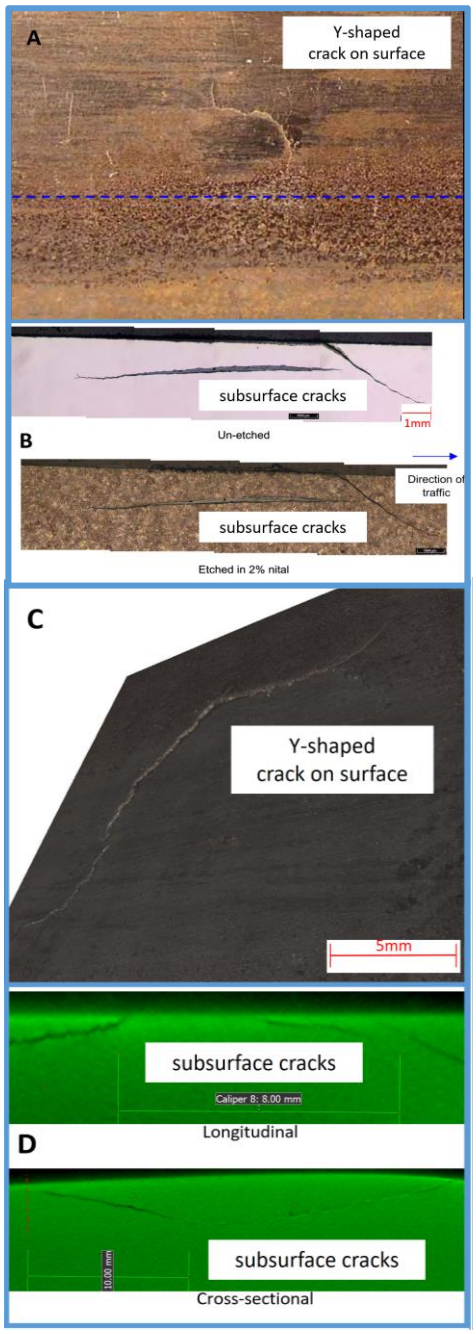

Figure 6: *Comparison of features of a squat from a Tata Steel report [19] with scan results from sample one. a) The surface of the squat from the report, b) Longitudinal cross sections from the report, c) Surface scan from Alicona of sample one, d) Longitudinal and cross sectional x-ray scans of sample one (red dotted line shows where orthogonal slices cross)*

The presence of the two cracks suggests the possibility of one crack initiating subsurface whilst the other initiated on the surface. Using the x-ray scanned volume that Figure 6d was taken from, it can be seen that moving through the sample towards the field corner shows that the cracks stay separate, although they may have connected within the region that was worn away. Moving through the sample towards the gauge corner shows the two cracks connecting as a very shallow crack parallel to the surface that makes up the bottom portion of the Y shape (when viewing the Y as written here).

Comparing the report to the scans makes it highly likely that the initiation was in this area, and the branching of the longitudinal crack occurs within 4mm of the longitudinal slice in Figure 6d, moving towards the gauge corner. Being that the Y-shaped crack is closer to the field corner than the gauge corner suggests that a two point contact between the wheel and the rail may have been responsible. High surface temperatures occur with lower creepage and train speed when the contact patch is reduced like in a two point contact [20]. Sample two also contains a similar Y-shaped crack in a similar region but the clarity of the two cracks is not as clear, although a higher resolution scan of that area is planned for future work due to the branching of a possible transverse crack being in the same region. The L-shaped crack tracks the boundary between the dark lobe of the squat and the shiny surface of the running band, it also appears to contain islands of a different phase of steel, possibly martensite. This crack will be the subject of further investigations.

Sample two

All of the samples showed the typical inverted V-shape that is expected in a longitudinal slice from a squat or stud. Sample one showed a branching crack propagating slightly deeper into the rail and sample two showed a lot more damage further along the rail from the expected inverted V-shaped crack. This damage was due to multiple branches of cracks that were turning down into the rail and continuing to branch further, as it is common for the leading crack to do. This damage was more significant than that in the other scanned samples, especially when considering the mere 11MGT of traffic experienced by sample two.

Another detail that showed through the full construction of the models was that the ‘C’ and ‘O’ shaped cracks found in the centre of the surface of samples two and four were the location where the inverted v-shaped crack had been truncated by wear (Figure 7). Sample one did not have this feature and sample three had a surface breaking crack in the same region but of a different morphology.

Sample two had much more damage than expected. Figure 8 shows a longitudinal section from the scan: although the clarity of the scan is low due to the size of the sample, parts of the transverse crack can be discerned up to 8mm deep into the railhead. Cracks can be seen reaching 10mm deep in other areas of lower overall visibility. A higher resolution scan will be conducted on this region to clarify the structure of the deeper crack and hopefully clarify the region that caused the crack to become a transverse defect.

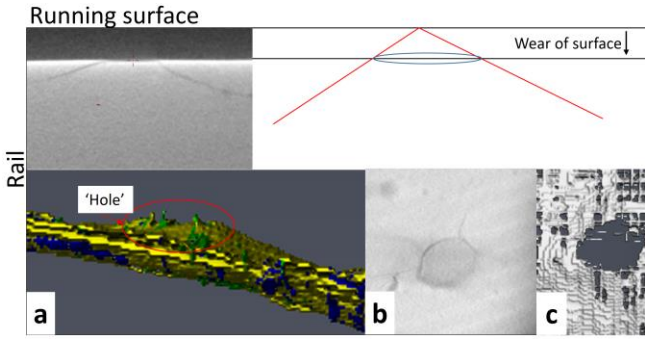

Figure 7: *A diagram showing how wear truncates a pair of cracks to leave what is seen in the scan slice. Inset; a) The 'hole' from the longitudinal view as modelled in the Avizo model of sample two, b) The original scan image of the surface of sample two, c) The same view as (b), but of the Avizo model*

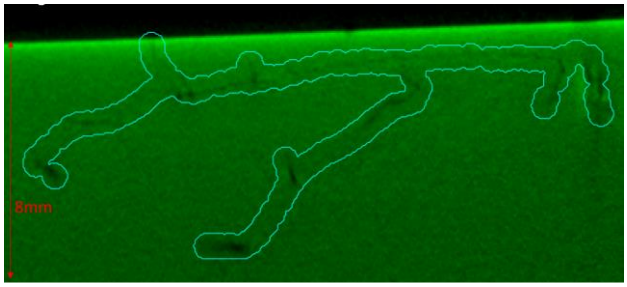

Figure 8: *Longitudinal orthoslice of sample two showing the branching cracks.*

5.2. Sample three

Due to the in-service break, the results obtainable from sample three were limited compared to the other samples. Its inclusion in the comparison was due to the known transverse defect. The undamaged lobe of the squat was still intact and it was possible to remove the upper plate using a cross-sectional cut between two of the longitudinal surface breaking cracks. This revealed a structure similar to the models of the scans along with a discrete vertical crack that broke the surface as a wide crack and penetrated slightly deeper into the rail as seen in Figure 9. The scan in Figure 9c shows the surface area before it was cut, which includes features that appear as two white cracks in the scan due to the information being lost within the crack rather than being captured by the detector. These fairly wide crack mouths are believed to be part of the remnant of the initiation site. Judging by the amount of folded over material just next to the 'white holes' there were high contact forces in this area. The material may have flowed from the ridge that often occurs between the two lobes of a squat as this ridge experiences very high contact forces. Figure 9e shows what appears to be a small void in the crack in area highlighted by the orange box in Figure 9b. This area was scanned (Figure 9f) and the morphology suggests that either there was a small void or the crack plane travelled around a possible inclusion like that shown in Figure 8.

5.3. Sample four

Sample four had much less damage than expected, based on the results of the ultrasound tests. The ultrasound gave reason to expect a weld defect as well as the surface defect. However, there was no sign of a weld defect in the upper 26mm of the head and the welds heat affected zone (HAZ) did not seem to have much influence on the crack planes overall morphology. The crack plane was extensive but travelled at a fairly constant angle with few deviations other than the 'dome' (Figure 7a) where it surfaces into the C-shaped hole, which is on the boundary between the weld and the rail, so the HAZ and differential wear are probably responsible for the squat. It was the most benign of the four samples as it was the only crack that did not branch.

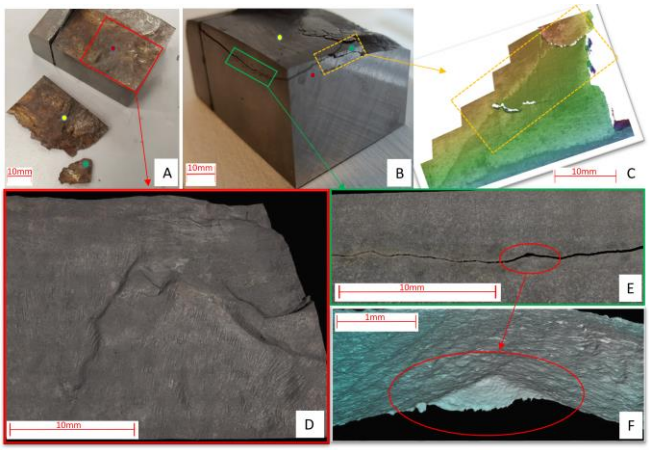

Figure 9: *The fracture surface under the remaining second lobe/ spot of the squat in sample three. A) The fracture surface immediately after removing the upper surface. B) The sample before the removal of the surface showing the two cracks propagating down into the rail from a possible initiation point. C) The 3D model of the possible initiation area taken before cutting with the orange box showing the common area D) The 3D model of the crack plane shown in A. E) An enlarged view of the green box in B showing either a pore or region where material was lost. F) A 3D model of the 'pore' showing that the crack travelled around something, perhaps an inclusion.*

5.4. Scan verification

In sample one, an orthoslice of interest was one that showed a crack branch down from what appeared to be a small void on the surface, which was visible from the surface scans. The crack then displayed interesting behaviour by branching in a circular shape as though propagating around something that it could not penetrate. There were also small shadows on the scans, which were investigated to see how real they were. Figure 10 shows the two comparisons of the scan slices mentioned and their accompanying micrograph. The upper red circle shows a region where the finer crack does not show but the larger crack does and the lower circle shows how a branching crack can create a shadow. Sample four also showed a shadow near the surface breaking feature in the centre of the rail and the verification of that scan is shown in Figure 11. Figure 11 shows; a shadow found on the crack within the CT scan, the cause of that shadow and verification of the structure shown in the green box, which is responsible for the C shaped crack that breaks the surface of the

running band. It also shows a zoomed image of the area that caused the shadow to appear: a small void, possible cleared during sample preparation and possibly a branching point for the crack.

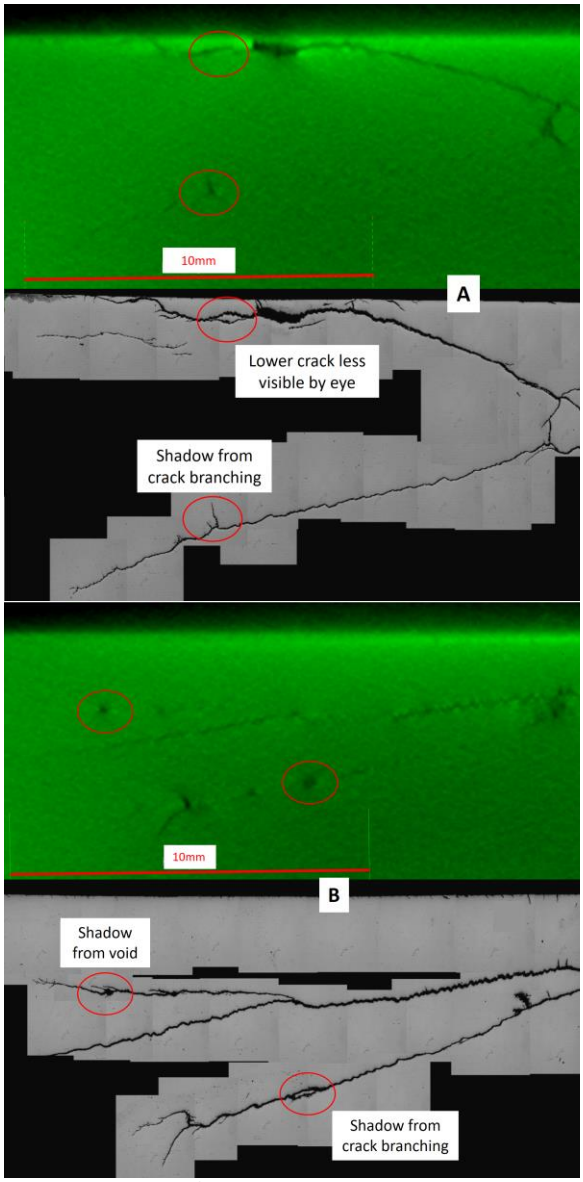

Figure 10: *Comparison of longitudinal CT scan orthoslice to longitudinal section in sample two a) The surface void visible from the surface scans with a shadow and its cause highlighted b) Branching that shows shadows in the scan and the same cause as (a) in the micrograph.*

6. Discussion

Although the four defects are from different countries and track environments, they all share a longitudinal crack along the edge of the running band. This shows how heavily developed they are as this is where the crack plane finally surfaces. This surfacing was probably recent in sample two as the crack is still rough. Both metro samples (one and two) had a Y-shaped crack that was also found in the literature [19]. This Y-crack is believed to be the first to develop of the various cracks found in samples one and two and is on the field corner half of the railhead rather than towards the gauge corner. The cooling that occurs after excessive wheel slip is higher outside the contact patch and considering the damage from thermal input is cause by tensile stress during cooling [21], this could explain why early cracks such as the Y-shaped crack occur easier on the edges of the contact patch. The presence of two unconnected cracks under the Y-shaped crack brings in the possibility of two initiations, one subsurface and one close to or on the surface. It is likely that one appeared first then the other as a result, as the leading-trailing crack theory in the literature mentions.

Samples two and four have a ‘hole’ in the running band where the conical crack has been truncated as the tip is worn down. This hole had a loose piece of material in the centre that was lost during cutting, so it was beneficial to have preserved this information in the scans.

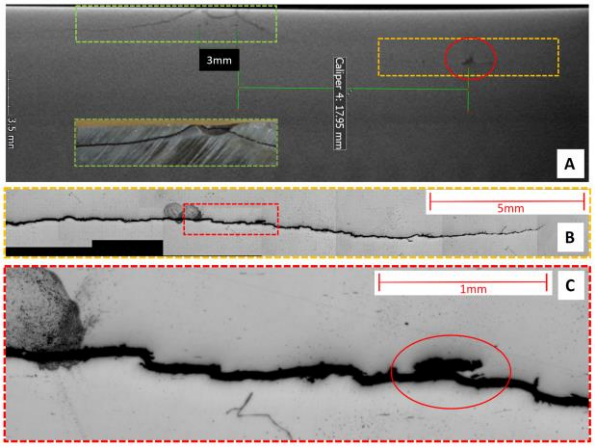

Figure 11: *Longitudinal slice through the c-shaped crack in the centre of the surface of sample four. a) CT scan orthoslice showing the surface breaking crack highlighted in the green box with a photo of the sectioned sample inset in the lower green box b) An unetched micrograph of the area highlighted in the orange box c) An expanded view of B, with a red circle showing the cause of the shadow in the CT scan orthoslice (a).*

Sample one was initially believed to be a stud because of its fairly smooth surface and the likelihood or a bad wheel slip event being from an incline. However, the presence of lipping on the edge of the rail (i.e. plastic flow) brought this into question. Sample one is lacking the ‘hole’ that was noted in sample two and four despite having significantly more surface damage than any of the other three samples (or the reported squat that it was compared to in section 6.1). The lack of plastic flow on the surface, smoothness in both directions and the tiny islands of WEL found make it highly likely that this is a stud and that the lipping was not due to the defect.

Sample two is believed to be a stud, primarily because of its very low MGT, smooth surface and lack of plastic deformation. Checks for lubricant penetration were not conducted on any of the samples as they were contaminated by cutting fluids whilst trying to expose the cracks. There were pits above the most damaged region with two pits being connected by a surface crack. Investigations into more samples that have this feature would be very beneficial as it may explain why the defect was so well developed considering there was so little traffic on that rail. This is based on the principle

that a rough surface causes much higher subsurface stresses.

The wider crack in the V on sample three is where the cracks meet near the surface making this a likely initiation point due to ductility exhaustion.

For sample four, there is only one region where there is variations in the cracks, the only other features are simple and linear cracks that propagate just under the surface as expected. The weld does not seem to affect the crack structure and the only noticeable difference is that the crack structure is longer in the longitudinal direction: this could be due to more MGTs, not necessarily the higher speeds experienced. Overall sample four had less branching than the metro or mixed traffic samples, possibly due to modern track construction and less traffic variation/ better profile matching between the wheel and rail.

The scans allow comparison of samples even if the same cuts were not made in sample preparation. Access to the sample that sample one was compared to was not available but being able to move through a volume allowed the same specific feature to be found, even though it was only ~1mm wide. A library of µ-CT scanned defects would allow a more comprehensive comparison of different defects and would aid in categorising them. The details in the scan were verified by comparison to micrographs of the sample after micro-preparation. Figure 10 and Figure 11 show that the shadow highlighted by the red circle is real and the faint traces of the upper crack are real too. The uppermost crack was not obviously a crack like the lower two were so the scan did not depict all of the cracks with the same clarity. This is due to the size of the sample scanned, i.e. smaller samples are easier to image clearly.

7. Conclusions

Studs from the metro networks in France and the UK seem to share a Y-shaped crack feature: containing subsurface cracks that seem to have developed independently rather than branching from a single point. This region is possibly part of the early initiation as the sample referenced in section 5.1 only contained this crack and some 'snakeskin'. This crack being located on the very edge of the contact patch suggests possible initiation by a two point contact/ hollow wheel.

Surface breaking 'holes' in sample two and four are a feature for two of the studs and are truncated inverted V-shaped structures typically found in both squats and studs.

Based on the four samples compared, studs may be far more common than initially expected, especially on metro and high speed lines. The track operators initially identified all the four samples as squats.

The four samples were determined to be as shown in Table 3:

Table 3: *Defect identity of samples examined*

Sample	Identity
One	Stud
Two	Stud
Three	Squat
Four	Stud

There would be great benefit in creating more CT volumes of squat and stud samples at various stages of development, allowing comparison of defects and aid in searches for specific features. It cannot be determined from this work if a CT scan can discern between a squat and a stud as all 3 samples that were scanned are believed to be studs.

Further research, including SEM, will be conducted on all four samples, further confirming their identity as squats or studs by looking at microstructural details such as plastic flow, WEL and crack paths. The composition of the regions within diverted cracks that created shadows in the scans will be investigated to identify any inclusions. Hardness mapping will also be used to look for variation in hardness from the thermal expansion and contraction experienced by the surface region of the railhead. Verification will be conducted as to the possibility that µ-CT can identify deformed microstructures and phases, such as martensite, due to the difference in the photons attenuation. Further µ-CT scans will be conducted on sample two to investigate the transverse branching crack origin. The surface L-shaped crack will be further investigated as it seems to be the origin of many of the cracks. Mechanical tests will be conducted using small scale and full scale rigs, to simulate the thermal damage observed in some of the samples presented. Work will also continue to improve the accuracy of the models of crack networks produced from the scans, to be presented in future work.

Acknowledgments

The authors would like to thank British Steel, London Underground and other track operators for the procurement of the samples and data associated with them. Thanks to the team at µ-VIS X-ray Imaging Centre at Southampton University for their support in producing and understanding the scanned volumes. Gratitude is also given for the conversations with industry and academia that were crucial to guiding this research.

Abstract: The paper examines possibilities for holistic modelling of the running gear / track interaction and related phenomena – in particular material deterioration phenomena. The required resolution, accuracy and challenges in understanding, describing and (in particular) modelling these phenomena are addressed. Special focus is put on contact modelling, which commonly sets the limit for the level of accuracy that can be achieved in subsequent analyses.

Keywords: numerical simulations, wheel–rail contact, contact mechanics, material deterioration

1. Introduction

A number of crucial phenomena originate in the contact between wheel and rail. These range from overall vehicle dynamics behaviour, over general degradation phenomena of wheel and rail running surfaces, through generation of noise and ground vibrations, and to deterioration of wheelset and track components that are located relatively far from the wheel/rail contact. The characteristics of the wheel–rail contact conditions will have an influence on all of these conditions. However, depending on the phenomena studied, some aspects will be more important than other. This is important to acknowledge since a very detailed modelling of the wheel–rail contact is often not feasible and will sometimes not even improve the quality of the results, as will be discussed below.

Depending on the the circumstances, different simplifications in modelling contact phenomena can be allowed, cf [1, 2]. The current study will discuss which simplifications that are plausible to make under which circumstances. It also aims to penetrate consequences of simplifications or more detailed analyses, and provide some examples of different approaches from the literature.

An aspects that needs to be highlighted when discussing simplifications for simulation purposes is how well the "reality" is known compared to how detailed the model is. This can be illustrated by an example from material modelling: The steel structure on the microscale is highly inhomogeneous, contains defects *etc*. However, numerical simulations can only investigate a specific microstructural configuration at the time. This will give a very detailed understanding providing all relevant characteristics of the microstructure are known, but the results are valid only for a very specific case. The next level of detail is to vary the microstructural configuration in a representative volume element, see e.g. [3]. The response of this volume element is presumed to be characteristic of the material. The bulk material response can therefore (ideally) be obtained by an averaging (also called homogenisation) of the response. The modelling approach with the least level of detail is to ignore the microstructure and directly derive the bulk material properties and employ them in a phenomenological model, but also here there are more or less sophisticated approaches, as will be discussed below.

Material properties at the bulk level are commonly well known, whereas properties at the microscale—which not only include the properties of the constituents, but also how these bond *etc*—are usually less known. If the detailed model includes a large amount of estimations on these properties, the overall *quantitative* predictive precision will not increase. Note that detailed modelling may still provide valuable *qualitative* insight into different mechanisms e.g. on the influence of different microstructural configurations.

A second aspect in the selection of modelling approach is what characteristics of the studied system that have the greatest influence on the studied phenomenon. If we continue the example with the microstructure, the relative strength of the constituents of the microstructure may be of importance. However, if for example the risk of subsurface initiated rolling contact fatigue is considered (see section 4.3) that influence will be very small compared to the influence of material defects. Consequently, from that perspective, reliable statistics on sizes of occurring material defects would provide more useful information than detailed statistics on the strength of the microstructure constituents. This also relates to the topic of what the simulations aim to capture versus what simplifications that can be made: If for example the simulations aim to capture the structural response, a much less detailed material model can typically be employed as compared to what is required for a rolling contact fatigue analysis (see section 4).

To summarize, any numerical simulation should preferably be preceded by an evaluation of what simplifications are suitable considering the aim of the simulation, the required precision, the available input data and the quality of this data, and computational and time limitations. This overview is intended to support such assessments.

2. The multiple levels of complexity of the wheel–rail interface

Wheel and rail surfaces are typically characterised by their global geometry. However, in closer view, also apparently smooth surfaces show geometrical deviations. One characterisation of this surface roughness following [4] is presented in Figure 1. In many cases the geometrical representation of wheel–rail contact only includes the nominal geometry (ideal surface according to Figure 1). However, it is not uncommon to also account for macroscopic deviations, e.g. due to plastic deformations and wear. In the context of wheel–rail contact, waviness mainly relates to corrugation and grind marks on rails, and out-of-roundness and cut-marks on wheels. Wheel and rail roughness are typically only dealt with implicitly, often in a context including "third-body" layers and friction modifiers. Commonly, this is done in relation to frictional characteristics and/or noise generation in the wheel–rail interface. There are however explicit analyses of the contact pressure subsurface stress field resulting from a rough wheel–rail contact. In [5] measured surface roughness from a Shinkansen rail was employed in numerical simulations of the elastic contact. In these simulations, the evaluated peak contact pressure exceeded the nominal magnitude by a factor of eight. Further, shear stress magnitudes in a thin layer below the surface was found to significantly exceed stress magnitudes corresponding to nominal contact stresses. Similar results have been found in other studies, e.g. [6].

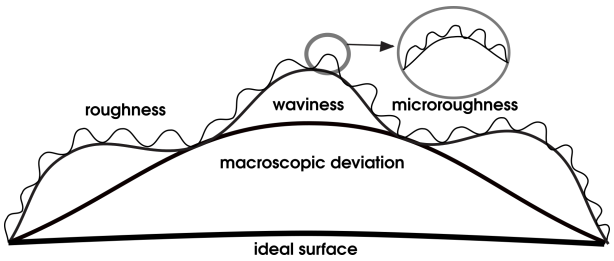

Fig. 1. Surface roughness on different scales.

This leads to the issue on how to model the response of the material in the contact interface. Analyses featuring nominal conditions often presume an elastic material response. However, if the roughness of contact surfaces is accounted for, the stress levels near the contact interface often become unrealistically high even if residual stress formation and plastic hardening in the surface layer (see e.g. [7]) are accounted for. To reach more realistic stress levels, plastic deformations then need to be accounted for.

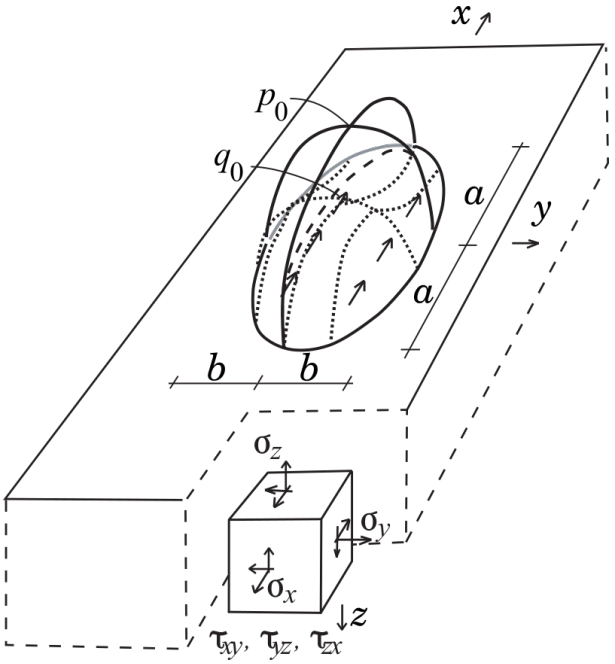
In cases of moderate roughness, the influence is limited to a very shallow depth (in [5] some 20–30 μm). Such a shallow depth corresponds to the size of one or some few metal grains. At such extreme stress and strain gradients it could be questioned if the material could really be considered as homogenous. Further, the severe deformations in the surface layers renders the material to be highly anisotropic, see e.g. [8]. Note that this operationally induced anisotropy in the surface layer (down to a depth of some few hundred microns) adds on top of a deeper anisotropy that is partly manufacturing induced, see e.g. [9].

The complications outlined in this section represent some of the challenges if a "complete" analysis of wheel–rail contact is to be modelled. If an analysis of progressive damage is to be included in the assessment, damage modelling, small crack growth *etc* are additional complications that need to be accounted for. These challenges, and the fact that surface roughness and the material microstructure are fairly stochastic parameters, restrict such detailed studies to focus on a certain aspect such as surface roughness [5] or a detailed microstructure [10]. For such analyses, the necessary simplifications in other areas tend to be somewhat inconsistent: In the examples above, surface roughness would imply an inhomogeneous microstructure, and an inhomogeneous microstructure invalidates the presumption required for Hertzian contact to be valid (see section 3).

Consequently, such detailed analyses are primarily aiming to further the understanding of one aspect of the wheel–rail interaction. For more holistic studies of wheel–rail contact, there is a need to simplify the analysis. In the sections below it will be discussed how this can be achieved, what simplifications that can be allowed, and what the implications of such simplifications are. Note that the required level of detail may change throughout the the operational life of a wheel or a rail. As an example, damage to the wheel and rail surfaces may introduce surface flaws that induce higher dynamic loads (see e.g. [11, 12]) and poor contact geometry conditions. This may need to be considered in further analyses, e.g. of subsequent crack growth, see e.g. [13].

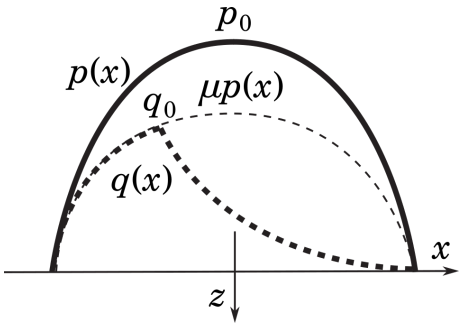
3. Approaches to contact stress analysis

For elastic bodies large enough to considered as half-spaces with non-conforming smooth macro- and micro-geometry, the pressure distribution can be described by Hertzian theory [14] as



$$p(x,y) = p_0\sqrt{1-\left(\frac{x}{a}\right)^2-\left(\frac{y}{b}\right)^2}, x \le a, y \le b \qquad (1)$$

where a and b are contact semi-axes and p is the contact pressure distribution (equal to $-\sigma_z$ at the surface), see Figure 2. The peak contact pressure is obtained as



$$p_0 = \frac{3F_z}{2\pi ab} \qquad (2)$$

with F_z being the normal load.

The Hertzian requirement of smooth macro-geometry allows the surfaces of the contacting bodies to be described by quadratic functions. Extensions to allow for other contact geometries exist for special cases, see e.g. [1]. For more general cases, numerical methods need to be employed. For contact between elastic bodies, boundary element (BE) based methods can be employed, see [15]. Although these methods typically retain the half-space assumption, they are commonly used also when this is not

(a) Three-dimensional view of Hertzian contact pressure and partial slip.

(b) Two-dimensional section in the xz-plane of Hertzian contact pressure (solid line) and interfacial shear under the presumption of full ($q(x) = \mu p(x)$, thin dashed line) and partial slip (thick dashed line) conditions.

Fig. 2. Hertzian contact pressure ($p(x,y)$), and interfacial shear ($q(x,y)$. Here μ denotes the (maximum) coefficient of friction.

fully applicable. As noted by Kalker [15] "The relative ease of the half-space approximation leads one to use it even when this may lead to serious errors."

Similar considerations relate to the frictional contact. Here the most straight-forward approach is to assume the frictional stress to be proportional to the contact pressure, i.e. $q = \mu p$ where μ is the coefficient of friction, see Figure 2. Such an assumption corresponds to a load case of full slip, i.e. the wheel slides on the rail. Under more common frictional conditions, the contact patch can be divided into a stick zone where there is no relative motion between wheel and rail, and a zone where slip occurs (i.e. where $q(x) = \mu p(x)$. There exist different methods to analyse the extent of these zones and the frictional stress distribution, $q(x)$, see e.g. [1, 15] and compare to the discussion in section 5.1.

To analyse contact under even more general conditions, finite element simulations are typically employed. In theory, this allows for essentially any contacting surface geometries, contact characteristics and material responses to be modelled, but there are of course significant practical limitations. Firstly, finite element (FE) contact simulations are computationally expensive, especially in a 3D analysis. One of the reasons is that the discretisation of the contact surface needs to be detailed (i.e. the FE mesh needs to be fine). If rolling contact is studied, this relates to the entire length of the rail and the wheel tread over which contact takes place. To limit this, there are approaches such as Arbitrary Lagrangian–Eulerian formulations [16] that limits the size of the area that requires a very fine discretisation. This simplification comes at the expense of the need to define more complex boundary conditions. These simulations can also capture the thermomechanical contact, which is occurring e.g. during braking. However, care must be taken since numerical dissipation that leads to under-prediction of temperatures may occur, see [17].

Finite element analyses can account for an elastoplastic material response. This however requires an appropriate constitutive model that is calibrated to capture important characteristics. Damage phenomena in the wheel–rail contact relate to a large number of load cycles. Calibration of a material model then needs to focus either on a correct representation of the first cycles, or on the response at a more stabilised stage after some tens of cycles [18]. Naturally, this is even further complicated if the loading has a variable magnitude. Similar challenges relate to the modelling of contact conditions in FE-analyses: In theory the FE-analyses are versatile tools. However, in practice, there are challenges in formulating and implementing complex contact models.

A major strength of FE-simulations is that the subsurface stress field is evaluated simultaneously as the contact stresses. Further, the analyses do not require any simplifying assumptions regarding the bulk characteristics of the bodies in contact. For example, material defects and cracks can be accounted for, but must then be properly modelled. In particular contact of crack faces needs to be accounted for (see e.g. [19]), and the high stress gradients in the vicinity of material defects requires a locally dense FE mesh (see e.g. [20]).

If contact stresses are instead obtained from analytical evaluations, the subsurface stress fields is typically derived via semi-analytical analyses where the response from concentrated contact "forces" are analysed and accumulated under the presumption that the contacting bodies can be seen as elastic half-spaces (i.e. that superposition is valid), see e.g. [21].

4. Rolling contact fatigue (RCF)

The field of rolling contact fatigue is discussed in detail in e.g. [22, 23, 24, 25]. In the current context we will only recognise that rolling contact fatigue (RCF) essentially can be divided into surface initiated RCF and subsurface initiated RCF. These two phenomena will be discussed below with special focus on implications on model resolution in terms of surface geometry and material characteristics. The discussion will focus on mechanically in-

duced surface initiated RCF, which is the most common form in wheel–rail contacts.

4.1. Surface initiated RCF

Surface initiated RCF typically relates to crack initiation through ratcheting (or in the case of alternating directions of frictional loading, low cycle fatigue), see [2, 26, 27]). Current models to predict ratcheting induced RCF based on simulation of train–track interaction include the $T\gamma$-model [28], and shakedown approaches [2, 29]. Here, the $T\gamma$-model relates the risk of RCF to the product of the tangential contact force (T) and the creep (γ), i.e.

$$D = F(T\gamma) \tag{3}$$

where D is the fatigue damage (inverse of the fatigue life) and F is a trilinear damage function.

Note that both T and γ are global quantities. Hence, any influence of contact patch size and/or detailed contact stress distribution is implicitly included in the $T\gamma$-magnitude and/or in the corresponding RCF damage function.

In contrast, the shakedown approach explicitly presumes Hertzian contact and (implicitly) full slip conditions. Further, the contact patch size is implicitly included in the analyses. This is clear if the shakedown analysis is expressed in terms of the FI_{surf} index [29]:

$$FI_{\text{surf}} = f - \frac{2\pi abk}{3F_z} \tag{4}$$

Here $f = \sqrt{F_x^2 + F_y^2}/\sqrt{F_z^2}$ is the traction coefficient, a and b the semi-axes of the Hertzian contact patch, k the yield limit in (cyclic) shear, and F_z the normal contact force. Surface initiated RCF is predicted for $FI_{\text{surf}} > 0$.

In wheel–rail contact, the contact stress distribution does not always relate to Hertzian contact and full slip as presumed in the shakedown analysis. To account for cases of partial slip, a "local" approach can be taken where the risk of surface initiated RCF is related to the maximum frictional stress, see [30, 25]. A similar approach can be adopted to the $T\gamma$-model [30]. It would seem that the increased resolution of a local model should allow more precise predictions of surface initiated RCF. This is however not necessarily the case. One reason is that local stresses may be so high that they cause plasticity, which would result in local stress magnitudes that are lower than what is predicted in an elastic analysis. This can of course be accounted for by elastoplastic stress analyses. However, also an elastoplastic stress/strain analysis combined with an RCF analysis using a local criteria will overestimate the risk of RCF. The reason is that fatigue is a non-local phenomenon due to statistical and stress gradient effects. A method to quantify this effect under RCF conditions was presented in [31] where it was also shown that a high cycle fatigue analysis showed little difference in predicted RCF between the case of full and partial slip. Consequently, the conclusion in [31] was that a full slip approximation could be reasonable to employ also for cases of partial slip.

In cases of very localised contact e.g. in very narrow contact bands or at surface defects, the assumption of Hertzian contact is not plausible. Defining a simple and robust RCF criterion for such conditions is a challenging task. Currently, the best option is probably to make a detailed evaluation of the dynamic loading and resulting stress evolution and then compare load cases qualitatively, cf [32]. To the authors' knowledge there are currently no generally applicable methods for quantitative predictions of RCF life corresponding to very localised contact. There are however methods developed for specific situations e.g. when the load can be considered to be a point load acting on an elastic half space, see e.g. [1, 27, 33]. Note that issues with non-hertzian contact conditions also relate to components such as insulated joints. Here, prediction of dynamic contact itself poses a problem, see e.g. [34]. If elastoplastic contact conditions are considered, the analysis is further complicated by the fact that the residual stresses will cause the stress/strain response to tend towards elastic as the the number of load passages increase. To capture this effect numerically, sophisticated material models are required, and several load cycles need to be simulated, as discussed in chapter 3. The vicinity to a (virtually) free edge at the contact interface further complicates the analysis since it is numerically challenging to capture the large plastic deformations, see e.g. [35]. If stresses and strains are correctly captured the fatigue life can be evaluated, see e.g. [36]. However, any quantitative prediction relies on a presumed mode of fatigue and on the selection of a "critical volume" (see [31]) that needs to be considered since fatigue (regardless of mode) is not a local phenomenon. The current lack in ability for quantitative predictions of the risk of RCF in cases where Hertzian contact conditions are not applicable is problematic since these condition usually correspond to highly stress magnitudes and a short service life, see e.g. [37].

It can finally be recalled that surface irregularities (surface defects, insulated joints etc) give rise to both a locally poor contact geometry and increased dynamic loads. The first effect is mainly an issue for crack initiation (including small crack growth), whereas the latter effect is significant also for cracks that propagate from the surface irregularity, see [13]. Here the non-locality of the fatigue phenomenon is less of a modelling issue since it is (or at least should be) included in the crack propagation model. There are however other major challenges related to the analysis of RCF crack growth predictions, see e.g. [38]. These topics are however outside the scope of the current study.

4.2. Material characteristics

The criteria above relate the risk of surface initiated RCF to the applied loading. In these models, the fatigue characteristics of the wheel and rail materials are described in very general manners: The $T\gamma$-model relates the loading to an RCF life that in some sense represents the fatigue

strength of the entire wheel–rail system. Similarly, the shakedown approach states that if the cyclic yield limit is exceeded plasticity will occur, which can be translated to a damage magnitude, see [39]. Neither of the approaches evaluate stress and strain evolutions in the (wheel or rail) materials and contrast these to the fatigue strength of the material. This complicates e.g. evaluation of RCF resilience of new materials. To carry out a stress/strain-based RCF evaluation, the fatigue mode first needs to be identified (or postulated) and the evolution of stress/strain evaluated. If the material response is presumed to be elastic and the response can be directly mapped to the contact stresses. If RCF formation instead relates to ratcheting or low cycle fatigue (LCF), the elastoplastic response of the material needs to be captured. The RCF life is then evaluated from a ratcheting criterion—typically the accumulated strain, see [40], or an LCF criterion (typically relating to the strain range or an energy measure). Such an evaluation will require detailed models for both the elastoplastic material response and the fatigue resistance. Note that any stress/strain-based evaluation also needs to consider the non-local nature of the fatigue phenomenon as discussed in section 4.

The approaches above typically presume an homogenous and isotropic material. There are examples in the literature of extensions both to anisotropic material, see e.g. [8] and inhomogeneous materials, see e.g. [10]. Such analyses requires knowledge of the detailed material characteristic in respect to these aspects. There will also be a need to translate the detailed analysis to the global response. This is a general challenge in studies that concern the material microstructure that relates to the discussion of a "representative volume element" in chapter 1. The case of fatigue is however far more complex than a more general analysis of e.g. stiffness or plasticity properties. The reason is once again due to the non-local nature of fatigue in the sense that a fatigue crack will interact with a fairly large volume of the microstructure as it initiates and grows.

An additional topic that will have an effect on surface initiated RCF crack initiation and growth is the presence of lubricants, see [25] and references therein. Also in this case there exist approaches to account for the influence of lubrication that range from very rough (decreasing the overall coefficient of friction) to the very detailed (explicit analysis of the mechanical response of a loaded lubricant within the crack, see e.g. [41]).

4.3. Subsurface initiated RCF

Subsurface initiated RCF cracks initiate from some millimetres to some centimetres below the surface. In the absence of any large dynamic bulk tensile stresses, growth of subsurface initiated rolling contact fatigue cracks is mainly shear driven (although local tensile stresses may appear in the vicinity of material defects, see e.g. [20]. Consequently, the magnitude of the shear stress will have a significant influence. For fairly shallow cracks, the detailed contact stress distribution will have a significant influence as it governs magnitude (and depth) of the maximum shear stress [42]. For deep initiation, this is less of an issue since nominal shear stress magnitudes will not be sufficient to initiate a crack in the absence of a large (in the order of a millimetre) material defect. Instead the occurrence and characteristics of material defects will be of importance. Material defects can be accounted for by an *ad hoc* reduction of the fatigue strength corresponding to the size of a defect that may be present, see [29]. Another option is to study the influence of material defects in detail [43]. Such a study can assess the material response in the vicinity of the defect under different circumstances. In particular, it can quantify the effect of interacting defects [20], which is important since closely located small defects tend to have the same effect as one large defect. Such detailed studies are however computationally demanding and restricted to specified conditions. Their major practical benefit is thus in an increased understanding that can be employed in more overall studies.

4.4. Thermo-mechanical RCF

So far we have not explicitly discussed simplified analyses and methods that presume 2D conditions even though there are such among the references. If the loading is purely mechanical, a plane strain approximation may be a reasonable simplification. It is however inherently impossible to make a 2D approximation of the 3D contact between wheel and rail—the scaling can only match one of several characteristic parameters, see [44]. In the case of pure thermal analysis, an axisymmetric approximation may be a reasonable assumption e.g. to simulate the formation of wheel flats [45], but it relates to the inherent presumption that the contact patch is round, which may be doubtful. So the 3D–2D-transition is far from uncomplicated even for purely mechanical contact. In a full thermo-mechanical contact, 2D approximations are not plausible at all. The reason is that the plane strain simplification will introduce major thermal strains due to the restricted thermal expansion, see [46] and that the presumption of axisymmetry is incompatible with the study of elastoplastic deformations due to a moving contact load.

In general, a thermal loading will add to the mechanical stresses, but the temperature increase will also affect the mechanical properties of the material. This can increase plasticity and wear depending on the circumstances. Severe thermal loading may also cause plastic deformation in compressive loading that will lead to high tensile residual stresses. This will promote crack initiation [47] and may even cause static (wheel or rail) fracture setting out from pre-existing cracks, cf. [48].

To account for the influence of thermal loading, the resulting residual stresses can be included in the fatigue assessments. This is fairly straight-forward if these are known [49] and the subsequent loading causes an elastic response. The next step is to include the temperature dependence of the material parameters in the FE analyses. This requires that the material properties are known or can be estimated. Note here that "material properties" relate to fatigue related parameters (cf. [50]), elastoplastic material characteristics (cf. [49]) and may include viscous characteristics if the strain rate is high. The next

step is to account for the thermal loading in a coupled thermo-mechanical stress/strain analysis. Such simulations show that the thermal loading will have significant effects already at a few hundred degrees [51, 52]. Under partial slip conditions, a shallow layer at the surface is highly strained due to the thermomechanical loading. Under partial slip, the strain magnitudes increase locally. Interestingly, for a wheel this effect is more pronounced under braking than under traction. [52]. If temperatures become higher, the analysis is even further complicated by the fact that phase transformations may occur, cf. [53].

5. Friction and wear

5.1. Friction

In general the friction characteristics of the wheel–rail interface depend on the surface roughness (at all levels, see Figure 1), on the influence of any friction modifiers or other environmental factors such as moisture and temperature, on loading conditions such as contact pressure and relative displacement between wheel and rail, and on the existence and characteristics of a third-body layer. A broad definition of the third body layer includes any substance in the wheel–rail interface such as friction modifiers and moisture, see e.g. [54]. This third-body layer often has a major effect on the friction characteristics—sand and crushed leaves can here be taken as extreme examples—but is generally hard to control since the wheel–rail interface is an open system.

The most simple approach to model the friction limit is through a single coefficient of friction, μ, in both static and dynamic conditions. This coefficient is in reality influenced by a number of factors such as temperature, contact pressure and slip velocity. Focusing on prediction of deterioration, the coefficient of friction mainly influences magnitudes of contact forces, stresses and relative displacements (slip) between wheel and rail. Since the magnitude of the coefficient of friction also depends on these parameters, a thorough evaluation is complex. Commonly in deterioration analyses (and especially those related to RCF), the friction is instead introduced through the use of the traction coefficient, f, and the presumption of full slip. This is explicitly done in the shakedown map (see equation 4). In the $T\gamma$-model the implicit presumption is that the detailed frictional stress distribution is not important and that friction thus can be represented by the frictional force magnitude, T.

More refined models of friction in analyses account for the influence of the creepage (rigid body sliding velocity in the contact patch divided by a reference speed, typically the travelling speed of the vehicle) on the frictional force, see e.g. [55]. A falling friction phenomenon may be observed when the creepage and corresponding slip velocity increase beyond friction saturation in the contact patch [56, 57, 58, 59]. Although numerically challenging, this phenomenon can be included in numerical simulation. This is useful in the context of vehicle dynamics, but also in relation to the occurrence of squeal noise generation, see e.g. [60].

The most detailed approach to simulate wheel–rail friction is a full geometrical representation of the microstructure, see e.g. [61]. Similar to the study of rolling contact fatigue, such detailed representation is not certain to enhance the predictive abilities since it will require presumptions on other aspects. In the case of friction, such assumptions relate e.g. to the contact geometry between asperities and the mechanical characteristics of these asperities at high loads.

5.2. Wear

Wear is commonly predicted using the Archard model [62] (with asperity size replaced by hardness [63])

$$V_{\mathrm{w}} = k\frac{F_z s}{H} \tag{5}$$

Here V_{w} is the wear volume, F_z the normal load, s the sliding distance, H the hardness and k a proportionality factor that may vary significantly with load conditions.

Another common option to predict wear in connection with RCF is to use the $T\gamma$-model in equation 3. As quantified by the damage function F, wear overtakes RCF as the dominant mode of deterioration for large $T\gamma$-magnitudes. This reflects the beneficial effect where incipient RCF cracks are worn off.

Since wear prediction models relate to slip , predicted wear will depend on how frictional characteristics are accounted for. Wear will also has an effect in changing contact geometry and also surface conditions. The latter can lead to a "wear-in"-effect where wear characteristics are altered over time e.g. due to reduced surface roughness.

Note that neither the Archard, nor the $T\gamma$ model employ any notion of the contact patch size. Further, the detailed contact conditions are implicitly embedded in k and H in the Archard model, and in the damage function of the $T\gamma$-model. Thus, for example, the influence of a less rough surface profile or the use of friction modifiers cannot be incorporated in these models without a recalibration of k (and possibly H) and the damage function, respectively.

This also has the implication that slip due to spin is not incorporated into the models in their original forms. In general, this is a larger issue for wear predictions than for RCF predictions since the spin gives large effects at the perimeter of the contact patch where the interfacial shear stress is low, but the slip can be high. To account for spin (and generally "non-smooth" contact stress distributions), a local wear criterion can be employed, see e.g [64, 30]. The use of local criteria have similar issues as discussed in the context of surface initiated RCF in section 4. However, gradient effects should be less of an issue for wear since it is a more of a local phenomenon taking place in a shallow surface layer.

Prediction of wear is usually made in an iterative process where contact stresses and displacement are predicted from multibody simulations. From these, wear rates are predicted and contact geometries updated. A straight-forward application of such a process often

leads to a "ragged" predicted geometry that needs to be "smoothed". Two main reason is that the operational load does not account for enough deviations in contact positions of passing wheels (or rails). A second reason is that too large geometry changes are imposed: Typically wear predicted for one load (collective) is multiplied to reflect a longer time of operation. A too high multiplication factor will introduce a "ragged" geometry and subsequent passages may tend to reinforce this tendency. From a multiscale perspective, an interesting question is how detailed the modelling needs to be too avoid these effects.

Both friction and wear rates are affected by temperature, see [65]. Typically this effect is only substantial at some hundred degrees. Thus, it is mainly an issue in brake block–tread contact.

6. Dynamic wheel–rail interaction

The dynamic interaction that determines the vehicle trajectory on the track is governed by the position, direction and magnitude of the wheel–rail contact forces. For modelling purposes it is therefore of essence to utilise contact models with the appropriate resolution for the task at hand. If for example ground vibrations due to train traffic are sought it might be sufficient to just represent the contact with a linear spring and only account for the vertical wheel–rail contact forces. If wear, fatigue or plastic deformation are to be estimated in contacts between surfaces with varying curvatures there could be a need to bring out the full arsenal of state-of-the art contact modelling tools.

Irregularities on the wheel and/or rail surface will give rise to increased stress magnitudes as discussed in section 4.1. They will however also give rise to increased dynamic loads with impact loads from wheel flats and RCF clusters as extreme examples. To correctly predict impact load magnitudes, a correct representation of the wheel defect geometry seems to be of more importance than the contact modelling [66]. Further, loads stemming from surface defects also tend to have a large high-frequency content. An example is rail corrugation where significant load frequencies extend to kHz [67]. At high speed operations, the main effect of a globally deteriorated vertical contact geometry e.g. in the form of corrugation is in generating high contact force magnitudes. At lower speeds, also the influence of the deteriorated contact geometries on higher contact stresses is of importance [68]. For isolated defects, the speed mainly affects the normal force magnitude, whereas the stress level seems to be mainly affected by the defect geometry [69].

As the contact moves towards the gauge corner of the rail and the flange of the wheel, both the detailed geometry and how the contact is modelled will have significant effects on the resulting contact forces and thereby the predicted dynamic behaviour of the vehicle [70]. The case is here complicated by the fact that the contact between flange and gauge corner tends towards conformal, especially for worn profiles. This invalidates one of the Hertzian presumptions. However as long as the curvatures of the surfaces in contact are constant, the Hertzian theory provides quite accurate results also for conformal contacts [71]. Also the violation of the elastic half-space assumption in the Hertzian theory has a small influence on the estimation of the contact pressures in conformal contacts with constant curvatures [72, 73]. The discrepancy between results from Hertzian theory and the actual contact pressure distribution and contact patch shape can however be large when there are significant curvature changes in the contact patch [74, 75, 76].

A special case where contact occurs over most of the lateral extension of the wheel tread is the transitions through switches and crossings (S&C). Here not only the lateral, but also the vertical geometry (deviations) will be of high significance as they behave as track irregularities and induce impact loading. The topic of wheel–rail contact in S&C is for example covered in [77] and [78] for switches and crossings, respectively.

Another aspect that relates to the contact conditions is the running stability of the vehicle [79]. Already at tangent track under nominal conditions the vehicle will be subjected to hunting motions. The wavelength of the hunting motion will be determined by the equivalent conicity provided by the wheel and rail profile combination. One measure of the equivalent conicity is defined as the difference between the rolling radius of the two wheels in a wheelset divided by two times the lateral wheelset displacement: $(\Delta r_r - \Delta r_l)/2\Delta y$. Due to the non-linear shapes of wheel and rail profiles, the equivalent conicity is a non-linear function of the lateral wheelset displacement and the value will depend on the displacement considered. The larger the equivalent conicity, the shorter the wavelength and the higher the frequency of the hunting motion will be for a given speed. The implication of this is that more kinetic energy will be fed into a wheelset with greater equivalent conicity and that the critical speed—the speed where the hunting oscillations become unstable—will be lower. From a contact mechanics perspective this means that contact modelling simplifications can influence the estimates of equivalent conicity and therefore also the estimates of a vehicle's critical speed. In this context it may also be noted that irregularities in the contact interface may trigger increased dynamic vibrations. If these effects are to be included in the numerical simulations, the contact modelling needs to be sufficiently refined.

Finally, it can be noted that the dynamic wheel–rail interaction is also significantly influenced by the frictional conditions between wheel and rail. This has been discussed in section 5 and will not be elaborated further here.

7. Conclusions

The current study provides an overview of how various phenomena related to the wheel–rail interface can be simulated. In all areas, simulation approaches span from very rough overview analytical or numerical models to very detailed numerical models. Benefits, challenges and difficulties in adopting varying levels of detail in simulations

are discussed. In general, detailed studies are computationally demanding and therefore typically restricted to specific conditions. The major benefit of detailed analysis is often in providing an increased understanding to improve overview simulation models and enhance operational practices. In contrast overview models are based on assumptions that are usually not fully met in reality. The usefulness of these models relies on how well they can reflect operational conditions despite the simplifications.

Depending on which (aspects of) phenomena that are studied, the required level of details in different aspects will differ greatly. As an example, the complexity a material model employed for detailed analysis of RCF brings little (if any) benefit to analysis of dynamic wheel–rail interaction. On the other hand, the analysis of dynamic wheel–rail interaction requires the simulation to account for a long stretch of track, whereas the detailed RCF study can feature small pieces of the materials in contact. Bearing in mind that detailed models extensively increase computational costs and requires more detailed input data, it is clear that a simulation framework for the mechanical interaction of the whole vehicle–track system needs to be based on modules of different levels of complexity and targeted towards different (aspects of) phenomena. The current study aims to aid in defining suitable levels of complexity for such simulation modules.

Abstract: Rail corrugation is a common issue, likely to develop on tight curves, which generally leads to high wheel-rail dynamic loads, increased noise production and poor ride comfort. A finite element model for the prediction of the self-excited vibrations of the leading wheelset-track system in a tight curved condition has been developed. The friction coupling between wheel and rail is included, assuming quasi-saturated creep forces. The results show a strong influence of the interaction effect of the wheelset geometry and the track gauge on the rail corrugation formation, indicating that the wheelset geometry and the tack gauge are potential inhibitor factors.

Keywords: Rutting corrugation; self-excited vibrations; complex eigenvalue analysis; creep forces saturation; wheelset-track system.

1. Introduction

Corrugations are a type of quasi-sinusoidal irregularities developing in both rails and wheels. They are classified generally as short wavelength irregularities. Rail corrugation has been constituting a serious issue ever since rail transportation spread as transportation means. In the 1930s, up to 46% of the German Railway network was seriously corrugated [1]. Rail corrugation gives rise to poor comfort, dynamic loading of both vehicle and track components and high noise levels. Measurements by Vadillo et al. [2] indicated that even in its initial phase and almost invisible, corrugation raised noise emission levels by 6 dB(A). Despite of the wide research on the topic, corrugation continues to be a problem whose principal mean of control is grinding of rail. However, grinding is rather a palliative than a solution since corrugation eventually represents. In the 1980s, grinding already cost the rail industry worldwide the order of at least US10^8 per annum [3]. It was reported that corrugation typically occurs primarily on the low rail in tight curves (usually curves with radius less than 450 m) and in a less extent in tangential tracks at traction or braking sites [3].

Rail corrugation formation mechanisms are presented by S.L. Grassie and J. Kalousek in their review [4], which is considered to be the most complete work on the subject, later reviewed by Grassie [5]. Their corrugation formation mechanism considers a wavelength-fixing-mechanism and a damage mechanism. The wavelength-fixing-mechanism represents the vibration behavior of the system in terms of vibration modes whose vibration frequency is directly related to the corrugation formation wavelength. The damage mechanism is the rail material removal mechanism. The most common damage mechanism is wear even though several other mechanisms can be found, i.e. plastic flow and plastic bending. Use of friction modifiers (FMs) is known to be useful for reducing corrugation formation, although its effect on the system is still not fully understood [6]. Other effective corrugation mitigation methods are rail hardening, as well as employing soft railpads in the railway track [4, 7].

Wavelength-fixing-mechanisms can be excited in different ways. Considering the literature available, there are two main schools of thought. The first one considers the excitation of the system in a broad frequency range caused by the longitudinal rail head irregularity, which is assumed to be always present in the form of a random profile with relatively low amplitude. The fluctuation of the friction forces at the same wavelength fixing mechanism frequency leads to differential wear and, in the long term, to corrugation. By its very nature, this first theory has been implemented using time domain accumulation wear models [8].

The second school of thought considers the instability of the wheel-rail system in particular situations, i.e. self-excited vibrations, as the cause of excitation of wavelength-fixing-mechanisms. The instability is considered to be caused by the interaction of the wheel and the rail through the contact patch when the creep forces are near saturation, i.e. when the maximum available tangential contact force μN is approached. A first method used to analyze the instability of the system is in time domain by taking into account the roll-slip vibrations between wheel and rail, which is the periodic passage of the contact condition from rolling to sliding due to either the periodic variation of the normal contact force between wheel and rail near saturation, or the negative slope of the friction-creepage relationship after saturation [8, 9]. Recently, the instability of the system has been analyzed in frequency domain by considering the friction-induced dynamic instabilities of the system due to the quasi-saturated friction forces in the neighborhood of a steady-state working condition of the system [6, 10, 11]. This method is suitable for the prediction of rutting corrugation in tight curves or in braking or traction sites, and well compatible for performing multiple-cases analyses since it is less time

consuming compared to time domain models. ABAQUS provides the implementation of the detection of the friction induced self-excited unstable vibration modes, i.e. Complex Eigenvalue Analysis (CEA). In 2006, AbuBakar and his group [12] have used the CEA together with a transient dynamic analysis for predicting brake squeal frequencies, and the effect of temperature-dependent friction of the brake stability. In 2009, Nouby et al. [13] have for the first time integrated the CEA with a design of experiment analysis in order to perform a parametric analysis of disc brake squeal by using statistical regression techniques.
The CEA has been used by Chen et al. to study both rail corrugation and wheel-rail squeal due to self-excited vibrations under saturated creep forces [6, 10, 11]. In the work by Chen et al. a transient dynamic analysis together with the CEA is used to predict rail corrugation induced by self-excited vibrations.

In this paper, a numerical procedure for the prediction of rutting corrugation on tight curved track is carried out through detection of the self-excited vibration of the wheel-track system. The numerical model includes a full track section and the leading wheelset of a 2-axle bogie, fully implemented in a Finite Element environment. Furthermore, a parameter analysis is performed by using the Design of Experiment (DOE) methodology to identify parameters with the most significant effects. The overall analysis methodology adopted in this paper combines multibody simulations for defining correctly the boundary conditions of the FE model and the steady-state position of the wheelset, and FE stability analyses conducted by means of the general purpose FE software ABAQUS 6.14.

2. Wheel-rail contact model

The analysis considers the official Abaqus User's Manual [14] as the technical reference. The FE contact interaction model, which considers a surface based approach, is applied to model the wheel-rail contact. The numerical discretization method considers the shape of both master and slave surfaces, such that the contact condition is distributed over the regions near the contacting nodes. The normal interaction between the interacting surfaces is modelled as a hard relationship between the normal pressure and the surfaces overclosure, i.e. the surfaces penetration. The relationship is enforced numerically by means of a penalty stiff approximation, which can be expressed as:

$$f_i = -\delta_i K_i \boldsymbol{n}_i$$

where f is the normal contact force, δ is the overclosure, K is the contact stiffness, $\boldsymbol{n}$ is the normal vector and i is the finite element node considered. The tangential contact interaction is composed by a simplified Coulomb friction model ($\tau = \mu N$) for a sufficiently high total contact slip, and an elastic slip ($\tau = \chi\varepsilon$, where χ is the sticking friction and ε is the total slip) for small values of contact slip in order to take into account the contact sticking creepage.

3. Complex Eigenvalue Analysis (CEA)

The complex eigenvalue analysis has been widely used mainly as a tool for predicting unstable frequencies in friction-induced vibration problems. The method consists of the computation of system eigenvalues and their corresponding mode shapes which in general are complex-valued functions. The real part of the eigenvalues are deployed as a parameters correlated to the particular mode shapes stability. In general, the system might experience instability because friction forces cause the stiffness matrix to be asymmetric [13].

3.1. Implementation procedure

ABAQUS versions 6.4 and above provide the implementation of the complex eigenvalue analysis for the stability prediction of friction-induced vibrations in FE models. Generally speaking, the equations of motion of a linear, discrete n d.o.f. (degrees of freedom) mechanical system are:

$$[M]\underline{\ddot{x}} + [C]\underline{\dot{x}} + [K]\underline{x} = \underline{q} \qquad (3.1)$$

where $[M]$, $[C]$ and $[K]$ are the mass, damping and structural stiffness matrices of the system (nxn), and $\underline{q}$ is the vector of the generalized external forces acting on the system. The structural matrices of the system are generally positive definite. In a structural/mechanical FE model, the vector $\underline{x}$ represents all the d.o.f. of the mesh nodes. In the case of the wheel-rail contact problem, the friction forces present in the contact patch is assumed to be the main source of vibration generation. The vector of external forces $\underline{q}$, which consists of only the friction forces, can be defined as a function of the displacement vector $\underline{x}$ and the localized contact stiffness matrix:

$$\underline{q} = \mu\left[K_f\right]\underline{x} \qquad (3.2)$$

where $\left[K_f\right]$ is the friction stiffness matrix, generally not symmetric, and μ is the friction coefficient at the contact patch. The governing equations can hence be rewritten as:

$$[M]\underline{\ddot{x}} + [C]\underline{\dot{x}} + \left[[K] - \mu\left[K_f\right]\right]\underline{x} = \underline{0} \qquad (3.3)$$

where $\left[[K] - \mu\left[K_f\right]\right]$ is not symmetric. Since the global stiffness matrix is not symmetric, various modes of the system might manifest flutter instability. The characteristic equations of the system can be expressed as:

$$\left(\lambda^2[M] + \lambda[C] + \left[[K] - \mu\left[K_f\right]\right]\right)\underline{\Phi} = \underline{0} \qquad (3.4)$$

where λ and $\underline{\Phi}$ are the eigenvalues and the eigenvectors of the system, respectively. In general, Eq. 3.4 gives complex eigenvalues.
In order to extract the eigenvalues and eigenvectors of the systems, numerical approximation methods are used. A complete discussion shall be found in the complete paper of this work.

Usually, the extraction is stopped at a user-defined number of eigenvalues. The complex eigenvalue λ_k can be expressed by means of its real and imaginary components $\lambda_k = \alpha_k \pm i\omega_k$. The general solution of the system can be obtained by superimposing the single eigenmodes:

$$x(t) = \sum_{k=1}^{n} \Phi_k e^{(\lambda_k)t} = \sum_{k=1}^{n} \Phi_k e^{(\alpha_k \pm i\omega_k)t} \quad (3.5)$$

The real part of the eigenvalue is the basis to judge the stability of the system. It can be found that when the real part of an eigenvalue is larger than zero, the nodal displacement *x(t)* will increase with time, meaning that the vibration of the system is growing and the system will become unstable at that particular vibration frequency [10]. A common parameter used to measure the propensity of self-excited vibration occurrence is the definition of an effective damping ratio for every single eigenmode of the system:

$$\xi_k = -2\frac{Re(\lambda_k)}{Im(\lambda_k)} \quad (3.6)$$

If the damping ratio is negative, the corresponding eigenmode is supposed to be unstable and has a tendency to induce self-excited vibrations.

The analysis steps needed for performing a complex eigenvalue analysis are hence the following:

- *Nonlinear steady-state analysis* of the wheelset-track system for applying the suspension forces on the bearings;
- *Nonlinear steady-state analysis* for imposing the lateral steady-state speed on the wheelset;
- *Natural frequency extraction* of the system without considering the friction coupling and damping to find the projection subspace;
- *Complex eigenvalue extraction* of the system that incorporates the effect of the friction coupling and damping;

The lateral steady-state speed of the wheelset, defined by considering the wheelset angle of attack $V_l = V \sin\psi$ is imposed by considering a *MOTION, TRANSLATION procedure and defining a TYPE=VELOCITY behavior to the wheelset FE domain.

3.2. *Corrugation Index*

The effective damping ratio δ is not sufficient to be used as the corrugation index. One has to also consider the potential slip at the contact patch that can be generated by the unstable modes. Therefore, the effective corrugation index (γ) is computed as:

$$\begin{cases} \gamma_k = 0 & if\ \xi_{k,min} > 0 \\ \gamma_k = \dfrac{\sum_{i=1}^{N} |\xi_i|\varphi_i}{\varphi_0} & if\ \xi_{k,min} < 0 \end{cases} \quad (3.7)$$

where *k* is the *k*-th analysis case, N is the number of unstable modes detected in the considered analysis case,

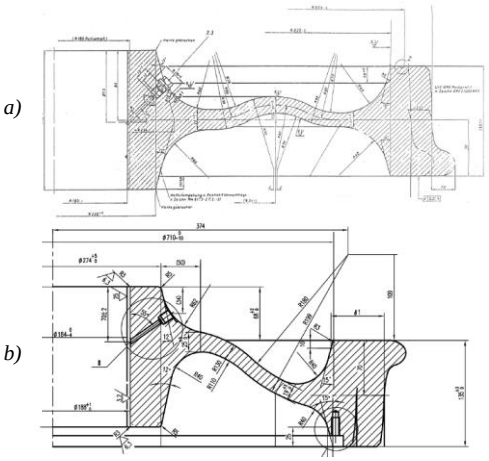

Figure 1: *Wheel transversal profiles: a) European S-shaped transversal profile. b) SFMZ06M1 transversal profile [12]*

ξ_i is the *i*-th unstable mode effective damping ratio, φ_0 is a normalization factor equal to 10^{-6} and φ_i is the *i*-th slip factor computed as:

$$\varphi_i = \sqrt{(u_{1w,i} - u_{1lr,i})^2 + (u_{3w,i} - u_{3lr,i})^2} \quad (3.8)$$

where *u* is the nodal mean normalized displacement of the unstable mode shape near the contact patch, in the transversal direction (*1*) and longitudinal direction (*3*) for the low wheel (*w*) and the low rail (l*r*). The nodal mean normalized displacements are computed as an average value of the relative displacement of the mode shape on five different nodes in the contact region. In this way, the effective damping ratio ξ_i is used as the instability index of the *i*-th mode, and φ_i is used as the slip index of the same mode.

4. Wheelset-track model

The model assembly represents a tight curved track section with curve radius $r = 300\ m$, superelevation $100\ mm$, rail inclination angle $1/20$, sleeper spacing $600\ mm$. Two different track gauges are considered in the analysis: the standard track gauge 1435 mm and a wider track gauge 1455 mm. The rails are modeled considering the track curvature, with a rail curvature angle $\beta = l/r$, where *l* is the rail track length and *r* is the curve radius. The rails and wheels are divided into geometrical sub-domains in order to apply a refined mesh near the contact patch.

The analysis considers standard rail, sleeper and wheelset geometries and standard wheel profiles (wheel running surface profiles). The standard UIC60 rail is used in the analysis. Two different wheel transversal profiles are considered, as shown in Figure 1. Specifically, a typical European S-shaped transversal wheel profile of 920 mm diameter and a Chinese transversal wheel profile (SFMZ06M1) of 840 mm diameter typically used in metro lines and used by Chen et al. in their corrugation analysis are considered [10].

The wheel profile used for both wheel transversal profiles is the standard ORE S1002 with flange height 28 mm. The sleepers used in the studied track are the typical Norwegian concrete sleeper JBV60 used with UIC60 rails.

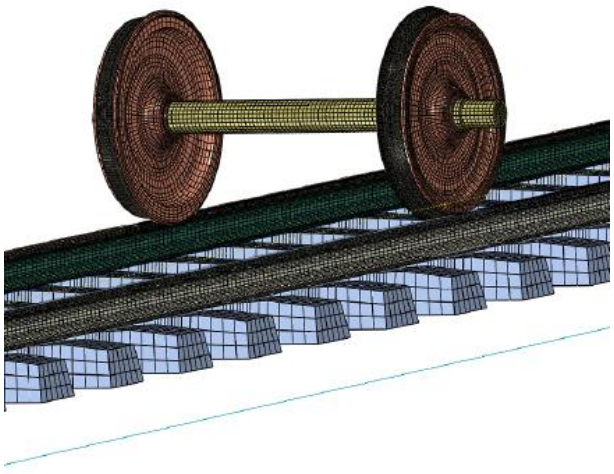

Figure 2: *FE meshed model overview*

4.1. Finite element model

All materials are assumed to be linear-elastic. The steel materials considered for the wheelset and for the rails are assumed to have the same mechanical properties. Table 1 shows the material parameters and structural parameters used in the model.

Figure 2 depicts an overview of the global meshed FE model used in the analysis. The real structural system has a longitudinal length that can be considered infinite. However, a relatively long track model is unfeasible to be used because it would lead to significant computational efforts. A trade-off between the rail length, the dynamic properties and the computational effort should be applied. Hence, the effect of the track longitudinal length on the vertical rail receptance has been analyzed in order to set an optimal track length in the FE model. This has been done by computing the track frequency response function (FRF) in the frequency range [0-2000 Hz] for several track lengths: 4200 mm, 7800 mm, 11400 mm and 36000 mm. The standard track length of 36000 mm led to an excessively slow computational time. The effect of the boundary conditions is predominant at 4200 mm length. An acceptable convergence of the dynamic behavior of the system is obtained for a track length of 11400 mm.

4.2. Implementation of steady-state curving behavior in FE model

The steady-state dynamic condition in a curved track of the system is necessary in order to set correctly the FE model for the CE analysis. The necessary input data coming from the dynamics are essentially the suspension forces acting on the wheelset bearings. The reference velocity considered is 40 km/h, corresponding to a cant excess of 37 mm. The total length of the track in the multibody simulation (MBS) model is 300 m.

The track is divided into three distinct sections: a straight section, a transition section, and a curved section. The first section is 24 m long. The transition section is 51 m long. The curved section is 225 m long. In the MBS model, the train is represented by one wagon. The car body lies on two bogies, each bogie has a leading wheelset and a trailing wheelset. The wheelsets are not motorized and modeled as rigid bodies. The weights of the car body and the bogie (excludes wheelsets) are 47.5 ton and 10 ton, respectively. As a reference, the vertical forces are positive if pointing upwards while the lateral forces are positive if pointing towards the field side. The yaw angle is positive in clockwise direction. Two different simulations are performed in relation to the two track gauges used in the analysis. Table 2 and Table 3 show the results with the standard gauge and the wider track gauge, respectively.

4.3. Design of Experiments (DOE) settings

It is useful to investigate how typical parameters of the wheelset track system affect the occurrence of corrugation in a tight curved condition in terms of variation of the corrugation index γ. The analysis is

Table 4: *Analysis factors*

focused on four main factors: rail pad stiffness, vertical ballast stiffness, wheelset transversal profile and gauge. Table 4 shows the factor levels used in the analysis. The rail pad stiffness levels, as well as the constant parameters of the rail pad, are determined from the study by K. Knothe and S.L. Grassie [15], while the stiffness levels and other constant parameters of the ballast are determined from the studies published by the EUROBALT project [16]. The lateral and longitudinal stiffness of the rail pad and the ballast are considered to be equal. The lateral rail pad stiffness is considered to be circa 20% of the vertical rail pad stiffness ($K_{pad,l} \simeq 0.2K_{pad,v}$). The DOE analysis is composed hence of 36 runs.

5. Results and discussion

The results of the analysis are given in terms of complex eigenvalues and complex eigenvectors, i.e. mode shapes, in the frequency range of interest and their associated effective damping ratio. Figure 3a depicts the typical distribution of the complex eigenvalues of the system in terms of effective damping ratio in the frequency range of interest [0-1200 Hz]. Here, the results refer to the track gauge of 1455 mm, an European wheelset design, a vertical rail pad stiffness of 340 MN/m and a vertical ballast stiffness of 20 MN/m. Figure 3b zooms in the distribution of the near-zero effective damping ratios. Two negative effective damping ratios are detected in the chart. Therefore, these two modes are related to unstable vibration modes, which in turn can give rise to relatively high vibrations at those particular frequencies and a consequent fluctuation of the contact forces, thus leading to rail corrugation. The first unstable mode is related to an unstable frequency of 340 Hz and an effective damping ratio of -0.0082, while the second one is related to an unstable frequency of 919 Hz and an effective damping ratio of -0.0067.

Figure 4 shows the mode shapes associated with the detected unstable modes. A great deal of the vibration at those frequencies occurs at the wheelset, and in particular at the wheel at the low rail. It is also interesting to note that the vibration of the wheel at the low rail mostly occurs in lateral direction. The sleepers are not participating in the vibration modes. This particular vibration displacement distribution can be associated with a high slip between the wheel at the low rail and the low rail and therefore to a high corrugation rate at the low rail. This result matches with the rutting corrugation experimental pieces of evidence that show a typical corrugation formation at tight curves on the low rail [3]. Moreover, the frequency of the most unstable mode is in the typical rutting frequency range.

For each DOE case the negative effective damping ratios with their associated frequency are obtained, as well as the minimum positive effective damping ratio if no unstable mode is detected. Thus, the corrugation index of each case can be obtained. In the DOE study, the main effects plot shows the average response for a given level of a factor (+, 0, -) for each of the studied factors. The main effects plot shows the influence of a single factor with respect to the full range of variation of the remaining factors of the analysis. In this way, the trend of the

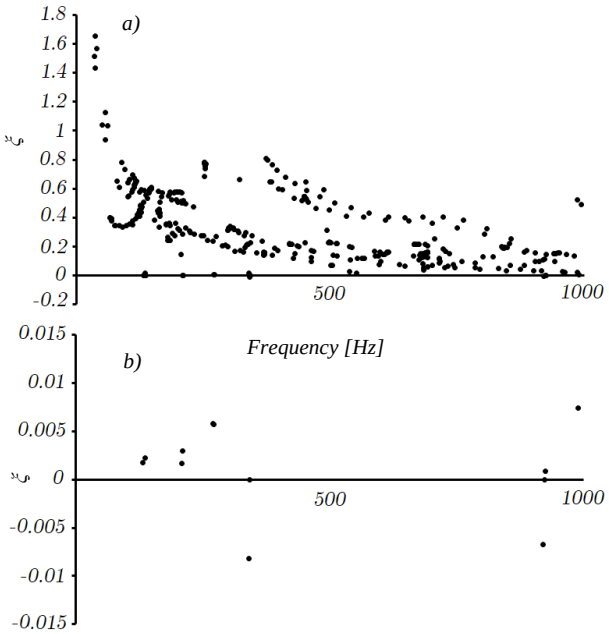

Figure 3: *Results in terms of effective damping ratios and their relative frequency. a) General results. b) Emphasis on the unstable eigenmodes.*

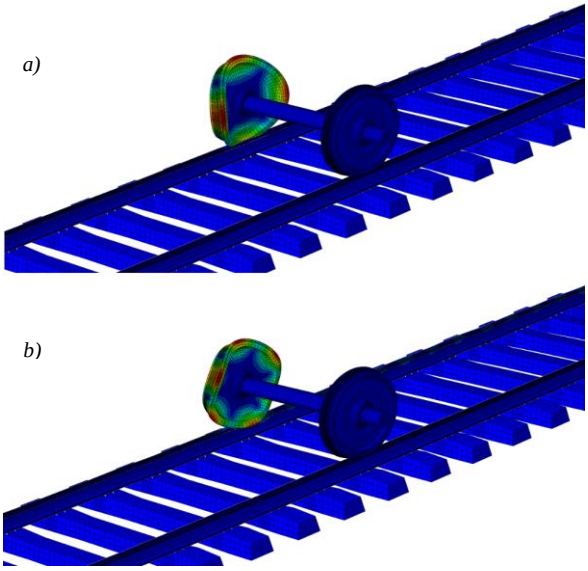

Figure 4: *Unstable modeshapes. a) Mode at frequency 340 Hz and effective damping ratio -0.0082. b) Mode at frequency 919 Hz and effective damping ratio -0.0067.*

influence of a single factor on the output variable can be determined. The interaction plots can also be determined by considering the variation of the average response of a factor due to the level of another factor.

Figure 5 and Figure 6 show the main effects plots of the four factors and the interaction effect plots with respect to the wheelset transversal profile. The two-level factors have been interpolated by using linear functions, while the three-level factors by using quadratic functions. From these charts, one can draw several conclusions:

- There is a maximum level of rail corrugation index for a medium vertical ballast stiffness value, i.e. 110 MN/m;

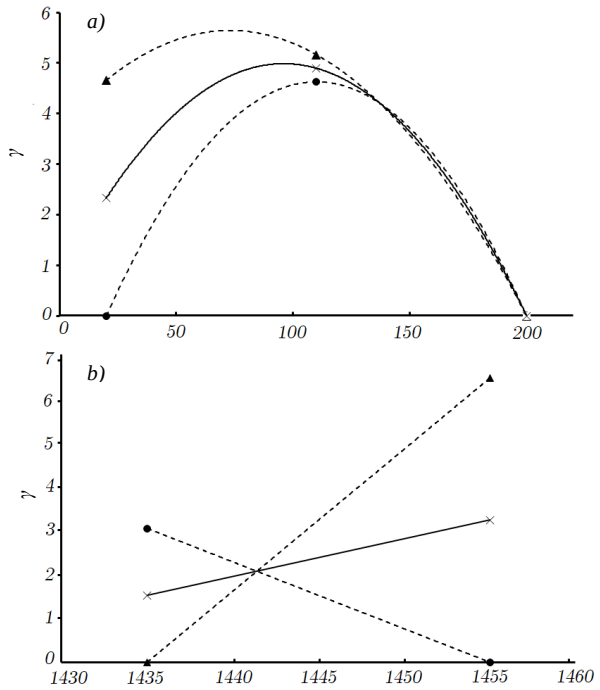

Figure 5: *Effects plots and interaction plots with respect to the wheelset transversal profile. a) Vertical ballast stiffness [MN/m]. b) Track gauge [mm]. (—): Main effects. (---●): Wheelset transversal profile: Chinese. (---▲): Wheelset transversal profile: European.*

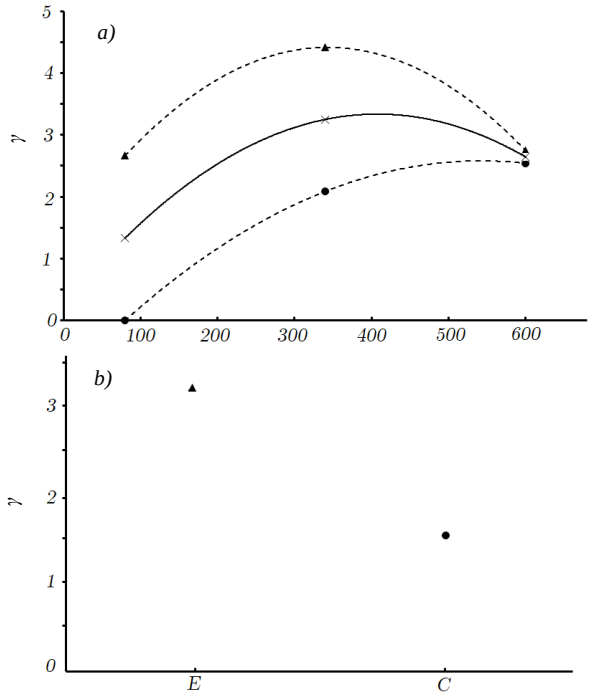

Figure 6: *Effects plots and interaction plots with respect to the wheelset transversal profile. a) Vertical railpad stiffness [MN/m]. b) Wheelset transversal profile [-]. (—): Main effects. (---●): Wheelset transversal profile: Chinese. (---▲): Wheelset transversal profile: European.*

- There is a minimum level of the rail corrugation index for a low rail pad stiffness value, i.e. 80 MN/m; This result is in accordance with most of the literature on rail corrugation in that the use of soft rail pads may be a mitigating factor (e.g.: [4, 7]).

Considering the interaction effect of both the track gauge and the wheelset transversal profile, one can detect a strong influence on rail corrugation, as shown in Figure 5b.

Therefore, it can be concluded that the effect of the track gauge on rail corrugation formation *greatly depends on the wheelset transversal profile*. For instance, in the case of European wheelset transversal profile, the system is affected by unstable modes only for widened track gauges, specifically for a track gauge of 1455 mm.

6. Conclusions

This paper focused on the still open research question of rail corrugation, aiming at finding novel practices for preventing rail corrugation initiation. Upon the corrugation mechanisms, the friction-induced self-excited vibrations of the wheelset-track system were believed as one of them, although it was less studied. This work aimed at expanding the knowledge on this less-researched theory/mechanism. A 3D finite element model, which coupled the wheelset and the track, was developed in ABAQUS. The effective damping ratio of the coupled wheelset-track system instability of the system, obtained through the complex eigenvalue analysis, was used to calculate the corrugation index.

The results obtained by this model are in good qualitative agreement with previous theoretical studies and with experimental evidences on rutting corrugation coming from field observation. The unstable modes detected in the analysis have always most of the vibration displacement on the wheel at the low rail. This is in good agreement with the evidence that rutting corrugation in tight curved tracks is almost always formed at the low rail. Furthermore, 85% of the unstable cases have the most unstable mode at a frequency between 340 and 495 Hz, which is a typical rutting fixing frequency. The design of experiment exercise predicts less intensive formation of corrugation for softer rail pads, which is in agreement with another research finding from the literature.

The design of experiments analysis also showed that there is a strong interaction effect of the track gauge and the wheelset transversal profile on rail corrugation. The current study shows that the gauge widening applied at tight curves may lead to instability of the wheelset-track system when using the European wheelset transversal profile, but not with the Chinese wheelset transversal profile considered in the study; however, without applying the gauge widening, corrugation occurs in the case of the Chinese wheelset transversal profile, but not the European wheelset transversal profile. The wheelset transversal profile and the track gauge can hence be considered together as potential inhibitor parameters in the corrugation optimization analysis to reduce rutting corrugation formation.

MODELLING OF CYCLIC PLASTICITY AND PHASE TRANSFORMATIONS DURING REPEATED LOCAL HEATING EVENTS IN RAIL AND WHEEL STEELS

Ali Esmaeili [1,*], Johan Ahlström[1], Magnus Ekh[1]

[1] CHARMEC / Department of Industrial and Materials Science, Chalmers University of Technology, Gothenburg, Sweden

[*] E-mail: ali.esmaeili@chalmers.se

Abstract: Short term local friction heating in railway operation might occur when a railway wheelset skids along the rail. The consequent temperature elevation is significant and may result in phase transformations in the pearlitic rail and wheel steels. The differences in thermal expansion, density and mechanical properties of the phases result in residual stresses and causes thermal damage in rail and wheel steels. This study enhances modelling of phase transformation kinetics and plasticity done in earlier studies by also including cyclic plasticity of the phases. A sequential (uncoupled) thermal and mechanical Finite Element (FE) analysis has been performed to compute residual stresses near the wheel-rail contact in a double wheel flat loading example.

Keywords: FE analysis; Pearlitic steel; Thermal damage; Phase transformation; Residual stress; Isotropic and kinematic hardening

1. Introduction

Due to the geometry of the railway rails and wheels, a typical wheel-rail interaction is a contact surface of merely the size of a coin. In conditions such as braking and traction, considerable thermal and mechanical loads localize at the contact interface which might result in rolling contact fatigue (RCF) damage.

During braking and traction processes, poor adhesion might result in sliding of the wheel on the rail surface. This can be caused by a defective, frozen or incorrectly tuned brake, as well as a low wheel-rail adhesion caused by environmental conditions (rain, snow, leaves, etc.). The slide may develop a localized region of high temperature due to the generation of heat from friction between the wheel and the rail track. The generated friction heat is sometimes enough to form austenite in a thin surface layer. When the wheel unlocks, the wheel often cools down sufficiently fast to cause martensitic White Etching Layer (WEL) formation [1].

The volume expansion due to martensite formation after the first heating pulse gives compressive residual stresses within the brittle martensitic volume, and tensile residual stresses in the un-affected pearlite/ferrite (base material) volume beneath it [2].

If repeated heating occurs in the same spot, the surface layer can either re-austenitise or re-order into a tempered martensite state [3, 4, 5]. Due to volume shrinkage on tempering the martensite, it becomes subjected to high tensile stresses, which is a well-known factor influencing fatigue initiation. Further, the transition zone between the hard martensite and the softer ferritic–pearlitic base material is narrow, which may lead to strain localization in subsequent mechanical loading.

In this study, the main focus is to predict the material behavior of rail and wheel steels subjected to repeated short-term local friction heating events. To this end, an accurate description of the kinetics and the constitutive relation for the pearlitic steel is desired. Hence, a FE computational procedure considering solid-state phase transformation is developed based on [6, 2]. The description of kinetics in [6, 2] is extended in a way that the strains in each individual phase are calculated separately and the homogenized properties and stress-strain fields of the material are obtained using the Taylor assumption [7]. To capture the dilatation effects on martensite tempering, both untempered and tempered martensitic phases are introduced. Furthermore, the current model incorporates a nonlinear isotropic and kinematic plastic constitutive relation [8] for each phase, to account for the microstructural dependence of the stress strain relation. The parameters of the utilized plastic model are identified against temperature dependent experimental data for the individual phases. In this context, the identification of the plastic model parameters is improved by utilizing data from experiments conducted on ferritic and pearlitic phases [9]. Also, the plastic material model is calibrated for untempered and tempered martensitic phases, individually, using the data presented in [5].

In the end of this paper, an FE model is used to analyze the resulting residual stresses close to the wheel-rail contact after a “Double wheel flat" loading. To do so, an axisymmetric disc sample is used to model the wheel and a (short term) purely thermal loading is applied.

The structure of this paper is as follows. In Section 2 the constitutive equations for the proposed phase transformation and cyclic plasticity model is formulated. The utilized experiments in the parameter identification and its results are presented in Section 3. Finally, in Section 4 the finite element simulation approach and the numerical example of phase transformation is presented.

2. Constitutive equations

In this paper we adopt the small strain kinematics with an additive decomposition of the strains $\boldsymbol{\epsilon}_x$ [10]:

$$\boldsymbol{\epsilon}_x = \boldsymbol{\epsilon}_x^e + \boldsymbol{\epsilon}_x^{\mathrm{p}} + \boldsymbol{\epsilon}_x^{\mathrm{th}} + \boldsymbol{\epsilon}_x^{\mathrm{tv}} \quad (1)$$

Here, $\boldsymbol{\epsilon}_x^{\mathrm{e}}$ is the elastic strain, $\boldsymbol{\epsilon}_x^{\mathrm{p}}$ the plastic strain, $\boldsymbol{\epsilon}_x^{\mathrm{th}}$ the thermal expansion strain and $\boldsymbol{\epsilon}_x^{\mathrm{tv}}$ transformation expansion strain, respectively. The subscript *x* denotes the strain component in phase *x*.

In the following, a more detailed description of the strains and phase transformations are given.

2.1. Thermal strain

Observations from dilatometry experiments, Figure 4, are used to characterize the evolution of specific volume changes of the material as a function of temperature. Variation of the relative change of length as a function of temperature ($\frac{\Delta L}{L_0} = f(T)$) is assumed to be linear in each phase which is represented by the thermal expansion strain:

$$\boldsymbol{\epsilon}_x^{\mathrm{th}} = \alpha_x \Delta T\, \boldsymbol{I} \quad (2)$$

where α_x is the thermal expansion coefficient for each phase, ΔT is the temperature increase from room temperature and $\boldsymbol{I}$ is the 2nd order identity tensor.

However, upon phase transformations in the material, the lattice structure may change. This is in principal accompanied by a change of the specific volume [11].

To account for the difference in specific volume of the phases, the transformation expansion strain for each phase is formulated (using mass conservation) as (cf. [12]):

$$\boldsymbol{\epsilon}_x^{\mathrm{tv}} = \frac{1}{3}\left(\frac{\rho_0}{\rho_x} - 1\right) \boldsymbol{I} \quad (3)$$

where ρ_0 denotes the initial density of the mixture at room temperature and ρ_x defines the density of each phase after complete transformation.

2.2. Plastic material model

In this section, the adopted plastic model is described. The relation between the elastic strain $\boldsymbol{\epsilon}_x^{\mathrm{e}}$ and the stress $\boldsymbol{\sigma}_x$ in each phase is assumed to follow the linear Hooke's law:

$$\boldsymbol{\sigma}_x = \mathbf{E}_x^{\mathrm{e}} : \boldsymbol{\epsilon}_x^{\mathrm{e}} = \mathbf{E}_x^{\mathrm{e}} : \left(\boldsymbol{\epsilon}_x - \boldsymbol{\epsilon}_x^{\mathrm{p}} - \boldsymbol{\epsilon}_x^{\mathrm{th}} - \boldsymbol{\epsilon}_x^{\mathrm{tv}}\right) \text{ for } x=1,n \quad (4)$$

Note that in the remaining of this subsection we skip the subscript *x* for brevity of presentation.

Linear isotropic elasticity will be assumed whereby it is convenient to decompose the stress $\boldsymbol{\sigma}$ into a volumetric $\sigma_{\mathrm{vol}} = \boldsymbol{I} : \boldsymbol{\sigma}$ and a deviatoric $\boldsymbol{\sigma}_{\mathrm{dev}} = \boldsymbol{\sigma} - \frac{\sigma_{\mathrm{vol}}}{3}\, \boldsymbol{I}$ part:

$$\boldsymbol{\sigma} = \frac{1}{3}\sigma_{\mathrm{vol}}\, \boldsymbol{I} + \boldsymbol{\sigma}_{\mathrm{dev}}, \sigma_{\mathrm{vol}} = 3K_{\mathrm{b}}\epsilon_{\mathrm{vol}}^{\mathrm{e}}, \boldsymbol{\sigma}_{\mathrm{dev}} = 2\mathrm{G}\boldsymbol{\epsilon}_{\mathrm{dev}}^{\mathrm{e}} \quad (5)$$

where *G* and K_{b} are shear and bulk modulus, respectively. The yield function *f* is assumed to be of von Mises' type, i.e.

$$f = \sqrt{\frac{3}{2}}\,|(\boldsymbol{\sigma}_{\mathrm{dev}} - \boldsymbol{X})| - (R + k) \quad (6)$$

where $\boldsymbol{X}$ is the kinematic hardening stress, R is the isotropic hardening stress and k the initial yield stress.

The evolution of isotropic hardening R is assumed to be of nonlinear type

$$\dot{R} = \dot{\lambda} b (Q - R) \quad (7)$$

where Q is the saturation hardening and b affects the initial hardening slope.

The kinematic hardening $\boldsymbol{X}$ is assumed to be additively decomposed into several hardening stresses $\boldsymbol{X}_i$, i.e. $\boldsymbol{X} = \sum_{i=1}^{n} \boldsymbol{X}_i$. The evolution equation for the kinematic hardening stresses $\boldsymbol{X}_i$ is based on the Armstrong-Frederick model with a linear and a nonlinear (dynamic recovery) part

$$\dot{\boldsymbol{X}}_i = \dot{\lambda}\left(\sqrt{\frac{2}{3}} C_i \frac{\boldsymbol{\sigma}_{\mathrm{dev}} - \boldsymbol{X}}{|\boldsymbol{\sigma}_{\mathrm{dev}} - \boldsymbol{X}|} - \gamma_i \boldsymbol{X}_i\right) \quad (8)$$

where C_i controls the initial hardening and γ_i the saturation hardening.

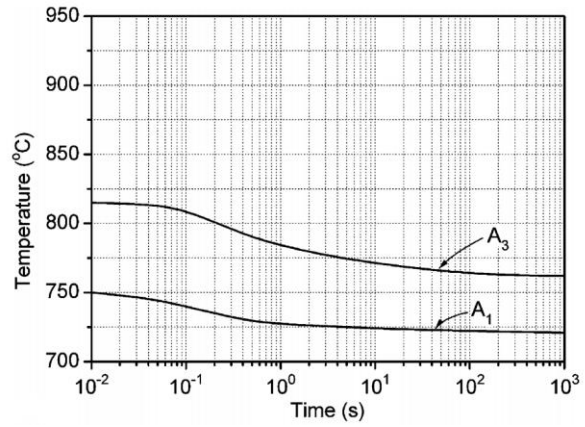
2.3. Homogenization

For the strains it is assumed that the total strain $\boldsymbol{\epsilon}_x$ in all the phases are equal and thereby becomes equal to the homogenized strain $\bar{\boldsymbol{\epsilon}}$, i.e. $\bar{\boldsymbol{\epsilon}} = \boldsymbol{\epsilon}_x$ (i.e. the classical Taylor assumption). However, the homogenized stress $\bar{\boldsymbol{\sigma}}$ is computed using the volume phase fractions $\boldsymbol{p}_x$ and the stresses $\boldsymbol{\sigma}_x$ of the individual phases according to the mixture rule:

$$\bar{\boldsymbol{\sigma}} = \sum_x p_x \boldsymbol{\sigma}_x = \sum_x p_x\, \mathbf{E}_x^{\mathrm{e}} : \boldsymbol{\epsilon}_x^{\mathrm{e}} = \sum_x p_x\, \mathbf{E}_x^{\mathrm{e}} : \left(\boldsymbol{\epsilon}_x - \boldsymbol{\epsilon}_x^{\mathrm{p}} - \boldsymbol{\epsilon}_x^{\mathrm{th}} - \boldsymbol{\epsilon}_x^{\mathrm{tv}}\right) \quad (9)$$

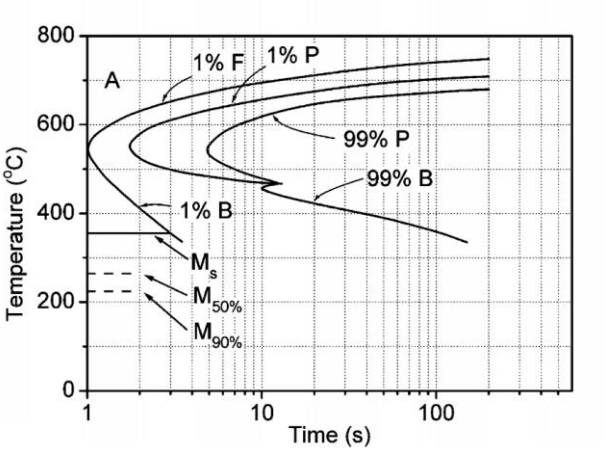
where it was used that the volume fraction of the phases must sum up to unity, i.e. $\sum_x p_x = 1$.

2.4. Phase transformation



In this section, the model adopted for the transformation kinetics of the pearlitic steel during the thermal heating and cooling is introduced. The main phases of a pearlitic steel are austenite (a), ferrite (f), pearlite (p), cementite (c), bainite (b) and martensite (m). In this study we have also chosen to treat tempered martensite (tm) as an individual phase.

The phase transformations that we consider in this paper are:



1. Austenitisation of ferrite, pearlite, cementite and bainite, i.e. f, p, c, b → a
2. Austenite to ferrite, pearlite and bainite, i.e. a → f, p, b
3. Austenite to martensite, i.e. a → m
4. Martensite to tempered martensite, i.e. m → tm
5. Tempered martensite to austenite, i.e. tm → a

which are further described below.

The austenitisation (transformation 1) is a diffusive transformation which occurs upon heating the steel above its austenite transition temperature T_{as}. To describe the kinetics of the austenitisation, the IT-diagram for austenitisation (so called Time Temperature Austenitisation (TTA) diagram) in Figure 1a is employed. For a given temperature in this diagram, the kinetics of crystallization of the diffusive and isothermal transformations are described utilizing the Avrami (JMAK) equation cf. [13]. The temperature dependent parameters of Avrami equation are identified from the TTA-diagram.

(a)

(b)

Figure 1 *(a) TTA diagram describing phase transformation kinetics during austenitisation at constant heating rates. (b) IT diagram describing isothermal transformation kinetics during cooling from austenite. Both diagrams are reproduced from Atlas zur w. der stähle* [14].

Remark. *Note that IT-diagrams are only valid for phase transformations taking place at constant temperatures. However, to treat the targeted application we must allow for variation in temperature. In this regard, Scheil's additive rule* [15] *is adopted which is described in detail in e.g.* [16].

The transformation from austenite to pearlite, ferrite and bainite (transformation 2) occurs during cooling.
Also, this transformation can be considered as diffusive, and thereby described by the JMAK equation and the Scheil's additive rule. The underlying IT-diagram is given in Figure 1b.
When austenite is subjected to rapid cooling (quenching), below the saturation temperature of martensite T_{ms}, a diffusionless austenite-martensite transformation takes place (transformation 3). The austenite-martensite transformation is considered to be athermal and modelled as purely temperature dependent following the Koistinen-Marburger [17] equation.

Upon tempering martensite (transformation 4), the dilatometry experiment in Figure 4 shows two main tempering stages for the martensite, which are visible as negative dilatation effects, cf. [5]. The first tempering stage occurs at around 160 ℃ and is associated with carbon segregation and precipitation of transition carbides, presumably ϵ carbide. The second tempering stage occurs between 220℃ and 400℃ and indicates further decomposition into ferrite and cementite.
However, in this study, for simplicity we have modelled tempered martensite as an individual phase and the characteristics of this phase are represented by its homogenized behaviour. Although the tempered martensite is not a phase in a thermodynamic sense but a microstructure consisting of a ferrite phase and an iron carbide phase. Also, the martensite to tempered martensite is modelled as purely temperature dependent. In order to capture the two stages of tempering a Sigmoid function is employed. If the temperature increase starts at $\check{T}$ the phase fraction martensite decreases from $p_m(\check{T})$ as follows

$$p_m(T) = p_m(\check{T})\left(\frac{k_1}{1+\exp(k_{\theta 1}(T_{\mathrm{tms},1}-T))} + \frac{1-k_1}{1+\exp(k_{\theta 2}(T_{\mathrm{tms},2}-T))}\right) \qquad (10)$$

while the increased tempered martensite is obtained as

$$p_{tm}(T) = p_{tm}(\check{T}) + p_m(\check{T}) - p_m(T) \qquad (11)$$

The numerical value of the constants in (10), are identified as $k_1 = 0.4$, $k_{\theta 1} = -0.12\ \mathrm{K}^{-1}$, $k_{\theta 2} = -0.04\mathrm{K}^{-1}$, $T_{\mathrm{tms},1} = 120$℃ and $T_{\mathrm{tms},2} = 320$℃ to fit the experimental data from [5].
The last transformation considered is tempered martensite to austenite (transformation 5) which takes place gradually during heating within a temperature range $0-30$℃ below the austenite start temperature T_{as} (from the austenitisation IT-diagram for ferrite and pearlite). Since the cementite in the tempered martensite is well dispersed, the diffusion of carbon for tempered martensite-austenite is rapid and the transformation is modelled as purely temperature dependent. The transformation starts at temperature $\tilde{T}_{\mathrm{as}}$ and ends at T_{as}. We have assumed that $\tilde{T}_{\mathrm{as}}$ is 30℃ lower than T_{as}. The transformation is assumed to be linear whereby
the decrease of phase fraction of tempered martensite becomes

$$p_{tm}(T) = p_{tm}(\tilde{T}_{\mathrm{as}}) + (1 - \frac{T-\tilde{T}_{\mathrm{as}}}{T_{\mathrm{as}}-\tilde{T}_{\mathrm{as}}}) \qquad (12)$$

while the corresponding increase of austenite becomes

$$p_a(T) = p_a(\tilde{T}_{\mathrm{as}}) + p_{tm}(\tilde{T}_{\mathrm{as}}) - p_{tm}(T) \qquad (13)$$

3. Parameter identification

The near-pearlitic steel studied in the present work is the ER7 wheel steel grade. The nominal composition of the material is shown in Table 1.

Table 1 *Chemical composition of ER7 wheel material, maximum levels, in wt %* [18].

Element	C	Si	Mn	Mo	Cr	Ni	Cu	S	P	V	Fe
ER7	0.52	0.40	0.80	0.08	0.30	0.30	0.30	0.015	0.020	0.06	Bal.

The initial state of the virgin steel at room temperature consists of p_p=0.9 (fine) pearlite and $p_f = 0.1$ (proeutectoid) ferrite.

3.1. Plastic model parameters

The nonlinear mixed isotropic and kinematic plastic material model described in subsection 2.2 is adopted to characterize the mechanical behavior of the individual phases of the material. In the following, the available experimental and estimated data for ER7 steel as well as the identified parameter values of the plastic model for each phase are presented.

3.1.1. Pearlite

To characterize the cyclic behavior of pearlitic ER7 wheel material, low cycle fatigue tests (according to the standard ASTM E606-12 [19]) were performed in [9] with fully reversed ($R_\epsilon = -1$) strain control with a triangular time history. In the tests, the strain rate was 5×10^{-3} s^{-1} and the strain amplitude 1%. The tests are conducted under isothermal conditions from room temperature 20℃ up to 625℃. In [20], an identification of Young's modulus E and yield stress k as well as the kinematic hardening parameters C_i and γ_i and isotropic hardening parameters b and Q were performed. The identified parameter values of the plastic material model at different temperatures for pearlite are presented in Table 1. The isotropic hardening and the 2nd kinematic hardening are, in accordance with [20], both assumed to evolve linearly, i.e. $b \to 0$ (in the code 10^{-6} [-]) and γ_2=0. The temperature dependence of the parameters is assumed to follow linear interpolation between the identified parameter values. Additionally, since the transversal behavior was not measured, the Poisson's ratio ν for the studied temperature range is taken from available data for mild steels [21] which are summarized in Table 3. More details on the experiments and their results can be found in [9].

Table 2 *Identified parameter values of the plastic model for pearlite.*

T [°C]	E [GPa]	k [MPa]	C_1 [MPa]	C_2 [MPa]	γ_1 [-]	$b.Q$ [MPa]
20	185.	305.	90000	4500	400	0
200	179.	310.	65000	7500	300	10
325	174.	380.	60000	5400	300	35
400	168.	327.	55500	5400	300	-2
600	165.	121.	90000	4500	900	-6
625	160.	73.	100000	4500	1350	-6

Table 3 *Variation of Poisson's ratio with temperature for mild steels from* [21].

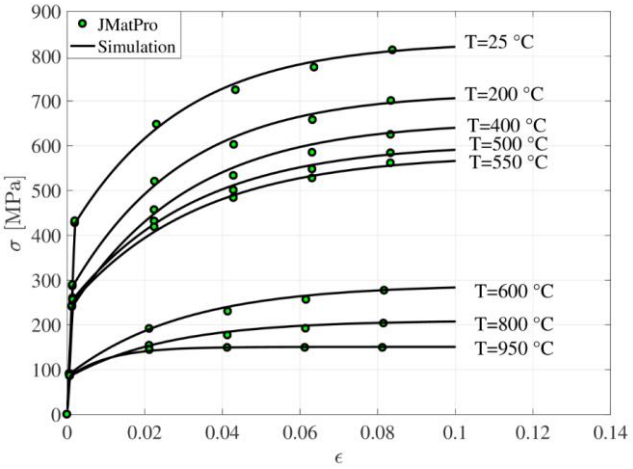
T [°C]	17	200	400	600	800	1000
Poisson's ratio ν	0.296	0.301	0.312	0.319	0.338	0.354

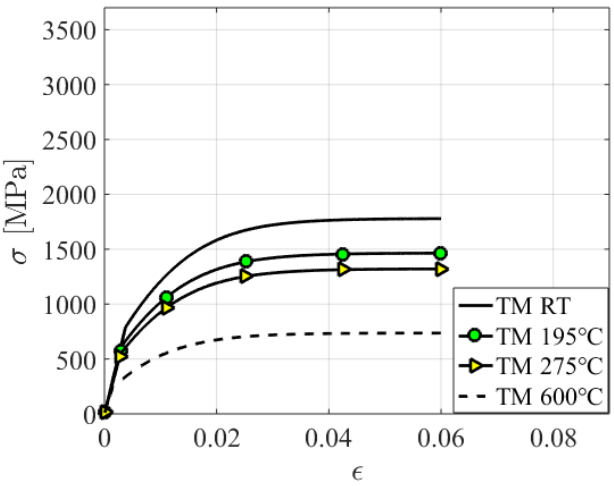
3.1.2. Austenite

Due to lack of experimental data for austenite, the mechanical properties of austenite are predicted using JMatPro6.0 (SenteSoftware), which uses the actual chemical composition of the material, presented in Table 1. Figure 2 shows the temperature dependent stress-strain data obtained for austenite together with results from calibrated plastic model. The associated values from the identification of the plastic model parameters are presented in Table 4. Since the provided data from JMatPro are for monotonic loading, not both the parameters of isotropic and kinematic hardening can be identified. Here, we assume purely kinematic hardening and no isotropic hardening, i.e. $b = 0$. One kinematic hardening variable is employed to capture the nonlinear stress-strain curves of the austenite, i.e. $C_2 = 0$. The temperature dependence of the parameters for austenite is also assumed to follow linear interpolation between the identified parameter values.

Table 4 *Identified parameter values of the plastic model for austenite.*

T [°C]	E [GPa]	k [MPa]	C_1 [MPa]	γ_1 [-]
20	210.	427	22000	55
200	200.	286	16000	37
400	183.	240	14500	35
500	172.	257	11500	33
550	165.	253	10500	32
600	159.	90	7000	35
800	129.	85	5000	40
950	114.	85	6500	100





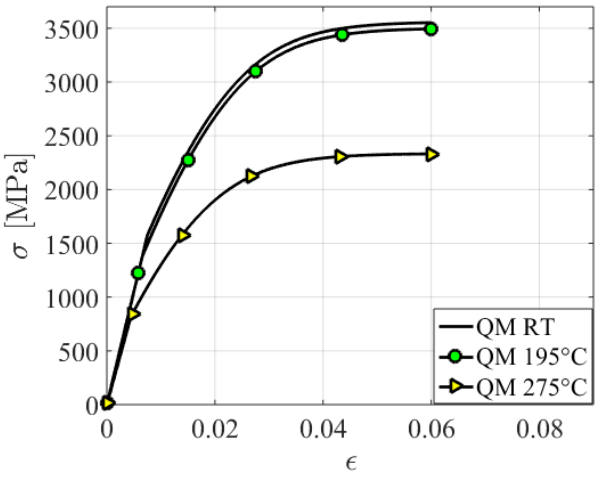


Figure 2 *Stress-strain curves obtained from JMatPro and calibration of the material model (Simulation) for austenite.*

3.1.3. Un-tempered and tempered martensite

The experimental and estimated data for un-tempered martensite (as-quenched martensite) QM and tempered martensite TM are taken from [5].

(a)

(b)

Figure 3 *Results of calibration of the plastic material model for (a) tempered martensite and (b) un-tempered martensite.*

Accordingly, the obtained material response for QM and TM together with results from calibrated plastic model are shown in Figure 3. The identified model parameter values are presented in Table 5 and Table 6.

Table 5 *Identified parameter values of the plastic model for un-tempered martensite (QM), γ_1=130.*

T [°C]	E [GPa]	k [MPa]	C_1 [MPa]
20	210.	1575	258000
195	210.	1380	275000
275	184.	817	197000

Table 6 *Identified parameter values of the plastic model for tempered martensite (TM), γ_1=130.*

T [°C]	E [GPa]	k [MPa]	C_1 [MPa]
20	210.	789	128000
600	170.	236	65000

Also for QM and TM, we choose to consider purely kinematic hardening plasticity, i.e. $b = 0$. One kinematic hardening in the plastic model was found to be enough (i.e. $C_2 = 0$) to capture the stress-strain curves for QM and TM. The value for γ_1=0 was found to be 130 for both phases for all temperatures.
Furthermore, the temperature dependence of the plastic model parameters for both QM and TM are assumed to follow linear interpolation between the identified parameter values.

3.2. Dilatometry

The thermal expansion/contraction characteristics of the considered near-pearlitic steel, upon heating to above austenitization temperatures (980℃) and then cooling to RT are examined by dilatometry experiments, reported in [6, 5]. The temperature history in the dilatometry experiments is chosen to mimic the conditions in a wheel-flat application. In this context, two heating cycles are conducted from room temperature to 980℃. The subsequent cooling is chosen to be rapid in order to form martensitic WEL by quenching the austenite. This is in accordance with the targeted application where after the heating events (wheel flats), as the wheel starts rolling again, a very rapid cooling ensues due to conduction into large volume of cold steel surrounding the wheel flat [22].
Since the experiments are performed without any external stress, i.e. $\bar{\boldsymbol{\sigma}} = \mathbf{0}$, the strain $\bar{\boldsymbol{\epsilon}}$ in each timestep is in general obtained by solving (e.g. using Newton iterations) the nonlinear equation

$$\bar{\boldsymbol{\sigma}} = \sum_x p_x \boldsymbol{\sigma}_x = \sum_x p_x \, \mathbf{E}_x^{\mathrm{e}} : \left(\boldsymbol{\epsilon}_x - \boldsymbol{\epsilon}_x^{\mathrm{p}} - \boldsymbol{\epsilon}_x^{\mathrm{th}} - \boldsymbol{\epsilon}_x^{\mathrm{tv}}\right) = \mathbf{0} \quad (14)$$

In Figure 4, the simulated $\Delta L/L_0$, in one Gauss point, during two cycles of thermal loading is shown. In each cycle with duration of $t = 2$ s, the temperature increases from RT to 1000℃ and cools down to RT.
In the figure, the experimental thermal strain $\Delta L/L_0$ during the 2nd run of tempering from [5] is also shown.

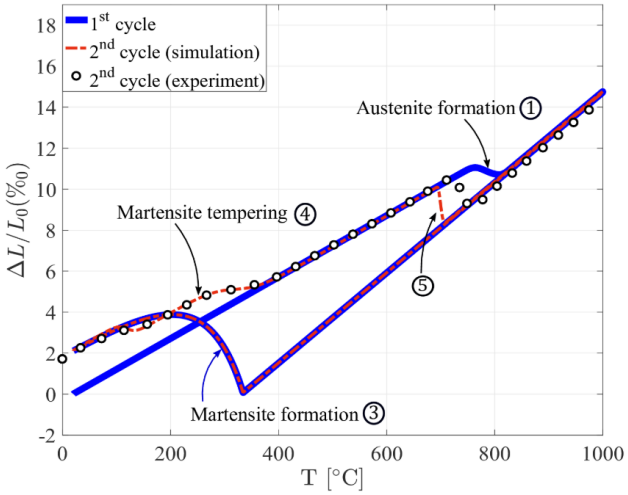

Figure 4 *Evolution of strain on heating and cooling of martensite, pearlite and austenite at higher temperatures. The experimental data from* [5] *are shown only for the 2nd run of tempering. The circled numbers refer to the phase transformation steps introduced in section 2.4.*

According to the dilatometry test data, the thermal expansion coefficient for ferrite, pearlitic, tempered and un-tempered martensite can be estimated to $\alpha_\alpha = 15 \times 10^{-6}$ K^{-1}(dominated by ferrite behaviour). Similarly, the thermal expansion coefficient for austenite is estimated to $\alpha_\gamma = 22 \times 10^{-6}$ K^{-1}.
In order to obtain the transformation expansion strain $\boldsymbol{\epsilon}_{\mathrm{x}}^{\mathrm{tv}}$ in Equation (3), the densities of different phases are determined from dilatometry experiments. Since, the base material at RT is considered to be in pearlitic/ferritic formations, the initial density of the mixture is assumed to be $\rho_0 = \rho_p$. Accordingly, the density of austenite, un-tempered and tempered martensite after complete transformation are estimated to $\rho_a \approx 1.02\rho_p$, $\rho_m \approx 0.99\rho_p$ and $\rho_{tm} = \rho_p$, respectively.

4. FE modeling

In this section, the aim is to simulate the influence of a "Double wheel flat" loading case on the residual stresses generated in the Thermally Affected Zone (TAZ) of a pearlitic steel.

4.1. Purely thermal double wheel flat

In this example, FE analyses of an axisymmetric model of an ER7 disc sample with radius 35 mm and thickness 20 mm are carried out, see Figure 5(a). Initially the temperature is increased homogeneously to T= 100°C in the disc which should represent the operational temperature.

To model the thermal loading from a double wheel flat, the following convective thermal boundary condition proposed in [4] is then applied to the upper surface within the radius $r_h = 5$ mm:

$$\phi(T) = q(1 - \exp(t_\lambda(T_{sat} - T))) \qquad (15)$$

where $T_{sat} = 1000$°C is the maximum temperature, $q = 50$ [W/m^2] is the maximum heat flux density and $t_\lambda = -0.01$ [K^{-1}] describes the saturation rate of ϕ. The remaining boundaries are assumed to be insulated, cf. Figure 5(b). This convective boundary condition is first applied during $\Delta t = 5$ s and then replaced by insulated conditions ($q = 0$) during cooling in 30 s. After that, this is repeated but now with a shorter heating time $\Delta t = 0.1$ s giving a lower pick temperature. After the second 30 s cooling the disc is cooled down to room temperature in an accelerated fashion by prescribing the temperature to room temperature on all the boundaries. The resulting temperature history in the node at the upper surface and $r = 0$ is shown in Figure 6.

Regarding the mechanical boundary conditions, axisymmetry is assumed around $r = 0$ (with one fixed node) while the other boundaries are assumed to be stress free.

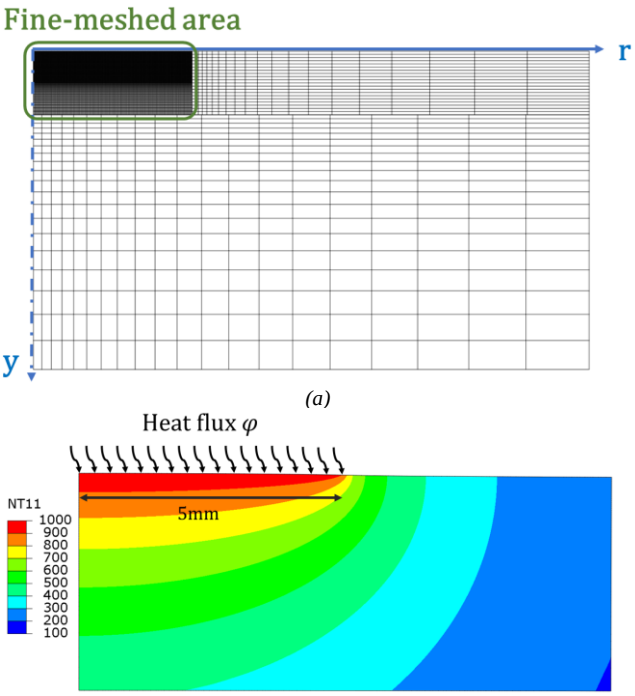

Figure 5 *(a) Axisymmetric mesh of the disc sample. entire model: 0 ≤ r ≤ 35.0 mm, 0 ≤ y ≤ 20.0 mm, Fine-meshed area: 0 ≤ r ≤ 10.0 mm, 0 ≤ y ≤ 4.0 mm. (b) Temperature distribution after heating Δt=5 s in the fine-meshed area. Heat influx ϕ is applied on the central part of top surface 0 ≤ r ≤ 5.0 mm, otherwise insulated surfaces.*

A sequential (uncoupled) temperature-displacement analysis is performed using the FE-software Abaqus 6.13 Standard. A selection of results computed for purely thermal loading (double wheel flat) are presented in Figure 7 and Figure 8.

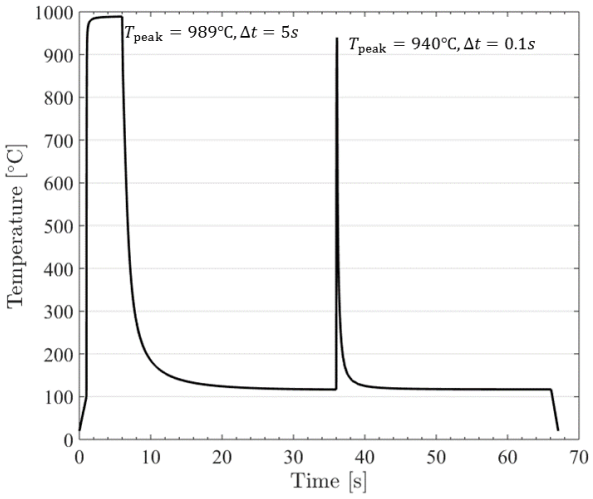

Figure 6 *Temperature history for the double wheel flat case for the top, centre surface node in the FE geometry. First, the wheel is preheated to its operational temperature T=100°C.*

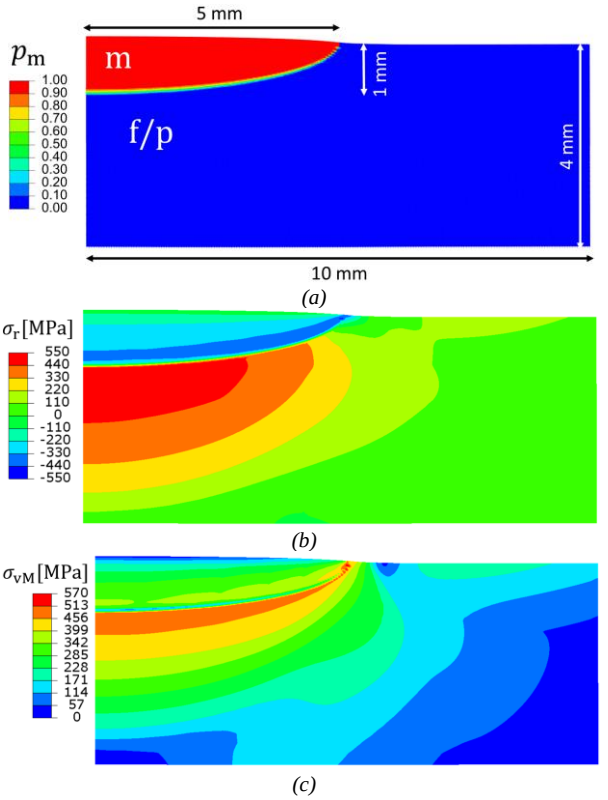

Figure 7 *Simulation results after heating Δt=5 s followed by 30 s cooling (t=36 s). (a) Martensite fraction (p_m), (b) Radial stresses (denoted "σ_r" with values in MPa) and (c) von Mises stresses (denoted "σ_{vM}" with values in MPa). The results are presented on the deformed (scaling factor 10) fine-meshed area, 4 × 10 mm large. In figure (a), m denotes the martensite layer and f/p the base (pearlitic/ferritic) material.*

As can be seen in Figure 7a, by increasing the temperature in part of the TAZ above austenitisation temperature and then rapidly quenching the material, an approximately 1 mm thick martensite layer forms on the surface of the disc sample. Since, the specific volume of martensite is larger than the specific volume of the base (pearlitic/ferritic) material, compressive residual stresses are generated within the martensite layer, see Figure 7b.

To fulfil the equilibrium in the disc, high tensile residual stresses are generated in the base material, right below the martensite layer. Comparing the value of von Mises stresses, in Figure 7c, with the yield strength of pearlite at RT (Table 2), it can be observed that the residual stresses result in plasticity in the base material.

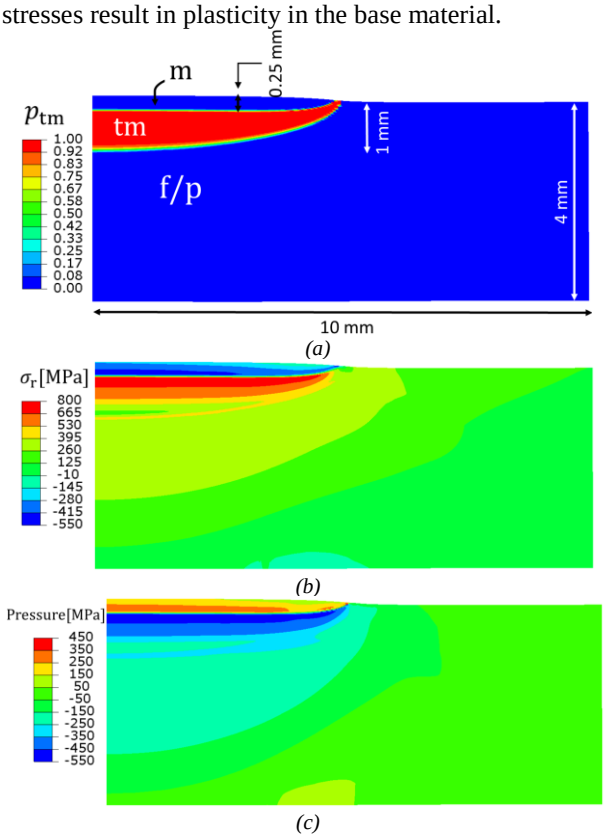

Figure 8 *Simulation results after final cooling to 20℃ (Δt=67.1 s). (a) Tempered martensite fraction (denoted p_{tm}), (b) Radial stresses (denoted "σ_r" with values in MPa) and (c) Hydrostatic pressure (denoted "Pressure" with values in MPa). The results are presented on the deformed (scaling factor 10) fine-meshed area, 4 × 10 mm large. In figure (a), m denotes the martensite layer, tm the tempered martensite layer and f/p the base (pearlitic/ferritic) material.*

In Figure 8 the simulation results after the second heating event and quenching to RT ($t = 67.1$ s) is shown. Since, during the 2nd heating event the wheel sliding time is assumed to be shorter $\Delta t = 0.1$ s (see Figure 6), the temperature elevates above the effective austenitisation temperature only within a thin surface (approximately 0.25 mm) layer of the disc. Consequently, only a thin layer out of the martensite layer, formed in the first heating event, is re-austenitised. After a rapid cooling, the re-austenitised layer transforms to as-quenched martensite. However, the remaining of the martensite layer formed in the first heating event becomes tempered martensite, see Figure 8. The rest of the material in the disc remains unaffected.

As can be seen in Figure 8b, once again compressive residual stresses are generated within the martensite layer. However, since the specific volume of fully tempered martensite is the same as the specific volume of the base material, high tensile residual stresses are generated in the tempered martensite layer.

This is also illustrated in Figure 8c where the hydrostatic pressure is shown. The negative hydrostatic pressure in the tempered martensite may result in brittle fracture.

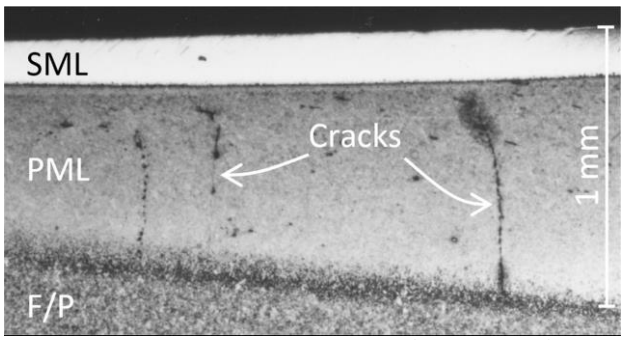

Figure 9 *Cross section through a double wheel flat. The top surface has been heated by skidding against the rail. The darker grey area (F/P) at the bottom of the picture represents the un-affected ferritic–pearlitic base material. The first skidding event yielded the thicker, primary martensite layer (PML), and the following skidding event re-austenitised a thinner, secondary layer (SML) and tempered the martensite in the PML* [6].

As a comparison, Figure 9 shows the cross section of a wheel tread which has been heated by skidding against rail in a double wheel flat scenario. It can be observed that several cracks are formed in the tempered martensite layer. According to the numerical predictions, high tensile residual stresses are generated in the tempered martensite layer and since the tempered martensite is rather brittle, it becomes susceptible to fatigue crack initiation and propagation.

5. Conclusions and outlook

A material model incorporating phase transformations and cyclic plasticity of near pearlitic steels have been developed. The considered phases are pearlite, ferrite, cementite, martensite and tempered martensite. Experimental data from tests conducted in [9] and [5] together with the software Jmatpro6.0 are used to calibrate the cyclic plasticity model for the different phases at a number of temperatures. The phase transformation modelling is based on IT-diagrams and dilatometry experiments in [6, 5] are used for calibration and validation.

The material model was used in FE simulations to study the arising phase fractions and residual stresses in the vicinity of a wheel-rail contact when subjected to "double wheel flat" loading. The first temperature increase (during 5s) and cooling gave an approximately 1 mm thick martensite layer. In this layer the compressive radial residual stress was up to 550 MPa while below this layer (pearlite) the tensile radial stresses was up to 550 MPa. After the second temperature increase (during 0.1 s) and cooling a thinner martensitic layer (approximately 0.25mm) was obtained. Below this layer the previous martensite transformed into tempered martensite. In the martensite the residual compressive radial stress was also now up to 550 MPa while in the tempered martensite the tensile radial stress was up to 800 MPa. Clearly, the results depend the number of and duration of heating events. But since the tempered martensite material is rather brittle and susceptible to crack initiation the resulting tensile stresses may result in crack initiation in the tempered martensite. This is also what is qualitatively observed when studying a cross section at a double wheel from Figure 9.

Abstract: Fatigue crack growth direction criteria are evaluated towards a twin-disc experiment from the literature. The experiment is modelled numerically at different crack lengths. Based on numerically evaluated stresses, strains and displacements, a range of crack growth direction criteria from the literature are evaluated and compared to the experimentally found crack growth direction. In the considered experiment, the growth is essentially shear driven. Of the evaluated criteria employed to a linear elastic analysis, the Maximum Shear Stress (MSS) and Vector Crack-Tip Displacement (VCTD) criteria are found to be able to capture the experimentally found crack growth direction throughout the fatigue life.

Keywords: FE-simulation; rolling contact fatigue; linear elastic fracture mechanics; elastic-plastic fracture mechanics; twin-disc specimen; shear-mode crack growth.

1. Introduction

Rolling contact fatigue of rails and wheels is a major reliability, economic and safety challenge for railways. Economic implications in North America for rail replacement alone are estimated as USD300 million annually and accidents may end up at costs of over one billion dollars [1].

To prevent accidents, crack initiation on wheels and rails should preferably be avoided. However, in most cases this will correspond to operational conditions where load capacity, speed and acceleration/braking are economically unsustainable. The realistic option is thus to minimize crack initiation (or rather prolong time to initiation as far as realistically possible) and remove any initiated cracks. In this case, a zero tolerance for cracks in the wheel/rail interface will lead to unsustainable operational conditions due to the amount of required inspections and (corrective) maintenance. Instead, the realistic option is to acknowledge that crack growth is a reasonably slow phenomenon, monitor crack initiation and growth and remove cracks before they reach a depth when removal becomes too costly, cause too large operational disturbances, or when the cracks are potentially a safety hazard.

Such a preventive maintenance approach generally requires the crack growth rate and direction to be known. For most load situations, the crack growth direction is not a major problem since (large) cracks tend to grow in a direction perpendicular to the largest principal stress. However, under some loading situations this is not always the case [2]. One such loading situation is that of rolling contact. Here, a surface initiated crack initially tends to propagate into wheel or rail at a shallow angle, after which it may deviate depending on the loading situation [3]. To be able to predict the crack growth direction of rolling contact fatigue cracks in wheels and rails is essential since the required maintenance actions and the safety risk relate to the *depth* of the rolling contact fatigue cracks and not the length of these cracks.

There are several criteria developed to predict the crack growth direction under multiaxial loading. In the current study, several such criteria from the literature are employed to loading conditions of a twin-disc fatigue crack growth experiment from the literature [4]. Finite element (FE) simulations of the experiment are carried out to evaluate the evolution of stress, strain and displacement fields in the twin-disc. Crack growth directions are predicted using the different criteria, and compared to experimentally found directions throughout the experiment.

The paper is organized as follows: The framework for evaluation of mixed-mode crack growth criteria is outlined in Section 2. The twin-disc experiment and the corresponding FE-model of the experiment are detailed in Section 3 which also contains a description of the criteria to predict crack growth directions. Finally, conclusions and future work are outlined in Section 4.

2. Framework for evaluation of criteria

Crack growth direction criteria are evaluated with respect to how well they match results of a twin-disc experiment [4]. The general framework for the evaluation is described in Box

[1] In distinction of crack growth criteria into linear elastic and elastic-plastic fracture mechanics criteria, it has been assumed that a) MTS, MSS and MSE criteria are evaluated based on known stress intensity factors, which are only valid for elastic bulk material response and b) CF and VCTD criteria can be evaluated for both linear elastic and elastic-plastic material responses.

1. Evaluated criteria are in Table 1 distinguished into linear elastic and elastic-plastic fracture mechanics criteria[1].

Box 1 *Framework for evaluation of mixed-mode crack growth direction criteria.*

1. Identification of twin-disc crack growth experiment with well-defined crack path.
2. Spatial characterization of the crack via image processing [5].
3. Modelling of the experiment at different crack lengths:
   (a) A finite element (FE) model of the twin-disc specimen is developed.
   (b) The final crack documented in the experiment is embedded in the FE-mesh. Crack-face (kinematic) constraints are enforced between parts of the final crack that are still intact at a specific fatigue life instance.
   (c) Physical modelling of the experiment is performed by prescribing load and boundary conditions corresponding to the experiment.
   (d) Linear elastic simulations with the developed model are performed featuring one load passage.
4. Crack growth direction criteria are evaluated based on resolved stresses, strains and displacements from the FE-analyses.
5. Predicted directions are compared to the experimentally found crack growth direction.

Table 1 *Crack growth direction criteria.*

Material response	Criterion
Elastic	Maximum tangential stress (MTS) [6]
	Maximum shear stress (MSS) [6]
	Minimum strain energy density (MSE) [7]
Elastic-plastic	Configurational force (CF) [8]
	Vector crack-tip displacement (VCTD) [9]

In case of linear elastic fracture mechanics criteria, a polar coordinate system is introduced with origin at the crack-tip, see Fig. 1. Stress components in the plane [10] can be expressed in terms of polar coordinates (r, ϑ) as

$$\sigma_{\vartheta\vartheta}(r,\vartheta) = \frac{1}{\sqrt{2\pi r}} \overbrace{\cos\frac{\vartheta}{2}\left[K_{\mathrm{I}}\cos^2\frac{\vartheta}{2} - \frac{3}{2}K_{\mathrm{II}}\sin\vartheta\right]}^{\tilde{\sigma}_{\vartheta\vartheta}(\vartheta)}, \quad (1)$$

$$\tau_{r\vartheta}(r,\vartheta) = \frac{1}{\sqrt{2\pi r}} \underbrace{\frac{1}{2}\cos\frac{\vartheta}{2}\left[K_{\mathrm{I}}\sin\vartheta + K_{\mathrm{II}}\left(3\cos\vartheta - 1\right)\right]}_{\tilde{\tau}_{r\vartheta}(\vartheta)}, \quad (2)$$

where K_{I} and K_{II} are stress intensity factors (SIFs) in modes I and II, respectively. In what follows, SIFs are computed from minimization of the error, in an integrated least squares sense, between the displacements obtained from FE-analyses and a displacements ansatz [11]. The ansatz is based on the first term in the infinite series expansion of the linear elastic crack-tip displacement fields [12]. Introducing known K_{I} and K_{II} in Eq. (1) or (2), crack growth direction predicted by the MTS or MSS criterion may be determined as the direction (defined by $\bar{\vartheta}$) which maximizes $\tilde{\sigma}_{\vartheta\vartheta}$ or $\tilde{\tau}_{r\vartheta}$, respectively. The procedure is similar for determining crack growth direction corresponding to the MSE criterion [7].

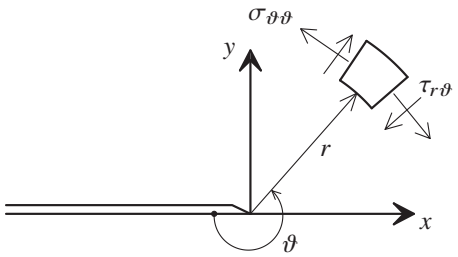

Figure 1 *Stress components in the plane with respect to polar coordinates system (r, ϑ) ($\vartheta \in [-\pi, \pi)$ with respect to the x-axis).*

It is common in the literature to replace K_{I} and K_{II} in Eqs. (1) and (2) by respective ranges over a load cycle, ΔK_{I} and ΔK_{II}, if fatigue crack growth is studied. Evaluation of ΔK_{I} and ΔK_{II} is straightforward only for proportional loading [13]. In order to cover non-proportional loading, maximization of $\Delta\tilde{\sigma}_{\vartheta\vartheta}$ or $\Delta\tilde{\tau}_{r\vartheta}$ in terms of ϑ has been proposed in the literature for the MTS and MSS criteria [14, 15]. The approach of maximization of $\Delta\tilde{\sigma}_{\vartheta\vartheta}$ is further detailed for the MTS criterion in Box 2. The procedure is similar for the MSS and MSE [7] criteria.

Box 2 *Framework for evaluation of fatigue crack growth direction with MTS criterion.*

1. A sufficiently large set of potential crack growth directions, $\vartheta \in [-\pi, \pi]$, is considered.
2. For each of the considered directions, the range,
$$\Delta\tilde{\sigma}_{\vartheta\vartheta}(\vartheta) = \tilde{\sigma}_{\vartheta\vartheta,\max_t}(\vartheta) - \tilde{\sigma}_{\vartheta\vartheta,\min_t}(\vartheta), \quad (3)$$
is computed. Here,
$$\tilde{\sigma}_{\vartheta\vartheta,\max_t}(\vartheta) = \max_t\left\{\tilde{\sigma}_{\vartheta\vartheta}(K_{\mathrm{I}}(t), K_{\mathrm{II}}(t), \vartheta)\right\}, \quad (4)$$
$$\tilde{\sigma}_{\vartheta\vartheta,\min_t}(\vartheta) = \min_t\left\{\tilde{\sigma}_{\vartheta\vartheta}(K_{\mathrm{I}}(t), K_{\mathrm{II}}(t), \vartheta)\right\}, \quad (5)$$
and $\tilde{\sigma}_{\vartheta\vartheta}(K_{\mathrm{I}}(t), K_{\mathrm{II}}(t), \vartheta)$ is computed from Eq. (1).
3. The preferred direction of growth is the direction which maximizes Eq. (3),
$$\bar{\vartheta} = \underset{\vartheta'}{\mathrm{argmax}}\left\{\Delta\tilde{\sigma}_{\vartheta\vartheta}(\vartheta')\right\}. \quad (6)$$

As for the elastic-plastic criteria, the configurational force is related to energetic changes associated with changes in the initial configuration of a continuum (e.g. a crack advance). In the adopted continuum mechanics setting [16], configurational force for linear elastic material response is determined from

$$\mathcal{G} = -\int_{\Omega} \boldsymbol{\Sigma} \cdot \boldsymbol{\nabla} \overline{W} \, \mathrm{d}\Omega \tag{7}$$

where $\boldsymbol{\Sigma} \overset{\text{def}}{=} \psi \boldsymbol{I} - \boldsymbol{h}^{\mathrm{T}} \cdot \boldsymbol{\sigma}$ is Eshelby energy-momentum tensor and $\overline{W}$ is a scalar-valued function. The quantities defining $\boldsymbol{\Sigma}$ are volume-specific free energy, ψ, displacement gradient, $\boldsymbol{h} = [\boldsymbol{u} \otimes \boldsymbol{\nabla}]$ and Cauchy stress, $\boldsymbol{\sigma}$. In fracture mechanics, the crack driving force acting on an elastic singularity can be obtained by projecting $\mathcal{G}$ onto the tangential direction of the underformed crack. This projection is commonly known as energy release rate [17] and is equivalent to the J-integral [18].

The direction of crack growth is determined as the direction of discrete configurational force at the crack-tip node, $\mathcal{G}_a$. Upon introducing discretization of $\overline{W}$ in Eq. (7), the configurational force at the crack-tip node can be expressed as

$$\mathcal{G}_a = -\int_{\Omega} \boldsymbol{\Sigma} \cdot \boldsymbol{\nabla} N_a \, \mathrm{d}\Omega, \tag{8}$$

where N_a is the shape function associated with crack-tip node a, see Fig. 2. Furthermore, $\mathcal{G}_a$ may be analyzed to the Cartesian coordinate system depicted in Fig. 3, such that we obtain the force vector,

$$\mathcal{G}_a = \mathcal{G}_{a,\parallel} \hat{\boldsymbol{e}}_{\parallel} + \mathcal{G}_{a,\perp} \hat{\boldsymbol{e}}_{\perp}. \tag{9}$$

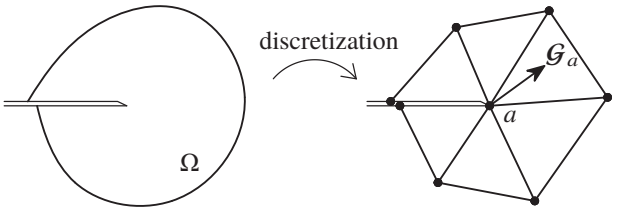

Figure 2 *Configurational force at the crack-tip node after discretization.*

In order to evaluate the fatigue crack growth direction based on the CF criterion, the framework described in Box 3 is proposed.

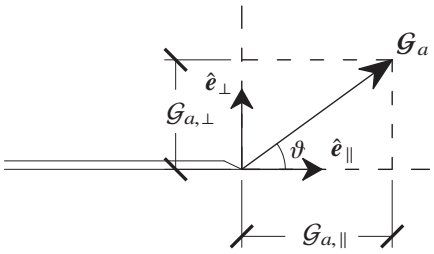

Figure 3 *Configurational force at the crack-tip analyzed in the local coordinate system of Fig. 1 with unit vectors $\hat{\boldsymbol{e}}_{\parallel}$ and $\hat{\boldsymbol{e}}_{\perp}$.*

[2] In what follows, δ_{I} and δ_{II} are always computed at a distance from the crack-tip, $d_h = h_{\mathrm{c}}$, where h_{c} is the characteristic element size of the FE-mesh. In the triangular FE-mesh employed in this study, h_{c} was chosen as the average over the finite elements within the crack region of the maximum side-length of each element.

Box 3 *Framework for evaluation of fatigue crack growth direction with CF criterion.*

1. Configurational force at the crack-tip node, $\mathcal{G}_a(t)$, is computed according to Eq. (9) at each time step of the load cycle.
2. The "amplitudes" of the configurational force components are evaluated as

$$\tilde{\mathcal{G}}_{a,\parallel}(t) = \mathcal{G}_{a,\parallel}(t) - \bar{\mathcal{G}}_{a,\parallel}, \tag{10}$$

$$\tilde{\mathcal{G}}_{a,\perp}(t) = \mathcal{G}_{a,\perp}(t) - \bar{\mathcal{G}}_{a,\perp}, \tag{11}$$

   where $\bar{\bullet} \overset{\text{def}}{=} 1/2([\bullet]_{\min} + [\bullet]_{\max})$ and $[\bullet]_{\min}$ and $[\bullet]_{\max}$ are minimum and maximum values over the load cycle. From components, $\tilde{\mathcal{G}}_{a,\parallel}$ and $\tilde{\mathcal{G}}_{a,\perp}$, the configurational force is defined as

$$\hat{\mathcal{G}}_a(t) = \langle \tilde{\mathcal{G}}_{a,\parallel}(t) \rangle \hat{\boldsymbol{e}}_{\parallel} + \tilde{\mathcal{G}}_{a,\perp}(t) \hat{\boldsymbol{e}}_{\perp}, \tag{12}$$

   where $\langle \bullet \rangle \overset{\text{def}}{=} 1/2(\bullet + |\bullet|)$.
3. The preferred direction of growth is determined from

$$\bar{\vartheta} = \arg \frac{\int \langle \mathrm{d_t} | \hat{\mathcal{G}}_a(t) | \rangle \hat{\boldsymbol{e}}_{\mathcal{G}}(t) \, \mathrm{d}t}{\int \langle \mathrm{d_t} | \hat{\mathcal{G}}_a(t) | \rangle \, \mathrm{d}t}, \tag{13}$$

   where $\mathrm{d_t}\bullet$ denotes time derivative and $|\bullet|$ denotes the Euclidean norm. The direction of $\hat{\mathcal{G}}_a$ in each time step is computed as

$$\hat{\boldsymbol{e}}_{\mathcal{G}}(t) = \frac{\hat{\mathcal{G}}_a(t)}{|\hat{\mathcal{G}}_a(t)|}. \tag{14}$$

The final criterion for crack growth direction considered here is the VCTD criterion [9]. According to this criterion, the crack growth takes place in the direction of the VCTD vector, which is evaluated from

$$\vartheta = \pm \arcsin \frac{\Delta\delta_{\mathrm{II}}}{\Delta\delta}, \tag{15}$$

where $\Delta\delta \overset{\text{def}}{=} \sqrt{\Delta\delta_{\mathrm{I}}^2 + 2\Delta\delta_{\mathrm{I}}|\Delta\delta_{\mathrm{II}}| + 2\Delta\delta_{\mathrm{II}}^2}$. Relative displacements, δ_{I} and δ_{II}, between the crack faces are determined at a pre-defined distance[2] from the crack-tip, d_h, see Fig. 4. The framework to evaluate fatigue crack growth direction based on the VCTD criterion is outlined in Box 4 and illustrated in Fig. 5.

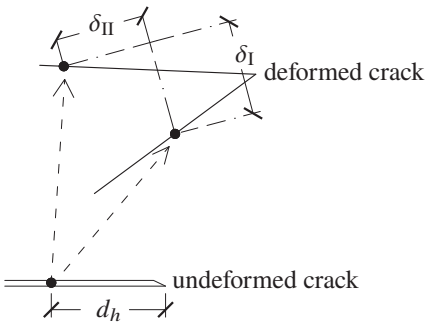

Figure 4 *Definition of relative crack-tip displacements δ_{I} and δ_{II}.*

Box 4 *Framework for evaluation of fatigue crack growth direction using the VCTD criterion.*

1. Crack-tip displacements, $\delta_{\mathrm{I}}(t)$ and $\delta_{\mathrm{II}}(t)$, are computed in each time step of the load cycle.
2. The "amplitudes" of the crack-tip displacements are defined as

$$\tilde{\delta}_{\mathrm{I}}(t) = \delta_{\mathrm{I}}(t) - \bar{\delta}_{\mathrm{I}}, \tag{16}$$
$$\tilde{\delta}_{\mathrm{II}}(t) = \delta_{\mathrm{II}}(t) - \bar{\delta}_{\mathrm{II}}. \tag{17}$$

From $\tilde{\delta}_{\mathrm{I}}$ and $\tilde{\delta}_{\mathrm{II}}$, we may define a crack driving force,

$$B(t) = \sqrt{\langle\tilde{\delta}_{\mathrm{I}}(t)\rangle^2 + 2\langle\tilde{\delta}_{\mathrm{I}}(t)\rangle|\tilde{\delta}_{\mathrm{II}}(t)| + 2\tilde{\delta}_{\mathrm{II}}(t)^2}. \tag{18}$$

3. The preferred direction of growth is defined as

$$\hat{\boldsymbol{e}} = \underset{\tilde{\boldsymbol{e}}\in\{\hat{\boldsymbol{e}}^+,\hat{\boldsymbol{e}}^-\}}{\operatorname{argmax}} |\tilde{\boldsymbol{e}}|, \tag{19}$$

where

$$\hat{\boldsymbol{e}}^{+/-} = \frac{\int \boldsymbol{e}^{+/-}(t)\,\mathrm{d}t}{\int \langle \mathrm{d}_t B(t)\rangle\,\mathrm{d}t}. \tag{20}$$

Trial steps, $\boldsymbol{e}^+$ and $\boldsymbol{e}^-$, are defined as

$$\boldsymbol{e}^+(t) = \langle \mathrm{d}_t B(t)\rangle \hat{\boldsymbol{e}}(t) f^+(t), \tag{21}$$
$$\boldsymbol{e}^-(t) = \langle \mathrm{d}_t B(t)\rangle \hat{\boldsymbol{e}}(t) f^-(t), \tag{22}$$

where $\hat{\boldsymbol{e}}(t)$ is the instantaneous unit vector in the direction determined by

$$\vartheta(t) = \arcsin\frac{\tilde{\delta}_{\mathrm{II}}(t)}{B(t)}, \tag{23}$$

and,

$$f^+(t) = \begin{cases} 0, & \tilde{\delta}_{\mathrm{II}} < 0 \;\&\; \frac{\delta_{\mathrm{I}}}{\|\delta_{\mathrm{II}}\|} < 1 \\ 1, & \tilde{\delta}_{\mathrm{II}} \geq 0 \text{ or } \frac{\delta_{\mathrm{I}}}{\|\delta_{\mathrm{II}}\|} \geq 1 \end{cases}, \tag{24}$$

$$f^-(t) = \begin{cases} 0, & \tilde{\delta}_{\mathrm{II}} > 0 \;\&\; \frac{\delta_{\mathrm{I}}}{\|\delta_{\mathrm{II}}\|} < 1 \\ 1, & \tilde{\delta}_{\mathrm{II}} \leq 0 \text{ or } \frac{\delta_{\mathrm{I}}}{\|\delta_{\mathrm{II}}\|} \geq 1 \end{cases}. \tag{25}$$

3. Evaluation of fatigue crack growth direction criteria for twin-disc experiment

3.1. Description of experiment

Predicted crack growth directions are compared to results from a twin-disc fatigue crack growth experiment [4] (experiment labelled "GO" in the cited work). The test is comprised of a wheel disc rolling on a rail disc as shown in Fig. 6. Applied load P results in a line contact with a maximum (theoretical) Hertzian contact pressure, $p_0 = 1500$ [MPa], under the assumption of linear elasticity. Materials of the wheel and rail discs are Standard AAR class B and R260 steel, respectively. 500 dry (unlubricated) cycles were first applied to the specimen, followed by 31 054 cycles with graphite in mineral oil (GO) as lubricant. Coefficients of friction were measured to some $\mu = 0.42$ and $\mu = 0.04$ during dry and lubricated cycles, respectively. Application of the aforementioned load cycles led to an approximately 900 [µm] long crack depicted in Fig. 7.

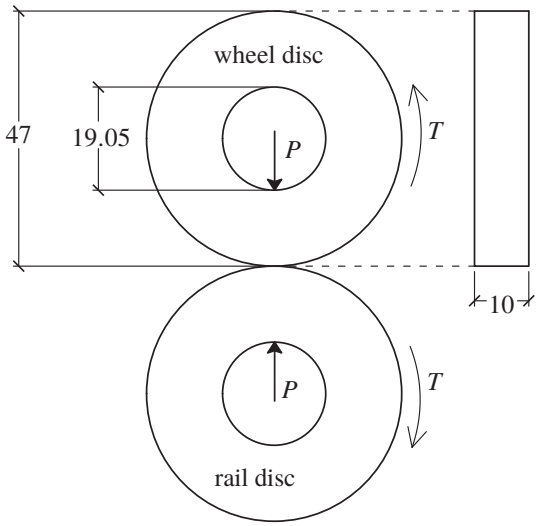

Figure 6 *Effective setting of twin-disc experiment adopted from [4] (dimensions in* [mm]*).*

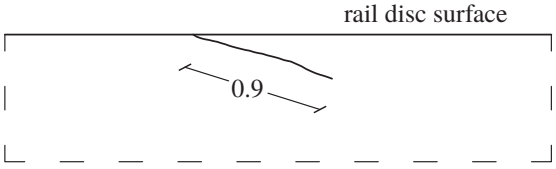

Figure 7 *Final crack in twin-disc experiment adopted from [4] (crack length in* [mm]*).*

3.2. Finite element model of experiment

Linear elastic plane strain simulations of the fatigue crack growth experiment described in Section 3.1 are performed at four instances of the crack growth. The crack length at the studied instances is achieved by constraining nodes of the inactive part of the crack as detailed in Section 2. A small (compared to the full disc) two-dimensional part of the rail disc is modelled with dimensions, $h = 10$ [mm] and $b = 20$ [mm]. The latter figures may be compared to the half-size of the contact patch under Hertzian contact conditions, which is $a \approx 0.3$ [mm]. The model is fixed in x-direction at the left and right boundaries and clamped at the bottom boundary, see Fig. 8. A linear elastic material response is assumed for the rail disc with Young's modulus and Poisson's ratio set to, $E = 209.82$ GPa and $\nu = 0.3$, respectively (the values of linear elastic parameters pertain to R260 steel).

The pressure distribution for elastic wheel and rail discs is determined from Hertzian solution as

$$\begin{cases} p_n(x) &= \frac{2P}{\pi a^2}(a^2 - (x-\bar{x})^2)^{1/2}, \; -a \leq x - \bar{x} \leq a, \\ p_t(x) &= \mu p_n(x), \end{cases} \tag{26}$$

where $P \approx 716$ [kN/m] is line-loading from the wheel disc. In addition, the coefficient of friction is set to $\mu = 0.04$, which is the value found in the experiment during the lubricated cycles. Coulomb friction and full-slip conditions are assumed for tangential contact between the discs. Contact stresses

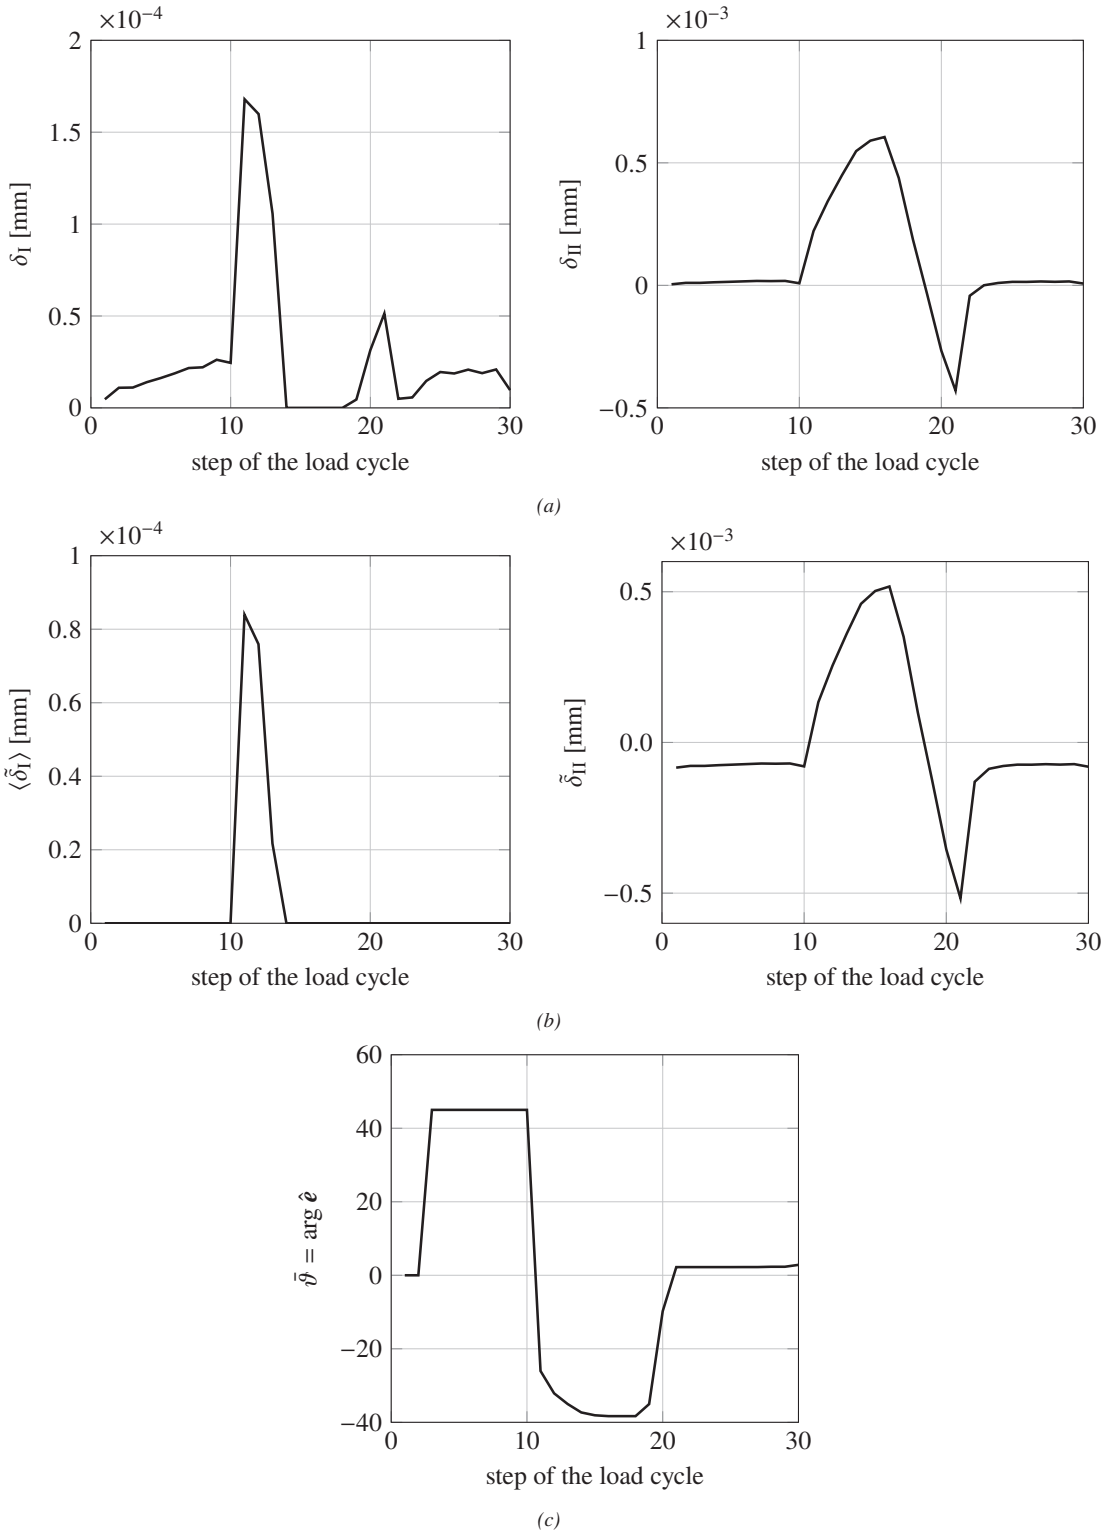

Figure 5 *Illustration of framework for evaluation of fatigue crack growth direction using the VCTD criterion (see Box 4). (a) Step 1: Compute $\delta_{\mathrm{I}}(t)$ and $\delta_{\mathrm{II}}(t)$. (b) Step 2: Compute $\langle\tilde{\delta}_{\mathrm{I}}(t)\rangle$ and $\tilde{\delta}_{\mathrm{II}}(t)$. (c) Step 3: Step-by-step computation of predicted crack growth direction, $\bar{\vartheta}$.*

from the wheel to rail disc are mapped as traction boundary conditions at the top boundary of the rail disc model. Normal contact between the crack faces is handled by a penalty contact formulation, which allows for finite sliding between the crack faces, and a node-to-surface contact discretization. The penalty parameter is set to $\tilde{K} = kh_{\mathrm{c}}/E \approx 0.2$, where $k = 1 \times 10^{15}$ [N/m^2/m] is the spring stiffness of contact elements and $h_{\mathrm{c}} \approx 4.5 \times 10^{-5}$ [m] is the characteristic size of the FE-mesh at the crack region. Friction-less contact is assumed between the crack faces, which can be viewed as an effect of lubrication that may have entered the crack.

FE-discretization of the model using linear triangular

elements is illustrated in Fig. 9. The FE-mesh is refined within a thin layer close to the top boundary and in the near-crack region, where large stress and strain gradients are present.

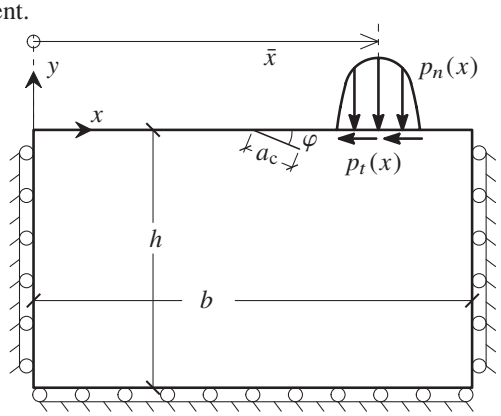

Figure 8 *Physical model of twin-disc fatigue crack growth experiment.*

At each of the four fatigue life instances, 1 wheel load passage was considered. The wheel load passage is comprised of 30 placements of wheel load, $(p_n(x), p_t(x))$ (see Eq. (26)), along the top boundary of the rail disc model. Most of the wheel load placements were near the crack region where the crack driving forces from the criteria obtain their maximum values. Predictions from the criteria are compared to experimentally found crack growth directions in Fig. 10. The crack path essentially coincides with predicted directions of the MSS criterion, which indicates that the crack is growing predominantly in shear- (co-planar) mode. Predictions from the VCTD criterion are also in close agreement with the experimental crack path throughout the whole fatigue life. The evolution over the load cycle of the pertinent quantities involved in the evaluation of fatigue crack growth direction based on the VCTD criterion is illustrated in Fig. 5 for the last evaluated fatigue life instance. In addition, the configurational force criterion captures crack path directions from the experiment well at the first two fatigue life instances. As expected, the MTS and MSE criteria cannot capture the stable shear-mode growth, since these criteria in principle postulate tensile-mode crack growth.

4. Conclusions and outlook

A framework has been developed for prediction of fatigue crack growth direction and comparison towards experiments. According to this framework, FE-simulations of fatigue crack growth experiments are performed at different instances of the fatigue life of the crack. The pertinent crack length is numerically realized by enforcement of crack-face constraints at the dormant part of the crack at the studied fatigue life instance. Fatigue crack growth direction criteria are evaluated based on the outcome of the FE-simulations. More specifically, the criteria are evaluated following the proposed framework outlined in Boxes 2, 3 and 4.

The proposed framework for assessment of fatigue crack growth direction criteria has been employed to a twin-disc fatigue crack growth experiment [4]. A single surface crack was documented in the experiment. A two-dimensional plane strain FE-model of the rail disc was developed. Pressure and traction from the wheel disc were applied as prescribed contact stresses on the rail disc. Friction-less contact was assumed between the crack faces.

The experiment was simulated at four instances of the fatigue life of the crack assuming a linear elastic material response for the rail disc. Numerical results show that MSS and VCTD criteria are able to capture the direction of growth throughout the whole fatigue life of the crack, see Fig. 10. In addition, predictions from the CF criterion were very close to the direction of the experimentally found crack path at the first two simulated fatigue life instances, after which the predictions deviated. Furthermore, it was shown that the shear-driven crack path found in the experiment could not be captured by the MTS and MSE criteria.

As a future work, it is fruitful to examine predictions from the criteria in cases where the mode of crack propagation shifts from stable shear- to tensile-mode growth [19]. Such a mode transition is common in rolling contact fatigue crack growth of rails, when rail bending becomes the dominant load. In addition, investigation of the effect of crack-face friction on predictions from the criteria is considered of high importance for the prediction of crack growth direction in rolling contact fatigue of rails.

Acknlowdgements

The current study is part of the on-going activities in CHARMEC – Chalmers Railway Mechanics (www.chalmers.se/charmec). Parts of the studies have been funded within the European Union's Horizon 2020 research and innovation program in the project In2Track under grant agreement No 730841.

The computations were performed on resources at Chalmers Centre for Computational Science and Engineering (C3SE) provided by the Swedish National Infrastructure for Computing (SNIC).

LOCOMOTIVE WHEEL TREAD POLYGONISATION CAUSED BY TORSIONAL AXLE SHAFT VIBRATION

Robert Fröhling [1], Ulrich Spangenberg [1], Eduard Reitmann [1,*]

[1] Transnet Freight Rail, Pretoria, South Africa

[*] E-mail: Eduard.Reitmann@Transnet.net

Abstract: Periodic out-of-round or polygonised wheels were detected on a fleet of high adhesion locomotives operating within South Africa. The polygonised wheels increased the vertical load spectrum of the locomotive resulting in accelerated component failures. During the initial investigation it was found that torsional axle vibration could lead to the polygonisation of the wheels. The torsional vibration of the locomotive axle was confirmed theoretically and experimentally through various physics models and on-track measurements. Based on the results, two potential torsional vibration excitation mechanisms were identified. A link was also established between the torsional vibration frequency, vehicle operating speed and the polygonisation order.

Keywords: Polygonisation; out-of-round; periodic wear; torsional vibration; self-excited vibration; forced vibration; harmonics; interharmonics.

1. Introduction

Periodic out-of-round or polygonised railway wheels can be generated by various traction-, suspension-, material- and/or track-related phenomena. Polygonised wheels increase the vertical load spectrum on the suspension and structural components of the locomotive. This results in accelerated and premature failure of components such as primary coil springs, gear cases and traction motors. Removing or minimising the source of the polygonisation is thus essential to reduce the maintenance cost and increase the operational availability of the affected rolling stock.

Many instances of polygonised railway wheels have been reported around the world. Tao et al. [1] measured the level of polygonal wheel wear on seven locomotive classes operating in China. Nielsen & Johansson [2] investigated various periodic non-roundness cases from Germany. Similarly, polygonised wheels have been observed and measured on a locomotive fleet operating in South Africa. These locomotives are driven by alternating current (AC) traction motors configured in a group-drive/bogie-control traction scheme.

The polygonisation on the locomotive fleet was initially confirmed through a series of manual measurements, as shown in Figure 1. The polygonisation order refers to the number of wave peaks or polygonal faces around the circumference of the wheel. Currently the data from an existing track mounted Weigh-in-Motion & Wheel-Impact-Monitoring (WIM-WIM) measurement system is used to quantify and monitor the amplitude and order of the polygonisation on each passing wheel [3].

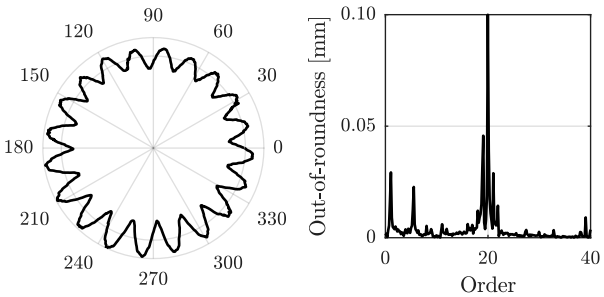

***Figure 1**. Radial measurement and order spectrum of a wheel with 20th order polygonisation.*

Nielsen & Johansson [2] reviewed several possible sources, concluding that polygonisation could be caused by either the wheel fixation during re-profiling, inhomogeneous material around the wheel circumference or by the natural vibration frequencies of the wheelset.

This paper explores the root cause of high-frequency periodic non-roundness or wheel polygonisation. It is suggested that polygonal wheel wear is caused by the resonance of torsional vibration of the locomotive axle when excited by either self-excited stick-slip or AC traction motor harmonics and interharmonics.

2. Background

The WIM-WIM polygonisation monitoring system was used to generate an overview of all the locomotives operating on a specific line, including the polygonised locomotive fleet.

Figure 2 shows the cumulative out-of-roundness distribution between different locomotive fleets operating on a specific line in South Africa. More than 15 % of the wheels on Fleet A showed out-of-roundness values higher than 0.2 mm whereas only a fraction of the wheels on the other locomotive fleets showed any polygonisation above 0.2 mm.

Figure 3 shows higher out-of-roundness amplitudes on the non-gear than on the gear side of the polygonised locomotive fleet.

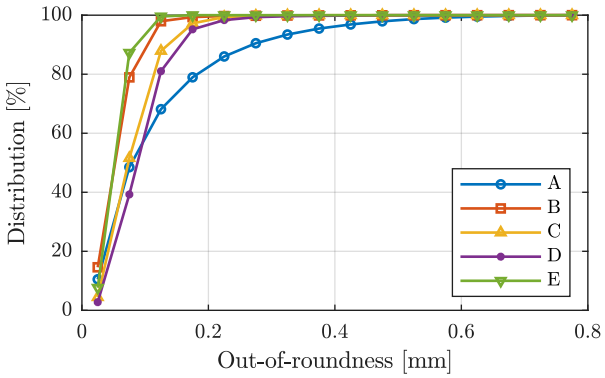

***Figure 2**. Cumulative out-of-roundness distribution between different locomotive fleets.*

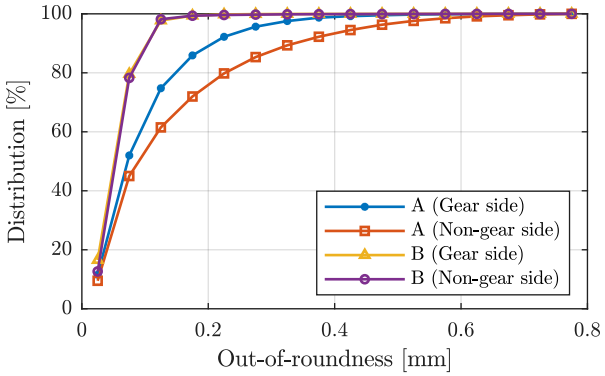

***Figure 3**. Comparison of the cumulative out-of-roundness distribution between two locomotive types (gear side vs. non-gear side wheels).*

An explanation for this asymmetric wear is that the nodal point of the first order torsional axle mode is not in the centre of the axle, thus causing an asymmetrical torsional response. The wheel with the larger angular displacement during the torsional vibration (non-gear side) is therefore expected to accumulate more periodic wear, i.e. more polygonisation.

Figure 4 shows the polygonal damage estimation based on the damage mechanisms explored in Section 6. The polygonal damage probability was estimated from the specific tractive effort, speed and curving combinations prescribed by the train handling profile. The dashed line represents the operating speed distribution on the line. The dotted line represents the polygonisation distribution of all locomotive wheels. This distribution was calculated from the WIM-WIM polygonisation monitoring system.

The following observations are made from this polygonal damage estimation:

1. The damage estimation distribution is different to the operating speed distribution. Thus, polygonal damage only occurs at specific operating conditions or locations on the line.
2. The damage estimation distribution is similar to the WIM-WIM polygonisation monitoring distribution.
3. The dominating polygonal frequency/order is governed by the operating speed.

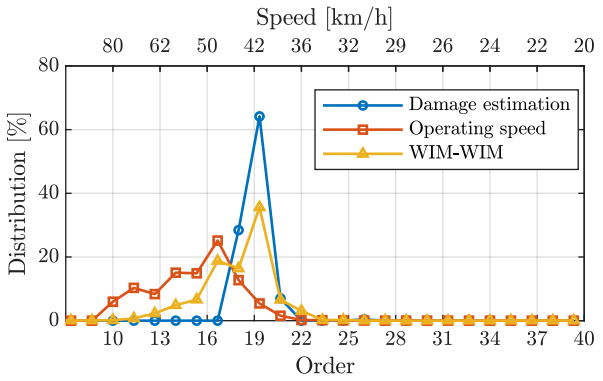

***Figure 4**. Polygonal damage estimation based on train handling.*

3. Adhesion characteristics

Creep curves are used to define the available adhesion between the wheel and the rail. The shape of the creep curve for small creep values (micro slip) is well defined and is readily calculated by contact models. The characteristic negative gradient of the friction coefficient at relatively large creep values is described by Polach [4]. Figure 5 shows typical creep curves for different rail surface conditions.

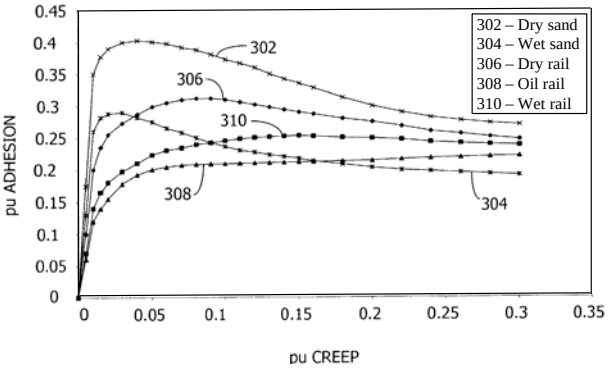

***Figure 5**. Adhesion characteristics under different rail surface conditions [5].*

The damping in the contact patch is dependent on the amount of creep. Damping changes from high positive damping for very small creep values to zero damping at saturated adhesion and negative damping beyond saturated adhesion.

4. On-track tests

A multi-body dynamics model of the locomotive was built in VI-Rail. The model predicted that a coupled mode of traction motor pitching and wheelset torsion was present at 60.4 Hz. On-track vehicle dynamic tests were thus performed to determine whether this coupled mode of vibration was excited while operating the locomotive under high adhesion demand conditions. Brand new wheels were fitted to the test locomotive to eliminate the effect of polygonised wheels on the measured results.

Many parameters were recorded during these tests. The responses considered in this paper include the vertical acceleration of the motor nose suspension, axle torsional strain, axle rotational speed and vehicle speed. A schematic of the test setup is shown in Figure 6.

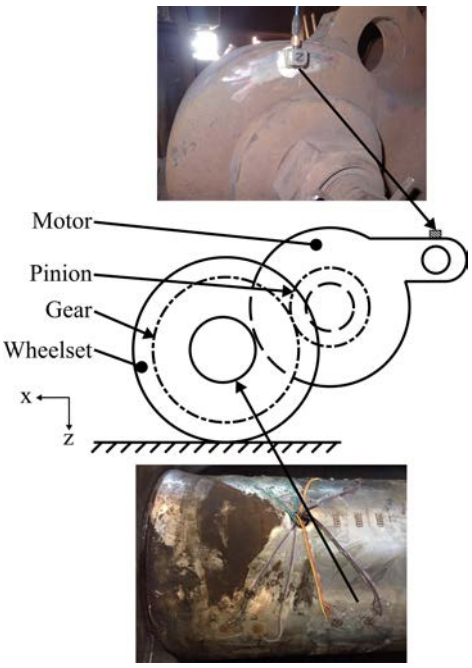

***Figure 6**. Test setup showing the location of the instrumentation.*

5. Tractive effort and adhesion capability

Figure 7 shows measured torsional vibration amplitudes at different speed/tractive effort combinations.

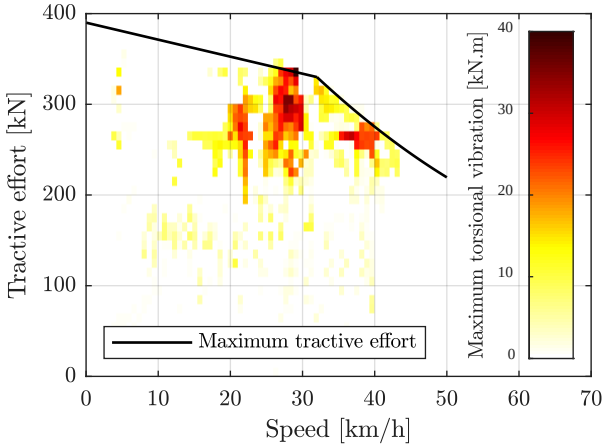

***Figure 7**. Torsional vibration under slipping conditions.*

High amplitude torsional vibration was measured for conditions well below the maximum tractive effort curve. Thus, although the intended maximum tractive effort could be achieved, there is a high probability of torsional vibration at high adhesion demands. Figure 8 illustrates possible speed/tractive effort conditions that may result in torsional vibration.

The excitation of torsional vibration below the maximum tractive effort curve may be explained by a combination of contact damping, applied tractive effort, adhesion demand and the inability of the bogie to equally distribute the adhesion between all the wheels of the locomotive. The combination of these factors will be referred to as the 'adhesion deficiency'.

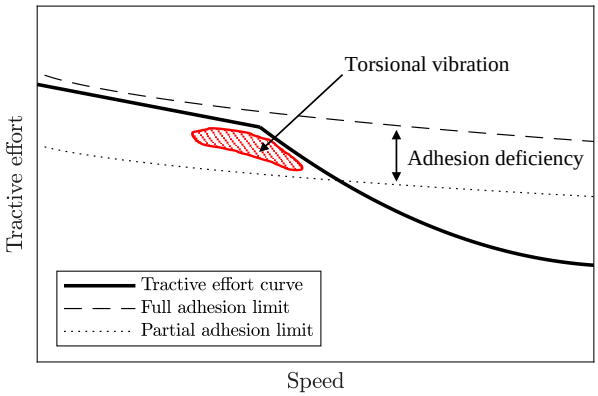

***Figure 8**. Adhesion deficiency.*

In a perfect world, all the wheels of a locomotive will operate at the same adhesion demand with zero adhesion deficiency, but in reality each wheel will have a different adhesion demand depending on the local creep-adhesion characteristics and wheel-rail steering forces.

Many factors may influence the adhesion deficiency, including:

1. Wheel-rail steering forces in curves
2. Bogie misalignment (skew bogies)
3. Wheel diameter differences
4. Asymmetric weight distribution
5. Rail surface contamination

6. Torsional vibration excitation mechanisms

Two excitation mechanisms are explored in this paper to determine their potential contribution to the excitation of torsional vibration and the development of polygonised wheels. The first mechanism is self-excited stick-slip vibration under saturated adhesion. The second mechanism is forced excitation by harmonics and interharmonics of AC traction motors.

6.1. Self-excited stick-slip vibration

Self-excited torsional stick-slip vibration has been identified and characterised by numerous researchers, including Müller & Kögel [6], Liu et al. [7] and Yuan et al. [8]. Self-excitation is caused by negative damping in the wheel-rail contact patch during saturated slip conditions.

The probability of saturated slipping conditions has increased significantly since the introduction of high adhesion locomotives driven by AC traction motors. Hirotsu et al. [9] highlighted that an AC traction motor has an inherent constant speed characteristic that rapidly decreases traction motor torque as soon as saturated slipping occurs. This characteristic will result in a steady-state constant slip condition past the saturated adhesion. This is ideal for the self-excited vibration of the drive system.

The excitation of the torsional resonance mode is particularly pronounced when there is a difference between the left and right wheel adhesion conditions [6]. This difference can either be as a result of different creep-adhesion properties in the wheel-rail contact patches or a difference in applied tractive forces. In other words, torsional vibration is more pronounced when the traction system is unable to optimally distribute the adhesion between the wheels of the locomotive, especially under high tractive conditions.

6.1.1. Simplified bogie simulation

A simplified mass-spring-damper physics model of the locomotive bogie was used to determine whether self-excited torsional stick-slip vibration could be initiated theoretically. The effect of different adhesion conditions between the left and right wheels was also studied.

Figure 9 shows the simulated adhesion results where only the right wheel exceeded saturated adhesion. Different creep characteristic curves were used between the left and right wheels. The creep characteristic curves were generated by substituting hypothetical adhesion (μ_0) and Kalker coefficients (k_A and k_S) into the creep theory described by Polach [4]. The dynamic component of the axle torsion was then plotted as a deviation from the hypothetical creep characteristic curve.

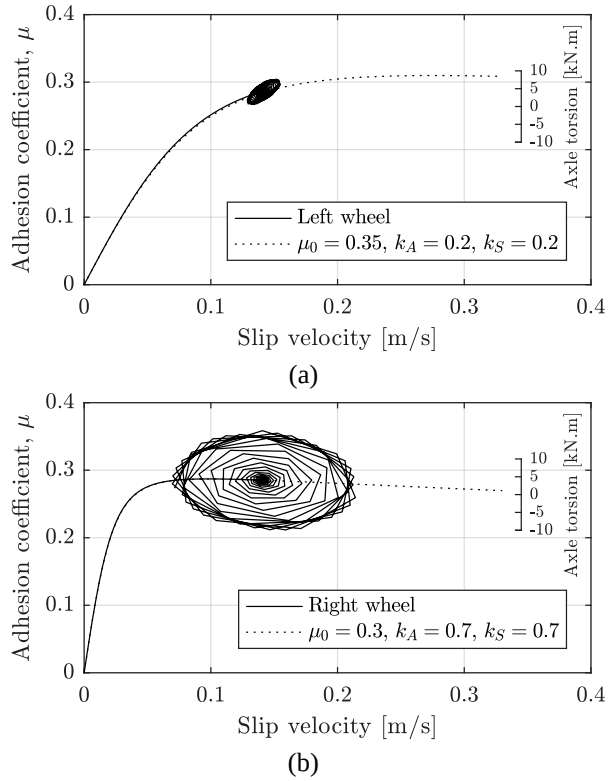

***Figure 9**. Simulation of torsional vibration under slipping conditions: (a) Left wheel. (b) Right wheel.*

For this simulation, the traction demand was gradually raised until the right hand wheel exceeded the maximum available adhesion. This caused the right hand wheel to, firstly, lose some of adhesion capability (the lost adhesion was then replenished by the left hand wheel that still had additional adhesion capability) and, secondly, to move into a negatively damped adhesion condition (negative slope). The negative damping then resulted in the self-excitation of the first torsional mode of the axle. Thus, from a theoretical point of view, the bogie configuration is able to initiate self-excited torsional stick-slip vibration under saturated adhesion conditions.

6.1.2. Experimental results

Figure 10 shows the measurement of axle torsional vibration under saturated slipping conditions on a dry section of tangent track. The axle torsion is expressed as strain-based voltage measurements. The slip velocity was calculated as the difference between the linear axle velocity (derived from the low-pass filtered rotor angular velocity measurements) and a reference vehicle speed from the trailing vehicle in the test train. The slip velocity should therefore be interpreted as the filtered mean wheel slip velocity rather than the individual wheel slip velocities, as used in Figure 9. The right hand plot shows the measured dynamic axle torsion as a deviation from a hypothetical adhesion characteristic curve. Essentially, the calculated slip velocity was used to position the measured axle torsional values on a hypothetical adhesion characteristic curve. The same configuration was used in Figure 11 and Figure 12.

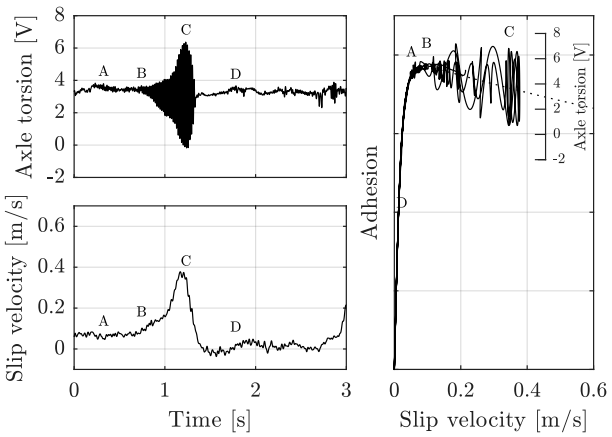

***Figure 10**. Discrete slip event on dry tangent track.*

As soon as the slip velocity increased beyond the point of maximum adhesion (Point B), the contact surface moved into a negative damping condition. This negative damping resulted in the self-excitation of the torsional mode. The amplitude of the torsional vibration increased up to the point where the anti-slip control of the control system identified the slip event (Point C). The controller then abruptly reduced the traction motor torque, reducing the slip velocity and consequently moving the contact surface to a stable, positively-damped condition (Point D). This positively damped condition then arrested the torsional oscillation.

Figure 11 shows the measurement of axle torsional vibration under saturated slipping conditions on a wet section of tangent track.

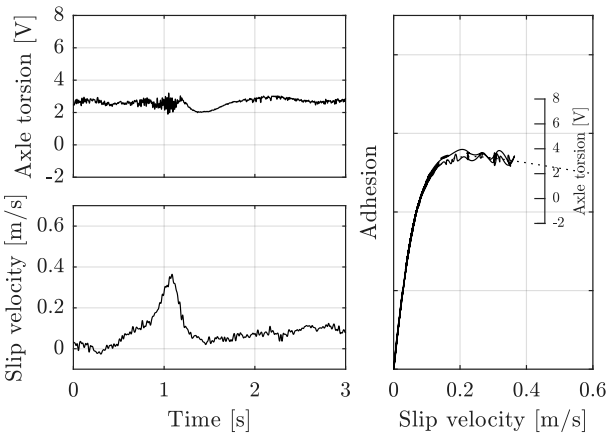

***Figure 11**. Discrete slip event on wet tangent track.*

From Figure 5, a wet rail is expected to have a smaller negative damping characteristic than a dry rail. Thus, as expected, a much lower amplitude of torsional vibration was observed on the wet rail than on the dry rail, even under similarly high slip velocities.

Figure 12 shows the measured torsional vibration of the axle under slipping conditions around a curve. Continuous slip/vibration was observed around a curve rather than the discrete slip/vibration events seen on tangent track (Figure 10 and Figure 11). This may be explained by the difference in steering forces between the wheels.

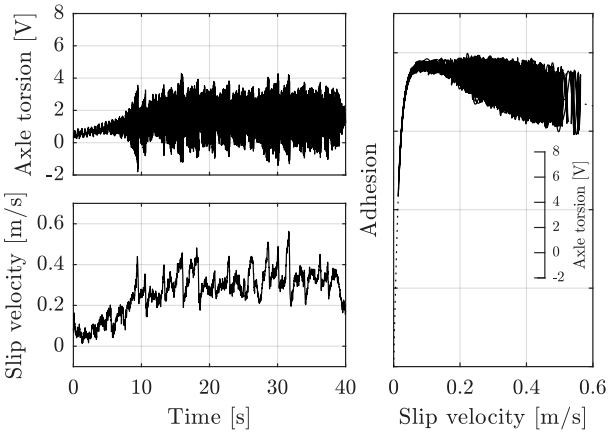

***Figure 12**. Continuous slip event around a curve.*

A difference between left and right steering forces will cause different slip velocities at the wheel-rail interface, even when the left and right rails have similar adhesion characteristics. This means that the one wheel can, under sufficiently high adhesion, exceed the maximum adhesion capability without the other wheel exceeding its own maximum adhesion capability. An unstable condition, similar to that shown in Figure 9 was obtained.

The fact that one wheel still has sufficient adhesion capability prevents the axle from accelerating up to a point where the anti-slip control is initiated (as with Point C in Figure 10). Even if the anti-slip control is initiated, it may not necessarily mean that the axle is returned to a completely stable, positively-damped condition (as with Point D in Figure 10) because of the different slip velocities. For example, if the anti-slip control lowers the mean slip velocity but only one of the wheels' slip velocity is lowered below saturated slip, the axle will still be in an unstable condition. This behaviour is demonstrated in Figure 12 where the anti-slip control was not able to return the axle to a stable condition because the slip velocity was not reduced sufficiently. This unstable condition then quickly allowed the torsional vibration to reappear.

Thus operating conditions that result in significant differences between the left and right adhesion conditions, such as curves, asymmetric weight distribution and skew bogies are more likely to produce periods of steady torsional vibration than conditions that have similar adhesion conditions, such as on tangent track. The majority of the periodic tread wear or polygonisation is therefore expected to accumulate under asymmetric adhesion conditions.

6.1.3. Speed-frequency response

Figure 13 shows a speed-frequency diagram of the axle torsion measured on a locomotive with new wheels under slipping conditions. The maximum values of all the test scenarios were reported at each speed increment. Only measured data with slip velocities higher than 0.5 km/h were considered for this analysis. Unfortunately, it was not possible to measure all speed/adhesion combinations during the on-track tests. However, a relatively good indication of the slipping behaviour at different speed combinations was still obtained.

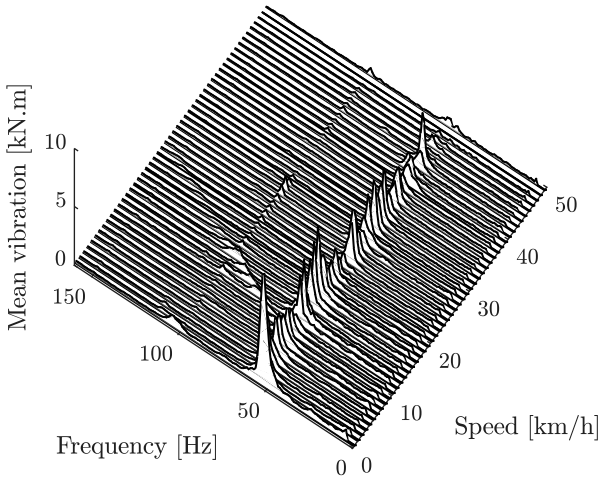

***Figure 13**. Speed-frequency diagram of locomotive with new wheels under slipping conditions.*

From Figure 13, the frequency of the coupled traction motor pitching and torsional mode was estimated at ±56 Hz. Torsional vibration was observed at almost all the testing speeds (up to 45 km/h) which implies that the self-excitation is speed-independent. Self-excitation can thus initiate torsional vibration at any speed if the wheel-rail interface is in a negatively damped slipping condition.

6.1.4. *Slip velocity influence*

Figure 14 shows the relationship between the wheel slip velocity and the torsional vibration amplitude during a dry rail, high adhesion test run through a curve.

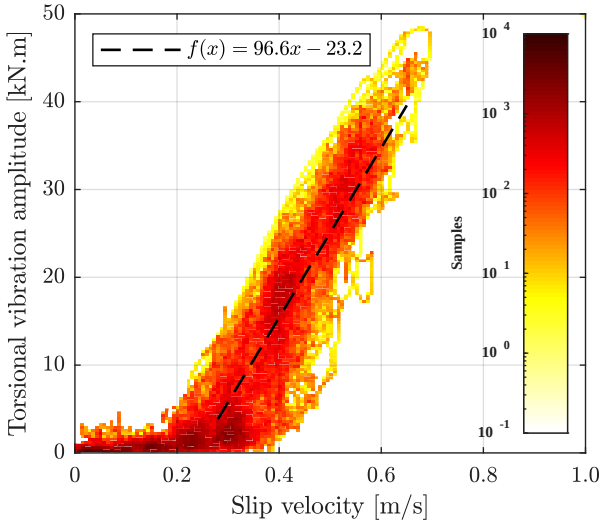

***Figure 14**. Vibration amplitude vs. slip velocity for locomotive with new wheels.*

The torsional vibration amplitude increased linearly above a slip velocity threshold of ±0.25 m/s. This threshold value most likely coincides with the maximum point of adhesion illustrated in Figure 5. As soon as this threshold is exceeded, the wheel-rail contact patch will move into a negatively damped condition that self-excites the torsional mode. Different relationships between slip velocity and torsional vibration amplitudes are expected for different adhesion conditions and/or creep curves.

6.1.5. *Wave-fixing*

The fixing of the polygonisation order can be attributed to the prescribed train handling profiles. A particular locomotive will always negotiate a particular curve (demanding a specific tractive effort) at approximately the same prescribed speed. This will cause the wear frequency (torsional natural frequency) to fix a particular out-of-roundness order onto the wheel. This fixed-wave periodic wear will accumulate as more distance is covered at the same operating speed and tractive effort combinations.

6.2. Torsional vibration caused by AC motors

The rotational speed of an AC motor is dependent on the frequency of the electrical power supplied to the motor. The rotational speed can therefore be controlled by means of a variable frequency drive (VFD). The VFD is normally not connected to a pure direct current (DC) power source but rather follows the process illustrated in Figure 15.

A single phase AC supply is drawn by the locomotive (under AC catenary) where after it is rectified and filtered to approximate a constant DC voltage supply. Alternatively, the DC voltage supply can be drawn directly from the overhead catenary.The DC supply voltage in most practical applications is not perfectly constant and may contain fluctuating artefacts from the rectification process. The DC supply is then inverted to a 3-phase AC output by the VFD. The VFD is able to control the frequency of the AC output and thus control the motor speed.

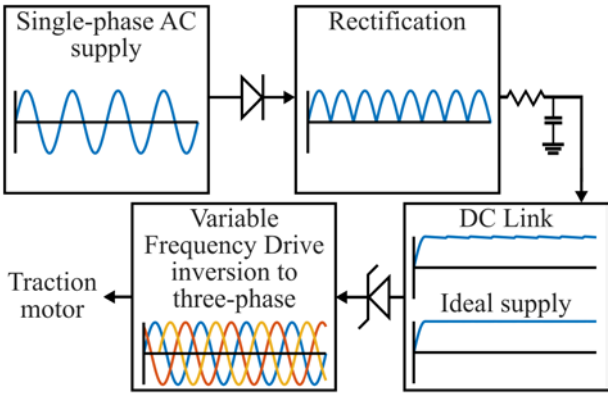

***Figure 15.** AC-DC-AC supply to traction motor.*

This conversion and inversion process causes harmonics and interharmonics in the output of the VFD, and consequently the input to the traction motor. Schramm et al. [10] showed that pulsating torque components are caused by the harmonics and interharmonics from a VFD. Harmonics and interharmonics are distortions in the current and voltage waveforms. VFD harmonics are integer multiples of the inverter operating frequency. Interharmonics are caused by the modulation between the switching function used to invert the DC supply to three-phase AC supply and the DC current ripple [11]. Interharmonics differ from harmonics in the sense that the frequencies of the interharmonics are not integer multiples of the fundamental frequency. Interharmonics are found between the fundamental harmonics of the VFD. The magnitudes of the VFD harmonics and interharmonics are determined by the type of drive and the switching algorithm of the inverter [12].

Excessive torsional vibrations excited by the harmonics and interharmonics from a VFD have led to catastrophic shaft and coupling failures [11, 13~18]. De la Roche and Howes [13] and Feese and Maxfield [15] showed that the torsional resonance was attenuated when operation of the AC motor was switched from VFD control to direct-on-line or across-the-line operation, thus bypassing the VFD. This switch to across-the-line operation caused the harmonics and interharmonics of the VFD to terminate and thus no longer excite torsional resonance. Holopainen et al. [17] mentioned that the modulations schemes of some VFDs produce distinct excitation frequencies, while others produce a spectrum which is a continuous function similar to white noise. The VFDs that produce a continuous spectrum may thus excite the torsional natural frequency at any operating speed, since the excitation spectrum of such a VFD is independent of the operating speed.

The VFD of the freight locomotive class under investigation may introduce varying degrees of these torsional excitation frequencies. High amplitude torsional rotations will occur during resonance and may lead to polygonal wheel wear.

Furthermore, wheel-rail contact damping is important under conditions of adhesion deficiency. Forced excitation by the traction motor may increase the response amplitude when the contact damping approaches zero. Negative contact damping may further increase the response amplitude when forced excitation is present.

6.2.1. Forced excitation by harmonics

The acceleration measurement on the traction motor nose suspension attachment indicated resonance around 56 Hz of the traction motor pitching mode, confirming that a coupled mode of traction motor pitching and wheelset torsion occurred (see Figure 16). Figure 16 includes harmonics that were calculated from motor rotor velocity measurements approximating the fundamental frequency of the VFD. The second harmonic of the VFD is predicted near the coupled vibration mode's natural frequency estimated at 56 Hz. This coupled mode resonates from around 95 s. Large amplitudes of vibration can be seen between 110 s to 128 s. Six gross wheel slipping events occurred.

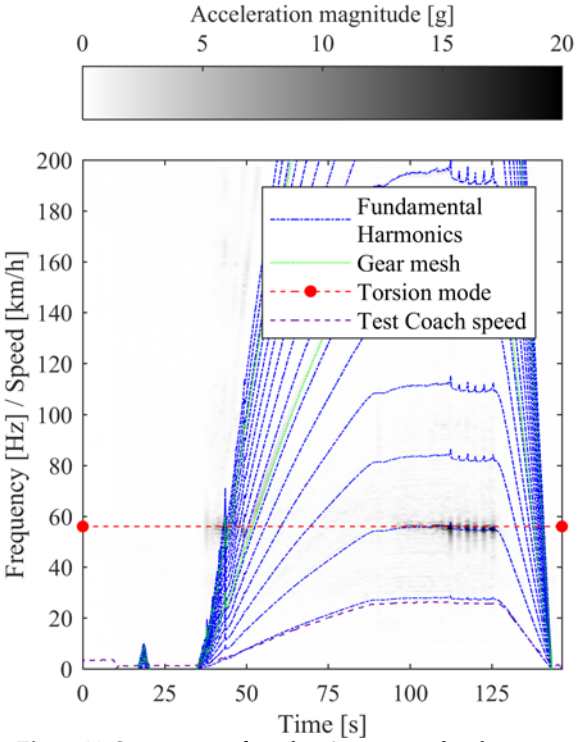

***Figure 16**. Spectrogram of acceleration measured at the motor nose suspension.*

This result was interpreted in conjunction with the creep curves of Figure 5. Forced excitation of the resonance of the coupled mode by the second VFD harmonic occurred when the locomotive was operating close to the adhesion limit before the first gross slipping event from 95 s to 112 s. It can be deduced that the wheelset operated close to the adhesion limit on the non-linear stable region of the creep curve, since gross wheel slippage did not occur during this time. As the contact damping approached zero relatively small amplitudes of vibration were observed. Once the adhesion limit was exceeded during the six slipping events the amplitude of torsional and motor pitching resonance intensified significantly. Forced excitation by the second harmonic was still occurring but due to the action of the negative damping in the unstable region of the creep curve, large vibration amplitudes were measured.

6.2.2. Forced excitation by interharmonics

The power supplied to the motor by the VFD is shown in Figure 17. Figure 17 and Figure 18 include harmonics that were calculated from motor rotor velocity measurements approximating the fundamental frequency of the VFD. Interharmonics are the well-defined lines occurring between the harmonics from 60 s to 100 s.

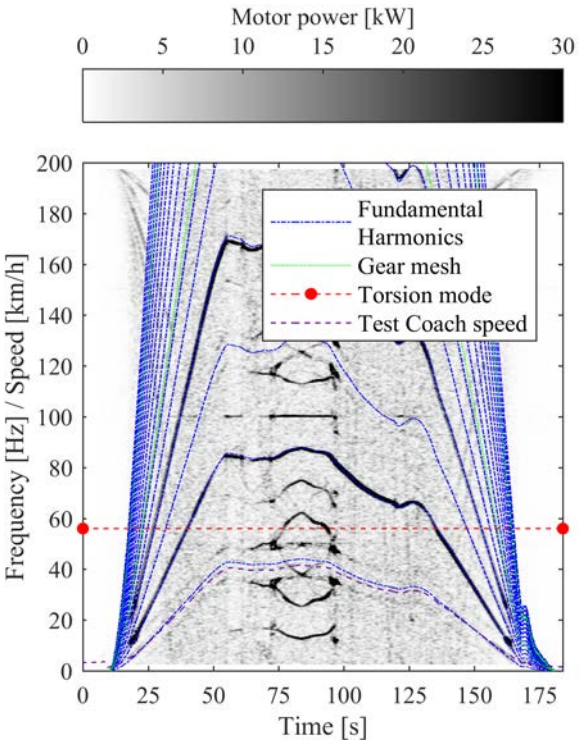

***Figure 17**. Measured motor power showing harmonics and interharmonics.*

The spectrogram in Figure 18 of the acceleration measured at the motor nose suspension attachment shows the resonance of the coupled mode between 72 s and 95 s. The frequency of the response of the coupled mode can be seen to follow the frequency of the interharmonic excitation with high amplitudes of vibration close to the torsional/coupled mode indicated by the red dashed line at 56 Hz. The test was conducted at a high tractive effort on tangent track. Note that although the wheelset was operating close to but not beyond the adhesion limit, no gross slipping of the wheel occurred in this instance. The interharmonic around 56 Hz is identifiable in Figure 17 and can be seen to excite the coupled mode between 72 s and 95 s

in Figure 18. Not all the interharmonics that were observed in Figure 17 are visible in Figure 18, confirming that resonance occurred due to excitation by this specific interharmonic.

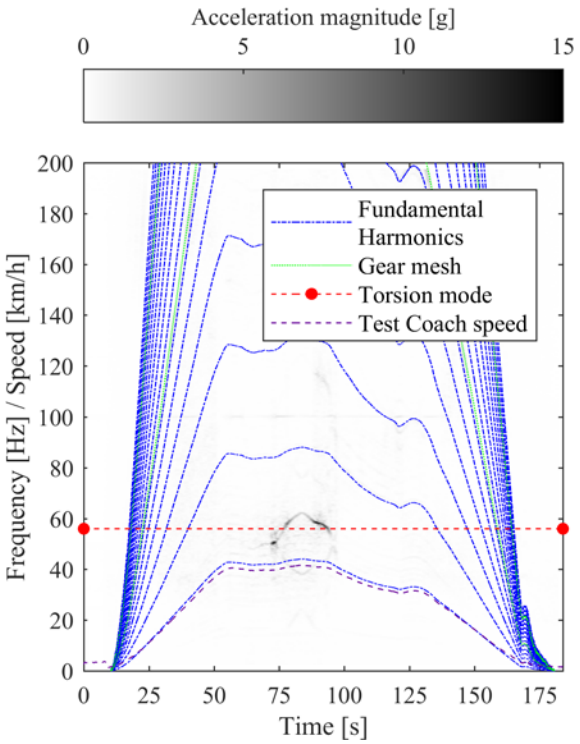

***Figure 18**. Spectrogram acceleration at motor nose suspension showing excitation of the torsional mode by interharmonics.*

The interharmonic that caused the forced excitation of the coupled mode occurred near the resonance frequency while the vehicle was travelling at approximately 40 km/h. The interharmonics are properties of the VFD and will thus always occur at the locations shown in Figure 17. It is thus expected that resonance of the coupled mode of vibration will occur each time that the vehicle travels at 40 km/h.

The amplitude of this vibration will be determined by the applied tractive effort and the damping from the creep curve. When the applied tractive effort is low, low response amplitudes are expected. In the same way high values of tractive effort will cause high response amplitudes. The amplitude of the response is also expected to be low when the creep results in high contact damping. The amplitude of the response will increase with an increase in the creep value due to the contact damping reducing. The amplitude of the response may increase severely once the limit of adhesion is exceeded and damping becomes negative.

6.2.3. Wave fixing

The WIM-WIM data of Figure 4 shows that the dominating polygonal or out-of-round order is the 20th order. The polygonal wheel order (N) can be shown to be a function of the nominal wheel radius (r_o), the frequency of vibration (f_n) and the vehicle speed (v_v) with $N = (2\pi r_o f_n)/v_v$. It can be shown that a speed of 38.6 km/h will result in a 20th order polygon when the nominal wheel radius is 0.61 m and the natural frequency of vibration is 56 Hz.

It was shown in Figure 18 that forced excitation by the interharmonic will occur while the vehicle is travelling at 40 km/h, which is close to 38.6 km/h. The amplitude of the response is determined by the applied traction and amount of contact damping. Thus, the wheel will wear into a 20th order polygon while the vehicle is travelling at 40 km/h and the interharmonic excites the coupled mode. The applied traction and amount of contact damping will determine the response amplitude and thus the rate of periodic wheel wear.

7. Polygonisation growth

Figure 19 shows a speed-frequency diagram of the vertical axle-box acceleration measured on a locomotive with polygonised wheels (without saturated slip).

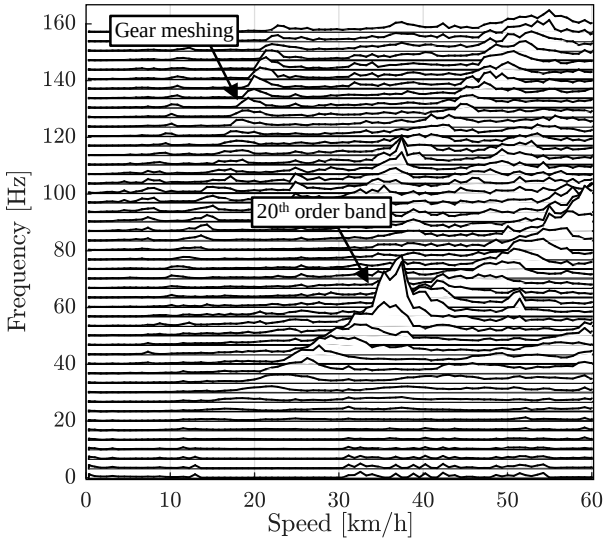

***Figure 19**. Speed-frequency diagram of locomotive with polygonised wheels.*

Once polygonisation is formed, a distinct speed-dependent frequency is introduced to the system. This speed-dependent frequency will excite the torsional mode without the need for slipping or forced excitation by the motor. The torsional oscillation from this excitation will then continue to increase the polygonisation amplitude.

Figure 20 shows how this wave-fixing → polygonisation growth → mechanical-excitation cycle results in an exponential growth of the polygonisation amplitude and, consequently, the vibration amplitude.

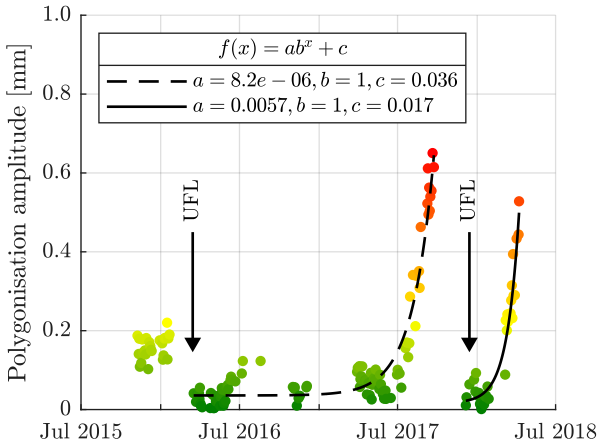

***Figure 20**. Polygonisation growth from the WIM-WIM polygonisation monitoring system.*

A clear reduction in polygonisation amplitude was observed after each underfloor lathe (UFL) wheel reprofiling action. After the first reprofiling, a 15-month period without excessive polygonisation growth was observed (March 2016 to June 2017) whereas only a 3-month period without excessive polygonisation growth was observed after the second reprofiling action. A possible reason for the accelerated growth after the second reprofiling action is that the polygonisation was not completely removed at the UFL which resulted in mechanically-forced excitation.

8. Conclusions

Using various physics models and on-track measurements, it was shown that wheel tread polygonisation can be accumulated through a coupled mode of traction motor pitching and torsional vibration of the locomotive axle.

Two torsional vibration excitation mechanisms were explored, namely self-excited stick-slip vibration under saturated adhesion and forced excitation by the harmonics and interharmonics from a VFD driven AC traction motor.

Two potential wave-fixing mechanisms were discussed and it was shown that an operating speed of around 40 km/h will result in a 20th order polygon for this particular locomotive type.

This study was focussed on the root cause of the polygonal wheel wear. Various mechanical and electrical countermeasures are proposed for further investigation and analysis. The mechanical countermeasures include a reduction in the adhesion deficiency, lowering of the maximum tractive effort, damping or moving the torsional natural frequency out of the operating range, modifying the train handling profiles, reduction of the stiffness of the motor nose suspension or frequent wheel reprofiling. The electrical countermeasures include a modification to the control system to detect and arrest the vibration, changing the switching algorithm of the VFD, changing the DC link to reduce DC link saturation and the use of destructive interference or noise cancelling technology as a source of additional torsional damping.

Abstract: A long-term iterative wear model is built to study the development of polygonal wear. Simulation parameter settings, including simulation steps, wheel profile updating strategy, number of harmonic Fourier series function, are analyzed to study the error of the wear model. A metro vehicle is presented as a case study, in which a vehicle speed that leads to a peculiar growth of wheel polygonization and poor ride comfort is identified by both simulation and on-track tests. With the help of polygonal wear simulation, the development of wheel polygonization is explained. Finally, some new strategies to investigate wheel polygonization are proposed.

Keywords: polygonal wear; metro; iterative long-term wear; polygonal order; polygonal depth; resonance

1. Introduction

Polygonal wheels are observed in a broad range of railway vehicles, including metro vehicles [1], high speed vehicles [2-3] and freight wagons [4]. Polygonization of railway wheel has significant effects on vibration of both vehicles and track components, especially in vertical direction, reducing the ride comfort, increasing noise and shortening life cycle of rail and vehicle. Although the dynamic impacts of polygonal wheels have been investigated widely [5-7], the studies on the growth mechanism of wheel polygonization yet are relatively rare.

Some studies [1,2,8] show the relationship between the bending resonance of wheelset and development of polygonal wheel from high speed vehicle and metro vehicle. Some researchers believe resonance of track components and train track dynamic interaction lead to the polygonal wheel [3,9]. A few other factors possibly leading to development of polygonal wear have also been studied, such as eccentric mass of wheel, inhomogeneous material, re-profiling tolerance etc. At the moment, systematic consensus has not been formed. It is generally believed that wheel polygonization comes from different factors in different cases, and thereby it is hard to propose effective and universal solutions to eliminate wheel polygonization in all cases.

However, in these analyses, a similar generic logic is to find a resonance frequency from track system or vehicle system that is equal to excitation frequency caused by polygonal wheel. Vehicle speed, an important and indispensable factor determining the excitation frequency produced by polygonal wheels is not considered in depth in many of previous studies, because of variation of vehicle speed in real operational service and it is hard to recognize the specific speed leading to wheel polygonization. This situation becomes more apparent for metro vehicles running on short-distance stations.

One of the primary barriers of investigating wheel polygonization is difficulty of simulating polygonal wear enlargement process. By achieving this, wheel polygonization could be analysed quantitatively and the development procedure could be clearly revealed. This paper mainly focuses on the simulation method for polygonal wear of railway wheels. One case study about a real metro vehicle is presented, in which a 'resonance speed' of the vehicle, i.e. a speed that leads to a peculiar growth of wheel polygonization and to poor ride comfort, is observed by means of both simulation and field on-track tests. New strategies for investigating the mechanism of polygonal wear are summarized based on the wear model and the metro vehicle case study.

2. Simulation method for polygonal wear of railway wheel

2.1. Assumptions and general scheme for polygonal wear model

The long-term iterative wear model presented in this paper is based on three assumptions. Firstly, the wheel and rail profiles are constant in a short time, so that in a single short-term calculation, variation of wheel and rail profiles is negligible. The second assumption named multiple time-scales means that a scaling coefficient is applied to the results of short-term dynamic simulation to simulate wear effects taking place over a longer time scale. The third assumption is about the dimension of wheel surface. The wheel profile is a 3-D surface, including transversal(y-axis) and circumferential (x-axis) direction. It is assumed that the wheel profile curve in transversal direction will not change and curves of wheel profile in circumferential direction are the same no matter where measured points on transversal profile are selected. In this paper, the averaged lateral position (almost the standard rolling circle of wheel) of contact patches on wheel tread is used to measure the conferential wheel profile.

The general idea of simulation method for polygonal wear in this paper can be summarized in figure 1. The iterative wear calculation is divided into four basic parts. At the beginning, a profile of an initial polygonal irregularity possibly derived from manufacturing process, inhomogeneous material or some other reasons is put into short term vehicle dynamic model. Then, the wheel-rail contact parameters including normal force, geometry of contact patch and creepage speeds are calculated in each

time step. These results will be used in wear model to obtain the wear depth in each contact patch. After that, the data of wear depth around the circumference is overlapped and accumulated. The wear depth curve needs to be processed by some special curve fitting methods to make it smooth and continuous from both ends of curve. Then, a new circumferential wheel profile is obtained and fed back into the short-term vehicle dynamic model again.

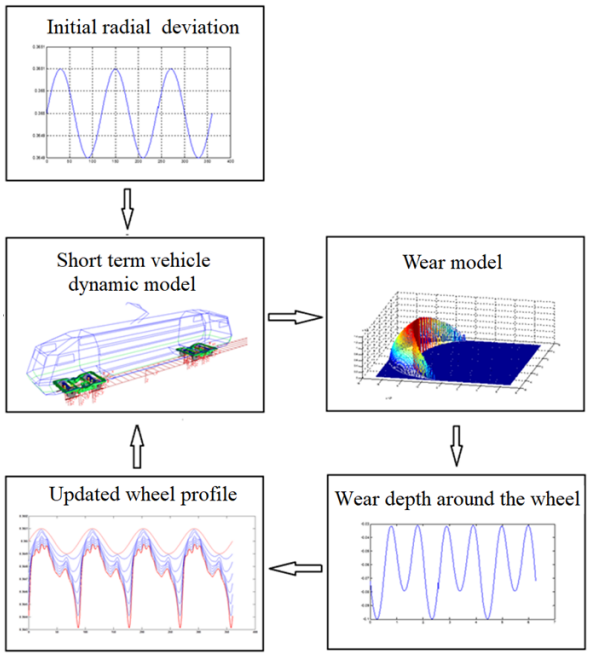

Figure 1 *Schematic simulation flowchart*

2.2. Wheel wear model

Several existing wheel wear models [10-12] have been introduced to study the wear of wheel tread in transversal direction, which has been a relatively mature research topic. These models include, among others, the Archard Model, the wear law based on frictional power. Since the wear mechanism taking place in the contact patch is identical for transversal and circumferential wear, it is reasonable to apply the same wear models to study polygonal wear.

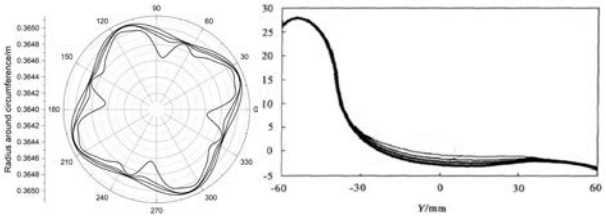
Archard model, as a classical material wear model has been generally used in railway engineering to calculate wear between wheel and rail. The primary mathematic expression is presented:

$$V_{wear} = k_w \frac{Nd}{H} \tag{1}$$

where V_{wear} is the volume of abraded material; N is the normal force applied on the surface; d is the sliding distance between two surfaces; H is the material hardness, and k_w is the wear coefficient.

Compared with Archard model, the wear model based on friction power between wheel and rail has be used more often in the few papers studying polygonal wear [2,8,13,14,15]. This model assumes that excavated mass is proportional to the wear power per unit area, see formula:

$$\Delta m = k(P_{RA}) \cdot W_R \tag{2}$$



where k (P_{RA}) is a friction coefficient, which is the function of wear power, varying according to wear intensity. The relationship between wear depth Δr and wear power inside contact patch is shown here.

$$\Delta r = \frac{\Delta m}{\rho A} = \frac{k(T_x v_x + T_y v_y + T_z v_z)\Delta t}{\rho A} \tag{3}$$

where, A is the area of contact patch, and Δt is integration step. T and v are creep force and creep speed respectively. This wear model is applied in this paper to simulate wear depth of each contact patch.

2.3. Smoothing of the wear depth curve

One challenging work in simulating polygonal wear is that the wheel circumferential curve is closed, different from the case in simulation of wheel tread wear. The comparison of the two issues can be seen from figure 2.

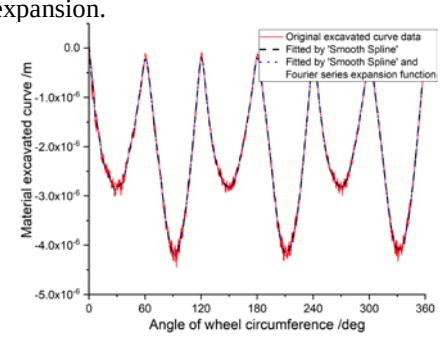
(a) *(b)*

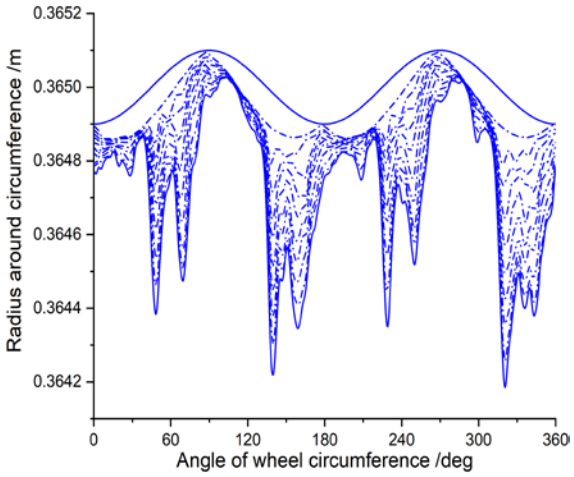
Figure 2 *Comparison between (a) closed curve lines in wheel polygonization wear and (b) unclosed lines in wheel tread wear*

Many tradition curve fitting methods like cubic interpolation and smoothing spline cannot fit a closed line and at the same time ensure that the fitted line is continuous and differentiable over the entire circumference. Simulation results show that even a small disturbance in curve zone connecting two ends will bring about great impacts and normal development features of polygonal wear could be covered. A fitting method based on Fourier Series (see equation 4) is introduced here to solve this problem. Trigonometric function itself can ensure fitted curves continuous and differentiable from 0 degree to 360 degrees. The linear combination of trigonometric function can approximate any shape of wear curves if harmonic number is large enough. The composition of polygonal curves in different orders can also be measured quantitatively by $d_i = \sqrt{a_i^2 + b_i^2}$.

$$\begin{aligned} y(x) &= a_0 + a_1\cos(x) + a_2\cos(2x) + \cdots + a_n\cos(nx) \\ &\quad + b_1\sin(x) + b_2\sin(2x) + \cdots + b_n\sin(nx) \\ &= a_0 + \sum_{i=1}^{n}(a_i\cos ix + b_i\sin ix) \end{aligned} \tag{4}$$

Before applying Fourier series expansion function to fit the wear curve, smoothing spline is used to filter the disturbance of original wear data. Figure 3 compares the original wear depth curves, the one filtered by the smoothing spline and the one resulting from Fourier series expansion.





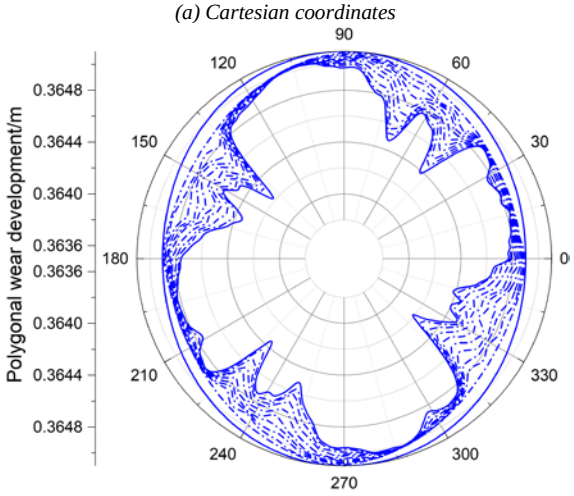


Figure 3 *Fitting effect for wear depth curves*

2.4. Example of simulation of polygonal wear

A dynamic model for a metro vehicle is built in SIMPACK, and FASTSIM is used to calculate wheel and rail contact. In simulation model, a sin function curve is applied as wheel profile in circumferential direction to simulate initial polygonal wheel. The number of wave crest is the order of wheel polygon, and the amplitude of sine wave is the depth of the polygon. An initial second order (ellipse shape) irregularity is applied on wheel profile. The development of polygonal wear of the vehicle running on a straight track at speed 80km/h is shown in Cartesian coordinates and polar coordinates in figure 4.

(a) Cartesian coordinates

(b) polar coordinate

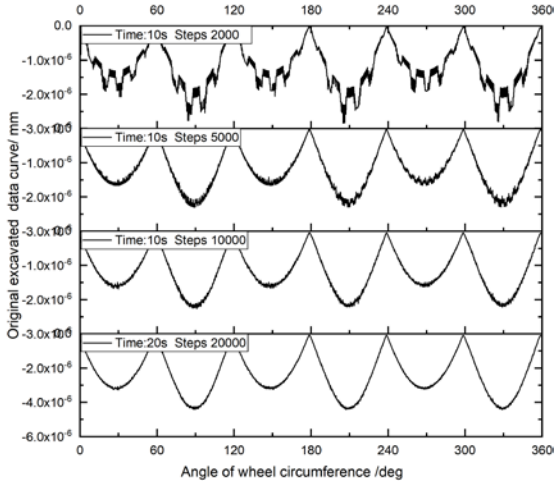
Figure 4 *Wear curves in (a)Cartesian coordinates and (b)polar coordinates*

From figure 4, it can be seen that with the development of wear, the depth of polygon becomes larger, and two new wave crests gradually appear from mid position of initial two crests. This typical evolution is also found when initial third and fourth order irregularities are applied. It is a conventional wear in a very slow speed. But when resonance of a certain component from vehicle or track system occurs, the wear will be intensive, and the features of this conventional slow wear will be covered.

3. Effect of simulation parameter setting and calculation error analysis

Even though the main simulation approach has been introduced in the section above, wear development shape could be sensitive to some parameter settings including simulation steps, curve fitting methods and wheel profile updating strategy.

3.1. Simulation steps



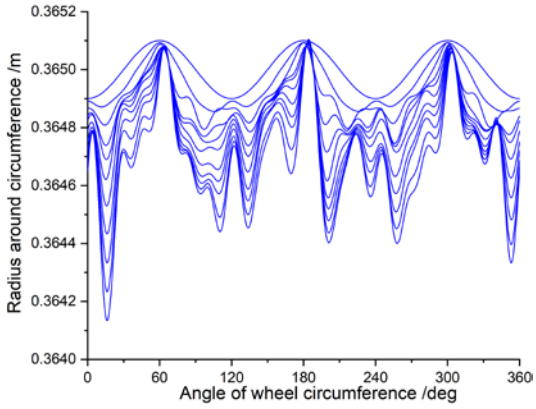


Figure 5 *Calculation of wear depth curve with different calculation steps*

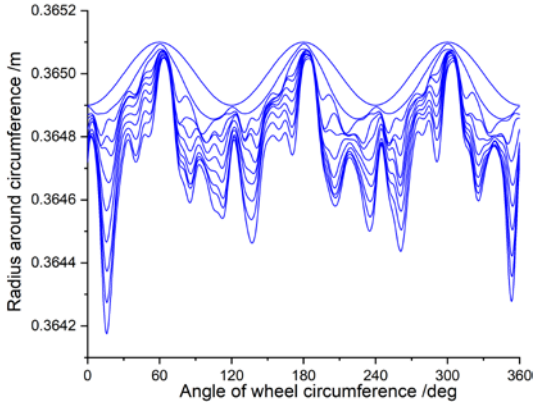
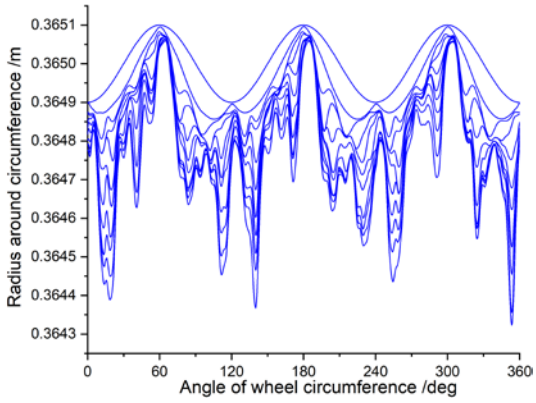
The length and number of simulation steps have effect on the simulation accuracy. If a long step length and a small number of step are set, the contact patches calculated around the wheel will not be fully overlapped, which brings about disturbance on material excavation curve. It could introduce error even when the smoothing spline is applied to filter the curves. The wear depth curves in a single short-term simulation with different simulation time and number of steps are shown in figure 5. It clearly shows that when the number of steps is beyond 10000, the curves are smooth. But it is hard to set a general standard for step number, because the disturbance could be larger if a more complicated wear curve appears in the following iterations. The number of simulation steps for following simulation is set in 20000.



3.2. Curve fitting methods

Another error of wear calculation comes from curve fitting methods. When an original wear depth curve is calculated from each contact patch, a smoothing spline is applied firstly to filter the disturbance of the curve and then Fourier expansion function is used to fit the curves. The parameter settings inside the two fitting methods have influence on the simulation of development of polygonal wear.



For the smoothing spline, it is not difficult to set a suitable ‘Smoothness’ to recognize real polygonal wear curve from disturbance when the number of calculation step is large and hormonic order of polygon is small. While in adverse cases, occurrence of error could not be completely avoided.

(a) n =20

(b) n =40

(c) n =100

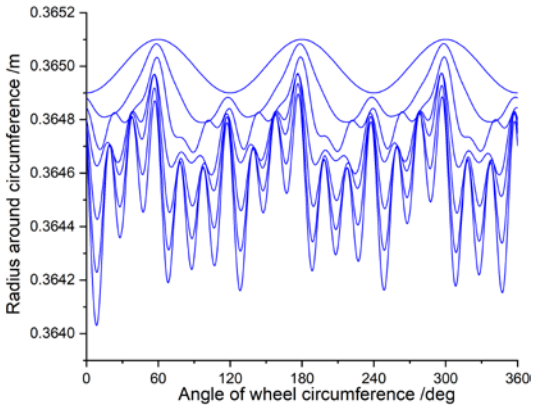


***Figure 6** Polygonal wear curves with different harmonic function number n; Simulation speed: 80km/h*

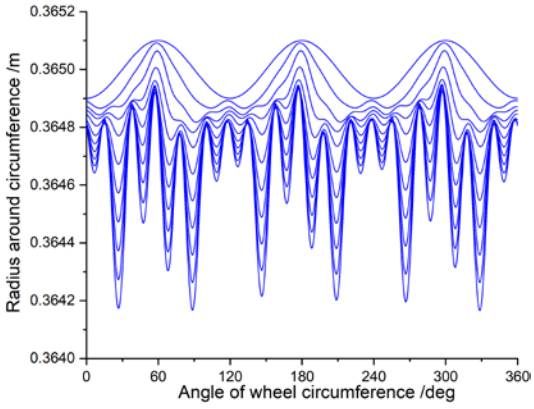
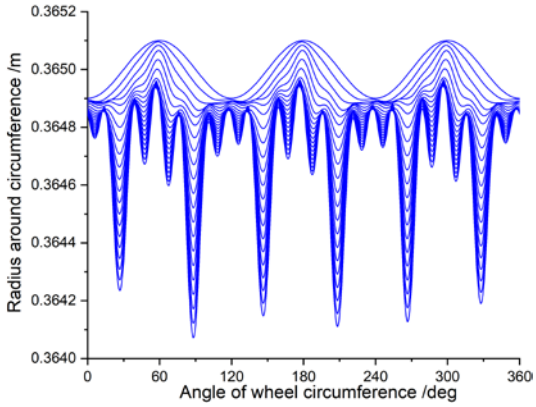
While for Fourier series expansion function, the number of harmonic function *n* (see formula 4) decides how much the curves can be approximated. Theoretically, *n* should be selected as much as possible to reduce the curve fitting error. However, the error introduced by 'Smooth spline' could also be recorded. When a relatively small *n* is used, some details of wear profiles, such as a negligible high frequency fluctuation, could be ignored. It could be reasonable if low order polygons are studied. Therefore, when small n is selected, Fourier series expansion function can be used as a second filter to remove error and to concentrate on the wanted range of orders. The figure 6 shows wear development curves when *n* is selected as 20, 40 and 100. It can be seen that the general development features are similar, but the wear profiles additionally show some short-wavelength fluctuations when n is equal to 100.



3.3. Wear profile updating condition

The condition for updating wheel profile is another important setting in long-term wear model. A constant depth ΔD is used to control the maximum distance between adjacent wear curves. When variation depth ΔD changes from 0.2mm to 0.05mm, polygonal wear of metro wheel with initial triangle irregularity at 40km/h is simulated, as is shown in figure 7.



Theoretically, the ΔD should be selected as small as possible. A simulation with too large variation depth ΔD is apparently far from real wear process, and will result in simulation error, as can be seen that the difference between figure 7 (a) and figure 7 (b), (c) is clear. However, too small variation depth ΔD means large number of iterations and more computing resource. When a large number of iterations are applied, a small error, for instance from curve fitting methods, could be gradually magnified. Therefore, too small ΔD should also be avoided. Despite the distinction between figure 7 (b) and (c) is still visible, the feature of polygonal wear development is quite similar. We consider when initial polygonal depth is 0.1mm, it is reasonable to use ΔD=0.1 and ΔD=0.05 as the wheel profile updating judgement.

(a) ΔD=0.2mm

(b) ΔD=0.1mm

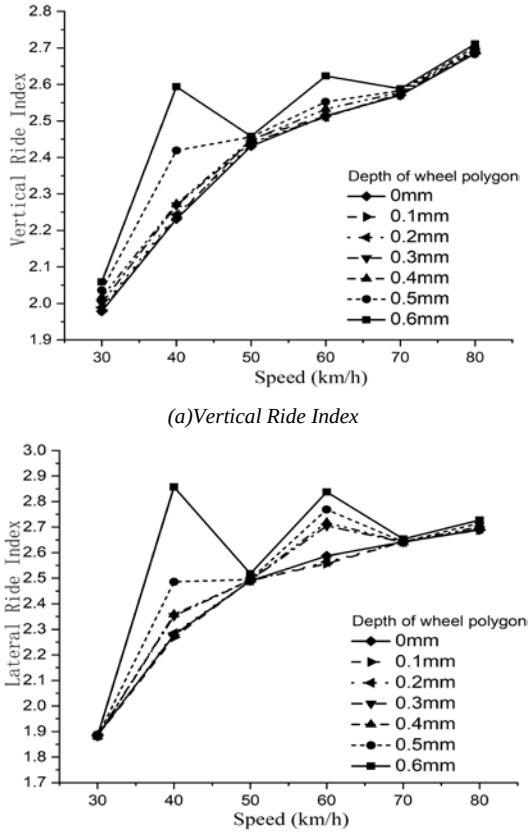
*(c) ΔD=0.05*mm

Figure 7 *Polygonal wear curves with different depth ΔD for profile update, simulation speed: 40km/h*

4. Case study: Polygonal wheel of a metro vehicle

4.1. Brief introduction for the metro vehicle

A metro vehicle with linear motor traction technology is found to have main eighth and ninth orders polygonal wheel problem when running several months after wheel re-profiling, directly leading to bad ride comfort. An uncommon feature of this bogie architecture is linear motor which is fixed by several rods with elastic rubber components connecting bogie frame in vertical, lateral and longitudinal directions. The wheels have an initial fourth order polygon after re-profiling. Simulation analysis and a long-term on-track test were carried out to explore this problem.

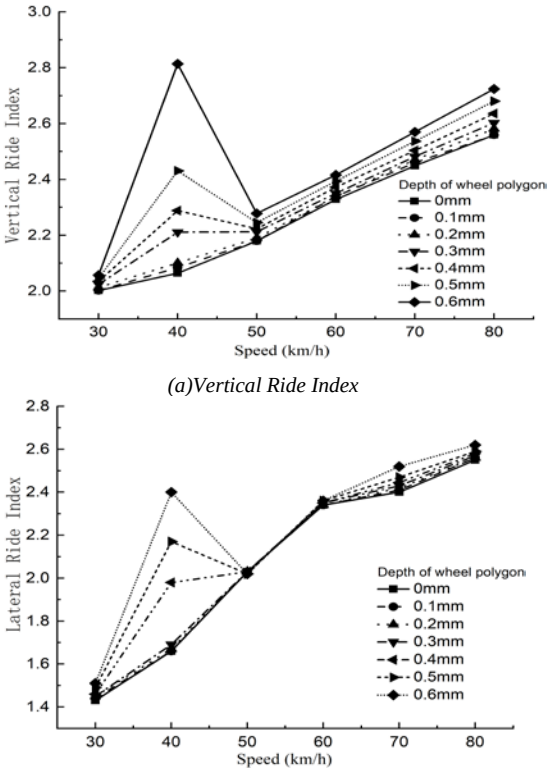


4.2. Dynamic performance of vehicle and resonance speed identification

For this metro vehicle, the frequency range of excitation caused by eighth and ninth order polygonal wheel in conventional running speeds (20-80km/h) is 22.7-87.2Hz. The natural frequencies of the most vehicle components are in range of 0-20Hz. The vibration modes of vehicle components whose natural frequency is within 20-90Hz are listed in table 1.

Table 1 Vibration modes and their natural frequency in 20-90Hz

Vibration modes	Natural frequency /Hz
Bogie frame yaw motion	32.5Hz
Bogie frame lateral motion	33.2Hz
Linear motor vertical motion	41.7Hz
Linear motor pitch motion	58.3 Hz
Linear motor rolling motion	78.5Hz



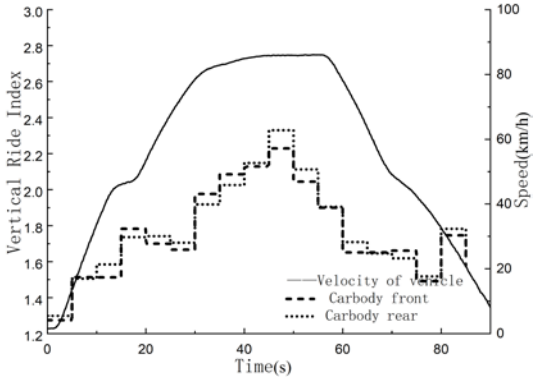
The Ride Index of the vehicle travelling at different speeds with eighth and ninth order polygonal wheels is calculated by numerical simulations, as is shown in figure 8 and figure 9.

(a)Vertical Ride Index

(b)Lateral Ride Index

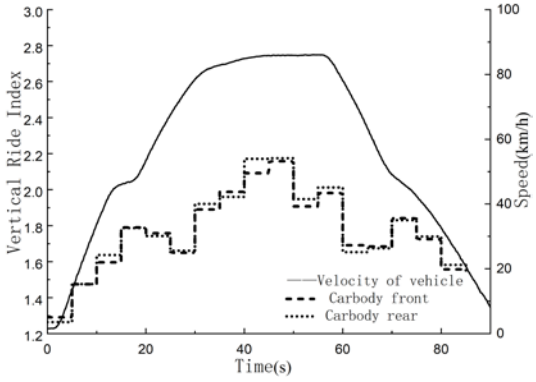
Figure 8 *Vertical and lateral Ride Index of vehicle with eighth order polygonal wheel at different speeds*

(a)Vertical Ride Index



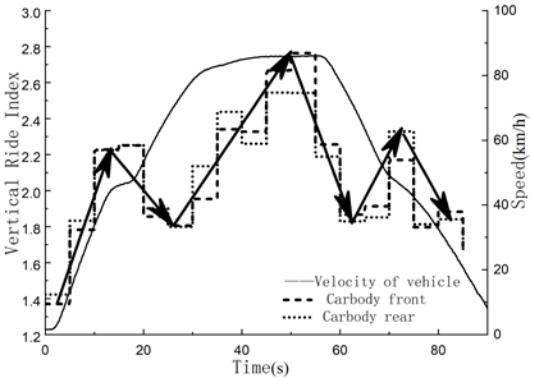
(b)Lateral Ride Index

Figure 9 *Vertical and lateral Ride Index of vehicle with ninth order polygonal wheel at different speeds*



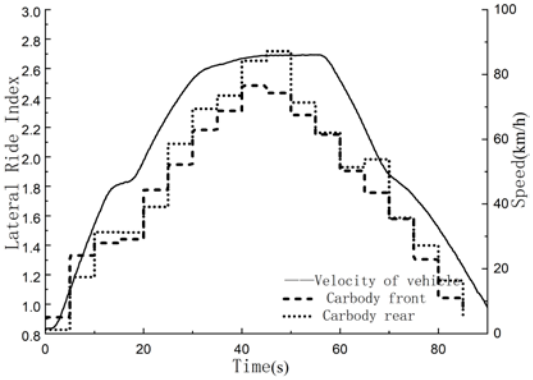
These figures show that Ride Index in both lateral and vertical direction has a peak value when the vehicle running speeds are close to 40km/h, and this peak point

becomes higher with increasement of polygon depth. This peculiar phenomenon raised attention and was analysed further. When the vehicle speed is 40km/h, eighth and ninth order polygonal wheel would produce 38.8Hz and 43.6Hz excitations which are near to the natural frequency of linear motor's vertical motion, 41.7Hz. Therefore, the motor resonance occurs, as a consequence, making both vertical and lateral Ride Index worse. The acceleration data from wheelset, bogie frame, linear motor and car body is verified to confirm the transmission of oscillation from wheelset to linear motor and to car body.

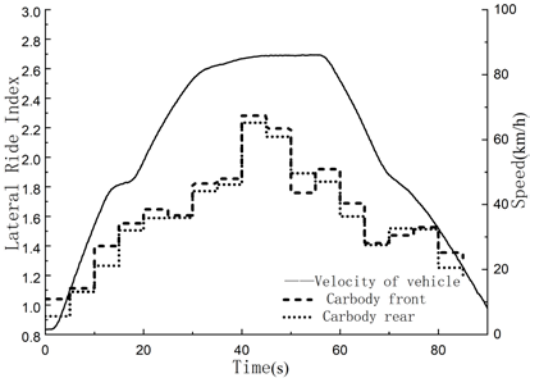


Besides, a long-term on-track tests were carried out in the first month, the second month and the sixth month after wheel re-profiling. The test is on main metro line including 20 metro stations. The tested vehicle is in tare condition and is operated in Auto Mode as it runs in conventional service. Because of this, the speed time history of the vehicle running between any two stations is very similar in three on-track tests at different time, and thereby the acceleration measured from car body and bogie frame among three tests can be compared. In this paper, test data on a typical track zone between two adjacent stations is chosen to present the dynamic characteristics of the vehicle. This track zone is straight, and the vehicle accelerates to 85km/h and then decelerates to zero within around 90 seconds. The vertical and lateral Ride Index is processed based on a set of acceleration time history data from car body per 5 seconds, which is shown in figure 10 and figure 11.

(a) 1 month after wheel re-profiling



(b) 2 months after wheel re-profiling



(c) 6 months after wheel re-profiling

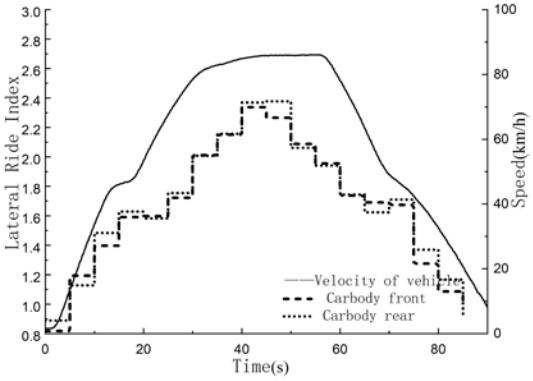


Figure 10 *Vertical Ride Index and speed time history curve measured between two metro stations*

(a) 1 month after wheel re-profiling

(b) 2 months after wheel re-profiling

(c) 6 months after wheel re-profiling

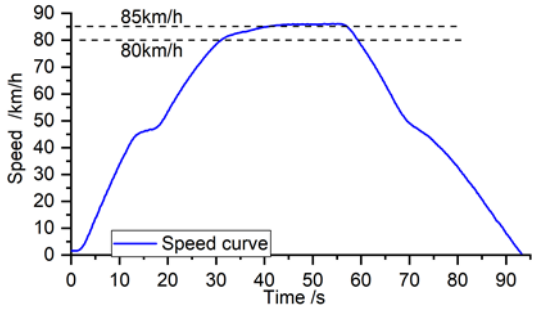
Figure 11 *Lateral Ride Index and speed time history curve measured between two metro stations*

From these figures, some points can be made as follows:

(a) When the vehicle travels at a speed of approximately

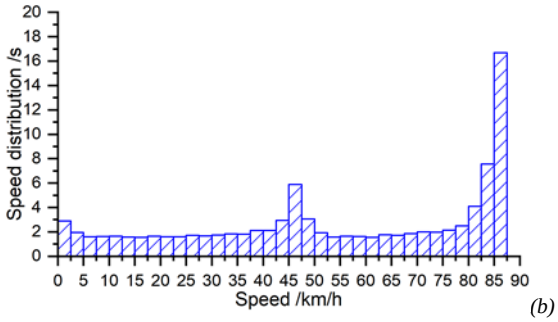
40km/h during the acceleration and deceleration transients，the vertical Ride Index becomes bad, and this characteristic become more obvious in later months with the progress of wheel polygonization.

(b) The general vertical Ride Index over the whole track zone is relatively good after re-profiling, but it will become increasingly worse from the first month to the sixth month after wheel re-profiling.



(c) The lateral Ride Index is relatively bad after wheel re-profiling especially when running speeds come to 80-85km/h. However, in the following months, the Ride Index becomes better.

The above three features are also observed on other test zones with similar track geometries and speed curve lines, while points (b) and (c) were noticed and claimed by the staff in the metro company even before the tests were carried out. As far as point (a) is concerned, it validates the simulation results in figure 8, confirming the specific issues with bad ride comfort at the speed of 40 km/h due to the resonance of the linear motor. Based on feature (b) and (c), it comes to a speculation that after wheel re-profiling, the development of polygonal wheel can be divided into different phases (at least two phases), in which running behaviour of the vehicle has different features. The reason for feature (b) and (c) will be discussed in next chapter 4.3.



4.3. Polygonal wear for the metro vehicle

After confirming the resonance phenomenon arose from worn eighth and ninth order wheel profile at around 40km/h. Another key speed 85km/h is easily to be found that will cause the similar resonance of linear motor when an initial fourth order wheel irregularity exists.

A typical speed time history data measured from on-track test in a straight zone is shown in figure 12 (a). Although the vehicle travels at non-constant speed, the distribution analysis from discrete speed data shows that the most frequent running speed is 85km/h, as is shown in figure 12 (b). Therefore, polygonal wear development at speed 85km/h could be of great importance.

(a) Speed time history curve on a typical test zone

(b)Speed class distribution

Figure 12 *Speed time history and its distribution*

On the basis of the long-term iterative wear model and the short-term metro vehicle dynamic model, the development of polygonal wear is simulated at different speeds. The initial fourth order polygon with depth 0.1mm is applied and wear profile updating condition ΔD is 0.1mm. Figure 13 and figure 14 present the development of wear at speed 85km/h and 70km/h.

In figure 13 ten iterative wear curves are divided into two stages by three bold solid red lines which clearly present the development phases of polygonal wear. In the phase 1, from top solid line to the fourth wear curve, the original four wave crests quickly grow into 8 wave crests. While in the phase 2, the dramatic growth of polygonal order disappears. Instead, the depth of polygon keeps increasing.

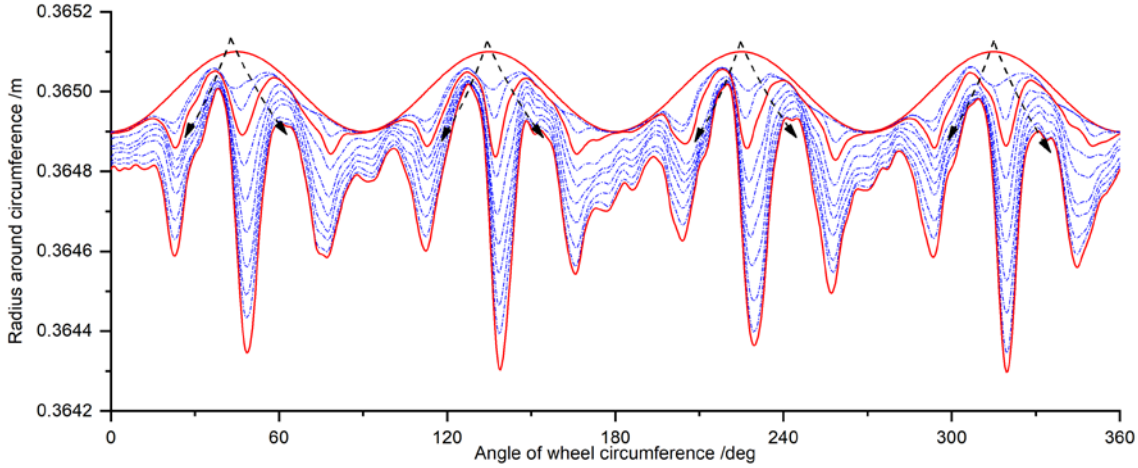


Figure 13 *The development of polygonal wear of the metro vehicle wheel at speed 85km/h, ΔD=0.1, harmonic order n=100*

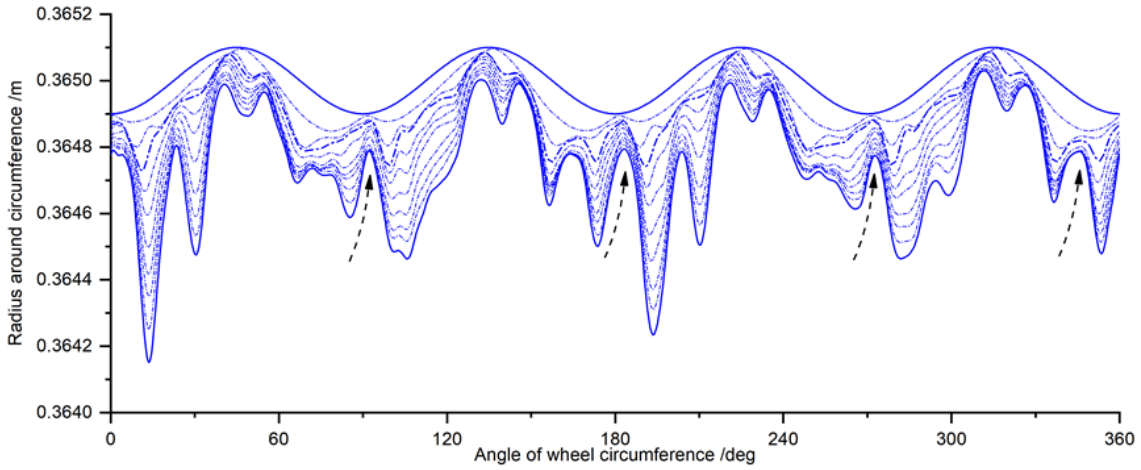

Figure 14 *The development of polygonal wear of the metro vehicle wheel at speed 70km/h, ΔD=0.1, harmonic order n=100*

At 70km/h, the frequency of wheel excitation is far away from natural frequency of linear motor, and the wear development shape is quite different from the characteristics in figure 13. In figure 14, the growth of orders is an ordinary wear type as is described in Chapter 2.4. It can also be found that wear growth rate at 85km/h is more intense than that at 70km/h. (Wear growth rate is not shown in above figures, it can be measured by running distance.)

Using the wear simulation model, the mechanism of polygonal wear leading to the modification of polygonal wear pattern from initial fourth order into eighth or ninth order can be explained as follows.

In the initial phase, with fourth order polygonal irregularity, the wheels will produce around 40Hz excitation at speed 85km/h, which cause resonance of linear motor. The vibration of car body, linear motor and wheelset in this situation becomes severe. According to speed distribution, keeping running velocity at 85km/h for a long time accelerates the polygonal wear development from initial fourth order into eighth and ninth order. The wear in this stage is intensive.

When eighth or ninth order polygonal wheel is formed, the wear comes to the second phase, in which the new higher order polygonal wheel at 85km/h will no longer lead to resonance of linear motor. In this stage, the order of polygon will not change dramatically, but the depth of eighth or ninth order polygon keeps increasing at a relatively low rate of growth.

This mechanism is in accordance with some peculiar phenomena observed in on-track tests, which has been introduced in Chapter 4.2. For feature (b), the deterioration of vertical Ride Index from the first month to the sixth month comes from the increase of polygon depth mainly in the second phase when eighth or ninth order polygon is formed. For feature (c), it can be observed that in the first month the lateral Ride Index is bad at 85km/h but in the sixth month the Ride Index becomes better. This is because in the first phase, the initial fourth order polygon at 85 km/h excites resonance of linear motor but when eighth or ninth order polygon is formed in later month, the resonance at 85 km/h disappears. Instead, another resonance speed at around 40km/h is observed.

4.4. Solution to eliminate polygonal wheel

According to the analysis above, the development of polygonal wheel comes from three interactive conditions. They are initial fourth order polygonal wheel, natural frequencies of liner motor and vehicle speed. Thereby, the solution could be proposed from three aspects.

(1) Changing natural frequencies of linear motor: The suspension parameters and mass properties of linear motor determine the natural frequencies of linear motor. Calculation shows that increasing vertical stiffness of rod rubber components connecting frame to 150% of its original value can avoid the resonance of the linear motor in the speed range from 0 to 90km/h, which is easily to be implemented. In the real project, implementation of changing the stiffness in real vehicle successfully alleviated the problem and improved the ride comfort. (2) Adjusting speed: Changing the vehicle speed has limited effect if the resonance speed cannot be avoided in real operational service. But reducing the time staying in the resonance speed range can still alleviate the polygonal wear. (3) Refining re-profiling technologies: Re-profiling machine and process could be improved to reduce initial wheel irregularity.

5. New strategies for investigating wheel polygonization

Based on the previous analysis for the metro vehicle, new strategies for investigating wheel polygonization are summarized, which could be applied generally in other types of railway vehicles.

(1) Identifying resonance speed(s)

Speed is an extremely important factor when polygonal wear is investigated, since it determines the frequency of wheel excitation. In analysis for the metro vehicle, a resonance speed is observed both in simulation and on-track tests. Identifying a resonance speed can lead us to a specific frequency, rather than an extensive frequency range. Testing dynamic behaviour of vehicle in varying speeds could be an approach to identify resonance speeds.

A simulation example for the metro vehicle can be seen in figure 15.

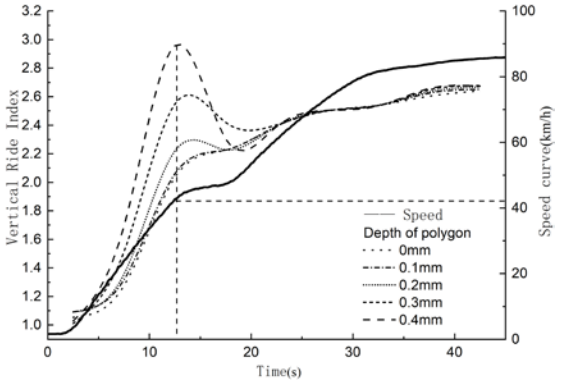

Figure 15 *Resonance speed identification in varying speeds*

(2) Developing phases of polygonal wear

When polygonal wheel of the metro vehicle is studied, the long-term on-track tests present that the dynamic behaviour of metro vehicle has different features in different stages. The polygonal wear simulation also clearly shows that the wear process can be divided into two phases, as is shown in figure 16. In phase 2, the depth of polygon keeps increasing, rather than the polygon order. By contrast, the essential process determining orders of polygon occurs in phase 1, which is more significant and deserves more attention.

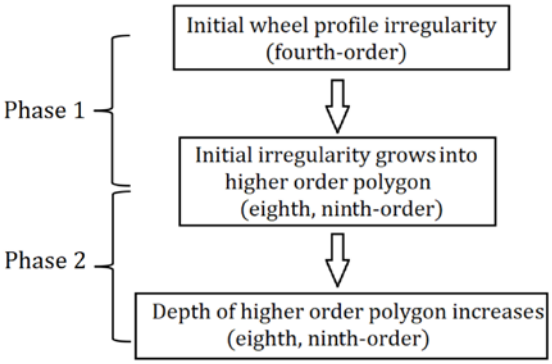

Figure 16 *Developing phases of polygonal wear*

However, when a wheel polygonization is observed, the initial polygonal wheel profile is easily to be ignored. Instead, the research usually starts with worn high order polygon. For instance, in our case study, it is common to start the investigation with worn 8 to 9 order, not the initial 4 order polygonal wheel profile. The resonance frequency of rail and vehicle system will be analysed at condition that 8 to 9 order polygonal wheel has been formed. But in this way, only Phase 2 will be involved, and the more important Phase 1 that determines the development from initial lower order to high order would be missed.

The investigation for the development of wheel polygonization should start with initial low order polygonal wheel profile, and frequency domain analysis should be carried out at this condition so that the analysis will cover the both phases of polygonal wheel development. When investigation's starting point changs from worn high order polygon to initial low order wheel polygon, a resonance frequency we try to find from rail and vehicle system could be largely reduced from hundreds of Hz that can only be found from vibration of track components, to dozens Hz which could be found from vehicle components vibration. For instance, in our case study, when 8 to 9 order polygonal wheel has been formed, the wheel excitation frequency will come to around 80Hz at 80km/h to 85km/h, which is higher than the natural frequencies of any vehicle components, but when a fourth order polygonal wheel is considered, a corresponding low wheel excitation frequency leads us to the resonance of the linear motor. Therefore, focusing on initial low order wheel polygon, rather than worn high order polygon can shift attention to some relatively low frequency vibrations.

6. Future work

Even though the simulation and analysis for polygonal wear of wheel are completed, there are still a lot of works need to be done in the future.

For near future, parameter settings for long-term wear model should be studied further to make simulation results more reliable and accurate. Different wear models and wheel rail contact calculation methods should be considered and compared. Flexibility of wheelset should also be taken into account. For long term study, if circumstance is allowed, the vibration of track components should be considered, and measured polygonal wear data should be used to test and refine the wear model.

7. Conclusions

In this work, a long-term iterative wear model is built to study the development of polygonal wheel. Simulation steps, wheel profile updating strategy and number of harmonic Fourier series function are three important parameters that will affect the accuracy of simulation. Conventional wear development at normal speed increases the depth of polygon and can also change the orders of the polygon but its growth rate is slow. The visible severe polygonal wear occurs at resonance speed, which is intensive and grows rapidly. A polygonal wheel of metro vehicle is analyzed comprehensively from simulation and on-track tests. For this vehicle, the interaction of initial wheel profile irregularity, vehicle speed, natural frequency of linear motor leads to the polygonal wear of wheel. The development of polygonal wear can be divided into at least two phases. In the first phase, an initial low order polygon grows into the high order polygon. In the second phase, the depth of order increases. Usually, the investigation for polygonal wear starts from worn high order of polygon wheel. But the initial low order polygon after wheel re-profiling deserves more attention. Identifying a resonance speed to find a specific resonance frequency is another key point to study mechanism of polygonal wear.

Abstract: This paper describes the measurement of the rolling-sliding contact condition between wheel and rail using ultrasound waves. Unique experiments were performed using a full-scale dynamic wheel/rail contact-testing machine and an ultrasonic array transducer. The ultrasonic array transducer provides a 2D measurement of dynamic interfacial stiffness. It was found that the running-in transitions of traction coefficient and contact stiffness were significantly influenced by the initial surface roughness. Contact stiffness appears to have an almost linear positive correlation with the traction coefficient. These findings might inform rail service providers about optimal wheel profiling methods to reduce the likelihood of wheel climb derailment.

Keywords: Rolling-sliding; full-scale rig; Ultrasound; Contact stiffness; Traction coefficient.

1. Introduction

Since the frictional condition between wheel and rail plays a vital role in the transmission of the driving force and braking force, it should be kept at an optimum level to secure the proper acceleration performance and braking distance. On the other hand, it is known that high traction coefficient and slip at curves could lead to severe wear and deformation of wheel and rail, energy consumption and squealing noise [1]. It also increases the risk of a wheel climb derailment occurring [2][3][4].

Nakahara *et al.* reported that the traction condition between a wheel and rail changes with a train traffic passage even in dry condition [5] and showed some transient traction curves using twin-disk testing which indicated that traction coefficient varies with the evolution of surface roughness during running-in [6]. Blau also addressed the tribological behaviour during running-in and reported typical examples of friction force transition curves [7] Notedly, it was mentioned that the friction force tends to increase significantly in the case of dry contact after the start of sliding contact. In these cases, it is commonly recognized that one of the main causes for such a transition is the evolution of surface topography with cyclic contacts [6][7]. Lundmark *et al.* [8] and Yamamoto *et al.* [9][10] also reported that the transition of traction coefficient is strongly influenced by the initial topography.

As the wheel and rail experience cyclic rolling-sliding with tangential force, the surface topography changes and therefore the interfacial condition alters dramatically during running-in. Therefore, it is important to understand how this interfacial condition evolves over time to understand the potential mechanisms for wheel climb derailment. However, the difficulty in obtaining accurate non-destructive interfacial measurements has hindered systematic experimental investigations. An increased understanding of these effects might inform rail service providers about optimal wheel profiling methods and lubrication programs to reduce the likelihood of wheel climb derailment.

Pressure-sensitive films can be used to observe contact area and stress in a static condition. However, these films may cause over-prediction of the contact area owing to the thickness of the film and changes in tangential force due to its different frictional properties. Practical implementation is also difficult because the film disintegrates under the high-pressure and shear between the wheel and the rail. Recently, ultrasonic techniques have been used to observe the contact between wheel and rail [11][12][13][14][15]. Though there are spatial resolution limits and considerations of transducer positioning to ensure the sound waves reflect off the area of interest, this technique can be used to non-invasively and directly observe the contact. When an ultrasonic wave strikes the interface between the wheel and rail, it is partially transmitted and partially reflected. The proportion of the wave reflected depends on the stiffness of the contact [16][17]. This approach has been used to determine the contact pressure distribution in wheel-rail contacts and the influence of wear, roughness and surface defects on the contact patch [12][14].

Recently, dynamic ultrasonic measurement of a rolling-sliding contact was achieved [18][19]. By use of this method, the dynamic contact condition with a rolling-sliding can be obtained for repeated cycles. Information about the contact condition under the cyclic tangential force might lead to the clarification of mechanism about tribological transition curve during running-in.

The aim of this work is to understand and characterize the tribological behaviour between wheel and rail during running-in. Ultrasonic reflection was used to evaluate interface condition in a rolling-sliding contact,

particularly contact stiffness over time as running-in occurs. The experiments were performed using a full-scale dynamic wheel/rail contact-testing machine and a 64 element ultrasonic array transducer consisting of 64 ultrasonic elements mounted in a rail. Transient traction coefficient was also measured during the test. Following these measurements, a comparison between contact stiffness and traction coefficient was carried out.

2. Methodology

2.1. Full-scale rig

Figure 1 shows a schematic diagram of the full-scale dynamic wheel/rail contact rig [18][19], which is equipped with a full scale wheel loaded onto a traversing rail. It can apply a normal force of up to 200 kN and tangential force of up to 60 kN using servo-controlled hydraulic cylinders. The rail is pushed and pulled at a velocity of up to 100 mm/s in the longitudinal direction. The wheel can be unconstrained so that its rotation is a result of the small force generated from the friction between the wheel and the rail, and it can also be forced to rotate slightly faster by the movement of an actuator which is connected to it via a chain. The difference in speed generates the tangential force. Each hydraulic cylinder has a load cell mounted in-line facilitating the measurement of traction coefficient from the division of tangential force by normal force.

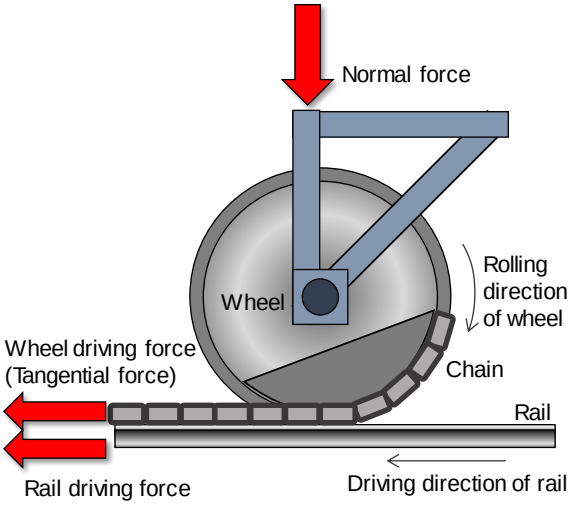

Figure 1 *Schematic diagram of the full-scale wheel/rail contact rig.*

Figure 2 shows a photograph of the ultrasonic array transducer and a schematic of the set-up. The transducer was mounted in the hole which was made in the rail in the direction parallel to the sleeper. Hence, the contact area can be scanned with the passage of the wheel on the rail where the transducer is mounted. The array transducer consists of 64 piezo elements arranged linearly each with a width of 0.5mm and a constant pitch of 0.6mm. The pitch of data in the rolling direction is determined by the ultrasonic array scanning frequency and the wheel rolling velocity. Since the scanning frequency was approximately 14 Hz and the rolling speed for these tests was 10 mm/s, the pitch of data in the rolling direction was approximately 0.7 mm. The frequency of the ultrasound is 5 MHz.

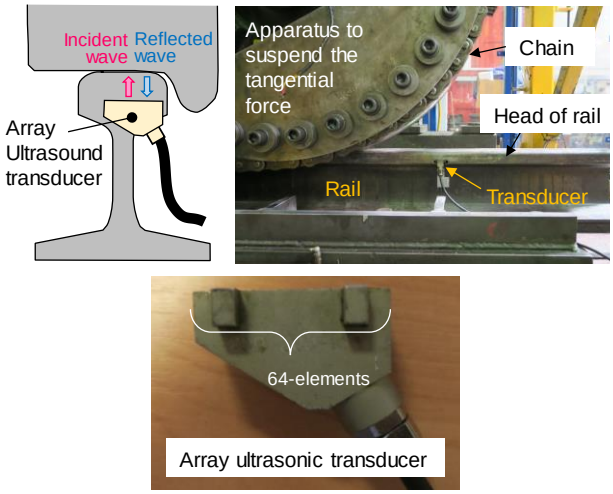

Figure 2 *Array ultrasound transducer and schematic of the set-up.*

2.2. Ultrasound technique

At an interface of two dissimilar materials, a part of the incident ultrasonic wave is transmitted through the interface and the other portion is reflected from the interface. For an interface of two dissimilar materials which have atomically smooth surface, the proportion of the reflected wave, described by the reflection coefficient R, is dependent on the acoustic impedance mismatch between the two materials and is given by [21]:

$$R = \frac{Z_2 - Z_1}{Z_2 + Z_1}, \quad (1)$$

where z_1 and z_2 are the acoustic impedances (which are the products of density and acoustic velocity) of the contacting materials. Therefore, for two perfectly bonded identical materials, the interface would have no reflection ($z_1 = z_2$, $R = 0$) and the entire wave is transmitted (without any losses). Conversely, an ultrasonic wave is almost completely reflected at an interface between two materials with substantially different acoustic impedances, as in the case of a solid and a gas ($R \approx 1$).

Real engineering interfaces are inherently rough and micro and macroscopic air gaps are formed at an interface. Presuming the length of the ultrasonic wave is long relative to the size of the air gaps the whole interface behaves as a single reflector and therefore R is also dependent on the contact stiffness of the interface. The contact stiffness, K, is a function of the surface topography, surface material properties and the contact pressure. As the surface topography changes due to elastic and plastic deformation, the measured reflection coefficient R will change accordingly as shown in Fig. 3. In principle, the degree of conformity at the interface can be determined by measuring the reflection coefficient of the ultrasonic wave.

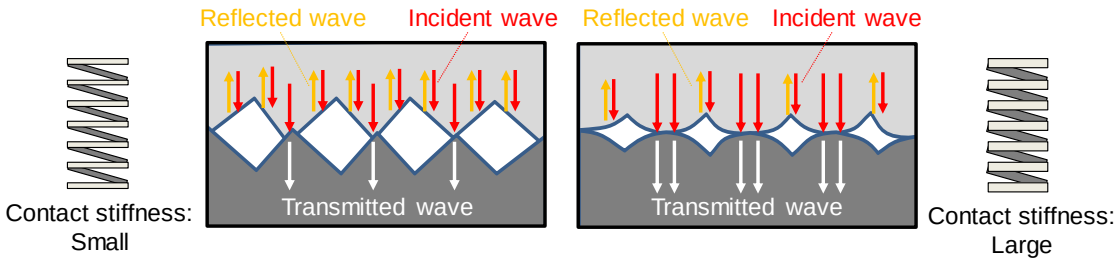

Figure 3 *Principle of measurement.*

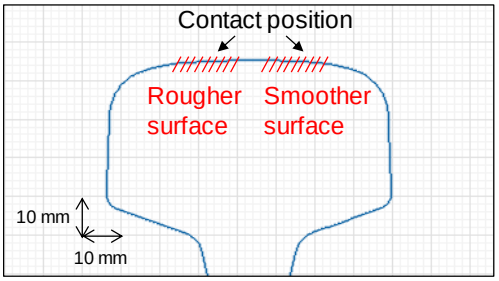
Schoenberg [20] used an interface 'spring model' to show how the reflection coefficient is related to contact stiffness:

$$R = \frac{z_2 - z_1 + i\omega(z_1 z_2 / K)}{z_2 + z_1 + i\omega(z_1 z_2 / K)} \qquad (2)$$

where ω is the angular frequency of the ultrasound and K is the interfacial contact stiffness. The contact stiffness, K is a function of the surface topography, surface material properties and the contact pressure and has a significant influence on the contact dynamics. In the case of present work, the materials on both sides of the interface are similar ($z_1 = z_2 = z$), then equation (2) reduces to:

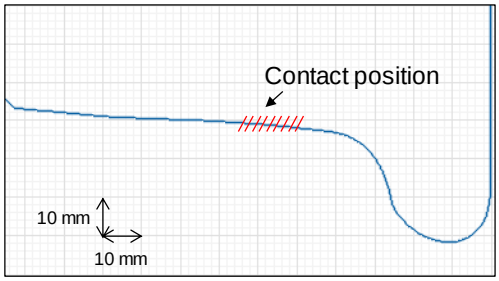
$$|R| = \frac{1}{\sqrt{1 + (2K/\omega z)^2}} \qquad (3)$$

Therefore, if the reflection coefficient, R, can be experimentally obtained, the contact stiffness, K can be estimated. Generally, normal contact stiffness can be distinguished from tangential contact stiffness depending on the loading direction. The contact stiffness in this paper means the normal contact stiffness unless otherwise specified.



Many researchers [11][12][13][14][15] have obtained the reflection coefficient R as the ratio of the reflected ultrasonic wave amplitude under load, H, to that when unloaded with no material in contact, H_0 (the reference).

$$R = \frac{H}{H_0} \qquad (4)$$



When unloaded, the contact is effectively steel against air and so the wave is fully reflected and H_0 is equivalent to the incident wave amplitude. This is a simple practical way to obtain the reflection coefficient and removes the influence of transducer characteristics, ultrasonic wave scattering and attenuation.

2.3. Test rail and wheel

Figure 4 shows the profile of test rail and wheel which were measured using a CALIPRI non-contact profile measurement device. The type of the test rail was UIC60A (EN 13674-1) at a length of 1200 mm and that of the test wheel was P8 (EN 13715) at a diameter of 920mm. Since the rail and the wheel were used for full-scale contact tests before this test, both had been slightly worn. There were two choices for contact position on the rail by the inverting the direction of the rail. Two roughness conditions were prepared on each side of the rail (Fig. 4(a)). One side was prepared with the high traction force which was applied by the rolling-sliding of the wheel on purpose to make a rougher surface. Also, the other side was prepared by polishing with sandpaper mainly along the longitudinal direction to create a smoother surface. On the other hand, the contact position of the wheel was fixed (Fig. 4(b)) and the roughness was not specially prepared.

(a) Rail

(b) Wheel

Figure 4 *Measured profile of test rail and wheel and contact position.*

Silicon polymer replicas (Microset 101 Fluid and NP10 Nozzle) were used to copy the surface topography of rail and wheel. After obtaining the replica, the roughness and surface topography were analyzed using an optical surface measurement system (InfiniteFocus, Alicona). Figure 5 shows the initial surface profile of rail and wheel for each case. The plus and minus sign of these profiles were reversed to be same as the actual urface because the profiles were obtained from the replica. The measurements were carried out five times per direction, lateral and tangential. Table 1 shows initial roughness value of rail and wheel which is the mean value of five measurements. condition of the wheel was it was. it was slightly different in each case. It can be found that the magnitude of rail roughness in rougher case is significantly larger than that in smoother case. On the other hand, the magnitude of wheel roughness in rougher

case is significantly smaller than that in smoother case. However, there was not significant difference like the rail roughness. As a consequence, two combinations of the rail surface and the wheel surface which have different initial roughness were prepared.

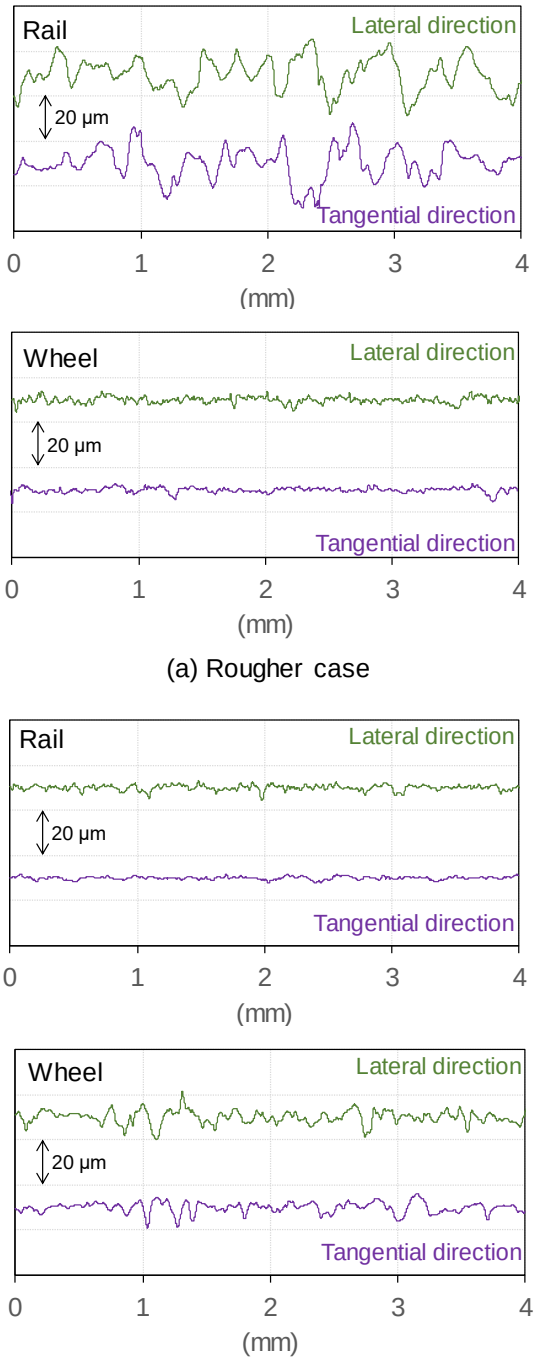


Figure 5 *Initial roughness profile of rail and wheel for each test.*

Table 1 *Initial roughness of test rail and wheel.*

Case	Roughness, Rq (μm)			
	Rail		Wheel	
	Lateral direction	Tangential direction	Lateral direction	Tangential direction
Rougher case	8.0	6.9	1.5	1.2
Smoother case	1.2	0.8	2.8	2.4

2.4. Test procedure

Table 2 shows the test conditions. The cyclic contact tests were continued up to 100 cycles in the test of the rougher case and 60 cycles that in the smoother case. Both tests were carried out after cleaning the surface using acetone. The measurement of traction coefficient and reflection coefficient were carried out continuously during the cyclic tests. Silicon polymer replicas were used for the evaluation of roughness as mentioned in section 2.3. These replicas were obtained after 100 cycles in the test of the rougher case and after 20 cycles in the test of the smoother case when the increase of traction coefficient showed saturation with the increase of cycles.

Table 2 *Test conditions.*

Normal force (kN)	80
Slip ratio (%)	3
Velocity (mm/s)	10 for measurement
Cycles for the measurement (cycles)	1-10, 13-20, 23-30, 33-40, 43-50, 53-60, (63-100, only in rougher case)
Timing for replicating the surface topography (cycles)	After 100 (rougher case) After 20 (smoother case)

3. Results

3.1. Change of traction coefficient with cyclic rolling

Figure 6 shows the relationship between the number of cycles and traction coefficient. Traction coefficient was calculated as the ratio of tangential force to drive the wheel and the normal force (Fig. 1) and the value was extracted at the moment the wheel passed the ultrasonic transducer. Both results of the rougher case and the smoother case showed the increase of traction coefficient with the increase of cycles and it is clearly found that the increase in the smoother case was more rapid than that of the rougher case. In both cases, the traction coefficient reached a plateau of approximately 0.5.

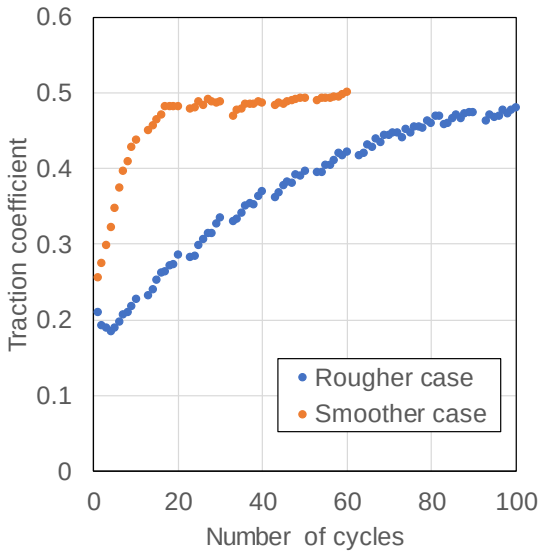

Figure 6 *Relationship between number of cycles and traction coefficient.*

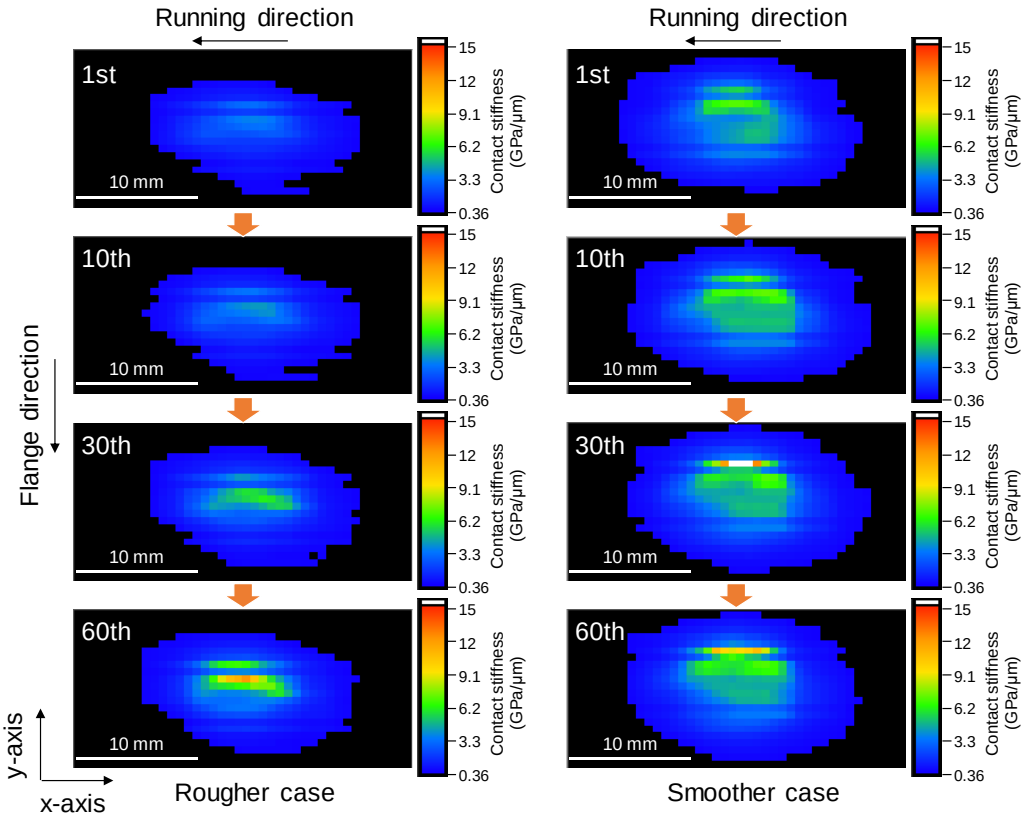

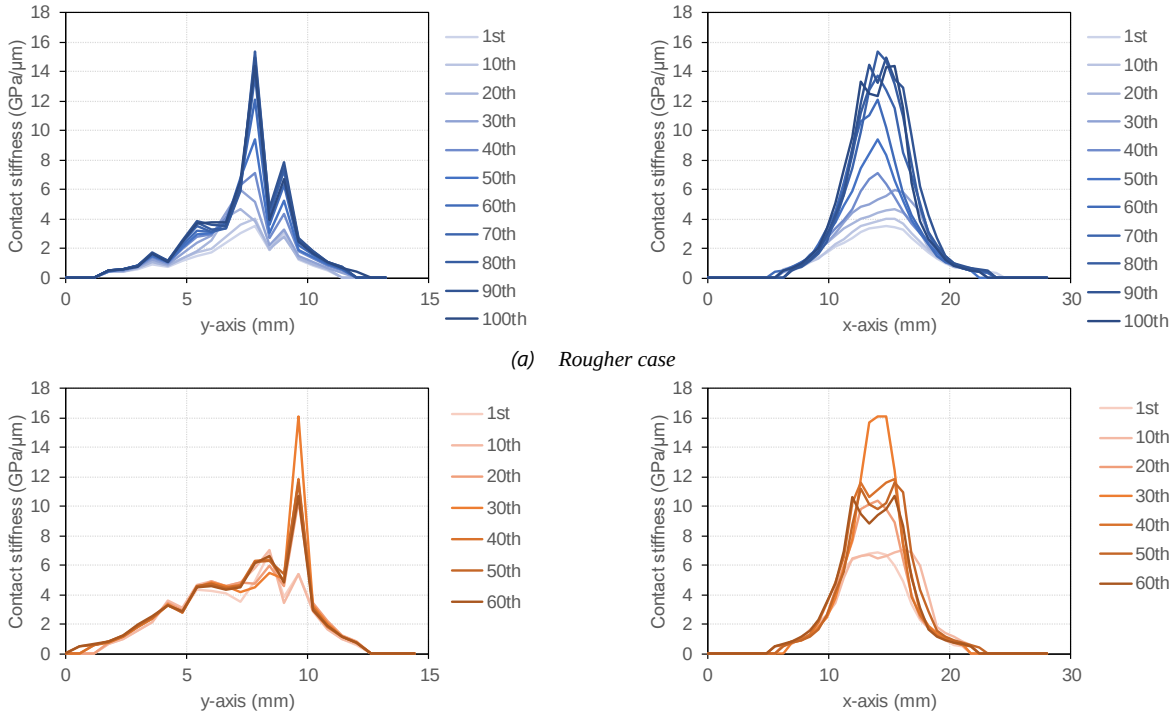

Figure 7 *Examples of the distribution of contact stiffness.*

(a) Rougher case

(b) Smoother case

Figure 8 *Examples of the line distribution of contact stiffness.*

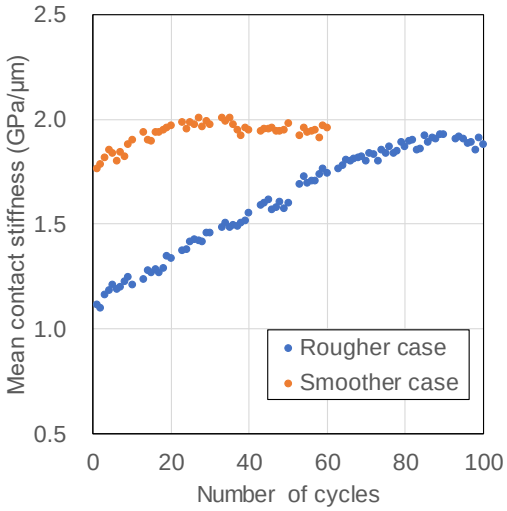
3.2. Change of contact stiffness with cyclic rolling

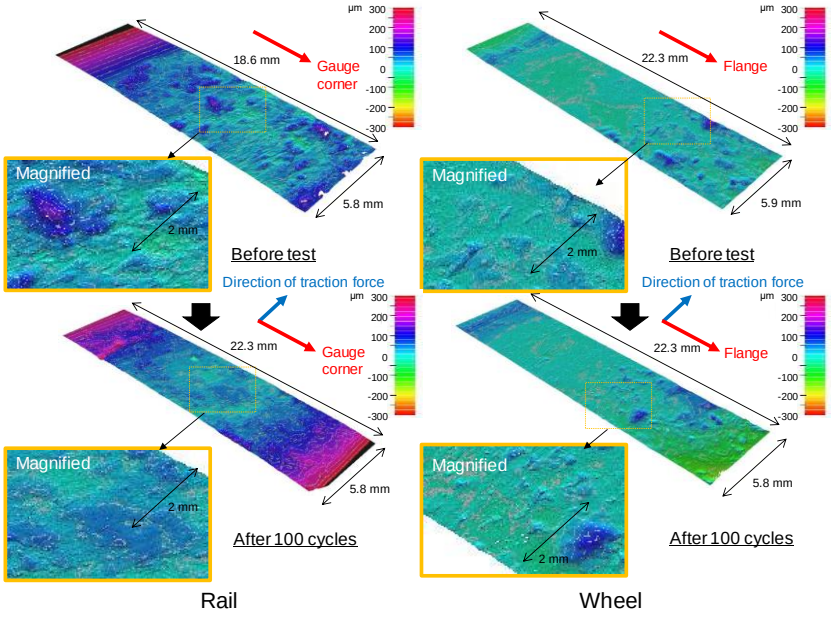
Figure 7 shows examples of the distribution of contact stiffness between wheel and rail which was measured continuously with the increase of cycles. Here the threshold value of contact stiffness to define the contact area was determined as the value which was calculated by a 10% decrease of reflection coefficient (R=0.9). The increase of contact stiffness with the increase of cycles can be seen the change of contours. Figure 8 shows examples of the line distribution of contact stiffness. Here, each line was selected to pass through the point which had the maximum contact stiffness. It was found that the increasing tendency is not uniform inside the contact area and there were some peak points which showed a significant increase for both cases.

Figure 9 shows the relationship between cycles and mean contact stiffness. Here, the mean value was calculated using the data which exceeded the threshold value above mentioned. The mean contact stiffness increased with the cyclic rolling and the value of the smoother case saturated more rapidly than that of the rougher case. This tendency was similar to the transition of traction coefficient.

3.3. *Change of surface topography with cyclic rolling*

Figure 10 shows the comparison of the surface topography before and after test cycles. Here, it needs to be noted that the what appears to be a projection is actually a dent because these images were obtained from the replica. Figure 10 (a) shows that the initial asperities on the rail were flattened dramatically. Fig. 10 (a) and (b) at the wheel after test cycles showed the evolution of stripe-like traces along with the traction force. It is thought that the traction force makes such traces.





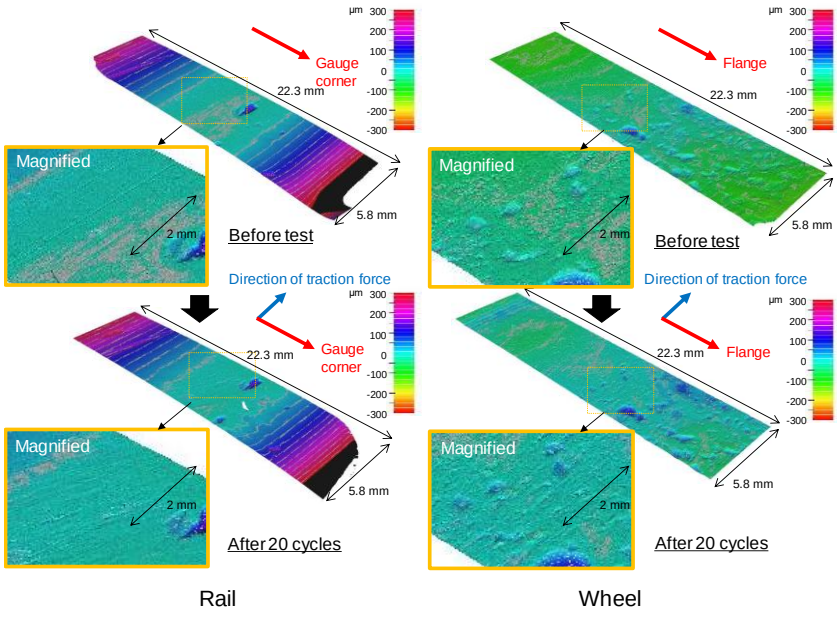


Figure 9 *Relationship between number of cycles and mean contact stiffness.*

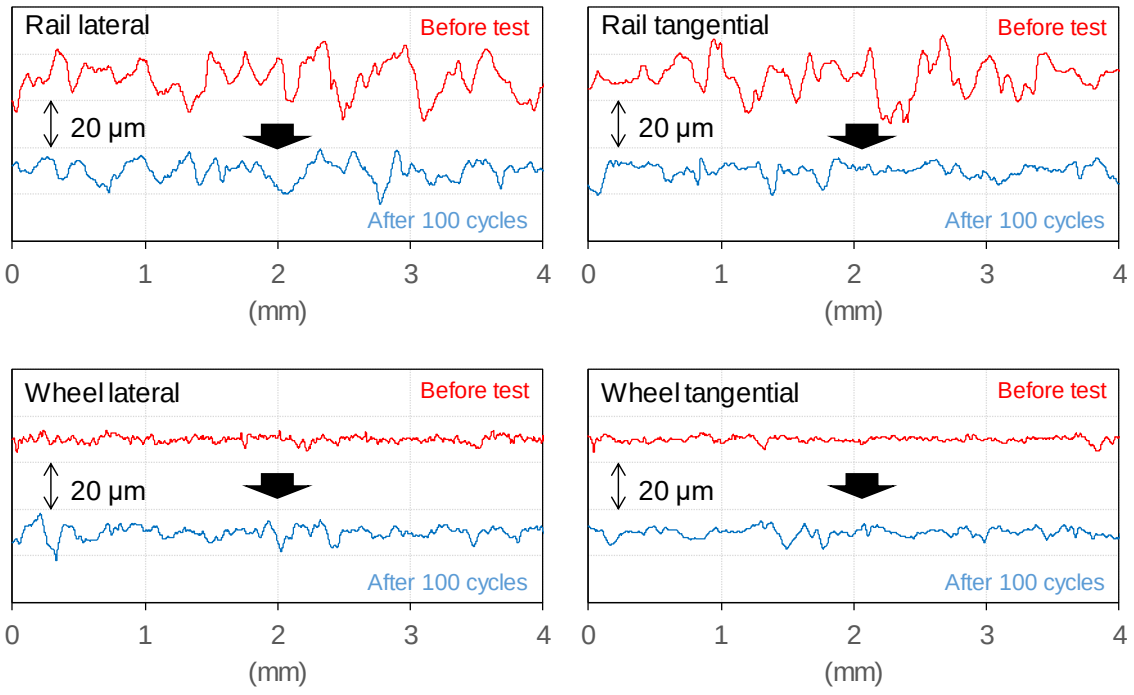
(a) Rougher case



(b) Smoother case

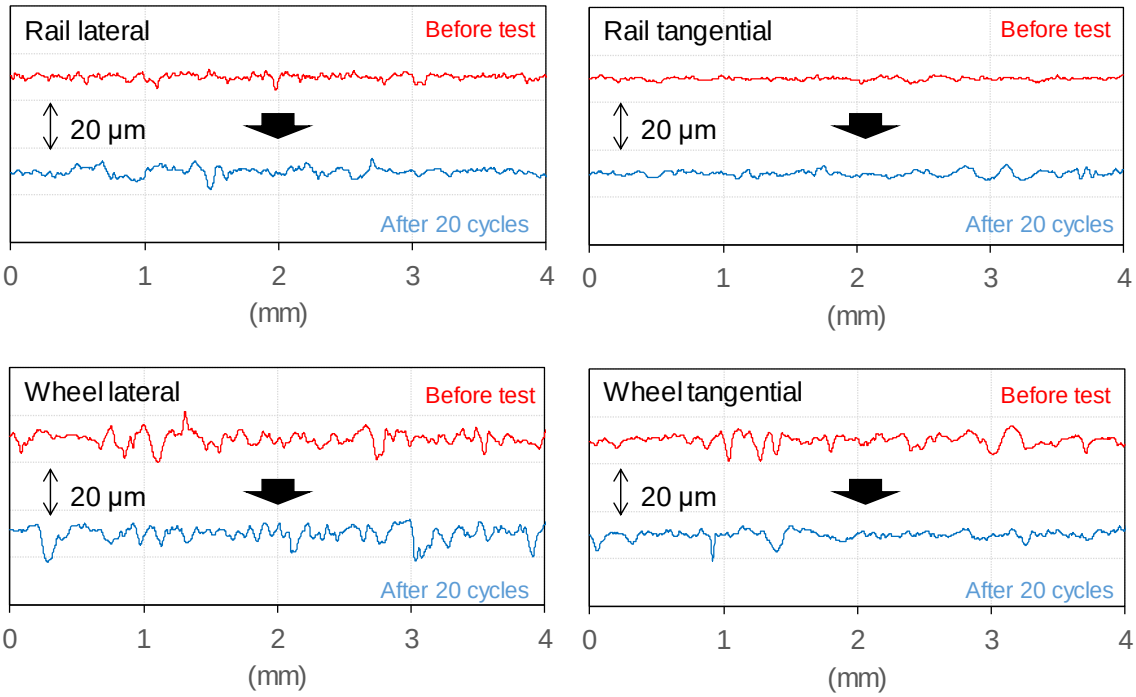


Figure 10 *Comparison of the surface topography between before and after test cycles.*

Figure 11 shows the comparison of the profiles before and after the test cycles. The measurement of profiles was carried out in a similar way to that described in section 2.3. Figure 11 (a)-Rail shows that the initial asperities were flattened dramatically. On the other hand, Fig. 11 (a)-Wheel shows that the roughness slightly increased after the cycles. It is thought that this increase was due to the compressions by the asperity summits of the rail surface or the surface texturing by the traction force. Figure 11 (b) shows that there was no significant difference before and after the cycles.

Figure 12 shows the comparison of root-mean-square roughness value (Rq) for each case, rail/wheel and directions. Here, these were mean values for five measurements and the error bar means the range from maximum value to minimum value, which is same as the actual surface (reverse value of replica). It is found that Rq of rail dramatically decreased and Rq of wheel slightly increased after the cyclic tests in the rougher case. There was no significant difference before and after the cycles in the smoother case.

(a) Rougher case

(b) Smoother case

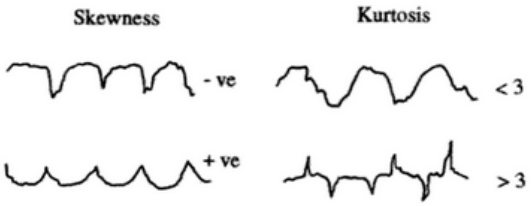
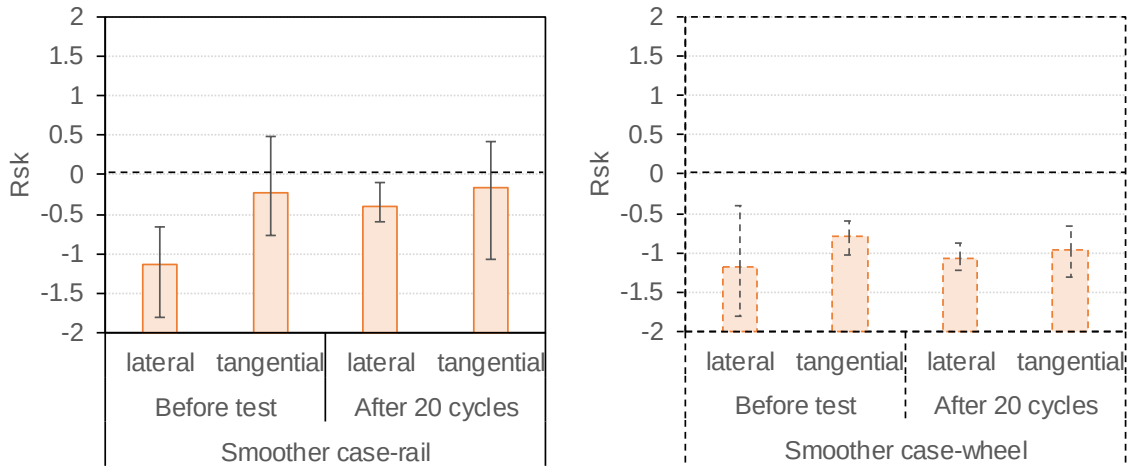
4. Discussion

The continuous evaluation of contact stiffness during the running-in period revealed that contact stiffness increases with an increase in cycles. However, the tendencies of increase differed from the rougher case to the smoother case. The increase of contact stiffness in the rougher case can be explained by the significant decrease in rail roughness. It is well known that the lower roughness, the larger contact stiffness is [22][23]. Though there was also an increase of contact stiffness in the smoother case, there was no significant change in roughness value.

For a more detailed analysis of surface topography, additional parameters, skewness (Rsk) and kurtosis (Rku) were evaluated. Figure 13 shows a schematic illustration of surface topography with ranging skewness and kurtosis. Skewness is the parameter to evaluate the symmetry of the roughness profile [24][25]. A zero value of Rsk means a symmetrical distribution, a negative value means the profile has an inclined distribution in the upper side of a mean line and a positive value means the profile has an inclined distribution in the lower side of a mean line. Kurtosis is the parameter to evaluate the sharpness of asperity summits of the roughness profile [24][25]. If Rku is smaller than three, it means there is a platykurtic distribution and if the value is larger than three, it means there is a leptokurtic distribution.





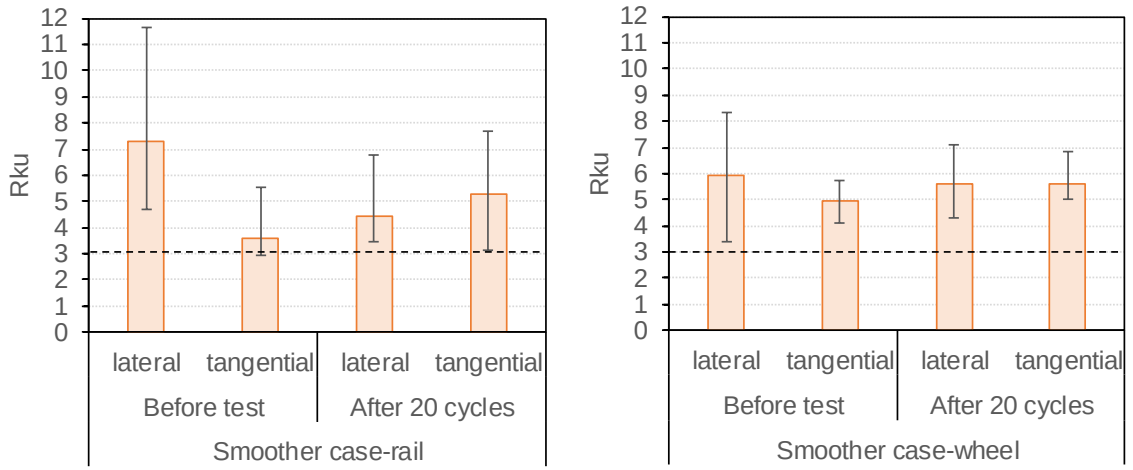


Figure 13 *Schematic illustration for surface topography with various skewness and kurtosis* [23].

Figure 14 (a) shows the comparison for skewness (Rsk) of the profile which was shown in Fig. 11. In the smoother case, there is a relatively large increase in the lateral direction of the rail before the test to after 20 cycles. Figure 14(b) shows the comparison for kurtosis (Rku) of the profile which was shown in Fig. 11. In the smoother case, there is a noticeable difference in the lateral direction on the rail before the test to after 20 cycles. Generally, a grinding process produces grooved surfaces with negative skewness but high kurtosis values [24]. Since the rail in the smoother case was prepared by polishing using sandpaper, it is reasonable that a negative Rsk value and large Rku value appeared before the test. It is thought that sharp scratching marks were deformed during the running-in period and the change of roughness distribution showed the difference in Rsk and Rku after the cyclic test even if the Rq was almost the same. Therefore, this change should have caused the slight increase of contact stiffness in the smoother case.

(a) Skewness (Rsk)

(b) Kurtosis (Rku)

Figure 14 *Comparison for the parameters of roughness.*

Figure 15 shows the relationship between mean contact stiffness and traction coefficient. It is found that the mean contact stiffness in the rougher case appears to have a positive correlation with the traction coefficient and it is close to being linear. On the other hand, the relationship in the smoother case was relatively skewed and there is a gap between the line in the rougher case and that in the smoother case in the region of low traction coefficient.

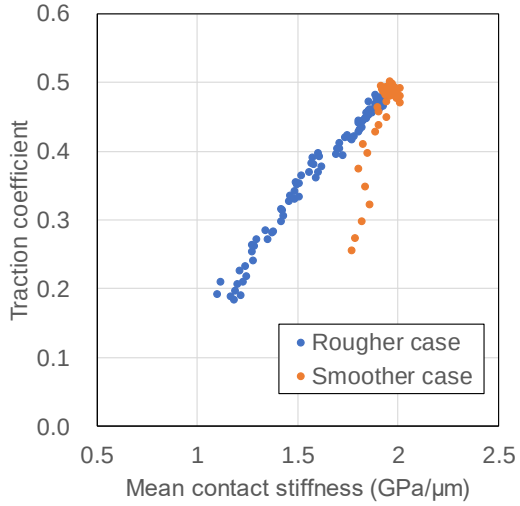

Figure 15 *Relationship between mean contact stiffness and traction coefficient.*

The reason is thought to be the slight difference in extreme surface conditions, such as moisture, contamination and oxide layer and they affected the traction coefficient more sensitively than the contact stiffness. It is thought that these influences decreased with the increase of the cyclic number and the wear of outer surface layer.

Figure 16 shows a schematic model of the transition of surface roughness and contact stiffness. Here, it is simplified as the contact between a completely flat surface and a rough surface. As mentioned in section 2.2, normal contact stiffness can be distinguished from tangential contact stiffness depending on the loading direction. Normal contact stiffness increases with the increase of cyclic rolling-sliding contacts and the decrease of roughness. There are numerous studies which discuss how tangential contact stiffness increases with the increase of normal contact stiffness and the ratio of tangential stiffness to normal stiffness is nearly constant [26][27]. The displacement along the tangential direction, Δx, would be qualitatively dominated by the slip ratio and it was constant, three percent, during this test. Therefore, it is thought that the tangential stress increased with the increase of normal contact stiffness as the following equation:

$$\sigma_t = cK \cdot \Delta x \quad (5)$$

where σ_t is tangential stress and c is the ratio of tangential stiffness to normal stiffness. As a consequence, there would be the linear-like relationship between normal contact stiffness and traction coefficient.

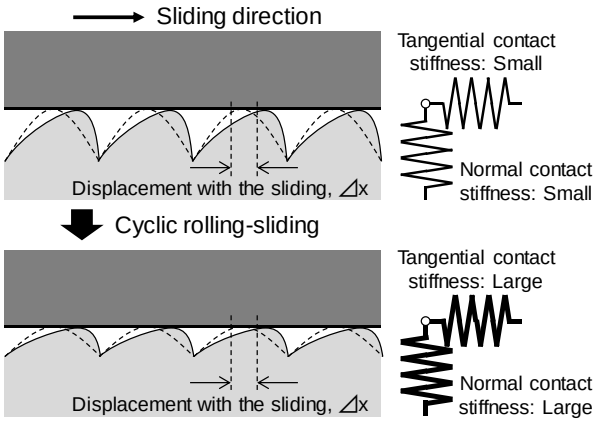

Figure 16 *Schematic model of the transition of surface roughness and contact stiffness.*

5. Conclusions

From the measurement of rolling-sliding contact condition between wheel and rail using ultrasound waves, the following conclusions can be drawn:

1. For both two initial roughness cases, the rougher case and the smoother case, showed the increase of traction coefficient with the increase of cycles and it is clearly found that the increase in the smoother case was more rapid than that of the rougher case.
2. Mean contact stiffness which was measured using ultrasound wave increased with the cyclic rolling and the value of the smoother case saturated more rapidly than that of the rougher case. This tendency was similar to the transition of traction coefficient.
3. Root-mean-square roughness in the rougher case showed that the initial asperity was flattened dramatically after the cyclic rolling-sliding. Though that in the smoother case showed no significant change, there were an increase in skewness and a decrease of kurtosis.
4. Mean contact stiffness appears to have a positive correlation with the traction coefficient and it closed to being linear. Based on the above results, a mechanical model of the effects of contact stiffness on traction characteristics during the running-in period was proposed.

Abstract: Risk of wheel-climb derailment increases if the traction coefficient in the wheel/rail contact is too high. This has been observed to happen more just after wheel turning. This novel work investigates how the traction coefficient raises during the running in period, when textured surfaces are used to represent, a freshly turned wheel. A peak in traction coefficient was observed that varied with magnitude of wheel texture. The subsurface structure also varied coincidentally. The work will allow recommendation of wheel turning to be made to help reduce the problem of wheel-climb derailment.

Keywords: running-in; traction coefficient; surface texture; plastic deformation; subsurface structure; flange climb.

1. Introduction

Since the frictional condition between railway wheel and rail has an important role in the transmission of driving force and braking force, it should be kept at a high level to secure the appropriate acceleration performance and braking distance. On the other hand, the risk of wheel climb derailment will be increased if the traction coefficient is too high at sharp curves because it generates a greater force in the lateral direction, namely towards the outside of a curve. The force presses the wheelset against the gauge corner of the outer rail and could cause the flange to climb up [1][2][3]. Therefore, it is important to understand the phenomenon and appropriately control the friction condition. The general method to control the friction condition is the application of lubrication between the wheel and rail. However, installation of lubrication equipment or work by hand at the depot would make an additional expense and a significant contamination around the bogie. Moreover, excessive lubrication risks causing slips.

A railway wheel experiences re-profiling several times during its whole life to reset it to the designed profile from the worn profile or to remove damage, such as wheel flat and cracks. And it is known that some derailments have occurred relatively soon after the re-profiling of wheels [4][5][6][7]. Just after the re-profiling, there are machining marks which depend on the shape of cutting tool and the feed rate at the wheel surface. Some reports mention the possibility that a rougher surface leads to a higher traction coefficient and it increases the risk of flange climb derailment [6][7][8]. Namely, they indicate that the spike-like machining marks cause an increase of traction during the running-in period as they plough into the rail material. Therefore, a smooth surface is recommended at the finishing of wheel machining sometimes [6][8]. On the other hand, there is another opinion that mentions that the traction force is increased with the deformation of machining marks and increase in real contact area [4], which means that adhesion predominantly affects the increase. Though the mechanism for the traction behaviour during running-in has not been clarified well, there are experimental results using a twin-disk test machine to investigate the influence of the surface texture on the traction characteristics as follows.

Yamamoto *et al.* reported that the traction coefficient of the interface between wheel tread/top of rail could be reduced by optimizing the texture using twin disk tests [9][10]. They indicated that application of these textures to a wheel during turning might reduce the risk of derailment. Therefore, there is a possibility to optimize the surface treatment of wheels by the use of the existing re-profiling equipment with more detailed investigation about the mechanism. Especially, which friction condition between wheel flange/rail gauge corner contact would relate best to the wheel climb derailment. Lundmark *et al.* carried out some case studies of frictional behaviour using different initial roughness and reported that the combination of a rough wheel disk and a smooth rail disk showed the lowest traction coefficient [11]. As a possible reason, the influence of a small difference in the hardness of the work hardened layer of a rough wheel was indicated. However, it has to be confirmed. To control the traction characteristics and provide a better solution to the flange climb derailment, understanding the behaviour at the interface of wheel/rail during the running-in period and generalizing the model is important.

It is well known that the transitions in frictional behaviour during running-in are influenced by not only the change in surface topography. They can also relate to changes in surface composition, microstructure and third-body layer, depending on the environment [12]. Baek *et al.* reported that the work hardening and tribochemical reactions near

the surface affect the transition of the traction coefficient differently between dry and wet conditions [13][14][15]. The aim of this work was to investigate the effects of applying surface texture on traction characteristics during the running-in period and to analyze the tribological mechanisms causing the effect under dry conditions. The tests were carried out using a twin-disk machine. Conditions that simulated the wheel flange/rail gauge corner contact were used. After the tests, the used disks were investigated using a contact-type roughness meter (Surfcorder SE3500, Kosaka Laboratory Ltd.), a micro-Vickers hardness testing machine (Durascan, Struers), optical microscope (Axio Observer, ZEISS), a SEM (Tabletop Microscope TM3030Plus, Hitachi High-Technologies) and an XPS surface analysis instrument (Supra, Kratos Analytical). The wear debris generated during the test was also collected and the amount was investigated. Finally, mechanistic modelling was presented to explain the effect of surface texture. These findings might inform rail service providers about optimal wheel profiling methods and surface treatments to reduce the likelihood of wheel climb derailments.

2. Methodology

2.1. Apparatus

Figure 1 shows a schematic diagram of the twin-disk rolling-sliding test machine [9][10][13][14][15], which is equipped with a small wheel disk and rail disk, and Table 1 shows the performance of the experimental apparatus. The wheel disk and the rail disk are connected to separate servomotors. These motors rotate independently and the slip ratio between the disks is prescribed by setting different rotational speeds for each motor. The braking motor is supported by a linear guide that can move in the axial direction. The vertical load is applied to the test disks by use of a coil spring.

Table 1 *Performance of the experimental apparatus.*

Rotational speed (rpm)	0~4000
Vertical load (kN)	0~0.5
Slip ratio (%)	0~5
Angle of attack (°)	-3 to +3

2.2. Test disks

Figure 2 shows the shape and dimension of the test disks. They were cut from actual railway wheels and rails; SSW-Q3S (JIS E 5402) and 50N (JIS E 1101) for the wheel and rail, respectively. In order to simulate the wheel flange/rail gauge corner contact, the wheel disk was made to be a “conical” shape and the rail disk was made to be a “crowned” shape. The shape was designed to have the same radius, 30 mm, at the contact point. Figure 3 shows the surface profiles of the test disks which were obtained using a contact-type roughness meter. Three different types of wheel disks were prepared through surface finishing operations. Disk-A is the most smooth surface which was acquired by grinding. Since the railway wheel is generally re-profiled by use of a machining tool, the micro textures on disks B and C created using this technique; 0.5 mm/rev and 1.0 mm/rev tool pitch were used for disk-B and disk-C, respectively. The direction of machining was parallel to the direction of disk rotation. This means that the machining marks were oriented across the direction of rotation to simulate the actual machining situation of the wheel. Rail disks had just one type of surface which was acquired by grinding. Table 2 shows the characteristics of disk surfaces. The roughness values were obtained using a roughness meter.

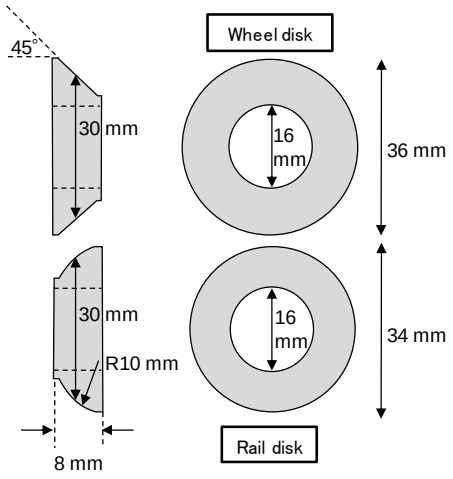

Figure 2 *Shape and dimension of test disks*

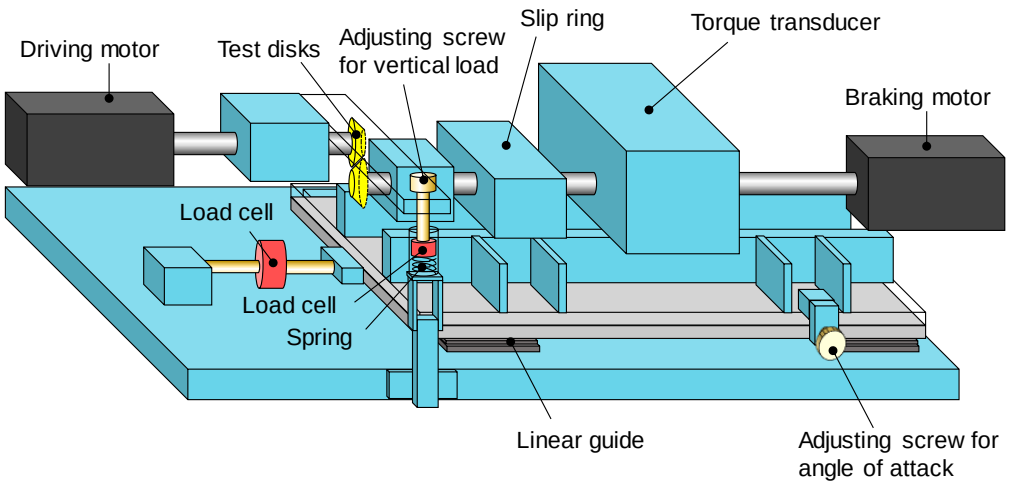

Figure 1 *Schematic diagram of the twin-disk rolling-sliding test machine.*

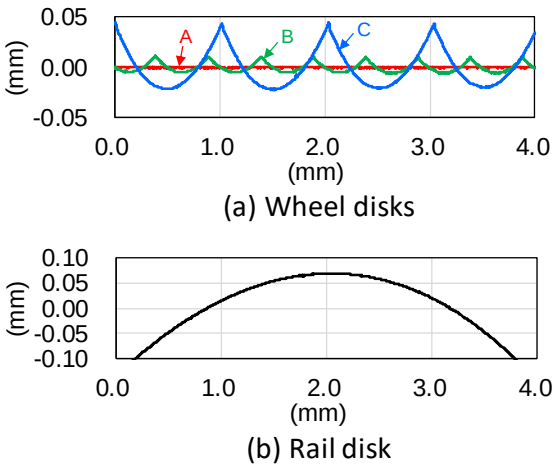

Figure 3 *Surface profile of test disks*

Table 2 *Characteristics of disk surface*

	Pitch of machining (mm)	Ra (μm)	Pz (μm)
Wheel disk-A	-	0.2	2.2
Wheel disk-B	0.5	3.5	16.7
Wheel disk-C	1.0	6.2	67.1
Rail disk	-	1.1	-

2.3. Test procedure

Table 3 shows the experimental conditions. In general, the Hertzian maximum contact pressure at the wheel flange/ rail gauge corner is up to 2700 MPa [16]. Accordingly, the standard contact pressure was set at 2200 MPa. The standard speed was set at 0.16 m/s; this was done to avoid resonance in the experimental apparatus. From the considerations of the contact situation at the wheel flange/rail gauge corner, the standard slip ratio and angle of attack were set at 2% and 1°, respectively. These values were defined by the results of preliminary simulations of a derailment.

Table 3 *Experimental conditions*

Rotational speed (rpm / m/s)	100 / 0.16
Vertical load (kN) / Hertzian maximum contact pressure (MPa)	0.3 / 2200
Slip ratio (%)	2
Angle of attack (°)	+1

The surfaces of the test disks were washed with petroleum ether in an ultrasonic washing vessel before the experiments to remove contaminants such as oil and dust. Figure 4 shows a set of wheel and rail disks after attachment on the experimental apparatus. In the experimental apparatus vertical load V and lateral load L were measured; but for detecting the traction coefficient in the lateral direction, these were used to determine the normal force N and the lateral tangential force F_y with the following equations:

$$N = V\cos\alpha + L\sin\alpha, \quad (1)$$

$$F_y = V\sin\alpha - L\cos\alpha \quad (2)$$

where α is the contact angle (45° in this experiment).

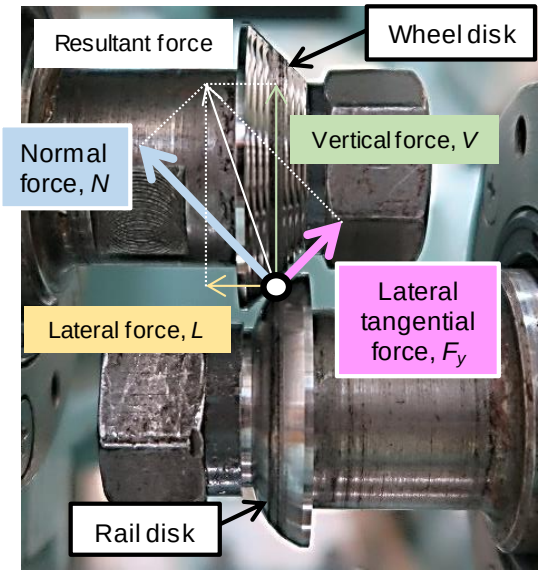

Figure 4 *A set of wheel disk and rail disk after attaching on the experimental apparatus*

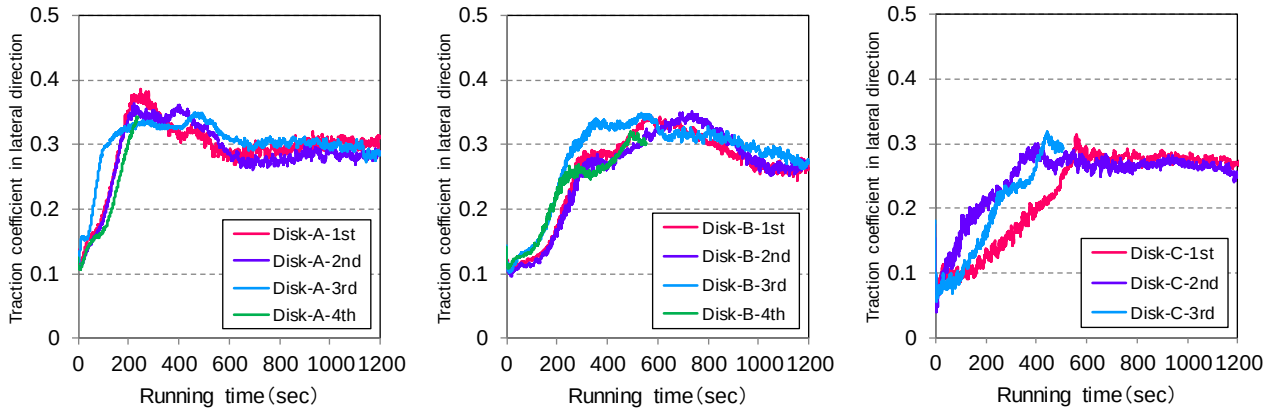

The surface profile was measured at different stages, the detail of stage is to be mentioned in next section, using an optical surface measurement system that had a vertical resolution of 50 nm and a contact-type roughness meter that had a vertical resolution of 200 nm. For the quantification of the plastic deformation by means of hardness, HV0.05 hardness profiles were performed from the deformed near-surface zone into the bulk using a micro-Vickers hardness testing machine. The metallic structures of cross sections were observed by an optical microscope and FEG-SEM with EBSD. Acceleration voltage of SEM and EBSD was 20 keV and spot size was 5 μm. The chemical component on the surface was analyzed by an XPS surface analysis instrument with the monochromated aluminium source.

3. Results

3.1. Effect of initial surface texture on traction coefficient

Figure 5 shows the change of traction coefficient in the lateral direction with running time. The tests were carried out three or four times at the same condition. It was found that the change of traction coefficient depends on the initial surface texture. The rougher the initial surface profile was, the smaller the peak value of traction coefficient was. Figure 6 shows the schematic patterns of the traction coefficient curve in Fig. 5. “Stage-I” means the condition before the test, “stage-II” means the condition around the peak of the traction coefficient and “stage-III” means the condition after the test. The rougher the initial surface profile was, the longer time took to reach the peak value.

Hereinafter, the analysis of the disks for each characteristic stage (I, II and III) were carried out. Here, the analysis for stage-II was carried out by discontinuing a test after confirming the reproducibility of the change of traction coefficient.

(a) Wheel disk-A *(b) Wheel disk-B* *(c) Wheel disk-B*

Figure 5 *Change of traction coefficient in the lateral direction with running time*

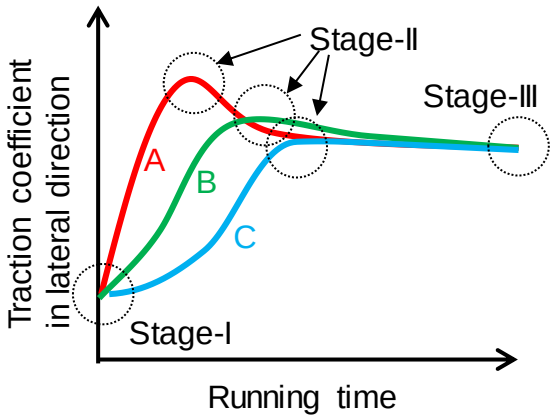

Figure 6 *Schematic patterns of the traction coefficient curves in Fig. 5*

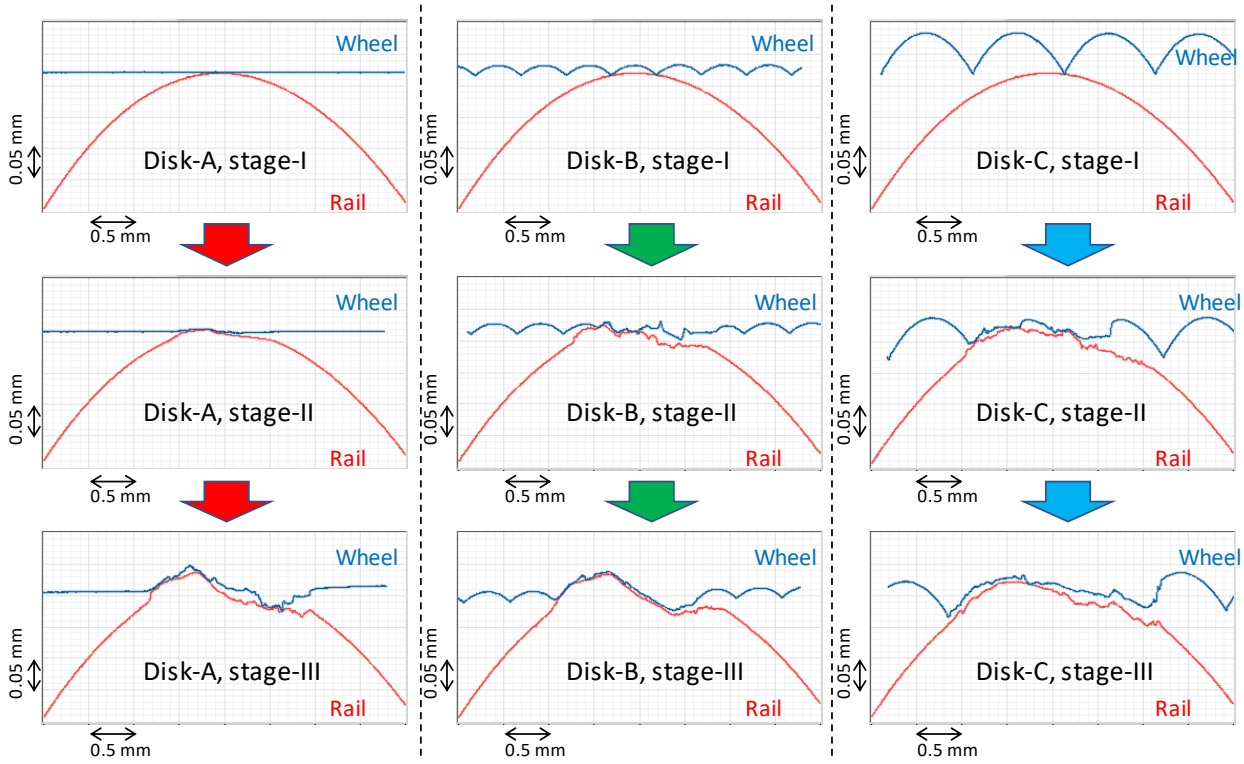
3.2. Surface texture

Figure 7 shows the change of surface topography of wheel disk-A and rail disk for each stage which was obtained using a contact-type roughness meter. It is clearly shown that the surface deformation increased with the progress of stage and the direction of plastic flow corresponded to that of lateral tangential force. The initial ridges of disk-B and disk-C were almost made flat at stage-II. Though disk-B and -C seem to increase in conformity with the progress of the stage, the surface of disk-A at stage-III seems to be rougher than that at stage-II. Stage-III seems to show that there is no significant difference on the surface shape and it indicates that all disks settle in the similar surface texture after running-in.



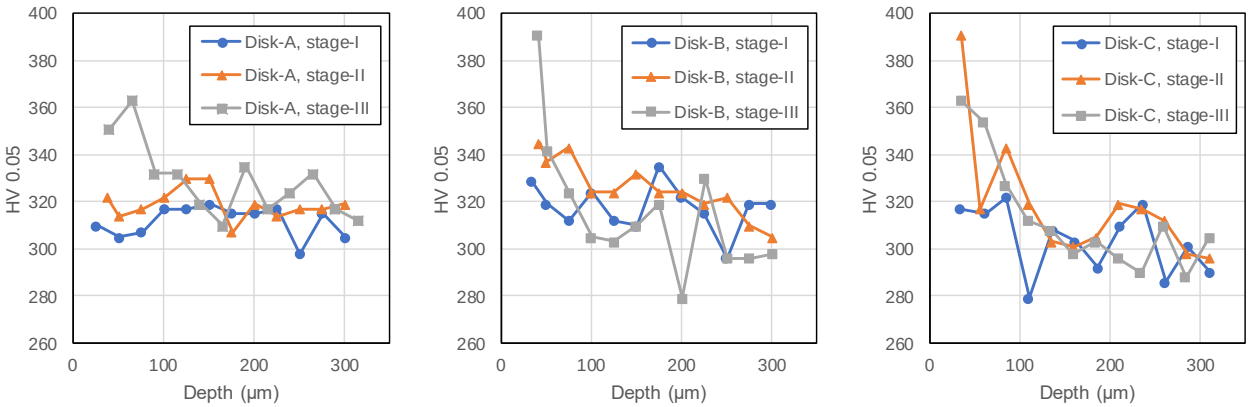


Figure 7 *Surface profile of test disks for each initial surface profile and stage.*

(a) *Wheel disk-A* ***(b)*** *Wheel disk-B* ***(c)*** *Wheel disk-B*

Figure 8 *Depth profile of hardness of test disks for each initial surface profile and stage.*

3.3. Hardness

Figure 8 shows the depth profile of hardness of test disks for each initial surface profile and stage. Comparing depth profiles of all disks at stage-II, it was found that the largest increase of hardness near the surface was on disk-C followed in order by disk-B and disk-A. The cause for the increase for the disk-C and disk-B seems to be the larger plastic deformation of the ridges which will be followed by work-hardening, than for disk-A, because the higher ridges are more easily deformed.

3.3. Metallic structure

Figure 9 shows the metallic structures observed by optical microscopy for each initial surface profile and stage. It is clearly shown that the plastic deformation was increased with the progress of stages for all disks. At stage-II, the depths of plastic flow (white arrows) of disk-B and disk-C were approximately 70 μm. On the other hand, that of disk-A would not be clearly seen beneath the surface. There was no difference among the disks at the point of stage-III, the depth of plastic flow of disk-B and disk-C were approximately 100 μm and that of disk-A was 90 μm. These appearances correspond to the results of the depth profile.

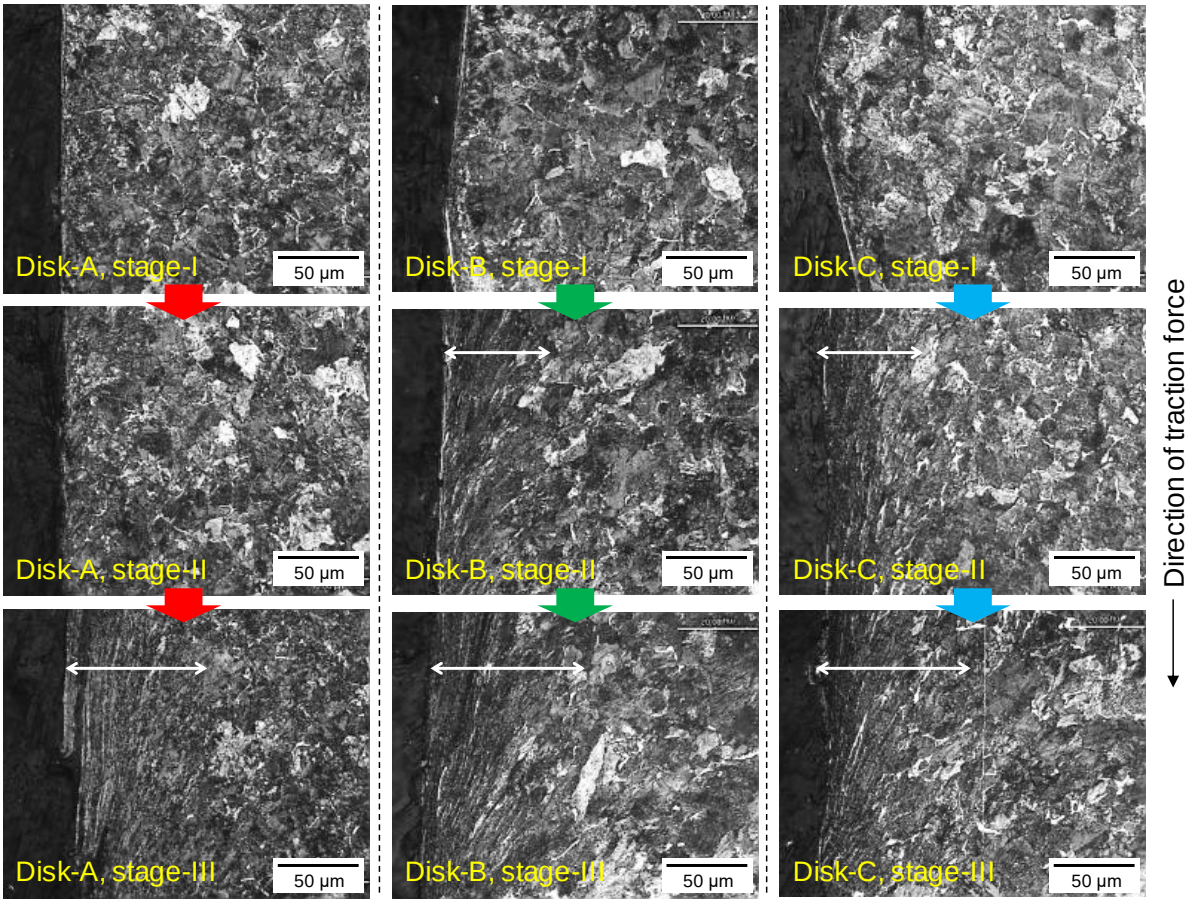

Figure 9 *Metallic structures measured by optical microscope for each initial surface profile and stage.*

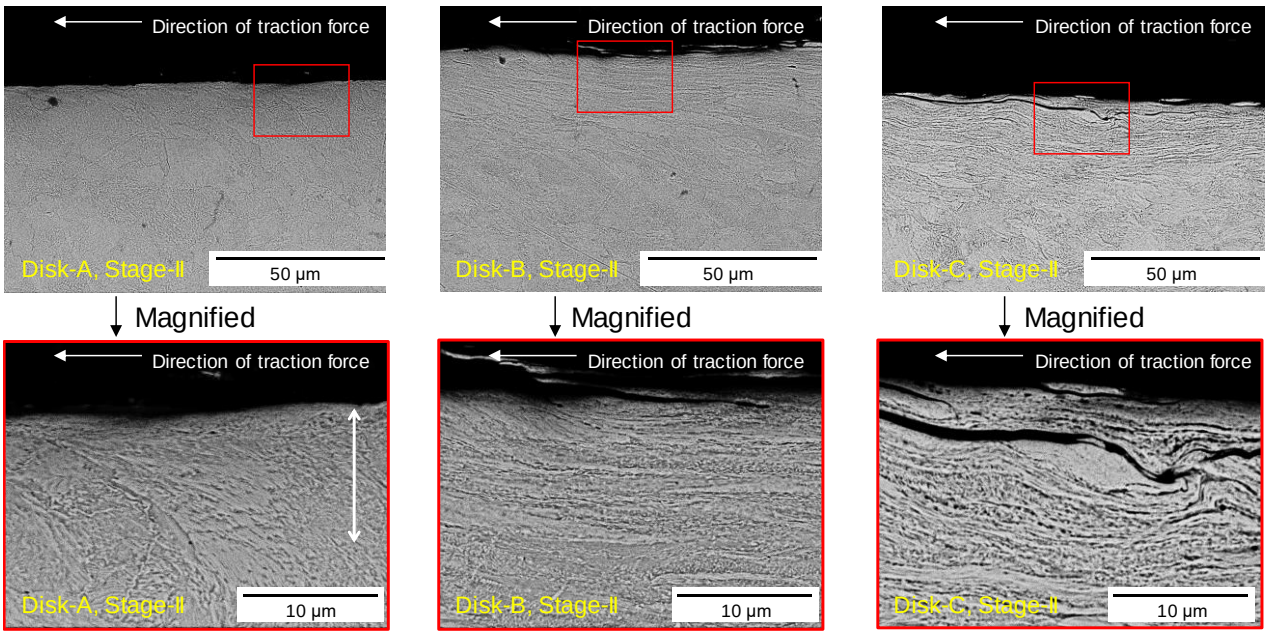

Figure 10 *Sub-surface SEM images for wheel disks at stage-II.*

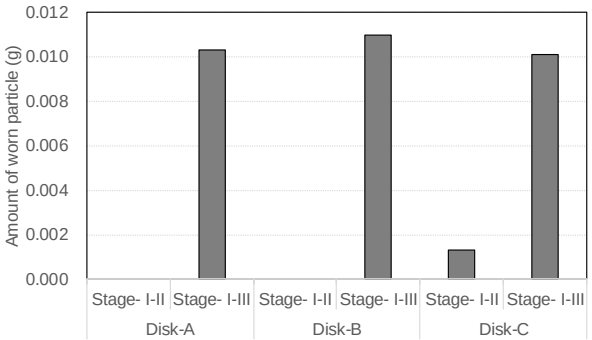
Figure 10 shows the sub-surface SEM images for wheel disks at stage-II. It was found that all disks generated plastic flow in the direction of the traction force, even in disk-A which was not confirmed in Fig. 9. However, the thickness of the layer which was affected by plastic flow of disk-A was significantly thinner than that of disk-B and disk-C. Although there was no significant difference of hardness in disk-A at stage-II in Fig. 8 because the layer was too thin, it is considered that the increase of hardness was generated at the top-surface. The depth of plastic flow (white arrow) of disk-A was approximately 10 μm

3.4. Amount of wear particles

Figure 11 shows the amount of wear particles created during experiments which were captured under the disks. These results show that there was almost no generation of wear particles between stage-I and stage-II and a large amount was generated between stage-II and stage-III. It would indicate that the surface roughness was deformed plastically until completing the conformation of surfaces and the adhesive wear started after that. There is almost no difference in the amount of wear particles throughout the experiments, from disk-A to disk-C.



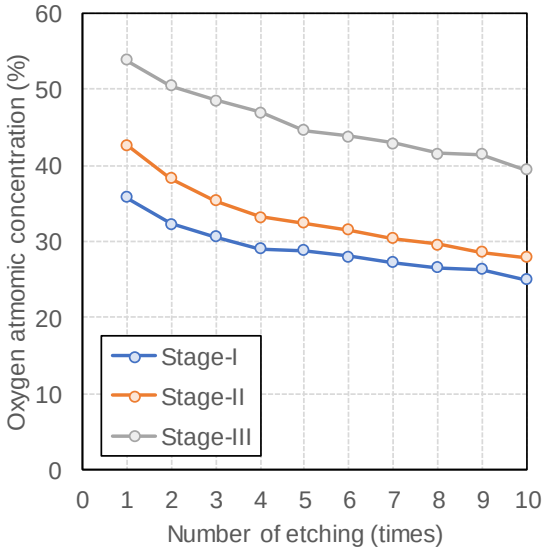


Figure 11 *Amount of wear particle during experiment which was caught under the disks.*

3.5. Chemical composition

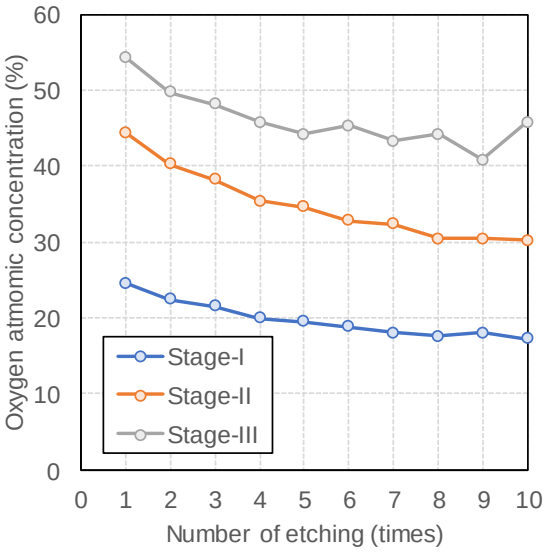

Figure 12 shows the depth profile of the oxygen concentration to iron concentration for each initial surface profile and stage. The depth profiles were collected from the same area. An Ar500+ at 20 keV source was used to etch away the surface for 300 seconds, and then restricted high resolution scans were collected over the O 1s and Fe $2p_{3/2}$ regions. This was repeated 10 times to build up a profile. The Ar500+ source at 20 keV has been shown to have an etch rate of 8.3 nm/min through Ta_2O_5 on Ta.

There was a slight difference in the oxygen concentration profile of each initial surface profile at stage-I and it is thought to be caused by a scattering of initial condition. However, there was no difference at stage-II and -III. It indicates that the oxidation state became similar soon after starting the test and progressed in the almost same way during each test. There is a tendency for the oxidation to increase with the progress of the test.

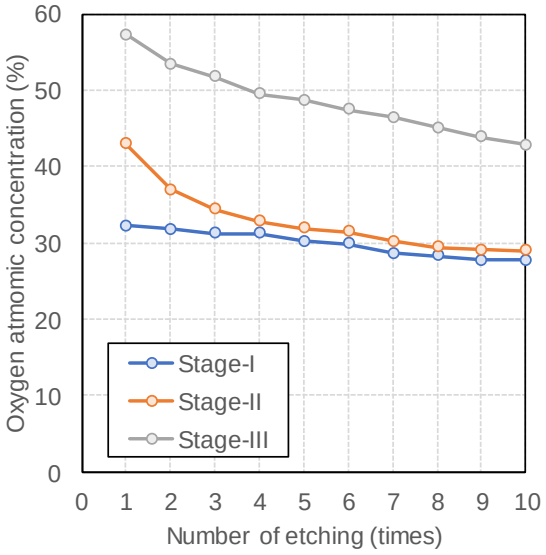

Figure 14 shows the high-resolution Fe 2p spectrum for the wear track on samples for stage-III. The iron oxide can be distinguished by the peak positions within the Fe 2p high resolution spectra, and also by the presence and position of additional satellite peaks [17] which generates by the excitation of outer-shell electron following the excitation of the core electron. Fe_3O_4 is not expected to show a satellite feature whilst Fe_2O_3 is expected to show a significant feature at 719 eV. Regarding the Fe $2p_{3/2}$ XPS peak positions, this peak is expected at 711.0 eV for Fe_2O_3, 710.6 eV for Fe_3O_4 and approximately 709.0 eV for FeO. Fe metal is expected at approximately 706.7 eV. The Fe 2p spectra shown here for the wear tracks appear to show little or no satellite features, suggesting the oxide is predominantly Fe_3O_4 and this is consistent with the Fe $2p_{3/2}$ peak position at approximately 710.6 eV for these samples.

4. Discussion

The results of the twin-disk tests which simulated the wheel flange/rail gauge corner contact showed that the machining pitch of the wheel strongly influences the traction characteristics during the running-in period. The larger the machining pitch was, the smaller peak value of traction coefficient was. These results agree with the previous twin-disk results which simulated the wheel tread/top of rail contact [10].

As the results of microstructural analysis show, the evolution of plastic flow was found on every type of specimen around near-surface region with the progress of the stages. At stage-II, the samples which had a longer machining pitch showed a deeper range of plastic flow beneath the contact point. Corresponding to this evolution of plastic flow, the depth profile of the hardness indicated that the long pitch surface generated more significant work hardening than the grinned surface. Figure 14 shows a schematic model of the effects of surface texture on traction characteristics during the running-in period.

From stage-I to stage-II, the surface asperities were deformed plastically, therefore the resistance of plastic flow was dominant on the tangential force. The fact that the amount of wear particles was extremely small between stage-I and stage-II indicates that the plastic deformation of the surface asperities and textures was proceeding in advance of the generation of the wear particles. It is known that the presence of significant flow in bulk gives a saturation of coefficient of friction with the increase of contact pressure [18][19][20]. Here, disk-B and disk-C, which had a machined surface, produced higher contact pressure than disk-A because of their conformational factor and suppress the increase of traction coefficient. Comparing metallic structures of all kinds of disks at stage II, it was found that disk-A had a quite small magnitude of plastic flow compared with disk-B and disk-C. It is thought that disk-B and disk-C were more easily plastically deformed and shake-down settled down earlier than disk-A.

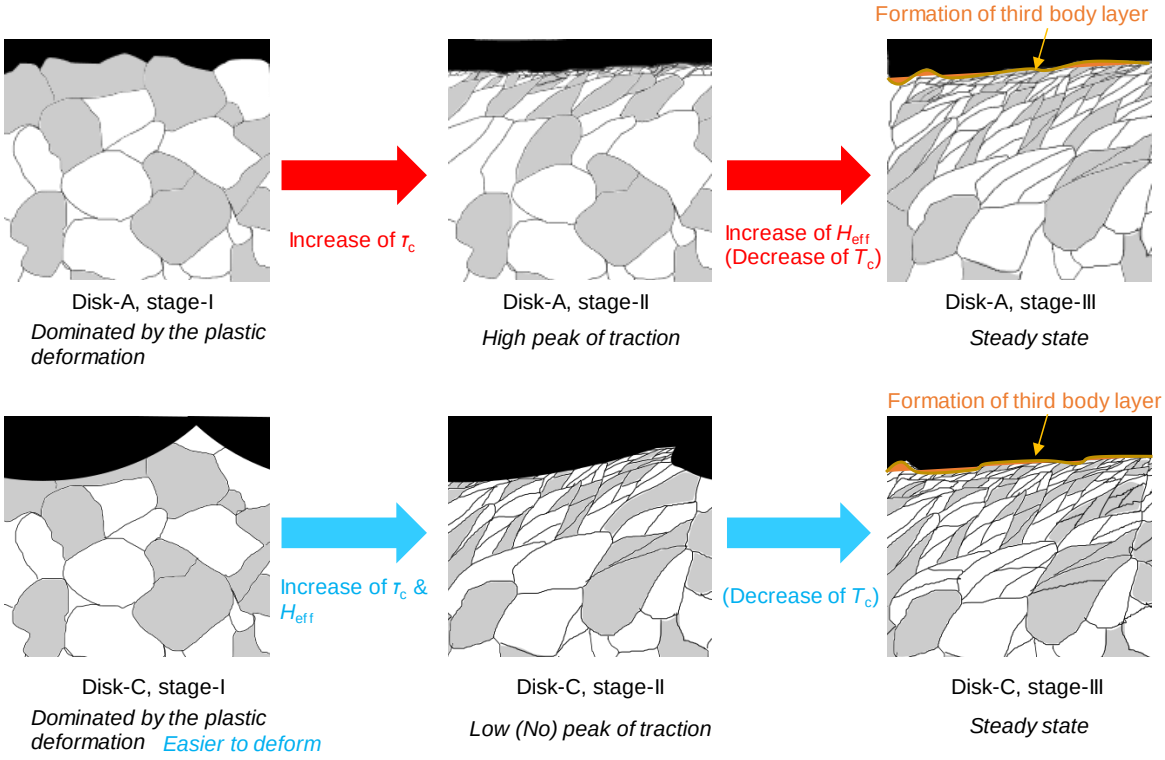

Figure 14 *Schematic model of the effects of surface texture on traction characteristics during the running-in period.*

From stage-II to stage-III, the traction coefficient decreased in the case of disk-A and slightly decreased and maintained in the case of disk-B and disk-C, respectively. In order to discuss the phenomenon, the Bowden-Tabor model on boundary friction [21] was applied as same as used by Halling [22] and Baek *et al.* [13]. Since the cycle of shake-down changed the interfacial condition from a plastic contact to an elastic contact, the traction coefficient can be expressed by the following formula with the concept of adhesion [13]:

$$\mu = \frac{\tau_c}{H_{eff}} \qquad (3)$$

where, τ_c is the shear strength of the contact interface and H_{eff} is the effective hardness. The effective hardness is the hardness involving the surface layer and it is different from the hardness of either the layer or substrate material. The effective hardness depends on the thickness of the surface layer and it closes to the layer hardness with the increase of thickness. In the case of disk-C (and B), (i) the plastic deformation near the surface dramatically evolves and the thick plastic flow layer is quickly formed between stage-I and stage-II, (ii) traction coefficient make a settlement with the high τ_c and H_{eff} between stage-II and stage-III. On the other hand, in the case of disk-A, (i) plastic deformation relatively slowly progresses and the thin plastic flow layer is formed between stage-I and stage-II, (ii) traction coefficient shows high value because of high τ_c and low H_{eff} and it decreases with an additional evolution of plastic deformation, which increases H_{eff}, between stage-II and stage-III.

Moreover, the generation of a third-body layer, which is consisted of oxides such as magnetite, was another factor to make a reduction in traction coefficient for all disks. It has been reported that the existence of third body layer would influence the traction characteristic [23] and especially magnetite could work as a self-lubricated film and prevents the increase in traction coefficient [15][24].

5. Conclusions

Investigations of a twin-disk test machine revealed a tribological phenomenon between textured wheel and rail materials during running-in period. The results of experiments and analysis are summarized as follows:

1. The twin-disk tests, which simulated the wheel flange/rail gauge corner contact, showed that the machining pitch of wheel strongly influences the traction characteristics during the running-in period. The larger the machining pitch was, the smaller peak value of traction coefficient was.
2. The microstructural analysis around the near-surface region of the characteristic stages, such as before test (stage-I), around the peak point of traction coefficient (stage-II), after test (stage-III), showed evolution of plastic flow was found on every type of specimen with the progress of stages.
3. At stage-II, the samples which had a longer machining pitch showed a deeper range of plastic flow beneath the contact point. Corresponding to this evolution of plastic flow, the depth profile of hardness indicated that the long pitch surface generated more significant work hardening than the unmachined surface.

Based on the above results, a mechanistic model of the effects of surface texture on traction characteristics during running-in period was proposed. It is considered that the major factors causing a decrease in the transient traction coefficient are plastic deformation of the surface texture. And the difference of peak value was generated by the difference of the depth of plastic flow. Above results indicate that there might be an appropriate texture or surface treatment to reduce the risk of flange climb derailment during running-in.

Abstract:
We have developed a measuring wheel that can identify the contact point of the wheel tread on the rail. This measuring wheel has strain gauges attached to the wheel web to detect the strain of wheel distortion by applied vertical force. From the comparison of the results of the static loaded test, the FEM analysis and the bench test, it is considered that the contact point of wheel tread is identified accurately from this measuring wheel. By this measuring wheel we can find the curving performance of a bogie by finding bogie state of four wheel contact points on the rail.

Keywords: wheel/rail contact point, curving performance, L/V or Y/Q or Q/P, wheel set

P and Q are defined as follow. The derailment coefficient is expressed as Q/P, which is same as Y/Q or L/V.

1. Introduction

There are many small radius curves in Tokyo subway. For this reason, various measures such as introducing radial steering bogie and applying friction modifiers and grease have been taken for railway vehicles to improve the running performance. In order to evaluate the curving performance which is improved by these countermeasures, it is very important to measure the contact point between the wheel and the rail in Figure 1. However, there are few methods for measuring the contact point [1] [2] [3]. Therefore, in this research, the authors propose a method to measure the contact point of wheel on the rail. Also, based on this measurement result, the curving performance of the vehicle can be evaluated.

2. Concept of measuring contact point

The authors obtained following investigation results by the previous study. It is shown in Figure 2 which shows the strain contour of the wheel surface when the vertical force is applied to the special wheel, for measuring the vertical force and the lateral force, obtained by FEM.

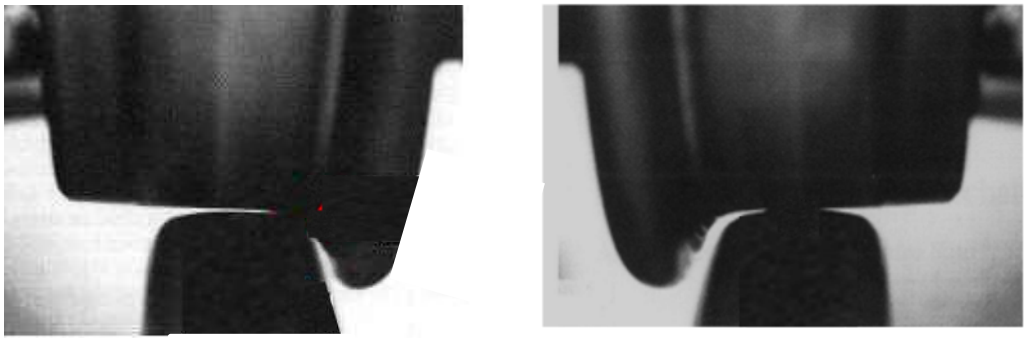

Figure 1 *Example of contact point between wheel and rail*

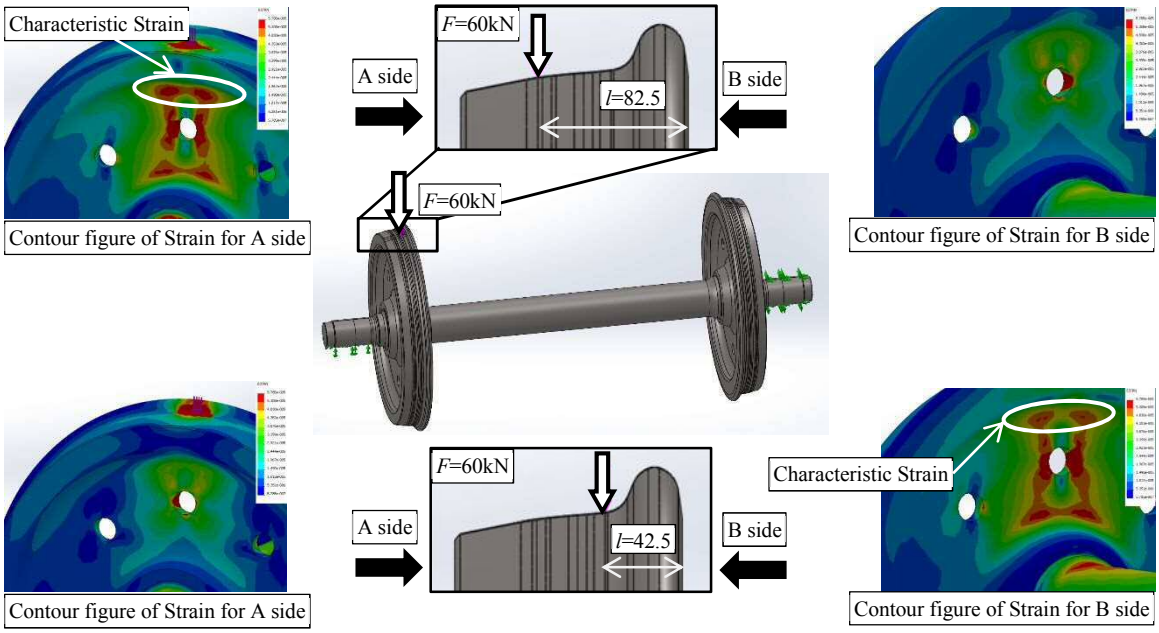

Figure 2 *Contour figure of Strain as the result of Wheel and Axle FEM*

When the load of 60kN is applied as a vertical load to the 82.5mm positon from the flange side, significant strain was produced on the front side (A side) of the wheel web, and small strain on the back side of it (B side).
On the other hand, when the load of 60kN is applied as a vertical load to the 42.5mm position from the flange side, small strain was produced on the front side (A side) of the wheel web, and significant strain on the back side of it (B side).
From this result, it is considered that the vertical force position, that is, the wheel contact point can be identified by measuring the amount of strain of the area between rim and web of wheel; means the white circle region at Figure 2.
Therefore the authors developed the following method of measuring wheel contact point.

3. Measuring method of contact point of wheel on the rail

To measure the contact point of the wheel, a special wheel set that can measures the lateral force and the vertical force acting on the wheel and rail is used. Because, these strains as mentioned above are also affected by the lateral force, it is necessary to investigate the influence beforehand. Therefore, strain gauges were attached at the boundary position between the rim and the web of the wheel to determine the contact point of the wheel (see Figure 3). Of these strain gauges, the strain gauge attached to the flange side is called ε_f, and the strain gauge attached to the anti-flange side is called ε_{af}. If the vertical force P_f acts on the flange side, ε_f has compressive strain and ε_{af} has tensile strain. On the contrary, vertical force P_{af} acts on the anti-flange side, ε_f has the tensile strain, and ε_{af} has compressive strain. As described above, these strains change on the contact point between the wheel and the rail. Therefore, by measuring the relation between strains obtained by these strain gauges and vertical force position on wheel tread in bench test, the authors can confirm the wheel contact point.
A new strain gauge is attached to this special wheel set, and the effect of lateral force and vertical force on this strain is also evaluated. That is, if the influence

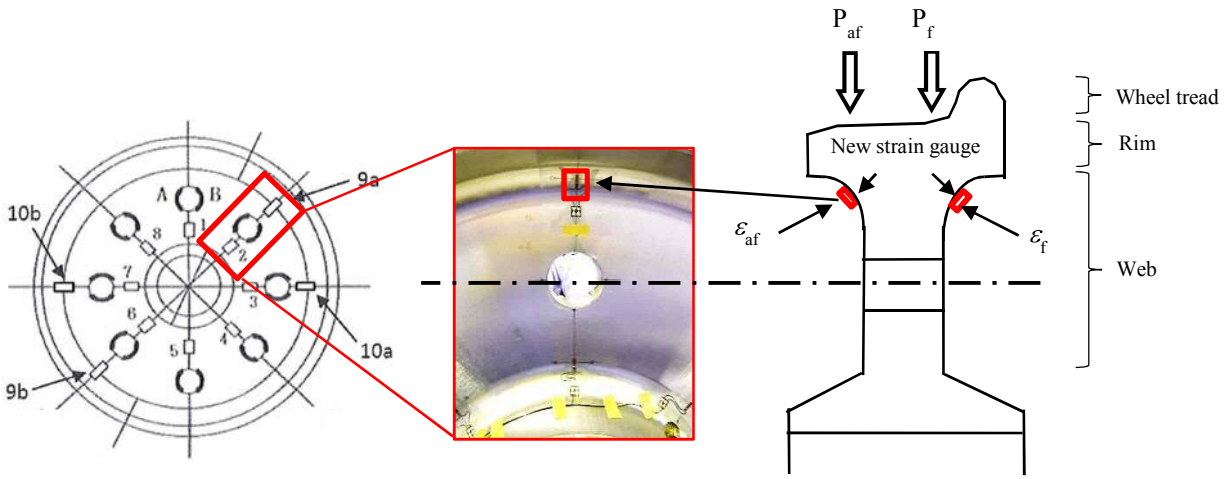

Figure 3 *Strain gauge for measuring contact point of wheel with gauges for lateral force and vertical force*

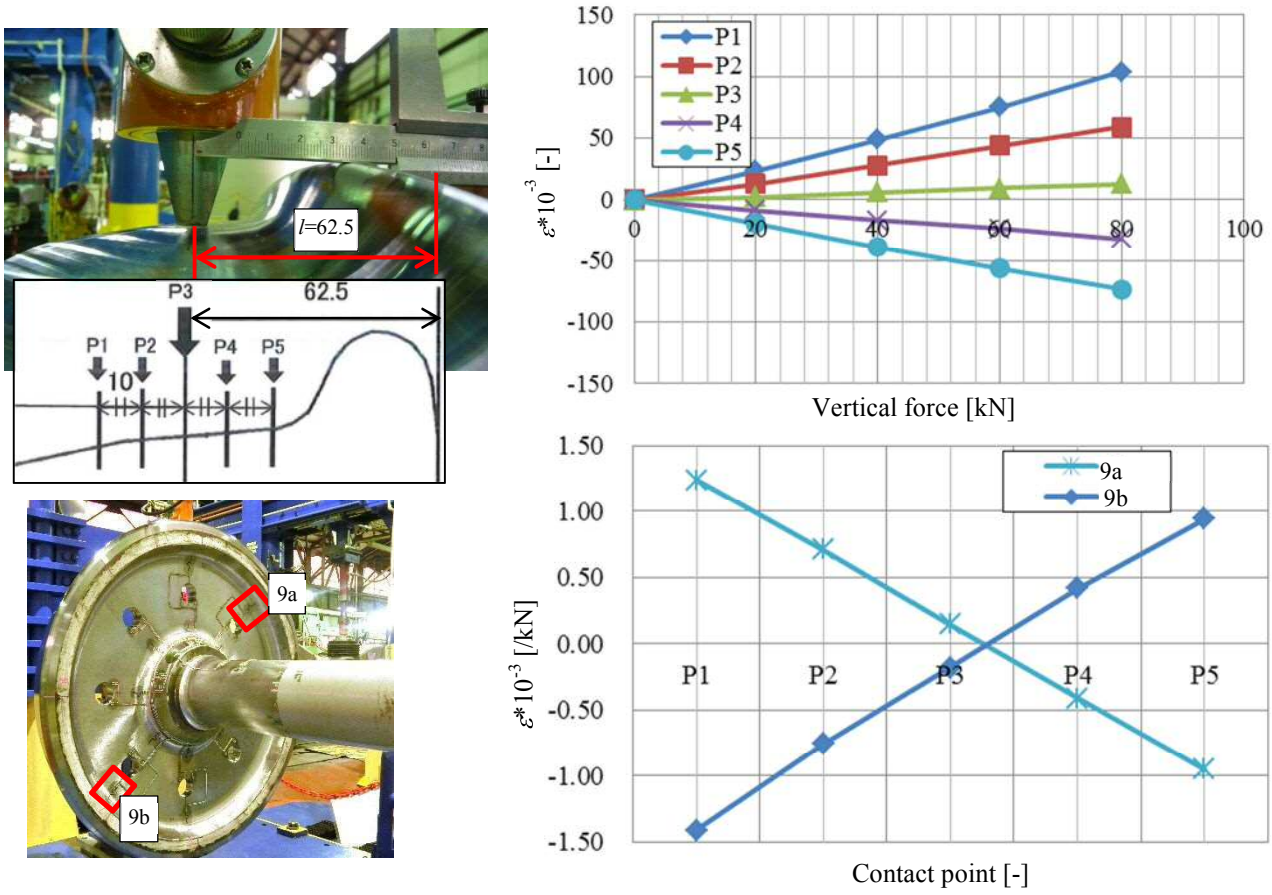

Figure 4 *Effect coefficients of lateral force and vertical force to strain for measuring wheel position*

coefficient of the vertical force (P) to this strain α and the influence coefficient of the lateral force (Q) is β, it can be expressed as Eq. (1). (*P and Q are defined as follow. The derailment coefficient is expressed as Q/P, which is same as Y/Q or L/V.*)

$$\varepsilon = \alpha(x) \cdot P + \beta \cdot Q \qquad (1)$$

Therefore, if a lateral force or a vertical force is added to the wheel beforehand, influence coefficients for this strain are obtained in advance.
The contact point of the wheel can be obtained by measuring the lateral force and the vertical force obtained in business line with the Eq. (1).

$\alpha(x)$ as the influence coefficient of the vertical force to wheel contact strain (ε) is a linear function of the wheel contact point x as show in Figure 4. That is explained as Eq. (1). Therefore, from Eq. (1) and (2), the contact point x is obtained as shown in Eq. (4).

$$\alpha(x) = ax + b \qquad (2)$$

From Eq. (1)

$$\varepsilon = (ax + b) \cdot P + \beta \cdot Q \qquad (3)$$

From Eq. (1) and (2)

$$x = \left(\left((\varepsilon - \beta \cdot Q)/P\right) - b\right)/a \qquad (4)$$

4. Prediction of strain generated on the wheel web by FEM analysis

FEM analysis was carried out to predict the influence of the contact point of the wheel on the strain of the wheel web. Fig.5 shows the FEM model of the wheel, vertical force loading position and the generated strain measurement position. The position of attachment of the strain gauge obtained from the FEM analysis result of Figure 5 is shown. The measurement position of the strain gauge are ε and ε' in Figure 6 and this figure shows the results of FEM analysis and static load test on the strain in ε, ε' part.

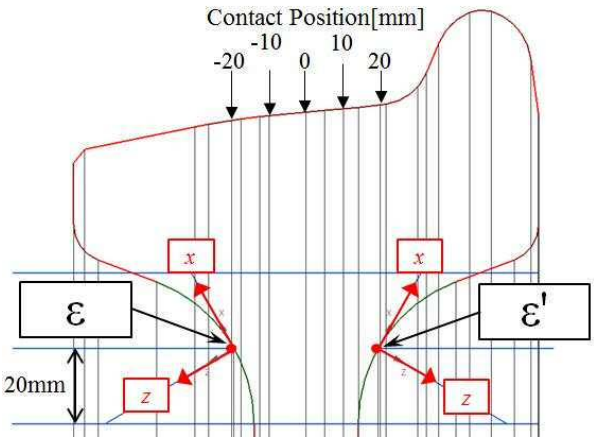

Figure 5 *Positon of applying vertical force on the wheel*

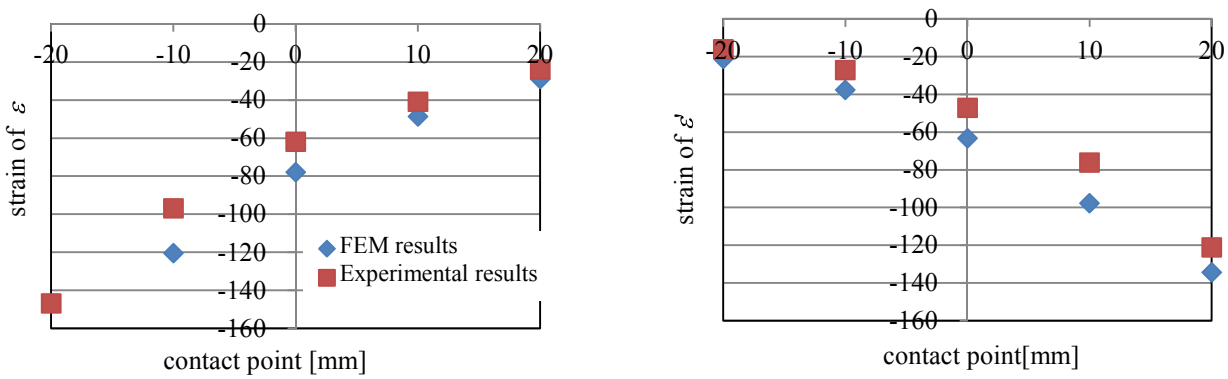

Figure 6 *Comparison of experimental and FEM strain by applying vertical force*

From the figure, the strain obtained from the FEM analysis result was almost the same as the strain generated by the static load test. From this result, it is understood that the strain obtained by the static load test continuously changes with respect to the contact point, and the wheel tread contact point can be accurately evaluated.

5. Validation by the bogie test stand

Figure 7 shows the bogie test stand used for verification. This testing machine can simulate a curved state, such as setting the attack angle between bogie and track and controlling rolling speed difference between right and left rolling according to the running distance difference between inner and outer rail. Track and bogie conditions are shown in Table 1. The bogie has the same structure as the bogie used for the service line (Figure 8).
Figure 9 shows the contact point of the wheel measured when the bogie is running straight line. Because the bogie is running on a straight line, there is no significant change

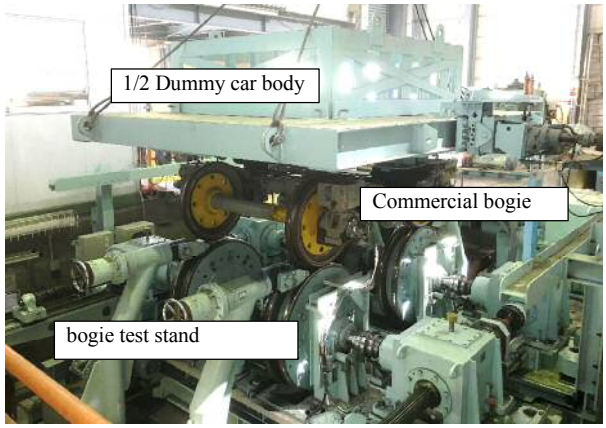

Figure 7 *Structure of bogie test stand*

Figure 8 *SS030 with the measuring wheels*

Table 1 *Test conditions and specifications of rail and bogie*

Running velocity	20km/h
Curve radius	600,400,300,250,200,160m

Gauge widening	10mm
Rail profile	50kgN
Experimental bogie	Mono link type axle box, without a bolster
Wheel base	1900mm
Wheel tread profile	Arc; profile tread suitable to sharp curve used in Tokyo metro

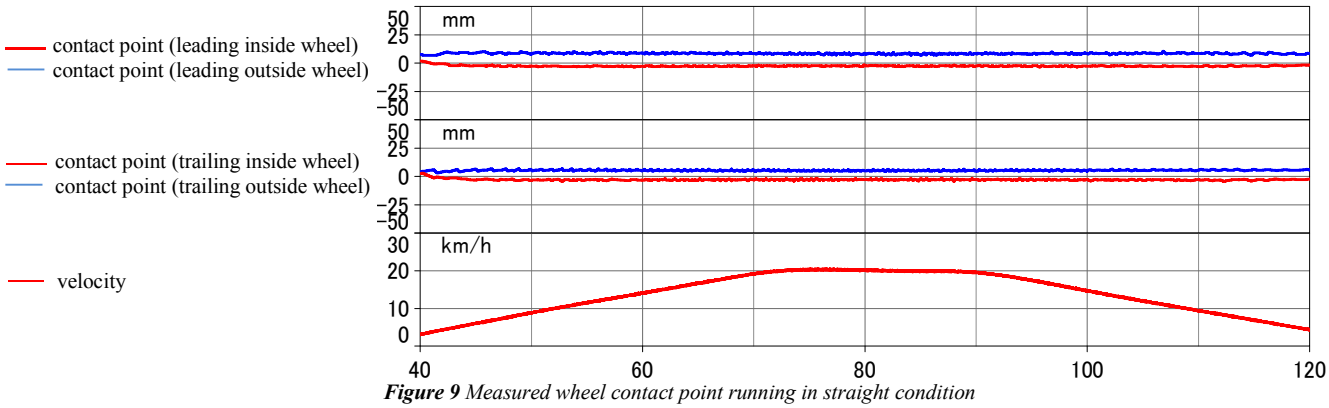

Figure 9 *Measured wheel contact point running in straight condition*

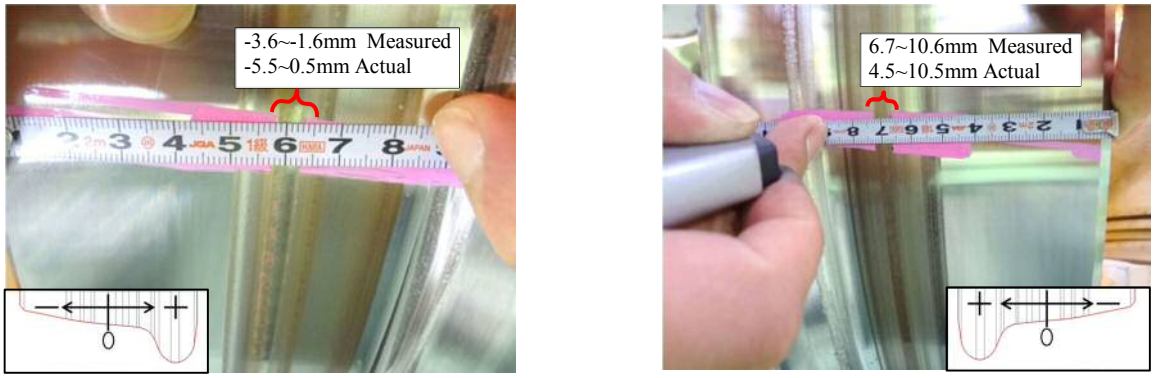

Figure 10 *Comparison of wheel contact point actual and measured*

in the contact point of the wheel. Also, Figure 10 shows the running trace of the wheel tread by painting before testing. For comparison, the contact point measured by the method developed this time is shown in the same figure.

As the result, the actual condition of the contact point and that of the measurement are almost in agreement, and it became clear that the contact point of the wheel can be measured by the method developed this time.

6. Application of this study

6.1 Wheel contact point and radial steering force

The authors performed the bench test by using this special wheel sets. The results are shown in *Figure 11*. And *Figure 6* shows the contact point of each wheel schematically. In sharp curve, leading wheel on outside rail moves to rail gage corner and makes flange contact. On the other hand, the leading wheel on inside rail moves to the center of the rail. On the contrary, the trailing wheels stand on the center of the rail. In this condition, the leading wheel set generates steering force, and

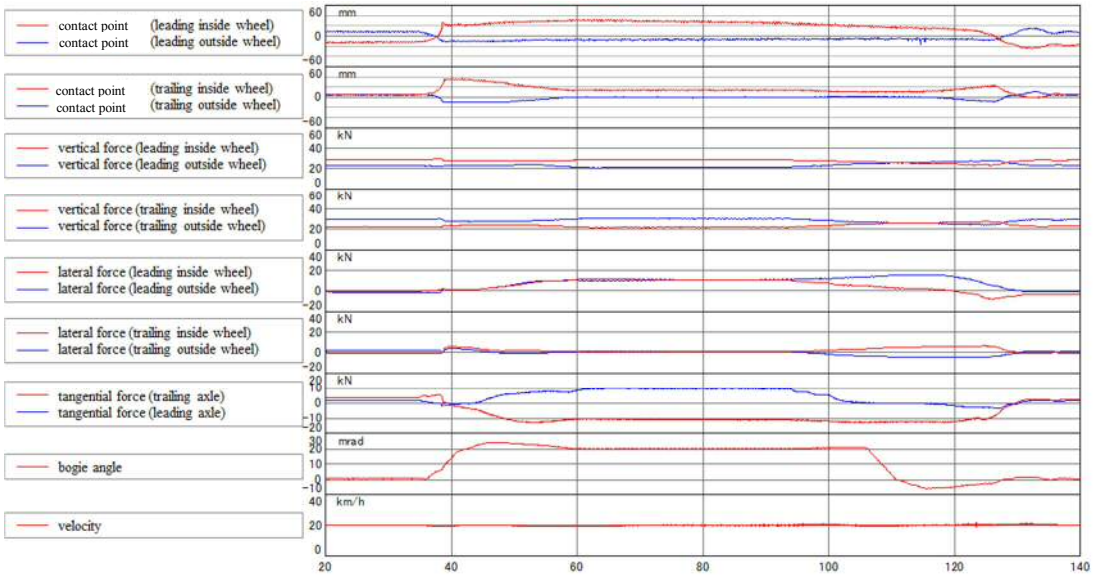

Figure 11 *Wave form of wheel contact point and several forces between wheel and rail*

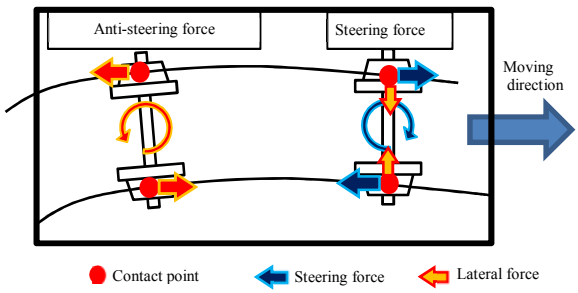

Figure 12 *Wheel contact point and Steering forces*

trailing wheel set generates anti-steering force. This anti-steering force produces lateral force of leading wheel on the outside rail.

6.2 Relationship between the radius of curvature and the contact point of the wheel

Another verification example of this research, the relationship between the radius of curvature, the position of the wheel and the force acting between the wheel and the rail was investigated. *Figure 13* shows the relationship between the radius curvature and the contact point of the wheel. In the sharp curve, the leading wheel flange contacts at rail gage corner with generation steering force and the trailing wheel contacts at the neutral position with generating anti-steering force. On the other hand, for the curve with a relatively large radius, it is understood that the leading wheel makes flange contact, but the rear wheel also moves to the rail gage corner.

As a result, it can be seen that no anti-steering force is generated on the trailing wheel. This condition reduces the lateral force of leading wheel.

7. Conclusion

Strain gauges capable of measuring the contact point of the wheel were attached to a special wheel that can measure lateral force and vertical force. Basic experiments were performed to find the relationship between lateral force, vertical force and wheel rail contact strain. Based on these relationships, the contact point of the wheel was determined.

As a result, it was found that the contact point of the wheel can be measured from a straight line to a curved line. Also, using these results, we can evaluate the curving performance of the bogie.

Abstract: Some type of wheel tread has the problems of serious wear on the part of wheel tread and flange, two point contacts and contact stress concentration, etc. In order to solve these problems and improve the wheel-rail contact condition, the shape of wheel tread should be redesigned. For a type of cone wheel tread, a new reverse optimal design method is used to increase the contact bandwidth and reduce the contact stress to solve these problems. The analysis results show that the designed wheel tread make the distribution of wheel-rail contact line more evenly and has a better dynamic performance on curve track.

Keywords: wheel-rail contact; wheel tread reverse design; equivalent conicity; Hertz contact; vehicle dynamic.

1. Introduction

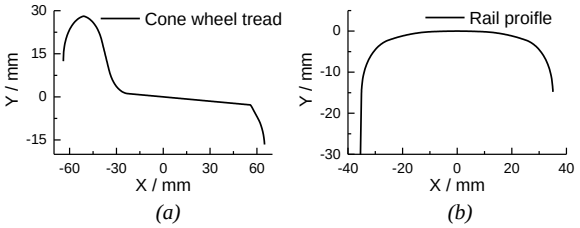
The wheel and rail are the most basic components in railway vehicle system, which play the role of carrying and guiding the vehicles on a track. In order to achieve the functions of vehicle‘s running and guiding, the wheels and rail have a complex shape. The wheel tread surface with a certain taper realizes vehicle‘s self-guidance on a curve track.

When vehicle running on track, wheel tread surfaces bear the full weight of vehicle and the adhesion in wheel-rail surface drive and guide the vehicle along the track to achieve vehicle’s tracking and braking. An ideal vehicle operating performance includes the better curve passing, derailment safety, running stability and safety, and those performance can be obtained by getting an optimal shape of wheel tread and rail surface [1].

At present, a standard wheel tread and rail surface are made up of straight segments and curve segments of diverse radius [2]. For the design of wheel tread shape, researchers did lot of works in the world and invented some design methods for different objectives and strategies.

Based on the measured shapes of wheel tread and rail surface, V. L. Markin [3], I.Y. Shevtsov [4] designed a new wheel tread according to rolling radius difference to get an optimal dynamics performance of vehicle. Hamid Jahed [5] used the information of rail surface and rolling radius difference to build an optimal model aimed at minimizing the error of the rolling radius difference, and verified the design result through dynamic simulation. G. Shen [6] provided a reverse design method of wheel tread according to the contact angle and rail surface, and developed a calculation program for this method. And he [7] also gave a design method aimed at the rolling radius difference. O. Polach [8] gave out a tread design method aimed at equivalent conicity. M. Ignesti [9,10] provided a worn tread design method according to the wear model. M. Novales [11] and J. Santamaria [12] proposed a tread shape optimization method using genetic algorithm.

Therefore, the methods of wheel tread design can be classified into different objects , such as rolling radius difference [3-6], contact angle [7], equivalent conicity [8], worn wheel tread profile [10,10,13] and track section [14], and genetic algorithm [11,12].



Since the wheel tread is restricted by the rail surface when wheelset is running on track, the wheel-rail parameters are not in continuous change under different wheelset lateral displacement, such as rolling radius difference, contact angle and equivalent conicity. Then the dynamic contact relationship of wheel-rail is complicated, and it is difficult to find an analytic expression for those parameters.

This paper presents a wheel tread reverse design method, which targeted at the rolling radius difference and the initial wheel-rail contact position, and builds an optimal model aimed at minimizing the error between the original and designed wheel tread profile to get an optimal design parameters. Under these parameters, a new optimal wheel tread profile can be designed though iterative numerical method.

Different from other related methods, this method not only can satisfy the rolling radius difference and wheel-rail initial contact position, but also can easy to control the designed wheel tread profile under different design parameters.

2. Wheel-rail contact characteristics of cone wheel tread

For a cone wheel tread and rail profile using in narrow track with rail gauge of 1m, the shapes of them are shown in figure 1.

(a) *(b)*

Figure 1 *The shape of wheel and rail profile: (a) Cone wheel tread. (b) Rail profile.*

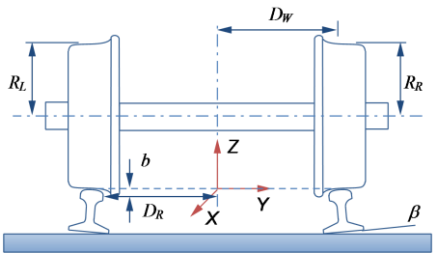


Figure 2 *Wheel-rail geometry parameters*

Wheel-rail system has a special geometric structure. For a general railway vehicle, its wheel-rail geometry structure can be shown as figure 2, where D_w is the half distance of nominal rolling circle between left and right wheel, R_L, R_R are the nominal rolling circle radius of left and right wheel respectively, D_R is half of rail gauge and b is the vertical distance between rail gauge measure point and the top of rail surface, β is the rail cant. For the cone wheel tread, the wheel-rail calculation parameters are shown in table1.

Table 1 *Calculation parameters of wheel-rail contact relationship*

Parameter type	**Value**
Nominal rolling radius	424 mm
Distance of nominal rolling circle	1055 mm
Track gauge	1000 mm
Vertical distance between rail gauge measure point	14 mm
Rail cant	1/40
Wheelset yaw angle	0 °
Wheelset lateral displacement range	-/+12 mm
Axle load	17 t

Under these calculation parameters, the wheel-rail contact parameters of cone wheel tread are shown in figure 3.

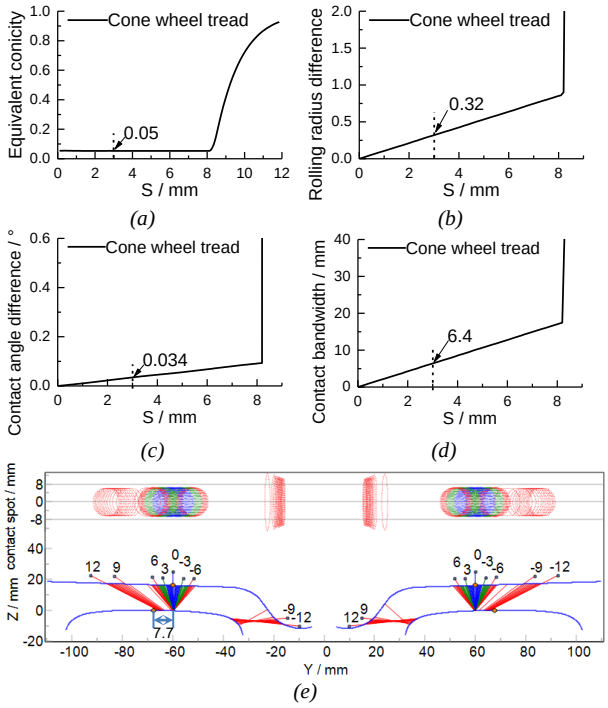

Figure 3 *Wheel-rail contact relationship of cone wheel tread: (a) Equivalent conicity. (b) Rolling radius difference. (c) Contact angle difference. (d) Contact bandwidth. (e) Contact spot and contact point distribution.*

It can be seen from figure 3 that:

(1) The rolling radius difference is close to a straight line with a slope of 1/20, and the equivalent conicity in UIC519 standard is 0.053 when wheelset move laterally 3mm (figure 3(a, b)).

(2) The contact points on wheel and rail surface are very concentrated, the contact bandwidth of contact points on rail surface is only 0.1mm when wheelset move laterally from -3 to +3mm, and the contact bandwidth on wheel tread is 6.4mm. The contact angle difference is also very small, and only has 0.034° (figure 3(c and d)).

(3) In figure 3(3), the numbers above wheel tread curve are the wheelset lateral displacement. The blue lines indicate the positions of wheel-rail contact points when wheelset moves laterally from -3 to 3 mm respect to its central line; The green lines indicate the positions of wheel-rail contact points when wheelset moves laterally from -6 to -3 mm and from 3 to 6 mm respect to its central line; The red lines indicate the positions of wheel-rail contact points when wheelset moves laterally from -12 to -6 mm and from 6 to 12 mm respect to its central line. The initial contact position on wheel tread is on the nominal rolling circle, and the initial contact position on rail surface is close to 7.7mm inside of the rail;

(4) Under the axle load of 17t, the wheel rail contact spot and contact stress are calculated by Hertz contact method. Wheel rail contact spot can be seen as an ellipse shape in the wheelset lateral displacement of 8.3mm. The diameter of ellipse contact spot in semi-major axis is 14mm, the diameter of ellipse contact spot in semi-short axis is 10mm, and the max contact stress is 1194.7Mpa.

Since there are no contact points around wheel nominal rolling circle and wheel flange until wheelset lateral displacement up to 8.3mm, the phenomenon of two point contact is easy to happen when vehicle passing a small curve track. It is very detrimental to wheel tread wear. The measured worn shape of cone wheel tread is shown in figure 4, and the parts of wheel tread and flange have serious wear, especially in the wheel flange part, the wear depth is up to 3mm.

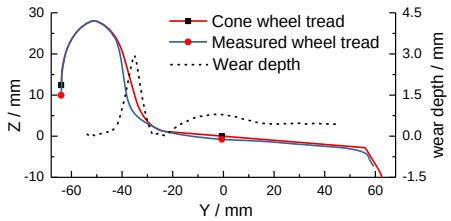

Figure 4 *The measured shape of cone wheel tread and the curve of wear depth*

Therefore, it is necessary to improve the wheel rail contact geometry by using wheel tread reverse design

method.

3. Optimal design of wheel tread shape

3.1 The theory of wheel tread reverse design

Due to some parts of wheel tread cannot contact with the rail surface, the non-contact part will not be able to design by using the information of rolling radius difference and the initial wheel-rail contact position. It needs to combine with a reference shape to make up a complete wheel tread shape. That is to say, a complete wheel tread profile consists with three parts, which are the reference part, the design part and the transition part as shown in figure 3. The locations of the transition part are changed with the design part, which need to adjust according to the size of design part.

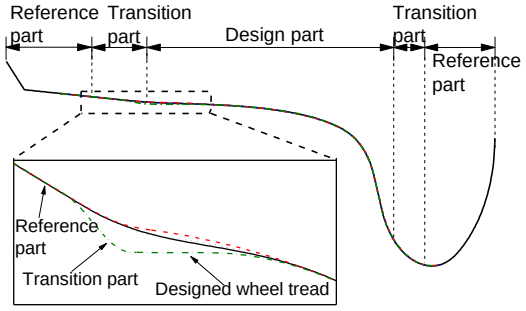

Figure 5 *Components of the reverse design shape of wheel tread*

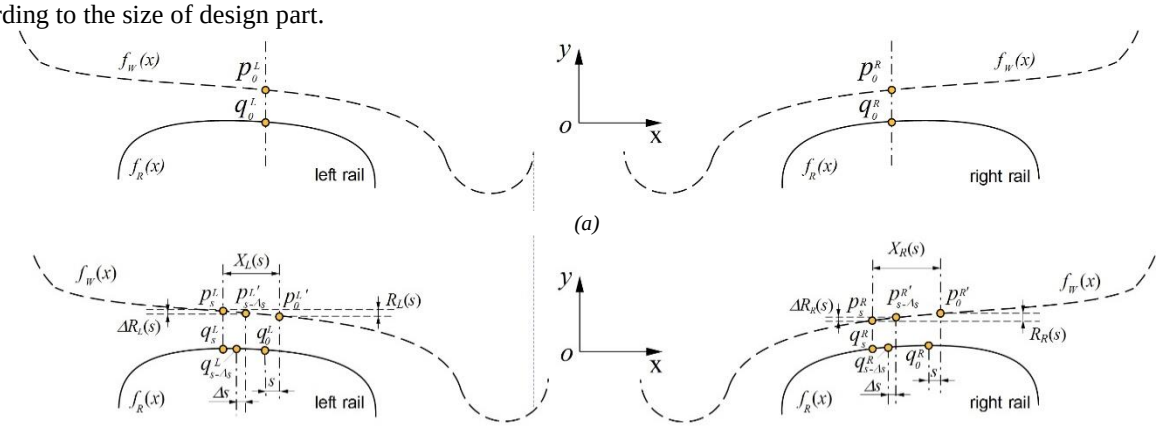

Figure 6 *The wheel-rail contact points under different wheelset lateral displacement: (a) Wheelset lateral displacement of 0 mm. (b) Wheelset lateral displacement of s*

Assumes that wheel tread shape is $f_w(x)$, rail surface shape is $f_R(x)$, so the slope functions of wheel tread and rail surface can be expressed as follow respectively:

$$\begin{cases} K_w(x) = f_w'(x) \\ K_R(x) = f_R'(x) \end{cases} \tag{1}$$

Under a certain rail surface $f_R(x)$, the shape of wheel tread can be designed base on the rolling radius difference $R(s)$, the initial contact point p_0 on wheel tread and q_0 on rail surface.

The wheelset lateral displacement is *s* and its step is Δs .When $s=0$, $R(s)=0$, the contact points on the left and right wheel tread are $p_0^L(-x_0, y_0)$ and $p_0^R(x_0, y_0)$, and the contact points on both side of rail surface are q_0^L and q_0^R ,which as shown in figure 6(a).

When $s \neq 0$ and the axle's roll does not be considered, the contact points on the left and right wheel tread are $p_s^L(x_s^L, y_s^L)$ and $p_s^R(x_s^R, y_s^R)$; the contact point on both side of rail surface are q_s^L and q_s^R; When the wheelset lateral displacement is $s-\Delta s$, the contact points on left and right wheel tread are $p_{s-\Delta s}^L(x_{s-\Delta s}^L, y_{s-\Delta s}^L)$ and $p_{s-\Delta s}^R(x_{s-\Delta s}^R, y_{s-\Delta s}^R)$ .Those wheel-rail contact points are shown in figure 6(b). Among them, when wheelset laterally move *s*, the points of p_0^L and p_0^R change to $p_0^{L'}$ and $p_0^{R'}$, and the points of $p_{s-\Delta s}^L$ and $p_{s-\Delta s}^R$ change to $p_{s-\Delta s}^{L'}$ and $p_{s-\Delta s}^{R'}$. But all the designed contact points on left and right wheel tread need meet the conditions of rolling radius difference.

$$R(s) = R_L(s) + R_R(s) \tag{2}$$

Where

$$\begin{cases} R_L(s) = y_s^L - y_0 \\ R_R(s) = y_0 - y_s^R \end{cases}$$

The contact bandwidth formula can be expressed as:

$$\begin{cases} X_L(s) = p_{0x}^{L'} - p_{sx}^L \\ X_R(s) = p_{0x}^{R'} - p_{sx}^R \end{cases} \tag{3}$$

Since the coordinates of design contact point on left and right wheel tread have four unknown parameters, and there is only one constraint condition of rolling radius difference, so another three constraint conditions should be needed to determine the position of contact points on

left and right wheel.

Then the wheel tread reverse design method can be transmitted into an optimization problem. Set the initial wheel tread shape is $f_w(x)$, the designed wheel tread shape is $f_w^D(x)$, the errors between them can be expressed as follows:

$$\Delta f_w(x) = f_w(x) - f_w^D(x) \quad (x_{\min} \le x \le x_{\max}) \quad (4)$$

The optimization objective function can be written as:

$$g = \min \int_{x_{\min}}^{x_{\max}} \Delta f_w(x)\,dx \quad (5)$$

It can be seen from figure 6(b) that:

$$\begin{cases} \Delta R(s) = R(s) - R(s-\Delta s) \\ \Delta R_L(s) = R_L(s) - R_L(s-\Delta s) \\ \Delta R_R(s) = R_R(s) - R_R(s-\Delta s) \end{cases} \quad (6)$$

Let's define η as a ratio of the given rolling radius difference $\Delta R(s)$ assigned to the left side wheel tread. Then:

$$\begin{cases} \Delta R_L(s) = \eta \cdot \Delta R(s) \\ \Delta R_R(s) = (1-\eta) \cdot \Delta R(s) \end{cases} \quad (7)$$

When wheelset move laterally from $s-\Delta s$ to s, $\Delta R_L(s)$ and $\Delta R_R(s)$ can be expressed as follow:

$$\begin{cases} \Delta R_L(s) = \int_{x_{s-\Delta s}^L}^{x_{s-\Delta s}^L + \Delta s} K_R(x)\,dx \\ \Delta R_R(s) = \int_{x_{s-\Delta s}^R - \Delta s}^{x_s^R} K_R(x)\,dx \end{cases} \quad (8)$$

The slope of point p_s^L and p_s^R are $K_R(x_s^L)$ and $K_R(x_s^R)$, the slope of point $p_{s-\Delta s}^L$ and $p_{s-\Delta s}^R$ are $K_R(x_{s-\Delta s}^L)$ and $K_R(x_{s-\Delta s}^R)$. When s is positive, the contact slopes of right wheel change faster. The contact slopes of left wheel change slower, which may be positive or negative. In order to control the change of left wheel slope, let's define ξ as the change rate of left wheel slope, namely:

$$\kappa = \xi \cdot K_R(x_{s-\Delta s}^L) \quad (9)$$

Where $0 \le \xi \le 1$.

When $K_R(x_s^L) < \kappa$, $K_R(x_s^L) = K_R(x_s^L)$; when $K_R(x_s^L) \ge \kappa$, $K_R(x_s^L) = \kappa$.

Due to the condition of $0 \le \xi \le 1$, the sign of $K_R(x_s^L)$ and $K_R(x_{s-\Delta s}^L)$ always keep the same, so the change rate of designed wheel tread slope is monotonous, and the designed wheel tread shape is two order continuous derivable

According to the given rolling radius difference $R(s)$ and the position of initial contact point q_0 on rail surface, and using the formulas (5~9) under the design parameters of η and ξ, the wheel tread shape can be reverse designed. The design process can be shown as follow:

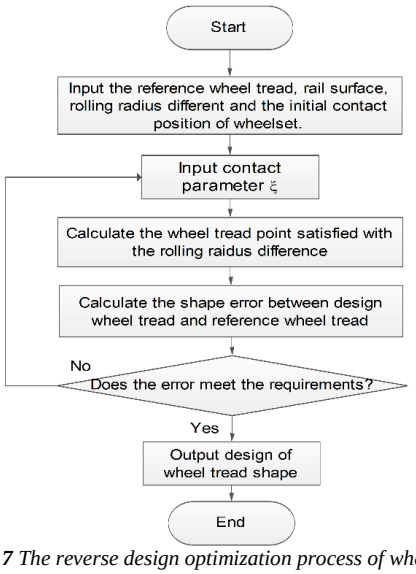

Figure 7 *The reverse design optimization process of wheel tread*

3.2 Wheel tread shape reverse design

3.2.1 Wheel tread design parameters

Using the cone wheel tread as a reference (figure 1(a)), the rolling radius difference (figure 3(b)), and the initial contact position on the inside of rail surface of 7.7mm, when the design parameters get the values of ξ =0.999 and η =0.99, a designed wheel tread can be gotten and it has a same shape as the reference cone wheel tread shown in figure 8.

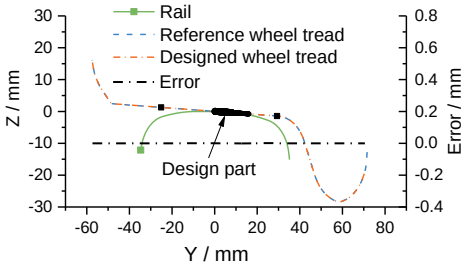

Figure 8 *The designed and reference wheel tread*

3.2.2 The position of initial contact position

The dynamic performance of vehicle is sensitive to the value of equivalent conicity, so the value of equivalent conicity cannot be changed arbitrarily. But the wheel-rail initial contact position can be modified. Under the same rolling radius difference curve and the design parameters of ξ =0.999 and η =0.99, changing the initial contact position on rail surface to 0~7mm, a series of wheel tread can be designed as shown in figure 9.

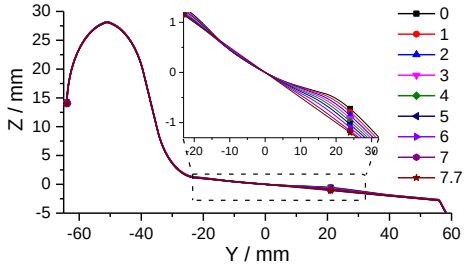

Figure 9 *The designed shapes of wheel tread under different initial contact position on rail surface*

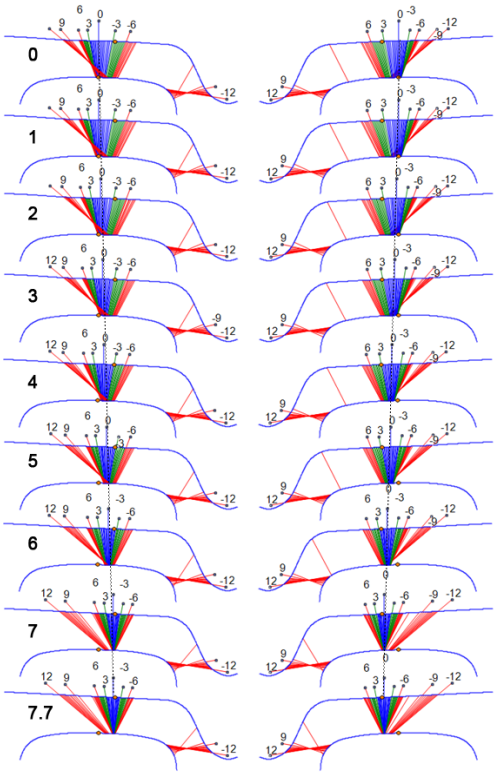
It can be seen from Figure 9 that the wheel tread profile is similar to a concave shape when the initial contact position close to the top of rail, which because the slope of rail surface on top is small and wheelset must move wider to meet the same rolling radius difference. The wheel-rail contact point distributions under different initial contact position are shown in figure 10.



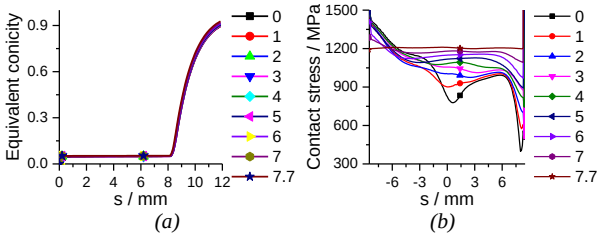


Figure 10 *The wheel-rail contact point distributions under different initial contact position*

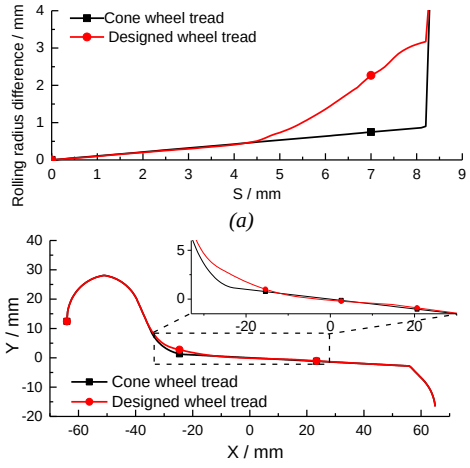
It can be seen from figure 10 that with the movement of initial contact position, the distribution of wheel rail contact points has changed significantly. But it still has two points of contact..

Although the initial contact position on rail surface have been changed, the equivalent conicity of each designed wheel tread are not changed at all as shown in figure 11(a). But wiht the initial contact position approaching to the top of rail, the contact stress of wheel-rail is reduced obviously (figure 11(b)).

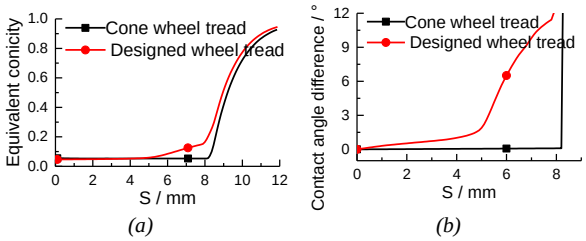


(a) *(b)*

Figure 11 *The equivalent conicity and contact stress of the designed wheel tread under different initial contact position on rail surface:(a) Equivalent conicity. (b) Contact stress.*

It can be seen from figure 11(b) that the contact stress of wheel-rail is smaller relatively when initial contact position is 1mm.

3.2.3 Alleviating two point contact problem



In order to alleviate the two point contact problem, it is necessary to increase the rolling radius difference when the rail surface contact at the root of wheel flange. The modified curve of rolling radius difference is shown in figure 12(a). Under the initial contact position of 1mm on top of rail surface and the wheel design parameters of ξ =0.999 and η=0.99, the new wheel tread shape can be designed and the result compared with cone wheel tread is shown in figure 12(b). The wheel-rail contact parameters of designed wheel tread compared with cone wheel tread are shown in figure 13.

(a)

(b)

Figure 12 *The rolling radius difference and the shape of designed wheel tread compared with cone wheel tread: (a) Rolling radius difference. (b) Wheel tread shape.*

(a) *(b)*

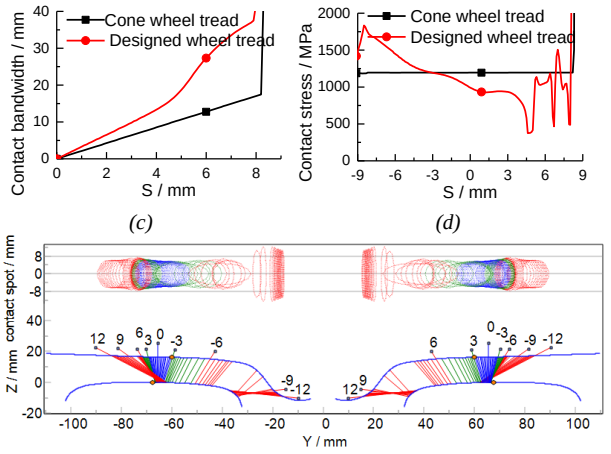


Figure 13 *Wheel-rail contact relationship of designed wheel tread compared with cone wheel tread: (a) Equivalent conicity. (b) Contact angle difference. (c) Contact bandwidth. (d) Contact stress. (e) Contact spot and contact point distribution.*

When wheelset laterally move 3mm, the wheel-rail contact parameters of these two wheel treads are listed in table2.

Table 2 *Wheel-rail contact parameters of cone wheel tread and designed wheel tread when wheelset laterally move 3mm*

Parameter type	Cone wheel tread	Designed wheel tread
Equivalent conicity	0.05	0.05
Rolling radius difference	0.32 mm	0.3 mm
Contact angle difference	0.034 °	0.73°
Contact bandwidth on wheel tread	6.4 mm	9.8 mm
Contact bandwidth on rail surface	0.1 mm	3.7 mm
Contact stress in ±3mm	1186 Mpa	<1186 Mpa
Contact point distribution	concentration	dispersion

It can be seen obviously that when wheelset laterally move 3mm, the designed wheel tread has the same values of equivalent conicity and rolling radius difference, has a larger contact angle difference and contact bandwidth on wheel and rail surface, and has a lower contact stress. And also the contact point distribution of designed wheel tread is more dispersed and the contact points at the nominal rolling circle can be transferred smoothly to the wheel flange.

4. Vehicle dynamic performance simulation

4.1 Curve passing performance under standard rail gauge

Based on the dynamic model build in SIMPACK software, the dynamic performance of the designed wheel tread and the original wheel tread have been analysed respectively. The results under different conditions of curve radius, super elevation and passing speed are shown in table 3 and 4.

Table 3 *Wear index analysis on small curve passing*

Curve radius	Super elevation	Running speed	Wear index		
			Cone tread	Designed tread	Decreased%
180	75	45	903.86	595.83	34.1
200	70	45	811.46	519.03	36
200	85	50	808.56	519.27	35.78
300	45	45	591.53	361.66	38.91
300	90	65	634.64	391.94	38.27
400	70	65	526.11	302.70	42.58
500	55	65	475.56	277.24	41.7
600	45	65	432.00	243.04	43.75
800	35	65	393.07	219.94	44.27

Table 4 *Wheel rail lateral force analysis on small curve passing*

Curve radius	Super elevation	Running speed	Wheel rail lateral force		
			Cone tread	Designed tread	Decreased%
180	75	45	30.00	28.74	4.3
200	70	45	29.428	27.32	7.14
200	85	50	29.31	27.54	6.14
300	45	45	26.77	24.03	10.11
300	90	65	29.01	27.28	6.2
400	70	65	26.38	22.81	13.6
500	55	65	25.28	21.69	14.2
600	45	65	23.70	19.76	16.87
800	35	65	22.27	18.14	18.54

It can be seen from table 3 and 4 that the wear indexes of designed wheel tread are smaller than the cone wheel tread, the maximum reduction rate is up to 44.27%. The wheel rail lateral forces are significantly reduced, and the maximum reduction rate is up to 18.54%.

4.2 Curve passing performance under different rail gauge

The derailment coefficient and wear index of designed and original wheel tread are analysed under different rail gauge from 999 to 1005mm in the curve radius of 200m and the super elevation of 85mm. The results are shown in table 5~6 and figure 14.

Table 5 *Derailment coefficient on different rail gauge*

Rail gauge	Derailment coefficient		
	Cone wheel tread	Designed wheel tread	Decreased%
999	0.56	0.51	8.65
1000	0.55	0.51	7.83
1001	0.55	0.51	7.29
1002	0.55	0.51	6.48
1003	0.54	0.51	5.78
1004	0.54	0.51	5.34
1005	0.53	0.51	5.21

Table 6 *Wear index on different rail gauge*

Rail gauge	Wear index		
	Cone wheel tread	Designed wheel tread	Decreased%
999	822.63	532.27	35.30
1000	823.86	532.20	35.40
1001	819.87	532.75	35.02
1002	821.12	528.65	35.62
1003	822.74	533.06	35.21
1004	818.39	530.74	35.15
1005	818.65	526.18	35.73

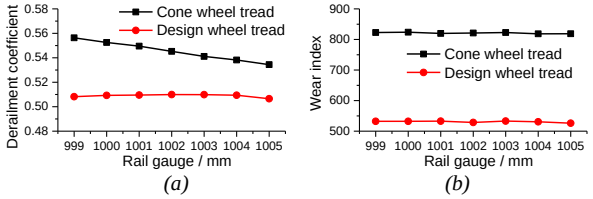

Figure 14 *The change of derailment coefficient and wear index under different distance of wheel back to back: (a) Derailment coefficient. (b) Wear index.*

It can be seen from table 5~6 and figure 14 that the derailment coefficients of designed tread are decreased obviously and the maximum reduction rate is up to 8.65% and the wear indexes are also decreased and the maximum reduction rate is up to 35.73%.

5. Conclusions

(1) A reverse design method of wheel tread is given, which targeted at the rolling radius difference and the initial wheel-rail contact position, and builded an optimal model aimed at minimizing the error between the original and designed wheel tread profile.

(2) This method can take rolling radius difference and wheel rail initial wheel-rail contact position as independent variables, and design an optimal wheel tread profile.

(3) This design method has improved the conical tread profile to increase the values of contact angle difference and contact bandwidth, make the distribution of wheel-rail contact point more evenly and reduce the contact stress. The improved wheel tread profile has alleviated the problem of two point contact, and improved the curving performance of the vehicle.

Abstract: A new wheel-rail contact model for sanding was establish based on the non-Hertz theory and FASTSIM method. A random sand grains generator and sand grain cursed model were included in this model to generate sand grains and update sand states. The mechanism of adhesion enhancement and the effect of sanding friction enhancement with differenet parameters of sand were discussed. A vehicle system braking process dynamic simulation with WSP control and sanding was carried out. The result shows that the model works well and can be used to do more research and guide the development of the new sanding device.

Keywords: non-Hertz contact; sanding model; adhesion enhancement; the volume of sand; braking process simulation.

1. Introduction

Railway transport is an efficient, convenient and economical way of transportation base on wheel and rail contact. Adhesion coefficient expressed by a ratio between the normal force and creep force acting in the contact is an important indicator reflecting wheel-rail contact status. It directly influences the traction and braking efficiency and even operation safety of the train. As we all know, the train works under complex and changeable climatic and environmental conditions, and the environmental conditions and natural contaminants such as rain, snow, frost, grease and fallen leaves, and so on, which have a great influence on the friction coefficient between the wheel and rail. Table 1 shows the variation in the coefficient of friction with different conditions [1]. It indicates that in some cases the friction coefficient is too low to the detriment of the normal operation of the train.

Table 1 Friction coefficients measured with a salient system tribometer[1]

Condition	Coefficient of friction
Sunshine dry rail, 19 °C	0.6–0.7
Recent rain, 5 °C	0.2–0.3
With a lot of grease on rail, 8 °C	0.05–0.1
Damp leaf film on rail, 8 °C	0.05–0.1

There are many issues that can be encountered if wheel-rail contact is in a low-adhesion condition. When the train traction, low-adhesion condition may reduce traction efficiency, lead to wheel slip, and even appear rail burn and crash on wheel tread. When the train braking, it will reduce the braking efficiency, increase the braking distance. In the more serious situation, the wheel may be locked by brake device and slide along the rail which causes wheel flat. At the same time, the low friction coefficient may result in decreased vehicle hunting stability, cause vehicle low-frequency shaking.

There are many existing countermeasures against low adhesion. One of the countermeasures is wheel slide protection (WSP) system which are the most common devices equipped on modern railway vehicles. Another effective, easy to achieve and the oldest method against low adhesion is sanding. Of cause, reasonable and appropriate train operations can also be an effective way to minimize wheel slide by braking earlier with a lower brake rate or avoid wheel slip by traction with lower acceleration. In addition, tread cleaning by abrasive block, rail cleaning by laser and magnetic track brakes are all feasible methods.

Sanding is a widely used method to change the contact state and friction coefficient between the wheel and rail, thereby increasing the coefficient of adhesion by spraying sand grains into wheel and rail contact interface in both traction and braking processes. There is some researches have been done towards particle size, hardness, feed rate and other parameters of sand on the effectiveness of adhesion enhancement of sanding [2~4]. On the other hand, some topics about the negative impact of sanding with inappropriate sanding parameters, such as wear [5], and electric isolation [6,7] were also discussed. Most of these works were based on scaled wheel-rail model or double disc rolling test or field test, that because there are not appropriate wheel-rail contact model for sanding simulation. The most wheel-rail contact models are based on the assumptions of homogeneity materials and smooth surfaces[8]. These assumptions are inappropriate when there are third bodies, such as sand grains, between wheel and rail. Consequently, this paper develops a wheel-rail contact model for sanding with non-homogeneous materials and nonsmooth surfaces. It was used to understand the mechanism of adhesion enhancement and analyze the influence of sanding on the adhesion enhancement.

2. Dynamic model for sanding simulation

In a low adhesion condition, for example, the friction coefficient is 0.05, the wheel will be locked and slides along the rail in a given brake force. If the wheel slip protection (WSP) system is activated and the sanding system is working, the status of the vehicle will be very different, that is what we want to simulate.

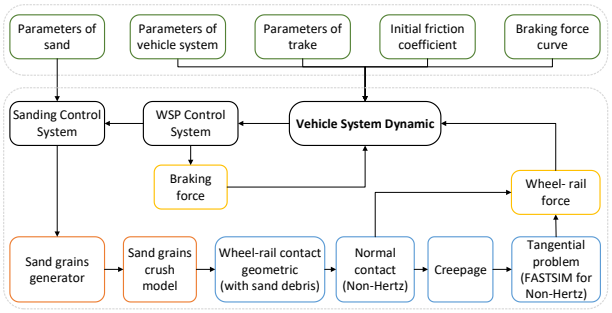

Figure 1 *Flowchart of vehicle dynamic simulation for sanding*

The flowchart shows the main process of the simulation code. The vehicle system dynamic model was established including the WSP system and Sanding control system for train braking processes simulation. The parameter of the vehicle, parameters of the track, initial friction coefficient and braking force curve are the input of vehicle system dynamic model. Simulation started at a given initial speed of the vehicle. The WSP control system determines whether it is necessary to activate the WSP system based on the creepage of the wheel. If WSP is activated, braking force will be modified according to WSP control strategy to replace initial braking force. In the meantime, sanding control system will activate the sanding system, if the estimated adhesion is too low, and begin to sand based on parameters of sand. Sand grains generator calculates number and distribution of sand grains. Sand grains crush model describe the shape and feature of sand grains in the wheel-rail contact area after wheel rolling. There is some sand debris remain in the wheel-rail contact area after crushing which affect geometric contact between wheel and rail and causes nonsmoothed contact between wheel and rail. Therefore, Hertzian contact is not applicable anymore and non-Hertz contact is used for normal contact force calculation. For wheel-rail tangential problem solving, a new FASTSIM suitable for non-Hertz was developed. Normal force and tangential force are combined to obtain wheel and rail force (longitudinal force, lateral force, vertical force and spin torque) for vehicle dynamic simulation.

2.1. Non-Hertz contact model

In the non-Hertz method, we consider that the distribution of the sand grains changes the contact gap between wheel and rail. Therefore, by directly using the geometric distance between wheel and rail to superimpose the shape of the sand grains and combining with the non-Hertzian influence coefficient matrix, we can calculate the normal contact pressure distribution through multiple iterations.

The schematic diagram for non-Hertz contact model of wheel-rail with sand is shown in figure 2.

Three surface functions are needed to define the undeformed shape of the wheel $f_1(x,y)$, the undeformed shape of the rail $f_2(x,y)$ and the shape of crushed sand grains $f_1(x,y)$, respectively. Assuming the sand fragments are always attached to the rail surface and wheel and rail just contact, the gap between wheel and rail including sand fragments before deformed is shown as following:

$$h(x,y) = f_2(x,y) + f_3(x,y) - f_1(x,y) \tag{1}$$

The rigid displacement of wheelset due to a normal approach δ_z between wheel and rail. The control equations of the wheel and rail normal contact are then given by:

$$\begin{cases} u_1 + u_2 = \delta_z - h(x,y) & (x,y) \in \Omega \\ u_1 + u_2 > \delta_z - h(x,y) & (x,y) \notin \Omega \\ p_n(x,y) \geq 0 & (x,y) \in \Omega \\ p_n(x,y) = 0 & (x,y) \notin \Omega \\ \iint_\Omega p_n(x,y)\, dxdy = P \end{cases} \tag{2}$$

where Ω is contact area, u_1 and u_2 are deformation of wheel and rail, respectively. $p_n(x,y)$ is pressure distribution of contact area. P is a total normal force. According to equations of Boussinesq, the relationship between deformation and point force can be written as:

$$\frac{1}{\pi E^*} \iint_\Omega \frac{p_n(\xi,\eta)\, d\xi d\eta}{\sqrt{(x-\xi)^2 + (y-\eta)^2}} = \delta_z - h(x,y) \tag{3}$$

To facilitate numerical solving the distribution of normal force, the contact area Ω is discretized into rectangular cells with sides $2a \times 2b$. A discrete version of the above equation given by Love [10] as:

$$\sum_{j=1}^{n} C_{ij} p_n(x_i, y_i) = \delta_z - h(x_i, y_i) \tag{4}$$

where C_{ij} is the influence coefficient that relates the deformation at element i to a unit pressure in element j expressed as:

$$\begin{aligned} \pi E_i^* C_{ij} = {} & (x+a)\ln\left\{\frac{(y+b)+\sqrt{(y+b)^2+(x+a)^2}}{(y-b)+\sqrt{(y-b)^2+(x+a)^2}}\right\} \\ & +(y+b)\ln\left\{\frac{(x+a)+\sqrt{(y+b)^2+(x+a)^2}}{(x-a)+\sqrt{(y+b)^2+(x-a)^2}}\right\} \\ & +(x-a)\ln\left\{\frac{(y-b)+\sqrt{(y-b)^2+(x-a)^2}}{(y+b)+\sqrt{(y+b)^2+(x-a)^2}}\right\} \\ & +(y-b)\ln\left\{\frac{(x-a)+\sqrt{(y-b)^2+(x-a)^2}}{(x+a)+\sqrt{(y-b)^2+(x+a)^2}}\right\} \end{aligned}$$

where, $\frac{1}{E_i^*} = \frac{1-v_1^2}{E_1} + \frac{1-v_2^2(x_i,y_i)}{E_2(x_i,y_i)}$, and $x = |x_i - x_j|, y = |y_i - y_j|$.

Because of the different mechanical properties of steel and sand, the E^* is no constant in the whole contact area. elastic module E_1 and Poisson's ratio v_1 are both constant for the wheel. $E_2(x_i,y_i)$ and $v_2(x_i,y_i)$ are elastic

module and Poisson's ratio of rail with sand at point (x_i, y_i). They are both varied as the distribution of sand.

In the beginning, the true contact area is unknown, so it is replaced by the intersection area as an assumed contact area. Unreal negative pressures appear in the solution to equation (4) for some elements which do not belong to the true contact area and should be excluded, and the system is solved again until all pressures are positive. The remaining elements now represent the true contact area [11]. By summing the normal forces of all the elements, the total wheel-rail normal force P is obtained.

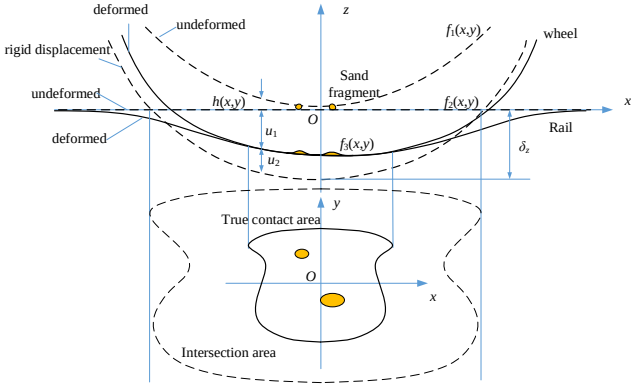

Figure 2 *Schematic diagram for non-Hertz contact model of wheel-rail with sand*

2.2. FASTSIM for non-Hertz

Ignoring the coupling between normal and tangential of wheel and rail contact, we assume that the normal and tangential problems can be solved separately [12]. For the tangential problem, FastSim is a frequently used method in vehicle dynamic numerical simulation. It is generally used for elliptical contact patch. in this article, the non-Hertz theory is adopted for normal contact. So, we need to improve FASTSIM to adapt to non-ellipse and non-smooth normal force distribution and nonhomogeneous frictional coefficients caused by sand grains in the contact area [13,14].

As shown in figure 3, A is a rectangular area selected for searching wheel-rail contact position and calculating the normal distance between wheel and rail. This area contains contact area C and exterior area E. It is well known that for wheel and rail rolling contact problems, the contact area is divided into a slip area S and adhesion area H. The following contact conditions tangential problem are defined.

$$\begin{cases} \mathbf{s}\ \text{free}, \mathbf{p} = 0 & \text{in exterior area } E \\ \|\mathbf{s}\| = 0, \|\mathbf{p}\| = g & \text{in adhesion area } H \\ \|\mathbf{s}\| > 0, \mathbf{p} = -g\mathbf{s}/\|\mathbf{s}\| & \text{in slip area } S \end{cases} \quad (5)$$

where $\mathbf{s}$ is the relative slip between wheel and rail. $\mathbf{p}$ is tangential force including longitudinal creep force p_x and lateral creep force p_y. g is traction boundary which is an important basis for distinguishing between slip and adhesion. It is determined by the normal force and the friction coefficient, both of which are affected by sanding, so it can be expressed as:

$$g(x, y) = \mu(x, y)p_n(x, y) \quad (6)$$

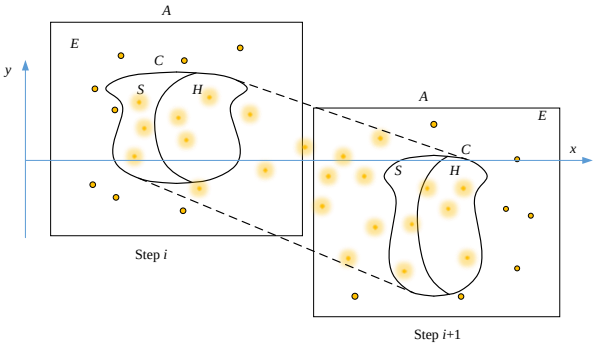

Figure 3 *Area definition schematic*

Once the normal contact problem has been solved and the distribution of the friction coefficient has been determined according to the state of the sand grains, the solution to the tangential problem can be reached by the FastSim algorithm. The FastSim algorithm developed by Prof. J.J. Kalker is based on the simplified elasticity theory[9]. This means the relationship between tangential force $\mathbf{p}$ and displacement $\mathbf{u}$ is a proportional:

$$\mathbf{u}(x, y) = L\mathbf{p}(x, y) \quad (7)$$

Flexibility coefficient L is the key to solve the above equation, but it is not easily available for non-elliptical contact area. It can be calculated by the following equation:

$$L = (|\xi|L_1 + |\eta|L_2 + \sqrt{ab}|\phi|L_3)/\sqrt{\xi^2 + \eta^2 + ab\phi^2} \quad (8)$$

where ξ, η and ϕ are longitudinal, lateral and spin creepages, respectively. a and b are the longitudinal and lateral semi-axes of the contact ellipse. L_1, L_2 and L_3 are the flexibility coefficients associated to each creepage, as following;

$$L_1 = \frac{8a}{3C_{11}G(x, y)}, \quad L_2 = \frac{8a}{3C_{22}G(x, y)}, \quad L_3 = \frac{\pi a\sqrt{a/b}}{3C_{23}G(x, y)} \quad (9)$$

where, G is the combined shear strength module, which is no constant anymore due to the existence of sand; C_{11}, C_{22}, and C_{23} are the Kalker coefficients. Obviously, flexibility coefficient and Kalker coefficients are closely related to semi-axes of the contact ellipse a and b. For non-ellipse, we need to give an equivalent ellipse semi-axle. Let, a_e equal to the length of the non-ellipse, A_c is equal to the area of the non-ellipse, $b_e = A_c/\pi a_e$. a and b in the equation (8) and equation (9) are replace with a_e and b_e.

The non-elliptical contact area is divided into a plurality of strips with width dy, each of which is divided into a plurality of rectangular element of $dx \times dy$. Assuming all element of each strip is adhesion area, and the deformation of the leading edge of the contact patch is 0, each strip is integrated from the leading edge to the trailing edge of the contact patch. If the tangential force vector exceeds the traction boundary, the element is in a slip area. The tangential force of this element is equal to the friction boundary multiplied by the direction of the slip vector. All strips are calculated in the same way until the calculation of the entire contact area is completed.

2.3. Random sand grains generator

The distribution of sand grains in the wheel-rail contact area is determined by the velocity of the vehicle. The sand amount dispensed by the sanders as well as the particle size. For constant mass sanding feed rate of $\dot{m}$ (kg/s) , a vehicle velocity v (m/s), an efficiency η, length of rail a (m) and average particle mass $\bar{m}_{sand}(kg)$, the amount of grains on average $\bar{n}$ yields [15]:

$$\bar{n} = \frac{a\dot{m}\eta}{\bar{m}_{sand}v} \tag{10}$$

$$d_i = norm_rand(\bar{d}, \sigma, \bar{n}) \tag{11}$$

Function $norm_rand$ returns an array with $\bar{n}$ elements of random diameters d_i chosen from a normal distribution with mean $\bar{d}$ and standard deviation σ . Assuming that the shape of the sand grain is spherical, the total mass of sand grains in this area is calculated by:

$$m_s = \sum_{i=1}^{\bar{n}} \rho_s \frac{\pi}{6} d_i^3 \tag{12}$$

The positions of the sand grains are also random, uniform distributed in the longitudinal direction and normally distributed in the lateral direction. During simulation, sand grains generator will be activated under a certain condition, and sand grains will be generated according to the above random distribution just before the first wheelset on both sides.

2.4. Sand grains crushed model

Before the sand grain enters the leading edge of the wheel and rail contact, the sand will be crushed into debris by the wheel. A part of debris ejected, and the remaining part will enter the contact area and affect the normal force distribution of wheel-rail contact[17]. The crushing process of a sand grain is shown in figure 4. One difficulty is how much amount can be left to enter the contact area is unknown. It depends on the debris eject velocity and rolling speed of the wheel. And it is represented by a splash coefficient in this article.

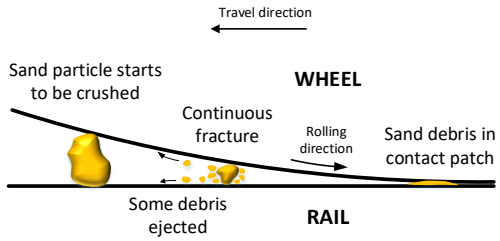

Figure 4 *Schematic diagram of a sand grain crushing process*

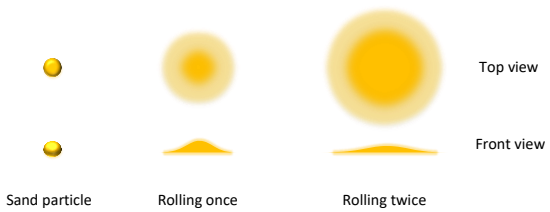

Figure 5 *development of the shape of sand fragments*

After the first wheel pass through, the sand grain is crushed. When the second wheel passes through again, there will be no debris splashing, but the distribution of sand fragments will be wider, and the height will decrease as shown in figure 5. The shape of sand fragments is described by Gauss filter. Gaussian kernel $K(x, y)$ with standard deviation σ is:

$$K(x, y) = k\frac{1}{2\pi\sigma}e^{-(x^2+y^2)/2\sigma^2} \tag{13}$$

The position of the all sand in the contact area is convolved with the relevant Gaussian kernel and superimposed to get the final shape of sand fragments. The friction coefficient matrix uses the same operating. R. S. Sayles[16] has given an equation to describe the particle aspect ratio (diameter/thickness) of sand fragments after crushed, that is:

$$\frac{D}{h} \geq \frac{E}{2H_s(1-v^2)} \tag{14}$$

Where, D and h are diameter and thickness of sand fragments, respectively. H_s is the hardness of sand particle. E and v are elastic module and Poisson's ratio, respectively. Therefore, parameters of the Gaussian kernel k and σ can be determined according to this equation.

Each time the wheel passes through the sand, the parameters of the Gaussian kernel are updated, making the shape of sand fragments wider and thinner in accordance with the expanding coefficient of sand fragments α.

During dynamic simulation, the movement of the contact patch between the two integration steps is discontinuous. The status of sand in the contact area of each step are updated, but some sand is missed between two steps. In fact, wheel and rail are in continuous contact. So, the sand on the path between two contact areas will be crushed as the same as the sand in the contact area. The upper and lower boundary lines are determined by linear interpolation to determine as shown by the dotted line in Figure 3. The sand grains within the boundary are selected, and the status of which are updated. Table 2 shows the parameters and values we used in this article for simulation.

Table2 *Parameters for wheel-rail contact model with sand*

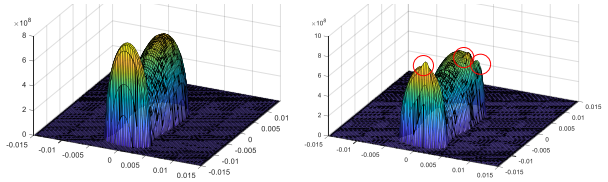
Parameter	Value
Basic friction coefficient of wheel and rail μ	0.05, 0.1,0.2
Elastic module of wheel and rail E (GPa)	210
Poisson's ratio of wheel and rail v	0.3
Basic friction coefficient of sand μ_s	0.4-0.5
Hardness of sand particle H_s(GPa)	10.7
Density of sand grains ρ_s(kg/m^3)	2.65e3
Constant mass sanding feed rate $\dot{m}$ (kg/s)	20,40,50
Sanding efficiency η	0.03
Average particle mass $\bar{m}$ (kg)	1e-5
Average diameters of sand grains $\bar{d}$ (mm)	0.8
Standard deviation of sand grains σ(mm)	0.6-4
Coefficient of Gaussian kernel k	1
Expanding coefficient of sand fragments α	1.5

2.5. Vehicle system dynamic model

Vehicle system dynamics model is established based on one type of EMU in China. It consists of a carbody, two bogie frames and four wheelsets with a total of seven inertial bodies. Each inertial body has 6 degrees of freedom (DOFs) and the whole vehicle has 42 DOFs. The vehicle adopts the suspension components including the rotary arm positioning, primary steel springs, primary vertical damper, air springs, secondary lateral dampers, yaw dampers, lateral stopping block and anti-rolling bars. The dynamic equation can be written like this:

$$\mathbf{M}\ddot{\boldsymbol{q}} + \mathbf{C}\dot{\boldsymbol{q}} + \mathbf{K}\boldsymbol{q} = \boldsymbol{F}_{wr} + \boldsymbol{F}_{b} \quad (15)$$

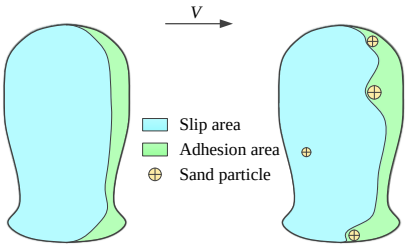
where, **M**, **C,** and **K** are mass matrix, damping matrix, and stiffness matrix, respectively. $\boldsymbol{q}$ is the DOF vector, $\boldsymbol{F}_{wr}$ wheel, and rail contact force vector, and $\boldsymbol{F}_{b}$ is braking force vector, which is controlled by the WSP control system according to system status.



WSP control strategy used in this article is simple. When the difference between the vehicle speed and the linear velocity of the wheel is greater than 10% of the vehicle speed, that is, the creepage reaches 10%, the braking torque is reduced by 30%, and if the creepage is reduced and less than 0, the braking torque is restored.

3. Discussion of the results

3.1. Mechanism of sanding friction enhancement



Sanding is a very effective way to deal with the low adhesion condition. There are some different opinion on the mechanism of sanding friction enhancement. One of those opinions at the micro level called ploughing phenomena is that sand fragments plastically embed in wheel and rail surface, with the creep motion of wheel-rail, the sand fragments stick in the wheel (softer material) surface and plough a groove in the rail surface(harder material)[17,18]. From a macro perspective, the sand changes the friction coefficient and distribution of normal force between wheel and rail, and it caused the changing of traction boundary and adhesion area to achieve friction enhancement. To further understanding the macroscopic mechanism, appropriate contact model for wheel and rail with sand is established. In this model, the sand affects many aspects of wheel and rail contact, such as the shape of the contact area, distribution of normal force, friction coefficient and shear module of wheel and rail, and flexibility coefficient for FASTSIM.

The results including distribution of normal force and slip areas with sand and without sand were calculated. The distribution of normal force is smooth in figure 6(a) without sand. And there are some peaks of the normal force marked out by the red circle in figure 6(b) for the sand case. The distribution of normal force was changed by sand which also affects the slip and adhesion areas at the same time as shown in figure 7. The adhesion area is enlarged around sand particle which appears near the boundary between adhesion area and slip area. We can understand the mechanism of adhesion enhancement with sand by the results. The appearance of peaks increase the normal force and improve the friction coefficient around the sand at the same time. These two aspects make the traction boundary greatly raised. If the sand particle appears near the boundary between adhesion and slip, it is a great possibility to change the slip state to adhesion state.

Figure 7 *Slip and Adhesion areas for creepage ξ_x=0.003: (a) No sand; (b) With sand.*

3.2. Effect of Sanding Friction enhancement

There are many factors that affect the effect of sanding friction enhancement, such as sanding feed rate, the size of sand grains and hardness, and so on. In this paper, the relationship between the adhesion coefficient and creepage for different sanding feed rate was calculated. Because of the randomness of the appearance of sand grains, we calculated 20 times for each sanding feed rate and statistically analyzed the results, draw the box figure as follows.

Sanding feed rate determines the amount of sand entering the contact area, and a significant effect on adhesion coefficient. The red solid line in figure 8 is the result without sand, which is equal to the basic friction coefficient 0.1 when the full slide happened. As the sanding feed rate increased, the maximum and average adhesion coefficient both increased with different creepage. It means that the influence of sand on adhesion enhancement is directly related to the sanding feed rate. Meanwhile, the enhancement is depended on the creepage or slip area. When the slip area is small, there is less chance of sand grains appearing in the slip area, and less possibility of the slip area becoming the adhesion area and increasing the traction boundary. That's why the adhesion coefficient increases insignificantly when the creepage is small.

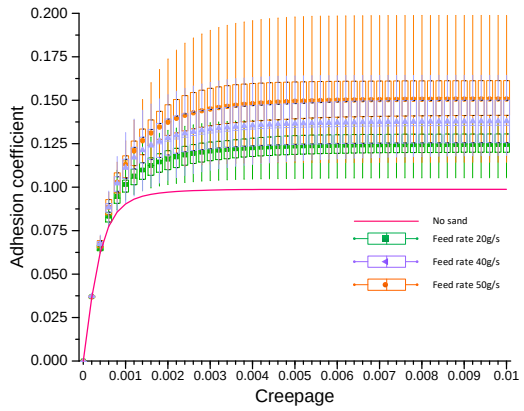

Figure 8 *Effect of sanding friction enhancement with different sanding feed rate*

Comparing the results of the different sanding feed rate, the more sand used, the better the effect of adhesion enhancement. At the same time dispersion also increases with the increase of sand mass. The adhesion coefficient increased by 25%, 37.5%, and 50% on average with 20 g/sec, 40g/sec and 50 g/sec respectively for large creepage. Of course, there is a certain randomness in the enhancement effect. For example, it may sometimes increase by around 100 %, but sometimes only reach about 25% at the same creep and sand mass. Overall, the effect of sanding is obvious for the low friction state of the wheel and rail.

Size of sand grains is another import parameter in our model because it is directly related to the debris of the sand grain after crushing. Figure 9 shows the effect of sanding friction enhancement with different size for feed rate equal to 40g/s. Three different sizes of sand grains were calculated. The mean diameters are 0.5mm, 0.8mm and 1.2mm, respectively. As can be seen from the results, the larger the particle size of the sand, the more obvious the effect of friction enhancement. At the same time, as the particle size increases, the dispersion of the enhancement effect also increases. This phenomenon can be explained as that large sand grain will remain larger debris in the contact area, but the randomness of the shape or distribution of fragment will increase.

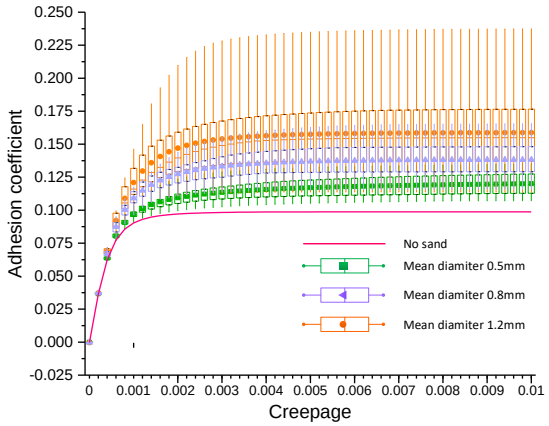

Figure 9 *Effect of sanding friction enhancement with different sand size* (feed rate = 40 g/s)

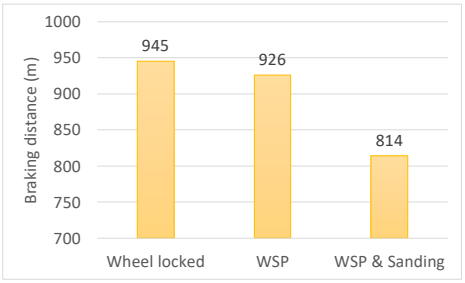
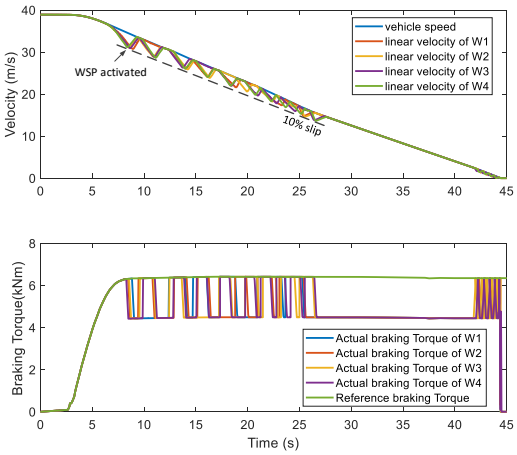
3.3. Braking process simulation with sanding

We developed the corresponding program according to the simulation process of the dynamic vehicle system braking process described at the beginning of the second section and performed dynamics simulation. Dynamic simulation of three working conditions, namely the braking process, the braking process with WSP control, braking process with WSP control and sanding, were performed. The basic friction coefficient of wheel/rail is 0.1, and the maximum braking torque produces a deceleration of 0.12G (gravity acceleration). Thus, the wheel will be locked without WSP control or friction enhancement such as sanding. The initial speed of the vehicle is 140 km/h, and the braking distances of those three working conditions after braking were shown in figure 10. As we can see from the figure, if the wheel were locked, the braking distance is 945 meters. It is only 19 meters shortened when WSP activated. If WSP and sanding system worked together, the braking distance can be reduced to 814 meters, almost 14% less than case 1.





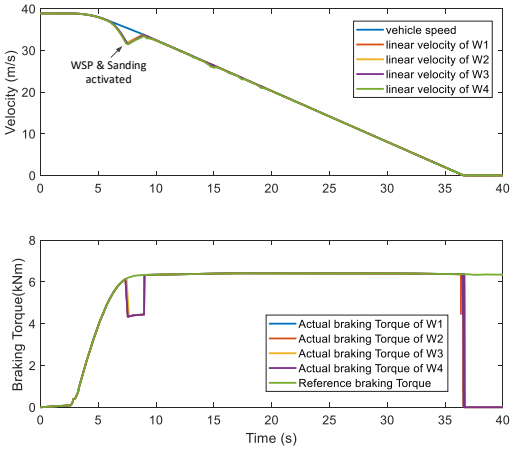


Figure 10 *Braking distance for three cases*

More details about velocity and braking torque for case 2 and case 3 are shown in figure 11. When only WSP activated, there are many operations to change the braking force in order to prevent the wheels from slipping. If WSP and sanding were activated together, the friction coefficient was improved, and the WSP system did not need to reduce braking torque to avoid slip. The average adhesion coefficients are 0.09 and 0.125 for case 2 and case 3, respectively.

(a)

(b)

Figure 11 *velocity and braking torque (a)braking with WSP control, (b) braking with WSP control and sanding*

In actual brake test, it was found that a sharp decline in adhesion improvement for axles further away from the sander. Our model can express well to this phenomenon. Sanding on both sides of rail only before the first wheelset, and adhesion coefficient of each axle was calculated during braking, and scatter plot were shown in figure 12. It can be seen from the scatter plot that the adhesion coefficient of the four wheelsets are improved compared to the basic friction coefficient of 0.05. The first wheelset's improvement is most noticeable, especially when the creep rate increases. The adhesion other wheelsets have also improved, but the improvement effect is gradually reduced as the wheelsets are away from the first wheelset. From the average adhesion coefficient for each axle, we can more clearly see the decline in the effectiveness of friction enhancement as shown in figure 13. There two reasons for this phenomenon, one is powdering of sand grains, another is the removal of sand from the rail head. The sand grains crushed model used in this article can simulate the sand fragments after powdering and mass loss by changing the coefficient of the crush shape function.

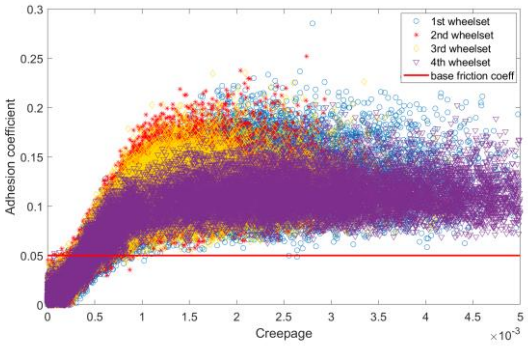

Figure 12 *scatter plot of adhesion coefficient with creepage*

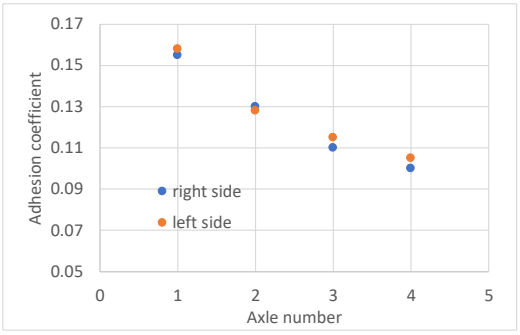

Figure 13 *Average adhesion coefficient of every wheel*

4. Conclusions

A new wheel/rail contact model for sanding was established based on the non-Hertz theory and FASTSIM method. On this basis, this article discussed the mechanism and influence of adhesion enhancement and carried out a vehicle system braking process dynamic simulation with WSP and sanding. The sand grains change the distribution of normal force and improve the friction coefficient around the sand at the same time. This leads to an increase of the adhesion area and adhesion coefficient enhancement. The influence of sand on adhesion enhancement is directly related to the amount of sand mass and the sizes of sand grains and depend on creepage. The more sand used, the better the effect of adhesion enhancement. At the same time dispersion also increases as the increase of sand mass. The larger the particle size of the sand, the more obvious the effect of friction enhancement. At the same time, as the particle size increases, the dispersion of the enhancement effect also increases. Overall, the enhancement effect of sanding is obvious for the low friction state of the wheel and rail. The new wheel-rail contact mode suit for vehicle braking with sanding simulation.

The further work is to understand the mechanism of sand friction enhancement from the micro level, verify the sand crushed model and the wheel-rail contact model through field test, and use simulation to guide the development of the new sanding device.

Abstract: The 3-D contact problem for an elastic sphere rolling over a thin viscoelastic layer bonded to an elastic half-space is considered. The Kelvin model is used to describe the layer viscoelastic properties in tangential direction. The layer compliance in normal direction is described by the Winkler model. The contact region is assumed to consist of a stick and slip subregions, which boundaries are unknown in advance. The contact stress distributions were studied for various values of sliding friction coefficient, relative slippage and the layer viscosity parameters.

Keywords: Rolling contact; friction modifier, viscoelastic layer; stick and slip regions, adhesion coefficient.

1. Introduction

In rolling contact the effect of imperfect elasticity of the thin surface layer plays an important role on contact characteristics and friction force. J. Kalker [1, 2] theoretically and experimentally analysed the rolling contact between two cylinders coated with viscoelastic layers. The numerical model was developed in this study for the analysis of stresses in subsurface layer, and laser Doppler anemometry was used to verify the numerical results. The analytical models to study the effect of a viscoelastic layer bonded to an elastic half space in rolling contact (2-D contact problem formulation) was developed in [3, 4].

The use of the friction modifiers nowadays to control the friction in rail/wheel contacts [5] gives the new application for the theory of the viscoelastic coated bodies in rolling contacts. Friction modifiers are deposited to rail rolling surface and together with other composition arising on the surface and containing oxides of iron, wear particles and other components they form the surface layer providing required shear stress distribution in contact region. It leads to decreasing the resistance to movement of freight cars and supplies economy of energy.

To study the effect of friction modifiers in wheel/rail rolling contact we consider the contact problem for the roller and the elastic base covered by the viscoelastic layer.

2. Problem formulation

The 3-D contact problem for an elastic sphere (1) rolling over a thin viscoelastic layer (3) bonded to an elastic half-space (2) is considered. The sphere of radius R rolls along the base with a constant angular ω and linear V velocities. The motion of the sphere can be considered as steady with respect to a moving coordinate system associated with the sphere. In Figure 1 a scheme of the contact is presented.

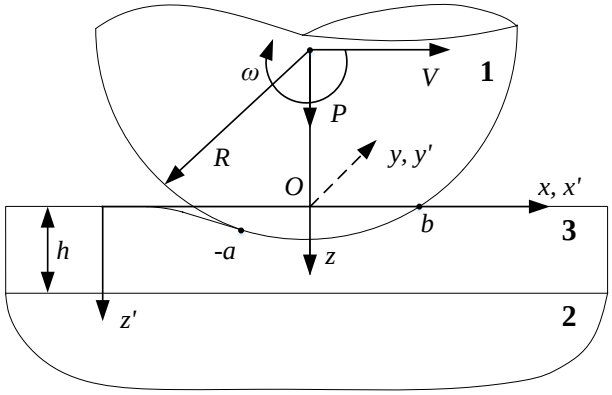

Figure 1 *Scheme of the contact*

Let the system of coordinates (*x', y', z'*) be connected with the elastic half-space and the system of coordinates (*x, y, z*) with the rolling sphere so that:

$$x' = x + Vt$$
$$y' = y \qquad (1)$$
$$z' = z$$

The origins of fixed and moving coordinates systems are located on the layer surface under the center of the sphere at some initial instant of time.

The shape of the sphere is described by the function:

$$f(x,y) = \frac{x^2 + y^2}{2R} \qquad (2)$$

where *R* is the radius of the sphere.

In the whole contact area Ω of the sphere and the coated elastic half-space the following contact condition, written in the moving system of coordinates, is satisfied:

$$w^{(1)}(x,y) + w^{(2)}(x,y) + w^{(3)}(x,y) = \eta - f(x,y) \qquad (3)$$

where $w_1(x, y)$, $w_2(x, y)$, $w_3(x, y)$ are the normal

displacements of the boundaries of the elastic sphere, of the elastic half-space and of the viscoelastic layer, respectively, η is the penetration of the sphere into the viscoelastic layer.

To determine the displacements of the elastic sphere ($z = 0$, $i = 1$) and the elastic half-space ($z = h$, $i = 2$) boundaries, we use the following relation:

$$w^{(i)}(x,y) = \frac{1-\nu_i^2}{\pi E_i} \iint\limits_{\Omega} \frac{p(\xi,\eta)\,d\xi\,d\eta}{\sqrt{(x-\xi)^2+(y-\eta)^2}} \qquad (4)$$

Here ν_i is the Poisson's ratio, E_i is the modulus of elasticity of the sphere ($i = 1$) and the half-space ($i = 2$), $p(x, y)$ is the contact pressure. In this model the normal stresses at the upper boundary of the layer ($z = 0$) and on the boundary between the viscoelastic layer and the elastic half-space ($z = h$) are considered to be equal.

We assume that the layer displacement in the normal direction is described by the Winkler model:

$$w^{(3)}(x,y) = \frac{h}{E_p}\left[p(x,y)\right]^m \qquad (5)$$

where h is the thickness, E_p is the longitudinal modulus of elasticity of the surface layer in normal direction and m is the index of pressure function power ($0 < m < 1$).

The following model is used to describe the thin viscoelastic layer shear behavior ($z = 0$) [6]:

$$\begin{aligned} u(x',y',t) + T_\varepsilon \frac{\partial u(x',y',t)}{\partial t} = \\ = \frac{h}{E_\tau}\left(\tau(x',y',t) + T_\sigma \frac{\partial \tau(x',y',t)}{\partial t}\right) \end{aligned} \qquad (6)$$

where $u\,(x', y', t)$ is the displacement of the viscoelastic layer in tangential direction, $\tau\,(x', y', t)$ is the contact shear stress, T_ε, T_σ are the retardation and relaxation times, respectively, E_τ is the longitudinal modulus of elasticity in tangential direction.

In the moving system of coordinates (x, y, z) the relation (6) has the form ($z = 0$):

$$\begin{aligned} u(x,y) - T_\varepsilon V \frac{\partial u(x,y)}{\partial x} = \\ = \frac{h}{E_\tau}\left(\tau(x,y) - T_\sigma V \frac{\partial \tau(x,y)}{\partial x}\right) \end{aligned} \qquad (7)$$

During rolling the contact region Ω is assumed to consist of a stick (Ω_A) and slip (Ω_S) subregions. The boundary of these subregions is unknown in advance. In the slip subregion the relation between the tangential stress and the contact pressure is described by the Coulomb law:

$$\left|\tau(x,y)\right| = \mu p(x,y),\ (x,y) \in \Omega_S \qquad (8)$$

Here μ is the friction coefficient.

In the stick subregion the velocities of the contacting points of the viscoelastic layer and the sphere are equal. In the moving system of coordinates this equation takes the form [3]:

$$\frac{\partial u(x,y)}{\partial x} = \Delta = \frac{\omega R - V}{V},\ (x,y) \in \Omega_A \qquad (9)$$

The tangential stress and the contact pressure in the stick subregion satisfy the following inequality.

$$\left|\tau(x,y)\right| \le \mu p(x,y),\ (x,y) \in \Omega_A \qquad (10)$$

The continuity conditions for tangential stresses and displacements at the boundary of the stick and slip subregions must be satisfied.

3. Method of the contact pressure calculation

Under the assumption that the contact shear stresses do not influence the normal contact pressure distribution, the problem is solved in two stages. Firstly, we calculate the contact pressure distribution in the contact area of the sphere and the layered half-space. Then these results are used to calculate the shear stress distribution.

Substituting the expressions for the normal displacements (5) of the layer and the normal displacements (4) of the half-space and the sphere into the equation (3) we derive the following equation for calculation of the contact pressure in the contact area:

$$\begin{aligned} K_{12} \iint\limits_{\Omega} \frac{p(\xi,\eta)}{\sqrt{(x-\xi)^2+(y-\eta)^2}}\,d\xi\,d\eta + \frac{h}{E_p}\,p(x,y) = \\ = \eta - f(x,y) \end{aligned} \qquad (11)$$

where:

$$K_{12} = \frac{1-\nu_1^2}{\pi E_1} + \frac{1-\nu_2^2}{\pi E_2} \qquad (12)$$

The relation between the total load P applied to the sphere and the contact pressure $p(x, y)$ follows from the equilibrium condition:

$$\iint\limits_{\Omega} p(x,y)\,dx\,dy = P \qquad (12)$$

On the boundary of the contact area and beyond it the contact pressure is equal to zero:

$$p(x,y) = 0,\ x \notin \Omega \qquad (13)$$

The problem of the contact pressure determination can be considered as axisymmetric because of the shapes of the contacting bodies are symmetrical.

We introduce the following dimensionless parameters and functions:

$$\begin{aligned} \rho = \frac{r}{a},\ \eta_1 = \frac{\eta}{a},\ p_1(\rho) = K_{12}\,p(a\rho), \\ B = \frac{h}{aK_{12}E_p},\ P_1 = K_{12}P,\ g(\rho) = \frac{f(\rho a)}{a} \end{aligned} \qquad (14)$$

where a is the radius of the contact area.

With these parameters the relations (11) и (12) have the following forms:

$$\begin{aligned} \int_0^1 K_1(\rho,\xi)\,\xi\,p_1(\xi)\,d\xi + B\left[p_1(\rho)\right]^m = \eta_1 - g(\rho) \\ 2\pi\int_0^1 p_1(\rho)\,\rho\,d\rho = P_1 \end{aligned} \qquad (15)$$

where

$$K_1(\rho,\xi)=\frac{4}{\rho+\xi}K\left(\frac{2\sqrt{\rho\xi}}{\rho+\xi}\right) \quad (16)$$

Here *K(t)* is the elliptic integral of the second kind.

Eqs (15) are the basic equations for the contact pressure calculations. The integral equation is solved using the method of successive approximations, which is described in more details in [7, 8]. After introduction of the function:

$$\Psi(\rho)=B\left[p_1(\rho)\right]^m-g(1)+g(\rho) \quad (17)$$

the problem is reduced to calculation of the limit of a sequence of functions:

$$\Psi_{n+1}(\rho)=-B^{-1}\int_0^1\tilde{K}\left[\Psi_n(\xi)+g(1)-g(\xi)\right]^{\frac{1}{m}}\xi d\xi \quad (18)$$
$$\tilde{K}\equiv\tilde{K}(\rho,\xi)=K_1(\rho,\xi)-K_1(1,\xi)$$

The equation (18) does not include the parameter η.

As the initial approximation, we take the function:

$$\Psi_0(\rho)=0 \quad (19)$$

Finally, on the current step, we receive the contact pressure in the contact area as the function of Ψ:

$$p_1(\rho)=B^{-\frac{1}{m}}\left[\Psi(\rho)+g(1)-g(\rho)\right]^{\frac{1}{m}} \quad (20)$$

4. Method of the shear stress calculation

The shear stresses in the contact region are calculated by using the strip method, which was described in [9]. The contact region is divided into 2*N* strips of equal thickness *a/N*, where *a* is the radius of contact area. The direction of the strips and the sphere rolling coincide with the direction of the *x* -axis. In each strip the shear stresses are evaluated independently.

At each *j*-th strip *(j=1,...N)* within the slip subregions Ω_S according to the equation (8) the Coulomb law is satisfied:

$$\tau_{1j}(\xi_j)=\mu p_{1j}(\xi_j),\ \xi_j\in\Omega_{S_j} \quad (21)$$

where

$$\tau_{1j}=K_{12}\tau_j,\ \xi_j=\frac{x_j}{a_j} \quad (22)$$

τ_{1j} is the dimensionless tangential stress in the *j* strip.

The displacements of the viscoelastic layer in the tangential direction in the slip subregions are determined from the relation (7) with taken into account relationship (21). With the dimensionless parameters the equation for tangential displacements has the form:

$$u_{1j}^{\ S}-\alpha_T\zeta_j\frac{\partial u_{1j}^{\ S}}{\partial\xi_j}=B_\tau\left(\mu p_j(\xi_j)-\zeta_j\mu\frac{\partial p_j}{\partial\xi_j}\right) \quad (23)$$

where

$$u_{1j}^{\ S}=\frac{u_j^{\ A}}{a_j},\ \zeta_j=\frac{T_\sigma V}{a_j},\ B_\tau=\frac{h}{aK_{12}E_\tau},\ \alpha_T=\frac{T_\varepsilon}{T_\sigma} \quad (24)$$

Parameter ζ_j is one of the variations of the Deborah number.

According to the relation (9) the displacement of the viscoelastic layer in the tangential direction within the stick subregion is determined from the equation:

$$\frac{du_{1j}^{A}}{d\xi_j}=\Delta=\frac{\omega R-V}{V},\ \xi_j\in\Omega_{A_j} \quad (25)$$

where Δ is the value of relative slippage.

The shear stress in the stick subregions can be calculated from (7):

$$u_{1j}^{\ A}-\alpha_T\zeta_j\frac{\partial u_{1j}^{\ A}}{\partial\xi_j}=B_\tau\left(\tau_{1j}(\xi_j)-\zeta_j\frac{\partial\tau_{1j}}{\partial\xi_j}\right) \quad (26)$$

where

$$u_{1j}^{\ A}=\frac{u_j^{\ A}}{a_j},\ \xi_j\in\Omega_{A_j} \quad (27)$$

The following boundary conditions for the stresses and displacements in the stick/slip subregion boundaries are satisfied:

$$u_{1j}^{S}(\xi_j-0)=u_{1j}^{A}(\xi_j+0)$$
$$\mu p_{1j}(\xi_j-0)=\tau_{1j}(\xi_j+0) \quad (28)$$

After the calculations of the displacement in the stick and slip subregions from equations (23), (25) and (28) for each given values of relative slippage Δ, the shear stresses can be evaluated from the equations (21), (26) and (28).

Repeating these calculations for each strip we obtain the shear stress distribution within the contact region and the configuration of the stick and slip subregions.

5. Results and discussion

The contact stress distribution was studied for various values of sliding friction coefficient μ, the mechanical properties of the surface layer (the ratio of retardation to relaxation times $\alpha_T = T_\varepsilon/T_\sigma$, the layer compliance in normal direction $B = h/(aK_{12}E_p)$, the layer compliance in tangential direction $B_\tau = h/(aK_{12}E_\tau)$ and for various values of the Deborah number $\zeta = T_\sigma V/a$.

In calculations we fixed the following dimensionless parameters introduced in (5), (14) and (16):

$$m=0,5,\ C=\frac{a^2}{2R^2}=0,9,\ P_1=K_{12}P,$$
$$\nu=0,3,\ E_p=2,1\times10^8\ \text{N/m}^2 \quad (29)$$

The typical contact pressure distribution is illustrated in Figure 2. Due to existence of a thin intermediate layer between elastic bodies the contact pressure distribution differs on the Hertz solution. The main difference appears at the peripheries part of the contact where zero derivatives of the pressure occur.

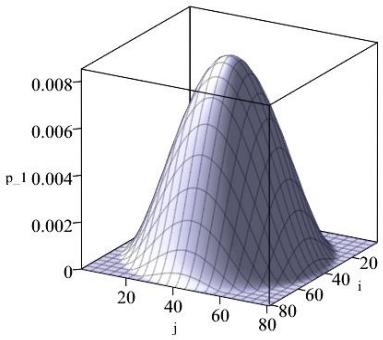

Figure 2 *Contact pressure distribution for*
*B = 5, m = 0,5, ν = 0,3, C = 0,9, E_p = 2,1*10^8 N/m^2, P_1 = 0,03*

Shear stress distributions are calculated for the following values of parameters:

$$m = 0,5,\ C = \frac{a^2}{2R^2} = 0,9,\ P_1 = K_{12}P,$$
$$\nu = 0,3,\ E_p = 2,1\times 10^8\ \text{N/m}^2 \qquad (30)$$

In Figure 3 shear stress distribution at the contact area is presented.

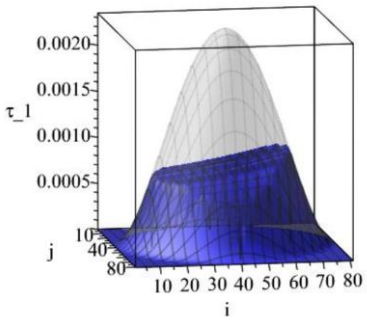

Figure 3 *Shear stress distribution for*
B = 10, B_τ = 5, ζ = 2, α_T = 5, μ = 0,3, Δ = 0,0003
(grey color corresponds to the case of complete slippage)

Shear stress distributions within different strips are illustrated in Figure 4:

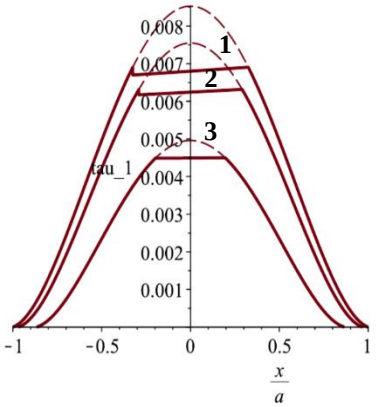

Figure 4 *Shear stress distributions within various strips for*
B = 5, B_τ = 10, ζ = 10, α_T = 5, μ = 0,3, Δ = 0,002 and
1 – j = 0, 2 – j = 10, 3 – j = 20, j is the strip number
(the dashed lines correspond to the case of complete slippage)

The results indicate that the stick subregion arises within the contact area if shear stresses are less than the limiting friction. The location of the stick subregion and the value of the shear stresses within this zone depend on the mechanical properties of the surface layer, relative slippage as well as the friction coefficient between the contacting bodies. The dashed curve corresponds to the case of complete slip within the contact region.

The slope of the shear stress graphs for the same value of the relative slippage is the same for different strips. The maximum width of the stick subregion and the highest value of the shear stress correspond to the central strip $(j = 0)$ of the contact area.

The shear stress distributions for different values of relative slippage for the central strip of the contact region are illustrated in Figure 5.

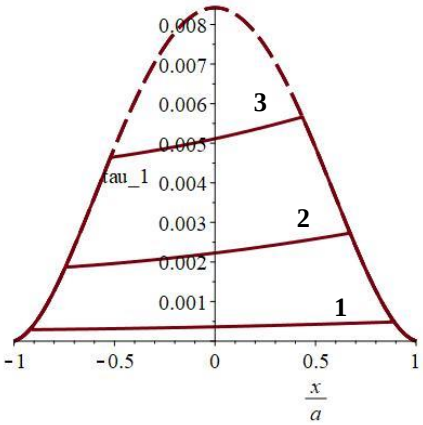

Figure 5 *Shear stress distributions within the central strip for*
B = 5, B_τ = 20, ζ = 2, α_T = 5, μ = 0,3, and
1 – Δ = 0,0005, 2 – Δ = 0,003, 3 – Δ = 0,008,
(the dashed line corresponds to the case of complete slippage)

The results indicate that the length of the central stick zone increases with the growth of the relative slippage parameter Δ. Further enlargement of this parameter leads to the case of complete slippage in the contact region. In this case the shear stress distribution in the whole contact area is described by the Coulomb law (8).

The shear stress distributions for the central strip of the contact region for different values of friction coefficient are presented in Figure 6. The friction coefficient value influences the shear stress distribution in the slip subregions and the stick subregion configuration. The plots in Figure 6 show that with the increase of the friction coefficient the boundaries of the stick subregion move to the contact area borders.

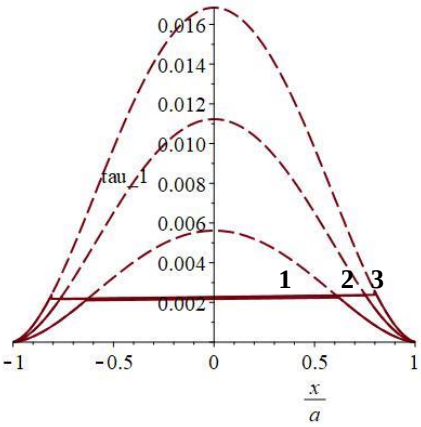

Figure 6 *Shear stress distributions for the central strip for $B = 5$, $B_\tau = 10$, $\zeta = 10$, $\alpha_T = 5$, $\Delta = 0{,}0003$, and $1 - \mu = 0{,}2$, $2 - \mu = 0{,}4$, $3 - \mu = 0{,}6$, (the dashed lines correspond to the cases of complete slippage)*

In Figure 7 the shear stress distributions for different values of parameter ζ are presented. Parameter ζ is related with the sphere velocity according to the equations (24).

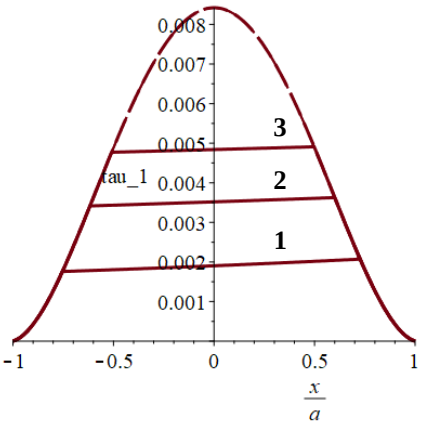

Figure 7 *Distribution of the shear stress for central strip for $B = 5$, $B_\tau = 10$, $\alpha_T = 5$, $\mu = 0{,}3$, $\Delta = 0{,}0005$ and $1 - \zeta = 5$, $2 - \zeta = 10$, $3 - \zeta = 15$ (the dashed line corresponds to the case of complete slippage)*

The results indicate that the size of stick subregion decreases with the growth of parameter ζ, which was introduced in (24) as one of the Deborah number presentation. The higher value of the shear stress in the stick subregion corresponds to the greater sphere velocity. Further growth of the velocity leads to the case of complete slippage in the contact region.

The stick subregion configuration was also studied for different values of layer compliance in tangential direction (Figure 8).

The parameter B_τ essentially influences on the size and displacement of the stick subregion within the contact region. For choosen values of relative slippage, sliding velocity and sliding friction coefficient, increasing of the parameter B_τ leads to the increase of the stick subregion.

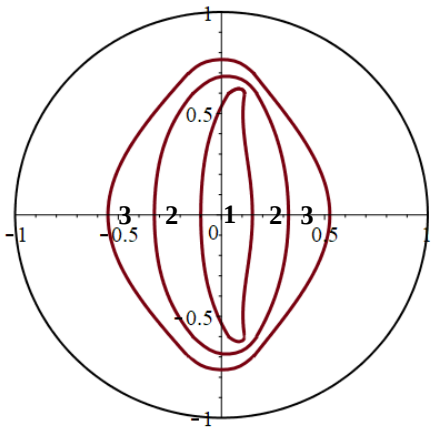

Figure 8 *Stick subregion configuration for $m = 0{,}5$, $\zeta = 10$, $\alpha_T = 5$, $\mu = 0{,}3$, $\Delta = 0{,}0005$, $B = 5$, and $1 - B_\tau = 2$, $2 - B_\tau = 5$, $3 - B_\tau = 10$ (the black line corresponds to the contact area boundary)*

The full traction force is specified by the following relation:

$$T = \iint_{\Omega} \tau(x, y) dx dy \qquad (31)$$

The dependence of the adhesion coefficient which is the ratio T/P (T and P are the traction and normal forces, respectively) on relative slippage Δ was calculated and analyzed for various ratios T_ε/T_σ of relaxation (T_σ) and retardation (T_ε) times in tangential direction, sliding friction coefficient (μ) and the layer material compliance (B) in normal direction. The surface layer thickness (h) was considered constant.

The results presented in the Figure 9 show that the relaxation and retardation times ratio T_ε/T_σ significantly influences the adhesion coefficient value.

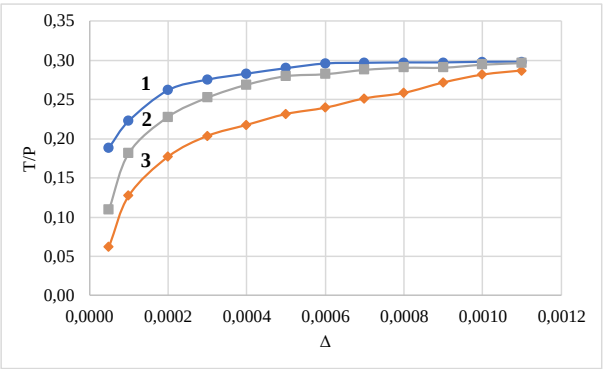

Figure 9 *The dependence of the ratio T/P on relative slippage for $B = 5$, $B_\tau = 10$, $\zeta = 10$, $\mu = 0{,}3$, $1 - \alpha_T = 15$, $2 - \alpha_T = 10$, $3 - \alpha_T = 5$*

The results indicate that for the same values of the relative slippage Δ increasing of relaxation (T_ε) to retardation (T_σ) times ratio (parameter α_T) leads to increasing of the traction force value. The ratio T/P increases with increasing of the relative slippage.

The dependencies of the ratio T/P on relative slippage for various values of the layer compliance in tangential direction are presented at Figure 10.

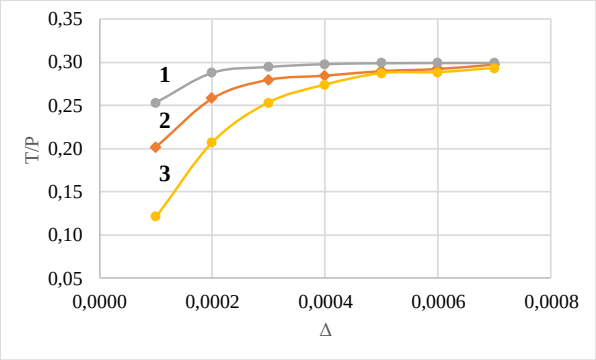

Figure 10 *The dependence of the ratio T/P on relative slippage for B = 10, ζ = 10, μ = 0,3, α_T = 5 and 1 – B_τ = 5, 2 – B_τ = 10, 3 – B_τ = 15*

Comparison of the curves shows that decrease of layer compliance value in tangential direction leads to the growth of ratio *T*/*P* for the same value of relative slippage Δ. The results also indicate that the case of full slippage can be realized at the less values of relative slippage for the layers with less layer compliance.

6. Conclusions

The method for solving the 3-D contact problem for the elastic sphere rolling over the elastic half-space which is covered by a thin viscoelastic layer is presented. It allows us to determine the size and configuration of the contact region and distributions of the normal and shear contact stresses as well as the location of the stick and slip subregions within the contact region.

Based on the developed model it is possible to control the traction force in rolling contact by using the appropriate surface layer properties (its thickness, elastic modulus, relaxation and retardation times), and sliding friction coefficient.

The results can be used for prediction of the friction modifier effect under various rolling conditions. The right selection of lubricating materials can contribute to effective reducing energy losses in the wheel-rail system.

A PRACTICAL METHODOLOGY TO PRIORITISE REPROFILING SITES FOR CORRUGATION REMOVAL

SL Grassie [1]

[1] RailMeasurement Ltd, 79 River Lane, CAMBRIDGE, UK CB5 8HP

[*] e-mail: stuart.grassie@railmeasurement.com

Abstract: A method is proposed to determine objectively where track or a railway system should be reprofiled to control corrugation. The method includes criteria that are pertinent to corrugation in different wavelength ranges. It has been applied successfully over 8 years on one tram system. Measurements also illustrate how it could have been applied to a metro line. Examples of "track memory" are given insofar as corrugation remains more or less fixed even after reprofiling.

Keywords: rail corrugation, rail reprofiling, rail grinding, reprofiling criteria

1. Introduction

Reprofiling is a key component of rail maintenance. Historically the main reason for reprofiling was to remove corrugation. This is still the main reason for reprofiling on several railways, in particular metros and light rail systems. Modification and maintenance of transverse profile and removal of rolling contact fatigue cracks (RCF) have become the main reasons for reprofiling on many railways, in particular heavy haul lines. Routine removal of any corrugation that may exist on these lines is now a welcome side-effect of reprofiling for RCF.

Perhaps surprisingly given this history, there is little if any practical guidance as to when reprofiling should be undertaken for corrugation removal or how this should be prioritised. In the author's experience, a decision is often made based on subjective assessment or, at best, measurements at a few locations. The obvious question arises as to how reprofiling could sensibly be prioritised by such means on a railway system with scores if not hundreds of km of track. The present paper proposes a method that can be used at a minimum to prioritise different sites to be reprofiled for corrugation removal. The method draws on a lifetime of practical experience in this field and has been implemented for several years on a couple of railway systems where the criteria have at least helped to prioritise grinding sites. It combines not only consideration of the severity of corrugation that is relevant to the different wavelength ranges in which it might occur but also a practical appreciation of the length of grinding site that is sensible to treat with a rail grinder. ("Grinding trains" are considered here, but this can be understood to include reprofiling trains more generally.) Individual corrugations can be measured with a straight edge and feeler gauges (albeit rather poorly) and a few metres of rail can be measured with simple manual equipment. However, these methods have limited practical application as a train cannot remove individual corrugations or even reprofile a few metres.

Standards exist such as EN13231-3 [1,2] that state a limit on irregularities that should exist on a rail after reprofiling. The limits are usually if not always stated for a reprofiling site, which begs the question as to how the reprofiling site is selected. The analysis specified in such standards may be thought to offer a means of deciding on the grinding site. However, this is not always as helpful as it might at first appear.

2. Methodology

A common first step in analysis of rail corrugation is to filter measurements into different wavelength ranges: 10-30mm, 30-100mm, 100-300mm and 300-1000mm are considered in refs [1,2] and in other reprofiling standards and specifications. If long wavelength corrugation is thought or known to be a problem, a longer wavelength range may be considered e.g. 1000-1500mm. The filtered profile is further processed in order to demonstrate compliance with a specification or standard.

Several types of analysis of the filtered profile can be considered, roughly in order from greater detail to lesser detail of the grinding site:

a) Consideration of the filtered profile itself.

b) Calculation of a moving average amplitude of the filtered profile as a function of distance. The calculation of moving average is made within a "window" of specified length.

c) Calculation of a "block average" of the filtered profile as a function of distance. This is calculated for a block of specified length.

Analysis according to point (a) is required in ref [2] whereas ref [1] requires analysis according to point (b). Methods of calculating moving averages of root-mean-square (RMS) amplitudes and peak-to-peak amplitudes are considered in Annex D of ref [1].

In each case, a limit is set on the filtered profile, moving average or block average. If a reprofiling site complies with a standard, the fraction of the site over which the limit is exceeded is typically less than a small percentage e.g. 5% for Class 1 reprofiling and 10% for Class 2 reprofiling in refs [1,2].

Analysis according to (a) and (b) offers initial guidance to how an operator could take a continuous measurement of a railway and process the measurement to determine where best to reprofile to remove corrugation (or conversely where reprofiling is least required). The analysis could be made in e.g. 100m sections or, with a little knowledge of the line, for inter-station sections or separately for curves and straights. Such a procedure requires some degree of subjective assessment as well as route knowledge.

It is proposed here that the "block average" i.e. item (c) is possibly the most useful method of analysing a corrugation record to determine where reprofiling should be undertaken on a railway. For the results presented here, the block average of RMS amplitudes has been used. This is

$$B(x,L) = \left(\frac{1}{L}\int_{x-L/2}^{x+L/2} y^2(x)dx\right)^{1/2}$$

where L is the block length and *y(x)* the filtered profile. In reality there are two block averages, $B_L(x,L)$ for the left rail and $B_R(x,L)$ for the right rail. These may differ significantly e.g. in curves.

A block length that provides the correct level of detail for present purposes is 50m.

In common with the approach taken in standards such as [1,2], the amplitude of the block average is compared to a limit and the areas are detected where the amplitude exceeds that limit. It is proposed here that an area of the track should be shown as appropriate for grinding if either $B_L(x,L)$ or $B_R(x,L)$ exceeds a prescribed limit.

The wavelength ranges in which corrugation occurs most commonly are 30-100mm and 100-300mm. The limits on block average that have been used here for these wavelength ranges are shown in Table 1 with the corresponding limits on moving average RMS amplitude from [1]. There is nothing sacrosanct about these limits: they could be adjusted up or down depending on the grinding budget available. However, it is strongly recommended that the limit varies approximately in proportion to the wavelength range, as illustrated by the figures in Table 1, and that once the limits have been decided these should be used consistently in order to reduce variation from one grinding campaign to the next. There is little point in having objective criteria that are applied subjectively.

Table 1 *Limits on block average RMS used to show areas requiring reprofiling*

wavelength range (mm)	limit on moving average RMS amplitude (μm), from [1]	limit on block average RMS amplitude (μm)
30-100	4	10
100-300	12	30

A further step in the proposed methodology is to consider the requirements of the reprofiling train. It is questionable whether blocks of less than 100m length can sensibly be reprofiled by even small reprofiling trains that are used for metros and light rail systems. To reprofile shorter distances risks leaving an excessive number of locations where irregularities are poorly controlled because the reprofiling equipment is sequenced down and up at the ends of the site. Moreover, if there were a couple of blocks that were shown by the analysis to require reprofiling, and if these were less than about 50m apart, it would reduce both work and areas of potentially poor finish to combine these sites into one. These requirements are included in the analysis undertaken here. The minimum length of track to be ground would depend on the grinder available.

3. Equipment

A fundamental requirement of the proposed technique is that a continuous or quasi-continuous measurement is made of the railway system: a quasi-continuous measurement could, for example, be one that is concatenated from several individual measurements or that is made from clear intermediate points, such as stations. The measurements must, moreover, be sufficiently accurate to give the technique some validity.

The measurements used here have been made using two different types of equipment: the so-called "bi-CAT" (Figure 1), which is a version of the CAT (Corrugation Analysis Trolley) equipment that has been developed for two rails; and the RCA or Rail Corrugation Analyser (Figure 2), which was developed initially for use on rail grinding trains. The CAT has been widely used and there is a significant volume of reference material e.g. [3-6]. There are two reference papers on the RCA in the open literature [7,8]: the equipment was designed for use on a reprofiling train rather than as an item of research equipment. The software provided with the CAT, bi-CAT and RCA includes the features discussed here: the analysis can be undertaken both rapidly and routinely once the measurements are available.

Figure 1 *bi-CAT (Corrugation Analysis Trolley for two rails)*

Figure 2 *Rail Corrugation Analyser (RCA)*

A CAT and bi-CAT were used annually for the period 2011-2018, except for 2015, in a survey of the same tram system. Measurements from this series of surveys are presented here. The RCA measurements that are presented were obtained on one line of a metro system on 4 occasions over a period of 31 months.

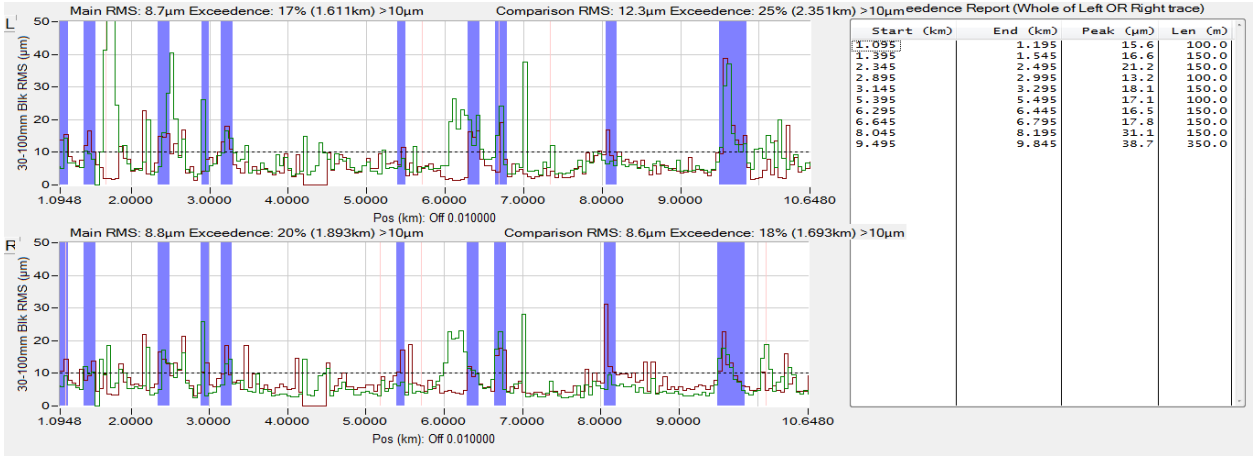

Figure 3 *Analysis of corrugation in 30-100mm wavelength range, showing recommended reprofiling areas*

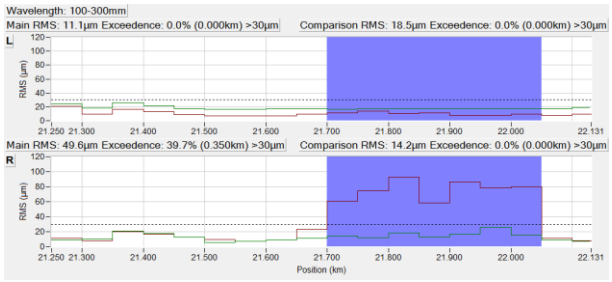
4. Results

4.1 long-term survey of a tram system

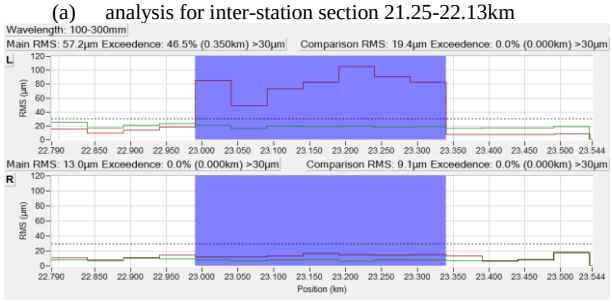
About 9km of measurements are shown in Figure 3 for one line of the tram system that was surveyed during the period 2011-2018. Corrugation in the 30-100mm wavelength range is shown as this was found to be more severe than corrugation in the 100-300mm range. The upper graph displays the block average RMS data for the line for the left rail; the lower graph is for the right rail. The areas in which reprofiling would be recommended based on the criteria given in Section 2 are tabulated at the side of the graphs. There are in fact two sets of measurements superposed in Figure 3; the tabulated data, and the corresponding purple areas in the graphs, are for the later set of measurements (in 2018). The 2018 measurements are shown in red in Figure 3. The corresponding measurements for 2017 are shown in green. The sites tabulated give a total of 1.55km to be reprofiled, or about 16% of the distance shown.

There is a striking consistency from one year to the next in the areas shown as requiring reprofiling. This consistency has indeed been found over the full 7 years of the survey. For this, and doubtless also other tram systems, the most severe corrugation is found where trams accelerate away from and brake into tram stops.



The overall recommendations that have been made from the corrugation survey on this tram system are also remarkably consistent over 7 years (Table 2) during which reprofiling has been undertaken annually, for both profile and corrugation management. The methodology proposed in Section 2 has been used since 2011 to select areas to reprofile for corrugation.

Table 2 *Summary grinding requirements, 2011-2018*

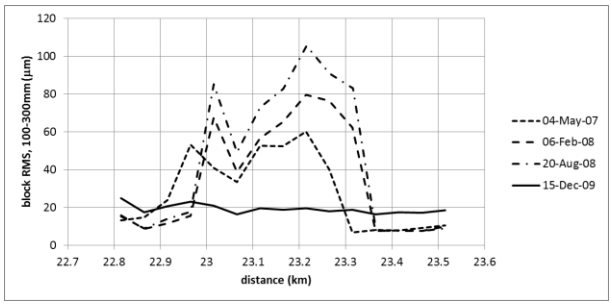


Year	km	%
2018	10.2	21
2017	12.6	26
2016	12.8	26
2014	8.2	17
2013	9.8	20
2012	11	23
2011	25	50

4.2 routine surveys of a metro line

RCA measurements are examined here from one line of a metro system. On this line corrugation exists in both the 30-100mm and 100-300mm wavelength ranges but is more severe in the latter range.

(a) analysis for inter-station section 21.25-22.13km



(b) analysis for inter-station section 22.79-23.54km

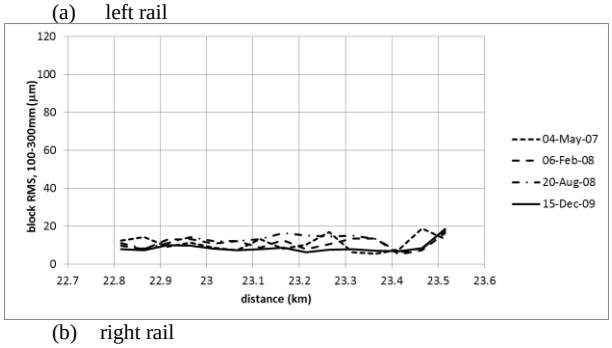


Figure 4 *Analysis of corrugation in 100-300mm wavelength range, showing recommended reprofiling areas for two inter-station sections on a metro line*

Areas that would be recommended for reprofiling are shown in Figure 4 for two inter-station sections on this line. The section of line in Figure 4(a) is in a right-hand curve whereas that in Figure 4(b) is in a left-hand curve: the low rail is corrugated in both cases, doubtless as a result of so-called "rutting" [9].

The red lines in each graph and the areas in which reprofiling would be recommended correspond to measurements made in August 2008. The green lines correspond to measurements taken after grinding, in December 2009. The whole line had been reprofiled in the interim, yet it is clear that only about 40% of both inter-station sections shown here would have required reprofiling for corrugation removal if the objective criteria proposed here had been used.

(a) left rail

(b) right rail

Figure 5 *Analysis of corrugation in 100-300mm wavelength range for inter-station section 22.7-23.6km, May 2007 to December 2009*

Measurements for the section of line 22.7-23.6km are shown in Figure 5 for four occasions over the period May 2007 to December 2009. There is again remarkable consistency in the area in which corrugation appears, as is shown also for the tram line in Figure 3. In this case, however, the corrugation develops steadily until being removed between August 2008 and December 2009.

5. Discussion and conclusions

Objective criteria and a corresponding methodology are proposed to determine where a length of track or a railway system should be reprofiled for corrugation removal. A novel feature of the methodology is that it considers some constraints imposed by a typical reprofiling train. Criteria for reprofiling are proposed that are relevant to the 30-100mm and 100-300mm wavelength ranges in which corrugation is most prevalent. These could be varied for other wavelength ranges and also according to the grinding budget available to the railway system.

The criteria have been applied over a period of 7 years on a tram system. The annual survey that is undertaken to guide the reprofiling campaign shows that after initial settlement, the recommendation is that about 20-26% of the track is consistently recommended for reprofiling. This could represent a significant saving over a subjective assessment of where reprofiling should be undertaken.

Measurements are presented for a metro line that have been taken over a period of more than 2 years. For this line the critical wavelength range for corrugation is 100-300mm. Corrugation is found to increase steadily in severity until reprofiling was undertaken before the final measurement. It is no longer known what criteria were used to decide where reprofiling should be undertaken. However, if the proposed method had been used, this would have resulted in reprofiling of only about 40% of the two heavily-curved inter-station sections for which measurements are shown.

Objective criteria for reprofiling in combination with the proposed methodology could result in significant savings in the maintenance budget for those railways where reprofiling for corrugation removal is routine.

Measurements taken on railway systems over several years show remarkable consistency in where corrugation occurs and where it recurs after reprofiling. This is an excellent illustration of "track memory". Examples are shown from a metro and a tram system. For the tram system, corrugation occurs mainly on entry to and exit from tram stops. For the metro line examined here, corrugation occurs on the low rail in curves.

Acknowledgments
The author is grateful to clients and railway systems who have supplied data and for their use of RailMeasurement equipment in doing so. He is also grateful to colleagues who have helped with analysis of these measurements.

Abstract: Wheel rail force is the direct result of wheel rail contact. The instrumented wheelsets can detect wheel rail force physically in real time. However the high cost and the inconvenient maintenance are difficulties need to be solved. So we developed a simple and low cost method of virtual measurement of wheel rail contact force in this paper. We use the axle box acceleration to identify the wheel rail force by big data machine learning technology. The test result shows that the method has a good effect on wheel rail vertical force identification.

Keywords: virtual measurement; wheel rail force; axle box acceleration; inspection data; machine learning.

1. Introduction

Nowadays, many countries use instrumented wheelsets to measure the wheel rail force for the reason that measuring wheel rail force gives a real time view of the wheel rail contact. Measuring the wheel rail force can ensure the vehicle is not susceptible to derailment. Then we can take necessary measures to reduce the risk of vehicle derailment when the wheel rail force exceeds safety limits. At present, although the instrumented wheelsets can detect wheel rail force physically in real time its cost is relatively high and its maintenance is very inconvenient [1]. It can only be installed on a few inspection trains.

The purpose of this research is to develop a simple and low cost method for virtual measurement of wheel rail contact. The mechanism analysis shows that there are some complicated nonlinear relationships between the vehicle's vibration response and wheel rail contact [2]. In particular, there is a strong nonlinear connection relationship between the axle box vibration acceleration and the wheel rail force [3]. So we can use the axle box acceleration to identify the wheel rail force. This is a typical regression problem [4], which we can use machine learning and data modelling techniques to solve in the era of big data.

The results of the research will do help for physical and virtual measurement of wheel rail contact. It will also bring an innovative solution to practical railway engineering problems such as wheel rail force identification because the accelerometers are very cheap, easy to install and maintain on the axle box of the running train [5].

2. Data acquisition and analysis technology

Data acquisition and preprocessing are the first steps in building a data model. Some simple pre-processing operations can be performed by preliminary analysis of the data.

2.1. Data acquisition

Wheel rail force and axle box acceleration data were collected by using instrumented wheelsets and accelerometer mounted on the high speed comprehensive inspection train, shown as figure 1 and 2. Comprehensive inspection train detects the high speed railway lines every day in China. It has collected a large amount of wheel rail force and axle box acceleration data which reaches to PB level.

***Fig. 1** High speed comprehensive inspection train*

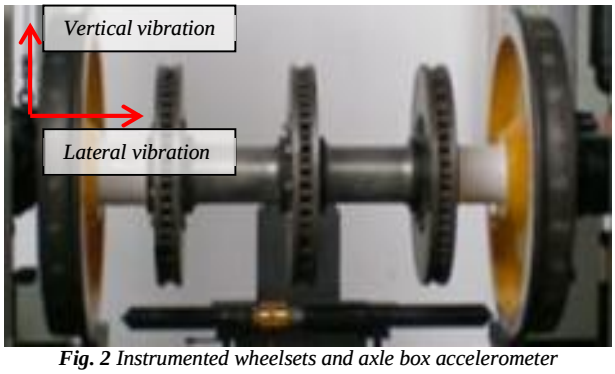

***Fig. 2** Instrumented wheelsets and axle box accelerometer*

Accelerometer captures axle box vibration acceleration in both vertical and lateral directions. The direction is consistent with the direction of wheel rail vertical and lateral forces.

2.2. Data analysis technology and pre-processing

The original detection data contains noise interference, which cannot be used directly to build a data model. Therefore, the analysis and pre-processing of data is an indispensable task. Time frequency analysis such as short-time Fourier transform is commonly used to analyse axle box acceleration and wheel rail force original detection data [6]. We can remove noise from wheel rail force and axle box acceleration data by separating and extracting the features of different frequency bands of the original data [7]. The method is effective for data pre-processing.

Adaptive Gaussian chirplet signal decomposition algorithm has the best time frequency resolution in all signal decomposition algorithms [8]. Moreover, it has the minimum time-frequency bandwidth product which is $1/(4\pi)$, so it can catch the partial time-frequency characteristic of signal accurately. It is widely used in non-linear and non-stationary signal decomposition, especially for the signal which is superposition of chirplet functions. We use this algorithm to decompose the original detection data computes very fast and it can avoid the cross term's interferer of the Wigner-Ville distribution.

The Gaussian chirplet's basis function is given as following:

$$h_m = (\frac{a_m}{p})^{\frac{1}{4}} \exp\{-\frac{a_m(t-t_m)^2}{2} + j[w_m + \frac{b_m(t-t_m)}{2}](t-t_m)\} \quad (1)$$

Where, a_m -is time scale factor; b_m -is frequency modulation rate; (t_m, w_m) -is the time-frequency centre of basis function.

The adaptive signal decomposition process is a kind of orthogonal matching projection method. Any signal s(t) to be decomposed can be expand as following:

$$s(t) = \sum_{p=0}^{\infty} B_p h_p(t) = \sum_{p=0}^{\infty} < s_p(t), h_p(t) > h_p(t) \quad (2)$$

Expansion coefficients B_p is defined as the inner product of $s_p(t)$ and $h_p(t)$, which reflects the similarity degree between the signal and the basis function. And $s_p(t)$ is the residual signal of $s_{p-1}(t)$ orthogonal projection to $h_{p-1}(t)$, the adaptive signal decomposition process is shown as following:

$$s(t) = \sum_{i=0}^{p-1} B_i h_i(t) + s_p(t) \quad (3)$$

Because Gaussian chirplet basis function has unit energy. Its norm is equal to 1. So, after p-1 steps decomposition we have:

$$\|s(t)\|^2 = \sum_{i=0}^{p-1} B_i^2 + \|s_p(t)\| \quad (4)$$

We want to find a basis function which is most similar with the decomposed signal in each step. When the inner product B_p is maximum, and the residual signal's energy is minimum. The decomposition progress will gradually converge. When the residual signal's energy is small enough to satisfy our requirement the decomposition progress ends. The optimize problem is shown as following:

$$B_i^2 = \max(< s_i(t), h_i(t) >)^2, \quad i \in (1,2,\cdots,p-1) \quad (5)$$

For example, we use the above algorithm to analyse and pre-process vertical axle box acceleration signal x(t) and wheel rail vertical force signal y(t), the result are shown as figure 3 and figure 4.

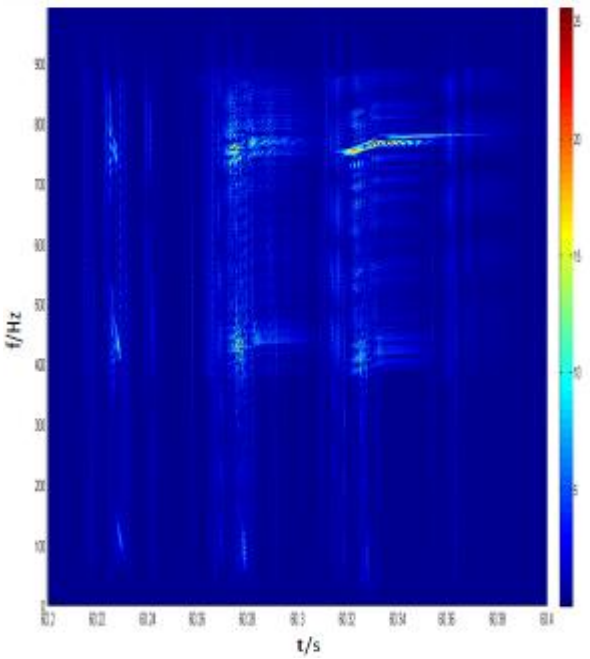

Fig. 3 *Time-frequency feature of vertical axle box acceleration*

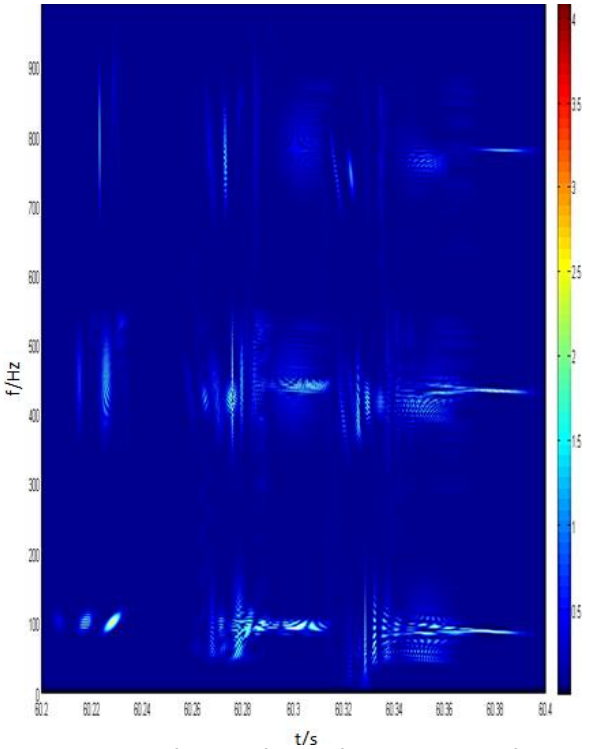

Fig. 4 *Time-frequency feature of wheel rail vertical force*

We can see from figure 3 and 4 that the pre-processing algorithm for signal adaptive decomposition overcomes the cross-term of Wigner-Ville distribution. It reveals the signal's time-frequency feature clearly. We can extract feature data for subsequent machine learning data modelling work.

3. Model establishment

When we finish changing the raw data into transformed data after data analysing and pre-processing, we need to build a model based on the transformed data. Wheel rail force identification belongs to the regression problem. So we will use regression analysis technology to recognize the patterns between the transformed data. Regression analysis estimates the conditional expectation of the dependent variable given the independent variables. A function of the independent variables called the regression function is to be estimated. Due to the strong nonlinearities between axle box acceleration and wheel rail force data, it is difficult to construct regression functions using traditional parametric methods. Therefore, we use the non-parametric machine learning regression method to study a predictor between them. The predictor does not take a predetermined form. It is constructed according to the information derived from the data. It needs larger sample sizes than parametric regression models because the data must supply the model structure as well as the model estimates. Artificial neural network is an effective non-parametric regression method.

3.1. Artificial neural network

Artificial Neural Network (ANN) is computational models inspired by brain central nervous systems that are capable of machine learning and pattern recognition. It is usually presented as a system of interconnected 'neurons' that can compute values from inputs by feeding information through the network, which has a good learning ability and has been widely used in many engineering areas.

However, those based on the traditional gradient descent and error back propagation learning algorithm, such as BP, RBF, has the following disadvantages [9]:

(1)The training speed is very slow because the input and output weights and the biases of hidden layer need to be tuned iteratively.

(2) The result may be trapped in local minima, and then we will get local optimal solution. So we are unable to find the global optimal solution.

(3) In training process, we must set a lot of training parameters such as learning rate. For example, the small learning rate will lead to very slow algorithm's convergence speed. On the contrary, the larger learning rate results in not convergence.

To avoid the above problems, we will use a memory based neural network that provides estimates of continuous variables and converges to the nonlinear regression surface. This general regression neural network (GRNN) is a one pass learning algorithm with a highly parallel structure, shown as figure 5.

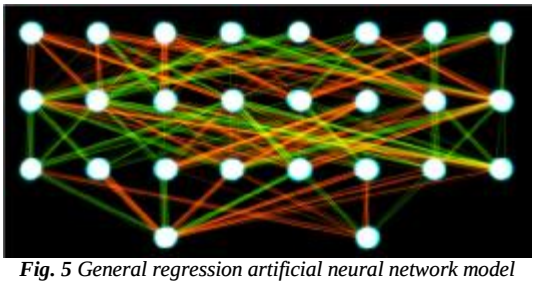

Fig. 5 *General regression artificial neural network model*

Even with sparse data in a multidimensional measurement space, the algorithm provides smooth transitions from one observed value to another. This algorithmic form can be used for any regression problem. The parallel network form can be used in applications such as virtual measurement of wheel rail force by axle box acceleration. Besides, the model establishment process is an iterative and interactive process. We need to carry out multiple tests to adjust the model parameters in order to get satisfactory results.

3.2. Deep learning regression

In recent years, deep artificial neural network has become a research hotspot in the field of machine learning. Deep learning allows computational models that are composed of multiple processing layers to learn representations of data with multiple levels of abstraction [10]. It discovers intricate structure in big data sets by using the backpropagation algorithm to indicate how a machine should change its internal parameters that are used to compute the representation in each layer from the representation in the previous layer. Therefore, it has a stronger ability to solve regression problem as a general regression neural network.

A deep neural network is an artificial neural network with multiple hidden layers between the input and output layers. For any deep artificial neural network, the structure is shown as figure 6. It consists of three parts: one input layer, multiple hidden layers (1 to v) and one output layer. The neuron nodes are fully connected between each layer. It is typically feedforward network in which data flows from the input layer to the output layer without looping back. The deep neural network can model complex non-linear relationships based on its deep complex structure.

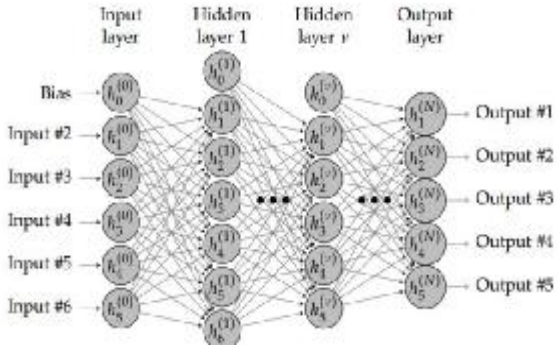

Fig. 6 *Structure of deep artificial neural network*

Deep learning algorithms are machine learning methods based on distributed representations. Deep learning attempts to learn high level features in big data by using structures composed of multiple non-linear transformations. The frequently used models are deep belief network, stacked auto-encoder and convolutional neural network [11].

Nowadays, we can easily complete deep learning training tasks using a variety of machine learning platforms with the help of the open source deep artificial neural network learning tools, such as Keras, Theano, TensorFlow and so on.

4. Test verification

We have tested the data model by field test inspection data which was got by high speed comprehensive inspection train run in high speed railway lines in China. The input parameters are axle box's lateral and vertical acceleration data. The output parameters are wheel rail vertical and lateral force data. The total number of training and testing groups exceeds one million samples. The experiments are carried out in research and application innovation centre for big data technology in railway, China academy of railway sciences corporation limited. We have designed some tests to verify the data model's ability.

4.1. Experimental data set

The experimental data set used in this study contains vehicle dynamic response acceleration and wheel rail force data at different speeds. The total number of data samples is over one million. The data format is as follows:

Table 1 *Data format*

No	Explanation	Unit
1	Speed	km/h
2	Axle box vertical acceleration	m/s^2
3	Axle box lateral acceleration	m/s^2
4	Vertical wheel rail force	KN
5	Lateral wheel rail force	KN

The division of test sets and training sets is based on the principle of cross-validation. We randomly selected 70% of the data to train the model, and used the remaining 30% to test the effect of the model. All experimental data needs to be subjected to data pre-processing operation in accordance with the method of Part 2.

4.2. Traditional method: linear regression

First, we use 'scikit-learn' machine learning package in Python to build a data model based on the training dataset using the linear regression function.

Linear regression is a linear approach to model the relationship between a dependent variable and one or more independent variables. For more than one independent variable, the process is called multiple linear regression.

Given a dataset $\{y_i, x_{i1}, \ldots, x_{ip}\}$, i=1 ⋯ n, represents sample data, p is the number of independent variables or features. The linear regression model assumes that the relationship between the dependent variable y and the p-vector of independent variables x is linear. This relationship is modelled through a disturbance term or error variable ε. It is an unobserved random variable that adds 'noise' to the linear relationship between the dependent variable and independent variables. The model takes the form:

$$y_i = \beta_0 + \beta_1 x_{i1} + \cdots + \beta_p x_{ip} + \varepsilon_i = x_i^T \beta + \varepsilon_i \quad (6)$$

Where T denotes the transpose, $x_i^T \beta$ is the inner product between vectors x_i and β. We can use 'scikit-learn' library for machine learning to implement linear regression function.

We use the correlation coefficient to evaluate the performance of the trained regression model. A correlation coefficient is a numerical measure of some type of correlation, meaning a statistical relationship between two variables. The variables may be two columns of a given data set of observations, often called a sample, or two components of a multivariate random variable with a known distribution. Several types of correlation coefficient exist, each with their own definition and own range of usability and characteristics. We use the Pearson product-moment correlation coefficient to evaluate the performance of the trained regression model in our test. The Pearson product-moment correlation coefficient, also known as r, is a measure of the strength and direction of the linear relationship between two variables that is defined as the covariance of the variables divided by the product of their standard deviations. This is the best known and most commonly used type of correlation coefficient; when the term "correlation coefficient" is used without further qualification, it usually refers to the Pearson product-moment correlation coefficient. The mean values of the two-dimensional data $x_1, x_2, \cdots x_n$ and $y_1, y_2, \cdots y_n$ are a and b, respectively. The Pearson product-moment correlation coefficient between the two variables is defined as follows:

$$r = \frac{\sum_{i=1}^{n}(x_i - \bar{x})(y_i - \bar{y})}{\sqrt{\sum_{i=1}^{n}(x_i - \bar{x})^2 \sum_{i=1}^{n}(y_i - \bar{y})}} = \frac{n\sum_{i=1}^{n} x_i y_i - \sum_{i=1}^{n} x_i \sum_{i=1}^{n} y_i}{\sqrt{[n\sum_{i=1}^{n} x_i^2 - (\sum_{i=1}^{n} x_i)^2][n\sum_{i=1}^{n} y_i^2 - (\sum_{i=1}^{n} y_i)^2]}} \quad (7)$$

The Pearson product-moment correlation coefficient r measures the linear correlation between the variables x and y, and can reflect the similarity between variables. When $0<r\leqslant 1$, it means that there is a positive correlation between variables; When $-1\leqslant r<0$, it means that there is a negative correlation between variables; When r=0, there is no linear correlation between variables. In the field of related analysis at the special cases, when $0<r\leqslant 0.3$, it is called weak correlation. When $0.3<r\leqslant 0.6$, it is called medium correlation. When r>0.6, it is called strong correlation.

The traditional linear regression method was used to establish data models based on the field test data. The wheel rail vertical force and the wheel rail lateral force were respectively identified. The results are shown in Figures 7 and 8.

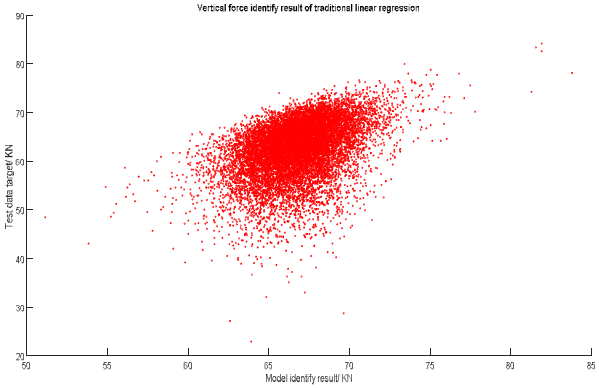

Fig. 7 *Vertical force identify result of traditional linear regression*

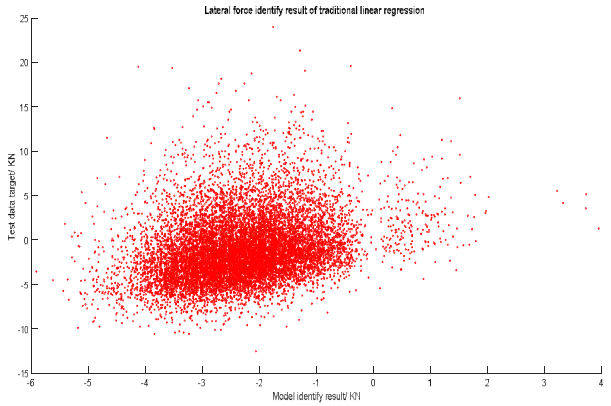

Fig. 8 *Lateral force identify result of traditional linear regression*

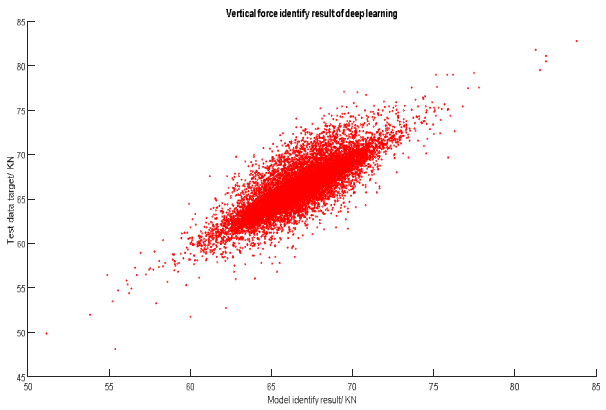

Fig. 9 *Vertical force identify result of deep learning*

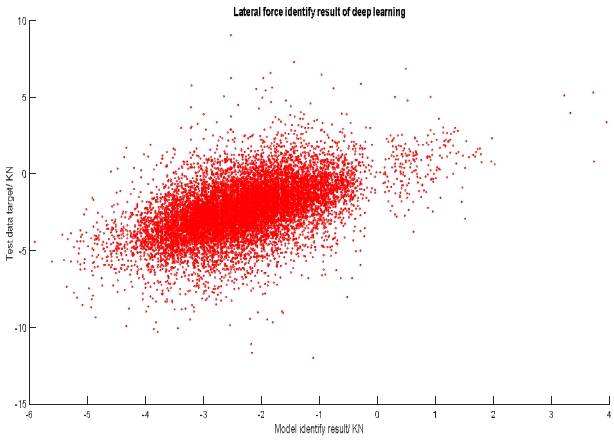

Fig. 10 *Lateral force identify result of deep learning*

It can be seen from figure 7 that the linear regression model has a correlation coefficient of 0.58 for the vertical force. This indicates a certain medium correlation between the wheel rail vertical force identified by the established linear regression data model and the field test data.

As can be seen from figure 8, the correlation coefficient of the linear regression model for the lateral force is 0.1. This indicates that the correlation between the wheel rail lateral force identified by the established linear regression data model and the field test data is very weak. It can be seen that the traditional linear regression model is not sufficient to describe the nonlinear relationship between the vibration acceleration of the axle box and the wheel rail force.

4.3. Deep learning regression

It can be seen from the experimental results of linear regression that there is a strong nonlinearity between the axle box acceleration and the wheel rail force data. Therefore, we will use deep learning techniques to build data models that identify the nonlinear relationship between the input and output.

We use Keras deep learning framework to achieve deep learning modelling process. We can regression with the Keras deep learning library in python.

We use 'scikit-learn' built-in function 'GridSearchCV()' to determine the optimal network depth 'max_deph' and the smallest sub-weight 'min_weight.' Then we establishe a five-layer neural network model based on deep neural network. The number of neurons in the middle hidden layer is 26, 16 and 9, respectively. The 'relu' activation function is activated in the middle layer, and the last layer uses the linear function to train the data model. At the same time we use the 'Batch Normalization' tool to reduce the data model's overfitting. Finally, we conducted a cross-validation test. The test set is cross-validated and the optimal result is selected as the model parameter according to the result of the cross-validation.

In addition, we continuously adjusted the parameters for training and tried different parameter optimization methods to achieve the optimal training effect during the experiment, and then we tested again. The obtained data model identification results are shown in Figure 9 and Figure 10.

It can be seen from figure 9 that the deep learning model has a correlation coefficient of 0.71 for the vertical force. This indicates there is a strong correlation between the wheel rail vertical force identified by the established deep learning data model and the field test data.

As can be seen from figure 10, the correlation coefficient of the deep learning model for the lateral force is 0.35. This indicates a certain medium correlation between the wheel rail lateral force identified by the established deep learning data model and the field test data.

The comparison results of data model identification results established by linear regression method and deep learning technology are shown in Table 2.

Table 2 *Test result*

Data model	Vertical force	Lateral force
Linear regression	0.58	0.1
Deep learning	0.71	0.35

It can be seen that the data model established by deep learning technology can well describe the nonlinear relationship between the axle box vibration acceleration and the wheel rail vertical force. However, the description of the complex nonlinear relationship between the axle box vibration acceleration and the wheel rail lateral force still needs to be improved in the future.

5. Conclusions

This paper proposes a new virtual measurement method for wheel rail contact force detection. The method of virtually measuring the wheel rail force using axle box acceleration is simple, effective and low cost. If this approach can be effectively combined with the mechanism modeling, in other words, using simulation data instead of field test inspection data to build the model, it can be widely used in railway engineering such as using in the daily commercial passenger trains or freight trains in the near future.

TWIN DISC EVALUATION OF THIRD BODY MATERIALS IN THE WHEEL/RAIL INTERFACE

Dmitry V. Gutsulyak[1], Louisa J. E. Stanlake[1,*], Hao Qi[1]

[1] L.B. Foster Rail Technologies, Corp. 4041 Remi Place, Burnaby, BC, Canada, V5A 4J8

[*] E-mail: lstanlake@lbfoster.com

Abstract:
Twin disc instruments are an essential tool for evaluating third body materials in the wheel/rail interface. Twin disc testing results (from two different scale instruments) were proven to correlate exceptionally well with field performance of Top of Rail products and Gauge Face greases. Furthermore, the twin disc instrument was utilized to evaluate the friction characteristics (creep curve) and Rolling Contact Fatigue (RCF) propagation potential of the TOR materials. Common environmental contaminants (leaves, clay, iron oxides) were studied for their potential to cause low adhesion conditions in presence of water. A correlation between material hardness and resultant friction levels was determined.

Keywords: Twin disc instrument, friction modifiers, gauge face greases, environmental contaminants, RCF, friction management, low adhesion.

1. Introduction

The third body layer in the wheel/rail interface not only determines the coefficient of traction (CoT), but also impacts the friction-creepage behaviour (positive, neutral, and negative friction), wheel/rail wear, and rolling contact fatigue (RCF) crack development and propagation. The composition of the third body layer constantly changes with variable environmental and operational conditions resulting in a wide range of materials found on tracks in various amounts. In addition to friction modifiers, lubricants, and adhesion enhancers, which are deliberately applied on tracks by railroads, there are a number of contaminants originating from surrounding environment, such as moisture, fallen leaves, dirt etc. Also, different forms of iron oxides and wear debris are always present on wheel and rail surfaces. Certain materials or their combinations may lead to accelerated wear and RCF crack propagation or result in low adhesion conditions, which can compromise railroad safety and operations.[1-4] The complex mixture of third body materials was once described using a "bathtub model" with multiple taps and drains, which illustrates the overall complexity of the system and hints at the difficulties of studying it in the field.[5] A better controlled and reproducible laboratory evaluation of typical third body layer constituents by using twin disc instruments provides a valuable insight on the effects of such materials on the wheel/rail interaction. However, new relevant twin disc testing methodologies are required for comprehensive studies.

2. Twin Disc Testing of Third Body Materials

2.1. Instrumentation

Twin disc testing was carried out using TE72 and TE73H twin disc rigs (manufactured by Phoenix Tribology Ltd.) as schematically shown in Figure 1 and Figure 2. The main difference between the two machines is the specimen size, where the TE72 uses 50 mm diameter discs and the TE73H uses 300 mm discs. Both instruments are automated where the input values (such as load, speed, slip, rates to achieve inputs) can be programmed into the software that controls the instrument. The specimen discs are loaded together (using pneumatic loading bellows) with force transducer feedback (uncertainty ± 0.25%) and are driven at controlled speeds using independently controlled variable speed Vector drives. Precision speed encoders in both motors are used to continually measure the rotational speed (uncertainty ± 0.01%). Torque transducers continually monitor the resultant torque (uncertainty ± 0.03%) which in turn is used to determine the coefficient of traction (CoT). Slip or creep levels are achieved by alteration of the rotational speed of each independent drive, where the wheel disc acts as the driving disc and the rail disc acts as the brake. A load cell mounted on the load bellows ensures that the required load is continually applied. Specimens used during the testing were manufactured from deep head hardened microalloy rail (368 Brinnel surface hardness and 124907 PSI yield strength) for the TE 72 instrument. The discs were machined to a diameter of 50 or 55 mm with a contact band width of 10 mm. Due to the size of the discs required for the TE73H (300 mm diameter, 10mm contact band) actual wheel and rail material could not be used. These discs were manufactured from D2 steel, which was heat treated to provide finished hardness of 59-61 Rc. All twin disc testing was completed using a line contact between the discs.

2.2. Retentivity Testing and CoT

Railroads are currently seeing rapid expansion of both Top of Rail (TOR) and Gauge Face (GF) technologies, and a number of alternative materials are emerging as these markets grow. Use of these materials can influence favourably wheel and rail life, noise and energy consumption. Detailed field validation of new products

is difficult and takes a significant amount of field resources to undertake. Recently, railroads have been looking to twin disc testing for initial screening of friction management products in an effort to save costs and time. A twin disc instrument with the ability to effectively simulate the conditions at the wheel/rail interface can be successfully used for preliminary evaluation of both TOR and GF products. Twin disc testing of solid wheel flange/rail gauge lubricants has already become a standard in the railroad industry,[6] however, there is a lot of potential to further expand the testing methodologies to include evaluation of liquid TOR and GF grease products. It is a highly useful tool to assess new and experimental friction management products as part of a comprehensive validation program. The twin disc can be used to assess the product durability by specially designed retentivity testing. The retentivity of friction management products under high load and creep can be used as an indicator of potential performance in the field, such as relative carry-down distances (effective track coverage with one application site) and required application rates.

2.2.1. TOR Product Retentivity Testing

Top of Rail products are very diverse in their chemical make-up and can be classified as water-based, oil-based or hybrid (combination of water and oil-based). The classification of TOR materials is also outlined further in [7]. The differences in chemical composition results in a wide variation of friction levels and material retentivity (durability) at the wheel-rail contact. Several friction modifiers have been studied in various prior twin disc studies,[4, 8-12] but there is no available data on direct retentivity comparison of different types of TOR products and their relative performance in the field. Materials for TOR application that were assessed in current study include TOR friction modifiers, lubricants and hybrid materials:

- TOR Friction Modifiers - water-based drying material (TOR Products A and B)
- TOR Hybrid Materials – oil and water-containing non-drying material. (TOR Product C)
- TOR Lubricants - oil-based non-drying materials (TOR Product D)

There are several twin disc retentivity testing methodologies possible, which depend on the instrument functionality and the type of material to be tested. The TOR material can be coated on one of the discs prior to test run. Alternatively, the TOR material can be applied directly to rotating discs with a syringe or special applicator that can apply small doses after achieving desirable test conditions. This dynamic application of the material was decided to be more suitable to study TOR materials that have different drying properties, as it allows for better simulation of material pick-up and conditioning of wheels/rails in the field. The dynamic retentivity twin disc graphs for TOR Products A through D are shown in Figure 3.

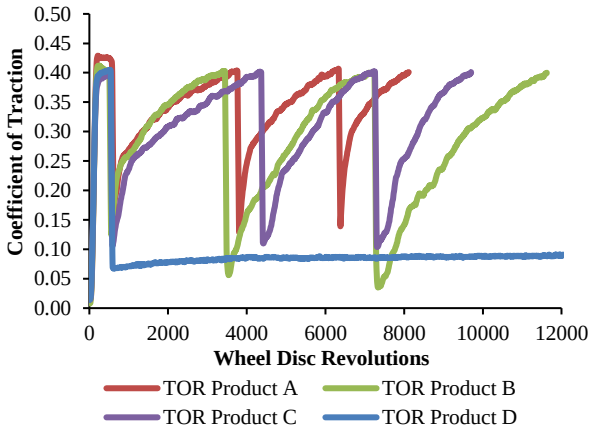

Figure 3 *Retentivity testing of TOR Products A-D on the TE72 instrument. Conditions used were: 500 rpm wheel disc speed, !000 MPa contact pressure and 1% creep, with 25 mg of product applied dropwise after reaching CoT of 0.4.*

Three sequential dynamic additions (1 drop, ~25 mg) were performed with a syringe for TOR Products A, B and C at 1% creep, 1 GPa contact pressure and 500 rpm wheel disc speed. The friction level drops immediately after each product addition and slowly climbs back to dry baseline as product wears off. The number of cycles required for the CoT to reach 0.4 is considered the product's retentivity. At this point most of the product

on the contact surface of the discs is considered worn off.[13] Thus, a new portion of the product was added each time after reaching this friction level. The only exception is oil-based TOR Product D, which exhibited such an extremely long retentivity and low friction level (CoT = 0.07-0.09) that only one addition of this product was used. Such behaviour of oil-based lubricant is in sharp contrast to friction modifiers and hybrid materials, which provide much faster increase in friction levels. Interestingly, addition of TOR Product B may result in initial friction levels below the oil lubricant level, but it quickly rises as the product dries out and/or wears off. The average twin disc retentivity results are summarized in Figure 4, which demonstrates the following order in the retentivity of the TOR products: Product A < Product C < Product B << Product D.

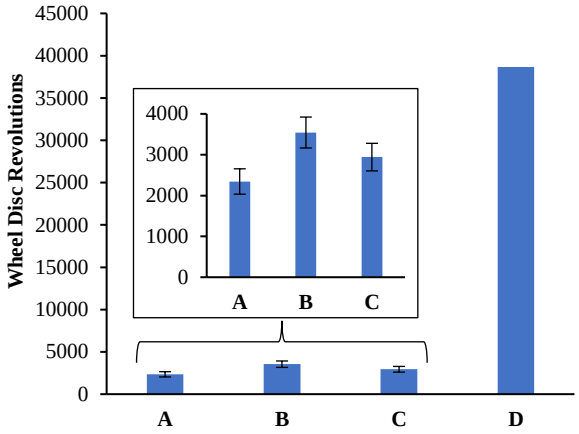

Figure 4 *Twin disc retentivity summary of TOR Products A-D using data from Figure 3.*

2.2.2. Field Trial Data for TOR Products

TOR Products A, B and C were applied on a Class II railroad through a trackside application unit that was installed 5.6 km (3.5 miles) east of a sharp 8º08' curve. The train traffic was bidirectional in the river grade (<1% gradient) test zone, with loaded trains travelling westbound. The test curve was equipped with strain gages to measure the lateral force reductions as a result of TOR product application. Use of push tribometer to measure TOR friction levels as a result of applying a TOR product can be misleading. Depending on the carry down properties of the material, more TOR product can end up on surface of the wheel as opposed to the rail, resulting in high friction readings (0.5 to 0.6) if a push tribometer is used to measure the TOR.[14] Lateral force measurement sites will provide force data independent on how the material is transferred to the test curve. The data collected in the test curve was filtered to ensure the comparison of results was using statistically significant values from similar train consists.[7, 15] Data was collected over a 1.5-month period, where track conditions remained the same during the duration of the trial. The application rate of each material was the same for each phase of the test and was confirmed by physical measurements. Baseline conditions, where no product was applied, were restored intermittently between the product phases. The data from each product phase was compared to the most relevant (closest in time) baseline value. Figure 5 shows the frequency distribution plot for TOR Products A, B and C at an application rate of 0.25 L/kaxle (L/1000 axles). Data from TOR Product A phase shows no relevant difference in lateral force distribution compared to the baseline, indicating this product did not carry down to the intended curve. Both TOR Product B and C phases show a drop in frequency of the high damaging forces greater than 12 kips. Furthermore, the distributions of data for TOR Product B and C are essentially the same indicating an equal carry down or product durability, which is in good correlation to the twin disc retentivity summary results shown in Figure 4. The performances of TOR Product B and C are still comparable at a higher application rate of 0.40 L/kaxle as shown in Figure 6, where and even further reduction of the high damaging lateral forces were noted.

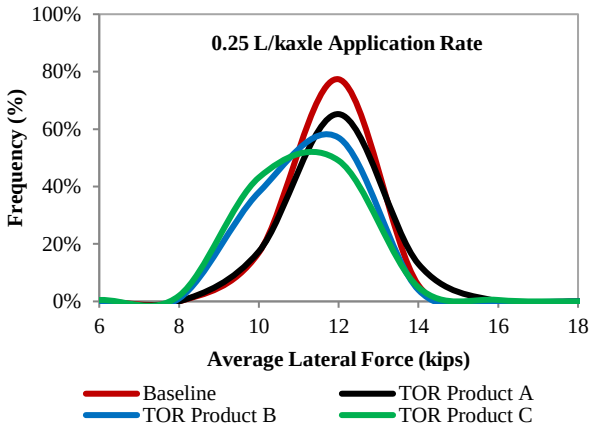

Figure 5 *Frequency distribution plots for TOR Products A, B and C at 0.25 L/kaxle application rate. Product A shows no lateral force reduction from Baseline, and Products B and C show an improvement in damaging lateral forces at 12-14 kips.*

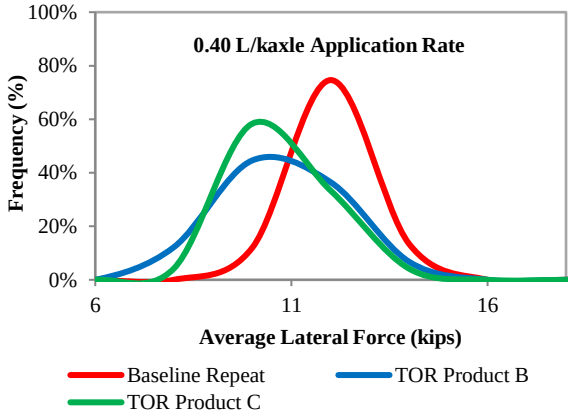

Figure 6 *Frequency distribution plots for TOR Products B and C at 0.40 L/kaxle application rate. Products B and C show comparable improvement in damaging lateral forces >11 kips.*

In a previous publication, [7] data from a field trial on a Class I railroad were shown where TOR Products B (friction modifier, FM) and D (TOR oil) were compared. From twin disc testing, TOR Product D was shown to have more than 10 times the durability compared to TOR Product B (Figure 4). This substantial difference in product durability for TOR Product D was corroborated in the field trial data, where TOR Product D was able to achieve the same lateral

force reductions as TOR Product B using the same application rate but at twice the application spacing (12.8 km (8 miles) compared to 6.4 km (4 miles)).

2.2.3. GF Grease Retentivity Testing

GF greases are not as diverse as TOR products in terms of chemical components. All GF greases are a matrix of thickener, base oil and additives (for example, anti-wear, extreme pressure and anti-oxidant), resulting in similar tribological mechanisms and behaviours. GF greases are used to lubricate the gauge face and gauge corner of the rail and as a result require a low friction level (the lower CoT the better). Twin disc machines have been used to evaluate GF grease retentivity and CoT,[16] however, the literature discussion has previously focused on the type of thickener used and solid lubricant additives and their relation to retentivity. More recently, Lewis et. al evaluated several GF greases using SUROS twin disc test rig,[17] and discussed the impact of surface roughness, wear, two different testing conditions (starved and fully lubricated) as well as test repeatability. In this section, the repeatability of GF grease twin disc durability testing and the consistency of product performance comparison on different scale (TE72 versus TE73H test rig) will be discussed with selected samples.

Many different types of GF grease samples have been evaluated on the TE72 test rig. Based on the authors' experience, the grease durability test will be repeatable if the machine is in stable condition, visually there is no obvious wear on both discs, no roughness change during the twin disc runs, and when a minimum amount of material is applied (to reduce the impact of material side flow back into the contact). One example is shown in Figure 7, where 3 repeated runs of Grease A and B were completed, showing a distinct difference in product durability and CoT value. Using the same contact conditions, Grease A shows a much longer retention time and obviously lower CoT. As both Grease A and B are mineral oil-based greases, the different performance shown is impacted by the different thickeners and additive packages.

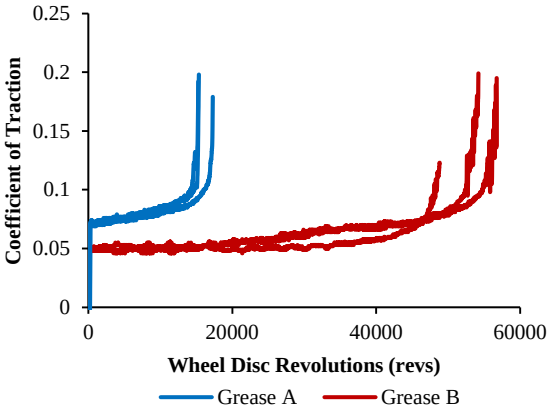

Figure 7 *Twin disc retentivity testing of Grease A and B using the TE72 instrument. Conditions used were: 600 rpm for wheel disc, 900 MPa contact pressure and 10% slip, with 5-7mg materials uniformly applied to rail disc prior to test. The testing shows consistent results that Grease B has more than twice the film durability of Grease A.*

The key difference between a small twin disc test rig to the actual wheel/rail interface is the scale, which is the reason full scale test rigs have also been extensively used in the past.[18,19] Full scale wheel rigs are more expensive and time consuming to operate than twin disc machines. To expand on the scale of the TE72 test rig, the TE73H test rig (which uses 300 mm diameter discs) was used which has much closer scale to real conditions. The capabilities of the TE73H test rig are slightly different to the TE72, as due to the size of discs the instrument has lower load, speed and slip capabilities than the TE72 rig. Furthermore, the discs are manufactured from D2 steel and have a different metallurgy and hardness to the discs used on the TE72 instrument. Despite the differences between instruments, trends in retentivity of greases can be produced on both instruments.

Figure 8 shows durability testing for four greases, (Grease C, D, E, and F) using the TE72 test rig. As twin disc testing repeatability has already been discussed, only one run is shown for each sample for clarification. Again, the retention time for four greases can be well differentiated. Using exact same samples, Figure 9 shows the results using TE73H test rig. Even though the running conditions (disc speed, contact pressure and slip) and scale are different, the exact same retentivity trend for Greases C-F was shown to be the same for both instruments: Grease F > Grease E > Grease D > Grease C.

During the durability twin disc test, both the speed and load are fixed, however, different regimes from the Stribeck are observed. In the Stribeck curve hydrodynamic lubrication is where the metal surfaces are fully separated, mixed lubrication is where there is partial metal/metal contact thus the grease and metal asperities share the applied load, and boundary lubrication means the load is mainly carried by the metal/metal contact.[20, 21] The results from twin disc testing on both instruments show that the retention curve may start at the hydrodynamic regime and finish at certain point in the mixed lubrication regime as grease begins to breakdown. Depending on the set CoT point to finish the test, sometimes the boundary regime may not be included in the graph. For example, all the grease retentivity graphs shown herein do not reach the point of the load mainly carried by metal/metal contact. This was indicated by minimal wear on the discs after the retentivity runs. The main part of the retentivity twin disc profile, which accounts for the majority of the retention time, the CoT is either relatively stable (Figure 8) or only has shallow change (Figure 9). This indicates the disc interface condition is within the Elasto-Hydrodynamic Lubrication (EHL) regime, which is situated between the mixed and hydrodynamic lubrication regimes. In EHL, there is minimum metal-metal contact and thus minimum wear. As the lubricant is gradually consumed/oxidized, metal to metal contact starts to increase, the anti-wear properties (and in some cases the extreme pressure additives) of the lubricants start to take the load bearing role and contribute to the end part of the graph. Bearing this concept in mind, it would be no surprise that same trend can be repeated for

two sizes of test rigs, as long as the conditions are in a moderate range – not too mild so the cycle time is long with increasing (machine) uncertainties, or too harsh so the CoT stable stage is too short. From the authors' point of view, either scale of twin disc could be used for GF grease durability screening test and comparison to give an indication to field (carry down) performance.

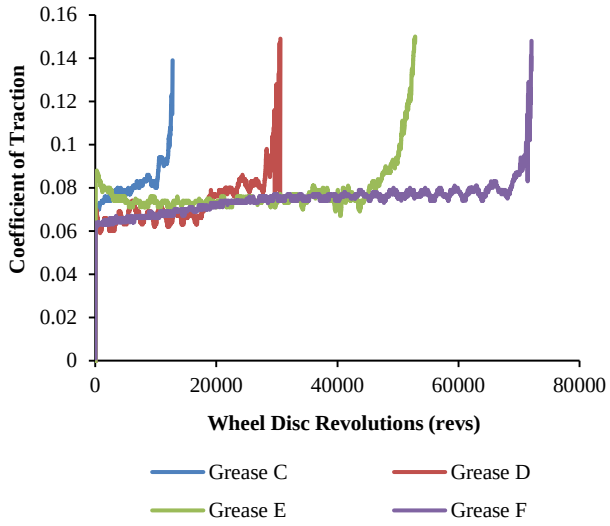

Figure 8 *Retentivity testing of Greases C-F on the TE72 instrument. Conditions used were: 600 rpm wheel disc speed, 900 MPa contact pressure and 10% slip, with 5-7 mg materials uniformly applied to rail disc prior to test.*

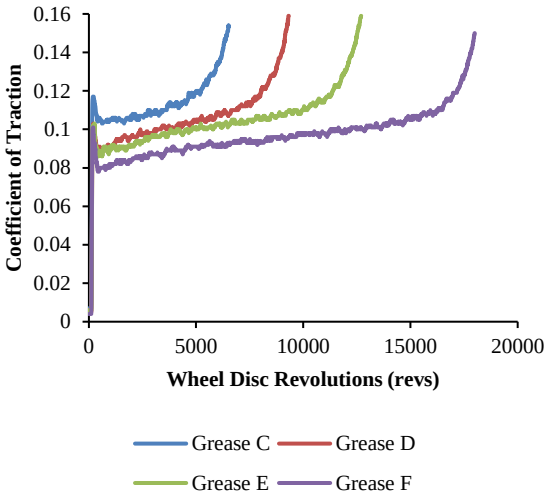

Figure 9 *Retentivity testing of Greases C-F on the TE73H instrument. Conditions used were: 500 rpm wheel disc speed, 300 MPa contact pressure and 5% slip, with ~20 mg materials uniformly applied to rail disc prior to test.*

2.2.4. Field Trial Data for GF Greases

GF grease twin disc data has been shown to correlate well with field performance when 5 different greases with varying retentivity values were compared.[13] The correlation between lab and field data was not as straightforward when 11 different greases with similar retentivity values were compared,[22] however, a general trend of increased retentivity to longer carry down was noted. Twin disc testing of GF greases as a tool to determine field performance is much more well-defined when the grease retentivity values have a wider distribution. Described below is field trial data comparing Grease A and B that correlates very well with twin disc data provided in Figure 7. Grease A and Grease B have considerable retentivity differences and have sizable differences in their field performance.

Grease A and B were compared side-by-side on a Class I railroad. The route was single track on river grade territory with multiple medium to sharp curves over the selected area. Traffic in the test zone was uni-directional unloaded coal trains and loaded intermodal trains with approximately 8,000 axles per day. A single gauge face tank equipped with hoses attached to application bars was used to apply the grease product. The application rate of the products was verified by manual output measurements at the unit, and were 0.20 kg/kaxle (0.45 lb/kaxle) and 0.09 kg/kaxle (0.20 lb/kaxle) for Grease A and B, respectively. Each product was applied for over a week before friction measurements and visual inspections were performed to ensure product application was consistent. The carry down of the products were assessed throughout a 13.7 km (8.5 mile) test zone; however, a sharp 8°36' curve that was located 13.2 km (8.2 miles) from the application unit was used as the key curve for identifying product effectiveness.

Visual inspection of the grease coverage was completed by using alcohol wipes to remove grease residue at the body of the test curve. Figure 10 shows the grease coverage photos for each grease in the 8°36' test curve. Presence of grease on the gauge corner and gauge face for both greases is confirmed by the photos, as there is a distinct difference observed on the rail from where the grease was removed. Grease A contains a black solid lubricant and will appear darker in colour during application, whereas Grease B is a white grease and will appear lighter in colour as it mixes with the iron oxides or other environmental contaminants in actual application. Furthermore, no presence of metal filings, indicative of rail wear from unlubricated conditions, were present.

A Salient Systems push tribometer was used for friction measurements of the gauge face and corner friction levels. When verifying grease performance, a friction reading on the gauge corner of 0.30 or greater is considered poor and often results metal filings that are visible in the rail bed. A gauge face reading of 0.20 to 0.25 is considered acceptable for grease coverage. As can be seen in the push tribometer results for Grease A and B in ***Figure 11***, the gauge corner and gauge face friction readings are all within the acceptable values for good grease coverage. This confirms that both greases can carry the 13.2 km effectively using application rates of 0.20 kg/kaxle for Grease A and 0.09 kg/kaxle for Grease B. Grease B could achieve good coverage at less than half the application rate of Grease A, which correlates very well to the twin disc retentivity data. Lower application rates of Grease A and B were attempted, but friction readings on the gauge corner were higher for both greases and resulted in metal filing

accumulation. The application rates mentioned earlier were found to be the lowest rates to achieve good coverage at the sharp 8°36' curve 13.2 km from the application site.

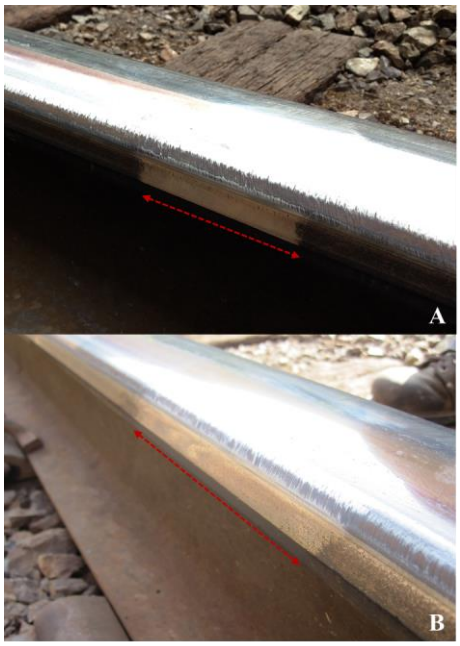

Figure 10 *Photos of grease presence on the 8°36' curve, 13.2 km from grease application site. Grease was removed using alcohol swab from the inclusive area indicated by red arrow. A) Photo of Grease A coverage, B) Photo of Grease B coverage.*

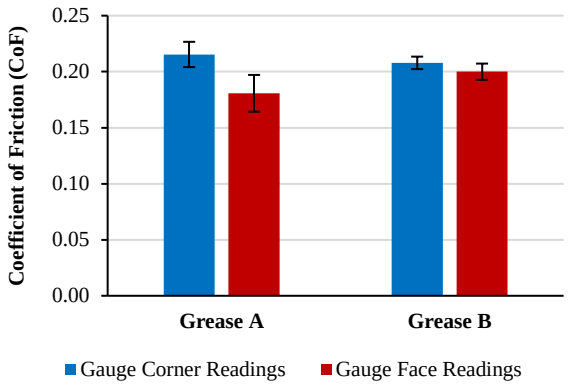

Figure 11 *Push tribometer CoF readings of the 8°36' curve located 13.2 km from the grease application site for both Grease A and B. Gauge corner readings are shown in blue and gauge face readings are shown in red. Grease A and B were applied at 0.20 kg/kaxle and 0.09 kg/kaxle, respectively.*

2.3. Creep Curve Development Using Twin Disc

Railways operate under variable creep, and a good understanding of different creep conditions is especially important for application of friction management materials in the wheel tread/TOR interface, as this contact region determines train traction and braking efforts. Multiple studies were conducted on the influence of creep on friction level.[9, 10, 23-26] There are three major types of traction/creepage behaviour: negative friction, neutral friction and positive friction (Figure 12).[18, 27] Negative friction is characterised by gradual decrease in friction force with increasing creep after reaching high friction maximum at certain creep level. Such behaviour is typical for dry unlubricated conditions and results in generation of stick-slip oscillations and corrugation development. [27] Neutral friction behaviour is typical for lubricants, where stable low friction level is achieved at saturated creep without any changes at higher creep. Positive friction behaviour is characterised by gradual increase in friction with increasing creep. This behaviour is highly desirable for the wheel tread/TOR interface as it allows to prevent stick-slip oscillations while achieving good traction and braking efforts. The positive friction behaviour is typical for TOR friction modifier application. [7]

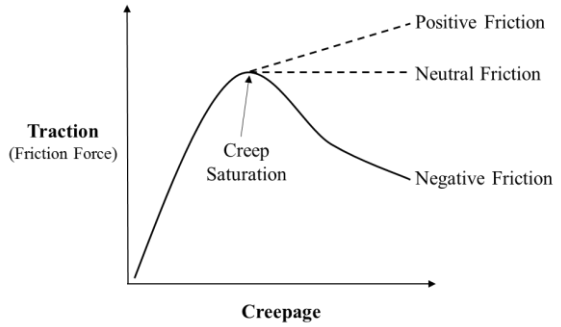

Figure 12 *Schematic illustration of the creep curve differentiating positive, negative, and neutral friction characteristics.* ***[18]***

Although creep values may be quite high occasionally, railroads mostly operate under lower creep conditions of up to 1-2% in the wheel tread/TOR interface.[28] Therefore, it is highly important to study the behaviour in this creep range for different types of products designed for wheel tread/TOR interface application. The TE72 twin disc instrument was used for creep curve development at low creep values and an example of the testing completed for TOR Product A is shown in Figure 13. The twin disc rig was first programmed to start with low creep of 0.25% under dry conditions until reaching a stable friction level. This dry stage is used to condition the discs to achieve consistent starting conditions. Subsequently, the material was added via syringe and the low creep level was maintained for certain time to allow for full conditioning of the discs. This step was used to monitor the friction changes during the material conditioning/drying. The amount of time required for conditioning will depend on the drying time (if any) of the TOR material. The instrument was then programmed to drop to 0% creep and ramp up quickly to a set creep. TOR Product A exhibits relatively stable friction levels within the time of the test at the last step creep values of up to 1%. However, gradual increase in the CoT was observed at final creep of 1.5%, which is indicative of material slowly wearing off. Thus, current testing methodology of multiple test runs at different creep values may also provide indication of the product's retentivity under different creep conditions. The average friction values observed at the set final creep values were used to plot a creep curve for TOR Product A through D (Figure 14). In alternative methodology, gradual increase/decrease of creep in the whole range of 0-2% during one test run may not be as informative as product continuously

wears off with changing the creep conditions, although this method allows for significantly faster generation of creep curves.[28]

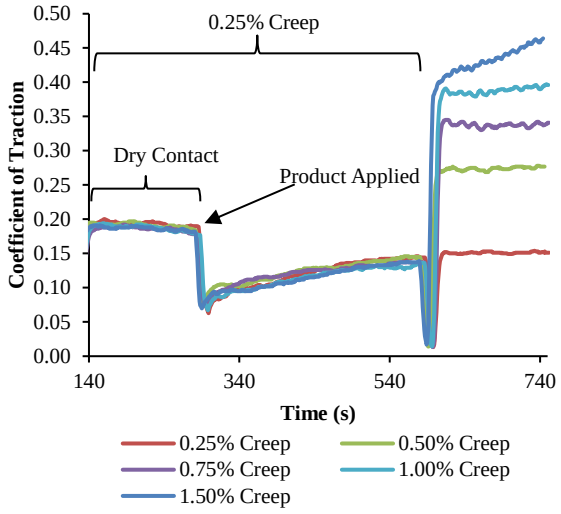

Figure 13 *Twin disc profiles with varying creep for TOR Product A using the TE72 instrument. For this methodology, the instrument takes 150 seconds to attain constant creep and pressure. Conditions used were: 400 rpm wheel disc speed, 900 MPa contact pressure and initially a 0.25% creep, with 50 mg of material added dropwise at 300 seconds. After a subsequent 300 seconds, the creep is changed to 0% and immediately changed to the set point creep (0.25% to 1.50%)*

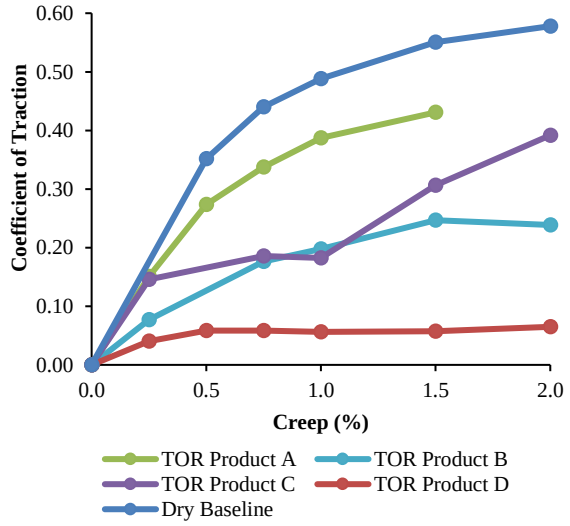

Figure 14 *Twin disc creep profiles of TOR Products A-D and dry baseline plotted using data attained on the TE72 instrument.*

A summary chart of creep curves for multiple products is shown in Figure 14. Notably, the creep curve under dry baseline conditions does not exhibit negative friction characteristics in the 0-2% creep range, which could be due to saturation happening at higher creep values (high twin disc vibrations were observed at higher creep values under dry conditions). Regardless, there is a clear difference in the behaviour of TOR friction modifiers and lubricants at different creep values. TOR lubricant product (TOR Product D) reaches saturation at 0.5% creep with the CoT of 0.58 and the friction level remains low at higher creep values, which corresponds to neutral friction characteristics according to classification in Figure 12. In contrast, TOR friction modifiers (TOR Products A-C) exhibit a gradual increase in friction levels with increasing creep, which corresponds to positive friction behaviour. Also, overall friction levels for friction modifiers always remain lower than baseline, but not as low as for a TOR oil-based lubricant (TOR Product D), which is another distinct feature of friction modifiers designed for providing intermediate friction levels.[7, 29]

2.4. Twin Disc RCF Crack Propagation Testing

Rolling Contact Fatigue (RCF) is a type of damage that occurs due to repeated high stresses in the wheel/rail interface.[30] It usually appears in a form of cracks on the gauge corner or TOR. However, it could easily propagate producing deep cracks and even transverse rail breaks, which represents a serious safety hazard.[30] One of distinct features of TOR friction modifiers is their ability to reduce wear and RCF crack development, which was successfully demonstrated in multiple laboratory experiments and field studies.[7] The benefits of friction modifier application were observed for wheels, rails, and special trackwork, such as switches.[31-35] The effect of other types of TOR products on RCF crack propagation is significantly less studied and appears controversial. There are several alarming reports, which demonstrate enormous acceleration of crack propagation with application of oil based and slow drying TOR products in laboratory twin disc tests due to fluid pressurization and crack surfaces lubrication.[4, 36] Contrary to these data, application of such materials in the field showed no evidence of such significant negative impact presumably due to regular grinding programs and well-controlled TOR product application rates.[7] Thus, grinding simulation was also conducted on a twin disc machine, which showed significantly less extent of the influence of oils on RCF crack propagation.[36]

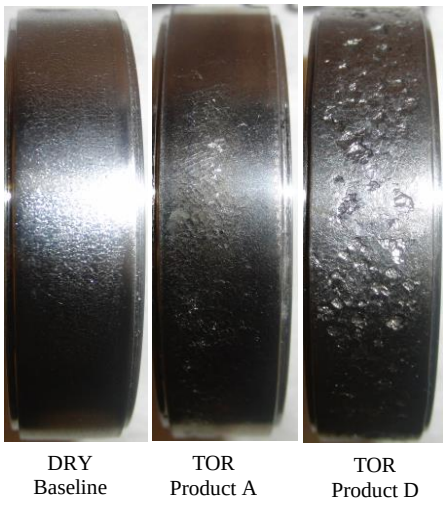

Figure 15 *The disc surface images after RCF crack propagation tests Conditions used were: 400 rpm wheel disc speed, 1500 MPa contact pressure, 1% creep, 4000 cycles DRY followed by 21000 cycles with product application (50mg every 500 cycles)*

The RCF crack propagation experiments were successfully reproduced on the TE72 twin instrument. In agreement with previous reports,[4] significant acceleration of crack growth was observed with application of oil based product D, while application of fast drying friction modifier TOR Product A did not accelerate crack propagation. The disc surface conditions after the tests are shown in Figure 15 for comparison. The critical crack lengths were achieved after 8500 revolutions with oil application, which resulted in visible flaking and a sudden increase in the CoT from 0.06 to 0.07 due to increase in surface roughness and appearance of wear debris (Figure 16). Subsequent oil application facilitates continuous surface material removal with significant damage after 20000 revolutions, which resulted in over 7 times higher wear in comparison with dry baseline. Sudden drops in the CoT were observed with each TOR Product A addition due to the drying properties of this material (Figure 16).

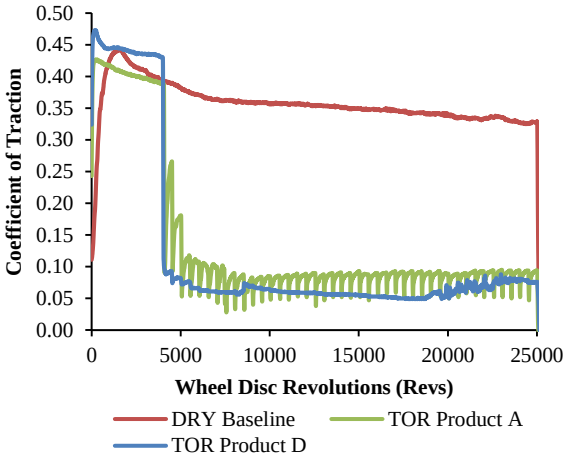

Figure 16 *Twin disc profile during RCF crack propagation tests. Conditions used were:. 400 rpm wheel disc speed, 1500 MPa contact pressure, 1% creep, 4000 cycles DRY followed by 21000 cycles with product application (50mg every 500 cycles)*

Based on reproducible twin disc testing from different research centers, it is evident the risk of accelerated RCF crack propagation is higher with application of oil based and slow drying TOR materials. However, regular grinding and significantly lower application rates in the field could mitigate it. There are several areas, which may still be affected by application of such materials if not properly maintained: tracks with poor grinding maintenance program, special trackwork areas with insufficient grinding (turnouts, crossovers, crossings etc.), and TOR product application sites, which may be exposed to high volumes of product.

2.5. Environmental Contaminants Twin Disc Testing

Many different environmental contaminants can be found in the third body of the wheel/rail interface such as moisture, fallen leaves, dirt, sand, and brake pad dust.[5, 37-40] Steel surface oxidation in the presence of atmospheric oxygen and moisture results in the formation of different oxides.[37, 41] There are many contaminants originating from crossings and goods carried (such as coal, grain, potash etc.). Some of the environmental contaminants may cause occurrence of low adhesion conditions, which can hamper railroad operations in many ways, such as increased braking distances, reduced acceleration, damage to wheels and rails (wheel flats and rail burns). Therefore, understanding the effect of "external" materials on the friction levels in the wheel/rail interface is of high current interest and worth exploring by twin disc methods.

Fallen leaves are well-known for causing extremely low adhesion conditions on railroads during autumn season. The effect of leaves on friction levels was previously studied in multiple field and laboratory experiments, which demonstrated occurrence of lowest adhesion conditions in the presence of moisture.[24, 42, 43] Simulation of leaf contaminated conditions was successfully conducted on the TE72 twin disc instrument at 1.5% creep, 3.6 kN load (1033 MPa) and 500 rpm disc speed (Figure 17). As depicted in Figure 17, addition of pure water results in immediate drop in friction level, but the CoT remains above 0.1, which is required for reliable operations according to Railway Safety and Standards Board (RSSB).[44] Subsequent addition of shredded leaves into the wet disc contact results in the CoT dropping to as low as 0.01. The extreme low friction level persists for some time after stopping water application as water remains in the contact area. The CoT raises to ~0.12 after full water evaporation, which corresponds to dry leaves friction level.

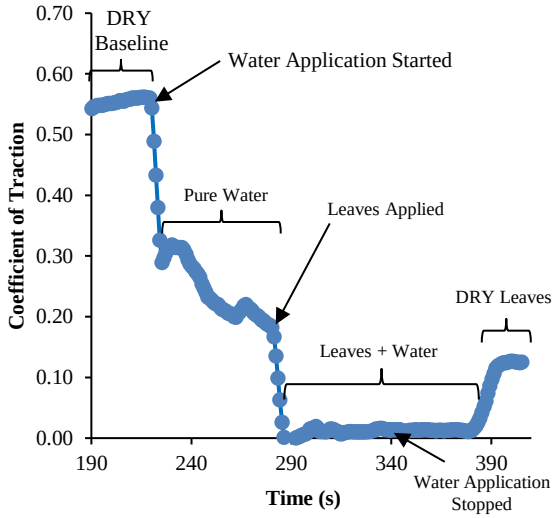

Figure 17 *Twin disc profile for water and leaves testing using the TE72 instrument. Conditions used were: 500 rpm wheel disc speed, 1033 MPa contact pressure and a 1.5% creep. Water was added dropwise at a rate of (0.5 mL per minute) starting at 225 seconds and ending at 340 seconds. Leaves were added (300 mg) directly into the disc contact at ~ 290 seconds.*

It was quickly realized during preliminary screening that combination of moisture with a number of materials may result in extremely low friction levels under twin disc simulated wheel tread/TOR conditions (Figure 19). It was found through twin disc testing that application of softer materials, such as clays, may drop the CoT significantly below the 0.1 threshold in the presence of

water. The friction levels restore quickly after water evaporation and fast wearing of dry powder residue at the end of test runs as shown in Figure 18 for several selected materials.

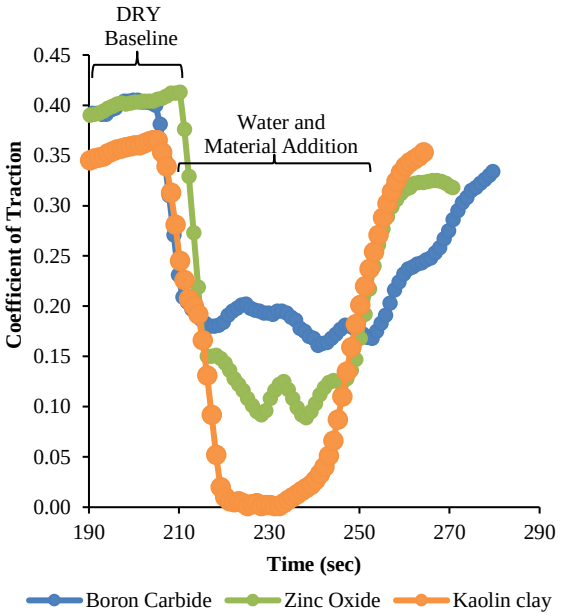

Figure 18 *Twin disc profile for water/material mixtures testing using the TE72 instrument. Conditions used were: 500 rpm wheel disc speed, 1033 MPa contact pressure and a 1.5% creep. Water was added dropwise at a rate of 0.5 mL/min starting at ~210 seconds and ending at ~240 seconds. Materials were added (1g total) directly into the disc contact during water application period.*

Overall, a correlation between material hardness and the friction levels was observed. Thus, all materials were divided into three groups based on their Mohs hardness: high hardness materials (Mohs hardness > 6), intermediate hardness materials (Mohs hardness 4-6), and low hardness materials (Mohs hardness < 4). As depicted in Figure 19, the low hardness materials demonstrated significantly lower minimum CoT in the presence of water in comparison with high hardness materials. Such behavior may be explained by the formation of stable low shear pastes with water, which separate the discs during the test run. On the other hand, the high hardness materials are proposed to be less prone to the formation of such stable pastes. In addition, application of such abrasive materials increases the surface roughness of the discs, which results in higher overall friction levels. Although some of the tested materials are not common railroad contaminants, many lower hardness compounds are typical components of soil, dust, gravel, and natural rocks surrounding railroad tracks. Furthermore, goethite is one of the major components of rust and commonly present on the wheel/rail surface. Therefore, the chances of rail contamination with such materials are relatively high, which could lead to low adhesion conditions in the presence of moisture. It should be noted that the twin disc experiments were conducted with large excess of corresponding materials and their potential influence on friction levels in the field may not be as noticeable.

Overall, some of the environmental contaminants may exhibit significantly lower friction levels than traditional railroad lubricants (oils and greases), however, the retentivity of environmental contaminants is significantly lower and may be highly dependent on the presence of water that evaporates quickly with train passes. The bonding strength (adhesion) of the contaminants to the wheel/rail surfaces is also of high importance. Twin disc testing indicated that most minerals do not adhere strongly to the twin disc's surfaces. It is postulated that such materials could be easily removed by a passing train or heavy rain. Conversely, leaves adhere strongly, which translates into a longer term effect on friction levels.

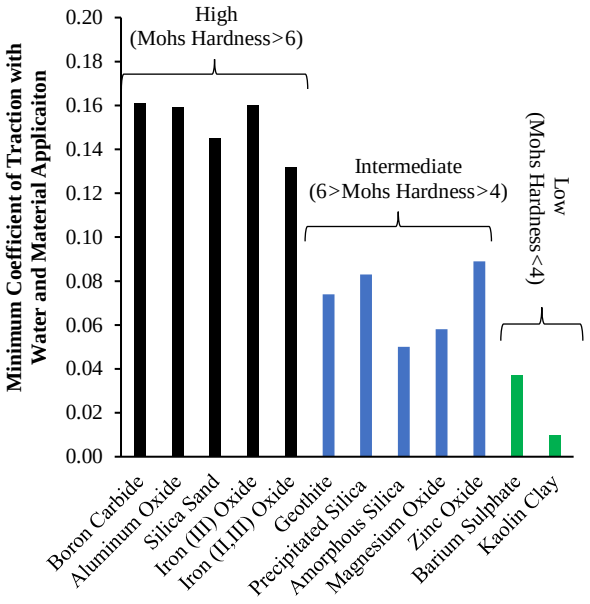

Figure 19 *Minimum coefficient of traction values from twin disc testing on the TE72 for various environmental contaminants mixed with water. High, intermediate and low labels refer to the hardness of the different materials.*

3. Conclusions

This results herein have demonstrated that the twin disc instrument can be a very useful tool for studying third body materials in the simulated wheel/rail interface. Durability of introduced materials, such as TOR materials and greases, can be quickly determined with robust testing methodologies. Strong correlations between twin disc retentivity and field performance were noted for both TOR and GF grease products. The ability to screen for durability of TOR or GF grease products accurately before a field trial is an advantage.

The flexibility of twin disc testing methodologies to be used on other instruments was substantiated in two ways: 1) GF grease retentivity testing on two different instruments at different scales showed the same grease retentivity trends, and 2) RCF propagation tests with TOR materials were successfully repeated and showed good correlation with previous reports.

Frictional behaviour at different longitudinal creep conditions was determined for TOR materials, which allows to differentiate between friction modifiers with positive friction characteristics and lubricants with neutral friction characteristics.

Twin disc studies on the influence of water with different contaminants has shown a relationship between the hardness of the contaminant and the resultant friction level. There is potential for some contaminants (such as clay) to cause very low adhesion conditions. These simulations can be useful in determining methods to combat low adhesion, which is an area of further research.

Abstract: A methodology of specimen geometry optimization for wear tests with two different diameters of specimens under high pressures has been developed based on FE simulations. The ratcheting prediction was done using Chaboche material model combined with a nonlinear isotropic hardening rule. The developed approach was verified on a twin disc test machine.

Keywords: Contact mechanics, twin disc test, FE method, ratcheting, rolling contact fatigue, Chaboche model.

1. Introduction

There are many approaches to the rolling contact fatigue (RCF) crack initiation prediction based on FE modelling [1]. Basically, contact defects are caused by three main damage mechanisms: wear, RCF and ratcheting. The accumulation of plastic deformation called ratcheting plays an important role for significant tractions. A robust cyclic plasticity model should be implemented into the FE code to have accurate stress-strain behaviour description [2]. However, a lot of experiments simulating the conditions of rolling contact are needed to calibrate the cyclic plasticity model properly [3]. The non-proportional loading should be generated in the multiaxial fatigue tests, for instance according to McDowell [4].

For railway freight traffic, the wheels from steels with high mechanical strength and hardness are manufactured. Being serviced on AAR railway net, especially wheel steel grade Class C according to AAR M107/M208 Standard with various steel modifications is used. This steel grade has ferritic-pearlitic microstructure that has for relevant steel carbon contents very low till negligible free ferrite microstructure portion. This microstructure configuration has a significant influence on service behaviour of wheel tread being in wheel/rail contact. The wheels having such steel microstructure have enhanced wear resistance and different RCF performance including different cyclic plastic strain accumulation (ratchetting). The change in the portion and morphology type of free ferrite changes the cyclic plastic strain accumulation process at wheel/rail contact system.
The process of exhausting the cyclic plastic strain with fatigue contact crack development as a result of its process is a characteristic phenomenon accompanying wavy wheel/rail contact motion. This motion has its tangential and axial component during wheel rotation depending on railway track conditions (straight track, curves).

Figs 1 and 2 show contact fatigue cracks growing at tangential direction and relevant local plastic strain at crack neighbourhood. This service degradation mechanism causes different development of cyclic plastic strain accumulation at above mentioned wheel motion direction components resulting at various fatigue contact crack morphologies.

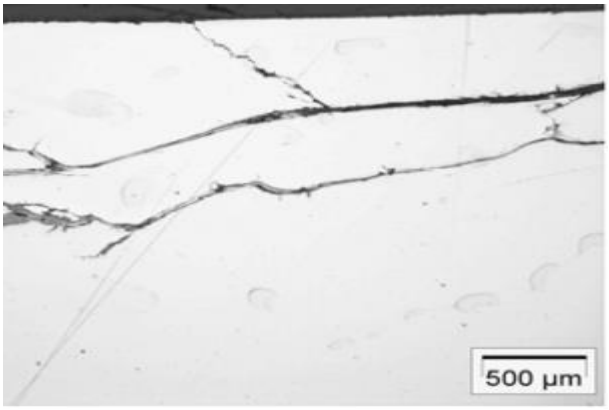

Figure 1 *Contact fatigue microcrack under the wheel tread (tangential section, without etching).*

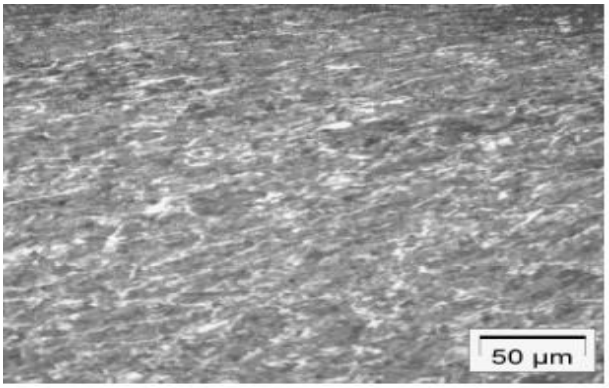

Figure 2 *Contact fatigue microcrack under the wheel tread, shear plastic strain (tangential section, etched).*

The assessment of influence degree connecting with wheel material cyclic plastic properties can, on the basis of laboratory simulation tests, contribute to proper choice of wheel steel grade configuration with high service resistance against wheel tread contact fatigue degradation. However, it should be noted, that desert sand presence in the wheel/rail contact requires special wheel materials to get better wear and rolling contact fatigue resistance [6]. The case simulation needs also a nonlinear contact analysis considering abrasive elements to explain the failure mechanism.

The rolling contact fatigue predictions under rolling/sliding conditions are usually done numerically by FE method and requires good FE mesh of contact bodies to obtain reliable results [7].

The experimental observations are mostly performed on a twin disc test machine or a rolling contact fatigue test machine with different diameters of rail/wheel specimens. In the twin disc test, the same geometry of both specimens and similar cyclic plastic behaviour of investigated materials are basic conditions to obtain reliable results of experiments. In the latter case the cyclic plastic properties of both materials play a significant role, especially under high contact pressures.

This contribution explains how to design the geometry of contact specimens with different diameters by means of FE simulations. The methodology was verified experimentally on the TUORS (Technical University of Ostrava – Rolling Sliding wear testing machine).

2. Problem description

The construction of TUORS testing machine ensures that specimens dimensions set the creepage [1]. For 0.75% creepage, the wheel disc diameter is 82.45mm (Fig.3) while the rail disc diameter is 215.55mm. In order to prevent excessive lateral deformation under high contact pressures, a 45-degree bevel was proposed for the wheel disc (Fig.3).

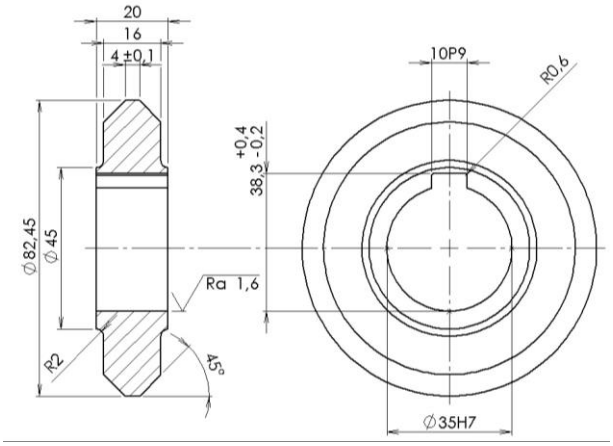

Figure 3 *Wheel specimen scheme – input geometry.*

The aim of FE simulations in this study was to find out appropriate angle of chamfering for the rail disc (Fig.4).

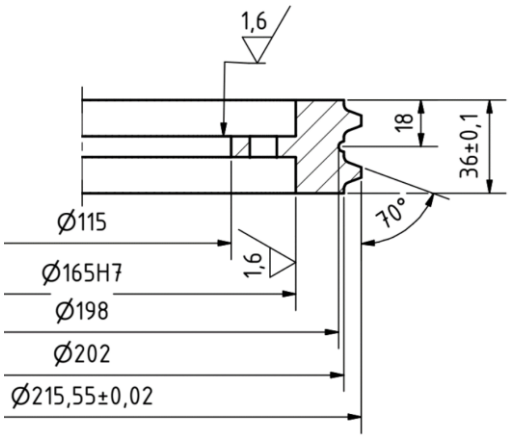

Figure 4 *Rail disc scheme – optimised geometry.*

There is a need to have the same lateral deformation in the wheel disc and the rail disc in order to have correct experimental conditions in the wear test. For accurate prediction of cyclic plastic deformations of both specimens an appropriate material model is required.

3. Cyclic plasticity modeling

The Class C steel is considered in this study for both specimens. The material shows a negligible strain rate sensitivity; thus the rate-independent incremental theory of plasticity can be considered. The theory is based on the additive rule

$$\boldsymbol{\varepsilon} = \boldsymbol{\varepsilon_e} + \boldsymbol{\varepsilon_p} \,, \tag{1}$$

and the Hooke's law to compute the stress tensor

$$\boldsymbol{\sigma} = \boldsymbol{D_e}\!:\boldsymbol{\varepsilon_e} = \boldsymbol{D_e}\!:(\boldsymbol{\varepsilon_e} - \boldsymbol{\varepsilon_p}) \,, \tag{2}$$

where $\boldsymbol{\varepsilon_p}$ is a plastic strain tensor and $\mathbf{D_e}$ is an elastic stiffness matrix and ":" denotes the tensor contraction. The elastic isotropic properties are defined by Young modulus E and Poisson's ratio μ. The von Mises yield condition is used in this form

$$f = \sqrt{\frac{3}{2}(\boldsymbol{s} - \boldsymbol{a})\!:(\boldsymbol{s} - \boldsymbol{a})} - \sigma_Y - R = 0 \,, \tag{3}$$

where $\mathbf{s}$ is a deviatoric part of the stress tensor $\boldsymbol{\sigma}$, $\mathbf{a}$ is a deviatoric part of the back stress $\boldsymbol{\alpha}$, σ_Y is the initial size of the elastic region and R is an isotropic variable.

In the case of active loading the normality rule is considered for the plastic strain increment computation in this study

$$d\varepsilon_p = d\lambda \frac{\partial f}{\partial \sigma} \tag{4}$$

where $d\lambda$ is a plastic multiplier. The evolution equation of back stress $\boldsymbol{\alpha}$ plays a crucial role for accurate ratcheting prediction.

In this contribution, the Chaboche model is considered [8] based on the superposition of particular back stress parts

$$\boldsymbol{a} = \sum_{i=1}^{M} \boldsymbol{a}^{(i)}, \tag{5}$$

on the nonlinear kinematic hardening rule according to Armstrong and Frederick [9], i.e.

$$d\boldsymbol{a}^{(i)} = \frac{2}{3} C_i d\boldsymbol{\varepsilon_p} - \gamma_i \boldsymbol{a}^{(i)} dp, \tag{6}$$

and on the nonlinear isotropic hardening rule

$$dR = b(R_\infty - R)dp, \tag{7}$$

where C_i, γ_i, b and R_∞ are material parameters. Five back stress parts (M=5) are considered in this study. All material parameters determined for Class C material from a large uniaxial hysteresis loop and a multiaxial ratcheting tests published in [3] are stated in the Table 1.

Table 1 *Material parameters of Chaboche model.*

Parameter(s)	Value(s)
E [MPa]	205000
μ [-]	0.3
σ_Y [MPa]	550
$C_{1\text{-}5}$ [MPa]	190230, 86250, 22463, 7478, 13810
$\gamma_{1\text{-}5}$ [-]	2222, 690, 215, 103, 2.1
R_∞ [MPa]	-100
b [-]	10

In the previous study [3], the results of so called McDowell tests realized on the Class C steel [4] were presented. The tests were performed under symmetric push-pull and repeated torsion loading with 90 degrees of phase shift between both loading axis (Fig.5). Four cases were realized with the maximal shear stress: 324 MPa; 360 MPa; 392 MPa; 458 MPa. The loading path corresponds to the half of circle in the diagram showing the axial stress vs the effective shear stress. An example of open hysteresis loops in initial cycles for shear components is shown in the Fig.5.

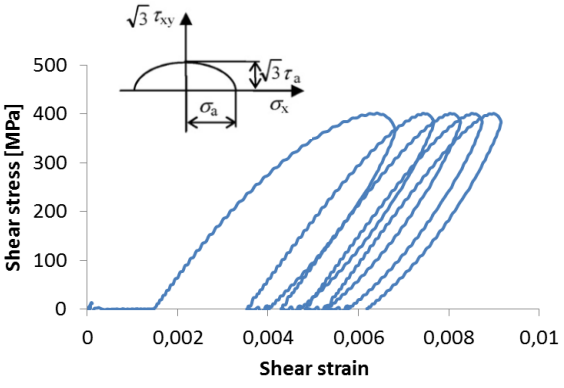

Figure 5 *Dependence of shear stress on shear strain in the case 3.*

Two material options were considered for ratcheting prediction of all four cases: Chaboche nonlinear kinematic hardening model combined with nonlinear isotropic hardening law and the modified AbdelKarim-Ohno kinematic hardening model with a memory surface [3]. The second constitutive model was implemented into the FE code using a fortran subroutine, see [2]. The both models give satisfactorily prediction of steady state of multiaxial ratcheting in so called McDowell tests [4] realized for the Class C steel. The ratcheting with rate decay is better described by the developed cyclic plasticity model (Fig. 6). In this study, all further numerical results were gained with the Chaboche model.

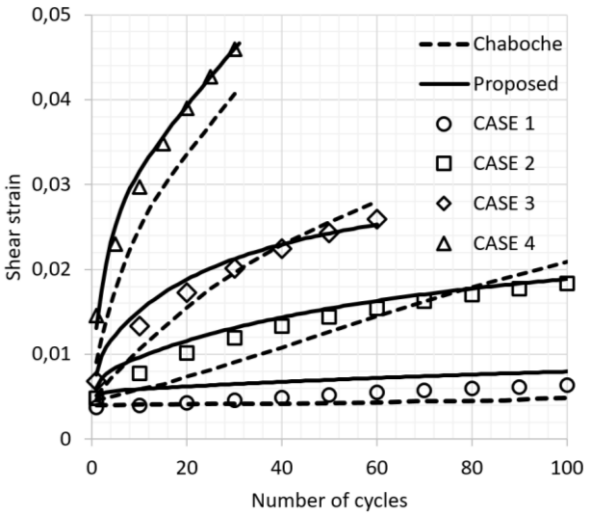

Figure 6 *Shear strain accumulation – comparison of predictions with experiment (symbols).*

4. Computational strategy

The 3D finite element model was created in ANSYS 18.0 using a parametric macro. Eight node elements SOLID185 were used for discretization. A similar FE strategy as in the paper [1] was used.

The maximal normal contact pressure was applied on the surface effect elements (element type SURF154) according to Hertz distribution [8]

$$p(x) = p_0 \sqrt{1 - \left(\frac{x}{a}\right)^2}, \tag{8}$$

with maximal pressure p_0=1800MPa and considering the half width of contact area a=1.892mm. Coulomb's friction law was applied for shear stress distribution on the contact area through the surface effect elements

$$\tau(x) = f \cdot p(x), \tag{9}$$

where f is the coefficient of friction.

The residual stresses from technology process in specimens was neglected in the analysis according to results obtained for different material in previous study [5].

The most important quantity for the optimization task is the lateral plastic strain in the corner point, which is depicted in the Fig.7.

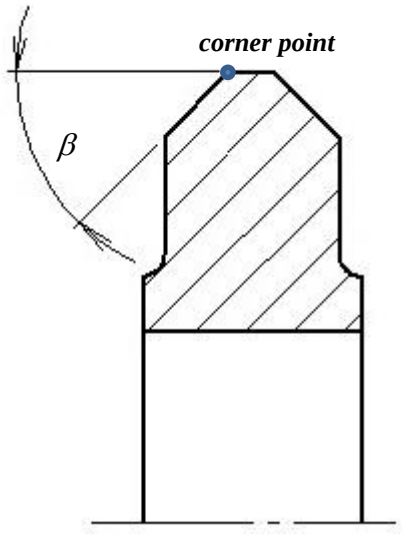

Figure 7 *Scheme of the specimen with the investigated point.*

The quantity is accumulated with increasing number of cycles, the ratcheting occurs. First of all, the quantity is predicted for sufficiently large number of cycles for the wheel disc. Wear tests are long-term tests, so the steady state of lateral displacement is the most important. The same value of lateral displacement increment in the last cycle of FE analysis should be gained in the rail disc analysis changing the angle of chamfering β (Fig.7), but considering difference in wheel and rail diameters. It means, that one must consider less number of cycles in the rail disc than in the wheel disc. According to the considered specimen's geometry a point on the rail contact area should absolve 0.38 less time number of cycles than a point on the wheel disc.

A number of computations should be performed to obtain final value of angle of chamfering β_{fin} in the final geometry of the rail disc.

5. Numerical analysis

The 3D model of wheel/rail disc created in ANSYS contains 49200 elements and 54571 nodes, see Fig.9. Appropriate displacement boundary conditions as well as symmetry boundary conditions were applied.

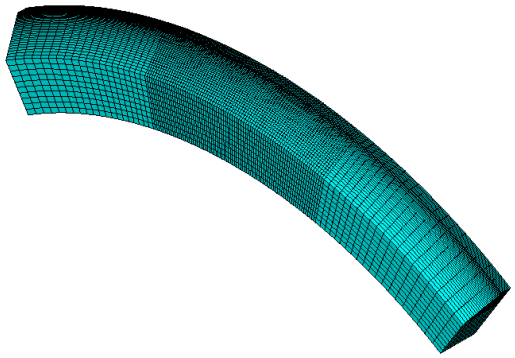

Figure 8 *FE model of the wheel disc (β=45°).*

The ratcheting behaviour is strongly influenced by the angle of chamfering β as can be seen in the Fig.9, where the lateral plastic strain history is visible for chosen values of β. It should be noted, that one cycle corresponds to 1s in each FE analysis.

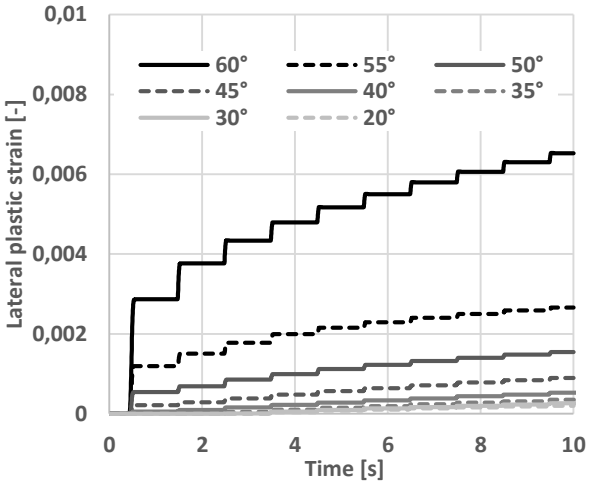

Figure 9 *Lateral plastic strain history in corner node from FE rail disc analysis for various angles of chamfering.*

Stabilization of plastic strain increment was very rapid in the case of rail disc simulation, see Fig.10.

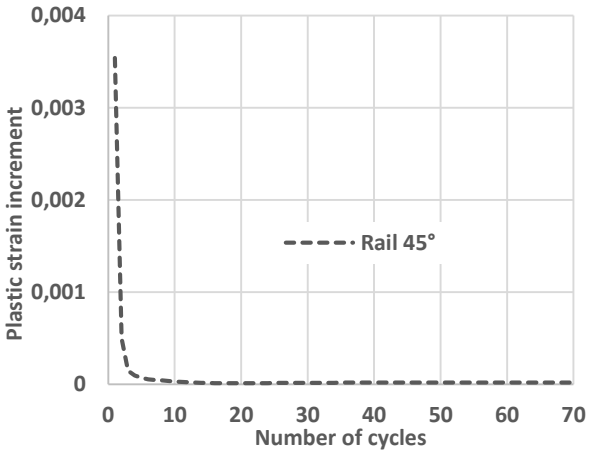

Figure 10 *Lateral plastic strain history in corner node from FE rail disc analysis for various angles of chamfering.*

The dependency of plastic strain increment on the angle of chamfering was approximated by an exponential function, see Fig.11.

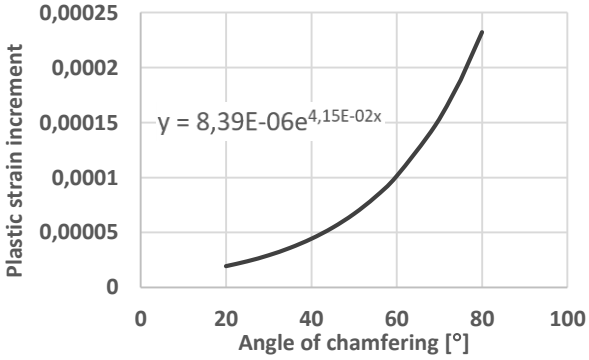

Figure 11 *Plastic strain increment for 10th cycle as a function of angle of chamfering*

Using the approximation function, the optimum value of the angle of chambering was calculated (β=69°). The actual angle of chambering in the rail disc was subsequently chosen to be 70°. The radial stress contours from the FE analysis of the rail disc considering its final configuration is shown in the Fig.12.

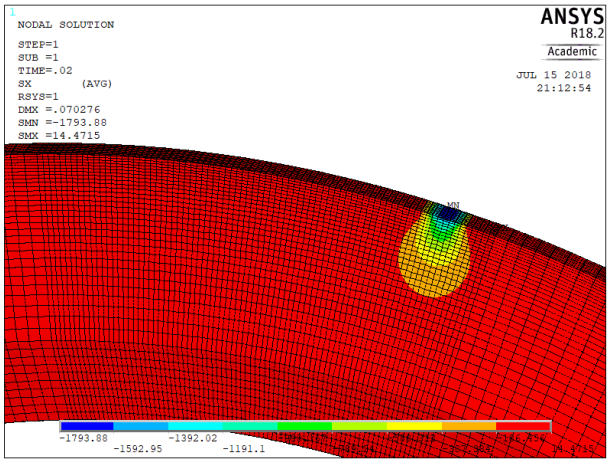

Figure 12 *Contours of radial stress component from the beginning of the FE analysis of the rail disc (β=70°).*

6. Experimental verification

For the verification of the proposed approach two rolling contact fatigue (RCF) tests were realized on the TUORS testing machine at the Laboratory of Contact Fatigue in the VSB-Technical University of Ostrava.

In the both tests, there was used the wheel disc with the angle of chambering β=45°. In the first RCF test the specimen of rail disc had no edge bevel (β=90°). The second test was performed with optimised geometry of the wheel specimen, which corresponds to the angle of chambering β=70°.

A comparison of traction coefficient history for both tests is shown in the Fig.12.

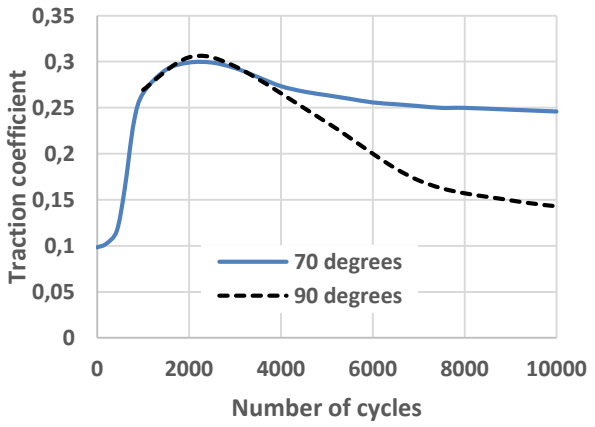

Figure 12 *The dependence of the traction coefficient and number of cycles*

The significant difference in the decrease of traction coefficient between the both tests confirms well the necessity of chamfering in the rail disc.

The actual drastic conditions of the experiment performed under contact pressure of 1800MPa and 0.75% of creepage are also confirmed by photographs of the surface of the test specimens, see Fig.13 and 14.

Figure 13 *The surface photo-documentation of wheel disc after 10000 cycles (Test 1 - 90 degrees)*

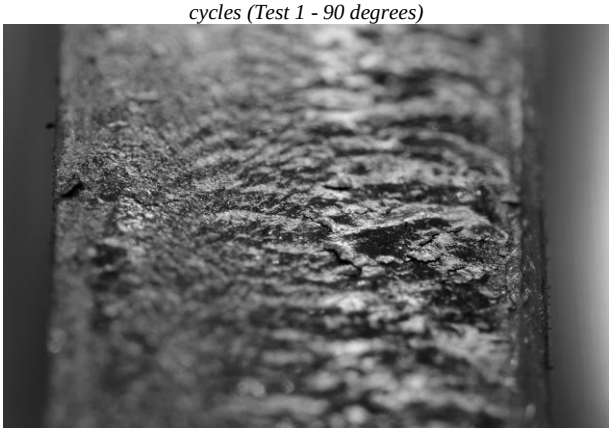

Figure 14 *The surface photo-documentation of rail disc after 10000 cycles (Test 1 - 90 degrees)*

The observation of the same specimen thickness in the second test with optimised rail geometry is also positive information to achieve stable experimental conditions by this approach.

7. Conclusions

This contribution describes the methodology suitable for design of specimen geometry in order to achieve good experimental conditions in a twin disc test with different diameters of specimens.

The FE simulation strategy has been described in detail. The mixed hardening material model according tp Chaboche with five back stress parts was calibrated based on McDowell tests performed on the Class C steel under different stress amplitudes.

Numerical results were successfully confirmed by tests performed on the rolling contact testing machine TUORS. The reduction of traction coefficient measured during the test with optimized rail disc geometry is negligible in comparison with the result of test realized on the standard specimen geometry, in which the angle of chamfering was equal to 90 degrees.

DEVELOPMENT OF GREASE TACKINESS TEST

Matt Harmon [1,*], Bryan Powell [2], Ingrid Barlebo-Larsen [2], Roger Lewis [1]

[1] Centre for Doctoral Training in Integrated Tribology, University of Sheffield, Sheffield, UK
[2] Stanhope-Seta, Chertsey, Surrey, UK

[*] E-mail: mharmon1@sheffield.ac.uk

Abstract: A test to evaluate the tackiness of grease has been developed using a standard tribometer. A preliminary study determined the test parameters to use in the subsequent experiments. Twelve different greases were tested and the results showed how the developed test method was able to differentiate between different greases. Additionally, results from pick-up tests using two of the greases and a scaled-wheel rig showed that the tackiness of a grease is related to grease pick-up on a wheel. The effect of "working" the grease prior to the test showed that the working had a significant effect on the tackiness of the grease. The test method was shown to be sensitive to small changes in the grease by adding small amounts of tackifier additive (0.1 % increments) to the grease.

Keywords: Grease, tackiness, laboratory test

1. Introduction

Greases are widely used in many different applications to improve the performance of systems and protect components from failure. Understanding the properties of a grease and impacts of additives is vital to selecting the appropriate grease/additive to use.

Grease is applied to the gauge corner of rail in curves. This reduces the friction and forces in the wheel-rail contact to reduce wear and rolling contact fatigue (RCF), prolonging the life of the rail and wheels. The grease transfers to the wheel flange from lubricators, often placed next to the rail in straight track. The wheel then carries it down the track, lubricating the rail in the subsequent curves. How much grease gets picked-up and carried down the track is important to ensure adequate lubrication of the rail curves. The tackiness of the grease plays an important part in this transfer process, ensuring enough grease is transferred from the lubricator to the wheel and then from the wheel to the rail.

There is a large body of published research on the effect flange lubrication has on tribological performance of the railways, such as RCF [1-2], retentivity [3], friction and wear [3–10]. These tests predominantly used small-scale laboratory tests (either pin-on-disc or twin-disc). There are few papers that study the physical application of grease to the track. This is important as without understanding how much grease to apply, or how far down the track the grease is carried, it is unknown if the performance benefits seen in the laboratory actually take place during operation in the field. Grease pick-up has been investigated at the University of Sheffield using a bespoke test rig [11-12]. There have also been a few field studies of flange lubrication [14-15]. Whilst the tribological performance and application of flange lubrication is vital to study, there is no mention in the literature of how the fundamental properties of grease effects the performance or application.

Currently there are no standard tests for grease tackiness and very few studies of tackiness in the literature. A standard lab test is required for tackiness for quality control purposes and for greases to be optimised for their specific application.

1.1. Aim

The aim of this work was to devise a test method to quantify tackiness of grease. This test would be able to be used in the future to link tackiness to performance benefits. Initially test parameters had to be determined that would produce consistent, reproducible results. To prove the test method works, the effect of roughness on tackiness and different greases were tested. Also, the effect of "working" the grease pre-test was analysed. Finally, the effect of adding small amounts of tackifer additive on the tackiness was assessed.

1.2. Grease tackiness research

Tackiness is described as the ability of the grease to form strings or threads [16]. It is often confused with adhesion which refers to the ability of the grease to stick to a surface. Figure 1 shows how a grease forms threads when a train wheel rolls through a grease applicator site. The grease is pumped through an applicator bar, forming bulbs of grease on the side of the rail. The wheel flange contacts these bulbs, transferring the grease onto the wheel. Tackiness is important in the wheel-rail contact as a tackier grease will form longer strings, enhancing grease pick-up from the GDU to the wheel. More grease pick-up on the wheel leads to better lubrication of the contact in curves which improves the life of the rail and wheels. Tackiness performance of a grease can be improved by incorporating additives to it. Tackiness additives are often high molecular weight polymers, susceptible to breakdown by high shear rates [17].

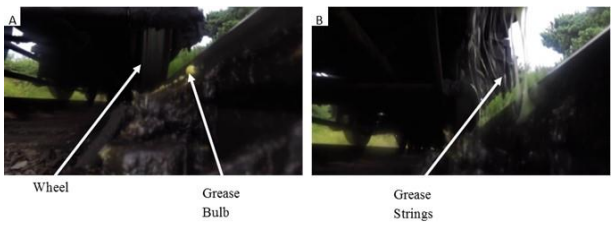

Figure 1 *Still images captured from video camera A) before contact between first wheel of train and grease bulb B) After first wheel has passed through lubricator site but before second wheel*

The simplest method of determining tackiness is a finger test. A blob of grease is squeezed between finger and thumb and then this finger and thumb are pulled apart. A similar test using a spatula is shown in Figure 2. This is currently used at the end of a manufacturing line during quality assurance to determine if the grease is an acceptable tackiness. The results from this test are based on observation, "feel" and are qualitative. For quality assurance purposes, a more standardised and quantative measurement would be extremely beneficial, also allowing comparison of different grease formulae.

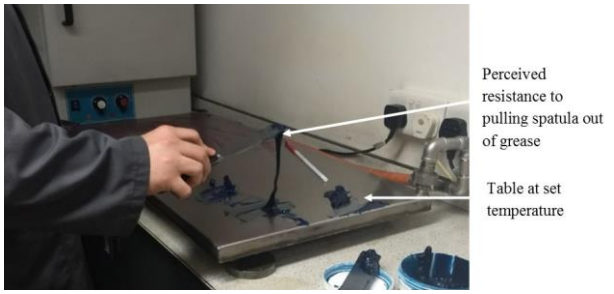

Figure 2 *Current tackiness test*

A more sophisticated method of measuring the tackiness is an open siphon technique described in detail in [17]. This method measures the length of a formed string of grease, the longer the string, the tackier the grease is said to be. Another test method is an approach/retraction method [16]. This method has been validated with cone penetration tests by comparing the cohesiveness results and has shown good correlation between the two methods. It uses a measured force during retraction to calculate the energy required to break the grease strings as a measure of tackiness. The final test method found uses a Capillary Break-up Extensional Rheometer to measure the string formed during retraction of two discs [18]. The diameter of the strand is measured via a laser as a function of time.

Work carried out by Strasburger et al. [19] showed different forms of separation according to the force trace produced during the test as seen in Figure 3. The results were obtained using an approach-retraction method. There were clear differences in the traces depending on the type of separation. Initially, the separation is characterised by the flow of the liquid where the force rises to maximum and then decays to zero as seen in Figure 3a. After a threshold value, cavitation causes a rapid decrease in force after the maximum value before a sharp turn and decaying to zero as seen in Figure 3b. Figure 3c shows a transitional period trace where there is both cavitation separation and separation by flow. The reason given by Strasburger et al. [19] for cavitation causing the rapid decrease in force is that at peak force, the tension in the liquid is released by bubbles which grow and join together to form a cavity. The expansion of this cavity causing the break of the fluid layer and the rate of decay of the force is related to how quickly this cavity expands. Cavitation causes the rapid break of any grease strings formed and so lowers the measured tackiness.

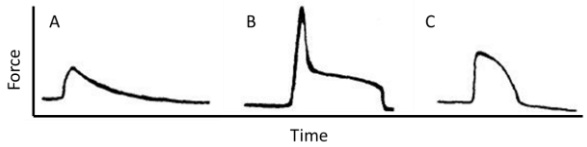

Figure 3 *Typical force traces for approach-retraction experiment results. A) trace typical of separation by flow between two surfaces C) trace typical of transition region between flow separation and cavitation separation B) trace typical of separation by cavitation [19]*

The polymer chains in greases must have the capacity to expand for a substance to be tacky and the important parameters governing tackiness are the molecular weight and the flexibility of the chains of molecules [17].

There is currently no one method that is universally accepted as a measure of grease tackiness. The only published research found describes the test methods rather than research into tackiness itself and focusses on oils rather than greases. Therefore, there is a need for development of the current available test methods for greases to ensure they are reproducible and produce consistent results. The approach-retraction method was used as an existing tribometer can be modified to carry out this form of test.

2. Test equipment

A tribometer was used in this work as its modular construction meant it could be tailored to fit the requirements. A linear lower drive with a vice was used to hold the lower specimen in position. A 50 N load cell was used to provide a suitable level of resolution. The UMT is controlled by creating a test script, defining the parameters which the computer then implements when the script is run. Figure 4 shows a typical test set-up. The upper specimen diameter is 29 mm; both specimens have a slight convex surface and machined from stainless steel 316. A video camera was used to record the test. A syringe was used to apply grease to the lower specimen using a mass balance accurate to ±0.0005 g to measure the amount of grease. A nominal amount of grease was pre-smeared on both specimens prior to each test starting. The grease used was a standard multi-purpose grease.

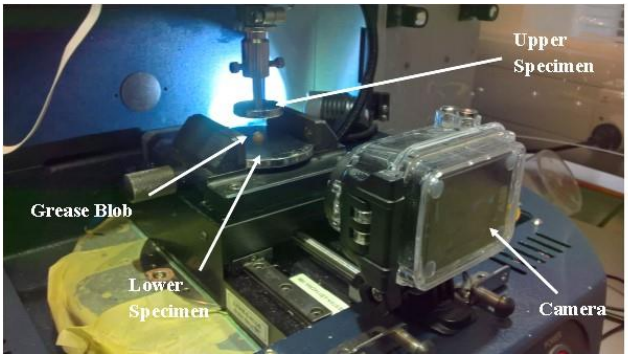

Figure 4 *Typical test set-up*

2.1. Test method

The method is an approach-retraction type experiment. This method was chosen due to its simplicity to implement.

All test followed a standard procedure:

- Specimens pre-smeared with a nominal amount of grease
- Blob of grease applied to lower specimen via syringe using mass balance
- Test script run:
  - Lowers upper specimen until set force is reached for 10 seconds
  - Retract upper specimen at set speed until grease strings broken
  - Excess grease removed from upper specimen
  - Lower specimen re-weighed to measure the grease pick-up onto the upper specimen

Figure 5 shows a schematic of the different stages of the test:

- Stage 1: the upper specimen is lowered until a set force is reached
- Stage 2: the upper specimen is held in position at the set force for a set time
- Stage 3: the upper specimen is raised, pulling the grease upwards forming a grease "string"
- Stage 4: the upper specimen continues to raise, the grease "string" is broken and some of the grease is transferred to the upper specimen

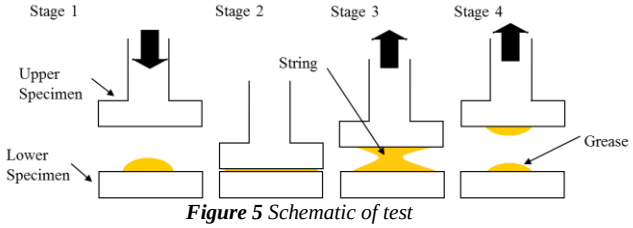

Figure 5 *Schematic of test*

Before carrying out testing, a number of parameters had to be determined:

- Initial compressive force
- Initial grease amount
- Retraction speed
- Repeatability of results

Each parameter was varied in turn in a preliminary study to analyse its effect and to decide what setting to use in the main investigation.

2.2. Data analysis

The test rig outputs a text file with the time, distance upper specimen moved and force inside it. Figure 6 shows an example of a typical force distance graph produced from data. This graph is just for the retraction period and not the loading period of the test. The force tends to zero as the grease strings break. This shape of graph is typical for slow rates of separation caused by the grease flowing between the two test specimens [19]. From work carried out by Achanta et al. [16] the three distinct regions represent different properties of the grease:

- Region A- the work done against the grease resistance
- Region B- the work required to start separation
- Region C- the work required to break the grease strings. This region allows tackiness to be calculated.

The area in Region C and the maximum force is calculated by implementing a MATLAB script.

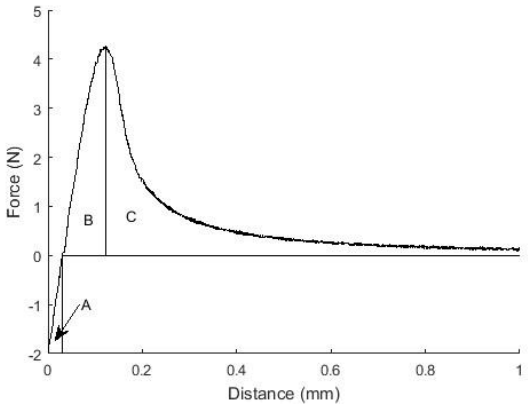

Figure 6 *Example force response graph*

Figure 7 shows the work done to break the grease strings for each of the preliminary tests. The ideal case is to maximise the work done to break the grease strings as this leads to a reduction in error overall. There is a clear linear correlation between initial grease amount (Figure 7C) and work done to break the grease strings. At the higher grease amounts, the relationship starts to change as some of the grease is squeezed outside the specimen circumference, therefore not effecting the results. There is also a linear correlation between retraction speed and work done (Figure 7B). In Figure 7A, there is a clear increase in work done as force increases with the work done dropping once cavitation effects start occurring. Cavitation effects are more severe at higher compressive forces. Figure 7D shows that the method produces repeatable results.

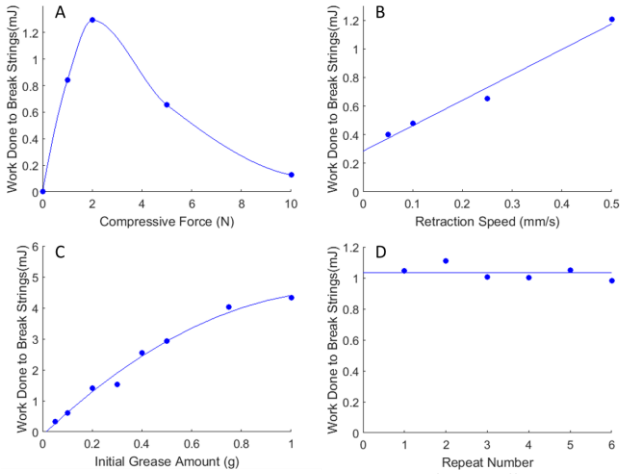

Figure 7 *Work done to break grease strings for A) different compressive forces B) different retraction speeds C) different initial grease amounts D) repeats of same parameters*

The force curve is influenced by cavitation effects, the parameters detailed in Table 1 to take forward to further tests were chosen to avoid cavitation.

Compressive force (N)	4
Retraction speed (mm/s)	0.25
Initial grease amount (g)	0.5

Table 1 *Chosen parameters from preliminary study*

These parameters are not representative of wheel-rail contact as usually there is more grease present, there is a greater compressive force, the speed is much faster and the wheel rolls over the grease rather than a straight vertical retraction. However, the parameters chosen will allow repeatable, reproducible results so that comparisons can be made and this method can be used to inform future tests in more realistic conditions.

3. Effect of specimen roughness and different greases

To investigate what effect the specimen roughness had on tackiness two specimen pairs were made, one with an Ra of 3 µm and a smoother pair with a Ra of 0.6 µm. Twelve different greases were tested on both pairs of specimens using the standard test method described in section 2.1. Some of the greases are different formulations of the same grease.

3.1. Results

Figure 8 shows the results from the testing with different greases using the different roughness specimens. It clearly shows that the rough specimens require more work to break the grease strings with a couple of exceptions. It is unclear why the roughness causes the tackiness to increase. It could be due to the rougher surface having larger asperities which area better shape for forming and holding onto the grease strings. The graph also shows that the test method is able to differentiate between different greases/different formulations of the same grease.

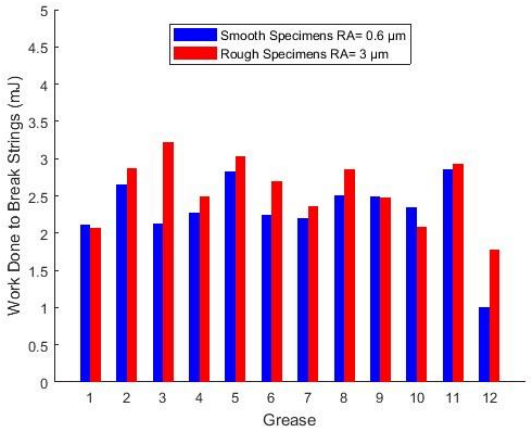

Figure 8 *Effect of roughness on the work done to break grease strings*

Figure 9 shows the percentage of grease picked-up on the upper specimen. There was no data for the smooth specimen for grease 10. There are no consistent conclusions that can be drawn from this graph. This is because the smooth specimens pick up more grease on some occasions and the rougher specimens pick-up more grease on other occasions.

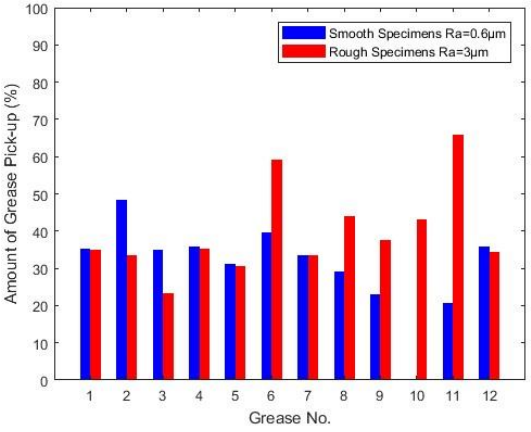

Figure 9 *Amount of grease pick-up on upper specimen*

Figure 10 compares the pick-up of two greases on a wheel from previous work done at The University of Sheffield. The tests used a scaled-wheel on a short section of rail with two different grease applicator bars tested. Figures 8 and 10 support the hypothesis that the tackier the grease, the greater the pick-up. This is because the tackiness will cause longer strings to form which will cause more of the grease to transfer to the upper specimen. It is difficult to know why this hypothesis is not supported in Figure 9. It is expected that this is because the contact conditions and motion is completely different between moving two conical plates vertically and rolling a wheel along a rail.

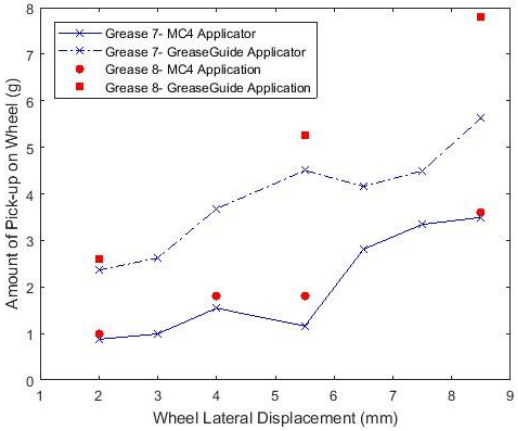

Figure 10 *Comparing pick-up of grease on a wheel from a scaled-wheel rig at the University of Sheffield for two different grease and two different grease applicator* ***bars.*** *Greases relate to greases 7 and 8 in Figure 8 and* ***Figure 9****.*

3.2. Conclusions

This section of work has shown that rougher specimens cause more work to be done to break the grease strings and hence mean the grease is seen as more tacky. This has not translated to a higher pick-up in the tribometer tests and it is unknown why this is. The tests have also been able to differentiate between many different greases and even between different formulations of the same grease. This has been further extended to a more realistic wheel-rail test rig where the grease with a higher tackiness has resulted in a higher pick-up of grease onto the wheel.

4. "Working" of grease

There has been anecdotal evidence that "working" of a grease prior to carrying out a tackiness test with it changes the tackiness of the grease. "Working" of the grease in this study means applying small amounts of compressive force to the grease before starting the separation test.

4.1. Test method

To investigate if this does occur and to attempt to quantify the effect, a modification to the standard test script detailed in section 2.1 was made (changes to script are highlighted in bold text below). A "working" stage was included prior to carrying out the "test" stage

- Specimens pre-smeared with a nominal amount of grease
- Blob of grease applied to lower specimen via syringe using mass balance
- Test script run
  - **Working stage**
    - **Lower upper specimen until force of 2N is reached for 2 seconds**
    - **Retract upper specimen at set speed for a small distance as shown in Table 2**
    - **Repeat previous two steps a set number of times**
  - Test Stage
    - Lower upper specimen until force of 2N is reached for **2** seconds
    - Retract upper specimen at set speed until grease strings broken
  - Excess grease removed from upper specimen
  - Lower specimen re-weighed to measure the grease pick-up onto the upper specimen

There were two types of "working" investigated with the parameters detailed in Table 2:

- Type A- peak force is reached during working stage, but strings are not completely broken
- Type B- peak force not reached during working stage

Type	Distance Retracted (mm)	Speed of Retraction (mm/s)
A	0.1	0.1
B	0.05	0.05

Table 2 *Parameters used during the working stage of script*

Figure 11 shows how the two types of working are different as it can clearly be seen that in type A, the peak force has been reached before the grease is compressed again. There is a slight overshoot of force as the grease is compressed, it is not expected that this makes a difference to the results. The graph shows five working steps.

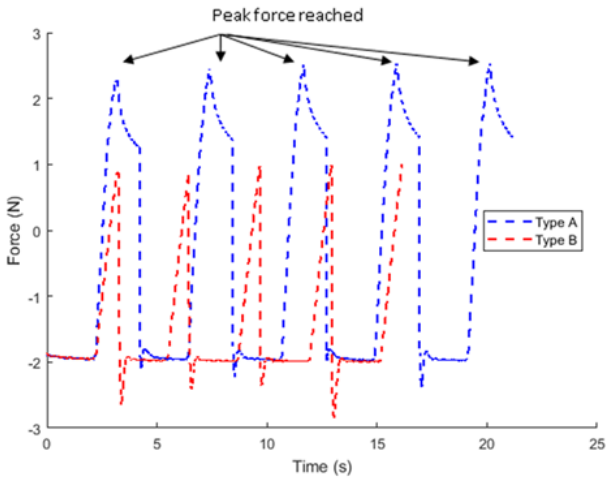

Figure 11 *Force time graph of five working stages*

4.2. Results

To show the effect of prior working of the grease, Figure 12 shows the peak pull-off force reached against the number of steps the grease was worked for before the test was carried out. For type A working the reduction in tackiness is linear as the number of working steps increases. Whereas for type B working, the relationship is increasing for number of working steps and quadratic.

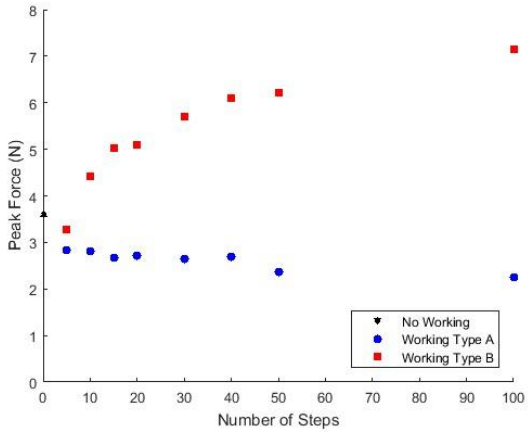

Figure 12 *Peak force reached during test for differing number of worked steps prior to test being carried out*

Figure 13 shows the work done to break the grease strings. Type B working required more energy than type A working to break the grease strings due to an increase in tackiness with this type of working.

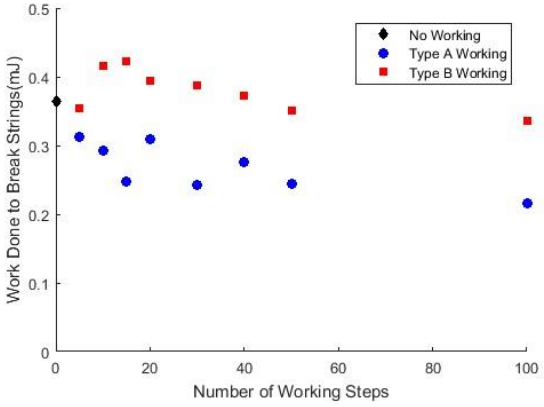

Figure 13 *Work required to break grease strings for both types of working*

4.3. Discussion

Figures 12 and 13 support each other. Both figures show a decrease in tackiness and adhesion for type A working and an increase in tackiness and adhesion for type B working. However, in Figure 13 there is a decrease in tackiness after 15 working steps. This is explained by understanding how the chains of molecules in the grease respond to the two different working types. For the type A working, the maximum pull-off force is reached which shears some of the long chains of molecules into smaller chains. This would happen at each working step so the more steps, the smaller the chains of molecules which need less force to cause separation when the upper specimen retracts fully. These shorter chains are also less elastic than longer chains causing the reduction in tackiness. This explains the linear relationship seen in Figure 12 and 13 for type A working. For type B working, the maximum pull-off force is not reached and the working steps have the effect of aligning the chains of molecules in the grease. This has the result that when the upper specimen is retracted fully, more chains of the molecules share the load and extend elastically, hence more force is required to pull the specimens apart and a corresponding increase in tackiness.

Two things working together cause the quadratic relationship seen in Figure 12 for type B working. First, the cavitation effect places an upper limit on the adhesion of the grease [19] and the more working steps that occur the greater the cavitation effect. Secondly, the working of the grease is aligning the molecules, but they can only be aligned by a finite amount. Initially, the chains are aligned randomly. Once working of the grease starts the chains get more aligned as the number of working steps increases. Therefore, once the majority of the molecules are aligned, further working of the grease has little effect. In Figure 13 tackiness starts reducing after 15 working steps. This is caused by cavitation occurring breaking the grease strings quicker. This shows that whilst increasing the number of working steps beyond a certain amount increases the adhesion of the grease, it reduces the tackiness.

4.4. Conclusions

This section of work has shown that working the grease prior to testing, changes the response of the grease. If the maximum pull-off force is not reached during working then the peak force seen increases with the number of steps the grease is worked for. If the maximum pull-off force is reached during working the opposite occurs. This is due to changes in the arrangement and length of the chains of molecules in the grease. The work done to break the grease strings shows that if maximum pull-off force is not reached during working the tackiness increases until cavitation effects occur and start to decrease the tackiness. If maximum pull-off force is reached during working of the grease then tackiness is reduced.

5. Tackifier additive

To test how sensitive the test method is, small amounts of a tackifier additive were added to the grease in increments of 0.1% by weight starting at 0%.

5.1. Test method

The standard test method described in section 2.1 was used in these tests. The initial grease amount was 0.5g, the retraction speed was 0.25mm/s and initial force was 4N. The samples were mixed using the following method:

- Base grease added to mixing pot (~70g)
- 0.1% by weight tackier additive added to mixing pot
- Mixed by hand for 3 minutes
- Sample removed via syringe (4-6g)
- Previous steps repeated to get all 5 samples
- Syringes placed in dry ultrasonic bath for 10 minutes and heated to 40°C
- Samples prepared 48 hours before testing

5.2. Results

Figure 14 shows the effect of adding the tackifier additive on the tackiness of the grease. The overall trend

is for an increase in tackiness although there is large amounts of scatter in the results. The scatter comes from the difficulty in ensuring that each test sample has the exact ratio of additive to base grease due to the small quantities involved.

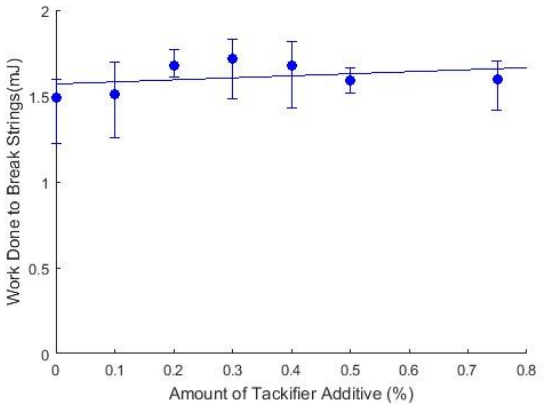

Figure 14 *Work done to break grease strings with different amounts of tackifier additive- improved grease mixing method used*

Figure 15 shows the mean peak force. It again shows an increased peak force for increasing tackifier additive.

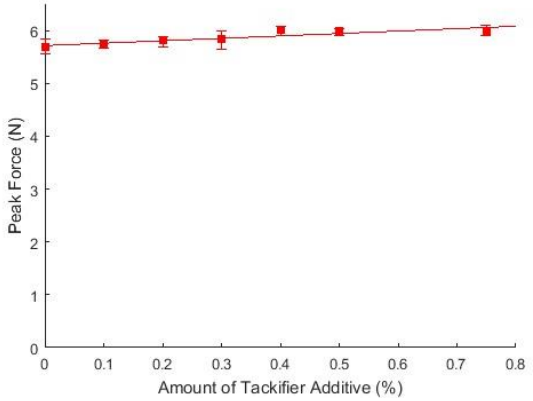

Figure 15 *Peak force vs amount of tackifier additive for both mixing methods*

5.3. Conclusions

This section of work has shown that the test method does detect small changes in the grease but careful preparation of samples is important to ensure any experimental error is not greater than the measured changes in tackiness.

6. Conclusions

A test method using a standard tribometer has been developed using an approach-retraction method. Initially, different test inputs were investigated to understand how the parameters affected the results. Parameters were chosen to limit the cavitation effects seen in results. The test method has been shown to be able to differentiate between different greases and so can be used as a benchmarking method. The effect of adding small amounts of a tackifier additive has shown that whilst it is difficult to get the right quantities of additive onto the test specimen, the effect of the additive can be seen in the maximum pull-off force results and tackiness of the grease. Working the grease prior to testing has an effect of the response of the grease and can be incorporated into the test method if required.

6.1. Further work

The test conditions can be expanded to cover different humidities/temperatures with an addition of an environmental chamber to the tribometer. The test could also be used with the conditions matched to a specific application. This would show if a better performing grease using this test method relates to a better performance in the real application.

Abstract: Accurate friction measurement is vital in order to apply appropriate friction control to the wheel/rail interface. This work analyses different friction measurement techniques under different conditions in the laboratory and the field. Tests have been carried out using a pendulum tester, hand-push tribometer, twin-disc machine, and full-scale rig in the UK and Colombia for a variety of interfacial conditions and rail hardness's. The pendulum has been found to be more sensitive to different conditions than the hand-push tribometer. This is due to the area that the pendulum sweeps being smaller, and so it can be more carefully controlled. Twin-disc and full-scale rig creep curves show good agreement between each other.

Keywords: Coefficient of friction, hand-push tribometer, pendulum, hardened rail, full-scale, twin-disc

1. Introduction

Controlling the Coefficient of Friction (COF) between the wheel and rail improves the performance and energy efficiency of the whole system. These improvements in performances can be:

- Reducing wear (applying a lubricant to gauge face in curves), thereby reducing maintenance work
- Reducing Rolling Contact Fatigue (RCF) (applying friction modifier to top of rail), again reducing maintenance requirements
- Fuel savings by lowering COF, reducing costs
- Reducing noise by lowering COF, improving environmental impact and passenger comfort
- Providing adequate COF for traction/braking by increasing friction with traction gels/sand in low adhesion areas. This is essential for the safe operation of the railway, ensuring trains are able to stop at stations/signals and ascend gradients etc.

In order to realise the benefits listed above, assessing the friction level at different locations on the track/rail and under different interfacial conditions is vital to know what form of friction management to apply. This is because the open nature of the railway means that contact conditions can vary spatially (even between the two rails) as well as temporally. There are a number of ways of measuring friction in the field and in the laboratory, but there is no current consensus or standard on which to base friction tests as each method has its limitations and benefits. Many studies report friction coefficients, but most have used only one friction measurement device without considering how the COF generated relates to a real train. This work included many different measurement techniques in the laboratory and the field, under different interfacial and climate conditions. This enables comparisons between the measurement devices to be made and the benefits/limitations of each device to be explored.

1.1. Aims and Objectives

The aim of this paper was to measure friction levels on the railhead using a pendulum device, full-scale rig, twin-disc rig, and a hand-pushed tribometer in the laboratory and in the field for a variety of interfacial conditions and rail hardness. This enabled comparisons between each of the measurement devices to be made.

1.2. Background section

A previous study [1] concluded that the pendulum has potential as an alternative friction measurement device. This work will extend the comparisons between the pendulum and hand-push tribometer under different conditions in the field as well as comparing the pendulum to twin-disc and full-scale friction measurements in the laboratory.

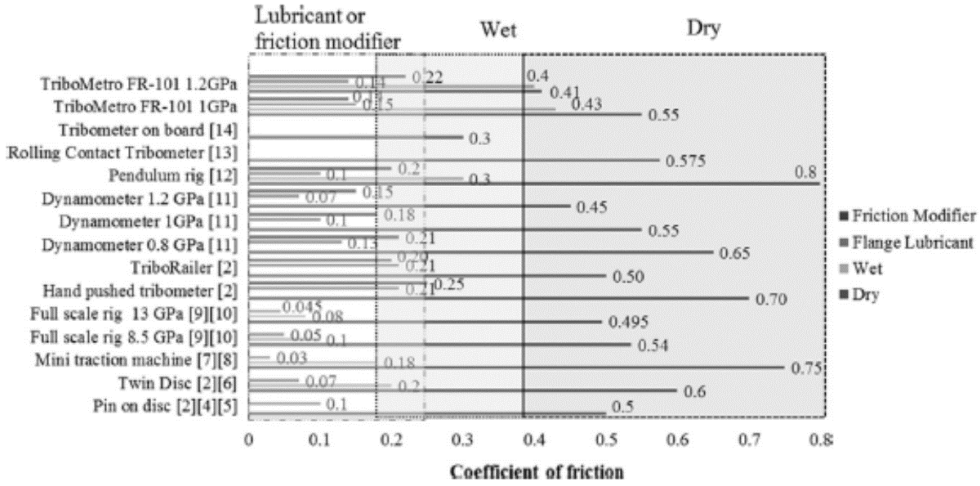

Figure 1 Typical values of COF using different measurement devices [2]

A recent study [2] compared different COF, reported in literature for different measurement techniques, see Figure 1. It noted that there were large ranges in values: greater than 0.4 for dry values, 0.2-0.4 for wet tests and 0-0.25 for lubricants. These large ranges are caused by a large number of factors, including: variations in contact pressure, local rail conditions, environmental conditions etc. and differences in measurement equipment used. Friction measurement devices can split into the following categories:

- Small-scale laboratory methods. These are most useful for gaining fundamental understanding of friction behaviour due to easily controllable conditions
- Full-scale laboratory methods. More realistic geometries compared to small-scale tests but often less versatile.
- Field measurement systems. Enable conditions in the field to be measured, but often at unrealistic geometry/contact pressure and climate/contaminants unable to be controlled.
- Instrumented train. Most accurate way of measuring friction due to realistic loads/speeds. However, limited control over climate, contaminants on the rail and often prohibitively expensive.

2. Method

2.1. Laboratory Tests

In the laboratory, experiments were performed using the Full-Scale wheel/rail Test Facility (FSTF) (shown in Figure 2A), Sheffield University ROlling and Sliding (SUROS) twin-disc machine at The University of Sheffield (Figure 3), and friction measurements using the pendulum (Figure 4).

The FSTF consists of a fixed location wheel that is free to rotate. A slide-bed moves the rail via hydraulic actuators and the load is applied via a load cell located above the wheel. Creep is controlled by a chain pulling the wheel. Three different interfacial conditions were used for the tests: dry, wet and Top Of Rail Friction Modifier (TORFM). The TORFM used is a water based particle suspension which evaporates in the contact leaving the solid particles behind to mix with the third-body layer present on the railhead. For the FSTF, a travelling distance of at least 350 mm was used with a velocity of 100 mm/s. Two different contact pressures were used for all the tests: 1.1 and 1.3 GPa corresponding to wheel loads of 80 and 110 kN [3] respectively. The tests were performed on R260 and hardened R400HT rails. A complete creep curve was obtained for the different interfacial conditions with at least three repeats at each creep level analysed to calculate the mean and standard deviation. Prior to the tests being carried out, 50 'cleaning' wheel passes were carried out at low contact pressure (0.8 GPa). This removed the oxide layer that was present on top of the rail. The wet tests were performed by applying three sprays to the contact band from a standard spray bottle containing deionized water. Each spray from the bottle results in approximately 0.7 g of water being emitted. For the TORFM tests, 3 ml was applied to the contact band by syringe, see Figure 2B. Five wheel passes at low contact pressure (0.8 GPa) were run to ensure the TORFM was spread across the contact evenly.

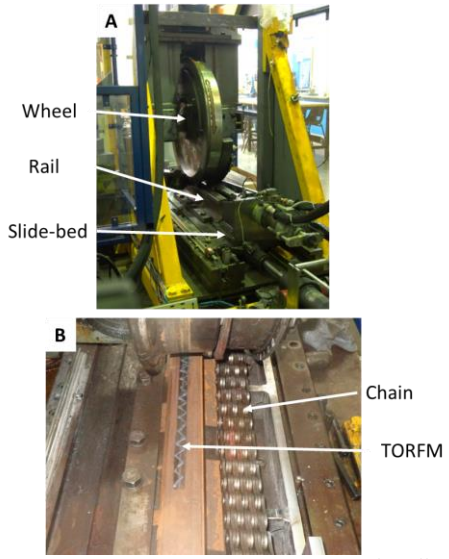

***Figure 2** A) Full-Scale Rig at The University of Sheffield B) Application of TORFM to contact band of rail*

SUROS (Figure 3) is a Colchester lathe with an independent AC motor attached to it to allow two 47 mm diameter discs to be driven independently. Load is applied to the wheel disc via a hydraulic actuator and friction is measured via a torque transducer attached to the shaft on the rail disc side of the machine. Tests were carried out on three rail steels: R260, R370HT, and R400HT. All tests were carried out dry and at 1.5 GPa. The discs were cleaned using an ultrasonic bath before tests were carried out.

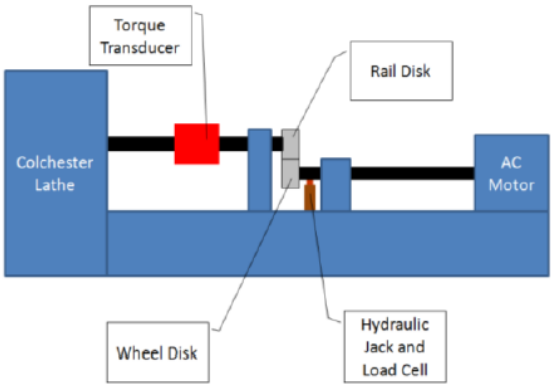

Figure 3 Schematic of SUROS twin-disc machine

Friction measurements were performed using the pendulum (as shown in Figure 4). The pendulum is placed on a flat level stand next to the rail. When released, the arm of the pendulum swings down, the rubber pad contacts the surface of the rail and the arm pushes a needle up the scale. It works on an energy loss principle. The more friction there is in the contact between the rubber pad and the test surface, the more energy is lost, and the higher the Pendulum Test Value (PTV) is. The PTV is converted to a Coefficient of Friction (COF) by using equation 1 [4]. The test method detailed in UK Slip Resistance Group guidelines was followed [4]. This method has been previously used for measuring friction on the rail in the laboratory, and showed good agreement with traction coefficients derived from twin disc testing [5]. Different rail materials were tested at various interfacial conditions: R400HT (dry, wet, dry TORFM, dry TORFM sprayed with water), R260 (dry, wet), R260 clad with DNS (dry only), R260 clad with stellite (dry only). For the different rail materials five repeats were performed for each combination. Additional tests were performed on two separate days using R260 rail to evaluate if different environmental conditions in the laboratory affect results. 100 swings were carried out in dry and wet condition to evaluate how the measurement changes over a period of time. For the wet tests, the rail was sprayed with water at the start of test only. 100 swings were also performed with different amounts of TORFM: 1.0 g, 0.5 g, 0.2 g, 0.1 g. 0.2 g was applied via a roller whereas the rest of the amounts were applied via a brush. The test was performed immediately after applying the TORFM, so it was still in its liquid form.

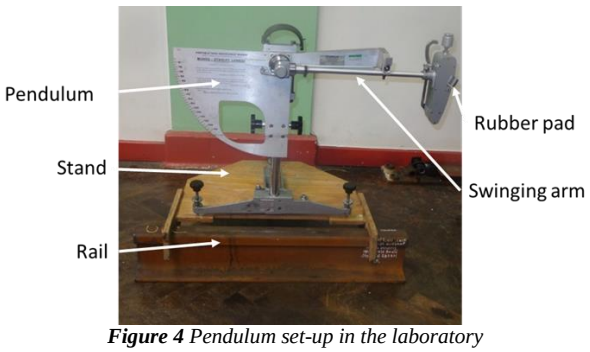

***Figure 4** Pendulum set-up in the laboratory*

$$COF_{pendulum} = \left(\frac{110}{PTV} - \frac{1}{3}\right)^{-1} \quad (1)$$

2.2. Field Tests

In the field, eight locations were tested: Long Marston (LM), Seven Valley Railway (SVR), Windermere and Oxenholme in the UK and four different curves on Metro de Medellín (MDM) in Colombia. SVR is a heritage railway located near Kidderminster. Three sites were tested near a grease applicator, Figure 5 shows the schematic of the sites. LM is a test loop located at Quinton Rail Technology Centre near Long Marston village. A straight section of the test loop was used to perform friction measurements. The Oxenholme site is located on a 50 m section of curve near to Oxenholme station, near Kendal. The Windermere site is located on a 50 m section of curve near to Windermere station in the Lake District. Oxenholme and Windermere are two ends of the same rail line.

Two different tribometers, along with a pendulum, were used to obtain friction readings under different rail conditions. Table 1 shows the details of the different field locations and Table 2 shows the different test conditions at each of the sites. The same method as detailed in section 2.1 was used to gain friction readings using the pendulum (Figure 6A). A Salient Systems push tribometer [6] was used for the hand-pushed tribometer readings in the UK (Figure 6B) and a TriboMetro FR-101 [7] tribometer was used in Colombia. The tribometers have a small wheel that can be set to measure any position on the railhead. As the tribometer is pushed along the rail, a brake is applied to the wheel until slip occurs. The torque and downward force required for slip to occur are recorded and coefficient of friction calculated. The TriboMetro FR-101 records an entire creep curve whereas the Salient Systems tribometer only displays the final coefficient of friction. For all tests a minimum of five repeats were made for each measurement site and condition.

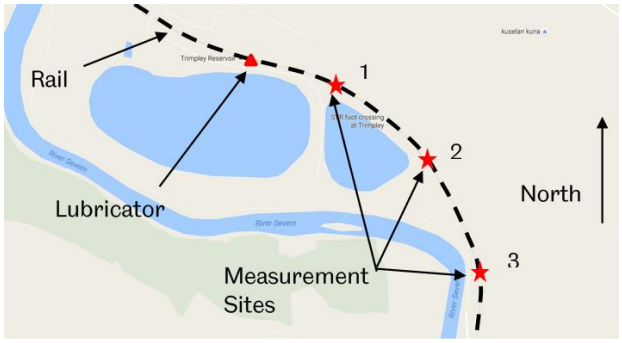

Figure 5 *Schematic of SVR test site*

Site	Date	Description	Temperature and Humidity
LM	10/10/17	One site was tested, straight track	12 °C, 91% RH.
SVR	21/10/17	Three sites were tested around a curve near a grease applicator	12 °C, 81% RH
Windermere and Oxenholme	30/07/12	Two sites tested near to the two stations	Not tested
MDM- C4 Tribometer	01/10/17	Three different sites in the same curve were tested	21 °C, 65% RH
MDM-C15- Tribometer	26/06/17	Curve radius: 300 m	22 °C, 63% RH
MDM-C32 Pendulum	26/06/17	Four sites tested around the curve. Curve radius: 350 m	18°C, 74% RH
MDM- C15- Pendulum	18/05/18	Three sites tested around the curve. Curve radius: 300 m	17°C, 80% RH

Table 1 *Details of field measurements*

Site	Measurement Device	Conditions Tested	Rail Material

3. Results

3.1. Laboratory test results

The results from the Full Scale Test Facility (FSTF) showed that the traction coefficient varies when the contact pressure is modified (see Figure 7). For the dry tests, the coefficient of friction is greater for the low pressure. For high slippages (10%) the traction coefficient is very similar for both pressures. When water was added to the contact the same trend was found, the traction coefficient is lower for the higher contact pressure. There are several explanations for such behaviour. For wheel/rail contact the most plausible explanation is that friction is dominated by adhesive interactions at the interface instead of sub-surface deformation (according to classical Bowden and Tabor binomial theory of friction) [8]. This means that the friction coefficient is mainly determined by the ratio between shear stress and hardness of the softer component of the tribological pair. Given that the contact between rail and wheel steels is very plastic, a significant increase in strain hardening is expected for greater loads. This causes the friction coefficient to reduce since the shear stress is much less affected by the plasticity effects [7]. The hardening effect has been previously observed in the field for this rail [9].

However, when a TORFM was added to the contact, the trend changed and the traction coefficient increased 43% for the high contact pressure; the contact changed significantly and a protective layer is thought to have formed at the surface, probably in the mixed lubrication regime (see Figure 8). When the contact pressure increased, the lubrication parameter on the x-axis of the Stribeck curve plot reduced, and consequently the

friction coefficient increased. An increase in shear strength of the protective film with pressure might also explain the increase in traction coefficient with load. Another interesting result was that, when the contact patch was completely saturated (high creepages around 10%), the traction coefficient was very similar for water and TORFM, and for all the different pressures. This suggests that, for high creepages, the increase in relative velocity might have caused the same lubrication regime during the test for water and for TORFM. That regime could be located in a Stribeck curve (see Figure 8) as the plateau dividing the boundary and mixed lubrication zones. In addition, with TORFM added to the rail, the traction coefficient was very low for low creepages. This could have been caused by the water in the TORFM acting as a lubricant. It might be interesting to perform additional tests on the rig by applying the TORFM to the top of rail, run 50 cycles at low slip to spread the TORFM and form the dry layer. After that, create the creep curve to see if the creep curve is different when the TORFM has formed a dry layer.

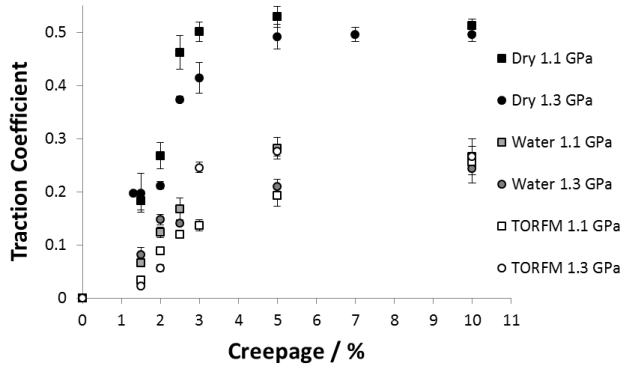

Figure 7 *Creep curve for hardened R400HT rail*

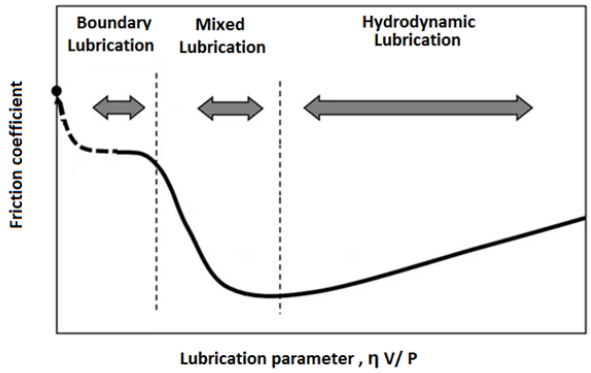

Figure 8 *Stribeck Curve, where η is the dynamic viscosity of the fluid, V is the speed in the contact and P is the normal load in the tribological contact*

Figure 9 shows a creep curve comparing R260 and R400HT for dry and TORFM conditions using the FSTF. It clearly shows that R260 has a higher traction coefficient for both interfacial conditions at all creepages.

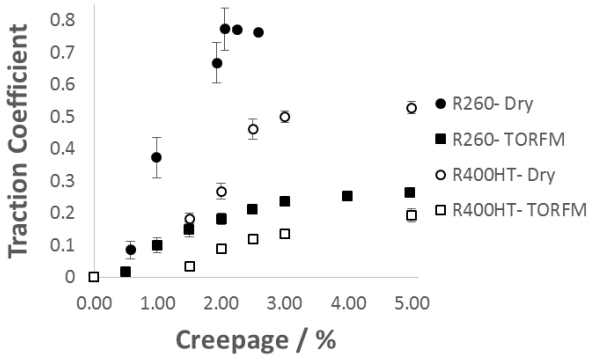

Figure 9 Creep curve for R260 and R400HT using FSTF

Figure 10 shows creep curves generated using SUROS. It clearly shows that R260 has a higher traction coefficient that the two harder rails. This is the same result as seen in Figure 9. R370HT and R400HT have very similar traction coefficients, with R370HT being slightly lower.

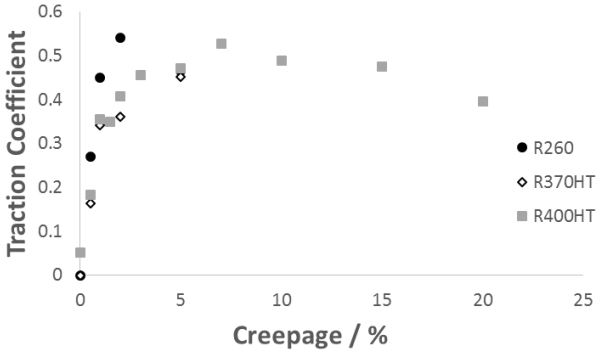

Figure 10 Creep curve for different rail materials using SUROS

Figure 11 compares the creep curves generated using the FSTF and the creep curve generated using SUROS. There is a clear overlap between the results from the two different test rigs, showing that both test scales produce similar results. The SUROS data was generated at a higher contact pressure which has the effect of decreasing the relative traction coefficient (according to Figure 7). This means that if the equivalent contact pressure was used as in the FSTF tests, the SUROS traction coefficient would be higher. Regardless of small changes in traction coefficient, the shape of the curve is the same in both test rigs.

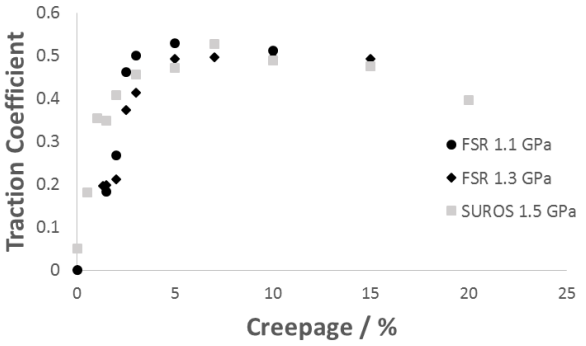

Figure 11 Creep curve comparing SUROS and FSTF

The results of the measurements using the pendulum in the laboratory show that the Coefficient of Friction (COF) for the dry conditions is between 0.62 and 0.87 for the different rails (Figure 12). The values are slightly higher for the R400HT than R260 rail. Clad rails produced the lowest values for dry tests. When water was added to the contact, the resulting, COF was very similar for both R400HT and R260 rail. An interesting result was obtained when water was added to a rail with a dry layer of FM; the coefficient of friction became very low with values similar to those obtained with wet and contaminated rail in the field (as seen in Figure 18).

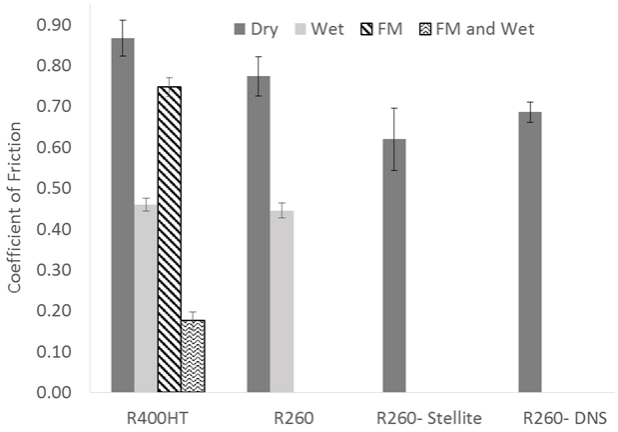

***Figure 12** Coefficient of friction obtained with pendulum in the laboratory*

Figure 13 shows the pendulum results carried out on two different days for 100 swings on R260 rail. For the dry tests, day one has a lower COF than day two. This could be caused by different environmental conditions in the lab between the two days. Both days show a trend of increasing COF with swing number for the dry tests. Dry day 2 COF is similar to the result seen in Figure 12. For the wet tests both days are initially similar and lower than the value in Figure 12 due to more water being used (1.5 ml applied via syringe). After a period of time the COF starts to increase. This is because the water is evaporating and being cleared from the contact with each swing of the pendulum. For day 2, the COF remains lower for longer and increases to a higher amount. The maximum COF increases above 1.0 in this case. This could be caused by the conversion from PTV to COF (Equation 1). This equation was developed for flat surfaces where the whole pendulum pad is in contact with the surface, whereas this is not the case for rail as seen in Figure 14 where only part of the pad is in contact with the rail.

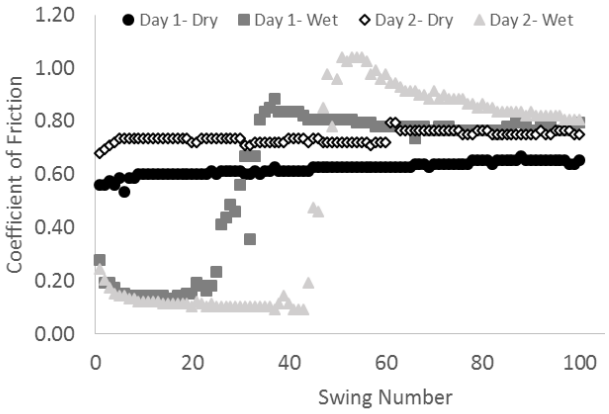

Figure 13 Pendulum tests on two different days for dry and wet conditions

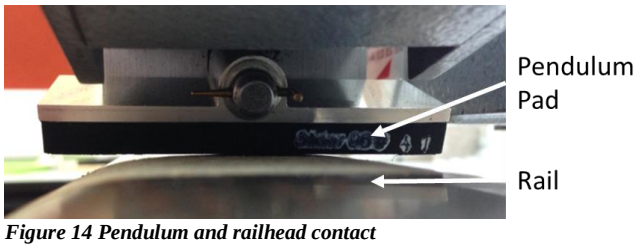

Figure 14 Pendulum and railhead contact

Figure 15 shows pendulum tests of different amounts of TORFM applied at the start of the test and not reapplied during the test. Increasing the applied amount increases the COF. For the amounts applied by brush, the COF increases with each swing after an initial decrease in the first 10 swings. The 0.2 g applied by roller has the lowest COF and is a similar value across all 100 swings. Figure 16A and Figure 16C show the difference between the two application techniques prior to the test starting. Figure 16B shows how the pendulum pad sweeps across a very narrow band of the railhead.

3.1. Field test results

The coefficient of friction obtained with the pendulum in the field for the tested sites under dry conditions is between 0.65 and 0.88 (see Figure 17). The multiple readings for MDM and SVR in Figure 17 are for different positions in the curves. The results for the two UK sites are similar and slightly lower than the results from Colombia. This is thought to be due to the humidity being higher in the UK than in Colombia [10] as well as the different rail materials, but it is not clear which has the greater effect. From Figure 12, it would be expected that the R400HT rail had a higher friction coefficient compared to R350HT, but this is not the case. However, the rail in the field will harden during service and so without hardness measurements from the sites it is difficult to fully analyse the differences between the rail materials.

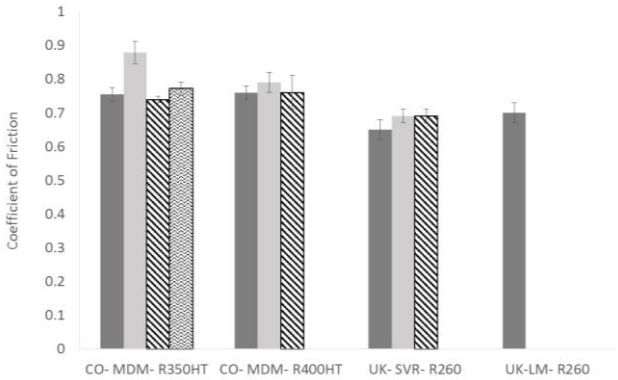

***Figure 17** Dry coefficient of friction obtained with pendulum for the tested sites*

Figure 18 shows the coefficient of friction on the gauge face at three sites around a curve at SVR (UK) for different interfacial conditions. The wet and contaminated values were obtained by testing the rail without cleaning it first. This means that there are unknown contaminants present on the rail during the test. The wet results are lower than the dry values due to water acting as a lubricant. Site two has a significantly lower value for the wet tests compared to sites one and three. There was more tree canopy observed on this section of the curve, which led to greater leaf contamination which is hard to clean. This could explain the significantly lower value.

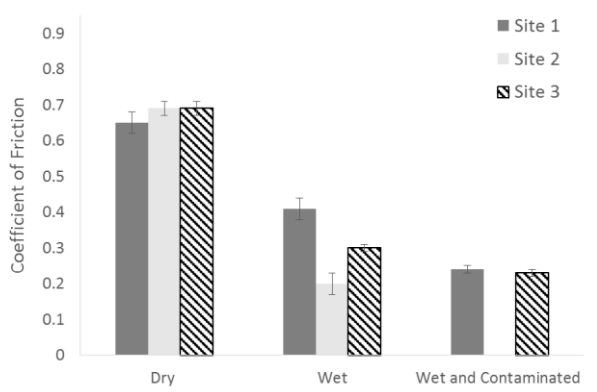

Figure 18 Coefficient of Friction obtained at SVR (UK) for different interfacial conditions using hand-push tribometer

Figure 19 shows the COF obtained by the hand-pushed tribometer on the TOR under dry conditions. The value of the dry coefficient of friction is lower at LM (UK) than in Colombia (CO-R260). As with the pendulum tests, the lower coefficient of friction is thought to be due to higher humidity in the UK. In addition, the measurements in Colombia were done using a contact pressure of 1.1 GPa (TriboMetro FR-101 tribometer). The contact pressure of the Salient System tribometer used in the UK is around 0.7 GPa [11], and measurements with a lower contact pressure will report higher coefficients of friction (as seen in Figure 7 and [12]). This means the values taken in the UK are higher than if tests had been done using the TriboMetro FR-101 tribometer. From the laboratory tests in Figure 12, the R400 HT rail material should be higher than the R260 rail, but the relationship is reversed in the results presented in Figure 19. It is not known why this is.

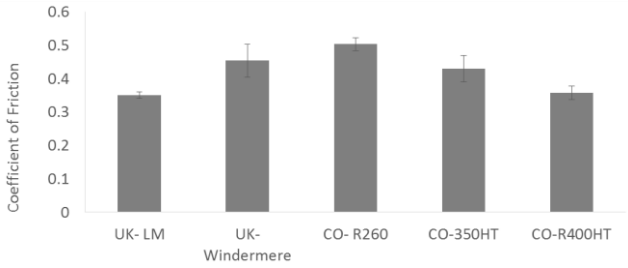

Figure 19 Coefficient of Friction obtained for dry TOR using hand-push tribometer

Figure 20 shows the results from hand-push tribometer tests at SVR and Colombia under wet conditions. The wet conditions were caused by rain and not controlled. SVR- Site 1- High Rail was located near to a lubricator (see Figure 5) and so the low friction coefficient is caused by grease migration from the gauge face to the TOR. Site 2 and Site 3 measurements took place on the high rail. The COF reduction at SVR site 2 that is seen in the wet tests in Figure 18 is also seen in the results here.

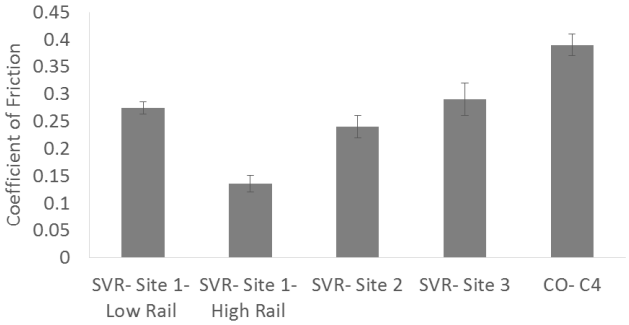

Figure 20 Coefficient of Friction obtained for wet TOR at SVR at different sites using hand-push tribometer

Figure 20 shows the results from the hand-push tribometer tests on the gauge face in dry conditions. The COF values are the same for the TOR (Figure 19) and the GF for the sites at SVR. This is because, as the tribometer is pushed along the track taking its readings, it is possible for the measuring wheel in the tribometer to pick up contamination from the rail. If this occurs early in the test, the contamination stays on the measuring wheel throughout the test. This was observed at the end of each 'push' of the tribometer; a black viscous substance had built up on the measuring wheel. The COF were higher at SVR than at Oxenholme and Windermere. As the tests took place on a curve and the rail was not cleaned before the test took place there was an unknown amount of grease present on the GF. This difference in amount of grease (and potentially other unknown contaminants) led to the difference in COF. There was more grease observed on the gauge face at Oxenholme than at Windermere, causing the difference in COF.

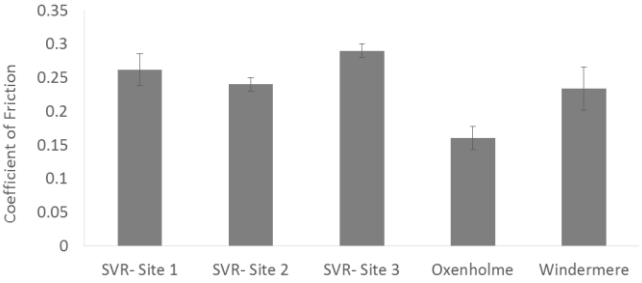

Figure 21 Coefficient of Friction obtained for gauge face using hand-push tribometer

4. Discussion

The results from the pendulum and tribometer show that the pendulum is more sensitive to different types of contaminants as the difference in values between the different interfacial conditions is larger. Measurements can also be carried out with a shorter section of rail (approximately 0.3 m in length). This means that the conditions being tested can be more carefully controlled. Additionally, measurements with the pendulum are more practical and quick compared to the hand-pushed tribometer. However, extensive tests with the same pad could lead to it becoming unevenly worn. Additionally, as seen in Figure 14, the contact is much smaller than the full pad width. This could cause an error in the conversion from PTV to COF. A recently developed tribometer [13] aims to overcome some of the issues with the hand-push tribometer. This new tribometer only uses a 0.5 m section of rail and can measure anywhere on the railhead and at varying contact pressures.

Figure 22 compares the COF measured by the pendulum for R400HT at 5% creep with the COF reported by the FSTF and SUROS. Clearly, the pendulum's measurements are higher for the three interfacial conditions tested. This is to be expected as the pendulum is a full sliding, rubber, rectangular pad on steel rail contact. Whereas, the FSTF is a rolling/sliding, steel on steel contact. Additionally, the contact pressure that the pendulum reaches is much smaller than in the FSTF or SUROS. These differences also cause the change in values between pendulum and tribometer. What is important is that the methods have produced the same ranking of interfacial conditions: dry has highest COF, water has the lowest COF and TORFM is between the two levels. SUROS has a similar but slightly lower COF compared to the FSTF results. However, the test was carried out at 1.5 GPa contact pressure which lowers the COF compared to the FSTF contact pressures. When this is taken into account the COF levels are very similar which shows that, despite the differences between SUROS and FSTF, there is good agreement between the measurements.

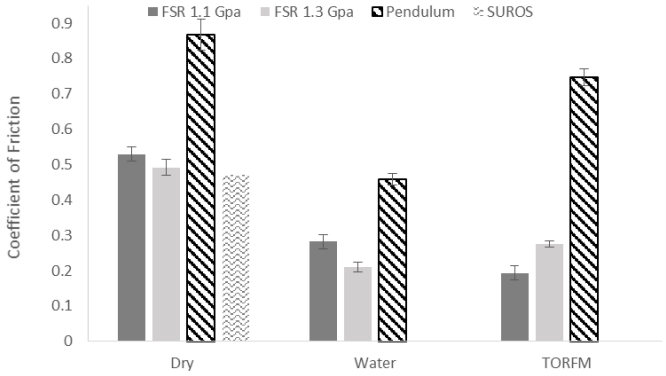

Figure 22 Comparison of FSTF to pendulum in the laboratory

Figure 23 shows the results from tests in the laboratory and the field. In all cases the results are lower in the field than they are in the laboratory. This is to be expected as there will always be traces of contamination in the field that are not present in the lab (despite any cleaning that occurs prior to test).

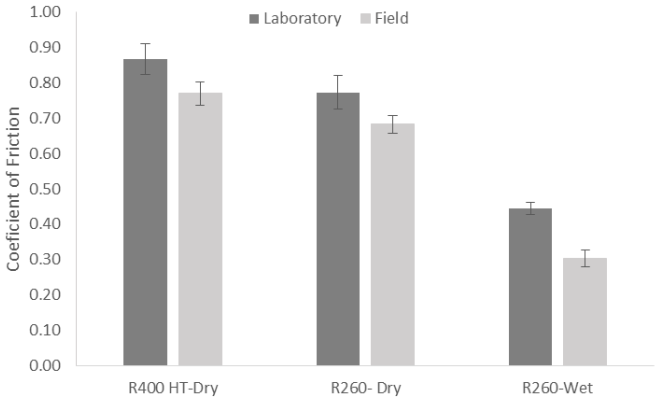

Figure 23- Pendulum tests in the laboratory and the field

For the FSTF (Figure 9), SUROS (Figure 10), and hand-push tribometer (Figure 19), the COF for R260 is reported to be higher than that for R400HT. However, for the pendulum (Figure 23). This relationship is reversed.

In the data presented in this work the dry and wet values fall into the ranges specified in Figure 1. Figure 24 shows work carried out with an instrumented train [14]. The data shown broadly matches the creep curves displayed in Figure 7- Figure 11 with some small differences. The steep negative gradient after saturation in Figure 24 is not present for any of the dry creep curves measured, but the location of the saturation point is the same. The fact that water lowers friction and shifts the saturation point to a higher creep level is the seen in Figure 7- Figure 11 and in Figure 24. This gives confidence that the laboratory tests represent conditions seen in the field by real trains.

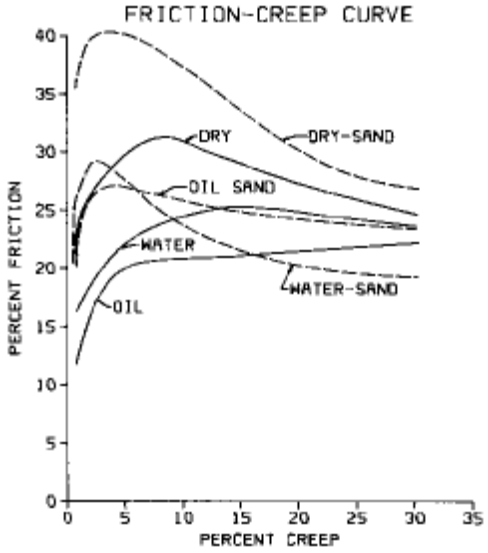

Figure 24- Creep curves measured with instrumented train [14]

The tests performed in MDM showed that in the field the pendulum is less sensitive to measure the differences in rail materials. The same trend was observed in the laboratory. The curves (C15 and C32) are on the same line and they are similar in terms of radius and the same trains are passing in both curves but the rail in every curve is different.

On the other hand, the hand-pushed is more sensitive to rail material than the pendulum given that the contact area can be reduced when the measuring wheel rotates against a harder rail. In the pendulum the contact are is controlled by the rubber and it is not affected significantly by the rail material.

5. Conclusions

The results from the Full-Scale Test Facility showed that the coefficient of friction varies when the contact pressure is modified. For the dry tests, the coefficient of friction is greater for the low pressure. The COF was reduced by 7% and 34% for the dry and wet conditions, when the contact pressure is increased for a fixed value of creepage of 5%. The FSTF tests show good agreement with the twin-disc tests, with the same relationships shown and values similar (taking into account different contact pressures).

The coefficient of friction obtained with the pendulum in the field for the tested sites under dry conditions is between 0.65 and 0.88. The minimum coefficient of friction obtained with the hand-pushed tribometer was measured at Seven Valley when the rail was wet and contaminated. The pendulum and hand-push tribometer showed the same relationships for different interfacial conditions. The pendulum can differentiate between different contaminants better than the tribometer can as the contact area is more controllable and there is greater variation in values. However, the conversion between the PTV and COF may need adjusting to take account of the smaller contact area on the railhead compared to its original use, measuring COF on flat surfaces.

Abstract: This paper investigates the wheel-rail contact forces and stress distributions that lead to lateral plastic flow of material in the railhead. A 250 m radius curve is taken as an example with rail profiles measured over an 8 month period. Vehicle dynamics simulations have been carried out to investigate how the wheel-rail contact forces change over time, as the rail profile evolves. The calculated forces have then been applied to a Finite Element Analysis (FEA) to investigate plastic work and cumulative strain within the rail.

The work presented in this paper is part of a larger project which has the aim of developing a simple analytical approach for predicting rates of plastic flow based on calculated wheel-rail contact forces (without the need for computationally intensive FEA analysis).

Vehicle speed on curves (and therefore cant excess/deficiency) appears to have a significant effect on rates of Effective Plastic Work (EPW) as does contact size and shape. Work is ongoing to continue investigating parameters that affect rates of lateral plastic flow and to develop a 'plastic work damage index'; building on a previous study [1].

Keywords: plastic deformation, shakedown, FEA, effective plastic work

1. Introduction

Gross plastic deformation, also known as plastic flow, is often evident on both the high (outer) and low (inner) rails of curves, particularly on freight routes. High rates of plastic flow can significantly reduce rail life. Plastic flow in low rails tends to displace material from the rail head toward the field side, see Figure 1. Whereas, plastic deformation in the high rail displaces material from the gauge face downward and outward to cause 'lipping'. The detailed mechanism of plastic flow is not completely understood.

Material at the wheel-rail interface frequently exceeds its elastic limit. Ratcheting failure, however, is not inevitable; instead, 'shakedown' may occur after a limited number of cycles. Plastic deformation will occur both prior to shakedown or during progressive ratcheting failures. However, it may be reasonable to expect that plastic deformation prior to shakedown will typically be limited compared to ratcheting failures. Therefore, the shakedown theorems [1,2] have been extensively used to design against ratcheting failures. For example, Ponter's [3] shakedown maps are commonly used to design against ratcheting failures in rails. However, Ponter's shakedown maps are only valid for circular Hertzian contacts with traction loads in the direction of travel. In a subsequent study, Ponter [4] demonstrated that both factors may significantly influence shakedown limits. Further, both of these studies approximate the contacting bodies as semi-infinite half-spaces. However, in practice shakedown limits are reduced as the contact approaches the rail edge [5]. Therefore, the half-space assumption may no longer be valid. All the above shakedown limits consider contacts in isolation; however, shakedown limits are considerably reduced by the passage of different wheel-rail contacts with different traction ratios [6]. Alternatively, non-linear finite elements methods have been used [7,8,9]. However, these methods are typically complex and computationally expensive. Furthermore, results are highly sensitive to the chosen material model and loading. Results, therefore, are not easily transferable to alternative materials or loadings.

Wheel-rail contacts in curves are highly elliptical with resultant tractions at a significant angle to the direction of travel. In some cases, the contacts may also approach the edge of the rail. These combinations are not covered by the shakedown maps in [4] and [5]. Consequently, infrastructure managers have no means of accurately predicting likely occurrence or severity of plastic flow. Furthermore, no clear guidance is available for measures which might reduce plastic flow, short of re-railing with higher grade steel.

The focus of the current paper is on a single curve with a known history of low rail plastic flow. However, it forms part of a larger project to develop a practical tool for understanding and predicting plastic flow in curves. The objective is to allow infrastructure managers to input data such as measured rail profiles and outputs from vehicle dynamics software, in order to predict plastic flow. The current project builds on a previous study [10], which proposed simple formulae to predict plastic flow from the outputs described above. However, these formulae require further validation and/or refinement. The methodology of the previous project is broadly adopted for the following work and is described below. This consists of vehicle dynamics simulation to obtain contact conditions, followed by non-linear finite element simulation of a single wheel passage. At this stage, the

focus is on understanding the early stages of plastic flow development, corresponding to the field data available for the site.

2. Methodology

A range of vehicle dynamics simulations have been undertaken to understand the distribution of potential contact conditions. These simulations include different running speeds and a range of worn rail and wheel shapes. These simulations are described in more detail within Section 4.

Outputs from the vehicle-track interaction simulations were then used as inputs to a non-linear static finite element model of the rail. To enable simulation of the full range of contact conditions, several potentially significant simplifications have been made. Firstly, Hertzian contact conditions have been assumed, consistent with the vehicle dynamic simulations. (Note that Hertzian conditions may no longer be valid for contacts approaching the rail edge. However, all contact conditions used in the current paper were located towards the central portion of the rail.) This simplification allows the relatively straightforward modelling of the wheel-rail contact as a moving pressure distribution. Full slippage between rail and wheel is assumed throughout. Therefore, tractions and spin pressures can be evaluated from simple analytical expressions. The following outputs from the vehicle-track simulations are required to describe each contact condition: the semi-axes of the contact ellipse; normal, lateral and longitudinal forces; spin moment; and lateral position relative to the gauge corner.

A simple bilinear kinematic hardening model is assumed throughout. For simplicity, all simulations assume no accumulation of plastic strain or residual stress prior to the application of any single contact. However, an increased yield strength is adopted to account for some work hardening in prior load cycles. The following material properties have therefore been adopted as representative of a rail which has already experienced some traffic (E=210 GPa, ν = 0.3, σ_Y=550Mpa, E_p = 20 GPa) [10].

A single passage of each contact is then applied to the finite element model. In the following discussion, it is assumed that the relative plastic deformation experienced during this first passage of the contact will roughly correlate with the longer term, cyclic deformation due to repeated application of the same contact. Therefore, initial high rates of plastic flow might be associated with a ratcheting failure or a large number of cycles to shakedown. This vastly reduces the computational effort required for each contact condition.

The previous project [10] identified a parameter termed 'effective plastic work' (*EPW*) as a good measure of overall plastic deformation. 'Effective plastic work' (*EPW*) is defined as follows:

$$EPW = \iiint P_W \, dV$$

where P_w is plastic work and the integral is evaluated over a 1mm wide cross-sectional slice through the rail. *EPW*, therefore, has units J/mm. EPW is directionless and therefore does not distinguish between longitudinal and lateral plastic deformation or between surface or subsurface deformations.

3. Case description

Results presented in this paper are based on a case study using measured rail profiles from a 250 m radius curve. This location has a CEN56E1 (BS113A) rail profile, has an installed cant of 60 mm with 6 mm gauge widening (i.e. a design gauge of 1441 mm). This curve was used by Network Rail to investigate the use of premium grade steels. As part of the study a control section of standard, grade 260 steel was included; the three measured profile shapes presented in Figure 1 are for that section of standard grade steel. The rail was ground to restore its profile and subsequent monitoring visits undertaken 4 weeks, 4 months and 9 months after this. During the monitoring visits measurements of the rail profiles were collected using a MiniProf [11]. Network Rail have kindly provided the measured profiles for use in this study. Figure 1 shows how the shape of the low (inner) rail of the curve evolved over the monitoring period, due to the combination of wear and plastic flow.

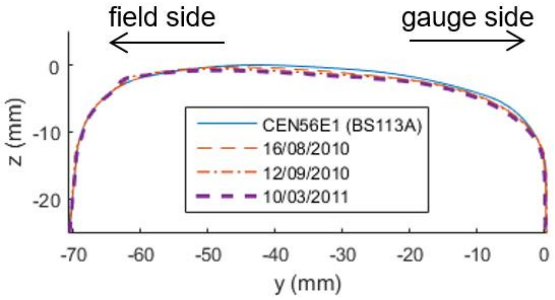

Figure 1a *Low rail profile changes July 2010 to March 2011*

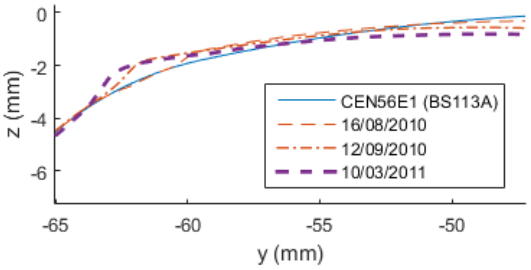

Figure 1b *Low rail profile close up of detailed rail head shape including .plastic flow*

As shown in Figure 1 wear removes material from the highest point of the rail head (which is the most likely contact point for wheels with any hollow wear); as a result of this the highest point of the rail slowly moves towards the field side of the rail as the rail wears. There is also visible evidence of field side plastic flow which is

developing over the trial period (in the relatively short time of 8 months).

Table 1 shows the traffic travelling over the sample curve at the time of the trial, giving wheelset passes per year. Vehicle dynamics simulations, and FEA analysis based on the outputs of those simulations presented in this paper are for the laden freight wagon only; which form the largest proportion of the traffic by tonnage.

***Table 1** Wheelset passes/year*

Vehicle type	Wheelset passes/year	Mega Gross Tonnes/annum
2 axle passenger vehicle	120,000	1.9
4 axle passenger vehicle	165,000	1.5
Laden freight wagon	200,000	5.0

4. Vehicle-track interaction

Vehicle dynamic simulations have been carried out for this study using the multibody vehicle dynamics software, Vampire® [12]. A laden coal wagon has been simulated with an axle load of 250 kN using Swing Motion bogies (SMB), running on P5 wheels [13]. A typical vehicle speed of 20 mph for this curve has been assumed, which gives a 12 mm cant excess (the effect of varying speed on the curve and therefore cant excess/deficiency is presented in section 4.3). Wheel-rail friction (μ) has been assumed to be 0.3.

4.1. Wheel shapes considered in this investigation

To take into account the varying worn wheel shapes, three different wheel profiles have been considered: a new P5 wheel, moderately worn P5 and heavily worn P5. The three wheel profiles are shown in Figure 2. A new P5 wheel profile has a cone angle of 1:20 at the centre of the tread. As shown in Figure 1, as the wheel wears, the centre of the tread becomes flatter; this means it is possible for the wheel to contact the rail closer to the field side of a low rail in a curve, especially if that rail is also heavily worn. NB the difference in the Y axis position of these wheels presented in Figure 2 has been artificially created to make it easier to see and compare all three wheel shapes.

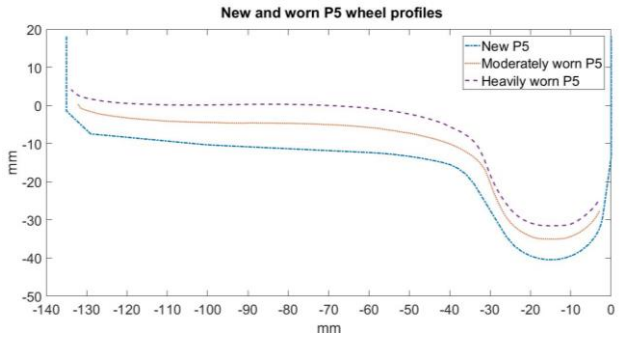

***Figure 2** New and worn P5 wheel profiles*

4.2. Effect of varying rail shape on contact position and wheel-rail forces

The worn shape of the rails and wheels has a significant effect on vehicle curving performance and is the primary reason for how lateral contact position on the rail can vary. Figures 3 - 6 show the contact positions on the low (left) rail for the three different wheel profiles considered for the leading and trailing wheelset on the front bogie of a freight wagon negotiating the case study curve at a speed of 20 mph (i.e. a cant excess of 12 mm); whilst Figure 7 shows a graph of how the contact positions vary over time. As shown in the figures new wheels have contact positions closer towards the centre of the rail; as wheel wear increases, the contact positions move towards the field side of the rail. For the first two measured profiles as the rail wears the wheel contact positions tend to generally move further out towards the field side; by the time of the third measured profile the wheel-rail contact has become more conformal and the contact positions are more spread out (NB in Figures 3 – 6 the gauge face is positioned a 0 on the x-axis, and the centre of the rail at -35mm).

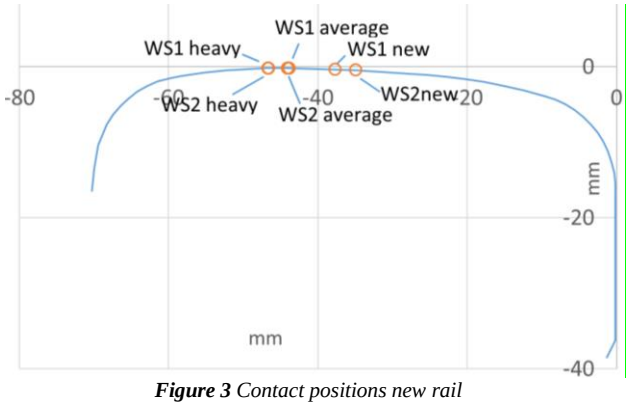

***Figure 3** Contact positions new rail*

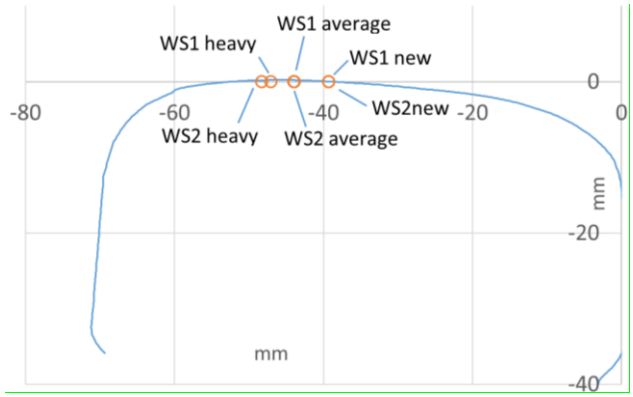

***Figure 4** Contact positions on rail shape 28 days after grinding*

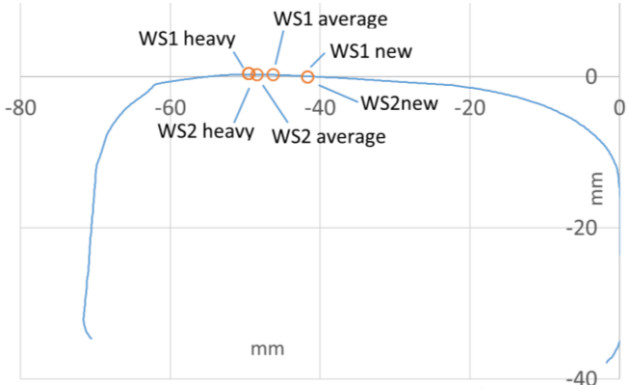

Figure 5 *Contact positions on rail shape 143 days after grinding*

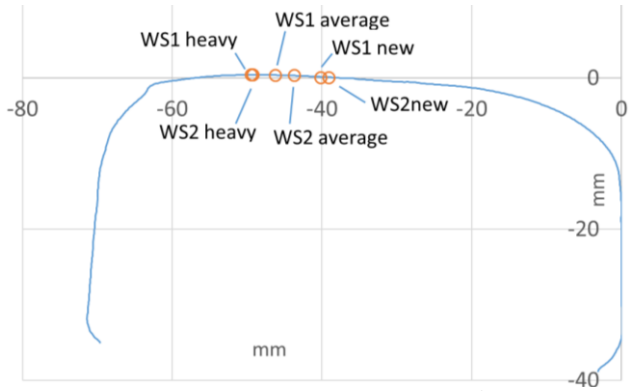

Figure 6 *Contact positions on rail shape 234 days after grinding*

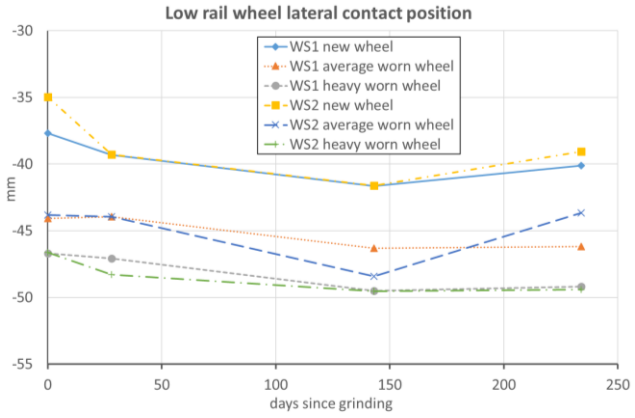

Figure 7 *Contact position variation over time*

As the contact positions (and shapes) vary depending on the worn shape of the rail, so do the forces transmitted at the wheel-rail contact. Figure 8 shows how the lateral force on the low (inner) rail of the curve vary with time, where a negative force is towards the field side of the rail. These are results from the same simulations used to calculate the contact positions shown in Figure 3 – 6.

At this speed (20 mph) it can be seen that the leading wheels on the low rail tend to have much higher lateral forces towards the field side (which suggest the leading wheelset will may be a larger contributor to lateral plastic flow than the trailing wheelset) than the trailing wheelsets. There is a variation in the lateral force as the rail shape evolves over time; however, it doesn't appear to be a significant variation.

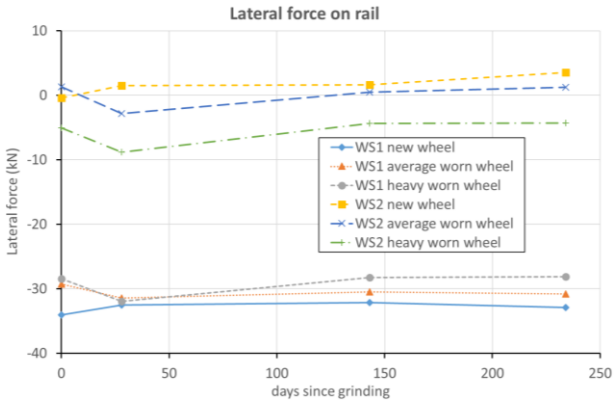

Figure 8 *Lateral force on low (left) rail*

Figure 9 shows the longitudinal force on the low (left) rail of the curve for wheelsets 1 and 2, where a positive force is forwards along the rail in the direction of travel (and a negative force is backwards). As shown (for this speed and therefore cant excess) the leading and trailing wheels give longitudinal forces on the opposite direction – as steering forces are opposing the primary yaw stiffness of the bogie. Whilst the forces do vary with time, there is no obvious trend to the variation.

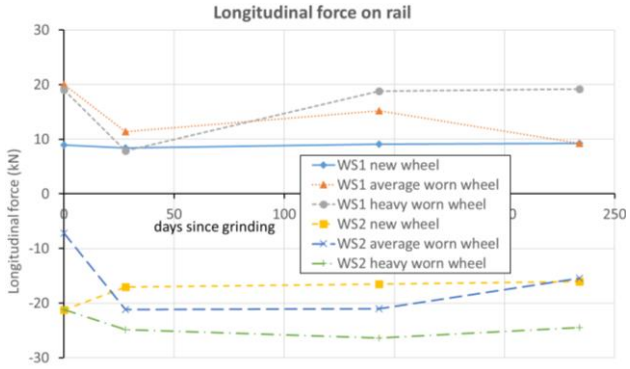

Figure 9 *Longitudinal force on low (left) rail*

4.3. Effect of cant excess/deficiency

To investigate the effect of cant excess or deficiency on plastic flow, simulations were carried out for the vehicle travelling around the curve at a range of speeds as shown in Table 2.

The cant excess/deficiency appears to have a very limited effect on the lateral contact position of wheels on the low rail for this curve and sample of rail shapes; as such no results for the effect of cant excess/deficiency on low rail contact position are presented here (NB in reality the amount of deficiency or excess will significantly affect curving forces, as discussed below, and those differing force would affect the worn rail shape).

Table 2 *Range of speeds and cant excess/deficiency used in simulations*

Speed	Cant excess, mm (+)/ deficiency (-)
5	57
10	48
20	12
22.5	0
25	-16
27.5	-31
30	-59
35	-88
37	-106

Figure 10 shows the effect of cant excess/deficiency on lateral, low rail contact force. In the figure a positive on the x-axis is cant excess; whilst negative is cant deficiency. A negative force on the y-axis is in a direction towards the field side. For the leading wheelset there is a clear relationship between cant excess and increased lateral force towards the field side of the rail. Under cant deficiency the trailing wheelset has a small lateral force towards the gauge side of the rail, at balancing cant the trailing wheelset has zero lateral force; whilst in cant excess the trailing wheelset also generates a small force towards the field side of the rail.

Based on this it would appear highly likely (and this is also observed on track) that cant excess (or lower cant deficiency) leads to higher rates of lateral plastic flow. A mixed traffic railway where installed cant is designed to accommodate faster moving passenger trains can result in slower running freight trains travelling through curves at higher cant excesses (especially when the freight train needs to stop or slow down near junctions to prioritise the movement of passenger trains).

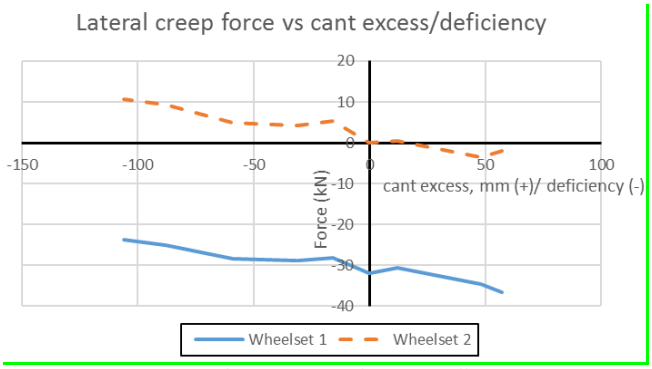

Figure 10 *Lateral force on low (left) rail at different cant excess/deficiencies*

Figure 11 shows the variation of longitudinal creep force on the low (left) rail with cant excess/deficiency. The longitudinal force generated by the leading wheelset tends to remain fairly similar, irrespective of cant excess. Whilst the trailing wheelset appears to have higher longitudinal forces close to balancing cant (when lateral force is very low) which then reduces with higher cant deficiency and also higher cant excess.

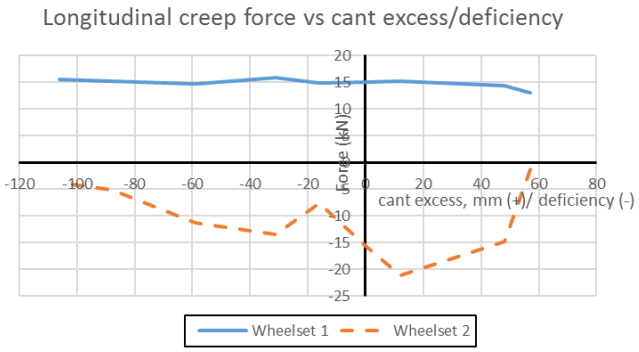

Figure 11 *Longitudinal force on low (left) rail at different cant excess/deficiencies*

5. Finite element analysis

5.1. Description of model

A static non-linear finite element model was developed within ANSYS Mechanical [13]. A full cross-section of rail 250mm in length was modelled for each rail profile. The model was fully fixed at the rail foot. Thus vertical and lateral bending of the rail was excluded, but twisting around the foot was possible. In the central 50mm length of the rail, a refined mesh of predominately $1mm^3$ cuboidal elements was used. Plastic deformation is generally concentrated near the rail surface. Therefore, the refined mesh extended to a depth of 14mm below the rail head. Linear elements were used throughout the mesh. Each contact patch (from Section 4) was incrementally moved along the central $2a$ of the rail; where a is the longitudinal contact semi-axis. A total of 40 individual increments were used to simulate this process. The sensitivity of results to both length of contact movement and the number of increments was tested. Neither parameter was found to significantly influence results.

5.2. Effective plastic work

In this section, results of the finite element analysis will be used to evaluate the effectiveness of EPW [10] as a simple measure of lateral plastic flow. In Figure 12, the maximum (directionless) residual displacement is plotted against EPW for all the cases modelled. It can be seen that a good correlation is achieved between these parameters. However, the visible changes in profile shape, highlighted in Figure 1, are likely due to lateral displacements toward the field side. Other residual displacements may be reversed by subsequent wheel passages or worn away. In Figure 13, maximum field side residual displacement is plotted against EPW. In this plot, the correlation is not as clear and two distinct groups of outliers are clearly visible. The directionless nature of EPW rather than the directional nature of lateral displacement would appear to explain this poorer correlation. On the whole, EPW appears a good measure of plastic flow although less effective at differentiating the direction of flow.

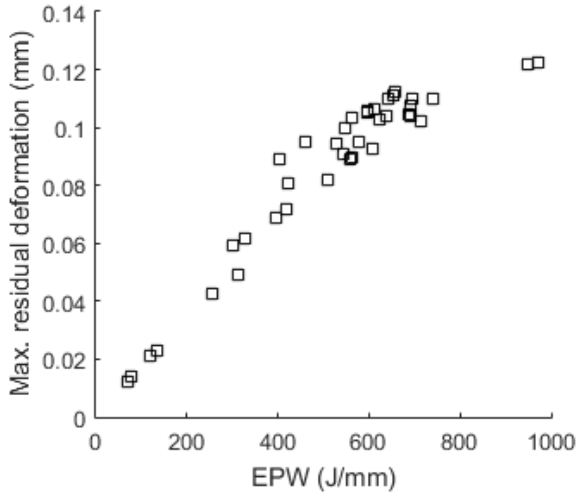

Figure 12 *Maximum residual displacement (total) at different levels of effective plastic work*

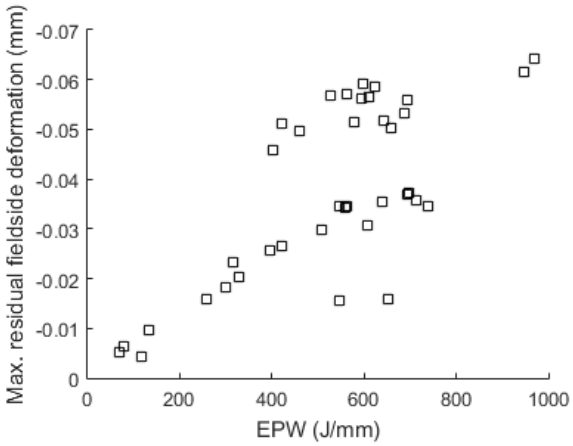

Figure 13 *Maximum residual displacement (toward field side) at different levels of effective plastic work [note displacement to the field side is negative]*

5.3. Examination of cyclic performance

A key assumption of the proposed methodology is that a single passage of the contact can be extrapolated to understand the relative cyclical behaviour of different contact conditions. To assess the validity of this assumption, six contact conditions with a range of EPW (400-1000 J/mm) were selected for further investigation. A further four passages of each contact was applied to the model, allowing strain and displacement to accumulate. All six contacts achieved shakedown within the first two passages. In Figure 14, a representative deformed shape is shown after the fifth passage of the contact. The other five deformed patterns were all similar. The deformed shape in Figure 14 does not correspond to the deformation pattern highlighted in Figure 1. In particular, it should be noted that the measured profiles and the contact locations (from vehicle-track simulations) suggest a much more global 'mechanism' than observed in Figure 14. This discrepancy will be investigated further in future work. The first step of this investigation will include examination of alternative material models. As observed in Figure 15, stresses in excess of the ultimate tensile strength of R260 (880 N/mm^2) [15] were observed in the majority of analyses. This is due to the bilinear kinematic material model adopted. The linear relationships observed in Figures 12 and 13 are likely to be altered as a result.

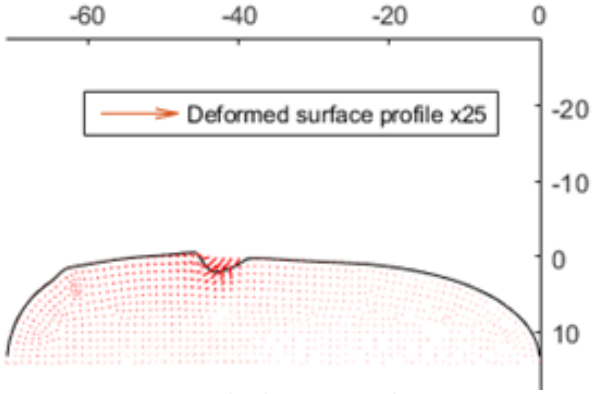

Figure 14 *Displacement after five passages of a contact [EPW = 971 J/mm]*

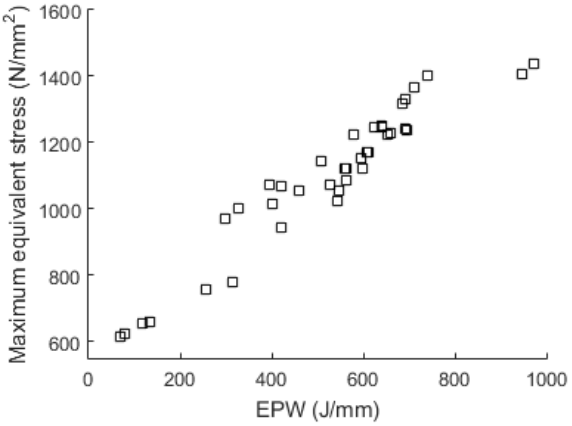

Figure 15 *Maximum stress (single wheel pass) at different levels of effective plastic work*

5.4. Practical implications

Finally, some practical implications will be drawn from the simulations. Firstly at the early stages considered, the propensity towards plastic flow remains relatively stable after an initial 'bedding in' period. This is clearly demonstrated in Figure 16. This is explained by the relatively stable contact conditions obtain from the vehicle-track simulations. In particular, the forces are largely unaffected and the lateral contact position is sufficiently central in all case for changing lateral restraint to be insignificant. However, over time wear will move contacts further toward the field side and ratcheting failures may consequently become more likely.

A further practical implication of the results is illustrated in Figure 17; it is clear that EPW increases significantly with cant excess. The increased EPWs correspond well with increased lateral forces on the low rail when running in cant excess (see Figure 10). The outlier for the trailing wheel at 57mm cant excess is due to an increased contact area and hence reduced contact stress. The increased contact area is a function of local rail geometry at this contact position.

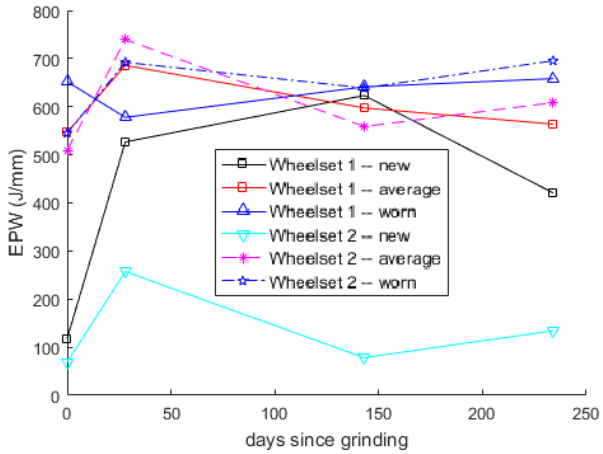

Figure 16 *Change in effective plastic work with time and rail wear*

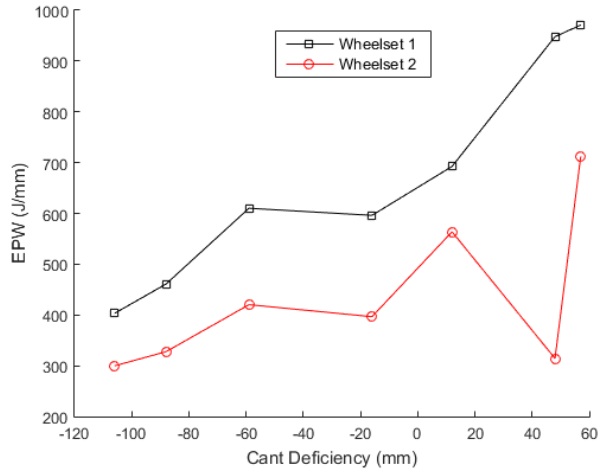

Figure 17 *Change in effective plastic work with cant excess/deficiency [using average wheel profile and rail profile measured on 02/12/10]*

6. Discussion and Conclusions

The analysis presented in the current paper focuses on worn/deformed rail shapes for the first 8 months subsequent to rail grinding. The contacts on the low rail, in this study, are located close to the centre-line of the rail. However, a relatively small change in contact position can significantly change contact area. An increased contact area will reduce stresses and hence plastic flow. In the longer term, the contact position will shift further toward the field side as the rail wears. In such cases there may be an increased likelihood of ratcheting failures. It should be noted that in such cases Hertzian conditions will not be present; however, most studies evaluating shakedown including Bower's study [5] of lateral restraint assume Hertzian contact conditions. Plastic flow occurring at more advanced wear states will be considered in the future. Partial slippage will also influence plastic flow by changing the distribution of traction within the contact area.

Several observations about relative severity of plastic flow for different contact positions can be made. First, the leading wheel is likely to be driving plastic flow due to higher forces particular when running with significant cant excess. However, where traction in the trailing contact are in opposing directions this may also contribute and requires further investigation. Secondly, results show the importance of considering the full range of potential operating conditions. This is particularly true of vehicle speed. Finite element results show that freight wagons moving at low speed are associated with a much higher value of EPW. On some curves, slow moving freight wagons may well be a common occurrence due mixed traffic operating conditions. Therefore, future work on plastic flow on low rails in curves should focus on low speed and high cant excesses.

It should be noted that several important simplifications have been made to enable quick evaluation of lateral plastic flow. In this context, the proposed EPW parameters appears to be a promising, but not straight forward indicator of lateral plastic flow. However, EPW may also be indicative of other damage mechanism such as alternating longitudinal plasticity or ratcheting. In any case, high EPW may be detrimental to rail life. Alternatively, EPW could be supplemented by considering further parameters such traction orientation.

A final further observation is that simple bilinear kinematic material models appear to considerably underestimate plastic deformations during repeated cycles. Additionally, very high stresses, in excess of the material UTS, are present even after a single wheel pass. Therefore, a multi-linear model is likely to yield better results, but is also likely to change the type of correlation between EPW and plastic flow.

Acknowledgments

The authors would like to thank RSSB for funding this work through their Strategic Partnership with the University of Huddersfield Institute of Railway Research, as well as Network Rail and British Steel who have supported this work by providing measured field data and guidance through a project steering committee.

THE NEW ROLLER RIG ATLAS – CHARACTERISTICS, METHODS AND RESULTS OF TESTS ABOUT CONDITIONS, IMPACT AND MEANS TO CONTROL ADHESION AND WHEEL SLIP OF RAIL VEHICLES

Martin Heller, Jörg Koch, Stefan Schneider, Thomas Rasel

Knorr-Bremse Systeme für Schienenfahrzeuge GmbH München

1. Introduction

The development of algorithms for brake control comprises sophisticated adaptive methods, precise electronic and pneumatic hardware and brake devices which guarantee accurate brake forces. But finally they are all dependent on the adhesion from wheel to rail. The algorithms may use the possible adhesion blind or may detect it for predictable stopping distances and to control side effects as wear and noise. The objectives for design and construction of the ATLAS were to discover the impact of the control algorithms to the adhesion as the base for further improvement not only of the brakes but of the system rail-vehicle / rail-track at all.

For this purpose the geometry, forces, brake equipment and methods to simulate environmental conditions for the roller rig ATLAS should be as close as possible to real trains and tracks. The presentation will describe the design of the test rig as well as the means for measuring and the control of the tests.

2. Methods of Testing

The methods of testing may be applied to various problems:

- Application of humidity, natural adhesion-modifying substances and temperatures to get results at the test rig, which correspond to tests at real tracks.
- Research, how the equipment of rail vehicle may get precise information about the adhesion conditions to ensure predictable stopping distances.
- Research, how the algorithms can produce a stable range of wheel slip, how this wheel slip may change the surface (cleanness and roughness) of wheel and track, and how this may ensure the required adhesion and the stopping distances.
- Test of new algorithms, which are able to compensate the variable adhesion conditions to ensure predictable stopping (or decelerating) distances without the influence of human experience of the driver (e.g. for autonomous driving).
- Test of new synthetic adhesion modifying substances, both for adhesion improvement and for wear and noise reduction.

3. Control and Measuring Equipment of the Test Rig

The formation of adhesion, wheel and rail cleaning and wrinkling is dependent on the energy caused by wear under the forces at the contact point. Therefor the test rig is designed to apply and to measure those real values. The control allows either to cause a required slip by the driving engines of the wheel and the rail, to get the information what adhesion is caused by a given slip-independent from any special brake or traction equipment. As well the test rig allows to use a given equipment, getting the results what slip it causes under all possible conditions, and to optimize its algorithm to influence the adhesion. A special task is to know the influence of the number of overruns after a singularity, application of sand e.g.

4. Results

The presentation will show examples of test results as
- different characteristics of the adhesion/slip characteristics, dependent on the type of the intermediate layer between rail and track,
- influence of the slip during braking to the cleaning and surface wrinkling,
- wear of the wheel and the track, caused by slip – showing the conflicting objectives between brake performance and material endurance.

ROLLING CONTACT FATIGUE: DAMAGE FUNCTION DEVELOPMENT FROM TWO-DISC TEST DATA

Martin Hiensch [1,2,*], Nico Burgelman [2]

[1] Delft University of Technology, section of Railway Engineering, Faculty of Civil Engineering and Geosciences, Stevinweg 1, 2628 CN Delft, The Netherlands

Abstract: The concept of the rail damage function provides vital understanding of the operational performance of rail grades in terms of surface degradation. Previously, material specific damage functions have been derived from measurements in track combined with vehicle-track simulations. However, from the occurring wide range in track loading conditions it is difficult to achieve clear characterization results from track data only.
To reach more controlled loading conditions, a rolling-sliding two-disc laboratory set up could be applied. The validation of a two-disc test approach in order to define rail/wheel interface wear and RCF response is the topic of the here proposed study.

Keywords: Rolling Contact Fatigue; wear; damage function; two-disc laboratory testing, rail grade selection.

1. Introduction

Rail damage functions describe the operational performance/ degradation of the rail running surface in dependence on the loading conditions imposed by the railway vehicle and rail grade. When damage functions are available for a wide range of rail grades, the track engineer can select the most appropriate for use at a given location, considering the loading levels and loading frequencies for that particular site.
Work has been undertaken in developing a parameter capable of describing damage development associated with RCF. Burstow [1] has found the wear energy number ($T\gamma$) to provide the best correlation between RCF damage simulation work and observed crack location in the field. $T\gamma$ is a measure of the energy dissipated within the wheel-rail contact, describing the amount of energy which would be available for initiating and propagating damage at the rail head. A material specific damage function is presented in [1], derived from track observations in combination with related vehicle-track simulations. The in [2] presented study extends this concept from conventional pearlitic rail to premium rail. From the occurring wide range in loading conditions in track (e.g. due to different vehicle types, wheel profiles, vehicle speed, traction, adhesion levels), it is difficult to achieve clear characterisation results from track data only. To obtain more controlled conditions, experimental two-disc machines are used in laboratories to investigate the wheel-rail interface, substituting the rail by one of the discs. This approach could be applied to both establish and validate the damage functions for the different materials and to understand the relationship between material properties and the RCF damage index to serve future rail grade development. The validation of the two-disc test approach in order to define rail/wheel interface wear and RCF response to $T\gamma$ loading levels is the topic of the here proposed study.
The development of a two-disc test rig for testing rolling-sliding contact under closely controlled conditions has been presented in [3,4]. It has been shown that the set-up allows the contact to be examined over a wide range of loads, speeds and slip ratios. RCF and wear behaviour of rail and wheel materials have been studied by means of two disc testing, among others in [5,6]. Initiation and growth of RCF cracks has been achieved during these tests, showing that the initiation of surface cracks to take place if the surface layer accumulates uni-directional plastic strain higher than the strain to failure. In search of improved lifetime performance many two-disc studies focus on describing the wear behaviour with regard to specific loading conditions. The aim of this study is to determine if the RCF-damage function can be derived from two-disc testing, addressing both the RCF and wear dominated regime.
Since two-disc machines often are scaled models, scaling factors of the involved physical laws need to be determined and respected in order to validly analyse the phenomena considered. Different researchers [7,8,9] have studied the effect of scaling and simulation of the wheel-roller contact instead of the wheel-rail contact. With respect to the creep forces, Jaschinsky [7] concludes shape similarity of the contact ellipse to be important when these are not saturated. $T\gamma$ is found to scale proportional to the normal force. In [10] Bosso conducts a comparison between the different scaling methods/ factors, discussing the kinematic problem for the finite radius of the roller (frictional forces and creepage). It is concluded that the contact forces and displacements in the field of contact of all methods show satisfactory results compared to the output obtained from a full-scale model.
The contact mechanics of the rail-vehicle motion is discussed in [11], presenting the development of the

theory of rolling contact. It is concluded that when traction-slip distribution inside the contact area is significant, Kalker full theory and FASTSIM calculations of the tangential forces and creepages are required to assess wear damage. Calculation of the tangential forces and creepages within the rolling-sliding contact at two-disc testing is discussed in [12], stressing the importance to prevent excessive profile wear of the two-discs since this will result in the contact pressure to lose its peak at the centre, resulting in the Hertzian theory not to be applicable anymore. With a developing 'ball-groove' conform contact the use of Kalker's FASTSIM code would lead to inaccurate results, requiring e.g. Kalker's CONTACT boundary element-based computer code.

The paper outline is the following. After the introduction in chapter one, the test rig design, scaling issues and consequent disc geometry and loading choices in test rig set-up will be discussed within chapter two. Chapter three presents the calculated equivalent Tγ levels with respect to slip ratios (longitudinal and lateral), normal load and friction levels using the FASTSIM algorithm for wheel-rail contact evaluation. The test protocol is presented in chapter four, discussing the control of the operational settings and executed measurements. Within chapter five the resulting RCF development will be presented for the different operational settings, providing the index values required to establish the RCF damage function. Evaluation of the test runs within chapter five also includes metallurgical analysis of the running surfaces, especially the micro-structure deformation levels and the development of the contact conditions. Discussion and conclusions are presented respectively within chapter six and seven.

2. Two-disc machine set-up

All tests have been conducted on the specially developed rolling-sliding two-disc machine at DEKRA Rail. Previous tests on this machine focused on the development of rail surface materials and alternative rail profiles, investigating friction characteristics and their contribution to squeal noise reduction [13]. This machine features two separately driven discs. With the here applied rotational speed in the order of 1000 to 1100 RPM, the resulting contact speed is 45 to 50 km/h.

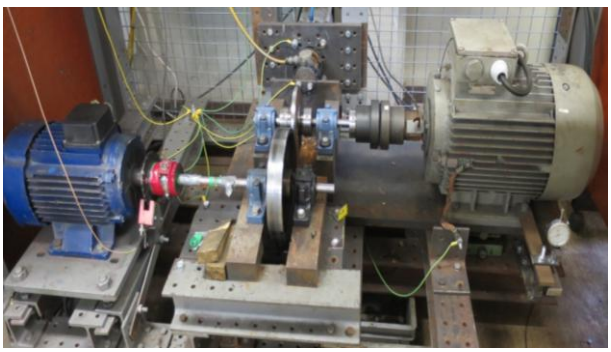

Figure 1 *Two-disc testing machine overview.*

Within figure 1 the set-up of the two-disc machine is shown. The rear (rail) disc, including bearings and engine, is mounted on a moveable support . This support is moved by a pneumatic cylinder, through a force transducer, which is in line with the disc-disc contact. Each disc is driven by a separate motor with frequency controller. At one of the driving axles the torque is measured, allowing to determine the coefficient of friction active between the two discs. Maintaining a set difference in circumferential speed between the wheel and the rail disc results in a longitudinal slip level. The wheel disc is acting as driving disc (maintaining the higher circumferential speed). Continuously measuring the rotational speed of both discs, a proportional–integral–derivative controller (PID) provides a control loop feedback mechanism to retain the desired longitudinal slip set-point.

The applied test rig configuration allows a contact angle to be set to one of the discs introducing lateral slip. Together with the longitudinal slip this simulates the dynamic conditions between wheel and rail when negotiating a curve. Lateral slip can be induced by lifting the support of the moveable disc on one side. This way, an angular difference in the planes of both discs is induced, causing a lateral slip of maximum 2%. During the here performed tests an angular rotation of 2 mrad (0.2% lateral slip) was maintained between the two discs. Initial alignment of the two discs has been carried out with help of a specialist 3-D laser measuring arm, with a specified accuracy of ± 0.013 mm.

2.1. *disc specimens*

The aim of the work is to validate the two-disc approach for RCF-damage function development. The chosen approach is to derive the RCF-damage index values for a rail grade for which the RCF damage function already has been established from field observations; the pearlitic normal rail grade R220 from [1]. For this purpose rail discs have been manufactured from a grade R220 rail (figure 2). Markings have been applied to identify the individual rail disc sections positioned in the head, web and foot of the rail.

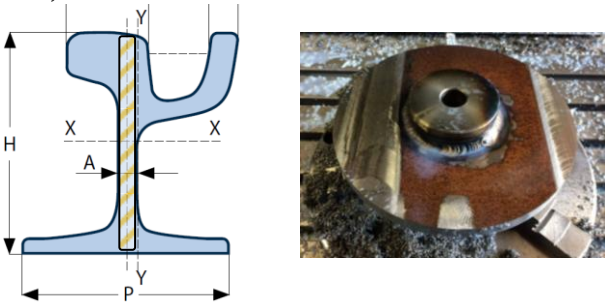

Figure 2 *Rail disc manufactured form a new UIC 59R2 profile rail.*

The rail disc diameter is 177mm, the transverse plane is curved (radius 12mm). The wheel disc is manufactured from medium-carbon steel C 45 (material nr. 1.0503). To improve the shape stability of the running surface the wheel disc has been hardened (heated to 840°C than quenched in oil). The transverse plane of the wheel disc diameter is flat. The wheel disc diameter is 240mm.

3. Contact loading

Regarding the effect of scaling and simulation of the wheel-rail contact Jaschinsky [7] concludes exact similarity of the contact ellipse to be important with respect to the creep forces when these are not saturated. The shape of the contact ellipse is defined by the contact ellipse ratio a/b with (a) representing half of the contact width and (b) half of the contact length.

The ratio of the contact ellipses as well as the normal contact stress can be determined by the Hertz theory [11]. The aim is to choose the curvature of the discs together with the normal load in such a way that during testing the resulting contact patch dimensions and normal contact stress correspond to those that occur in track. To this end a representative train-track configuration has been selected which is known to develop RCF damage (Headcheck) in track; a Dutch VIRM intercity vehicle negotiating a 1200 m radius curve. Relevant track and vehicle details are presented in [2]. The calculated contact ellipse ratio (a/b) for this track-vehicle configuration, derived from the in [2] performed train-track simulations, is 2.7 with the mean contact stress being 1050 MPa. The in chapter 2 presented disc curvatures together with disc material properties (elastic modulus and Poisson's ratio) and an applied normal load of 900N results in an a/b ratio and mean contact stress similar to the calculated vehicle-track reference situation.

The occurring friction coefficient can be calculated from the normal force (Fn), the longitudinal slip and the torque (T). If full slip occurs, the friction coefficient is equal to T / r / Fn, with r being the radius of the disc. At low (partial) slip the coefficient of friction can be calculated using the FASTSIM algorithm. This algorithm is used to derive the below figure 3, allowing the active coefficient of friction during testing to be determined from the graph.

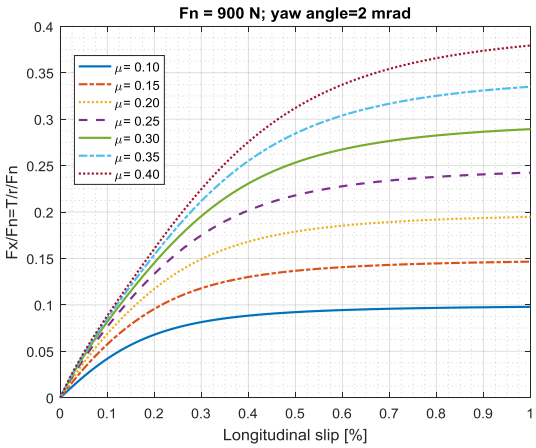

Figure 3 *Traction force relative to the normal force (Fx/Fn=T/r/Fn) as a function of longitudinal slip and friction coefficient. The graph is valid for a set angular rotation between the two discs of 2 mrad.*

Starting from the level of friction coefficient, creepages, normal load and disc curvature, the resulting value of wear index Tγ can be calculated using the FASTSIM algorithm [11] for wheel-rail contact evaluation. Since [7] concludes Tγ to scale proportional to the normal force an equivalent Tγ for a full size wheel can be calculated from the Tγ for the two disc set up (figure 4).

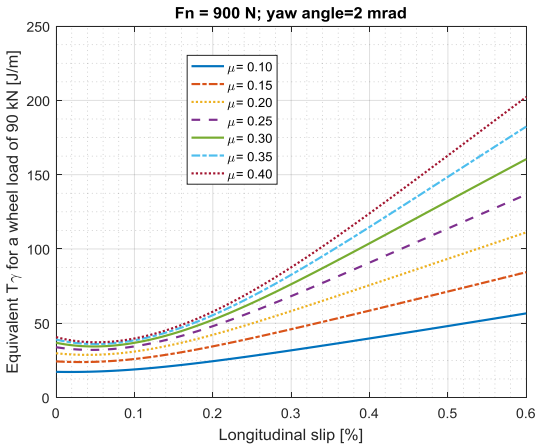

Figure 4 *Equivalent Tγ for 90 kN wheel load as a function of longitudinal slip and friction coefficient. The graph is valid for a set angular rotation between the two discs of 2 mrad.*

As explained by [6] the initiation of surface cracks takes place if the surface layer accumulates uni-directional plastic strain higher than the strain to failure. In rolling-sliding contacts, the amount of this accumulation is a function of the coefficient of friction, the maximum contact pressure and the shear yield strength of the material. Tyfour et al. also showed the initiation of fatigue cracks is connected to dry rolling-sliding test runs with relatively high levels of friction, positioning the maximum shear stress at the contact surface. Crack propagation is triggered when subsequent wet rolling-sliding test runs are applied. Due to lubrication the coefficient of friction will drop, positioning the maximum shear stress below the contact surface. At the same time fluid will be trapped within the cracks, stimulating crack propagation due to hydrostatic pressure build up and lubrication of the crack faces, both resulting in increased stresses at the crack tip. Since the purpose of the here performed study is to establish the RCF life as the number of rail-disc cycles required to initiate a fatigue crack only dry rolling-sliding tests have been performed.

4. Testing procedure

Prior to the start of each test run the contact surface roughness of both discs is measured as well as the surface cross sectional profile, after which the surfaces are cleaned using an degreasing agent. To provide initial strain hardening below the contacting surfaces a run-in period of 3000 dry cycles is applied with 1000 N of normal load and zero longitudinal slip. Subsequently longitudinal slip is applied. After the torque/ friction has stabilized the resulting coefficient of friction is determined. Based upon the measured coefficient of friction the slip percentages are set and adjusted during testing accordingly to those that the desired Tγ loading value is achieved.

Assessing RCF-life

The 'RCF damage index' expresses the number of cycles before visible RCF cracks can be expected on the

rail head. Burstow [1] suggests, for reasons of feasibility, a minimum surface length of approximately 2 mm, stating that cracks to be visible at this length must have developed beyond the initiation stage and some crack growth must have taken place. Similarly RCF life for the roller rig is defined as the number of rail disc rolling-sliding cycles required to initiate a fatigue crack of a visible length. With the 1:5 scale of the two-disc machine a crack length of 0.40 mm is applied here.

Crack detection/ metallographic analysis

During the actual test-run operation the running surface is monitored after every 20.000 rail disc cycles (approx. 15 minutes of run time). Monitoring of the running surface consists of visual inspection using a stereo microscope. Early crack detection is further supported by Eddy current measurements. During each test run the rotational speed of both discs, the normal load and torque are continuously sampled. Every 100.000 cycles measurements regarding surface roughness and cross profile are repeated. After completion of the full test, surface roughness and profiles are again measured after which the rail disc can be sectioned and prepared for metallographic analysis and hardness measurements.

5. Results and analysis

Index values with regard to the R220 RCF-damage function have been derived for two loading levels of Tγ. One selected level (Tγ=65 J/m) is positioned at the peak of the function, marking the transition from the RCF dominated region to the region of mixed RCF-Wear. From [1] the corresponding index value to this position is 100.000 cycles (figure 14). The other test loading level is chosen at Tγ=120 J/m for which [1] indicates 200.000 cycles to visible RCF damage. Test results at the two applied Tγ loading levels are summarized in Table 1 and Table 2.

Table 1 *Testing conditions and results for Tγ loading level = 65 J/m*

	Test number		
	1	2	3
Roughness (Ra) rail/ wheel.	Initial: 0.26/0.69 End: 0.34/0.35	Initial: 0.21/0.66 End: 0.32/0.32	Initial: 0.22/0.62 End: 0.38/0.32

5.1. Surface crack detection

Surface crack development has been visually determined (figure 5). Surprisingly cracks at the rail disc running surface are seen to initiate only at the rail disc running surface positioned within the former rail head. At the here tested loading levels no cracks are seen to develop within the disc circumference machined from the rail web or foot area (figure 6).

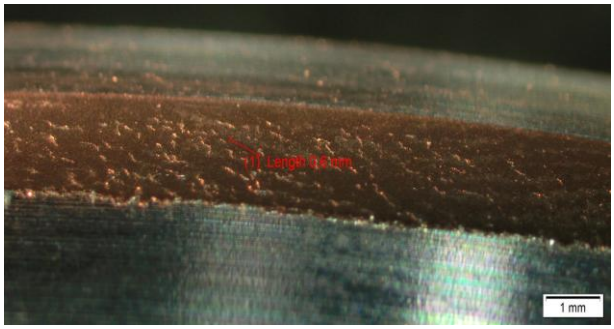

Figure 5 *Rail disc circumference positioned within the rail head area showing cracks at the running surface (load: Tγ 65 J/m, 280k cycles). This part of the circumference is further referred to as 'area H'*

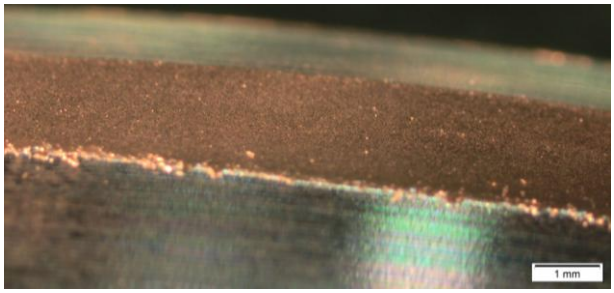

Figure 6 *Rail disc circumference positioned within the rail web area showing no cracks at the running surface (load: Tγ 65 J/m, 280k cycles). This part of the circumference is further referred to as 'area W'*

5.2. Running band development

Due to wear and plastic deformation the shape of the rail disc running band is seen to widen during testing. At the Tγ loading level of 65 J/m the running band maintains a uniform appearance over the circumference of the rail disc. However, during testing at 120 J/m a wavy pattern is seen to appear; a repetitive widening of the contact band. This wavy pattern develops evenly over the rail

disc circumference. Again cracks are only seen to appear within the rail disc circumference machined from the rail head. With the formation of this wavy pattern cracks no longer form uniformly over the running band but are seen to form in clusters, suggesting local differences in loading. These patches of cracks appear mainly in the wider parts of the running band however individual cracks are seen also at some of the narrow sections.

5.3. Metallographic analysis

From the rail disc running surface at area H (head) and area W (web) both longitudinal and lateral cross sections were prepared for metallurgical examination. The morphology of the observed surface cracks at area H is characterized as a 'flake' (figure 7). The observed damage is similar to the in [6] presented damage after only dry cycle testing. Accordingly to [6] RCF crack development is caused when a dry cycle test sequence is followed by wet rolling sliding cycles. From the rail disc transverse cross section (figure 8), the deformation at the running surface as a result from the applied lateral slip can be observed.

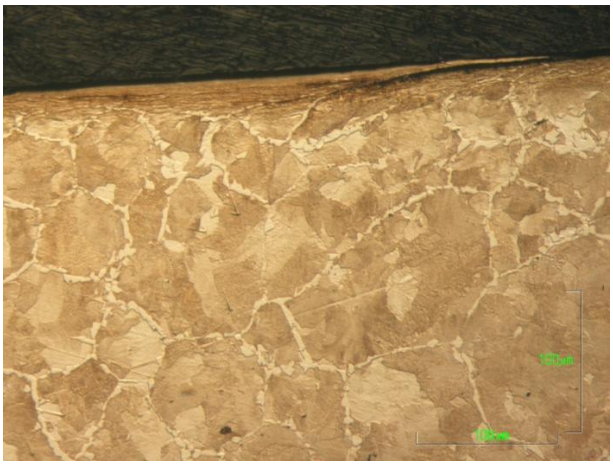

Figure 7 *Crack morphology of a flake, longitudinal cross section – area H (load: Tγ 65 J/m, 280k cycles).*

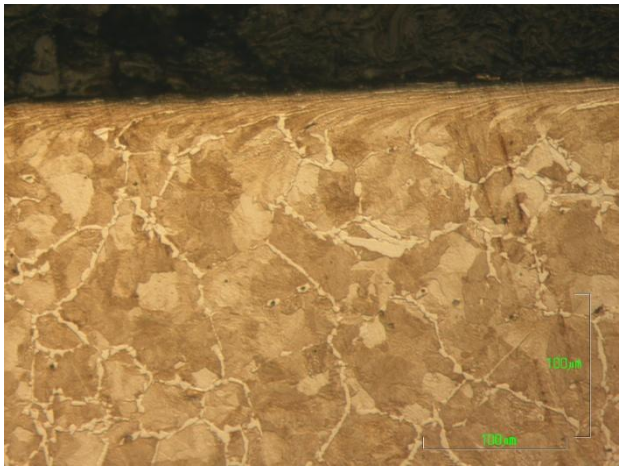

Figure 8 *Transverse cross section over the rail disc running surface, area H (load: Tγ 65 J/m, 280k cycles).*

The microstructure analysis shows clear differences between the rail disc material from the rail head (H) and rail web (W). Area H possesses a pearlitic structure with a network of ferrite positioned at the pre-austenite grain boundaries. Contrary to the microstructure of area H, the microstructure of transversal cross section of area W shows a significant higher percentage of free ferrite, displaying a dominant orientation (figure 9). This orientation is very likely to be the result of the rolling process during rail production. The observed difference in microstructure is reflected by the material hardness, measured at the non-deformed base material. The average micro hardness value at the rail web (W) is 266 HV(500g) against 300 HV(500g) at the rail head (H). From the differences in hardness and microstructure a difference in wear behaviour is to be expected. This is confirmed by the executed rail disc cross profile measurements, showing a difference in profile wear between the different circumferential sections. After 280k cycles the measured maximum vertical wear at area H is 0.7 mm against 1.2 mm at area W. The increased wear rate at area W can explain for the absence of cracks in this part of the disc circumference, shifting the damage response within this section into the fully wear dominated regime.

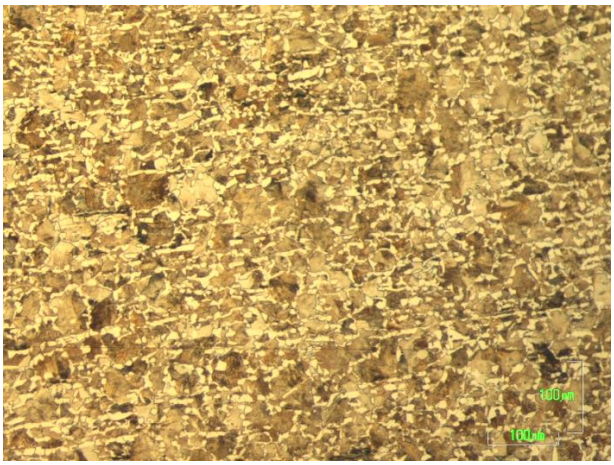

Figure 9 *Microstructure at area 'W'(transverse cross section). The rail web material shows a texture composed of pearlite (brown) and lines of free ferrite (white).*

5.4. Contact conditions

From the performed miniprof profile measurements the development of the contacting surfaces has been established. As shown in Figure 10 the rail disc profile gets flatter and asymmetric. The asymmetry is caused by plastic deformation. It has been confirmed that high part of the profile is develops in the direction of the slip. The wheel disc does not show any significant change in profile.

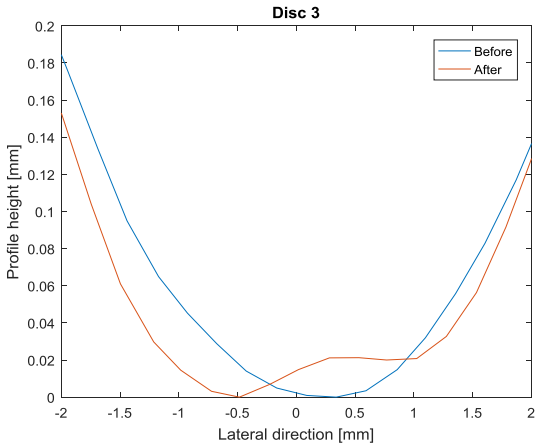

Figure 10 *The lateral profile of rail disc 3 before and after testing.*

Due to the shape of the rail disc profile, the contact pressure distribution and the Tγ cannot be evaluated using Hertz/FastSim. Therefore, Kalker full theory [11] has been applied, using our own Matlab implementation. Figures 11 and 12 show the resulting contact pressure distribution. It can be seen that the maximum contact pressure decreases during testing. However, the equivalent Tγ, as calculated using Kalker full theory, remains unaffected by the change in contact pressure distribution. Therefore figures 3 and 4 remain valid and may be used throughout the test for estimating the friction coefficient and calculating the Tγ at specified settings of the test setup.

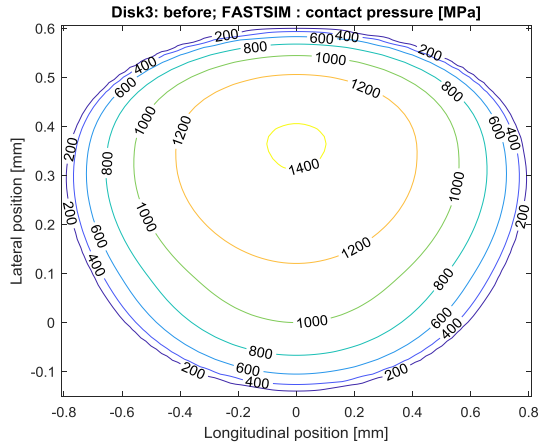

Figure 12 *Contact pressure of disc 3 before testing, as calculated using Kalker full theory.*

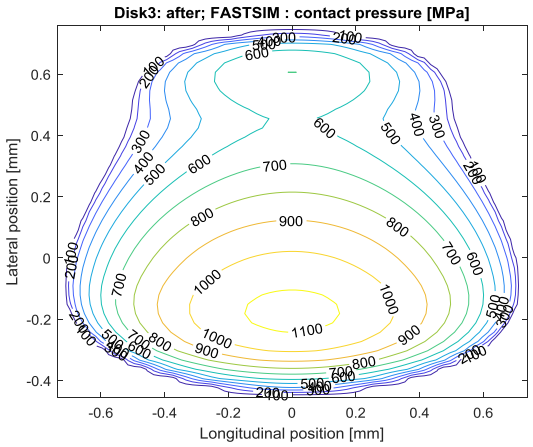

Figure 13 *Contact pressure of disc 3 after testing, as calculated using Kalker full theory.*

5.5. Validation result

Damage function indices for the different Tγ loading levels have been determined from the observed cycles to the initiation of visual surface cracks with a length of 0.40 mm. The resulting indices are presented in figure 14. The RCF damage function of the R220 rail grade as established by Burstow [1] is shown by the black line. For the examined wear numbers (65 and 120 J/m) the rail disc indices established by two-disc testing can observed to be in the same order of magnitude as that of the R220 RCF damage function.

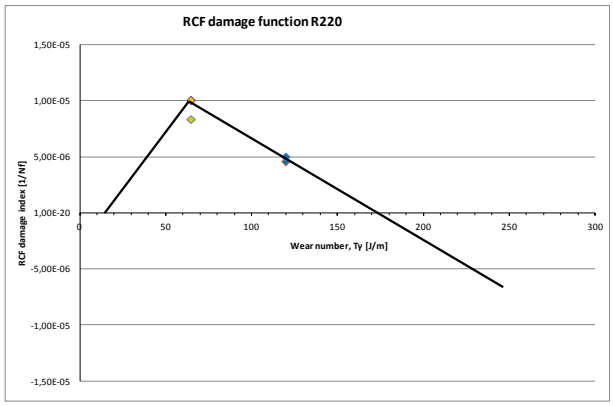

Figure14 *Damage function indices at loading levels Tγ 65 and 120 J/m established with two-disc testing, depicted within the RCF damage function of R220 as established by Burstow [1].*

6. Discussion

RCF and wear behaviour of rail and wheel materials has been studied by means of two-disc testing also in the past. Many of these earlier studies focus on describing the wear behaviour with regard to specific loading conditions, usually applying longitudinal slip only. The aim of this study is to validate a two-disc test approach supporting future description of the full range of the RCF damage function, addressing both the RCF and wear dominated regime. The applied test rig configuration allows a contact angle to be set to one of the discs thus introducing, beside longitudinal slip from the set difference in circumferential speed, also lateral slip to simulate the dynamic conditions between wheel and rail when negotiating a curve.

Regarding test rig design, scaling issues and consequent design and loading choices in the test rig set-up are important especially from the viewpoint of contact patch ratio and normal contact stresses. The curvature of the discs together with the normal load are chosen in a way that the resulting contact patch dimensions, and normal contact stress during testing correspond to those that occur at Headcheck sensitive track locations.
Equivalent Tγ levels are calculated with respect to slip ratios (longitudinal and lateral), normal load and friction levels using the FASTSIM algorithm for wheel-rail contact evaluation. Depending on the development of the coefficient of friction between the two discs and the targeted value of Tγ the set longitudinal slip is adjusted. The applied range varied from a minimum value of 0.25% to a maximum of 0.69%. For all executed tests the level of friction coefficient is seen to stabilize at around 0.2 indicating this to be independent of the here applied values of longitudinal slip. Higher values of longitudinal slip are seen to result in an increase of the resulting surface roughness. Due to wear and deformation at the running band the rail disc profile is seen to change during testing. With increasing Tγ loading level an increase in wear rate can be observed. The equivalent Tγ, as calculated using Kalker full theory, remains unaffected by the observed change in profile and corresponding contact pressure distribution.

Similar to the RCF damage model of Burstow [1] which is based on visual crack length initiation in track, the RCF life for the roller rig is defined as the number of rail disc rolling-sliding cycles required to initiate a fatigue crack of a visible length. With the 1:5 scale of the two-disc machine a crack length of 0.40 mm is applied here.
Machining the disc from a rail resulted in part of the circumference to be positioned at the initial rail head, part in the web and part in the foot to the rail. Unlike the rail disc running surface positioned within the former rail head, the disc circumference from the web area is showing no crack initiation. From the differences in microstructure and hardness between the rail head and rail web material a difference in wear resistance is to be expected. This is confirmed by the executed rail disc cross profile measurements, with web wear rate being 1.7 times that of head wear. The higher wear rate at the web section can explain for the absence of cracks in this part of the disc circumference, shifting the damage response within this section into the fully wear dominated regime.
For the examined wear numbers (65 and 120 J/m) the RCF damage function indices established by two-disc testing can be observed to be in the same order of magnitude as that of the R220 RCF damage function as established by Burstow [1]. With increased Tγ and related wear loading a wavy pattern is seen to develop at the rail disc. Further investigation is required to understand the full impact of this development regarding testing conditions.
The RCF damage functions have significant engineering relevance. Their application allows for a dedicated rail grade selection, adapted to site-specific operational conditions. They can be used either in plain track and in the design of special parts of the rail network, such as switches and crossings and can be expected to significantly affect the life-cycle costs. A validated method for a controlled quantitative determination of the RCF damage function will provide a solid base for a future optimisation of rail grade design, selection and maintenance.

7. Conclusion

RCF-damage function indices have been established using a rolling-sliding two-disc laboratory set up. The applied test rig configuration allows both longitudinal and lateral slip to be introduced into the contact, corresponding to the dynamic conditions between wheel and rail when negotiating a curve. For purpose of laboratory set-up validation, performed tests investigate the damage response of rail grade R220. For this rail grade the RCF-damage function is already available from field observations [1].
For the examined wear numbers the RCF damage function indices established by two-disc testing can be observed to be in the same order of magnitude as that of the R220 RCF damage function as established from field observations. The validation result suggest that the two-disc approach can be used to support future work to establish RCF-damage functions within a well defined laboratory environment.

8. Future work

Further validation work could aim at Tγ loading levels within the regime of full wear (Tγ> 170 J/m). The development of the running band especially during testing at higher loading levels and how this could affect the loading conditions needs to be further investigated. Two-disc testing can start to determine the RCF damage functions for a range of rail grades, from which the individual contribution towards (track) loading response and related rail grade selection can be appreciated.
The initiation of cracks/flakes during testing is seen to only occur at the rail disc running surface positioned within the former rail head , the disc circumference from the web/foot area showed no crack initiation. This difference in response to loading levels needs to be further investigated.

Abstract: In recent years, rail breakage due to transverse crack originating from the gauge corner cracks has occurred in the heat treated rails in Japan. We carried out rail bending test with artificially-processing crack in rail head to investigate transverse crack growth rate and tendency using various rails. In addition, to investigate effect of residual stress on transverse crack growth rate, some specimens were subjected to annealing treatment in order to reduce the residual stress in the rail head. We compared the test results with the estimated values using compact tension test results (conform to ASTM647), and verified the validity of the estimated values by the theoretical formula in order to estimate the transverse crack propagation in the heat treated rail accurately.

Keywords: Rolling contact fatigue; Gauge corner crack; Rail bending test; Transverse crack; Stress intensity factor.

1. Introduction

The rail is an important element of the railway track. Rail maintenance for preventing rail failures is very important for ensuring railway safety. Rolling contact fatigue (RCF) is one of the rail failures in the rail head occurring frequently by repeated train running. In recent years, rail breakage due to transverse crack originating from the gauge corner cracks has occurred in the heat treated rails in Japan. In order to maintain heat treated rails appropriately, there has been increased research on crack propagation. A lot of sophisticated crack propagation models have been proposed so far [1~3]. Generally, elemental test pieces taken from a rail head were used, the properties of transverse crack growth on a full-scale rail have not been so far elucidated enough.

Figure 1(a) shows the outline of the Squat of rail head. In the process of Squat due to the rolling contact fatigue damage to the rail head, horizontal crack growth occurs, and branches toward the bottom of the rail (herein after referred to as "Transverse crack"). On the other hand, in the head of heat treatment rail in recent years, rail breakage due to transverse crack originating from gauge corner crack has occurred. Therefore railway operators conduct periodic inspections by visual inspection, rail ultrasonic flaw detection, etc. and carry out the installation of fish plate and timely replacement of rail. However, these measures require a great deal of cost, and in order to optimize the inspection cycle and measure, it is required to research on crack propagation.

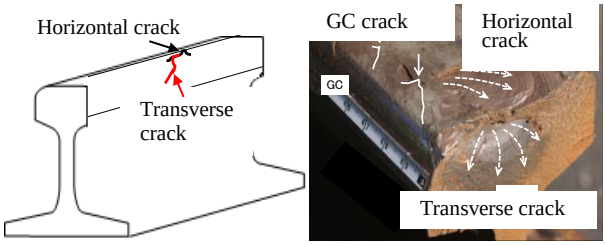

Figure 1 *The example of rail failure caused by RCF in Japan: (a) Squat (b) GC crack*

In this research, we carried out rail bending test using various rails with artificially-processing crack in the rail head to investigate the transverse crack growth rate and tendency (hereinafter referred to as Transverse crack propagation test). We compared the test results with the estimated values using a compact tension test (conform to ASTM647, hereinafter referred to as CT test), and verified the validity of the estimated values by the theoretical formula in order to estimate the transverse crack propagation in the heat treated rail accurately.

2. Compact tension test(CT test)

In order to investigate the crack propagation rate of the rail head, a CT test in which those specimens prescribed in ASTM E 647 (shown in Figure. 2) were taken from the head of a new heat treatment rail (HT320) and non-heat treatment rail (HR235, hereinafter referred to as ordinary rail) were carried out. Since it is considered that the residual stress generated at the time of the rail production influences the crack growth test result, an annealing treatment is applied to remove the influence. In addition, in order to investigate the difference in the crack propagation direction with respect to the head of the rail, two directions, that is, the horizontal and vertical direction of the rail were selected as the direction in which the specimens were sampled. Then, the specimens taken from horizontal direction are divided into two depth “shallow” and “deep” to evaluate the effect of difference of hardness. In the test, 100 kN electrohydraulic fatigue tester was used as a load type with constant load control, with a load rate of 10 Hz, and in three stages stress ratio R (minimum stress / maximum stress) of 0.01, 0.1, 0.5.

Table 1 shows the coefficient and values of the Paris rule obtained from each test result, and Figure 3 shows an example of the crack growth test result. The straight line part of the relationship between da / dN and ΔK is known

as the Paris rule which represents the rate of propagation of fatigue crack.

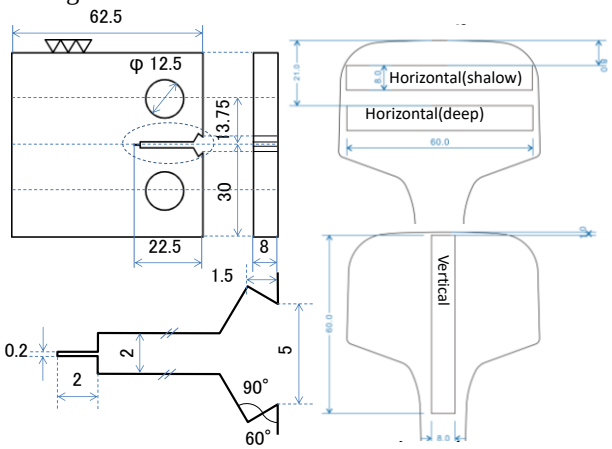

Figure 2 *Specimen for CT test (prescribed in ASTM E 647)*

Table 1 *The result of CT test*

Test piece				Material coefficient	
Rail type	Cutting direction*	depth	Stress ratio	m	C
HT320 (heat treated)	H	shallow	0.1	3.71	$4.21*10^{-13}$
	H	deep	0.1	3.8	$3.49*10^{-13}$
	V	-	0.1	3.81	$3.54*10^{-13}$
	V	-	0.5	3.17	$5.77*10^{-12}$
	H	shallow	0.5	2.94	$9.46*10^{-12}$
HR235 Non-heat treated)	V	-	0.1	3.65	$7.23*10^{-13}$
	H	shallow	0.1	3.66	$7.78*10^{-13}$
	V	-	0.01	3.64	$5.53*10^{-13}$
	H	shallow	0.5	3.26	$4.06*10^{-12}$

* H; horizontal V; vertical

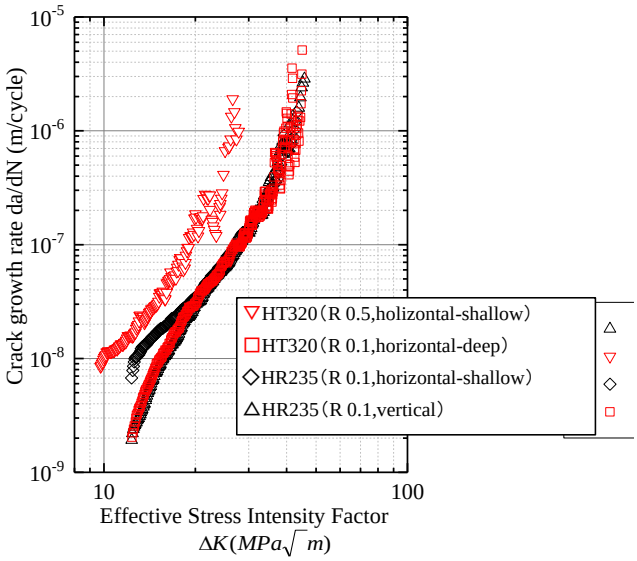

Figure 3 *The example of results of CT test*

From the results of these series of tests, it was shown that the rail steel type, depth, and the difference in the sampling direction of the test piece hardly affect the crack growth tendency. On the other hand, the crack growth rate tended to increase as the stress ratio became larger.

3. Transverse crack propagation test

In order to ascertain the difference in the rate of head crack propagation of various rails, a transverse crack propagation test of the actual rail head was carried out using a rail bending fatigue testing machine.

3.1 Outline of the test

In order to investigate the rate of propagation of transverse crack in the head, a transverse crack propagation test was performed on various actual rails. The specimens in this test are shown in Table 2. In this test, we used the annealed rail(reducing the residual stress) to evaluate effect of the residual stress and heat treated rail with eccentric artificial flaw of 10 mm assuming a gauge corner crack so on. At the rail head top of each specimen artificial scratches (semicircular slits with a radius of 5 mm) as shown in Figure 4 were processed. In order to prevent uneven deformation or plastic deformation from occurring at the tip of the artificial flaw, it was produced by electric discharge machining.

Table 2 *The specimen condition*

Rail type (50kgN JIS Rail)	Used or not	Anneal	The location of artificial crack	Stress amplitude
Ordinary (HR 235,Non-heat treated)	—	—	Centre	100 (N/mm^2)
	—	Anneal	Centre	
	Used	—	Centre	
	Used	Anneal	Centre	
HT 320((heat treated))	—	—	Centre	
	—	—	Eccentric	

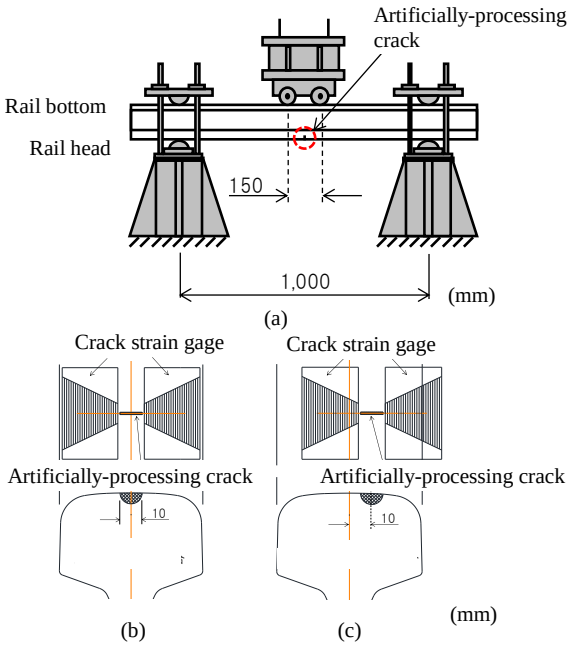

Figure 4 *The transverse crack propagation test (a) summary for the test (b) position of the crack gage in case of crack location in center (c) in case of eccentric.*

The transverse crack propagation test was carried out, using a rail bending fatigue testing machine as shown in Figure. 4, with a rail head upside down (hereinafter referred to as "head-down"), Table 3 shows the conditions of this test.

Table 3 *Transverse crack propagation test arrangements*

Item	Condition
Loading Method	4 points bending
The distance between loading point	150mm
The condition rail placement	Head down
Load direction	Vertical
Test atmosphere	Normal temperature, air
Load frequency	3Hz

The stress condition were set, in order to generate stress amplitude of 140 N/mm^2 was generated until a pre-crack reached from the artificial scratch to a propagation depth of about 5 mm (about 10 mm from the top of the head), and then loading stress was repeated after the stress amplitude was reduced to 100 N/mm^2. However, since this is a crack propagation test conducted at head-down, it is necessary to distinguish from the transverse crack propagation in this test from that in such cases as the actual track where the temperature stress and the variable stress of compression due to the train load are applied.

Two methods were applied as the method of investigating the relation between the number of cycles of loading and the transverse crack propagation rate. One is a method for investigating the boundary appearing on the fatigue fracture surface utilizing the fact that the fatigue crack propagation rate changes due to fluctuation of head whole stress amplitude (beach mark). This fluctuation is obtained by changing the load from a small one to a large one.

The other is a method for investigating the amount of crack propagation on the rail surface using a crack strain gauge attached to both sides of the artificial crack on the rail head top surface and converting it into the transverse depth. The beach mark appears on the fracture surface after repeated loads, it is possible to grasp the transverse depth by measuring the beach mark on the fracture surface. But under certain specimen and test condition, there is a possibility that no beach mark of the specimen appears, which may make it impossible to not be possible to measure. Although using the crack gauge method, we can accurately grasp the amount of crack propagation toward the surface of the rail, it is not a crack propagation amount in the rail depth direction. Therefore, in order to obtain the crack transvers propagation (depth) rate, we used both measurement methods and it is necessary to convert the value detected by the crack gauge to the transverse depth.

As shown in Figure. 5, the fatigue fracture surface generally spreads from the artificial injury to in an elliptical shape. Therefore, the crack length detected by the crack gauge was multiplied by the elliptical flattening ratio to obtain the transverse depth. The oblations was calculated by determining the elliptical shape from the coordinate point of the beach mark in the fatigue fracture surface or the boundary where the rate of progress of the fatigue crack changes. The flattening ratio is determined from the long axis and the short axis of the ellipse as shown in below.

$$f = \frac{a - b}{a} \qquad (1)$$

Where, f : flattening ratio, a : long axis, b : short axis

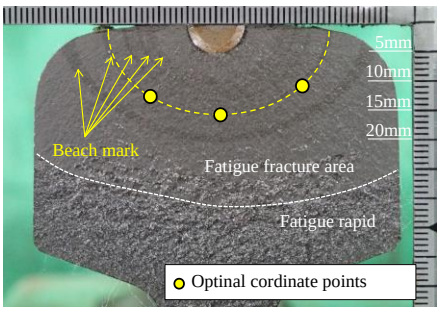

Figure 5 *The example of transverse crack propagation*

3.2 Test results

The results of the transverse crack propagation test are shown in Figure. 6, and the example of the fracture surface after the test is shown in Figure 7. In this case, the horizontal axis of Figure. 6 shows the number of loading cycle, and the vertical axis shows the transverse depth from the top surface. All specimens were broken. The test results are as follows.

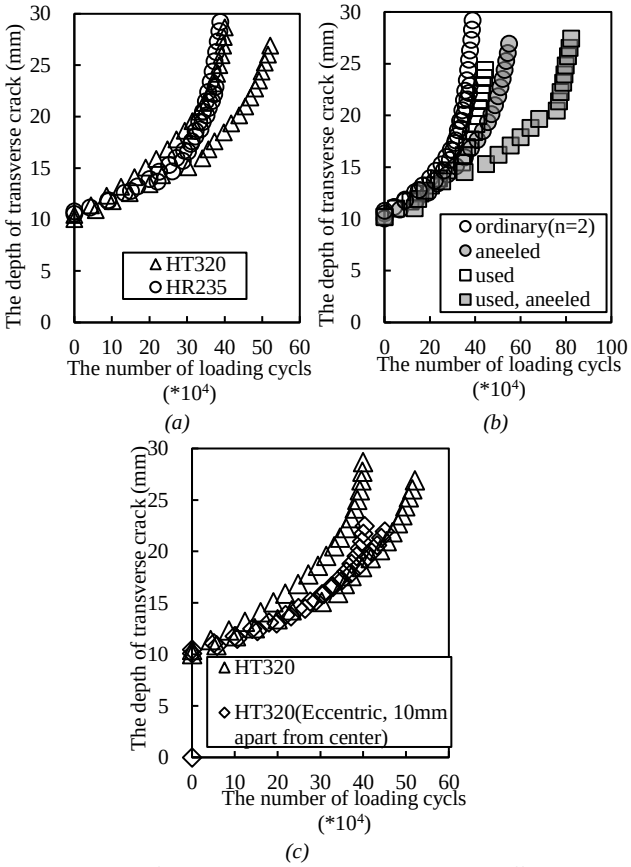

Figure 6 *Results of transverse crack propagation test, (a) Different rail type (b) Effect for residual stress (HR235) (c) Effect for crack position (HT320)*

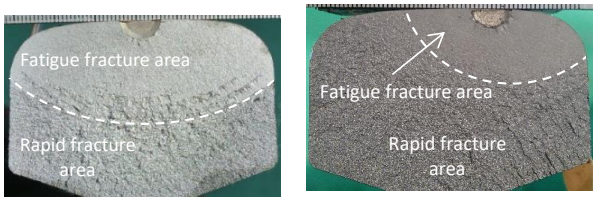

Figure 7 *Example of fracture surface after test (a) in case of the crack location in the center (b) in the eccentric*

(a) As a whole, the transverse crack propagation rate tended to increase as the transverse depth increased.
(b) Figure. 6 (a) shows the data of two ordinary rails and two heat treated rails. The crack propagation rate of one heat treatment rail is slower than that of the other three. This variation is presumed to be due to the different residual stress of the rail head of each specimen. The effect of the steel type was small compared to other factors to be described later.
(c) As shown in Figure. 6 (b), the crack propagation speed in two kinds of rails annealed for the purpose of reducing the residual stress were relatively slow compared with the non-treated products. Although the residual stress of the rail is balanced inside the rail, compression and tensile stresses are present locally, and it is thought that they affect the rate of transverse crack propagation strongly. It is known that tensile residual stress is generated at the centre position of the rail head. From this test result it is shown that the residual stress is affecting the rate of transverse crack propagation. Furthermore, in this test, there is no significant difference between new and used rail.
(d) According to Figure. 6 (c), there is no clear difference in the tendency of the transverse crack propagation rate between the case of eccentricity and that of center of the rail head regarding the position of the artificial crack. Figure. 7 shows that the fracture occurred at a shallow position in the case of eccentricity compared to in the case of center. That means when the transverse crack generated nearby gage corner, rail would be broken at shallow depth.

4. The measurements of residual stress

In order to investigate the influence of the residual stress on the transverse crack propagation rate, the rail head residual stress inside the rail was measured by the two methods of (1) Cutting method and (2) MIRS method.

4.1 Cutting method

In order to confirm the effect of annealing on the reduction of the residual stress, residual stress inside the head of the rail annealed was measured by the cutting method. Table 4 shows the results of measuring the residual stress. Here, the residual stress inside the head of the annealed rail was measured at 9 points and that on the surface of the top or side of its head at 3 points. Although the residual stress inside the rail head of the annealed specimen has largely disappeared, that on the surface has a value of about 50 N/mm^2.

4.2 Measurement of residual stress by the MIRS method

In recent years, residual stress measurement methods for inside various metals have been developed, one of which is the MIRS method. As shown in Figure. 8, a hole is made in the depth direction at the center of the rail head top surface, and the diameter of the hole is precisely measured by the air amount using a micro air probe. Next, the periphery of the hole is cut off in a cylindrical shape to release the residual stress, and finally the diameter of the hole is measured again so that residual stress is measured from the difference between the diameter of the hole before cutting and that after cutting. The measurement result is shown in Fig. As a whole, tensile residual stress was observed at a depth of 10 to 30 mm, and the average value in that range was 66N/mm^2, 72N /mm^2 for new ordinary rail and heat treated rail, respectively. In the range from the top surface to the depth of about 10 mm, the change in residual stress according to the depth is large.

4.3 Summary and consideration of residual stress measurement results

The results of the measurement of the residual stress by the cutting and the MIRS method are summarized in Table 5.

Measurement of residual stress by cutting method was also carried in past studies [4], and results similar to this measurement result in this research.

Using the residual stress measurement results, we will consider the results of the transverse crack propagation test. Regarding the transverse crack propagation test specimens, the residual stress of the annealed rail is about 0 N/mm^2 inside the head. Whereas the residual stress of the no annealed rail is about 100N/mm^2, which is clearly large residual stress compared with the annealed rails at the same depth. From this, it is judged that there is an increase in the crack growth rate due to the existence of a larger residual stress.

Figure.10 is a conceptual diagram of the effective stress intensity factor range and the stress ratio obtained from each stress generated in the head of the rail in the transverse crack propagation test. It is obvious that the crack propagation rate becomes faster when the effective stress intensity factor range ΔK and the stress ratio R are larger according to the test results (Figure 3) so far. In the transverse crack propagation test, as the vertical load acts from the state where residual stress exists, bending stress amplitude of tension is generated at the head of the rail. Since the residual stress is a positive value, the stress intensity factor due to the bending stress amplitude is the effective stress intensity factor range ΔK. ΔK is the same value on each transverse crack tests because tensile stress by vertical forth were same on their tests.

Next, the stress ratio R is defined as the minimum stress / the maximum stress. The stress condition on the head down test is as follows;

Minimum Stress: Residual Stress

Maximum Stress: Residual Stress + Bending Tensile Stress Amplitude by Vertical Load

As the tensile residual stress increases, the stress ratio also increases. It is believed that the difference in the stress ratio has a large effect on the difference in the rate of transverse crack growth between test results of annealed and non- annealed rails.

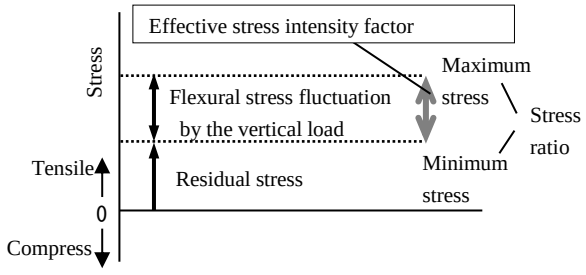

Figure 10 *Conceptual diagram of the effective stress intensity factor range and the stress ratio obtained from each stress generated in the head of the rail in the transverse crack propagation test*

5. Comparison test results with theoretical values

5.1 Stress Intensity Factor

To quantitatively verify the rate of transverse crack propagation of the rail head based on the results of the transverse crack propagation test, we compare the estimated values using the test results with theoretical equation. Estimation method based on linear fracture mechanics is used for estimation. This estimation method is to calculate the stress intensity factor from the crack shape and generated stress and substitute it into the fatigue crack growth rule. In the past study [5], it is assumed that the crack grows concentrically and the stress intensity factor is calculated using the following equation for the head transverse crack propagation.

$$K_I = \frac{2}{\pi}\sigma\sqrt{\pi a} \tag{2}$$

Where K I: stress intensity factor, σ: crack stress, a: radius of discoid crack

Since this theoretical formula is a formula in the case where the discoid crack in the infinite body is in a state of uniform tensile stress, in this article. Whereas, for a half ellipse on a rectangular cross section, Stress intensity factor was represented by the formula (3), when bending stress acted on the shape crack used [6].

$$K_I = M_k \frac{\sigma\sqrt{\pi a}}{E(k)} \qquad k^2 = 1-(a/c)^2$$

$$E(k) = \int_0^{\frac{\pi}{2}} \sqrt{1-k^2\sin\phi}\,d\phi \tag{3}$$

$$(0 < c/a < 1.0,\quad 0 \leqq c/t < 1.0,\quad 0 \leqq \varphi \leqq \pi)$$

Where, K_I: stress intensity factor, M_k: correction coefficient of elliptical crack in a rectangle, a, c: minor axis and major axis of an elliptical crack

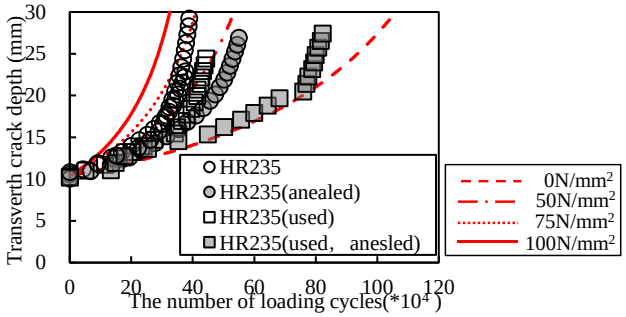
In addition, we used equation (4) by which the stress ratio proposed in the past can take into account for the fatigue crack propagation law of rail steel so that residual stress can be taken into consideration [7].

$$da/dN = C(\Delta K_{eq})^m$$

$$\Delta K_{eq} = \sqrt{\Delta K \cdot K_{max}} \tag{4}$$

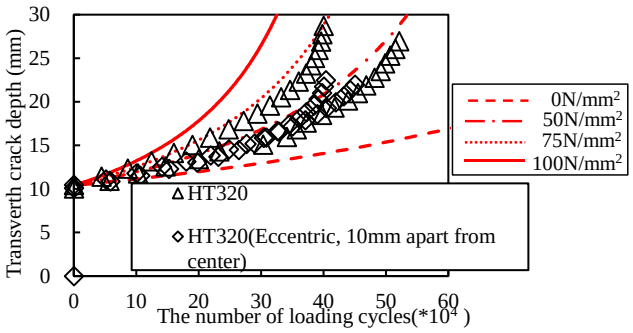
Where: ΔK: effective stress intensity factor range (MPa $\sqrt{}$m), K_{max}: stress intensity factor under the maximum stress, a: crack size (mm), N:number of cycles of stress fluctuations repetition, m, C: the material value

For the material value, m=3.65 and C=7.23×10^{-13} obtained in the CT test results were used. In this equation, K_{max} was the stress intensity factor obtained by substituting the stress plus the residual stress and the bending stress (4). Although the residual stress is originally distributed in the rail in a planar manner and its value differs from position to position, in this estimation, we assumed as the same value in whole inside rail head where the value is residual stress; 0, 50, 75 and 100N/ mm^2.



5.2 Comparison of the result

The comparison between the test result and the estimated value is shown in Figure 11.



The test results both the ordinary rail and the heat treated rail is within the estimated value calculated from the residual stress of 0 to 100N/mm^2. Regarding the test results of ordinary rails, the annealed rails were within estimated values when the residual stress was assumed to

be 0 to 50N/mm^2. According to the measurement result of residual stress, it was about 0 N/mm^2 inside the rail head and about 50 N/mm^2 of the surface, so that estimated value is good well with the tendency of the test. Other rails were within estimated values when the residual stress was assumed to be 50 to 100N/ mm^2. The test results of the heat treated rail showed almost the same tendency as the estimated value assuming residual stress be 50 or 75 N/mm^2. Considering that the tensile residual stress is generated at a depth of 10 to 30 mm and the average value of the range is 66 N / mm^2, 72 N / mm^2 for ordinary rail and heat treated rail, this estimated value is considered reasonable.

The effect of the residual stress on the rate of transverse crack propagation showed by the transverse fracture test could be verified quantitatively from the study of the estimated value by the theoretical formula. When the crack occurred, it is possible to predict the crack propagation accurately by this estimate method assumed on the rail stress generated by train running and temperature fluctuation so on.

(a)

(b)

Figure 11 *Comparison between the results of test with estimated value on the transverse crack test(a) Ordinary rail (b) Heat treated rail*

6. Conclusions

In order to ascertain the rate of transverse crack propagation in heat treatment rails, we conducted a basic head - down crack propagation test using various real rails with artificial scratches on the heads, and examined the crack propagation tendency of each rails. The results are as follows.

(1) As a result of the head - down transverse crack propagation test, there was no noticeable difference in the progress tendency and the transverse crack propagation rate between the ordinary rail and the heat treated rail. In addition, the transverse crack rate of ordinary rails annealed for the purpose of reducing the residual stress of the rail head showed a tendency to be slower than that of non - treated products. In addition, for specimens with artificial scratches eccentric by 10 mm from the center of rail head top surface on the heat treatment rail which are assumed to be cracks in the gauge corners, the crack propagation tendency and the transverse crack growth rate with the artificial crack at center position is not significant different. As a result of comparison, specimens with eccentric artificial flaws resulted in fracture at relatively shallow positions.

(2) As a result of the comparison of the test result with the value estimated using the stress intensity factor, the test results of ordinary rail and heat treated rail are within the estimated values calculated assuming residual stress 0 to 100N/mm^2.

(3) The effect of the residual stress on the rate of transverse crack propagation suggested by the transverse fracture test could be verified quantitatively from the study of the estimated value by the theoretical formula. When the crack occurred, it is possible to predict the crack propagation accurately by this estimate method assumed on the rail stress generated by train running and temperature fluctuation so on.

This transverse crack propagation test is conducted in a head down state and examined by generating a simple tensile bending stress at the head of the rail. In the actual service line, the bending stress of the compression due to the train load and the stress of the rail axial force due to the fluctuation of the rail temperature are generated. From now on, we plan to grasp the transverse crack propagation rate under test conditions closer to actual phenomena.

Abstract: A high frequency bogie hunting and low frequency carbody hunting problem of a high speed passenger car is investigated using numerical method and field tests. Comparisons of simulation and carbody acceleration test results in the time domain and frequency domain represent an important part of model validation, as this is the best possibility to assess the validity of dynamic performance of the vehicle model. The simulation results of lateral and vertical acceleration of carbody have a good agreement with the test results.
The phenomenon of bogie hunting and carbody shaking behaviour that occurs during operation of a high-speed passenger car is introduced. The characteristic of bogie hunting and carbody hunting is analyzed based the on-track test. To avoid bogie hunting and carbody hunting installing the yaw damper A and B for a high-speed bogie, two improvement measures, optimal wheelset guidance stiffness and wheel profile, are provided. The results show than the modification of wheelset guidance stiffness and wheel profile can improve vehicle stability and wheel wear performance.

Keywords: wheelset guidance stiffness; wheel profile; hunting; simulation model; high-speed rain.

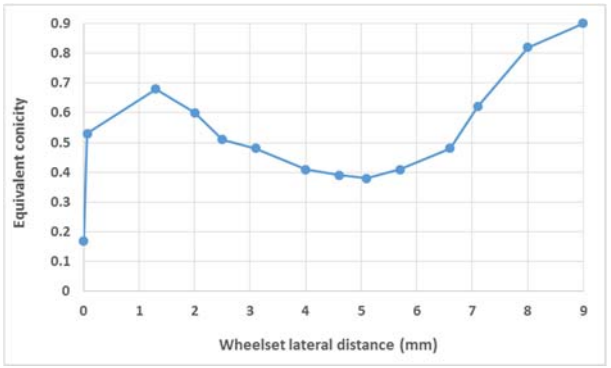
1. Introduction

With the rapid development of China's high-speed railway, the operation mileage has exceeded 22,000 km, accounting for more than 60% of the world's high-speed railway, and about 2500 units in service.

Wear phenomena due to wheel–rail interaction represent a critical aspect in railway applications; in fact the consequent evolution of rail and wheel profiles involves serious effects on both dynamical and stability characteristics of vehicles. A high level of wheelset conicity allows good curving behaviour even in the tightest curve, without flange contact. This can however, lead to a relatively low critical speed and possibly dangerous hunting instability. A low level of wheelset conicity on the other hand, allows stable operation at high speeds, but flange clearance will quickly be used up in curves, resulting in flange contact and possible flange climb derailment. Flange angle and root radius are also variables that can have a significant effect on the potential for derailment.

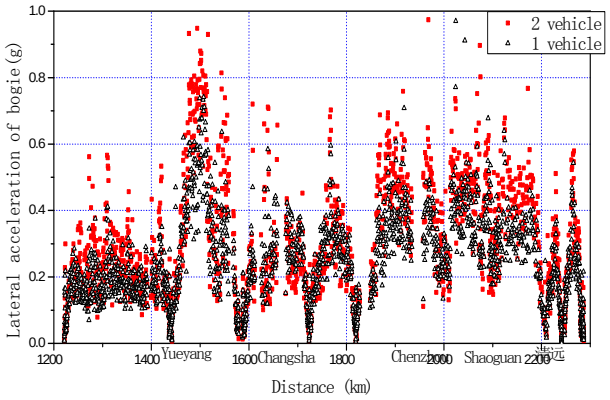
Most papers reported on hunting stability focus on bogie hunting, as the unstable bogie hunting is very common and can cause serious safety problems. Few research works have paid attention to the carbody hunting and solutions to the unstable carbody hunting problem. [2] showed that hunting motion is one of self-excited vibration by the experiments on the scaled roller rig. [3] adopted continuation-based bifurcation analysis to investigate various aspects of the nonlinearity for railway vehicles [3] used the QR algorithm to calculate the eigenvalues of the system Jacobian matrix, in the neighbourhood of which the shooting method is applied to determine the limit cycle of the non-linear vehicle system. The work of Polach [4,5] showed that the form of bifurcation, subcritical or supercritical, was mainly influenced by the nonlinearity of wheel – rail contact geometry. [6] investigated the combined influence of the longitudinal and lateral suspensions on the hunting stability, and it was shown that, carbody hunting can be suppressed if the critical speed of wheelset hunting is high compared to the speed where the kinematic frequency of the wheelset coincides with the natural frequency of the body oscillation. [7] investigated the low frequency carbody hunting of high-speed passenger car using field test results and simulation. [8] presented the bogie hunting instability based on the carbody elastic vibration of high-speed vehicles.

In order to have a perfect performance of high-speed stability, RCF and wear, engineers will have some measures, such as optimal wheel profiles or optimal bogie suspension components. [9] showed that a modified wheel profile, by reducing both normal contact stress and traction, can play a significant role in mitigating RCF. [10] optimaled wheel profile using a numerical technique which the contact angle function for known contact angles and rail profile, a corresponding wheel profile was found. [11] used a direct optimisation procedure based on a genetic algorithm for design of a wheel profile for railway vehicles.



In this paper, a high frequency bogie hunting and low frequency carbody hunting problem of a high speed passenger car is investigated using numerical method and field tests. Comparisons of simulation and carbody acceleration test results in the time domain and frequency domain represent an important part of model validation, as this is the best possibility to assess the validity of dynamic performance of the vehicle model.

The simulation results of lateral and vertical acceleration of carbody have a good agreement with the test results. The phenomenon of bogie hunting and carbody shaking behaviour that occurs during operation of a high-speed passenger car is introduced. The characteristic of bogie hunting and carbody hunting is analyzed based the on-track test. To avoid bogie hunting and carbody hunting, two improvement measures, optimal wheelset guidance stiffness and wheel profile, are provided.

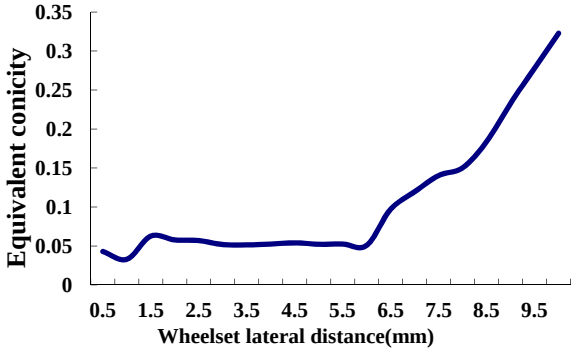


2. Measurement

With the increase of the operation, the wheel profile changes lead to higher equivalent conicity for a high-speed passenger car. In field test, the bogie lateral acceleration will be greater than 0.8g if the equivalent conicity increases more than about 0.4 for the serious wear wheel.

Figure 1 shows that the value of equivalent conicity will be greater than 0.45, when the train running is greater than about 200, 000 km. At this time, bogies will experience 5~10 Hz periodical vibration, which is what the people generally call hunting.

(a) Wheel-rail equivalent conicity



(b) Frame lateral acceleraton

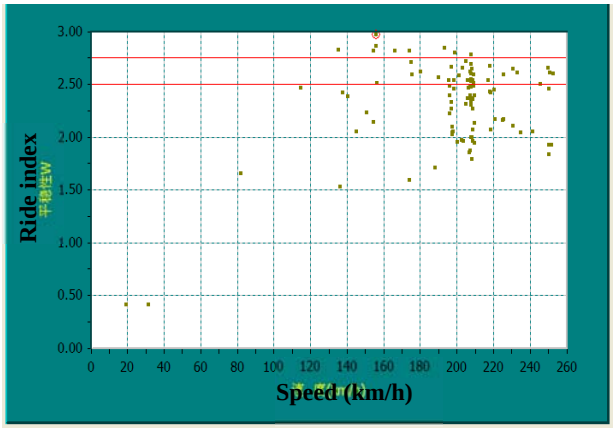


***Figure 1** Equivalent conicity and frame lateral acceleration for hunting bogie.*

For the same high-speed passenger car, there may be periodical vibrationof the carbody (hunting carbody) due to the too low equivalent conicity when the re-profiling of wheelset is just completed.

Figure 2 illustrated that the ride index will go up to 3, so the comfort of trains will have deteriorated badly, when the equivalent conicity decreases to about 0.07 after the wheel re-profiling.

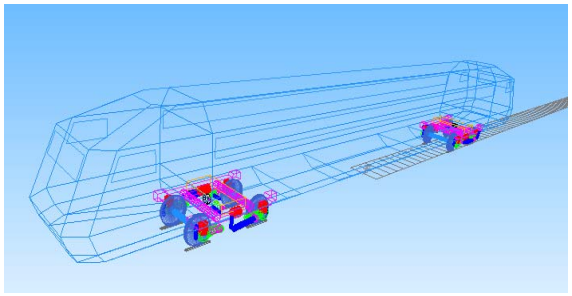
(a) Wheel-rail equivalent conicity

(b) The ride index of carbody..

***Figure 2** Equivalent conicity and ride index for hunting carbody.*

3. Model and validation

In this paper, the simulation model of high-speed passenger car is established using the Simpack multi-body dynamics software package. The vehicle model which is comprised of two bogie subsystems is modelled using a multi-body dynamics approach which fully takes into account the non-linear characters of wheel-rail contact, suspension parameters and buffer. The wheel-rail creep force is calculated by the Kalker nonlinear creep theory.



The simulation model of vehicle dynamics is composed of one car body, two bogie frames, four wheelsets and eight axleboxes. The car body, frames, and wheelsets have 6 degrees of freedom, namely the longitudinal, horizontal, vertical, rolling, nodding, pitching, yawing (the vertical and rolling of wheelset is independence movement), and the axlebox have 1 degrees of freedom, namely pitching. The model has a total of 50 degrees of freedom. As shown in table 1.

Table 1. Degrees of freedom vehicle model.

Freedom	Longitudinal	Lateral	Vertical	Rolling	Nodding	Yawing
Carbody	X_c	Y_c	Z_c	Φ_c	θ_c	ψ_c
Bogie frame	$X_{b1\sim2}$	$Y_{b1\sim2}$	$Z_{b1\sim2}$	$\Phi_{b1\sim2}$	$\theta_{b1\sim2}$	$\psi_{b1\sim2}$
Wheelset	$X_{w1\sim2}$	$Y_{w1\sim2}$	$Z^*_{w1\sim2}$	$\Phi^*_{w1\sim2}$	$\theta_{w1\sim2}$	$\Psi_{w1\sim2}$

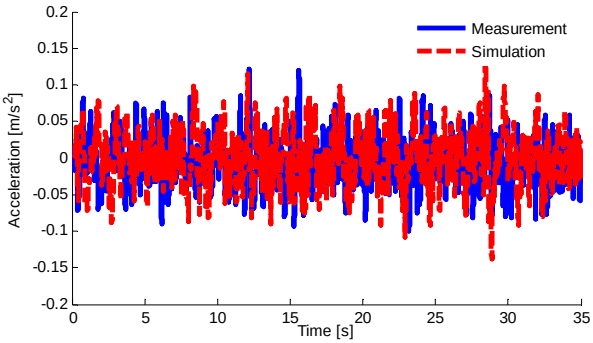
(a). A high-speed passenger car



(b). Vehicle dynamic model

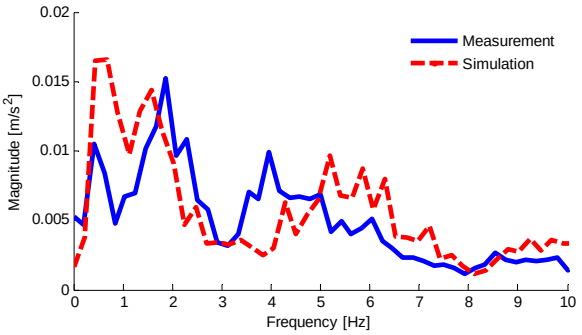


Figure 3 *Vehicle simulation model.*

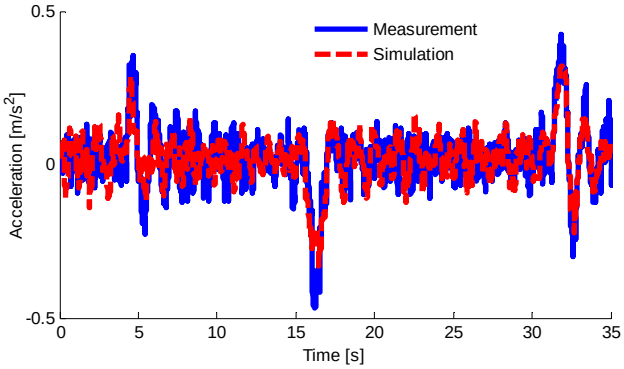
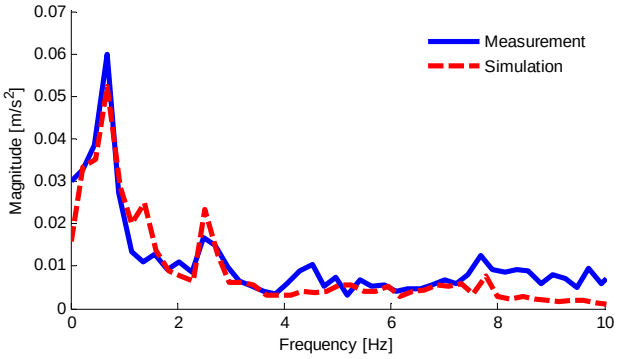
The acceleration of carbody and track geometry irregularities are measured using the sensors based a high-speed comprehensive test train on a representative line and the speed is 300 km/h. The rail profiles are measured using MINIPROF. The measured results of wheel-rail forces, rail profile and track irregularities that have been undertaken to validate the dynamic simulation model of the vehicle.

Comparisons of simulation and carbody acceleration test results in the time domain and frequency domain represent an important part of model validation, as this is the best possibility to assess the validity of dynamic performance of the vehicle model.



(a) Time domain



(b) Frequency domain

Figure 4 *Simulation-measurement comparisons of lateral acceleration of carbody.*

(a) Time domain

(b) Frequency domain

Figure 5 *Simulation-measurement comparisons of vertical acceleration of carbody.*

Results show that the simulation results agree very well with field test in time-domain and frequency-domain, so the simulation model can be used to compute the dynamics of trains such as critical speed, ride index and wear index.

4. Preliminary results

This bogie of high-speed passenger car has 2 types of yaw damper, yaw damper A and B. There are differences in the damping characteristics of the two types of yaw damper.

The yaw damper A is more prone to hunting carbody, but the yaw damper B is more prone to hunting bogie.

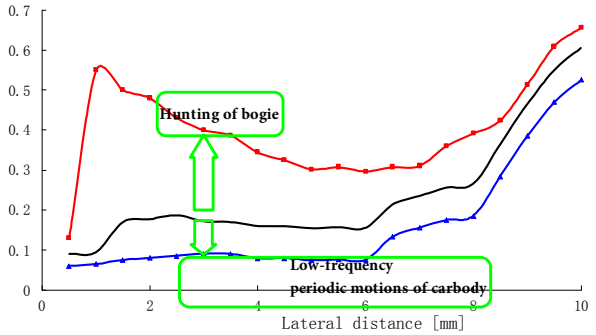


Figure 6 *Variation range of equivalent conicity.*

In order to resolve the stability of high-speed passenger car under higher equivalent conicity and lower equivalent conicity for the yaw damper A and B, the critical speed are analysed for various wheelset guidance stiffness.

4.1. Yaw damper A

For a low equivalent conicity, the critical speed of the vehicle decreases as the guidance stiffness increases, and for a high equivalent taper tread, the critical speed of the vehicle increases and then decreases as the guidance stiffness increases.

A series of wheelset guidance stiffness in the range of 20MN/m to 40MN/m, which can guarantee excellent stability for the high equivalent conicity and the low equivalent conicity.

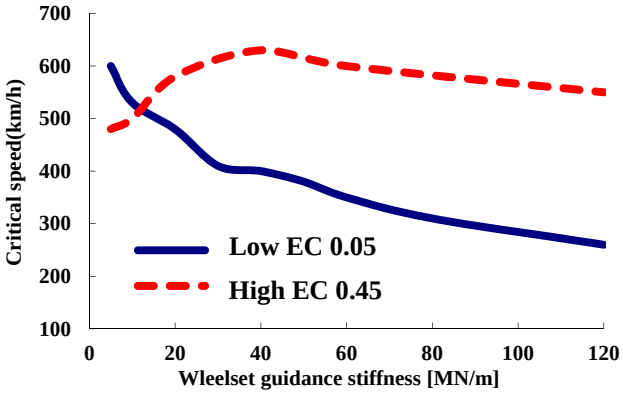

Figure 7 *The wheelset guidance stiffness and equivalent conicity effecting in critical speed for yaw damper A.*

Figure 8 shows that the wear index sharply increases as the radius of the curve decreases. Although the speed on the 400m radius curve is only 88 km/h, its wear power of wheel is several ten times larger than the large curve. Generally, wheel edge wear occurs on the sharp curves. wear index on the curve is significantly reduced as the wheelset guidance stiffness is reduced.

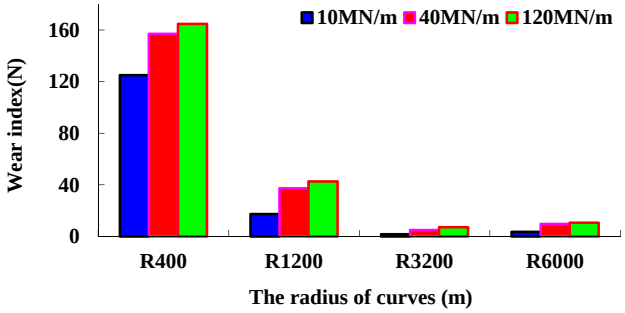

Figure.8 *Effect of wheelset guidance stiffness on wear index for different curves.*

Considering comprehensively, when applying the yaw damper A, it is recommended to reduce the guidance stiffness to about 20 MN/m, which can not only solve the problem of hunting bogie, but also improve the low-frequency periodical vibration of the carbody on large curves. This measure will reduce the wheel wear, extend the service life of the wheel, and improve the comfort of the high-speed passenger car.

4.2. Yaw damper B

The change rule of critical speed is similar for low and high equivalent conicity : the critical speed will increase with the decreases of wheelset guidance stiffness, but the critical speed began to decrease when the wheelset guidance stiffness reaches 10 MN/m. Therefore, it can be considered that the wheelset guidance stiffness is reduced to 20MN/m, so that it has higher stability for the lower and higher equivalent conicity.

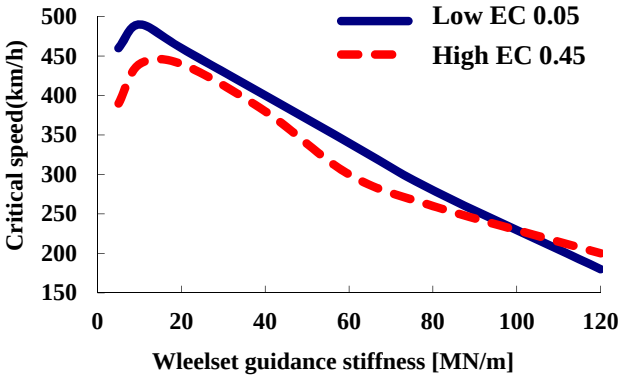

Figure 9 *The wheelset guidance stiffness and equivalent conicity effecting in critical speed for yaw damper B.*

The change rule of critical speed is similar for low and high equivalent conicity : the critical speed will increase with the decreases of wheelset guidance stiffness, but the critical speed bes reaches 10 MN/m. Therefore, it can be considered that the wheelset guidance stiffness is reduced to 20MN/m, so that it has higher stability for the lower and higher equivalent conicity.

The wheel profile A and B were choosed to optimize wheelset guidance stiffness for perfect dynamics of high-speed passenger car. The Fig.10 shown than the nominal equivalent conicity of profile B is 0.09 and the nominal equivalent conicity of profile A is 0.05.

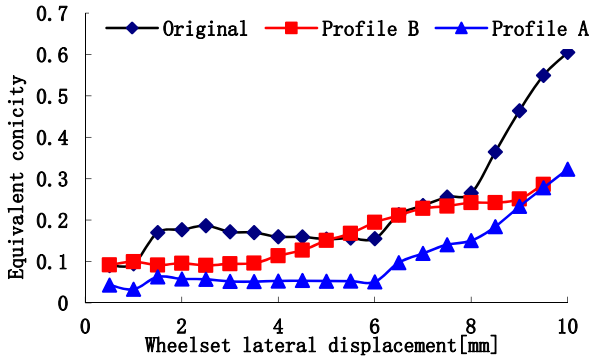

Figure.10 *Equivalent conicity for various wheel profile.*

The ride index of original profile and A wheel profile are large, therefore the stability and comfort is poor. The stability and comfort of profile B is relatively superior when the wheelset guidance stiffness is 20 MN/m, because the ride index is the smallest.

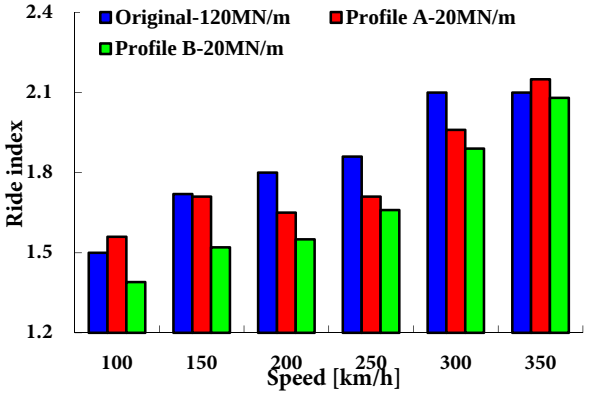

Figure.11 *Effect of speed on ride index for various wheel profile.*

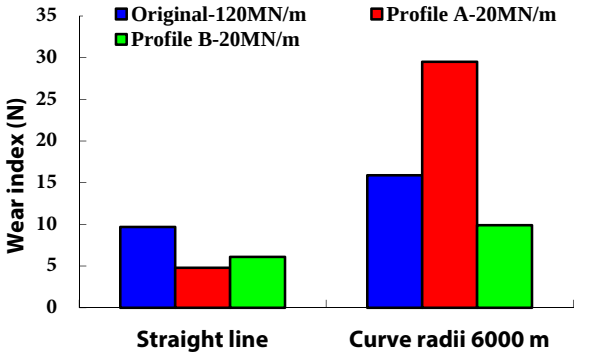

Figure.12 *Effect of wheel profile on wear index for different lines.*

On the straight line, the wear index of profile A is the minimum, about 5 N, and the wear index of original profile is the largest, about 10 N. On the curve radii 6000m, the wear index of profile A increases sharply, about 30 N, and the wear index of profile B is the minimum, about 10 N. The wear index of profile B is about 40% less than original profile, which is about 66% less than profile A. As the equivalent conicity of the profile A is very small, it lead to the poor curving performance and the high wheel-rail wear, generally, low-frequency periodic motions of carbody can be triggered easily.

For this bogie of high-speed passenger car, if it uses a wheel profile with an equivalent conicity that is similar to the wheel profile B (that is, the equivalent conicity is about 0.1), and reduces the wheelset guidance stiffness to 20 MN/m, the wheel wear will be greatly reduced and the lateral stability will be significantly improved.

5. Conclusions

In order to propose technical measures to improve the performance of a high-speed passenger car, especially for the hunting bogie and hunting carbody, the dynamic simulation model of a high-speed passenger car was established. For the yaw damper A and B used in this high-speed bogie, the wheelset guidance stiffness is optimized to improve vehicle stability and wheel wear performance.

The results are as follows.

(1) The simulation model of high-speed passenger car was established using the Simpack multi-body dynamics software package. In order to verify the accuracy of the simulation model, the carbody vibration acceleration of simulation were compared with results in field test in time domain and frequency domain respectively. It is found that the calculation results are basically consistent with the test results, so the model can reflect the basic dynamic characteristics of the vehicle.

(2) Comprehensively, when the yaw damper A is applied for this bogie, it is recommended to reduce the guidance stiffness to about 20 MN/m, which can not only solve the problem of hunting bogie, but also improve the low-frequency periodical vibration of the carbody on large curves.

(3) When the yaw damper B is applied for this bogie, and we changes the wheelset guidance stiffness from 120 MN/m to 20 MN/N, meanwhile choose the profile B, the critical speed and ride comfort will be significantly improved and the wheel-rail wear will be reduced by about 40%.

(4) These measures will reduce the wheel wear, extend the service life of the wheel, and improve the comfort of the high-speed passenger car.

A STUDY OF THE RAIL WEAR ON SHARP CURVES IN EMU MAINTENANCE DEPOT

Huafeng HU [1], Maorui HOU [2], Zhongwei FENG [2], Xing FANG

[1] China Railway Corporation, P.R.China
[2] *China Academy of Railway Sciences, P.R.China；*

[*] E-mail: houmaorui@126.com

Abstract: In order to analyze the effects of curve radius, gauge widening and wheel-rail friction coefficient on rail wear, a rail wear test was carried out for two curves. In order to propose technical measures to reduce rail wear, the dynamic simulation model of high-speed passenger car was established. This paper investigated the parameters, such as curve radius, gauge widening and friction coefficient, that affect rail wear on sharp curves. Results show that rail gauge corner wear on sharp curves is serious and uneven. Increasing the radius and gauge widening of the sharp curve will reduce the rail gauge corner wear. Rail lubrication can reduce rail gauge corner wear by about 40%~70%, and improve the service life of the rail on the sharp curves.

Keywords: EMU maintenance depot; Sharp curves; Rail wear; Wear index.

1. Introduction

Wear of rails leads to problems including a widening of the track gauge, loss of rail profile leading to high rail-wheel forces and poor dynamics. The outer rail in sharp curves can wear excessively since this is supplying cornering forces.

It needs to build the maintenance depot or parking lot to carry out the daily maintenance for EMU. The EMU maintenance depots usually have more sharp curves due to the large size and the location is limited by the terrain conditions. The curve of radius equals to or less than 300m almost exists in the every depot.

The gauge corner wear especially for the sharp curves became the decisive factor for the service life. Meanwhile, the rim wear of a wheel also was aggravated, and the re-profile was increased. Therefore, it's a great significance to reduce the gauge corner wear on the sharp curve, which will extend the service life of the rail, reduce the maintenance cost, and ensure the safety of driving.

D. Eadie carried out a wheel-rail friction coefficient adjustment test on a rolling test bench. The non-lubricated steel rails had serious wear on the specified surface and rapid development of fatigue cracks. After lubrication, the rail wear was reduced by approximately two times compared with unlubricated [1]. In the Shinkansen of Japan, two curves with a radius of 400 m and a radius of 900 m were selected to carry out a two-year rail abrasion field test to analyze the changes in the lateral force, the angle of attack and the deformation of the rails after rail grinding [2]. SUN Guoying analyzed the influence of rail slope, rail gauge, ultra-high maintenance and other factors on the rail side grinding, and proposed preventive measures to reduce rail side wear.

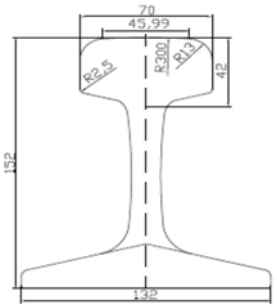
2. Measurement

The rail wear of two curves radii 280m was measured for a more than one year in an EMU maintenance depot.
As it is shown in Tab.1, the type of rail is TB 50, the cant is 15mm, the gauge widening of Line A is 5mm, but the gauge widening of Line B is 15mm. The traffics are more or less at same between the two curves.

The photos of measuring point and rail wear are shown in Figure.2.

Table 1 *Important parameters of curves.*

Name	Rail type (kg·m-1)	Radius (m)	Length (m)	Gauge widening (mm)	Cant (mm)
Line A	50	280	905	5	15
Line B	50	280	921	15	15



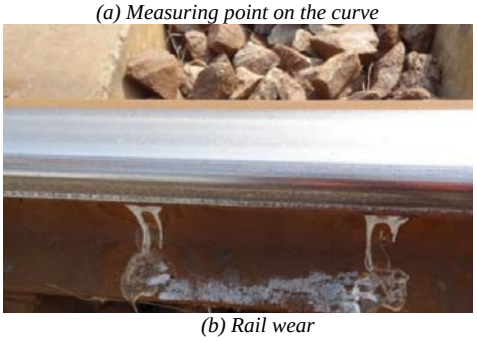


Figure 1 *The rail profile of track TB50.*

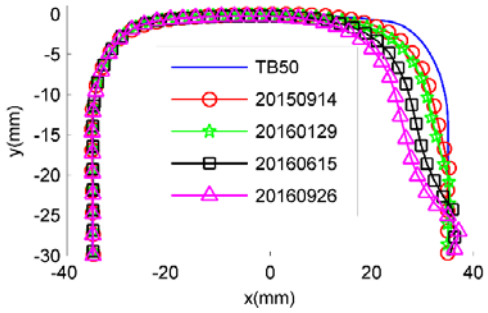
Figure 1 shows the the top part of track TB50 is mainly composed of 3 segments of arc and the top of the rail is a radius of 300 mm.

(a) Measuring point on the curve



(b) Rail wear

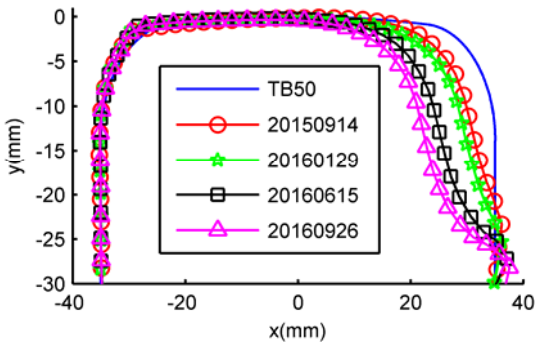


Figure 2 *Photos of the sharp curve.*

Table 2 lists the gauge corner wear of line A and other information such as time, MGT.

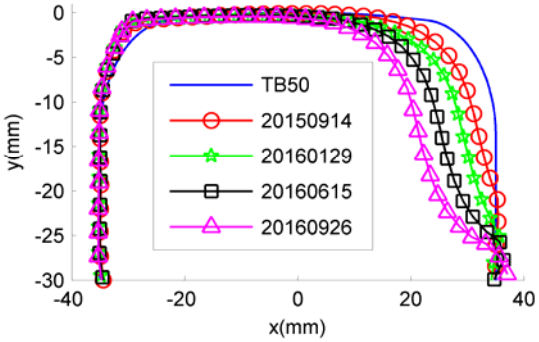

Fig.3 shows that the maximum gauge corner wear is about 12.69mm on the point 3, the minimum gauge corner wear of point 1 is about 8.05mm. Due to the uneven curvature, the gauge corner wear between the three measuring points is quite different: the gauge corner wear in the middle curve is relatively small, the gauge corner wear at the end of the curve is the largest.

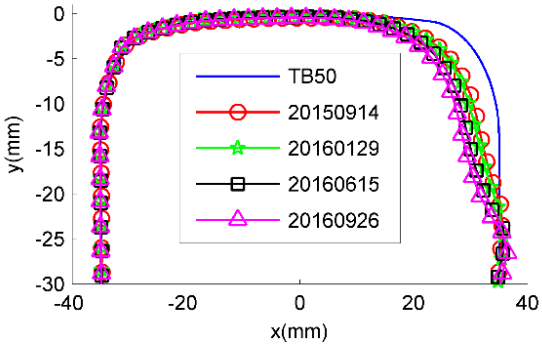
5	20160926	12.69	1.53	8.30

Table.3 *The ratio of gauge corner wear of measuring point 3 on line B*

Number	Time	Gauge corner wear /mm	Ratio of gauge corner wear /mm /Mt	MGT /Mt
1	20150615	—	—	New rail
2	20150914	2.32	0.47	4.95
3	20160129	3.00	0.47	6.44
4	20160615	4.60	0.58	7.92
5	20160926	5.53	0.61	9.03



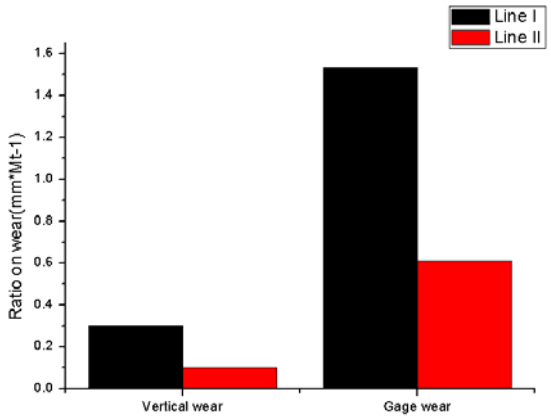


Figure 4 *Measuring point 3 on the line B.*

(c) Ratio wear

Figure 5 *Comparison of the gauge corner wear between line A and line B.*

Figure 5 shows that the maximum gauge corner wear of line A is about 12.69mm, the maximum gauge corner wear of line B is about 5.53mm, and the vertical wear are light. For the curve line A, the gauge corner wear ratio of the line B is less than 60%.

3. Analysis method

3.1. Vehicle dynamic model

In this paper, the rail wear simulations of a passenger train on sharp curves are conducted using the UM multi-body dynamics software package. The vehicle model which is comprised of two bogie subsystems is modeled using a multi-body dynamics approaches which fully takes into account the non-linear characters of wheel-rail contact, suspension parameters and buffer.

The wheel-rail contact force is measured using the instrumented wheelset based a high-speed train on a curve with the radius of 300m. The rail profiles are measured using MINIPROF and track geometry irregularities are measured using instrument. The measured results of wheel-rail forces, rail profile and track irregularities that have been undertaken to validate the dynamic simulation model of the vehicle.

(a) Track geometry irregularities measurement

(b) Rail profile measurement

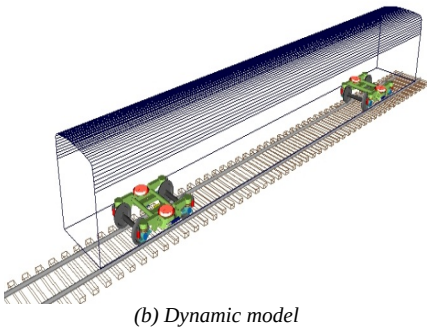

Figure 6 *Track geometry irregularities, rail profile measurement.*

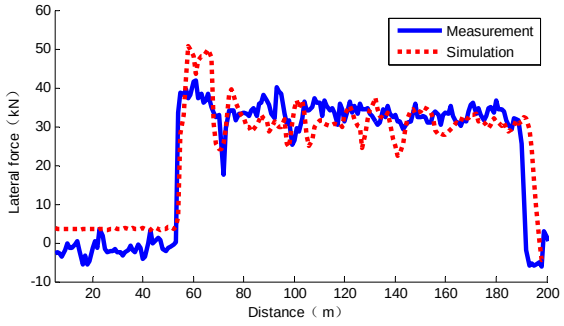
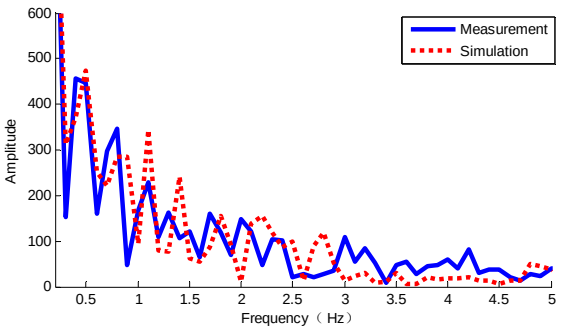
The vehicle dynamics model using primary and secondary suspension, and considering the nonlinear characteristics of wheel-rail contact, lateral stop, damper and yaw damper are established by Multi-body dynamic software. The wheel-rail creep force is calculated by the Kalker nonlinear creep theory.

The simulation model of vehicle dynamics is composed of one-car body, two bogie frames, four wheelsets and eight axleboxes. The car body, frames, and wheelsets have 6 degrees of freedom, namely the longitudinal, horizontal, vertical, rolling, nodding, pitching, yawing (the vertical and rolling of wheelset is independence movement), and the axlebox have 1 degree of freedom, namely pitching. The model has a total of 50 degrees of freedom.



(a) High-speed train



(b) Dynamic model

Figure 7 *Vehicle simulation model.*

(a) Time domain

(b) Frequency domain

Figure 8 *Simulation-measurement comparisons of lateral wheel-rail force.*

Results show that the simulation results agree well with field test in time-domain and frequency-domain, so the simulation model can be used to output wheel-rail force, attack angle and wear index.

3.2. Wear index and wear modelling

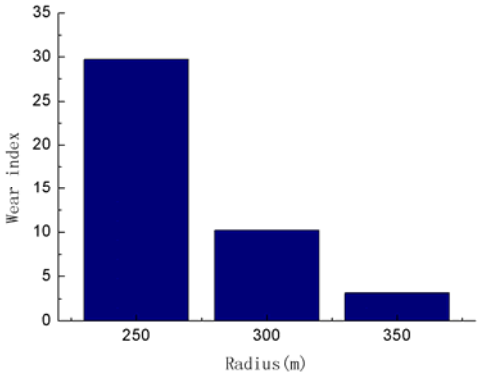
Rail wear depends on the location of the point of contact between wheel and rail which will influence the degree of sliding on the contact. Large differences in contact position can be seen between different fleets of vehicles due to differences in suspension characteristics, but also between different wheels on the same vehicle.

The detailed analysis of contact phenomena occurring at wheel-rail interface is a key ingredient in view of understanding and modelling wear. The wear index (WI) developed to date for predicting wear of rails/wheels have about ten wear indexes such as Elkins index, Vogel index, Heumann index and so on.

Because this paper studies the influence of the friction coefficient of the wheel-rail on the gauge corner wear, the friction coefficient is not constant. Therefore, the Heumann wear index before the simplified Vogel index was used to evaluate the severity of the gauge corner wear.

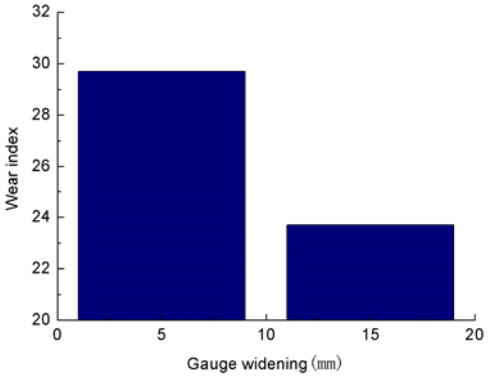
$$WI = \mu * F * \alpha$$

Where: μ is the coefficient of friction, F is the flange force and α is the angle of attack.



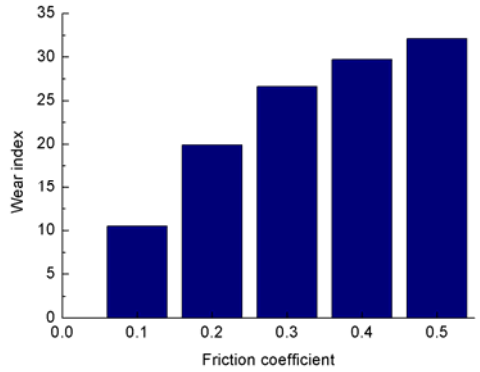
4. Preliminary results

This part investigated the parameters, such as curve radius, gauge widening and friction coefficient, that affect rail wear on sharp curves. The ‘wear index’ is the averaged value from the simulation results.



Results show that the wear index of radius 300m is less than about 65% for radius 250m, and the wear index of radius 350m is less than about 70% for radius 300m. The increase of the radius of the curve has a significant effect on reducing the gauge corner wear. When designing the EMU maintenance depot, the radius of the curve should be increased as much as possible under the conditions of the site conditions.

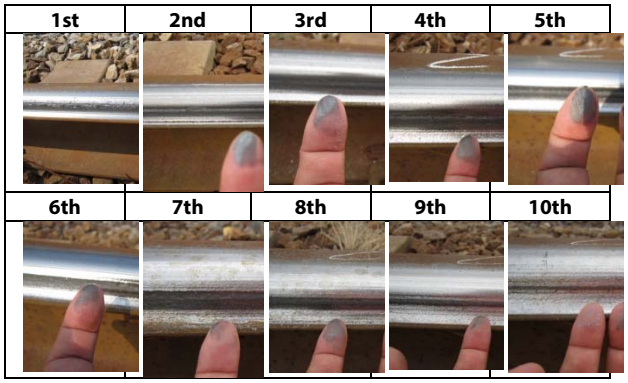
For the gauge widening 5mm, the wear index is 29.7, which has increased by about 20% compared to the gauge widening 15mm. Due to the low running speed of the EMU and the absence of passengers, a larger gauge width will help reduce the flange force and reduce the gauge corner wear for the sharp curve in EMU maintenance depot.



Commonly, the friction coefficient on the rail corner ranges from 0.1 to 0.5 due to the rail lubrication. The wear index of friction 0.1is 10.5, which has decreased by about 50% compared to the friction coefficient 0.2. It can be seen that if the rail corner lubrication measures are adopted, the coefficient of wheel-rail friction is reduced from 0.5 to 0.1 to 0.2, the rail gauge corner wear will be reduced by about 70% to 40%.

(a
(a). Curve radius

(b) Gauge widening



(c) Friction coefficient

***Figure 9** The effects of curve radius, gauge widening, and friction coefficient on wear index.*

In order to verify the effect of wheel-rail lubrication, a 300m radius curve was selected for verification test. After the rails are lubricated on the rail corner, the gauge corner wear is tested daily and tested continuously for 10 days. The lubrication test illustrated that the rail wear will reduced by about 50% when the lubricating oil is sprayed in 7 days.

Table 3 The field test of rail lubrication.

5. Conclusions

In order to analyze the effects of curve radius, gauge widening and wheel-rail friction coefficient on rail wear, a rail wear test was carried out for two curves. In order to propose technical measures to reduce rail wear, the dynamic simulation model of High-speed train was established. The results are as follows.

(1) When designing the EMU maintenance depot, the radius of the curve should be increased as much as possible under the conditions of the site conditions.

(2) The rail gauge corner wear can be reduced with a proper increase of the track gauge as the train is generally empty and running at a low speed in EMU depot. It is recommended to set the gauge to 15 mm for the curve of radius 250 m as a larger gauge width will help reduce the flange force and reduce the gauge corner wear.

(3) If the measures of rail lubrication are taken to reduce the wheel-rail friction coefficient, rail gauge corner wear will reduce about 70% ~ 40%, and significantly reduce the wheel flange wear, improve the rail service life of the sharp curves.

Abstract: In this paper, the influence of the high-order wheel polygon on a certain type high speed EMU vehicle dynamic performance is studied. A rigid-flexible body coupled multi-body dynamics model for studying is established by using SIMPACK and ANSYS software. The simulation results show that the high-order wheel polygon will all bring about the vertical vibration acceleration increase of the wheelset, bogie frame and car body at different speed levels and the maximum vertical vibration acceleration of the wheelset can increase about 5 times due to the influence of wheel polygon at 200 km/h. Due to the damping effect of the primary and secondary suspension, the influence of the wheel polygon on the vibration acceleration of bogie frame and car body is smaller than the wheelset. The wheel polygon has an important influence on the wheel-rail vertical force, which can result in the significant fluctuation of the wheel-rail force. Especially when the vehicle speed reaches 250 km/h, the minimum wheel-rail force can reduce by 57%. The high-order wheel polygon which typically existed in some a certain type high speed EMU has little effect on ride comfort. Severe wheel polygon can probably cause running safety problem for a certain type high speed EMU at the speed of more than 250 km/h.

Keywords: high speed vehicle; high-order wheel polygon; rigid-flexible body coupling model; dynamic performance.

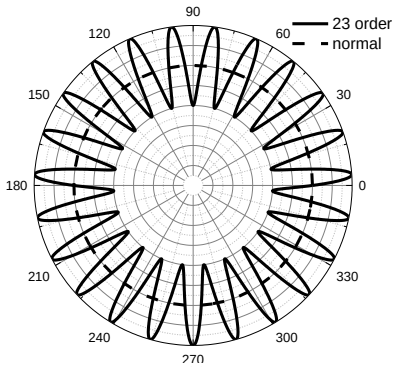
1. Introduction

With the rapid development of urban rail transit, the problem of wheel harmonic wear becomes more and more prominent. The wheel harmonic wear is also called the wheel polygon wear, which refers to the uneven wear of the wheel in the nominal rolling direction of the railway vehicle. Wheel polygon will cause a strong impact between wheel and rail, severe vehicle and track vibration. Vehicle and track components will probably be damaged by the results of impact of wheel and rail, then it will seriously affect traffic safety, deteriorate operation quality and produce wheel/rail noise and passenger discomfort[1-2].

J. Kalousek and L. Johnson[3] confirmed the wheel polygon by studying the wheel wear of Canadian passenger trains and demonstrated that wheel non-circular wear could be reduced and the formation of rail corrugation could be alleviated by reducing the misalignment of the wheelsets. JC. O. Nielsen and Johansson[4] described the latest research progress of wheel non-roundness in 2000, classifying wheel non-roundness into: wheel flats, local depression, spalling, shelling, wheel polygon and other forms. Through considering the wheel-rail contact as elastic, Kaiser and Popp[5] showed that the major vibration frequency range in which the wheel polygon had some influence on high-speed trains major was 50-500Hz, and believed that the change of wheel-rail contact relationship caused by the wheel polygon led to severe wheel/rail vibration. By establishing a vehicle/track coupling dynamics model considering elliptical wheel, Zhang Xueshan[6] showed that with the increase of the out-of-roundness of the wheel, the running quality of the vehicle system seriously deteriorated, the lateral stability and wheel load reduction ratio greatly reduced, the component life of vehicle/track system shortened, the risk of derailment increased. Zhou Dianmai[7] and others believed that due to up and down movement of primary spring of the vehicle using the arm positioning structure, the wheels in the rail direction would produce a regular small slide, resulting in polygons wheel wear. Wu Yue[8] and others has found that variable speed operation can effectively control the generation and development of wheel polygonal wear. After studying dynamic behaviour of the vehicle with wheel polygon by establishing rigid and flexible coupling dynamics model, Li Guiyu[9] pointed out that high-order wheel polygon could change vehicle critical speed and wheel/rail vertical force.

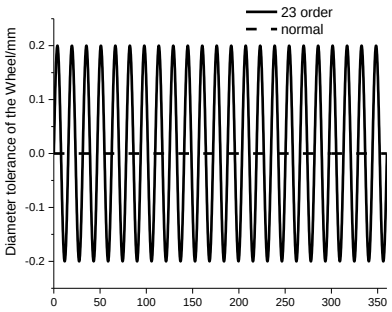
In this paper, taking a certain type high-speed EMU in china as study object, a rigid-flexible coupling dynamic model, in which the wheel, axle box and bogie are considered as flexible bodies, is established to study the influence of typical high-order polygon on dynamic performance of high speed vehicle.

2. Rigid-Flexible Body Coupling Dynamic Model



2.1. Mathematical Model of Wheel Polygon

The mathematical model of high-order wheel polygon is as follows. Assuming the perfect nominal rolling circle diameter of normal wheel and 23-order polygonal wheel are shown in Figure 1 (a), the ideal polygonal wheel radial runout can be plotted as Figure1 (b) . Therefore, the ideal 23 cycle harmonic can be described as formula 1[10]:



$$\begin{cases} \Delta r = \mathrm{A} \cdot \sin(\mathrm{n} \cdot \beta + \beta_0) \\ r(\beta) = \mathrm{R} - \Delta \mathrm{r} \\ \beta(t) = \beta(t-1) + \omega \Delta t \end{cases} \quad (1)$$

Where Δr is diameter tolerance of the wheel; A is the

wheel polygon amplitude；n is the wheel polygon order；β is the angle of rotated of the wheel；β_0 is the initial phase angle；r is the real wheel radius；R is the mean wheel radius；ω is angular velocity。

(a)

(b)

Fig.1 *diameter tolerance of 23 order wheel polygon*

The passing frequency of the wheel polygon can be calculated by the formula (2)

$$f = \frac{nv}{2\pi R} \quad (2)$$

Where n is the order;V is vehicle speed (m/s); R is wheel radius (m).

The passing frequency of 23-order wheel polygon at different speed levels listed in table 1.

Table 1 Passing Frequency

Speed/（km/h）	50	100	150	200	250	300
Passing Frequency/Hz	118	236	354	473	591	709

2.2. Vehicle System Dynamics Model

In order to more really simulate the influence of high-order wheel polygon on dynamic performance of high speed vehicle, A rigid-flexible body coupling dynamic model is established.

Firstly, Based on a certain type EMU dynamic parameters, the multi-rigid vehicle system dynamic model including one car body, two frames, four wheelsets and four axle boxes is established by SIMPACK software. The degree of freedom of the model is shown in Table 2, wherein the wheelset, the bogie and the car body have 6 rigid degrees of freedom respectively, and the axle box has only one degree of freedom of rotation. The whole multi-rigid vehicle system dynamic model includes 50 rigid degrees of freedom.

Table 2 The Degree of Freedom

Body	longitudinal	Lateral	Vertical	Roll	Pitch	Yaw
Car body	X	Y	Z	α	β	γ
Bogie frame	X	Y	Z	α	β	γ
Wheelset	X	Y	Z	α	β	γ
Axle box	—	—	—	—	β	—

Secondly the wheelset axle box and frame are modeled with flexible body. The flexible body modeling steps are as follows.

- The three-dimensional model of wheelsets, axle box and bogie is established by using SolidWorks software.
- The modal reduction of wheelsets, axle box and bogie is carried out by using ANSYS substructure analysis respectively.
- Choosing the master freedom degree(DOF) to generate *.sub and *.cdb files.
- Based on the above *.sub and *.cdb files, the *.fbi file is generated by the flexible body module of SIMPACK,
- Using the above *.fbi file to replace the original rigid wheelset, axle box and bogie.

The established rigid-flexible coupling dynamic model is shown in figure 2.

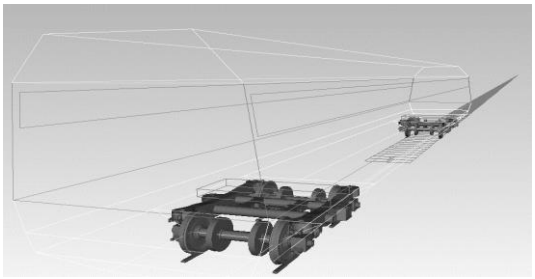


Figure 2 *Rigid-flexible body Coupling Dynamic Model*

2.3. Preliminary Calculation

When Vehicle runs on the rail with no irregularity, the changes of wheelset center position with time between different models are plotted in figure 3. As seen in figure 3, the center position of the flexible wheelset fluctuates between zero position owing to the bending deflection of the wheelset. Therefore, the actual movement characteristics of the wheelset with wheelset flexibility modeling can be better reflected.

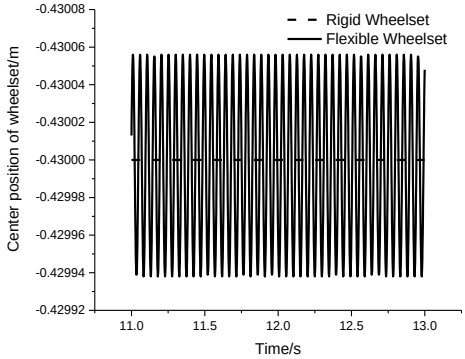

Figure 3 *Center Position of Wheelset*

The deceleration method was used to calculate the critical speed of the above dynamic model: The initial speed is set to 600km/h, and an acceleration of 0.5m/s^2 opposite to the velocity direction is applied to the car body, and irregularities are applied at the initial 500m. If the wheelset's lateral displacement has decreased less than 0.1mm, that speed is believed as nonlinear critical speed. As seen from Figure 4, the wheelset displacement is less than 0.1mm when the speed is 508km/h. Therefore, the nonlinear critical speed obtained by the deceleration method is 508km/h.

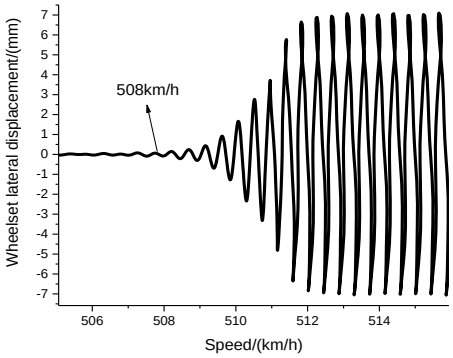

Figure 4 *Wheelset lateral displacement-velocity Curve*

3. Simulation Analysis

The typical field measured a certain type high speed EMU wheel polygon data analysis result is shown in Figure 5. As seen from Figure 5, the field measured wheel polygon is dominated by 23-24 orders. Considering that high-order polygonal wave depth of severe measured polygonal wheel can reach above 0.02mm, in order to more really study the influence of high-order polygon on dynamic performance of a certain type high speed EMU vehicle, the 23 order wheel polygon whose wave depth is 0.02mm is chosen as research object in this paper. Supposing that the wheel polygons are loaded into the 1-8 wheel of the model by the simple harmonic function, the phase angle deviation of the wheel polygon is not considered in the simulation. The sampling frequency of the simulation calculation is set at 3000Hz, the simulation track is set at 10Km with the Beijing-Shanghai high speed railway track irregularity, and the simulation time is 20s. The vibration and wheel/rail vertical force responses caused by 23-order wheel polygons with 0.02mm amplitude were simulated at 50km/h, 100km/h, 150km/h, 200km/h, 250km/h and 300km/h respectively.

3.1. Vibration Respomse

The vertical vibration acceleration signals of the wheelsets, bogie frame and car body caused by the normal wheels and 23 order polygonal wheels with 0.02mm amplitude at 200km/h were shown in Figure 6. As seen from Figure 6, the wheel polygon has the most important influence on the vibration acceleration of the wheelset. The wheelset vertical vibration acceleration maximum amplitude of the polygonal wheel can reach about 5 times that of the normal wheel. Due to the damping effect of the primary and secondary suspension, the influence of the wheel polygon on the vibration acceleration of bogie frame and car body is smaller than the wheelset. The bogie frame vertical vibration acceleration maximum amplitude of the polygonal wheel is about 2 times that of the normal wheel. The car body vertical vibration acceleration maximum amplitude of the polygonal wheel is slightly greater than that of the normal wheel.

Figure5 *Measured wheel polygon roughness level*

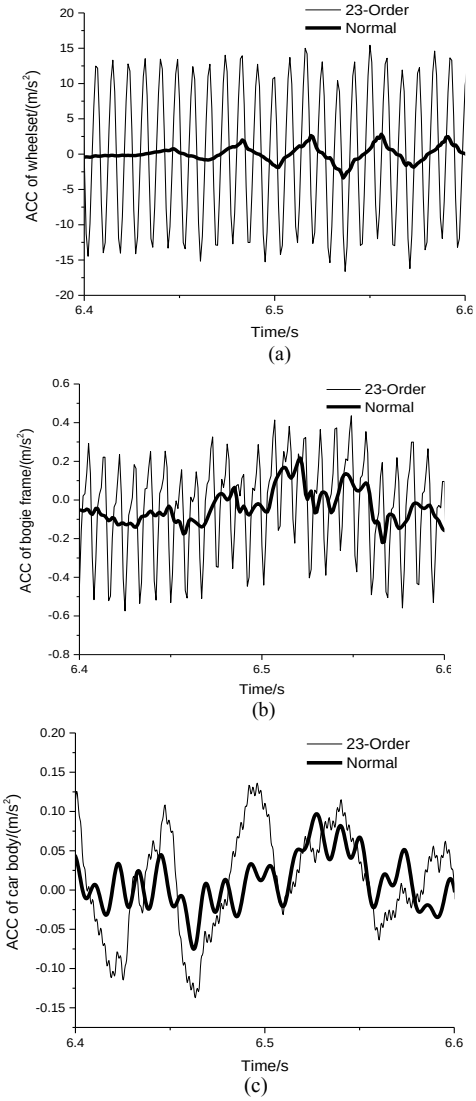

Figure6 *Vibration acceleration of wheelset, bogie frame and car body*

3.2. Comfort

In this paper, the ride comfort index is calculated according to Sperling standard. The criteria for evaluating rail vehicle ride comfort in China is shown in table 3.

The calculated lateral ride comfort index is shown in Figure 7. As seen from Figure 7, the 23 order wheel

polygon has a certain influence on the vertical comfort at each speed level. At most of speed levels, the vertical ride comfort index has increased by 10%-13%. However at 300 km/h, the vertical ride comfort index has significantly increased by more than 15%. Wheel polygon has less influence on the lateral comfort, but the lateral ride comfort index sudden increases at the speed of 300km/h, but the lateral ride comfort index in each speed level does not exceed 2.5. Because the excitation frequency of the calculated 23 order wheel polygon at each speed level is above 100Hz and the main frequency range on calculation of comfort is less than 80Hz, the wheel polygon has less influence on the vehicle ride comfort.

Table 3 Evaluation criteria for rail vehicle ride comfort in China

Comfort Level	assessment	Vehicle type		
		passenger train	locomotive	freight train
1	excellent	<2.5	<2.75	<3.5
2	good	2.5~2.75	2.75~3.10	3.5~4.0
3	qualified	2.75~3.0	3.10~3.45	4.0~4.25

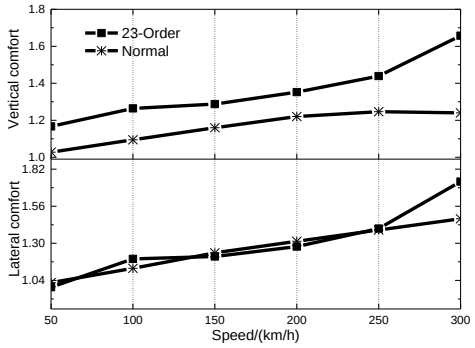

Figure 7 *Comfort index*

3.3 Safety

Safety evaluation indexes mainly include wheel-rail vertical force, derailment coefficient and wheel load reduction ratio etc.

（1）Wheel-rail vertical force

The wheel-rail vertical force characteristics in time and frequency domain under six speed levels are shown in Figure 8. As seen from Figure 8, with the increase of vehicle speeds, the fluctuation of the wheel-rail vertical force gradually increases. When the speed is lower than 250 km/h, the fluctuation range of wheel-rail force is within 40kN~70kN. However, the minimum wheel-rail force has reduced to 15kN when the speed reached 300km/h.

The frequency domain analysis of wheel and rail force signal showed that the dominant frequency is consistent with wheel polygon passing frequency at six different speed levels. Therefore, wheel polygon is the main cause of the fluctuation of wheel-rail force.

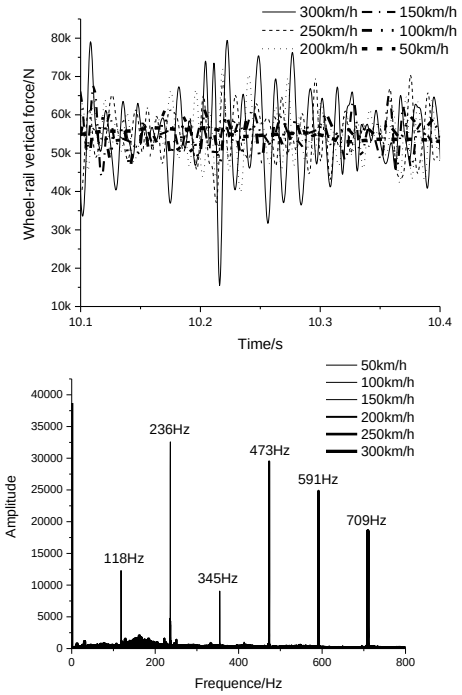

Figure 8 *Wheel-rail vertical force characteristic in time and frequency domain*

The maximum and minimum vertical wheel-rail vertical force at different speed levels is shown in Figure 9,

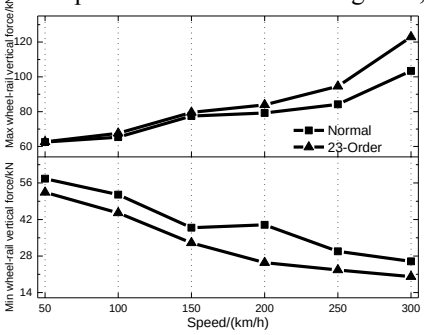

Figure9 *Max/Min wheel-rail vertical force*

As seen from Figure 9, the high-order wheel polygon has an important influence on wheel-rail force. With the increase of vehicle speed, the influence of wheel polygons on the maximum and minimum wheel-rail force increases. However, the wheel polygons has greater influence on the minimum force than maximum force. The result is shown in Table 4. As seen from Table 4, the increase of maximum wheel-rail force has been only 10% at the speed of 250km/h. The decrease of minimum wheel-rail force has exceeded more than 30% when the speed exceeds 200km/h, especially the decrease rate has reached 57% at 200km/h.

Table 4 Maximum and minimum wheel and rail vertical force

Speed/(km/h)	Max wheel-rail vertical force			Min wheel-rail vertical force		
	Normal/kN	Polygon/kN	Amplitude /%	Normal/kN	Polygon/kN	Amplitude /%
50	62.5062	62.6209	0.18%	57.6575	52.4065	10%
100	65.3323	67.5677	3%	51.523	44.5354	15%
150	77.4979	79.5455	2.5%	38.8471	33.0577	17%
200	79.2394	83.9251	5%	39.9635	25.4542	57%
250	84.2111	94.5891	10%	29.8053	22.6589	31%

300	103.409	122.918	15%	25.9754	20.0919	29%

（2）Derailment coefficient and wheel load reduction ratio

According to TB/T 2360-93 standard in China, The safety limits of derailment coefficient for good level is 0.8. However, derailment coefficient cannot be used to determine the safety of the vehicle individually and it should be used with wheel load reduction ratio together to determine the safety of the vehicle. In china, GB 5599-1985 standard specifies second limit for wheel load reduction ratio that is less than 0.6. Therefore, a comprehensive analysis of derailment coefficient and wheel load reduction ratio at each speed level is carried out, the result is shown in Figure 12. As seen from Figure 12, derailment coefficient and wheel load reduction ratio do not exceed the limit when the speed is below 250km/h. However, the derailment coefficient and wheel load reduction ratio all exceeded the limit value at the speed of 300km/h.

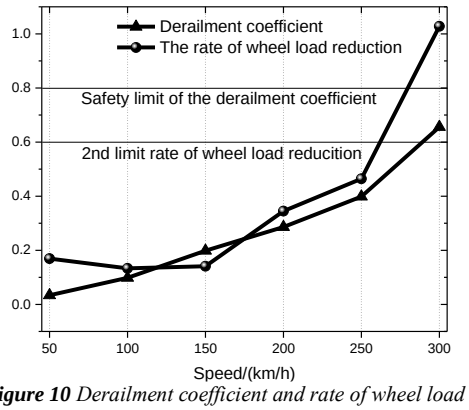

Figure 10 *Derailment coefficient and rate of wheel load reduction*

4. Conclusion

A rigid-flexible body coupled multi-body dynamics model for studying the influence of the high-order wheel polygon on a certain type high speed EMU vehicle dynamic performance is established by using SIMPACK and ANSYS software. The simulation results are as follows.

(1) The high-order wheel polygon will all bring about the vertical vibration acceleration increase of the wheelset, bogie frame and car body at different speed levels. The maximum vertical vibration acceleration of the wheelset can increase about 5 times due to the influence of wheel polygon at 200 km/h. Due to the damping effect of the primary and secondary suspension, the influence of the wheel polygon on the vibration acceleration of bogie frame and car body is smaller than the wheelset.

(2) The wheel polygon has an important influence on the wheel-rail vertical force, which can result in the significant fluctuation of the wheel-rail force. Especially when the vehicle speed reaches 250 km/h, the minimum wheel-rail force can reduce by 57%.

(3) The high-order wheel polygon which typically existed in a certain type high speed EMU has little effect on ride comfort.

(4) Severe wheel polygon can probably cause running safety problem for a certain type high speed EMU at the speed of more than 250 km/h.

Abstract: The derailment coefficient indicates the running safety against the flange-climb derailment. The value of the derailment coefficient is influenced by track and vehicle conditions. A monitoring bogie which can collect the derailment coefficient during commercial operations has been developed. However, there is no efficient method for handling a large-scale data collected by the monitoring bogie. This paper presents an analysis tool which can easily handle such data and detect a place where the derailment coefficient increases. The tool provides sufficient information regarding the friction characteristics and the estimated track irregularity utilizing the monitoring bogie.

Keywords: Wheel-rail contact; Derailment coefficient; Condition monitoring; Data analysis; MBD simulation.

1. Introduction

In order to prevent derailment accidents, safety measures based on the derailment coefficient should be taken. The derailment coefficient is calculated by wheel-rail contact forces and it indicates the running safety of the railway vehicle against the flange-climb derailment [1]. The derailment coefficient is affected by many factors such as track irregularities, vehicle parameters and friction characteristics between wheel and rail. It is generally known that the value of the derailment coefficient changes every moment even though the vehicle runs in the same curve in a day. Therefore, a frequent condition monitoring of the derailment coefficient during commercial operation is desired. However, the common measurement method needs a special measurement wheelset equipped with strain gauges mounted on wheel face. The method is not applicable to commercial operations in terms of safety and durability of the measurement system. Therefore, the number of measurements is limited and data during commercial operations with passengers onboard cannot be collected.

As a solution to such problem, a new type of monitoring bogie named "PQ monitoring bogie" which can observe the derailment coefficient during commercial operations has been developed and introduced into Tokyo Metro company [2,3]. Although the measurement of the wheel-rail contact force in any curves during commercial operations had been possible and collected a large-scale data by the bogie, there was no way to make the most of such large-scale data because an efficient method for dealing with such data was not been developed. To make use of the merits of the continuous monitoring, it is essential to process the data efficiently.

This paper introduces a tool for the analysis of the running safety of the vehicle based on the wheel-rail contact forces collected by the PQ monitoring bogie. The tool has been developed using MATLAB for the aim of handling a large-scale data efficiently. The tool can detect curves where the derailment coefficient locally increases. It is also possible to analyze factors which increase the derailment coefficient. In addition to the development of the tool, a method to estimate the track irregularity of twist which greatly influences the derailment coefficient is mentioned. This method makes it possible to evaluate the derailment coefficient with the wheel load reduction caused by the track twist. Finally, this paper shows some examples of analysis regarding running safety of the vehicle using the developed tool.

2. Monitoring of wheel-rail contact forces

2.1. Monitoring bogie

The derailment coefficient is calculated as Lateral /Vertical contact force acting on the leading outside wheel in a bogie and is denoted as "L/V". In Japan, as shown in Fig. 1, L/V is correspondingly called as "Q/P", and the name of the PQ monitoring bogie stems from the notation. The higher Q/P indicates that the probability of occurrence of the flange-climb is also higher.

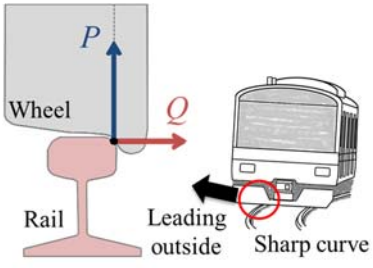

Figure 1 *Wheel-rail contact forces.*

On the other hand, ratio of the lateral contact force and the vertical contact force in the leading inside wheel is called "κ". When a vehicle runs on sharp curves, κ is almost equivalent to the friction coefficient in the leading inside wheel and rail. When this value is large, the lateral force on the outside wheel becomes large and Q/P increases consequently.

The PQ monitoring bogie can measure the wheel-rail contact forces during commercial operations using non-contact gap sensors and displacement sensors shown in Fig. 2. The vertical forces P acting into the wheels are measured by the vertical deformation of the axles springs by the magneto-strictive sensors, and the lateral forces Q are measured by the bending deflection of the wheels using non-contact eddy-current gap sensors attached to the axle-boxes [2,3]. These sampling interval is 24 msec. The monitoring bogie obtains the running position by integrating the wheel rotation speed obtained by speed generator. Using the bogie, continuous observation of the lateral and the vertical forces on each wheel during the vehicle runs in commercial operations is possible.

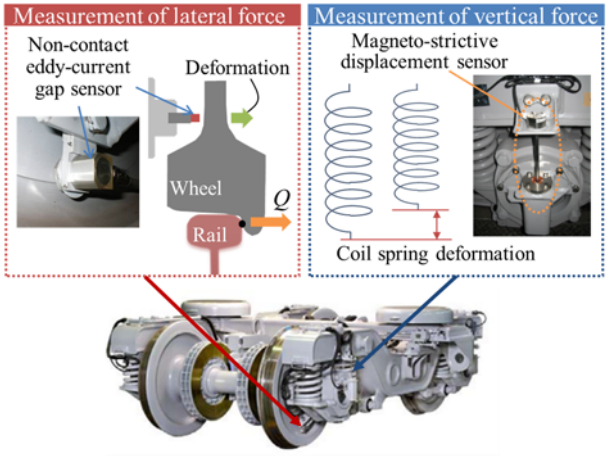

***Figure 2 PQ** Monitoring bogie.*

Fig. 3 shows Q/P and κ actually collected by the monitoring bogie in a sharp curve during commercial operations. The number of measurements is 5. These data are collected by the same bogie in a day. The curve radius in circular curve is 164 m and the curve has transition curves at both entry and exit side of the circular curve. It can be seen that the value of Q/P and κ change every run. The waveforms are similar to each other, but these amplitudes fluctuate even in a day.

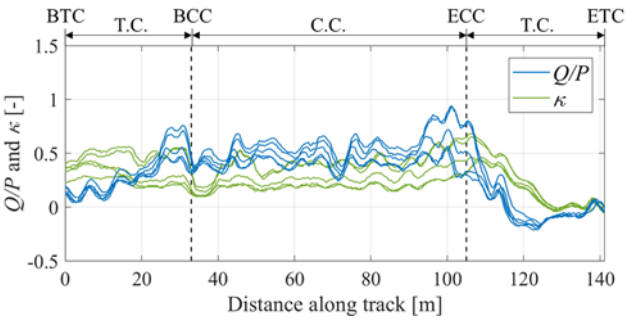

***Figure 3** Derailment coefficient Q/P and κ in a curve (N=5).*

2.2. Efficient data preprocessing

Time-separated large-scale data of the wheel-rail contact forces are collected by the monitoring bogie. There are more than 100 curves in the subway line which is treated in this paper. For the analysis of the running safety of the vehicle in sharp curves, the data should be handled in each curve. Hence, the continuously measured data are divided along with curves based on the database of the absolute position of the curves as shown in Fig. 4. In this preprocess, two types of data are created. "Waveform data" is time series data in each curve. "Maximum point data" is the momentary value observed at the point where Q/P becomes the maximum in a curve.

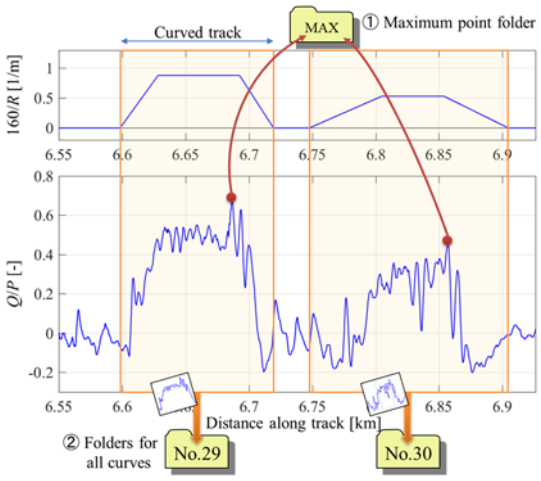

***Figure 4** Data sort and allocation image.*

3. Estimation of track irregularity of twist

3.1. Calculation of twist

In this study, as a value for the evaluation of running safety in addition to above mentioned Q/P and κ, an estimation method of the track irregularity of twist utilizing the monitoring bogie is introduced. The track irregularity of twist is a torsion of the railway surface comprised by points of wheel-rail contact in a bogie. It may affect the running safety by reducing the wheel load. Especially in the exit-side transition curve, in addition to irregularity, a structural twist exists due to the transition of rail cant, and the derailment coefficient tends to increase locally as shown in Fig. 5. Therefore, for the analysis of the running safety, it is desirable to keep an eye on the value of the irregularity of twist and the derailment coefficient simultaneously.

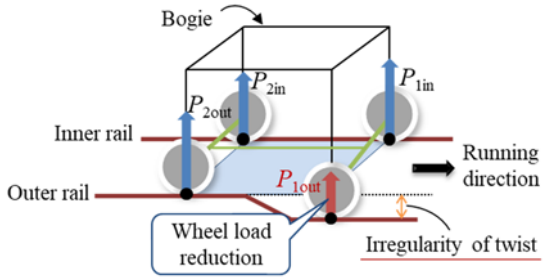

***Figure 5** Structural irregularity of twist.*

First, a torsion of the plane "L_s" expressed by the vertical displacement of axle springs in four wheels (z_{s1out}, z_{s1in}, z_{s2out}, and z_{s2in}) is calculated as follow:

$$L_s(x) = \{z_{s1out}(x) + z_{s2in}(x)\} - \{z_{s1in}(x) + z_{s2out}(x)\} \quad (1)$$

Here, x is the running position of leading axle along track. As mentioned above, the monitoring bogie measures the vertical displacement of axle springs for estimation of P. Next, the track irregularity of twist "L" is calculated as following formula [4].

$$L(x) = \frac{b}{b_1} \cdot L_s(x) \tag{2}$$

Here, the torsion in the axle spring L_s is converted to the torsion of the rail surface expressed by the vertical rail displacement in four wheels based on the relationship between the half of gauge width "b" and the half of the distance between left and right side of the vertical displacement sensor of axle springs "b_1". Fig. 6 shows these relationships.

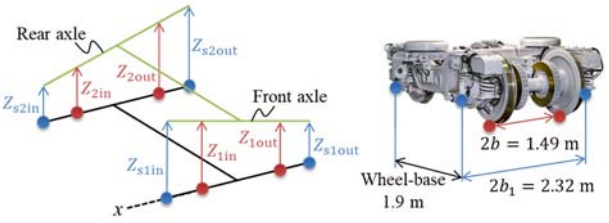

Figure 6 *Image of twist and vertical displacement.*

3.2. Correction method

In this paper, above mentioned estimation method is tried for simulation firstly. A vehicle and a track model are built and a curve passage simulation is carried out based on Simpack as shown in Fig. 7.

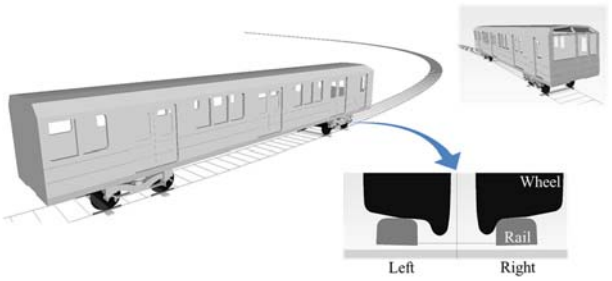

Figure 7 *Vehicle and track model on Simpack.*

The vehicle model is built according to the parameters of a subway car including the monitoring bogie. The track model is assumed as a sharp curve. Curve radius in circular curve is 171 m. The estimation result based on Eq. 2 is shown in Fig. 8 as "Eq. 2".

In this simulation, the track irregularities are only caused by the rail cant transition. From the comparison of the estimated value with the structural value, it can be seen that there are some estimation errors which value in circular curve is about 1.5 mm. The error at circular curve is due to the wheel lateral displacement of leading and trailing wheelset during curving. The leading wheelset laterally moves when running on a sharp curve. It causes a roll angle of the wheelset. The value, 1.5 mm is different from another condition and the value changes due to such as the specifications of curve, the friction coefficient and the wheel-rail geometry.

In order to reduce above mentioned error, a correction method is proposed as following. At first, a mean value of L in circular curve is calculated as follows:

$$\overline{L_{CC}} = \frac{1}{n}\sum_{k=0}^{n} L(x_{BCC'}+k\cdot\Delta x) \tag{3}$$

where,

$$n = \frac{x_{ECC'} - x_{BCC'}}{\Delta x}$$

$$x_{BCC'} = x_{BCC} + \frac{1}{10}(x_{ECC} - x_{BCC})$$

$$x_{ECC'} = x_{ECC} - \frac{1}{10}(x_{ECC} - x_{BCC})$$

Here, x_{BCC} is the place of beginning of the circular curve, x_{ECC} is the end of a circular curve. The first and last ten percent of the circular curve are excluded from the calculation of the mean value. Shift value "s" is defined from the calculated mean value as follow:

$$s(x) = \begin{cases} \overline{L_{CC}} \cdot \dfrac{x - x_{BTC}}{x_{BCC} - x_{BTC}} & (x_{BTC} < x \le x_{BCC}) \\ \overline{L_{CC}} & (x_{BCC} < x \le x_{ECC}) \\ \overline{L_{CC}} \cdot \dfrac{x_{ETC} - x}{x_{ETC} - x_{ECC}} & (x_{ECC} < x \le x_{ETC}) \end{cases} \tag{4}$$

Here, x_{BTC} is the beginning of a transition curve, x_{ETC} is the place of the end of a transition curve. Finally, the estimated irregularity of twist is corrected as follow:

$$L_C(x) = L(x) - s(x) \tag{5}$$

An estimation result in Eq. 5 is shown in Fig. 8 as "Corrected". The proposed method shows close agreement with the structural value.

The above method is also applied to the actual monitoring bogie. The estimated value of the irregularity of twist using monitoring bogie is shown in Fig. 9 as "Estimated". Here, the estimated value is compared with a measurement by the track inspection car. In this

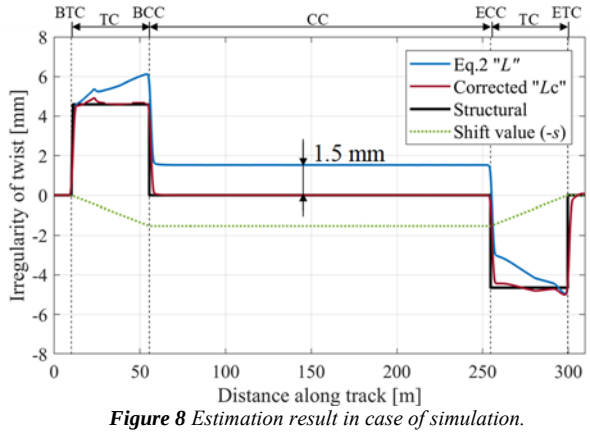

Figure 8 *Estimation result in case of simulation.*

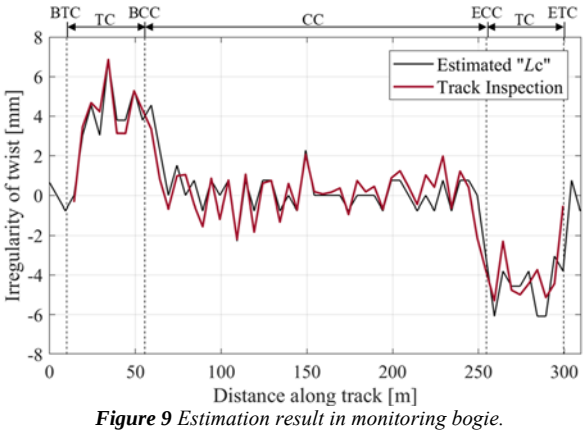

Figure 9 *Estimation result in monitoring bogie.*

comparison, both measurements are carried out in same curve and same day. The amplitude of the measured value with the track inspection car is multiplied by 1.9/2.5 so that the difference of wheel-base, of which the monitoring bogie is 1.9 m and the track inspection car is 2.5 m, should fairly compared. In addition, the estimated value is changed to 5 m interval which is the measurement interval of the track inspection car. Although there is a difference in each measurement method, the estimated value shows good agreement with the track inspection car. Using the monitoring bogie, it is possible to evaluate the running safety while considering the track irregularity of twist.

4. Data analysis tool

In order to utilize a large scale data such as Q/P, κ and estimated irregularity of twist L_C for the analysis of running safety efficiently, an analysis tool is developed using MATLAB. Fig. 10 shows the main interface of the tool. The analysis tool can easily handle a large-scale data collected by the monitoring bogie. A flow of analysis with the tool is described as follows.

At first, the analyst inputs a measurement date in table No. 1, then "Maximum point data" are plotted automatically on graph No. 3 and No. 4. Graph No. 3 shows the maximum value of the derailment coefficient observed by the monitoring bogie per one pass in each curve. The horizontal axis is the curve radius. When a train runs round trip, it passes over 200 curves. So, if the train runs 5 round trips in a day, the number of data exceeds 1000. It is seen that Q/P becomes large especially in sharp curves. From this graph, it is possible to detect data which value of the derailment coefficient increases in the commercial line in any period.

After detecting the place where we should focus on, it is required to investigate more detailed data. By clicking on "Maximum point data" on the graph No. 3, "Waveform data" of Q/P and κ are searched and displayed on the graph No. 5 automatically. Estimated L_C is also plotted on the graph No. 6. The observed place on the track and the specifications of selected curve such as the curve radius, the cant and the slack, and presence of the rail lubricator are also displayed in No. 2. In this way, the analysis tool assists an analyst by showing needed data automatically.

5. Example of data analysis

5.1. Analysis based on "Waveform data"

This paper presents some examples of analysis based on detailed data displayed in the tool. Here, three curves where the derailment coefficient tends to be large are chosen. Table 1 shows the specification of curves. The curve radius R, the cant C and the slack S in circular curve are almost same value in these curves. The cant transition rate is obtained by dividing the length of exit transition curve by C.

Table 1 *Specification of curves.*

	No. 1	No. 2	No. 3
R [m]	160	164	160
C [mm]	120	119	120
S [mm]	13	13	13
Cant transition rate	437.04	304.24	270.12
V (mean at Q/P peak) [km/h]	42	45	35
Rail lubrication	Both sides	-	-

Fig. 11~13 show Q/P, κ, and L_C in each curve. All data are measured in a month, and the number of data is 112. The value of L_C does not change so much even though 112 data are displayed at the same time. It proves that the above estimation method can be applied to various conditions. When the value of L_C is negative, it means the leading outside wheel load P_{1out} decreases due to the twist.

In curve No. 1, Q/P changes between 0.3 and 0.8 in CC for each run as shown in Fig.11(a). Fig. 12(a) shows

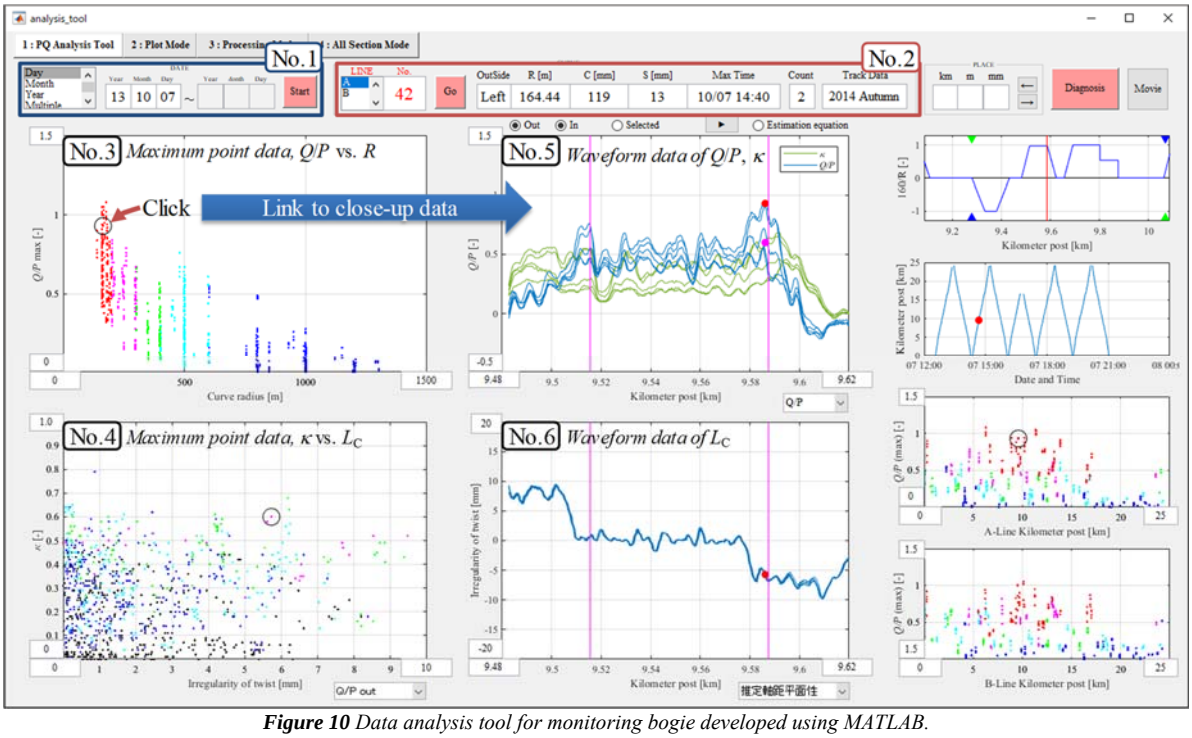

Figure 10 *Data analysis tool for monitoring bogie developed using MATLAB.*

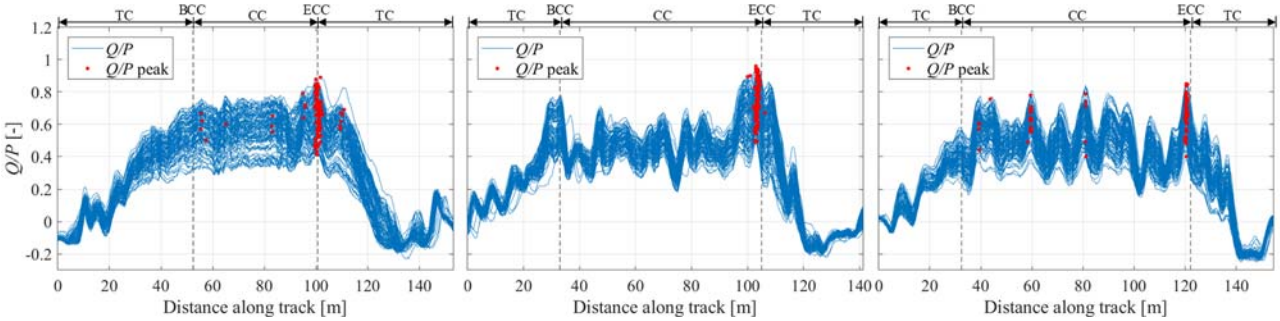
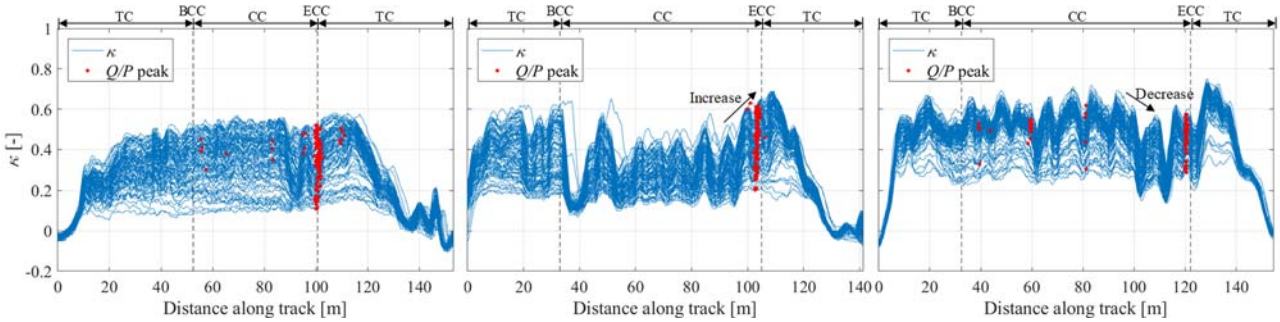
that κ also changes dramatically from 0.1 to 0.5. This curve has rail lubricators so that the friction coefficient should be minimized. When κ is large, Q/P increases. As it can be seen in "Maximum point data" plotted by red dots, Q/P have a peak around ECC. From Fig. 13(a), it is estimated that this local increase of Q/P is caused by the wheel load reduction due to the irregularity of twist. As summary in this curve, the derailment coefficient increases due to the increase of κ and the peak appears around ECC owing to the irregularity of twist including transition of the rail cant.



In curve No. 2, Q/P is not large in most of CC However, a local increase is occurred around ECC. Fig. 12(b) shows that κ is also large at same place. In addition, L_C is larger than curve No. 1 in ECC because the cant transition rate is small. It is considered that these two factors generate local increase of Q/P. Therefore, there should be paid attention especially around ECC.

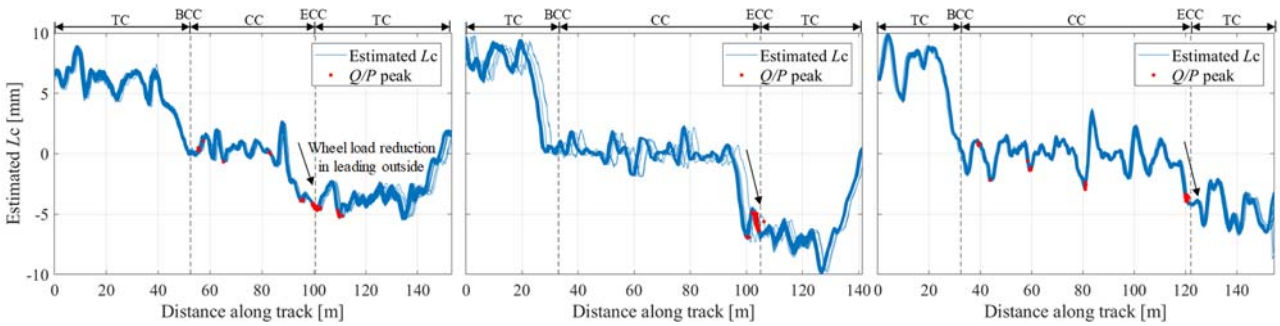
In curve No. 3, the waveforms of Q/P are most fluctuating in CC as shown in Fig. 11(c). This curve has several peaks of Q/P in CC and around ECC. From Fig. 13(c), these peaks are appeared in the valley of waveform of L_C. It is estimated that this vibration is due to track irregularities. Focused on around ECC, κ tends to be small just before ECC. In addition, although the cant transition rate is the smallest among three curves, actually occurring values of L_C are smaller than curve No. 2. Therefore, the maximum of Q/P is not significantly increased like curve No. 2.

From these results, even if in similar sharp curves, the trend of derailment coefficient appears differently according to the effect of the friction coefficient and the track irregularity.



5.2. Comparison with "Maximum point data"

The analysis tool can make comparison of some curves using "Maximum point data". Fig. 14 and 15 show the data in three curves corresponding to Fig. 11~13. Fig. 14 shows the relationship of Q/P and κ. Here, r is the correlation coefficient between κ and Q/P. As shown in Fig. 14, κ and Q/P are well correlated in all curves. The fact indicates that Q/P will be decreased by lubricating the inner rail. The value of L_C is shown in Fig. 15. L_C in curve No. 2 is the largest among three curves. Especially in this curve, it is required to be careful because both κ and L_C are large. In curve No. 3, the distribution of L_C is divided into two groups because Q/P have multiple peaks. In this curve, Q/P is smaller than other curves because L_C



(a) Curve No. 1 (N = 112) (b) Curve No. 2 (N = 112) (c) Curve No. 3 (N = 112)

Figure 11 *Derailment coefficient Q/P in each curve.*

Figure 13 *Estimated track irregularity of twist L_C in each curve.*

is not so large. Based on the result of comparison with some curves, it is possible to grasp the characteristics of curves and to take countermeasure for each curve.

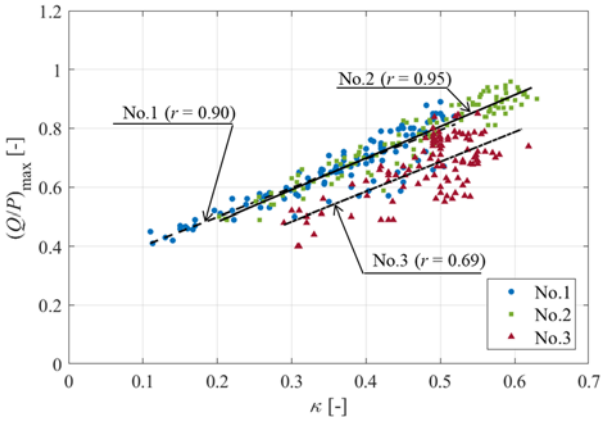

Figure 14 *Q/P vs. κ in three curves.*

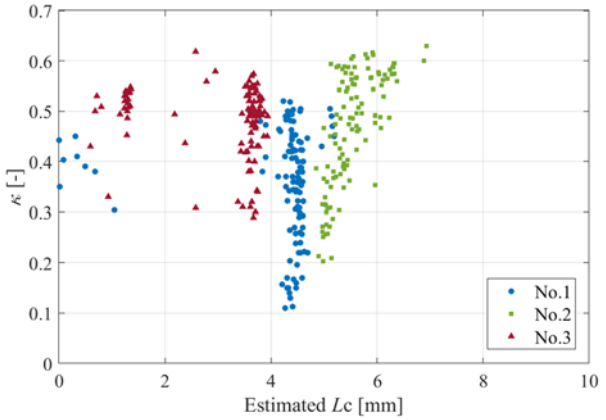

Figure 15 *κ vs. L_C in three curves.*

5.3. Daily change of derailment coefficient

Fig. 16 shows the daily change of Q/P and κ in curve No. 2 for two months. The first half of the period is corresponding to the data shown in the previous section. Displayed data in the figure are averaged in a day. In this curve, Q/P was large at the beginning of the period and it decreased at the end of the period. κ also changes like Q/P. Thus, in this curve, the friction coefficient in inner rail is decreased by lubricating, and Q/P is also decreased consequently. By investigating time series data like this, it is possible to find curves where the derailment coefficient tends to increase. In addition, it is also possible to check whether the countermeasures such as lubrication of rails and the maintenance of track irregularity work effective or not.

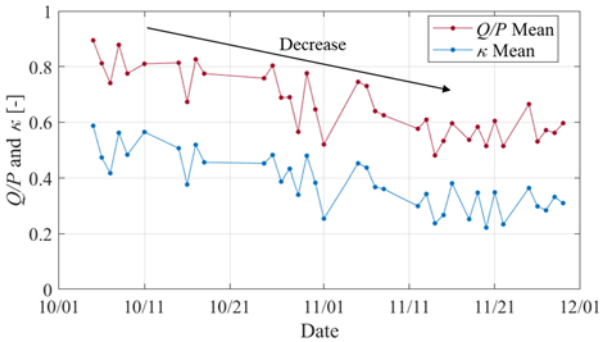

Figure 16 *Daily change of Q/P and κ in curve No.2.*

6. Conclusions

This paper mentioned an efficient method to utilize continuous measurement data of wheel-rail contact forces collected by the monitoring bogie during commercial operations.

Based on the result of multi-body dynamics simulation, the method to estimate the track irregularity of twist using the monitoring bogie is proposed.

An analysis tool for a large-scale data collected from the monitoring data is developed. The tool can extract curves where the derailment coefficient increases. It is also possible to analyze the running safety of the railway vehicle based on the derailment coefficient, friction conditions and track irregularity of twist.

From these results, an optimal plan for the reduction of the derailment coefficient according to the characteristics of each curve can be suggested.

Abstract: In this study, the low adhesion mechanism due to leaf contamination in autumn was investigated through pin-on-flat tests and chemical analyses of a leaf-derived material. A black material was synthesised with water-extract of sycamore leaves and rail steel (R260). The black material formed in brown leaf extracts was found to cause very low adhesion, which is lower than that of commercial engine oil. Five techniques of chemical analysis, such as laser Raman Spectroscopy and X-ray Photoelectron Spectroscopy, revealed that the black material contained graphitic carbon, phosphates and iron oxides or iron carboxylate, and they are likely to cause low adhesion.

Keywords: Low adhesion, leaf contamination, chemical analysis, pin-on-flat, graphitic carbon, iron oxide, phosphate

1. Introduction

Traction between wheels and rails, which is often expressed as "adhesion" in railway industries, is one of the most critical factors for train control: acceleration and deceleration. The friction coefficient, COF, is required to be at least 0.2 and 0.09 for traction and braking, respectively [1]. However, the rail surface is often contaminated with various sources due to the open environment of railway tracks, and the adhesion condition is sometimes below the required level.

Among various contamination sources, leaves falling on the line in autumn have a significant impact on train operation [2]. They form a black, hard and "Teflon-like" film on the rail, which decreases the traction coefficient to 0.1 or lower when a small amount of water, such as light rain or morning dew, is present [3], [4]. The leaf film often causes serious problems in terms of safety and service, such as station overruns [5], collisions [6] and amended timetables [7], [8]. In addition, the annual loss due to leaf contamination was reported to be £50 million in the United Kingdom [9] and 100 million SEK in Sweden [10].

This leaf contamination problem has been studied for the development of more efficient and effective mitigation methods. Recently, many researchers have tried to reveal what leaf films consist of and to clarify the mechanism of low adhesion conditions, using techniques of chemical analysis. For instance, an Infra-Red Reflection Absorption Microspectroscopy (IR) analysis suggests that pectin in leaves causes a chemical reaction with rail steels, forming an iron pectate [11]. In the chemical reaction process, pectin possibly forms a gel by crosslinking with Fe ions from rail steels, and this gel could cause low adhesion. Another theory about the low adhesion mechanism is a friction-reducing layer formed on rails because of a chemical reaction between leaves and rail steels [12]. Glow Discharge Optical Emission Spectroscopy (GD-OES) reveals that a field rail sample contaminated with leaves contains organic elements and iron, forming a mixed layer with iron oxides and organics. This mixed layer could cause low adhesion as well.

However, these theories have some drawbacks. For example, carboxylate bands detected during IR analysis do not necessarily derive from pectin; they could be attributed to other materials which have an ester in their structure. In the friction-reducing layer theory, the chemical reaction process has not yet been considered. In spite of the significant progress of these studies, a detailed mechanism of how organics in leaves react with rail steels is still unknown. If this mechanism is clarified, it could lead to a development of innovative methods, which can prevent leaf film formation.

Hence, this study aims to identify the key materials for low adhesion and to obtain the chemical information of those materials. As a first step, several hypotheses for low adhesion were developed, such as bulk leaf, adhered leaf film and pectin gel, as reported in [4]. Based on these theories, the candidates of possible substances are narrow-downed, and the identified material was investigated, using several chemical analysis techniques.

2. Methods and Materials

2.1. Test samples

Six types of leaf-related samples were examined in this study: leaf powder (LP), leaf extract (LE) and black precipitation powder (BP) for green and brown sycamore leaves, as shown in Figure 1. Brown sycamore leaves

were collected in Sheffield between November and December 2015. Green leaves were picked from trees at the same site between October and November 2016 and kept in a freezer to minimise decay.

Bulk leaves were chopped by a food processor, and then they were filtered by a strainer, separating small pieces from relatively large pieces. The former was categorised as LP, and the latter was leaf mulch (LM). The typical size of the LP particles was between 15 and 800 µm, measured with an optical microscope. LE was made by mixing LM with distilled water at a ratio of 1g of LM to 50 ml of water. After mixing, the mixture was left for one to five days, then it was filtered with filter-paper, removing small particles.

The BP was synthesised with LE and a plate made of rail steel (R260). A rail plate was immersed in LE and left for one to three days, forming black precipitation due to a chemical reaction between iron from the plate and dissolved organics in the LE. Then, the mixture was heated and brought to a boil to accelerate the chemical reaction and evaporate the water. Due to this heating process, the black precipitation was dried, and they were ground using a pestle and mortar. Typically, the size of the BP particles was between 10 and 100 µm, measured in the same manner as the LP particles. It should be noted that high flash temperatures can be achieved in the wheel/rail contact due to localised slip in the wheel/rail contact [4]. Consecutive wheel passes over a leaf on the rail would add temperature to the leaf. Thus, this boiling process does not excessively enhance the chemical reaction, as high temperatures are expected in addition to high contact pressures up to 1 GPa.

For some chemical analysis, two types of BP films were analysed: a thin BP film and thick BP film. BP thin films were prepared on a small piece of rail steel, approximately 10×10×4 mm. They were formed on the piece following the procedure of BP formation; however, no heat was applied to the steel piece unlike in the BP formation. This method allows replication of the black material on railway tracks as naturally as possible. BP thick films were formed on the small steel piece, fully following the procedure of BP formation.

2.2. Viscosity measurements

Viscosity measurements were performed with a Brookfield DV1 Viscometer. A viscosity value was measured at 100 rpm and 30 °C, with a SC4-18 spindle.

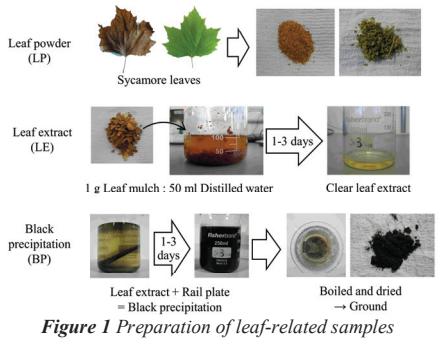

Figure 1 *Preparation of leaf-related samples*

2.3. Friction tests

A basic ball-on-flat test was conducted using the six leaf-related samples, as shown in Figure 2. This test aimed to investigate the hypotheses for low adhesion: bulk leaf and pectin gel [4]. The LP represents a bulk leaf on the line, and the LE and BP examine the pectin hypothesis. As a reference, three liquid samples were also tested: distilled water, engine oil (Servol 15W-40, Morris lubricant) and pectin 0.1 wt% solution. Pectin powder was purchased from Sigma-Aldrich (product number: P9135, CAS number: 9000-69-5). The concentration of pectin solution was determined by the viscosity value of the LEs.

Table 1 summarises the experimental conditions of the friction tests. Specimens were a 5mm diameter stainless-steel ball and a plate made of R260 rail steel (66×25×4 mm), which typically had a surface roughness between 0.4 and 0.5 µm Rq. LP and BP were diluted with distilled water, making a five wt% solution. The solution was applied to the rail plate, but LE was directly applied to the plate, without being diluted. A Bruker UMT machine was used for the friction tests, following this process; approximately 0.2 ml of sample solution was applied to the fixed rail plate. Then the ball was pressed into the plate with 10 N, giving an average Hertzian contact pressure of 1.56 GPa. The ball was then reciprocated for six minutes at 0.4 Hz, while the friction coefficient (COF) was measured. The COFs were averaged for every 20 seconds and evaluated. The measurement was repeated at least three times, and the standard deviation was calculated to show the spread in COF values.

2.4. Characterisation

Several analyses were carried out for mainly BP: X-Ray Fluorescence (XRF), X-Ray Diffraction (XRD), Laser Raman Spectroscopy (RS), X-Ray Photoelectron Spectroscopy (XPS) and Fourier Transform Infrared spectroscopy (FT-IR). Table 2 summarises the experimental details of each analysis technique applied in this study.

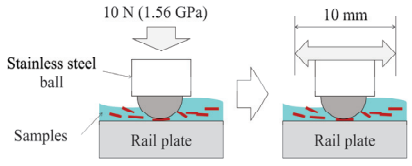

Figure 2 *Experimental procedure of friction tests*

Table 1 *Experimental conditions of friction tests*

Parameter	Value
Applied force [N]	10
Average Hertzian pressure [GPa]	1.56
Time [seconds]	360
Stroke [mm]	10
Frequency [Hz]	0.4
Sampling frequency [Hz]	100
Top stainless-steel ball diameter [mm]	5
Sample amount [ml]	0.2
Concentration (LP and BP) [wt%]	5

Table 2 Summary of chemical analysis techniques

Analysis	Experimental details
XRF	• Fisherscope XAN 250 • Sample: BP • Elements between aluminium and uranium are detectable
XRD	• PANalytical X'Pert^3 Powder • Sample: BP • Crystal materials are detectable
RS	• Renishaw inVia Raman Microscope • Samples: BP and BP thin film • 514.5 nm laser and x50 objective lens • 1 mW/10 sec exposure or 2 mW/20 sec exposure
XPS	• Kratos Analytical Axis Supra • Samples: BP thick film and BP thin film • Surface up to 10 nm can be measured
FT-IR	• Bruker ALPHA Platinum-ATR • Sample: BP • Noise between 1900 and 2200 cm^{-1}

3. Results

3.1. Viscosity measurements

Table 3 summarises the viscosity values of green leaf extract (GLE), brown leaf extract (BLE), distilled water and pectin 0.1 wt% solution. The viscosity values of GLE and BLE were found to be at the same level as distilled water. In contrast, the artificial pectin 0.1 wt% solution exhibited higher value than LEs. This result indicates that leaf components with high molecular weight are unlikely to dissolve into LEs in terms of viscosity values. If pectin dissolves in LEs as suggested in [11], a concentration of pectin in LEs could be very low, under 0.1 wt% at least. Or pectin could be decomposed from polysaccharide to monomer (a structural unit), such as galacturonic acid [13], and it does not affect viscosity values.

3.2. Friction tests

3.2.1. Leaf extracts

Figure 3 illustrates the results of friction tests with green leaf extract (GLE) and brown leaf extract (BLE): three days extraction GLE and one day extraction BLE. Both GLE and BLE showed a medium-low level of friction between 0.2 and 0.25 after six minutes. This range of COF is lower than the distilled water (around 0.45) and pectin solution (around 0.3). This result shows that LEs have some impurities which affect friction levels, and they are unlikely to be pectin. Additionally, black material was formed after some tests, showing a good agreement with the previous research [11]. However, no black materials were found after the tests of pectin 0.1 wt% solution, suggesting that the artificial pectin has nothing to do with the chemical reaction.

3.2.2. Leaf powder solution

Figure 4 depicts the results of friction tests with green leaf powder (GLP) and brown leaf powder (BLP) 5 wt% solutions. Both GLP and BLP solutions exhibited COFs, which are lower than the engine oil up to 60 seconds. They showed a medium-low friction level around 0.15 to 0.2, which is much lower than the level of distilled water.

This result suggests that LP prevents the metal-metal contact between the ball and plate, acting as a solid lubricant. As the experiment proceeds, the LP solution is gradually removed from the contact area. Subsequently,

Table 3 Viscosity measurements

Extraction time	Viscosity [mPa·s]			
	GLE	BLE	Reference	
1 day	1.08	1.08	Distilled water	1.08
2 days	1.05	1.02	Pectin 0.1 wt%	1.62

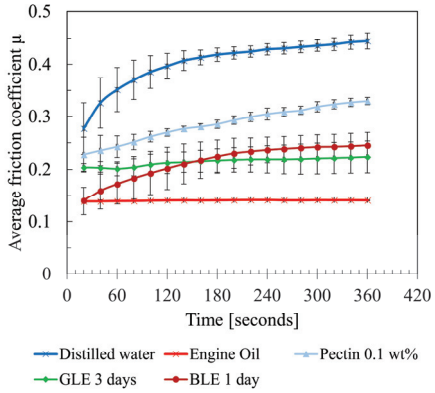

Figure 3 Friction test results of GLE and BLE

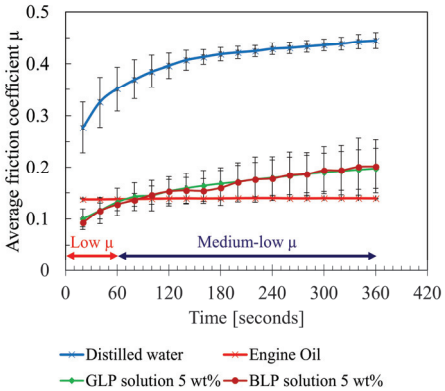

Figure 4 Friction test results of GLP and BLP solution

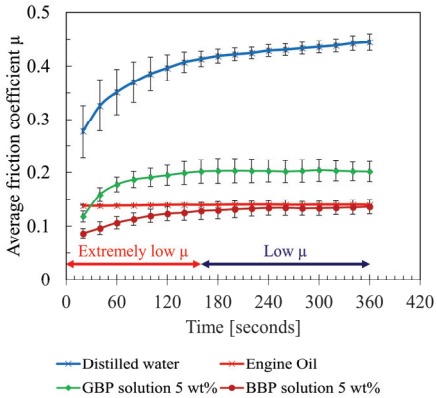

Figure 5 Friction test results of GBP and BBP solution

the friction level increases due to less solid lubrication effects of the LP. Instead, LE affects the friction condition more, and the COF is around 0.2 after six minutes due to the mixed lubrication effect of LP and LE.

It should be noted that both GLP and BLP became black during the tests; the chemical reaction quickly occurs on the surface of LP, where the concentration of impurities could be high.

3.2.3. *Black precipitation powder solution*

Figure 5 exhibits the results of friction tests with black precipitation powder formed in green leaf extracts (GBP) and black precipitation powder formed in brown leaf extracts (BBP) five wt% solutions. Surprisingly, the BBP solution showed extremely low friction, which is lower than the engine oil up to 160 seconds and the same level afterwards. In contrast, GBP solution showed a stable COF around 0.2, although it exhibited very low friction for the initial 20 seconds.

This result indicates that BBP is a key material for low adhesion. Moreover, the difference between GBP and BBP in terms of materials could identify a substance which is directly relevant to low adhesion.

Overall, the friction tests showed three main findings:

- Bulk leaf powder acts as a solid lubricant if it is in the contact area.
- Water-soluble organics in sycamore leaves do not lower the COFs, although they help the formation of black materials.
- The black material is mainly responsible for low adhesion.

Thus, the "Bulk leaf" hypothesis in [4] is likely to be true as the low COFs were confirmed. However, the hypotheses "Adhered leaf film" and "Pectin gel" could be untrue in terms of pectin as a key material, because pectin is unlikely to be in LEs as a thickening agent and also to cause the chemical reaction. Rather than a long pectin chain, there could be decomposed pectin molecules or other organics in LEs, and they can form a black material which finally causes low adhesion.

3.3. *Material analysis*

3.3.1. *X-Ray Fluorescence (XRF)*

Figure 6 depicts the XRF results of GLP, GBP, BLP and BBP. Both GLP and BLP contained a relatively large amount of calcium (Ca) and potassium (K), as well as a small amount of chlorine (Cl), manganese (Mn) and iron (Fe). In contrast, GBP and BBP were found to contain mainly Fe, followed by K, Ca, Cl and Mn. This result shows that Fe ions dissolve into LEs from rail plates and they induce the chemical reaction. The dissolved Fe ions presumably react with various ions and molecules in LEs, including K, Ca and Cl ions.

It should be noted that the number of counts cannot be directly compared to each other, because the amount of sample powder was not accurately controlled. Thereby, the counts ought to be taken as a reference.

3.3.2. *X-Ray Diffraction (XRD)*

Figure 7 illustrates the XRD results of GBP and BBP. BBP exhibited several sharp peaks, showing that some crystal materials were present. In contrast, GBP did not show any peaks, suggesting no crystal structure was in the sample. The assignments of the detected peaks were conducted by searching in the database (Powder Diffraction File provided by the International Centre for Diffraction Data: PDF-4). It was found that these XRD patterns of BBP derived from potassium chloride (KCl: strong peaks) and calcium sulphate ($CaSO_4$: relatively weak peaks), although the small two peaks at 20.7 and 31.05 were not identified. It should be noted that no patterns in the XRD data could suggest that amorphous materials are present rather than crystal structures, and it does not mean that there is no KCl and $CaSO_4$ in GBP.

3.3.3. *Laser Raman Spectroscopy (RS)*

Figure 8 shows the acquired Raman spectra of GBP, BBP and activated charcoal, which was purchased from Sigma-Aldrich (product number: C9157, CAS number: 7440-44-0). Both GBP and BBP showed similar peaks, which are around 1350 cm^{-1} (shoulder) and 1570 cm^{-1} (strong). They are typical features of amorphous carbon [14], called disordered band (D) and graphitic band (G), respectively [15], [16]. The wide peak around 2850 cm^{-1} was assigned to amorphous carbon as well [15], although these peaks in GBP and BBP were not as clear as the activated charcoal. The small and wide peak around 600 cm^{-1} in BBP could be a mixture of magnetite (Fe_3O_4) and hematite (α-Fe_2O_3), which has a shift of 533.6 cm^{-1} and 611.9 cm^{-1}, respectively [17]. The overlapping band around 1430 cm^{-1} was difficult to assign; it could be carboxylate ions (COO^-) in carboxylic acid salts [18], taking into account the result of FT-IR analysis described later in 3.3.5.

In general, an intensity ratio of D and G band (I_D/I_G) can be used to evaluate the degree of graphitisation [15], [16], [19], [20]; the ratios were around 0.64, 0.76 and 1.02, for the GBP, BBP and activated charcoal, respectively. These relatively low ratios in GBP and BBP suggest that their carbon materials have a less disordered structure and are close to graphite.

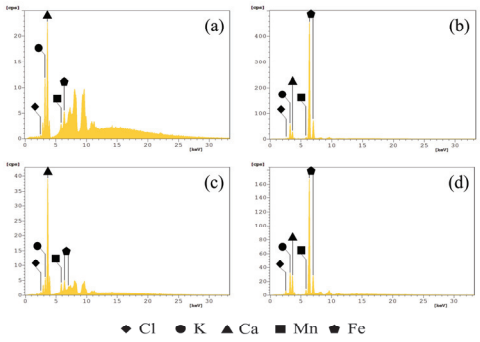

Figure 6 *XRF results: (a) GLP. (b) GBP. (c) BLP. (d) BBP.*

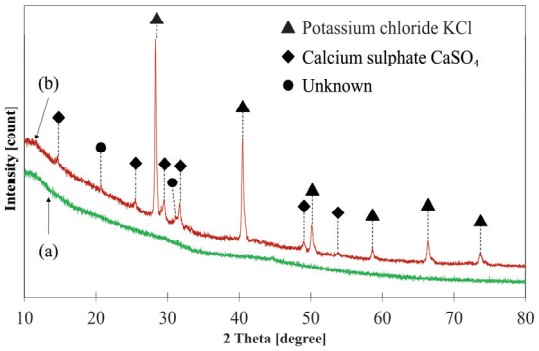

Figure 7 *XRD results: (a) GBP. (b) BBP.*

This graphite-like carbon could be one of the reasons why low adhesion happened during the friction test. Furthermore, a sugar-derived carbon, which is often studied as a material of electrodes, has been reported to have a more graphitic structure than usual amorphous carbon, e.g. carbon black [16], [19]. Hence, the Raman spectra also indicate that GBP and BBP might derive from dissolved sugars in LEs, which are highly likely in water-extracts of leaves, such as green tea [21].

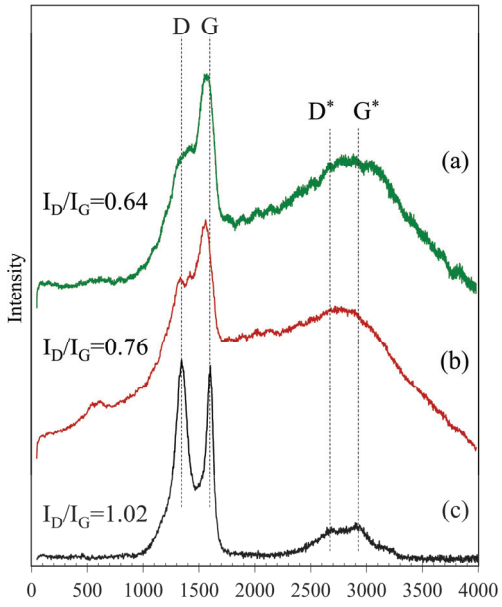

Figure 8 *Raman spectra: (a) GBP. (b) BBP. (c) Activated charcoal.*

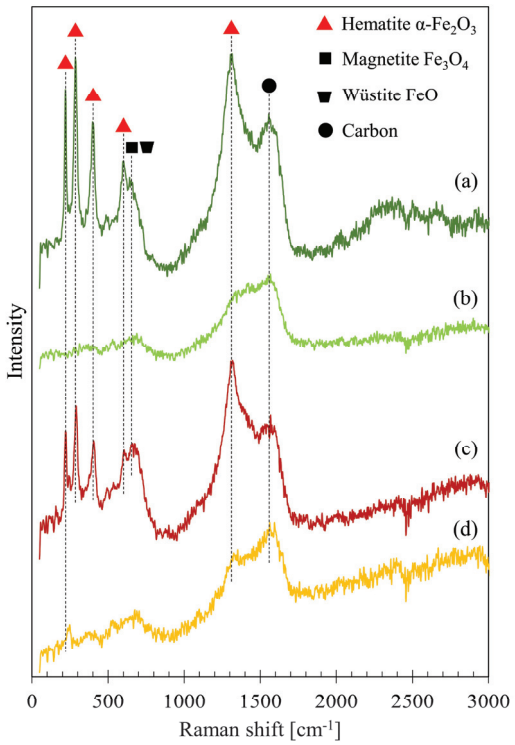

Figure 9 *Raman spectra of GBP and BBP thin films measured with different laser power:*
(a) GBP 2 mW. (b) GBP 1 mW. (c) BBP 2 mW. (d) BBP 1 mW.

Figure 9 depicts the Raman spectra of GBP and BBP thin films formed on a small piece of rail steel without boiling. For these samples, two different levels of laser powder were tested: 1 and 2 mW. Both GBP and BBP thin films showed sharp peaks with the 2 mW laser. In contrast, these clear peaks were not seen in the spectra measured with the 1 mW laser power except D and G bands of carbon. Table 4 summarises the observed Raman shifts and their assignments. Relatively sharp peaks around 220, 290, 400, 600 and 1310 cm^{-1} were assigned to α-Fe_2O_3. The broad and small peak around 650 cm^{-1} could belong to a mixture of Fe_3O_4 or FeO (Wüstite), and the broad but high peak around 1560 cm^{-1} was assigned to amorphous carbon. The differences between the measured and reference values could be attributed to the different laser power since the position of peaks shifted to lower wavenumbers when the higher laser power is used in the case of iron oxides [17].

The broad peak at 650 cm^{-1} indicates that Fe_3O_4 originally exists in the samples; FeO is often seen in the transformation process from Fe_3O_4 to other types of iron oxides, which is possibly α-Fe_2O_3 in this case [17]. This transition happens if the laser power is intense enough to cause decomposition of Fe_3O_4. Therefore, these peaks seem to originate from Fe_3O_4.

In RS, the sample surface may be degraded if the laser power is too high [22], and heat induced by the laser affects measurements [23]. In fact, the laser with high power, such as 10 mW, burned the surface of BP during trials. In Figure 9, it seems that the 1 mW laser gives no damage, but the 2 mW laser does, and it possibly burns the surface carbon layer and exposes the iron oxides underneath the surface layer. The detected peaks of iron oxides do not derive from the rail plate since the depth penetration of graphite is approximately 50 nm [14]. Thus, the Raman spectra in Figure 8 and Figure 9 predict a structure of GBP and BBP; Fe_3O_4 or a mixture of α-Fe_2O_3 and Fe_3O_4 becomes a core, and a thin amorphous carbon layer probably grows on the surface of the iron oxide, which might be a sugar-derived carbon formed with sugars in LEs.

Table 4 *Assignments of Raman shifts measured in GBP and BBP thin films with 2 mW laser*

GBP cm^{-1}	BBP cm^{-1}	Assignment	Reference	
220	222	α-Fe_2O_3	226.7	[17]
286	290	α-Fe_2O_3	292.5 299.3	[17]
398	406	α-Fe_2O_3	410.9	[17], [24]
602	606	α-Fe_2O_3	611.9	[17]
642	651 662	FeO Fe_3O_4	652 662.7	[17] [24]
1305	1317	α-Fe_2O_3	1320	[17], [24]
1556	1567	Amorphous carbon Sugar-derived carbon	1575 1580	[14] [16]

3.3.4. *X-Ray Photoelectron Spectroscopy (XPS)*

Figure 10 shows the XPS spectra of GBP thick film with the heat treatment and GBP thin film without the heat treatment. In the same manner, Figure 11 depicts the XPS spectra of BBP thick film and BBP thin film. Both GBP and BBP films were found to contain various elements, such as carbon, oxygen and iron, showing a good agreement with the previous study [12] and the results of XRF and XRD. Some elements were only seen in thick film samples, indicating that the boiling process affects the chemical reaction for the formation of compounds which contain calcium, sulphur, potassium, magnesium, chlorine and silicon.

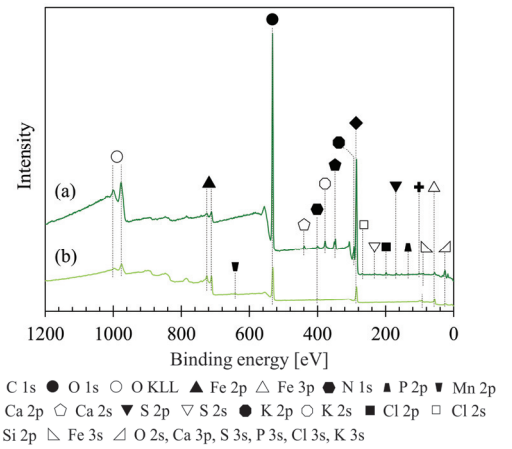

Figure 10 *XPS results of GBP: (a) Thick GBP film. (b) Thin GBP film.*

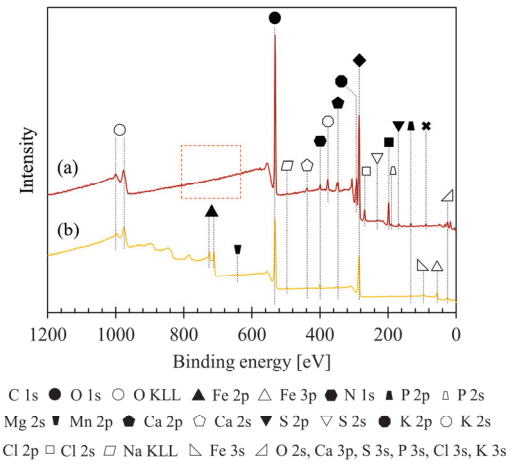

Figure 11 *XPS results of BBP: (a) Thick BBP film. (b) Thin BBP film.*

Table 5 summarises the chemical composition of each element shown in average atomic percent (at%) with the standard deviation. It was revealed that carbon and oxygen accounted for approximately 90 at% in both thick and thin films. Iron was also present in GBP and BBP thin films formed without heat treatment, accounting for 3-7 at%. However, less or no iron was observed in GBP and BBP thick films, showing that the heat treatment enhanced the chemical reaction which formed the organic layer on iron oxide cores. This change in the iron concentration supports the prediction of a structure: organic layer (carbon layer) on an iron oxide core described in 3.3.3. It should be noted that the concentration of sodium was not taken into account due to the lack of the detection in the primary region: Na 1s at 1071.8 eV.

Chemical shifts in binding energies (B.E) were obtained from high-resolution spectra to investigate the chemical conditions of C, O and Fe. Figure 12 illustrates C 1s high-resolution spectra of thin and thick films of GBP and BBP and their fittings. C 1s was found to have a complex structure, containing four components, and their chemical shifts were not dramatically changed after the heat treatment for both GBP and BBP films. The B.Es were roughly 285.0, 286.6, 288.2, 289.2 eV and assigned to C-C (amorphous carbon), C-O-C, C=O, O=C-O, respectively [25]–[28]. This complex structure is often seen in graphene oxide which is generally obtained by oxidising graphite particles [29], [30], although the observed C 1s did not contain clear sp^2 at 284 eV, which should be present in graphite [25].

Figure 13 shows O 1s high-resolution spectra and fittings. O 1s had a complex structure, showing three to five chemical shifts. Thin GBP had five components (530.1, 531.5, 532.5, 533.4 and 534.5 eV), and thick GBP film had three (531.5, 532.9 and 534.4 eV). In the same manner, Thin BBP contained three components (530.6, 532.9 and 535.1 eV), and thick BBP film had three (531.5, 532.8 and 534.4 eV). Chemical shifts in O 1s are generally difficult to be assigned; however, the components at 530.1-530.6 eV were assigned to metal oxides and peaks at 531.5-533.4 eV to organic bonds, such as C-O, C=O, O=C-O [25]–[27]. The small components around 534.5-535.1 eV could be water or oxidised graphene [30]–[32].

From these chemical shifts, the heating process was found to affect the chemical conditions; metal oxide peak, which is probably iron oxide in this case, vanished

Table 5 *The average chemical compositions of GBP and BBP films in atomic percent*

Atomic %	C	O	Fe	N	Mg	P	Mn	Ca	S	K	Cl	Si
Thick GBP	59.3 ±1.3	35.3 ±0.9	0.8 ±0.1	0.7 ±0.1	-	0.2 ±0.1	-	1.4 ±0.1	0.6 ±0.1	1.0 ±0.3	0.4 ±0.1	0.4 ±0.1
Thin GBP	55.1 ±2.0	35.0 ±0.8	7.2 ±0.8	1.8 ±0.3	-	0.5 ±0.2	0.5 ±0.2	-	-	-	-	-
Thick BBP	55.2 ±1.1	31.7 ±2.2	-	1.4 ±0.1	1.5 ±0.2	1.2 ±0.1	-	1.8 ±0.1	1.0 ±0.3	2.2 ±1.2	4.0 ±1.4	-
Thin BBP	63.3 ±0.3	28.8 ±0.7	3.4 ±0.4	2.8 ±0.3	-	0.8 ±0.3	0.2 ±0.1	0.7 ±0.1	-	-	-	-

after the heat treatment. This disappearance means that iron oxides are buried in the organic layer due to the heat treatment, supporting the idea developed from the iron concentration. Another suggestion from the chemical shifts is that oxidised graphene might be on the surface. Oxidised graphene has been reported to exhibit a large chemical shift around 534-534.5 eV, and this chemical shift is attributed to water contamination [30], [31] or oligomer of vinylene carbonate on graphene surface [32].

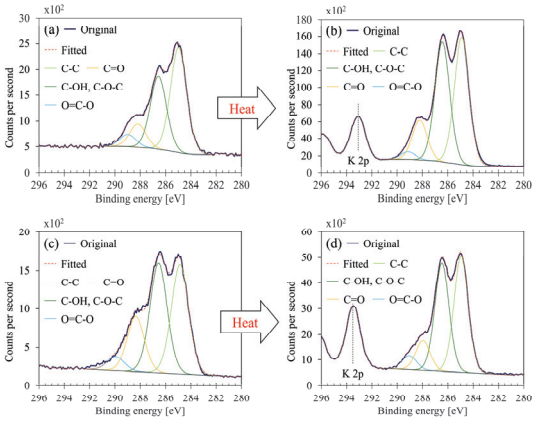

Figure 12 *C 1s curve fittings: (a) GBP thin film. (b) GBP thick film. (c) BBP thin film. (d) BBP thick film.*

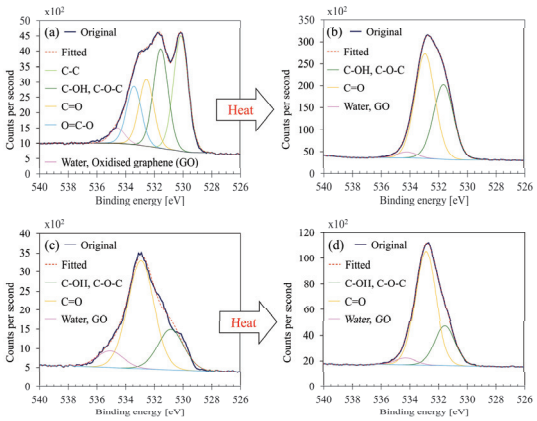

Figure 13 *O 1 s curve fittings: (a) GBP thin film. (b) GBP thick film. (c) BBP thin film. (d) BBP thick film.*

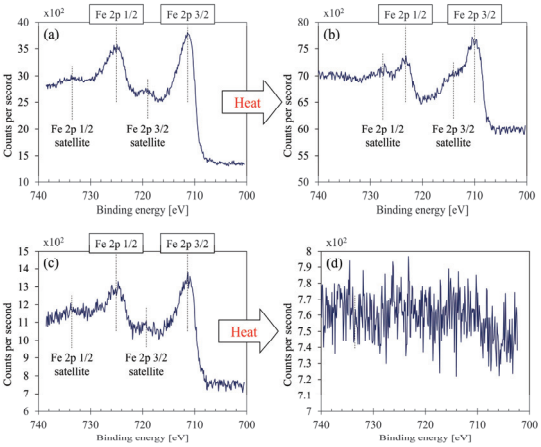

Figure 14 *Fe 2p curve fittings: (a) GBP thin film. (b) GBP thick film. (c) BBP thin film. (d) BBP thick film.*

Considering that the surface carbon seems to be partially graphitic as described in 3.3.3, the small component around 534.5 eV might come from the oxidised or water-contaminated graphite surface.

Figure 14 illustrates Fe 2p high-resolution spectra. The chemical shifts in Fe 2p 3/2 were 711.2 and 710.2 eV in GBP thin and thick films, respectively. Taking into account the satellite peaks, these chemical shifts should be from iron oxides, and they are mainly hematite (α-Fe_2O_3) and possibly magnetite (Fe_3O_4) [25], [26], [33]. In contrast, Fe 2p was not observed in BBP thick film although it was present in BBP thin film (711.2 eV, possibly Fe_2O_3). This is a clear difference between the GBP and BBP thick films, suggesting that the amorphous carbon layer on the BBP sample is thicker than that of GBP.

Chemical shifts in the other elements were also measured, although they are not shown here. The chemical shift of N 1s around 400.1 eV shows that organic matrix (C-NH_2) is likely in both GBP and BBP rather than nitrites or nitrates [25], [26]. Phosphorus is likely to exist as a metal phosphate, possibly bonding to calcium or iron. Calcium, sulphur, potassium and chloride were mainly assigned to $CaSO_4$ and KCl respectively, as they were detected in XRD analysis. Magnesium, silicon and manganese do not seem to involve the chemical reaction since they were occasionally detected and their concentrations were less than the others.

3.3.5. Fourier Transform Infrared Spectroscopy (FT-IR)

Figure 15 shows the FT-IR spectra of GBP and BBP with the original GLP and BLP spectra for comparison. Both GBP and BBP exhibited a similar absorbance: around 3250, 2930, 1600, 1400, and 1100 cm^{-1}. In contrast, the GLP and BLP showed more complex absorption with peaks around 3260, 2920, 2850, 1610, and 1030 cm^{-1}. However, some of the absorption bands can be assigned: OH stretching at 3260 cm^{-1}, CH stretching at 2920 and 2850 cm^{-1}, C=O double bonds around 1610 cm^{-1}, and C-O stretching around 1030 cm^{-1}. The comparison between BP and LP shows that the black material is different from raw leaves, e.g. less clear CH stretching or another peak of C=O in BP.

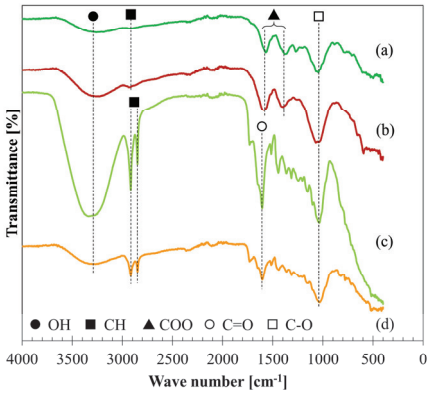

Figure 15 *FT-IR spectra: (a) GBP. (b) BBP. (c) GLP. (d) BLP.*

The assignment of each absorbance in GBP and BBP is shown in Table 6, referring to the literature [11], [18], [34]–[36]. The absorption around 3250 cm^{-1} was attributed to OH, which could form both types of hydrogen bonds: inter- or intra-molecular hydrogen bonds. The weak peak at 2930 cm^{-1} could derive from saturated CH bonds because unsaturated and aromatic CH frequencies are slightly over 3000 cm^{-1} and two sharp peaks should be observed in the case of methyl or methylene groups. In the same manner, NH stretching mode is unlikely because it shows relatively sharp peaks around 3500-3300 cm^{-1}.

Due to the unlikely presence of aromatic CH bonds, two absorbances were assigned to carboxylate ions (COO^-), which usually show doublet peaks at 1610-1550 (asymmetric) and 1420-1300 cm^{-1} (symmetric) [11], [18], [34]. C=O double bonds in esters or ketones could be possible in this region, which should appear around 1740 and 1710 cm^{-1}, respectively [34]. However, the significant shifts of the observed absorptions to lower wavenumbers clearly shows that they derived from carboxylate ions rather than esters and ketones. N=O double bonds are possible in this region; however, they are unlikely due to the small atomic concentration of nitrogen and the chemical shift found in 3.3.4.

The band around 1030 cm^{-1} should be CO stretching mode which comes from various organics in GBP and BBP. Further analysis and assignment were not conducted for this CO bond since the region below 1500 cm^{-1} has many overlaps and is not diagnostically useful [34].

Considering the presence of Fe^{2+} or Fe^{3+} on the surface as described in 3.3.4, it is likely that iron-carboxylic salt is formed in GBP and BBP underneath the surface. Fe ions could form a chelate (ligand) structure with some carboxylates, such as oxalate (ferric oxalate) and acetate (ferric acetate) [37], [38]. Synthesised metal carboxylates exhibit COO^- absorption around 1510-1590 cm^{-1} for asymmetric mode and 1400-1430 cm^{-1} for symmetric mode [36], which roughly corresponds to the observed values in GBP and BBP.

RS and XPS analysis suggest that iron oxides are likely rather than iron carboxylate. However, the thermal energy by laser irradiation in RS could induce the transition of iron carboxylate to iron oxides. Moreover, XPS does not reflect the bulk properties, and the chemical shifts of ferric oxalates in XPS show approximately the same values as iron oxides [39]. Considering all the information from RS, XPS and FT-IR analyses, it is concluded that both GBP and BBP could contain both iron carboxylates and iron oxides, and iron carboxylates are predominant in the bulk black material. Therefore, the iron carboxylates are formed with dissolved Fe ions and carboxylic acids in LEs, then some of them transform to iron oxides due to further oxidisation, especially on the surface.

Table 6 *Assignment of each infrared band in GBP and BBP*

Assignment	GBP absorption cm^{-1}	BBP absorption cm^{-1}	Reference
OH stretch	3280	3232	[34]
CH stretch	2934	2938	[34]
COO^- ion Asymmetric Symmetric C=O stretch	 1570 1379	 1593 1398	 [11], [18], [34]–[36]
CO stretch	1046	1071	[11], [34]

4. Discussion

In this study, tribological tests were performed as well as material analysis of the black precipitation. Consequently, it was revealed that the black precipitation was the primary material of low adhesion and it consisted of iron and organics after the chemical reaction process. The low adhesion mechanism should be discussed in this section, as well as the chemical reaction process for the formation of black precipitation.

4.1. Low adhesion mechanism

As described in 3.2, BP was identified as the main leaf-lubricant for low friction, as well as solid leaf powder, although solid leaves seem to have a limited effect. The material analyses described in 3.3 revealed that BP was likely to contain graphitic carbon, iron oxides and phosphate compounds. To sum up, the low adhesion conditions seem to be caused by four factors: graphitic carbon, solid leaf, iron oxide and phosphate compound.

Figure 16 shows a schematic diagram of the low adhesion mechanism due to leaves on the line. Graphite has been recognised as a solid lubricant and widely used [40]. Although the synthesised black material does not have a perfect graphite structure, it should be partially graphitised and be able to contribute to low friction conditions. Solid leaves can reduce the friction level when they are present in the contact area, preventing contact between wheels and rails. Iron oxides are also well-known for their lubricity in the wheel/rail contact [4], [24]. Phosphate compounds are one of the typical anti-wear additives for lubricating oils, such as Zinc dialkyl-dithiophosphate (ZDDP). In particular, iron phosphate films formed on steels have been reported to protect the iron surface and reduce wear [41], and its mechanism has been explained [42]. Furthermore, if the phosphate in BP forms a phospholipid, it dramatically decreases the friction levels in wet conditions [43].

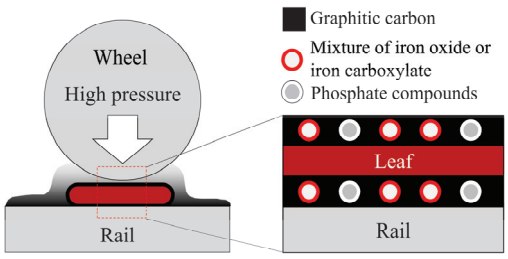

Figure 16 *Schematic figure of low friction mechanism due to leaves*

Considering the concentration of these materials, the graphite-like carbon should be the predominant cause, followed by bulk leaves and iron oxides, and the phosphate compounds might have a limited effect on low friction. Furthermore, the thickness of carbon layers grown on iron oxides or iron carboxylates could have a significant effect on low adhesion, because BBP had a thicker carbon layer and only BBP caused very low friction.

The synthesised black material was found to contain potassium chloride (KCl) and calcium sulphate ($CaSO_4$), and they might be lubricants as well. However, the reported COF of KCl thin films in an ultra-high vacuum chamber is not significantly low, around 0.27 [44]. Additionally, $CaSO_4$ has a low COF between 0.15 and 0.2 at high temperature (500 or 600 °C), but it is generally brittle at room temperature and does not work as a lubricant [45], [46]. Thereby, KCl and $CaSO_4$ in the synthesised black powder are unlikely to be a lubricant.

4.2. Literature review of a chemical reaction

In this study, organics in leaf extracts were found to involve the chemical reaction with dissolved iron ions, and they should be carboxylates and able to form a chelate structure with Fe ions. Moreover, sugars could be the source of the organic layer on the top. To find out a possible theory of a chemical reaction process between organics and iron, literature was reviewed.

Taking into account the results of RS, the Maillard reaction could be the most realistic candidate for the black material formation. The Maillard reaction is caused by reducing sugars and amino acids, and odorous brown pigments, called melanoidin, are generally produced after the reaction [47], [48]. Both GBP and BBP have a strong and honey-like smell, especially after the boiling process. Furthermore, nitrogen was detected in XPS analysis with the chemical shift of organic matrix containing nitrogen, which might come from amino acids buried in the BP.

Reducing sugars, such as glucose and fructose, have been detected in tea, as well as amino acids, such as glutamine and threonine [21], [49], [50]. Leaf extracts used in this study are practically a cup of sycamore tea; therefore, the Maillard reaction could happen in terms of materials. Furthermore, iron and iron oxide have been reported to promote the Maillard reaction [51], [52]. Additionally, melanoidin is known to have antioxidant activity [47]; melanoidin can catch metal ions, possibly forming a chelate structure with them [53]–[55]. These facts seem to have a close linkage to the findings in this study: sugar-derived carbon in RS and chelate structure of iron carboxylate in FT-IR. In fact, the FT-IR spectrum of Maillard reaction products presented in [47] has very similar absorption bands: 3411, 1635, 1404 and 1076 cm^{-1}.

Another possibility to produce a black pigment with organics and irons is iron-based ink, such as iron-gall ink [56]–[59]. Although the chemical reaction process has not yet been elucidated, black pigments can be made with irons and tannin-derived polyphenolic compounds, such as gallic acids, ellagic acids and catechin derivatives. They have been detected in tea as a water-soluble material [21], [50], [60], and also they can form a chelate structure with iron oxides [61]–[63], which shows a good agreement with the results in this study. Moreover, the FT-IR spectrum of the laboratory-made iron gall ink shows similar absorption patterns (1640, 1424 and 1083 cm^{-1}) [57]. Furthermore, RS spectrum of iron gall ink and historical ink sample also exhibits similar Raman shifts: 1475, 1310 and broad 640-490 cm^{-1} in [59] and 1590, 1315 and 1006 cm^{-1} ($CaSO_4$, detected in XRD and XPS analysis in this study) in [56].

It could be possible to suppose that organic acids simply form a chelate structure with dissolved iron ions, and then a further chemical reaction occurs on its surface. For example, oxalate or malate can be found in plant leaf extracts [49], [64], and ferric oxalate or iron malate could be formed in LEs. Alternatively, iron ions might be able to react with gluconic acids [35] or form an iron-sugar complex [65], [66], although the possibility seems lower than the other candidates.

To summarise, three candidates that can explain the chemical reaction process are proposed through the literature review: Maillard reaction, iron-based pigment and organic acid.

4.3. Possible chemical reaction process

A chemical reaction process is supposed as shown in Figure 17. Firstly, Fe ions are dissolved into LEs, possibly with the help of organic acids. Then, the dissolved Fe ions form a chelate structure with carboxylic acids or tannic acids in LEs, as suggested in FT-IR analysis. Subsequently, Fe ions are wrapped with

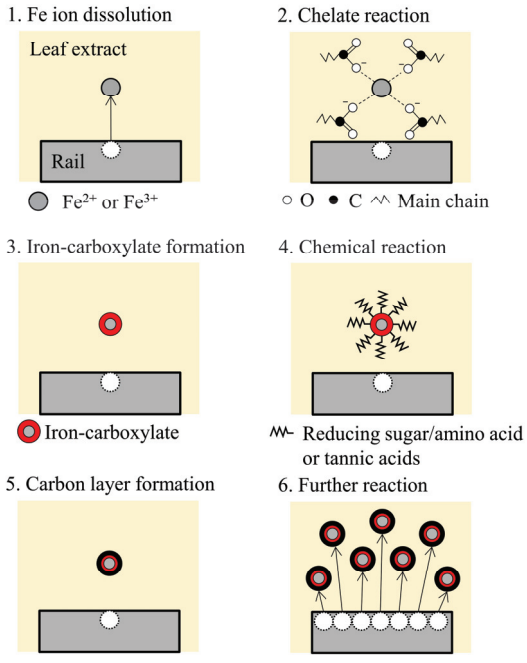

Figure 17 *Supposed chemical reaction process*

organic molecules such as reducing sugars and amino acids. At step four, a chemical reaction occurs with organics on the surface of Fe ions, forming a carbon layer on the surface; it could be the Maillard reaction or formation of iron-gall ink. The process one to five can be applied to other dissolved Fe ions, and finally, black precipitation is formed with a three-layer structure: carbon layer on the surface, chelate layer in the middle and Fe ion as a core.

It should be noted that this process is a suggestion based on the information from the material analysis of the black materials, which were synthesised in the laboratory. In the actual wheel/rail contact, high pressure applied to leaves could affect the chemical reaction process, as well as high temperature induced by sliding in the wheel/rail contact [4]. To examine the proposed chemical reaction process, further experiments and analyses are necessary: identification of key organics in leaf extracts and comparison between a laboratory-developed black material and a blackened leaf film seen on the actual railway tracks.

5. Conclusions

In this study, the low friction mechanism due to leaf contamination on railway tracks was investigated through pin-on-flat tests and material analyses, as well as the chemical reaction process between leaf organics and rail steels. Six types of leaf-related sample were tested: sycamore leaf powder, leaf extract and black material for green and brown sycamore leaves. The black material was synthesised with leaf extracts and rail steels (R260), and especially, the black material formed in brown leaf extracts exhibited extremely low friction for 6 minutes, which is similar to that of the commercial engine oil. The leaf powder also lowered the friction level for the first 1 minute; however, the leaf extract did not show low friction. Material analyses were intensively conducted for the black material, using five techniques: X-Ray Fluorescence, X-Ray Diffraction, Laser Raman Spectroscopy, X-Ray Photoelectron Spectroscopy and Fourier Transform Infrared Spectroscopy. These analyses revealed that dissolved iron ions in leaf extracts react with organics, such as reducing sugars, amino acids and tannic acids, possibly forming a chelate structure. Then, the graphitic carbon layer is formed on the formed iron carboxylates or iron oxides with a small amount of KCl, $CaSO_4$ and phosphate compounds. This carbon material is seemingly a result of the Maillard reaction or iron-gall ink formation. Therefore, the low friction was concluded to be caused by four factors: firstly graphitic carbon, secondly bulk leaves, thirdly iron oxides, and finally phosphate compounds in the black material. The chemical reaction process was proposed; however, further experiments and analyses are necessary to examine this proposal.

Acknowledgements
We gratefully acknowledge the financial support from East Japan Railway Company and Railway Safety and Standard Board. We would also like to thank Mr. Robert J Hanson at the Department of Chemistry, University of Sheffield, for his assistance with the FT-IR analysis, and Mr. Anup Chalisey at Railway Safety and Standard Board, for comments that greatly improved the manuscript of this proceedings.

FRICTION BETWEEN PEARLITIC STEEL SURFACES

Casey Jessop [1,*], Johan Ahlström [1]

[1] Department of Industrial and Materials Science, Chalmers University of Technology, Gothenburg, Sweden

[*] E-mail: casey.jessop@chalmers.se

Abstract: Experiments rubbing two pearlitic rail steel surfaces against each other were done using an axial-torsion test rig. After the experiments were completed, the surfaces were observed under stereomicroscope, and the wear debris were examined. The aim of the experiments was to evaluate the variation of friction coefficient between two surfaces of pearlitic rail steel, mimicking the friction which occurs between the faces of a crack during Rolling Contact Fatigue (RCF) loading. For both dry and wet conditions, the sliding velocity, the angles of rotation, and the average normal force were varied. It was found that the most significant effect of changing angles of rotation is on the formation of ridges on the contact surface with large angles, leading to a higher friction coefficient. The presence of water reduces the friction coefficient and leads to less deformation and wear in the contact surface.

Keywords: Rail steel; rail-wheel tribology; rolling friction; sliding wear; third-body layer.

1. Introduction

In the railway industry, tribology is an important topic since the contact in between rails and wheels are subjected to varying temperature and climatic conditions in operation, which affect both friction and wear. Another important concern is the effect of environment on crack face tribology, that is, the contact between crack faces during crack propagation due to Rolling Contact Fatigue (RCF) loading. The effect of crack face friction on the propagation of subsurface cracks has been studied in the past [1], [2], however, since these cracks have no opening to the surface, the penetration of water and other fluids was not considered in the models. Nevertheless, the presence of water or another fluid is thought to be necessary for the propagation of squat and squat-type defects in rails [3], [4], and it is thought that the friction has an important effect on crack propagation and branching [3], [5]–[7].

Furthermore, the presence of third-body materials such as oxides or sheared bulk material, are also important considerations [5], [6]. Several studies have been conducted using, for example, pin-on-disk and test rig experiments, and the analysis of third-body materials present in field as a consequence of wheel-rail contact in different stick and slip conditions, have been compared to laboratory experiments [4], [8], [9].

Squats and squat type defects are of particular interest in the field of RCF in rails. The darkened surface associated to these defects is thought to originate from a depression of the surface, due to the loss of material/wear occurring between the crack faces, which causes the surface of the rail not to be worn at a different rate than the rest of the rail. The growth of squats is significantly influenced by the crack face friction as well as the presence of fluids and wear debris. These phenomena remain less studied than the crack initiation associated to squats. However, crack face friction has a major influence on the crack growth since the friction as well as the surface asperities which are present on the crack faces have an influence on the stress intensity factors (SIF) in Mode II and Mode III loading, as well as on crack closure (Mode I loading). Research done on shear mode crack propagation has also shown that the main driving forces for branching of Mode II cracks are crack face friction and wedging, caused by surface asperities [10], particularly if the contacting crack faces are closed [11].

The present study evaluates the friction between two pearlitic R260 rail steel surfaces in different combinations of compression and torsional loading under dry and wet conditions in order to determine the influence of these parameters on the friction coefficient.

2. Experimental

The aim of the experiments is to evaluate the friction coefficient between two surfaces of pearlitic rail steel, mimicking the friction which occurs between the faces of a crack in a rail during train operation. Two halves of a test bar (shown schematically in Figure 1), representing the crack faces, are subjected to a normal force and rotated back and forth against each other in different conditions.. The product of the normal stress and the friction coefficient is equivalent to the friction stress which is present between opposing crack faces under ideal contact conditions [10]. All tests were run in a MTS 809 axial-torsion servo-hydraulic testing machine with closed loop control. The tests were run in axial force, and torsional rotation control, and in some tests an extensometer was used to measure axial and torsional strains locally with high precision. The test bars were in machined condition. The effect of the different conditions is measured using the friction coefficient as a basis. The parameters which are varied are the sliding velocity (rate of rotation), the angles of rotation (stroke/length of sliding movement), and the average normal force (see Table 1). A more detailed description of the test parameters for given tests are included in Table 2. After the experiments were completed, the surfaces were

observed using optical microscope and the wear products evaluated.

Table 1 Experiment parameters.

	Min	Max
Rate of rotation	0.1 °/sec	5 °/sec
Angles of rotation	± 0.5°	± 10°
Normal force	-0.5 kN	-8 kN

Table 2 Detailed parameters of tests included in results. (Tests 19 and 20 were run in wet conditions.)

Test	Rate of rotation (°/sec)	Angles of rotation (°)	Normal force (kN)
5	5	5	0.5
9	5	1	2
11	5	5	2
15	1	5	4
16	1	5	4
17	5	5	4
18	5	5	4
19	*1*	*10*	*4*
20	*1*	*5*	*8*
23	0.1	1	4
26	0.5	0.5	4
28	0.1	0.5	4
29	0.5	10	4

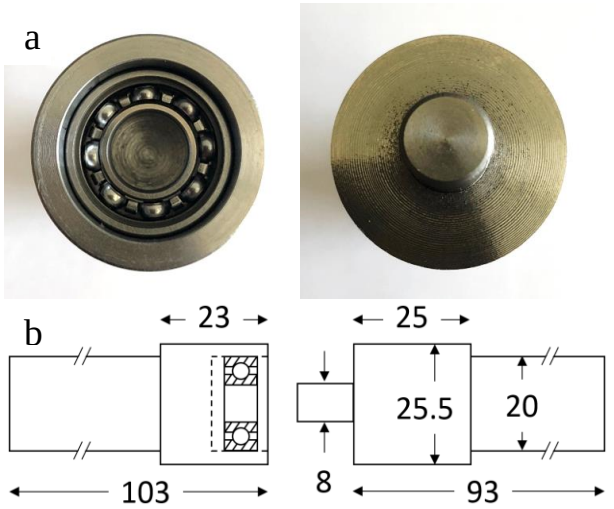

Figure 1 (a) Top view of R260 rail steel surfaces in machined condition, and (b) schematic of test bar used in friction experiments with dimensions in mm.

The friction coefficient is determined by measuring the torque during the experiments. That is, the friction is determined by the torque required to rotate the sample under a given normal force. The exact position of the spots in true contact are not known, but the reasonably thin, circular contact band enables an approximate quantification according to:

$$\mu = T/F \cdot r$$

Where T is torque [kN·mm], F is the normal force [kN], and r is the average radius in the contact [mm].

Tests were run in dry and wet conditions at room temperature. For the wet set up, a funnel filled with deionized water was attached to the test bar, as shown in Figure 2. The surfaces are initially dry; the water is only added to the funnel after the faces of the two halves are pressed together with the full axial load, and the contact surface is thus sealed. That is, the water only surrounds the test bar, and any penetration which occurs is due to the intrusion of water in between the steel surfaces during twisting.

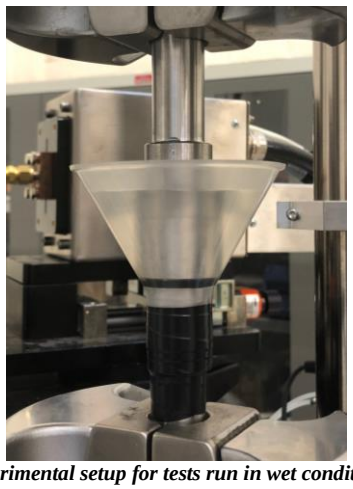

Figure 2 Experimental setup for tests run in wet conditions. The test bar is surrounded by deionized water and mounted into the machine.

The rotation sensor of the machine was found to give a sufficient measure of the relative motion/rotation of the steel halves. This can be shown from the relation between the rotation measured by the machine sensor and that measured by the extensometer. The correlation is found using the following relation:

$$\tan(\varphi) = r \cdot \theta / L$$

Where φ is the torsional strain [rad] measured by the extensometer on the test specimen, r·θ is the torsional rotation measured by the machine rotation sensor, and L is the distance between the extensometer pins [mm]. Figure 3 (Test 25) shows the direct relation between the rotation measured from the machine and that from the extensometer. The first cycle (shown as the dashed line) is different from the remaining cycles in the experiment. The points lie on two lines with slope approximately equal to 1. The reason for the two lines is the rotation direction, that is, the top line is the clockwise rotation, and the bottom line is the counter-clockwise direction. This graph makes it evident that the rotation sensor and the machine rotate the given angle range (i.e. +0.5° to –0.5°), and that the movement is identical during the slide (slope 1:1), but there is a delay before true sliding starts after each turning point. The transition between the two straight lines is due to elastic and plastic strains in the machine, gripping and test bars on the change in direction of rotation of the machine. On sliding under constant torque, the relation is constant, and the rotation sensor is a sufficient measure of relative movement in the contact surface.

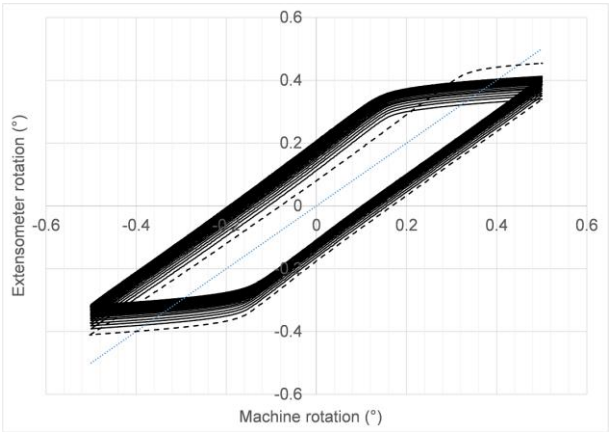

Figure 3 Correlation between the machine rotation ($r\cdot\theta/L$) and the relative rotation of the test specimen ($\tan(\varphi)$) during testing. The "points" lie on two lines with slope ~1, showing the direct relation between the rotation measured by the machine and the extensometer. (The first cycle is shown with dashed line, and a 1:1 slope is plotted for reference.)

3. Results

The results from the experiments evaluating the effect of varying the rate of rotation (0.1°/sec to 5°/sec), the angles of rotation (±0.5° to 10°), as well as the average normal contact force (-0.5 kN to -8 kN) on the friction coefficient are presented, and the effect of each parameter is treated its own section.

3.1 Rotation

The friction coefficient seems to be dependent of the direction of the rotation, that is, the clockwise direction always has a higher friction coefficient than the counter-clockwise rotation. This can clearly be seen in Figure 4, where experiments were repeated with first cycle starting in clockwise (+) and counter-clockwise (-) directions. Higher values are measured for the clockwise direction. However, the maximum and minimum values of the friction coefficient, as well as the average, remain approximately the same in all tests irrespective of the initial rotation direction, as seen in Table 3.

Table 3 Friction coefficient values for direction of rotation.

Test	Direction	Rate of rotation (°/s)	Friction coefficient			
			Max	Min	Diff	Ave
15	+	1	0.65	0.57	0.08	0.61
16	-	1	0.68	0.59	0.09	0.64
17	-	5	0.67	0.58	0.09	0.63
18	+	5	0.70	0.61	0.09	0.66

It can also be seen from Figure 4 that the rate of rotation does not have a significant effect on the measured friction coefficient. All parameters except the rate of rotation were kept the same for both series. Tests 15 and 16 were run at 1°/s and Tests 17 and 18 were run at 5°/s. The minimum and maximum values of the friction coefficient are approximately the same.

Furthermore, the effect of the angles of rotation on this effect can be seen in Figure 6. The experiments were repeated for the same overall distance of contact. Test 28 was run for 1000 cycles with range ±0.5°, and Test 29 was run for 50 cycles with range ±10°. It can clearly be seen that the difference between the measured friction coefficients based on the direction of rotation is decreased when the angles of rotation are decreased. It was also found that the friction coefficient stabilizes already within the first 30 cycles in Test 29, while it takes nearly 500 cycles to stabilize in Test 28. It should be noted that these cycles are equivalent to approximately 120 mm and 100 mm of travel, according to the machine rotation, respectively. In addition, no significant effect of the rate of rotation can be seen between Test 28 and Test 29, which were run at 0.1°/s and 0.5°/s, respectively.

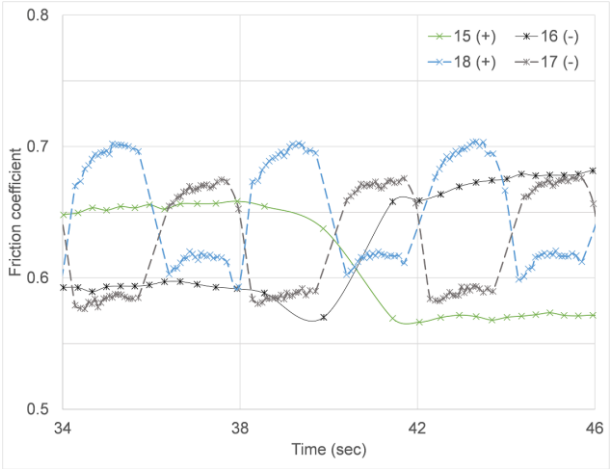

Figure 4 Friction coefficient as a function of time, showing the effect of the direction of rotation. Maximum values are obtained for the half-cycle with clockwise rotation.

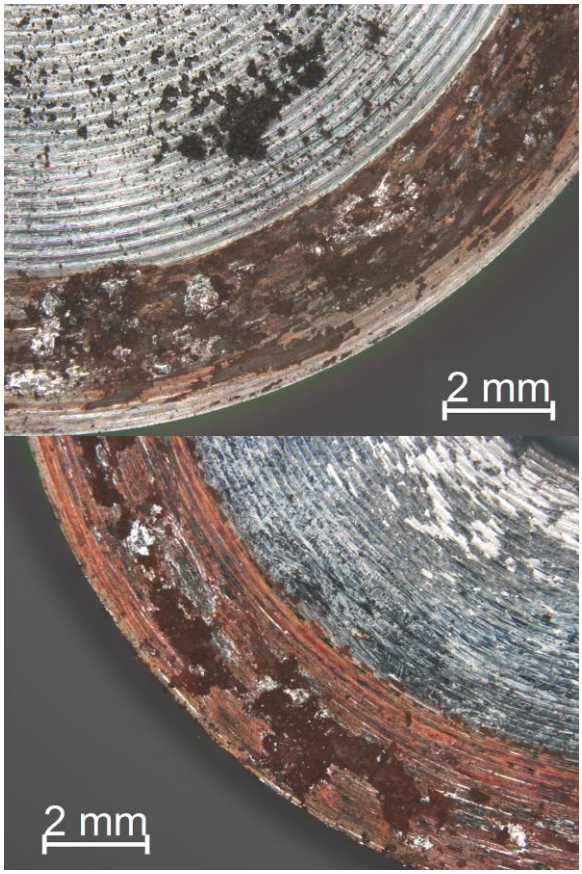

Figure 5 Surface of test bars after testing with first cycle starting in clockwise (top) and counter-clockwise (bottom). No difference is observed.

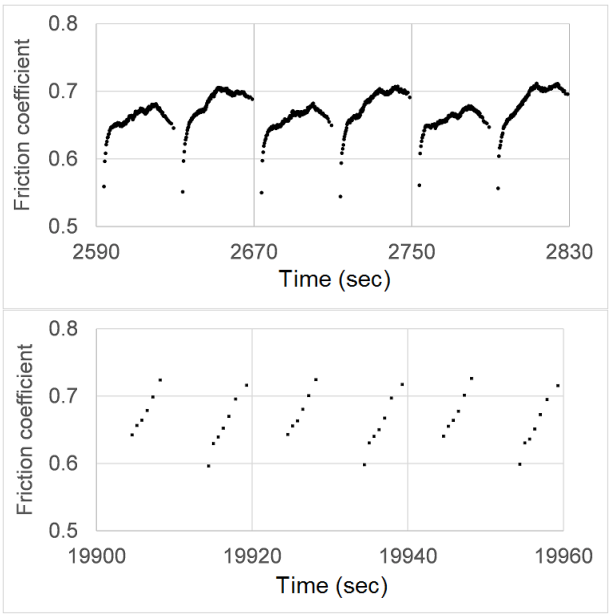

Figure 6 Friction coefficient as a function of time. Each vertical gridline corresponds to the time for one cycle. That is, two separate series of points are obtained for the clockwise and counter-clockwise rotations. The effect of the direction of rotation is evident in (top) Test 29, however almost non-existent in (bottom) Test 28.

3.2 Normal force

Figure 7 shows the torque versus angle of rotation for several experiments. It can be seen that the torque increases with increasing compressive normal force. This is expected since the torque is directly related to the applied normal force, as previously mentioned. However, there seems to be a more stable behaviour between the torque and rotation with larger angles of rotation that is, less spread in the measured values of the torque.

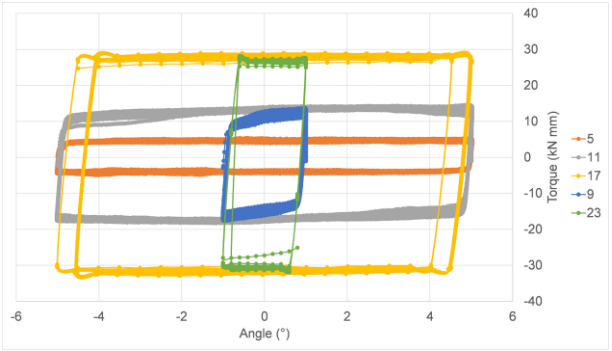

Figure 7 Effect of varying normal force and angles of rotation on Torque.

Large variations of friction coefficient measurements with respect to the direction of rotation are seen in, for example, Figure 4, however the effect is diminished with larger compressive forces. For this reason, most experiments were conducted with higher compressive forces of 2 kN or 4 kN, yielding nominal contact pressures of 70 MPa and 140 MPa, respectively. Figure 8 shows the effect of varying the normal force on the friction coefficient. It can be seen from Table 4 that the average value remains approximately the same, however the spread between the data points as well as the difference between the maximum and minimum values is significant for small normal force, and decreases with increasing normal force.

Table 4 Friction coefficient values for varying normal force.

Test	Normal force (kN)	Average contact pressure (MPa)	Friction coefficient			
			Max	Min	Diff	Ave
5	0.5	17.5	0.82	0.68	0.14	0.75
11	2	70	0.75	0.58	0.17	0.67
18	4	140	0.70	0.61	0.09	0.66

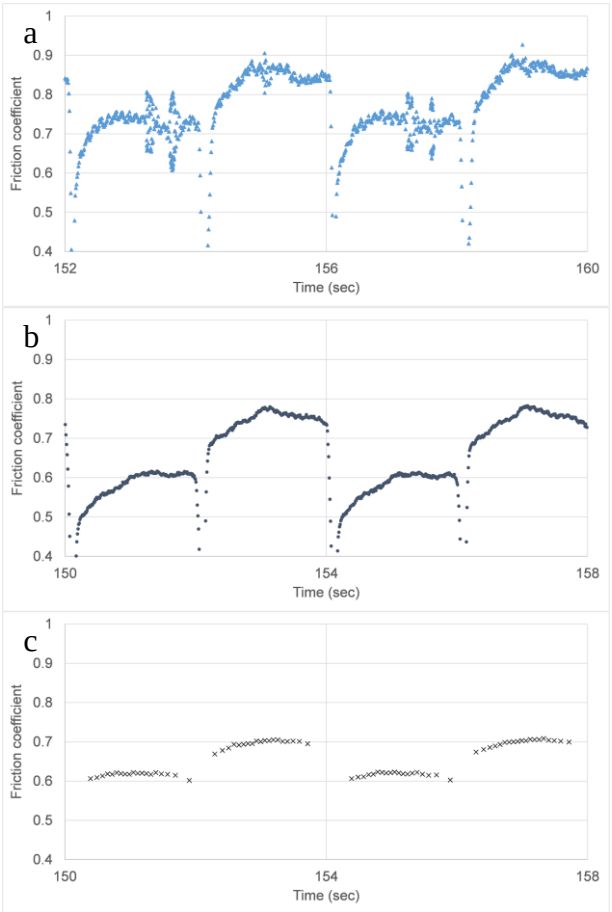

Figure 8 Friction coefficient with respect to time for different normal forces equivalent to: (a) 17.5 MPa, (b) 70 MPa, and (c) 140 MPa. The average friction coefficient remains the same, however the difference between the maximum and minimum values decreases with increasing normal force.

3.3 Dry vs wet

After the friction experiments, the surfaces of the test bars were investigated. Figure 9 shows the large deformation on the used test bars which occurred for testing in dry, room-temperature condition, as well as the significant amount of third body particles (wear debris) which can be observed when the halves are separated. The surface topography resembles that found in squat defects, which have been examined in previous work [12]. The ridges which are present on the crack faces, shown in Figure 9(c) are thought to originate from the relative sliding between the crack faces during the passage of wheels on the rails.

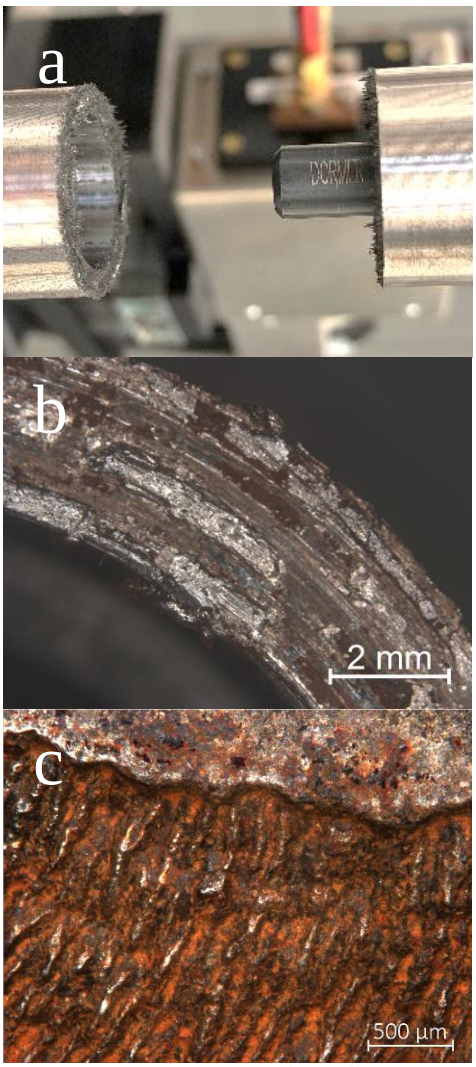

Figure 9 (a) Wear particles between surfaces after testing. (c) Surface of test bar after friction experiments resembling (b) detail of ridges on squat crack face.

Figure 10 shows the surfaces of the test bars after testing in dry versus wet conditions. It is clearly seen that the deformation and wear particles are more present on the dry test bar. Furthermore, it was observed that any wear which occurred on the surfaces of the wet test bars was near the inner radius of contact. That is, the exterior remains almost the same as the initial state. It can also be seen in Figure 12 that the friction coefficient is decreased when the tests are run in wet conditions. The average friction coefficient calculated for dry and wet conditions are 0.68 and 0.39, respectively.

Figure 10 Surfaces of test bar after testing in (left) dry and (right) wet conditions. The more pronounced deformation and wear in the dry conditions is apparent and a reflection of the larger coefficients of frictions calculated.

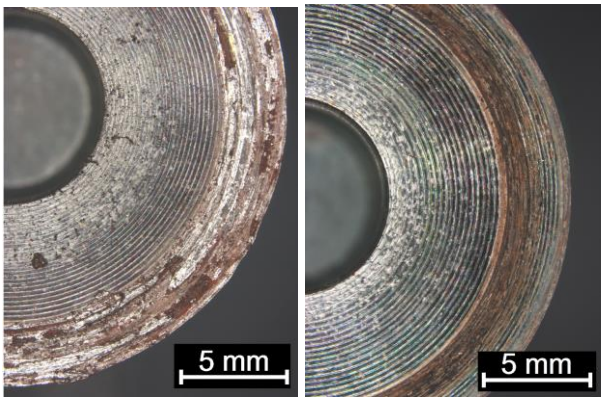

Figure 11 Surfaces of test bar after testing in (left) dry and (right) wet conditions. The more pronounced deformation and wear in the dry conditions is apparent and a reflection of the larger coefficients of frictions calculated. The periphery of the contact surface in the wet tests remains in original condition, while the inner radius is worn and corroded.

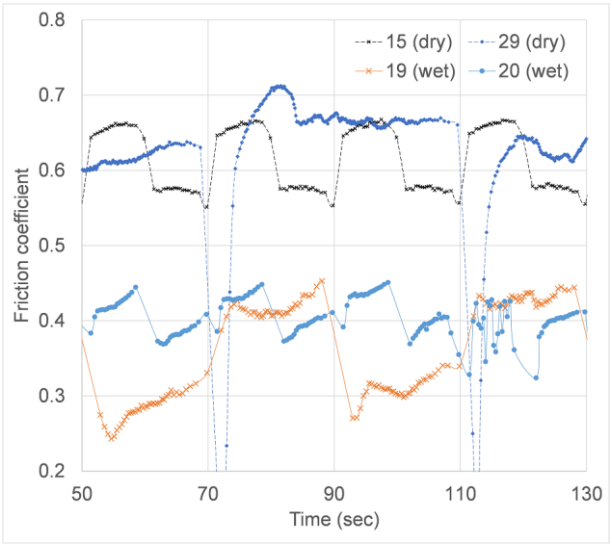

Figure 12 Calculated friction coefficient for tests in dry and wet conditions (140 MPa, ±5°, 1°/s).

4. Discussion

4.1. Rotation

With respect to rotation, the parameters which were varied were the range of angles and the rate of rotation. It was found that the friction coefficient is affected by the direction of the rotation (clockwise versus counter-clockwise). For this reason, the direction of the rotation was also investigated. As seen in Figure 4, the maximum value of friction coefficient is always obtained in the clockwise direction, and the minimum in the opposite direction. The maximum and minimum values, as well as the average, remain approximately the same regardless of the direction and rate of rotation.

However, although the average friction coefficient remains similar for difference ranges of angles, the difference between the maximum and minimum values decreases with decreasing angles of rotation, as shown in Figure 6. A possible reason for the directional dependence, which must be further investigated, is the starting topography of the test bars due to machining. A smaller range of angles of rotation would be less affected by the starting surface roughness. Furthermore, the effect

of the initial roughness on the formation of ridges is more significant at larger range of angles. The surfaces after testing, shown in Figure 13, show little deformation and wear in the test with small range of angles of rotation, and the periphery remains untouched (shown in detail in Figure 14). Meanwhile, the larger angles of rotation lead to a more uniform deformation along the entire contact surface. Similarly, it has been found that an increased stabilized friction coefficient results due to larger rotation angles due to the larger tangential force induced by a more severe surface [13]. It can also be seen that the layer of debris on the small angles sample is uniform and quite dense. The one on the larger angles is more "loose" and accumulates in certain areas. Some areas remain untouched on the surface as well, and this seems to coincide with where the wear debris accumulate. The presence of these debris is thought to have an effect of the stabilization of the friction coefficient, through the "dynamic balance between debris escape and formation at contacting surfaces" [14].

Figure 13 Surface deformation after same "sliding distance". The rate or rotation and normal force are the same for both tests, the only varied parameter is the range of angles: (top) ±0.5°, and (bottom) ±10°.

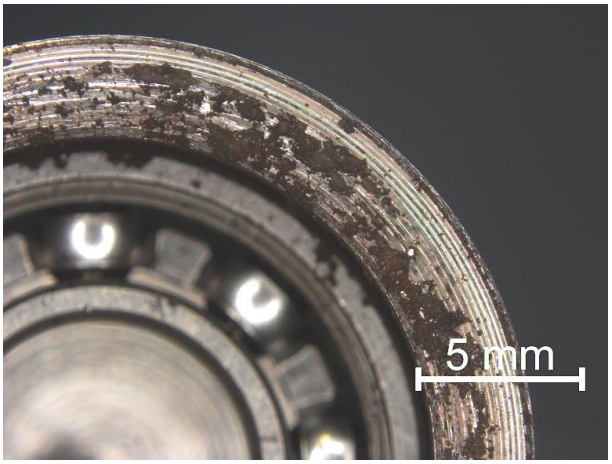

Figure 14 Surface after testing. The deformation and accumulation in concentrated in the centre of the contact surface, while the periphery essentially remains as initial condition.

4.2. Normal force

The results presented show that an increase in the normal force causes an increase in the torque measured. As mentioned, this is to be expected, since the torque is directly related to the applied normal force. However it was found that the behaviour is more stable with increased normal loads. This could be related to the initial surface texture present on the steel test bars, for which a higher compressive load would keep the contact between asperities the same throughout the rotation, causing less fluctuation.

Furthermore, the directional dependence of the friction coefficient remains for tests in the range of normal forces examined. However, the spread between the friction coefficient values calculated in one direction versus the opposite is less significant for higher loads, as shown in Figure 8. This can also be related to the torque, since the friction coefficient is simply a factor between the normal force applied and the measured torque.

4.3. Dry vs wet

The test bar surfaces were observed after testing in dry and wet conditions. It was observed that there is large deformation occurring for the dry tests, especially at large angles of rotation, accompanied by a large amount of wear debris. However, the test bars from wet condition remain almost in the initial state, with some deformation and debris accumulation in the centre of the contact surface. This is in agreement with the friction coefficient values which have been calculated. That is, the larger friction coefficients calculated for dry testing conditions suggest more plastic deformation occurring, since friction is due in part to the deformation of the materials which are in contact. It seems the formation of ridges on the surface would increase the friction occurring between the steel halves, and this effect is more present with larger angles of rotation, as previously discussed.

In wet test condition, the deformation and debris accumulation occurs only in the smallest radius of the contact surfaces. This suggests that the intrusion of water in during twisting prevents wear of the outermost radius, which may be due to lower contact between the steel surfaces.

5. Conclusions

As a result of the present study, it can be concluded that:

(1) There appears to be a directional dependence of the measured coefficient of friction. The first half of the cycle (i.e. clockwise rotation) has higher values of coefficient of friction than the second half (i.e. counter-clockwise rotation).

(2) The initial smooth finish on the steel surfaces leads to an initially low coefficient of friction. After some run-in time, the coefficient of friction increases until it stabilizes. The friction coefficient then decreases slightly with more use. In terms of this effect on crack growth would be that the products of corrosion which

gather between the crack faces due to wear, will lead to a decreased coefficient of friction, since this third body layer acts as a lubrication. This in turn facilitates crack growth by increasing the net stress intensity at the crack tip.

(3) The repeated twisting of the two steel faces leads to the formation of asperities on the faces. This feature similar to the "ridges" which have been observed on the crack faces of so-called squats in railway rails. The compressive forces added to the twisting motion, imposes preferential deformation of the materials. It is thought that the surface asperities which appear on the surface of rolling contact fatigue cracks causes crack closure, which in turn will affect the SIFs related to Mode II and III, and hinder crack propagation.

(4) Increasing the angles of rotation increases the formation of ridges on the two surfaces, and leads to higher maximum coefficient of friction. Larger angles of rotation (e.g. ±10°) also lead to more significant directional dependence as compared to very small (e.g. ±0.5°) range. This effect could be due to the initial machined surface finish, but must be further investigated.

(5) The average coefficient of friction is similar for most experiments, however the variation during the tests (i.e. the difference between peak values) decreases with increasing normal force.

(6) The average coefficient of friction decreases when water is present between the steel surfaces. This decrease leads to less wear, and a smoother, uniform deformation of the surfaces. The deformation is concentrated in the inner radius of contact. It appears that the presence of water between the surfaces would lead to no wear/deformation as far as the water penetrates.

The effect of crack face friction on crack propagation is an important issue which requires further investigation. The purpose of the present study is to determine the changes in coefficient of friction from different parameters. The results are expected to provide suitable data for crack face friction in upcoming experimental and numerical studies of RCF crack propagation by the authors.

Abstract: Double-flange contact is a feature of a number of guided light transit systems. These systems are guided along a rail that fits into a groove in a wheel, both sides of the groove act as wheel flanges. The rail can contact both sides of the groove at the same time, producing contact conditions that are not included in classical wheel-rail contact theories. An improved wheelset axial slice projection method was proposed in this article in accordance with specific double flange structure of GLT. The geometric relation is used to analyze three cases of single-point contact, two-point contact and three-point contact. This paper presents the influence factors of derailment and applies it to determine design changes that reduce the risk of derailment. Derailment in this context means the vehicle is no-longer guided.

Keywords: Contact mechanics, rail-wheel systems; Guided Light Transit (GLT); double flange; derailment analysis.

1. Introduction

Guided Light Transit (GLT) is a public transport system that used to be manufactured by Bombardier Transportation [1]. GLT and the similar Translohr [2] are often described as the tram equivalent of rubber-tyred metro technology, but this is not strictly accurate [3]; while the GLT follows a central rail (Figure 1), the rail does not support the vehicle, and when not being guided, the actual wheels are as independent as those of a regular bus. The wheels of rubber-tyred metros, on the other hand, are bound and guided by their rails in the same way as are steel-wheeled trains.

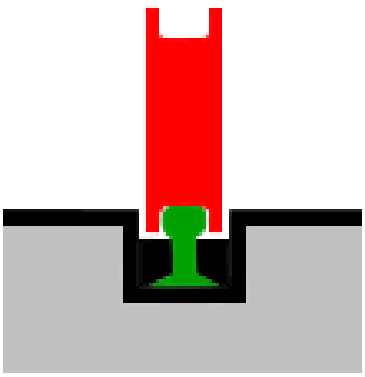

Figure 1 *Diagram of GLT guided wheel and rail*

A derailment of the guide wheel results in the vehicle following a different route to that intended; the supporting rubber wheels will still support the vehicle safely, but the vehicle can strike buildings, other vehicles, or pedestrians causing damage and injuries. There have been several derailments of vehicles using these systems, 22 were reported in the French city of Caen [1].

Figure 2 shows a derailment on a 15 m radius curve (tight curves are often associated with the derailments) that happened on a test line of a factory. This work was prompted by the need to understand and prevent these incidents.

Figure2 *Photo of derailment on a small curve*

2. Literature Review

The trajectory method and wheel set axial slice projection method are current algorithms that can be used to calculate the geometry of wheel-rail contacts. The trajectory method's rationale is to use a proper mathematical model to describe wheel-rail profiles based on the geometry of wheels and rails. In this method, all positions of wheel-rail contacts, once determined, are located on a curve. Then, by coordinate transformation of wheel-rail contact positions, the 3D problem of wheel-rail contacts is converted into a 2D problem [4]. By initially using geometric relations to find possible contact points on each segment of a suitably orientated wheel, this method reduces the initial contact problem to a one-dimensional minimization of separation distances. This permits the study of the spatial constraint relations between arbitrary wheel and rail profiles. Wang [5] used

this method to calculate the geometric parameters of contact in the presence of a non-zero angle of attack (the sin of this angle is the dot product of the wheelset axis unit vector with the rail generator unit vector). On the other hand, the wheel set axial slice projection method is used to slice the wheels axially so that the wheels' tread is discretized into curves. The curves are further discretized into coordinates in space. In this way, the wheels' treads become discretized surface points. Subsequently, by projection of these points into local coordinates of the rail, normal rail clearances are located and the contacts can be calculated [6].

Ayasse and Chollet [7] studied wheel/rail contact problems using a semi-Hertzian method; contact with strips along the rail were modeled using Hertzian theory with geometric interpenetration distances for each strip giving different conditions across the rail. The resulting contact profile was smoothed to remove non-physical sharp corners. Pascal and Sauvage [8] adopted a multi-Hertz method to investigate the contact match between a wheel with a S1002 profile and a rail with a UIC60 profile. Piotrowski and Kik [9] proposed an advanced computation method for wheel/rail contact based on virtual penetration theory.

In terms of roll freedom, single wheel is different from the traditional rigid wheelset. All of the above methods are based on the geometric relationship of two wheels in wheelsets, which does not apply to the analysis of wheel/rail contact relationship when the wheel has a double flange. Therefore, a new wheel rail contact algorithm is proposed and the conditions affecting derailment are analyzed.

3. Computation of geometric parameters of wheel-rail contact

3.1. Principles of solving wheel-rail contact

Wheel-rail contact is treated as rigid contact in both trajectory and wheelset axial slice projection methods, therefore satisfying the following two conditions:

（1） Wheelset and rail do not undergo elastic deformation and are regarded as rigid bodies;

（2） Wheelset and rail are in constant contact (occasional separation of the two can be ignored).

For conventional railway vehicles, only one group of vertical displacement z and roll angle ϕ values exists that satisfy the conditions of rigid contact for one group of lateral displacement y and yaw angle α values. z and ϕ values for different degrees of freedom and other contact parameters can be obtained by iterative simulations, since they are all functions of y and α and are characterized by one-to-one mapping relationships. Therefore, a contact table can be easily generated using discrete values of independent degrees of freedom y and α.

Both the trajectory method and wheel set axial slice projection method can be used for general wheel-rail contact problems for conventional railway vehicles, but this is not true for GLT. In general, the tread of GLT contacts with the top of the guiding rail which is an inverted U-shape (Fig.3a). A vertical load of up to 7.5 kN is applied to maintain contact. When negotiating a curve, there will be a large lateral force, and the wheel will contact the top and side of the guiding rail: two point contact (Fig3b). If the curve radius is too small, the guiding wheel can have a large yaw angle, and may contact both faces of the rail: three point contact (Fig3c). Once in three point contact it is possible for the wheel to seize up and derail.

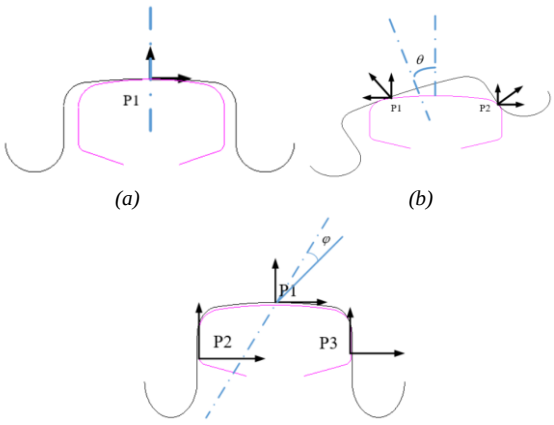

***Figure 3** Contact state of wheel and rail*

For the GLT's wheel, there are four degrees of freedom: (1) vertical displacement, (2) lateral displacement, (3) roll, and (4) yaw: all measured relative to the rail. Based on the wheel-rail contact geometry for GLT, we propose an improved wheel set axial slice projection method. Via coordinate transformation, the overall profile is divided into three parts. Then, multi-point contacts can be calculated by geometrical relationship. Once the contact areas' positions and size have been determined, normal contact force at the wheel-rail contact patches can be calculated by Hertz theory. Creep force can be solved using Kalker's simplified theory model for wheel-rail contact. From these calculations, a multi-dimensional contact table can be generated.

3.2. Coordinate transformation

For conventional railway vehicles, if any horizontal coordinate corresponds to one singular, definite vertical coordinate, the wheel-rail configuration can be described with a function. In the case of GLT, however, there is no one-to-one relationship. Thus, an improved wheelset axial slice projection method is developed in this study for solving these contact problems.

An ideal, straight rail is a cylinder, so all contour lines obtained by slicing the rail perpendicular to its axis are the same. Therefore, the profile of the guide rail's top surface is independent of longitudinal coordinate x, and related to the horizontal coordinate, y, and the vertical coordinate, z (Figure 4).

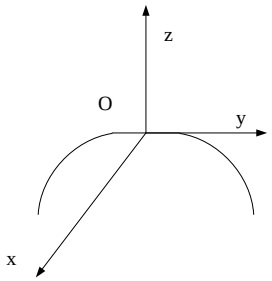

Figure 4 *Rail's coordinate system, Oxyz*

An idealised wheel is a surface of revolution of a contour line. The guide wheel's profile needs to be related to the rail's x, y and z coordinates. In the wheelset's coordinate system Gwx"y"z" (Figure 5), a plane x" = 0 is drawn to cut the wheel. The main contour line (x" = 0, y", z" = $z_0''(y'')$) is the intersection of this plane with the wheel's periphery. The intersection between the wheel and a set of n planes parallel to x" = 0 define a set of contour lines for x" = x_i', (i=1,2,...,n). The equations of these contour lines are related to the main contour line, since (x" = x_i'', y", z" = $\sqrt{z_0''(y'')^2 - x_i''^2}$).

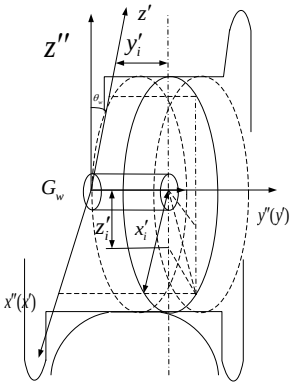

Figure 5 *Wheel set axial slice projection method*

The equations of all of the contour lines, constitutes the wheel tread's surface. We can transform the coordinates of each point on the contour surface to the rail's coordinate system. The wheel set's coordinate system is first rotated around the vertical (z") axis by an amount equal to the yaw angle φ_ω, and then around the longitudinal axis (x") by an amount equal to the side roll angle θ_ω. Thus, the coordinate system Gwx"y"z" of the wheelset is transformed to the coordinate system Oxyz of the rail.

$$\begin{cases} x = x''\cos\varphi_\omega - y''\cos\theta_\omega\sin\varphi_\omega + z''\sin\theta_\omega\sin\varphi_\omega \\ y = x''\sin\varphi_\omega + y''\cos\theta_\omega\cos\varphi_\omega - z''\sin\theta_\omega\cos\varphi_\omega \\ z = y''\sin\theta_\omega + z''\cos\theta_\omega \end{cases} \quad (3)$$

3.3. Computation of parameters of wheel-rail contact geometry

The wheel-rail contact of GLT is very special. There are three kinds of contact state between the single wheel and rail, one-point, two-point, and three-point. Because of the existence of two wheel flanges, the contact angle curve of the wheel is not monotonous (Fig.6). So when calculating wheel-rail contact points, it is rather troublesome to use the whole wheel profile. The wheel profile can be divided into three parts, see Figure76 Two connection points are used as segmentation points respectively. As shown in Figure 7, the contact angle at the connection point between the flange and the tread is less than the contact angle of the rail head.

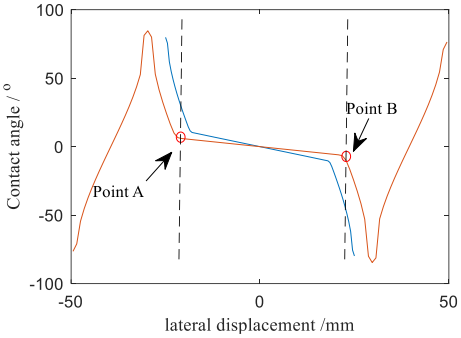

Figure 6 *The contact angle of the wheel tread and the rail profile*

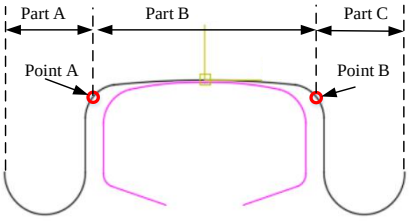

Figure 7 *Wheel profile division diagram*

According to the divided geometric profile of guiding wheel/rail, the improved wheelset axial slice projection method is proposed (Fig 8).

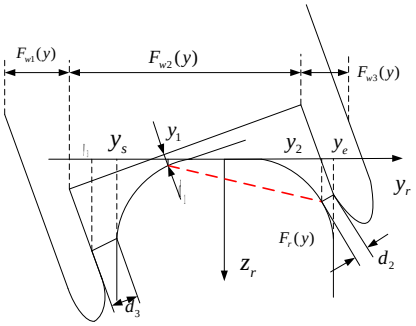

Figure 8 *A schematic diagram of multipoint contact calculation*

The distance between slices |x_i' - x_{i-1}"| has a direct bearing on computational accuracy in the wheelset axial slice projection method. When the distances are too large, the accuracy will be low. When they are too small, the computation load is too high. According to the literature [4], when non-zero yaw angle occurs, only the areas within D/8 (where D is the diameter of the wheel) on both sides of the main contour line of the wheel tread need to be scanned to determine all the contacts, regardless of other conditions. But in this paper, the yaw angle of the single wheel is greater than that of the wheelset. The scope of the calculation is expanded to D/4. The main calculation steps are as follows:

（3） Adjust the lateral displacement and yaw angle of the wheel.

（4） Set the roll angle as zero, and calculate the distance between the three parts of the wheel and the rail, d_1, d_2 and d_3. The location of the minimum value of d_2 in the middle part is calculated, and the other two distances are used as the judging conditions.

（5） If $\min[F_{w1}-F_r]>0$ and $\min[F_{w3}-F_r]>0$, it is a single-point contact. At this point, the degree of freedom of the roll is added. Change the roll angle and stop calculating until both of them is less than 0.

（6） If $\min[F_{w1}-F_r]<0$ or $\min[F_{w3}-F_r]<0$, it is two-point contact (Fig.8). modify value of roll angle

$$\Delta\theta=\frac{(F_{w2}(y_1)-F_r(y_1))-(F_{w3}(y_2)-F_r(y_2))}{F_r(y_2)\text{-}F_r(y_1)}$$

, and repeat step 3;

（7） If $\min[F_{w1}-F_r]<0$ and $\min[F_{w3}-F_r]<0$, it is three-point contact (Fig3c), the system has redundant constraints: stop calculating.

4. Computation of wheel-rail contact force

4.1. Creepage between wheel and rail Coordinate transformation

An important parameter for calculating the creep force in rolling contact is the creepage between the wheel and the rail. Carter was the first to discover the importance of creepage in the dynamics of rail vehicles; he defined longitudinal and lateral creepage[10]. According to Carter, the three different creepages are defined as follows:

$$\begin{aligned}\xi_x&=\frac{v_{wcx}-v_{rcx}}{v_0}=\frac{\Delta v_{cx}}{v_0}\\ \xi_y&=\frac{v_{wcy}-v_{rcy}}{v_0}=\frac{\Delta v_{cy}}{v_0}\\ \xi_n&=\frac{\omega_{wn}-\omega_{rn}}{v_0}=\frac{\Delta\omega_n}{v_0}\end{aligned}\tag{4}$$

where ξ_x,ξ_y,ξ_n are longitudinal, lateral and spin creepage, respectively. v_{wcx} and v_{wcy} are the wheels' longitudinal and transverse velocities at the contact point, respectively. v_{rcx} and v_{rcy} are the rail's longitudinal and transverse velocities at the contact point, respectively. ω_{wn} and ω_{rn} are the projection of angular velocities of the wheel and rail's rotations at the contact point onto the n_i direction, respectively. v_0 is the wheelset's nominal velocity.

Let $\mathbf{R}_c$ be the position vector of the contact point under the global coordinate system. As shown in Figure 5, the wheel is represented by:

$$\begin{aligned}\mathbf{R}_c&=xi+yj+zk+\Delta_y j'-rk'\\&=[x-\Delta_y\cos\theta_w\sin\varphi_w-r\sin\theta_w\sin\varphi_w]i\\&+[y+\Delta_y\cos\theta_w\cos\varphi_w+r\sin\theta_w\cos\varphi_w]j\\&+[z+\Delta_y sin\theta_w-rcos\theta_w]k\end{aligned}\tag{5}$$

where r is the left wheel's rolling radius; Δ_y is the contact point's transverse displacement relative to the equilibrium position; and a is the distance from the wheelset's central point to the left wheel's center.

According to the definition of creepage,

$$\begin{cases}\xi_x=\left[\mathbf{R}_c'\cdot\mathbf{e}_1-v\left(\dfrac{r}{r_0}\right)\cos\varphi\right]/v\\ \xi_y=\left[\mathbf{R}_c'\cdot\mathbf{e}_2\right]/v\\ \xi_n=\left[\boldsymbol{\omega}\cdot\mathbf{e}_3\right]/v\end{cases}\tag{6}$$

where, $\omega=\dot\theta i'+\left(\dfrac{v}{r_0}+\dot\varphi\sin\theta\right)j'+\dot\varphi\cos\theta k'$, $\mathbf{e}_1,\mathbf{e}_2,\mathbf{e}_3$ are fixed to the transient contact points on the wheel.

4.2. Creepage between wheel and rail Coordinate

Creep force can be calculated using Kalker's simplified theory for wheel-rail contact [8]. This can only be done, however, under the assumption that the elastic displacement in the contact area is, at any given moment, only related to the force acting on this point, and that the displacement in a specific direction is only related to the force acting in that specific direction. Three flexibility coefficients are introduced. The two tangential force components can be expressed as:

$$\begin{cases}p_x(x,y)=\left(\dfrac{\xi_x}{L_x}-\dfrac{y\cdot\xi_n}{L_z}\right)\left(x-a_0(y)\right)\\ p_y(x,y)=\left(\dfrac{\xi_y}{L_y}+\dfrac{x\cdot\xi_n}{L_z}\right)\left(x-a_0(y)\right)\end{cases}\tag{7}$$

where $a_0(y)=a\sqrt{\left[1-(y/b)^2\right]}$, $L_x=\dfrac{8a}{3GC_{11}}$, $L_y=\dfrac{8a}{3GC_{22}}$, $L_y=\dfrac{\pi a}{4GC_{23}}\sqrt{\dfrac{a}{b}}$, ξ_x,ξ_y,ξ_n are longitudinal, lateral, and spin creepage, respectively; a is the contact patch's long axis; b is the contact patch's short axis; G is the modulus of elasticity; and C_{ij} is the creep coefficient, which depends on $\dfrac{a}{b}$ and Poisson's ratio.

5. Dynamic analysis of a single wheel

Based on the above analysis, the location and contact force of the contact point can be obtained. As shown in Fig. 9, the following general equations of dynamics can

be obtained (When there is only one contact point, delete the relevant items of contact point 2.):

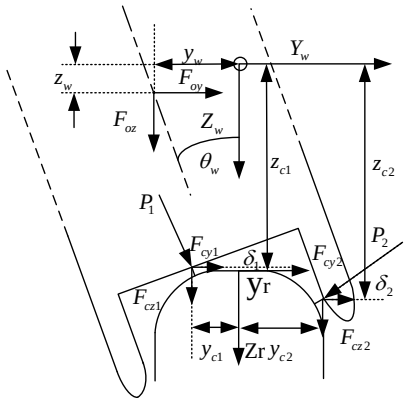

Figure 9 *Force analysis of single wheel*

$$\begin{cases} m_w\ddot{y}_w = F_{oy} + F_{cy1} + F_{cy2} + P_1\sin(\delta_1+\theta_w) - P_2\sin(\delta_2+\theta_w) \\ m_w\ddot{z}_w = F_{oz} + F_{cz1} + F_{cz2} + G_w + P_1\cos(\delta_1+\theta_w) + P_2\cos(\delta_2+\theta_w) \\ I_w\ddot{\theta} = F_{oz}y_w + F_{oy}z_w + G_w y_w + (F_{cy1} - P_1\sin(\delta_1+\theta_w))z_{c1} + \\ (F_{cz1} + P_1\cos(\delta_1+\theta_w))y_{c1} \\ \quad +(F_{cy2} + P_2\sin(\delta_2+\theta_w))z_{c2} + F_{cz2} + (P_2\cos(\delta_2+\theta_w))y_{c2} \end{cases} \quad (8)$$

where P is the normal force of the contact point; δ is the contact angle at the contact point. F_{oy} and F_{oz} are the lateral and vertical forces of primary spring; F_{cy} and F_{cz} are the lateral and vertical components of the creep force. G_w is the weight of the wheel.

6. Dynamic analysis of a single wheel

6.1. Dynamic simulation model

The dynamic simulation model of the GLT tram consists of five bodies, four axes, and four guiding devices. To simplify the model, four parallel connected rods in the bogie are considered as a whole body, and a virtual body of negligible mass and moment of inertia is introduced to link the tyre and the guide device. The rotation angle of the tyre is then consistent with that of the guide device. The rigid bodies are linked by springs and dampers, and the inter-body hinge structure is simplified as a combination of a spring and damper. The Pacejka Magic function was used as the running tyre model (The introduction of the model and the parameters of the vehicle refer to [2], Fig.10 shows the dynamic model of the GLT developed in SIMPACK).

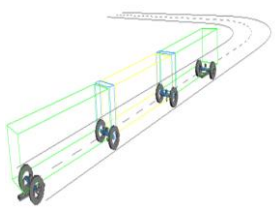

Figure 10 *vehicle dynamics model*

6.2. Wheel tread and steel rail profile

Fig. 11 provides the GLT tram's wheel-rail profile. The guide rail is composed of 1 arc of R100 mm, 2 arcs of R8 mm. The total width of the guide rail is 50 mm. The wheel tread is composed of 1 arc of R200 mm, 2 arcs of R8 mm and 2 arcs of R10 mm. The total width of the guide wheel is 59 mm.

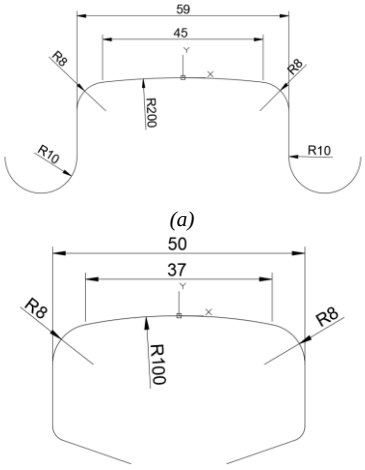

Figure 11 *GLT's guiding wheel (a) and rail (b) profiles*

6.3. Analysis of wheel rail contact

Referring to the method proposed in Section 2.3, the wheel-rail relationship of GLT vehicle is analyzed. In Figure 12, the red asterisks stand for single-point contact. When there is one point contact, for any yaw and lateral displacement that is a range of roll angle. In addition, the surface on the interface of red dots is formed by two-point contact. When two point-contact occurs, the roll degree of freedom becomes coupled with the lateral displacement and yaw angle, so that only a single value corresponds to the direction of the Z axis. Another limit is the occurrence of three point contact, which is what we want to avoid in design. This is related to the minimum curve radius allowed by the design. As shown in Figure 13, the largest yaw angle of this example is 0.084 rad. In addition, using the initial preload of the wheel, 2 kN, the maximum lateral force can be obtained by combining the contact point analysis and the dynamic equation; the result of the calculation in this paper is 3.5 kN.

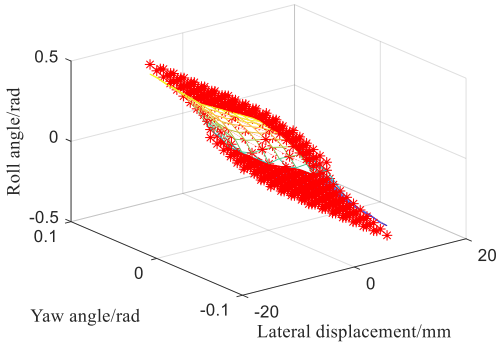

Figure 12 *Distribution of contact points of wheel/rail*

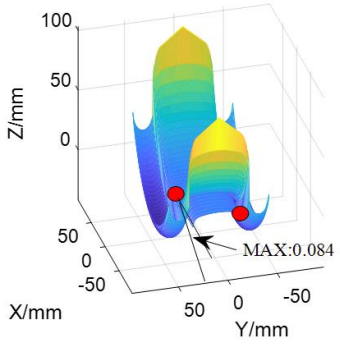

Figure 13 *The maximum yaw angle of the wheel/rail*

6.4. Derailment analysis

The main reason for derailment is that the lateral component of force at the contact point is not enough. Two possible influences: wheel/rail gap, and wheel/rail profiles, were analysed to investigate guidance. The wheel/rail guiding force and guiding wheel contact state when passing through 15 m radius curve were calculated. The maximum yaw angle was calculated to be 0.05 rad which is less than the theoretical maximum 0.084 rad, therefore, the guiding wheel was not predicted to seize up under this condition. However, the guiding force was 5.67 kN (Fig.14), which exceeds the theoretical value of 3.5 kN, so derailment may occur. In this case, changing the wheel/rail gap or wheel/rail profiles to increase force and avoid derailment.

As shown in Figure 15, the basic principle is to change the location of the contact point when the lateral displacement is constant, so as to increase the slope difference between two points and improve the guiding force.

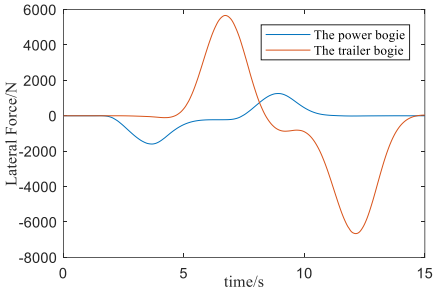

Figure 14 *Lateral force of guiding mechanism*

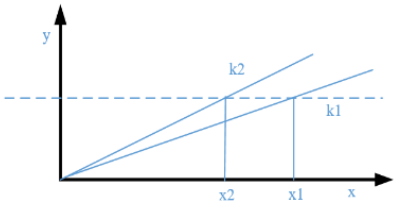

Figure15 *slope diagram of contact point*

7. Conclusion

Double-flange contact is a feature of a number of guided light transit systems. In terms of roll freedom, it is different from the traditional rigid wheelset. In order to get the wheel-rail contact states, an improved wheelset axial slice projection method was proposed in this article in accordance with the specific double flange structure of GLT. The contact point distribution and contact force were calculated. Simulation and theoretical results show that derailment occurs due to lack of guiding force. The main two influences, wheel/rail gap and wheel/rail profiles, were analysed to improve derailment performance.

Follow-up work will optimize the tread based on influence factors to provide greater guidance force, so as to reduce the possibility of derailment.

Abstract: Transportation Technology Center, Inc. (TTCI) is evaluating 14 of the latest high-performance wheel steels, supplied by 11 manufacturers from around the world. The wheels were tested for mechanical and metallurgical properties. They currently are running under wagons at the Facility for Accelerated Service Testing (FAST), where they have accumulated an average of 27,000 km. After running for about 40,000 km, the top performing wheels will begin revenue service testing in 2019 on a North American railroad. AAR Class C wheels also will be tested in revenue service for a comparison to the high-performance wheels. All wheels will be visually and ultrasonically monitored.

Keywords: Wheel, steel, rail-wheel systems; HPW; high performance; microcleanliness; ultrasonic.

1. Introduction

This test of the next generation of high-performance wheel steels, designated HPW2, builds upon information from the first high-performance wheel test, called HPW1, that began in 2008 [1]. The HPW1 evaluated state-of-the-art wheel steels from multiple manufacturers. At that time, the requirements for AAR Class D wheels were not defined, so test wheels were designated as high-performance wheels (HPWs). HPW2 follows the same structure as HPW1, consisting of laboratory testing, on-track testing at Transportation Technology Center (TTC), and revenue service testing.

HPW2 is evaluating 14 wheel steels from 11 different manufacturers. Results will reference a randomly generated supplier number. Names of individual manufacturers are kept confidential.

HPW2 began when TTCI played host to a meeting with representatives from railroads and wheel suppliers. Results and information obtained from the HPW1 test were presented and discussed, as well as properties and performance of state-of-the-art wheel steels. It was decided that there would not be specific requirements for HPW2, except that the mechanical properties for the wheels must meet the minimum AAR Class C requirements.

For this test, all wheels were to be 914 mm (36 inches) in diameter, either J (2 wear) or K (1 wear) design. All wheelsets used AAR Class K axles and AAR Class K bearings. The wheel tread profile was specified as AAR 1B wide flange.

2. Research Methods

This long-term test consists of three phases: laboratory testing, on-track testing at TTC, and revenue service testing.

2.1. Laboratory Testing

Each manufacturer submitted three, unmounted 914 mm diameter wheels for laboratory testing. This testing included:

- Tensile strength, yield strength, and related properties at 25 °C and at 540 °C
- Fracture toughness at 25 °C
- Microcleanliness
- Microstructural analysis

2.1.1. Mechanical Testing

Four tensile specimens were extracted from the rim of one of each supplier's wheels per AAR standard M-107/M-208, Appendix C. [2] Two were tested at 25 °C and two were tested at 540 °C.

Two fracture toughness specimens were extracted from the rim of one of each supplier's wheels per AAR standard M-107/M-208, Appendix C. [2] They were tested at 25 °C.

2.1.2. Microcleanliness

Because the metallurgical cleanliness of steel can affect wheel life and performance, AAR M107/M-208 requires a microcleanliness evaluation at specific intervals. Six rectangular specimens are cut from the rim, such that the bottom of each specimen is 12.7 mm below the tread. The samples are then mounted, ground, and polished to a mirror finish.

The image analysis software used a grid of 17 fields by 14 fields for each analysis. The software also controlled stage movement. Each field measured 0.70 mm^2. AAR M-107/M-208 requires 0.70 mm^2 per field and minimum of 167 mm^2 total analyzed area.

Image analysis software considers more than 200 fields on the specimen to measure void and inclusion content. The image of each field is captured as an 8-bit grayscale image and each pixel's intensity value is measured on a scale of 0 to 255. Pixels with intensities above 179 are classified as solid steel, while those below are designated as either voids, oxides or sulfides. For this test, intensities greater than 160 were designated as solid steel.

To determine whether the microcleanliness varies with depth below the tread, a different approach was used. For this research, only one sample was taken from each supplier. The sample was analyzed multiple times down to about 20 mm, in approximately 1 mm increments. This method resulted in 264 individual analyses. A simplified schematic of microcleanliness analysis planes is given in Figure 1.

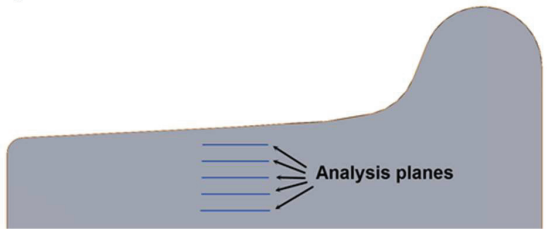

Figure 1 Simplified *schematic of microcleanliness analysis planes*

The classification of metallurgical discontinuities also was changed to create a general cleanliness comparison of the steels. Pixels with intensity values of 160 or lower were designated as generic discontinuities. The top picture in Figure 2 shows an image of a field at 100x magnification. Figure 3 shows the same field, but the pixels below a gray scale intensity of 160 are flagged red as discontinuities. The image analysis software calculates the count and the percent area of discontinuities for each field and for the entire sample.

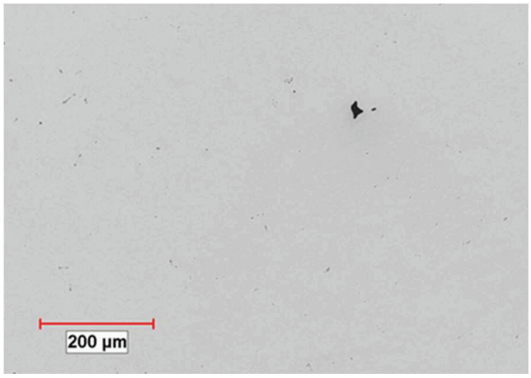

Figure 2 Image *of field captured during microcleanliness analysis*

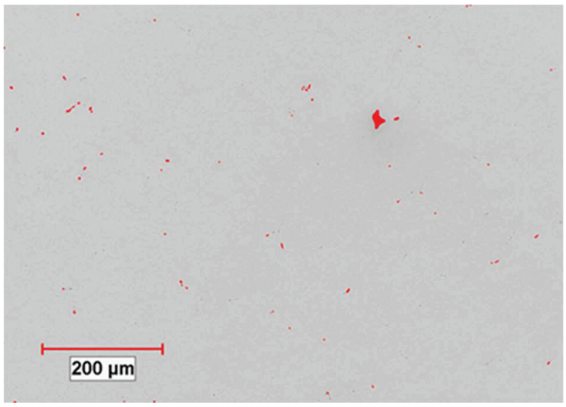

Figure 3 *Image of field showing areas flagged in red as discontinuities*

2.1.3. Microstructural Analysis

A specimen was removed from the rim of each wheel type for microstructural analysis. The top surface of each specimen was the tread surface. The specimens were ground and polished, then etched with 2-percent Nital to reveal the microstructure.

2.2. Durability Testing at TTC

To evaluate the HPW2 test wheels outside of the laboratory, a durability test was initiated at FAST. This loop is 4.3 km long and contains 5- and 6-degree curves and is designed to cause accelerated wear of components.

During FAST train operations, the direction of travel changes every two days. The wheelsets were machined to the FAST profile, which provides better contact with the rail. Two to three wheelsets from each supplier were installed under 10 open hopper wagons, each loaded to 130 tons gross load. Wheel positions were selected by using random numbers.

The wheels will accumulate a minimum of 40,000 km before selecting the best performer for the revenue service portion of the test.

A thorough visual examination was performed prior to the initiation of the durability test. The wheels also were examined ultrasonically before the start of the test to verify integrity. No indications were detected. The tread profile of each wheel was measured with a MiniProf™ profilometer before the test to establish a baseline for wear.

Visual examinations for each wheel were performed after approximately 18,000 km and 27,000 km. Ultrasonic testing of each wheel was performed at 27,000 km.

In the durability test and in the revenue service test, wheels that are removed for high impact load, usually greater than 40,800 kg, or that contain condemnable amounts of shelling per the Field Manual of the AAR Interchange Rules [3] will be considered removed for cause. Other removals will not be counted as removal for cause.

3. Results

3.1. *Laboratory Test Results*

3.1.1. *Mechanical Testing*

The ultimate tensile strength values at 25°C for each of the HPW2 steels is shown in Figure 4. The horizontal dashed line is 1082 MPa, the minimum requirement per AAR M-107/M-208 [2]. UTS values for suppliers 4, 5, and 12 were below the requirement. The largest deviation was 5-percent below minimum.

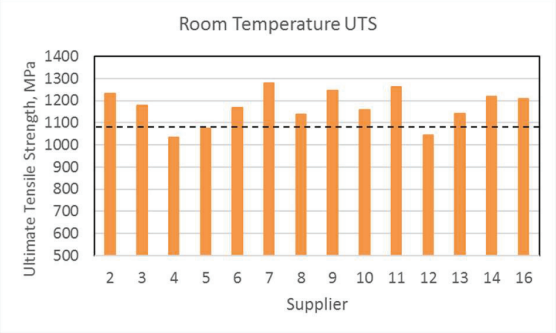

Figure 4 *Room temperature UTS values for HPW2 wheels*

The yield strength values at 25°C for each of the HPW2 steels are shown in Figure 5. The horizontal dashed line represents 758 MPa, the minimum requirement per AAR M-107/M-208 [2]. Suppliers 3, 4, 6, and 10 were below the requirement. The largest deviation was 8-percent below minimum.

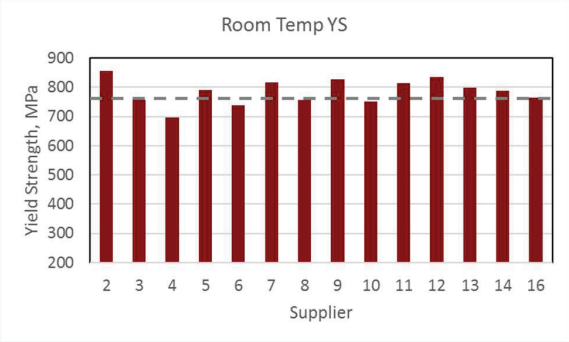

Figure 5 *Room temperature 0.2% yield strength values for HPW2 wheels*

The fracture toughness values at 25°C for the HPW2 steels are shown in Figure 6. The horizontal dashed line represents 35 MPa√m, the minimum requirement per AAR M-107/M-208 [2]. All steels met this minimum requirement.

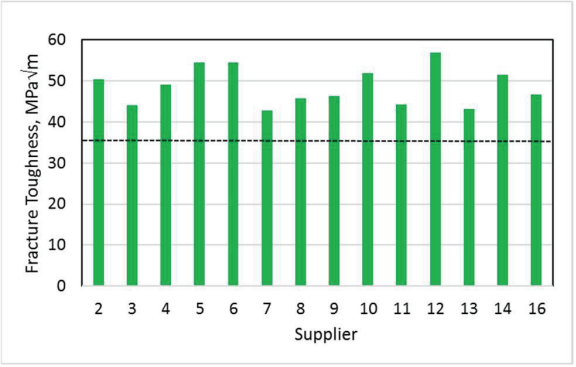

Figure 6 *Room temperature fracture toughness values for HPW2 wheels*

The ratio of ultimate tensile strength to yield strength (UTS/YS) was also a property of interest. This can be used as measure of a material's ability to work harden. This ratio for each of the HPW2 suppliers is plotted in Figure 7.

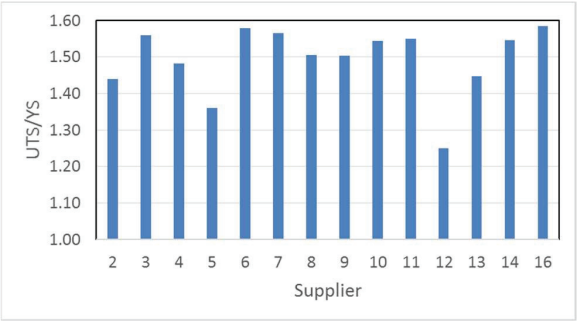

Figure 7 *UTS/YS ratios for HPW2 wheels*

Steels with low values of this ratio would be expected to exhaust their work hardening ability sooner and experience more surface initiated cracking, possibly leading to more high impact wheels. Supplier 12 had the lowest value of this ratio. Tests revealed that Supplier 12 also had the lowest microhardness values.

3.1.2. *Microcleanliness Results*

The AAR M-107/M-208 microcleanliness requirements are given in Table 1 [2]. These are given as reference values since this was not performed according to the AAR standard.

Table 1 AAR microcleanliness requirements

Discontinuity Type	Maximum
Voids + Oxides (mean)	0.100%
Voids + Oxides (maximum)	0.750%
Sulfides (mean)	0.750%

It was unknown whether the microcleanliness would vary significantly at depths other than the 12.7 mm specified by M-107/M-208. The graph in Figure 8 shows the variation of microcleanliness with depth below the tread surface. Most of the steels showed little change over the tested range. Two of the steels had consistently higher than the main group and showed more variation; this could be due to the manufacturing process. It is important to note that though the discontinuity types were combined

in this research. Gray scale values for voids and inclusions were also lowered slightly compared to the standard test. The dashed line at 12.7 mm below the tread surface is the depth of the standard test.

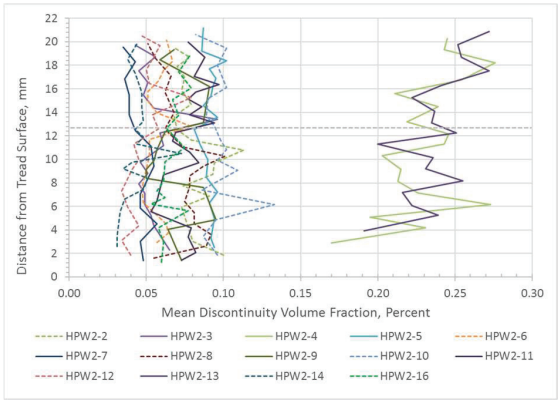

Figure 8 *Microcleanliness map from 2 mm to 20 mm for HPW2 wheels*

3.1.3. *Microstructural Analysis Results*

One steel, Supplier 5, contained a mixture of pearlite and bainite, as shown in Figure 9. All other steels contained fully pearlitic microstructures. A typical example of a pearlite microstructure is shown in Figure 10.

AAR M-107/M-208 states that the metallographic sample should not contain martensite. No martensite was detected in any of the samples.

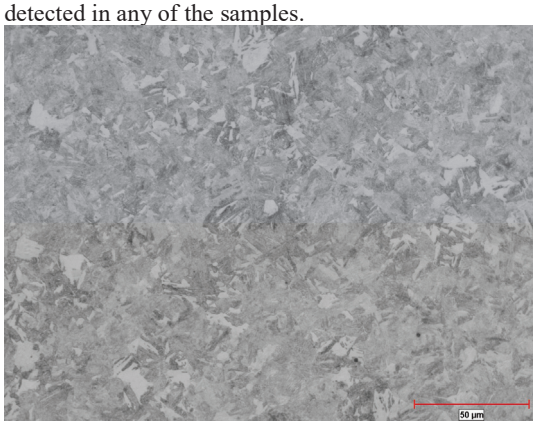

Figure 9 Pearlitic-bainitic microstructure from Supplier 5 at 500x magnification

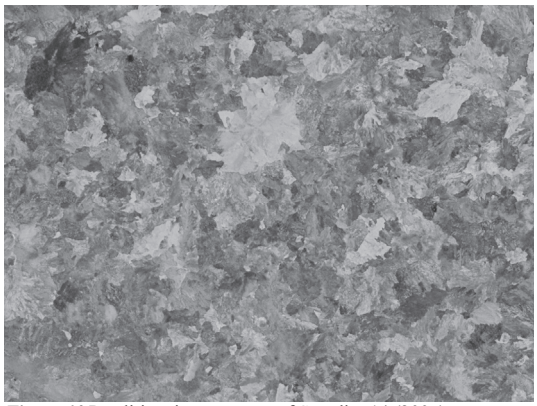

Figure 10 Pearlitic microstructure of Supplier 14 (200x)

3.2. *Durability Test Results*

The wheels have travelled an average of 27,000 km at FAST so far, with some wheels as high as 33,000 km. Two visual, profile, and ultrasonic inspections have been performed.

3.2.1. Wheel Tread Condition

In general, the wheel treads are in good condition. Spalling has occurred on many of the wheels, but this also has happened on many non-test wheels. The damage began within one week after the wheels began running at FAST, but has not become significantly worse. None of the observed spalling is condemnable. It has developed on wheels from at least half of the manufacturers. Due to its occurrence on many non-test wheels in the FAST train, the spalling damage may be due to the varying rail profiles and types used at FAST.

Figure 11 shows minor surface initiated cracks due to the resultant of the longitudinal and lateral force vectors. Approximately 33 percent of the suppliers show this minor surface damage.

Figure 11 *Surface initiated cracks on HPW2 wheel caused by steering tractions after 33,000 km*

A wheel tread from Supplier 9 is shown in Figure 12. It contains minor pitting, caused by pull out of material during rolling. Many of the wheels in this test show similar surfaces, as do many wheels in revenue service.

Figure 13 shows the small surface initiated cracks and minor pitting associated with wheels from several suppliers and has also been seen in revenue service.

Figure 12 *Wheel tread with minor pitting after 27,000 km*

Figure 13 *Wheel from Supplier 12, showing small surface initiated cracks and minor pitting*

3.2.2. Ultrasonic Examination

Each test wheel was ultrasonically tested before the test began and after 27,000 km. One indication, a subsurface crack, was found on one wheel that ran for approximately 25,000 km. Routine ultrasonic inspections will monitor the growth of this crack and the potential formation of cracks in other wheels.

3.2.3. Wheel Wear

The flange width wear, hollowing, and area loss were measured after aligning the profiles. The values were normalized by dividing the wear by the kilometers traveled, then multiplied by 10^3. Figure 14 shows the normalized flange width wear for each supplier.

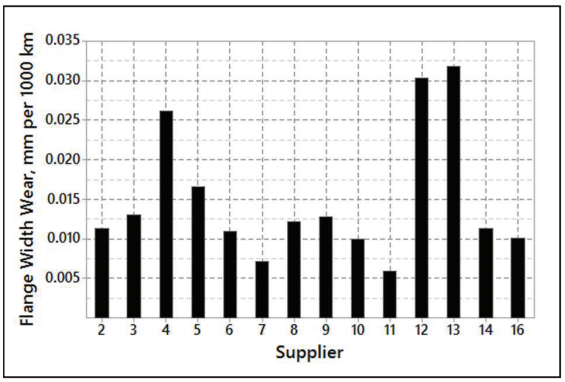

Figure 14 *Normalized flange width wear of the HPW2 wheels*

Suppliers 4, 12, and 13 had the highest mean flange width wear. Their individual distributions were statistically higher than many other suppliers. Wheels from these suppliers may show faster flange wear than those from other HPW2 wheels when in revenue service. Suppliers 7 and 11 had the lowest mean values.

Area loss was also measured using the Miniprof™ software. These values were again normalized by dividing the area loss by the distance traveled, then multiplying by 10^3. These normalized values are shown in Figure 15.

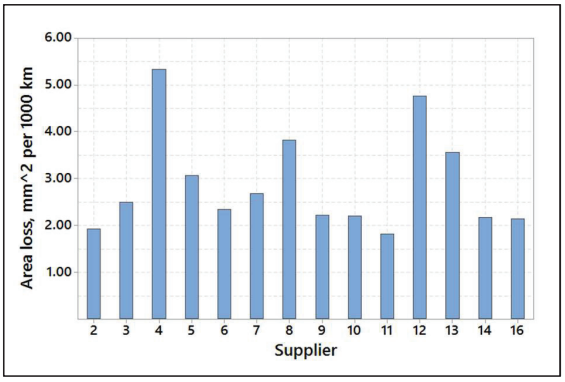

Figure 15 *Normalized area loss of HPW2 wheels*

Suppliers 4, 8, 12, and 13 have the highest mean values. The distributions of the individual values are also statistically higher than many of the other suppliers, indicating that these wheels may exhibit more overall wear than the other suppliers. Suppliers 2 and 11 showed statistically lower area losses than many other suppliers.

4. Future Work

The test wheelsets also will run at FAST during late 2018, giving them approximately 40,000 km total. After achieving this distance, the best-performing steels, as determined by wear, surface condition, and absence of subsurface cracks, will be selected for participation in the revenue service part of the test. The revenue service portion of the test will run on one North American railroad and is scheduled to begin in 2019.

5. Conclusions

The laboratory testing of these high-performance wheel steels showed that the microcleanliness generally exhibited minor variations at depths 2-20 mm below the tread surface. Thirteen of the 14 steels had pearlitic microstructures, while one had a bainitic-pearlitic microstructure.

The test wheels have accumulated 27,000 km in the on-track durability test. None have been removed. Several wheel steels have statistically greater flange width wear and area loss compared to the other steels. This part of the test will continue until about 40,000 km. The best performing steels will be selected to participate in the revenue service test, scheduled to begin in 2019 on a U.S. railroad.

ROLLING CONTACT FATIGUE ASSESSMENT OF REPAIR RAIL WELDS

Elena Kabo*, Anders Ekberg and Michele Maglio

M2/CHARMEC, Chalmers University of Technology

* E-mail: elena.kabo@chalmers.se

Abstract: A repair welding procedure is numerically simulated. To validate the numerical model, analyses of the temperature evolution are compared to full-scale test results. Further simulations are then carried out to evaluate the residual stress formation during welding and how the residual stress field is influenced by subsequent wheel passages. The influence of residual stresses from welding and the subsequent residual stress redistribution during operations on the risk of rolling contact fatigue (RCF) is discussed and analyzed. It is found that high tensile stresses are formed during welding, however these shake down substantially during subsequent operations. The influence on RCF is found to be moderate on the surface and somewhat more severe in a layer at the bottom of the repair weld. In addition to residual stresses, there is also a risk that welding introduces material defects and alters material properties. The influence of such phenomena on RCF are discussed.

Keywords: rail repair welding; residual stresses; rolling contact fatigue; stress redistribution; FE simulations; thermomechanical analysis.

1. Introduction

Rail welds are common in railway tracks. They are unavoidable if continuous rails are to be employed, but also used for repair purposes. The latter is becoming increasingly interesting as a cost-effective alternative to rail replacement. The general topic of rail welding is currently studied in the European project WRIST [1]. The more specific topic of repair welding has recently been investigated in the European project In2Rail [2].

It is well known that rail welds from a mechanical point of view may act as weak points in the track system. Investigations on the influence of rail welds commonly focus on the plain fatigue properties of the welds. The reason is that high tensile stresses and material and/or geometry defects may cause fatigue cracks to initiate in the rail web or in the rail foot. However, there is also a risk that rolling contact fatigue (RCF) may initiate in the rail head. As repair welding introduces a weld that is larger than common welds used for joining, such a risk of RCF could increase.

The current study focuses on RCF aspects of welds in general and repair welds in particular. The current work builds on the studies in [2] and [3]. However, the research in those studies (and in [1]) does not target RCF issues. This study expands the previous investigations through a detailed assessment of how welding—and in particular repair welding—will affect RCF.

2. Scope

The current study is aimed to improve the understanding of how rail welds will increase the risk of RCF. It will outline important factors influencing different forms of RCF and quantify their contributions. As regards the altered stress and strain fields due to welding, the study will demonstrate how an RCF assessment of a repair weld can be included in a numerical simulation of the welding process and subsequent operational loading.

In general terms, a rail weld will introduce a distortion in the wheel/rail contact geometry. This distortion consists of material hardness variations and/or geometry irregularities of the contact surface. The distortion will cause changes (typically detrimental) in contact load magnitudes and contact stress distributions that may increase over time due to localised wear. This topic is investigated e.g. in [2] and will not explicitly be further investigated in the current study.

The welding process will also introduce severe temperature variations. These may give rise to material transformations such as martensite formation. The formation of hard and brittle martensite is highly undesirable. To avoid martensite formation, the temperature evolution must be within specific limits. In particular, the cooling rate must be confined. This topic is studied in [2] and not pursued further here. However also material in the weld and in the surrounding heat affected zone that has not experienced such adverse phase transformation has been affected by the welding process. The study will discuss how altered properties of the material in the weld and the heat affected zone will influence the risk of various forms of RCF with a focus on how the material cleanliness, strength and ductility can be quantified and included in numerical assessments of the risk of RCF.

The temperature variations will also affect the stress and strain fields. In particular, significant residual stresses may form when the weld and surrounding material cool down. To analyse the formation of residual stresses and their redistributions during subsequent operations, numerical simulations of a repair welding process and

subsequent rolling load passages are carried out. The effect of the altered stress and strain fields on various forms of RCF is discussed.

3. Temperature evolution during repair welding

The repair weld studied features a milled cavity where weld beads are sequentially deposited. Details of the rail repair welding process are described in [2] where also tests and metallographic analyses are presented.

To characterise the evolution of the thermal field, the corresponding stress redistributions and the resulting residual stress field, detailed finite element simulations are performed.

3.1. Numerical simulation of temperature evolution during welding

The simulations feature a 250 mm length of 60E1 rail head profile with a flat lower part where a centred 100 mm long and 10 mm deep cavity with 45° inclined slopes is introduced, see Figure 1. The vertical ends have a prescribed ambient temperature of 20°C. Temperature dependent rail material data obtained from British Steel and reported in [2] were employed in the numerical simulations.

Before welding, the rail piece was pre-heated to 80 °C. The repair welding featured three layers of beads (coloured bands in Figure 1), each modelled by subsequently positioning three bead segments with a four-second cooling period in-between each segment. There are in total 192 such segments in the model. After each layer a three-minute cooling period was applied. At the end of the welding process the weld was cooled down for 180 seconds.

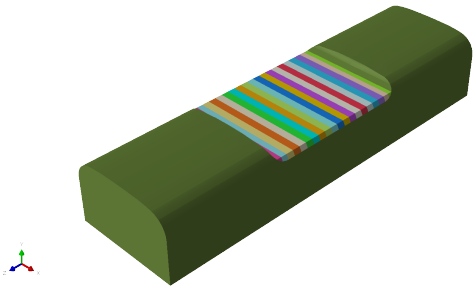

Figure 1 *Geometry of milled cavity and the first layer of weld beads used for the repair welding.*

3.2. Validation towards experimental data

To validate the accuracy of the numerical simulations of the repair welding process, evaluated temperatures were compared to temperatures measured in a full-scale test. In Figure 2 measured and predicted temperatures for thermocouple 5 (TC5) are compared. The finite element node selected to represent TC5 was located on the rail head center line, at a depth of 10 mm from the running surface and at a lateral distance of 3.1 mm from the lateral side of the cavity.

Note that the test featured four welding layers to ensure the cavity was completely filled. The excess material of the fourth layer (which was most of the material in that layer) was then ground off. As seen from Figure 2, the simulations overpredict the temperatures. There are several potential reasons for the discrepancy between the measured and predicted temperatures. One uncertainty is the unknown temperature of the filler material. As seen, a better match is obtained for a less warm filler material. However, for realistic filler material temperatures there is still not a perfect match. A plausible reason is that the cooling times between each layer deposition in the field test held in 2008 were longer with respect to those used in 2016 on which the simulations are designed, see [3]. The rail in the experiments was thus allowed to get much cooler with respect to the one considered in the simulations.

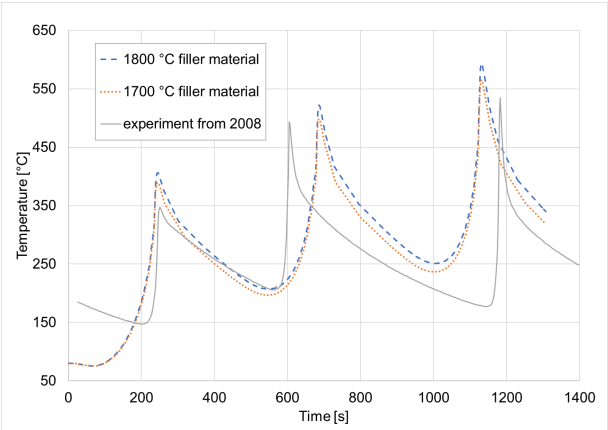

Figure 2 *Predicted and measured temperatures for TC5. Measured data are from [4], however the time scale has been modified to match the simulations.*

The discrepancy found between simulations and measurements is likely to be a combination of different modelling assumptions, such as the filler temperature, presumed thermal conduction, convection to the air and uncertainties in temperature measurements. In the simulations, the thermal conduction is governed by the temperature dependent data. It may however be noted that these data were only available for temperatures up to 700 °C. For higher temperatures material data corresponding to 700 °C were used. Convection to air, q_s, is evaluated with a steel-to-air convection coefficient of 25 [W/m^2/°C]. Naturally, altered values of the material properties will affect the results.

Further, at the tests temperatures were measured by thermocouples. The accuracy, attachment and position of these thermocouples may significantly affect the results. To obtain a quantification of the influence of the position of the thermocouple, temperature histories were evaluated for a number of points in the vicinity of TC5. The results are presented in Figure 3. As seen, also minor deviations in the position of temperature evaluation will have significant effects.

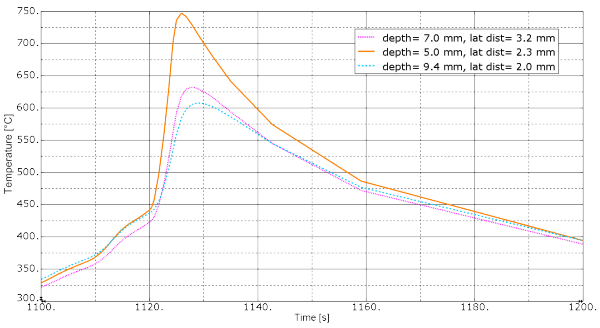

Figure 3 *Predicted thermal history for the third welding pass.*

4. Residual stress formation during repair welding

To investigate the formation of residual stresses from the repair welding process, a thermomechanical analysis was carried out. The simulation featured the same repair weld geometry as in the thermal simulation and the welding was applied in the same manner. The FE discretization of the rail features a refined mesh that extended some centimetre outside the repair weld area, see *Figure 4*. In total, the 3D FE-model consists of 26492 8-node linear brick elements (C3D8, see [5]) with 89 001 degrees-of-freedom in total.

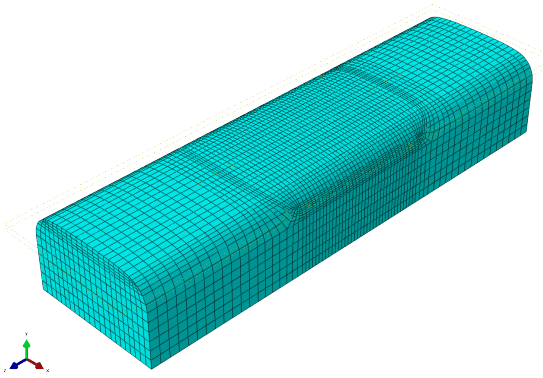

Figure 4 *FE mesh for thermomechanical analysis.*

The vertical rail ends have a prescribed ambient temperature (20 °C), and a strip at the bottom of the railhead is mechanically clamped, see *Figure 5*.

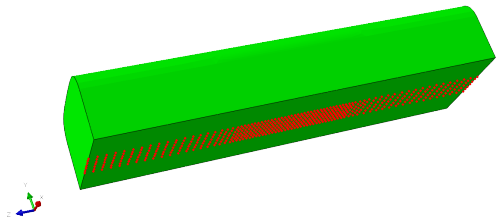

Figure 5 *FE mesh with clamped nodes indicated in red.*

The welding process is simulated by a preheating stage where the rail base material is heated to 80 °C, after which the weld beads are employed in the same manner as for the thermal simulation. To simulate the welding process, the Abaqus Welding Interface (AWI) for Abaqus 6.14-2 was employed.

Welding typically results in high tensile residual stresses after cooling. In general, this has to do with the fact that welding introduces thermal gradients: If the temperature increase was uniform there would be no major residual stresses since this would in essence only give a uniform expansion of the entire component. For a local heating, the expansion would be restricted and result in compressive stresses. If sufficiently high, plastic deformations due to this compression would then lead to tensile residual stresses during cooling.

For the studied repair welding, the numerically predicted residual stresses in terms of von Mises effective stress magnitudes are presented in Figure 6. It is seen that the highest residual stresses are found at the starting edge of the weld process zone, which is reasonable since the molten weld material there interacts with the (relatively) cool base material. In *Figure 7* the maximum principal stress of the residual stress field is presented. It is seen that there are very high tensile stresses in the repair zone.

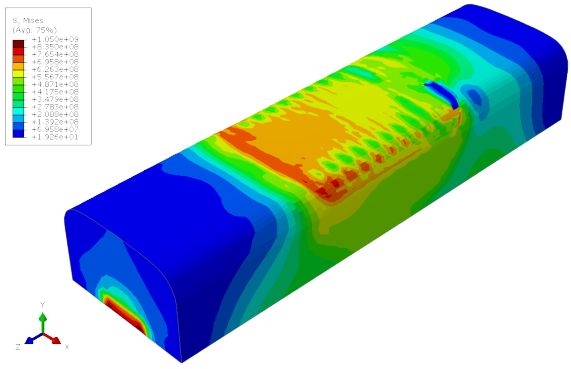

Figure 6 *Predicted von Mises residual stress [Pa] at the end of the cooling stage after repair welding.*

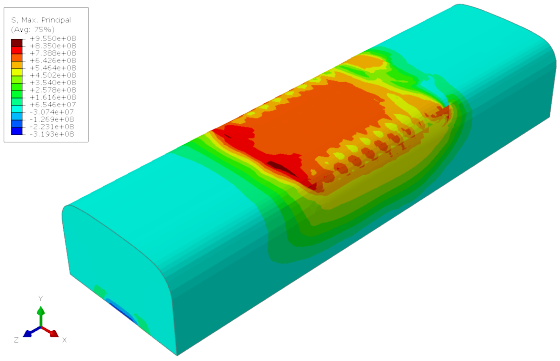

Figure 7 *Predicted maximum principal residual stress [Pa] at the end of the cooling stage after repair welding.*

5. Stress redistribution due to rolling contact

In general, high tensile residual stresses will increase the propensity for fatigue. However, the residual stresses presented in *Figure 6* and *Figure 7* reflect the state of the repair weld just after welding and cooling down. This (quasi-)static loading will in itself not cause a fatigue failure. Instead fatigue will be a result of the operational loading (that provides the dynamic loading necessary for fatigue crack initiation and growth) in combination with

the high tensile residual stresses (that open up micro- and macro-cracks and thereby accelerate the fatigue cracking process).

The operational loading consists of rolling contact between the rail and passing wheels. The high stress magnitudes pertaining to such rolling contact loading will affect the residual stress field. To investigate and quantify this effect, numerical simulations were carried out. Here, the rail section with the repair weld and the residual stress field stemming from the repair welding process was subjected to a passing Hertzian contact load with a peak pressure of $p_0 = 1.32$ GPa and contact semi-axes of $a = 7.5$ and $b = 5.8$ mm in the rolling and the transverse directions, respectively. This corresponds to an axle load of 25 tons acting on a wheel with a radius of 0.46 m in contact with a rail with a 0.3 m head radius.

The Hertzian contact stress distribution can be expressed as

$$p = p_0 \left(1 - \left(\frac{x}{a} \right)^2 - \left(\frac{y}{b} \right)^2 \right)^{1/2} \qquad (1)$$

for a coordinate system that has its origin at the center of the contact patch, with x in the rolling, and y in the transverse direction, and with $x<a$ and $y<b$.

No wheel–rail friction was considered. This was motivated by the fact that repair welding often is carried out to repair squats that commonly appear on tangent tracks or in shallow curves. At these location, frictional stresses are moderate. Further, applied frictional stresses (and higher dynamic wheel loads) will give a more profound influence on the residual stress field. In this sense, the studied conditions will represent a "base case" of operational loading.

Two materials are considered in the simulation of the repair weld process: a filler material (Esab Tubrodur 35 OM) and a rail material (R260). The elastic material properties (e.g. modulus of elasticity, thermal expansion, thermal conductivity and specific heat) for both materials are temperature dependent. Values for temperatures up to 700°C are presented in [3]. Elastoplastic material behaviour was characterised using an isotropic hardening model with temperature dependent characteristics. The data are derived from the material property simulation software JMatPro v. 9.1 [6] following the procedure in [7]. The same elastoplastic material properties were used for the filler as for the base material.

The stress and strain evolutions during two load passages are evaluated. In particular, the stress evolutions in four elements are studied in detail. The centroids of these elements are located one and three millimetres below the surface. Two of these elements are located at the edge of the weld, and the other two at the centre of the repair weld, see *Figure 8*.

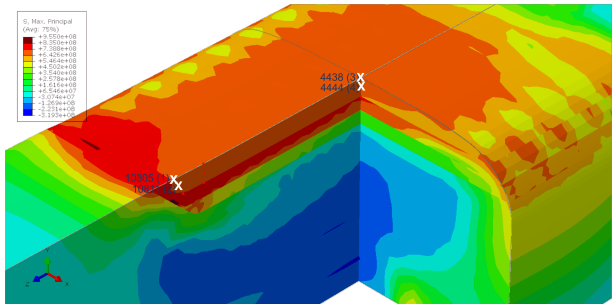

Figure 8 *Maximum principal residual stress [Pa] and material points where detailed stress and strain evolution are evaluated.*

The evolution of the largest principal stresses in these four points during the two passages of the Hertzian contact stress is presented in *Figure 9*. It is seen that the passing contact load induces a high compressive stress. The off-set in time for the two positions along the rail is due to the fact that the load passes over the repair weld from right to left. After the load has passed, the residual stress decreases to a magnitude of some 300 MPa at the surface and some 100 MPa at a depth of some 2 mm. The second load passage has only a minor effect on the residual principal stresses. This is partly a consequence of the isotropic hardening model used in the simulations; in reality, the state of stress is likely to take more load passages to stabilize.

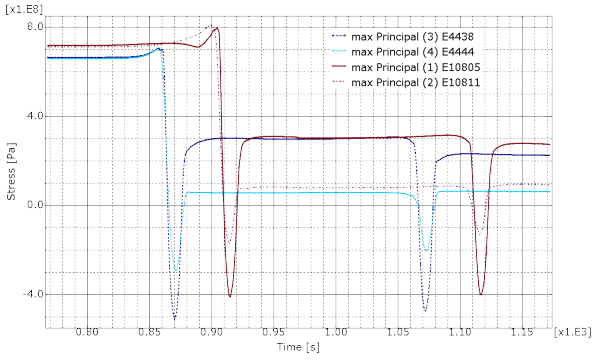

Figure 9 *Principal stress evolution in the four material points indicated in* ***Figure 8****.*

The reduced magnitude of the maximum principal stress due to the rolling contact load seems to depend more on the depth below the surface than on the position in the repair weld. This is even more clear in the overview presented in *Figure 10*. The residual stress magnitude in the repair weld is found to be moderate. There is however a zone with a higher tensile residual stress at the bottom of the repair weld.

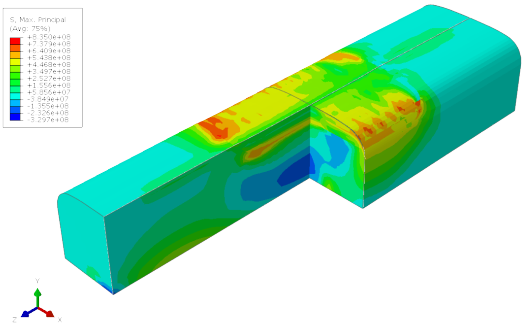

Figure 10 *Maximum principal residual stress after two load passages.*

6. Rolling contact fatigue assessment

The risk of RCF is complicated to assess, especially in a general manner. It will depend on the operational loading and the material strength. This chapter aims mainly to estimate the decrease in fatigue resistance due to the repair weld.

As for the tensile residual stress, the effect will depend on the fatigue mechanism. If crack initiation is presumed to occur due to high cycle fatigue, the influence of the residual stress can be quantified using a multiaxial high cycle fatigue criterion is required. If we select the Dang Van criterion [8], the Dang Van stress can be expressed as

$$\sigma_{eqdv}(t) = \tau_a(t) + c_{dv} \cdot \sigma_h(t) \qquad (2)$$

Here τ_a is the deviation of the shear stress from its mid value during a stress cycle, t is time and $\sigma_h = (\sigma_x + \sigma_y + \sigma_z)/3$ is the hydrostatic stress. It can be shown [9] that a residual stress will only have an influence on the hydrostatic stress term. The magnitude of the influence will be determined by c_{dv} which is a material parameter that for rail common steels have a magnitude of $c_{dv} = 1/3$, see [10]. Fatigue initiation is predicted when the magnitude of $\max(\sigma_{eqdv}(t))$ exceeds the (reduced) fatigue limit in shear.

As seen, the Dang Van stress includes the hydrostatic stress and not the largest principal stress. For the studied material points (see *Figure 8*) the residual hydrostatic stresses after rolling contact loading are given in *Table 1*.

Table 1 *Residual hydrostatic stresses after two rolling contact passages.*

Material point	Residual hydrostatic stress, $\sigma_{h,res}$ [MPa]
4438 (center, 1 mm)	247
4444 (center, 3 mm)	–124
10805 (edge, 1 mm)	225
10811 (edge 3 mm)	–56

It is seen that the influence at the surface is on the order of 80 MPa. This magnitude can be compared to the (reduced) fatigue limit in shear which, depending on the material conditions, corresponds to a σ_{eqdv}-magnitude of some hundred MPa (cf. the discussion on subsurface initiated RCF below). However, at the surface RCF is induced mainly as a consequence of plastic ratchetting during frictional rolling. Under such conditions, the wheel/rail friction will affect the residual stress even further. In addition, a high cycle fatigue criterion is not fully appropriate to characterise ratchetting induced RCF.

At two millimetres below the surface (points 4444 and 10811) the residual stress is compressive and of a low magnitude. This should not have any significant effect on the risk of fatigue initiation. However, at a depth of 10 mm there is a band with high tensile residual stresses. This depth corresponds to the bottom of the weld. A node in this band was selected for further evaluation, see *Figure 11*.

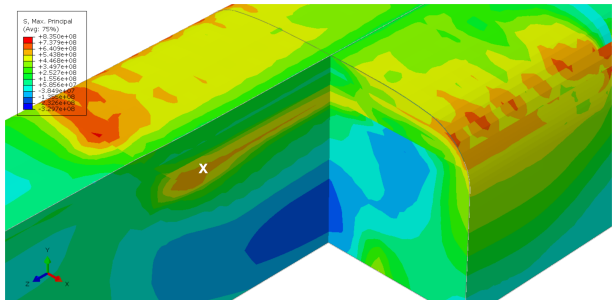

Figure 11 *Node for assessment of residual stress.*

To estimate the influence on the fatigue strength, the hydrostatic stress in the selected node was evaluated to be $\sigma_{h,res} = 305$ MPa. For subsurface initiated RCF, the fatigue index FI_{sub} that sets out from the Dang Van stress can be used. Following the procedure above (with $c_{dv} = 1/3$), we obtain a contribution to the Dang Van stress from the residual stress on the order of 100 MPa.

For subsurface initiated RCF, the material cleanliness is crucial. As motivated in [9] and [11], an approximate fatigue criterion for subsurface initiated RCF can be expressed as

$$FI_{sub} \approx F_z/(4\pi ab) + c_{dv} \cdot \sigma_{h,res} > \sigma_u/3 \cdot (d/d_0)^{-1/6} \qquad (3)$$

Here σ_u is the fracture stress, d the diameter of a material defect, d_0 the diameter of a "commonly occurring" defect. With reasonable values ($\sigma_u = 900$ MPa, $d = 1$ mm, $d_0 = 30$ µm), equation (3) becomes

$$330 \text{ MPa} > 250 \text{ MPa} \qquad (4)$$

According to equation (3), fatigue is thus likely due to a combination of high residual stresses and potential material defects. However, equation (3) is based on the magnitude of the maximum shear stress ($(\sigma_1 - \sigma_3)/2$) at the depth where it reaches its maximum, which is roughly 3 mm below the surface [12]. At the ten-millimetre depth of the weld interface, the maximum shear stress has roughly half the magnitude, and equation (3) becomes

$$165 \text{ MPa} < 250 \text{ MPa} \qquad (5)$$

Thus, subsurface initiated RCF is not predicted, but margins for larger material defects are fairly small. Note that insufficient bonding between weld and the base material will constitute such a material defect. Note also that the prediction is based on the presumption that the largest shear stress amplitude (i.e. deviation from mid value during a cycle) in the weld interface is related to the

maximum shear stress (i.e. $(\sigma_1 - \sigma_3)/2$), which may not be the case.

The weld process may affect other material characteristics than the material cleanliness. Regarding initiation of subsurface initiated RCF, the most influential such parameter would be the fatigue limit. The effect of an altered fatigue limit would be directly reflected on the factor $\sigma_u/3$ in equation (3). For initiation of surface initiated RCF, the two important material characteristics are the cyclic yield limit and the material ductility. If surface initiated RCF is predicted to occur due to ratchetting, a decreased ductility manifested by a decreased fracture strain would be reflected by a similar proportional decrease in fatigue life since RCF is predicted when the accumulated strain exceeds the fracture strain [13] (which in rolling contact is far higher than the uniaxial magnitude). A decrease in the cyclic yield limit would increase the propensity for plastic deformation and thereby lead to a shorter RCF life. How large this effect would be will depend on how the pertinent material hardening characteristics will be affected by the heat treatment.

As for the operational loading, it may increase at a repair weld due to a deteriorated weld geometry, as noted in chapter 2 and investigated in [2]. As long as the increased stress magnitude remains below the fatigue limit, such an increase will have no influence. However, when the fatigue limit is exceeded, the fatigue life will decrease exponentially with the load magnitude. Note that the definition of "load" will depend on the fatigue mechanism at hand.

7. Conclusions and future work

The study has established a simulation framework for assessment of (repair) weld methods. These simulations can be employed as part of a "virtual homologation" of (repair) welding processes. It has further detailed how various features of the weld process will affect risks of different forms of RCF. In particular, the influence on the residual stress formation has been investigated.

A numerical simulation of the thermomechanical response during a repair welding process has been made. It was shown that large tensile residual stresses formed during cooling. Numerical simulations of subsequent rolling contact showed that residual stress magnitudes were substantially decreased due to the rolling contact. For surface initiated RCF, the effect of these residual stresses is therefore likely to be small. However, a zone with high tensile stresses at the bottom of the repair weld remained. The influence of this residual stress and the effect of any material defects that may result from the welding process are quantified. It is shown that under nominal conditions with a 1 mm large material defect, fatigue initiation in the weld interface is not predicted by the Dang Van criterion. However, the margins are fairly small especially considering that the Dang Van criterion tends to be non-conservative under conditions of high tensile residual stresses. Consequently, caution should be taken in the manufacturing of the weld to minimize the risk of material defects, especially in the weld interface. It is also important that the repair weld is deep enough to avoid the weld interface to be positioned in the zone with the largest subsurface shear stresses. Further, increased stress magnitudes caused by a deteriorated weld geometry should be limited (and preferably avoided).

Regarding future work, it can be noted that the material model employed in the analysis is based on isotropic hardening, which is less suitable for rolling contact conditions. In general, the hardening effects are likely to be exaggerated in comparison to the actual performance. Introducing a material model better suited for rolling contact conditions is however not trivial since the same model needs to be employed for the welding simulations. This means that (cyclic) material parameters need to be derived for a large range of temperatures.

Regarding the fatigue assessments, these have mainly been based on simplified criteria for surface and subsurface initiated RCF. This provides a first estimation regarding the risk of RCF. Improved estimations could be obtained by more detailed analyses.

It should finally be pointed out that the numerical simulations carried out in the paper can be coupled to simulations of train–track interaction in the vicinity of a rail weld. Such analyses would provide significant support for example in defining inspection intervals for welds.

Acknowledgments

The current study is part of the on-going activities in CHARMEC – Chalmers Railway Mechanics (www.chalmers.se/charmec). Parts of the studies have been funded within the European Union's Horizon 2020 research and innovation programme in the projects In2Rail and In2Track under grant agreements No 635900 and 730841.

Abstract: Torsion and axial fatigue tests of wheel steel with artificial defects and finite element analyses of heavy haul car wheels are performed to evaluate subsurface crack initiations due to cyclic rolling contact. The critical defect size for subsurface crack initiation is estimated to be 1.1 mm according to multiaxial fatigue evaluation. This indicates that the subsurface cracks might be initiated in service conditions as the critical size is less than 1.6 mm, which is the maximum size of an internal defect of the wheel rim in AAR specification. Therefore, high-cleanliness wheels are believed to be effective for preventing subsurface cracks.

Keywords: Rolling contact fatigue; subsurface crack; vertical split rim; defect size; torsion fatigue test; finite element analysis.

1. Introduction

Rolling contact fatigue (RCF) failures are one of the most common causes for the removal of heavy haul car wheels [1]. RCF failures are characterized by two crack initiation modes: surface crack initiations and subsurface crack initiations. Internal defects such as voids and non-metallic inclusions are known to be the possible origins of subsurface cracks [2~6]. An internal horizontal crack occurs typically at the depth of the maximum shear stress associated with Hertzian contact. Thus, it is important to reveal the effect of internal defect sizes on subsurface crack initiations to reduce removals of the heavy haul car wheels. Some studies have been conducted regarding subsurface-initiated RCF of railway wheels [7~11]. However, the relationship between subsurface crack initiations and internal defect size, or the critical defect sizes for subsurface crack initiations in the service conditions have not been sufficiently studied.

In order to evaluate the effect of defect size on fatigue of wheel steel, fatigue tests (torsional and axial) containing artificial defects are performed. The subsurface stress states of actual wheels are thereafter evaluated using finite element analyses. Finally, the critical defect sizes for subsurface crack initiation are estimated using the multiaxial fatigue evaluation method according to the results of fatigue tests and finite element analyses.

2. Fatigue limit with different defect size

2.1. Test material

The fatigue tests are conducted by using AAR Class-C wheel steel. This steel is a 0.7% carbon steel with pearlite structure as shown in Figure 1. The Vickes hardness of the steel is HV330.

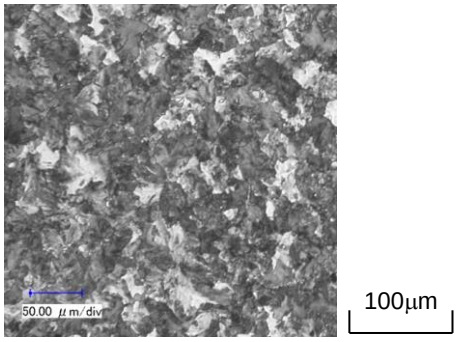

Figure 1 *Microstructure of wheel steel.*

2.2. Fatigue test specimens and test conditions

Figure 2 illustrates the configurations of torsion and axial fatigue test specimens. Round bar test specimens with a diameter of 6 mm were used. Some test specimens contained small artificial defects. To introduce artificial defects into the test specimens, small holes were machined via wire electric discharge machining at the surface. The shapes of the cross-sections of the holes are illustrated in Figure 3. The diameters of the holes are 0.2 mm and 0.5 mm.

Table 1 lists the torsion and axial fatigue test conditions. Fully reversed fatigue tests, whose stress ratio was -1, were conducted. The cyclic loading frequencies were 33 Hz for the torsion fatigue tests and 10 Hz for the axial fatigue tests. Both the tests were performed at ambient temperature, and the number of cycles to terminate the tests was set as 10^7.

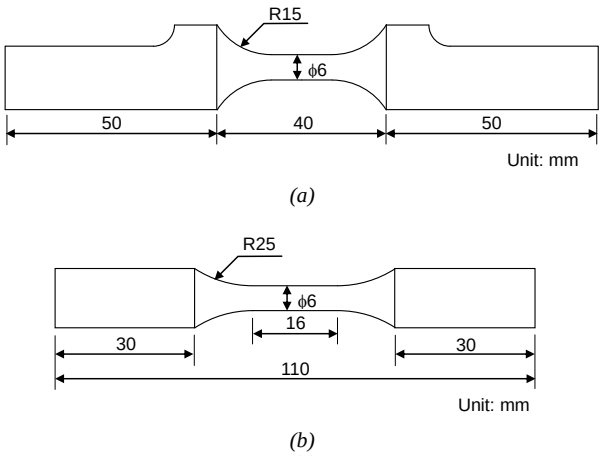

Figure 2 *Schematic illustrations of fatigue test specimens: (a) Torsion. (b) Axial load.*

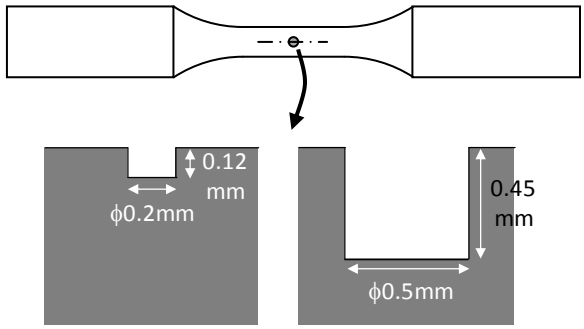

Figure 3 *Schematic illustrations of artificial defects in fatigue test specimens.*

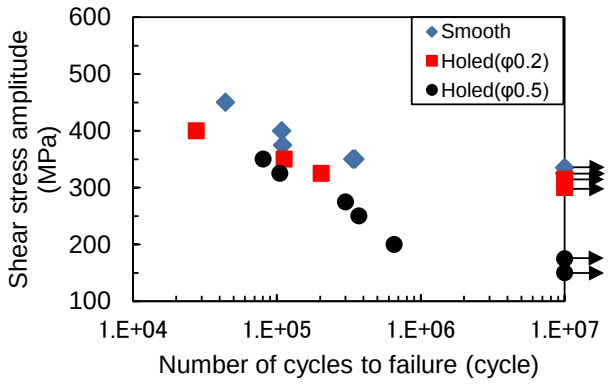

Table 1 *Torsion and axial fatigue test conditions.*

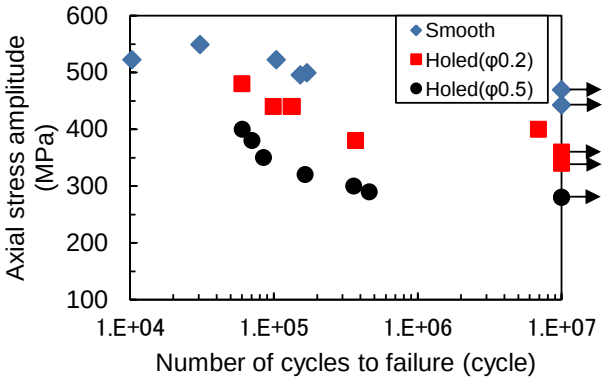
Loading type	Torsion	Axial load
Stress ratio	-1	-1
Frequency (Hz)	33	10
Number of cycles to terminate	10^7 cycles	10^7 cycles



2.3. Test results

Figure 4 shows the S–N curves obtained from the torsion and axial fatigue tests. The specimens with artificial defect have lower fatigue limits and shorter fatigue lives than the smooth specimens. Both fatigue limits and fatigue lives decrease with the increase in the size of artificial defects. The decrease in the fatigue limits owing to the artificial defects in the torsion fatigue tests is less than that in the axial fatigue tests.

The fracture surfaces of the torsion and axial fatigue test specimens with artificial defects are shown in Figure 5. The edges of holes on the surface of the test specimen are the origins of the fatigue cracks in all the test specimens. There are no inclusions and voids as the crack origins. Thus, the relationship between the fatigue limits and defect sizes can be evaluated based on the results of these fatigue tests.

2.4. Effect of defect size on fatigue limits

To evaluate the relationship between the shear and axial fatigue limits and defect size, $\sqrt{area}$ model [12] and

El-Haddad model [13] were applied. They are expressed as follows:

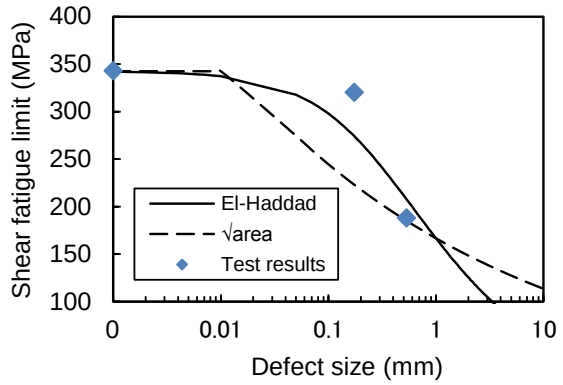
$\sqrt{area}$ model (torsion):

$$\tau_w = 1.14\ (HV+120)/\left(\sqrt{area}\right)^{1/6} \quad (1)$$

$\sqrt{area}$ model (axial load):

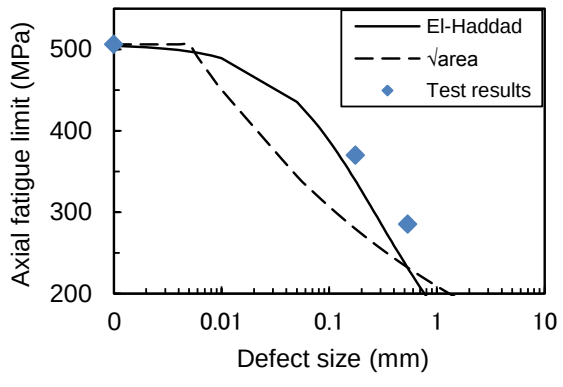
$$\sigma_w = 1.43\ (HV+120)/\left(\sqrt{area}\right)^{1/6} \quad (2)$$

El-Haddad model (torsion):



$$\tau_w = \tau_{w0}(l_0/(l+l_0))^2,\ \ l_0 = (\Delta K_{Ith}/\tau_{w0}/2)^2/\pi \quad (3)$$

El-Haddad model (axial load):



$$\sigma_w = \sigma_{w0}(l_0/(l+l_0))^2,\ \ l_0 = (\Delta K_{Ith}/\sigma_{w0}/2)^2/\pi \quad (4)$$

Here, τ_w is the shear fatigue limit with small defects, σ_w is the axial fatigue limit with small defects, *area* is the area of small defects, τ_{w0} is the shear fatigue limit of smooth specimens, σ_{w0} is the axial fatigue limit of smooth specimens, l is the length of small defects and ΔK_{Ith} is the threshold of mode-I crack propagation. ΔK_{Ith} in formulas (3) and (4) is 15.1 MPa$\sqrt{m}$, which is obtained from the crack growth test with the compact tension specimens.

The relationship between the shear or axial fatigue limits and the defect sizes is presented in Figure 6. The results of both the torsion and axial fatigue tests correspond to $\sqrt{area}$ model and El-Haddad model as shown in Figure 6. The fatigue limits decreased significantly for defect size greater than 0.2 mm. Therefore, the occurrence frequency of large defects is important for the initiation of subsurface cracks.

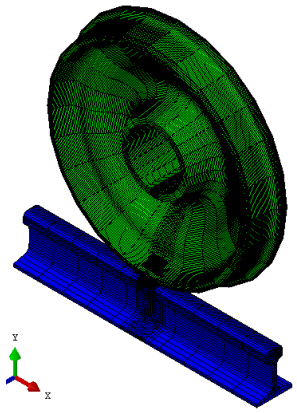
3. Stress analysis of actual wheel

3.1. Finite element models

Residual stresses from heat treatments and rolling contact stresses with rails significantly affect the stress distributions at the subsurface of the wheel rims. Thermal stress analyses simulating the heat treatments and contact analyses simulating rolling contact between the wheels and rails are performed [14]. Figure 7 illustrates the finite element models. A piece of wheel and a piece of rail of length 1 m long are employed in these analyses. The diameter of the wheel model is 38 inch, which corresponds to the B38 wheel (125 Ton, Class-C, single wear freight car wheel) in AAR specification [15]. The material properties of AAR Class-C wheel steel are used for the wheel model. An elasto-plastic model for the wheel models and an elastic model for the rail models are employed.



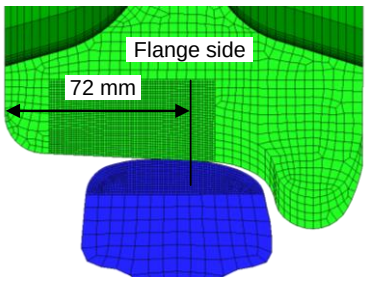


Figure 7 *Finite element analysis model.*

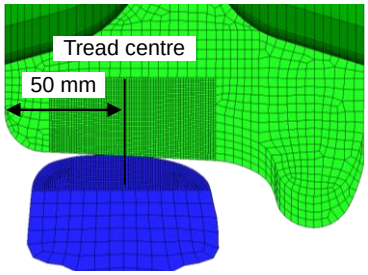
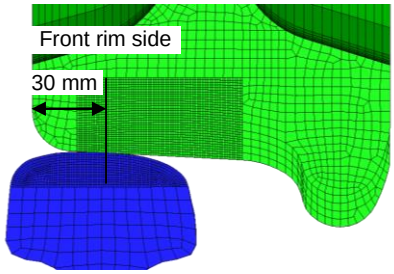


3.2. Finite element analysis conditions

Heat transfer and thermal stress analyses simulating wheel heat treatment are first performed. A heat transfer coefficient equivalent to that of water cooling is applied to the tread surface in the quenching step of the heat transfer analyses to calculate the wheel temperature distributions. Subsequently, the thermal stress analyses are conducted by importing the temperature distributions obtained via the heat transfer analyses to calculate the residual stresses of the heat treatment.



Wheel–rail contact analyses are performed after importing the residual stresses of the heat treatment. The contact positions between the wheel models and the rail models are shown in Figure 8. There are three positions: flange side, tread centre and front rim side. The wheel model positions are adjusted to make the centre of contact area coincide with the above contact positions. The analysis conditions are shown in Figure 9. New and hollow wear profiles are used for the tread profiles of the wheel model as shown in Figure 9. The worn profile is obtained from survey of TTCI (Transportation Technology Center, Inc.) [3]. The rim thickness of the new profile model is 38.1 mm and the worn profile model is 25.4 mm. A profile of the rail model is defined based on the worn profile obtained in the field as presented in Figure 9.

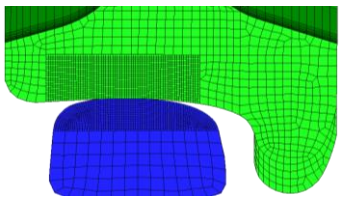
Figure 8 *Contact positions between the wheel and rail models: (a) Flange side contact. (b) Centre contact. (c) Front rim side contact.*



(a)

(b)

Figure 9 *Finite element analysis conditions and contact surface profile: (a) Loading and slip conditions. (b) New wheel profile. (c) Worn wheel profile.*

(c)

Figure 9 *Continued.*

The applied vertical load in the wheel model is 175 kN, which is equivalent to half the maximum axle load. A slip ratio of 0.5% and a friction coefficient of 0.3 are used between the wheel and the rail models. The wheel model rolls 40 mm along the rail model with the vertical load and the slip in the contact analyses. Subsequently, the vertical load is unloaded and the wheel model returns to the initial position. These steps are conducted repeatedly for three cycles in the analyses. Three loading cycles are decided to apply because the residual stresses in the evaluation area are almost the same between at the second loading cycle and at the third loading cycle. A cyclic stress-strain curve of the wheel material is used for the wheel model. A Young's modulus of 206 GPa and a Poisson's ratio of 0.3 are used. All the finite element analyses are performed using the commercial software ABAQUS 6.12.

3.3. Finite element analysis results

Figure 10 shows the shear stress $\tau_{r\theta}$ (r: radial direction, θ: circumferential direction) distribution at the cross-section of the wheel rim during the third rolling cycle. This figure shows the result in a case where the contact position is the tread centre with the new tread profile. The stress $\tau_{r\theta}$, which has the most significant effect on RCF crack initiation, is the highest at the subsurface. This corresponds to the observation that, on railroad wheels, some RCF cracks are initiated below the tread surface.

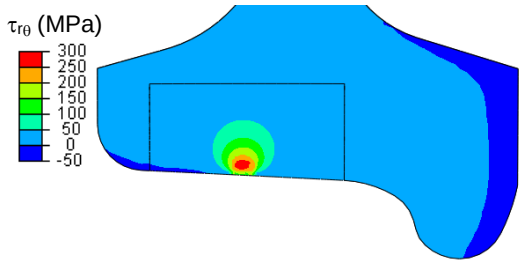


Figure 10 *Shear stress $\tau_{r\theta}$ distribution at the cross-section of new wheel rim in the case of centre contact.*

The variation of stress components during the wheel rolling at the maximum $\tau_{r\theta}$ position in Figure 10 is shown in Figure 11. The variation of $\tau_{r\theta}$ is almost fully reversed with rolling contact. This cyclic shear stress is considered to be the cause of subsurface crack initiations. In addition, each of the normal stress components varies under compressive field with rolling contact. These compressive stresses are also considered to affect subsurface crack initiations. Thus, a multiaxial fatigue strength evaluation method should be applied to evaluate the criteria of RCF crack initiations at the subsurface.

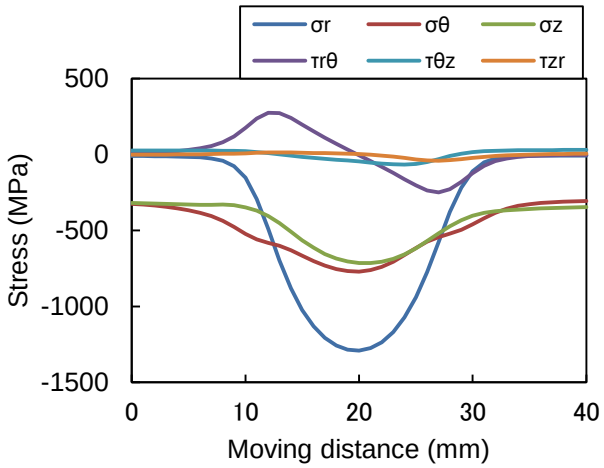

Figure 11 *Stress histories at the subsurface with rolling contact of new wheel in the case of centre contact (r: radial direction, θ: circumferential direction and z: axial direction).*

4. Critical defect size for subsurface crack initiations

4.1. Multiaxial stress evaluation

The rolling contact loading results in multiaxial stress states with a combination of shear and compressive stresses. The criteria for subsurface RCF crack initiations from internal defects are evaluated by applying the McDiarmid method [16], which is one of the multiaxial fatigue evaluation models. Other models, such as Findley [17], Dang Van [18] and Sines [19] are also attempted, however the McDiarmid is applied because it gives higher fatigue damage prediction than the other models, within a reasonable range in this study. The planes of the maximum shear stress variation $\Delta\tau_{max}$ are determined as critical planes, and thereafter, the criterion for subsurface crack initiation is calculated from the relationship between $\Delta\tau_{max}$ and normal stresses σ_n to the critical planes. The McDiarmid model can be expressed as follows:

$$\Delta\tau_{eq,max} = \Delta\tau_{max} - k \cdot \sigma_{n,max} \quad (5)$$

where $\Delta\tau_{eq,max}$ is the pure shear stress range with an equivalent fatigue damage in the multiaxial stress state, $\sigma_{n,max}$ is σ_n at the maximum fatigue damage and k is a material constant (=0.3538). k is obtained by applying the shear fatigue limit as $\Delta\tau_{eq,max}$, the axial fatigue limit converted to shear stress as $\Delta\tau_{max,}$ and the maximum normal stress to the $\Delta\tau_{max}$ plane as $\sigma_{n,max}$. The fatigue damages at the subsurface increase for larger $\Delta\tau_{eq,max}$. The loading conditions at which the subsurface cracks are more likely to be initiated can be identified by comparing $\Delta\tau_{eq,max}$ obtained from the finite element analyses.

The values of $\Delta\tau_{eq,max}$ for each loading condition are shown in Figure 12. $\Delta\tau_{eq,max}$ is calculated from the average stresses at the subsurface for a depth of 3 – 6 mm as the main area of the subsurface crack initiations is at depth range. The new profile wheel has higher $\Delta\tau_{eq,max}$ at the flange side, whereas the worn profile wheel has higher $\Delta\tau_{eq,max}$ at the front rim side as presented in Figure 12. The maximum contact pressure at the front rim side of the worn wheel model is higher than that at the other positions. This is probably one of the reasons why $\Delta\tau_{eq,max}$ is higher at the front rim side in the worn profile wheel. $\Delta\tau_{eq,max}$ has different values depending on the tread profile or the contact positions as shown in Figure 12. However, calculating $\Delta\tau_{eq,max}$ from the average stresses at all the contact positions is appropriate as it is difficult to identify the frequencies of the contact at each position or frequencies of the appearance of large internal defects at each position for the actual wheels. The average $\Delta\tau_{eq,max}$ values are also shown in Figure 12. The average $\Delta\tau_{eq,max}$ values of the new and worn profile wheels are almost the same. This indicates that the tread profiles have a less significant effect on the critical defect size for subsurface crack initiations within the finite element analysis conditions.

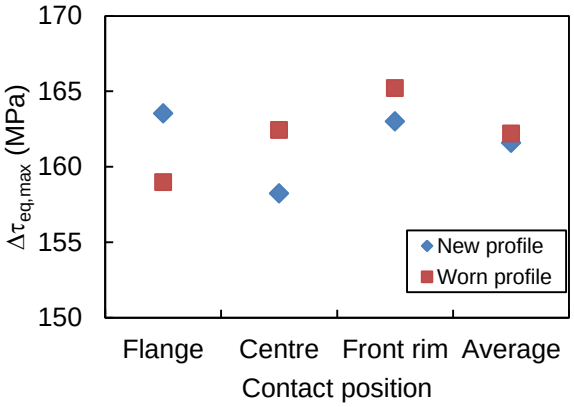

Figure 12 *$\Delta\tau_{eq,max}$ at each contact position.*

4.2. Critical defect size of subsurface crack initiation

Applying $\Delta\tau_{eq,max}$ and the fatigue limits with different defect size enables to estimate the critical defect size for the subsurface crack initiations in the actual wheels. A defect size that is an intersection of $\Delta\tau_{eq,max}$ and the shear fatigue limit prediction formulas with defects is defined as the critical defect size as shown in Figure 13. The subsurface cracks are predicted to be initiated in the wheels with larger defects than the critical size, and finally RCF failures are predicted to occur in these wheels.

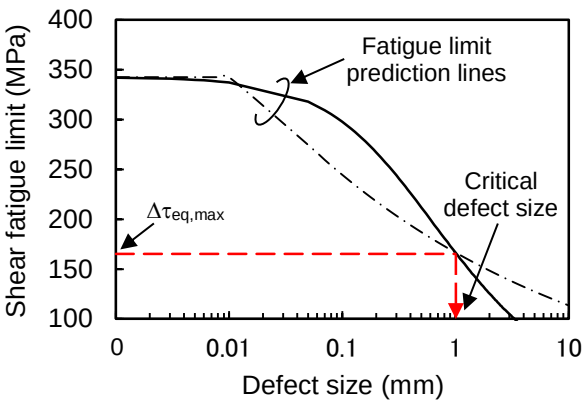

Figure 13 *Critical defect size estimation method.*

Table 2 presents the critical defect sizes estimated using this method. The critical defect sizes for each contact position and the average critical defect sizes for all the contact positions are presented in the table. The critical defect sizes are not necessarily the same for different contact positions or different tread profiles, similar to $\Delta\tau_{eq,max}$. However, the average critical defect sizes of the new and worn profiles are equivalent, i.e., 1.1 mm. The specification of AAR regarding the maximum internal defect size of the wheel rim is about 1.6 mm. The defects of size more than 1.1 mm are possibly included in the wheels used in North American freight car services. This indicates that RCF failures might occur in the wheels with defects greater than 1.1 mm in size. Therefore, high-cleanliness wheels are believed to be effective to prevent wheel removals for causes related to the presence of subsurface cracks.

Table 2 *Calculated critical defect sizes at each contact position and the average of critical defect sizes.*

Tread profile	Critical defect size (mm)			
	Flange	Centre	Front rim	Average
New wheel	1.1	1.3	1.1	1.1
Worn wheel	1.2	1.1	1.0	1.1

5. Conclusions

The effect of defect size on the subsurface crack initiations in RCF failures of heavy haul car wheels was evaluated. The torsion and axial fatigue tests of the wheel steel with small artificial defects were conducted. The fatigue limits of the wheel steel decrease with an increase in the artificial defect size. The shear and axial fatigue limits with different defect sizes correspond well to the formulas of $\sqrt{area}$ and El-Haddad.

Finite element analyses of the actual wheel model were conducted to calculate the variations of stresses at the subsurface during rolling contact. The largest shear stresses occur below the tread surface which increase the likelihood of initiating subsurface cracks. The equivalent shear stresses $\Delta\tau_{eq,max}$ based on the multiaxial fatigue evaluation model, which is the McDiarmid model, depend on the wheel-rail contact positions or the tread profiles. However, the average $\Delta\tau_{eq,max}$ values at all the contact positions are equivalent for different tread profiles. The estimated critical defect size for the subsurface crack initiations is 1.1 mm, which is obtained from $\Delta\tau_{eq,max}$ and the shear fatigue limits with different defect sizes. Wheels, which meet the Ultrasonic test required by the AAR may still have porosity or non-metallic inclusions greater than the critical defect size, and are more likely to develop subsurface cracks. Wheels with indications smaller than 1.1 mm are not likely to initiate subsurface cracks. Therefore, high-cleanliness wheels are believed to be more effective in preventing a subsurface crack from propagating to a critical length.

Regarding the future works, further analysis planned for the subsurface crack includes evaluation of the effect of wheel size and tread brake on the subsurface crack initiation.

Abstract: A novel tribo-testing method using a pin-on-plate tribometer was developed to test and visualise the coefficient of friction over surfaces with oxides present to examine low adhesion issues. Iron oxides were both synthesised and deposited on rail steel substrates. Powdered oxide layers of single types were deposited to investigate individual oxides. Composition was analysed using x-ray diffraction and scanning electron microscopy before testing. Magnetite, Haematite and Lepidocrocite were formed when water alone was applied to the surfaces. Low friction was observed on oxidised sample surfaces only outside high roughness, oxide pitted, areas, but these conditions were shown to be transient.

Keywords: friction, low adhesion; railhead contamination; iron oxides.

1. Introduction

Traction available between the wheels and rails is a crucial factor in safe and effective operation of railways. Leaf contamination is often cited as one of the main causes of very low traction, or 'low adhesion', but almost half of incidents during the autumn period are reported to have no leaf contamination [1] meaning that other contaminants, such as the presence of oxides on the railhead, being responsible.

Oxides, particularly when in combination with small amounts of water such as that caused by light drizzle, high humidity or 'close to dewpoint' conditions have been shown to reduce the traction available at the wheel/rail interface [2].

1.1. Background

The influence of iron oxides on the wheel/rail contact has been explored in a recent review [3], however agreement between researchers on the mechanism in which adhesion is reduced by oxides has not been reached. Recent work to update old research by Beagley [4] supports the hypothesis that the cause of this low friction is likely due to a high viscosity layer as very low traction has been achieved sporadically in twin-disc tests [5]. Often these studies are targeted at understanding wear and not friction or identifying the conditions which may lead to low adhesion [3][6][7].

In-contact oxide studies of the railhead have been performed using a portable X-ray diffraction (XRD) rig which explore the influence of train movements on the oxide composition [8][9]. The three oxy-hydroxides of α-, β- and γ-FeOOH (goethite, akageneite and lepidocrocite respectively) were the focus of the studies. The study shows that the β-FeOOH and γ-FeOOH compounds are removed much faster than the α-FeOOH under the mechanical action of train passes.

Low adhesion caused by oxides on the railhead is notoriously difficult to reproduce in the laboratory [5][10]. Studies have suggested that the reason for this is a very narrow band of conditions required to cause the phenomena. In addition to this and unlike leaf layers which have been shown to form a black durable surface taking around 300 axle passes to be removed [11], the composition of oxides on the railhead surface undergo significant compositional changes after only a few train passes [8]. Therefore, the reason for the difficulty simulating low adhesion conditions from oxide effects in the lab may be due to the transient nature of the surface conditions.

Tribo-testers typically used for studying the wheel/rail contact such as twin-disk and pin-on-disc tribometers have the limitation that a surface undergoing testing is rapidly exposed to many cycles. As a result, sensitive surface conditions may be destroyed by the mechanical action of testing before data recording has begun. These tribometers often also attempt to achieve a singular or average COF for a surface which may be insufficient to investigate surfaces not of a homogeneous nature, such as rusted surfaces.

Synthesising the oxides onto substrates for testing through exposure to different conditions for subsequent tribo-testing has been explored [6][12], but treatments are often crude for accelerating the oxidation process and may not adequately simulate actual conditions during corrosion.

1.2. Objectives

A first objective of this work was to explore and simulate trackside conditions for understanding how the conditions lead to the formation of individual oxide types on the railhead.

A second objective was to develop a novel method for assessing the oxide-friction effects using a controllable

number of passes (including single-pass) to examine oxides both synthesised on a surface, as well as artificially deposited as single oxide powders. The purpose of this was to investigate the mechanism of friction changing behaviours of oxides and scrutinise individual oxide compounds.

2. Railhead conditions

The chemical and physical conditions of the railhead were investigated by weather monitoring and railhead swabbing campaigns to form a basis for simulating realistic conditions in the lab as well as identifying compounds of interest.

2.1. Physical conditions

To establish a basis for conditions to simulate, trackside environmental monitoring has been undertaken using a custom-made datalogger which records the ambient temperature, humidity and presence of rainfall in addition to the temperature of the railhead by means of a temperature probe attached to the side of the rail. The dew point temperature was calculated from the humidity and environmental temperature.

Conditions were logged at the Quinton Rail Technology Centre test track in October 2017 alongside a field-trials experimentation group. Particularly low traction conditions were noted by the driver on the morning of the 12th. Figure 1 gives the trackside environmental conditions experienced the night before when there were no vehicle movements. Two events are noted: a period of light rain in the evening before as well as a prolonged drop in the railhead temperature below that of the dewpoint.

2.2. Railhead swabbing

A swabbing procedure was developed to obtain samples of the material from the railhead onto glass microfiber and cellulose filter paper. The swabs were then analysed using XRD.

A variety of iron oxides and oxide-hydroxides were identified including magnetite, maghemite, haematite, goethite, akageneite, lepidocrocite and wüstite. Swabs taken after the night monitored in figure 1, which can be seen in Figure 10 of the appendix, showed the presence of akageneite, lepidocrocite and wüstite.

3. Methodology

The test specimens consisted of 42mm diameter disks cut from the top of grade R260 rail stock. Before each substrate was prepared as a sample the surface was ground using progressively fine silicon carbide paper up to 1500grit. The final stage of grinding was done in isopropanol before the surface was rinsed with isopropanol.

3.1. Oxide Synthesis

To investigate the effect of various environmental conditions on the oxide compounds formed, these samples underwent a controlled exposure to various environments.

3.1.1. Trackside environment simulation

Temperature was controlled using a refrigerator set to 7°C and in an air-conditioned room (20°C).

Humidity was controlled using sealed containers containing saturated solutions of specific salts and a mesh suspended above the surface of the liquid onto which the substrates were placed. The air above the saturated solution set up a buffered equilibrium with the solution and maintains a constant humidity. Salt

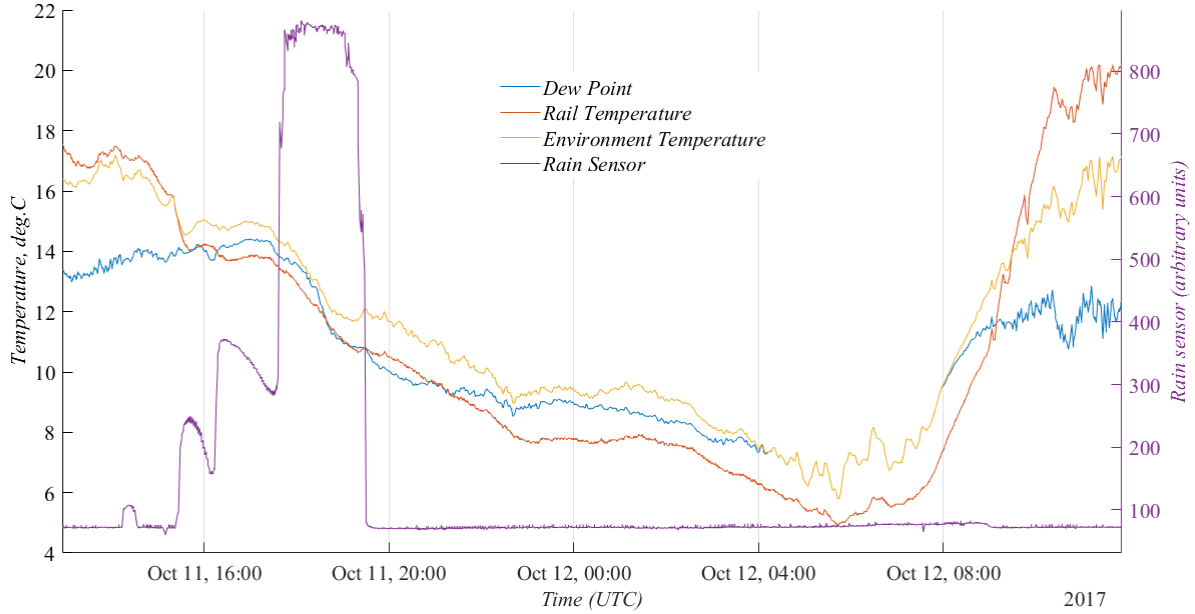

Figure 1 *Trackside environmental monitoring station data.*

solutions and their target humidity are given in Table 1.

The various sample preparation treatments for oxide synthesis are given in Table 2.

Table 1 *List of saturated salt solutions used for simulating environmental conditions.*

Saturated solution salt	Humidity above solution surface (% RH)	Condition simulated
None (Distilled water)	100	V. high humidity
Potassium Chloride	85	Normal humidity
Sodium Chloride	75	Medium low humidity
Sodium bromide	60	Low humidity

Table 2 *Descriptions of simulation conditions, after which the samples are placed with the control sample until testing.*

Treatment	Description
A – Control	Control – Stored at room temperature (~20°C) and at 85%RH
B – Dew	A condensation cycle – Cooled to 7°C at 60% for 3 hours then placed in 100%RH container at room temperature for 5 hours to induce dew formation.
C - Drizzle	Sample sprayed with 0.1ml of distilled water which is left to evaporate.
D – Mixed	As for B but sample is sprayed after 30 minutes of being placed in 100%RH container.
E – Mixed (simulated from data)	Temperatures, humidity and water spray are controlled to simulate the overnight trackside conditions recorded
F – Flooded	5ml of distilled water placed carefully on the substrate surface to flood the surface.

3.2. Oxide deposition

To examine the effect of individual oxides on the COF of the surfaces, samples were treated using drop-deposition whereby powdered oxide in a liquid suspension is placed on the disk surface and the solvent allowed to evaporate under room conditions leaving behind a layer of the oxide. Magnetite, haematite, goethite and lepidocrocite powder obtained from the Sigma Aldrich and Alfa Aesar suppliers with particle sizes of approximately 50-100nm, 0.1-5µm, 1-2µm and 1-5µm respectively.

A first batch of samples was prepared using distilled water as a solvent. 1g.dm^{-3} concentration suspensions of the oxides were deposited in volumes of 5ml per sample.

A second batch was prepared using isopropanol as the solvent. 1g.dm^{-3} was used again; however, due to the lower surface tension, only 2ml could be applied per disc to avoid overflow.

3.3. Surface analysis

The chemical and physical properties of the surfaces were analysed through the techniques described in this subsection.

3.3.1. Surface topography

An optical profilometer was used to determine the thickness of the deposited surface layer and the substrates were weighed before and after treatment to find the layer density.

A scanning electron microscope was used to closely image the deposited layers as well as investigate the morphologies of the oxides synthesised.

3.3.2. Oxide composition

A PANalytical X'Pert-3 powder X-Ray diffractometer mounted in glancing incidence geometry and equipped with a Cu anode was used to analyse the samples. The steel substrates are mounted in bulk sample holders and placed in the sample cassette.

Continuous scans of each sample were performed between the 2θ angles of 20 to 65 degrees using a step size of 0.02 degrees and incident angle of 14° with a solar slit of 2° to maximise the x-ray beam intensity. The sample stage was rotated during scans and 4.664 seconds exposure taken per step.

Positions and relative intensities of peaks on the scans were then matched to the peaks of known compounds to identify the contaminants present on the surfaces using the ICDD PDF-4+ database [14].

3.4. Tribo-testing

A Brucker UMT tribo-tester was used to perform pin on plate testing of the disc samples. The top drive consists of a 10mm diameter stainless steel ball. The ball is loaded against the sample surface at with a force of 7N to achieve a mean contact pressure of 590MPa and Maximum Hertzian contact pressure of 890MPa. Under these conditions the ball initially formed contacted the plate with an approximate diameter of 0.12mm. Between rounds of testing, tests were randomised.
