The co-simulation method uses the TCP/IP protocol to enable the co-simulation between a detailed in-house track system simulation package and a commercial vehicle system dynamics simulation package (GENSYS). The biggest advantage of the co-simulation method is to improve the accuracy and reduce the simulation time. The application of a parallel computing technique, such as the Message Passing Interface (MPI), which defines the rules regarding communications between different computer cores, offers the flexibility for further extension of the simulation model, for example, to add a Longitudinal Train Dynamics model and a traction control model into the simulation. In this case, no changes are needed to the current architecture, and the add-on models can be "plugged in" easily.

The dynamic wheel-rail responses and the rail bending stress due to ballast voids have been investigated. The simulations clearly indicate the significant influence of ballast voids on wheel-rail dynamic forces. The effect of multiple ballast voids on the bending stress is dramatic. If the number of consecutive sleepers without support are equal to or more than 3, track maintenance should be conducted immediately, otherwise the rail service life would be reduced greatly due to the large bending stresses. For five sleepers without support, the von Mises stress on the rail top surface is more than doubled when the rail bending stress is accounted for.

Abstract: A novel rail non-uniform wear prediction model has been developed for analysing the influence of the tread hollow worn wheel on the rail wear. Taking into account the track random irregularity, rail non-uniform wear distribution and its effect on wheel-rail dynamic interaction are investigated, aiming at a high-speed vehicle with different tread hollow–worn wheels running on the tangent track. Simulation results indicate that hollow wheels will give rise to noteworthy change on the rail non-uniform wear distribution, resulting in a significant increase of rail wear, and have a distinct effect on the wheel-rail interaction.

Keywords: Rail non-uniform wear; track random irregularity; Hollow-worn wheel; Kalker's variational method; MKP contact model; vehicle-track coupled dynamics.

1. Introduction

Hollow shape wear is a common phenomenon on the wheels of Chinese high-speed vehicle [1]. The hollow worn wheel may worsen the wheel-rail interaction, and then has a significant influence on wheel-rail wear evolution.

There has been plenty of research focusing on the influence of hollow-worn on the vehicle dynamics. Sawley and Wu [2] surveyed the characteristics of the hollow-worn wheels in North American service, and then quantified the effect of the depth of hollow on the wheel-rail dynamic interaction based on vehicle dynamics simulation. Tavakkoli et al. [3] investigated the effect of tread hollowing on the dynamic behaviour of a passenger coach, the results showed that, when the false flange induced by the hollow-worn wheel was greater than 2mm, lateral oscillations of wagon increased and hunting phenomenon might occur. Polach and Nicklisch [4] proposed new wheel/rail contact geometry parameters to assess the vehicle dynamic behaviour of worn wheel with different running distance. Fröhling et al. [5] used the finite element simulation and shakedown analysis to study the effect of hollow wear on the surface initiated rolling contact fatigue.

It is obvious that hollow worn wheel will accelerate the wear rate of both wheel and rail. In the last 20 years, several sophisticated, realistic and credible wheel wear prediction models have been proposed [6]~[9]. Even though the wear mechanisms of wheel and rail are quite similar, there are still differences between wheel and rail wear prediction as the service conditions are different. Rail wear prediction is a more complex work with respect to wheel wear simulation due to the variety of contact conditions. Few rail wear prediction models have been developed over the years [10]~[12]. Moreover, most of the previous studies focused on uniform rail wear, which assumed that the worn rail profile remained unchanged along the longitudinal direction of the track. However, due to the impact of track random irregularity, wheel-rail dynamic interaction is variable at different cross-sections of the rail, so is the corresponding rail wear. Thus, a non-uniform rail wear prediction model can be more accurate to reflect the actual rail wear characteristics.

In the present work, a non-uniform rail wear prediction model is proposed to assess the effect of hollow worn wheel on the rail non-uniform wear. The methodology is described in Section 2, involving vehicle–track dynamics, wheel-rail rolling contact analysis, material wear model, assignment, sampling and accumulation strategy, profile update and smooth strategy. Based on the proposed model, Section 3 presents the evolution of the rail non-uniform wear when a high-speed vehicle with different tread hollow–worn wheels passes through. Finally, Section 4 concludes the paper with a summary and an outlook to the future work.

2. Methodology

2.1. General architecture of the model

The procedure of rail wear simulation is similar to wheel wear simulation, but there are two major differences:
(1) Wear on the wheel is influenced by the railway network that it traverse, whereas wear on the rail is the combined result of all passing wheels;
(2) In wheel wear simulation, all sample data from the dynamic simulation have the same effect on the wheelset transverse wear for each simulation set, whereas the dynamic sample data could only influence the rail wear at the corresponding location.

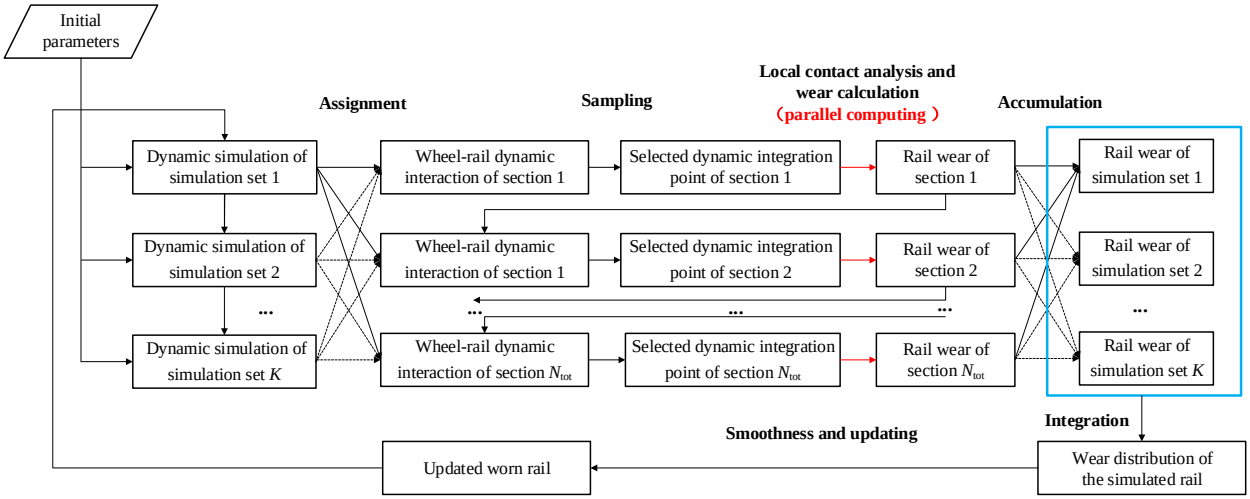

Figure 1 *Flow chart of the rail profile non-uniform wear prediction model.*

According to the first difference, all rail service conditions that have influence on the wheel-rail dynamic interaction should be considered, which include the operating conditions (speed, traction, braking …) and the contact conditions between wheel and rail [13] (wheel profile, friction, creep scaling…) [10]. In this paper, the total number of simulation sets is assumed to be K.

According to the second difference, rail wear is non-uniform along the track as the wheel-rail dynamic interaction is variable at different positions. Nevertheless, wheel-rail dynamic interactions of two adjacent rail sections are similar, and therefore the corresponding rail wear. Meanwhile, there is slight change of rail wear along the longitudinal direction due to the plastic flow of material. In view of these reasons, rail wear of specific cross-sections with regular intervals are calculated in this paper, and the rail wear inside the calculated cross-sections is interpolated. The total number of calculated cross-sections is assumed to be N_{tot}.

Flow chart of the rail non-uniform wear evolution prediction procedure is shown in Figure 1. The numerical simulation of rail wear consists of five main parts: (1) wheel-rail dynamic interaction simulation, (2) wheel-rail rolling contact analysis, (3) calculation of rail wear, (4) assignment, sampling and accumulation, (5) smoothness and updating of rail profile.

As shown in Figure 1, rail non-uniform wear prediction is a feed-back process. Before the wear loop calculation, all the rail serve conditions are defined, such as vehicle/track dynamic parameter, initial rail profile, operating conditions, etc. Wear calculation is started from vehicle-track dynamic simulation, and wheel-rail global contact parameters at each dynamic integration step are obtained. The wheel-rail dynamic contact parameters are assigned and sampled to get the available contact parameters for rail wear calculation of every cross section. Then, rail wear of each cross-section is solved sequentially according to the available contact parameters of corresponding cross-section. In rail wear calculation, the available contact parameters are the inputs for the local wheel-rail rolling contact analysis to calculate the detailed normal and tangential contact behaviours inside the available contact patches. The wheel-rail local contact parameters are further used in the material wear model to obtain the wear distribution in each available contact patch. The wear distributions of all the available contact patches are added to get the rail wear of the corresponding cross section. For each calculated cross-section, local contact analysis and wear distributions calculation of all available contact patches are performed based on parallel computation to improve the computational efficiency. For each simulation set, by accumulating rail wear of all cross sections, wear distribution of the whole simulated rail is obtained. Considering the influences of all the simulation sets, wear distribution of the simulated rail is integrated. With a certain smoothness and updating strategy, the new non-uniform worn rail profiles are updated, and fed back to the next rail wear simulation cycle.

2.2. Wheel-rail dynamic interaction model

Rail non-uniform wear may give rise to the roughness on rail surface, which results in enhanced medium-high frequency vibration and multi-points contact between wheel and rail. Vehicle-track coupled dynamics model [14] is used in wheel-rail dynamic interaction calculation, which can better reflect wheel-rail medium-high frequency interaction. A new robust non-Hertzian normal contact model named MKP contact model [15] and the modified FASTSIM are utilized to calculate wheel-rail normal and creep contact force.

The traditional vehicle-track coupled model is shown in Figure 2. The passenger vehicle model is adopted, in which the car body, two bogies and the four wheelsets are modelled as rigid bodies, the primary and secondary are regarded as spring-damping elements. There are 35 DOFs in total, including the vertical displacement Z, the lateral displacement Y, the roll angle ϕ, the yaw angle ψ and the pitch angle β of every rigid body. The longitudinal motions of the vehicle is ignored.

The slab track model which includes the vibrations of the rail and the slab is used for track system dynamic

simulation. Three motions of rail vibration are considered: vertical Z_r, lateral Y_r and torsional ϕ_t, and two motions of slab vibration are considered: vertical Z_s, lateral Y_s. Both the left and the right rail are treated as the continuous Bernoulli–Euler beams which are discretely supported at rail–sleeper junctions by springs-damping elements. The track slabs are described as elastic rectangle plates supported by viscoelastic foundation in vertical motion and regarded as rigid body in lateral motion. For more information about the track model, see Ref. [14].

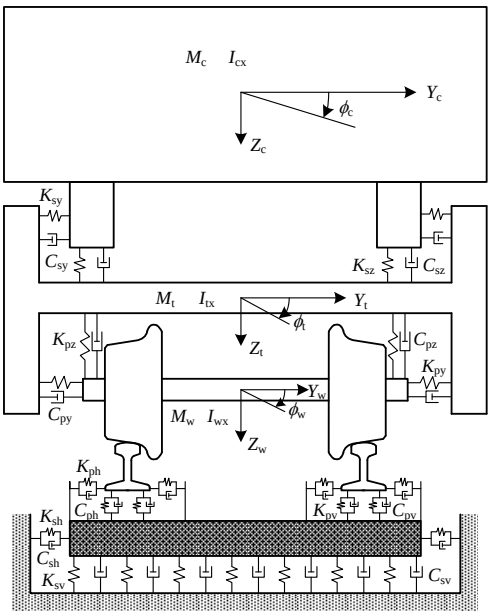

Figure 2 *Vehicle-track coupled dynamic model.*

MKP contact model [15] is a simplified non-Hertzian contact model based on virtual penetration, see Figure 3. Since MKP contact model exhibits a good computational accuracy, stability and efficiency, it is adopted to calculate the wheel-rail normal contact force. According to MKP contact model, wheel-rail normal force can be expressed as follows:

$$N=\frac{\pi^2 E}{4\left(1-\mu^2\right)}\times \sum_{i=1}^{N_c}\int_{y_{ri}}^{y_{li}}\frac{x_{li}^2(y)\delta(y)}{\sum_{j=1}^{N_c}\int_{y_{rj}}^{y_{lj}}\int_{-x_{lj}}^{x_{lj}}\sqrt{\frac{x_{lj}^2(\eta)-\xi^2}{\xi^2+(\eta-y)^2}}d\xi d\eta}dy \quad (1)$$

In Equation (1), E and μ are the elastic modulus and Poisson's ratio of wheel and rail, $\delta(y)$ is the elastic deformation of the coordinate $(0, y)$, y_l and y_r are the left and right edges of the contact patch, $x_l(y)$ and $-x_l(y)$ are the front and rear edges of the contact area, the subscript 'i' represent the serial number of the contact patch, N_c is the total number of contact patches.

To estimate the wheel-rail creep force, FASTSIM procedure with modified elasticity parameters is applied in every contact patch. According to Ref. [16], the elasticity parameters for non-elliptic contact patch can be written by:

$$L_{1i}=\frac{2\pi\int_{y_{li}}^{y_{ri}}x_{li}^2(y)dy}{GA_iC_{11i}},\quad L_{2i}=\frac{2\pi\int_{y_{li}}^{y_{ri}}x_{li}^2(y)dy}{GA_iC_{22i}},\quad L_{3i}=\frac{2\pi^{3/2}\int_{y_{li}}^{y_{ri}}x_{li}^3(y)dy}{3GA_i^{3/2}C_{23i}} \quad (2)$$

where A_i is the area of the i^{th} contact patch; C_{11i}, C_{22i}, and C_{23i} are Kalker's creep coefficients of the i^{th} contact patch, functions of the semi-axes ratio of the equivalent ellipses of the i^{th} contact patch [16].

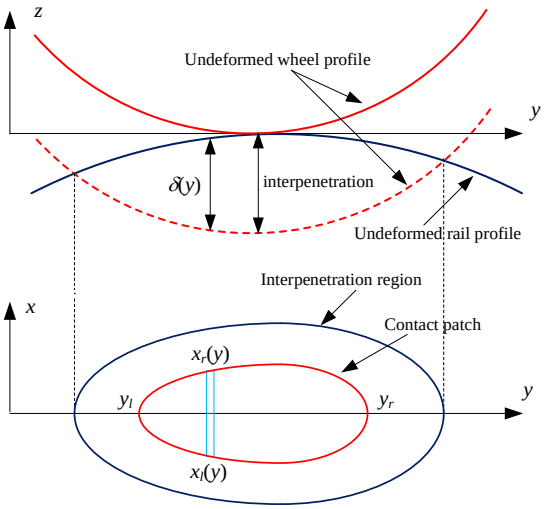

Figure 3 *Schematic of the MKP contact model.*

The complete dynamic model can be obtained by combining the vehicle dynamic model, track dynamic model and wheel-rail contact model. By solving the dynamic model with numerical method, wheel-rail global contact variables of each dynamic integration point are obtained.

2.3. Assignment and sampling strategy

According to Section 2.1, rail wear of the specific cross-sections with regular intervals are calculated, see Figure 4. The span of two adjacent sections are assumed to be l_{step}, so the total length of the wear simulation zone can be written as follows:

$$l_{tot}=(N_{tot}-1)l_{step} \quad (3)$$

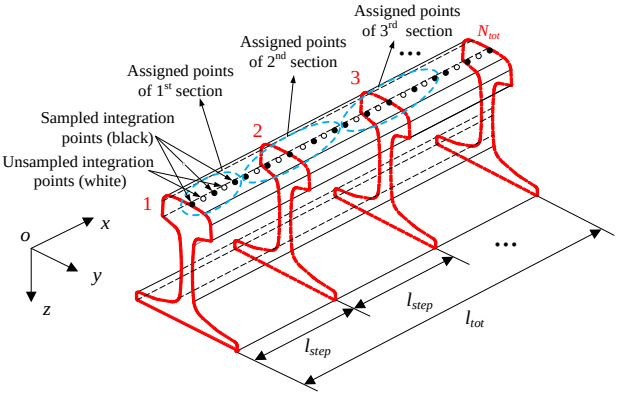

Figure 4 *Schematic of the assignment and sampling strategy*

Assume that the left and right edges of the assigned

region for the i^{th} cross section are l_{sLi} and l_{sRi} along the x-direction from the cross-section. That is, when the distance between the location of the j^{th} dynamic integration point and the i^{th} cross-section is less than l_{sLi} (left side integration point) or l_{sRi} (right side integration point), the global contact variables of the j^{th} dynamic integration point have potential effect on the rail wear of the i^{th} cross-section. According to Figure 4, l_{sLi} and l_{sRi} can be expressed as follows:

$$l_{sLi} = \begin{cases} 0, & i = 1 \\ l_{step}/2, & i \neq 1 \end{cases}$$
$$l_{sRi} = \begin{cases} 0, & i = N_{tot} \\ l_{step}/2, & i \neq N_{tot} \end{cases} \quad (4)$$

The assigned integration points are further sampled for higher computational efficiency. Fixed sampling frequency and equally spaced sampling are adopted for each cross section of each simulation set. The sampled integration points for each cross section are considered to be the valid integration points for wear calculation.

2.4. *Wheel-rail local contact model*

Kalker's variational method [17] is applied for wheel-rail local contact analysis. With regard to local contact calculation, Kalker's variational method has relatively high computational accuracy, but huge computational effort. Thanks to the parallel computation in post processing, Kalker's variational method is adopted with acceptable calculation efficiency.

Detailed description of Kalker's variational method can be found in Ref. [17]. The numerical method that applied to solve the normal contact problem is NORM and Newton-Raphson iteration method. Gauss-Seidel solver is used to solve the steady rolling contact problem in numerical analysis, see Ref [18].

The outputs of wheel-rail local contact analysis are used for wear calculation, which include the surface traction and the elastic sliding velocity distribution inside the contact patch.

2.5. *Wear model*

To evaluate rail wear, material wear model developed by the University of Sheffield [19] is adopted. Material wear depth when the wheelset traveled by unit distance can be written as follows:

$$\delta_w(x,y) = \frac{K_w(I_w(x,y))}{\rho} \quad (5)$$

where K_w (μg/m/mm^2) is the wear rate that describes the mass(μg) of the removed material for unit surface(mm^2) after pass-through unit distance(m), $I_w(x,y)$ (N/mm^2) is the local frictional index inside the contact patch, ρ is the density of the rail. As shown in Figure 5, wear rate can be expressed as follows:

$$k_w(I_w) = \begin{cases} 5.3 * I_w & I_w < 10.4 \\ 55.1 & 10.4 \le I_w \le 77.2 \\ 61.9 * I_w - 4778.7 & I_w > 77.2 \end{cases} \quad (6)$$

The frictional index I_w can be written as follows:

$$I_w(x,y) = p(x,y)\gamma(x,y) \quad (7)$$

where $p(x,y)$ is the surface traction distribution, and $\gamma(x,y)$ is the local creep.

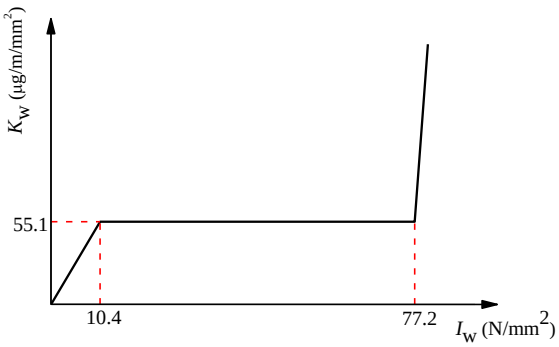

Figure 5 *Wear rate K_W for different wear index I_w.*

2.6. *Accumulation strategy*

Assume that the wheel-rail dynamic interaction as well as wear distribution remains unchanged when the contact patch passes through the dynamic simulation positions at sampled integration points. The wear depth after the wheelset traveled by can be therefore obtained by accumulating the wear distributions of the contact patch along the x-direction, which can be expressed as follows:

$$\delta(y) = \int_{x_l(y)}^{x_r(y)} \delta_w(x,y)dx \quad (8)$$

All wear distributions of sampled integration points are assumed to have an indistinguishable contribution to the rail wear of corresponding cross section for each simulation set. Considering the influences of all sampled points and four wheelsets, wear depth of the i^{th} cross-section for the k^{th} simulation set after one vehicle's passage can be written as follows:

$$\delta_{L,Rik}(y) = \frac{\sum_{n=1}^{4}\sum_{m=1}^{N_{sam}} \delta_{L,Riknm}(y)}{N_{sam}}, \quad (9)$$
$$k = 1 \sim K, i = 1 \sim N_{tot}$$

where $\delta_{L,Riknm}(y)$ is the left/right rail wear distribution of the m^{th} sampled point for the n^{th} wheelset at the i^{th} cross-section in the case of the k^{th} simulate set.

Considering K simulation sets, the average wear depth of the i^{th} cross-section after one vehicle's passaage can be expressed as follows:

$$\delta_{L,Ri}(y) = \sum_{k=1}^{K} \delta_{L,Rik}(y) \times p_k, \; i = 1 \sim N_{tot} \quad (10)$$

where p_k is the probability of the k^{th} simulate set.

2.7. *Smoothing and update strategy*

The original calculated rail wear profiles are smoothed by the moving average smoothing method. Assume all rail profiles remain unchanged until new update. When the maximum rail wear depth of all the cross-sections

reaches the prescribed threshold 0.1mm, update the rail profiles for new rail wear simulation cycle. Spline interpolation function method is applied to obtain the worn rail profile of all dynamic integration points and form the rail profile of calculated cross-section.

3. Simulation results

3.1. Simulation conditions

The proposed rail non-uniform wear prediction model is applied to predict the wear evolution of a 100 m long rail of tangent track with initial rail profile of standard profile CHN 60.

In order to investigate the influence of the worn wear wheel on rail non-uniform wear, one type of vehicle and operating condition together with four types of wheel profile are used in this study. A Chinese high-speed vehicle CRH2 EMU run on Chinese CRTS I slab track with the speed 300 km/h is employed. One standard wheel profile and three worn wheel profiles are adopted. The detailed information of the wheel profile is shown in Table 1, and the comparison of the four wheel profiles is shown in Figure 6. The worn profile is obtained by interpolating the measured wheel profile [1] of other travelling distance. As shown in Figure 6, the main wear region on the wheel tread concentrates on the adjacent area ranging from −20 to 20 mm around the nominal rolling circle.

Table 1 *Wheel profile used in simulation*

wheel number	travelling distance	percent
1st wheel	0km (standard)	25%
2nd wheel	50, 000 km	25%
3rd wheel	100, 000 km	25%
4th wheel	150, 000 km	25%

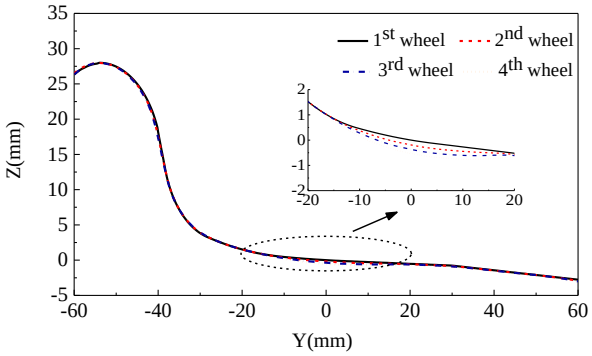

Figure 6 *Comparison of wheel profiles*

Taking into consideration of the effect of track random irregularity on rail wear, the average spectrum [1] of Chinese high-speed railway non-ballasted track is adopted. Figure 7 shows the track random irregularity of the simulated track. The span of two adjacent cross-sections l_{step} is selected to be 0.25 m, the sampling number for each cross section of each simulation set N_{sam} is set as 8, and the rail profile is updated 20 times in total.

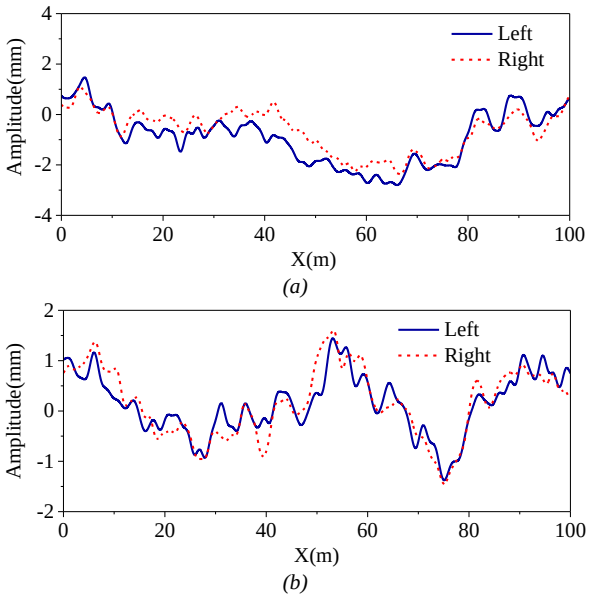

Figure 7 *Track random irregularity: (a) Vertical irregularity. (b) Alignment irregularity.*

3.2. contact geometry between wheel and standard rail

Wheel wear has a great influence on the location of the wheel-rail contact geometry, and the determination of the location of the potential wear.

The static location of the contact point between wheel and rail is considered at first. The wheelset lateral displacement is set to range from -5 mm to 5 mm, and the yaw angle is ignored. Figure 8 shows the contact point locations on wheel and rail profiles. It can be seen from Figure 8 that the contact points focus on the rail center for standard wheel, and located at the boundary of the main wear region for hollow-worn wheel. There are two main discontinuous contact areas for worn wheel, and the spacing of the two contact areas increases with the increase of wheel wear.

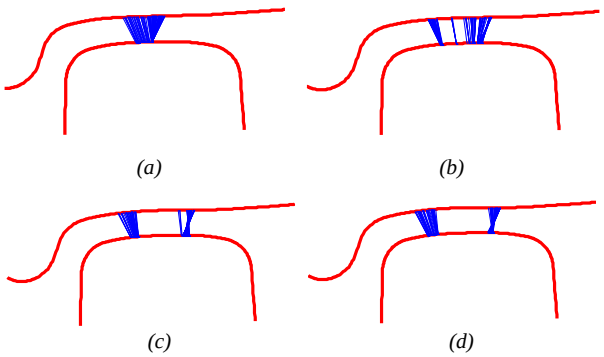

Figure 8 *Contact point locations on wheel and rail profiles: (a) 1st wheel. (b) 2nd wheel. (c) 3rd wheel. (d) 4th wheel*

Figure 9 indicates the dynamic trajectory of the contact patch on the standard rail as the wheel passes through. The result is obtained by the vehicle-track dynamic model, the dynamic trajectory of the left wheel of the first wheelset is presented. Similar with the static contact that

shown in Figure 8, the dynamic trajectory of the standard wheel and the hollow-worn wheel is quite different. The dynamic trajectory of the standard wheel is located at the rail center, and remains almost unchanged along the rolling direction. The dynamic trajectory of the hollow-worn wheel is distributed in two isolated areas at the boundary of the main wear region, which implies that instantaneous two-point contact is caused by hollow wear.

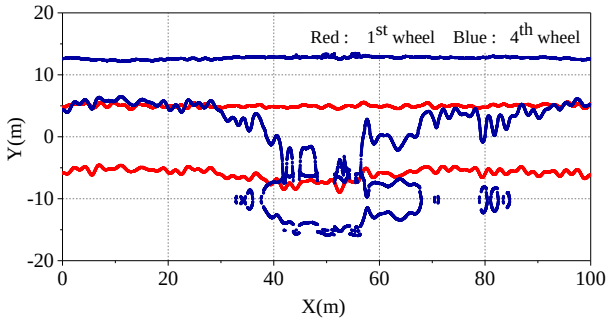

Figure 9 *Dynamic trajectory locations on the rail*

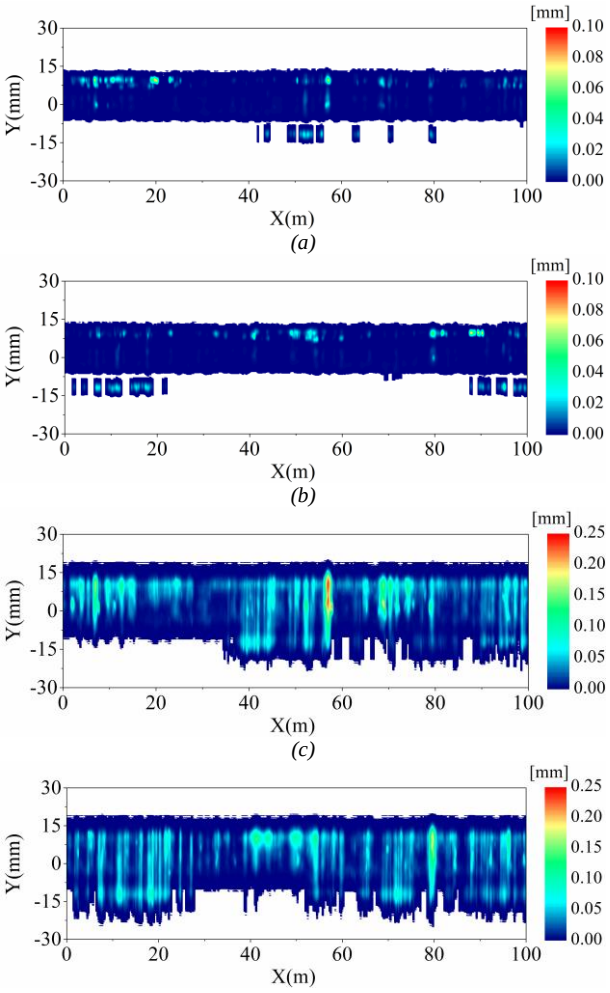
3.3. Rail wear distribution characteristics

Rail non-uniform distribution characteristics under the influence of the worn wheel and the track random irregularity are presented in this section (see Figure 10-Figure 12).

Wear distributions of the simulation zone after the 1st and 20th updates are shown in Figure 10. The accumulated number of passages after the 1st and 20th updates are 46096 and 737302, respectively. Positive X point to the rolling direction and positive Y points from the gauge side to the rail center. The magnitude of the wear depth is identified by the color variation.

As seen in Figure 10(a) and Figure 10(b), there are two separate wear regions after the 1st update. Two points contact induced by hollow wear (see Figure 8 and Figure 9) is the origin of the two separate wear regions. The main wear band locates at the rail center away from the gauge side, and the corresponding Y-coordinate ranges from -7mm to 14 mm. Another wear band is close to the main wear band and the corresponding Y-coordinate ranges from -15 mm to -8 mm. Rail wear is non-uniform along the track with two distinct regions that have larger wear depth, which are located around 9mm and -11mm. It can be found in Figure 10(c) and Figure 10(d) that, with the increase of the update times, the rail bandwidth gradually broadens and two distinct wear regions are merged into one continuous wear region. The boundary of the wear band away from the gauge side is straight and parallel to the rolling direction, and the boundary of the wear band close to the gauge side obviously changes along the track.



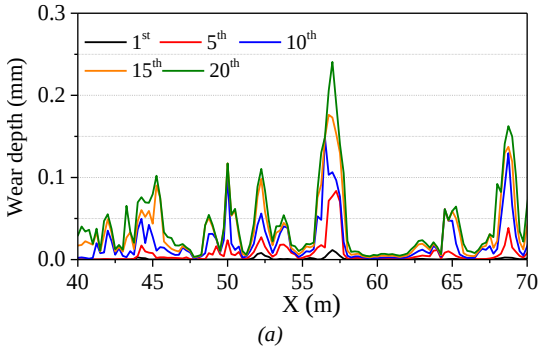


Figure 10 *Wear distribution of the simulation zone: (a) Left rail after 1st update. (b) Right rail after 1st update. (c) Left rail after 20th update. (d) Right rail after 20th update.*

For the rail wear after the 20th update in Figure 10, the maximum wear depth occurs at X=57 m, Y=4.2 mm of the left rail. The wear depth of the longitudinal section Y=4.2 mm and the total wear area distribution along the track are displayed in Figure 11. Non-uniform distributions of the wear depth and wear area have the similar evolution rules. It seems that the wear rate distribution of the whole service life is determined by the original wear distribution. The locations where the rail wear is relatively serious after the 20th update are highly consistent with that after the 1st update.

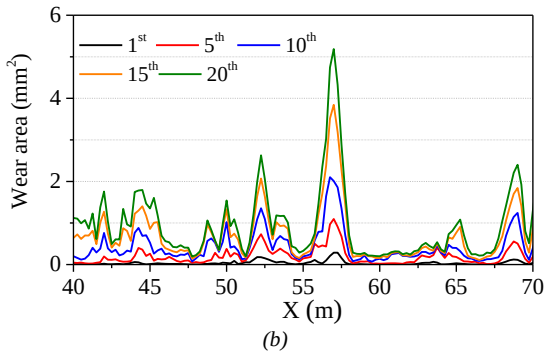

Figure 11 *Wear distribution along the rolling direction after different update times: (a) Left rail wear depth at Y=4.2mm. (b) Total wear area of the cross-section.*

Wear depth evolution of the cross-section at the left rail of X=57 m is shown in Figure 12. Wear distribution changes considerably and gets smoothly with the increasing profile updating times. Wear difference at different positions gradually decreases. Wear region gets wider due to the continuous update, and has a faster expansion towards the gauge side.

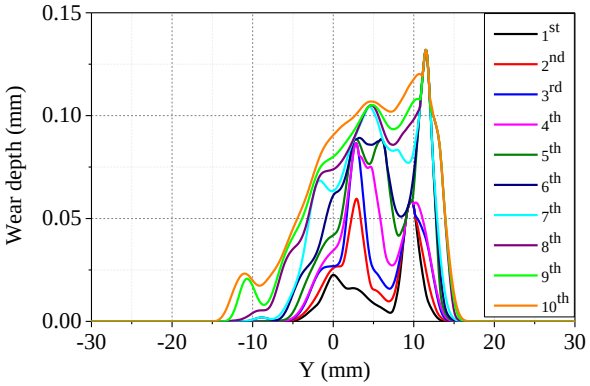

Figure 12 *Left rail wear depth of the cross-section of X=67m*

3.4. Influence of hollow-worn wheel on wear rate

Effect of different wheel on rail wear distribution is further studied. Figure 13 shows the contribution of each wheel on the left rail wear distribution after the 20th update. Figure 13 indicates that the influence of the standard wheel (1st wheel) and slightly worn wheel (2nd wheel) are similar, and the influence of two serious hollow-worn wheels (3rd wheel and 4th wheel) are similar. For the 1st and 2nd wheel, rail wear bands are symmetry about the rail center, and the maximum wear depth position locates at the rail center (X=0 mm). For serious worn wheels, rail bandwidths are broader than that induced by the 1st wheel and 2nd wheel, and the rail wear distributes in two distinct wear regions with higher wear depth as a result of tread hollow wear. It can be concluded that the initial wheel-rail contact geometry described in Section 3.2 directly affects the distribution of the rail wear.

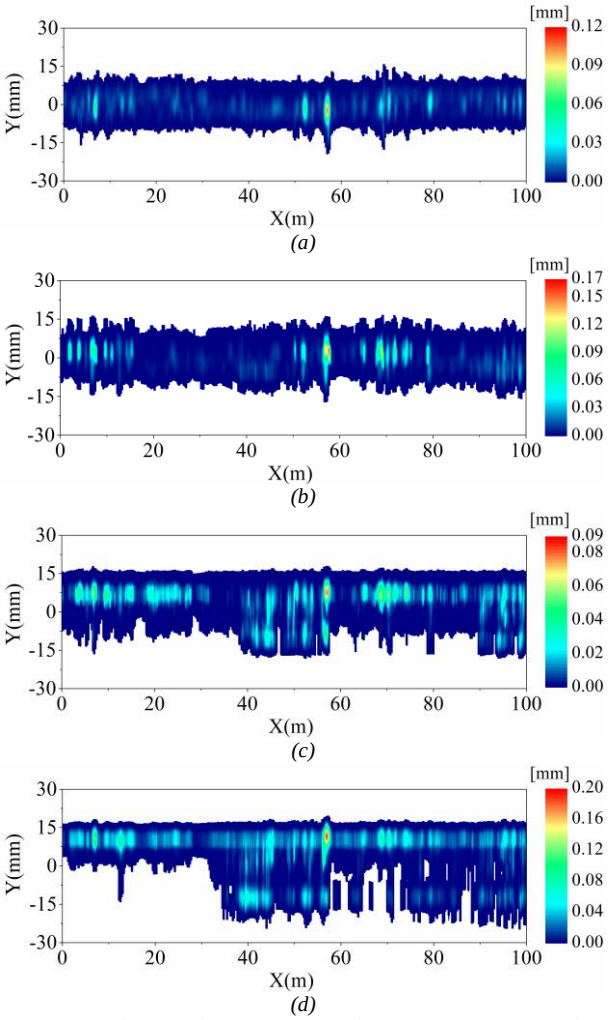

Figure 13 *Influence of worn wheel on left rail wear distribution after 20th update: (a) Influence of 1st wheel. (b) Influence of 2nd wheel. (c) Influence of 3rd wheel. (d) Influence of 4th wheel*

Hollow wear also has impact on the rail wear rate. The average wear area of all the calculated cross-sections of both the left and right rail is used to evaluate the rail wear rate. In Figure 14, the contribution of each wheel in different update times on the average rail wear area is illustrated. As shown in Figure 14(a), the average rail wear area increases almost linearly with the increasing number of passages, but more serious worn wheel results in higher wear rate. The ratio of the average wear area induced by each wheel to the total average wear area in different update times can be found in Figure 14(b). The ratio doesn't change too much in different update times. The ratio of standard wheel (1st wheel) and slightly worn wheel (2nd wheel) are similar, which is about 10%~15%. The ratio of the 3rd wheel is relative large, which is about 20%~30%. The ratio of the 4th wheel is about 50%, significantly larger than other wheels.

The comparisons exhibited in Figure 13 and Figure 14 indicate that slightly worn wheel will not give rise to noteworthy change of the wear distribution and the wear rate, however, serious hollow wear will result in dramatical increase of the rail wear bandwidth and the wear rate .

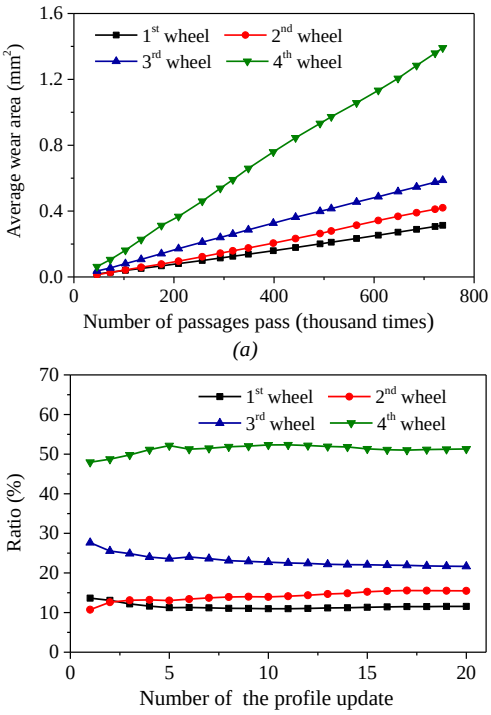

Figure 14 *Influence of hollow-worn wheel on average wear area: (a) Average wear area. (b) Ratio of average wear area induced by each wheel to total average wear area.*

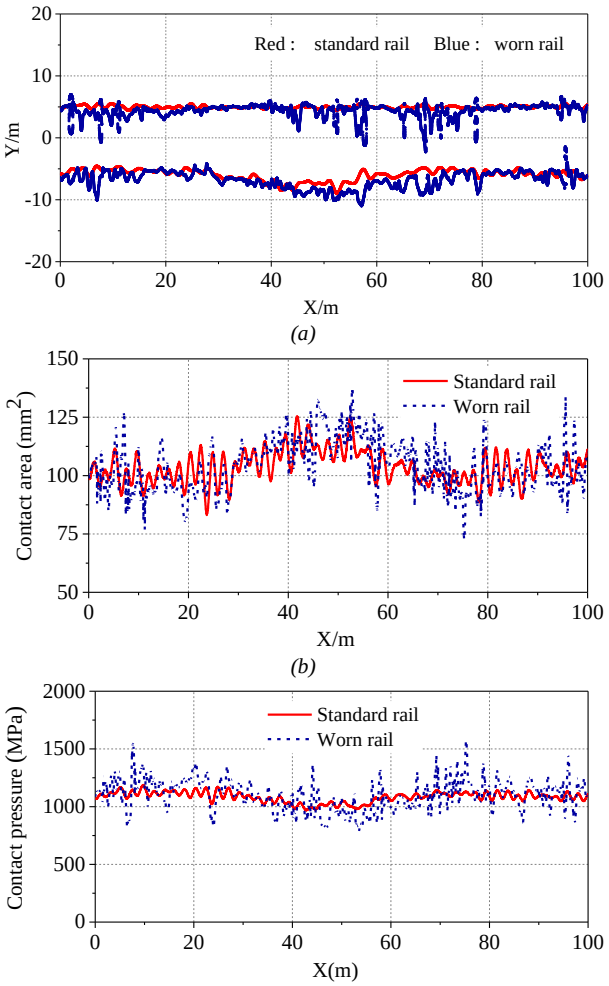
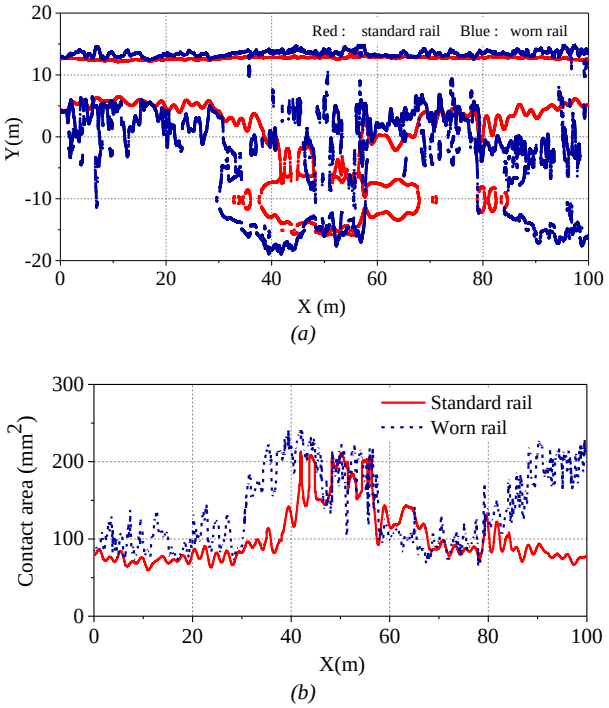
3.5. Wheel-rail interaction evolution

Rail wear causes change of the wheel-rail dynamic contact geometry, then affects the wheel-rail contact force, and even pose a threat to running security. The evolution of the contact behaviour between wheel and rail under the influence of rail non-uniform wear is shown in Figure 15 and Figure 16. In Figure 15 and Figure 16, worn rail refers to the rail after the 20th update.

It can be seen from Figure 15 that rail wear has little effect on the vibrations of the considered contact variables. As shown in Figure 15(a), there exists transient wheel-rail multi-points contact due to the irregular wear of rail surface. The variations of the wheel-rail contact area and maximum wheel-rail normal contact pressure induced by worn rail are larger and more frequent, see Figure 15(b) and Figure 15(c).

It can be observed from Figure 16 that worn rail has a significant influence on the vibration of the contact variable for hollow-worn wheel. The dynamic trajectory locations on the rail shown in Figure 16(a) indicate that the trajectory becomes more irregular for worn rail, and wheel-rail multi-points occur frequently. Due to the frequent multi-points contact and conformal contact, the wheel-rail contact area increases and the maximum wheel-rail normal pressure decreases obviously for worn wear case. It is visible that the rail wear will reduce the non-adaptability between the hollow-worn wheel and the standard rail profile and it may be possible to reduce the risk of rolling contact fatigue.





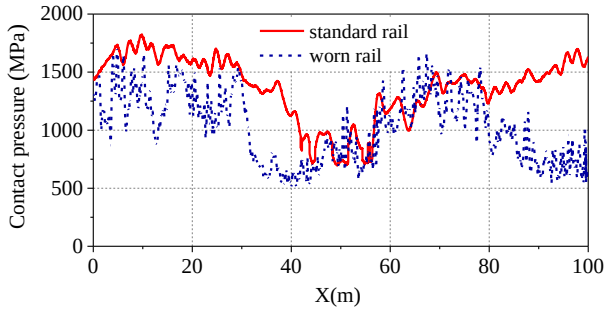


Figure 15 *Contact behaviour between standard wheel (1st wheel) and rail: (a) Dynamic trajectory locations on the rail. (b) Area of wheel-rail contact patch. (c) Maximum wheel-rail normal contact pressure.*

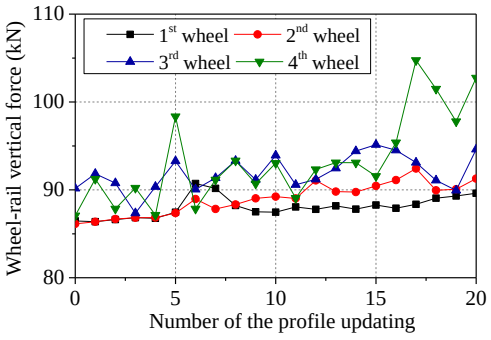

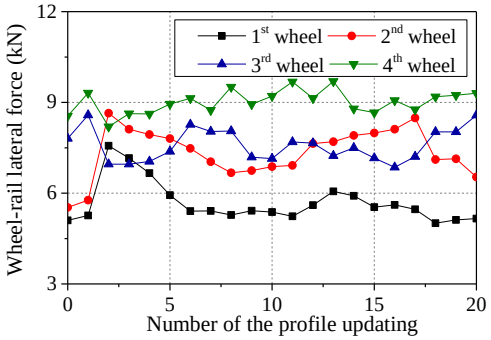

(c)

Figure 16 *Contact behaviour between hollow-worn wheel (4th wheel) and rail: (a) Dynamic trajectory locations on the rail. (b) Area of wheel-rail contact patch. (c) Maximum wheel-rail normal contact pressure.*

The influence of the rail non-uniform wear on the wheel-rail contact is further presented in Figure 17. It can be found in Figure 17(a) that rail wear has little effect on the maximum wheel-rail vertical force for both standard wheel (1st wheel) and slightly worn wheel (2nd wheel), while it apparently leads to increases of the maximum wheel-rail vertical forces for two serious hollow-worn wheels (3rd wheel and 4th wheel). As shown in Figure 17 (b), the maximum wheel-rail lateral force is mainly affected by initial wheel hollow wear, and the influence of the rail wear is relative small. Generally, more serious wheel wear results in higher maximum wheel-rail lateral force.

(b)

Figure 17 *Influence of rail wear on wheel-rail contact force: (a) Maximum wheel-rail vertical force. (b) Maximum wheel-rail lateral force.*

4. Conclusions and future work

This paper presents a numerical model for rail non-uniform wear simulation. The prediction model is based on the vehicle-track coupled dynamics, Kalker's variational method, and the material wear model developed by University of Sheffield. Taking the service characteristics of the rail into consideration, a novel assignment, sampling and accumulation strategy is applied to obtain the wear distribution of special cross-sections. Parallel computing is adopted in the procedure to speed up the calculation.

The non-uniform wear of a 100 m long rail when a high-speed vehicle with different tread hollow–worn wheels pass through is calculated by the proposed numerical procedure. The main conclusions from the numerical calculation are as follows:

- The random track irregularity will result in non-uniform rail wear along the longitudinal direction. There are two separate wear regions at the initial moment, which are induced by two points contact between hollow worn wheel and rail. Nevertheless, with continuous wear update, the rail bandwidths gradually broaden and those two distinct wear regions are merged into one continuous wear region.
- Slightly worn wheel will not lead to significant change of the rail non-uniform wear distribution and the rail wear rate, however, the rail wear bandwidth and the wear rate increase dramatically for serious hollow-worn wheel.
- Rail wear has a significant influence on wheel-rail contact behaviour for serious hollow-worn wheel, which can be reflected by the frequent multi-points contact, noticeably increased area of the contact patch and the decreased maximum normal contact pressure. Wheel-rail vertical contact force and lateral contact force are hardly influenced by the rail non-uniform wear, while the effect of tread hollow wear is significant.

In the present paper the influence of vehicle types, traction, braking, etc. are ignored. More complex and actual simulation sets should be taken into account in the future work. Furthermore, the proposed model needs to be further verified and improved by comparing with the field measurements.

E-mail: daniel.szablewski@nrc-cnrc.gc.ca, alok.jahagirdar@nrc-cnrc.gc.ca

Abstract: Accurate quantification of Rolling Contact Fatigue (RCF) cracks in a broad range of rail steels remains elusive due mostly to the complexity of analysis required to map the RCF occurrence in rails utilized in a variety of track and loading conditions. Presented work proposes a way forward to map RCF cracks based on their position on the railhead, their depth, length and angle to the running surface. Results for five (5) rail steels are shown in detail. In addition, the plastic deformation layer in these rail steels is assessed by both light optical microscopy and microhardness techniques.

Keywords: rail, wear, rolling contact fatigue, crack morphology, plastic deformation, RCF matrix, rail maintenance, eddy current

1. Introduction

Wear and rolling contact fatigue (RCF) in premium and intermediate hardness rail steels has been investigated in the recent past [1-10]. These investigations considered wear and RCF performance in 20 different rail steel types utilized in a ~35-tonne/axle heavy axle load (HAL) train environment in a 349-meter (m) radius curve, with as much as 500 million gross tons (MGT) accumulation on the rails over their life-cycle in track [1-8], as well as twin disk testing [9,10]. Recent investigations on rail steels point to a number of relevant observations:

- RCF is the dominant mode of failure in premium rail steels, as the RCF growth rate in premium rails outpaces rail wear rate. [2,4,5,7,8]
- An increase in premium rail hardness is achieved primarily through an increase in carbon content. However, rails with hyper-eutectoid carbon compositions are prone to occurrence of grain boundary cementite (Fe_3C) phase, which has detrimental influence on RCF formation and propagation in rail steels. [1,4,5,7]
- In hypoeutectoid steels RCF initiation was observed at highly strained grain boundary pro-eutectoid ferrite phase. [12,13]
- There is a poor relationship between carbon content in premium rail steels and the respective rail hardness. This is attributed to the influence of thermo-mechanical rail processing during rail production and its significant influence on the rail microstructure. [4,5,7]
- Decarburization in rail steels at the running surface decreases the rail running surface hardness, while increasing the wear rate and RCF crack growth rate. [9,10]
- Current RCF assessment methods on the rail head running surface are mostly qualitative (i.e. visual, dye penetrant based or magnetic particle based) or semi-quantitative (i.e. machine vision systems), where image acquisition and its rating is done automatically by a machine, effectively removing the user influence on the results. However, quantitative methods (i.e. eddy current) are gaining an interest in the railroad community as these methods offer a numerical assessment of RCF and are user independent. [8,11]
- Initial investigations suggest that eddy current (EC) and magnetic flux inspection methods have the potential to accurately measure RCF depth in the rail. More work needs to be done to verify calibration and accuracy of these methods. [11]

Considering these past results, the next step in RCF research would be to develop growth rate prediction models as a function of rail position in the curve and accumulated tonnage in the rail life-cycle. This could be achieved through detailed investigation of RCF morphologies in rails at variable points in their life-cycle. Quantitative RCF results from such investigation would be placed in an 'RCF Matrix'.

2. Development of an 'RCF Matrix'

RCF morphology can be subdivided into quantitative features to identify the important aspects of the crack, such as: position on the railhead, length, depth, angle to running surface, and amount of branching. These RCF morphological features are largely dependent on how the rail is utilized in track (i.e. what track curvature the rail is placed in, and what the tonnage accumulation is on the rail). Past RCF investigations of worn premium rails that have been utilized in a high rail position [7,8] have shown that RCF angle is shallow on the lower gage face corner (GFC) and becomes more steep as the position shifts to the top-of-rail (TOR) running surface (Figure 1).

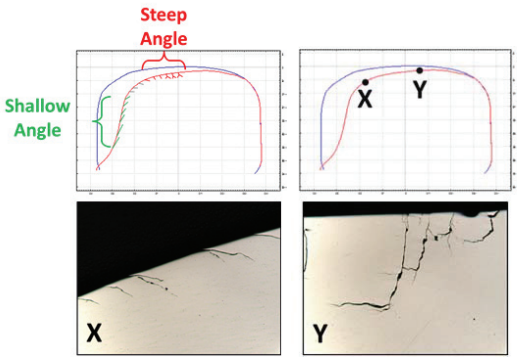

Figure. 1 Typical high rail RCF crack morphology for rail utilized in HAL traffic environment. [8]

A detailed analysis of the depth and angle features of RCF cracks in three different rail grades (with varying amounts of carbon content) that originated from the same operating track environment, revealed that crack depth is a function of the rail grade utilized in service. In other words, in this RCF study cracks propagated faster in rails with higher carbon content. However, all investigated rails had a similar distribution of crack angles to the running surface (Figure 2). This suggests that RCF crack angle is a function of wheel/rail contact and train operating conditions, rather than rail type utilized in track.

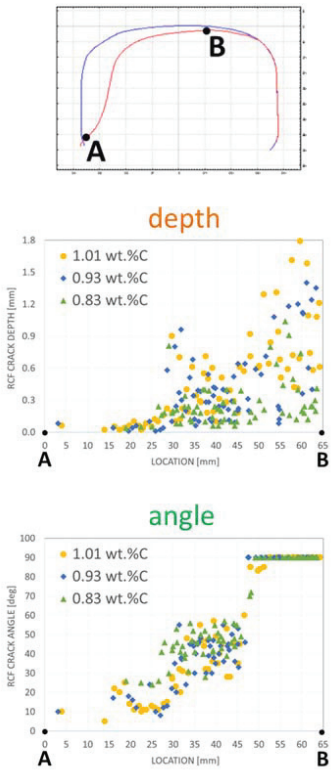

Figure. 2 RCF crack depth and angle for three rail grades with varying carbon contents. [8]

The study presented above was done on a limited number of rail steels placed in one specific track location. To better understand the behavior of RCF on a global scale more analysis layers need to be considered. These include the following:

- rail grade (i.e. standard, intermediate, premium)
- track curvature (i.e. variable radius)
- tonnage accumulation (i.e. MGT)
- running surface condition (i.e. dry, lubricated, TOR friction modified)
- traffic type (i.e. axle load, train speed)
- maintenance grinding (frequency and amount)

In addition, the way in which RCF is investigated needs to be methodical in approach to allow accurate comparison of results across multiple layers. This is a massive undertaking that will require a great deal of resources, some of which were outlined in recent presentations [14,15].

The acquired RCF morphology quantitative results can be placed in a matrix to develop RCF growth rate models for specific set of track conditions. The number of layers present in this matrix (some of which were outlined above) means that the matrix would be multi-dimensional. The information would be accessible in a 2-dimensional format depending on the layers of interest under consideration.

3. Investigation of 5 Rail Types

The results presented in this paper outline RCF metrics for five (5) rail types across 5 different curvatures and MGT levels (see Table 1). This investigation serves as an outline of a methodical approach to RCF crack analysis in rail steels.

Table 1: Rail curvature, approximate accumulated MGT, origin, and type for 5 rails investigated.

Sample #	Curvature [deg]/[m radius]	Approx. Accum. [MGT]/m-tonne	Rail Origin	Rail Type
1	0 / tangent	1050 / 953	CN Superior (MP T368.6)	Algoma-Canada CC 115 RE (1980)
2	1.0 / 1747	750 / 680	NS Hardy	136 RE (1990)
3	2.0 / 873	630 / 572	BNSF Staples (MP 200.69)	136 RE (1994)
4	4.45 / 392	570 / 517	CN Superior (MP 417.3H)	Beth Steelton 136 RE (1997)
5	4.75 / 368	570 / 517	CN Superior (MP 467.23)	Beth Steelton 136 RE (1997)

The rails range from tangent to 368 m-radius curve track. All rails investigated (except for tangent track) were from the high rail location, and were taken out of service following regular rail replacement. As a result, accumulated MGT for each rail is a reflection of in-service life-cycle for that specific rail at the utilized track location. This explains the decrease in accumulated MGT as the track curvature increases, as high rails utilized in higher curvatures reach the gage face wear limit(s) (depending on railroad operating practice) faster than high rails at lower curvatures.

Rail acquisition for metallography and RCF investigation remains a highly opportunistic endeavour, as rails with remaining wear life-cycle are usually not removed from service prematurely. As a result, this type of study acquires rails with variable MGT from variable curvatures. A challenge that can only be overcome by collecting large volumes of samples, with the targeted aim of acquiring a distribution of MGT at fixed curvatures, which in turn would allow a direct MGT comparison of RCF metrics (as described in this paper) across variable curvatures.

A collection of large volumes of samples remains the primary goal of this type of investigation, and this goal will be pursued in the near future. For now, presented results are for the 5 rail types addressed in Table 1.

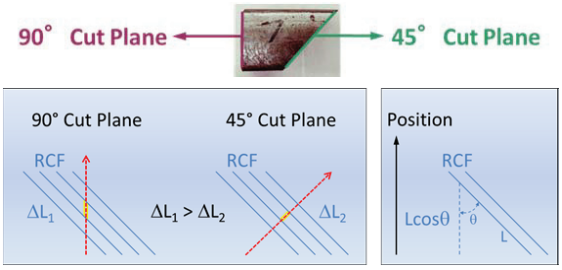
4. Sample Sectioning

The rail samples (except the tangent) were cut at two locations: 90° and 45° cut planes, as indicated in Figure 3. The tangent was only cut at a 90° plane. Since the RCF is closely related to the longitudinal wheel creep and subsequently to wheel angle-of-attack (AoA) in relation to the rail running surface [16] the cracks

initiate at an angle to the rail longitudinal direction, as indicated in Figure 3. As a result, the selected cut planes for RCF analysis are aimed at capturing two slices of the 3-dimensional crack planes to understand the crack metrics (i.e. length, depth and angle) in relation to position on the railhead.

When considering visible RCF cracks on the running surface in a selected rail type the 90° cut plane yields less RCF cracks than the 45° cut plane. This is due to the fact that spacing between subsequent RCF cracks in a 90° cut direction (ΔL_1) is greater than RCF spacing in a 45° cut plane (ΔL_2). This becomes more apparent when viewing RCF results presented in Figure 5.

Since the 45° cut plane covers a greater distance than does a 90° cut plane, the RCF position on the railhead needs to be related to the vertical cut plane to allow a direct comparison of RCF position between the two cuts. To that end, a vertical component of the RCF position on the railhead (f_y=Lcosθ) was taken for all the crack position in the 45° cut plane (as indicated in Figure 3).



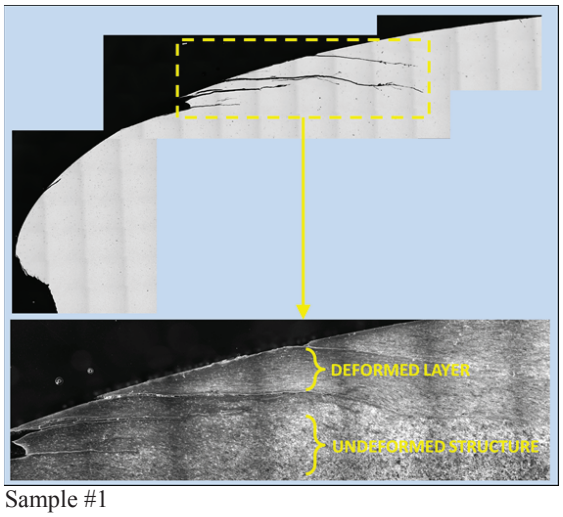


Figure 3. TOR view indicating the orientation of 90° and 45° cut planes as they relate to RCF visible on the rail surface. Calculation of position component (f_y) for 45° cut plane is also indicated.

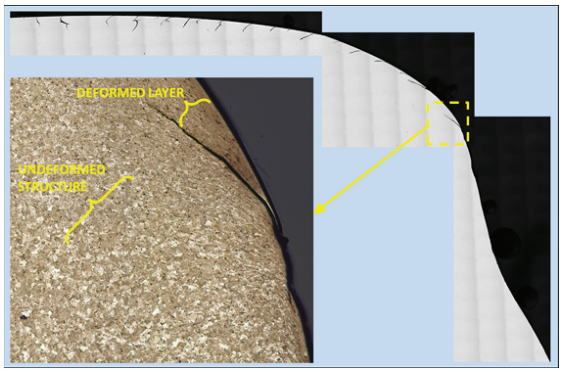
5. Sample Metallography

A comparison of the RCF morphology in 90° cut planes revealed that RCF in tangent track tends to produce long shallow cracks that extend quite some distance into the bulk structure of the rail (see Sample #1 in Figure 4). The deformation that is accompanying these cracks is confined to layers between these cracks, as evidenced by the nital etched micrograph. Grain boundaries in deformed layers are indistinguishable, however the flow pattern of these deformed grains is quite clear and coincides with the plastic deformation of the rail running surface due to lateral creep forces [16]. The microstructure of the bulk rail is undeformed however, and the grain pattern is clearly evident in that structure.



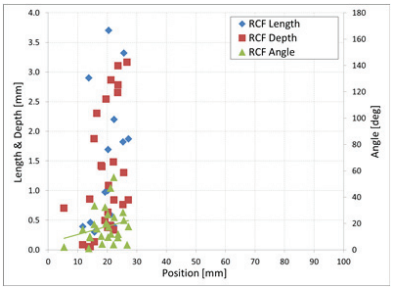
At higher curvatures (368 m-radius in Sample #4) the wheel flanging on the gage side of the rail introduces a substantial amount of localized downward metal shear in the rail. This deforms the microstructure (with metal flowlines running downwards at shallow angles, as shown in Sample #4 etched micrograph), though the bulk of the microstructure is also undeformed. Visual observation of crack angle as a function of position on the rail cross-section indicates a shallow to steep progression where gauge face RCF cracks are primarily in the 10-20° angle range, and TOR RCF cracks are primarily in the 70-90° range.

Sample #1

Sample #2

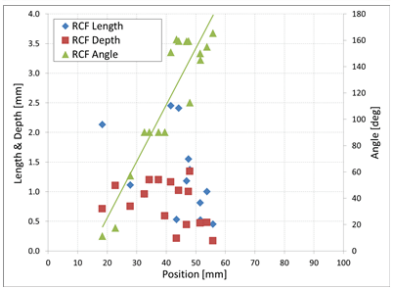
Sample #4

Figure 4. 90° cut plane mosaics of Sample #1, 2, and 4 indicating cross-sectional differences in RCF morphology along with the deformed layer (as evidenced by the 4% nital etched samples viewed under dark field (sample #1) and bright field (sample #4) conditions).



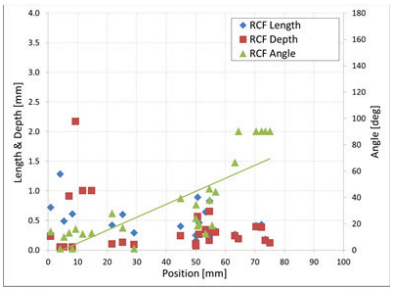
These observations hold true for intermediate curvatures as well (see Sample #2 in Figure 4), which goes to show that wheel flanging (causing top to bottom creep in rail structure) and wheel tread (causing lateral creep in rail structure) have a high degree of influence on the microstructure deformation in rail steel at the running surface. This in turn causes RCF crack initiation and propagation in these local structures.

6. RCF Quantitative Analysis

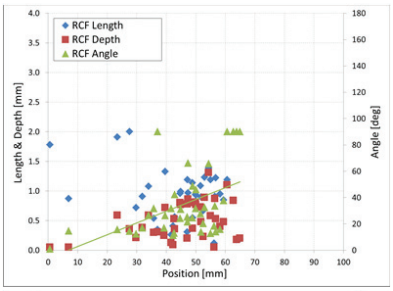


Measurements of the RCF cracks in the investigated rail steels were carried out for crack length, depth and angle at 90° and 45° cut planes. Measurement results as a function of position on the rail running surface (with 0 mm representing the gauge face corner of the high rail, and 100 mm the TOR running surface location) are

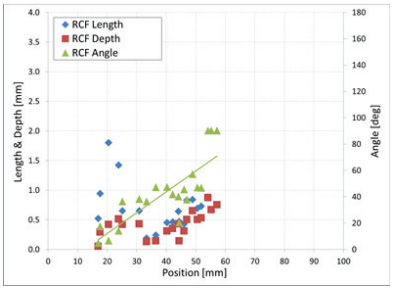
presented in Figure 5. The 45° cut plane for sample #1 was not be obtained.



90° Cut Plane



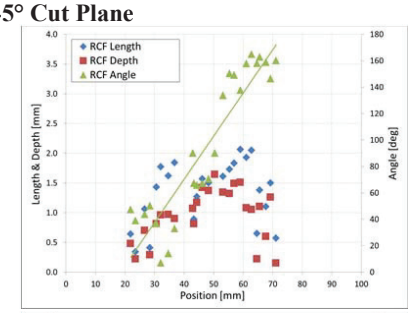
Sample #1



Sample #2

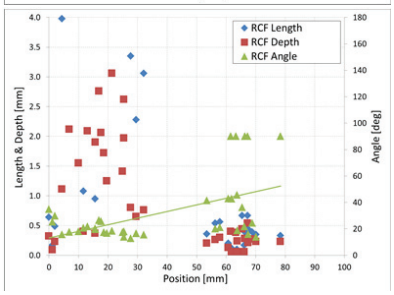
Sample #3

Sample #4



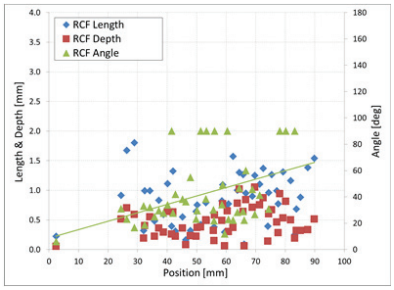
Sample #5

RCF cracks in tangent rail (sample #1) were observed on a relatively narrow band of the running surface close to the gauge face corner of the rail (see Figures 4 and 5). The angle range of RCF cracks in these rails was also relatively shallow (average 10-25° range, with select cracks reaching up to 40-50° range). The rise in RCF crack angles with increasing position was more substantial at higher degree curvatures. The highest angle rise was observed in sample #2.

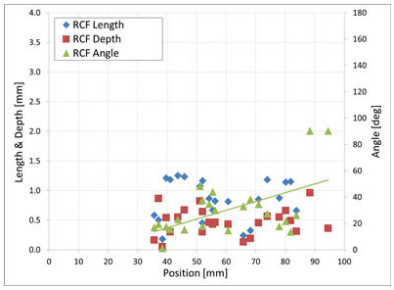


The 45° cut plane intersected a greater number of cracks (with the shortest distance between them due to the perpendicular orientation of the observed plane to crack initiation surface witness marks). As a result, the density of cracks in the 45° cut plane was greater than that in the 90° cut plane, as evidenced in the results.

In samples #2 and #3 the depth measurements appeared greater in the 45° cut plane, indicating that the 90° cut plane most likely did not catch the dominant growth direction of the cracks.



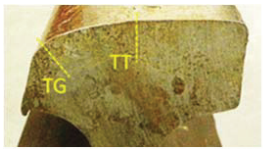
45° Cut Plane



Sample #2

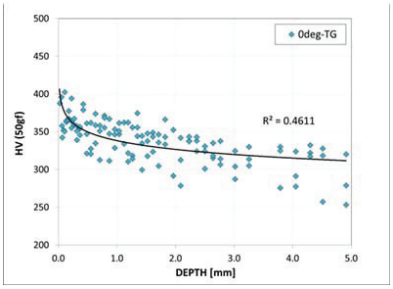
Sample #3

Sample #4



Sample #5

Figure 5. RCF measured Length, Depth and Angle as a function of position on the railhead for 90° and 45° cut planes.



However, in other rail types (samples #4 and #5) the measured depth of cracks appeared relatively unchanged indicating that dominant crack growth direction was approximately mid-way through the taken cut planes.

Definite trends in the crack depths and lengths could not be established with the limited available number of rail samples. As a result, acquisition of these trends will be postponed until more rails with RCF cracks are collected and analysed by presented methodology.

Sample #5

Figure 6. Vickers (50gf) microhardness traces for Transverse Gauge (TG) and Transverse Top-of-Rail (TT) locations.

7. Microhardness Analysis

Microhardness assessment in the investigated rail steels was carried out at two locations: the Transverse TOR and Transverse Gauge, TT and TG respectively (see Figure 6). 50gf load was utilized with a Vickers indenter to ensure a high density of measurements in the localized deformed layer of each rail type's TT and TG locations. Indent size and depth to running surface measurements were carried out on a light optical microscope at X500 magnification to guarantee a high degree of accuracy in data sets.

In all the measured profiles the deformed layer extended to approximate maximum depth of 2mm, with the bulk rail hardness stabilizing the hardness measurements past that depth. Average bulk hardness for all rail types was in the 290-320HV range, whereas the peak deformed layer hardness was in the 350-400HV range. The TG traces indicated more deformation in rail samples #1, 3, and 4, and TT traces in rail samples #2 and 5. However, the most obvious difference occurred in sample #1, whereas other samples showed relatively smaller hardness differences between the two locations.

For tangent rail (sample #1) this suggests that excessive plastic deformation at the TG location leads to a higher hardness zone near the running surface, which in turn leads to RCF formation at that location (see Figures 4-6). For other rail types the plastic flow layer (evidenced by microhardness measurements) is more even on the rail running surface, meaning that wheel contact on these rails is most likely conformal. This leads to RCF distribution over a wider range of rail contact surface (as show in Figure 5).

Presented results highlight the influence of plastic metal flow on RCF crack initiation and propagation. More rails are needed to build stronger trends in the collected data.

8. Conclusions

This paper outlined a systematic approach to analysing RCF cracks in revenue service rails. Focus was on measuring crack length, depth and angle as a function of position on the rail running surface, and then to relate these results to plastic metal flow measured by microhardness tests and observed through sample metallography techniques.

Results indicate that in tangent rail (sample #1) high degree of plastic deformation at TG location leads to a high hardness zone, which in turn leads to localized RCF occurrence (see Figure 4-6). Other rails however indicate a more uniform RCF crack distribution, which is supported by a more uniform plastic zone distribution, evidenced by the close proximity of TG and TT microhardness traces. This suggests that wheel/rail contact in these rails is most likely conformal.

The main aim of this work was to provide a systematic approach to analysing RCF cracks. This goal was achieved with the 5 analysed rails at various track curvatures and MGT accumulated levels. However, greater usefulness of this data will be realized by systematically organizing the results into an RCF matrix, accessible through a variety of input layers described in section 2 of this paper. To achieve that however, more rails with RCF are needed for analysis.

Placing the presented results into an RCF matrix will allow a comprehensive documentation of RCF features in service rails. This approach will permit easy access of RCF metrics by on-track maintenance personnel to facilitate the optimization of grinding schedules. It will also grant access of data to RCF modelling experts to facilitate more accurate forecasting of RCF growth in tracks under varying operating conditions. Both of these end user groups will benefit from the acquired information to facilitate the extension of rail life-cycles.

In addition, accurate prediction of RCF behaviour in service rails is critical to enable safe train operating practices. The presented results aim at accomplishing that goal.

9. Future Work

NRC continues to acquire rails with variable amounts of RCF for analysis of crack morphologies. The main idea behind this is to continue populating the RCF matrix for variable rail placement, loading, and other in-service operating conditions. Analysis of greater volume of rails is needed to build robust trends in the results. As these become available they will be reported to the railroad community at large.

[*] E-mail: tanaka.hirofumi.96@rtri.or.jp

Abstract: In this paper, we analyzed regularly measured data of rail surface roughness on a commercial line, and developed mathematical model to estimate the growth of the rail corrugation. First of all, we confirmed the growth trend of the rail surface roughness can be modeled by the applying function of growth curve as a result of analyzing of regularly measured data of rail surface roughness. Next, we examined the effective and economical grinding method for rail corrugation maintenance. As a result, we confirmed that maintenance cost can be reduced by the rail grinding that almost removes the corrugation roughness.

Keywords: Rail corrugation, rail surface roughness, growth model, growth curve, rail grinding, saturation

1. Introduction

The rail corrugation is a periodical rail surface roughness formed along with the repetition running of a vehicle. Various problems occur when such a rail corrugation is generated on a railway track. For instance, it causes not only a large noise and vibration but also track irregularity and deterioration of track material [1, 2, 3]. Moreover, it is generated on various alignments and on various track structures. Therefore, the railway operators should manage the rail corrugation appropriately and efficiently.

The maintenance of the rail corrugation is generally removal of rail surface roughness by the rail grinding. Therefore, the railway operator should adequately understand the situation of the occurrence of the rail corrugation and its growth, and should decide the schedule of rail grinding car on necessary time at necessary section based on this information. However, after the rail grinding, the rail corrugation will be generated again in a short term in many cases, and the railway operators will suffer from it.

In this study, first of all, we regularly measured rail surface roughness of rail corrugation for a long time in some curve sections on a commercial line, and analysed a growth of the rail corrugation. Next, we developed a growth model of the rail corrugation based on the results of the analysis of the measured data. Finally, we proposed a technique of rail grinding to manage the rail corrugation economically by using the model.

2. Analysis of growth of rail surface roughness

2.1. Measurement of rail surface roughness

To measure the rail surface roughness in the commercial lines, we developed "Rail surface roughness continuous measuring trolley" as shown in Fig. 1 [4]. This trolley adopts an asymmetrical chord offset method with uses of three laser displacement sensors arranged at inequitable intervals. Therefore, this device can measure the rail surface roughness in continuously, does not depend on the moving speed of the trolley. In addition, by appropriate arrangement of sensors, we can completely avoid the bandwidth where the measurement amplitude of the rail surface roughness becomes gain zero. In our device, it is guaranteed to be able to measure the rail surface roughness within the range of the wavelength 26-700mm by high accuracy. In this wavelength band, the gain is 0.2 or more.

Figure 1 *Externals of our developed "rail surface roughness continuous measuring trolley."*

Table 1 is a specification of major components of the developed trolley. When this device is transported, the device can be stored in an aluminum trunk after dismantled. When this device is used for measurement in the field, the device can be assembled in easily. According to this feature, we have been measuring the rail surface roughness of the rail corrugation in a lot of commercial lines with this device. For practical application of this device, the software for controlling the device and processing the measured data was developed. And this software installed on lap top computer of the attachment for the device.

Table 1 *Specification of major components of the developed trolley.*

Size	(Carrying) W750mm×H400mm×D400mm (Assembled) About 600mm×500mm×(Gauge＋100)mm
Total weight	60kg in carrying case 45kg for assembled trolley
Power supply	Battery(DC10V)
Continuous operating time	10 hours or more
Measuring Speed	0 to 6 km/h (typically walking speed)
Principle of measurement	Asymmetrical chord offset method (25mm - 230mm chord)
Measuring Sensor	Laser displacement sensor, no-contact
Measurable wavelength	27-700mm (Measurement gain 0.2 or more within this range)
Sampling interval	1mm (possible to change arbitrarily in the program)
Resolution of measurements	0.001mm (Resolution of sensors)
Measurable range in rail cross section	±20mm from rail centre
Other feature	Adjustable arbitrary gauge, insulated trolley, manual marker input, equipped with PC for control and data processing

2.2. Measurement results of rail surface roughness in a commercial line

Figure 2 shows that the example waveforms of the rail surface roughness regularly of low rail measured for a long term over four years on a commercial line. These waveforms were processed by the band-pass filter of wavelength 50-200mm. The passing tonnage of measured section is about 18MGT per year, and the structure is tunnel. This railway route is located in the metropolitan area, where only commuter trains run. In this route, there are a lot of sharp curves, and a lot of rail corrugations are generated. In either curve, even if the rail surface roughness removed by the rail grinding, the rail corrugation repeated the recurrence. Therefore, the rail grinding by the rail grinding car is executed by judging the maintenance depot every 1-3 years according to the growth of the rail corrugation. In this route, 16-stones grinding car is operated. The interval of the rail grinding of curve A is per a year, and grinding average numbers are 25 passes. The interval of the rail grinding of curve B is per two years, and grinding average numbers are 15 passes.

Figure 3 shows the situation of the occurrence of the rail corrugation in the curve A and curve B. Figure 4 shows the frequency analysis results of the rail surface roughness in the curve A and curve B. The growth speed of the rail corrugation in curve A is faster than in curve B. Curve A is 185m in radius, cant 105mm, the track structure is the ballastless track with resilient sleeper, and the vehicle runs about 45 km/h on it. A significant rail corrugation of the wavelength about 60mm had been generated on the top of rail surface of the low rail of this section. Curve B is 300m in radius, cant 40mm, the track structure is the ballastless track with direct fastened concrete sleeper and ballasted track, and the vehicle runs about 60 km/h on it. On ballastless track of this section, a rail corrugation of the wavelength about 140mm had been generated on the top of rail surface of the low rail. On the other hand, on ballasted track of this section, a rail corrugation of the wavelength about 50mm had been generated on the top of rail surface of the low rail.

Figure 5 *Examples of expansion waveforms of rail corrugation on low rail: (a) Curve A. (b) ballastless track on curve B. (c) ballasted track on curve B.*

Figure 5 shows examples of expansion waveforms of rail corrugation on low rail. These waveforms are the data at time when the rail corrugation had grown up greatly in the measuring period. Though the amplitude and wavelength are different, the shape of roughness waveform of the rail corrugation shows like the sine wave.

Figure 6 shows the relation between average rail surface roughness and accumulated passing tonnage. In this figure, we assume that rail surface roughness is an ideal sine wave, and then the amplitude of the average rail surface roughness can be calculated from standard deviation of rail surface roughness by using the equation (1).

$$A = 2\sqrt{2}\sigma \qquad (1)$$

where A is the amplitude of the average rail surface roughness, σ is the standard deviation of it.

As shown in Figure 6(a), in the curve A, the rail surface roughness grew up to about 0.10mm rapidly in a short

term after the rail grinding, before reaching 10MGT. The maximum roughness measured by this curve in the past is about 0.12mm, and the rail surface roughness shows the tendency not to grow up to 0.11mm or more. However, the rail grinding in this curve was executed at the cycle of about one year. As shown in Figure 6(b) and 6(b), in the curve B, the rail surface roughness grew up at a slower speed compared with the curve A. The maximum roughness measured in this curve in the past, it was about 0.10mm on the ballastless track, and it was about 0.05mm on the ballasted track. Moreover, the rail surface roughness on the ballastless track has grown up until to about 0.05mm, and on the ballasted track has grown up until to about 0.04mm for two and half years, that is 45MGT However, the rail grinding in this curve was executed at the cycle of about two and half years. The difference of the growth trend of the rail corrugation of the curve A and the curve B is thought that the influences about the curve radius, the track structure, the vehicle, and the service condition, and so on.

3. Modeling by growth curve of rail surface roughness and economical rail grinding method

3.1. Modeling of growth of rail surface roughness

Figure 7 shows the growth model of the rail surface roughness of the rail corrugation based on analysis result of measurement data on the commercial line. We assumed that there were three stages for growth process of rail corrugation; formation, growth and saturation periods. In our assumed model, the rail surface roughness increases gradually in the formation period. Next, the rail surface roughness increases rapidly in the growth period. Afterwards, an increase in the rail surface roughness becomes gradual again and it is saturated at the end in the saturation period. Then, we think that some growth curve is suitable as the model to express the trend of such tendency mathematically. The growth curve is the generic name of the function that shows the tendency to increase by the sigmoid shape with time.

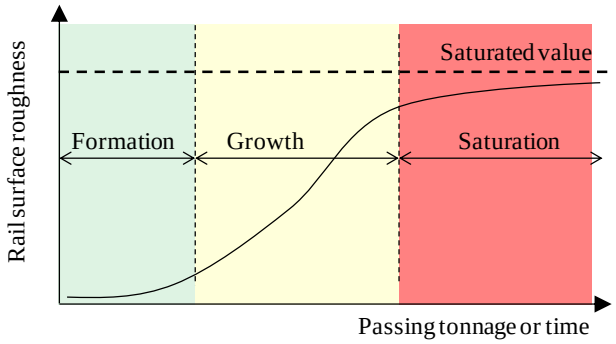

Figure 7 *Growth model of the rail surface roughness of the rail corrugation.*

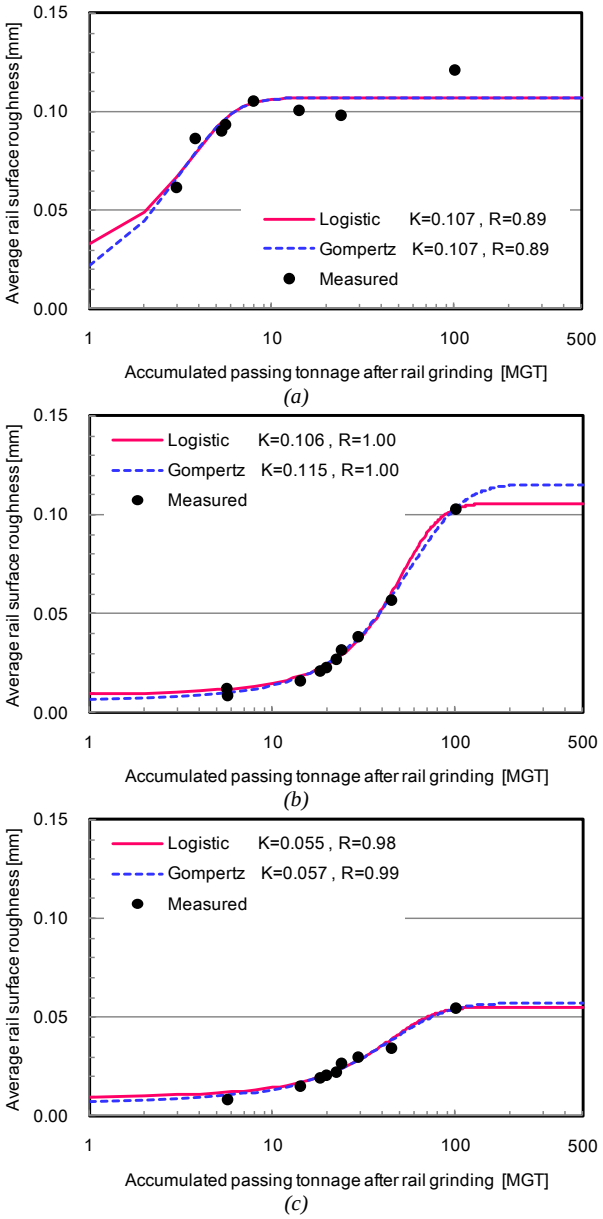

Typical growth curves and these function types are shown in Table 2. In this paper, we paid attention to two kinds of growth curves, the Logistic curve and the Gompertz curve. Both curves are provided by three parameters; K is saturation value, a and b are constants, t is variable.

Table 2 *Typical growth curve and its function formula.*

Function type	Function formula	Parameter
Logistic curve	$f(t)=\dfrac{K}{1+ae^{-bt}}$	K : saturation value a,b :constants t :variable
Gompertz curve	$f(t)=Ke^{-ae^{-bt}}$	K : saturation value a,b :constant t :variable

Figure 8 show the results of fitting to the rail surface roughness data shown in Fig. 5. Each parameter of the curves was decided according to the ordinaly least squares regression. There was a rail grinding history of two or more times in the measurement period as shown in Figure 6. Therefore, a horizontal axis of each plot is displayed by the passing tonnage from the rail grinding of the nearest. Both the logistic curve and the Gompertz curves show high agreement to the measured data in the curve A and the curve B.

As shown in the Figure 8, the data of curve A caught the transition from the growth period to saturation period, and the data of curve B caught the transition from the formation period to growth period. We confirmed the model proposed in Figure 7 was appropriate from these results.

Fiure8 *Fitting results of growth curve to measured data of rail surface roughness: (a) Curve A; (b) ballastless track on curve B. (c) ballasted track on curve B.*

Torstensson, et al. [5] and Eadie, et al. [6].also regularly measured the rail surface roughness. These results suggest that the growth of the roughness of the rail corrugation show the tendency to increase by the sigmoid shape with time. However, they were not examined for the tendency to agree with the growth curve.

3.2. Application of the proposed model to decide economical rail grinding strategy

Here, the remaining roughness after the rail grinding comes to cause to the growth (i.e. recurrence) of the rail corrugation greatly if we assumed an above-mentioned growth model of rail corrugation. Figure 9 shows the example of the trial calculation at the rail grinding cycle by considering the difference of the remaining roughness after the rail grinding. Here, we consider the situation that saturation roughness before rail grinding is 0.2mm. And, two cases of the remained roughness after the rail grinding is 0.005mm (remained roughness is 2.5%) and 0.05mm (remained roughness is 25%). The case where the remaining roughness is 0.005mm assumed an excellent finishing condition. The case where the remaining roughness is 0.05mm assumed a bad finishing condition.

In this example, the rail grinding cycle of the case that the remaining roughness is 0.05mm becomes 6.8 MGT. On the other hand, the rail grinding cycle of the case that the remaining roughness is 0.005mm becomes 9.3 MGT. That is, the rail grinding cycle can be extended by about as much as 37%. Here, the needed pass number of rail grinding of one maintenance is 10 passes in the case of remaining roughness is 0.005mm, and is eight passes in the case of remaining roughness in 0.05mm, because we assume the a removal roughness by one pass to be 0.02mmm. We calculated the total pass number of rail grinding up to 30 MGT by using these conditions.

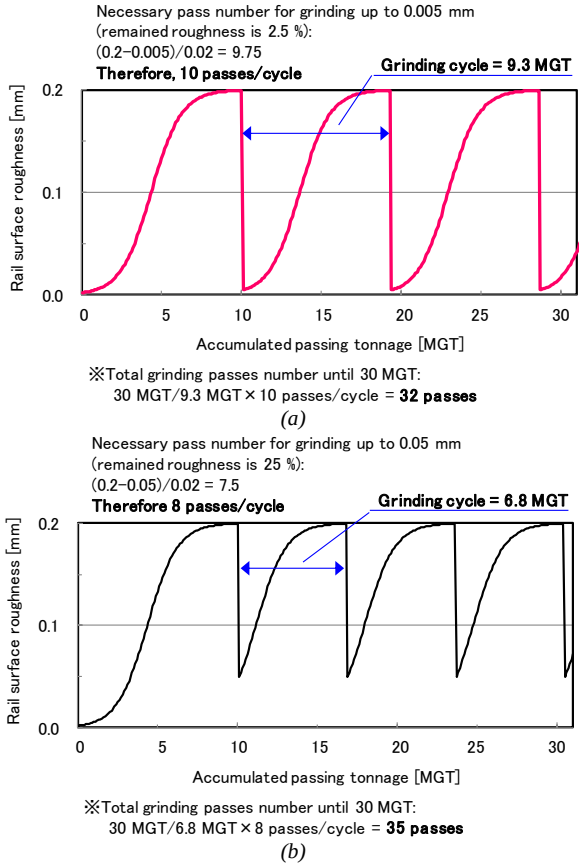

Figure 9 *Remained rail surface roughness after rail grinding and speed of recurrence of rail corrugation:(a) Almost removal; (b) Remained rail surface roughness.*

As a result, we confirmed that the excellent finishing work can reduce the total pass number about 10% compared with the bad finishing work. This result shows the rail grinding method that excellent finishing work is economical, not only to extend the rail grinding cycle but also to reduce the total pass number in a certain period.

3.3. Proposal of method of selecting rail grinding section

The rail grinding car is often operated for the removal of the rolling contact fatigue layer on the rail surface. Therefore, the operation of the rail grinding car that can be allotted to a roughness removal of the rail corrugation is limited. This means it is necessary to maximum use the operation of the limited rail grinding car, the railway operator should understand the generation section and the extent of the rail corrugation, and specify a larger section of the rail corrugation of each railway route.

To understand the generation section and the level of the rail corrugation of each railway route, for instance, the use of "Rail corrugation monitoring device [2]" developed by us shown in Figure 10 is effective. It measures the noise by the floor face on the commercial train, and helps to recognize the generation section and the level of the rail corrugation simply. When the axle-box acceleration is regularly measured with the track inspection car, it is possible to manage of the rail corrugation even by the axle-box acceleration similarly [7].

The management level of the rail corrugation is different according to the railway operator and the railway route. However, by using the rail corrugation monitoring device and the axle-box acceleration, we think that it becomes possible to operate the rail grinding car systematically by regularly understanding the condition of the rail corrugation of the railway route. Moreover, further efficiency improvement of the operation of the rail grinding car is expected by using "Rail grinding car schedule planning system [8]" that we developed.

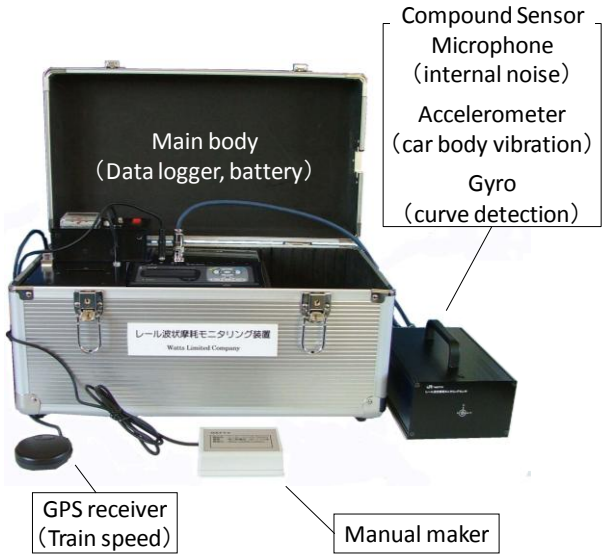

Figure 10 *Externals of our developed "portable and on-board monitoring device for rail corrugation."*

4. Conclusions

It is important to understand the growth of the rail surface roughness to manage the rail corrugation efficiently. In this paper, we analyzed a transition of rail surface roughness regularly measured on a few commercial line, and developed the mathematical model to estimate the growth of the rail corrugation.

(1) The transition process of the rail surface roughness of the rail corrugation can be classified into the formation period, the growth period and the saturation period according to the increase of passing tonnage or time. We developed the growth curve model as a function of passing tonnage to explain this behaviour. This model was based on the analysis result of the actual rail surface roughness data that we had collected through regularly measurement.

(2) We have shown that the rail grinding car can be operated efficiently by using our prediction model. In addition, we have shown that the maintenance cost can be reduced by making the rail surface roughness after the rail grinding smooth.

Acknowledgments

The authors would like to thank the railway operator with the cooperation for measurement of the rail corrugation in the commercial line.

LOCOMOTIVE WHEEL WEAR SIMULATION IN COMPLEX ENVIRONMENT OF WHEEL-RAIL INTERFACE

Gongquan Tao, Zefeng Wen*, Qinghua Guan, Xin Zhao, Yun Luo, Xuesong Jin

State Key Laboratory of Traction Power, Southwest Jiaotong University, Chengdu 610031, China

* E-mail: zfwen@home.swjtu.edu.cn

Abstract: This paper developed a locomotive wheel wear simulation model, which includes a 3D locomotive track coupled dynamics model, a rolling contact model for rail traction vehicle based on Kalker's simplified theory, a PI-based creep control model and a wheel material wear model based on frictional power. The effects of traction/braking and creep control on wheel wear are comprehensively investigated. The results indicate that traction and braking have a great influence on wheel wear, which should be considered for locomotive wheel wear simulation. It is a better way to control creep by using a control mode with variable creep threshold value.

Keywords: wheel wear; wheel-rail interface; contact mechanics; traction and braking; creep control.

1. Introduction

With the development of heavy haul railway, the traffic capacity and traction power are gradually increasing. The contact forces of locomotive, especially the tangential forces, generated on wheel-rail interface are more severe than those of the truck or other rolling stock. To ensure high adhesion level, sanding is often used during traction or braking period to avoid sliding or idling. For the purpose of sustainable development and efficient utilization of energy, the electric braking is mainly used during the normal operation, which means the braking forces are mainly supplied by the locomotive. Generally, the locomotives are equipped with wheel flange lubrication device to reduce wheel flange wear, and lubrication device is also equipped at the tight curves to reduce rail wear on gauge face. Moreover, some contaminants or the third body, such as water, oil, leaves, frost, snow and etc., are inevitable to occur on the rail surface. Migration of the flange lubricant to the top of high rail has considerable influence on curving behaviour of rail traction vehicle [1], which could affect the wheel wear behaviour on curved tracks. These factors make it difficult to predict the wheel wear of locomotive.

Enblom and Berg [2] investigated the influence of braking and contact environment on wheel wear based on KTH approach. In their simulation, the trailer car of X10 was used, which is equipped with disc brakes only. Wheel wear on both tangent and curved track was studied during braking course. The research results indicated that braking has a significant influence on wheel wear, which will increase tread wear at tangent track and the wear at the field side on the inner wheels at curved track, meanwhile reduce the flange wear on the outer wheels especially in sharp curves. Therefore, the influence of braking on wheel wear should not be neglected. Zhang et al. [3] studied the causes of flange wear and hollow-worn tread of HXN5 locomotive wheels through wear simulation. The effect of traction and braking on locomotive wear is not included in their study. However, the acceleration and deceleration of the train is controlled by the locomotive, whose effect should be taken into account for the wear prediction of locomotive wheels. Nia et al. [4] studied the RCF and wear evolution of iron-ore locomotive wheels. The approach proposed by Jendel [5] was used to evaluate the wheel wear evolution. The effects of traction and braking were considered, and a PID controller was employed to apply the traction and braking forces. However, only constant speed operating was simulated, and the traction/braking forces applied to the locomotive were used to balance the running resistance. Pradhan et al. [6] developed a methodology to evaluate the wheel wear evolution and its influence on the vehicle dynamics. A non-elliptic contact model named STRIPES [7] and modified FASTSIM were used as a post-processing to calculate the normal and tangential contact parameters, respectively. The KTH wear function was employed to estimate the wheel material removed by wear. The wheel wear of the vehicle running in a specific sector of Indian railways was simulated. The influence of traction and braking was taken into account, but the traction/braking control was out of scope. The University of Florence has done a lot of work on wheel and rail profile wear simulation [8-12]. The study was mainly focused on wheel wear of non-powered vehicle and wheel-rail interface was assumed as typical dry condition.

The service environment of locomotive wheel is quite complicated. In the past, the wheel wear simulation mainly focused on the trailered wheels, traction/braking is seldom taken into account, especially the effects of creep control on wheel/rail wear. Tian and Liu's [13-15] investigations indicate that creep/traction control has a crucial influence on wear, particularly during the acceleration course under low speed. This paper focuses on the locomotive wheel wear simulation in complex environment of wheel-rail interface. An online wheel wear model developed by the authors [16] was put forward. An advanced creep force calculation model

considering large traction creepage and variable friction coefficient proposed by Spiryagin et al. [17] is used to calculate the wheel/rail tangential contact forces, creep and stresses distribution within contact patch. A basic PI-based creep controller [14] is employed to limit the creep values. Moreover, wheel/rail multi-point contact proposed by Ren et al. [18] is also adopted. The effects of traction/braking and creep control on wheel wear are comprehensively investigated in this study.

2. Simulation modelling

An online wheel wear prediction model taking into account the track flexibility has been proposed by the authors [16]. The model consists of two parts which interact with each other, (a) a 3D dynamic model of a locomotive coupled with a ballast track, which was developed based on the vehicle/track coupled dynamics theory [19], and (b) a model for the wear estimation. The wear estimation was treated as online solution rather than post-processing. The wheel wear prediction model was put forward recently. The capacity of the model is further enforced. The effects of wheel flange lubrication or rail gauge face lubrication, multi-point contact, the variation of wheel/rail friction conditions and creep control on wheel wear can be considered. The architecture of the wheel wear simulation model is shown in Fig. 1. Each part of the model is briefly described as follows.

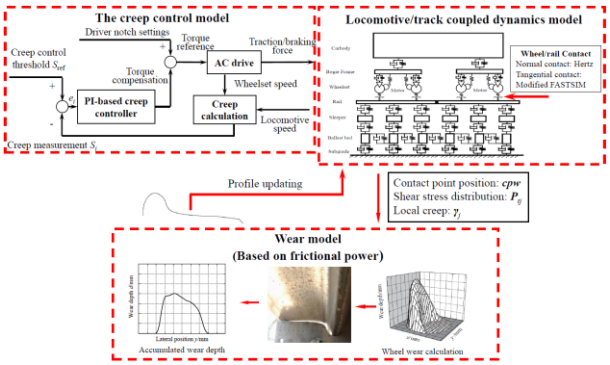

Figure 1 *General architecture of the wheel wear prediction model in complex environment of wheel-rail interface.*

2.1. Locomotive-track coupled dynamics model

Based on the vehicle-track coupled dynamics theory [16], a 3D dynamic model of a locomotive coupled with a ballast track is developed. The locomotive-track coupled dynamics model includes four subsystems: the locomotive, track and wheel-rail contact and creep control. The flexibility of components, such as wheelset, bogie frame and car body, is ignored in the locomotive subsystem. The bogie is provided with two stages of suspensions. Three-dimensional spring-damper elements are employed to represent the primary and secondary suspensions. The non-linear characteristics of suspension system are considered, such as vertical damper of primary and secondary suspensions and lateral damper of secondary suspension. The track flexibility is taken into account in detail in current model. The rails are modelled with Timoshenko beams discretely supported by sleepers, and the effects of vertical, lateral and torsional deformation of rails on wheel-rail creepages and spin are considered. Each sleeper is assumed to be a lumped mass, and the lateral, vertical and roll motion are considered. The ballast bed is treated as equivalent rigid ballast bodies. Only the vertical motion of the ballast bed is taken into account. The equivalent springs and dampers are employed to simulate the connections between each part of the track. The detailed dynamics model can be found in Ref. [16]. The dynamics model was validated by field measurement. It was put forward recently, focusing on wheel-rail contact modelling and creep control, which are described in the next sections.

2.2. The wheel-rail contact model

The wheel-rail contact model is the key subsystem which couples the locomotive subsystem with the track subsystem at wheel-rail interfaces. To improve the wheel-rail contact calculation, especially for curving negotiation, a wheel-rail multi-point contact method proposed by Ren et al. [18] is employed to determine contact point number and wheel-rail contact position, which is based on 'tracing line method' presented by Wang [20]. The multi-point contact method is established in three dimensions and the effect of the wheelset yaw motion on contact position can be considered.

The nonlinear Hertzian elastic contact theory is used to estimate the wheel-rail normal contact forces, which is written as [21]:

$$P(t)=\begin{cases}\left[\frac{1}{G}\delta_i(t)\right]^{3/2}, & \delta_i(t)>0\\ 0, & \delta_i(t)\le 0\end{cases} \quad (1)$$

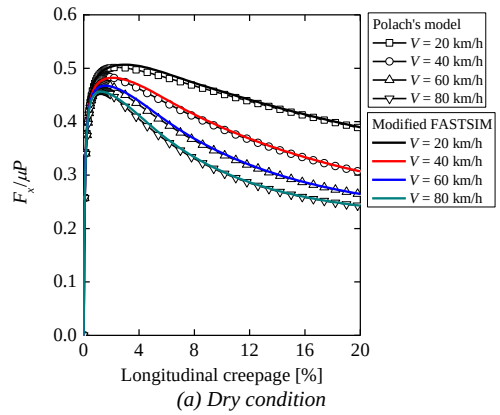
where $\delta_i(t)$ is the normal elastic compression deformation of the wheels and rails at the contact points. G is the wheel/rail contact constant, and it is different for conical profiles and worn-shaped profiles, which is written as [21]:

$$G=\begin{cases}4.57R^{-0.149}\times10^{-8}\left(\mathrm{m/N^{2/3}}\right), \text{ for conical profile}\\ 3.86R^{-0.115}\times10^{-8}\left(\mathrm{m/N^{2/3}}\right), \text{ for worn-shaped profile}\end{cases} \quad (2)$$

where R is the wheel radius (m).

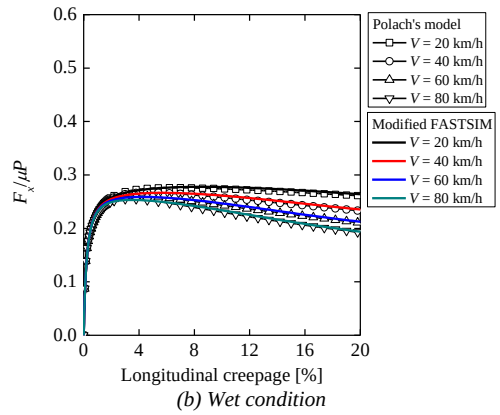
During acceleration course, especially for low speed, the longitudinal creepage is generally quite large. The creep characteristics in traction/braking conditions have obvious differences compared to those in normal condition, which was demonstrated by field measurement [22-23]. Stick-slip oscillation will arise if the creep force exceeds the saturation point. The traditional creep forces model, such as Kalker's simplified theory [24] and Shen's theory [25], cannot describe this phenomenon. To solve this issue, a methodology of creep forces considering large traction creepage has been proposed by Polach [22]. However, it cannot obtain the creep and stresses distribution within the contact patch, which are necessary for wear estimation with the local wear prediction model. Fortunately, a similar model was developed by Spiryagin et al. [17], which combines Kalker's simplified theory [24] and Polach model [22]. The large traction creepages and variable friction coefficient are considered in this model. Not only the global creep forces, but also their distributions can be obtained. It can be easily

implemented in dynamics simulation. The detailed information about this method can be found in Ref. [17].



Typical model parameters for dry and wet conditions of Polach's model are listed in Table 1. In order to employ Spiryagin's method (modified FASTSIM) to calculate the creep forces, the model parameters should be identified once more. The modified FASTSIM model parameters are identified in comparison with calculation results of Polach's model. The identified model parameters for modified FASTSIM are listed in Table 2, and the results of these two models are compared as shown in Fig. 2. The creep forces calculated by the two models are in good agreement by using the parameters listed in Table 1 and Table 2.

Table 1 *Typical model parameters for dry and wet conditions of Polach's model* [22]



Model parameter (Polach's model)	Wheel-rail conditions	
	Dry	Wet
k_A	1.00	0.30
k_S	0.40	0.10

2.3. The creep control model

As is well known, the saturation and negative slope characteristics of adhesion induce some complex dynamic problems for locomotives, such as stick-slip oscillation. The effective utilization of the wheel-rail adhesion is fairly concerned, especially under low adhesion conditions during the locomotive acceleration course. Generally, locomotives are equipped with traction control system to improve the utilization of adhesion. A lot of adhesion control models have been proposed in recent years, such as proportional-integral (PI), proportional-integral-differential (PID), fuzzy logic and neural network control. These creep control models have different complexity. The traction effort also has some difference controlled by different creep control models. Some results in references indicated that the PI-based creep controller can effectively control torque at low adhesion [13], and the difference of results between PI controller and more complicated model fuzzy logic controller is relatively small [26]. Therefore, a basic PI-based creep controller [13] is employed to limit the creep values in this paper, as shown in Fig. 3. All wheelsets have independent creep controllers. The control process is presented as follows. The creep control threshold and driver notch settings are set in advance. According to the driver notch settings, the torque is applied to AC drive. The wheel speed and locomotive speed are collected every time. The creep should be estimated according to the wheelset speed and locomotive speed. If the creep exceeds the creep control threshold value, the creep controller will be triggered. Then the torque should be compensated to avoid wheels skidding or idling.

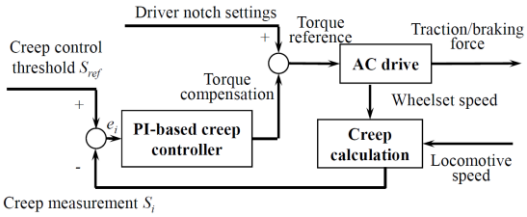

Figure 3 *PI creep control diagram* [13].

The creep used for the creep controller is estimated as follows:

$$S_i = \frac{\omega_i R - v}{v} \tag{3}$$

where ω is the rotational speed of the wheelset, v is the locomotive speed and R is the wheel nominal radius. The wheelset number is denoted by i (i = 1~4). The locomotive speed is calculated by means of the wheelset speed with weighted average.

According to Ref. [13], the proportional and integral constants are set to 1.5×10^7 and 2.0×10^5 for the PI controller, respectively. The torque compensation can be calculated as [13]:

$$T_{compi} = \begin{cases} 0 & \text{if } e_i \geq 0 \\ 1.5\times10^7 \times e_i + 2\times10^5 \times \int_{t_1}^{t_2} e_i \mathrm{d}t & \text{if } e_i < 0 \end{cases} \tag{4}$$

where t_1 is the time when estimated creep starts exceeding threshold value and t_2 is the current time when the creep is still larger than the threshold value, e_i is the

difference between creep threshold value S_{ref} and estimated creep S_i ($e_i = S_{ref} - S_i$).

2.4. The wear estimation model

The wear function considering the energy dissipated in the wheel-rail contact patch with worn material, developed by University of Sheffield [26-27], is used to evaluate the amount of removed material and its distribution along the wheel profile. The USFD wear function is obtained by a twin-disc machine using the wheel and rail material cut from R8T wheel rims and UIC60 900A rail sections. The wear function in dry condition can be expressed as:

$$K_w = \begin{cases} 5.3 \times I_w & I_w < 10.4 \\ 55.0 & 10.4 \le I_w \le 77.2 \\ 61.9 \times I_w - 4778.7 & I_w > 77.2 \end{cases} \quad (5)$$

where I_w (N/mm^2) is the local frictional power in the contact patch and can be written as:

$$I_w(x,y) = \mathrm{p}(x,y) \cdot \gamma(x,y) \quad (6)$$

where p(x,y) and γ(x,y) are the traction stresses and local creep in each point (x,y) of the contact patch particle, respectively.

Wear mechanism and transitions of wheel and rail material in water condition are totally different from those in dry condition. Test results in Ref. [30] indicated that when $T\gamma/A(I_w)$>10 N/mm^2 it will result in a damage transition from mild wear regime to severe wear regime for rail material under dry condition. However, the value is about 40 N/mm^2 in water condition. Therefore, the wear function in dry condition cannot be used to estimate the wear in water condition. The wear function for CL60 wheel material in water condition is available in Ref. [29], which is used to predict wheel wear in wet condition in this paper.

3. Simulation results

3.1. The effects of traction and braking on wheel wear

Traction and barking have a great influence on the creepages and creep forces, especially in the beginning of speedup, which will inevitably increase wheel wear. In this section the effects of traction and braking on wheel wear are investigated.

The locomotive acceleration operation generally occurs on the straight track. Therefore, the effect of traction on wheel wear was performed on straight track. The wheel-rail interface was assumed as typical dry condition. The model parameters of dry condition in Table 2 were used in the modified FASTSIM, and the USFD wear function in dry condition was used to estimate the wheel wear evolution. In the simulation, the total weight of the freight is 4500 t. Because only one unit of locomotive is built in the dynamics model, so the traction weight is only 2250 t. It is assumed that the locomotive and freights have the same speed. Freight dynamics model is not built in current study, the inertial force and the total running resistance are applied at the end of locomotive at the buffer height. The initial speed of the locomotive is set to 10 km/h. The wheel wear was calculated during the locomotive accelerating from 10 km/h to 80 km/h, which is under the highest acceleration condition. The traction curve of the locomotive in that condition is presented in Fig. 4. The traction force gradually increases from zero to the target value at first three seconds according to the traction curve. The locomotive dynamics model excludes gear transmission system, so the traction torque is directly applied to the wheelsets. The track random irregularity of China Railway mainlines [19] is used in current study.

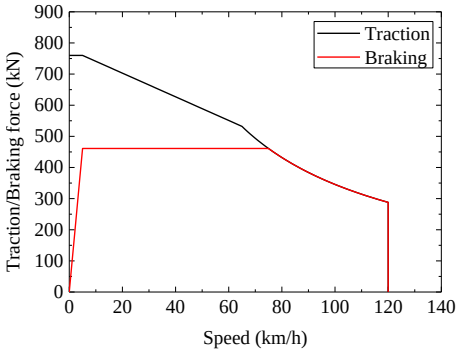

Figure 4 *Traction/braking curve of the locomotive under the highest drive notch.*

Fig. 5 presents the wheel wear distribution during the locomotive acceleration course from 10 km/h to 80 km/h. As a comparison, the wheel wear without traction is also simulated. To ensure the locomotive speed consistent with that under traction condition, the total traction force of the locomotive is applied to the centre of gravity of the car body without traction. Because the simulation is performed in straight track, the wear of left and right wheel is similar, therefore, only the wear of left wheel is presented in Fig. 5. Under the traction condition, the wear depth of the second wheelset is maximal and the third wheelset is minimal. Moreover, the wear spreading of the trailing wheelset of each bogie is more concentrated than the leading wheelset for both with and without traction condition. The reason is that: (1) the traction torque of each wheelset is the same under dry condition. Due to the weight transition for traction condition, the longitudinal creepage of wheelset 1 to 4 decreases in turn, resulting in different wear of each wheelset; (2) the first and the third wheelset are the leading wheelset of each bogie. Lateral displacement and angle of attack of leading wheelset are larger than those of trailing wheelset, which makes the contact band wider and the wear spreading more uniform for the leading wheelset. For the case of without traction, the wear spreading is similar to that under traction condition, but the wear depth is smaller. More, there is no weight transition, the wear of leading wheelset for both bogies is almost the same and the trailing wheelset has the same phenomenon.

The comparison of wear area is shown in Fig. 6. The difference between each wheelset is quite small. The wear area under traction condition is about 1.6 times of that without traction. These results indicate that the traction cannot be neglected for locomotive wheel wear simulation. Otherwise, the wheel wear will be significantly underestimated.

The wheel wear under braking condition on straight track

is also simulated for the locomotive decelerating from 80 km/h to 10 km/h. The simulation results are not shown in this paper. The brief conclusion is that the wear area under braking condition is about 1.3 times of that without braking.

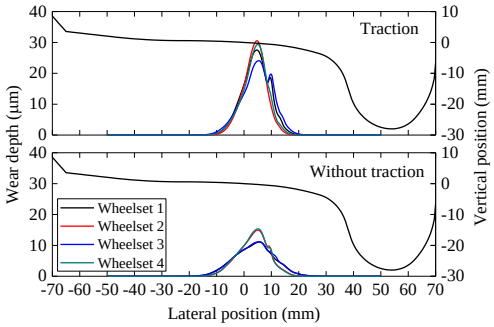

Figure 5 *The influence of traction on wear distribution.*

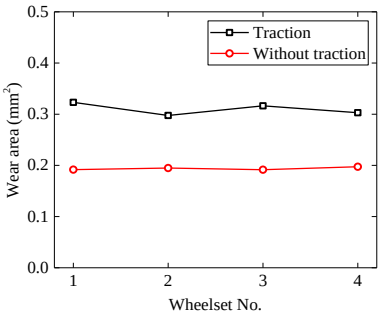

Figure 6 *The influence of traction on wear area.*

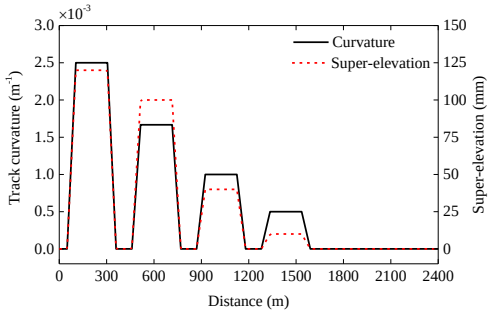
Except for the straight track case, the influence of braking on wheel wear on curved track is also investigated. A virtual track including four curves is designed for this study, as shown in Fig. 7. All the curves are assumed as left-hand curve. That is to say, when the locomotive runs on the virtual track the left wheel is always on the outer rail. The wheel wear was calculated during the locomotive decelerating from 80 km/h to 10 km/h under the highest deceleration conditions. The braking curve of the locomotive in that condition is presented in Fig. 4. The braking force gradually increases from zero to the target value within 1.5 s according to the braking curve. The wheel-rail interface is assumed as dry condition. The total running distance during the simulation is 2263 m.



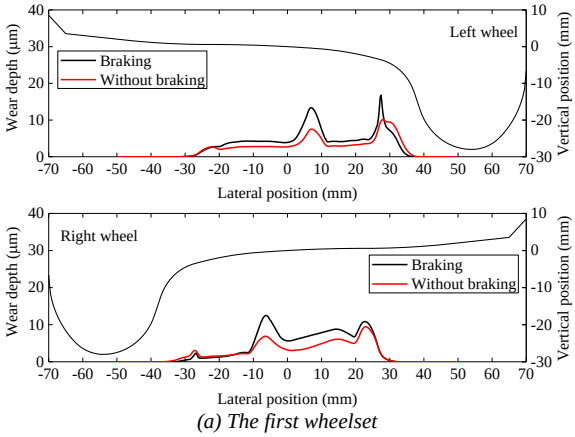


Figure 7 *Curvature and super-elevation for a virtual track.*

Fig. 8 illustrates the wheel wear distribution of the first bogie for the locomotive deceleration on curved tracks. The wear distribution with braking is almost consistent with that without braking, but the wear amount of the former is larger than that of the latter. The wear spreading of the second bogie's wheelset is the same with that of the first bogie's wheelset. The results are not shown in this paper. There is two wear peaks for the leading wheelset, however, the trailing wheelset has only one peak. When the locomotive runs on curved track with radius $R \leq 1000$ m, the contact position of the leading wheelset is mainly at wheel flange or wheel flange root for the outer wheel, and for the inner wheel the contact position is located at field side. However, the contact position is concentrated near the nominal rolling circle for large radius curved track and straight track. Therefore, two wear regions are formed in the leading wheelset. However, the contact position of trailing wheelset is mainly located at the centre part of wheel tread. The wear depth of trailing wheelset is much higher than that of leading wheelset. If the travelling direction of the locomotive cannot be reversed and the distribution of the left and right curves on the line is more uniform, it is easy for all wheels to exhibit obvious flange wear. It is demonstrated by the field measurement results as shown in Fig. 9.

(a) The first wheelset

(b) The second wheelset

Figure 8 *The influence of braking on wear distribution.*

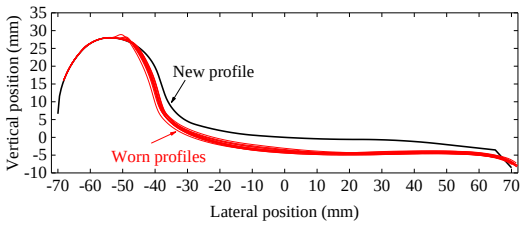

Figure 9 *Field measurement of locomotive wheel profiles.*

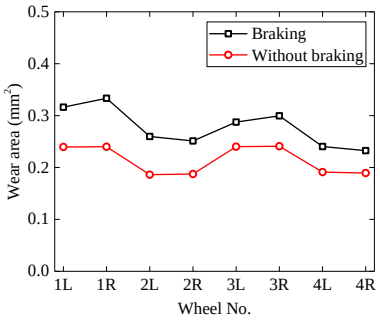
The comparison of wear area for the locomotive deceleration on curved tracks is presented in Fig. 10. The

wear law is similar for the two cases. The same as the straight track case, the wear area under braking condition is about 1.3 times of that without braking. These results indicate that the braking cannot be neglected for locomotive wheel wear simulation.



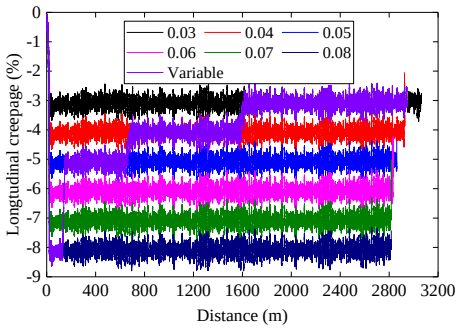


Figure 10 *The influence of braking on wear area.*

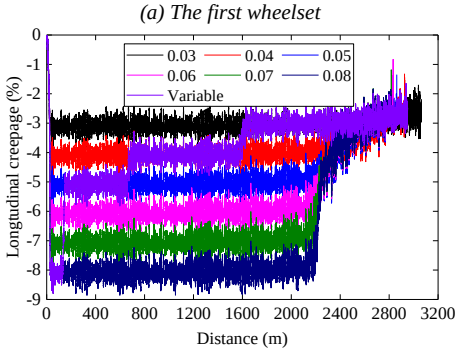
3.2. The effects of creep control on wheel wear



The longitudinal creepage is relatively small in dry condition. The creep controller is not triggered in dry condition. However, the maximal adhesion coefficient in wet condition is lower than that in dry condition (see Fig. 2). If the wheel-rail interface is in wet condition during the locomotive starting, the creep controller will be triggered due to excessive creepage, which leads to the traction torque compensation. The creep threshold value in the creep controller has an effect on the traction effort. Meanwhile, if the adhesion coefficient in wheel-rail interface is insufficient, the creep controller can make the creepage fluctuate near a certain value. These factors will affect the wheel/rail wear.

The effects of creep control on wheel wear were performed in straight track under traction condition. The wheel-rail interface is assumed as wet condition. The model parameters of wet condition in Table 2 were used in the modified FASTSIM and the SWJTU wear function in water condition was used to estimate the wheel wear evolution. Seven modes of creep controller were assumed, six of which was set to a constant creep threshold value. The creep threshold value is from 0.03 to 0.08 in turn. Moreover, a variable creep threshold value control mode is also set up. The creep threshold value varies with locomotive speed. The value is 0.08, 0.05, 0.04 and 0.03 when the locomotive speed is lower than 20, 40, 60 and 80 km/h, respectively.

Fig. 11 shows the wheel-rail longitudinal creepage of the first and the fourth wheelset. Due to the weight transition under traction condition, the axle load of the first and the fourth wheelset is reduced and increased, respectively. The longitudinal creepage of the first wheelset varies around the creep threshold value. For the fourth wheelset, the maximal adhesion force will be larger than the traction force when the locomotive speed reaches a certain value, then the actual creep gradually decreases and the creep controller will not be triggered. The creep is estimated through the rotational speed of the wheelset and the nominal rolling radius in the PI-based creep control model, and the locomotive speed is estimated by means of the wheelset speed with weighted average. The wheelset will oscillate in lateral direction excited by the track irregularities. The actual rolling radius of the wheel is not consistent with the nominal rolling radius at different wheelset lateral displacement. The wheelset speed estimated with the nominal rolling radius may have some error. Moreover, the effects of rail flexible deformation and the track irregularities on wheel-rail creepages are considered in the dynamics model. Therefore, the creepage estimated in creep control model may have some difference with the actual wheel-rail longitudinal creepage.

(a) The first wheelset

(b) The fourth wheelset

Figure 11 *Longitudinal creepage during locomotive accelerating from 10 to 80 km/h under wet condition.*

Fig. 12 presents the wear distribution of the first wheelset under different creep threshold conditions. The width of wear spreading is almost the same for all the simulation cases. The wear depth increases with the creep threshold value. Comparison of wear area is shown in Fig. 13. The running distance is different for different creep threshold value when the locomotive accelerates from 10 km/h to 80 km/h. The wear area is normalized by the running distance. The wear area increases linearly with the creep threshold value. Moreover, due to the weight transition under traction condition, the axle load gradually increases from the first to the fourth wheelset and the wear area also gradually increases. The reason is that the longitudinal creepage varies near the creep threshold value for most time. That is to say, the adhesion coefficient of each wheelset is almost the same. The traction effort is higher for the wheelset with higher axle load, so the wear of it is more severe. It is a better way to

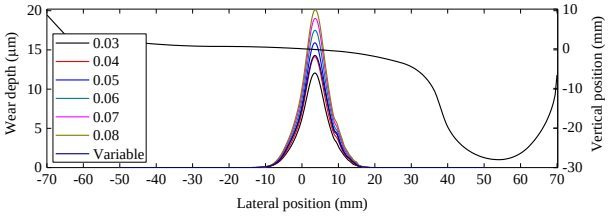


Figure 12 *Wear distribution with different creep threshold values.*

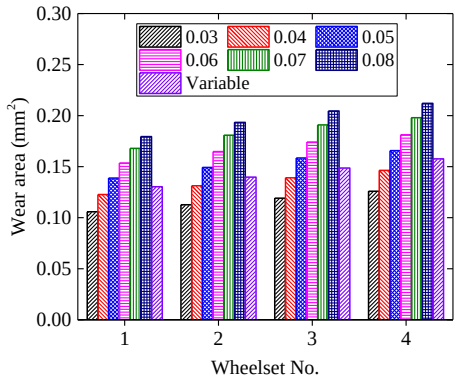

Figure 13 *Wear area with different creep threshold values.*

control creep by using a control mode with variable creep threshold value, which means a higher creep threshold value should be adopted at low speed and a lower creep threshold value at high speed.

4. Conclusions

A locomotive wheel wear simulation model is developed in this paper. The proposed model consists of two parts, namely, (a) a locomotive-track coupled dynamics model and (b) a model for the wear estimation. Based on the vehicle-track coupled dynamics theory, a 3D dynamics model of a locomotive coupled with a ballasted track is developed. The locomotive-track coupled dynamics model includes four subsystems: the locomotive, track, wheel–rail contact and creep control. The locomotive subsystem is modelled based on a multi-body dynamic theory. The flexibility of all the components of the locomotive is ignored, but the track flexibility is considered in the current model. A rolling contact model for rail traction vehicle based on Kalker's simplified theory is used to solve the tangential contact problem and the Hertzian theory is employed to calculate the normal contact. A PI-based creep control model is adopted to avoid skidding or idling occurring under traction and braking conditions. The wear function considering the energy dissipated in the wheel-rail contact patch with a worn material is used to estimate the wheel wear. The effects of traction/braking in dry condition and creep control in wet condition on wheel wear are comprehensively investigated. The results indicate that the traction and braking have a great influence on wheel wear, which should be taken into account for locomotive wheel wear simulation. The wheel wear will be underestimated if the traction and braking are neglected. The wheel wear increases linearly with the creep threshold value. The optimal creep control strategy can guarantee the exertion of traction force. Meanwhile, it can ensure the wheel wear in a low level. It is a better way to control creep by using a variable creep threshold control mode related to locomotive speed.

Abstract: For the development of rail materials with improved properties regarding rolling contact fatigue and wear it is at first important to know and understand the loading conditions in railway operation. Based on the loading conditions crack initiation can be predicted. This has been done with the so-called wedge model, which takes the plastic shear deformation condition in a layer near the rail surface into account. Results for a specific railway operation scenario and test rig experiments are compared, which contributes to the understanding of the transferability of test rig results to the behaviour in the field.

Keywords: Rolling contact fatigue, crack initiation, railway operation, test rig, modelling

1. Introduction

Development of rail materials with improved resistance to rolling contact fatigue (RCF) and wear is a time-consuming and cost-intensive process. This process may involve different kinds of laboratory experiments on various scales, including, but not limited to, small-scale twin disc tests and full-scale test rig experiments, as well as track tests. The required time to perform such experiments ranges from as short as 1 hour for twin disc experiments (see e.g. [1]) to several years for track tests (see e.g. [2, 3]). Full-scale test rig experiments (see e.g. [4, 5]), in which one full-size wheel rolls repeatedly over one piece of rail, require typically several days of testing time. The relatively short testing times make full-scale test rig experiments attractive from a development point of view in order to examine the relationship between loading conditions and damage patterns in a reproducible and systematic way.

Although railway operation and full-scale test rig experiments involve both full-scale wheels and rails there are differences: During railway operation different vehicles (with different dynamic characteristics, different wheel profile geometries, et cetera) pass a section of rail, which results in a broad variation of contact positions and contact conditions (contact geometry, creepage, normal force) on the rail. Furthermore it can be assumed that non-conformal contact conditions prevail.

In a typical full-scale wheel rail test rig experiment usually only one wheel rolls repeatedly over a piece of rail. An initially non-conformal contact usually becomes more and more conformal with increasing number of load cycles.

Experimental parameters such as normal force or creepage can be varied and precisely controlled during the experiment, however precise control of the (wheel) profile geometry is more difficult to realize.

Experimental analyses of gauge corner cracks on rails from railway operation and from test rig experiments show a very similar damage pattern which indicates that the damage mechanism is the same in both cases. Examples of rails with rolling contact fatigue cracks at the gauge corner from railway operation (see Figure 1a) and from full-scale test rig experiment (see Figure 1b) are shown below.

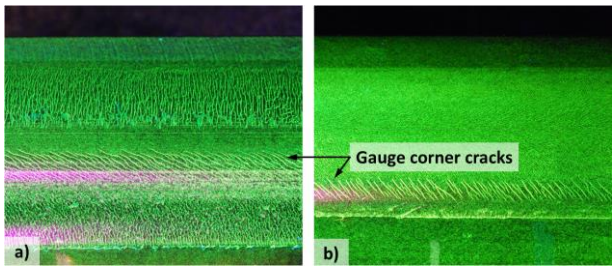

Figure 1: *Magnetic particle inspection images showing gauge corner cracks on a) a rail from metro operation, and b) a rail from a full-scale test rig experiment. The wheel is travelling from left to right in both images.*

It is the important role of the voestalpine test rig to reproduce the material behaviour under railway operation conditions in experiments in order to assess the performance of materials at an early stage in the development process. This paper addresses a methodology to analyse and finally transfer RCF-relevant railway operation conditions of a specific track section into an experimental test setting.

2. Methodology

Simulation data of railway operation, generated by multi-body dynamics simulations of railway vehicles, and simulation data of full-scale test rig experiments are both assessed with respect to RCF crack initiation. RCF relevant loading conditions are identified and compared to each other for both scenarios.

2.1. Multi-body dynamics simulations

For the multi-body dynamics simulations of the railway vehicles the commercial software SIMPACK is used. The three vehicle types in the simulation (one type with a conventional bogie, two types with self-steering bogies) cover all the vehicle types in operation in the chosen simulation scenario: An underground metro line. The different vehicle types are represented in the simulation according to their ratio in operation. The investigated scenario is a curve with a radius of 300 m, which is negotiated at a constant velocity of 19.7 m/s, and at a cant deficiency of 29 mm.

Each vehicle of the trains consists of two bogies with two axles each. Axle 1 and axle 3 are the leading axles of the leading respectively trailing bogie. For each of the vehicle types, 10 sets of wheel profiles have been chosen from a number of measured wheel profiles. One set of profiles consists of one individual wheel profile for each of the wheels of the vehicle. The different wheel profiles in the simulation cover a range of contact conditions and should generate a representative distribution of loading conditions for the fatigue analysis. On the rail side a standard rail profile is used. Typical measured track irregularities are prescribed in the simulation so that not only quasi-static curving forces are considered in the fatigue analysis, but also contributions to the contact forces from the dynamic vehicle behaviour.

2.2. Full scale test rig simulations

The full-scale test rig simulations have been done with a simulation tool that is described in detail in [6]. This model determines the contact loading by a stripe-wise contact model to allow an efficient approximation of non-elliptic, curved, conformal contacts which may be encountered in full-scale test rig experiments.

2.3. Rolling contact fatigue assessment

The propensity towards crack initiation is assessed with the so-called wedge model. It has been developed for the prediction of head check crack initiation on rails in metro operations [7, 8]. The key feature of the model is that it takes (severe) plastic shear deformation at the surface into account when estimating rolling contact fatigue crack initiation. Severe plastic shear deformation at the surface may facilitate (macroscopic) crack initiation if possible crack paths are oriented at an oblique angle to the surface.

This assumption has been supported recently by crack growth experiments in samples which have been deformed by high pressure torsion. Due to the high plastic shear deformation pearlite lamellae align parallel to the shear plane. In such samples fatigue crack growth rates are highest if the crack plane is parallel to the shear plane [9].

The shear deformation structure of the material near the surface can be described by the plastic shear angle α. In case of simple shear α is calculated as the change of displacement parallel to the contact surface u^p_x due to plasticity with depth below the surface z as [8, 10]:

$$\tan(\alpha) = \frac{du_x^p}{dz} \qquad (1)$$

To assess the contribution of the plastic shear deformation to rolling contact fatigue crack initiation in the model the distribution of the plastic shear angle near the surface $\alpha(z)$ is compared to a reference distribution of the plastic shear angle $\alpha_R(z)$ which is assumed favourable for crack initiation. This is done for a surface layer of z_c = 130 µm thickness (crack initiation layer) in terms of a similarity parameter A_α.

$$A_\alpha = 1 - \frac{2}{(\alpha(z=z_c)-\alpha(z=0))\cdot z_c}\int_0^{z_c}|\alpha - \alpha_R|dz \qquad (2)$$

The reference distribution of the plastic shear angle $\alpha_R(z)$ has been established based on investigations of rail specimens from railway operation and from test rigs experiments previously [8]. For this purpose the plastic shear angle α in RCF-affected parts of the rail is determined from the visible predominant orientation of microstructural features in metallographic sections [11].

If the reference distribution of the plastic shear angle $\alpha_R(z)$ is a linear function of z the similarity parameter A_α ranges from 0 (actual distribution of the plastic shear angle is not similar to reference distribution of the plastic shear angle) to 1 (actual distribution of the plastic shear angle equals the reference distribution of the plastic shear angle) [8]. Depending on the distribution of the plastic shear angle near the surface three important cases with respect to wear and crack initiation may be distinguished [8]:

In the absence of plastic shear deformation the actual distribution of the plastic shear angle in the crack initiation layer is dissimilar to the reference distribution of the plastic shear angle resulting in a similarity parameter of $A_\alpha = 0$. The fatigue crack growth rates can then be assumed equal in all directions of the crack initiation layer.

In case of severe plastic shear deformation at the surface the actual distribution of the plastic shear angle does not match the reference distribution of the plastic shear angle either. Thus the similarity parameter A_α is 0 as well in the extreme case. Pearlite lamellae are oriented parallel to the surface. (Microscopic) fatigue cracks thus grow preferably parallel to the surface contributing to the generation of wear particles.

In case of medium plastic shear deformation the actual distribution of the plastic shear angle in the crack initiation layer may match the reference distribution exactly, resulting in a similarity parameter $A_\alpha = 1$. In this case the pearlite lamellae in the crack initiation layer are predominately oriented at an oblique angle to the surface, causing (microscopic) fatigue cracks growing away from the surface and promoting the initiation of (macroscopic) fatigue cracks.

The fatigue life calculation in the wedge model is based on the effective stress σ_A. It is calculated from the maximum (tensile) principal stress σ^* during the load cycle, the similarity parameter A_α (quantifying the influence of the plastic shear deformation on the crack initiation), and the parameter f_t (quantifying the influence of traction and braking) as [8]:

$$\sigma_A = \max(\sigma^*(t)) \cdot (1 + k_A \cdot A_\alpha) \cdot f_t \qquad (3)$$

The constant k_A and the constant in the parameter f_t have been determined by wheel-rail test rig experiments [6, 8]. The effective stress σ_A is then used with Basquin's equation and linear damage accumulation to estimate the damage D_A with respect to rolling contact fatigue crack initiation [8].

In the model the area of contact is partitioned into stripes, which are concatenated in lateral direction of the rail. For each stripe the Hertzian (line) contact length, the normal force and the creepages need to be given. The tangential contact problem (including the tangential stress distribution) is then determined by a stripe-wise brush model [8].

With such a discretization both typical concentrated contacts in railway operation and typical conformal contacts (in lateral direction of the rail) in full-scale test rig experiments can be handled.

3. Results and discussion

3.1. Crack initiation assessment: Railway operation scenario

Results of the multi-body dynamics simulations have been used as input data for the wedge model as described in section 2.3 to assess fatigue crack initiation. Figure 2 shows the local maximum normal contact pressure p_0 as a function of the lateral position y on the rail for a typical position along the rail. Contact patches with an area of less than 20 mm² have been excluded from the calculation because these are often linked to the occurrence of unrealistically high (linear-elastic) contact stress values in the multi-body simulation results. The contact patches concentrate in two regions: At the top of the rail and in an area next to the gauge corner. The majority of contacts with high maximum normal pressure are observed near the gauge corner.

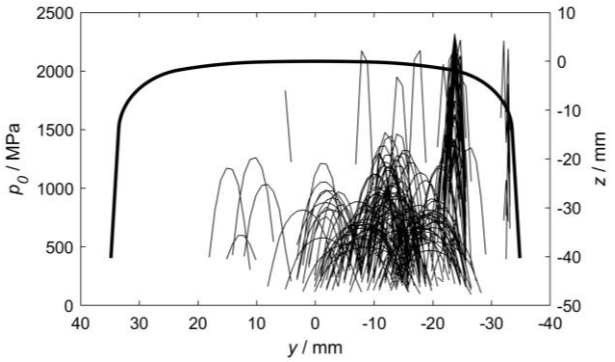

***Figure 2**: Local maximum normal contact pressure p_0 as a function of lateral position y on the high rail.*

Calculating the relative damage value $\log(D_a/\max(D_a))$ with the wedge model as described in section 2.3 (see Figure 3) reveals similar values for the contact region on top of rail and for the region near the gauge corner which is in agreement with experimental observations (see Figure 1a). However higher local maximum normal pressures occur near the gauge corner. This result can be explained by examining the effective stresses value σ_a for the individual contacts (see Figure 4) together with the similarity parameter A_α which quantifies the plastic shear deformation condition on the rail surface with respect to crack initiation (see Figure 5).

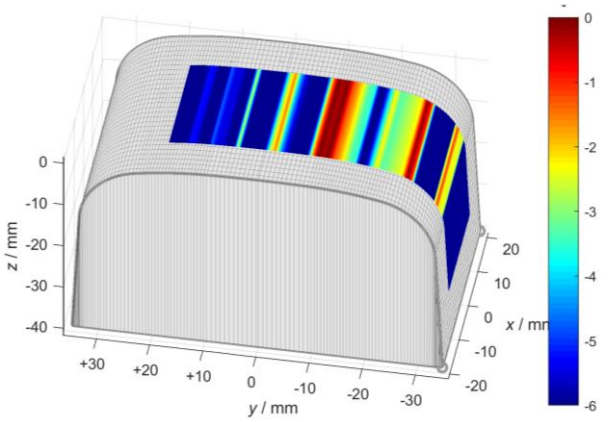

***Figure 3**: Normalized damage values $\log(D_a/\max(D_a))$ as a function of lateral position y on the rail.*

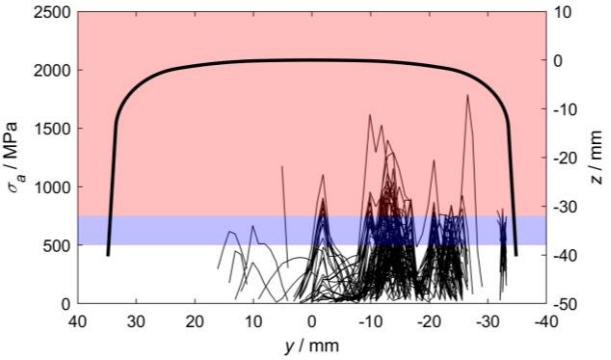

***Figure 4**: Effective stress σ_a for crack initiation in the wedge model of individual contacts.*

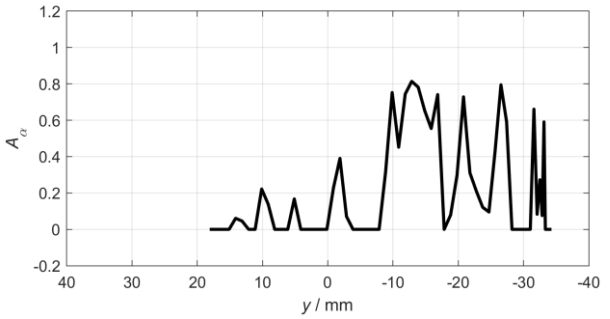

***Figure 5**: Plastic shear deformation condition with respect to propensity to crack initiation quantified with the similarity parameter A_α.*

Effective stresses σ_a at the top of rail are higher than those near the gauge corner of the rail. This is a consequence of different values of the similarity parameter A_α as defined in Equation 2 at these positions on the rail surface. The plastic shear deformation condition between lateral rail positions y = −10 mm and y = −20 mm is similar to the reference shear strain distribution as described in section 2.3 and thus favourable for fatigue crack initiation. This results in a high value of the similarity parameter A_α which generates a high effective stress σ_a for crack initiation in the wedge model. Between lateral rail positions y = −20 mm and y = −30 mm contact stresses and plastic shear deformation are higher, which results in a

lower value of the similarity parameter A_α and thus lower effective stress values σ_a for the region near the gauge corner. When interpreting the data in Figure 3 one needs to keep in mind that the individual contacts in Figure 3 are associated with different number of load cycles because of different relative portions of the vehicle types in railway operation. The damage value depends on both the value of the effective stress and the number of load cycles.

To further examine which contacts contribute to damage according to the wedge model the effective stress values σ_a in Figure 4 are categorized as "low" for values below 500 MPa, "medium" for values in between 500 MPa and 750 MPa, and "high" for values above 750 MPa. The data of Figure 4 are replotted in Figure 6 as local maximum normal contact pressure p_0 as a function of the local coefficient of adhesion *T/N*. "Local" refers to the contact conditions in stripes of 1 mm width in lateral rail direction. This means that, for example, a contact with a total width of 5 mm contributes five points in Figure 6.

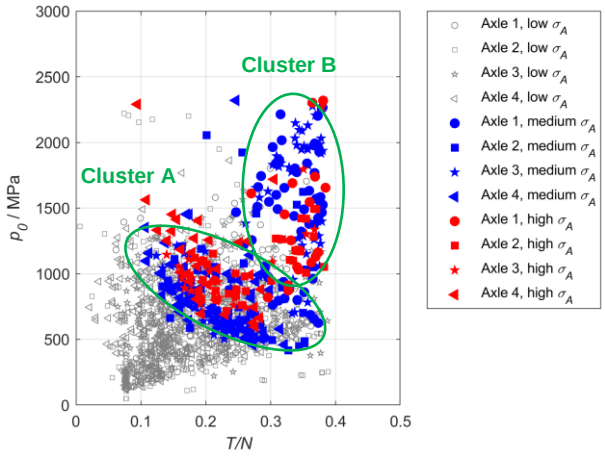

***Figure 6**: Local maximum normal contact pressure p_0 as a function of local coefficient of adhesion T/N. The symbols refer to the respective axle of the vehicle. Local effective stresses between 500 MPa and 750 MPa (blue) and above 750 MPa (red) are highlighted with filled symbols.*

For the investigated scenario of metro operation in a curve of 300 m curve radius the local contact conditions with medium and high effective stresses σ_a form two clusters (see Figure 6): Cluster A with medium local normal contact pressures p_0 and medium to high values of adhesion *T/N*, and cluster B with high values of adhesion *T/N* and medium to high values of local maximum normal contact pressure p_0 (see Figure 6). The majority of points with medium to high values of the effective stress σ_a are located in cluster A.

Figure 7 shows only contact conditions which result from leading axles of the leading bogies (Axle 1) and leading axles of trailing bogies (Axle 3) of the different vehicle types considered in the simulation. Medium and high effective stress values σ_a of axle 1 are predominately found in cluster B, whereas medium and high effective stress values σ_a of axle 3 are found predominately in cluster A, but also in cluster B for the scenario investigated.

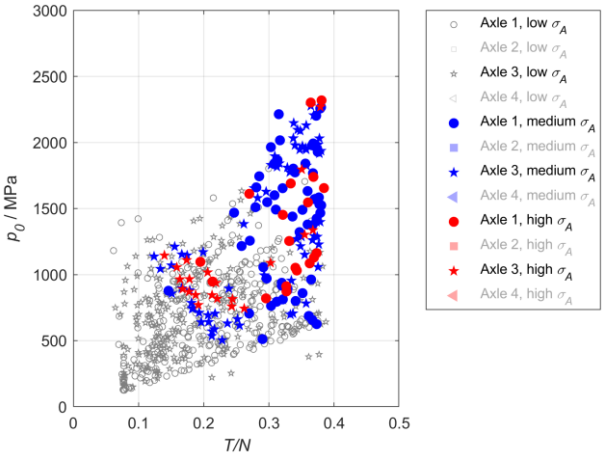

***Figure 7**: Local maximum normal contact pressure p_0 as a function of local coefficient of adhesion T/N for leading axles of leading (Axle 1) and trailing bogie (Axle 3). Local effective stresses between 500 MPa and 750 MPa (blue) and above 750 MPa (red) are highlighted with filled symbols.*

Local contact conditions with medium to high effective stress values associated with trailing axles of the leading bogies (Axle 2) are located predominately in cluster A, with some high effective stress values located in cluster B (see Figure 8). Local contact conditions with medium and high σ_a values originating from trailing axles of the trailing bogies (Axle 4) of the different vehicles are predominately found in cluster B.

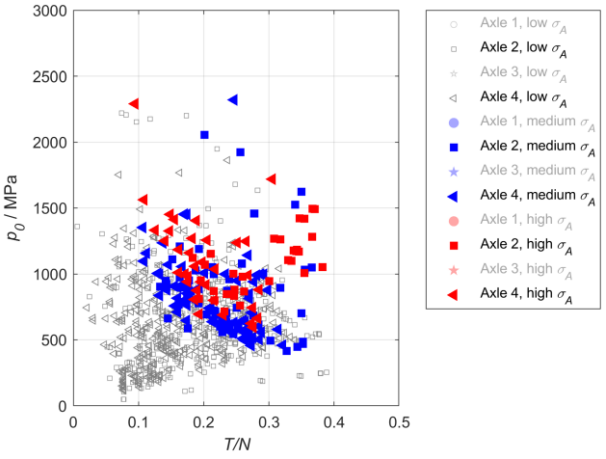

***Figure 8**: Local maximum normal contact pressure p_0 as a function of local coefficient of adhesion T/N for trailing axles of leading (Axle 2) and trailing bogies (Axle 4). Local effective stresses between 500 MPa and 750 MPa (blue) and above 750 MPa (red) are highlighted with filled symbols.*

3.2. Test rig experiments

The investigations and the methodology described above are the basis to reproduce RCF-relevant loading conditions on the full-scale wheel rail test rig. As an example, loading conditions according to cluster A (in Figure 6) are reproduced by choosing appropriate test rig parameters. These include the vertical wheel force, the lateral wheel force, the angle of attack of the wheel, or the torque applied to the wheel.

The contact geometry can only be controlled to a limited degree during the experiment, because one wheel rolls repeatedly over one piece of rail which usually leads to

the development of a conformal contact in lateral direction of the rail due to wear and plastic deformation. This contact may extend from the top of the rail to the side of the rail as illustrated in Figure 9. Within such a contact different loading conditions are realized due to varying rolling radius and inclination of the surface.

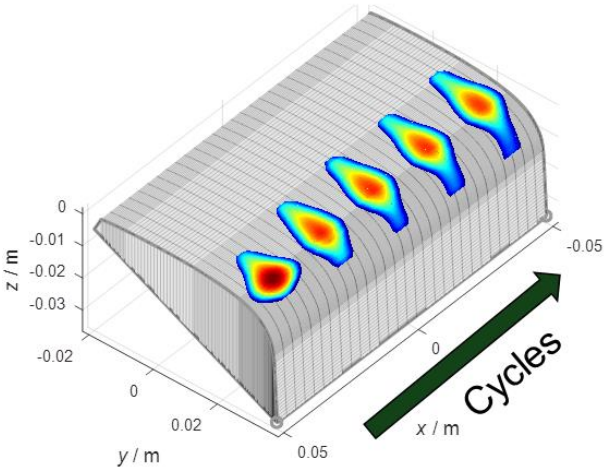

***Figure 9**: Typical evolution of a conformal contact in a full-scale wheel rail test rig experiment with increasing number of load cycles.*

The analysis of the effective stress controlling the crack initiation in the wedge model for a typical experiment reveals that the local contact conditions related with medium and high values of the effective stress σ_a fall well in the range of conditions of cluster A of the railway operation scenario (see Figure 10). In the figure the angle of attack of the wheel was varied from 0° to −0.25°. Reducing the absolute value of the angle of attack reduces the lateral creepage and thus extends the covered parameter range towards lower *T/N* values.

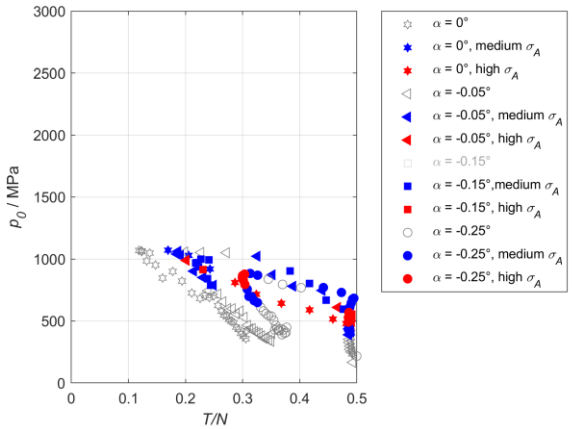

***Figure 10**: Local maximum normal contact pressure p_0 as a function of local coefficient of adhesion T/N for different angles of attack α of the wheel in a full-scale wheel rail test rig simulation. Local effective stresses between 500 MPa and 750 MPa (blue) and above 750 MPa (red) are highlighted with filled symbols.*

The range of local contact conditions in the investigated test rig scenario is narrower than the range of conditions in the railway operation scenario, which is not surprising because the railway operation scenario involves multiple wheels with individual profile geometries, whereas the range of contact conditions in the test rig experiment is realized within one single (conformal) contact patch. Nevertheless the range of local contact conditions on the test rig falls into the range of contact conditions of cluster A in the railway operation scenario.

4. Summary and conclusions

In railway operation different typical local contact conditions are observed for the different axles of railway vehicles in certain scenarios. These local contact conditions vary widely due to the track geometry, varying wheel profile geometries and the dynamic vehicle behaviour. The methodology described in this work can be applied to simulation data of multi-body simulations of railway vehicles with concentrated contacts, as well as to conformal contact conditions typical for full-scale test rig experiments.

Thereby relevant loading conditions with respect to rolling contact fatigue crack initiation can be identified and reproduced on a test rig. Despite the occurrence of concentrated contacts in railway operation in contrast to conformal contact conditions in typical full-scale test rig experiments, the local contact conditions relevant for crack initiation can be reproduced in a test rig experiment as demonstrated for the scenario of a curve with 300 m curve radius. The methodology contributes to the understanding how contact loading conditions with respect to fatigue crack initiation in railway operation are linked to those in test rig experiments.

Abstract: It is widely known that head check usually appears at the gauge corner (GC) of the high rail in a curved section with a radius of about 800m. However, some head checks were found appearing at the rail head surface of the low rail in some commercial lines of Japan railway, and its generation conditions as well the formation mechanism are not yet clear. In order to make clear of the occurrence reason of causing this type of head check, this study had an investigation on-site where had head check appeared and conducted the crack propagation observation with a cut of defect rail. Moreover, the rail-wheel contact analysis by use of the multibody dynamics was performed for clarifying the contact conditions between the rail-wheel at the site of the head check appearance. The research results show that the longitudinal creep mainly affect the occurrence and the propagation of the head check in the low rail.

Keywords: head check; low rail; multibody dynamics; rail-wheel contact; longitudinal creep; SIMPACK.

1. Introduction

The severe contact stress and slip are caused by train passage on the rail. As a result, the phenomenon such as crack initiation and wear occurs on the rail running surface. Rail squats and head check are mentioned as the representative examples of rail defects. Rail squats will cause rail failures in case of the deep crack propagation. Therefore, many researches of the rail squats such as studies on the crack propagation [1, 2] or the proposal of countermeasure method [3 - 5] have been conducted. On the other hand, the head check [6, 7] is widely known as the defect that appears at the gauge corner on the high rail and their appearances at many such sites are confirmed. Recently, some head checks have appeared on the surface of the rail head of the low rail in Japanese railway (Fig.1).

Figure 1 *Head check appearance of the low rail:*

Because of the continuous appearance of the head checks on the rail surface at these sites, ultrasonic flaw detection cannot be carried out at these sites. Furthermore, the vertical vibration of passing vehicles at these sites becomes significant (Fig.2). However, the formation mechanism and the initiation factors of the head check of the low rail have not been clarified. In this research, we conducted the on-site investigation, the analysis of the rail on which the head check appeared, and the rail-wheel contact analysis by use of the multibody dynamics.

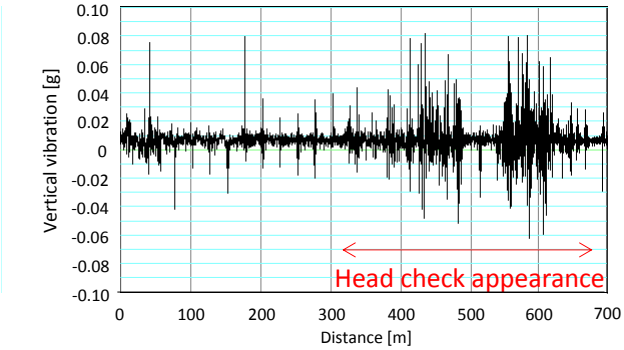

Figure 2 *Examples of the vertical vibration of vehicle at the head check appearance section of the low rail:*

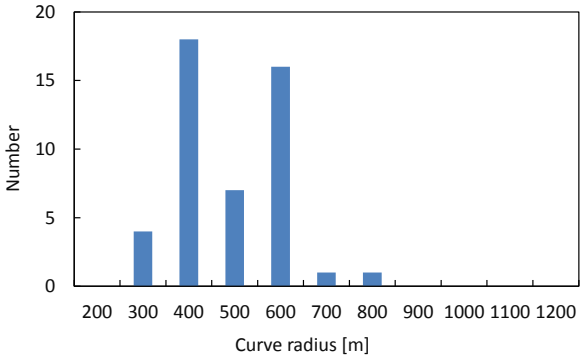
2. On-site investigation

We conducted the on-site investigation to clarify the conditions of head check appearance of the low rail. The details of the investigation are shown in this chapter.

2.1. Outline of the site of the head check occurrence

We conducted the investigation of the site where the head check appears on the low rail. The total number of the on-site investigation is 50. First of all, we summarized the radii of the curvatures of these sites. The results are shown in Fig.3.



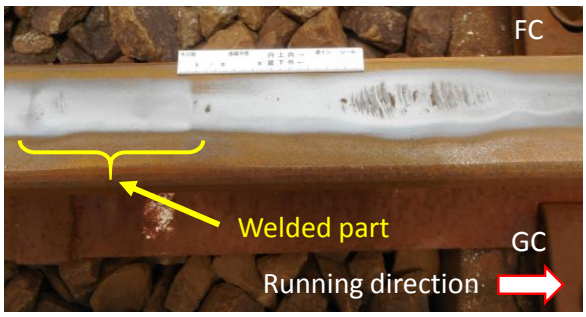


Figure 3 *The radii of the curvature at the head check appearance of the low rail:*

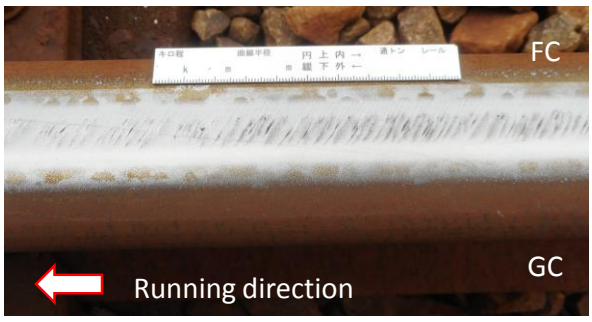


It is confirmed that the head check of the low rail tends to appear in the curved sections where the radii are from400m to 600m. Since the head check at the gauge corner of the high rail tends to appear in the curved sections where the radii are from 700m to 800m, the head check of the low rail seems to appear in the sharp curve sections.

2.2. The formation of the head check of the low rail

We conducted the investigation of the site where the head check appeared on the low rail as described in the previous section. According to the on-site investigation, it has been confirmed that the head check of the low rail can be classified into three types. The features of each type of the head check are described below (see in Fig.4).

(a) Near the welded part type

(b) Continuous type

(c) Discontinuous type

Figure 4 *Types of the head check appearance of the low rail:*

(a) Near the welded part type

This type of the head check appears only at the place which is located just after the wheel passes the welded part. As the feature of the appearance of this type, the width of the band of the contact surface of the rail with the wheel is changed gradually in the rail longitudinal direction different from the band width of the rail-wheel contact surface appearing before and after the head check. Furthermore, some part of the head check portion were observed to scale off. This type of head check is considered to be a fatigue damage accumulated due to the contact force which is generated by the wheel load vibration caused by the unevenness of the rail surface at the welded part.

(b) Continuous type

This type of the head check appears in the curved section continuously. As the feature of the appearance, the band width of the contact surface of the rail with the wheel is not changed in the rail longitudinal direction, and the scale off of the surface is very rare. No significant vertical vibration of the vehicle is observed in the section where the head check of this type appears. Tracing the surface of this type of the head check with the figures, it is smooth in the direction of train running. On the other hand, it feel rugged in the opposite direction. In other words, the rail surface where the head check of this typed appears becomes like the scales of the fish.

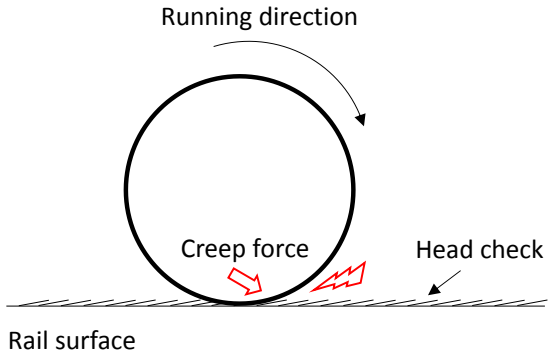
(c) Discontinuous type

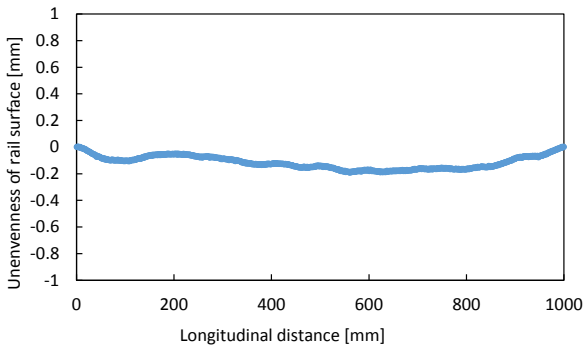
This type of the head check appears in the curved section discontinuously in the longitudinal direction of the rail. As the feature of the appearance, the band width of the contact surface of the rail with the wheel changes complicatedly. Especially, the band width of the contact surface of the rail where the crack mouthes of the head check gather densely is wide, and the band width of the contact surface of the rail where the crack mouthes do not exist is narrow. Therefore, the contact condition of the rail-wheel changes complicatedly at the place where this type of the head check exists. The head check which is shown in Fig.1 is classified as this discontinuous type. In addition, in the same way as the type of the head check described in (b), the rail surface where this type of the head check appears becomes like the scales of the fish.

The appearance site of the head check of the near the welded part type is limited and the initiation factor of this type of the head check is inferred to be the unevenness of

the rail surface produced just after the welding process. Therefore, hereinafter we examined the initiation factors of the head check classified as (b) the continuous type and (c) the discontinuous type described in the previous section.

As described above, with respect to the head check classified as (b) the continuous type and (c) the discontinuous type, when we trace the surfaces of these types of the head checks with the fingers, it is smooth in the direction of train running and we feel rugged in the opposite direction. That is, the rail surfaces of these types of the head checks become like the scales of the fish. As a reason for this feature, it is thought that the longitudinal creep force acts continuously on the contact surface of the rail-wheel during train passage and the rail surface is plastically deformed gradually as a result (Fig.5).





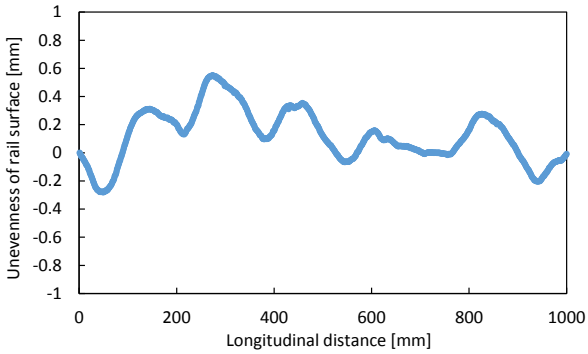


Figure 5 *Illustration of the plastically deformation due to the rail-wheel contact:*

2.3. The unevenness of rail

The unevenness of the rail surface changes complicatedly in the case of the head check of the discontinuous type. As a result of the occurrence of the head check on the low rail, the vertical vibration of the vehicles passing the head check site becomes significant as shown in Fig.2. Therefore, we measured the unevenness of the rail surface of the head check of the discontinuous type. In addition, we also measured the unevenness of the rail surface of the head check of the continuous type for comparison. These measurement results are shown in Fig.6.

(a) Continuous type

(b) Discontinuous type

Figure 6 *Measurement results of the unevenness of rail surface:*

The rail surface where the head check of the continuous type appears is almost flat although slight irregularities are observed (see in Fig.6 (a)). On the other hand, the unevenness of the rail surface changes complicatedly in case of the head check of the discontinuous type (see in Fig.6 (b)). Therefore, we conducted the power spectrum analysis of the unevenness of rail surface where the head check of the discontinuous type appears. The results are shown in Fig.7.

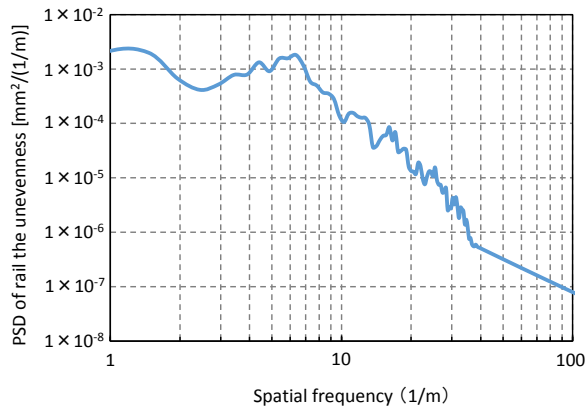

Figure 7 *The results of the power spectrum analysis of the unevenness of rail surface:*

According to the power spectrum analysis of the surface unevenness the head check of the discontinuous type, the spatial frequency of 6.3[1/m] was dominant. In other words, it is thought that the wavelength of the surface unevenness of this rail is approximately 160mm.

3. Analysis of the rail laid in service

In order to examine the initiation factors of the head check of the low rail, we conducted the analysis of the rails which are laid in the curved section in service. The rails for analysis had the head check on the rail head. We conducted the cross sectional observation of the rails to check the crack propagation and the plastic flow caused by the rail-wheel rolling contact.

3.1. Outline of the rails for analysis

The rails for analysis were laid as the low rails in the curved section of which the radius is 600m. The head checks appearing on the rail surface are classified as (c) the discontinuous type described in the previous section. The outlook of the rail is shown in Fig.8.

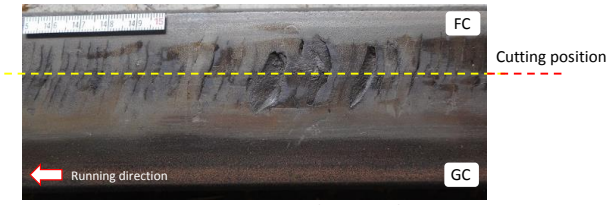

Figure 8 *The outside of the rail for analysis:*

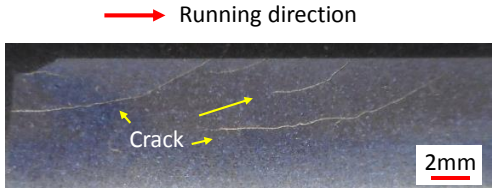
The width of rolling contact surface of the rail-wheel changes complicatedly (see in Fig.1). That is, the width of the contact surface is wide at the place where the head checks appear densely, and the width is narrow at the place where the head checks do not exist. Furthermore, it is also confirmed that the contact surface is set aside to field corner (FC).
In order to observe the crack propagation and the cross sectional structure, we cut the rail along the dotted line shown in Fig.8.

3.2. Crack propagation

The results of the cross sectional observation of the rail for analysis is shown in Fig.9.



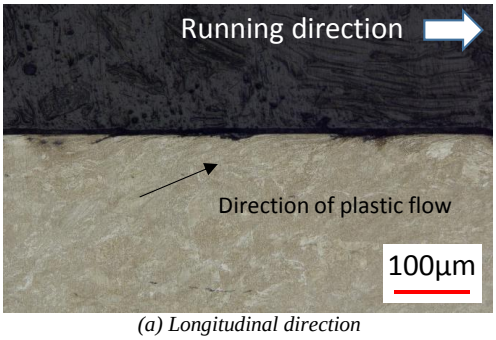


Figure 9 *The observation results of the crack propagations:*

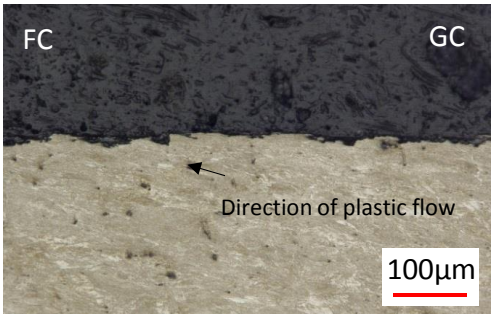

It is confirmed that the crack of the head check propagates in the direction opposite to the train running direction, starting from the rail surface. Furthermore, some cracks propagate into a layered structure inside the rail. Therefore, it is hard to detect the deepest crack by use of ultrasonic flaw detector from the surface of the rail head, because ultrasonic is obstructed by the crack which propagates near the surface of rail. In this research, the maximum value of the depth of the propagating crack is 4mm.

3.3. Plastic flow

In order to examine the contact conditions of the rail-wheel that have the effect on the initiation and propagation of the head check, the cross sectional observation of the rail was conducted. The rail for analysis was cut along the longitudinal direction and the transverse direction, polished and etched with 3% 4atal to observe the plastic flow under the rail surface using the optical microscopy.
The results of the cross sectional observation of the rail is shown in Fig.10.

(a) Longitudinal direction

(b) Transverse direction

Figure 10 *The observation results of the plastic flow:*

It is confirmed that the plastic flow under the rail surface was observed both in the train running direction on the longitudinal cross section and on the FC side on the transverse cross section. Therefore, the plastic flow under the rail surface was confirmed in the rail for analysis which has the head check on the rail surface as shown in Fig.11. Incidentally, the relation between the direction of the crack mouth of the head check in low rail and the direction of the plastic flow is consistent with the relationship between the direction of the crack mouth of the head check and the creep force described in the previous research [8]. Hence, it is thought that the contact force between the rail-wheel which causes the plastic flow under the rail surface affects the initiation of the head check of the low rail.

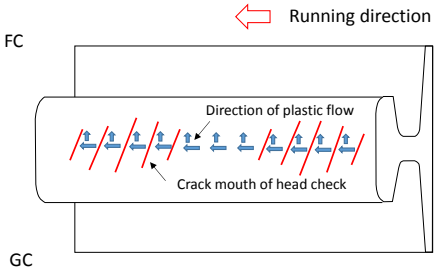

Figure 11 *The illustration of the direction of plastic flow:*

4. Rail-wheel contact analysis by the model constructed at the head check appearance site

In this section, we examined the factors influencing the propagation of the head check based on the rail-wheel contact conditions at the site of the head check appearance of the low rail. Therefore, we constructed the vehicle dynamics analysis to clarify the contact conditions between the rail-wheel at the site of the head

check appearance by use of the multibody dynamics (Simpack). Based on the analytical results, we examined the factors influencing for the head check propagation. The details are shown below.

4.1. Outline of the analytical model

The unevenness of the rail surface where the discontinuous type of the head check appeared is changed complicatedly. Especially, at the site where we conducted the on-site investigation in this study, it confirmed that the wavelength of the unevenness of the rail surface is approximately 160mm. Therefore, we examined the contact conditions between the rail-wheel in case of the vehicle running on the track having such evenness of rail surface. The outlook of the analytical model is shown in Fig.12.

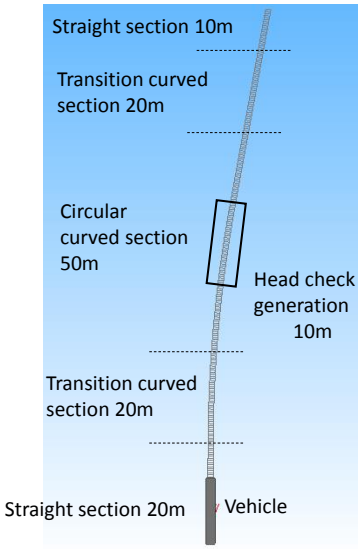

Figure 12 *The illustration of the analytical model:*

The analytical track model is constructed by one curved section which consists of a circular curve of the radius of 600m and both the straight sections and the transition curved sections before and after the circular curve. In the analytical model of track, the worn profile of rails measured at the site was adopted as the rail profile. The area around center of the circular curved section, where the head checks appear on the in low rail was modelled, and the unevenness of the rail surface of the model was set such that the wavelength is 160mm and the amplitude is 0.01mm; those of the unevenness at the investigation site. Furthermore, the running speed of vehicle was set at 30km/h and the value of the cant in the circular curved section was set at 13mm, the balance cant corresponding to its vehicle speed of 30km/h. The details of the track model are shown in Table 1.

On the other hand, the vehicle model consist of 1 car body, 2 bogie frames and 4 wheelsets (see in Fig.13). Each body is rigid and has 6 degrees of freedom. This vehicle model simulates the standard vehicle used on the Japanese commuter line.

Table 1 *The details of the track model.*

Curve radius	600 [m]
Cant	13 [mm]

Unevenness of rail surface	Wavelength 160 [mm] Amplitude 0.01 [mm]
Length of the uneven section	10 [m]
Rail profiles	Measured

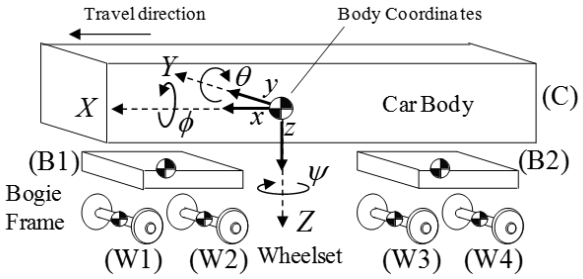

Figure 13 *Analytical model of vehicle:*

4.2. Analytical results

The analytical results of the rail-wheel contact conditions in the modelled area which is located at the center of the circular curved section and has the head check of the low rail as described in the previous section are shown below. First of all, according to the feeling of tracing the rail surface with the finger as described in the chapter 2 and the observation of the crack propagation as described in the chapter 3, it is thought that the longitudinal creep force affects the head check propagation. Therefore, the analytical results of the longitudinal creep force in this section are shown in Fig.14.

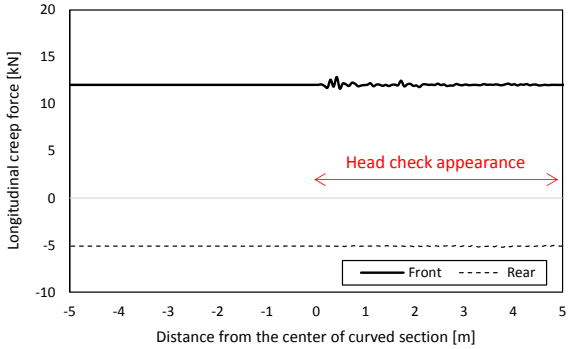

Figure 14 *The analytical results of the longitudinal creep force:*

It is confirmed that the longitudinal creep force generated at the contact surface between the rail-wheel of the low rail fluctuates to a large extent in the section where the head check appears. On the other hand, no fluctuation of the longitudinal creep force is observed in the section where the head check of the low rail does not appear. The factor of the difference of these analytical results might be the unevenness set on the rail surface which will cause the head check. Therefore, we analysed the wheel load and the longitudinal creep ratio generated in these sections. These results are shown in Fig.15 and 16.

As shown in Fig.15, it is confirmed that the wheel loads is fluctuating in the section where the head checks appear. Furthermore, it is also confirmed that the longitudinal creep ratio is fluctuating in the section of head check occurrence. The factors of these results are considered to be the unevenness of the rail surface. That is, the values of the wheel load and the longitudinal creep ratio are low at the convex position, and high at the concave position.

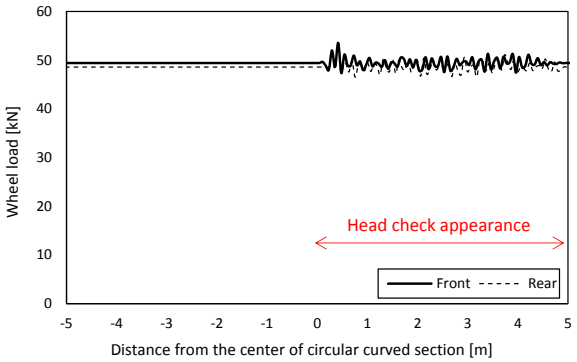

Figure 15 *The analytical results of the wheel loads:*

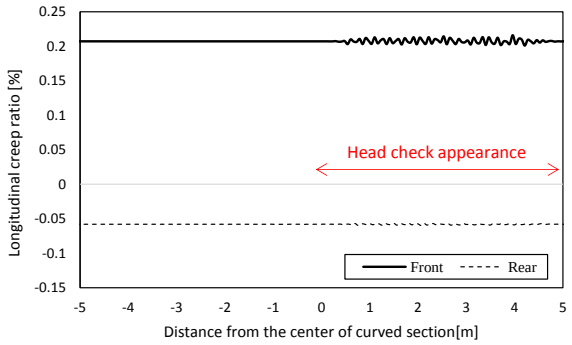

Figure 16 *The analytical results of the longitudinal creepage:*

According to the these analytical results, it is thought that the longitudinal creep force is fluctuating due to the unevenness of rail surface, and the cracks of head check propagates deeply at the concave position as a result of the rail-wheel contact conditions. Actually, the plastic flow was confirmed on the rail surface on the FC side at the concave position, therefore, it is thought that the contact conditions of the rail-wheel is severe at the concave position compared with those before and after the concave position (see in Fig.17).

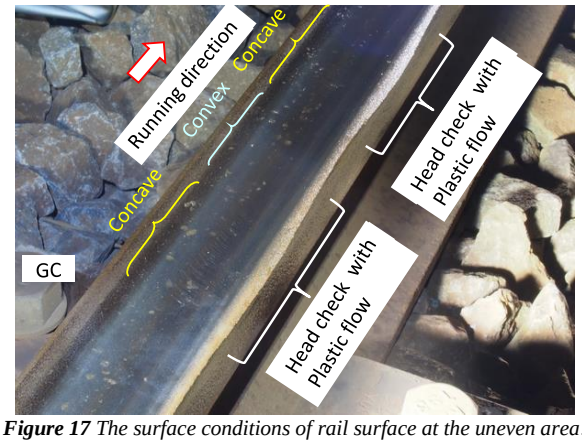

Figure 17 *The surface conditions of rail surface at the uneven area:*

5. Investigation of the initiation factors of the head check of the low rail based on the rail-wheel contact analysis

In order to examine the initiation factors of the head check of the low rail, we conducted the rail-wheel contact analysis by use of the multibody dynamics (Simpack) with respect to the modelled curved section with a radius of 600m, then based on the analysis results, we examined the initiation factors of the head check of the low rail.

5.1. Outline of the analytical rail

We conducted the rail-wheel contact analysis by modelling the curved section with a radius of 600m of the actual network where appearance of many head checks of the low rail were confirmed. The details of the track model is shown in Table 2. Incidentally, two types of the vehicles, that is, the tilting train and the non-tilting train were running in the actual networks where the head check appearance was confirmed. Therefore, we conducted the rail-wheel contact analysis for these two types of the vehicles. The details of the vehicle model and the running conditions of each train are shown in Table 3 and 4.

Table 2 *The details of the track model.*

Curve radius	600 [m]
Cant	100 [mm]
Gauge widening	0 [mm]
Longitudinal gradient	Downward 10 [‰]
Rail profiles	Designed
Straight section (Entrance side)	100 [m]
Transition curved section (Entrance side)	100 [m]
Circular curved section	200 [m]
Transition curved section (Exit side)	100 [m]
Straight section (Exit side)	100 [m]

Table 3 *The details of the vehicle model (Tilting train).*

Vehicle type	Tilting train
Running speed	115 [km/h]
Weight	40000 [kg]
Tread profile	Modified arc
Wheel diameter	810 [mm]

Table 4 *The details of the vehicle model (non-tilting train).*

Vehicle type	Non-tilting train
Running speed	115 [km/h]
Weight	40000 [kg]
Tread profile	Modified arc
Wheel diameter	860 [mm]

As shown in Table 2, the value of the setting cant for this curved section is 100mm. On the other hand, the value of the equilibrium cant for the vehicle running at 100km/h is calculated as 185mm. Therefore, as for the vehicles

running in this curved section, the cant deficiency is calculated as 85mm.

5.2. Analytical results

The analytical results of two types of the vehicles described in the previous section are shown below.
According to the cross sectional observation explained in Chapter 3, it is thought that the longitudinal creep generated on the contact surface between the low rail and the wheel affects to the initiation of the head check of the low rail. The analytical results of the longitudinal creep ratio on the contact surface between the low rail and the wheel is shown in Fig.18.

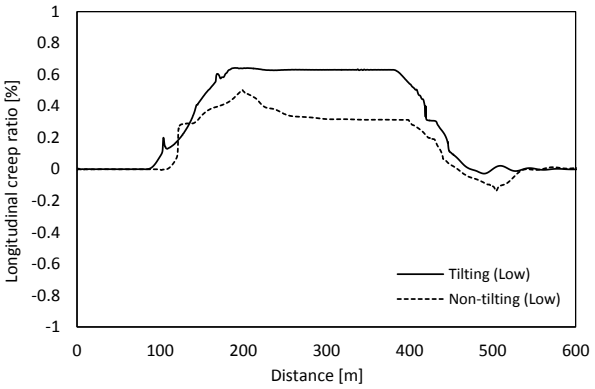

Figure 18 *The analytical results of the longitudinal creep ratio:*

As shown in Fig.18, it is confirmed that the longitudinal creep ratio generates in the curved section. Especially, the value of the longitudinal creep ratio in case of the tilting train is approximately twice as large as the value in case of the non-tilting train. Such difference of the longitudinal creep ratio between two types of vehicle may be caused related with the difference of the wheel diameter on the high rail and that on the low rail. Therefore, we plotted the analytical results of the difference between the diameter of the wheel on the high rail and that on the low rail. These results are shown in Fig.19.

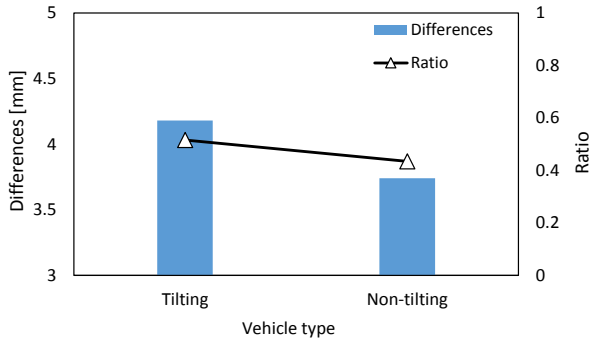

Figure 19 *The analytical results of the differences between the diameters of the wheel at the high rail and low rail:*

As shown in Fig.19, the difference between the diameter of the wheel on the high rail and that on the low rail in the circular curved section can be confirmed. Especially, the value of the difference of the diameter of the wheel of on the high and that on the low rail in case of the tilting train is higher than that in case of the non-tilting train. This may be caused as follows; because the lateral force generated by the tilting train is higher than that by the non-tilting train (see in Fig.20), the wheel axle moves towards the outside of the curve more in case of it's the tilting train than in case of the non-tilting train, resulting in more difference between the diameter of the wheel on the high rail and that on the low rail (see in Fig.21). Moreover, because the diameter of the wheel of the tilting train is smaller than that of the non-tilting train, the longitudinal creep ratio generated on the low rail becomes larger in case of the tilting train.

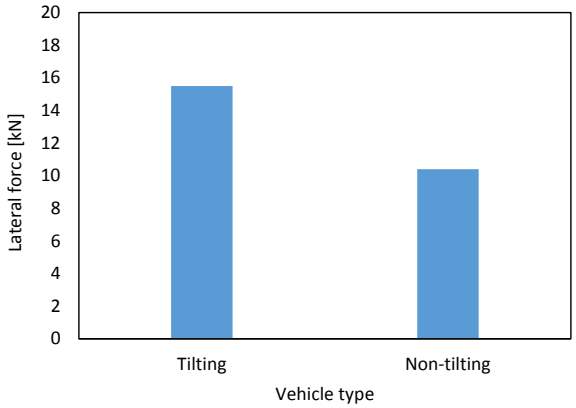

Figure 20 *The analytical results of the lateral force:*

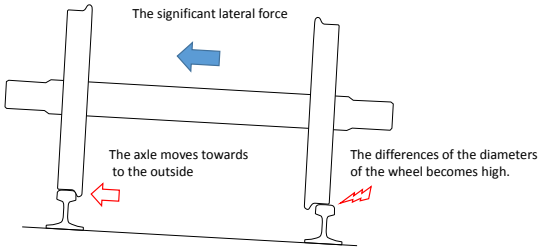

Figure 21 *The illustration of rail-wheel contact conditions at the head check appearance of the low rail:*

Finally, the longitudinal creep ratio was generated on the rail-wheel contact surface of the low rail due to the large difference between the diameter of the wheel on high rail and that on the low rail in the case where the tilting train runs in the curved section with a radius of 600m. In addition, this longitudinal creep ratio resulted in the appearance of the head check on low rail.

6. Conclusions

In this research, we conducted the on-site investigation, the analysis of the rail head check and the rail-wheel contact analysis with respect to the head check generation on the low rail. As a result, the following knowledge was obtained.
The cracks of the head check on the low rail propagates in the direction opposite to the train running along the plastic flow.
The significant longitudinal creep force was generated in the concave area on the rail surface due to the wheel load variation of the running vehicle in the curved section where the head check occurred on the low rail.
The longitudinal creep ratio was generated on the wheel and the low rail contact surface due to the high wheel load

and the large difference between the diameter of the wheel on the high rail and that on the low rail in case of the tilting train running in the curved section with a radius of 600m. As a result, the longitudinal creep affected the occurrence and the propagation of the head check of the low rail.

Acknowledgments
The authors would like to thank H. Tanaka who belongs to track geometry and maintenance laboratory of Railway Technical Research Institute for helpful measurement of the rail unevenness and discussions.

Abstract: The problem of tramways safety is crucial, and it is related to the optimization of the wheel-track contact and to the reduction of the wear progress, to prevent dangerous derailments. Currently, in the Florentine tramway, the check of the tracks' wear conditions and the maintenance are based on instrumented trolleys, capable of measuring just the profile. The aim of this paper is to show some experimental results about the detection and evaluation of tracks' wear by using non-contact optical metrology 3D scanners. Based on the experimental results, the systematic use of these technologies can be taken into consideration.

Keywords: Rail/wheel interaction; wear; 3D wear maps; 3D optical scanners; tram-ways safety, trolley for service applications.

1. Introduction

The problem of tramways safety is crucial, as an efficient, safe and sustainable mobility is a cornerstone of a smart city.
As a part of the tramway maintenance program, the comprehension and evaluation of the wheel-rail contact situation is extremely important, as well as the knowledge of the wear phenomenon [1-5]. The assessment and reduction of the wear progress is fundamental to prevent dangerous derailments; in-fact the track degradation condition is a basic information to plan subsequent service actions. Furthermore, high quality rolling components guarantee reliability, safety and driving comfort [6,7].
Currently, the evaluation of the rail quality consists of visual inspections, while the technical diagnostics involves the measurement of some geometric parameters and the comparison with reference threshold values.
In this paper, the case of the Florentine tramway is analysed. Currently, the check of the tracks' wear conditions and maintenance status are based on the application of instrumented trolleys, capable of measuring just the 2D profile of the rail by contact profilometers, according to [8,9]. These diagnostic trolleys are the most commonly used apparatuses for maintenance operations of tracks, and restitute 2D measures of the rail sections, that can be used to indirectly evaluate geometrical parameters such as the track gauge, the cant of the track, the side wear and others.
On the other hand, 3D digital models of components are becoming more and more essential for tribology issues, like the wear progress monitoring in mechanical and biomedical structures [10-12].
For this reason, in this paper, an innovative method to detect the rails' wear using 3D vision systems is proposed. This method is a novelty in the field of the analysis of wheel-rail interaction and allows more complete and reliable detections of the condition of the tram-way infrastructure with respect to the usual application of 2D laser optical profilometers.
Even if a few papers describe the use of 3D optical scanning instruments for tribological issues, they do not deal with wheel-rail wear assessments, but they show the improved effectiveness of 3D instruments with respect to the commonly used 2D ones [13-17].

2. Current instruments used in the Florence's tram-way for service application

The current instruments (Figure 1) used to diagnose the health condition of the rails in the tramway of Florence are the following:

- An electronic hand-pushed diagnostic trolley designed for continuous measurements of track gauge, cant, traveled distance and crooked. In particular, it has an odometric wheel recording the progress and rollers detecting the track gauge by means of an appropriate mechanism.
- A gauge able to detect the track gauge and cant. This is used mainly in track switches, where the trolley can derail.

Figure 2 shows a graph of the track gauge measured by the mentioned current instruments.

3. The detection of the rails' wear by 3D scanner: laboratory results

In this section preliminary laboratory results of the wear evaluation of a portion of rail are presented using an innovative method to detect wear by means a portable metrological 3D optical scanner. The obtained measures were compared with the ones obtained by profilometers. The wear was computed by comparing the measured rail profiles to reference homolog 3D parts and 2D profiles.

3.1. Materials and methods

The analyzed rail portion has 400 mm of length and it has been taken as a specimen and its profile is Ri60 R13 (Fig.3). A part of rail was manually worn according to a typical wear case for a straight track.

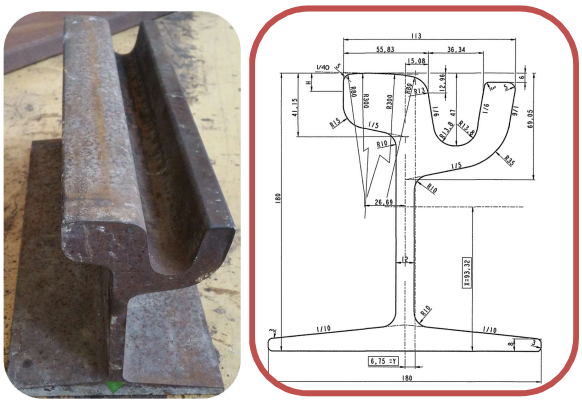

Figure 3 *Rail portion and profile*

The Figure 4 shows the rail after it was worn out. The area most affected by wear are the counter rail (1), the throat (2), the flange (3), the rolling thread (4).

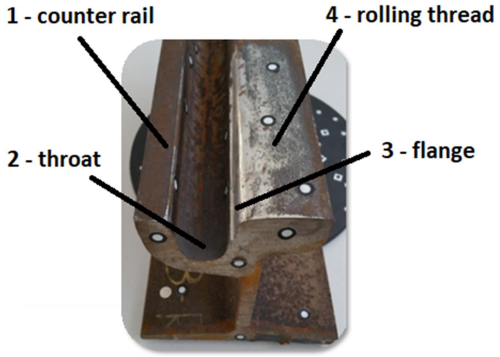

Figure 4 *Worn out rail portion*

The used 2D measuring instruments is a contact stylus profilometer (Figure 5): Linear Height LH600E/EG - Series 518 (Mitutoyo Corp., Kawasaki, Japan)

Figure 5 *Pofilometer Linear Height LH-600E/EG*

The inspection procedure was performed using the software VXinspect (Creaform Inc., Levis, Quebec).
The used optical sensor is a portable 3D laser scanner named HandySCAN 3D (Figure 6), with an accuracy up to 30 microns and equipped with a current generator and a PC to control the scan performances. Markers have been used to facilitate the scanning operation and the real-time alignment frame by frame.

Figure 6 *HandySCAN 3D*

The employment of the 3D scanner to detect wear involves the use of the wear assessment method, applied with 3D optical non-contact metrological techniques, to evaluate 3D wear distribution [10]. The method is performed according to the digital procedure by the following steps:
– generation of positioning model using targets that can be easily detected by the optical scanner,
– 3D optical scanning,
– 3D data processing and wear detection by inspection procedures.
Thus, comparing the digitized 3D model of the worn rail with a reference 3D model of the non-worn rail 3D color maps of deviations can be built; they represent the distribution of the discrepancies between the surfaces in the reference and in the worn models.
In laboratory, the rail portion was scanned before it was worn out. The resulting mesh was compared to the reference CAD model of the rail. The result showed a perfect fitting between the CAD model perfectly and the real rail sample. Thus, the CAD model was used as a reference model for the next steps.
All the resulting meshes were post treated by VXmodel and optimized. The scanned worn model was compared to the reference model by the digital inspection

procedure. Different inspection procedures were analyzed in order to propose the best way to perform 3D wear mapping as Figure 7 shows: in the first method (a), two planes and one cylinder were used, in the second one (b), three planes. When the meshes are aligned and superimposed to the reference models, the deviation between them has been evaluated.

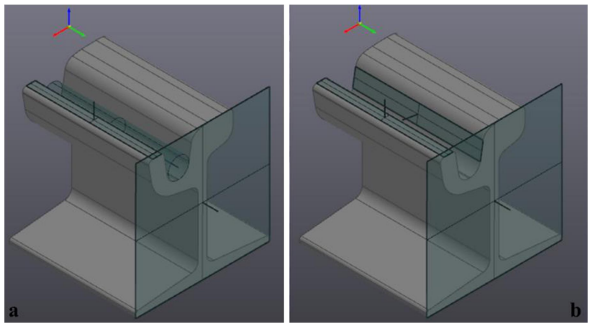

Figure 7 *Definition of entities for the alignment procedure: counter rail plane, vertical plane and throat cylinder (a); counter rail plane, vertical plane and flange plane (b).*

3.2. Preliminary laboratory results

Figure 8 shows the results of the analysis and in particular the 3D and 2D wear maps of the worn track portion, obtained by aligning reference and worn models according to method (*a*). The values picked on the 3D wear maps correspond to the average wear depths.

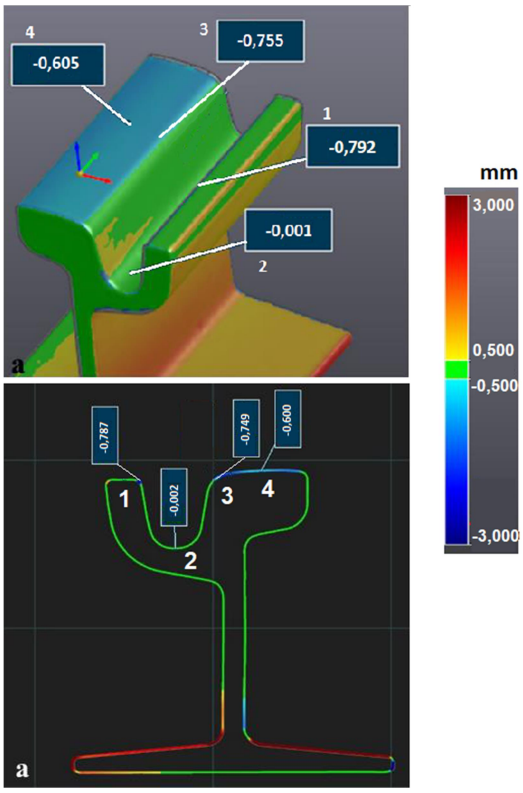

Figure 8 *Wear thicknesses according to method (a): 3D and 2D inspection.*

Table 1 reports all the results of the 3D and 2D wear detections, according to method (a) and method (b) in terms of deviations between 3D and 2D measures.

Table 1 *Deviation between 3D and 2D measures.*

Deviations in mm	**Method (a)**	**Method (b)**
Point 1 – counter rail	0.005	0.011
Point 2 – throat	0.001	0.005
Point 3 - flange	0.006	0.002
Point 4 – rolling thread	0.005	0.006

According to the practice and results, the elements mainly affected by the wear phenomenon are: the rolling thread, the counter rail and in a particular way the flange. Values in Table 1 demonstrate that the use of 3D scanner lightly overestimates the wear depths over the rail surface and the overestimation is in the range of 1 to 11 microns. This means that the new 3D digital method can be used as a precautionary measure. Furthermore, the alignment method (a) results as the best, since the reference surfaces allow to have a null value of wear in correspondence of the throat and of the plane of the counter rail during the rail-wheel relative motion, as expected. In fact, with alignment (a), one can notice that the wear starts from a null value and increases in correspondence of the rolling thread and reaches a peak in the flange zone. It is again null in the throat and it has another peak in the counter flange. This is what should happen in the real practice.
Regarding method (b), it gives results close to the method (a), even if it underestimates the pick of wear in correspondence of the flange and overestimates the wear thickness of the rolling thread. In fact, taking the flange plane as a reference, the wear corresponding to the throat does not result to be null as it should be.

All these laboratory results and the demonstrated efficiency of the 3D wear evaluation method, compared to the 2D prior ones, encouraged online tests.
Furthermore, it has been shown that the use of 3D optical digitizers, to measure wear volumes and distributions of tram-way rolling components, gives a more complete and global view of the wear phenomenon. The alignment method to be used for the online tests is method (a), according to the previous discussion.

4. Detecting the rails wear by 3D scanner: on-line results

Online tests were carried out on the Florentine tramway line in correspondence of the crossroads Anulare Viali: the part of track between the Leopolda and the railway-station of Santa Maria Novella in Florence.
The shape of the track is rectilinear at the beginning and a clothoid in its final part. The clothoid shape was due to the introduction of an exchange in that position during the tramway construction.
Due to this shape, wear is severe in that portion of track and trams must decelerate, increasing the travel times. The scanning phase was carried out both in the curved portion and in the rectilinear one. Physical sticky markers were positioned on the rail surface (Fig. 9) to

detect, in order to generate a positioning model and to avoid alignment errors over the total rail length [10].
The scanning session allowed to gather 3D data at 0.1 mm of resolution and in real time.

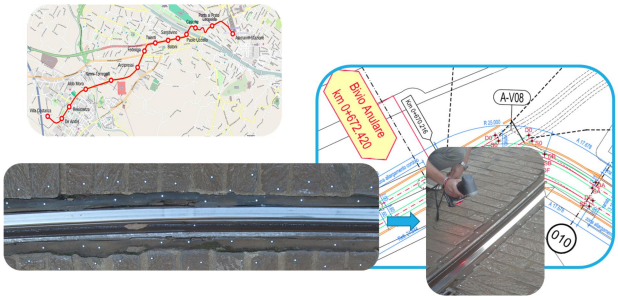

Fig. 9 On-line track experimental campaigns

4.1. Wear inspection of the rectilinear track portion

The 3D model of the rectilinear worn portion of the track was aligned to the reference CAD model by applying the method (a). Figure 10 shows the resulting wear map. The results demonstrate that the flange and the counter rail are the parts mainly affected by wear, followed by the rolling thread.

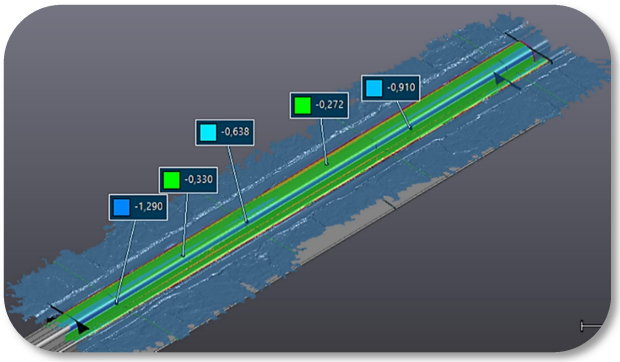

Fig. 10 Wear map on tramway line: rectilinear portion

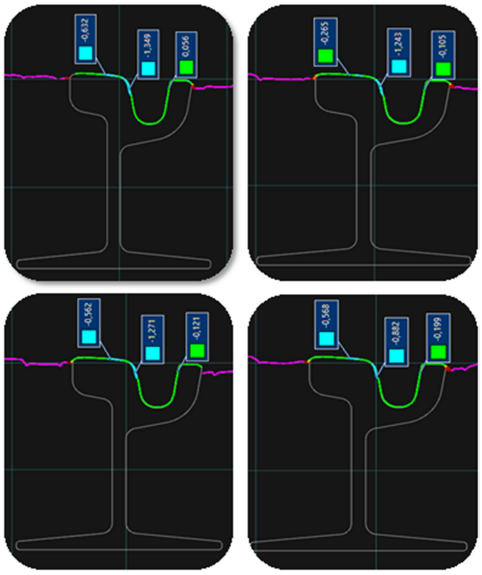

Fig. 11 Extracted sections from the 3D wear map on the rectilinear portion

Figure 11 represents four 2D sections extracted from the 3D wear maps, where the contact zone between wheel and track occurs along the rolling thread. As expected, the wear is mainly concentrated over the flange and close to the rolling thread, even if the wear thicknesses are very low, since the path is rectilinear.
Figure 12 reports the results obtained by the 3D wear maps every 150 mm of distance from the beginning, as normally the current instruments measure.

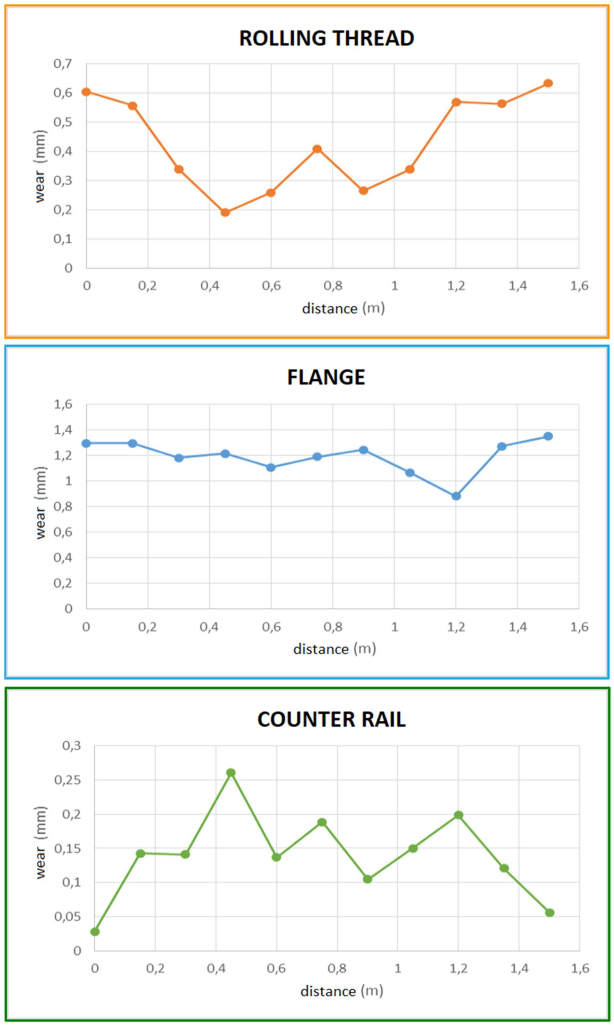

Fig. 12 Wear results every 150 m of distance for the rectilinear portion

4.2. Wear inspection of the curvilinear track portion

The shape of the curvilinear portion consists of a circumferential arc and a clothoid, so the aligning method (a) was applied by taking into considerations curved surfaces and 2D sections every 150 mm of progression, as it happens by using the current wear evaluation instruments. The obtained results in term of wear maps and extracted sections are reported in in Fig. 13.
Wear values in correspondence of the flange, the rolling thread and the counter rail were extracted by 3D results considering every 150 mm and the results are reported in Figure 14.

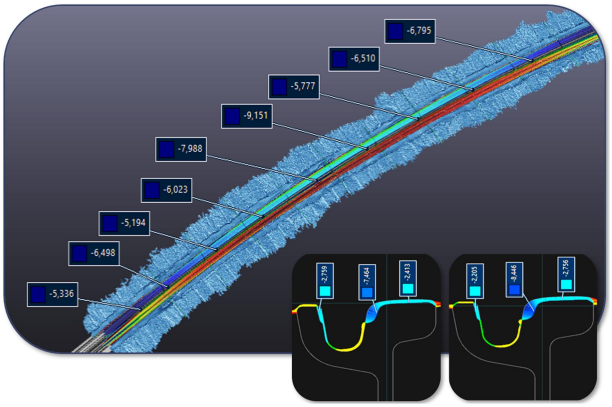

Fig. 13 *Wear map on tramway line: curvilinear portion and two sections*

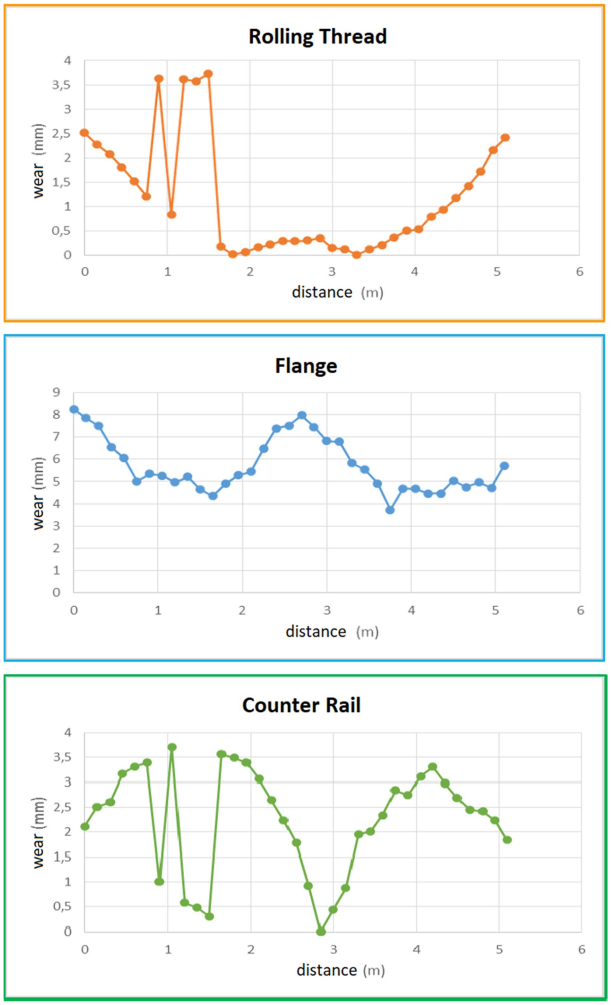

Fig. 14 *Wear results every 150 m of distance for the curvilinear portion*

From Fig. 14 one can see that the maximum wear thickness of the flange is about 8.5 mm, it is about 2.7 mm for the rolling thread and 3.8 for the counter rail.
This means that both in the rectilinear and in the curvilinear portions, the flange is the part of the track mainly affected by wear, but the wear depth is about six times higher over the curve than over the rectilinear portion.
Thanks to these experimental campaigns, it was possible to study the comparison between the 3D results obtained by 3D scanning and the 2D results obtained by applying the current instrumented trolley of the Florentine tramway.

5. Comparison between 3D and 2D online results

The comparison between 3D and 2D online results allowed to compare the track gauge measured by the 3D scanner and the one measured by the 2D instrumented trolley, commonly used by the maintenance service team of the Florentine tramway.
The results of this comparison for the curved rail portion are reported in Fig. 15. To obtain the track gauge from the 3D measures, the lateral wear, resulting from the 3D wear analysis, was used to be subtracted to the nominal deviation, according to the following equation:

$$D_{meas} - D_{nom} = Wear_{bil}$$

Where D_{meas} is the measured deviation, D_{nom} is the nominal deviation and $wear_{bil}$ is the bilateral wear. In this calculation the 60% of the lateral wear was attributed to the outer rail, while the 40% to the inner rail. In Fig. 15 the data are compared distance by distance. The 2D data were measured by the trolley two months before the 3D data. This means that the deviation between 3D and 2D data is even smaller than the one calculated by comparison. In this case Fig. 15 also reports the wear progress during 2 months.

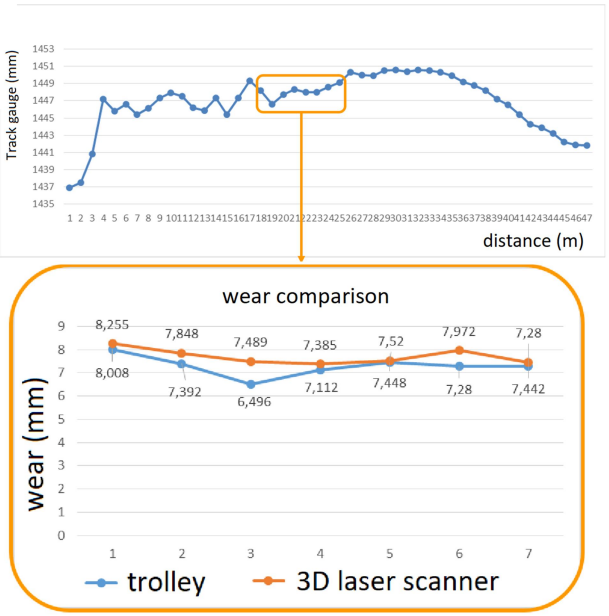

Fig. 15*. Comparison between 3D and 2D online results*

6. Conclusions

In this work the feasibility of using a 3D digital wear evaluation method has been investigated with the aim of implementing new strategies for the maintenance service of tramways and especially of the Florentine tramway.

Laboratory tests have confirmed the validity and usability 3D optical metrology scanners, as the 3D laboratory data fit with the 2D measures obtained by ultra-accurate contact profilometers. Furthermore, the use of 3D scanners allows the construction of complete 3D wear maps, which give an overall panorama of the wear phenomenon over the whole tracks' surfaces and not just every 150 mm of distance.

The application of 3D measurements on the tramway line allowed to gather data about the 3D wear maps over a rectilinear path and over a critical curvilinear portion, where the maintenance service is often concentrated. In fact, the maximum wear depth over the rectilinear portion of the rail is about 1.5 mm while over the curvilinear portion is about 8.5 mm.

The comparison between 3D and 2D online measurements gave consistency to this novel 3D application, as 3D and 2D results are pretty comparable, but 3D results are even more complete and give a better chance to predict the wear progress trend.

Moreover, these analyses can be used to develop theoretical models of wear prediction. Further developments of this research work will provide the detailed study of some 3D instrumented trolley to be used for the ordinary maintenance programs.

Acknowledgments

Authors warmly acknowledge the Florentime tramway and GEST S.p.A. staff for their support and in particular Eng. Gaetano Zumbo for providing 2D data. Authors also acknowledge V-GER SRL for providing the 3D instrumentations and software which allowed to gather the 3D results.

LOCAL PLASTICITY MODELLING AND ITS INFLUENCE ON WHEEL-RAIL FRICTION

C.D. van der Wekken [1,*], E.A.H. Vollebregt [1]

[1] VORtech CMCC, Westlandseweg 40d, 2624 AD Delft

[*] E-mail: niels.vanderwekken@vortech.nl

Abstract: Friction is an interesting topic because of its important influence in wear during wheel-rail contact and vehicle system dynamics. To be able to reduce wear while maintaining safe and fast operation of the train network a better understanding of friction and the role of friction modifiers is key. Inspired by the approaches of Tomberger [1] and Meierhofer [2] in this paper we will present a model to calculate the amount of local plastic deformation occurring in rolling contact. This model is compatible with the variational theory and has been implemented in the CONTACT software.

Keywords: Plastic deformation; friction; traction; rolling contact; half-space assumption; third body layer.

1. Introduction

Friction is an important topic because of its influence on vehicle dynamics and wear in the wheel-rail system. To reduce wear, while maintaining safe and fast operation of railways, a better understanding of friction and friction modifiers is key. However, with increased research and measurements on friction [3, 4], it becomes ever more clear that the underlying physics are not well understood. The main thing that is clear is that "Coulomb friction" works as a first estimate only and more detailed modeling is necessary to capture the underlying effects.

Supported by a programme of the US Federal Railroad Administration, VORtech CMCC is developing physics-based sub-models for friction related phenomena for the CONTACT software [5]. Inspired by the works of Tomberger et al. [1] and Meierhofer et al. [2] these sub-models are: the wheel and rail surface temperatures, the surface roughness, the presence of fluids and friction modifiers, and the effects of plastic deformation in the near surface layer. This paper concentrates on the last aspect, incorporating "local plasticity" in CONTACT. A sub-model is being developed to capture the effects of plastic deformation and of the accompanying third body layer where this plastic deformation occurs.

A local plasticity model has been developed. Section 2 describes different approaches others have taken, followed by what will form the basis for our model. Section 3 describes the mathematical details of our model. After incorporating this model into Kalker's complete contact theory test runs are performed. In Section 4 the results, including the influence of plasticity on the coefficient of traction, are compared to results obtained by Meierhofer [2]. Finally, our conclusions can be found in Section 5.

2. Modeling approach

Six et al. [6, 7] present the division of plastic phenomena in "global" and "local" plasticity. Plasticity is qualified as "global" if it occurs on the range of millimeters, while local plasticity occurs in the range of microns. Next to the typical size of their effect, global plasticity has a short shakedown cycle. After some initial deformation of fresh material, the material will harden and not deform further. Local plasticity, called "tribological plasticity" in [7], is described as the plasticity that occurs on the scale of the materials asperities. This is an ongoing process. The asperities deform plastically, are removed from the surface by wear, and after this, new asperities will wield the contact forces, exposing the new asperities to wear.

Following the distinction of global and local plasticity of Six there are two different scenarios to consider. First there is the global plastic deformation. Different models exist to deal with this case, for example the approach by Sebès [8] or the one by Hauer [9]. These models dealing with changing of the profile shapes, however, do not give insight in the effects of plastic deformation and the appearance of a third body layer on the friction during rolling. To achieve this, it is necessary to look at a local plasticity model, one such a model is described by Meierhofer [2]. Our approach uses the ideas of Meierhofer's model, based on a simplification of the stress-strain curve by Hou [10], although the details are worked out differently.

Hou's simplification of the stress-strain curve starts with a fully elastic linear relation between the shear stress and the shear strain, through the (elastic) shear modulus G. Then once the yield point is reached plastic deformation will start to occur, and the shear stress and strain will relate through another linear relation, with a new (plastic) shear modulus k. This is schematically represented in Figure 1.

The model used by Meierhofer starts from a parabolic solution to the normal problem. Tangentially, the bulk materials are described as linearly elastic, using a polynomial series approach for plane strain situations.

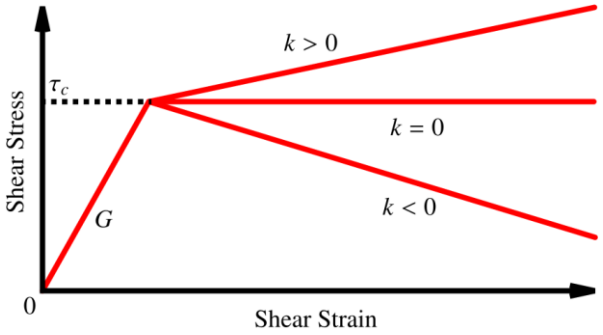

Figure 1: *Simplified stress-strain curves proposed by Hou [10], relating shear stress τ to shear strain γ by elastic (G) and plastic (k) regimes, with strain-hardening ($k > 0$), elastic-perfectly plastic ($k = 0$) and strain-weakening characteristics ($k < 0$).*

The characteristic of Figure 1 is added through a third body layer based on independent brushes of sprints, like Kalker's simplified theory [11] (FASTSIM), with varying stiffness proportional to G or k depending on the actual value of τ.

Meierhofer's local plasticity formulation appears to be incompatible with the variational theory [12] as implemented in CONTACT. The main reason is that the tractions τ or p are used as primary unknowns, for which the characteristic of Figure 1 must be inverted. The relationship then becomes multi-valued if $k = 0$ or $k < 0$. Even if the tractions are known at all places, the displacements still cannot be computed.

In the context of the Extended CONTACT model [13], plastic effects will be captured in an infinitesimal third body layer while the bulk material of the rail and wheel are still assumed to be elastic half-spaces. This thin layer will therefore not be an extra layer with specified thickness in the calculations, but will represent the layer where tangential plastic deformation in the surfaces of the two bulk bodies occurs. This results in a local plasticity model that is compatible with the current implementation of the Extended CONTACT software.

A model is constructed for tangential plastic deformation. An intuitive idea of how this works out is given in Figures 2 to 6. This shows how the relative surface displacements may be accommodated, for increasing amounts of rigid slip w. Initially, w is accounted for by elastic deformation u_{el}. Plastic deformation u_{pl} arises if the stress needed grows up to the yield limit τ_c, and slip s arises if the local Coulomb maximum μp_n is reached. This shows that rigid slip (creepage) may be accommodated in three different ways, using elastic deformation, plastic deformation and true slip. The mixture in which they occur depends on the parameters of the problem, like the material rigidity G, yield limit τ_c, the pressure p_n, and the coefficient of friction μ.

3. Model implementation

Following the model by Hou [10] we use a constant modulus of rigidity G in the elastic regime and a different, constant modulus of rigidity k in the plastic regime. This means that in the plastic regime, the relation between the total traction and total displacements will be linear again. The actual value of this parameter k should be determined experimentally, this is out of the scope of our work, where we focus on the theoretical model only.

Figure 2: *At low creepage, the surfaces' relative displacement can be accommodated easily by elastic displacement.*

Figure 3: *Surface tractions τ increase in proportion to the elastic displacement u^{el}. At some amount of rigid slip w, the required traction τ just reached the yield point τ_c.*

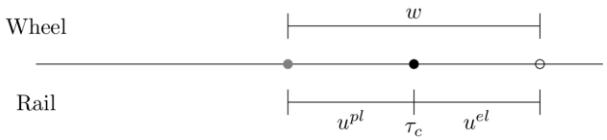

Figure 4: *The creep is a bit larger than in Figure 3. Because there is no elastic deformation anymore beyond the yield point, the additional creeping is compensated for through plastic deformation. The yield limit τ_c can change depending on the value of k.*

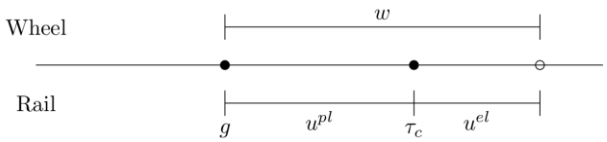

Figure 5: *The rigid slip w is chosen such that the material hardens up to the original traction bound, $\tau_c = g = \mu p_n$.*

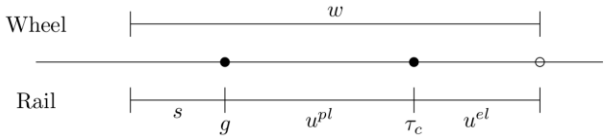

Figure 6: *With rigid slip w requiring tractions larger than the traction bound g, there will be actual slip s next to elastic and plastic deformation.*

One main equation in rolling contact is the so-called "slip equation":

$$\mathbf{s}_{rel} = \mathbf{w}_{rel} + \frac{1}{V}\frac{\mathrm{D}\mathbf{u}}{\mathrm{D}t}. \qquad (1)$$

Here $\mathbf{s}_{rel}$ is the actual (micro-) slip relative to the rolling velocity V, that is linked to the rigid slip $\mathbf{w}_{rel}$, imposed by creepage, and to material deformation: $\mathrm{D}\mathbf{u}/\mathrm{D}t$. The displacements are written as the sum of elastic and plastic displacements:

$$\mathbf{u} = \mathbf{u}_{tot} = \mathbf{u}_{el} + \mathbf{u}_{pl}. \qquad (2)$$

Using the halfspace approach, the elastic displacements are found with Green's functions, aggregating the effect of the tractions $\mathbf{p}(\mathbf{y})$:

$$\mathbf{u}_{el}(\mathbf{x}) = \iint_C \mathbf{A}(\mathbf{x},\mathbf{y})\mathbf{p}(\mathbf{y})dS. \qquad (3)$$

Micro-slip is supposed to occur where the traction bound is reached, which is modelled using Coulomb friction. This sets the local traction bound g as the product of normal pressure p_n with μ, the local coefficient of friction.

$$g = \mu p_n. \tag{4}$$

Plasticity is introduced where the tractions reach the current yield stress τ_c, which depends on the amount of plastic deformation that occurred previously. Inverting the stress-strain relationship of Figure 1, this is obtained as:

$$\tau_c = \tau_{c0} + \tilde{k} u^*_{pl}, \tag{5}$$

where $\tilde{k} = Gk/(G-k)$, and where:

$$u^*_{pl} = \int_t \left\| \frac{\mathrm{D}\mathbf{u}_{pl}}{\mathrm{D}t} \right\| dt. \tag{6}$$

This aggregates the total plastic deformation experienced by the material in absolute sense, irrespective of the direction in which the deformation occurs. Thereby, deforming in one direction does not cancel previous deformation in the opposite direction, in line with the concepts of material fatigue.

The final part of the model consists of the contact conditions, that specify how the tractions $\mathbf{p}$, micro-slip $\mathbf{s}$ and plastic deformation $\mathbf{u}_{pl}$ are related. Four different regimes are considered for the exterior area E, elastic adhesion H, plastic adhesion P, and slip area S:

$$\text{in } E: \quad \|\mathbf{p}\| = 0, \qquad \mathbf{s} \text{ free}, \qquad \frac{\mathrm{D}\mathbf{u}_{pl}}{\mathrm{D}t} = \mathbf{0}, \tag{7}$$

$$\text{in } H: \quad \|\mathbf{p}\| \le \min(g, \tau_c), \qquad \mathbf{s} = \mathbf{0}, \qquad \frac{\mathrm{D}\mathbf{u}_{pl}}{\mathrm{D}t} = \mathbf{0}, \tag{8}$$

$$\text{in } S: \quad \|\mathbf{p}\| = g \le \tau_c, \qquad \mathbf{s} // \mathbf{p}, \qquad \frac{\mathrm{D}\mathbf{u}_{pl}}{\mathrm{D}t} = \mathbf{0}, \tag{9}$$

$$\text{in } P: \quad \|\mathbf{p}\| = \tau_c < g, \qquad \mathbf{s} = \mathbf{0}, \qquad \frac{\mathrm{D}\mathbf{u}_{pl}}{\mathrm{D}t} // \mathbf{p}. \tag{10}$$

These equations reduce to the variational theory when $\tau_c = \infty, \mathbf{u}_{pl} = 0$: the exterior area is free of traction, no slip occurs unless the traction bound is reached, and where slip occurs, this is in the direction opposite to the tractions. The extension concerns the introduction of a yield limit. This provides a different upper bound for the elastic adhesion regime. Once the yield point is reached, plastic deformation occurs. In this case, plastic deformation itself may alter the yield limit, as described in Equations (5) and (6). On the one hand, this makes the system stronger non-linear than the original model. On the other hand, this resolves most of the ambiguities that could occur when $g = \tau_c$.

4. Results

2D Carter testcase: The model of the previous paragraph is implemented in CONTACT for 2D situations. Figure 7 shows the results for the Carter testcase for a range of different values $k_{rel} = k/G$. In any case, material enters the contact area on the right with adhesion, $p_x < \min(g, \tau_c)$. The current yield limit τ_c then starts at the fresh yield value τ_{c0}. Tractions build up gradually until the yield limit is reached, that's lower than the traction bound g. The material then deforms plastically, the yield limit τ_c changing dependent on the value of k. Finally, the traction bound g lowers because of the pressures reducing. Slip is then found at the trailing end of the contact (left side), with no further plasticity and constant τ_c.

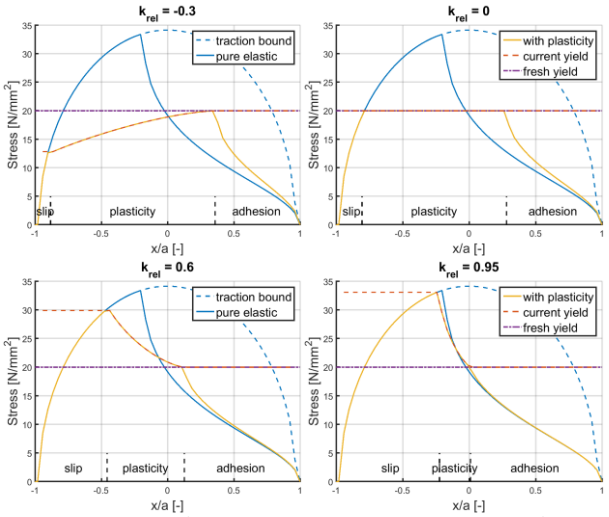

Figure 7: *Results of the extended model with local plasticity for the 2D Carter testcase, for* $k_rel = k/G = -0.3, 0, 0.6,$ *and* 0.95.

The biggest plasticity area P is found at the lowest value of k_{rel}. This gives the lowest tractions on the left side of the contact area, increasing the tractions on the right. The plasticity area reduces when k_{rel} is increased further and further, with the tractions converging to those of the elastic case. Note that $\tilde{k} \to \infty$ as $k_{rel} \uparrow 1$, such that just a small bit of u^*_{pl} is needed in order to lift τ_c up to g.

Meierhofer testcase: The second testcase considered concerns the configuration as described by Meierhofer et al. [2]. This uses the input parameters as listed in Table 1. Two computations are performed, for creepages $\xi = 0.3$ and 1.0%. The results are shown in Figure 8, next to those obtained by Meierhofer et al.

Table 1 *Parameters used in the Meierhofer-testcase (Figure 8) and the computation of creep curves (Figure 9).*

Parameter	Symbol	Quantity
Elastic modulus of rigidity	G	$77519.4\ MPa$
Plastic modulus of rigidity	k	$3000\ MPa$
Initial yield strength	τ_{c0}	$200\ MPa$
Poisson's ratio	ν	0.29
Coefficient of friction	μ	0.5
Total normal force	F_0	$1323.6\ N/mm$

The figure shows that the results are generally in good agreement with each other, even though the two models are based on different computational approaches. Our model generally finds somewhat higher stresses, both in the purely elastic case and in the extended model where plasticity is included.

Note that Meierhofer's model starts from a parabolic pressure distribution, and uses a series expansion for the elastic displacements. Next, a third body layer is

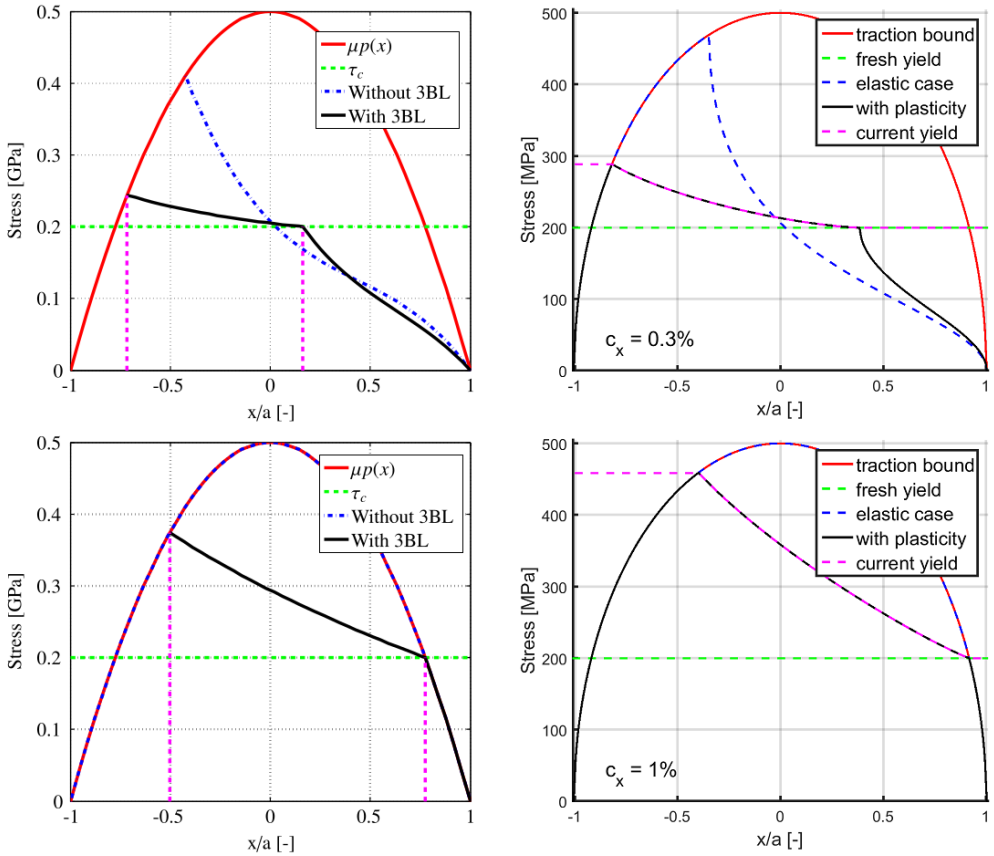

Figure 8: *Left: results from Meierhofer [2, Fig 7]. Right: results of the Extended CONTACT model. Parameters are given in Table 1. Top: creep $\xi = 0.3\%$, bot: $\xi = 1.0\%$.*

introduced of a finite thickness h, with a purely local relationship $u_{3bl}(x) = -h \cdot \tau(x)/m(x)$. This describes a spring with variable stiffness $m(x)$. One drawback of this spring is that it has no permanent plastic deformation, energy could be stored first and then be regained upon unloading.

Calculation of creep-force curves: The third test concerns the effect of local plasticity on the coefficient of traction, as shown in Figure 9. This shows the relative tangential force F_x/F_n as a function of creepage c_x. The initial yield value is $\tau_{c0} = 200\,MPa$ in the graph on the left, versus $\tau_{c0} = 350\,MPa$ on the right. The various lines in each graph are given for different values of the parameter k_{rel}.

The figure shows that local plasticity reduces the tangential forces compared to the elastic model. How this works out depends on the ratio $k_{rel} = k/G$. For $k_{rel} > 0$, the curves eventually tend to the original maximum μ, yet this happens slower and slower as k_{rel} is reduced. This relates to the situation of $k_{rel} = 0.95$ in Figure 7. When c_x is increased, the actual yield limit τ_c will be pushed up as well, until ultimately, the original tractions p_x are regained.

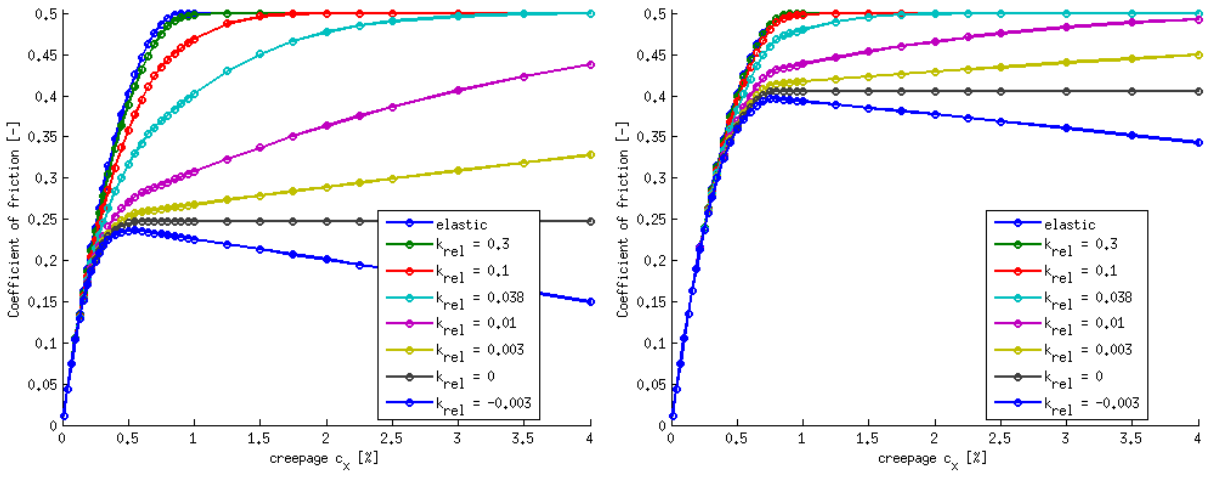

Figure 9: *Coefficient of traction as a function of the amount of creep. Parameters are given in Table 1. Left: $\tau_{c0} = 200\,MPa$, right: $\tau_{c0} = 250\,Mpa$.*

At $k_{rel} = 0$, the creep-force curves saturate at a lower maximum than the original maximum μ. This new maximum is seen to depend on the yield limit τ_{c0}. This is understood using the situation of $k_{rel} = 0$ in Figure 7. With plasticity, there's an effective traction bound $\min(g, \tau_{c0})$, i.e. the higher values of g are chopped off. This reduces the maximum F_x that may be delivered. This effect becomes stronger when τ_{c0} is reduced. Finally, at $k_{rel} < 0$, the creep-force curves are seen to approach the lower maximum of $k_{rel} = 0$ first, but then show a decreasing trend if c_x is increased further.

5. Conclusions and discussion

Previously, in CONTACT the assumption was made that all deformation was purely elastic. There is strong evidence of plastic deformation of the wheel and rail materials in the vicinity of the contacting surfaces. Part of this plasticity is termed "global", related to peak pressures due to non-conforming profiles. Another part termed "local plasticity" is concerned with the tangential shear stresses. It is hypothesised that this local plasticity continues to exist even after the surfaces are run in, and that it may alter the creep-force behaviour significantly.

The CONTACT model has been extended to account for this local plasticity. The existence of a tangential yield stress τ_c is postulated for this. It then becomes possible to increase the amount of stress beyond the initial yield stress by moving from the elastic domain into the plastic domain locally.

Plastic deformation $\delta\mathbf{u}_{pl}$ occurs in the direction of the tractions $\mathbf{p}$ where this yield stress is reached, much alike the occurrence of micro-slip $\mathbf{s}$ where the tangential traction bound $g = \mu p_n$ is reached for Coulomb friction. The tangential yield stress is postulated to change with the amount of accumulated plasticity u_{pl}^*, using the three simplified schemes of Hou et al. [10]: $k > 0,\ k = 0,\ k < 0$. This is expressed in a model of equalities and constraints in equations (2) – (10). This model is discretized and then solved rigorously by distinction of the possible regimes.

The new model deviates from the one by Meierhofer et al. in at least three different ways. Firstly, we allow for plasticity to occur in the wheel and rail surfaces instead of confining it to the third body layer. The quantity $\mathbf{u}_{pl}$ tells how much the opposing surfaces are displaced with respect to each other, without information on the vertical distributed of this. Secondly, the condition is added that $\delta\mathbf{u}_{pl} // \mathbf{p}$, to ensure that $\boldsymbol{u}_{pl}$ remains in tact upon relieving the stress, such that energy is lost by plastification. In the model by Meierhofer et al., the third body layer acts as a spring with variable stiffness that undoes "plastic deformation" when the stresses diminish. Energy may still be dissipated in their model, increasing the micro-slip $\mathbf{s}$ compared to the fully elastic situation. However, this is not guaranteed in situations with mixed creepage. Further, the energy is dissipated at the wrong place, affecting for instance the calculation of surface temperatures. A third difference between the two models concerns the method of discretization. The series of polynomial terms used by Meierhofer et al. is essentially restricted to 2D situations, whereas the grid used in CONTACT supports 3D situations also. Note that this is not yet worked out for the plasticity calculation.

Calculations with the new model show the robustness of the calculation of different regimes, over a wide range of k_{rel}, τ_{c0} and creepages ξ. The results of the model are largely similar to those of Meierhofer et al., truncating the tangential tractions $\mathbf{p}$ in regions with high pressures. This has a pronounced effect on the creep versus creep-force behavior, particularly at small values of k_{rel}. A much slower transition from the linear to the saturated regimes is obtained, resembling the results of twin-disc experiments presented in [2].

This results in a lower coefficient of traction. How much lower this coefficient is, and therefore if there is a significant difference to the elastic model depends on physical material parameters. Especially materials that experience little work hardening under plastic deformation are sensitive to loss of traction compared to the elastic model.

Abstract: London Underground is facing the challenge of increasing timetables against spending cuts across renewals and maintenance in all assets. In order to meet this challenge it is reviewing all maintenance practices to make sure they are appropriate for current asset conditions. Management of the wheel-rail interface is critical to maximising the life of wheels and rails through preventative maintenance regimes that ensure all activities offer value for money and safe operation. This paper describes what has been achieved so far through asset monitoring regimes, and how these results have compared to predictions from theoretical models.

Keywords: Wheel profile management, rail profile management, rolling contact fatigue, adhesion management, preventative maintenance.

1. Introduction

Management of the wheel-rail interface (WRI) on London Underground (LUL) has been at best sporadic throughout its history. The level of attention paid to it has often been driven by the political landscape of the day and reactions to major failures of the interface[1].

Since December 2017 the final vestiges of the Public Private Partnership (PPP) have been removed and for the first time since December 2002 LUL has been re-organised into one business with single points of accountability for Track and Fleet.

In September 2012 the first author setup a WRI team within central engineering that would permanently be responsible for the management of the interface, initially across the former BCV (Bakerloo, Victoria, Central) and SSL (Circle, District, Hammersmith & City, Metropolitan) lines but now encompassing the final JNP (Jubilee, Northern and Piccadilly) lines.

LUL have made huge strides in the management of the wheel-rail interface through the implementation of preventative wheel re-profiling regimes and a rail grinding regime which targets the sites most at risk to rolling contact fatigue (RCF).

However, against a backdrop of increasing tonnages and reduction in spending it is even more imperative that the WRI team is able to quantify the benefits of all maintenance activities. A key element of this strategy is the ability to accurately predict when wheels and rails will fail and implement appropriate preventative maintenance activities.

This paper discusses the progress which has been made by LUL to implement this strategy alongside attempts to validate the accuracy of predictions made utilising currently available damage models, such as the Whole Life Rail Model (WLRM)[2].

2. Preventative Wheel Turning

LUL consists of a number of different fleets which historically have managed their wheelsets in different ways. The majority of fleets operated a ‘run to fail’ policy through the use of maintenance and ‘go/no-go’ gauges. These gauges are used to identify when wheels are approaching flange height, thickness and hollowing limits, but if they still pass the ‘go/no-go’ gauge then they could be returned to service with wheel turning planned in before the next inspection. Typically inspection intervals were set at 14 days, but the majority of fleets are now set at 28 days.

It was clear from an initial review of each fleet’s Minimum Action Codes (MAC) for wheel defects, that they had been written based on their particular failure mode rather than representing the severity of the defect and potential risk. A review carried out by the WRI team resulted in consistency across all fleets in how defects were treated and recorded, albeit with some parameters varying based on different vehicle requirements for wheel diameters.

A ‘run to fail’ policy was suitable when running a much more limited service with spare train capacity. However as timetables have increased with signaling upgrades more trains are required to operate the enhanced service and unscheduled maintenance must be avoided at all costs.

A planned preventative wheel re-profiling regime is required to ensure enough trains are available for service that meet the required standards and also allows for wheel lathe demand to be accurately forecasted.

The WRI team launched a campaign of measuring wheel profile measurements using a Miniprof™ device across each individual fleet, as no automated measuring

systems exist on the LUL network. The aim of this campaign was to establish the principal mode of failure and the rate of degradation so that a preventative wheel turning interval could be implemented within each Train Maintenance Regime (TMR).

The majority of LUL stocks operate using an LT5 wheel profile, with a number of legacy fleet still employing the LT3 forerunner. The LT5 wheel profile was introduced as part of the Jubilee line extension in 1999[3].

The aim of the introduction of the LT5 was to introduce a wheel profile which was more compatible with the flat bottom rail which would be the predominant rail type on the majority of the line following the extension. The entire line was also ground to an E1 profile so that even the remaining bullhead sites would have the same profile.

The profiles both have a coning angle of 1 in 20 but the LT5 has a more gradual change in radius where the tread meets the flange angle. This results in a more gradual change in rolling radius, generating a greater steering force for less lateral shift of the wheelset (**Fig 1**). It also results in in a greater lateral shift requirement before flange contact is reached, typically around 600m in radius for LT5 compared to 1000m for LT3.

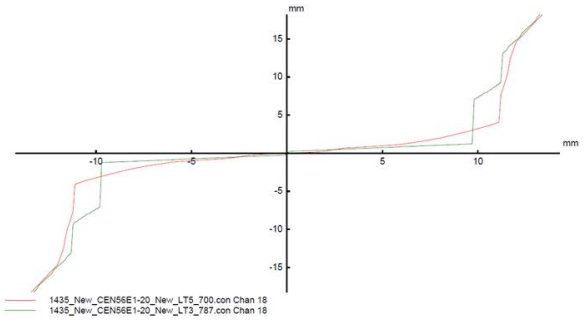

Fig 1 Rolling radius difference for LT5 (red) v LT3 (green) for E1 rail

The different stocks by line, starting wheel profile and preventative turn frequency can be seen in **Table 1**.

Stock	Line	Wheel Profile	Turn Interval
72TS	Bakerloo	LT3	2.5 years
73TS	Piccadilly	LT3	TBC
92TS	Central/W&C	LT5	900 days
95TS	Northern	LT3	7000 hours
96TS	Jubilee	LT5	180k km
09TS	Victoria	LT5	140/280k km
S7	District/H&C	LT5	180k km
S8	Metropolitan	LT5	200k km

Table 1 Stock by line with wheel profile and turn interval

Table 1 shows the range of different variables by which fleet maintenance is carried out, although all of the turn intervals were first determined in kilometres travelled by the WRI study. This has caused a number of issues whereby legacy fleets have to convert days or hours into kilometres run from the tachometers.

As a one off exercise this is possible but it is not how routine maintenance is planned. For example, the 96TS maintenance is carried out on service days but depending on the paths that trains are routed the difference in one service day can be as much as 400km.

The failure mode for LT3 wheel profiles is predominantly through reaching flange height or width limits, the coning angle is retained throughout the lifecycle (**Fig 2**). There are also signs of tread rollover and visual RCF in the flange root but these are usually within safety limits when wheels are turned (**Fig 3**).

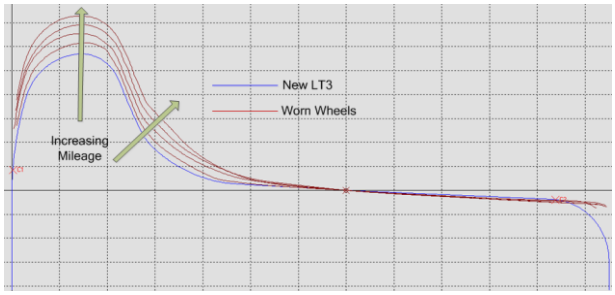

Fig 2 Failure mode of LT3 wheel profiles

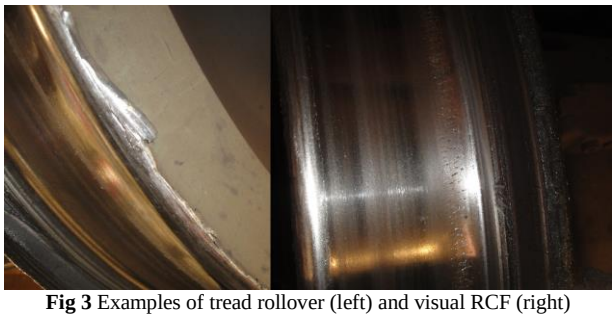

Fig 3 Examples of tread rollover (left) and visual RCF (right)

The LT5 profile primarily fails through a combination of wheel hollowing and tread rollover (**Fig 4**), however they are also more likely to fail through visual RCF. The hollowing limit is set at 2mm as this is the point at which all conicity is lost and the wheel is therefore no longer capable of generating any steering force.

This results in much higher forces being generated at the tread of the wheel-rail interface as the wheel wears, but lower wear rates are experienced at the flange root. As with all wheel profile design a compromise between vehicle stability, rolling radius difference and rail gauge/wheel flange must be established.

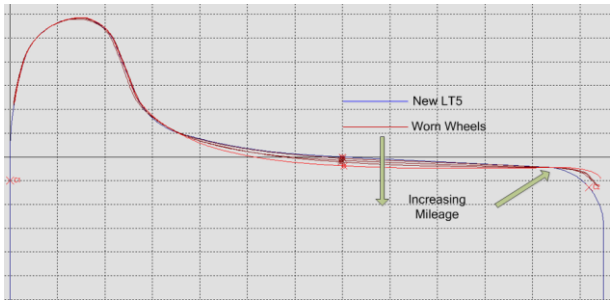

Fig 4 Failure mode of LT5 wheel profiles

The variation in failure modes for the LT5 wheel can be best illustrated by the difference between the S-Stock variations, S7 and S8. The S-Stock serves the sub-surface lines of LUL where due to the cut and cover tunnel construction these are much larger trains than the

other tube stocks. The tare axle loads of these vehicles are nearer 8 tonnes as opposed to 5 tonnes for tube stocks.

The number post fix refers to the number of cars per unit, with the S8 serving the Metropolitan lines where platforms are longer. Although there are areas of inter-running between the Hammersmith and City and Circle lines the S7 spends a greater proportion of running in central areas of London where there is a much higher concentration of tight curves.

Therefore, the S7 fails more through visual RCF and tread rollover than on profile wear. The S8 which runs a large proportion above ground with longer inter-station sections fails for hollowing due to increased running in the centre of the tread.

In terms of managing the WRI the benefit of understanding the wheel profiles in service at anytime is that it allows incredibly accurate modelling to be done as all wheel and rail contact conditions are measured rather than assumed.

3. Rolling Contact Fatigue Monitoring

Historically LUL was not a railway which suffered from RCF as it ran trains which were not as effective at steering through tight radius curves and lubrication was not closely controlled, therefore it was dominated by wear.

It was also predominantly 30ft (18m) bullhead rail joined by fishplates and therefore rail replacement was both much quicker as no welding was used, and bullhead rail was designed to be transposed and changed from high to low rail.

As LUL began to convert to flatbottom rail in the 1980s and move towards stressed, Continously Welded Rail (CWR), changing rails within the short engineering hours windows became more expensive and difficult. As will be further discussed in **Section 4** managing bullhead rail and joints is still a major issue for LUL.

As newer trains have been introduced and more focus on managing wear was implemented, due to the greater costs involved, the failure mode of rails has moved from wear to RCF. The emphasis in rail management, as in wheel management, is on reducing failures by introducing preventative maintenance regimes such as rail grinding.

However, monitoring RCF was still based on surface crack length which does not necessarily reflect the depth and does not indicate the level of maintenance required to rectify the defect. It is also incredibly labour intensive requiring precise visual inspection and detailed data recording.

Therefore, in 2013 LUL introduced the Rail Surface Crack Measurement (RSCM) system manufactured by MRX to enable the depth of RCF to be measured. This resulted in a change to the standard and approximately 20km of re-railing was required based on the results of network wide testing.

This represented approximately 2.5% of the network (400km of mainline with 800km of rail) and since 2013 an average of 1km of re-railing has been carried out per annum, approximately 0.1% when testing has been carried out at approximate intervals of 40MGT.

Fig 5 Rail Surface Crack Measurement Operator Propelled Unit

A lot of this re-railing was completed on much older rail, principally bullhead rail on timber sleepers in the deep tube which the renewals program has aimed to replace with flat bottom rails on concrete sleepers, or more recently direct fix methods.

There are a number of areas within the deep tube where rail grinding is not possible due to limited ventilation where diesel plant cannot operate. Therefore, it is even more imperative that LUL has a method of predicting RCF growth rates in order to schedule rail grinding at the correct frequency on a risk basis.

4. Rail Defect Management

Rail defects and broken rails are managed centrally through a team within track engineering, of which the WRI team is a key stakeholder within this committee.

The number of broken rails experienced on LUL has reduced significantly in the last 20 years. This has been delivered through a combination of a comprehensive track renewal programme which has removed a lot of life expired track and improved ultrasonic testing techniques.

These have included the B-Scan recordable traces and an Ultrasonic Interval Inspection Programme (UIIP) which varies the testing based on defect history and tonnage. The maximum testing interval on LUL is 6MGT but when adjusted for rail defects can be nearer 3MGT on high intensity service lines such as the Victoria where there is a train every 100 seconds in the peak.

However, the broken rails in the last 7 years appears to be reaching something of a plateau averaging 11 (**Fig 6**) through this period. This may be a reflection of the

focus of track renewals moving from plain line to points and crossing (P&C) and an overall reduction in the track renewals budget.

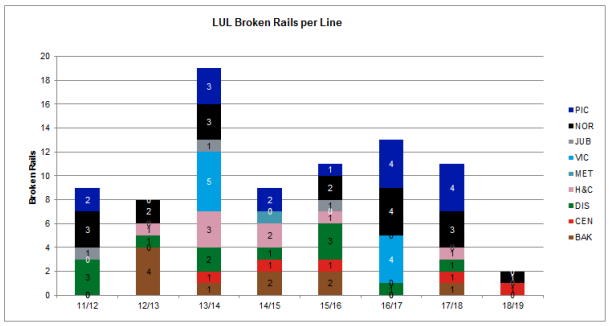

Fig 6 Broken Rails on LUL per year (18/19 to July)

Further analysis of the rail type for each break highlights the greatest risk is the remaining bullhead rail on the network (**Fig 7**). The approximate proportion of rail type is now 60% flatbottom to 40% bullhead across the network yet 90% of rail breaks occur in bullhead rail.

The breaks which have occurred in flatbottom rail in that time have generally been related to a defective batch of flashbutt welds, alumino-thermic welds which have had gross porosity, or rail foot corrosion. These are all either extremely difficult or impossible to detect ultrasonically.

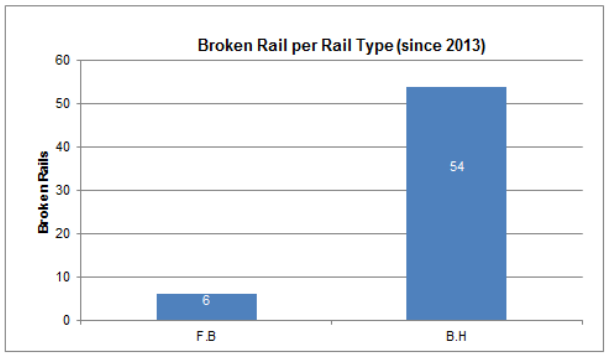

Fig 7 Rail Breaks by rail type

The most common failure leading to bullhead broken rails relates to fishplate fretting. This is where due to movement of rails at the joint edge the plate rubs against the rail foot and can act as a stress raiser from which cracks can be generated. These then propagate to bolt holes, up through the top surface causing a full fracture, an example of which can be seen in **Fig 8** with a close up of the initiation point from the fretting in **Fig 9**.

The initiation of this type of defect from the external web of the rail is untestable by ultrasonics until the crack reaches the centre of the rail by which time it is often too late and fast fracture has already occurred. Therefore, prevention of this type of defect is solely reliant on visual inspection which is mostly carried out at night in tunnel sections with limited lighting.

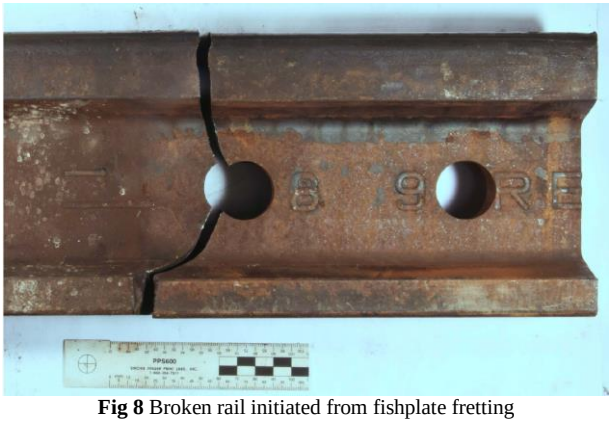

Fig 8 Broken rail initiated from fishplate fretting

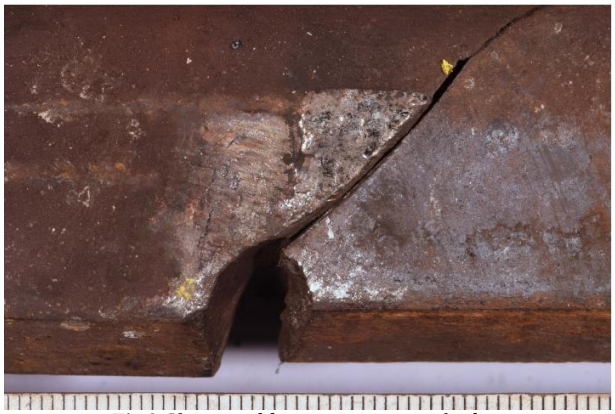

Fig 9 Close up of fretting initiation at the foot

Introduction of better torque wrenches and instructions to tighten joints specifically has reduced the occurrence but the numbers of bullhead joints still on the network makes this a question of balancing the resource carefully. The Northern line alone consists of over 700 bullhead joints (reduced by c.800 in the last 3 years), and the high proportion of bullhead rail remaining on the Northern and Piccadilly means they are consistently highest in broken rail numbers.

Another technology that was introduced around 5 years ago was the requirement that where fishplates could not be removed by welding, they are Cold Bolt Hole Expanded (CBX). This ensures that when cracks do develop the harder structure around the bolthole ensures that they propagate to the surface giving a greater chance of detection and lower risk of loss of running table in the event of a broken rail (**Fig 10**).

Fig 10 A broken rail where CBX had been carried out

In terms of rail defects the most frequently occurring defect on the network is the so called squat type defect. This has been shown to be caused by re-acceleration from low speed of AC-traction type rolling stock[4]. This is reflected in the high numbers on the Jubilee, Northern and Central lines in **Fig 11**.

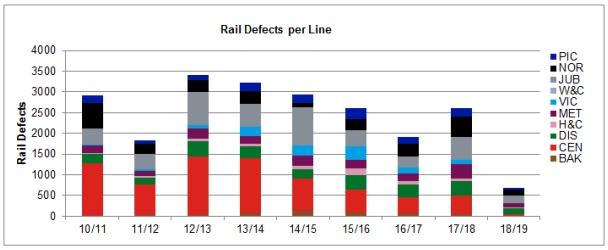

Fig 11 Severity of rail defects since 2010

This type of defect is increasing on the sub-surface lines where S-Stock is now operating but the concentration of defects seen on other lines has not yet occurred, but is predicted when Automatic Train Control (ATC) is introduced in the next 2 years.

Proactive rail grinding of these areas is taking place as it has been shown in the past that grinding on an approximate 2 year cycle reduces re-occurrence rates. The increase in 2017/18 was due to the trialing of a grinding method which did not remove sufficient removal of material from the railhead to prevent re-occurrence and is no longer in use.

The overall amount of rail defects has been fairly consistent, even though squat type defects are only actioned if they reach a certain depth, and this is reflected in **Fig 12**. The overall trend in emergency defects has been very good which indicates that although defects are occurring they are being discovered at an early enough stage through ultrasonic testing so that speed restrictions and immediate interventions are not required.

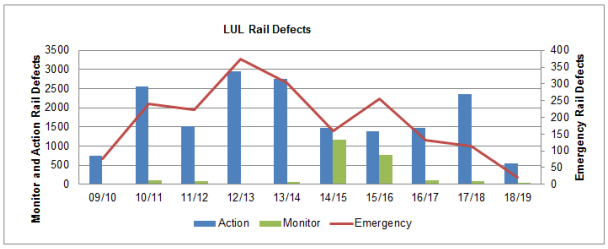

Fig 12 Classification of Rail Defects

5. Whole Life Rail Model

Following the introduction of RSCM it was hoped that establishing growth rates of RCF would be possible through repeated testing. This has been possible in some areas but it is not sufficiently accurate in the first 0.5 – 1mm of crack growth which is the region where cracks could be removed during grinding in engineering hours.

Therefore, in order to provide a more accurate prediction of RCF on the LUL network the WRI team have carried out detailed Vampire™ vehicle dynamics simulations of the entire network in order to predict changes in wheel-rail forces and ascertain realistic expectations of the wheel-rail interface.

The product of creep forces and creepage has been utilised to give T_γ which could then be converted to an RCF damage factor based on the Whole Life Rail Model[2] (WLRM) which was developed based on simulation outputs and field observations from the GB national mainline network following the Hatfield derailment.

The raw T_γ results from the original work[2] gave good predictions in areas where classic high-rail RCF was observed, but in an attempt to improve the predictions under different track conditions from the model[5] different methods of scaling the T_γ were investigated.

An example of the circle plots which were developed during this work can be seen in **Fig 13**, where the predicted damaging wheel-rail contacts are plotted for the leading and trailing wheelset for a site which is being intensively monitored as part of the LUL rail management strategy.

These plots allow interpretation of the contact position on the rail (indicated by the radial y position with gauge face in the middle of the circle), direction of the creep forces (represented by angular position around the circular plot) and the magnitude of the force or damage. In this case the coloured spots indicate the magnitude of the predicted T_γ.

This site (RCF-CEN-7) is a 70m radius curve on the Central line, colloquially known as the Caxton curve, which has historically been extremely challenging from a rail management perspective and has now been re-railed using a premium rail steel, British Steel's HP335. **Fig 13** illustrates where the WLRM has proved to be accurate in predicting the regions on the rail which are more susceptible to RCF or wear damage.

The circle plots for the right hand rail (low rail) for the leading and trailing axles (leading: top right, trailing: bottom right) show that the leading axle T_γ is in the region where wear will be dominant which results in the rail crown flattening observed on site (indicated by green spots, T_γ >175N). However, some of the wheel profiles are capable of generating lower levels of T_γ (indicated by yellow spots, $T_\gamma \approx$ 15 - 30N) nearer the gauge corner at an angle of approximately 120 degrees to the direction of travel.

In comparison, the trailing axle generates T_γ levels which are at the peak of the WLRM damage function near the gauge corner of the rail at approximately 180 degrees to the direction of travel (indicated by the red spots, T_γ 45 – 75N) which suggests a high susceptibility to low rail gauge corner cracking which has been observed on site.

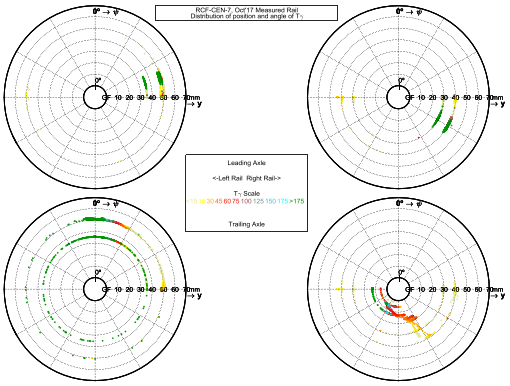

Fig 13 Circle plots for RCF-CEN-7

On the high rail (left rail); due to the presence of a check rail at the site no gauge corner contact is predicted on the leading wheelset and therefore high levels of T_γ are predicted on the crown of the rail at 90 degrees, which is indicative of plastic flow and/or longitudinal cracking on the rail head. The trailing wheelset generates high levels of T_γ in the longitudinal direction which is indicates a high susceptibility to horizontal cracking on the rail head. These are all consistent with what has been observed on site.

Generic simulations have been run for all different stocks and combinations of wheel/rail profiles in order to identify the radius for peak RCF generation. This shows that peak RCF generation will be in the 400-600m region for leading axles and 200m for trailing axles on high rails. A similar pattern is also seen for the low rail.

An example of this can be seen in **Fig 14** where the right photo is of a 200m radius curve taken using Magnetic Particle Inspection (MPI) to highlight the cracks. Sections highlighted in blue shows a region of flange contact which is in wear, an orange section of lighter RCF being generated by the leading axle and a green area where deeper RCF is being generated by the trailing axle.

As a comparison the left hand picture shows a 400m radius curve also taken under MPI both taken at an accumulated tonnage of 30 million gross tonnes (MGT). The section highlighted in green shows that only the leading axle is capable of generating RCF near the gauge corner with no trailing axle RCF being generated in the middle of the rail.

Typically this would compare to 1000m radius for a more 'mainline' type stock[6] which is consistent with the requirements for softer primary yaw stiffness in metro stocks due to the frequency of tigher radii curves. Although at lower radii curve certain areas of the rail will be dominated by wear this is offset by other areas moving into RCF generation and in terms of setting a grinding frequency lower radii curves will still dominate any programme.

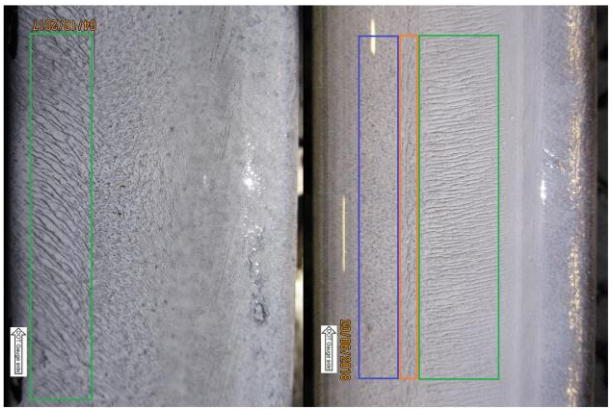

Fig 14 400m left and 200m right

RCF-CEN-7 was ground at 21MGT post installation of the HP335 rails. No RCF was detectable by RSCM but by taking pre and post rail profiles, it was established that 0.6mm was removed across the railhead and all RCF cracks were removed (**Fig 15**).

The ability to predict where RCF will occur has been proven to be reasonably accurate but the rate at which crack depths generate has not been possible using the WLRM. It is this rate that is crucial to planning how to control RCF as illustrated RCF-CEN-7.

If the depth of RCF to be removed based on the interval since last grind could be established then the output per shift could be more accurately predicted and a cost/benefit analysis carried out that may result in certain sites being cheaper to re-rail.

Fig 15 also shows that although RCF is being generated at this site severe corrugation also needs to be controlled. It has not yet been possible to develop a model for these growth rates as there are even more variables that need to be taken into account. However, when extreme curvatures such as this are considered RCF and corrugation are always identified.

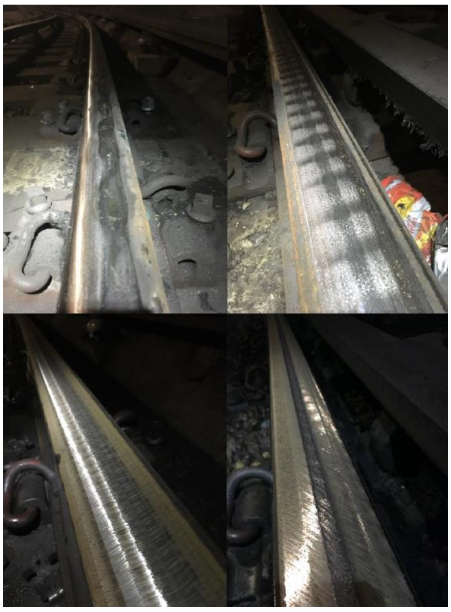

Fig 15 Pre (top) and Post (bottom) grinding RCF-CEN-7

6. Rail Management Strategy

The rail management strategy is to ensure that maximum asset life is obtained through an effective preventative maintenance regime. The principle maintenance mechanism for rails is through rail re-profiling either through grinding or milling. Rail grinding on LUL at current prices is 16 times cheaper than re-railing for whole life cost.

RSCM and use of the WLRM have all contributed to developing rail re-profiling frequencies but due to the limitations discussed a more basic monitoring regime was implemented to quicker define suitable intervention frequencies.

Approximately 50 monitoring sites were chosen where the date of re-railing was known, either through the original RSCM re-rail sites for RCF or track renewals, across a range of curvatures and lines to cover as many different conditions as possible.

These are monitored for wear and profile using Miniprof™ and visually using photographs under MPI to identify the growth of RCF and when rails are likely to become ultrasonically untestable (UUR) such as in **Fig 16** where the right hand picture had reached this state.

This has highlighted that the depth of RCF is not always the determining factor in rail life. It is the density of cracks, which have no depth with RSCM, which can prevent the ultrasonic signal reaching the bottom of the rail and lead to UUR. This is classified as an actionable rail defect as although there may be no defects other than the RCF there could be more serious, undetectable defects which could lead to fast fracture and broken rails.

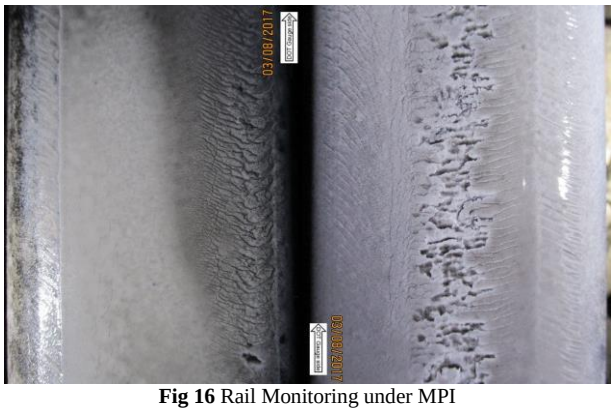

Fig 16 Rail Monitoring under MPI

A visual assessment of the photographs taken under MPI is graded as either: no cracks, visual cracks or breakout where pitting and scarring is visible. The crack and breakout series were then plotted with radius of curvature on the x-axis and tonnage in MGT on the y-axis (**Fig 17**).

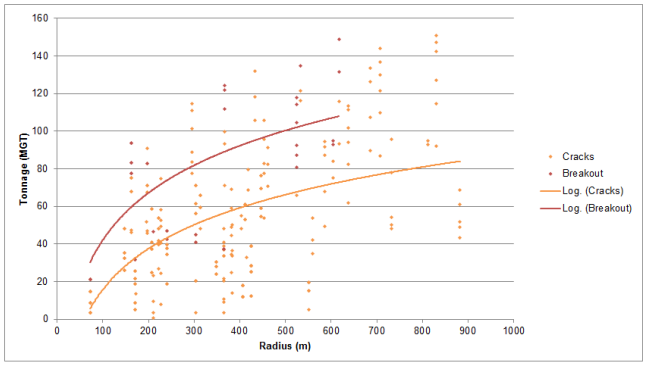

Fig 17 Rail Condition Model

A logarithmic best fit line through these two series shows a rough correlation for an estimated minimum and maximum rail re-profiling frequency to be set. This will at least allow for sites which have not been re-profiled to be flagged as at risk of becoming UUR.

No thorough statistical analysis of this data has yet been undertaken and the next phase will be to model each site in detail to ascertain realistic service conditions of the rail and identify if other parameters allow a more accurate model to be developed.

However, based on this model LUL would need to re-profile 110km of track per annum for RCF. This is difficult to deliver purely within engineering hours due to other maintenance requirements, which also need to be carried out, and the reduction in available shifts since the introduction of Night Tube on certain lines.

Engineering hours can up to 3½ hours long but this will include setting up of possessions (due to the variety of signaling systems across the network machines cannot run in traffic), travelling to site and handback checks which often means the actual 'spark' time available is less than an hour.

In order to make rail grinding a more efficient activity then more 'spark' time must be made available through closures or extended engineering hours as the fixed time required at the start and end of the shift cannot be changed.

Rail re-profiling is not the only heavy maintenance activity which is restricted by the limited access available. Major projects, renewals and tamping are limited by the same restrictions.

Access planning requires a minimum of 8 weeks notice for requests but when lines are undergoing major upgrades then realistically access planning is a 6 month lead time. Therefore, the ability to predict when and where to put the re-profiling resource available will become even more critical.

7. Adhesion Management

Adhesion management across the underground is done through a combination of track based lubricators (**Fig 18**) of various types as well as train borne 'stick' systems on a number of newer trains (**Fig 20**). Top of rail (TOR) protection is provided by track based units for specific sites and is provided on-board on 09TS and S-Stock, although it is yet to be fitted on the latter.

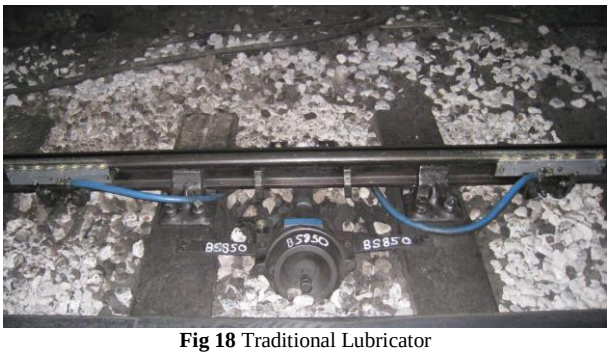

Fig 18 Traditional Lubricator

Fig 20 On board adhesion management

The area of adhesion management is where there is the most diverse range of solutions that have been applied across the network. This is a legacy of both the PPP structure and also that it is the least closely controlled area by standards.

As previously discussed the underground was a railway dominated by wear and hence in the early 2000s a lot of resource was dedicated to getting wear under control by installing a lot of trackside lubricators. As RCF has become the more dominant failure mode with new rolling stock a concerted effort has been made to remove as many of these as possible.

Vehicle dynamic simulations have greatly aided this decision by being able to prove to Track and Fleet maintainers that flange contact only starts to occur at 600m radius curves for LT5 wheel profiles and 1000m for LT3. The biggest benefits have been obtained on the S-Stock lines where it has replaced the C and D-Stocks.

Although D-Stock had similar curving performance to the S-Stock a lot of track based lubricators were in situ purely for C-Stock which had a much poorer curving performance. Neither C nor D-Stock had any on board adhesion management.

Since these stocks have been removed from service all track lubricators have been removed on curves above 600m in radius, approximately 50 units which no longer require maintenance during engineering hours.

The next phase of development will be to ascertain a radius of curvature, or length of curve, at which the on-board adhesion management systems are sufficient to maintain current wear rates with no additional track based lubrication.

The most catastrophic episodes in the history of LUL have been related to unilateral decisions being made about adhesion management where there is insufficient understanding of the interface[7]. A recent example of this is where track lubrication was turned off on the Jubilee line extension in October 2016.

This was the most recent extension to the underground network connecting central London with Stratford in the east end, but principally to increase capacity to the financial centre of Canary Wharf. It was opened in stages from May to December 1999.

This consists of the most modern track form on the underground being entirely constructed in flat bottom rail with concrete direct fix. There are no curves of less than 300m in radius but due to a stiffer track form it does suffer from severe rail corrugation.

Due to these issues rail profiles have been well controlled through regular rail grinding and wear rates are low with very little re-railing being required. However, since these lubricators have been removed there has been a significant increase in the consumption of the on board Kelsan® Low Coefficient Friction (LCF) sticks (**Fig 21**).

There has been an increased consumption of 56% in 2017 compared to a baseline average taken from 2012 to 2016. This has resulted in approximately £20k per annum cost to the fleet maintainer.

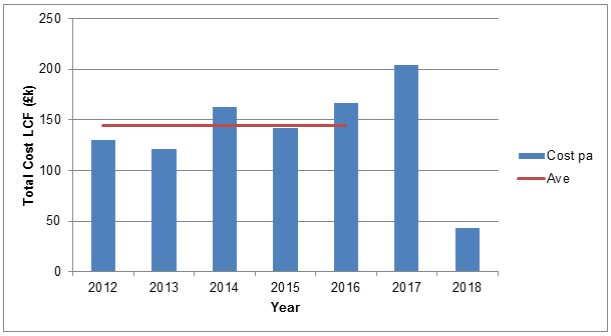

Fig 21 LCF costs on the Jubilee Line

Fortunately in this case this appears to have had no effect on the wear rates of either wheels or rails. The savings to the track maintainer have been in the region of £156k per annum, therefore still reducing the overall costs by £136k per annum.

However, the 96TS currently has a 14 day exam underframe inspection when the LCF is re-filled. A trial is currently underway to show that with some design

changes to the applicators that this can be extended to 28 days without the LCF being consumed prior to this and leaving the interface with no protection.

TOR track units have been used across the underground, generally related to the management of low rail wheel squeal or rail corrugation at specific sites using KELTRACK® liquid friction modifier.

KELSAN® High Positive Friction (HPF) is currently used on the 09TS to provide tread friction control and will shortly be rolled out onto the S-Stock. Unfortunately the 09TS was never baselined before installation but the S-Stock wheel wear rates which have been will allow accurate quantification of the benefits.

The overall adhesion strategy for LUL is to provide as much on the train as possible and only leave remaining track based solutions where required. This is due to the maintenance of on board systems being much easier to manage within a depot environment when trains are stabled compared to the ever more limited access to the track which requires travelling to specific sites alongside the other issues already discussed.

8. Conclusions

Understanding of the WRI on LUL has increased enormously in the last 6 years through a combination of: detailed data collection and analysis, introduction of modern technologies to more accurately quantify rail defects and vehicle dynamics modelling to more accurately predict failures.

Wheel turning is now a routine maintenance activity which can be planned accurately to ensure compliance to the standards and maintain conicity. As timetables continue to require more trains in service, then a 'run to fail' regime is no longer a sufficient maintenance strategy. Accurate planning also enables wheel lathes to avoid routine turning during the autumn leaf fall season especially on lines vulnerable to wheel flats.

RCF is now the dominant failure mode on LUL rather than wear and rail replacement is a far more costly activity than it was with legacy components. Preventative rail re-profiling is essential to avoiding emergency rail defects which results in disruption to the travelling public and expensive reactive maintenance.

Rail re-profiling in engineering hours will always be far more expensive than operating in closures and the operational business will have to make difficult decisions in future, balancing cost and impact if efficiencies are to be realised.

Rail monitoring techniques have vastly improved in recent years and allow the planning of maintenance interventions more accurately than before, but given the reduced access available and longer lead times to secure it, they are not yet accurate enough to solely rely on condition based measurements.

However, improvements in condition monitoring techniques will provide the opportunity to further develop and validate the current damage modelling tools to better predict the damage rates observed on LUL. Work is currently progressing in-collaboration with the Institute of Railway Research to develop improved models to support rail asset management.

The application of the WLRM has highlighted the most at risk curvatures to LUL and a more generically developed in-house model has given us a better idea of the rates of failure to plan interventions. The next phase of this will be to try and model sites in even more detail to understand if the accuracy of predictions can be improved.

Adhesion management strategy requires tighter definition to ensure the right solutions are used for the right problems. Too often in LUL's long history has it been seen as an area where easy cost savings can be gained without fully understanding the implications of those changes. The results of such decisions can be catastrophic and often take at least 2 years to become apparent when reactive and costly interventions are required.

The next phase in the continuous improvement cycle will be to ascertain if the starting wheel profiles are correct and whether a further iteration is required to develop LT6. This will also include optimisation of the contact conditions at points and crossings (P&C) as well as plain line track.

Improvements to legacy bullhead rail, which given the current spending constraints means LUL are going to have to manage the increased risk presented for the foreseeable future. Changes to the rolled profile are already being explored to ascertain if better RCF resistance and improved vehicle stability can be achieved. This again will require better modelling and improved interaction within P&C.

The work that has been done by the WRI team so far has not been ground breaking in any sense but it requires detailed understanding to be implemented in to long term strategies. In the current climate of immediate cost saving initiatives it is difficult to offer up efficiencies which may take up to two years to come to fruition but the lessons of the past show the costs of getting it wrong.

Management of the WRI is a continuous maintenance activity that needs to be carefully monitored across all its asset sub groups. The detailed understanding of how all the elements interact is not required by each individual asset but knowing they are part of a very delicately balanced system is paramount to avoiding catastrophic failure[7].

The purpose of the WRI team is to provide the engineering leadership to each asset and ensure that the right activities are carried out at the right time, such that no one is even aware that the system is being managed.

Acknowledgments
The results presented within this paper have been collated by dedicated engineers that form the wheel-rail interface team alongside the first author and I would like to express my thanks to them for their continued efforts and expertise: Matthew Lee, Christine Baldwin and Dennis Johnston-Webber. I would also like to thank Dan Harrison for turning my thoughts into legible English.

Paul Baker has trawled through his archives to give me some of the historical context from the Victoria line in the 1990s for which I am extremely grateful.

Eric Magel (National Research Council of Canada) was extremely helpful in helping to identify suitable monitoring sites, and has continued to support the research through the International Collaborative Research Initiative.

Abstract: Field tests were carried out for a commuter train in revenue service equipped with cast iron and organic composite brake blocks. Temperatures for wheel tread, wheel web and brake blocks and wear of wheel treads and brake blocks were recorded. The measured temperatures are used for calibrating a thermal model for assessment of wheel and block temperatures. In addition, the results from thermal and wear simulations are presented. Comparisons are made between measured and simulated temperatures and wear. The wear of the cast iron brake blocks estimated using simulated temperatures and a temperature-dependent wear model calibrated from pin-on-disc experiments is in agreement with measured wear results from field tests.

Keywords: tread braking, field experiments, calibration, thermocouples, temperatures, frictional heating, finite element simulations

1. Introduction

Tread brakes are a commonly used frictional braking system in railway vehicles. They are used either as sole braking system or in combination with other systems such as disc brakes and/or electrodynamic (ED) brakes. Use of ED brakes is preferred during normal operating conditions, with frictional brakes providing a smaller part of the braking effort. However, in case the ED brake becomes partially or fully non-functional, the frictional brakes must be able to take a substantial part of the braking effort. Wear of wheel treads and brake blocks contributes as one of the main reasons for the regular train maintenance and therefore prediction of wear is essential for controlling life cycle costs of trains.

Research work on railway brakes has been ongoing in CHARMEC since many years (see www. chalmers.se/charmec). In the doctoral thesis by Tore Vernersson [1] the thermomechanical interaction between brake block and wheel tread was studied to search for the mechanisms behind the growth of wheel roughness. A thermal model was developed for calculation of wheel and block temperatures including cooling by convection and from the rail. Rig experiments and field tests were performed and the results were used to calibrate the models. In the doctoral thesis by Shahab Teimourimanesh [2], the thermal capacity of tread braked railway wheels was studied in particular for metro applications. One important finding was that the convection cooling for prolonged braking application is in general lower for metro than for freight application and that the first axle in a train may show much higher convection cooling. The results of the two doctoral theses are published internationally. Further, in an experimental pin-on-disc study [3], the temperature dependence of wear for different brake block materials was studied. Moreover, in a numerical study [4], wear of the block for in-field conditions was estimated for a short train route with multiple stop braking cycles using a wear rate model calibrated using the aforementioned experimental study.

In the present study, the focus is on block and wheel temperatures and on, brake block and wheel wear at revenue traffic. They are investigated by a combination of field experiments, at SLL Roslagsbanan in Stockholm, and numerical simulations. The field testing is divided in two phases: short-term and long-term data collection. In the short-term data collection, train in-service data are sampled from on-train computerized braking control units where thermocouples are used to measure temperatures at wheel tread, wheel web and brake blocks. The data are sampled using a wireless data logging equipment. Wear of wheel tread is measured at regular intervals using a MiniProf device and wear of brake blocks is measured by weighing. In the long-term data collection, temperature measurements are not included. An overall objective of this study is to develop simulation models for predicting long-term wear of wheel treads and brake blocks. In the present paper, the short-term data collection phase is reported.

Since many years there has been a strive to replace cast iron brake blocks by composition or sinter brake blocks in order to reduce rolling noise. Currently, research work in this area is performed in the project Fr8Rail, which is part of the EU project Shift2Rail. One of the challenges is the winter behaviour of the composition blocks, which is illustrated by the situation at SLL Roslagsbanan. Here organic composition blocks were introduced in the early 1990ies. Soon it was found that certain conditions of snow would severely reduce the braking capacity. The behaviour was also reproduced in at rig test in 1992, in which different organic composition blocks were

tested [5]. In cases of exposure to wet snow, the behaviour of reduced friction found in-field could be reproduced in the rig tests. To avoid this problem seasonal use of cast iron and organic composition brake blocks were introduced and this means that both these block types are represented in the present study.

2. Field tests

Field tests have been carried out on an X10p commuter train operating in the Stockholm urban rail network Roslagsbanan. Each trainset consists of three cars: motor coach, middle trailer and driving trailer with maximum operating speed of 80 km/h. All cars are equipped with 1 Bg tread brakes, with cast iron brake blocks on the motor car and organic composite brake blocks on the remaining cars. It is to be noted that the tests were performed in early summer and for the winter season the entire trainset is equipped with cast iron brake blocks.

During braking, the brake force is distributed between the ED brakes and tread brakes for the motor car. For the other two cars, the brake force is applied only via tread brakes. Data were acquired for normal braking when the train was in revenue traffic. Two separate wheels were instrumented, one on the motor car and another on the driving trailer car, see Figure 1. The selection of the wheels for instrumentation is motivated by an earlier field study, for details see [6].

2.1. Instrumentation set-up

In the initial instrumentation set-up, both wheels were equipped with three surface thermocouples on the wheel web (field side), three sliding thermocouples on the wheel tread (over the block contact width) and two surface thermocouples inserted into holes drilled into the brake blocks. Each wheel was instrumented with a 3-channel temperature data logger which was fastened on a plate designed specially to fit into existing threaded holes (intended to be used for Galene plates [7] for reduction of rolling noise). The 3-channel temperature data logger was used for logging wheel web temperatures at three different radial positions, see Figure 2a.

A 6-channel temperature data logger (mounted on the bogie frame) was used for each of the two wheelsets to log temperatures of the wheel tread (three positions on tread based on the wheel–block contact width) and brake block temperatures (two thermocouples inserted inside drilled holes, see Figure 2b). A voltage data logger was placed inside the motor car to log speed, brake pressure and Metacone spring load data (for estimating axle loads). In addition, a data logger was used to log the GPS and acceleration data.

However, this set-up exhibited severe electrical disturbances for the measured temperature for the 6-channel temperature data loggers mounted on the bogie frame. The wires used for connecting thermocouples to data loggers were not shielded during this set-up. For this reason, incorrect negative temperatures were recorded when the train was running. These electrical disturbances were not present when the train was at standstill. Interestingly, the 3-channel temperature data loggers mounted on the wheels did not show these disturbances. Possibly, this was due to the metal plate acting as a shield from electromagnetic interference (EMI) and also that the wires for the thermocouples were positioned along the wheel surface, see Figure 2b.

Figure 2 *Top view of the train with and the instrumented wheels in dark grey.*

Figure 1 *Photos of the instrumentation part 1. (a) Plate mounted on field side of wheel rim with data logger behind it and three surface thermocouples attached to wheel web. (b) Cast iron block with drilled-in thermocouples (holes with diameter 5 mm and depth 40 mm).*

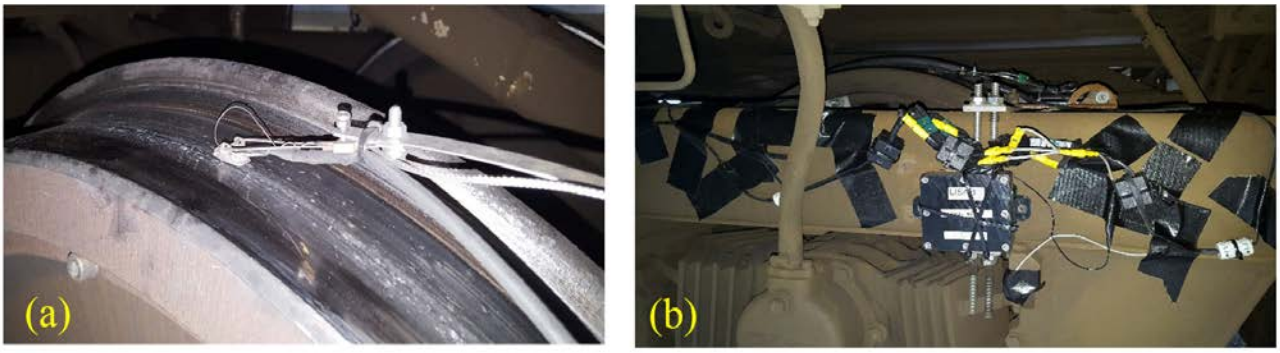

Figure 3 *Photos of the instrumentation part 2. (a) Arrangement of surface thermocouple glued on top of a sliding thermocouples to measure wheel tread temperatures. (b) Data logger and cables mounted on bogie frame.*

After numerous changes of the set-up followed by trial runs of the train, a working set-up was found. In this working set-up, the 6-channel temperature data loggers were excluded for the testing, since they proved sensitive to disturbances and instead only the two 3-channel temperature data loggers were used along with the voltage and GPS data loggers in the motor car. The wires for the thermocouples and extension cables for 3-channel temperature data loggers equipped with a steel braided shielding.

This shielding was grounded to the data logger and the shields were electrically insulated using shrink fit rubber tubing and also electrical tape. Only thermocouples that gave electrical insulation to the measuring device were used. Even though the wire of sliding thermocouple was shielded, it still showed disturbances during temperature measurement. One 3-channel temperature data logger (one channel for tread temperature and two channels for brake block) was attached to the bogie frame, see Figure 3b. The set-up for the wheel web temperature was kept unchanged. Finally, the addition of ferrite cores mounted on thermocouple wires near the data logger were used to eliminate the disturbances in the signals. Here, it was found essential to make the shielded thermocouple wire make one revolution through the ferrite core. After data collection for the motor car, a similar set-up was prepared for the driving trailer car and data were acquired.

During the entire field test campaign the voltage data logger was mounted inside the motor car, since only one such device was available. The plan was to use the measured brake pressure for the motor car and from that derive the brake pressure for the driving trailer car.

3. Simulation model and calibration

Temperatures of wheel and of brake blocks are calculated using a thermal model from measured variations of speed and brake power. Cooling by convection and radiation are accounted for and also the cooling influence on the wheel tread from the conduction of heat introduced by the rolling contact with the cold rail. The brake power is assumed to be generated between brake block and wheel tread assuming constant pressure over the entire contact area.

Wear of blocks and the wheel tread are estimated using the model described in [8], which is a modified version of Archard's wear law [9]. The wear rate is traditionally assumed to be proportional to the sliding velocity and normal contact pressure, but in addition to this, the wear rate coefficients is here presumed temperature-dependent. In the following the main features of the modelling are described. For details, see [4].

3.1. Thermal model

Prior to the analysis, heat flux generated at the wheel-block interface is calculated from the train data. The brake power is calculated using speed-dependent coefficients of friction for the two brake block materials (for cast iron blocks [10]), the measured normal brake force on blocks and the measured train speed. The mean heat flux generated over the wheel−block contact area is hence calculated as

$$q^{\text{brake}} = \frac{Q^{\text{brake}}}{BL_{\text{b}}} \tag{1}$$

where Q^{brake} is the brake power, and B and L_{b} are the contact width and length of the brake blocks. The heat flux is assumed to be constant over the width of the wheel tread. The heat is partitioned between brake block and wheel using thermal resistances that are essential for a proper mimicking of temperatures during braking, see Figure 4.

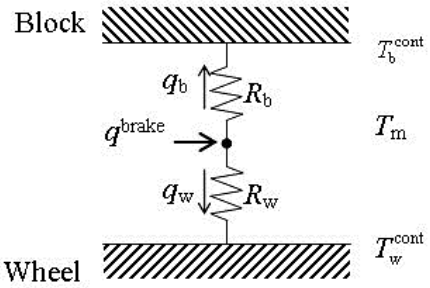

Figure 4 *Schematic diagram of heat partitioning model for a unit surface. Of a total generated heat flux q^{brake}, the flux q_{w} goes to wheel and the flux q_{b} to block. Contact surface temperatures are $T_{\text{w}}^{\text{cont}}$ and $T_{\text{b}}^{\text{cont}}$ for wheel and block, respectively. Common interface temperature is T_{m}. Thermal resistances are denoted R_{b} and R_{w}.*

An axisymmetric representation of block(s) and wheel is used for calculation of wheel and block temperatures, implemented in a user-friendly code [11], for calculating temperature histories for the train on the route. The block

and block holder are modelled using an axisymmetric model with modified thermal properties to account for the actual circumferential lengths. Convection and radiation boundary conditions are accounted for and also the rail chill effect that is introduced using a convection type of boundary condition. Cooling by convection is modelled using classical formulae where an empirical relationship between the radial Nusselt number and the train speed is utilized, thus accounting for the radial variation of the cooling by convection heat transfer. Convection cooling of the brake blocks is calculated using the same method, but then accounting only for a fixed part of that calculated value.

The wear behaviour of the brake block materials and the wheel tread during braking depends on, e g, speed, axle load and braking retardation. In the present study, the wear rate $\dot{w}$ [m/s] of the block or the tread is calculated in local form as

$$\dot{w} = k_w \mu p v \quad (2)$$

where k_w [m^2/N] is the temperature-dependent material wear property adapted from [3]. Wear of the wheel tread due to wheel-rail rolling contact is neglected. Wear of the surfaces are assessed in a post-processing procedure when temperatures, contact pressure and speed are known.

3.2. Calibration of models

The thermal model is calibrated for the specific train essentially by introducing a scaling factor of the convective cooling used in previous studies on a freight wagon [12] and on a metro train [6]. The calibration procedure means minimization of the squared differences of temperatures at the positions of measurement for in-field testing and for simulations.

After calibration of the thermal model, wear predictions can straightforwardly be produced from the calculated results. Regarding wear of the brake blocks, a scaling factor is introduced to account for differences between the specifics of the present in-field study and the ones for the pin-on-disc tests [3]. For the wheel tread, no temperature-dependent wear relationship is available. However, as a starting point for introducing such a relationship, the behaviour of the sinter brake block material in [3] is tentatively introduced, featuring a slight increase of the wear with increasing temperature.

Some specific considerations are needed in order to compare the wheel wear estimates found by the numerical modelling and the measured wear, which is measured over a prolonged time. Based on an assumption that the wear of the materials is the same for different routes, the estimated wear is scaled by the estimated ratio of braking power for the prolonged time to the braking power for the numerical simulated period.

4. Results

In this section results are shown for the measured temperatures and wear of wheels and brake blocks. The plan to derive the brake pressure for the driving trailer car, using the measured brake pressure for the motor car did not work. Prior to testing, the assumption was that the brake pressure for motor car is 1.25 times higher than the driving trailer car (measured at standstill). Later it was found that this assumption was not true and there was no correlation between them. So, for the driving trailer car, there was no logged data brake pressure and Metacone spring load. However, measured temperature results are presented in this section. In addition, results from calibrated thermal model are shown for the wheel and brake blocks in the motor car.

4.1. Measured data

Figure 5 shows the measured temperatures for wheel tread, wheel web and cast iron brake block along with the train speed and brake pressure for the motor car. Results

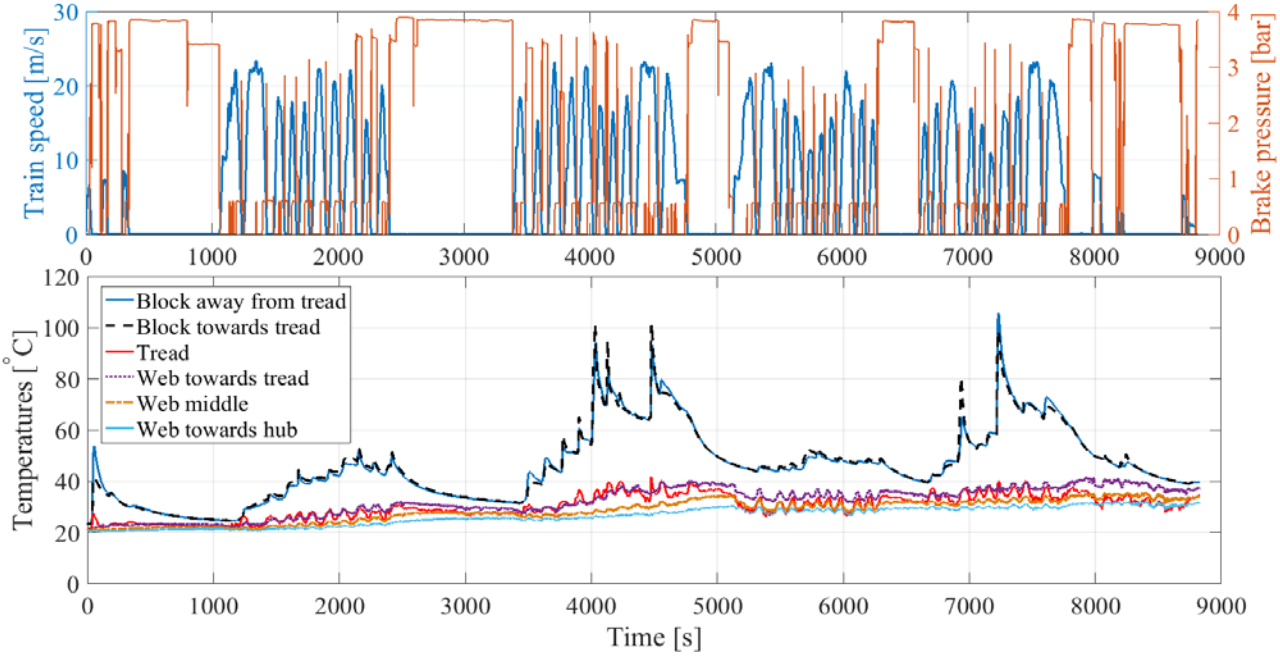

Figure 5 *Measured data for motor car fitted with cast iron brake blocks. (Top) Train speed [m/s] and brake pressure [bar]. (Bottom) Temperatures [°C] for brake block, wheel tread and wheel web.*

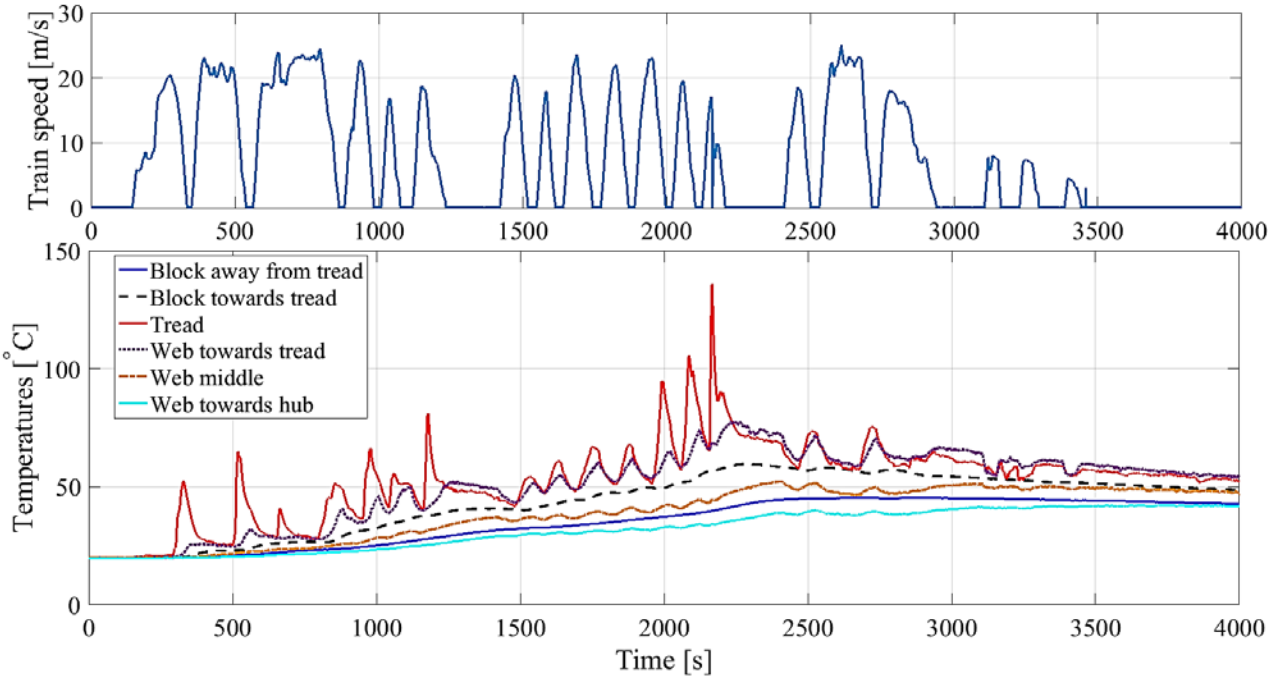

Figure 6 *Measured data for driving trailer car fitted with organic composite brake blocks. (Top) Train speed [m/s]. (Bottom) Temperatures [°C] for brake block, wheel tread and wheel web.*

show that the brake block takes a major part of the heat generated during braking. For the wheel, the temperatures are low in general for tread and also for the wheel web. Block temperatures towards tread are higher for most of the measurement compared to the block side far from wheel tread. Although, at some occasions the temperatures are higher for the block side far for tread. The reason for this could be due to misalignment of thermocouples along the brake block depth, which might have occurred during installation. For the wheel, the temperatures at tread are lower than at wheel web (towards tread) for a major part of the measurement. This was due to the uplift of the surface thermocouple attached to the slider caused by tension in the thermocouple wire. At some parts of the measurement, the tread temperatures were higher compared to those for wheel web (towards tread).

For the driving trailer car equipped with organic composite brake blocks, the results for temperature measurement are shown in Figure 6, along with the speed signal (measured for motor car). Results show that during braking a major part of the heat generated goes into the wheel instead of brake blocks, which in contrary to results for the motor car. Block temperatures towards tread are higher compared to the block side far from wheel tread during entire test run. Wheel tread temperatures increased rapidly during braking and also the wheel web (towards tread) temperature. It can clearly be observed in Figure 6 that after braking at standstill the tread cools faster than the wheel web (towards tread).

The brake blocks corresponding to the instrumented wheels were weighed using a high precision weighing scale (accuracy of 0.1 g). Wear data for the brake blocks (mass removed from blocks) are presented in relation to distance covered by the train (mileage) in Table 1. The results show that the wear rate calculated from the first measurement corresponds well with the second measurement for the organic composite brake block. For the cast iron brake block, the second measurement results in a lower wear rate than for the first one. Note that the cast iron brake block is fitted in the motor car, where the ED brakes take a high part of the braking load, effectively reducing the wear of these blocks. However, more wear data would provide a better understanding of the wear rates for the brake blocks.

Table 1 *Decrease in brake block mass [g] along with the corresponding mileage of the train [km] and wear rate [g/km] for cast iron (CI) blocks and for organic composite (OC) blocks.*

Mileage [km]	CI [g]	OC [g]	Wear rate [g/km]	
			CI	OC
4700	396	170	0.0843	0.0362
1040	71	38	0.0683	0.0365

For the instrumented wheels, MiniProf was used to measure the wheel profiles. The results for the wheel wear are shown in terms of increase of flange height (ΔSh) versus mileage of the train. Figure 7 shows the results for ΔSh for the motor and driving trailer car wheels, where values at zero are the reference values. Measurements were taken at 3-4 different positions along the wheel circumference, and the average of Sh was calculated and ΔSh was derived. It is to be noted that ΔSh is assumed at a distance of 70 mm from the flange side of the wheel. For the driving trailer, a modified position Sh_{mod} (at a distance of 80 mm from the flange side of the wheel) is used. This modification is introduced because of a larger contact width of the organic composite brake block.

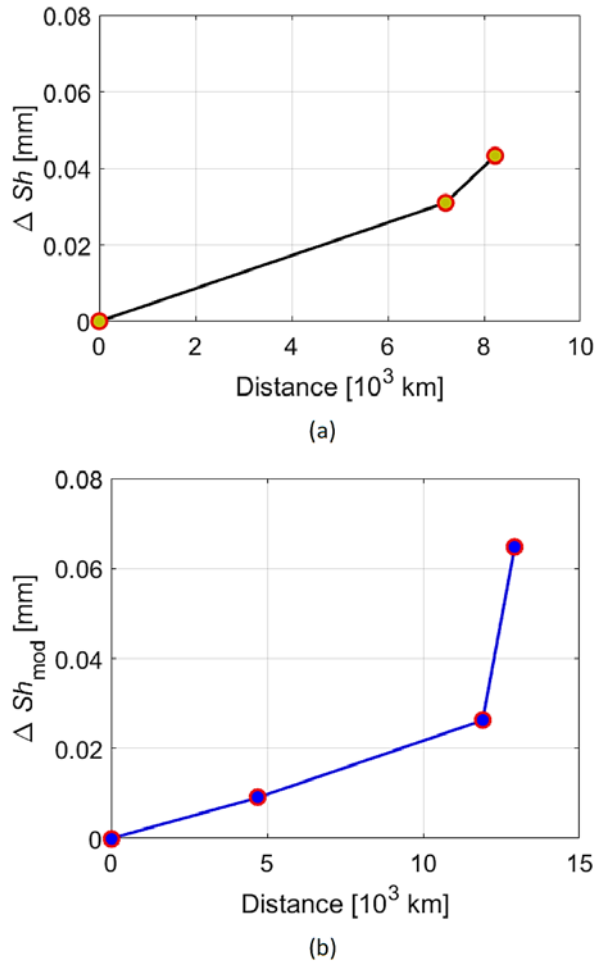

Figure 7 *Measured ΔSh for the (a) motor car and* ΔSh_{mod} *(b) driving trailer car with mileage. The values represented are calculated average of change in Sh parameter.*

For the motor car, two measurements were available and for the driving trailer three measurements are available. In Figure 7a, results show a gradual increase in *Sh* for the motor car. While for the driving trailer car (see Figure 7b) the increase in flange height is gradual for first two measurements, followed by a rapid increase over a short distance. A more detailed analysis of the wheel profile measurements would provide a better understanding of the wheel wear.

4.2. Simulations

A preliminary calibration of the thermal model was performed using the data pertaining to the motor car which is equipped with cast iron brake blocks. The temperature results from the optimized model are given in Figure 8 together with measured temperatures. It can be observed that the temperatures are generally low for both wheel and brake blocks, which is a consequence of the active ED-braking on the motor car. It was further found that the same convection cooling model parameters as for a freight wagon could readily be utilized, which perhaps can be understood when examining the open build of the train around the wheels which resembles that of a freight wagon. However, the thermal resistances between brake block and wheel were found to be reduced by 80 % for the present tests as compared to previous results from brake rig tests [13] which is a consequence of the relatively small temperature difference between blocks and tread.

One problem encountered at calibration was that the brake block temperatures vary substantially from one set of brake cycles to another set of brake cycles. This is an effect introduced by frictionally induced thermoelastic instabilities that make the actual contact between brake block and tread to be for only a part of the nominal block contact area. Occasionally it can be found for a central

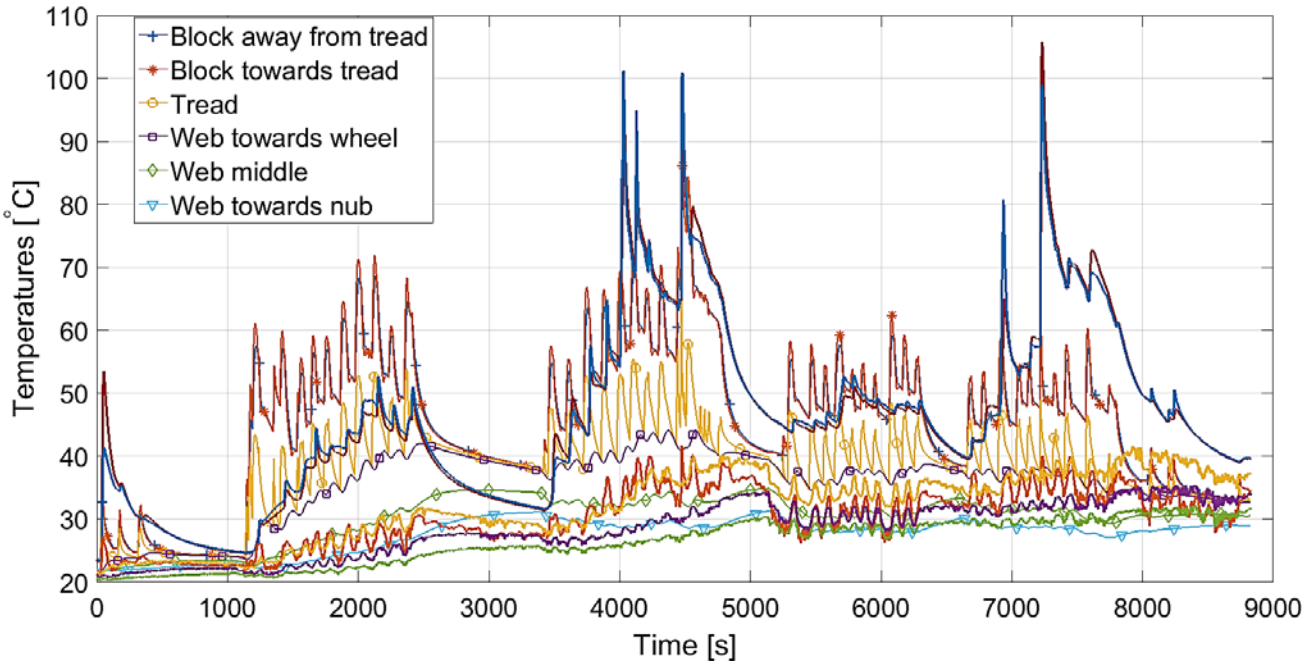

Figure 8 *Temperatures for brake blocks, wheel tread and wheel web for motor car. Simulated temperatures (calculated using calibrated thermal model) are highlighted with thin line and markers. Measured temperatures are highlighted with bold lines (without markers) and similar colours for clear comparisons.*

positon directly below the thermocouples at centre of the blocks, resulting in high measured temperatures and sometimes it is elsewhere, tentatively towards block ends, ending up with low measured temperatures [8]. The thermal model can only fit those variations in an average sense.

The simulated results can be used for calculating block wear according to eq (2) and utilizing the wear rate results from the pin-on-disc study [3]. Implementing this, it was found that the wear of the cast iron brake block is estimated to 4.3 g for the 51.8 km route that required 9.1 MJ of braking on this wheel. This means that the wear of the blocks corresponds to 0.083 g/km or to 0.48 g/MJ. The resulting wear rate based on distance is very close to the values found for the full-scale testing, see Table 1, giving 0.084 g/km and 0.068 g/km for the two studied time frames.

The energy related block wear could tentatively also be compared to the results from the field tests. In a preliminary study of on-train computer data for the motor car, it is found that the average braking efforts is 59.5 J/m for the Roslagståget train. Employing this value means that the wear data given in Table 1 for the cast iron brake blocks are 1.42 g/MJ and 1.15 g/MJ, respectively, which then should be compared to the value for the simulated route 0.48 g/MJ. As a side-point, the energy related wear for the organic composite blocks corresponds to 0.13 g/MJ, based on the data given in Table 1 and again utilizing on-train computer data yielding 275 J/km for the driving trailer car (with no ED braking).

5. Conclusions

In this study, railway wheel and brake block temperatures and also wear of blocks and treads were studied for an urban train by a combination of field tests and simulations. Motor and driving trailer cars, equipped with cast iron and organic composite brake blocks respectively, were studied during a field test campaign. The initial experimental set-up exhibited severe electrical disturbances for measured temperatures. A combination of shielded and insulated thermocouple wires along with the use of ferrite cores mitigated the disturbances.

Wear rate data for brake blocks showed that the organic composite brake block on the driving trailer car has a consistent wear rate. However, the wear rate of the cast iron block shows larger differences for the two assessed periods of train travel. Possibly could this be a result of the active ED-braking. Wear of the wheel tread was presented in terms of change in flange height with respect to covered distance. A more detailed analysis of the measured wheel profiles is required for a better understanding of the wheel wear.

Measured data from the field tests were used to calibrate a thermal model that allows for calculation of temperatures of wheel tread, wheel web and of brake blocks for the motor car. However, since the brake pressure data for the driving trailer car was not available, the calibration of the model could not be carried out for this car. Block wear of the cast iron material was estimated by implementing a temperature-dependent wear model used in combination with temperatures from the thermal model. The results for the estimated wear of the brake block are in reasonable agreement with the ones from in-field tests.

In future work, another short-term testing will be conducted for the driving trailer car with detailed measurement of temperatures and braking data followed by calibration of the thermal simulation model. Additional long-term testing for motor and driving trailer cars will be carried out, which will provide a better understanding of block wear and it will also provide a basis for analysis of wheel tread wear. The calibrated thermal models will then be used to predict temperatures during the long-term tests followed by calibration of wear models by comparison with measured wear data.

Abstract: Wheel rail contact forces measurements play a critical role in the vehicle acceptance tests for derailment safety evaluations. The common approach of continuous measurements is an indirect method through measuring deformations of the wheelset by strain gauges. The conventional instrumented wheelset has drilled holes on the wheel web and axle for loads decoupling, higher sensitivity, and wiring for the slip ring. As the structural integrity is damaged, it is not suitable for long-term field tests respect to the wearing process of the wheels. This article introduced a implementation method of the nondestructive instrumented wheelset that the strain gauges are placed only on inside wheel web, and signal transmission is implemented by wireless telemetry device. The strain gauge positioning method based on strain gradient and waveform rectifying technique for vertical force identifications were highlighted in this article.

Keywords: nondestructive instrumented wheelset; continuous contact force measurements; strain gauges; wireless telemetry system; FEM.

1. Introduction

Wheel rail contact forces measurements play a critical role in the vehicle acceptance tests for derailment safety evaluations [1]. This technology is also used in academic research tests such as wheel polygonised wear, rail corrugation, vibration transmission between the vehicles and infrastructures. The most popular approach is an indirect method by measuring elastic deformations of the wheelsets by strain gauges [2]. When the wheel runs over the rail, the periodic strains occurring on the wheel web and the axle could be acquired through Wheatstone bridge circuit. The double bridge signals in rotating coordinate which have 90-degrees phase delays can be demodulated with rotating angles to obtain continuous contact forces in global coordinate system. That is the basic principle of the instrumented wheelset, and it is required high SNR (signal noise ratio) bridge outputs as well as low bridge coupling effects under multiple direction contact forces. E. Gomez et al. [3] introduced some general approaches for instrumented wheelset and concentrated on the high order error controlling method through strain gauge position adjusting. Gullers P. et al. [4] introduced instrumented wheelset that could measure high frequency forces up to 2000 Hz and adopt dynamic modification factor to eliminate the resonance effects of the wheel web. Furthermore, Hiromichi Kanehara et al. [5] studied wheel rail contact points detection method based on bending stress distribution.

Generally, as shown in figure 1, the holes drilled on the wheel web are the most suitable positions to get the highest sensitivity to the vertical loads and the lowest cross sensitivity to the lateral loads. The strain gauges on the double sides of wheel web closed to the hub are of highest sensitivity to the lateral loads and the lowest coupling effects to the vertical loads as well. In short, this scheme is the benchmark for all other implementation methods.

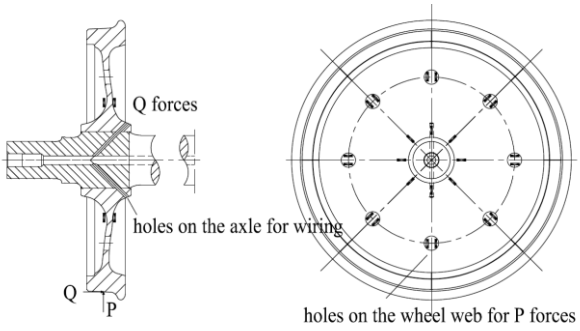

Figure 1 *Conventional instrumented wheelset with drilled holes*

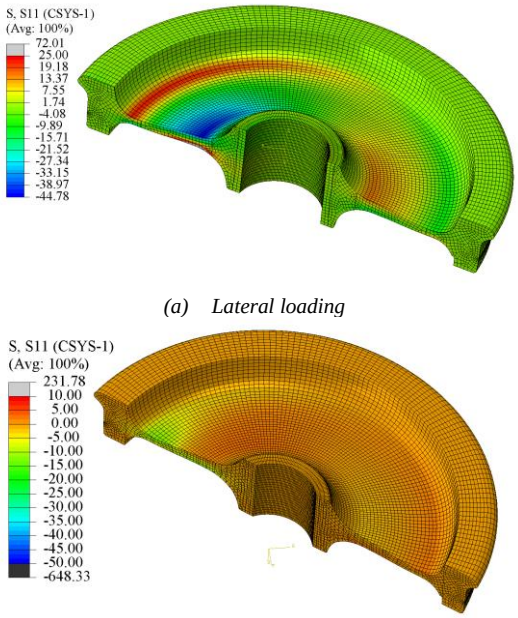
Due to the wiring holes on the axle and auxiliary holes on the web, the structural integrity of the wheelset is damaged, and it is only used for acceptance tests or short-term tests for running safety. Nowadays, there is a strong need for a non-destructive instrumented wheelset in long-term tracking tests along with the wear process of the wheels. Placing the strain gauges on the inside wheel web and together with wireless signal transferring system is a feasible solution for the nondestructive instrumented wheelset. This article introduced the implementation principle of the method. The positioning method of the strain gauges based on strain gradients, and the waveform rectifying method for the vertical force were highlighted.



2. Principle of the nondestructive instrumented wheelset

Expect for traction and braking states, the lateral and vertical contact forces are of more meanings to the vehicle running safety evaluations such as derailment factors and overturn ratios. This article only concentrated on the lateral and vertical force identifications through elastic deformations of the inside wheel web. It is found that wheel web has uneven deformations under the

vertical and lateral loads through FEA. The critical requirement of positioning strain gauges is to get the lowest cross sensitivity to the external loads. It is implemented by algebraic operations of the individual strain gauge through bridge assembling according to the strain gradient features respectively.

2.1. Strain gauges positioning method based on strain gradients

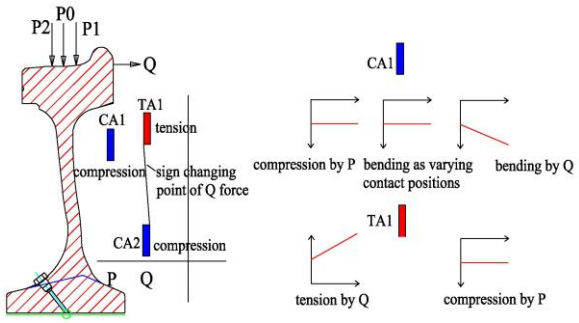
Wheel web stress distributions under vertical and lateral loads were calculated individually to get strain gradient features along the radial direction, as shown in figure 2. Vertical load of varying contact positions is considered as its great influence on the bending stress distributions.

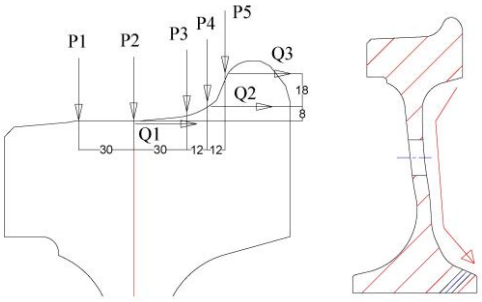
(a) Lateral loading

(b) Vertical loading

Figure 2 *Stress distributions in radial direction*

The most sensitive zones on the wheel web are CA1, TA1, and CA2 respective to the lateral (Q) and vertical (P) forces, as shown in figure 3. The stress gradient of TA1 is determined mainly by the lateral force, and it is used for the Q identification. The stress gradient of CA1 is more complicated as the influence zones of the Q and P forces are overlapping. Generally, the strains of CA1 are induced by the vertical force, additional bending moment as the misaligned contact position, and bending moment by lateral force. The area CA2 is closer to the wheel hub and its strain gradient is largely depend on the lateral force.





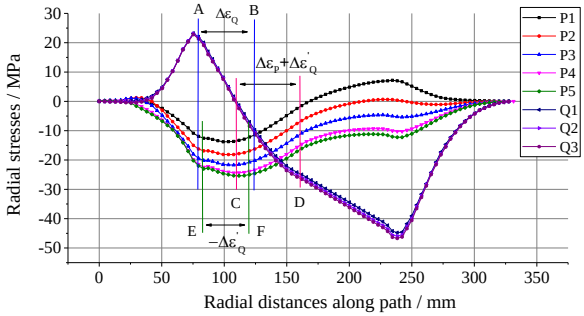


Figure 3 *Sensitive areas on the inside wheel web*

The detailed FEA results is shown in figure 4. The stress difference between position A and position B are chosen for Q force identification as its steep gradient respect to the lateral load. Meanwhile, the two points have the identical stresses induced by the P force that means coupling effects could be eliminated. The P force identification is more difficult than the Q force. Firstly, the strain values and the influence zone on the wheel web induced by the P force are much smaller than the Q force, and the lower SNR is inevitable. Secondly, the effects of the varying contact positions must be considered. Based on the above limitations, the position C, D, E, and F are chosen for the P force identification. As illustrated in figure 4, the stress distributions between C and D under varying the P loading positions are of the identical gradient and just be in different levels caused by the additional bending moments induced by the misaligned contact point. When the two strain gauges are placed at the two positions, the strain difference also contains bending component induced by the Q force which can be compensated by the strain difference between the position E and F. Especially, as the concave slope feature of the P force, the points pair of E and F has the identical feature as the points pair of A and B, that means the stress difference is only sensitive to the Q force.

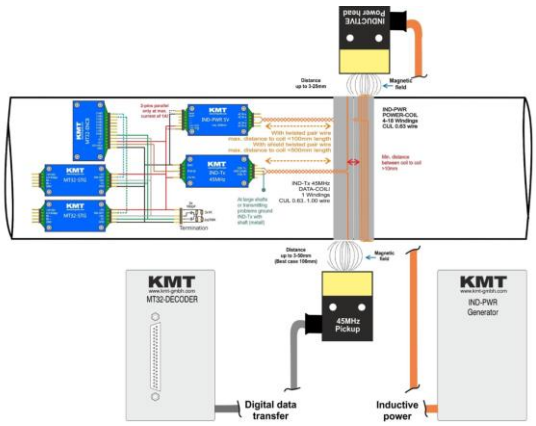
(a) Loading points and result plotting path

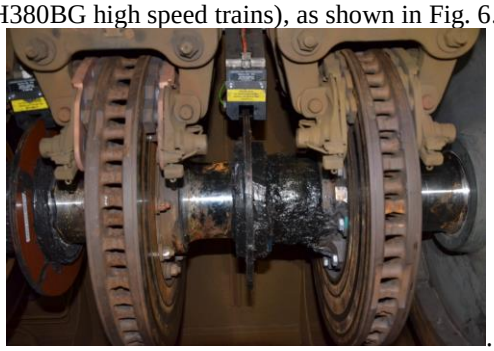
(b) Radial stress distributions

Figure 4 *Stress distribution curves of the inside wheel web under the Q/P forces*

2.2. Wireless inductive telemetry system for signal transferring

To avoid drilling wiring holes on the axle, wireless signal transmission system must be adopted. The analog signals of the bridge outputs are conditioned and digitalized firstly and then transferred out by inductive ring. The inverse D/A transform, acquisition, and digital signal processes are further processed outside of the rotating wheelset. Otherwise, power supply of the telemetry system is also implemented by resonant inductive ring. The scheme of the commercial system from KMT is shown in figure 5.





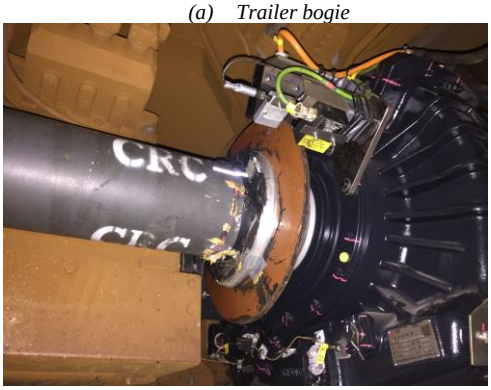


Figure 5 *KMT telemetry system*

Auxiliary brackets for inductive ring and coil packaging blocks are special designed for motor and trailer bogies (CRH380BG high speed trains), as shown in Fig. 6.

(a) Trailer bogie

(b) Motor bogie

Figure 6 *Auxiliary brackets for wireless inductive signal transferring system for CRH380B high-speed train*

3. Strain gauges layouts and demodulating technique

The Wheatstone bridge circuits consist of multiple strain gauges that algebraic operations for stress gradients could be implemented by layouts and wire connections. This section gives a detailed description on the layouts for the Q and P force identifications and special process for the P force due to its difficulties arise from small influence zone.

3.1. Lateral contact force identification

As mentioned above, the position A and B are chosen to calculate strain difference which is sensitive to the Q force only. Each branch of the full bridge consists of 2 gauges for minus operation. The full bridge is comprised of 2 opposite sectors of each has 2 branches with 60 degrees angle, as shown in figure 7.

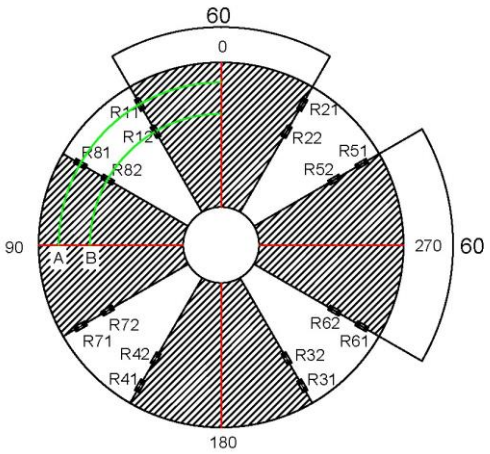

Figure 7 *Q force identification bridge layout*

The layout of the two Wheatstone bridges with 90 degrees phase delay is shown in figure 8. That is a common approach to demodulate signals from rotating parts.

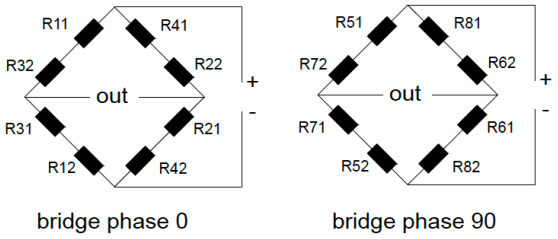

Figure 8 *Double Wheatstone bridges for Q force identification*

The relationship of the bridge output v_{out} and the bridge excitation voltage v_{ext} can be written as:

$$\frac{v_{out}}{v_{ext}} = G \times \left\{ \left(\varepsilon_{11} - \varepsilon_{12} \right) - \left(\varepsilon_{31} - \varepsilon_{32} \right) + \left(\varepsilon_{21} - \varepsilon_{22} \right) - \left(\varepsilon_{41} - \varepsilon_{42} \right) \right\} \quad (1)$$

Where G is bridge factor of the circuit.

In this chapter, the dynamic stress time history of the wheel web is obtained by FEA. The wheel was fixed, and the forces were applied on the circumferential contact points step by step to simulate rolling states. The dynamic stress difference between the position A and B in a full rolling turn is shown in figure 9. It is clearly showed that influence zone of the lateral force Q is more than a half circle of the wheel web. The signal of the strain gauge changes smoothly when the action point of the Q force runs over the wheel thread.

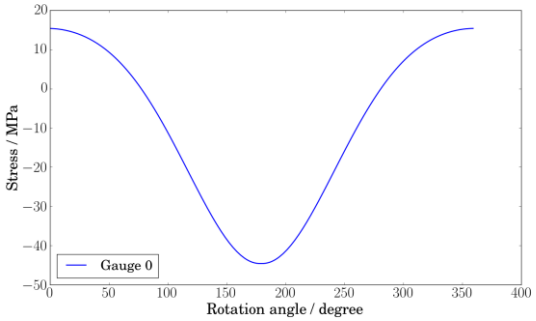

Figure 9 *Dynamic stress difference (A, B) time history (Q)*

The outputs of the two bridges were calculated according to the equation (1), and the demodulated signals were calculated as follow:

$$\varepsilon_d = \varepsilon_{p0} \cdot \cos\theta - \varepsilon_{p90} \cdot \sin\theta \qquad (2)$$

Where ε_d , ε_0 , and ε_{90} are demodulated signals, output signals of the phase 0 and phase 90 bridges respetivly, θ is the rotation angle of the wheelset.

The two-phase bridges outputs and the demodulated signals are shown in figure 10. There are tiny 4th order harmonic ripples which can be eliminated by filtering in post process.

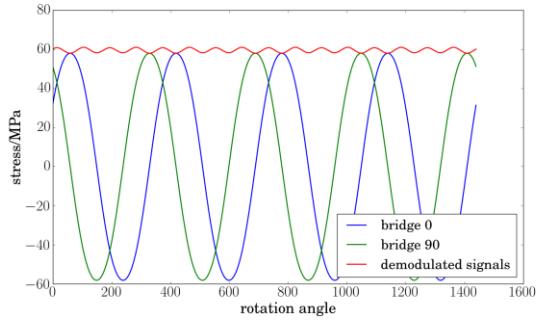

Figure 10 *Outputs of the bridges and demodulated signals*

3.2. Vertical contact force identification

The output waveform of a single strain gauge at the loading condition only the P force exists, as shown in figure 11, is much like a pulse with steep slope. As stress of the wheel web is less sensitive to the vertical loads, the sector angle of the influence zone is less than 60 degrees. Additional difficulties arise in demodulation process when the similar bridge layout as Q force adopted, as shown in figure 12. The algebraic operation for the strain gauges within a chain in radial direction brings a similar pulse waveform just with a different value. The demodulated signals of this scheme have large ripples with the same frequency as the wheelset rotating. It will dramatically reduce the SNR level of the demodulated signals and cannot be eliminated by further filtering process.

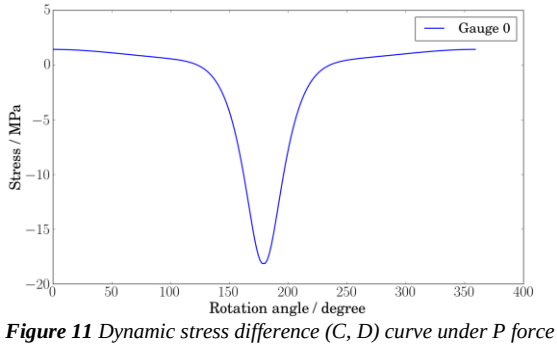

Figure 11 *Dynamic stress difference (C, D) curve under P force*

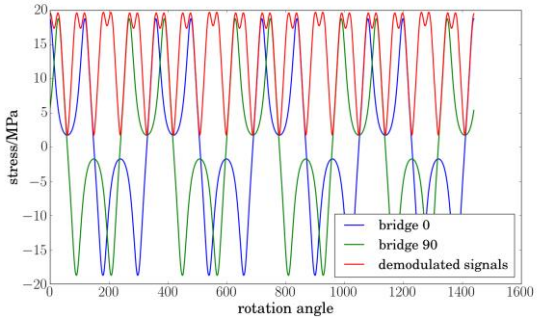

Figure 12 *Outputs of the bridges and demodulated signals (without waveform rectifying)*

In this section, a waveform rectifying technique is introduced for reducing ripple effects of the demodulated signals of the P force. It is inspired from the shape of the Q force influence zone that expanding sensitive sector angle could dramatically reduce the demodulation errors. As shown in figure 13, a quarter bridge is expanded to 5 branches on which the position C, D, E, and F are chosen for algebraic operations including stress difference calculations and compensation for coupling effects of the Q force.

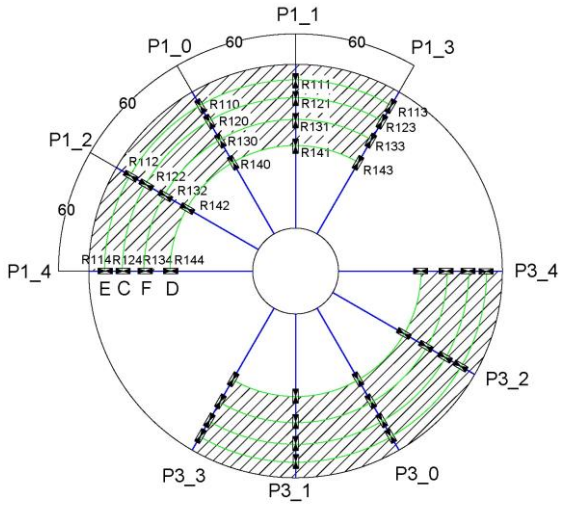

Figure 23 *Strain gauges layout for P force identification*

The quantities of the strains gauges in circumferential direction are increased for two reasons: firstly, the sector of the P force influence zone must be increased for reducing demodulation ripples. Secondly, the sensitivity of the bridge outputs to the vertical force should be increased for higher sensitivity. Assembling of the strain gauges in series at the same position in radial direction brings an approximated waveform like the Q force that means it brings wider circumferential influence zone. Only half of the bridge for the P force identification is shown in figure 13. The branch P1_1 and P1_3 have 30° and 60° phase advances respect to the central branch P0_0, and the branch P1_2 and P1_4 have symmetric phase delays. The strain gauges on the branch P1_1 and P1_3 have attenuation factors 0.8 and 0.6 respective to the central branch P1_0. The strain gauges on the branch P1_2 and P1_4 have the same attenuation factors respectively. The attenuation factor is implemented by selecting the strain gauges with scaled resistance values.

The strain gauges of the quarter of the bridge at the same radial positions are connected in series that means the strain outputs are summed up. Figure 14 shows the synthetic stress history of the gauge chain of the position E.

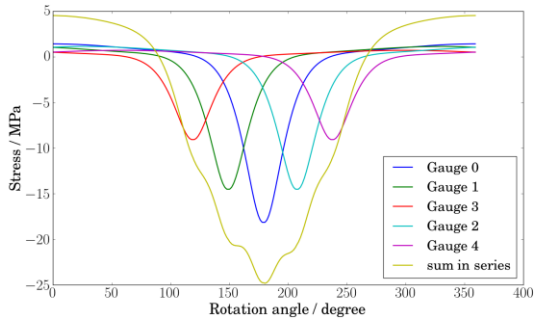

Figure 34 *Stress history of the strain gauge chain in series (5 gauges)*

If only P1_1 and P1_2 are kept, the overlapping area is reduced, and the synthetic signal is shown in figure 15.

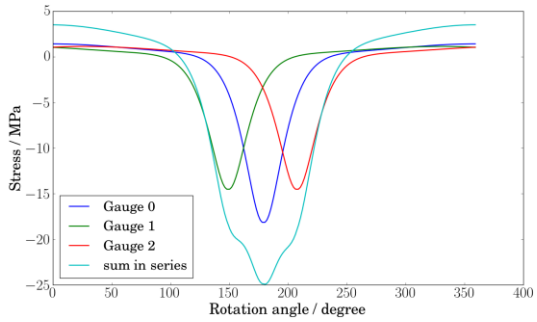

Figure 45 *Stress history of the strain gauge chain in series (3 gauges)*

The layout of the full bridge phase 0 is shown in figure 16. The relationship of the bridge output v_{out} and the excitation voltage v_{ext} can be written as:

$$\frac{v_{out}}{v_{ext}} = G \times \left\{ \sum_{k=0}^{4} \left(\varepsilon_{12k} + \varepsilon_{13k} - \varepsilon_{11k} - \varepsilon_{14k} \right) - \sum_{k=0}^{4} \left(\varepsilon_{32k} + \varepsilon_{33k} - \varepsilon_{31k} - \varepsilon_{34k} \right) + \sum_{k=0}^{4} \left(\varepsilon_{22k} + \varepsilon_{23k} - \varepsilon_{21k} - \varepsilon_{24k} \right) - \sum_{k=0}^{4} \left(\varepsilon_{42k} + \varepsilon_{43k} - \varepsilon_{41k} - \varepsilon_{44k} \right) \right\} \quad (3)$$

Where G is bridge factor of the circuit and k is strain gauge quantity arranged circumferentially. The bridge of phase 90 has the same layout as the phase 0.

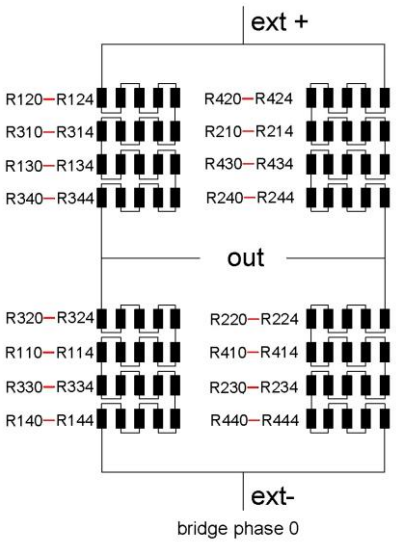

Figure 56 *Wheatstone bridge of phase 0 for the P force identification*

The demodulated and bridges output signals is shown in figure 17, and the 4th order errors are reduced to a small scale that can be filtered by further processes.

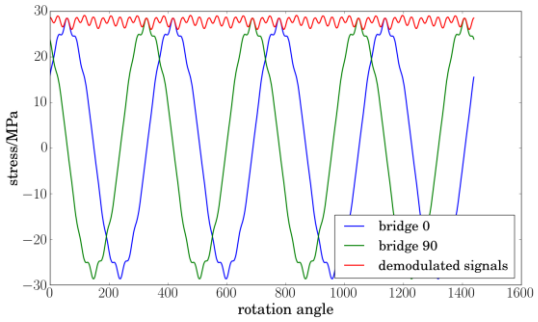

Figure 67 *Outputs of the bridges and demodulated signals (5 gauges scheme)*

As mentioned before, if the circumferential chain only consists of 3 strain gauges, P1_0, P1_1 and P1_2 are kept for instance, the demodulation errors will be increased dramatically, as shown in figure 18. The calibration factor could be treated as fluctuant curve respect to the rotation angles. That needs real-time processing of the two-phase bridges outputs.

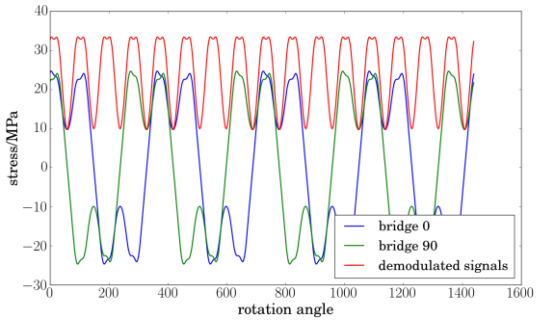

Figure 78 *Outputs of the bridges and demodulated signals (3 gauges scheme)*

4. Test rig calibration

The calibration tests were carried out by the test rig, as shown in figure 19, that lateral and vertical loads can be applied individually through the cylinders. The wheelset can also rotate at a low speed for dynamic calibration.

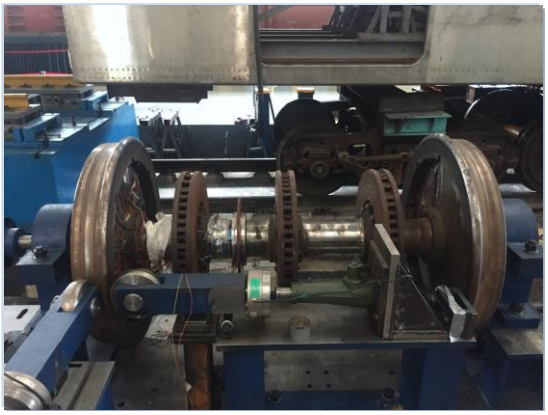

Figure 89 *Calibration test rig*

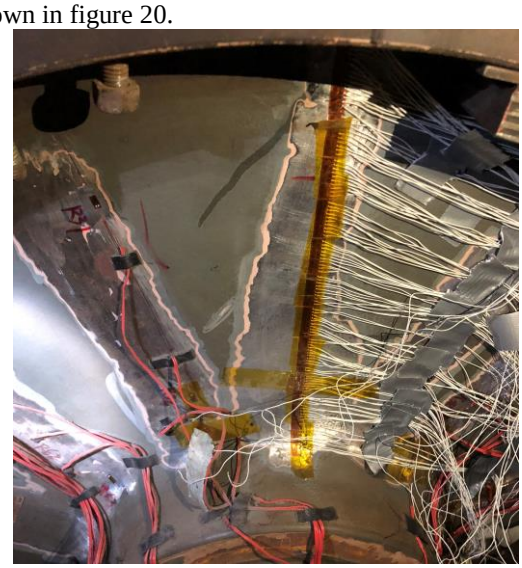
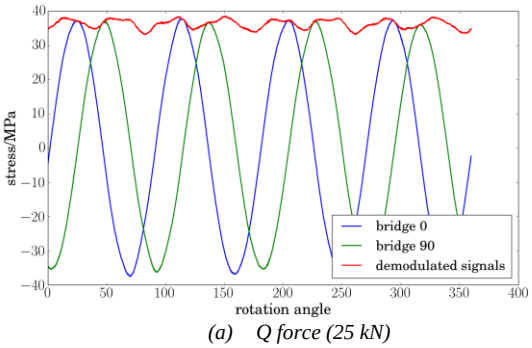
As mentioned in chapter 2, the critical positions of the strain gauges depend on the strain gradients or strain distributions. The more realistic gradient curves could be obtained by gauge chain sticking along the wheel web, as shown in figure 20.





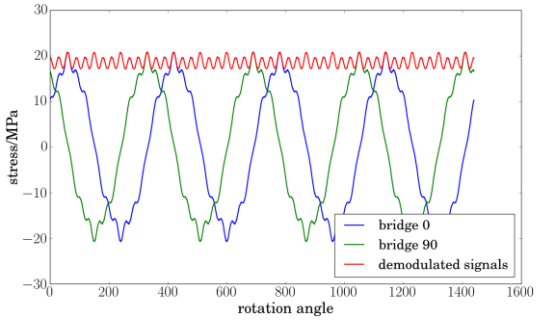


Figure 20 *Positioning through strain gauges chain*

The output of the bridges and demodulated signals at the test rig were shown in figure 21.

(a) Q force (25 kN)

(b) P force (85 kN, nominal rolling circle point)

Figure 21 Bridges outputs and demodulated signals at the calibration test rig

5. Conclusions

The nondestructive instrumented wheelset could be implemented inside wheel web strain gauge placing scheme together with wireless signal transmission system.

(1) Strain gradients are used for strain gauges poisoning to eliminate decoupling effects.

(2) Rectifying technique is introduced for vertical force identification as its small influence zone.

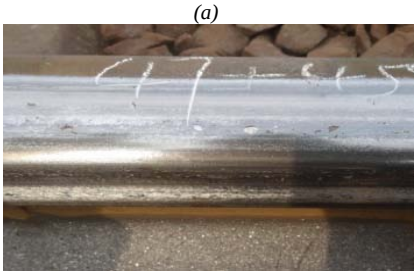
Abstract:In order to control the initiation and development of rail wear and rolling contact fatigue damage, and improve dynamic performance of bogies in curves by means of rail grinding, this paper presents an optimized design method for rail profiles based on wheel rolling radius difference function with specific computing methods as well as a computer software, taking the wheel-rail contact relationship between a measured wheel and rail profiles as an example for the optimization design. A field test is also conducted to verify it. The results indicate that the designed profiles for rail grinding operations based on wheel rolling radius difference function can effectively improve the geometric relationship of wheel-rail interface, a wheel-rail two-point fitting contact can be generated at high rail in curves, and the wheel-rail contact stress is well controlled while rail wear is reduced. Computer simulation results are in compliance with the field test results. Optimum rail profiles can be obtained by reverse design of the optimized wheel rolling radius difference function. It provides a new idea and design basis for the design of target rail profiles for rail grinding on curves.

Keywords: Rail grinding; Rail side-wear; Rolling contact fatigue; Profile optimization; Vehicle dynamics, Rolling radius difference; Field test.



1. Introduction

Wearing and fatigue failure are two major factors that affect rail's performance status and shorten the service life of rails, especially at sharp curves where rails would have to be replaced in very short time due to severe wearing or material failure. The most popular problem that is seen on the high rail at sharp curves is side-wearing (see Figure 1 blow). Majority of the reasons for rail replacement at sharp curves by railway bureaus in China is excessive side wearing. Railway operators are facing heavy cost for rail replacing and maintenance operations.

With the research study on wheel/rail interface getting deeper and deeper in recent years, it has become common acknowledgement that rail wearing and rail fatigue failure can be controlled by improving wheel-rail interacting relationship. The interface improvement between wheels and rails does not only include the improvement of dynamic performance of vehicles in the macro aspects but also include such micro aspects as the distribution of wheel/rail contacts, wheel/rail contact stress and wearing on both wheels and rails. When looking at the profiles of wheels and rails, it is reflected as the improvement in both cross sectional and longitudinal sectional profiles. When working on rails, people would normally eliminate the uncouthness in longitudinal direction by repair grinding, while for the cross sections, grinding is mostly done to reach certain pre-set profiles. One of the key open issues here is "how to determine or choose a proper rail profile as the target profile".

Figure1 *Side-wearing of High Rail: (a) Side-worn Profiles; (b) Surface Status.*

2. Methods and Issues Related to Optimization of Wheel/Rail Profiles

As of today, a number of experts from both home and abroad have already carried out studies on the optimization of wheel and rail profile design. For example, the radius-fitting based tread profile design method proposed by W.You[1]establishes conformal contact between the wheel tread and rail, which results in good curve negotiability and reduced rail wearing. With the method of Response Surface Fitting (RSF), Shevstov[2-4]separates the overall optimization of tread surface into several sub-grade levels and reduced contact

stress and lowered rolling wearing rate are obtained by means of MARS computing method. Through genetic algorithm, Perrson[5] uses series of treat surfaces with good dynamic performances as the base materials and generates the filial generation through random matching, crossing and mutation. The filial generation is then inspected and verified by means of functions. Dabin Cui [6-7] sets up target functions for the wheel/rail normal gap and contact stress level and proposes treat fitting optimization method based on sequential quadratic programming. Considering the influence to dynamic performance of rolling stocks due to wheel/rail contact functions, XiaoboZhong[8] proposes the reversed optimization method of wheel tread. Di Cheng [9] proposes multiple optimization targets of wheels. Eric[10]proposes rail profile optimization method with projected wheel geometrical contact characteristics by means of controlling the distribution range of the contact points between wheel and rail.

Above-mentioned optimization methods can typically be put into three groups:

(1) Improving optimization efficiency with reduced optimization variables through fitting design: this principle shows direct benefits in reduction of the number of optimization variables and improved the efficiency of optimization computing, while it also carries obvious weakness that the profile can only be designed based on a limited number of geometrical factors (straight line and curves) and the description of profiles cannot be performed as accurately as what discrete points can do;

(2) Disintegrating profile optimization into several sub-level optimizations by means of abstracting Eigen functions with matched wheels and rails: the benefits here are direct thanks to the introduction of Eigen functions of matched wheels and rails which are directly related to wheel/rail dynamics. In addition, with the application of MARS method, complicated optimizations can then be disintegrated into sub-level issues of less complexity. But the difficulty seen here is how to choose proper wheel/rail matching parameters since there is no proven standard for such work.

(3) Optimization with modern mathematical computing method: the benefits are seen as the complete conversion of actual profile design into mathematical descriptions and it clearly marks the target. With restrict theoretical basis of mathematical calculation, there is always an optimized profile (though it might not be the best) obtained no matter how the process goes. But the difficulty here is that modern computing methods take preference of variables to reach a solution and the amount of computing work is always huge and time consuming.

Based on the methods mentioned above, and in order to facilitate rail grinding operations, especially for the asymmetrical grinding operation at curves, this Paper proposes a new computing method for profile design with the understanding of Shevstove's optimization method. This new design method realizes quick rail profile design based on wheel profile and a given curve of rolling radius difference by means of direct back stepping method. Meanwhile, a computer program is established to realize quick design of target rail profiles for rail grinding operations.

3. Description of Computing Method

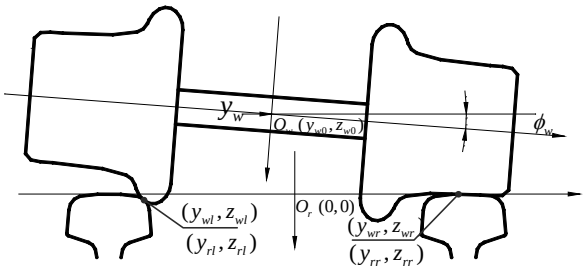

Figure2 *Computing Model of Wheel Rail Contacts.*

Figure 2 shows the computing model of single rigid contact on the wheel/rail contact surface, where wheel set coordinate origin O_w is fixed at the centred of wheelset, track coordinate origin *Or* is fixed at the centre of common tangent to the top of rails, and the positive direction of the coordinate system is as shown by figure 2. At the given lateral shift y_w and side rolling angle $\varnothing_w$, the wheelset contacts the rail with left and right contact points at (y_{wl},z_{wl}) and (y_{wr},z_{wr}) respectively in wheelset coordinate system, and at (y_{rl},z_{rl}) and (y_{rr},z_{rr}) in rail coordinate system. When the rail coordinate system is chosen as the global coordinate system, the coordinate origin of wheelset system then becomes (y_{w0},z_{w0}) in the global system, thus we have the following geometry relationship:

$$\phi_w(y_w) = \frac{\Delta R(y_w) - (z_{rl}(y_w) - z_{rr}(y_w))}{y_{wr}(y_w) - y_{wl}(y_w)} \tag{1}$$

$$y_{rl}(y_w) - y_w = y_{wl}(y_w) \cdot \cos(\phi_w(y_w)) - z_{wl}(y_w) \cdot \sin(\phi_w(y_w)) \tag{2}$$

$$y_{rr}(y_w) - y_w = y_{wr}(y_w) \cdot \cos(\phi_w(y_w)) - z_{wr}(y_w) \cdot \sin(\phi_w(y_w)) \tag{3}$$

Since the contact point of rail and contact point on wheel are the same point, added with the fact that both rail and wheel surfaces are smooth, a common tangent plane therefore exists at the contact point where the gradient of both wheel and rail is the same, i.e.:

$$\frac{dz_{rl}(y_w)}{dy_{rl}(y_w)} = tg\left(arctg\frac{dz_{wl}(y_w)}{dy_{wl}(y_w)} + \phi_w(y_w)\right) \tag{4}$$

$$\frac{dz_{rr}(y_w)}{dy_{rr}(y_w)} = tg\left(arctg\frac{dz_{wr}(y_w)}{dy_{wr}(y_w)} + \phi_w(y_w) \right) \quad (5)$$

With the fact that wheel/rail contact is a single-point contact, then:

$$z_{wl}(y_w) - z_{rl}(y_w) = \min\left\{ z_{wl} - z_{rl} \Big|_{y=y_w} \right\} = 0 \quad (6)$$

$$z_{wr}(y_w) - z_{rr}(y_w) = \min\left\{ z_{wr} - z_{rr} \Big|_{y=y_w} \right\} = 0 \quad (7)$$

In addition, constraining relationship exists here to assure the concavity and convexity of the designed profile:

$$sign\left(\frac{d^2 z_{wl}}{dy_{wl}^2} \right) = sign\left(\frac{d^2 z_{rl}}{dy_{rl}^2} \right) \equiv 1 \quad (8)$$

$$sign\left(\frac{d^2 z_{wr}}{dy_{wr}^2} \right) = sign\left(\frac{d^2 z_{rr}}{dy_{rr}^2} \right) \equiv 1 \quad (9)$$

When value of Δ_R in formula (1) is given, formulas (1) – (9) form a complete constraining assemblage for profile design. The solution will provide the location of the wheel/rail contact point with a given rolling radius difference. Target profile will then obtained through recursive computation.

4. Design Process

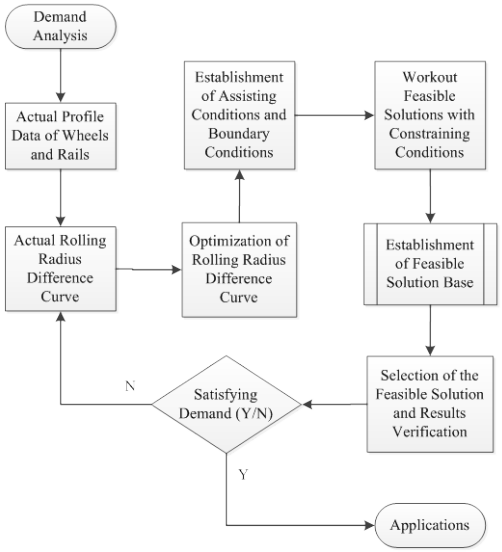

Figure3 *Flow Chart of Profile Design Process for Rail at Curves.*

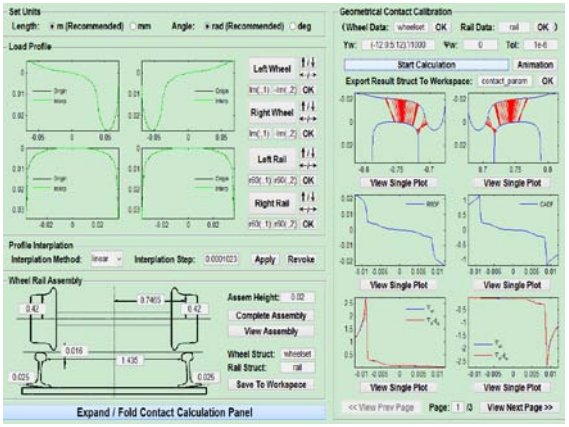

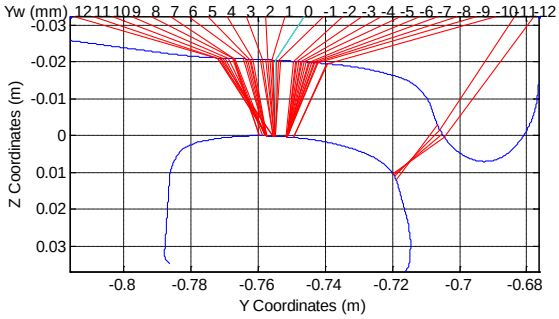

Figure4 *Computer Simulation Calculation.*

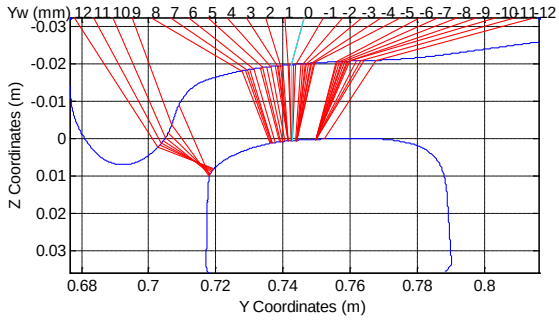
Compared with open-loop conventional computing method and current optimization computing method which is featured by the large computing work load, the rail profile design method proposed by this Paper generates a closed loop structure. Design process is shown by Figure 3 and computer software developed for the design work is shown as figure 4.



The design process starts with the actual measurements of rail profiles. With given wheel/rail fitting parameters, rolling radius difference curve between left side and right side wheels is then obtained through calculation of geometrical contacts. The fore-going results are used as datum for the design of optimized rolling radius difference curve, which is also the target curve. The mathematical modelling method as mentioned previously works on the solutions by converting the open questions into inverse problems. Optimized sections obtained therein are then aligned with the rest of the profile to form a complete profile. The whole process starting from demand analysis ending at applications involves all procedures of statistics, analysing, design, verification, merge algorithm, etc.. The profile design itself is conducted as per the actual track conditions and with the consideration of the dynamics of the vehicles. It processes both wheels and rails as one system and generates efficient and accurate solutions by means of special inverse computation methods. It makes possible to build up expert system and its achievements can be used to generate target rail profiles in rail grinding operations.

5. Case Study of Profile Design

This Section describes the profile design for one actual track line. The wheel/rail fitting conditions were confirmed through actual measurements on both wheel profiles and rail profiles. Optimization of wheel/rail interface was conducted following the above mentioned design methods and procedures. Figure 5 below demonstrates the wheel/rail profile fitting conditions out of actual measurements.

(a)

(b)

Figure5 *Actual Measurement: Wheel-Rail Interface: (a)High Rail at Curve. (b) Low Rail at Curve.*

Figure 6 below shows the relevant rolling radius difference curve:

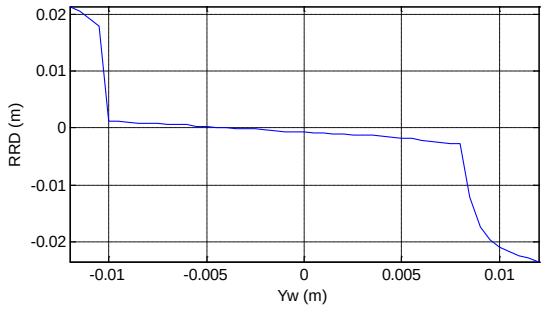


Figure6 *Wheel/Rail Rolling Radius Difference based on Actual Measurements.*

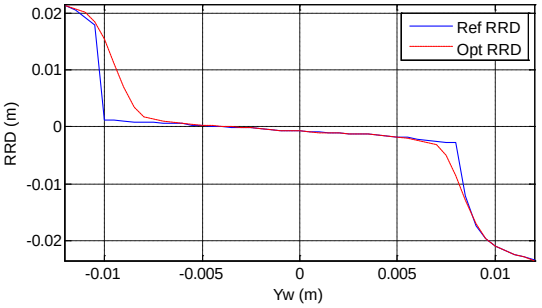
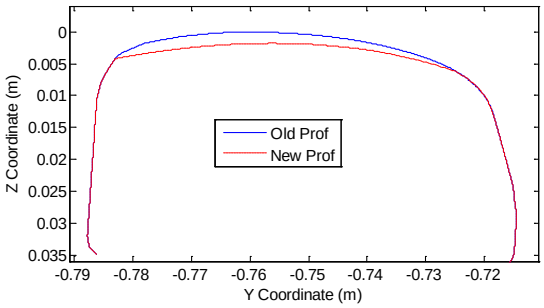
Figure5 and figure6 show us that the location of contact points on high rail is slightly different from that on low rail. Contact points on top of rail are mostly concentrated within a +/-9mm range in the lateral shift (due to the gauge widening from rail side wearing). A leaping clearance occurs right after that location and severe impact will be experienced upon the wheel contacts the rail. It negatively affects the driving quality at curves. While, in reality, steadiness on tangent lines and negotiability at curves have to be both taken into account, in other words, the rolling radius difference value needs to be at a low level when the lateral shift is small and to be a higher value when the lateral shift is normal (before flanging happens). Figure 7 below shows the rolling radius difference curve before and after optimization:





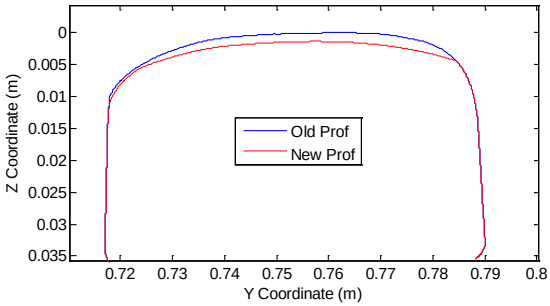


Figure7 *Rolling Radius Difference Curves Before and After Optimization.*

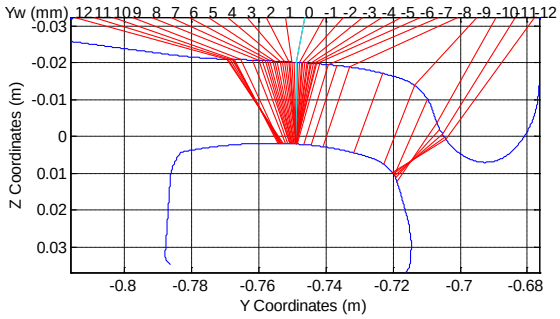
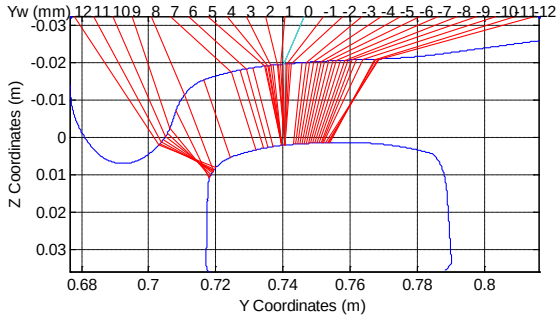
Figure 8 shows the new profile after optimization



(a)



(b)

Figure8 *Rail Profiles Before and After Optimization: (a) High Rail at Curve. (b) Low Rail at Curve.*

The fitting relationship between the optimized rail profile and wheel is shown by figure 9:

(a)

(b)

Figure9 *Wheel/Rail Interface after Optimization: (a) High Rail at Curve. (b) Low Rail at Curve*

With the comparison of Figure 9 with figure 5, it is obvious that wheel/rail contact with optimized rail profile becomes more even with top of rail being the major contacting area where radius of profile curves are large. Wheel/rail contact stress is effectively reduced. In addition, the leaping/jumping contacts at gauge corners are completely eliminated and the contacts are distributed all across the gauge side. Under the circumstances of small curve radius and large wheel later shift, two-point fitting contact and conformal contact at local areas are generated on the high rail at curves. It helps to reduce wheel/rail wearing and control wheel/rail contact stress. The relatively larger rolling radius difference generated at the same time can effectively lower derailment risks and improves curve negotiability.

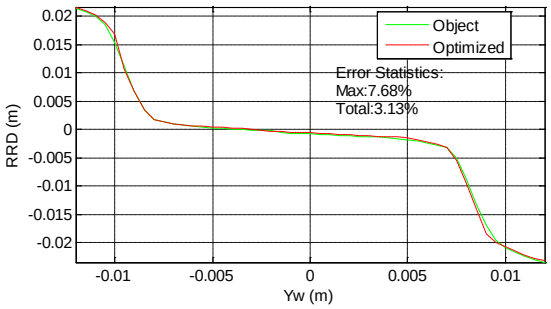


Figure10 *Optimized Rolling Radius Difference Curve and Objective Rolling Radius Difference Curve.*

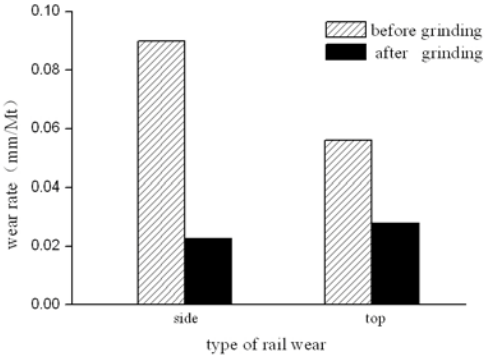
Figure 10 shows the comparison between the rolling radius difference curve when the wheel profile fits with optimized rail profile and the objective rolling radius difference curve as shown in figure 7. It can be seen the general deviation is 3.13% and the off value is less than 5%. It proves that design results are highly consistent to the expected results and the design results are reliable.

6. Field Tests

To confirm the feasibility of the design method and verify its actual performance, target profile [11] was obtained on a track line after the grinding operation with the implementation of the abovementioned profile design method. Continuous monitoring was conducted on this track line afterwards.



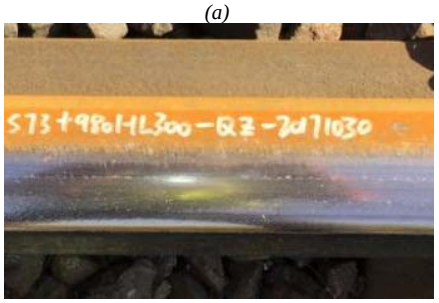


Figure11 *Comparison of Wearing Rates Before and After Grinding*

Figure 11 shows the wearing rate comparison of the high rail before grinding and the wearing rate six months after grinding (about 30MGT). It can be seen that both side wearing and vertical wearing were under effective control after the rail was ground to designed profile. Control of side wearing was very good and the wearing rate was about 1/4 of that before grinding. These numbers are in good compliance with the theoretical analysis described in Section 4. Therefore, the rail profile design method proposed by this Paper is able to effectively control the wearing of high rails at curves and rail service life is extended.

(a)

(b)

Figure12 *Surface Status of High Rail: (a) Before Grinding. (b) 6 Months after Grinding.*

(a)

(b)

Figure13 Surface Status of Low Rail: (a) Before Grinding. (b) 6 Months after Grinding.

Figure 12 and 13 are showing the surface status of both high rail and low rail before grinding and 6 months after grinding. Rail defects, such as fatigue cracks and spalling of material existed on the rail surface before grinding. Only some minimal micro cracks were seen 6 months after the grinding and no spalling of material was ever found. Thus, both rail wearing and fatigue damages were under good control after the rail was ground to the designed profile.

7. Conclusions

This Paper introduces a rail profile design method for grinding of rails at curves and this method is based on actual wheel/rail profile measurements and optimization functions of rolling radius difference. Specific computing method and computer simulation software are both developed. Actual implementation has been carried out in the grinding of track line. All of the results prove that the optimized rail profile effectively improves the geometrical relationship between wheels and rails, eliminates jumping issues at the wheel/rail contact points on working side of the rail, two-point fitting contact and wheel/rail conformal contact on rail working side are generated when the curve radius is small and later shift is big. Theoretical analysing results are in good consistence with field test results. Field tests also prove that the wearing rate of high rail at curves is substantially reduced after the high rail is ground to the profile that is designed with this method, and wheel/rail contact fatigue is effectively improved at the same time. Reduction of rail wearing and control of fatigue development are both realized. Therefore, this design method is effective and feasible. It provides a new guideline for rail profile design of grinding operations at curves and can be used as basic supports for such works.

Abstract: In order to recognize the influence of flange bearing frog crossing on wheel degradation, the 3D explicit FE model, material wear model and shakedown theory are integrated as a numerical simulation tool for evaluating wheel degradation as wheel switches into frog in diverging route. The precise distribution of frictional rolling contact solutions can be derived through transient contact calculations, after which, numerical methodology is applied to investigate wheel degradation. The results indicate that wheel flange degradation exacerbated by frog can mainly be manifested as higher stress field and narrower contact patch, which induced more plastic deformation, wear and RCF damage.

Keywords: flange bearing frog crossing; explicit FE simulation; degradation mechanism; frictional rolling contact; sliding smooth filtering method.

1. Introduction

Faced with the prospects of doubling freight traffic demand in the next few years and significant increase in passenger traffic in China, wheel/rail degradation and its dynamic problems have become more and more prominent [1] with the continuous increase of train formation number and traction quality. Flange bearing frog crossing can eliminate the flangeway gap for mainline rail, and evaluation of these frogs has proven the prominent advantages in reducing dynamic loads on the mainline route of the frog. This will however, result in wheels in diverging route to experience a special process owing to the complex structure of frog, which is accomplished by having diverging route wheels climb over the mainline rail using ramps, where each wheel is flange bearing as it crosses the mainline rail. The flange bearing frog crossing (Figure-1) consists of the tread bearing part, the mainline rail and the flange bearing part [2], and thus leading to more complicated wheel-rail relation and higher irregularity amplitude in geometry compared to fixed frog. Variable cross-section and ramp of frog rails are used to ensure that the frog can intersect different tracks at the same level, which leads to multi-point contact and sharp change of spatial wheel/rail contact positions, inevitably exacerbating the dynamic frictional contact behavior and accelerating related degradation of the frog. In addition, the evolution of wheel-rail profiles exacerbated by wear and RCF damage will influence the distribution of contact point pairs [3]. The above factors are bound to cause deteriorations in vehicle performance after long-term services, which include motion stability, riding comfort and derailment prevention, as a result, a scientific numerical simulation can be an efficient way for evaluating the influence of flange bearing frog crossing on wheel degradation.

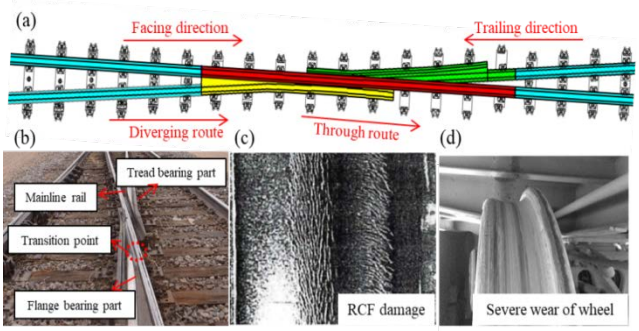

Figure-1 *flange bearing frog crossing: (a) Schematic diagram of flange bearing frog crossing; (b) Structural composition of frog; (c) RCF damage of wheel; (d) Severe wear of wheel.*

The numerical simulation method adopted for predicting degradation of wheels is highly significant in guiding maintenance management to guarantee the safety of operating vehicle. The wheel degradation prediction method is composed of the vehicle-track coupling dynamics, wheel-rail contact mechanics and material wear model much like rail wear prediction. Based on the wheel-rail wear theory and relevant experimental studies, Ping Wang [4] et al. studied the influence degrees of 19 related parameters such as friction coefficient and axle load on the wear of turnout rail using unreplicated saturated factorial method and vehicle-track coupling dynamics theory; T. Jendel [5-6] calculated the contact solutions based on the vehicle-track coupling dynamics model considering the discrete method of railway, track irregularity, wheel-rail friction coefficient and so on. The contact solution calculated above will be inputted to deal with accurate determination of wheel wear distribution according to material wear model, the wheel profiles can then be updated with the smoothing of wear depth, and then the new set of wheel profile updated are adopted in vehicle-track coupling dynamics model to perform calculation until the wheel running mileage reached the set value. T. Telliskivi [7] calculated the normal / tangential surface forces based on the quickly simplified

semi-Winkler method and then predicted the wheel-rail wear distribution for dry and clean wheel-rail contact surfaces according to Archard's wear model, with the simulated results coinciding well with experimental data. F. Braghin and R. Lewis [8] established a mathematical model consisting of vehicle-track coupling dynamics, wheel-rail contact theory and material wear model, and then the accuracy of the quick wear calculation method is verified according to the full-scale wear test. The wear distribution results can then be used as a guidance for optimizing wheel profile and vehicle parameters. With the rapid development of vehicle-track coupling dynamics and computational power, in order to recognize the accurate wear distribution characteristics and evolution mechanism in the presence of wheel/rail interaction, factors such as reciprocating rolling and shear deformation had been successively involved in simulation. F.J. Franklin and I. Widiyarta[9] et al. presented a numerical analysis method capable of evaluating local rail materials failure, which could be adopted to obtain the wheel-rail RCF damage and profile wear distribution, considering the accumulated shear strain under a reciprocating rolling load. Clayton P.[10] et al. measured the wheel-rail wear with an Amsler wear tester, and a method based on experimental results is put forward for reducing the rail wear effectively, and then the wear distribution was analyzed under the influence of different material matching in wheel/rail system; R. Enblom[11] investigated the influence of elastic shear deformation and vehicle braking on wheel-rail wear rates by means of different contact theory method, which can provide a theoretical basis for the quick and accurate calculations of wheel/rail wear. L.Y. Shevtsov and V.L. Markine[12] proposed the method to obtain the most optimal equivalent conicity based on the competitive relationship between RCF damage and wear, which can reduce the wheel-rail wear effectively and ensure the driving safety of vehicles. M. Ignesti and M. Malvezzi[13] et al. presented the wheel-rail profile wear prediction model for wheel/rail profile evolution, the wheel/rail profile updating were calculated based on the maximum accumulated gross tonnage and running distance, and the simulated results coincided well with that of the field test. In terms of turnout, E Doulgerakis[14] presented a methodology for distribution of non-uniform wear on wheel, which considered the influence of variable cross-section turnout on wheel profile and wear. A. Johansson[15] developed a numerical method made up of a model of vehicle-turnout coupling dynamics and a model for the wear estimation, which were adopted to predict the damages of turnout rail at different axle loads. Xu[16] et al. analyzed the influence of the curved switch rail evolution on dynamic wheel/rail frictional contact behavior, which were validated in collaboration with field measurement, and then the distribution of Mises stress and contact stress on typical worn curved switch rail sections were presented based on 3D stationary finite element model of turnout. B.A. Palsson and J.C.O. Nielsen[17] analyzed the influence of wheel profile evolution and friction coefficient on frog rail damage based on the Latin hypercube method and random sampling method, and then the frictional work is adopted to represent the degree of damage of the frog rail.

Based on the references above, the wheel-load transition regions and variations of rail profiles existing in frog will lead to sharp change of wheel / rail spatial contact positions and multi-point contact phenomenon respectively. In addition, the positions of contact points on variable cross-section turnout rails will also change along the longitudinal direction, manifested as complicated stress field, an increase in wheel/rail coupled dynamic response, non-uniform distribution of wear / RCF damage and so on. Furthermore, the frictional rolling contact solutions obtained from the references above are mainly steady-state computed results. However, the wheel-rail contact parameters will change sharply under the influence of load transition and impact effect in turnout, indicating obviously transient contact characteristics. In addition, the rolling contact theories in the references solved the frictional contact and structural vibration independently, hence the wave propagation and local high frequency structural vibration may not have been considered properly. In the meantime, the research objects were mainly focused on the influence of railway line or high-speed turnout on wheel degradation, few studies on the influence of flange bearing frog crossing on wheel wear, RCF damage and plastic deformation have been presented. Therefore, it is crucial that recognizing the effect of flange bearing frog crossing on wheel degradation using the numerical simulation tool considering the flexible wheel/rail deformation, transient frictional contact behavior and local structural vibration characteristics.

2. Simulating wheel degradation in flange bearing frog crossing

This section presents a method for investigating the influence of flange bearing frog crossing on characteristics of the wheel degradation, which covers three parts: (1) the 3D explicit finite element wheel-frog model for simulating the transient frictional rolling contact behaviour, where the research object adopted in the model is the 12# turnout with a nominal profile of 75kg/m rail. The transient frictional rolling contact solution is calculated based on explicit integration algorithm through inputting measured parameters including rail pad stiffness, damping and so on, and then the contact solution will be used as the input parameter for the material wear model and shakedown theory to obtain the wear and RCF damage in contact patch. (2) the data processing module, the degradation of wheel calculated above will be smoothed and superposed according to smooth filtering method and accumulated wear method, and finally (3) the prediction of wheel degradation, including the distribution of modified wear, RCF fatigue damage index and plastic deformation. For the complete flow chart, see Figure-2.

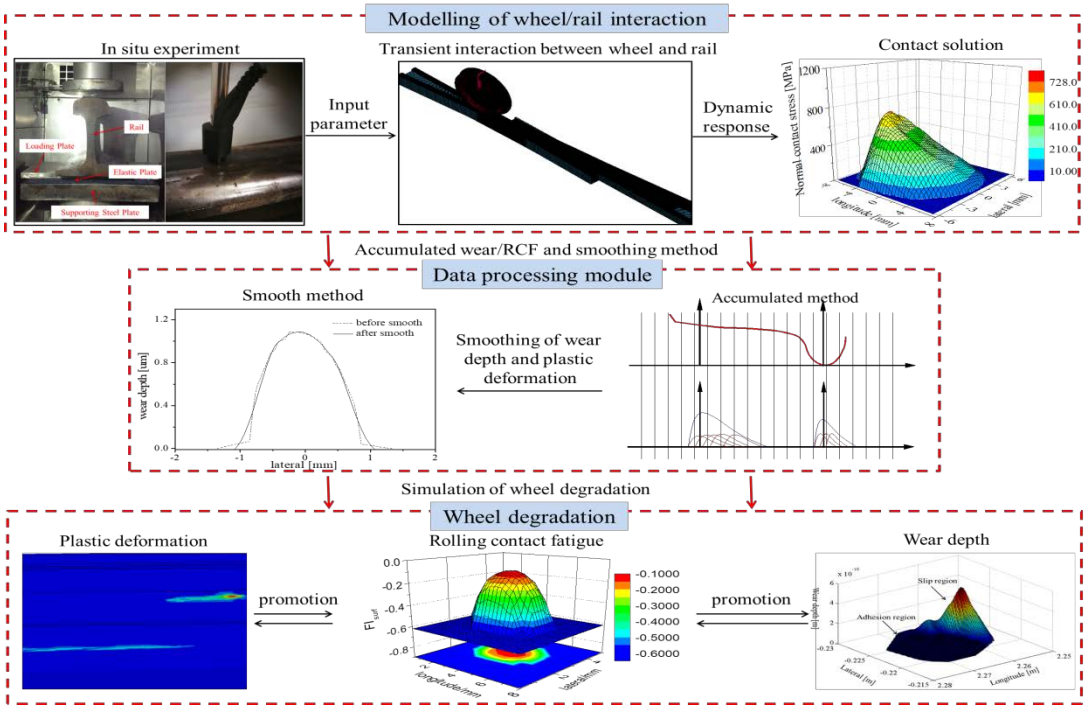

Figure-2 *Flowchart of the simulation method in flange bearing frog crossing*

2.1 In situ measurements

The rail pad will accelerate the ageing process under the coupling effect of multi-factors, including temperature, high frequency impact, cyclic wheel-load and so on, which will result in severe mechanical degradation and inaccurate results of wheel-rail contact solutions. The variability of vibration and elastic properties cannot guarantee precise dynamic wheel-rail interaction, which is connected closely to the accuracy of predicting wheel degradation. To reproduce the actual operating conditions between wheel and frog rail, the simulation precision can be promoted by measuring rail pad stiffness / damping in service.

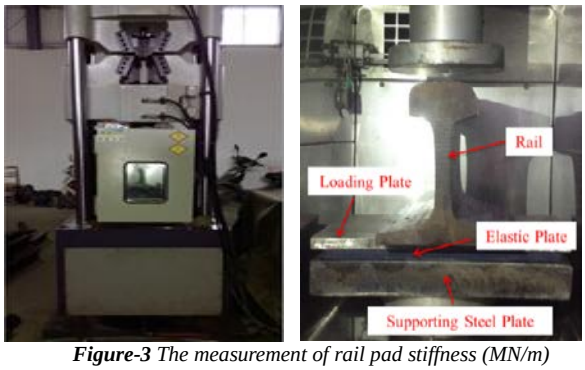

Figure-3 *The measurement of rail pad stiffness (MN/m)*

In order to obtain the stiffness and damping of rail pad in service, the stiffness (Figure-3) can be measured through a microcomputer controlled electro-hydraulic servo universal tester (Shanghai, range: 120kN, loading accuracy: 0.5kN) with a temperature box (range: -70~120°C, accuracy: 1°C). The damping can be obtained according to Equation (1)~(3) [19-20] as shown below:

$$K''(f,T) = (\rho T / \rho_0 T_0) K''(f_r, T_0) \quad (1)$$

$$F = K'(1 + i\beta)S \quad (2)$$

$$C = K'\beta / \omega = K''/\omega \quad (3)$$

Where: K^n is the energy dissipation stiffness of pad; ρ is the material density kg/m^3 under temperature T; ρ_0 is the material density kg/m^3 under the test temperature T_0; K' is the energy storage stiffness N/m; β is the dissipation factor; i is the imaginary unit; ω is the load angle frequency; C is the damping coefficient of rail pad. The obtained stiffness and damping coefficient are 88.4MN/m and 58.6$kN/(mm/s)$respectively.

2.2 Simulation of wheel-frog dynamic interaction

The dynamic wheel/rail interaction at flange bearing frog crossing is simulated through the commercial software ANSYS/LSDYNA. An overview of frog is given in Figure-4. First, the typical cross-section is selected to generate a continuously variable frog profile through the Bézier curve fitting, and then the 3D parametric model of flange bearing frog crossing will be established based on software Creo. The dispersed parts are then assembled according to spatial wheel/rail contact geometric constraint characteristics, then the assembled result will be imported to Hypermesh after the assembly process is finished. The frog rail and wheel with practical geometric profiles are discretized by 8-node hexahedron solid elements with the same material property assignation, with the hardness and yield strength values of wheel/rail are 2.94GPa and 580MPa respectively. In addition, parts over the primary suspension of the vehicle are simplified as lumped mass points, which are connected with the wheel axle through primary suspension modeled by discrete spring-damping element. The axle load is 25t and the stiffness / damping of primary suspension are 17 MN·m^{-1} and 3 kN·s·m^{-1} respectively while the fiction between wheel and rail is defined using Coulomb's friction law and the fiction coefficient is set to 0.5. The stiffness and damping values are 88.4 MN·m^{-1} and 58.6 kN·s·m^{-1} respectively for a

long-term service rail pad while the corresponding values of each spring-damper pair is determined according to both the proportion size of bearing areas in each part and numbers of spring-damping elements. The high frequency response of vehicle-track coupling system depends mainly on the flexibility of the wheels and rails [21], therefore the high frequency characteristics under wheel-frog interaction can be considered thoroughly using 3D modeling (Figure-5) while the linkage function of the horizontal bolt is simulated with beam element.

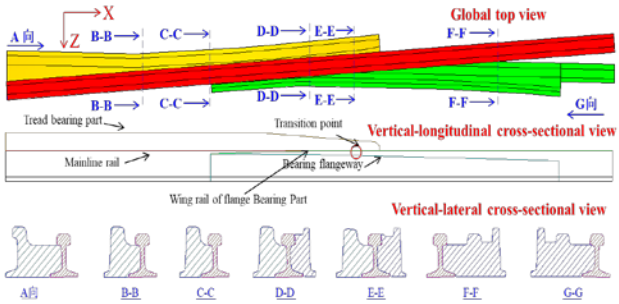

Figure-4 *Drawing of flange bearing frog crossing*

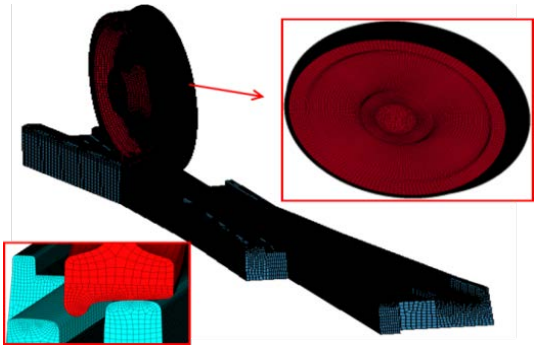

Figure-5 *The FE model with close-ups mesh*

Figure-5 shows the explicit finite element model for the transient rolling contact solution, where the wheel and frog rail are presented through transitional solid meshes. The characteristic length of potential contact region elements are less than 1mm, and wheel-rail frictional rolling contact behavior is calculated according to surface-to-surface contact algorithm based on the penalty function method. In order to reduce the disturbance excited by status changes (from static to dynamic) and to stabilize the dynamic wheel-rail interaction as soon as possible, the wheel/rail contact behavior at frog regions can be simulated according to implicit-explicit integration algorithm, the calculation procedure is shown as follows: the static equilibrium under gravity of model is calculated through implicit solver when the wheel stands still on frog (static implicit solution), the nodal displacements calculated above can be defined as the initial state of explicit calculation, while the initial translational and angular velocities as well as driving torque will also be added to the initial states, and finally the transient wheel/rail interaction is simulated using the explicit solver based on explicit integration algorithm (transient explicit solution). The transient rolling contact solution (Figure-6) covers the contact stress, rail surface shear stress and microslip, etc.

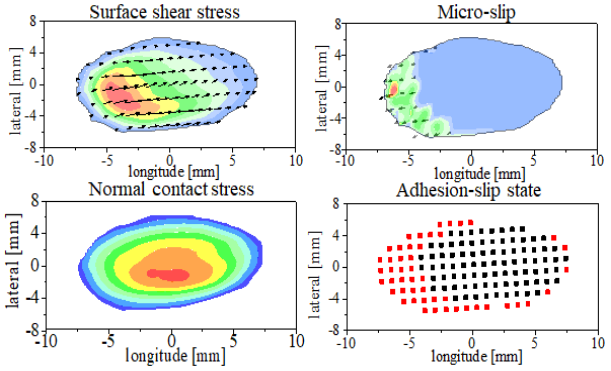

Figure-6 *Contact solution obtained from explicit FE model*

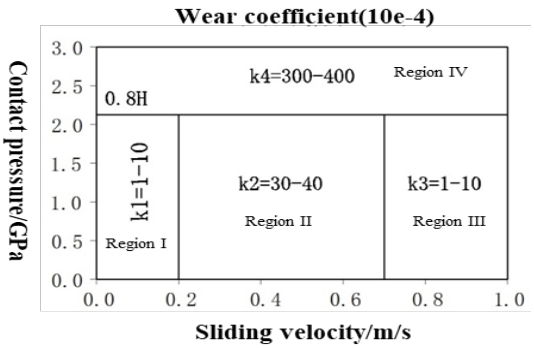
2.3 Material wear model



To predict the distribution of material wear loss on wheel/rail contact interface, the removed material in contact patches will be calculated based on Archard's wear law [23], which hypothesizes that the wear exists only in the sliding region, the wear within a contact patch can be expressed as:

$$V_{\text{wear}} = k_w F_n d / H \qquad (4)$$

Where: V_w is the wear volume of wheel/rail material; F_n is the normal contact force; d is the relative wheel-rail slip distance; H is the material hardness for wear calculation; k_w is the Archard wear coefficient that can be obtained based on contact stress and relative slip speed. Figure-7 is obtained from multiple tests, which is mainly comprised of 4 regions. The precise values are hard to obtain due to the inhomogeneous distribution of wear coefficient in different regions. It is supposed that the wear coefficient is set to a mean value in corresponding regions to reduce calculation work, i.e. $k_1=k_3=5e^{-4}$, $k_2=3.5e^{-3}$, $k_4=3.5e^{-2}$, then the wear depth Δz can be expressed as follows:

$$\Delta z = \frac{v_w}{A} = \frac{k_w p d}{H} = \frac{k_w}{H} \sum_{i=1}^{n} p_i \Delta s_i \Delta T \qquad (5)$$

Where: p is the contact stress; A is the wear area in the contact patch of the wheel; ΔT is the time step for output result.

Fiureg-7 *Wear coefficient of Archard's model*

2.4 RCF prediction method

The stress-strain status of the wheel under dynamic wheel-rail frictional contact might be subject to elasticity, elastic shakedown, plastic shakedown or ratcheting. The statuses mentioned above are mainly influenced by material hardening characteristics, wheel/rail contact behavior, load frequency and residual stress [22]. The residual stress, owing to reciprocating rolling load, will

continue to increase, which induces the dramatic change in the wheel materials' mechanical property. In Figure-8, (a) shows that the deformation between structures is subject to complete elasticity while the value of the wheel-load is within the elastic limit; (b) means that when the maximum local stress exceeds the yield limit, the deformation induced by subsequent cyclic load effects will be elastic under the function of the local residual stress together with plastic hardening owing to the plastic deformation, which is considered as elastic shakedown. When the maximum local stress is increased further, phenomenon (c) and (d) will happen: when maximum local stress is within the material shakedown limit, (c) represents the closed cyclic stress-strain curves with no accumulated plastic deformation occurring, which is also considered as plastic shakedown (low cycle fatigue); when the cyclic stress-strain curve is continuous unclosed, leading to accumulated plastic deformation under cyclic load, the initiation and propagation of cracks will be observed in local contact regions after long-term service, which is considered as ratcheting material characteristics, ratcheting effect (d) and plastic shakedown (c) are considered as the main factors resulting in damage of wheel.

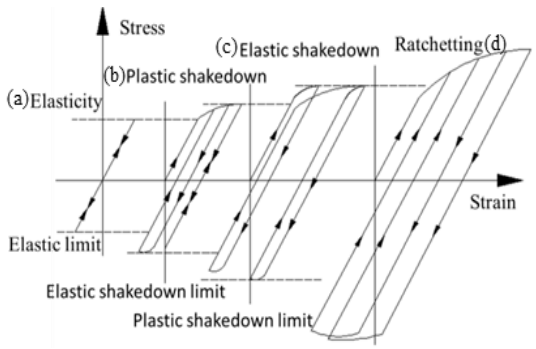


Figure-8 *Material properties of contact body under cyclic load*

An integrated evaluation on RCF damage is decided based on the shakedown theory, where *WP* is the work point determined collaboratively by traction coefficient and contact stress, the fatigue index FI_{surf} can be expressed as follows:

$$FI_{\text{surf}} = \mu \frac{2\pi abk}{3F_n} \qquad (6)$$

Where: F_n is the normal contact force, a and b are the lengths of semi-major / semi-minor axis respectively, K is the yield strength in simple shear. According to the shakedown theory, fatigue cracks will be liable to initiate and propagate on wheel-rail contact surface when work points lie in ratcheting effect region (i.e. $FI_{surf} > 0$).

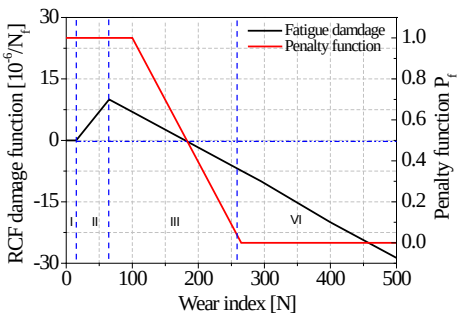

Figure-9 *The RCF partition and penalty function*

The RCF fatigue partition approach basically predicts the competition relation between RCF fatigue damage and wear, the dominant effects of RCF fatigue damage and wear can be obtained in different regions. The RCF fatigue damage is zero in region I, the load is within the shakedown limit so that the accumulated RCF will not grow; in region II, the RCF will increase with wear index, reaches a maximum without the development of wear; in region III, the development speed of wear is faster than that of RCF, RCF will decrease to zero with the increase of wear index; in region IV, the wear will be the dominant effect without occurrence of RCF.

From the RCF partition figure, the RCF fatigue damage will not decrease with no wear occurred when the wear index is no more than 100N, while the wear will be the dominant degradation way without RCF damage when the wear index is more than 265N. Therefor the RCF damage fatigue can be calculated as below:

$$D_i = \frac{(p_f \cdot FI_{surf})^4}{10}, \forall FI_{surf} > 0 \qquad (7)$$

Where: p_f is the penalty function obtained from figure-9. The material will be destroyed when the accumulated D is equal to one, so the method can be used for analyzing magnitude and distribution of RCF fatigue and damage of wheel.

2.5 Simulation of accumulated wear and data smoothing method

The accumulated method mainly covers the simplified accumulated method and the precise accumulated method. The error between the results calculated from the two methods is about 10% [24]. To improve the calculation efficiency, the simplified accumulated method is adopted to analyze the wheel degradation. The wear and RCF damage is first analyzed respectively based on contact solutions calculated above, then the simplified accumulation method is adopted to simulate, with the assumption that the properties of wheel-rail contact patch remain constant when the wheel rolls over it. The wear within the contact patch can be superposed along the running direction to calculate the accumulated wear depth of the wheel, the superimposition mode of RCF damage is similar to that of wear, therefore taking wear as an example.

For the simplified accumulated method, the material wear model is used to calculate wear depth on each element in the contact patch. The number of elements in contact patches along longitudinal and lateral direction are *MX* and *MY*, the equation of simplified accumulated method is shown below:

$$W_D(j) = \sum_{i=1}^{MX} w(i,j),\ j = 1 - MY \qquad (8)$$

Where: i and j are the element numbers of contact patch along the longitudinal and lateral directions respectively; $w(i,j)$ is the corresponding wear depth of cell(i,j); $W_D(j)$ is the wear volume of j^{th} cell in contact patch when the wheel is passing by.

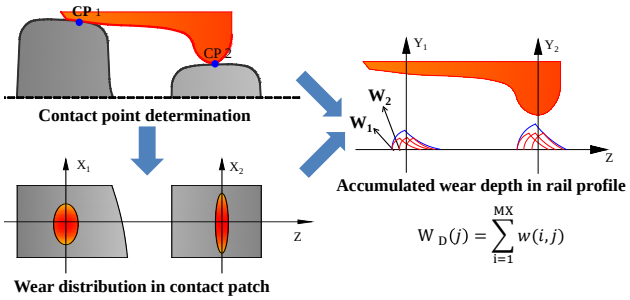

Figure-10 *The procedure of simplified wear accumulated method*

The wheel wear obtained from the simulation is jagged and different from the practical situation due to the discrete error of finite element method and discontinuity of the dynamic simulation process; in practice, however, the elastic-plastic compressional deformation of wheel-rail contact makes the wear distribution along the profile smooth, hence, in order to obtain reliable simulation results, a suitable smooth filtering method should be adopted. In this paper, the sliding smooth filtering method is adopted to smooth the curve surface of contact solutions and accumulated wear during different calculation stages. The unstable calculation data $\{y_j\}$ can be considered as stable for some appropriate small sections, the random fluctuation caused by $\{e_j\}$can be reduced through moving averaging. The smoothing value $\{f_j\}$ can be obtained when N data are subject to local averaging in a small section successively along the full length. The closer the data being to the center of the smoothed section, the more obvious the influence of the smoothing effect; therefore different weighted means can be adopted to constrain the action of random errors, the expression of which is shown below:

$$f_k = \sum_{i=q}^{p} w_i y_{k+1},\ k = q+1, q+2, \ldots, N-p \qquad (9)$$

Where: ω_i is the weight coefficient, and $\sum_{i=q}^{p} \omega_i = 1$; m is the number of data within the sliding smooth region; p and q are any integer less than m, and $p+q+m=1$; f_j is the unstable set consisting of N data. When the smooth treatment is performed according to Equation (8), the smoothing effect will be worse with a smaller m, and it will be hard to restrain errors; the smoothing effect will be better with a bigger m; however, the high frequency variation of definite part might be weakened, therefore a reasonable parameter must be selected for smoothing. The m is set to 7 with the better smoothing effect according to the multi-trail calculation.

3. Simulating results of wheel degradation

The transition regions and frictional contact behavior with flange bearing mode have a remarkable influence on wheel degradation. The degradation, which includes plastic strain, wear and RCF damages, are calculated respectively including transient frictional rolling contact and ratcheting. These results can be adopted as a theoretical basis for analyzing the influence of flange bearing frog crossing on wheel degradation.

3.1 Simulation results of wheel-rail force

Due to the transition characteristics and multipoint contact as well as the variable rail profile in frog, leading to non-uniform distribution of wear, plastic deformation and RCF damage, the wheel-rail contact force should be analyzed to evaluate the influence of flange bearing frog crossing on wheel degradation:

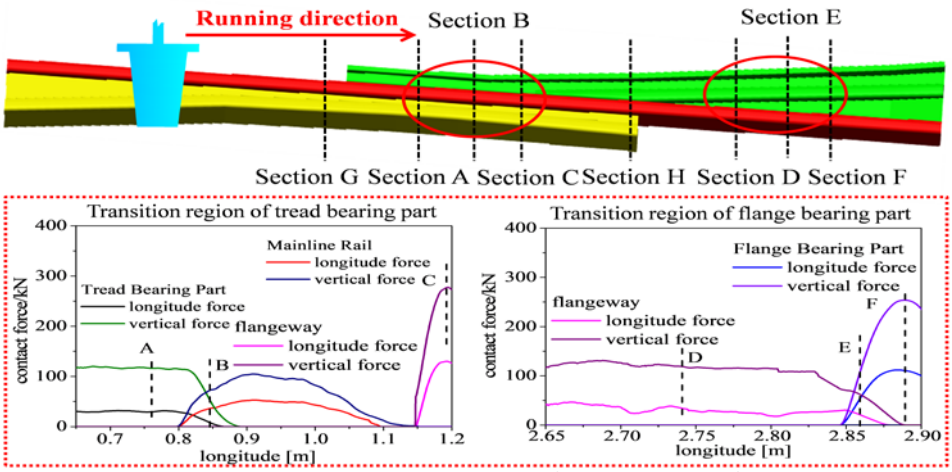

Figure-11 *The time history curve of dynamic wheel/rail force*

The typical cross-section corresponding to steady operation status (A, D), two-point contact status (B, E) and maximum force states (C, F) are selected and a detailed analysis is made at these typical sections. The maximum wheel-rail contact force is 271.9kN when the wheel moves in a diverging route, which is located around the transition point of the frog. An excitation source similar to structural irregularity is formed due to the 3.5mm height difference between mainline rail and bearing flangeway; therefore, the drastic wheel-rail interaction will be excited at the transition point during the impact. The height of contact patches on mainline rail will decrease with the wheel running forward during the transition in tread bearing part, which provides the function similar to unloading. As a result, the maximum force excited on the mainline rail is relatively lower. Due to the impact and complex wheel-rail contact relationships in the flange bearing part during transition, leading to complicated and variable dynamic stress acting on the wheel, the maximum wheel-rail force is

252kN at the location of the impact, and promoting a dynamic damaging effect on the wheel. In addition, the misalignment between trajectory of contact patch and running direction will contribute to the plastic flow and wear of the wheel [26]. The attenuation speed of longitudinal contact force is quicker than that of the vertical force during transition, however the amplitude of longitudinal force is higher than the vertical force due to the greater influence of irregularity on longitudinal force; in practice, the stress field acting on rail will be exacerbated by structural irregularities combined with the impact loading, which will accelerate wear rate and RCF crack initiation as shown in Figure-1.

3.2 The simulation results of wheel-rail contact geometric relationship of frog

In order to make a detailed evaluation concerning the evolution of wheel-rail contact behavior at the flange bearing frog crossing region, an analysis of the wheel-rail contact geometric relationship of typical sections must be conducted.

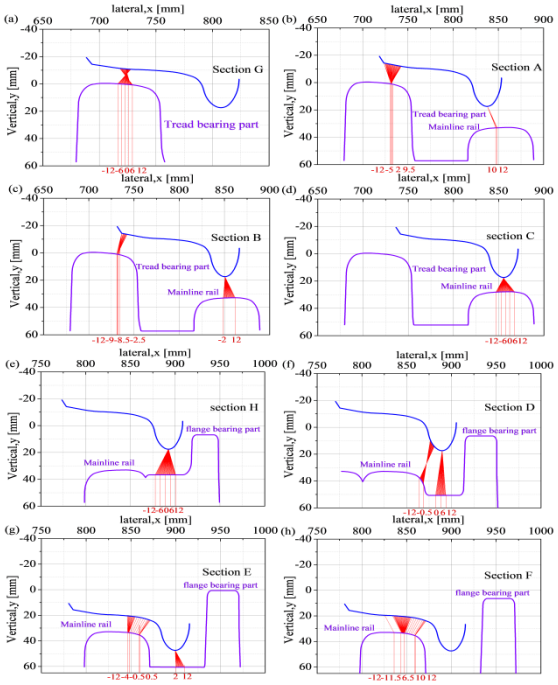

Figure-12 *Contact geometry relationship of tread bearing part (a-d) and flange bearing part (e-h)*

As shown in Figure-12, the wheel load transition procedure (facing move) covers the following steps: First, the wheel load will be transferred from tread to flange with the height decrease of bearing wing rail in the flange bearing part, then with the height increase of the bearing flangeway, the wheel will climb over the mainline rail using ramps when the height of the mainline rail is lower than the wheel flange, and finally, the wheel-load will be transformed from flange to tread in the tread bearing part with the increased height of the tread bearing rail. The wheel-rail contact patch will be moved to the field side of the wheel in the tread bearing part due to the misalignment between the longitudinal axis and the rolling direction, the field side of tread and flange top will come into contact with rail together (two-point contact), the flange bearing frog crossing is subject to special contact modes including flange bearing; when the wheel-rail contact patch is located at the flange bearing part, except the mutual contact between flange top / tread and rail, a certain lateral displacement may occur to the flange close to rail, which will result in side wear between the wheel flange and the frog rail. Therefore, the wheel-load transition characteristics are more complicated than those of the fixed frog crossing.

3.3 The simulation results of plastic deformation during transition

Figure-13 shows the corresponding plastic strain of the wheel during the transition, assuming the downward direction of initial wheel contact position as the polar axis and the wheel rolling direction as the positive rotation:

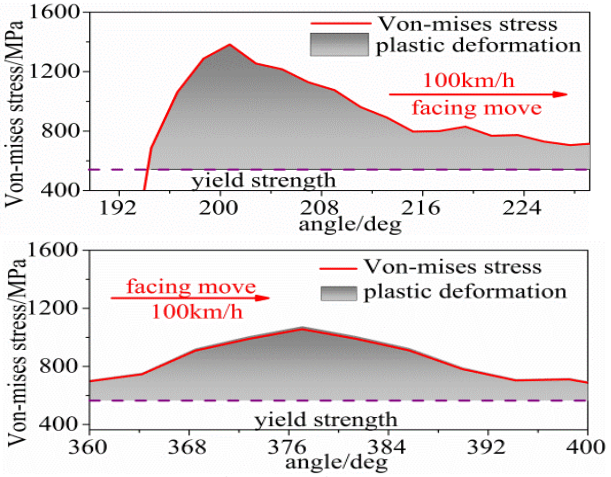

Figure-13 *Plastic deformation of wheel in tread bearing part (top) and flange bearing part (bottom)*

Plastic deformation exacerbated by wheel-rail impact vibration may significantly influence wheel degradation [25]. The Mises stress is employed to evaluate plastic deformation, maximum Mises stress is far higher than its yield limit on the bearing flangeway owing to impact and flange bearing, leading to severe local plastic deformation of the wheel. Due to the larger size of the contact area and lower wheel-rail contact radius difference, the plastic deformation on the wheel tread is relatively small. The contact behavior is highly significant speeding up the development rate of plastic deformation on wheel, especially the flange, leading to local depression of wheel and poor running quality. In addition, the local plastic deformation on the wheel will develop and accumulate at the location of impact under reciprocating wheel load, exacerbating the impact, and extending and accelerating degradation; as a result, the wheel material will fail after reaching the toughness limit in long-term service, leading to plastic flow and damages [26], which threaten the driving safety.

3.4 The simulation results of wear during transition

According to simulation results, the microslip of wheel-rail interface in the adhesion regions of a contact patch is zero, therefore the wear only occurs in the sliding region as shown in Figure-14. The wear is the

combination effect of pressure and microslip, the maximum value of wear depth located around the edge of contact patches is 0.34nm during the transition, so the wheel flange should relatively be the weakest part. When the wheel-load is transferred from tread to flange, the growth of wear depth amplitude induced by transition characteristics and impact in tread bearing part is 84.8%; however, when the wheel-load is transferred from flange to tread, the growth of the wear depth amplitude induced by transition characteristics and impact in flange bearing part is 29.7%, which is far less than that in the tread bearing part due to the lower irregularity magnitude and flange bearing mode. Wear will develop and accumulate at the location of the impact, exacerbating the impact, and extending and accelerating the wear on worn wheel profile [1]. As a result, it is necessary to recognize wear distribution on wheels in contact patch.

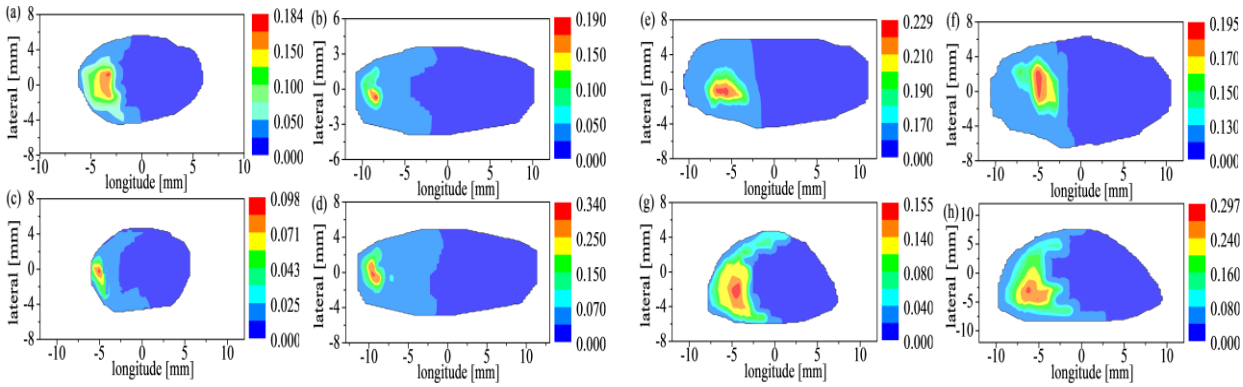

Figure-14 *Wheel wear depth in contact patch: (a), (d), (e) and (f) the wear depth located at the section A, C, D and F, (b) and (f) the wear depth located at the section B and E with the flange bearing, (c) and (g) the wear depth located at the section B and E with the tread bearing.*

The accumulated wear depths on the wheel are mainly located at the taping point and at the field side of tread as well as the flange top due to the complicated geometric wheel-rail contact relationship; therefore the influence of flange bearing frog crossing on wear depth development rate of wheel flange is relatively more dramatic. Accumulated tread wear depth mainly occurs around the taping point during the impact while the value of wear depth is lower than the flange contact regions due to the larger size of the tread contact area and lower contact radius difference. The degree of wear for flange is more severe than for tread due to the higher stress field effect combined with microslip, speeding up the degradation of the wheel. Therefore, the flange bearing frog crossing can evidently boost the wear development rate on wheel on top regions of flange.

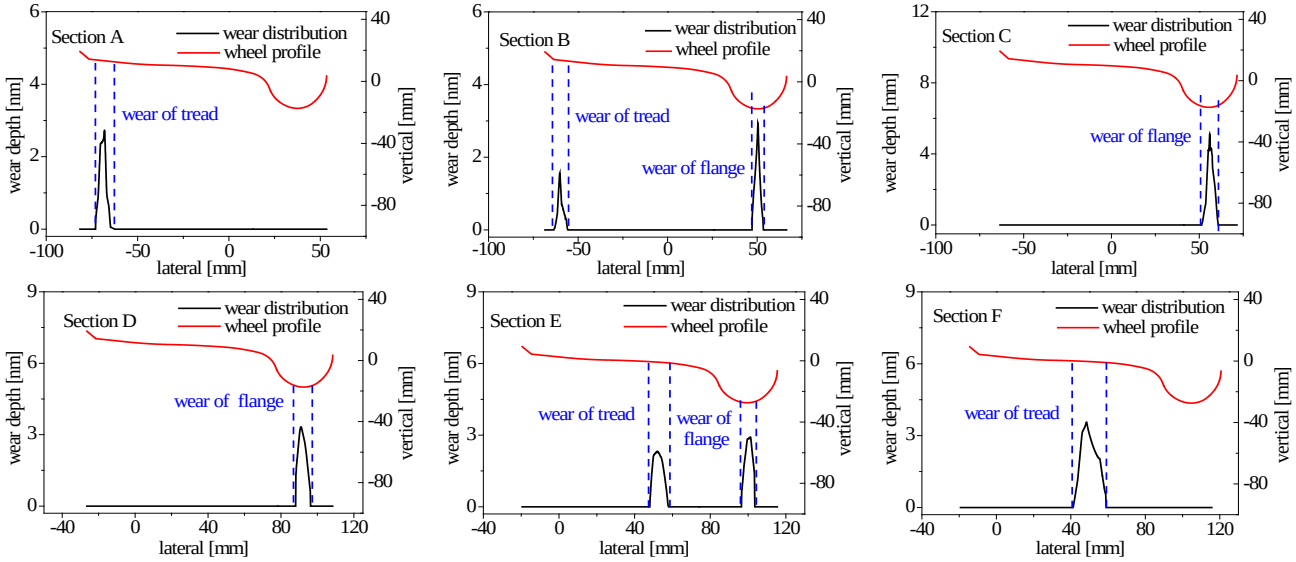

Figure-15 *Accumulated wheel wear depth for a single pass of typical cross section*

The magnitude and distribution characteristics of wear depth along wheel profile is shown as Figure-16, the flange and tread of wheel will contact with the frog rail at the same time within a certain distance, which range from 0.8m~0.9m and 2.84~2.88m respectively, the wheel-rail contact patch is focused on the flange top while the spatial coordination of tread contact patches are varying all the time. When the wheel-rail contact patches are located at tread bearing part during transition, the wear band will be transformed to the field side of wheel tread as the wheel moves forward, the wear induced by flange bearing is more severe in tread bearing part compared to that in flange bearing part during impact, the wear band located at surface of bearing flangeway is larger and narrower, and the maximum wear is 5.2nm located at flange top. The band of wear located at surface of wheel correspond to instants with the maximum wheel-rail normal pressure is the most

serious, due to the impact on flange and transition characteristics, together with the violent effects of wheel-rail vertical pressure exacerbated by smaller size of contact area on flange, the larger wheel-rail normal pressure will speed up the wear of flange top.

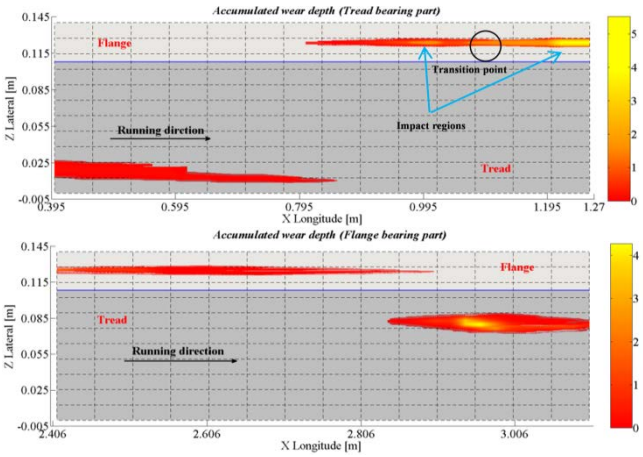

Figure-16 *Accumulated wear depth along wheel profile*

3.5 The simulation results of RCF damage during transition

As shown in Figure-17, the wheel RCF fatigue index under the interaction between tread and frog rail without impact or transition is small, the wheel is not likely liable to RCF damage; however the maximum RCF fatigue index in contact patch during transition is located at wheel flange top due to the effect of high microslip and impact vibration induced by structural irregularity. When the material is subject to the ratcheting effect in local regions of contact patch, such regions will be liable to low cycle fatigue. The material will lose its toughness and fail with the increase of tangential load in flange bearing regions, the RCF fatigue index in contact patches of wheel tread is 0.1 during the impact, which is less than that in flange bearing regions. The size of contact area accounting for surface rolling contact fatigue is relatively high, and which has a large area ratio of contact patches. The flange top in the weakest part is easily liable to RCF fatigue damage during the impact. The RCF fatigue failure of the flange top can evidently be boosted by the flange bearing frog crossing.

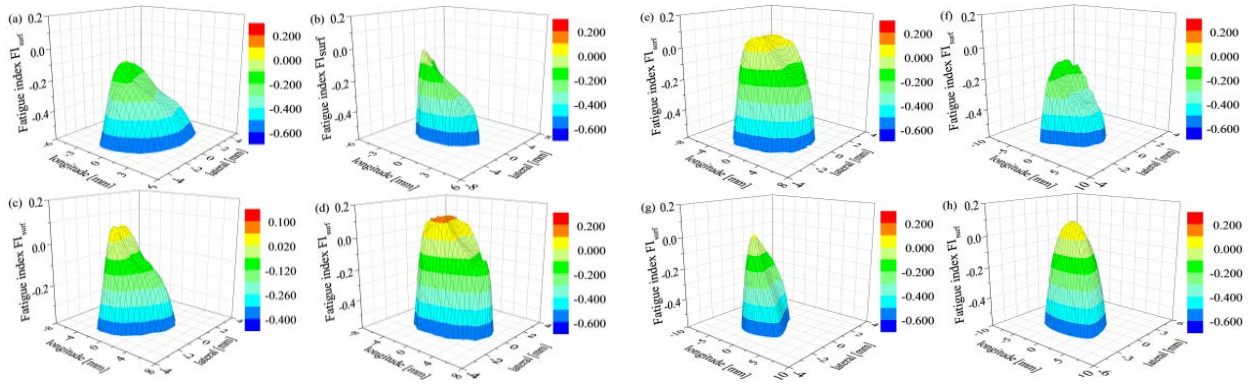

Figure-17 *Fatigue index in contact patch of wheel: (a), (d), (e) and (f) the fatigue index located at the section A, C, D and F, (b) and (f) the fatigue index located at the section B and E with the flange bearing, (c) and (g) the fatigue index located at the section B and E with the tread bearing.*

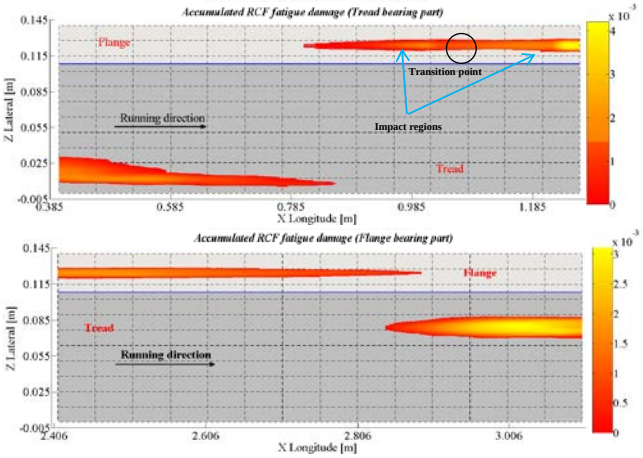

Figure-18 *Accumulated RCF fatigue damage along wheel profile*

The magnitude and distribution characterizes of RCF fatigue damage is shown as Fig-18 below: the RCF fatigue damage are mainly distributed in flange top and taping point as well as filed side of wheel, the maximum RCF fatigue damage is 0.0032. But relatively speaking, the maximum RCF fatigue damage of wheel is 0.005 which is mainly located at flange top, while the flange of wheel suffers from the RCF fatigue damage, therefore, due to the longer and narrower RCF fatigue damage band located on flange top, the internal crack initiation, crack propagation and final fracture of wheel will be induced by the shear stress exacerbated by impact, so flange top is the relatively fatigue damage regions of high risk. Due to the impact and height difference between mainline rail and flangeway, the band of RCF damage fatigue will be longer and narrower in the local impact regions with two relatively large values.

The band of RCF fatigue damage on wheel tread is relatively brighter compared to that of wear due to the competition of wear and RCF, the material of rail surface subjected to tangential stress exacerbated by impact and transition characteristics will speed up the wear development rate, the severe wear can remove the material suffered from RCF on surface of rail, and the development rate of RCF fatigue damage will be suppressed to some extent.

4. Conclusion

In this paper, the explicit finite element model, which considered wheel-rail flexibility deformation, transient contact behavior and local structure vibration, is used to analyze the influence of flange bearing frog crossing on wheel degradation, the results of simulation, including non-uniform wear, RCF damage and plastic deformation, indicate that:

There exists a special contact stage of flange solely bearing the wheel-load; in addition, the two-point contact resulting from flange close to rail under a certain lateral displacement may also occur. Therefore, the variation in rail profiles and complicated transition characteristics will result in a complex dynamic wheel-rail contact geometry relation along the frog, which leads to non-uniform distribution of wear, RCF damage and plastic deformation of wheel. The maximum wear depth is located around the edge of contact patches due to the tangential wheel-rail force. The longitudinal force quickly decreases to zero while the amplitude of the longitudinal force during impact is higher than that of the vertical force, the transition characteristics and frog irregularity can prominently strengthen the interaction between wheel and rail. Due to the smaller size of the contact area and larger contact radius difference as well as flange bearing mode during the impact, the wheel wear is relatively severe when the flange is solely bearing the wheel-load, the flange bearing frog crossing can speed up the wheel wear rate, especially on wheel flange top. The maximum RCF fatigue index in contact patches of flange top is located at ratcheting effect regions based on the shakedown theory. The material of the flange top will be subject to low cycle fatigue under ratcheting effect, therefore the flange bearing frog crossing can promote the initiation and propagation of RCF crack on the top regions of wheel flange.

The update of wheel profile and influence of worn profile on wheel-rail interaction have not been taken into account, and there is a need to improve simulation model to calculate the evolution of wheel profile in long-term service under cyclic rolling load in future work.

STUDY ON RAIL WEAR PREDICTION AND FRICTION CONTROL FOR HEAVY HAUL RAILWAY

Wang Pu*, Wang Shuguo, Li Wei, Si Daolin

Railway Engineering Research Institute, China Academy of Railway Sciences Corporation Limited, Beijing 100081

* E-mail: wpwp2012@yeah.net

Abstract: A rail wear prediction model is established based on vehicle-track coupling dynamics and material wear theory, and the corresponding calculating program is written. The influence of surface friction on wear distribution and development is studied. The results show that rail lubrication can significantly reduce the wear in tangent section. In curve section, when the outer rail is lubricated, the wear amplitude of outer rail reduces remarkably and that of inner rail tends to increase. When the inner rail is lubricated, the influence is just the opposite, but the wear changes are gradual. In actual operation, the friction of outer rail can be reduced properly, which can slow down the wear development of outer rail significantly and will not cause obvious wear aggravation of inner rail.

Keywords: Heavy haul railway; rail wear; numerical prediction; vehicle-track coupling dynamics; friction control.

1. Introduction

The phenomenon of rail wear exists extensively in China's heavy haul railway, which becomes a significant problem influencing the security and economy of heavy haul transportation. The rail wear is caused by the wheel-rail dynamic interaction, determined by the matching relationship of vehicle and track parameters. Meanwhile the wear is related to the operating conditions and material properties. There are a lot of influencing factors and the formation mechanism is complicated [1~3]. In order to prolong the service life of rail and reduce the work and cost of maintenance, it is necessary to study the mechanism and influencing factors of rail wear. The wear development is a long-term process. It will take a lot of time and manpower to study the effect of various factors on wear through systematic field experiments. In addition, it is impossible to adjust the parameters of the vehicle and the line frequently. Therefore, it is difficult to study the influencing factors and laws by field experiments. Establishing simulation model and conducting numerical experiment is the most feasible and effective method at present. But most of the simulation studies on the influencing factors of wear usually use wear power, wear index, etc. as the evaluation criteria [4~6], which can only qualitatively characterize the wear intensity and can't quantify the impact on the distribution and development of wear.

The wheel/rail lubrication is recognized as one of the important technical measures to solve the wear problem. In developed countries of heavy haul railway, such as North America, South Africa and Brazil, lubrication technology is widely used to extend the life of rail. China also invests a lot of manpower and material resources to undertake the wheel/rail lubrication work. However, the current researches are mainly carried out on lubricating equipment, materials, and coating methods. In fact, the lubrication improves the wheel-rail interaction and wear development by changing the friction coefficient of contact interface. Different changes of friction coefficient will have different effects on the wear. How to obtain the optimal adjustment scheme of wheel-rail friction coefficient and the precise control of friction coefficient by lubrication are yet to be further studied.

Aiming at the shortage of current researches, a rail wear prediction model is established and the corresponding calculation program is written, which can realize the quantitative prediction analysis of the distribution and development of wear. Then the influence of friction control on the distribution and development of rail wear is studied by numerical experiment. The research can provide theoretical basis for the simulation calculation and the optimization of wear reduction measures.

2. Vehicle-track coupling dynamics model

The prediction of the wear distribution and development is based on the vehicle-track coupling dynamics simulation and wheel-rail local contact analysis. Firstly, the coupling dynamics model of heavy haul vehicle and track is established.

The vehicle model is built based on the three-piece bogie freight car. Six degrees of freedom rigid body is used to simulate the vehicle body and bogie parts like bolster, side frame, axle box and wheelset. The contact friction interactions between vehicle body and center plate / side bearing, wedge and bolster / side frame, side frame and axle box are simulated by point-plane contact unit combination, and the actual clearances between the parts are fully considered. A bilinear stiffness-damping unit is used to simulate the central suspension spring.

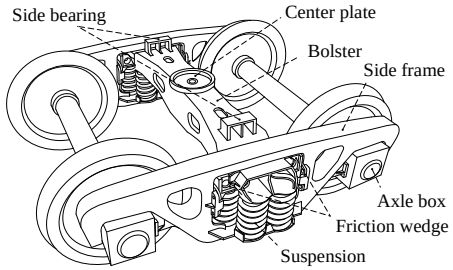

Figure 1 *Three-piece bogie.*

Wheel-rail contact is mainly calculated based on Hertz's contact theory [7] and Kalker's FASTSIM algorithm [8], mainly including the detection of contact point position, the calculation of overall contact mechanics indexes (contact force, creepage, etc.), and the calculation of local contact mechanics indexes in contact patch (distributions of contact stress, creeping stress, sliding velocity, etc.).

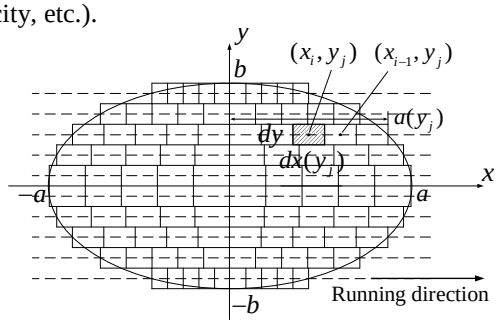

Figure 2 *Discretization of contact patch.*

The wheel-rail contact force is closely related to the lower track structure. So the model fully takes into account the elastic and damping characteristics of track, and the stiffness and damping parameters are based on measured data.

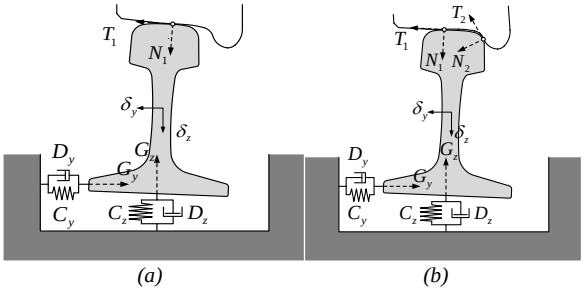

Figure 3 *Diagram of forces of rail model: (a) Single-point contact. (b) Two-point contact.*

3. Prediction model of distribution and development of rail wear

The wear depth distribution in wheel-rail contact patch is calculated based on the geometry feature of contact patch and the distributions of sliding and adhesion zones, normal contact stress and creeping velocity which are obtained through the dynamics and contact model. The meshing of contact patch is consistent with that in wheel-rail contact calculation, as shown in figure 2. For each dynamic integration step, the contact patch is divided into n_y strips along y axis, and then each strip is divided into n_x discrete rectangular elements. The size of each discrete element is calculated by the following formula.

$$\begin{cases} dx(y) = 2a\sqrt{1-(y/b)^2} \,/\, n_x \\ dy = 2b / n_y \end{cases} \tag{1}$$

where dy is the length of discrete rectangular element along y direction, $dx(y)$ is the length along x direction which is determined by the y-coordinate of the center of discrete element, a and b are respectively the semi-major axis and semi-minor axis.

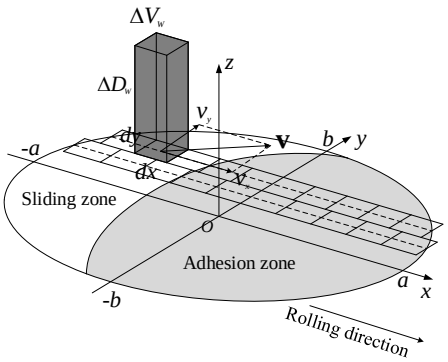

Figure 4 *Calculation model of rail wear distribution.*

For each discrete element of contact patch, the wear volume loss is calculated based on Archard's material wear theory [9], as shown in figure 4.

$$\Delta V_w(x,y) = k_w(x,y)\frac{p(x,y)\cdot dx(y)\cdot dy\cdot \Delta s(x,y)}{H} \tag{2}$$

where (x, y) is the position coordinate of the center of discrete element under the contact patch coordinate system, $\Delta V_w(x,y)$ is the wear volume loss on the discrete element, $\Delta s(x,y)$ is the wheel-rail relative sliding distance corresponding to the discrete element, $k_w(x,y)$ is the wear coefficient, $p(x,y)$ is the normal stress of the center of discrete element which is calculated by the following formula.

$$p(x,y) = \frac{3N}{2\pi ab}\sqrt{1-(\frac{x}{a})^2-(\frac{y}{b})^2} \tag{3}$$

where N is the total normal contact force on the contact patch.

The distribution of adhesion and sliding zones can be obtained in the process of wheel-rail local contact calculation. If the discrete element is located in the adhesion zone, the sliding distance $\Delta s(x,y) = 0$ and no wear occurs. If the discrete element is located in the sliding zone, $\Delta s(x,y)$ is calculated by the following formula.

$$\Delta s(x,y) = \frac{\left\|\mathbf{v}(x,y)\right\|\cdot dx(y)}{V_0} \tag{4}$$

where V_0 is the rolling speed of wheel, $\mathbf{v}(x,y)$ is the wheel-rail relative sliding speed on the discrete element which is calculated by the following formula.

$$\mathbf{v}(x,y) = \mathbf{v}_r(x,y) - \mathbf{v}_e(x,y) = \begin{bmatrix} \xi_x - \phi y \\ \xi_y + \phi x \end{bmatrix} \cdot V_0 - \begin{bmatrix} \dfrac{\partial u_x(x,y)}{\partial x} \\ \dfrac{\partial u_y(x,y)}{\partial x} \end{bmatrix} \cdot V_0 \quad (5)$$

where $\mathbf{v}_r(x,y)$ represents the sliding velocity component of rigid body, $\mathbf{v}_e(x,y)$ indicates the sliding velocity component of elastic deformation, ξ_x, ξ_y and ϕ are the longitudinal, transverse and spin creepages, $\mathbf{u}(x,y) = (u_x(x,y), u_y(x,y))$ is the elastic deformation displacement on the discrete element. Generally, the sliding component of elastic deformation $\mathbf{v}_e(x,y)$ is much smaller than that of rigid body $\mathbf{v}_r(x,y)$, so it is ignored in calculation.

Through the above calculation, the wear volume $\Delta V_w(x,y)$ on each discrete element in the contact patch can be obtained, and then the corresponding wear depth $\Delta D_w(x,y)$ can be obtained.

$$\Delta D_w(x,y) = \frac{\Delta V_w(x,y)}{dx(y) \cdot dy} \quad (6)$$

By adding the wear depth of discrete elements with the same y-coordinate, the wear depth of each longitudinal bar in the contact patch can be obtained, which is the distribution of wear depth along the wheel/rail profile.

For each integration step, the corresponding wear depth distribution along the wheel/rail profile (under the contact patch coordinate system) can be obtained through the above calculation. Then, the wear distribution is located to the rail profile coordinate system based on the position information of wheel-rail contact point. The physical meaning is the rail profile wear caused by the wheel passing through the current position. Then the wear distributions for every integration step are averaged, and the result's meaning is the caused rail profile wear depth distribution when the wheel passes one time. Through adding the results of the four wheels on the same side, the wear depth distribution of the corresponding rail for the vehicle passing one time can be obtained, which is defined as the rail wear rate c^r, as shown in figure 5. c^r is a function of the horizontal coordinate y^r of rail profile coordinate system.

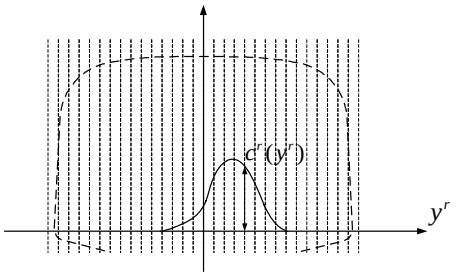

Figure 5 *Diagram of rail wear rate.*

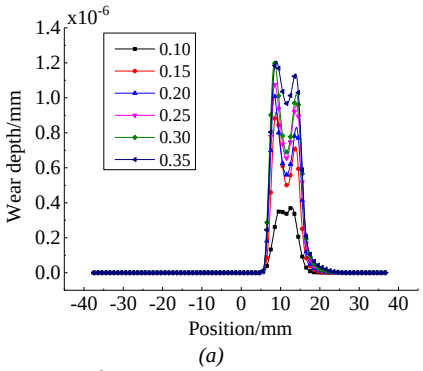
4. The influence of friction coefficient on the distribution and development of wear

The influences of friction coefficient changes of inner and outer rails on the rail wear are analyzed through numerical experiments respectively for tangent and curve sections, exploring the actual effects of different friction coefficient schemes. The purpose is to provide theoretical basis for the track friction control management of China's heavy haul railway.



4.1. Tangent section

Firstly, the influence of friction coefficient on the rail wear is analyzed under different axle loads in tangent section. Since the wheel-rail dynamic interaction and wear of the two rails are similar in tangent section, the friction coefficients of the two rails are set the same. The design of experiment conditions is shown in table 1. The parameters of C80 freight car are adopted for the heavy haul vehicle model, and the LM wheel profile and 75kg/m rail are used.

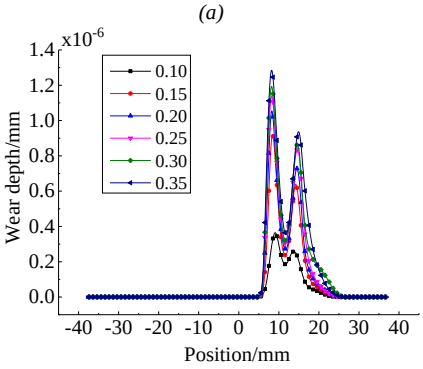


Table 1 *Experiment design in tangent section.*

Axle load	25t	30t
Friction coefficient	0.10	0.10
	0.15	0.15
	0.20	0.20
	0.25	0.25
	0.30	0.30
	0.35	0.35

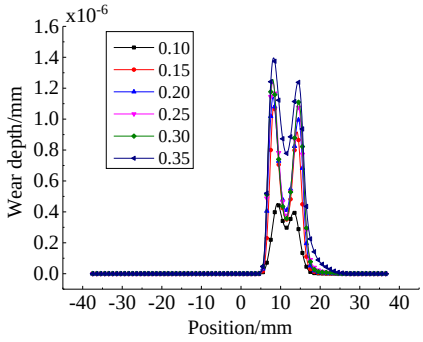

Figure 6 shows the calculation results of rail wear rate under different friction coefficients and different axle loads. That is the caused wear depth distribution along rail profile for unit carrying weight (100t). In order to show the influence of friction coefficient on rail wear loss more visually, the rail wear rate (wear depth distribution curve) is integrated on the position coordinate and the rail wear area loss rate can be obtained for different conditions, as shown in figure 7.

(d)

Figure 6 *Rail wear rate in tangent section: (a) Left rail, 25t axle load. (b) Right rail, 25t axle load. (c) Left rail, 30t axle load. (d) Right rail, 30t axle load.*

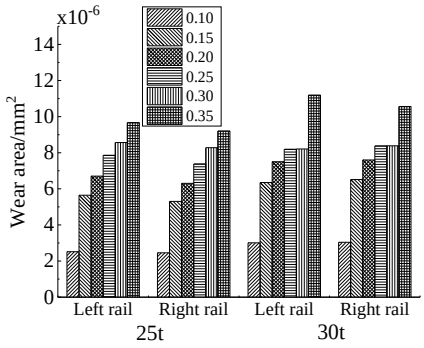

Figure 7 *Rail wear area loss in tangent section.*

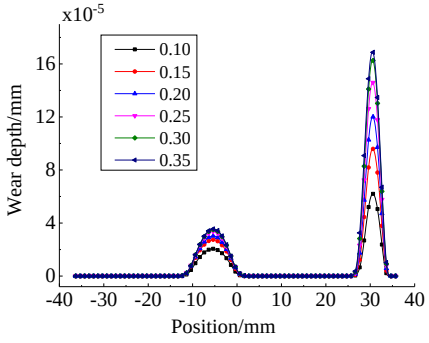
It can be seen that, with the decrease of wheel-rail friction coefficient, the distribution region of rail wear is basically unchanged, which is the section (5mm, 30mm) in the inner side of rail. The wear is distributed like a saddle, and the wear range and amplitude gradually decrease. When the friction coefficient decreases from 0.15 to 0.10, the wear reduction is especially significant. It can be seen more visually from figure 7 that, the decrease of friction coefficient can significantly reduce the rail wear loss under different axle loads. The reduction amplitude is up to 55.41% when the friction coefficient decreases from 0.15 to 0.10.



4.2. Curve section

In this part, the influence of friction coefficient on the rail wear is analyzed in curve section. Due to the influences of plane linetype, elevation of outer rail, track gauge widening and so on, there are some differences between the forces of inner rail and outer rail, and the wear developments are not the same, either. Therefore, different lubrication strategies can be adopted respectively for the inner and outer rails in the maintenance so as to minimize the wear. In the numerical experiments, the friction coefficients of inner rail and outer rail are set independently, and the influences of friction coefficients of inner and outer rails are explored respectively. The design of experiment conditions is shown in table 2. The vehicle speed is set to 60km/h. The curve radius is 400m, and the length of circular curve is 200m. The length of the front / back transition curve is 200mm, and the length of the front / back tangent section is 60m. The elevation of outer rail is 90mm, and the rail cant is 1/40.

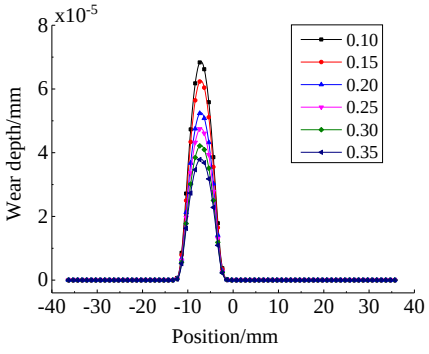


Table 2 *Experiment design in curved section.*

Influence of friction coefficient of outer rail		**Influence of friction coefficient of inner rail**	
Friction coefficient of outer rail	Friction coefficient of inner rail	Friction coefficient of outer rail	Friction coefficient of inner rail
0.10	0.25	0.25	0.10
0.15			0.15
0.20			0.20
0.25			0.25
0.30			0.30
0.35			0.35

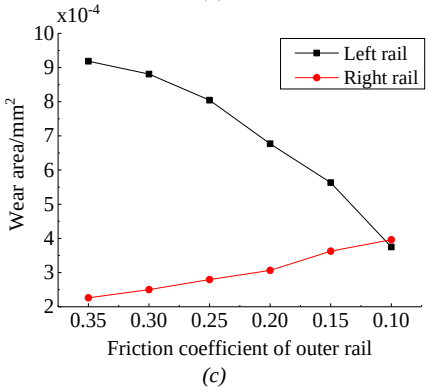

Figure 8 and 9 show the calculation results of rail wear rate and wear area loss under different friction coefficients of outer rail and inner rail.

(a)

(b)

(c)

Figure 8 *Influences of the friction coefficient of outer rail: (a) Wear*

rate of left/outer rail. (b) Wear rate of right/inner rail. (c) Wear area loss.

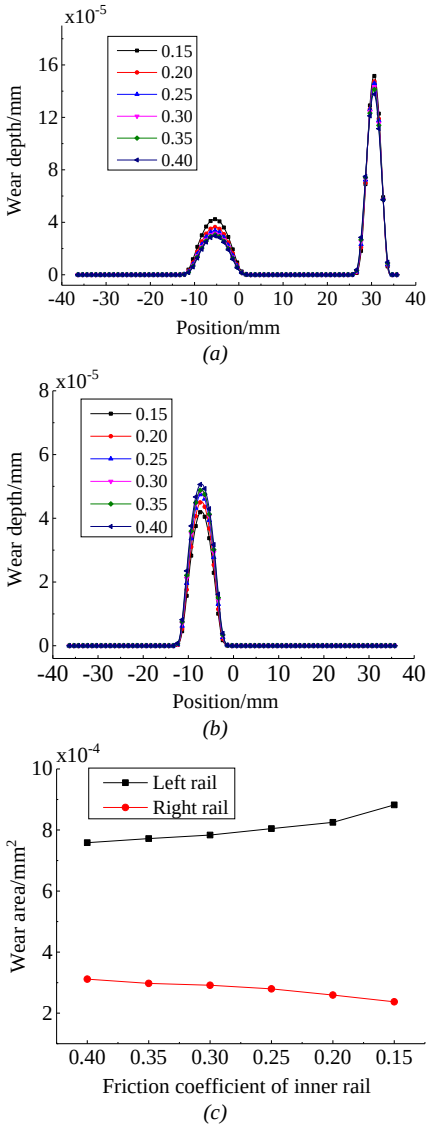

Figure 9 *Influences of the friction coefficient of inner rail: (a) Wear rate of left/outer rail. (b) Wear rate of right/inner rail. (c) Wear area loss.*

It can be seen that the changes of friction coefficients of the inner and outer rails have different influences on the wear in curve section. When the friction coefficient of inner rail is constant and that of outer rail changes from 0.35 to 0.10, the wear distribution ranges of the two rails remain unchanged and the wear shapes are also similar basically, but the wear amplitude of outer rail decreases significantly and that of inner rail tends to increase. It can also be seen from the figure of wear area loss that the wear reduction amplitude of outer rail is up to 59.19%, and the wear decreasing speed of outer rail is obviously greater than the wear increasing speed of inner rail.

When the friction coefficient of outer rail is constant and that of inner rail decreases from 0.40 to 0.15, the wear distribution ranges and shapes of the two rails are neither much affected, but the wear amplitude of outer rail gradually increases and that of inner rail decreases, which is exactly contrary to the influence of friction coefficient of outer rail. It can be seen from the figure of wear area loss that the wear increase amplitude of outer rail is 16.31%, and the wear reduction amplitude of inner rail is 23.85%. The wear changes of the two rails caused by the decrease of friction coefficient of inner rail are both gradual.

In actual operation, the wear of outer rail is usually more serious in curve section, so the lubrication of outer rail can be considered to reduce the friction coefficient properly, which can significantly slow down the wear development of outer rail and will not cause obvious increase of the wear of inner rail.

5. Conclusions

A prediction model of rail wear is established based on the vehicle-track coupling dynamics and material wear theory, which can realize the quantitative prediction analysis of the wear distribution and development. Then the influence of friction control on the distribution and development of rail wear is studied systematically. The main conclusions are as follows.

(1) In tangent section, the distribution region and shape of rail wear are basically unchanged after the lubrication. The wear range and amplitude gradually decrease.

(2) In curve section, the lubrication treatments of inner rail and outer rail have different effects on the wear. After the outer rail is lubricated, the wear distribution characteristics of the two rails remain unchanged, but the wear amplitude of outer rail reduces remarkably and that of inner rail tends to increase. The wear decreasing speed of outer rail is significantly larger than the wear increasing speed of inner rail. The influence of the lubrication of inner rail is the exact opposite, but the caused wear changes are gradual.

(3) In actual operation, the wear of outer rail tends to be more serious. The friction of outer rail can be reduced properly, which can significantly reduce the wear of outer rail and will not cause obvious increase of the wear of inner rail.

This work can provide theoretical basis and reference for the wear simulation calculation and the maintenance.

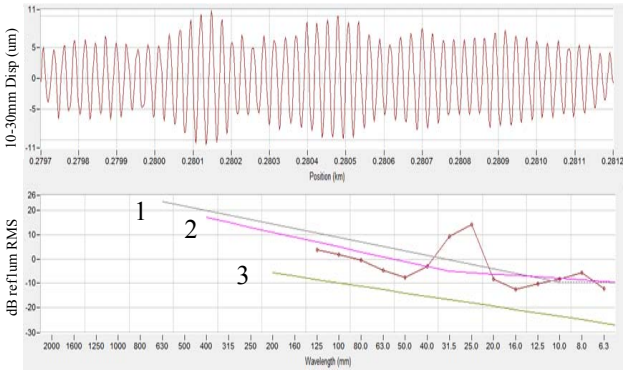
Abstract: Rail corrugation growth induced by standing wave between the wheels and resilient track is validated numerically. Combining wheel/track dynamics, rolling contact mechanics and wear, the formation process of rail corrugation under single and multiple wheel-rail interaction are simulated, basing on a slab track model. It is found that the standing wave-shaped profile of rail corrugation with a 2.5m wavelength that equals to the wheelbase is formed for multiple wheel-rail interaction, but it is not for single wheel-rail interaction. Therefore, the fast growth of rail corrugation mainly results from standing wave which is caused by deformation wave interference between the wheels.
Keywords: Rail corrugation; standing wave; wear; resilient track; wave interference

1. Introduction



Short pitch rail corrugation has been observed to produce clearly at some sections in Shanghai metro lines where high-elastic rail fasteners (about 10kN/mm)are used to isolate the vibration of track system to the infrastructure, see in **Figure 1**, but it mildly or seldom appear at the sections where high support stiffness fasteners (about 60kN/mm) are used. Because of its adverse influences, such as vibration, noise, frequent rail grinding and replacements, it is essential to establish the cause of this specific corrugation formation and explore solutions.

The growth process of rail corrugation is taken as a positive feedback loop and many factors, such as the dynamic behaviour of vehicle and track systems, the rolling contact mechanics and long-term wear, and the railway operation conditions etc., can influence it. Grassie[1] classified rail corrugation into six types by their characteristic and mechanisms. According to reference [1] the formation of short pitch rail corrugation or “roaring rails” is associated with the pinned-pinned resonance of rail vibration. At the pinned-pinned resonance the rail oscillates sinusoidally with a wavelength of twice the sleeper pitch and nodes above the sleepers[2]. However, pinned-pinned mode is weaker at the track using the high-elastic fasteners[2, 3]. In addition, this mode is related to the track's dynamic behaviour and can be suppressed by multi-wheel-rail interactions because of the wave reflections among the wheels[4]. This means that the short pitch rail corrugation at the resilient tracks has other formation mechanism.

As regards mechanism, so for, almost all works show that the various corrugations found are essentially caused by wheel-rail dynamic resonances, which are excited at certain frequencies rather than wavelength independent of vehicle speed. Grassie et al.[5] used a linear model to study the property of the wheel-rail interaction forces. Frederick[6] developed a method to assess the correlation between vertical and lateral train-track dynamic responses and wear. Based on the Fourier decomposition of the profile irregularities, Hempelmann[7] found that corrugations are a direct consequence of the resonance peaks of the dynamical components. In these works, the wheel-rail dynamic resonances all result from a single wheel-rail interaction model in which the effects on rail corrugation of the multiple wheel-rail interaction may be ignored due to using higher support stiffness rail fastener, e.g. 350kN/mm.

Figure 1 *Corrugation occurs at resilient track of a viaduct line in Shanghai*

By contrast, many researchers addressed the influences on corrugation formation of multiple wheels. Igeland[8] firstly developed a multiple wheel-rail model that is composed of track system and two wheels of one bogie and found that the wavelength of corrugation is related closely to the wheelbase, but the cause of corrugation was not clearly explained in detail. Manabe[9] investigated wavelength fixing mechanism of rail corrugation by using a simple model in which a pair of masses moves on an Euler-Bernoulli beam. While the following studies are based on a multiple wheels model that involve four wheels belonging two bogies of the adjacent cars on the rail. Wu and Thompson[4] studied the multi-wheel-rail interactions on four wheels of adjacent bogies and the active and passive force were defined. And the influences on contact force of different pad stiffness under multiple wheel/rail interaction were explored and the effects on short pitch corrugation of multiple wheel/rail interaction were briefly discussed in frequency domain[10]. Furthermore, the corrugation growth rate was calculated in the basis of the active force and it was found that corrugation is related to several resonances rather than a specific one [11]. Wu and Wang[12] studied the growth and suppression of short pitch rail corrugation, in which the active force was believed to be responsible for short pitch corrugation and standing wave only was mentioned but not demonstrated. Fang and Wang et al. [13] proposed that the wave reflection from the wheels on the rail is responsible for the short pitch rail corrugation at resilient tracks of metros and explored the corresponding mitigation measure. However，in five latter papers three important factors were ignored in their model: one of which is that the wheel is moving, although the wheel velocity is far smaller than the phase velocity of the bending wave in the rail. Secondly, the passive force that is the effect on one wheel of bending wave excited by the other wheels was ignored. Thirdly, since the frequency-domain model used to predict the dynamics of wheels and track is linear, it is confined to exploration of the initiation of corrugation growth and low roughness amplitude input, and the time-varying evolution process of rail corrugation cannot be obtained from it. Therefore, the results mentioned above need to be further improved, and the formation mechanisms of rail corrugation are still unclear or elusive under the multiple wheel-rail interaction at resilient track.

In order to gain a clear understanding of the cause of short pitch corrugation at resilient track, these factors essential are considered by author. In the present paper, short pitch rail corrugation induced the standing wave between the wheels is verified numerically by combining wheel/track dynamics, rolling contact and wear in the time domain. At first, the multi-wheel-rail interaction due to the standing wave between multiple wheels is investigated using a time-domain slab track model in the basis of the frequency-domain analysis, coupled with four mass wheels belonged two bogies of the adjacent cars. Secondly, the rolling contact and wear between the wheel and rail are simply analysed according to Hertz theory. And then the growth of short pitch rail corrugation are simulated to form a positive feedback loop with and without reflections. It is found that short pitch rail corrugation will occur at multiple resonance frequencies of the active force, especially where the active forces for wheel 1 and 2 are peaked simultaneously. It indicates that the prediction on the short pitch rail corrugation of the active force is believable. At the resilient track, however, the fast growth of short pitch rail corrugation mainly results from the standing wave between the wheels which is caused by a combination of the active and passive force, namely the deformation wave interference between the wheels.

In the paper described here, only the vertical interactions between the wheels and track are involved. Since the pinned-pinned resonance is weak at the slab track using the high-elastic rail fasteners and multiple wheel-rail interactions also suppress the formation of the pinned-pinned resonance owing to the wave reflection of rail vibration between the wheels[2-4], the continuously supported track model is used due to its simplicity and high efficiency in calculation.

2. Multi-wheel-rail interaction at resilient slab track

In this section a continuously supported slab track model, coupled with four wheels of the adjacent bogies, is developed for the time-domain simulation of the multi-wheel-rail interaction related to wave reflections among wheels.

2.1. Modeling of track-wheels

Figure 2 depictures the theoretical model of the continuously supported slab track-wheels system for vertical vibration. As symmetry only half a track is considered in the model. The rail is modeled as a finite Euler-Bernoulli beam on a continuous elastic foundation. The stiffness of non-ballasted bed is much larger than the high compliance rail fasteners, therefore it is treated to be a rigid body. The high compliance rail fasteners are modeled by continuous spring. The parameters for the CHN 60 rail are

$$E = 2.1\times10^{11}\ \mathrm{N/m^2}, \rho = 7850\mathrm{kg/m^3}, A = 7.745\times10^{-3}\ \mathrm{m^2},$$

$$I = 32.17\times10^{-6}\ \mathrm{m^4}, \eta_r = 0.01$$

where E is the Young's modulus, ρ the density, η_r the loss factor of the rail, A the cross-sectional area, I the area moment of inertia. The parameters for the continuous support are

$$k_p = 16M\mathrm{N/m^2}, \eta_p = 0.2$$

where k_p is the rail fastener stiffness, η_p the loss factor of the rail fastener.

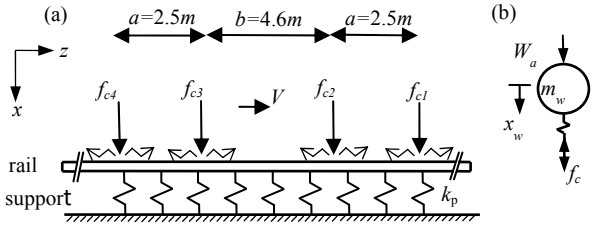

Figure 2 *Continuously supported slab track-wheels model:(a)track model. (b) wheel-rail interaction model*

Four moving wheels belonging to two bogies of the adjacent cars are involved. Since the wave interference of rail vibration is the strongest among the four wheels of the adjacent bogies, the effects of other wheels far away from these four wheels may be ignored due to decay of wave propagation [4].The mass of the wheel is chosen to be 750kg. The vehicle is simplified to a static load W_a acting on the wheels and it is chosen as W_a=80 kN. These four wheels is spaced at intervals of a =2.5m and b=4.6m and move along the rail with a constant velocity. The wheel-rail contact forces for wheel 1,2,3 and 4 are represented by f_{c1},f_{c2},f_{c3} and f_{c4}, respectively. The contact spring between the wheel and the rail is treated as a non-linear Hertzian stiffness.

Some points must be taken account of in the modelling. In order to approximate an infinite long track, the rail model should be long enough to be able to attenuate the propagating wave reflected from the ends. In addition, if the rail is long enough, the boundary conditions of the beam will not influence the wheel-rail interaction in the mid-section of the beam, as the rail deflection at the ends almost vanishes, whatever the beam is fixed or simply supported. Accordingly, the rail length here is chosen to be 84 m and the middle section of it are used to investigate the multi-wheel-rail interaction.

In the continuously supported slab track system the vertical vibration of the rail excited by four moving wheels is governed by

$$\rho A\frac{\partial^2 x_r}{\partial t^2}+EI\frac{\partial^4 x_r}{\partial t^4}+k_p x_r=\sum_{k=1}^{N_k} f_{ck}\delta\left(z-z_{wk}\right),\quad k=1,2,\ldots,N_k \tag{1}$$

where x_r represents the displacement of the rail. N_k represents the number of the wheel involved in the model and it is chosen as N_k=4. k_p represents the support stiffness of elastic layer. f_{ck} represents the excitation force to the rail at the position z_{wk} from the dynamic interaction of the kth wheels and the rail. δ is the Dirac delta function.

The equations of motion of the mass wheel are given by

$$m_w\ddot{x}_{wk}=W_a-f_{ck} \tag{2}$$

Where m_w represents the mass of the wheel. x_{wk} represents the displacement of the kth wheel. f_{ck} is the wheel-rail contact force to the rail at the kth wheel and is calculated by

$$f_{ck}=\begin{cases}C_H\left[x_{wk}-x_r\left(z_{wk}\right)-r\right]^{3/2}, & x_{wk}-x_r\left(z_{wk}\right)-r>0\\ 0, & x_{wk}-x_r\left(z_{wk}\right)-r\le 0\end{cases} \tag{3}$$

where C_H represents the Hertzian constant, taken as C_H=93.7GN/m$^{3/2}$. r represents the initial roughness or corrugation on the rail and it is positive for sinking and negative for rough as a sign convention. Here, the wheel/rail interaction model, Eq. (3), is non-linear, nevertheless the track model and the wheel model, Eqs. (1)-(3), are linear. To solve the response of the wheel and rail, the modal analysis method is applied to the calculation of rail response, see in Appendix A, and then combined with the corresponding results, the wheel/rail interaction force are calculated numerically in the basis of the forth-order-Runge-Kutta method.

2.2. Behavior of multi-wheel-rail interactions

The dynamic behaviors of the multiple wheels/track coupling system are investigated basing on the model developed in **Figure 2**. The active wheel/rail interaction forces are presented in **Figure 3** for a unit harmonic force excited at wheel 1 and 2, respectively(As symmetry, the active force for wheel 1 and 2 are given here.). It can been observed from **Figure 3** that many resonance peaks are generated in 100~1k Hz. Since the wheel 2 suffers wave reflections from the front and rear part, more peaks occur in the active force curve for it than that for wheel 1. There are no resonance peaks in the single wheel-rail force, which means that these peaks result from the wave interference among multiple wheels. Short pitch corrugation is believed to be associated with these force peaks of the active forces. And because the passive wheel-rail forces are generated by the roughness at different places, whose phases are assumed to be uncorrelated[11], and thus they are not considered to have net effects on the formation of corrugation and is ignored[12], the active force is expected to be responsible for the rail corrugation. Some analyses of corrugation growth and the field observation therefore are needed to verify further the effect on short pitch rail corrugation of the active force.

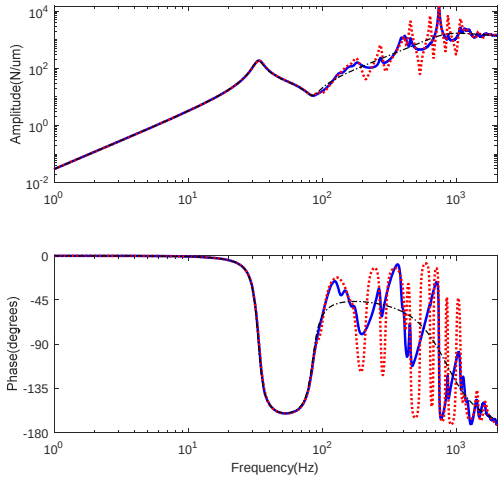

Figure 3 *Active wheel-rail interaction forces:(_____)excitation at wheel 1, (- - - - - -)excitation at wheel 2. (– . – . –) Single wheel-rail interaction.*

According to the model in **Figure 2**, the time-domain simulations of the multi-wheel-rail interaction are carried out by using Eqs. (1)-(3). Because initial roughness with small amplitude has less effect on corrugation growth, initial roughness is generated by 400 harmonics with random phase and the average amplitude of 2 um and wavelengths included are evenly distributed in 13~180mm[14]. **Figure 4** shows the results of the multi-wheel-rail interaction at resilient slab track. The train velocity V is 20m/s. The distances 0m, 2.5m, 5m and 7.5m in **Figure 4** correspond to the positions of two wheels belonging a bogie on the rail. The results are shown in terms of the wheel/rail interaction force for wheel 1 and 2 in both the time series and the frequency spectrum. From the time series in **Figure 4** the wheel/rail interaction force for wheel 1 and 2 can be observed to be fluctuating cyclically with a period of d /V, in which the

length of wheelbase between wheel 1 and 2 d is 2.5m. The reason for this is that when the soft rail fastener is used at slab track, standing wave is formed in the rail due to deformation wave interference between the wheels. This type of standing wave is formed before the passage of the wheel and the moving wheels are excited by it because the phase velocity of bending wave in the rail is much larger than wheel velocity. Standing wave therefore lead to large fluctuations in the wheel-rail interaction force, resulting in uneven wear and rail corrugation. At wheel speed 20m/s the corresponding frequency of occurrence is 8Hz, so that the contact force for wheel 1 and 2 is peaked mildly near this frequency, respectively, see in **Figure 4**. In addition, in the wheel/rail interaction force spectrum the resonance peak at about 33.6Hz is mainly related with the wheel receptance, while those in 100~1kHz for wheel 1 and 2 are produced by the excitation on wheels of standing wave in the rail. Therefore, compared **Figure 4** with **Figure 3**, the active force for wheel 1 and 2 don't match the wheel/rail interaction forces from the time-domain simulation only at about 8Hz, respectively. This is because the passive force is ignored and the wheel is assumed to be static in the moving roughness model. Since especially in 100~1kHz, the active force for wheel 1 and 2 agree with the time-domain simulations of the multi-wheel-rail interaction, respectively, the prediction on the short pitch rail corrugation of the active force seem to be believable. However, the short pitch rail corrugation mainly results from the standing wave which is caused by deformation wave interference between the wheels and is the joint consequence of the active and passive force.

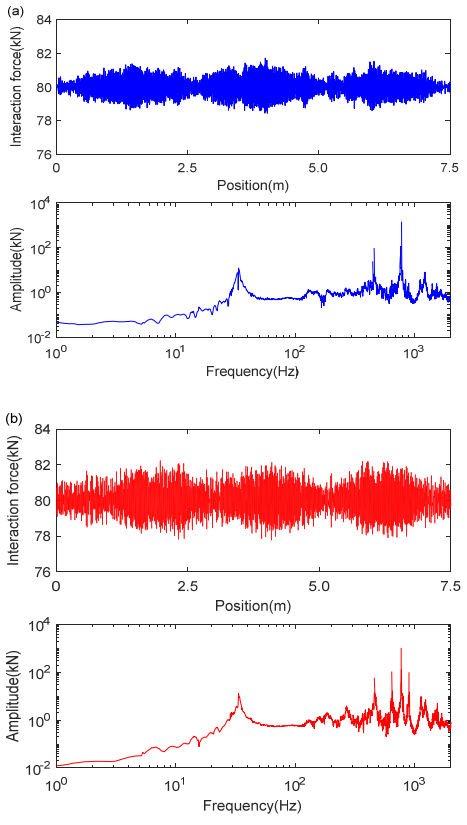

Figure 4 *Multi-wheel-rail interaction forces in time series and the frequency spectrum: (a) for wheel 1; (b) for wheel 2, wheel velocity V=20m/s, the length of wheelbase between wheel 1 and 2 d=2.5 m*

3. Rolling contact mechanics and wear

The rail corrugation is the result of combined action from the dynamic wheel-rail interaction, rolling contact and a long-term wear.The tangential contact between the wheel and rail is modelled using the two-dimensional contact model, in which cylindrical wheel is assumed to roll on the rough rail with a constant speed and a constant contact patch width. In this model, the contact mechanics is assumed to be steady at each micro step along the rail except the longitudinal slip velocity.The time-varying normal contact force and geometry and the terms produced by them are involved in the slip velocity.

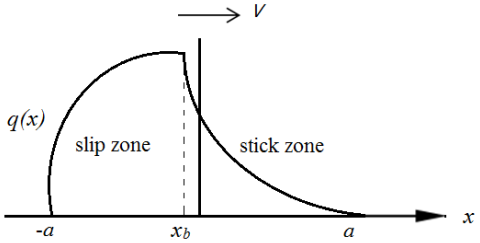

Figure 5 *Assumed longitudinal traction distribution.*

It is assumed that the wheel and rail deform as elastic half-spaces when they are in rolling contact and thus Hertz theory holds. The longitudinal slip region caused by traction can be distinguished from the stick region within the contact patch formed at each micro step. According to Carter, as also used by Grassie and Johnson[15] and Nielsen[16], and the longitudinal traction distribution is illustrated in **Figure 5**, where at a constant wheel speed V, the centre of contact patch is shifted approximately with the moving wheel as a new contact patch is generated at each tiny step.

In the slip zone the traction $q(x,t)$is equal to the vertical normal pressure $p(x, t)$ times the friction coefficient μ=0.3 and is given by

$$q(x,t) = \mu p(x,t) \tag{4}$$

where the integration of the traction $q(x,t)$ over the contact patch is equal to the total longitudinal traction Q=15 kN. The vertical wheel-rail contact force $f_c(t)$can be calculated as a time history using the multiple wheel-rail interaction model shown in **Figure 2** and at each position of the moving wheel the vertical nomal pressure $p(x,t)$ is dimermined by this force $f_c(t)$ which is calculated by an equation[14]. In addition, in **Figure 5** half the contact patch length a and the boundary of the stick and slip zones x_b are all determined by $f_c(t)$, and the formulas of calculating them are referred to [14] .

The slip velocity $v(x,t)$ for unsteady rolling contact without spin is given by:

$$v(x,t) = V\left[\xi + \frac{\partial u(x,t)}{\partial x} - \frac{\partial u(x,t)}{\partial t}\right] \tag{5}$$

where V is the wheel speed, ξ is the longitudinal creepage and it is calculated in the steady contact without spin[14]; the other two terms are caused by time-varying contact force $f_c(t)$and geometry in the unsteady rolling contact, in which $u(x,t)$ represents the relative displacement between the wheel and rail and partial differential terms result from the unsteady rolling contact The corresponding formula is referred to [11].

Wear is generated only in slip zone and assumed to be proportional to the frictional work. In the local coordinate of the contact patch as described in **Figure 4**, the local wear in each tiny time step Δt can be solved by

$$W_t(x) = Kq(x,t)v(x,t)\Delta t \tag{6}$$

where K is a material related constant and chosen to be 2.5×10^9 kg/Nm[17].

As a result, the local wear depth $\Delta r_t(l)$ in the slip zone of the local coordinate is obtained by

$$\Delta r_t(l) = \frac{W_t(x)}{\rho} \tag{7}$$

where ρ is the material density of the rail.

4. Scheme of corrugation development

The vibration wave reflections between multiple moving wheels and resilient track can modify the wheel-rail interaction, contact conditions and wear and thereby the profile of the rail corrugation. And the active and passive force both are included in wheel/rail interaction and rail corrugation. However, since the passive wheel-rail forces are regarded as in random phase and are not considered to have net effects on the growth of rail corrugation, the active wheel-rail force is believed to be responsible for the rail corrugation due to the multi-wheel-rail interaction[12]. To address this possibility and improve the understanding of the cause of short pitch rail corrugation, the formation process of rail corrugation need to be investigated under the multi-wheel-rail interaction. Based on the causes of the active and passive wheel-rail forces [4], the schemes of corrugation development are presented in **Figure 6** to simulate the corresponding formation processes of rail corrugation. **Figure 6** (a) and (b) shows the development scheme of rail corrugation caused by wheel 1 and 2 under the roughness excitation, respectively, in which one of wheels interacts with the rough rail, the others merely play a role in reflecting vibration wave form and keep interacting with an absolutely smooth rail. For comparison the corresponding scheme for the single wheel under the roughness excitation is given in **Figure 6** (c). In addition, **Figure 6** (d) shows the case in practice in which the growth process of rail corrugation is produced under the multiple wheel-rail interaction and the active and passive force both are involved due to the roughness excitation on each wheel. In addition, in this case multiple wheels may simultaneously produce wear at corresponding positions and the successive wheels are influenced by the new roughness caused by the previous wheel.

Based on the schemes illustrated in **Figure 6**, the formation process of rail corrugation are simulated after a large number passages of wheels in time domain. Calculations are performed in uniform time step during the rolling contact of the wheel and rail. According to the friction work the local wear is obtained in slip zone by Eq.(7). The total wear, namely the vertical corrugation along the length of the rail, is an accumulation process of local material removal in slip zone of contact patch at each time step.

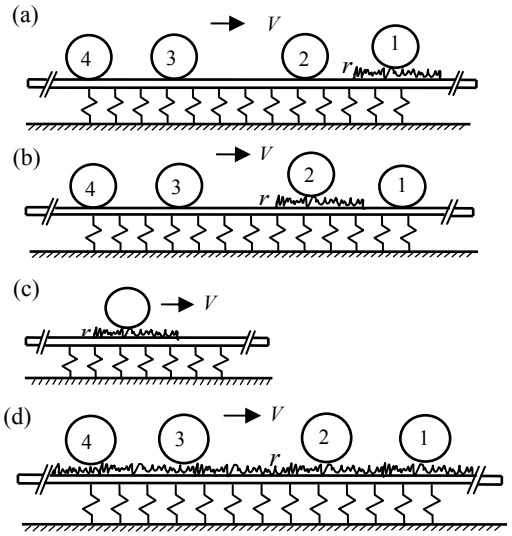

Figure 6 *Scheme of corrugation development: (a) for wheel 1 suffered one side of wave reflection; (b) for wheel 2 suffered two sides of wave reflections; (c) single wheel/rail interaction without wave reflections; (d) four wheels/rail interactions. r represents the roughness on the railhead.*

After one passage for a wheel, the global wear depth $\Delta r(l)$ can be obtained by the accumulation of each local wear depth $\Delta r_t(l)$ according to the position of each wheel on the rail. To save the calculation time, the global wear depth $\Delta r(l)$ is magnified an integer N=1000 times. One passage of a wheel therefore amount to the effect of 1000 wheel passages on corrugation growth[14, 17-19], while as for the case in **Figure 6** (d), one loop iterate is equivalent to 4000 wheel passages. A new corrugated profile $r_n(l)$ after one passage of a wheel is obtained by

$$r_n(l) = r_{n-1}(l) + N\Delta r_n(l) \qquad n = 1,2,\ldots\ldots \tag{8}$$

where the old roughness profile $r_{n-1}(l)$ on the rail is used as the roughness input to the wheel-rail interaction in the nth calculation loop.

The rail length considered for the profile development is 84 m. To neglect the effects from the ends, the middle section of the corrugated rail is used for the investigation of rail corrugation. Corrugation growth is simulated for a Chinese A-type metro vehicle interacting with the track consisting of CHN60 rail. The cylindrical wheel of radius is R_w= 420mm.

5. Numerical results and discussion

To examine corrugation growth due to the standing wave between moving wheels, the formation processes of corrugation are simulated under excitations of the harmonic and broadband roughness, respectively, in this section.

5.1. Harmonic roughness excitation

The processes of corrugation growth are investigated using the harmonic roughness excitation at four frequency points for wheel 1 and 2, respectively. These frequency points correspond to four resonance peaks, namely 870, 769, 625 and 454 Hz in active force for wheel 2 and 1, see in **Figure 3**. By this means, the predictions on short pitch rail corrugation of the active force based on the linear, frequency-domain model can be validated at resilient track and the uneven wear due to

wave reflection can be examined. This is useful for the explanation of the corrugation growth with multiple wavelengths at resilient track.

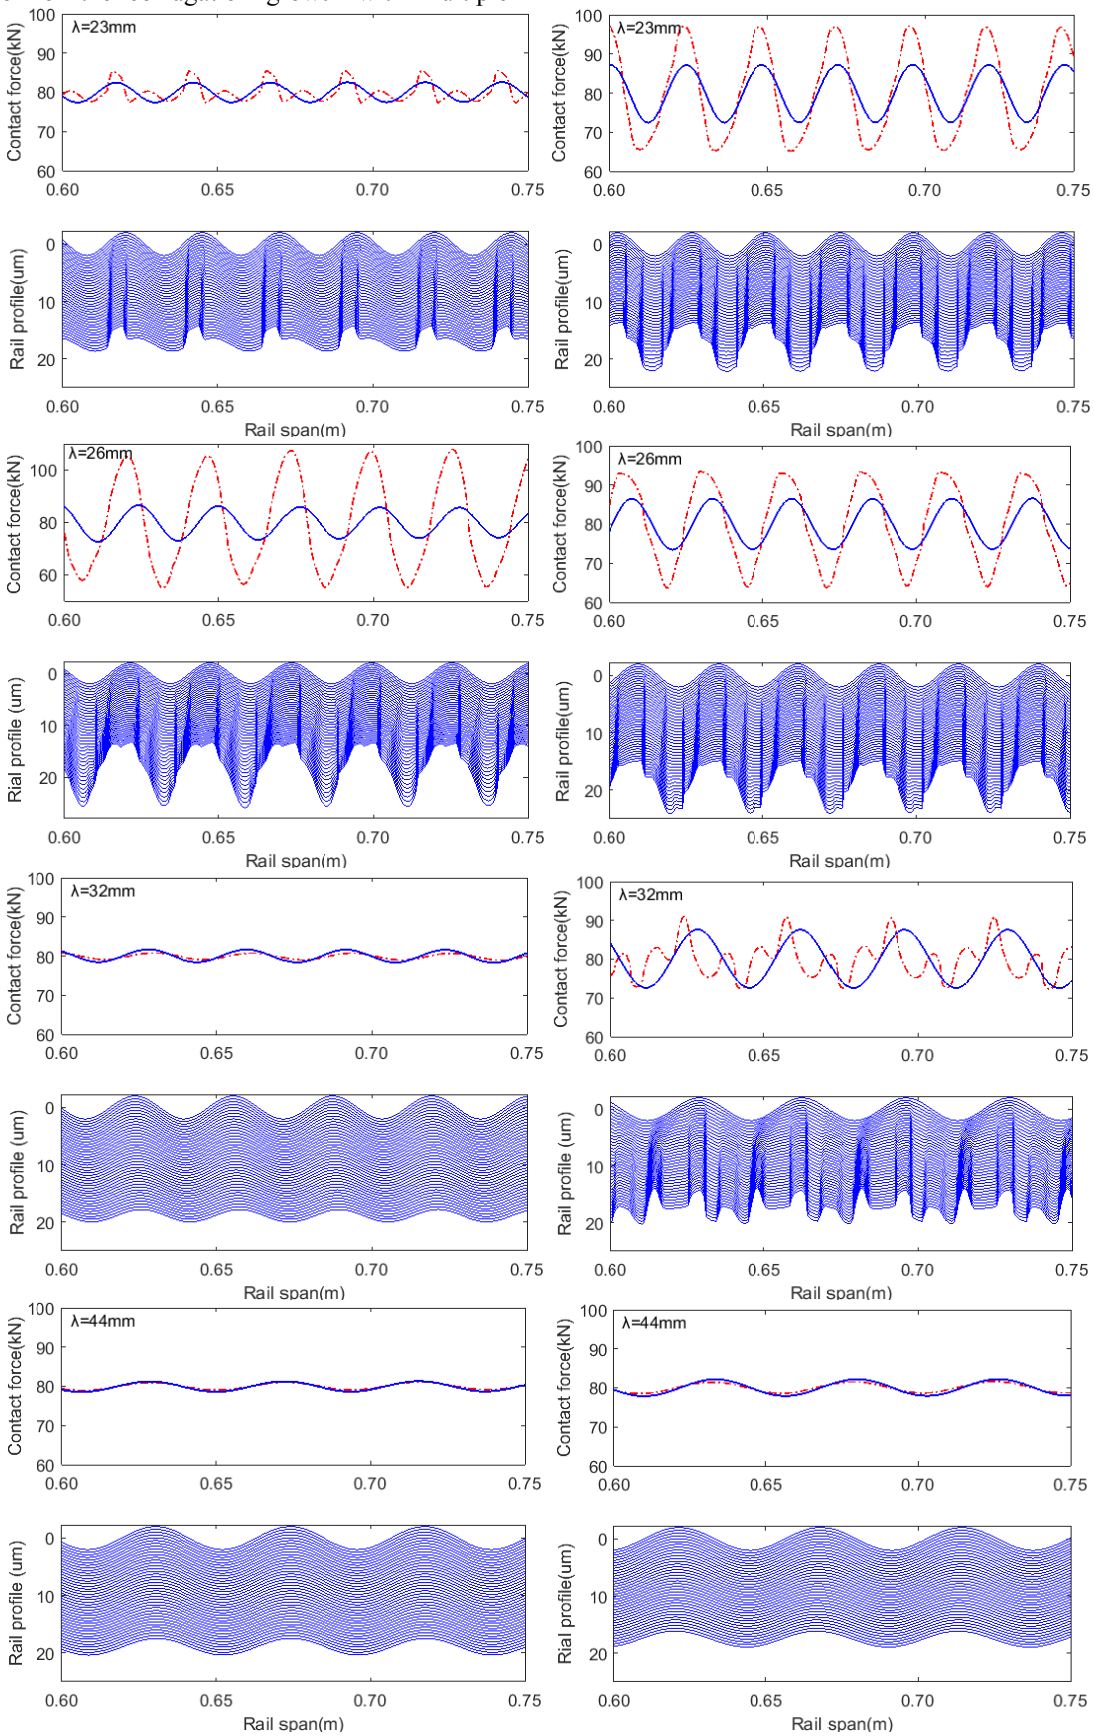

Figure 7 *Contact force and evolution process of rail corrugation with harmonic roughness excitation for wheel 1 (left column) and wheel 2 (right column) at velocity 20m/s, after 80,000 passages of wheel. The wavelengths of harmonic roughness excitation, λ, is 23mm, 26mm, 32mm and 44mm, respectively. (———)(bold)Contact force at beginning, (– · – · –)Contact force after 80,000 passages of wheel. Profiles are shown after every 2,000 wheel passages.*

Since wheel 1 receives wave reflection from the rear part of it, while wheel 2 suffers wave reflections from the front part and the rear part, basing on the schemes in **Figure 6** (a) and (b), rail corrugations caused by wheel 1 and 2 under wave reflections are simulated with the harmonic roughness inputs considered, respectively. **Figure 7** shows contact force and growth process of rail corrugation under the harmonic roughness excitation for wheel 1 (left column) and wheel 2 (right column)after 80,000 passages of wheel. The corresponding wavelengths of harmonic roughness excitation are 23mm, 26mm, 32mm and 44mm, respectively. With respect to 23mm wavelength excitation, corrugation from wheel 1 can be seen to contain many components of short wavelengths and is not developed almost, whereas that from wheel 2 grows rapidly and forms the fixing wavelength. The reason for this is that the resonance peak at 625Hz is formed in the active force for wheel 2 which suffer wave reflections from two sides, but for wheel 1 it is not. Note that under 26mm wavelength excitation, corrugation from wheel 1 and 2 both grow quickly and all have a fixing wavelength. This is because the active force for wheel 1 and 2 both have a resonance peak at about 759Hz and the corresponding amplitude is highest. Initial corrugation of 32mm wavelength is flattened by wheel 1, while that is grinded up by wheel 2. With the initial corrugation of 44mm wavelength, rail corrugation produced by wheel 1 and 2 both are developed slowly. These are because the amplitude of dynamic contact force is low and the shorter wavelength components grow more rapidly. Consequently, the larger dynamic force has the capacity to expedite corrugation growth and corrugation growth is more rapidly at shorter wavelength. Compared with **Figure 3**, corrugation simulation are matching to the resonance peaks of active force for wheel 1 and 2, respectively, although the non-linear contact stiffness is considered here. In addition, rail corrugation will potentially appear at frequencies where the dynamic active forces for wheel 1 and wheel 2 are peaked simultaneously.

5.2. Broadband random roughness excitation

Harmonic roughness at resonance frequencies heretofore has been taken in consideration. In fact, the initial roughness consists of irregularity on contacting surfaces of the wheel and rail and has broadband spectra on a range of wavelengths. In addition, because the non-linear rolling contact is taken into consideration in the contact model, the moving roughness model in the frequency domain doesn't apply. To further verify the growth of short pitch rail corrugation and the effect on it of active force, a broadband roughness is used as the initial profile input for the time-domain simulation of corrugation growth. And it is generated by 400 harmonics with random phase and the average amplitude of 2 um and wavelengths included are evenly distributed in 13~180mm[14]. At velocity 20m/s this broadband roughness may lead to the wheel-rail interaction in about 100~1500 Hz.

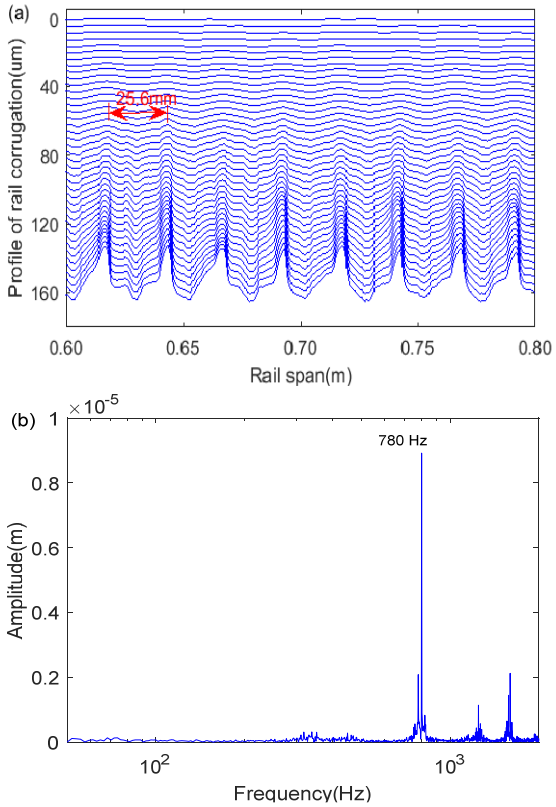

Figure 8 *Rail corrugation formed by wheel 1 under wave reflections after 200,000 passages of wheel. Profiles are shown after every 5,000 wheel passages. (a)Growth process of rail corrugation; (b) Frequency spectrum of the corrugation profile.*

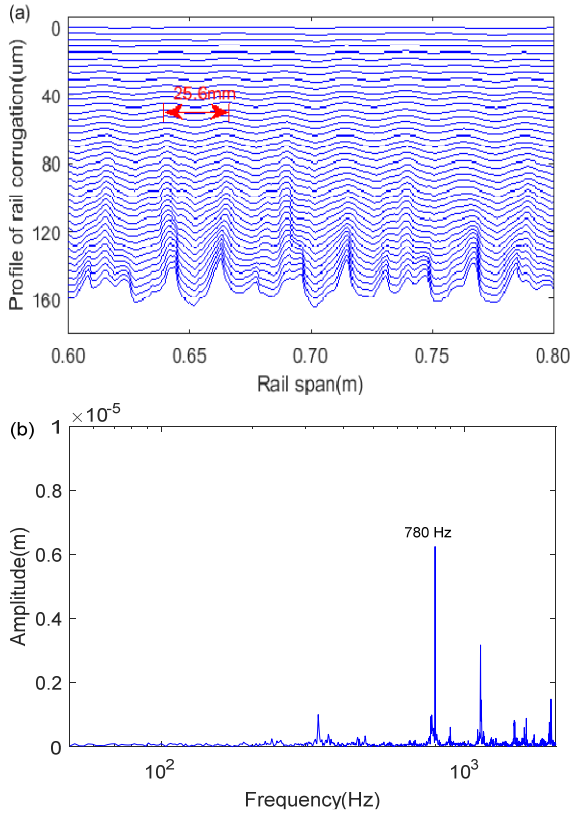

Figure 9 *Rail corrugation formed by wheel 2 under wave reflections after 200,000 passages of wheel. Profiles are shown after every 5,000 wheel passages. (a)Growth process of rail corrugation; (b)Frequency spectrum of the corrugation profile.*

Under the broadband roughness excitation considered, corrugation caused by wheel 1 and 2 under wave

reflection are investigated, respectively. Numerical simulations are performed still basing on the scheme, see in **Figure 6** (a) and (b). The results from wheel 1 and 2 are presented in **Figure 8** and **Figure 9**, respectively, in terms of the growth process of rail corrugation and the frequency spectrum of rail profile after 200,000 passages of wheel. From **Figure 8** (a) rail corrugation with a 25.6mm wavelength can be seen to be formed by wheel 1 under wave reflection. And short wavelength components are overlapped on it, which correspond to components above 1kHz and result from the resonance of the wheel/rail contact spring. From **Figure 8** (b) rail corrugation at 780 Hz can be seen to grow fastest, which just corresponds to the 25.6mm wavelength component at velocity 20m/s and agree with the highest peak in active force. At about 300 Hz and 400Hz, by contrast, corrugation grows slowly. Consequently, corrugation growth is more rapid under the larger interaction force and short pitch rail corrugation caused by wheel 1 occur at multiple frequencies where the active force for wheel 1 are peaked. As for wheel 2, short pitch rail corrugation with multiple wavelengths are developed by it suffering wave reflections, see in **Figure 9** (a). The 25.6mm wavelength component occurs firstly. After 100,000 passages of wheel, corrugation of 25.6mm wavelength become irregular gradually and many longer and shorter wavelength components are evolved from corrugation of 25.6mm wavelength. It can be seen from **Figure 9** (b) that corrugation growth at 780Hz (25.6mm) is slower than that from wheel 1, while those at about 300Hz and above 1000Hz grow faster than those by wheel 1, respectively. This is because wheel 2 suffers wave reflections from the front part and the rear part of it so that the dynamic contact force at wheel 2 is fluctuated more drastically and thus the uneven wear are scattered in multiple frequencies(wavelengths). Accordingly, short pitch rail corrugation caused by wheel 2 are associated with multiple frequencies which also is approximately in accordance with the resonance peak of the active force for wheel 2. On the basis of the above results, the prediction on short pitch rail corrugation of the active force seem to be believable at resilient track.

Although the simulation results produced by wheel 1 and 2 basically coinside with the active force based on the moving roughness model, the passive force is involved by implication. In practice, the active and passive interaction force both are involved in the wheel-rail interaction and in the corrugation formation at same time. In addition, under multiple wheel-rail interaction multiple wheels may simultaneously cause wear at corresponding positions and the successive wheels are influenced by the new roughness caused by the previous wheel. Therefore, the growth process of rail corrugation caused by four wheels belonging two bogies of adjacent cars after a sufficient passages of wheels, based on the scheme in Fig 4 (d), are simulated with the broadband roughness considered, which is the case in practice. The results are presented in **Figure 10** in terms of formation process of rail corrugation and spectrum of the corrugation profile.

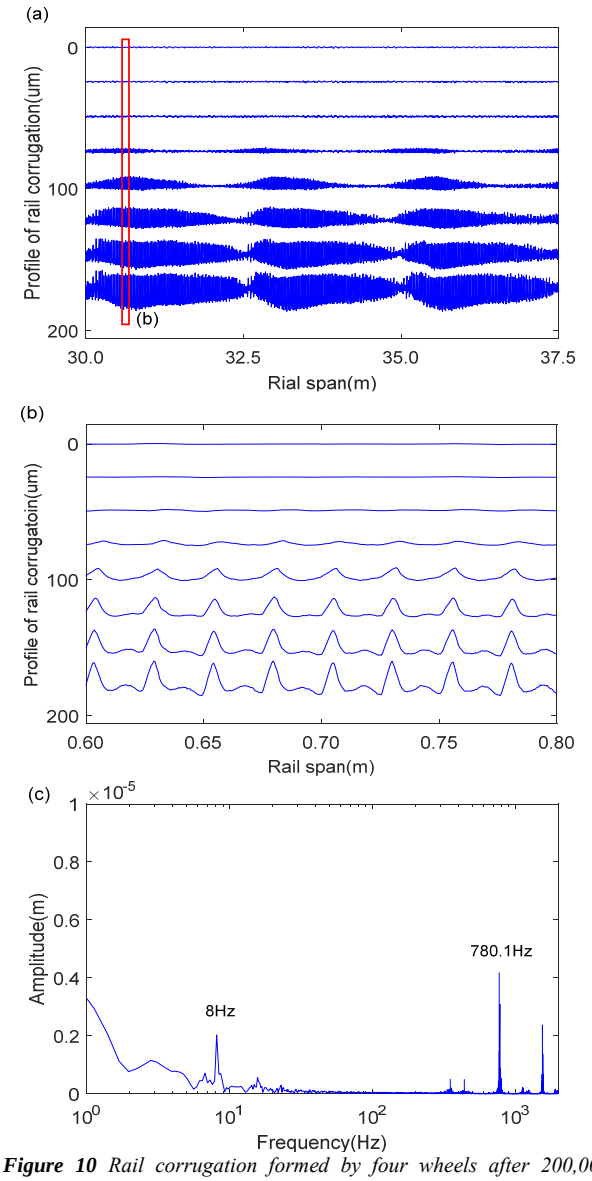

Figure 10 *Rail corrugation formed by four wheels after 200,000 passages of wheel. Profiles are shown after every 30,000 wheel passages. (a) Macro profile of rail corrugation; (b) Micro profile of rail corrugation; (c) Frequency spectrum of the corrugation profile.*

From **Figure 10** (a) the standing wave-shaped profile of rail corrugation with a 2.5m wavelength can be seen to be formed under the multiple wheel-rail interaction, which correspond to the frequencies 8Hz at wheel velocity 20m/s. The reason for this is that rail fastener stiffness is low, e.g. about 16 MN/m^2, so that standing wave with a 2.5m wavelength is produced in the rail due to the reflection at the wheel 1 and 2. Because the bending wave velocity in the rail is far larger than the wheel speed, this type of standing wave is formed before the passage of the wheels and occurs periodically with the moving wheels. It is this type of standing wave that leads to large fluctuation in the wheel-rail interaction force and thus short pitch rail corrugation. In addition, as standing wave between the moving wheels with a wheelbase of 2.5m is caused earlier than that with a wheelbase of 4.6m, corrugation profile with a 2.5m wavelength appear firstly.

Obviously, this longer wavelength component is inconsistent with the resonance peak of the active force for wheel 1 and 2. The main reason is that the passive interaction force is included in the wheel/rail interaction and wear besides of the active force and the wheel/rail parameter excitation caused by moving wheels at bogie-passing frequency is not considered in the moving roughness model.

Figure 10 (b) shows the micro profile of rail corrugation at resilient track. It can be seen From **Figure 10** (b) that a shorter component with 25.6mm wavelength is overlapped on the longer component to grow simultaneously, which correspond to the frequency 780.1Hz at velocity 20m/s. Corrugation at 780.1Hz grow more rapidly than those at about 300 and 400 Hz, see in **Figure 10** (c). This is because rail corrugation is heavier at shorter wavelength and proportional to the amplitude of the dynamic contact force. With the increasing passages of the wheels it is possible that corrugation growth is shifted gradually to a longer wavelength. Compared **Figure 10** (c) with **Figure 3**, therefore, the prediction on the short pitch rail corrugation of active force is believable in 100~1kHz, especially at the frequencies where the active forces for wheel 1 and 2 is peaked simultaneously. However, the rapid growth of short pitch rail corrugation mainly results from standing wave between the wheels which is caused by a combination of the active and passive force at the resilient track, namely deformation wave interference between the wheels.

Between the single and multiple wheel-rail interaction the biggest difference is deformation wave interference from other wheels. For comparison, single wheel-rail interaction is taken account of. The corresponding growth process of rail corrugation, according to the scheme in **Figure 6** (c), is presented in **Figure 11** under the broadband roughness excitation considered. It can be observed from **Figure 11** (a) that the standing wave-shaped profile of rail corrugation with 2.5m wavelength disappear under single wheel-rail interaction. The main reason is the absence of deformation wave interference from other wheels. From **Figure 11** (b) and (c) rail corrugation can be seen to still grows at 780Hz, but it is slow, compared with **Figure 11.** The reason for this is that although there is no the deformation wave interference from other wheels, unilateral deformation wave also can be caused by single wheel itself. this type of deformation can also lead to the variation of contact geometry between the wheel and rail and thereby uneven wear. Moreover, below 1000Hz rail corrugation can be seen to occur only at 780Hz after 200,000 passages of wheel. This still is related with the absence of deformation wave interference from other wheels. For the same reason there is no peak at the contact force curve under single wheel-rail interaction, but an inflection point appears at around 780Hz, see in **Figure 3.** Accordingly, it can be concluded that the standing wave caused by deformation wave interference between the wheels accelerate corrugation growth and promote it to be related with multiple frequencies.

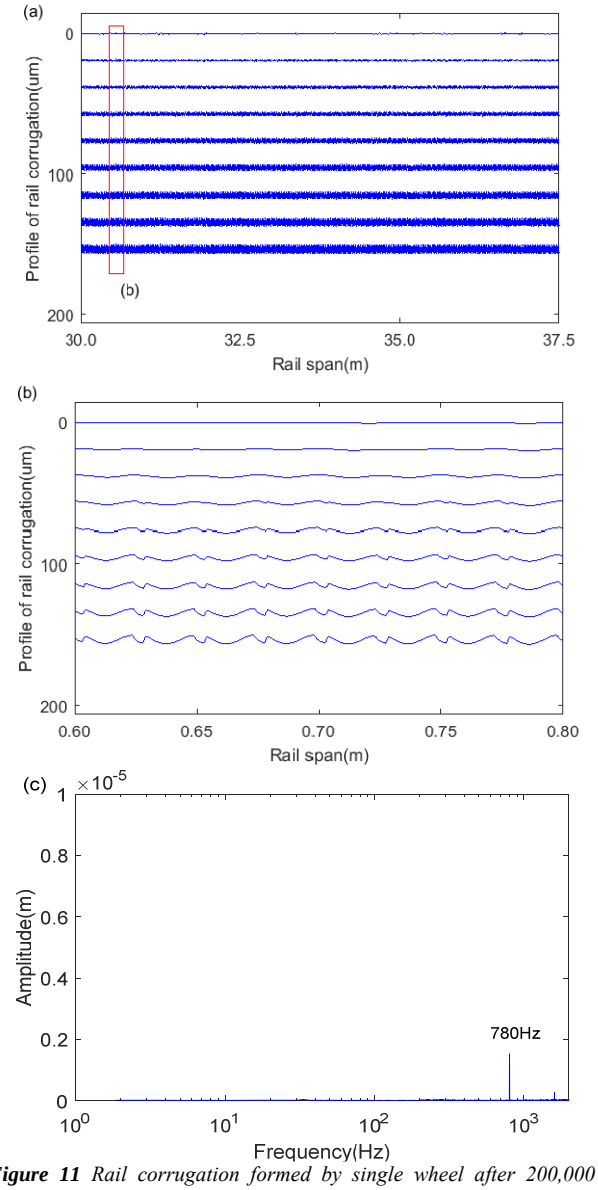

Figure 11 *Rail corrugation formed by single wheel after 200,000 passages of wheel. Profiles are shown after every 30,000 wheel passages. (a) Macro profile of rail corrugation; (b) Micro profile of rail corrugation; (c) Frequency spectrum of the corrugation profile*

6. Conclusions

The active force caused by the roughness excitation is believed to be responsible for short pitch rail corrugation, while the passive force produced by the roughness at different places is ignored in the formation of corrugation due to the phases assumed to be uncorrelated. In practice, however, the active and passive force both are included in the multi-wheel-rail interaction and the corrugation formation. To demonstrate it, a time-domain model is developed to represent a continuously supported slab track. The multi-wheel-rail interaction due to the standing wave between multiple wheels is investigated using a time-domain slab track model in the basis of the frequency-domain analysis, coupled with four mass wheels belonged two bogies of the adjacent cars. The growth of short pitch rail corrugation are investigated for different cases with and without standing wave by

combining the wheel-track dynamics, rolling contact and long-time wear.

Because the phase velocity of wave in the rail is far larger than the wheel velocity and the rail fastener is soft, the standing wave between wheels is produced in the rail due to reflections at wheels and periodically occur with the moving wheels. Under its excitation the contact force fluctuate periodically with a 2.5m wavelength, while the components in 100~1kHz have a higher level and are consistent with those in active force. The simulation of corrugation formation for difference cases show that in 100~1kHz, short pitch rail corrugation occur at multiple resonance frequencies of the corresponding active force, especially where the active forces for wheel 1 and 2 are peaked simultaneously. It means that the prediction on the short pitch rail corrugation of the active force is believable. it is also found that the standing wave-shaped profile of rail corrugation with a 2.5m wavelength is formed under multiple wheel-rail interaction, but it is not for single wheel-rail interaction. And The shorter wavelength component is overlapped on standing wave-shaped profile to grow more rapidly and with the increasing wear it is possibly shifted to a longer wavelength. Accordingly, rail corrugation growth is associated with multiple wavelengths under multiple wheel-rail interaction at resilient track. While the standing wave-shaped profile disappear under single wheel-rail interaction, and rail corrugation slowly grow at single frequency due to unilateral deformation wave caused by single wheel itself. Therefore, at resilient track, the rapid growth of short pitch rail corrugation mainly results from the excitation of standing wave which is caused by a combination of the active and passive force, namely the deformation wave interference between the wheels. According to the cause for rail corrugation growth outlined above, adjusting the intervals between the wheels or the number of the wheels may prevent standing wave and thereby mitigate rail corrugation growth, but they are not studied in this work.

Appendix A

The rail response is calculated by using the modal analysis method. The sum of the response in each mode is to work out the rail vibration response, given by

$$x_r(z,t)=\sum_{m=1}^{M}X_m(z)q_m(t) \tag{9}$$

where $X_m(z)$ is the mode-shape function and is obtained by

$$X_m(z)=\sqrt{\frac{2}{\rho AL}}\sin(\frac{m\pi z}{L}) \tag{10}$$

Replacing $x_r(z,t)$ with Eq.(9) in Eq.(1), multiplying both sides of the Eq. (1) by $X_n(z)$, integrating over the rail length L and taking advantage of the orthogonality

$$\int_0^L \rho AX_m(z)X_n(z)dz=\begin{cases}1, & m=n\\ 0, & m\neq n\end{cases} \tag{11}$$

brings about the disappearance of the Dirac delta functions and Eq.(1) turns into

$$\ddot{q}_n+\frac{EI}{\rho A}(\frac{n\pi}{L})^4q_n+\frac{1}{\rho A}k_pq_n =\sum_{k=1}^{N_k}f_{ck}X_n(z_{wk}),\quad n=1,2\ldots\ldots M \tag{12}$$

Combined with Eq. (2) and Eq. (3), Eq. (12) may be solved numerically basing on the forth order Runge-Kutta method. After the numerical solutions to the generalized coordinates $q_n(t)$ are obtained, the rail response can be calculated by Eq. (9). The number of modes for the summation is chosen to be 500 for a credible solution of the rail response.

Abstract: In this paper, the acceptance of wheel-rail contact nonlinearity with respect to hunting stability for railway vehicles is studied. The field measurement of wheel profile was introduced to give insight into the evolution law in the long-term operations. The vehicle system dynamic model is developed to study the influence of wheel-rail nonlinearity on the hunting stability. It is found that wheel-rail contact conicity with the negative slop is of great effect on the bogie hunting stability. To properly maintain the wheel and rail profiles can improve the bogie hunting stability.
Keywords: Wheel-rail contact nonlinearity; hunting stability; dynamic model; field test.

1. Introduction

The hunting stability is an important issue for vehicle systems that determines the maximum operating speeds of the vehicles on tracks. For the Chinese high speed trains, it is occasionally found that some high speed vehicles appear hunting motions in the particular locations of the track after a certain operating mileages due to the wheel and rail profile wear which causes the lateral acceleration alarm of the bogie and abnormal vibrations of the carbody. But the hunting motions can vanish after re-profiling the wheel or grinding the rail head, which means that the stability behavior is improved by modifying the wheel/rail contact relations. Since the hunting stability will affect the comfort and safe operation of the train, high attentions have been paid by researchers to extensively study this important issue theoretically and experimentally in recently years [1-5]. The vehicle hunting stability can be improved by the better combination of wheel and rail profiles or even under worn conditions. The equivalent conicity of wheel/rail contact is an important parameter that can be taken to evaluate the vehicle hunting stability.

The occurrence of hunting motions is of great influence on the ride comfort and running safety of railway vehicles. Matsudaria [6] showed that hunting motion is one of self-excited vibration by the experiments on the scaled roller rig. Wichens [7] took the gravity stiffness of the wheelset into consideration to discuss the bogie stability problem and pointed that creep forces and wheel conicity are the main indicator of hunting instability. True [8] adopted continuation-based bifurcation analysis to investigate various aspects of the nonlinearity for railway vehicles. Schupp [9] linked up this method with the software SIMPACK, a general simulation package for multi-body system dynamics. Zeng [10] used QR algorithm to calculate the eigenvalues of the system Jacobian matrix, in the neighborhood of which the shooting method is applied to determine the limit cycle of the nonlinear vehicle system. The matlab numerical continuation packages (MATCONT) for the bifurcation analysis of dynamical systems started in 2000 and the first publications appeared in 2003 [11]. In order to study the hunting behavior on tangent or curved tracks, a mathematical model with particular emphasis on the wheel-rail contact was developed by Bruni [12]. The work of Polach [13-14] showed that the form of bifurcation, subcritical or supercritical, was mainly influenced by the nonlinearity of wheel-rail contact geometry. A new parameter called nonlinearity parameter was proposed in reference [4]. This parameter as well as the equivalent conicity is of great influence on the form of bifurcation diagram and the vehicle behaviour.

In this paper, the acceptance of wheel-rail contact nonlinearity with respect to hunting stability for railway vehicles is studied. The field measurement of wheel profile was introduced to give insight into the evolution law in the long-term operations. The vehicle system dynamic model is developed to study the influence of wheel-rail nonlinearity on the hunting stability.

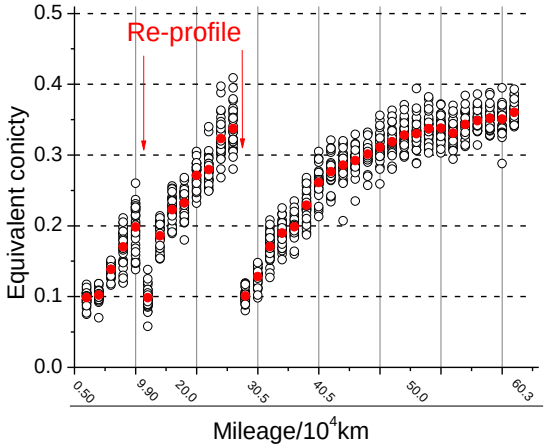
2. Evaluation of wheel-rail contact nonlinearity by filed measurement

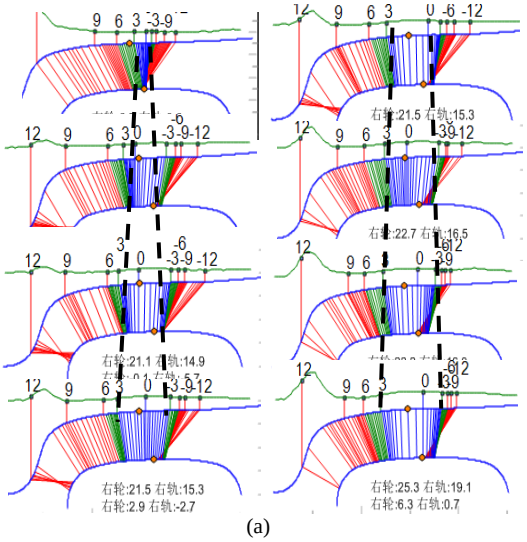
The equivalent conicity is traditionally used to assess the wheel/rail contact geometry for railway vehicles. However, the equivalent conicity as a linearised parameter does not present the nonlinear characteristics of the wheel/rail contact geometry. The former researches in Europe showed that the bogie hunting stability is of great relevance to the wheel-rail contact nonlinearity [3,4]. The so called “nonlinearity parameter” has recently been proposed with the aim to extend the commonly used characterization of wheel/rail contact geometry by one equivalent conicity value. Besides, the contact bandwidth is proposed to represent the nonlinear characteristic of wheel-rail contact [5]. In this paper, the evaluation of wheel-rail contact nonlinearity by field measurement of a high speed train in China is presented, see Figure 1. In general, the indices of wheel-rail contact nonlinearity consists of :

- Nonlinear parameter of conicity(NP) [4],
- Contact bandwidth [5],
- Contact angle.

The field measurement of wheel profile was carried

out to give insight into the evolution law in the long-term operations. As show in Figure 1, the wheel-rail contact equivalent conicity was calculated based on the measured wheel profiles in three re-profile periods. Herein, the new rail profile was adopt to calculate the wheel-rail contact relations. It is seen the equivalent conicity increase gradually with the increasing operation mileage. Obviously, to re-profile the wheels can decrease to equivalent conicity. The effect of wheel-rail contact conicity on hunting stability will be discussed in the following section.





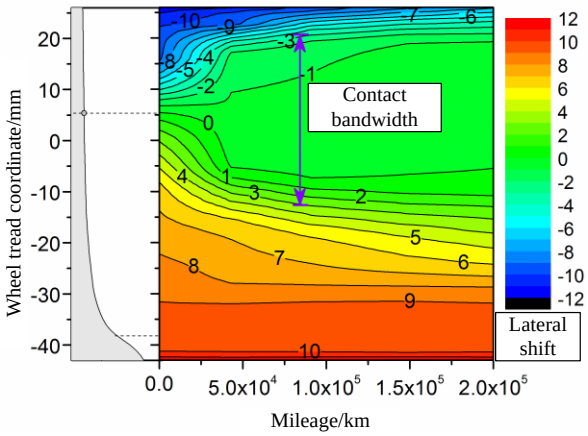


Figure 1 *Evaluation of equivalent conicity based on filed measurement.*

Besides, the distribution of wheel-rail contact points at different operation mileage of a whole re-profile period is given in Figure 2(a). A concentrated distribution of wheel-rail contact points can be observed at the new wheel profile with a lateral shift of ±3mm. However, the distribution of wheel-rail contact points will become more and more distributed with the increasing mileage. Thus, a new parameter, i.e. contact bandwidth, was introduced to quantitatively present this phenomenon [5]. The evaluation of contact bandwidth based on filed measurement is shown in Figure 2(b). It is seen the contact bandwidth increases gradually with the running mileage. However, both the contact conicity and bandwidth change synchronously due to the wheel and rail wear. That means it is impossible to study the effect of either of the two factors on hunting stability.

3. Dynamic modelling

In this section, the numerical simulations are conducted to give insight into the occurring mechanism and consequent effects of the carbody elastic vibrations due to bogie hunting instability. The scheme of the vehicle system is illustrated in Figure 3(a). In the multi rigid body model, the vehicle is consisted of four conventional wheelsets, two pairs of bogie frame and one carbody with six accessory devices under the frame. For the vehicle system, each bogie frame and under-frame equipment has six independent degrees of freedom (DoF) which allows free movements or rotations with respect to the lateral, vertical and longitudinal direction, respectively. The vertical and roll motion of the wheel set are dependent on the lateral and yaw motion, so the wheelset has four independent and two dependent DoF. In all, 64 independent degrees of freedom of rigid motions in this model are considered.

In the vehicle dynamic model, the nonlinearity of the suspension system is of great influence on the vehicle hunting stability. While the yaw damper is one of the most important component to avoid unstable hunting oscillations of high speed vehicles, which connects the bogie frame with the carbody longitudinally. Thus, the actual characteristic of the yaw damper is fully considered in this paper, see Figure 3(b). The Maxwell model is suitable to be adopted in simulations. Besides, the wheel-rail contact nonlinearity is also of great effect on both the bifurcation form and the critical speed. In the next section of this paper, the investigation of wheel-rail contact nonlinearity and its subsequent effect on the vehicle dynamics will be specially presented.

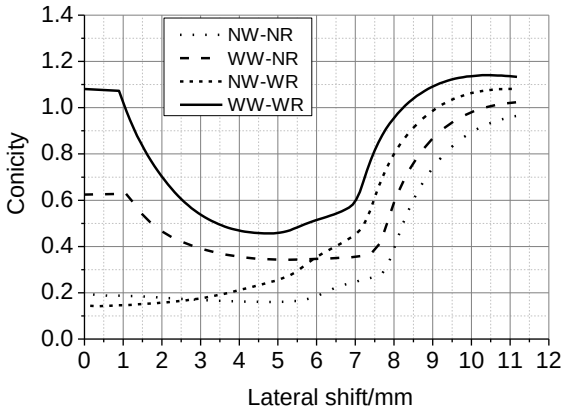
4. Investigation of bogie hunting phenomenon



It was indicated from on-track test that the bogie hunting behavior only occurred in some particular locations of the track. The worn wheel and un-grinding rail profiles in the abnormal section were measured to give insight into the wheel-rail contact relations. The comparison of the new wheel profile (called NW) and the worn wheel profile (called WW) is shown in Figure 4(a), which shows the hollow wear of wheel tread occurs. The comparison of the new rail profile (called NR) and the worn or un-grinding rail profile (called WR) is shown in Figure 4 (b), from which it is seen the inner gauge corner of worn rail is sharper. It is found that the wheel-rail contact points for new wheel matched with new rail (NW-NR) are mainly located around the rolling cycle and the rail top little towards inside, while the contacts for worn wheel matched with worn rail (WW-WR) concentrated on the wheel throat cycle and inner gauge corner, which easily leads to a high equivalent conicity. Figure 4(c) illustrates the equivalent conicities varying with the wheelset lateral displacement for different wheel-rail contact conditions, including 'NW-NR', new wheel with worn rail (NW-WR), worn wheel with new rail (WW-NR) and 'WW-WR' contacts. For the new wheel profiles matched up with new or worn rails (NW-NR or NW-WR), the equivalent conicity is between 0.08-0.35 before flange contact. The equivalent conicity for the 'WW-NR' condition is a little higher than the new wheel profiles. However, the combination of worn wheel and worn rail profile can lead to an unreasonable the equivalent conicity exceeding 0.5 and is easier to cause bogie hunting instability.

(a)

(b)

(c)

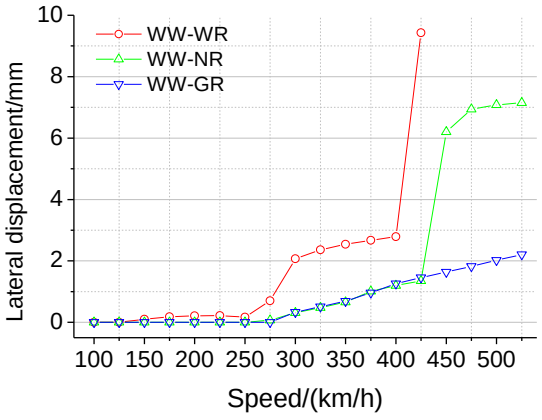


Figure 4 *Investigation of measured wheel-rail contact relations; (a) comparison of new and worn wheel profile; (b) comparison of new and worn rail profile; (c) wheel-rail contact conicity.*

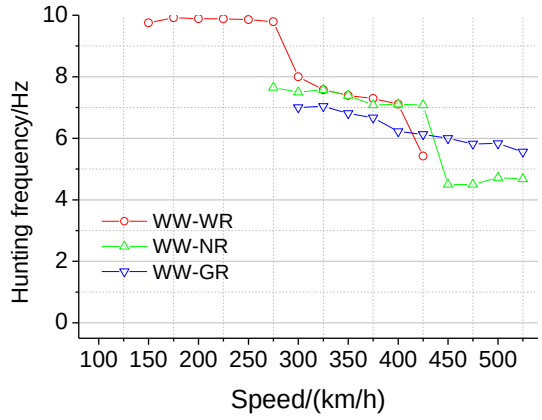
The measured worn wheel profiles matched up with un-grinding rail profiles are then integrated into the vehicle system dynamic model to reproduce the bogie hunting phenomenon. The bifurcation graph and hunting frequency are shown in Figure 5. It is seen the critical speed of 'WW-WR' drop to around 150km/h, although when the oscillation amplitude is quite small. While the critical speed of 'WW-NR' and 'WW-GR' is higher than that of 'WW-WR'. An interesting phenomenon can also be observed, that is the oscillation amplitude is increasing with higher speed, but the hunting frequency is decreasing. The nonlinear parameter in ref [4] can show the average contact conicity in a certain range of wheelset conciliation. It means that the average contact conicity in a large lateral shift of wheelset is smaller than that in a small lateral shift, due to the nonlinearity of wheel-rail contact conicity curve.



In general, the worn wheel profiles possess a poor adaptability to the un-grinding rail profiles. To proper maintain the rail profile can improve the wheel-rail contact relations, which further extends the re-profile period.

The lateral acceleration of bogie frame is commonly used to evaluate the bogie hunting instability. The calculated lateral acceleration for the vehicle equipped with worn wheel profiles is shown in Figure 6. For the 'WW-WR' situation, the oscillation amplitude with the frequency of 8.2Hz is close to 8m/s^2, which exceeds the allowable limit. Both the amplitude and frequency at 'WW-NR' are smaller than that of 'WW-WR'. It should be mentioned that the characteristic of amplitude and

frequency with track irregularity is different with that of smooth oscillation. The amplitude of wheelset oscillation is determined by the track irregularity, while the frequency is affected by the average wheel-rail contact conicity. The lateral acceleration is proportional to the oscillation amplitude and has a squared relation to the hunting frequency.

5. Effect of wheel-rail contact nonlinearity on hunting stability

In this section, the effect of wheel-rail contact nonlinearity on hunting stability of railway vehicles is studied. In order to make comparison with the conclusion in Ref [5], similar wheel-rail contact conditions in China are adopted. It is found that the bogie hunting stability for railway vehicles is of great relevance to the nonlinear parameter of wheel-rail contact. The equivalent conicity at the lateral shift of 3mm does not sufficiently consider the nonlinear characteristic. In this paper, a reverse design method [15] for railway wheel profiles is utilised to obtain the target wheel-rail contact relations.

Figure 7(a) and 8(a) give different dR function curves. The relationship between the dR function and the lateral displacement of wheelset presents as quadratic parabola. Thus, there exists a linear relationship between the slop of dR function, i.e. conicity, and lateral displacement of wheelset. When the opening direction of the quadratic parabola is downwards, the slope of the design section is negative. On the contrary, when the opening direction is upward, the slope of the design section is positive, see Figure 7(b) and 8(b).

It is also found that the bifurcation type, supercritical or subcritical, is relevant to the slop sign of conicity curve for both vehicles, see Figure 7(c) and 8(c). When the slop of conicity curve is positive, the type of bifurcation is subcritical. There exist two stable limit cycles in the vehicle system. An unstable limit cycle may exists between them but has not been calculated in this paper. When the slop of conicity curve is negative, the type of bifurcation is supercritical. There exists only one limit cycle in the vehicle system.

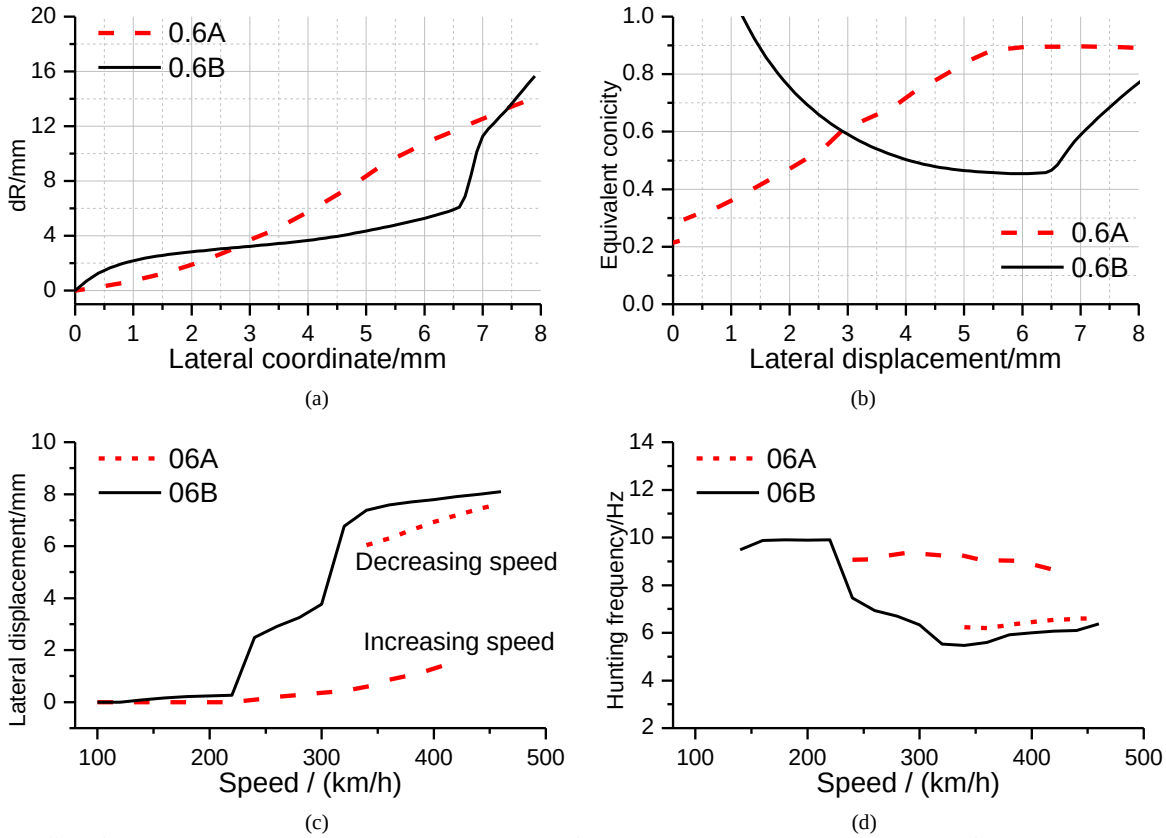

Figure 7 *Effect of wheel-rail contact nonlinearity on hunting stability of high speed vehicle with yaw damper; (a) dR function; (b) conicity curve;(c) bifurcation graph; (d) hunting frequency.*

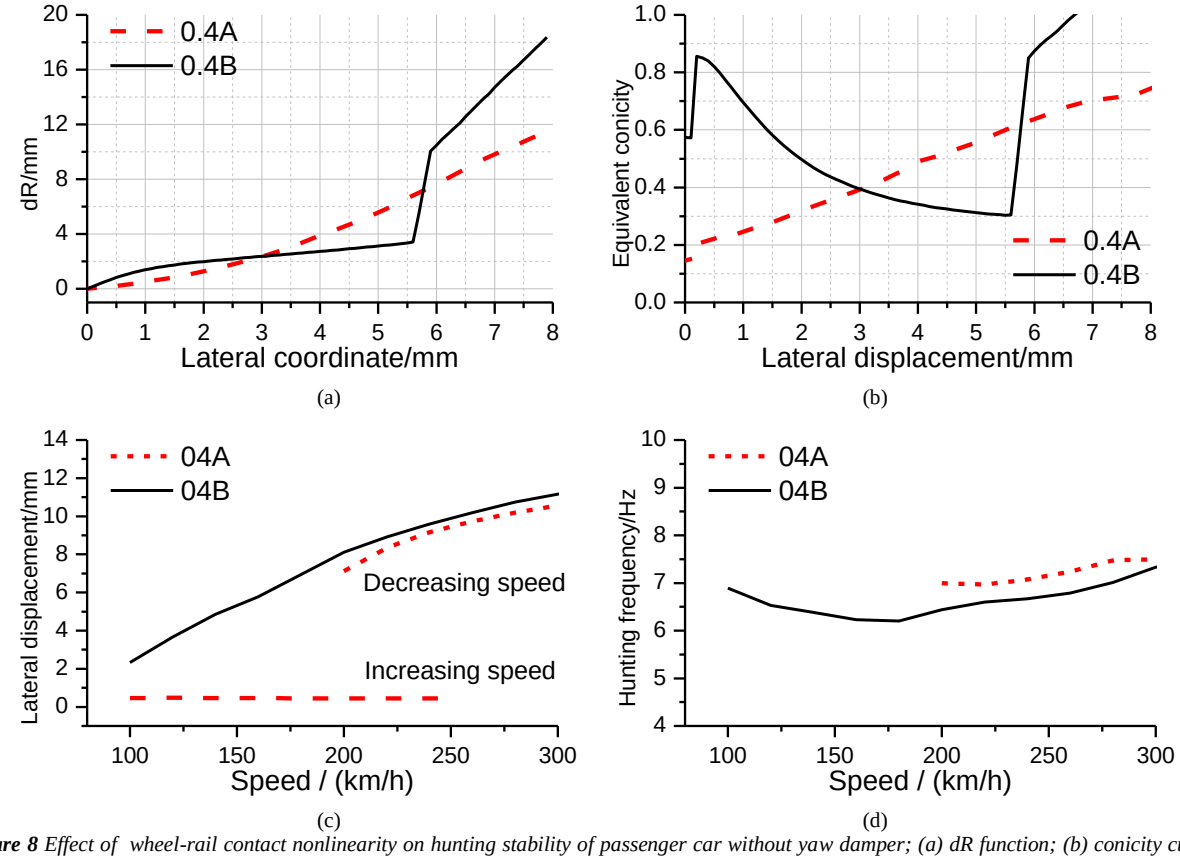

Figure 8 *Effect of wheel-rail contact nonlinearity on hunting stability of passenger car without yaw damper; (a) dR function; (b) conicity curve;(c) bifurcation graph; (d) hunting frequency.*

The contact relationship between a set of designed wheel profile matched up with the new rail profile is given in Figure 9. The original dR function curve is obtained from measured 'WW-WR' contacts. The designed section of the dR function curved is scaled with a series of factors, while the undersigned sections remain the same to the original profile, see Figure 9(a). The transition section between them is smoothly interpreted by cubic spline function. It is seen that the equivalent conicity evenly increases with the scaling factor, see Figure 9(b). Figure 9(c) gives the distribution of contact points at different scaling factors. It can be seen that the initial contact points locates at side of the rail corner. At this time, the contact between the rail corner and the wheel flange cycle is easy to result in high conicity. With the increase of the scaling factor, the contact bandwidth becomes larger.

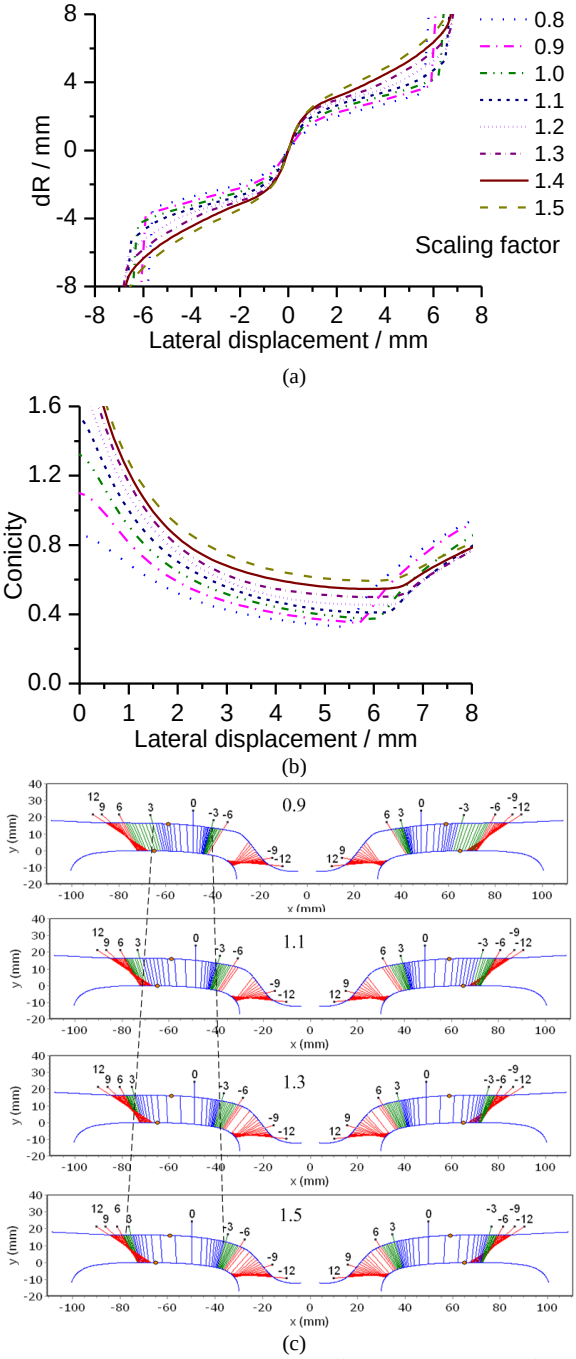

Figure 9 *Designed wheel profile with different conicity; (a) dR function; (b)conicity curve; (c) contact bandwidth.*

Although the slop of conicity curve is the same, the level of conicity is different. Finally, the effect of level of conicity on the bogie hunting stability can be studied. The calculation results show that with the increase of conicity level, the lower the critical speed of the vehicle system, see Figure 10(a). The amplitude of wheelset oscillation increases with increasing running speed. The hunting frequency will decrease with the increasing amplitude of wheelset oscillation, see Figure 10(b). In fact, the acceptance of wheel-rail contact nonlinearity is determined by the bogie stability. The critical speed based on the bifurcation graph can be applied to mathematically determine the acceptable wheel-rail contact nonlinearity. In engineer applications, the lateral acceleration of bogie frame, with properly filtered and calculated, is commonly used to assess the acceptance of wheel-rail contact nonlinearity.

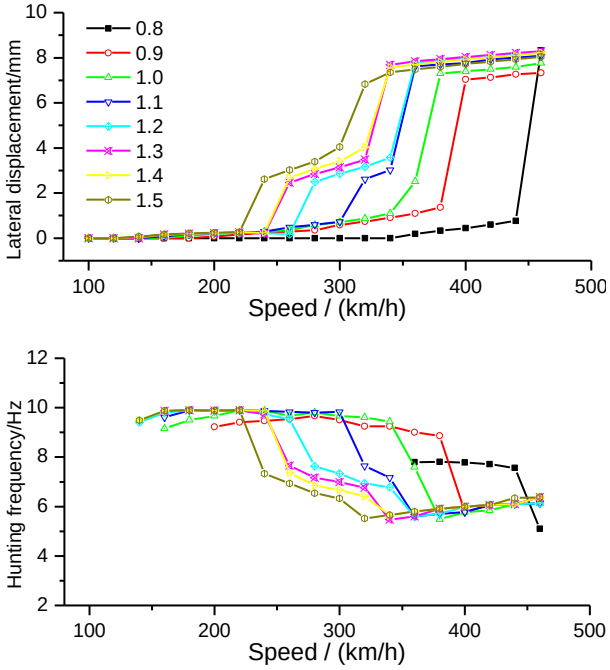

Figure 10 *Influence of coniciy level on bogie hunting stability; (a) bifurcation graph; (b) hunting frequency.*

6. Conclusions

Based on the investigation into wheel-rail contact nonlinearity and bogie hunting instability by on-track tests and numerical simulations, some conclusions can be drawn:

1) The combination of un-grinding rail and worn wheel profiles may cause large wheel-rail contact conicity. The developed dynamic model of the vehicle system can well reproduce the phenomenon of the bogie hunting instability. The dynamic behavior of vehicle system under different wheel-rail contact conditions (new & worn wheels and rail profiles) shows that wheel-rail nonlinearity is the main factor resulting in the bogie hunting instability.
2) To re-profile the wheels can eliminate the bogie hunting instability, but is not an economic approach. An efficient manner to deal with issue is to properly maintain rails, e.g. grinding rail corners or to modify the wheel profile by decreasing the slop in the wheel throat.

Abstract: The wet-rail phenomenon causes low adhesion between wheel and rail throughout the year, but the causes of it are currently unclear and it has been difficult to simulate in a laboratory. It has been previously proposed that a mixture of iron oxides and small amounts of water can be present on the railhead and cause low adhesion. This paper will outline work that has been done using a combination of modelling, rheology and experimental validation using a twin disc test rig to determine whether this paste is able to cause low adhesion. Very low traction coefficients were observed when a high viscosity mixture of hematite powder and water was added to a twin disc contact, which provides information about how the wet-rail phenomenon may occur.

Keywords: Friction, Rheology, Wet-Rail, Low Adhesion, Iron Oxide, Oxide

1. Introduction

Low adhesion between wheel and rail is a recurrent problem for the rail industry. Low adhesion can lead to wheel slides and slips during acceleration and deceleration, which can cause large amounts of damage to the wheel and rail as well as causing safety issues and delays.

Low adhesion has been well documented throughout the autumn season due to organic contamination, but also takes place throughout the year when no visible contamination is seen on the railhead, due to what is known as the wet-rail phenomenon. It is thought to occur when there are low levels of water on the railhead, formed by dew, mist or light rain, rather than heavy rain. Previous analysis of Network Rail station overruns showed that during the autumn season, no railhead leaf contamination was seen for approximately 50 % of incidents, as seen in Tab. 1 [1]. It also showed an increase in low adhesion incidents during morning hours where no precipitation had fallen, likely because of dew formation on the railhead [2]. A graph from this work is shown in Fig. 1 [2].

The conditions and mechanisms that cause the phenomenon are not fully understood. It does not occur very often and under what is likely to be a narrow window of conditions, which means that it can be difficult to recreate and study.

Table 1. *Incidents where contamination has been reported after an incident* [1].

Year	Leaf contamination reported	No leaf contamination reported
2010	85	82
2011	20	27
2012	80	67
Total	185	176

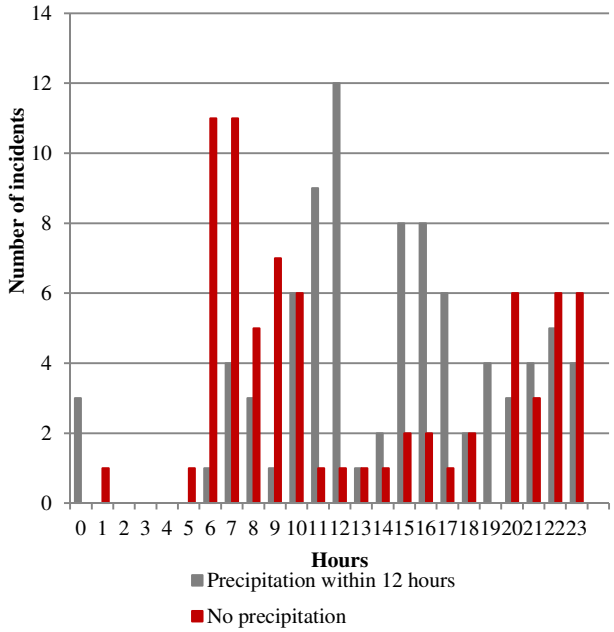

Figure 1 *Number of Network Rail station overruns where precipitation has fallen within 12 hours before the incident and those where no precipitation had fallen, plotted against hour of the day [2].*

Beagley et al. [3] suggested that a paste could be present on the railhead and cause low adhesion, formed from a small amount of water provided by dew, mist or light rain and wear debris containing iron oxides. Twin disc tests run on discs with a layer of wear debris under wet conditions where water application was halted show the friction coefficient was reduced as the contact dried, before rising back up to dry levels as the paste created in the contact was removed. Beagley's twin disc results have been plotted in modern software and shown in Fig. 2 [4]. Low adhesion has been reportedly caused by clay and coal contamination [5], which would create a similar paste on the railhead.

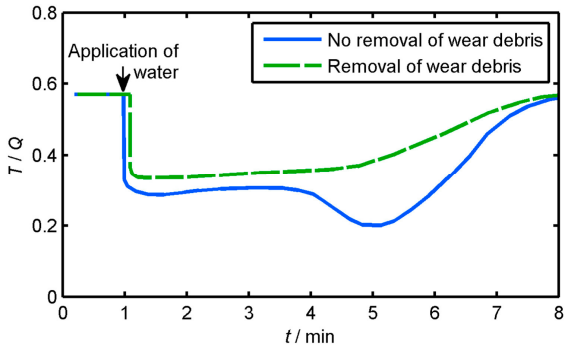

Figure 2 *Previous results from twin disc testing, showing the lower adhesion level when wear debris (including iron oxides) is mixed with water to form a paste, compared to water alone (wear debris removed with iron brush). Water was applied for a short time only, afterwards contact dried out. T/Q is the traction coefficient* [4].

Aside from these observations, very little work has been carried out to investigate why low adhesion occurs without leaf contamination. Wet-rail conditions have not been previously simulated under repeatable conditions using realistic contaminants on either large or small scale rigs, likely because of the specific conditions needed. This work simulates the wet-rail phenomenon on a small scale, twin disc test rig to better understand how it occurs, which in turn can lead to the development of better mitigation strategies.

An "adhesion" model, based on squeeze film theory [6], was developed in previous work [4] which uses Beagley's yield shear stress data from a paste composed of hematite and water, made to different weight percentages (wt. %) [3], showed how friction varies when the proportion of oxide and water in the paste is changed when tested in a high pressure torsion (HPT) test rig. Further input parameters into the model are paste layer thickness and roughness of the contacting bodies. A small range was identified where, dependent on the normal load, the thickness of the paste layer and the surface roughness, ultra-low friction occurred at a specific solid hematite fraction, seen in Fig. 3. This model is intended to describe the change in adhesion under quasi-static conditions (hydrodynamic effects and influence of shear stresses on paste yielding not considered yet) in a qualitative way helping to explain why it has been difficult to achieve low adhesion due to the wet-rail phenomenon in laboratory tests.

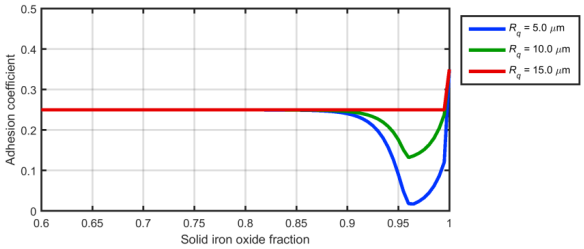

Figure 3 *Previously modelled results for the change in adhesion coefficient for different solid oxide fractions of hematite and water pastes at different surface roughness'* [4].

The aim of this work was to combine oxide paste rheology measurements, adhesion modelling and twin disc testing to validate the hypothesis that iron oxide and water alone could cause ultra-low adhesion due to the "wet-rail" phenomenon.

Rheology measurements for different weight percentages of hematite pastes were taken to update the previously proposed adhesion model updated with new rheometry data and analyse any changes observed. Twin disc testing and roughness profiles were used to provide experimental validation for the model.

2. Methodology

2.1 Rheometry

Hematite powder was mixed with water to form pastes of different weight percentages (wt. %). For instance, 10 ml of a 60 wt. % paste was formed from 6 g of hematite powder and 4 g of water. The pastes were shaken thoroughly before addition to each of the following test methods.

A TA Instruments AR2000 rheometer was set up with a 40 mm parallel plate geometry, a labelled diagram of the rheometer is shown in Fig. 4. Hematite paste was added to the substrate table and the parallel plate lowered to 1 mm above the table surface. The parallel plate was then spun with increasing torque over 10 minutes until spinning at 100 rpm. The torque, converted to shear stress, needed to spin the parallel plate at increasing rate is logged, with the yield shear stress being the point at which the parallel plate begins to spin. The rheometer then reduced the torque to zero over the next 10 minutes to produce results for the reducing rate.

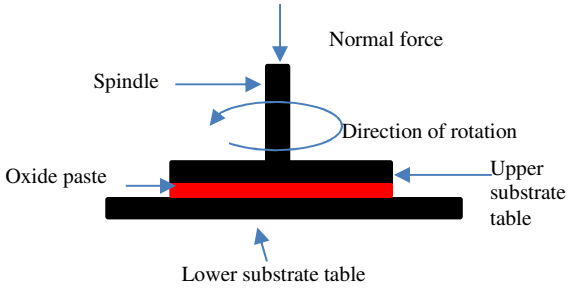

Figure 4 *A schematic diagram of the rheometer set-up used in this work.*

2.2 Modelling

A detailed description of the model ("adhesion" model) can be found in [4], but the basic outline will be described here. The model is based on a HPT test rig and squeeze film theory [7]. The model uses yield shear stress, amount of paste entering the contact, surface roughness and the boundary wet friction coefficient as input values to generate the predicted adhesion coefficient for each weight percentage of hematite paste. This work looks to adapt this model to fit twin disc testing and updates the model with input values that are found from the experimental tests carried out in this work.

The adhesion coefficient, f, can be taken as the tangential force in a contact, divided by the normal force applied. Therefore in a contact that contains an iron

oxide paste between two parallel plates, the coefficient in this model can be taken as the sum of the tangential forces from the plate asperities (T_B) and the iron oxide (T_C), divided by the sum of the normal force upon the asperities (N_B) and iron oxide (N_C).

$$f = \frac{T_B + T_C}{N_B + N_C} \qquad (1)$$

The relationship between the yield shear stress and percentage solid of an oxide paste (see Fig. 7) was used as a key initial input into the adhesion model and influences surface separation.

Friction is metal-metal asperity dominated at low yield stress of iron oxide paste, which results in the adhesion coefficient being equal to the boundary friction coefficient. As the yield stress increases, the iron oxide paste is able to support more of the normal force and therefore influences the adhesion coefficient.

The adhesion coefficient of a wet contact, without oxide addition, is used as an upper boundary friction. The low viscosity of water will not support the parallel plate load so the boundary friction is used to provide an upper friction limit which is entirely metal on metal. Increasing the wt. % of iron oxide will reduce the amount of metal-metal contact between the plates because of the increased shear stress and reduce the adhesion coefficient. When the contact becomes too dry at very high weight percentages, the adhesion coefficient will rise rapidly.

2.3 Experimental verification

The SUROS twin disc test rig is able to log the traction coefficient of two counter-rotating steel discs, made from rail and wheel material. Contact conditions of 400 RPM, 1500 MPa and 2 % slip were used. A detailed description of the test rig is found in [8] and a schematic diagram is shown in Fig. 5 [9].

30, 40, 50, 60 and 70 wt. % hematite and water pastes were added to the rotating discs at a rate of 2 ml/min via a syringe pump, able to accurately and continuously dispense the required volume of paste, and the traction coefficient logged. Water alone and dry hematite powder were added to represent 0 and 100 wt. % hematite. The paste was added drop-wise to the upper disc so that it was rotated into the contact. 30, 40, 50 and 60 wt. % hematite pastes were run for 400 cycles each, but difficulties were encountered when adding the 70 % hematite paste due to the high viscosity, the paste appeared to "bounce" off the rotating discs rather than sticking and being pulled into the contact as seen in the less viscous pastes. Because of this, the 70 wt. % test was only run for 200 cycles before the oxide applicator became clogged and unusable.

Specimens were analysed after testing using an Alicona 3D profileometer, which was able to generate roughness and approximate layer thickness data without deforming the oxide layer due to physical contact.

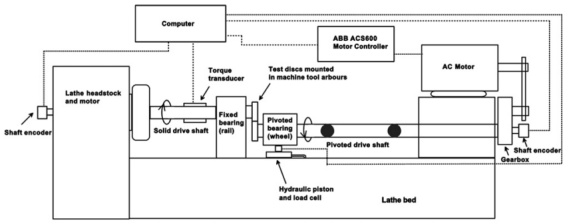

Figure 5 *A schematic diagram of the twin disc SUROS rig used in this work* [9].

3. Results

3.1 Rheology

The yield shear stress of each wt. % hematite paste used is shown in Fig. 6. Two results were taken for each wt. % and have been plotted against Beagley's previous data [3]. As expected the yield shear stress increases with increasing wt. % of hematite paste. The new results show a far higher yield stress at the higher weight percentages than the previous results. Extrapolation to 100 weight %, which has been carried out in previous work, is likely to be incorrect because the behaviour of the oxide suspension is complex and difficult to predict without experimental results.

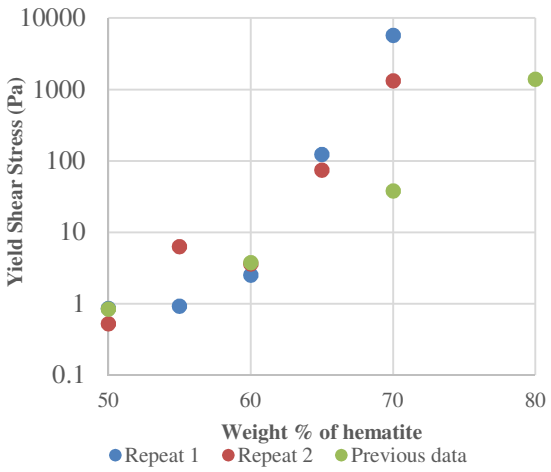

Figure 6 *Yield shear stress for different wt. % of hematite.*

Viscosity was plotted against shear rate and shown in Fig. 7. As expected, the viscosity increased with increasing oxide weight percentage. The viscosity was seen to decrease overall with increased shear rate over the 10 minute test. Hysteresis effects were seen, where the viscosity on a decreasing rate (down) did not follow that of the increasing rate (up). When testing the 55 and 60 wt. % pastes, a sudden increase in viscosity was seen at a shear rate of approximately 7/s.

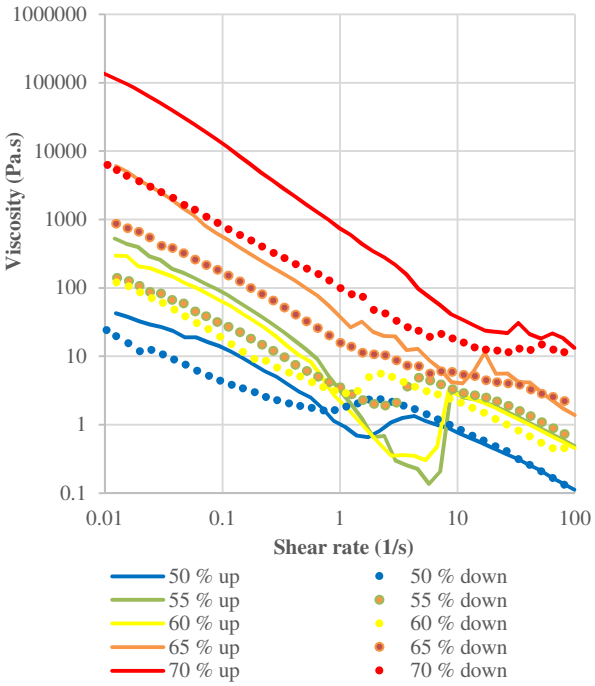

Figure 7 *Viscosity plotted against shear rate for different wt. % of hematite paste.*

3.2 Modelling

The model was updated with the more recent shear yield stresses, shown in Fig. 6, which produced higher values than the previous results and would likely be even higher still if a realistic contact pressure could be used due to particles being more likely to lock together. This caused the model to predict that the weight percentage of hematite paste that could cause low traction may be lower than previously predicted and would likely shift to even lower values if the correct load could be applied.

The model was modified to fit the smaller contact area of the SUROS specimens rather than the HPT, estimated as two cylinders using Hertzian contact. The roughness and specimen separation inputs were modified to those that had been obtained in the experimental validation, as described in the next section. The model retained a similar shape after these changes, but there was a shift in the predicted results so that the reduction in traction coefficient occurred at lower percentage weights, the traction minimum was now located at 87 % rather than 97 %, as shown in Fig. 9.

3.3 Experimental verification

Hematite pastes from 30-70 wt. % were tested at 2 % slip at 400 rpm and 1500 MPa, results are shown in Fig. 8. A box plot of average results, plotted against the modelling output is shown in Fig. 9. Higher weight percentages of hematite paste, up to 60 %, produced a lower traction coefficient. 70 wt. % gives a large spread of results due to difficulties in applying the viscous paste, but very low minimum traction coefficient values of 0.02 were seen when the paste entered the contact.

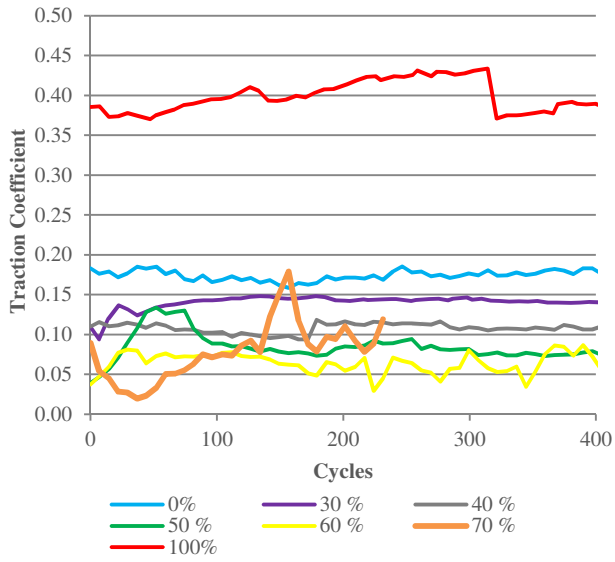

Figure 8 *Raw results for twin disc testing for different wt.. % of hematite.*

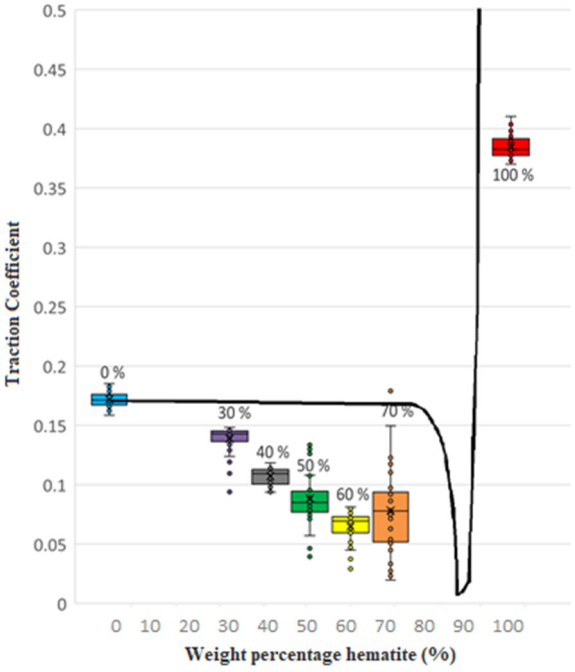

Figure 9 *Average traction coefficient for twin disc testing for different wt. % of hematite, plotted against the adhesion modelling output.*

A layer of compressed hematite was present on the specimen surface after testing in sections, leaving the exposed metal layer underneath. These "pits" in the layer were analysed using the Alicona 3D profileometer and found to be 12 µm deep which may provide an indication of the paste thickness during these tests. The specimen discs became smoother throughout the test, with an initial combined wheel and rail roughness (Ra) of 0.8 µm for the lateral direction (perpendicular to rotation direction) and 2 µm for the longitudinal direction (parallel to rotation direction). When specimen discs for the 60 wt. % hematite paste were stopped after 400 cycles they were found to have a lower combined roughness of 0.7 µm in the lateral direction and 0.8 µm in the longitudinal direction.

4. Discussion

4.1 Rheometry

The biggest difference between the results from the modern rheometer is that it cannot recreate the pressure of the real wheel-rail contact. However, the yield shear stress results produced are all higher than those obtained previously and would likely become even higher still if the pressure could be increased to representative values, as there would be preferential squeezing out of the water component in the paste and a higher chance of particles locking together during rotation. There is still a rapid increase in shear yield stress as the wt. % of hematite increases. The viscosity of hematite suspensions tested decreased throughout the tests. This decrease in viscosity was likely to be due to time dependent shear thinning behaviour, where movement between particles becomes easier over the test duration due to the breakdown of the electrostatic network between particles as shear occurs. This would also explain the hysteresis behaviour seen, where the viscosity is lower on the decreasing rate than the increasing rate due to the particles already having been in motion during the increasing shear rate. The viscosity of the 55 and 60 wt. % suspensions rapidly increases at a shear rate of 1/7 s, where the particles "lock", a result that should be looked into during future tests. The phenomenon of "shear banding" was seen during preliminary rheometry tests, this has been noted previously in similar suspensions [10]. In this case, excess water was added outside the parallel plate to provide an additional water bath to prevent the outer paste surface from drying out, a common rheometry practice. During tests without this additional water bath, the rheometer began to rotate at a slow rate when the paste yielded. When the additional water bath was added, the paste yielded at a similar stress but the rate increased rapidly. A shear band of water was pulled into the contact and dramatically lowered the shear stress, which may provide an explanation of the mechanism which causes the wet-rail phenomenon.

4.2 Modelling

As a result of the twin disc work, the roughness, layer thickness and baseline wet traction coefficient could be updated in the model. The rheometry work produced new results for shear yield stress which could also be added. Changes to the model affect the initial "wet" traction coefficient and shift the adhesion reduction zone slightly, but the trend in traction coefficient remains the same, with a very sudden reduction in traction coefficient at a certain weight percentage of hematite paste, followed by a steep rise back up to dry values. The model using the updated input variables predicts a low adhesion zone between 75 and 85 wt. %.

The model could not be modified entirely to fit the SUROS geometry due to the large differences in size and shape, along with dynamic effects that could occur. The dynamic effects will likely change the layer thickness of oxide paste in the contact and move the adhesion minimum, but it is unclear by how much. However, qualitatively the model is in agreement with the adhesion results from the SUROS machine. Thus, it seems to consider the most important physical phenomena even though certain refinements are needed (consideration of hydrodynamic effects and influence of shear stresses on paste yielding).

The second dynamic effect, rapid separation of oxide paste into water and hematite, is one that has been seen using the rheometer and during SUROS tests. Water has been seen during testing to be squeezed out preferentially to the hematite and therefore increasing the concentration of hematite in the contact. This is visible in the experimental results, where lower hematite weight percentages still reduce the traction coefficient due to water being squeezed out which increases the hematite weight percentage in the contact.

4.3 Experimental validation

The experimental results showed that hematite and water alone are able to produce very low traction conditions, simulating the wet-rail phenomenon. A decrease in traction coefficient with increasing weight percentage of hematite between 0 and 70 % is observed, with a very low traction coefficient minimum of 0.02 being achieved when the 70 % paste entered the contact. In comparison, the modelled traction coefficient remains as a wet value until a rapid decrease at approximately 75 wt. % hematite, where the traction falls to the very low minimum of 0.01 before rapidly rising back up to very high traction coefficient at approximately 85 wt. % hematite.

The experimental results show a more gradual decrease in traction coefficient than the model, even 30 wt. % hematite shows a slightly lower traction coefficient than water alone. It is important to note that the wt. % hematite paste added to the contact is not necessarily the wt. % that will be present in the contact. A compacted layer of hematite is present on the discs after testing so the suspension may separate in the contact, water is likely to be pushed out of the contact preferentially to the hematite particles. As a result, hematite is likely to become increasingly concentrated and build up in the contact as water is pushed out, which may explain why even the 30 wt. % hematite suspension was able to lower the traction coefficient compared to water alone.

The model predicts that the traction coefficient will only drop to very low values when the combined roughness of the wheel and rail is low. Mild wear occurs and the twin disc specimens naturally become smoother when paste is added during the test. The low roughness values seen during the tests are similar to those collected during a previous railway study, which found that the roughness of wheel and rail was high after grinding, but decreased rapidly [11].

The measurements of oxide layer thickness allows the generate approximate values that can be fed into the model but need to be treated carefully , as the thickness of oxide layer after disc contact may be different from that in the contact itself due to evaporation of water or damage during transportation.

5. Conclusions

A combination of rheological measurements, adhesion modelling and twin disc traction testing has been used to further understand the role that iron oxides and small amounts of water plays in the wet-rail phenomenon. The rheometry has provided input data to the adhesion model. The large differences in viscosity and yield stress between different weight percentages of hematite pastes may explain the small window of conditions that cause low traction, as seen in the modelling. Shear banding may be able to explain how the wheel will slip on a rail, water may be pulled in to the contact to produce an easily sheared band above the more viscous hematite paste.

The updated model followed a similar pattern to the previous, but showed a reduction in traction at lower weight percentages of hematite paste than previously predicted. The model could not be entirely modified to suit the dynamic and far smaller SUROS contact but predictions were made to how these would affect the output.

The twin disc testing showed that low adhesion can be created and sustained in laboratory conditions using iron oxide and water alone, which has been difficult to achieve in the past. The results show a reduction in traction coefficient at the higher wt. % of hematite suspensions, with weight percentages above 60 % producing very low values if they were able to enter the contact. The trend of decreasing traction coefficient with increasing weight percentage of hematite is expected to continue up to a certain point, before rising up rapidly to a dry value which is a similar pattern to that seen in the modelling. This method to produce very low traction using hematite and water alone can be used as a platform to test wet-rail mitigation methods in future work.

The traction coefficients seen in both the model and experimental results would be low enough to cause significantly low traction issues on a railway and the iron oxide paste formed could account for the low adhesion incidents that have been attributed to the wet-rail phenomenon.

THE DEVELOPMENT OF A TRACTION GEL ASSESSMENT METHOD

Ben White, Roger Lewis

* E-mail: bwhite2@sheffield.ac.uk

Abstract: Very low traction conditions due to organic contamination, which are a common problem in the wheel-rail interface, were recreated on a twin disc test rig using a wetted pectin layer. This low adhesion simulation was used to test the effectiveness of traction gels, currently used to enhance traction on the railways, at increasing the traction coefficient. The method outlined in this paper could be used to develop more effective traction enhancing products for railway use.

Keywords: Friction, Leaves, Traction Gels, Low Adhesion.

1. Introduction

Low friction between wheel and rail can be caused by organic contamination such as leaf matter, which is most prevalent during the autumn season. An organic layer is formed from leaves when compressed in the wheel-rail contact, this can be very difficult to remove and cause very low friction conditions when moisture is present [1]. This organic matter mixes with other debris such as oxidised wear particles, oil and crushed ballast [2].

A locomotive can operate effectively with a wheel-rail friction coefficient above 0.09, below 0.06 is classed as very low adhesion [3]. A friction coefficient below this results in difficulties when a train needs to accelerate or brake, this can cause safety issues and economic issues due to delayed trains, station overruns and wheel flats [4].

An example creep curve of low traction caused by wet leaves in a laboratory twin disc test rig is shown in Figure 1 [5]. Tribotrain data from a stretch of track is shown in Figure 2 [6]. Tree locations are labelled which leads to organic contamination and low traction values.

Traction gels are applied to the railhead to prevent low friction by removing the organic layer using abrasive action, they contain solid particles suspended in a gel. Sand and small metal particles act as the solid abrasives to help remove a contaminating layer when they enter the contact patch between wheel and rail. A balance is necessary; they need to be abrasive enough to remove the layer, but cannot cause excessive wear to the wheel and rail.

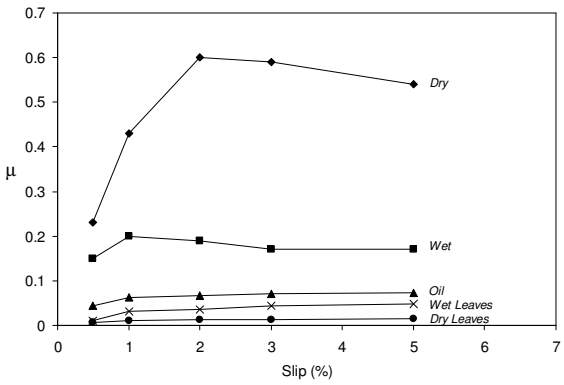

Fig. 1 *Twin disc creep curves for different test conditions* [5]

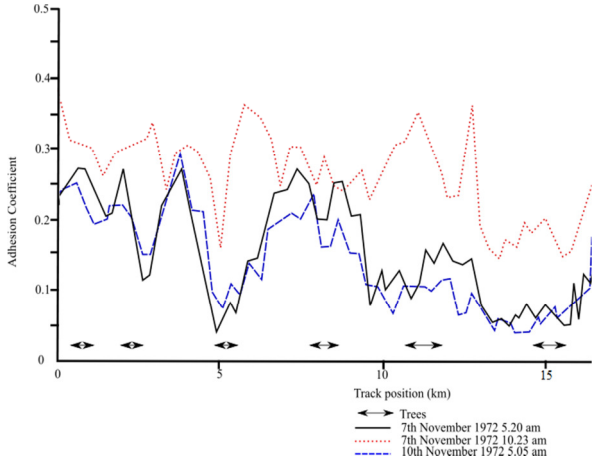

Fig. 2 *Tribotrain data showing adhesion levels plotted against tree locations* [6]

Traction gels can be pumped onto the rail from trackside or trainborne dispensers so the gel component needs to be pumpable using the traction gel dispensers, work over a range of environmental conditions and not interfere with the traction recovery effects of the solid particles.

There are currently few guidelines that determine what the properties of a traction gel should be, the products can be complicated mixtures of chemicals and it is often hard to compare the effectiveness of traction recovery between products. To measure the effectiveness of these gels, a repeatable low adhesion situation needs to be recreated and their effect on friction measured. Unfortunately, repeatable low adhesion conditions are difficult to recreate in full-scale track testing because of the number of variables

such as wheel, rail and environmental conditions, along with difficulties in measuring the friction coefficient.

Small scale testing has its limitations such as scaling size and speed factors, but provides more easily controllable conditions and more precise friction coefficient measurements. Testing is quicker, cheaper and more repeatable low adhesion conditions can be created. An ideal test method to compare traction gels would achieve the following:

- Produce the low traction coefficients seen in a real low adhesion situation when wetted, below 0.09 and ideally below 0.06.
- Build a layer over the steel test specimen that is representative of the organic contamination seen on a real railway track.
- Produce a repeatable layer so that different traction gels can be tested under identical conditions.
- Contain only compounds that could be found on the railway rather than unrepresentative "artificial" contaminants.

It is difficult to determine what the properties of a "representative" leaf layer should be, as hardness and thickness seem to vary between reports, many are only measured under dry conditions and not the wet conditions that produce low traction. A previous British Rail report has reported the layer to usually be approximately 100 µm thick, but up to 200 µm in some situations [2].

Leaf contamination is most often seen as a hard, black layer on the railhead [7] but a previous report by British Rail [2] has stated that "under wet conditions the leaf film loses much of its cohesive strength and its bond to the rail surface is weakened. The properties of the wet layer resemble more closely those of a viscous fluid rather than those of a solid film". The report stated that the organic material is likely to act as a collector, trapping iron oxide, wear particles and oil to form the black layer. Another interesting point to note from this paper is that it states that the track down-rail to the leaf contaminated track remained extremely slippery after rain and yet was not visibly contaminated due to an invisible, sticky layer.

Analysis of a railhead leaf film has also shown that it is made up of up to 56 % iron and iron oxides [2]. If this is the case, it seems possible that the viscous paste that is squeezed from the leaves is the cause of low adhesion and the solid matter simply provides the visible bulk rather than influencing adhesion.

As a result, traction gels could be designed for two purposes; to remove the hard black leaf layer before low adhesion occurs when dry or to remove the softer leaf layer and increase tractions during low adhesion conditions when wet. The latter is likely to be most representative of traction gel use is currently employed on the railways, with traction gel application often following water jetting using a railhead treatment train, so the current work has focussed on wet, low adhesion conditions.

Work has been carried out previously to assess sand performance using leaf layers formed by adding leaves to a twin disc machine, which were difficult to create consistently due to the large pieces of organic matter [8]. Another set of tests assessed traction gel performance using a leaf layer formed from smaller and more uniform leaf pieces, but used carboxymethylcellulose as a binder, which is not naturally found on the railhead and produces very low traction alone [9].

The British Rail paper [2] hypothesised that this remaining slippery layer was a component of the leaf "juice" that was squeezed out of the solid matter, but could not produce low traction with any of the individual leaf constituents using the Amsler twin disc machine. A chart of the traction coefficients obtained using leaf debris scraped from rails, along with some of the different individual leaf constituents that were tested is shown in Table 1 [2].

Tab. 1 *Leaf constituents tested on an Amsler twin disc machine* [2]

Leaf Constituent	Wet traction coefficient
Leaf "debris" scraped from rails	0.05
Leaf "juice"	0.12
Leaf proteins	0.2
Cellulose	0.2
Stearic acid	0.1

Because of the difficulties in creating a repeatable leaf film that will produce low adhesion on the railhead, other methods are currently used to create "artificial" low adhesion conditions, such as detergent or paper tape [10].

Paper tape, a brown paper covered with an organic adhesive, has been used for low adhesion simulations [10]. The organic adhesive is generally arabic gum, a hydrocolloid which forms a sticky gel when mixed with water. The thin layer of arabic gum becomes a viscous paste when wetted and causes very low traction. The paper may act to lower the roughness in the contact patch whilst the Arabic gum produces a viscous hydrocolloid paste when mixed with water. Both this and the detergent method involve adding "artificial" contaminant that would create unrepresentative railhead conditions and the detergent in particular does no build a layer on the railhead so would not provide a suitable traction gel test method.

It was hypothesised in the current work that if a single leaf constituent was found to produce low traction, it could be tested alone which would help remove the consistency issues when testing leaf solid matter and focus on a single and more repeatable compound. If the British Rail paper is correct and the low adhesion conditions are caused by a water soluble, viscous and transparent layer then pectin is the only leaf component

that matches these criteria.

A set of tests carried out as a preliminary study to this work concluded that a pectin solution could produce low traction. Pectin is a hydrocolloid, with similar properties to the arabic gum used in the paper tape method, found in plant matter and has been previously found on the railhead [7][11][12], it causes low traction when dissolved in water and added to a twin disc contact. Previous reports have shown it to be a major constituent of leaf films formed on railways and it forms a sticky, transparent gel when dissolved in water which can dry to form a hard layer, so may cause the invisible contamination discussed in the British Rail low adhesion analysis [2]. This work tested traction gel performance on a small scale, twin disc test rig by creating an organic layer using a pectin solution that produced low adhesion and then assessed how well the traction gels were able to regain traction.

Simply adding pectin solution to the twin disc contact produced very low traction of approximately 0.02, but this solution would dilute the traction gel and would not simulate the rehydration of a hard layer which occurs in real railhead leaf contamination. A method was designed to build up a pectin layer, hardened by heat and pressure, on two test specimens which could then be rehydrated with water to produce low adhesion. This simulated an organic surface layer and produced more reliable results than using a layer built from leaf material.

2. Test methodologies

The SUROS twin disc test rig at the University of Sheffield was used for this work. A schematic of the rig is shown in Figure 3. The rig applies a normal force to two counter-rotating steel discs, one manufactured from wheel and one from rail material. The specimen discs, one driven by a Colchester Mascot lathe and the other by an AC motor, rotate at different speeds which produces creepage in the contact. A more detailed description of the SUROS rig is shown in [13].

The SUROS rig logs the traction coefficient over the test and has been used previously to observe how the traction coefficient changes when sand is added [14], which was thought to operate in a similar way to the traction gels tested in this paper.

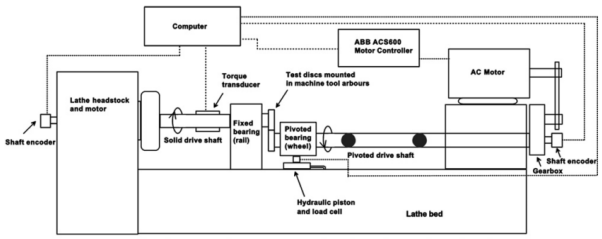

Fig. 3 *Schematic diagrams of the SUROS rig*

A pectin solution was made from 7.5 % by weight pectin and 92.5 % by weight water. The solution was placed in an ultrasonic bath and stirred over 60 minutes to ensure that it was homogeneous.

A pectin layer was formed on the rail disc by applying the pectin solution for 2000 cycles via a syringe in a conditioning test, a higher slip value of 3 % was used for this to provide more heat and the pectin layer was hardened onto the disc under the heat and pressure of the contact. The pectin solution was added at approximately 5 ml/min but this was difficult to add accurately due to the high viscosity of pectin solution. However, the contact was kept saturated with pectin solution with excess gel being flung of the discs so the volume on the discs will remain similar. Very low traction coefficients of 0.02 were observed during this conditioning test when the pectin solution was added.

The discs were separated and left to dry for 10 minutes after the initial conditioning test. At this point a transparent pectin layer was present on the disc surfaces which created a shiny finish on the specimens. 1 g of traction gel was added to the surface of the lower specimen and smeared over the surface using a spatula, which ensured the coverage was as even as possible. 1 ml of water was then added to the upper specimen using a syringe, shortly before discs were contacted and run at 2 % slip, chosen because it has produced a saturated creep in previous tests but caused less disc damage than 3 %. The test was run with no extra pectin or water addition until a dry traction coefficient was observed.

Five different traction gels were assessed in this work. These included the three products currently approved for use on the UK railway network and two prototype formulations. A dry baseline test was also carried out on a pectin layer run under dry conditions. A wet baseline test was carried out with 2 ml water on clean specimens with no pectin layer. A summary of the conditioning test and the traction gel recovery test is shown in Table 2.

Tab. 2 *A summary of twin disc test conditions*

Test	**Conditioning**	**Traction Gel Recovery**
Creep (%)	3	2
Pressure (MPa)	1500	1500
RPM	400	400
Conditions	Pectin solution applied during test at 5 ml/min	Pectin layer wetted and traction gel applied before disc contact

3. Results

Different gels produced different rates of traction recovery, but all were able to remove the organic contamination and restore sufficient levels of traction. The first 30 cycles of each test were discounted because it took 30 cycles for the slip to reach the desired value. Traction coefficients for the next 100 cycles at full load and slip for each gel are shown in Figure 4. The traction coefficient recovery per cycle was determined for each gel and shown in Figure 5.

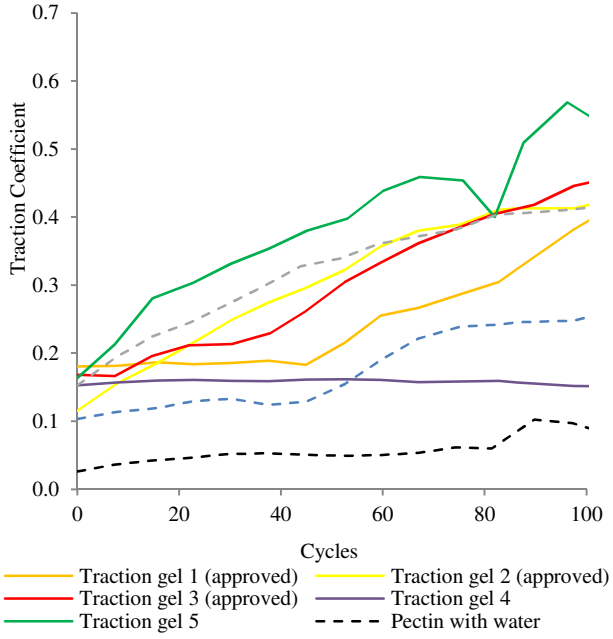

***Fig. 4** Results from the traction recovery tests*

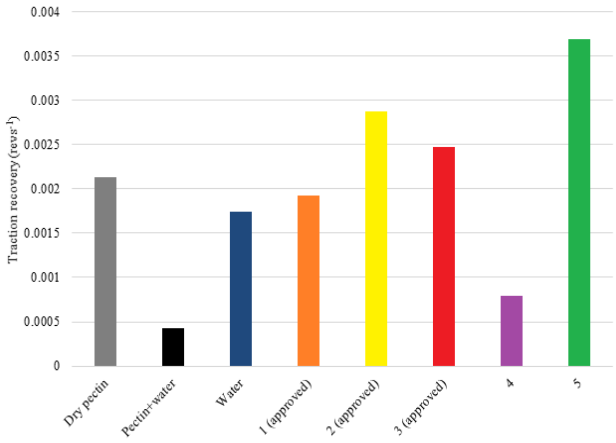

***Fig. 5** Traction coefficient recovery per cycle*

Disc roughness can be split into lateral and longitudinal directions, as shown in Figure 6. The unused test specimen has a roughness of 2 µm longitudinal and 0.7 µm lateral. After the pectin layer has been formed, the test specimens have a lateral roughness of 0.25 µm and a longitudinal roughness of 0.15 µm, with the pectin producing a smooth glaze on the specimen surface.

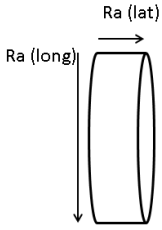

***Fig. 6** A schematic diagram showing longitudinal and lateral roughness of a SUROS disc*

XPS tests were carried out by the University of Sheffield Surface Analysis Centre using a Kratos Supra with a monochromatic aluminium source, two points of each sample were analysed and a low resolution "sweep" was carried out before obtaining high resolution spectra for each element present. Samples were in the form of powders and pressed into soft indium foil for analysis, used because it would not show up on the analysed XPS spectra.

A sample of pectin powder was analysed using an XPS spectrometer before it was formed into a solution and added to the contact. Another sample was taken from a specimen surface after the conditioning step to analyse the pectin layer that was formed.

4. Discussion

The pectin layer and water produces a very low initial traction coefficient of 0.025, which slowly rises to 0.1 over 100 cycles. It stays below the critical 0.06 threshold for 80 cycles before rising rapidly when the contact dries out. This layer built from a combination of pectin and water has produced very low traction with the addition of water alone and therefore seems to be a good base for assessing traction gel performance.

Water alone, with no organic contamination, starts at a traction coefficient of 0.1 and rises steadily to 0.23 after 100 cycles as the contact dries out, it does not produce a low traction coefficient. Dry pectin begins at 0.15 and rises very quickly to reach a traction coefficient of 0.41 after 100 cycles. All traction gels begin at similar traction coefficients, between 0.1 and 0.14. Traction gel 2 begins at the lowest traction coefficient at 0.1, but this is a level that a train can efficiently operate at.

It can be seen from Figure 4 that the ability to increase traction after the initial disc contact varies between gels. Traction gels 1, 2, 3 and 5 are able to recover traction under wet conditions and presumably remove the pectin layer faster than dry conditions with just a pectin layer.

Traction gel 4, a prototype, provides the lowest traction recovery characteristics. This used a similar base gel, but contained a different type of solid particle that were a different shape than others. Traction gel 4 caused lower traction than that seen when water alone was added to the contact, without organic contamination and did not increase the traction coefficient during the first 100 cycles. The solid particles were likely rapidly removed from the contact, leaving the gel behind which does not produce dangerously low traction but keeps the contact wet for a longer period of time than water alone. The traction coefficient does not begin to rise until later in the test when the contact dries out at approximately 250 cycles.

The initial traction starting point and number of cycles taken to reach dry value were two methods of assessing traction gel performance, but these would be highly dependent on the pectin layer thickness, which may not be consistent between tests.
It was hypothesised that the best method to assess

traction gel performance was to assess the rate of traction increase per cycle, which could be linked to the speed at which the pectin layer is removed from the contact. This has been used in previous traction gel performance comparisons [9]. Figure 5 presents the results for this and shows a good correlation to the results seen in Figure 4. The downside to this method is that the initial traction coefficient varies between gels, which is not necessarily due to traction gel performance and could be due to variation in initial conditions such as gel and water coverage. As a result, products such as traction gel 2 start on a lower traction coefficient and rise to a high dry level over 100 cycles so obtain a very high traction recovery per cycle which may be due to the lower initial traction coefficient rather than superior performance.

All traction gels tested provide some sort of traction recovery in comparison to pectin and water alone and recovered traction to above 0.06 by the time the SUROS slip value stabilised at 30 cycles. Traction gels 1, 2, 3 and 5 all have a traction recovery rate that is above that of the water without any organic contamination, which is sufficient for normal railway operation.

The XPS spectrums are similar which suggests that the pectin has not changed considerably during the disc contact but there are a few minor changes. The main difference between the two spectrums is that the pectin layered specimen contains a peak at 707 eV, which shows that iron oxide in the form of hematite has entered the layer formed on the SUROS specimen, which is what has been noted previously in railhead samples.

There is an increased level of nitrogen and silicone in the layer. The nitrogen, present in the organic molecules, is likely due to a reaction with the air under the high heat and pressure of the contact. The source of the silicone is unclear but could be due to contamination during sample transportation.

Small scale testing will always have scaling effects so the next stage would be to assess the traction gel performance on a full scale rig or field testing. The current method may be difficult to generate repeatable conditions such as thickness when forming the pectin layer which makes "ranking" the traction gels difficult, but the SUROS rig was able to produce low adhesion conditions and show which traction gels are effective in this situation and which are not. This test methodology may provide a good comparison for improving product formulations, where the effects of changing a product formulation can be assessed.

5. Conclusions

The pectin layer formed gives repeatable low adhesion on the SUROS twin disc rig. The layer formed has similar characteristics to a layer formed on a real railhead, producing low traction when wetted and being difficult to remove. The pectin layer is transparent and it is likely that the layer is softened by water addition, similar properties to that seen in field testing. Iron oxide has also been formed in the contact and entered the contaminating layer, which has been seen in samples taken from a railhead.

All gels tested were able to remove organic contamination and increase the traction coefficient to adequate levels for braking and traction, typically above 0.1. The time taken to reach these levels and the rate of traction recovery depended on the traction gel used. The results from traction gel 4 highlight the importance of testing the effectiveness of these products, a change in solid particle shape produced a large difference in traction recovery properties.

Modifications to the test method for future work could include "bulking" out the pectin layer with uniform organic matter which may create a thicker organic layer if required. Another set of tests on the gel component itself, without any solid particles, could ensure that the gel component alone does not cause low traction. Tests could be designed to measure other factors such as retentivity as well as the traction coefficient.

Further analysis of the test method would need to be carried out in order to "rank" the products, including validating the results in a full scale field test. However, the method proposed here provides a platform expand upon and carry out a more detailed set of tests in future.

Abstract: A new numerical model of wheel/rail in rolling contact is proposed to study the adhesion mechanism with considering surface roughness and interfacial contamination at high-speed. A thermal starved partial elastohydrodynamic lubrication theory (EHL) is hired in the model. The elastic-plastic asperity contact model used in the numerical model is proposed based on amount of Finite Element (FEM) analysis. Multilevel method is used to solve modified Reynolds equation and sweeping column method is used to solve energy and heat conduction equations. Through using the present model, the pressure field, fractional film content and temperature field are obtained. The effects of train speed, surface roughness amplitudes and inlet film thickness on the adhesion coefficient are obtained.
Keywords: wheel/rail adhesion, starvation condition, thermal effect, elastic-plastic contact, rolling contact.

1. Introduction

Adhesion in railway engineering is defined as the ratio of traction force over the normal force between wheel and rail. In China, thousands of kilometres of high-speed railways have been put into use, and the traction and braking capabilities of railway vehicles mainly depends on the adhesion between wheel and rail. Studies had shown that the adhesion coefficient can meet the normal operation requirements when the surfaces of wheel and rail are clean enough [1~2]. However, oil, water, moisture, fallen leaves and their mixtures always can be found on the wheel/rail contact interface, which make the study on the adhesion characteristics to be more complicated. Oil and water had been universally accepted as the main interfacial contaminations that lead to low adhesion issues [2~3], which can lead to some wheel/rail damages such as skidding marks on the rail and flats on the wheel, as shown in Fig.1. Therefore, it is necessary to clarify the adhesion mechanism under interfacial contaminations.

The wheel/rail adhesion phenomena under interfacial contaminations had been studied both numerically and experimentally for several decades. In the aspect of experimental method, Ohyama et.al had conducted a series of laboratory tests under dry, wet and oil-contamination conditions by scaled twin-disc rolling contact testing machine. They investigated the effect of train speed, contact pressure and surface roughness on the adhesion coefficient [1, 4~5]. Chen et.al conducted a lot of adhesion tests under wet condition using a scaled twin-disc machine. They mainly focused on the effect of surface parameters on the adhesion coefficient [6, 7]. Other adhesion tests had been conducted under different contaminations at low speed condition [8~10]. The full-scale testing was carried out by Zhang *et al.* to study various interfacial conditions on adhesion at high-speed condition [11]. In the aspect of numerical method, few studies had been published compared with the achievement in experimental tests. The average flow mixed EHL theory had been applied to analyse the adhesion coefficient under different contaminations [12~15]. In addition, Tomberger, Popvici et.al used the deterministic model to study the traction coefficient under wet condition [16].

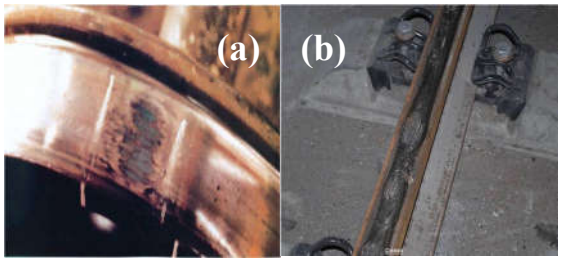

Figure 1 *Damages of wheel/rail under low adhesion. (a) Scratch on the wheel surface; (b) Scratch on the rail top.*

The studies mentioned above are based on enough inlet water or oil supply. However, water and oil on the top of rail may exist in various forms, such as moisture, light rain and drops of oil. In those conditions, the interfacial lubrication state will become starvation. It is universally acknowledged by various references that the wheel/rail adhesion under interfacial liquid contaminations affected by central film thickness (h) and surface roughness (σ) [15]. However, in real operation conditions, the amount of lubricant at the inlet is often insufficient such as light rain or small amount of oil along the running direction, to establish fully flooded condition. In that case, interfacial contamination may only partially fill the gap somewhere in EHL region. In the literature, however, no numerical analysis work has been carried

out to investigate how starvation lubrication occurs on rail top and/or wheel tread could affect the wheel/rail adhesion.

This paper aims to fill such gap using a two-dimensional adhesion model of the wheel and rail. The present model considers the high-speed wheel-rail rolling contact under starvation conditions, the thermal effect of the interfacial liquid, and the elastic-plastic behavior of the asperity contact.

2. Numerical model

2.1. Physical Micro-contact Model

Since the three-dimensional problem for the thermal model is very complicated, especially considering the starvation, it is simplified as a two-dimensional model in the present work for the preliminary discussion of wheel/rail mixed starvation lubrication. The numerical model proposed in the paper includes two sub-models. The first one is the wheel/rail contact model under starved interfacial contamination, and the other one is the temperature calculation of interfacial liquid across the film and inside the wheel and rail. Fig.2 is the schematic diagram of the wheel/rail contact model under mixed starved contamination. Seeing from the micro point of view, the wheel/rail contact is fulfilled by surface roughness on the two surfaces. The distribution of the surface roughness amplitude on the two surfaces is assumed to have a Gaussian distribution. The composite standard deviation of the combined roughness is related to the individual standard deviations by: $\sigma = \sqrt{\sigma_1^2 + \sigma_2^2}$. σ_1 and σ_2 are the standard deviations of the roughness amplitudes.

Fig.2 also demonstrates three kinds of the surface roughness orientation, which is described by the surface pattern parameter $\gamma = \lambda_{0.5x} / \lambda_{0.5y}$, where $\lambda_{0.5x}$ and $\lambda_{0.5y}$ are the autocorrelation lengths along *x*- and *y*- directions, respectively [17].

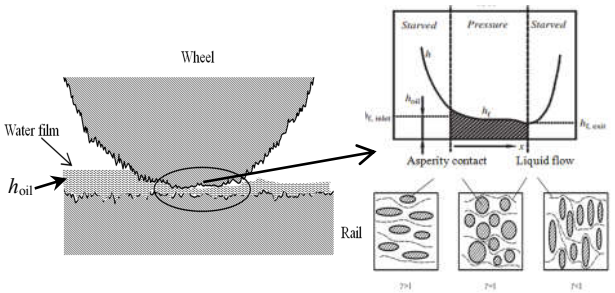

Figure 2 *2D wheel/rail contact model under starved interfacial contamination*

It should be noticed that the wheel/rail contact model for starved condition is different from flooded lubrication. The whole contact area was divided into the pressurized and the starved regions. In pressurized region, the lubricant completely fills the gap. The starved regions, which are called the cavitation regions, are distributed in the inlet and outlet regions. In this region, only part of lubricant fills the gap and the lubrication pressure cannot build [18]. References show that the starvation level of EHL is dependent on the level that lubricant fills the gap at the inlet, or the thickness of supply oil layer at the inlet (defined as h_{oil} in Fig. 2) [18].

2.2. Rheological model

The non-Newtonian property of the interfacial liquid is described by Ree-Erying model [19].

$$\frac{\partial u}{\partial z} = \frac{\tau_0}{\eta} \sinh\left(\frac{\tau}{\tau_0}\right) \tag{1}$$

Where u, τ and η are the velocity, shear stress and viscosity of the lubricant. τ_0 is the characteristic shear stress of the Eyring fluid, which is assumed to be constant in the present paper. By introducing the equivalent viscosity η^* of the fluid as

$$\eta^* = \eta\left(\frac{\tau}{\tau_0}\right) \Big/ \sinh\left(\frac{\tau}{\tau_0}\right) \tag{2}$$

2.3. Basic Dimensional Equations

The interfacial liquid pressure is governed by the average Reynolds equation considering surface roughness, non-Newtonian property and thermal effect for a steady-state line contact. However, this equation is based on the fully flooded condition. In fact, the starved condition may happen during the railway operation condition. The EHL analysis of the starved problems had been successfully solved by many researchers without considering surface roughness [20, 21]. In this model, in order to consider the effect of starvation, a modify on Reynolds equation by introducing the fractional film content θ to the wedge form is applied based on the work presented by Jakobsson and Floberg [22] and Olsson [23] who introduced the concept of fractional film content. The fractional film content variable is defined as the ratio between the lubricant layer thickness H_l and the gap height H at that location as follows.

$$\theta = \frac{H_l}{H} \tag{3}$$

In the present model, the lubricant is assumed to continuously distribute across the film [18]. That is because although lubricant only partly fills the gap, the lubricant at that location can be modelled as a continuum with a modified density of $\theta\overline{\rho}^*$, where $\overline{\rho}^*$ is the density of the lubricant. Based on this concept, the following modified Reynolds equation in dimensionless form can be derived.

$$\frac{\partial}{\partial X}\left(\varepsilon_x \frac{\partial P}{\partial X}\right) = \frac{\partial(\theta\overline{\rho}^* H_T)}{\partial X} \tag{4}$$

where

$\lambda = \frac{3}{4}\pi^2 \frac{U}{W^2}$, $\varepsilon_x = \phi_x \overline{\left(\frac{\rho}{\eta}\right)}_e H^3 / \lambda$, $\overline{\rho}^* = \overline{\rho}_e' \overline{\eta}(U_2 - U_1) + \overline{\rho}_e U_1$,

$\overline{\left(\frac{\rho}{\eta}\right)}_e = 12\left(\frac{\overline{\eta}_e \overline{\rho}_e'}{\overline{\eta}_e} - \overline{\rho}_e''\right)$, $\overline{\rho}_e' = \int_0^1 \left[\overline{\rho}\int_0^Z \frac{1}{\overline{\eta}} dZ'\right] dZ$,

$\overline{\rho}_e'' = \int_0^1 \left[\overline{\rho}\int_0^Z \frac{Z'}{\overline{\eta}} dZ'\right] dZ$, $\frac{1}{\overline{\eta}_e} = \int_0^1 \frac{1}{\overline{\eta}} dZ$, $\frac{1}{\overline{\eta}_e} = \int_0^1 \frac{Z}{\overline{\eta}} dZ$, $\overline{\rho}_e = \int_0^1 \overline{\rho} dZ$.

With the following boundary conditions

$$P(X_{in}) = P(X_{out}) = 0$$

and the complementarity conditions

$$\begin{cases} P(X)(1-\theta(X)) = 0 \\ P(X) \geq 0, 0 \leq \theta(X) \leq 1 \end{cases} \quad (5)$$

In the pressurized region, the lubricant completely fills the gap between the wheel and rail, hence $\theta = 1$, and Eq.(4) is reduced to the common average flow Reynolds equation; while in the starved region or the cavitation region the lubricant partly fills in the gap, hence $0 < \theta < 1$ [18].

H is the dimensionless nominal film thickness defined as the distance between the mean level of the two surfaces and H_T is the dimensionless local film thickness, which is assumed to be of the form:

$$H_T = \frac{H}{2}\left[1 + erf\left(\frac{H}{\bar{\sigma}}\right)\right] + \frac{\bar{\sigma}}{\sqrt{2\pi}}\exp\left(-\frac{H^2}{\bar{\sigma}^2}\right) \quad (6)$$

In equation (4), ϕ_x is the pressure flow factors in x direction, which is fitted into the empirical relations of form as follows [17].

$$\phi_x = 1 - Ce^{-r'(H/\bar{\sigma})} \quad \text{for } \gamma \leq 1$$

$$\phi_x = 1 + C\left(\frac{H}{\bar{\sigma}}\right)^{-\gamma} \quad \text{for } \gamma > 1$$

where the constants C and r' are given as the functions of γ presented by Patir and Cheng [17]. $\bar{\sigma}$ is the dimensionless composite surface roughness.

The Roelands equation is applied to oil and water, which can consider the effect of temperature on the viscosity. It can be defined as follows [24]:

$$\bar{\eta}(P,\bar{T}) = \exp\left\{\left[\ln(\eta_0)+9.67\right]\left[-1+(1+5.1\times10^{-9}p_H P)^z\left(\frac{\bar{T}-\frac{138}{T_0}}{1-\frac{138}{T_0}}\right)^{-s_0}\right]\right\} \quad (7)$$

Where p_H is the maximum Hertz contact pressure; η_0 is the initial viscosity of liquid at ambient pressure, and thus Z=0.6, s_0=-1.1.

Since the Ree-Erying model is applied in the model, the equivalent viscosity $\bar{\eta}^*$ of the interfacial liquid should be obtained after determining the shear stress $\bar{\tau}$. It can be expressed as the following dimensionless form [25].

$$\bar{\tau} = \bar{\tau}_a + \left(\frac{h_0}{b}\right)\bar{z}H\frac{dP}{dX} \quad (8)$$

$$\bar{\tau}_a = \bar{\tau}_0 \ln\frac{\sqrt{(U_a-U_b)^2 + CH^2(\bar{F}_1^2 - \bar{F}_2^2)} - (U_a - U_b)}{CH(\bar{F}_1 + \bar{F}_2)}$$

Where $\bar{F}_1 = H\int_0^1 \frac{\bar{\tau}_0}{\bar{\eta}}\cosh\left(\frac{\bar{z}H}{\bar{\tau}_0}\left(\frac{h_0}{b}\right)\frac{dP}{dX}\right)d\bar{z}$, h_0=b^2/R, $\bar{z} = \frac{z'}{h}$,

$\bar{F}_2 = H\int_0^1 \frac{\bar{\tau}_0}{\bar{\eta}}\sinh\left(\frac{\bar{z}H}{\bar{\tau}_0}\left(\frac{h_0}{b}\right)\frac{dP}{dX}\right)d\bar{z}$, $CH = \frac{p_h h_0}{\eta_0 U}$.

The density relationship between pressure and temperature is expressed as

$$\bar{\rho}(P,\bar{T}) = 1 + \frac{0.6\times10^{-9}p_H P}{1+1.7\times10^{-9}p_H P} - D_t(\bar{T}-1) \quad (9)$$

Where T_0 is the initial temperature; D_t is 0.00065 T_0.

The published papers on the force-compliance relationship of mean asperity contact pressure and average gap is based on the work of Greenwood and Williamson (GW) [26]. GW model is an elastic model. However, the asperities may deform elastically, elasto-plastically or plastically under the wheel/rail contact force. ZMC [26], JG [27] and KE [28] models can consider the elastic, elastic-plastic, and fully plastic states of the asperities deformation. However, the existing elastic-plastic solutions suffer from several deficiencies caused mainly by assuming some arbitrary contact pressure distribution or an arbitrary evolution of the plastic region inside the sphere [27]. In addition, although FEM methods have been applied by many researchers, their formulas are not based on the wheel/rail surface roughness conditions.

In the present paper, firstly, large number of field tests of the real wheel/rail surfaces had been carried out. By analyzing the results, it should be concluded that the testing roughness profiles can be accurately fit by 8 orders Fourier approximation, shown in Fig.3. In that case, the radius of the asperities being contact can be obtained. An accurate FEM model was developed which simulated a rigid flat contact over a sphere. Results show that the radius of sphere has less effect on the contact pressure. Therefore, a typical radius of the asperity is applied in the FEM model. By numerous simulations, the empirical equations for the asperity contact pressure and nominal areas can be obtained. They can be expressed as follows.

$$\begin{cases} w^* \leq 1, \ P^* = (w^*)^{3/2} \\ 1 < w^* \leq 4.68, P^* = 1.053(w^*)^{1.405} \\ 4.68 < w^* \leq 40, P^* = 1.32(w^*)^{1.287} \\ 40 < w^* \leq 200, P^* = 2.03(w^*)^{1.175} \end{cases} \quad (10)$$

$$\begin{cases} w^* \leq 1, \ A^* = w^* \\ 1 < w^* \leq 4.68, A^* = 1.113(w^*)^{1.032} \\ 4.68 < w^* \leq 40, A^* = 0.992(w^*)^{1.133} \\ 40 < w^* \leq 200, A^* = 1.052(w^*)^{1.119} \end{cases} \quad (11)$$

Where, w^*, P^*, A^* are the dimensionless forms of the interference gap, contact pressure and contact area. They can be expressed as follows.

$$w^* = w / w_c, P^* = P / P_c, A^* = A / A_c$$

Where

$$P_c = \frac{4}{3}\left(\frac{R}{E'}\right)^2\left(\frac{C}{2}\pi S_y\right)^3, A_c = \pi^3\left(\frac{CS_yR}{2E'}\right)^2, w_c = \left(\frac{\pi CS_y}{2E'}\right)^2 R$$

R is the radius of the asperity profile on contact point; E' is the equivalent elastic module; S_y is the yield stress.

It should be noticed that in Eq.(10) the asperity contact has four typical stages which is governed by w^*. For $w^* < 1$, the deformation is elastic; for $1 < w^* \le 4.68$, the deformation is elastic-plastic and the plastic reaches the interface; for $4.68 < w^* \le 40$, the deformation changes from elastic-plastic to fully plastic; while for $40 < w^* < 200$, the deformation is fully plastic. As to the wheel/rail contact force, the deformation will belong to the four states.

In order to investigate the accuracy of the present formula, Fig.4 compares the relationship among the present formula and the KE and JG models. Results show that the present formula agrees well with JG which is more accurate than KE model.

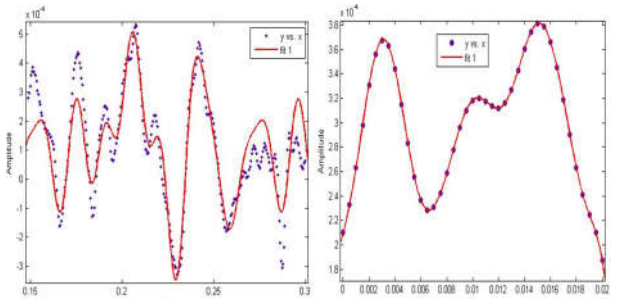

Figure 3 *Measurement of surface roughness profile and their fitting curves*

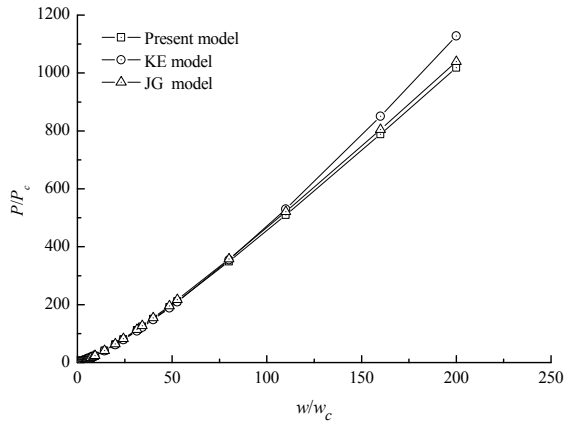

Figure 4 *Mean separations of the surfaces as a function of load*

In the present paper, the amplitude distribution of roughness is Gaussian. Based on the single asperity contact formula, the contact pressure between wheel and rail can be expressed as follows.

$$\overline{P}=\frac{P}{A_n E}=\frac{2}{3}H_d\pi\beta K w_c / E\left(\int_{d^*}^{d^*+w_c} I^{1.5}\mathrm{d}z^* + 1.053\int_{d^*+w_c}^{d^*+4.68w_c} I^{1.405}\mathrm{d}z^* + 1.32\int_{d^*+4.68w_c}^{d^*+40w_c} I^{1.287}\mathrm{d}z^* + 2.023\int_{d^*+40w_c}^{\infty} I^{1.175}\mathrm{d}z^*\right) \quad (12)$$

Where $I=\left(\frac{z^*-d^*}{w_c}\right)$, $z^*=\frac{z}{\sigma}$, $d^*=\left(\frac{\bar{h}}{\sigma}-\frac{G}{\xi}\right)$,

$$J=\phi^*(z^*)=\frac{1}{\sqrt{2\pi}}\left(\frac{\sigma}{\sigma_s}\right)e^{-(\sigma/\sigma_s)^2(z^{*2}/2)}.$$

G and ξ are constants. The variables with star superscript are normalized by σ. H_d is Brinell hardness; h^* denotes the dimensionless average gap; z^* is the dimensionless height of asperity; σ_s represents the standard deviation of surface heights; y_s^* denotes the distance between the mean of asperity heights and that of surface heights. Referring to the work of McCool, the following relationships apply [29]:

$$y_s^*=\frac{0.0459}{\beta}\sigma,\ \sigma_s=\sqrt{1-\frac{3.7169\times10^{-4}}{\beta^2}}\sigma$$

Another important characteristic of micro asperities is the plasticity index ψ, which was defined in the form [30].

$$\psi=\frac{2E}{1.5\pi k_1 H_d}\left(\frac{\sigma}{R}\right)^{1/2}\left(1-\frac{3.717\times10^{-4}}{\beta^2}\right)^{1/4}$$

Where, since some parameters in the equation are hard to determine, some of them are obtained from the Ref.29. In the model, the corresponding values of β and σ/R of different surfaces were obtained from the experimental observation by Nuri and Halling. k_1 is a constant which is set to be 0.4.

The dimensionless film thickness equation is written as

$$H(X)=H_0+\frac{X^2}{2}-\frac{1}{\pi}\int_{X_{in}}^{X_{out}}(P+P_a)\ln|X-S|\,dS \quad (13)$$

where H_0 is the compliance at the center of contact area; P and P_a are the dimensionless liquid and asperity contact pressure respectively.

In Fig.1, it should be noticed that the wheel/rail normal force is carried by the interfacial liquid and the asperities of wheel/rail. The dimensionless force balance equation can be expressed as:

$$W=W_e+W_a=\int_{Af}P\mathrm{d}A+\int_{Ac}P_a\mathrm{d}A \quad (14)$$

The pressure field can be obtained by linking and solving Eqs.(1-14). And the temperature field can be obtained by solving the following equations.

The general dimensionless energy equation across the film thickness for line contact is

$$Pr\cdot Re\left(\bar{\rho}U\frac{\partial\bar{T}}{\partial X}-\frac{\bar{q}}{H}\frac{\partial\bar{T}}{\partial\bar{z}}\right)-\frac{1}{H^2}\frac{\partial^2\bar{T}}{\partial\bar{z}^2}=-Ec\cdot Yt\left(\frac{h_o}{b}\right)^2+\frac{\bar{T}}{\bar{\rho}}\frac{\partial\bar{\rho}}{\partial\bar{T}}U\frac{\partial P}{\partial X}+Ec\cdot Yt\left(\frac{h_o}{b}\right)\frac{\bar{\tau}}{H}\frac{\partial U}{\partial\bar{z}} \quad (15)$$

In Eq. (15), the dimensionless parameters are:

$$\begin{cases} Pr=\dfrac{c_p\eta_0}{k}, Re^*=Re\left(\dfrac{h_0}{b}\right)^2, Re=\dfrac{\rho_0 Ub}{\eta_0} \\ Ec=\dfrac{U^2}{c_pT_0}, Yt=\dfrac{c_p b p_H}{Uk}, \bar{q}=\dfrac{\partial}{\partial X}\left(H\int_0^{\bar{z}}\bar{\rho}Ud\bar{z}'\right) \end{cases},$$

where c_p, k_f are the specific heat and thermal conductivity, respectively. b is the half Hertzian contact length.

And U in the above equation can be obtained by integrating Eq.(1).

$$U=U_a+\int_0^{\bar{z}}\frac{\partial U}{\partial \bar{z}}d\bar{z}' \tag{16}$$

Based on the work done by Yang.et.al [31], the temperature field in the wheel and rail is obtained by solving the following equations in dimensionless form:

$$CN_aU_a\frac{\partial \bar{T}}{\partial X}=\frac{\partial^2\bar{T}}{\partial \bar{z}_a^2},\ CN_bU_b\frac{\partial \bar{T}}{\partial X}=\frac{\partial^2\bar{T}}{\partial \bar{z}_b^2} \tag{17,18}$$

Where $CN_a=bUc_a\rho_a/k_a, CN_b=bUc_b\rho_b/k_b, \bar{z}_{a,b}=\dfrac{z_{a,b}}{h}$. k_a and k_b are the thermal conductivity of solid a and b respectively. c_a and c_b are the specific heat of solids a and b.

On the two liquid–solid interfaces, the following heat flux continuity conditions must be satisfied:

$$\left(\frac{\partial \bar{T}}{\partial \bar{z}_a}\right)_{\bar{z}_a=0}=CM_a\frac{1}{H}\left(\frac{\partial \bar{T}}{\partial \bar{z}}\right)_{\bar{z}=0},\ \left(\frac{\partial \bar{T}}{\partial \bar{z}_b}\right)_{\bar{z}_b=0}=CM_b\frac{1}{H}\left(\frac{\partial \bar{T}}{\partial \bar{z}}\right)_{\bar{z}=1} \tag{19,20}$$

Where

$$CM_a=\frac{k_f}{k_a}\frac{b}{h_o}, CM_b=\frac{k_f}{k_b}\frac{b}{h_o}, \bar{T}_a=\left(\bar{T}\right)_{\bar{z}_a=0,\bar{z}=0}, \bar{T}_b=\left(\bar{T}\right)_{\bar{z}_b=0,\bar{z}=1}.$$

The temperature calculating domains for liquid and solids can be found in Ref.31.

The adhesion ability is related to the traction force, which is obtained from the pressure field. In the present paper, the adhesion coefficient is defined as the ratio of traction force and the normal force in the following forms.

$$f=\frac{F_e+\mu_aF_a}{W}=\frac{\int_{X_{in}}^{X_{out}}\bar{\tau}dX+\mu_a\int_{X_{in}}^{X_{out}}P_adX}{W} \tag{21}$$

where μ_a is the friction coefficient on the asperity contact; $\bar{\tau}$ is the shear stress of the interfacial liquid which can be expressed as follows.

$$\bar{\tau}=\frac{u_R\eta_0}{p_Hh_0}\frac{\bar{\eta}}{H}\frac{\partial U}{\partial Z} \tag{22}$$

3. Numerical procedure

In order to obtain the adhesion coefficient, the Eqs.(1-14) should be discretised using difference method and solved simultaneously by the multigrid method. The simulation procedure is carried out by the pressure-temperature iteration between Reynolds Eq. (1-14) and the energy Eqs. (15-20) with their boundary conditions. Since the starvation and cavitation are involved in the present model, the numerical procedure is different from the flooded case. The pressure P and the fractional film content θ were treated as separate variables in a Gauss–Seidel line relaxation. The fractional film can be obtained from the following iteration form [20].

$$\theta_i=\left[\varepsilon_{i-1/2}P_{i-1}-\left(\varepsilon_{i-1/2}+\varepsilon_{i+1/2}\right)P_i+\varepsilon_{i+1/2}P_{i+1}\right]/\left[\Delta_X\left(\bar{\rho}H\right)_i\right] -\Delta_XF_i/\left(\bar{\rho}H\right)_i+\left(\overline{\rho\theta}H\right)_{i-1}/\left(\bar{\rho}H\right)_i \tag{23}$$

In order to overcome the convergence problem, some measurements should be taken according to the work done by Wijnant [32]. When the pressure is calculated each time, one should check the following supplementary conditions [33]. If $P_i>0$, then let $\theta=1$; if $P_i<0$, then $P_i=0$, and θ_i should be integrate from Eq.(23). Once θ_i is calculated, the supplementary conditions should be checked again. If $\theta_i<1$, then one should have $P_i=0$. If $\theta_i>1$, then take $\theta_i=1$. The general flowchart for the present model is illustrated in Fig.5.

4. Results and Discussions

It is assumed that the two surfaces of the bodies in contact have isotropic roughness pattern. The main input data used in common conditions are listed in Table 1 based on the Chinese high-speed train CRH2. The main input parameters of water and oil common to all the results are listed in Table 1. In this section, the contact characteristics such as the distributions of liquid pressure, asperity pressure and film thickness are obtained under starved contamination. In addition, the temperature field is also investigated in the section. Furthermore, the effects of the train speed, surface roughness and inlet film thickness layer on the adhesion coefficient under water or oil starved contamination condition were discussed.

Table 1 *Parameters used in the simulation*

Parameter	Oil	Water
Ambient viscosity of lubricant, η_0, N s/m^2	0.08	0.00103
Ambient density of lubricant, ρ_0, kg/m^3	870	1000
Density of solids a and b, $\rho_{a,b}$, kg/m^3	7850	7850
Specific heat of lubricant, c_p, J/kg K	2000	4200
Specific heat of solids a and b, $c_{a,b}$, J/kg K	470	470
Thermal conductivity of lubricant, k, W/m K	0.14	0.6
Thermal conductivity of solids a and b, $k_{a,b}$, W/m K	46	46
Material parameter G, dimensionless	4980	155
Ambient temperature, T_0, K	313	313
Characteristic shear stress of the Eyring fluid, Pa	10^7	10^7
Friction coefficient of asperity contact	0.45	0.45
Surface roughness $\sigma_{1,2}$, μm	3.5	3.5

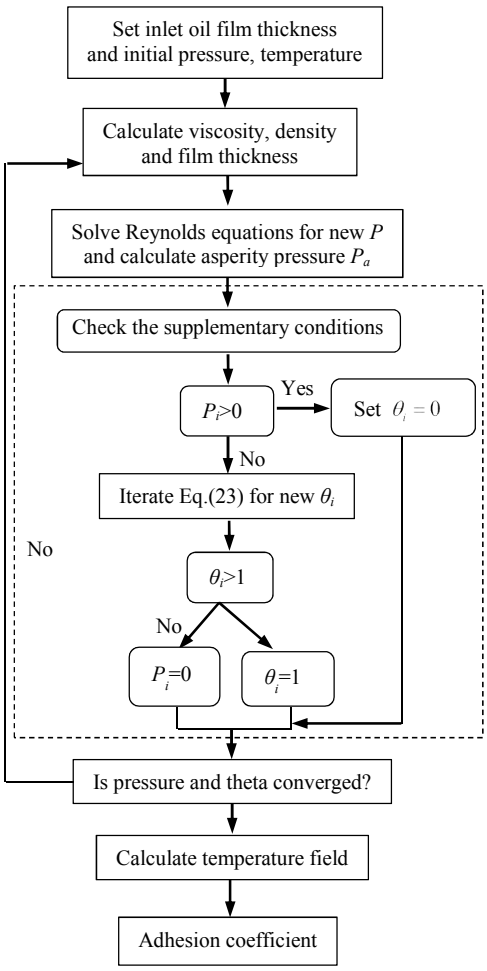

Figure 5 *Flowchart of starved interfacial contamination*

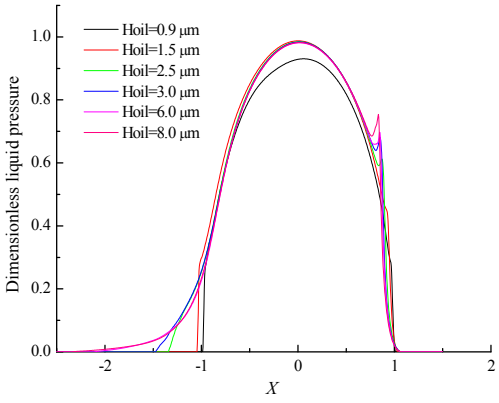

4.1. Contact characteristics

Based on the parameters listed in Table 1, the obtained contact characteristics have been plotted in Fig. 6 and 7, which shows the variations of film thickness, liquid pressure, asperity contact pressure and variable θ corresponding to different inlet oil layer thicknesses under starved contamination for the water and the oil conditions. Six effective thickness of the oil-supply layers *hoil* are selected to investigate the wheel/rail contact characteristics. They are 0.9 μm, 1.5 μm, 2.5 μm, 3.0 μm, 6 μm and 8 μm. It should be noticed that the calculation domain for the six cases are set into $-2.5 \le X \le 1.5$, and the train speed is 300 km/h.

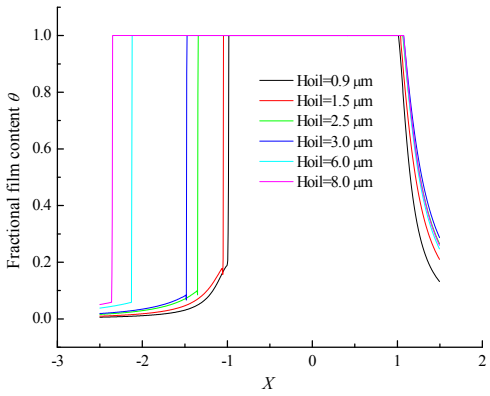

Fig.6 (a) shows the typical EHL distributions of liquid pressure with different inlet oil layer thickness *hoil*. The results show that the spike of liquid pressure near the outlet region vanished when the inlet oil layer thickness less than 3 μm. That is different from the flooded case. In addition, the results also show that it has the smallest maximum liquid pressure when the inlet oil thickness is 0.9 μm. It also can be seen in Fig.6 (a) and (b) that no obvious cavitation area is found in the inlet region, when the inlet oil layer thickness is 8 μm. That means the lubrication state will be a fully flooded condition when the inlet oil layer thickness is larger than 8 μm for the present simulation case. With the decline of the inlet oil layer thickness, the amount of lubricant in the inlet cannot establish the fully flooded condition. Therefore, the cavitation boundary appears to be getting closer to the contact zone, as shown in Fig.6 (a). It should be noted that the abrupt change of dp/dx in the inlet region represents the position of the boundary between the pressurized region and the starved region in the present study. When the inlet oil layer thickness is down to 0.9 μm, the inlet region is completely the flooded area and it becomes nearly the same as the Hertz contact zone, as shown in Fig. 5.

Fig.6 (b) shows the distributions of the fractional content θ with different inlet oil layer thickness. With the decline of θ, the cavitation becomes close to the border of the Hertz contact zone, which is similar to the distribution of liquid pressure in Fig.6 (a).There are two cavitation areas in the inlet and outlet regions, respectively. It shows that, the fractional film content gradually improves from the constant inlet oil supply and has a jump to unity where the pressure starts to build up. And its location of jump is related to the *hoil*. At the outlet of the contact zone, since the space suddenly increases for the fluid and the cavitation exists, the fractional film content θ decreases rapidly. The results show that the location of the cavitation area in the outlet is closer to the Hertz border when *hoil* is smaller. It should be noticed that in the area where the θ=1 is corresponding to the area of P>0, and θ<1 is corresponding to the area of P=0 in Fig.6 (a).

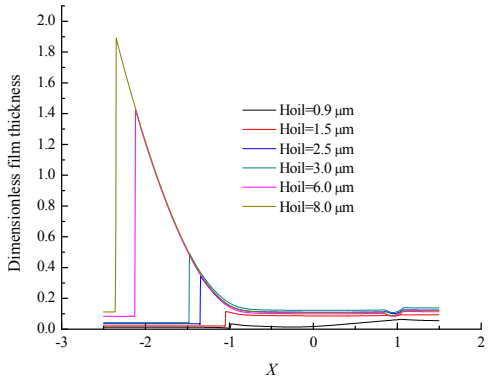

Fig.6 (c) shows the profiles of film thickness with different inlet oil layer thickness. They are different from the flooded case [15]. It is known from the definition of θ that the fluid film thickness equals to the total gap h in the area where θ=1, which can be seen from the corresponding areas in Fig. 6 (c). In addition, because the fractional film content has a jump at the inlet region, see Fig. 6 (b), the fluid film thickness also has a jump at the same boundary, and the value of the fluid film thickness beyond the jump boundary is equal to *hoil*, see Fig.6 (c). Furthermore, it also can be seen from Fig.6 (c) that the film thickness increases with the inlet oil layer thickness *hoil* when *hoil* is less than 4 μm. While when *hoil* is larger than 4 μm, the film thickness decreases with the increasing of *hoil*.

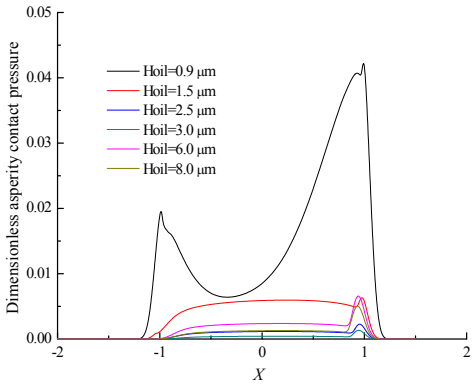
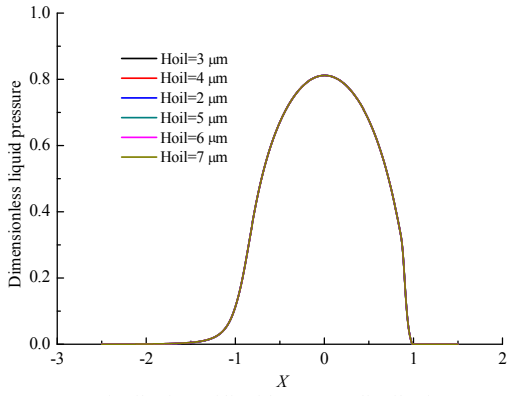


(a) Distribution of liquid pressure distribution

(b) Distribution of fractional film thickness content θ

(c) Distribution of film thickness



(d) Distribution of asperity contact pressure

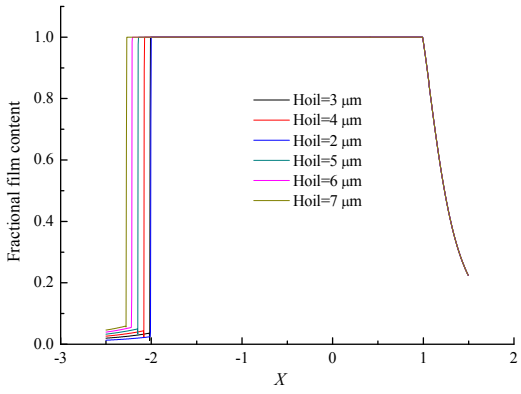


Figure 6 *Wheel/rail contact characteristics under starved oil contamination*

Fig.6 (d) shows the distribution of asperity contact pressure with different inlet oil layer thickness *hoil*. It can be found that the distributions of the film thickness and the asperity contact pressure have a reflection relationship in Fig. 6 (c) and (d) which is similar to the flooded case. Fig. 6 (d) also shows that the smaller *hoil* gets the larger asperity contact pressure. And the inlet oil layer thickness *hoil* has the same effect on the asperity contact pressure.

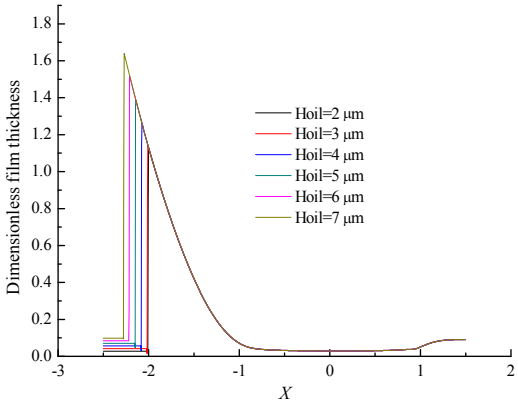

Fig.7 shows the contact characteristics with starved water contamination. There are also six kinds of inlet oil layer thickness *hoil*, which are from 2 μm to 7 μm. The vehicle speed is 150 km/h. The calculation domain is the same as the oil contamination. It can be found in Fig.7 (a) and (d) that the inlet oil layer thickness *hoil* has less effect on the liquid and asperity contact pressure. That is because the viscosity of water is small, which makes the centre film thickness do not change significantly, shown in Fig.7 (c). Fig.7 (b) shows the distribution of the fractional film content θ with different inlet oil layer thickness *hoil*. The results in Fig.7 (b) indicate that *hoil* has the effect on the location of the cavitation boundary. The smaller *hoil* is much easier to make the cavitation boundary close to the Hertz contact zone. It is similar to the oil starved case. However, *hoil* has less effect on the fractional film content in the outlet cavitation region, which is different from the oil case in Fig.6 (b). Fig.7 (b) also indicates that the inlet oil layer thickness only has effect on the inlet cavitation region which is similar to Fig.7 (a). Fig.7 (d) shows the distributions of asperity contact pressure with different inlet oil layer thickness *hoil* under water contamination. It also has a reflection relationship with film thickness in Fig.7 (c). It can be found from Fig.6 (d) and Fig.7 (d) that water contamination gets the larger asperity contact pressure than that of oil contamination.

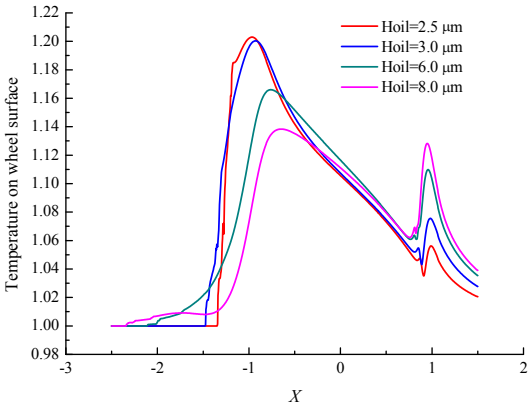
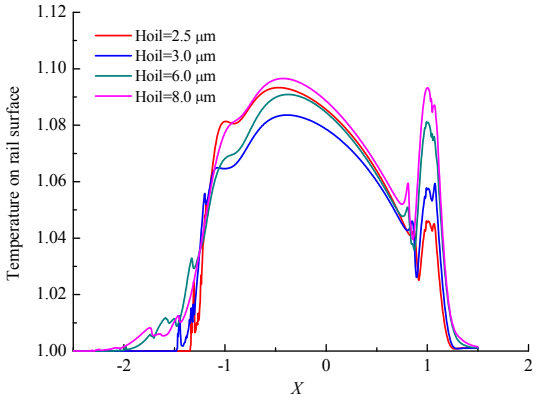
(b) Distribution of fractional film thickness content

(c) Distribution of film thickness



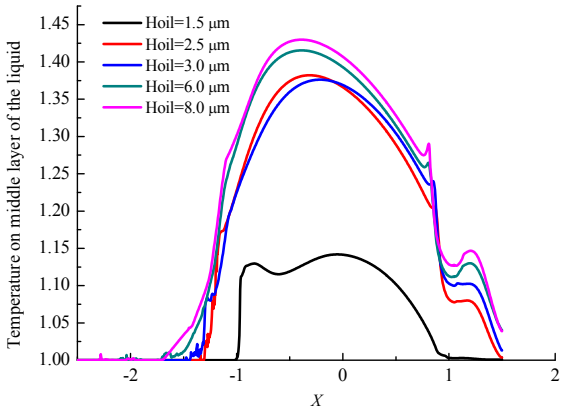
(d) Distribution of asperity contact pressure

Figure 7 *Wheel/rail contact characteristics under starved oil contamination*



4.2. Temperature field

Fig. 8 shows the variation of the temperatures on wheel surface ($\overline{T}_w$), rail surface ($\overline{T}_r$) and the middle layer of the film $\overline{T}_m$ under the oil contamination for the starved condition with different inlet oil layer thickness *hoil* . The vehicle speed is 300 km/h. And the slip ratio is 0.01. It can be seen that the three temperatures increases with the increase of the coordinate *x*, and the middle layer temperature is much higher than the two surface temperatures. This variation of the temperatures in Fig.8 is similar to the flooded case [15]. It can be found that the temperatures in the cavitation areas are equal to the ambient temperature. That is because the liquid pressure in the cavitation area is zero. The temperatures begin to increase from the end of cavitation areas, reach a maximum, and then the temperature has a steep fall and then forms a spike near the outlet cavitation areas. The locations of the spike and inlet cavitation are related to the inlet oil layer thickness *hoil*, which is corresponding to the distribution of liquid pressure in Fig.6 (a). This tendency is different from the flooded cases. It should be noticed that inlet oil layer thickness *hoil* has a significant effect on the maximum temperature of the vertical directions. Before the lubrication becoming flooded, temperatures on the rail surface and in the middle layer of the film thickness increases with the decline of oil layer thickness *hoil*. When the lubrication state changes to flooded case, the temperatures increase with the increase of oil layer thickness *hoil*. While the temperature on the wheel surface increases with the increasing oil layer thickness *hoil*. The results also show that the locations of the maximum temperatures for the three locations are related to the values of oil layer thickness *hoil*.



It is also shown from Fig. 8 that the middle layer temperature is much higher than the surface temperatures. A decompression cooling effect is visible in the temperature distribution near the outlet region in the two lubricated case [15].

(a) Temperature on wheel surface $\overline{T}_w$

(b) Temperature on rail surface $\overline{T}_r$

(c) Temperature on the middle layer of film $\overline{T}_m$

Figure 8 *Temperature field under starved oil contamination*

4.3. Effect of train speed

The vehicle speed has been proved to be one of the most important effects on wheel/rail adhesion, especially with the interfacial contamination [1-5]. Fig. 9 shows the variation of the wheel/rail adhesion with train speed under oil and water contaminations. Both the starvation condition and flooded lubrication are considered. The main parameters of water and oil used in the simulation procedures are similar. Fig.9 shows that adhesion coefficient decreases with the increase of train speed under both flooded and starved interfacial contaminations. The tendency in Fig.9 had been validated in the experimental results [4, 5] and results calculated by authors using the previous numerical model

[15]. The reason for the variation tendency may be that the center film thickness increases with the train speed. The adhesion coefficient mainly depends on the asperity load ratio. The increase of center film thickness leads to the decrease of asperity load ratio.

It should be noticed that there is no difference of adhesion coefficient between the flooded and starved water contamination with the increasing train speed. Whereas the adhesion coefficient under oil starved contamination is larger than that under the flooded contamination. This also can be explained from distributions of the film thickness in Fig.6 (c) and Fig.7 (c) for the starved conditions. From Fig. 9, it also shows that the effect of oil on the top of railhead is larger than that of water on the wheel/rail adhesion under starvation case.

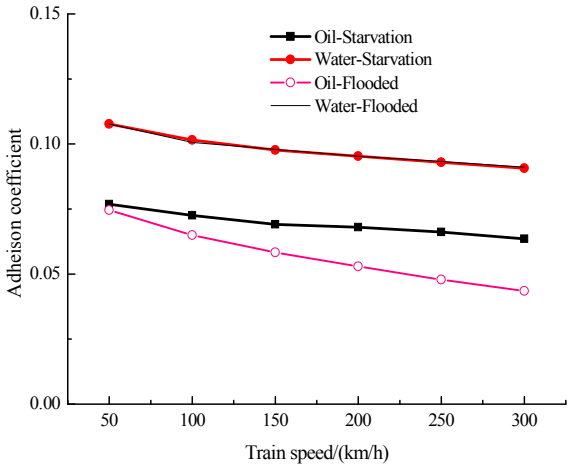


Figure 9 *Effect of train speed on the adhesion coefficient*

4.4. Effect of the inlet film thickness hoil

In the above sections, it can be found that the inlet film thickness *hoil* has a significant effect on the wheel/rail contact characteristics. Fig.10 investigates the dimensionless asperity contact force with different inlet film thickness and surface roughness under oil contamination. The results show an interesting finding. With the increase of inlet film thickness up to *hoil*=4 μm, the asperity contact force decreases. When *hoil*>4 μm, the asperity force have a slight increase. This tendency is available to the different surface roughness. The value of *hoil* can be used to judge the degree of starvation, which can describe the light rain or heavy rain in the real running condition. It should be noticed that the inlet oil or water apply determines the adhesion level. The effect of surface roughness on the adhesion can be found in Fig.10. The rougher surface gets the larger adhesion force, which is similar to the flooded case.

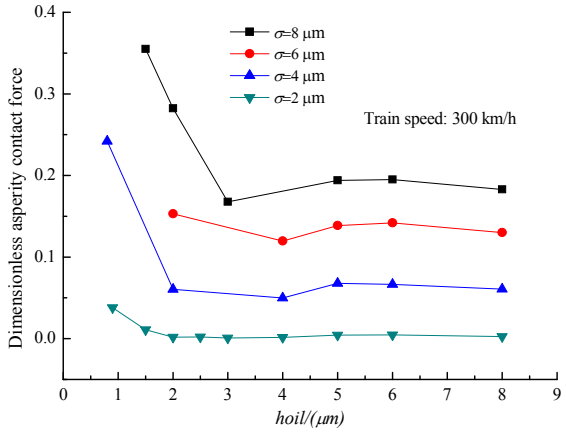

Figure 10 *Effect of inlet film thickness on asperity contact force*

5. Conclusions

The present paper proposed a new numerical model of wheel/rail in rolling contact to study the adhesion characteristics at high-speed. This model can consider the surface roughness, starved interfacial contamination, non-Newtonian property and thermal effect. Through the numerical procedure, the conclusions can be made as follows.

(1) As to the oil contamination, when the inlet oil layer thickness is down to 0.9 μm, the inlet region is completely the cavitation area and it becomes nearly the same as the Hertz contact zone. As to water contamination, the inlet oil layer thickness *hoil* has less effect on the liquid and asperity contact pressure.

(2) The boundaries of the inlet cavitation area are controlled by the inlet oil layer thickness *hoil* for both oil and water starved cases. With the decline of the inlet oil layer thickness, the cavitation boundary appears to be getting closer to the contact zone.

(3) The wheel/rail adhesion coefficient decreases with the increase of running speed under both oil and water contamination. And the variation of train speed with adhesion coefficient under starvation case is the same as the flooded case.

(4) With the increase of inlet film thickness up to *hoil*=4 μm, the asperity contact force decreases. When *hoil*>4 μm, the asperity force have a slight increase.

It should be noticed that the three-dimensional model will be established to consider the leakage of the interfacial contamination. In addition, high-speed rolling contact experiments are expected to carry out to verify the present numerical model to ensure safety and stability of high-speed railways in the near future.

Abstract: In Chinese metro lines, Vanguard fastener system is widely used as vibration damping fastening. However, the rails mounted with this fastener system are deeply affected by rail corrugation. This paper studies the formation mechanism of rail corrugation at a tight curved metro track with Vanguard fasteners through the numerical simulation method. A self-excited vibration finite element model consisting of a leading wheelset and the track system is set up. The parameter sensitivity analysis is conducted to identify the dominant factors affecting the rail corrugation. Then, the countermeasures to suppress or eliminate the rail corrugation are put forward based on the analysis results. The results show that the self-induced vibration of the wheelset-track system aroused by the saturated creep force between the wheel and the rail is responsible for the severe rail corrugation on the inner rail. The passing frequency and wavelength of the rail corrugation predicted by the model are very close to the field measured data. The parameter sensitivity analysis reveals that the elastic modulus and the damping coefficient of the rubber rest pad in the Vanguard fasteners have a significant influence on rail corrugation. Increasing the elastic modulus and the damping coefficient can effectively restrain or even eliminate the rail corrugation. Bringing the damping coefficient of the rubber rest pad above 0.0001 can significantly alleviate the rail corrugation.
Keywords: Rail corrugation; friction-induced vibration; Vanguard fasteners; friction and wear; wheelset-track system.

1. Introduction

With rapid development of economy, China's urbanization process is getting faster and faster, which poses a major challenge to the urban transportation system. The characteristics of high speed, high volume, punctuality, safety and environmental friendliness make the urban subway system the first choice to alleviate urban traffic congestion. However, the rapid growth of subway lines also bring vibration and noise, which affect the residents along the lines as well as vibration sensitive buildings and equipments. To alleviate the vibration and noise of the subway system, some vibration damping fastenings, such as Cologne-egg type fasteners and Vanguard fasteners, have been used in China' subway lines. However, after installing the subway lines with these fastener systems for a period of time, severe rail corrugation appeared on the rails [1, 2], which poses a great challenge to the safety of subway vehicles. Vanguard fastener system is mainly used in the curved track. After a period of operation of a subway track with the Vanguard fasteners, serious rail corrugation with wavelength of 50-70 mm appeared on the inner rail surface, as shown in Figure 1. However, the rail corrugation on

Figure. 1 Rail corrugation of the inner rail on a tight curved track with Vanguard fasteners.

the outer rail is not obvious and invisible to the naked eyes. At present, the formation mechanism of the rail corrugation occuring in the track mounted with Cologne-egg type fasteners has been fully studied [3-5]. But, it is a serious shortage of research on the mechanism and countermeasures of rail corrugation occuring in the track with Vanguard fasteners.

Rail corrugation is one of the most complicated and detrimental problems in railway engineering. For decades, many scholars and researchers have done an enormous amount of researches on rail corrugation. According to the wavelength fixing mechanism and the material damage mechanism, the rail corrugation can be divided into six types [6]: heavy haul, light rail, booted sleeper, contact fatigue, rutting and roaring rails (short-pitch corrugation). Among them, the formation mechanism of the short-pitch corrugation remains an enigma, and has perplexed many researchers for several decades. The existing formation mechanism of rail corrugation can be roughly divided into two categories: (1) rail corrugation is a consequence of the fluctuation of friction work due to the transient dynamic interaction between the vehicle and the track [7-9] and (2) the stick-slip self-induced vibration of the wheel/rail system is responsible for the rail corrugation [10,11]. Based on these two theories, some countermeasures are developed to suppress rail corrugation, such as tuned rail vibration absorber [12-14], friction modifier [15, 16]. However, some perplexing features of rail corrugation cannot be fully understood using the existing theories. For example, the model based on the first category theory is not a self-excited model. In that case, it is assumed that there is an initial irregularity on the surfaces of the wheels and the rails. When the wheelset is rolling on the rails, the resonances of the vehicle-track system at some specific frequencies are excited, and then the contact force between the wheel and the rail will fluctuate at same frequency, which leads to nonuniform wear on the surface of the rails, as a consequence, rail corrugation is created. Interestingly, the model also generates rail corrugation under the excitation of a white-noise roughness [8]. However, the white-noise roughness on the surfaces of the wheels and the rails is ubiquitous, which means that all rails in the straight track and the inner and outer rails of a curved track will be affected by rail corrugation. Apparently, the theory cannot explain an extremely common phenomenon of rail corrugation: when the radius of a curved track is less than 350 m, one hundred percent of the inner rail of the curved track will be subjected to rail corrugation. But rail corrugation on the outer rail of the same curved track is not obvious and almost invisible to naked eyes. When the radius of a curved track is more than 650-800 m or in a straight track, rail corrugation rarely appears on both rails of the track. Even if rail corrugation occurs, there is also a strong uncertainty that cannot be predicted. Obviously, this theory cannot explain the above rail corrugation phenomenon. In the second category, it is believed that the stick-slip vibration of the wheel/rail system is the cause of rail corrugation. However, the frequency of the rail corrugation predicted by the model based on this theory is in the range of 20–80 Hz [11], which is not consistent with the actual rail corrugation frequency.

Aiming at the weakness of existing theories in explaining these corrugation phenomenons. Chen [17] proposes a theory of friction-excited vibration of the wheel-track system causing rail corrugation. The theory holds that when the wheelset passes a tight curved track, the large lateral displacement and the attact angle cause the creep force between the wheel and rail to become saturated, which lead to the wheelset sliding on the rails. Then, the friction-induced vibration of the wheelset-track system will be excited easily by the friction force between the wheel and the rail. Finally, the rail corrugation will be created. At the same time, Kurzeck [18] and Kurzeck and Hecht [19] also carried out similar researches. In recent years, a variety of rail corrugation in subway lines have been deeply studied by Chen's research group, and these complicated rail corrugation phenomenons have been reproduced successfully using the theory [20-25]. Also, Omar [26] in Milan polytechnic university completed the main research work of his dissertation based on Chen's theory. The results from his dissertation are consistent with the actual rail corrugation.

The aim of the present work is to study the formation mechanism and countermeasures of the rail corrugation occuring in the subway track mounted with Vanguard fasteners through numerical simulation. A friction-induced vibration finite element model consisting of a leading wheelset, two rails, Vanguard fasteners system and track slab is established. Stability of the wheelset-track system is studied using the complex eigenvalue analysis method. The dominant factors affecting the rail corrugation are identified through the parameter sensitivity analysis to develop some countermeasures against the rail corrugation. The results show that the saturated creep force is responsible for the severe rail corrugation at the tight curved track with Vanguard fasteners. The wavelength of the rail corrugation is 51.4 mm, which is very close to the actual wavelength. Increasing the modulus of elasticity and damping coefficient of the rubber rest pad of Vanguard fasteners can effectively suppress or even eliminate the rail corrugation.

2. Numerical simulation model and theoretical method

2.1. Finite element model of the wheelset-track system

The inner rail of a tight curved subway track installed with Vanguard fasteners is subjected to severe corrugation after operating for a period of time. In this paper, the theory of frictional self-excited vibration is used to study the formation mechanism of the rail corrugation. A self-excited vibration finite element model consisting of a leading wheelset, rails and Vanguard fastener system is set up. The contact model is shown in Figure 2. The track system consists of the rails, Vanguard fasteners and the track slab. The rubber vibration damper plate under the track slab is simplified as a series of grounding springs and dampers distributed evenly at the bottom of the track slab, whose vertical stiffness and damping are K_{SV}, C_{SV}, respectively. As shown in Figure 2, the contact point between the outer wheel and the outer rail is located between the rail profile and the wheel flange, the contact point on the other side is located between the rail head and the wheel tread. The left and right side contact angles are δ_L, δ_R, respectively. N_L and N_R are normal contact forces on the left and right sides of the wheelset, respectively. F_L and F_R are wheel/rail creep forces on the left and right sides of the

wheelset, respectively. The contact angle δ_L is 27.51 °and δ_R is 1.18 °, which are calculated by the multi-body dynamic software Simpack. The primary suspension forces are F_{SVL}=41000 N, F_{SLL}=2400 N and F_{SVR}=37000 N, F_{SLR}=2400 N, respectively. The radius of the curved track is 390 m.

Figure. 3 The finite element model of the wheelset-track system on a tight curved track with Vanguard fasteners: (a) The overview of the model. (b) The front view of the model. (c) Contact details between the wheels and rails.

Figure. 3 is the finite element model of the wheel-track system. The model consists of a leading wheelset, two rails, track slab and the fastener system. The wheelset is located in the middle of the rails so that the effect of the fixed boundary condition at the ends of the rails on the simulation results can be mitigated. The track length is taken as the span length of 60 fasteners according to references [20], the track span is 625 mm. The massless springs and dampers simplified from the rubber vibration damper plate are distributed evenly on each node at the bottom of the track slab. The track cant is 1:40. The nominal radius of the wheelset is 840 mm, with a worn tread. The contact relationships between the wheelset and the rail and between the rail waist and the rubber rest pad are established in the finite element model. The wheel/rail friction coefficient is 0.3, the friction coefficient between the rail waist and the rubber rest pad is 0.75. The 8-node incompatible solid element is used to mesh the model. The model contains 629617 solid elements, 9963 damping elements, 9963 spring elements and 897020 nodes. The linear elastic material model adopted in the model, and their material parameter values are shown in Table 1.

Table 1 Material parameter values of the wheelset-track system.

Parts	Density ρ (kg/m^3)	Modulus of elasticity E (MPa)	Possion ratio v	Damping coefficient β
Wheelset	7800	210000	0.3	--
rail	7800	210000	0.3	--
Track slab	2400	32400	0.24	--
Side plate	7800	200000	0.3	--
Rubber rest pad	900	20	0.4	1e-5

2.2. Finite element method for self-excited vibration of the wheel-track system

In this paper, the complex eigenvalue method of ABAQUS code is used to analyze the dynamic stability of the wheelset-track system, whose theoretical basis is as follows [17]: First, the equation of motion of the wheelset-track system is established:

$$[M]\ddot{x}+[C]\dot{x}+[K]x=0 \tag{1}$$

where [*M*] is the mass matrix, which is symmetric and positive definite. [*C*] is the damping matrix and [*K*] is the stiffness matrix. $\ddot{x}$, $\dot{x}$ and x are the nodal acceleration, velocity and displacement vectors, respectively. Due to the friction, the stiffness matric and damping matric of the motion equation (1) are asymmetric matrixes. For the equations of motion with asymmetric stiffness matric and damping matric, the solution can be expressed as follows:

$$x(t)=\sum_{k=1}^{n}\varphi_k \exp(\alpha_k+j\omega_k)t \tag{2}$$

Where α_k+jω_k is the *k*th eigenvalue, x(t) is the displacement. The stability of the system can be determined through the real part α_k of the eigenvalue. It can be seen from Equation (2) that when the real part of an eigenvalue is greater than zero, the nodal displacement x(t) will increase exponentially with time, which means the vibration of the system is growing and the system will become unstable. But not all vibrations with a real part larger than zero will amplify infinitely due to the system damping, here the effective damping ratio is introduced

to estimate the propensity of the unstable vibration. The effective damping ratio is defined as:

$$\xi = -2\,\mathrm{R_e}(\lambda) / \left|\mathrm{I_m}(\lambda)\right| \quad (3)$$

where Re(λ) is the real part of the eigenvalue, Im(λ) is the imaginary part of the eigenvalue. It is only when the effective damping ratio is negative that the unstable vibration of the system can occur. Generally speaking, the unstable vibration can overcome the system damping and develop as long as the absolute effective damping ratio is greater than 0.001. The smaller the effective damping ratio, the more likely the corresponding unstable vibration will occur.

2.3. Analysis of the corrugation wear

When studing the formation mechanism of the short-pitch rail corrugation, a commonly accepted assume is that its material removal mechanism is uneven wear of rail surface caused by the fluctuation of friction work between the wheel and the rail. Any factors that cause friction work fluctuation are the potential causes of rail corrugation. In this section, corrugation wear will be related to the self-excited vibration of the wheelset-track system through the fluctuation of the friction work. Brockley proposed a modified wear model as follows [27]:

$$w = K(H - C) \quad (4)$$

where w is the volume wear rate, K the wear constant, H the friction power ($H=FV$), F the creep force, V the relative velocity and C the durability friction work rate. Equation (4) can be used to explain the formation mechanism of corrugation wear caused by self-excited vibration of the wheelset-track system. When the wheelset negotiates a tight curved track, the wheel/rail creep force will become saturated. In that case, the wheelset will slide on the rails. The creep force F is equal to the dynamic sliding friction ($F=\mu N$, μ is the wheel-rail friction coefficient, N is the total normal contact force). The self-induced vibration of the wheelset-track system will be easily excited by the friction force between the wheel and the rail. When the friction-induced vibration of the wheelset-track system occurs, the wheel-rail normal contact force will fluctuate at same frequency, and the friction work H will fluctuate to cause the fluctuation of the wear rate w at the same frequency. As a consequence, rail corrugation will be created on the rail surface.

3. Results and discussion

3.1. Unsteady vibration modal analysis of the wheelset-track system

According to the field measurements, the wavelength of the rail corrugation occurring at the curved track installed with Vanguard fasteners is in the range of 50-70 mm, the speed of the vehicle passing through this subway section is 59 km/h, and the corresponding corrugation frequency is in the range of 234-320 Hz. In this paper, the complex eigenvalue method is used to analyze the frequency distribution of the unstable vibration of the wheel-track system when the vehicle passes through the small radius curve subway section. The frequency of rail corrugation is in the range of 20-800 Hz. So, this paper studies only the unstable vibration in the frequency range of 20-800 Hz. As shown in Figure 6, there are 8 unstable vibration frequencies, among which the unstable vibration with a frequency of 319 Hz has the smallest effective damping ratio of -0.0152, which is the most likely unstable vibration. The wavelength of rail corrugation caused by that unstable vibration with frequency of 319 Hz is about 51.4 mm, which is very close to the measured data. Figure 7 is the corresponding vibration mode of this unstable vibration, it can be seen that the unstable vibration mainly occurs in the inner rail and the inner wheel of the wheelset, which means that the rail corrugation caused by the unstable vibration with the frequency of 319 Hz will mainly appear on the inner rail, which is consistent with the reality. The effective damping ratios of the other unstable vibrations are greater than -0.001, which are not enough to overcome the system damping to cause rail corrugation.

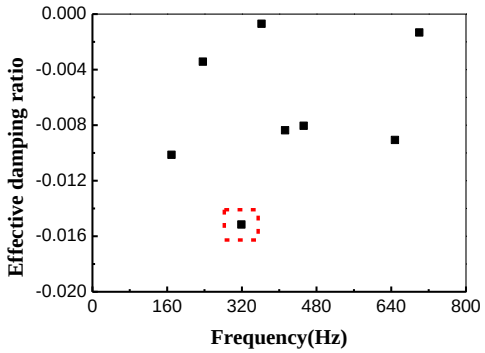

Figure. 6 Distribution of the unstable vibration frequencies of the wheelset-track system with Vanguard fasteners at a tight curved track.

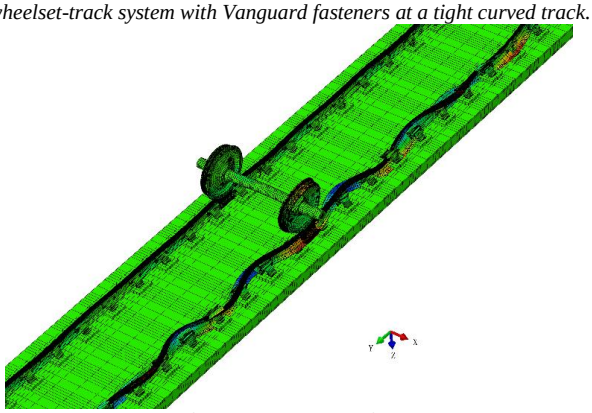

Figure. 7 Mode shape of unstable vibration of the wheelset-track system with Vanguard fasteners on a tight curved track: f_R =319Hz, ζ =-0.0152

3.2. Effect of the elastic modulus of the rubber rest pad on the unstable vibration of the system

With its special features, while achieving vibration isolation, Vanguard fastener also brings severe rail corrugation. Because of its low elastic modulus, the rubber rest pad supported between the rail waist and the side plate makes the rail have large vertical displacement, which enlightens a study on the relationship between the elastic modulus of rubber rest pad and rail corrugation. The range of modulus of elasticity studied in this section is 10-50 MPa. Noting that the Rayleigh damping model proportional to the stiffness matrix ($[C]=\beta[K]$) is used to consider the damping of the rubber rest pad [28]. The stiffness matrix is related to the modulus of elasticity E. Therefore, in order to exclude the influence of the damping coefficient β, the damping coefficient β=0 is

taken when study the influence of the modulus of elasticity.

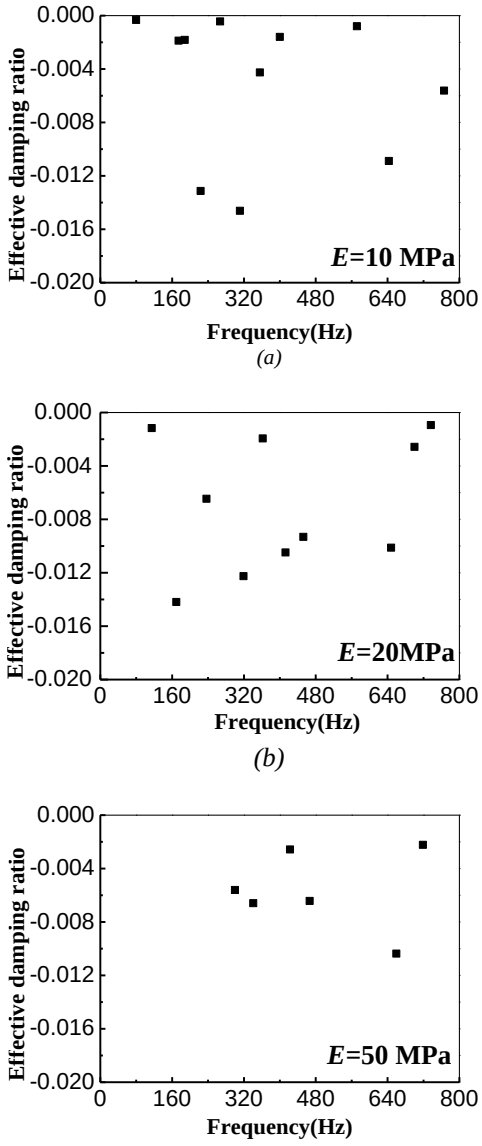

Figure. 8 Effect of the modulus of elasticity of the rubber rest pad on the unstable vibration of the wheelset-track system: (a) E=10 MPa. (b) E=20 MPa. (c) E=50 MPa.

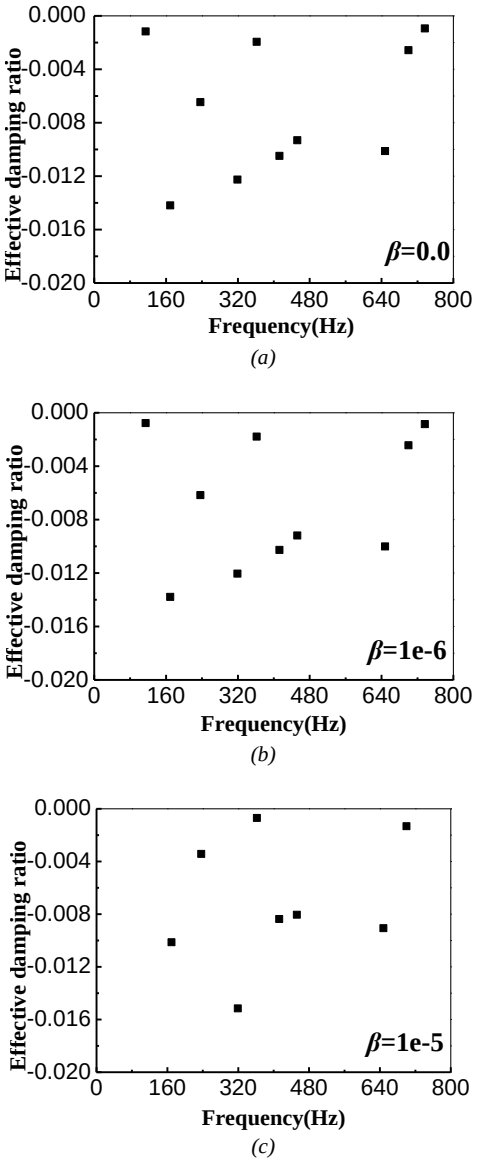

Figure. 8 shows the effect of the modulus of elasticity of the rubber rest pad on the unstable vibration of the wheelset-track system. It can be seen that the number of unstable vibrations and the absolute values of their effective damping ratios decrease significantly with the increase of the elastic modulus. When the elastic modulus increases from 20 MPa to 50 MPa, the number of the unstable vibration of the system decreases from 10 to 6. The frequency of the most likely unstable vibration moves to the high frequency zone when the elastic modulus increases, which means that the wavelength of the rail corrugation becomes shorter when the elastic modulus increases. The above results show that the greater the modulus of elasticity of the rubber rest pad, the less likely the rails suffer from corrugation. It suggested that improving the modulus of elasticity of the rubber rest pad is beneficial to the suppression of rail corrugation.

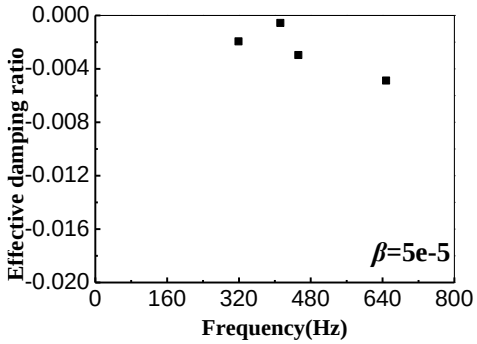
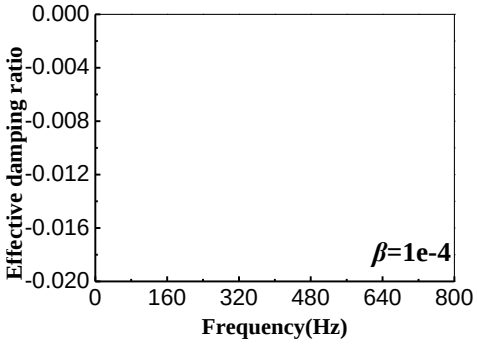


3.3. Effect of the damping coefficient of the rubber rest pad

Damping has an important influence on the unstable vibration of the wheelset-track system. It is commonly believed that the greater the damping, the stronger the vibration suppression to the unstable vibration. In this section, the effect of the damping coefficient of the rubber rest pad on rail corrugation is studied. The Rayleigh damping model is applied to consider the material damping of the rubber rest pad, in which the damping matrix is a linear combination of the stiffness matrix and the mass matrix [29]:



$$C = \alpha[M] + \beta[K] \tag{4}$$

where, α and β are the Rayleigh constant. In this paper, it is assumed that the damping matrix is directly proportional to the stiffness matrix, that is, α=0. In order to study the influence of the damping coefficient on the rail corrugation, the unstable vibration of the wheelset-track system is studied when the damping coefficient β changes in the range of 0-0.0001.

(d)

(e)

Figure. 9 Effect of the damping coefficient of the rubber rest pad on the unstable vibration of the wheelset-track system: (a) β=0.0. (b) β=1e^{-6}. (c) β=1e^{-5}. (d) β=5e^{-5}. (e) β=1e^{-4}

Figure. 9 shows the effect of the damping coefficient on the unstable vibration of the wheelset-track system. From Figure. 9, the frequency of the most likely unstable vibration moves to the high frequency zone with the increase of the damping coefficient, which indicates that the bigger the damping coefficient is, the shorter the wavelength of the rail corrugation. From Figure. 9(a)-(e), it can be seen that with the increase of the damping coefficient, the number of the unstable vibration and the absolute value of the effective damping ratio decrease significantly. When the damping coefficient increases from 1e^{-5} to 5e^{-5}, the number of unstable vibration of the system is reduced from 8 to 4. When the damping coefficient further increases to 1e^{-4}, the unstable vibration of the wheel-track system completely disappeared, which indicates that the rail corrugation will be suppressed to the greatest extent. From the above results, it can be concluded that increasing the damping coefficient of the rubber rest pad can effectively suppress the rail corrugation. Bringing the damping coefficient of the rubber rest pad above 0.0001 can significantly alleviate the rail corrugation.

4. Conclusions

This paper presents a numerical study on the formation mechanism of the rail corrugation occuring on the rails of the tight curved track mounted with Vanguard fasteners. The complex eigenvalue method is used to analyzed the dynamic stability of the wheelset-track system. Some countermeasures are proposed based on the parameter sensitivity analysis results. The conclusions are given as follows:

(1) When the vehicle negotiates the small radius curved track with Vanguard fasteners, the friction-induced vibration of the wheelset-track system caused by the saturated wheel/rail creep force is responsible for the severe corrugation on the inner rail. The wavelength of the rail corrugation is 51 mm, and the frequency of the corrugation is 319 Hz, which is consistent with the field measurement data.

(2) The modulus of elasticity and the damping coefficient of the rubber rest pad have a significant influence on the rail corrugation. The greater the elastic modulus and the damping coefficient, the lower the possibility of the appearance of the rail corrugation occurrence, and the shorter the wavelength of the rail corrugation. Increasing the modulus of elasticity are beneficial to suppression of the rail corrugation occuring in the sharp curve metro track installed with Vanguard fasteners. Bring the damping coefficient of the rubber rest pad above 0.0001 can significantly alleviate the rail corrugation.

Abstract:There are many vibration excitation sources in the wheel-rail system when the train runs, and the wheel-rail noise generated by each excitation source is superposed on each other. The noise reduction effect of the sound barrier calculated by the traditional method is not satisfactory. In order to further study the application of sound barrier in the noise reduction of wheel-rail noise, aiming at the generation mechanism of wheel and rail noise, the noise reduction effect of the acoustic barrier was simulated and the optimization design of high-speed railway sound barrier was advised.

Keywords:wheel/rail noise;interaction between wheel and rail;mechanism of wheel/rail noise generation; noise control;noise barrier.

1 Introduction

The noise of rail traffic affects the health of passengers and residents along the railways. It is one of the most important issues in society to control rail traffic noise. When the train speed is lower than 300km/h, the wheel-rail noise is the main source of railway noise[1]. Research on the mechanism and control method of wheel-rail noise can promote the innovation and development of rail transit technology, which has important environmental protection value and social significance.

At present, the control methods of wheel-rail noise mainly include three methods: low noise optimization of wheel-rail system structure, noise control of wheel-rail noise and control of wheel-rail noise broadcasting. In the low-noise optimization of wheel-rail system structure, A two-dimensional finite element model of the wheel cross-section was established by Thompson[2,3] using the two-dimensional boundary element method, Accordingtothe wheel axisymmetric, the free vibration characteristics of the wheel were analyzed. The effects of wheel diameter, spoke plate and wheel hub thickness on the sound emission efficiency and sound radiation directivity of the wheel were analyzed. A comparative analysis of field test results and laboratory test results were conducted by Sato[4] , also the vibratic characteristics of the wavy and straight spoke wheels were studied. Efthimeros and Nielsen et al[5,6] optimized the geometry of railway wheels and discussed ways and effects of reducing wheel and rail noise from the aspect of wheel optimization. The acoustic radiation model of sleeper was established using the acoustic boundary method, the effects of sleeper material, shape, track pad and track bed parameters on the sound emission of sleeper were studied by Nielsen[6]. Study The orbital parameters that affect the wheel / rail rolling noise were studied with wheel and rail rolling noise software TWINS, the viewpoint of optimizing the stiffness of track pad can reduce the total noise radiation of the track were made by Vincent et al[7] .

Jin[8,9]researched on the control of wheel-rail noisesource,pointed out that the rail grinding can ensure the smoothness of the rail contact surface, reduce the rail surface irregularity, improve the wheel-rail contact conditions, and reduce the generation of wheel-rail noise. In the control of wheel-rail noise source, in addition to rail grinding, installing vibration absorber on the rails to absorb rail vibration energy can also reduce the radiation of wheel-rail noise[10~12]. To make full use of the sound absorbing effect of the particles of the ballast,the sound absorbing panel or sound absorption block could be laid on the surface of the ballastless concrete slab, and slat groove can alsobeinstalled on the ballastlesstrack[13].In the control of wheel-rail noise broadcastroute,noise barriers are mostly used to reduce the wheel-rail noise.Jiang[14]developed a wideband impedance composite sound barrier based on the noisereduction requirements of the light rail and the deficiency of the sound barrier. A measuring method of the sound absorption coefficient of multi-channel impulse response was proposed, and the effectiveness of the method was proved byexperiments.Wang[15]researched the influence of sound barrier height on its noise reduction performance by using SYSNOISE acoustic software. Research showed that adding a double-sided sound absorption barrier between two tracks could improve the overall noise reduction effect. Yang[16] considered that the arc-shaped and T-shaped sound barrier had the best noise reduction effect by calculating the sound barrier insertion loss, and the sound barrier had better noise reduction effect on high-frequency noise than the low-frequency noise. The acoustic barrier model was established by Wu[17~19] by using the finite element software ANSYS and referring to the finite element software ANSYS and referring to the relevant experimental section of Wuhan-Guangzhou high-speed rail. And the noise reduction effect of different height upright reflective sound barrier was researched by

acoustic analysis software SYSNOISE.
Using noise barrier to reduce the wheel and rail noise, construction more convenient, well-designed sound barrier noise reduction effect is obvious. In order to further study the application of noise barrier in noise reduction of wheel-rail noise and the effect of noise reduction,In this paper the sound barrier model was established using SYSNOISE and ANSYS, aiming at the generation mechanism of wheel and rail noise, the noise reduction effect of the acoustic barrier was simulated and the optimization design of high-speed railway sound barrier was advised.

2 Simulation analysis model establishment

Combining the generation mechanism of wheel-rail noise and the noise-reduction characteristics of sound barrier, this paper first uses the finite element analysis software ANSYS to establish the relevant model, and then uses SYSNOISE to automatically convert the finite element model into a boundary element model for simulation calculation.

2. 1 Model parameter

As a reference object of a certain base section of Wuhan-Guangzhou high-speed railway, the sound barrier is mainly composed of steel structural columns and sound insulation screen panels. See Table 1 for acoustic barrier parameters and Table 2 for roadbed parameters.The geometric dimensions of the body structure refer to the CRH380A model, the grouping length is 203000mm, the towing vehicle length is 26500mm, the middle vehicle length is 25000mm, the vehicle width is 3380mm, the vehicle height is 3700mm, and the maximum operating speed is 350km/h.In the model analysis, the following assumptions are made: Considering the reflection of the car body, the roadbed and the vehicle body are set as rigid bodies and the corresponding rigid boundary conditions are set; the noise propagation medium is air, and the ideal gas is assumed; the sound barrier is a reflective sound barrier, It is also assumed to be a rigid body.

Table1*Parameters of sound barrier*

Item	Modulus of elasticity（Pa）	Poisson ratio	Density（kg/m^3）	Damping
Sound barrier column	2.06×10^{11}	0.3	7850	0.002
Sound insulation panel	7.2×10^{10}	0.33	2800	0.00001

Table2*Parameters of subgrade*

Modulus of elasticity（Pa）	Poisson ratio	Density（kg/m^3）
5×10^7	0.3	2600

2.2 Field point grid and its setting in simulation analysis

The noise field grid is used to describe the relative relationship between a certain position in the sound field and the train sound source. The smaller the grid size is, the smoother the sound pressure cloud diagram is. In order to fully analyze the three-dimensional spatial sound field distribution of high-speed railway noise after barriers of sound barriers, two grids with parallel and vertical field points are established respectively.The specific parameters are as follows:

The grid point 1 is an XY plane grid, which is parallel to the direction of the normal line of the sound barrier. It is 0.4m in height, 70m in length and 40m in length and is divided into 20×20 grids. Grid 1 is mainly used to analyze the attenuation law of noise in the XY plane and the distribution of sound pressure after noise barrier noise reduction. The detailed site grid and node numbers are shown in Figure 1.

The site grid 2 is the XZ plane grid, which is perpendicular to the normal direction of the sound barrier, 30m from the center of the railway line, 70m long and 30m high, and is divided into 20×20 grids. Grid 2 is mainly used to analyze the attenuation law of noise in the XZ plane at the railway boundary and the sound pressure distribution after denoising of the sound barrier. The detailed site grid and node numbers are shown in Figure 2.

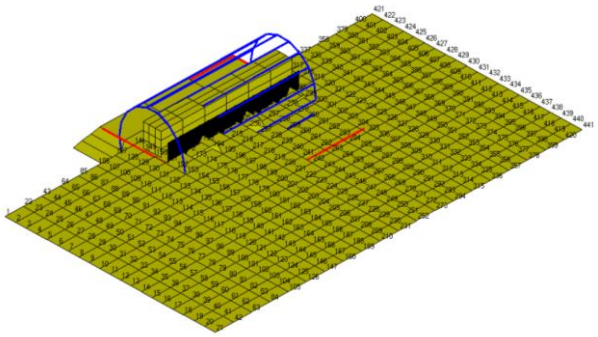

Figure1*XY plane grid schematic diagram*

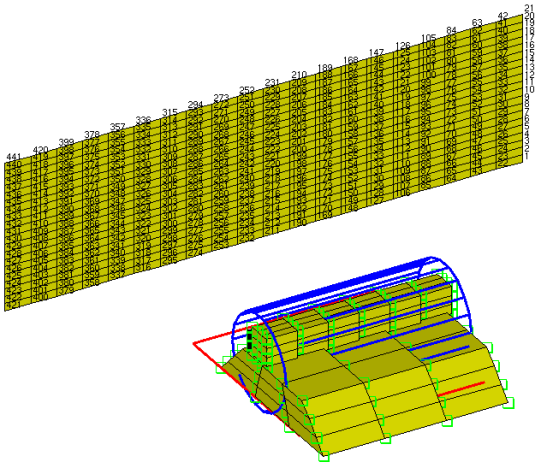

Figure2*YZ plane grid schematic diagram*

3 Analysis of simulation results

3.1 Comparison and analysis of sound source model

In most simulation analysis, people usually mix all the sound sources of the train together and analyze them in a single sound source mode without considering the superposition of various sound sources. However, studies have shown that when the train running speed is lower than 300km/h, the proportion of aerodynamic noise is reduced, and the sound source position is shifted downwards, the high-speed railway noise source model can be simplified to a dual sound source mode.

In order to compare the simulation results of two kinds of sound source modes, this paper compares and analyzes the simulation results of the two sound source models and the field measurement results based on the field test of a certain road section of Wuhan-Guangzhou Passenger Dedicated Line.When performing single sound source mode simulation analysis, only one line source should be set 3m away from the track surface.When performing double sound source model simulation analysis, a line source should be set 1m away from the track surface to simulate wheel-rail noise and aerodynamic noise, and a point source analog noise collector should be set at a distance of 4m from the track surface（Figure 3）. Figure 4 shows a schematic diagram of the test point, which includes two noise measurement points A and B.

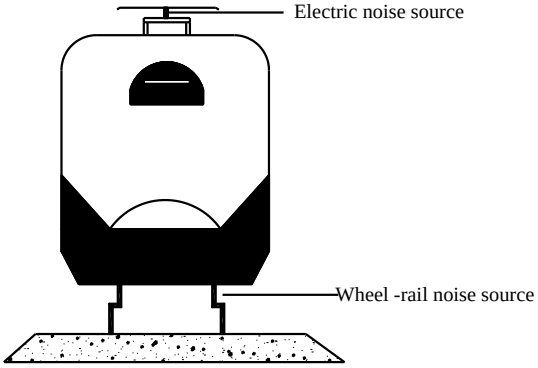

Figure3*Schematic diagram of double sound source model*

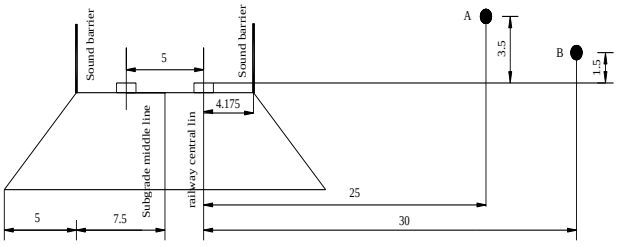

Figure4 *Schematic diagram of test point (unit: m)*

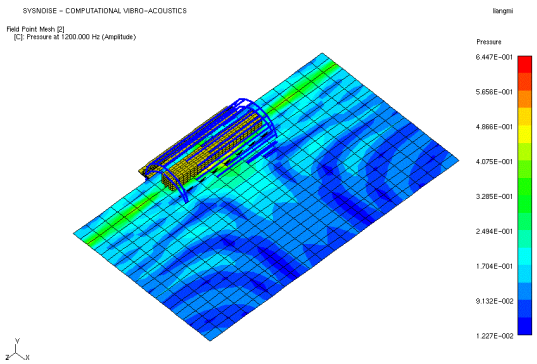
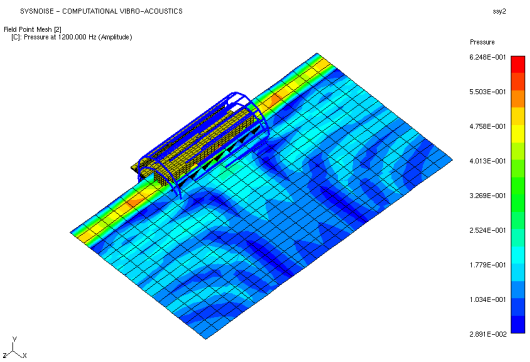
Table 3 shows the comparison table of simulation results and actual measurement results. It can be seen that the simulation results under the dual sound source mode are close to the actual measurement results, which basically meet the accuracy requirements and can better reflect the sound source characteristics of the high-speed railway.In contrast, since the single sound source mode mixes all the sound sources of the train and does not consider the superposition effect of different sound sources, the noise level of the single sound source mode is generally smaller than the actual measurement result, and the maximum deviation reaches 8 dBA.



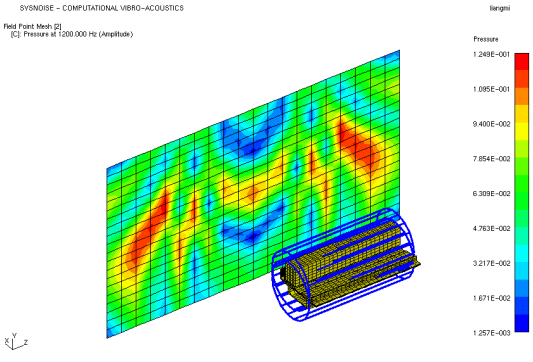
Due to the neglect of the influence of the collector noise directly across the sound barrier, the simulation results of the insertion loss of the sound barrier in the single sound source mode are also significantly higher.The measured results and the simulation results in the dual-source mode have a sound-barrier insertion loss of about 6~8 dBA, while the single-source mode noise barrier insertion loss reaches 10.7~13.1 dBA.As a result, the calculation result in the single sound source mode can easily satisfy the specified noise value, resulting in a noise reduction effect after the sound barrier is completed.

Table3 *Comparison between simulation results and measured results（Unit: dBA）*

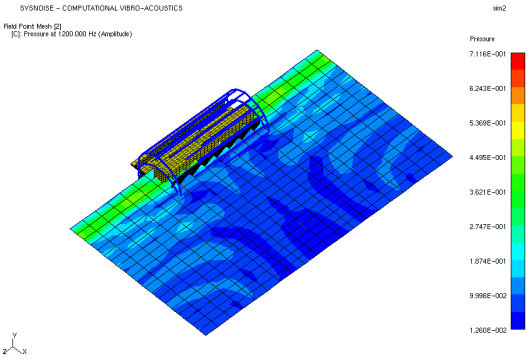


Item	Monitoring point position			Insertion loss
	A	B	B	
	Without sound barrier	Without sound barrier	With sound barrier	
Single sound source model	80.1~82.5	81.8~83.4	68.1~69.3	10.7~13.1
Double sound source model	88.9~82.5	87.4~89.6	79.2~80.8	5.9~8.7
Measured results	82.8~91.8	88.7~89.2	80.7~81.6	6.5~8.7

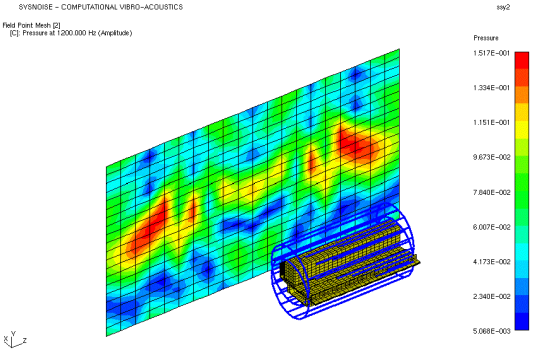
3.2Analysis of noise reduction effect of different height sound barriers



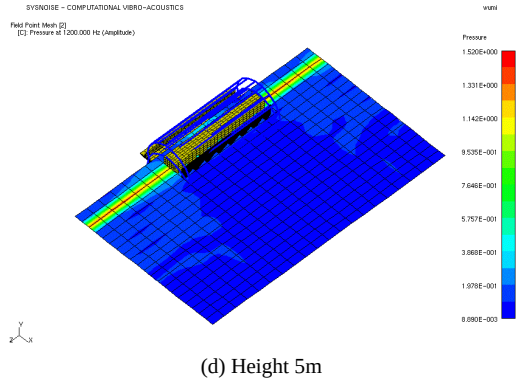
In order to exactly reflect the influence of the sound barrier height on its noise reduction performance. In this paper, the noise reduction performance of the sound barrier is analyzed using the double sound source model. In the simulation analysis, the upright reflective sound barrier is taken as the representative. The sound barrier height is 2.0m~6.0m, the calculation frequency is 400~5000Hz, and the calculation step length is 100Hz. Since the simulation results have lots of pictures, the sound pressure cloud pictures with the noise frequency of 1200 Hz are used as an example for comparison and analysis (Figure 5&Figure 6).



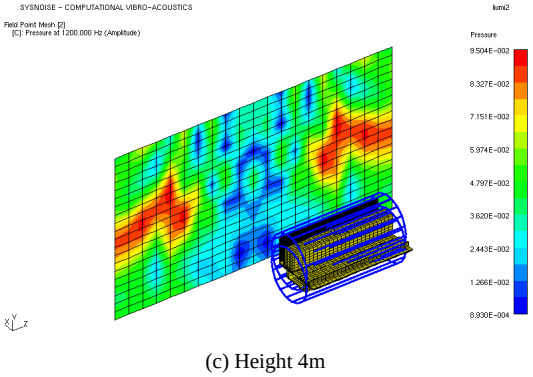
(a) Height 2m



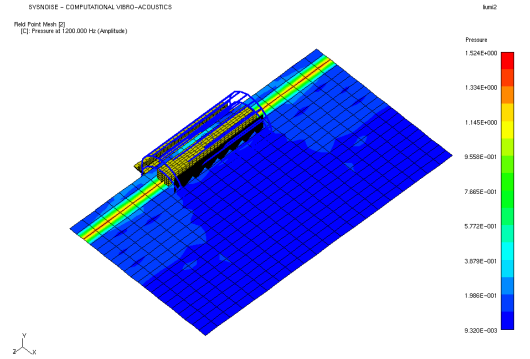
(b) Height 3m



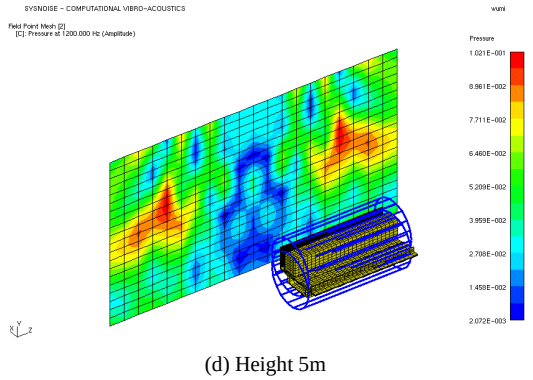
(a) Height 2m



(c) Height 4m

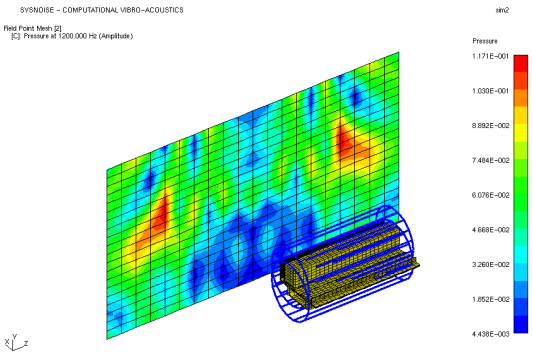


(b) Height 3m



(d) Height 5m

(c) Height 4m



(e) Height 6m

(d) Height 5m

Figure5 *Sound pressure cloud map of XZ plane at different frequencies of sound barriers at different heights*

(e) Height 6m

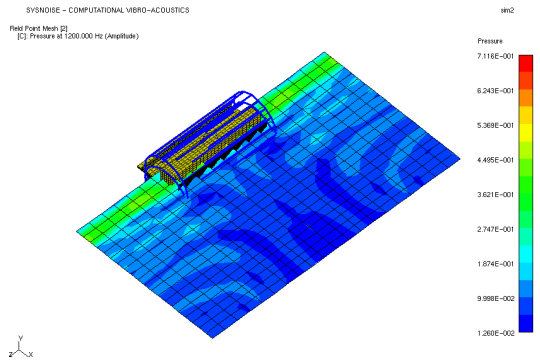


Figure6*Sound pressure cloud map of YZ plane at different frequencies of sound barriers at different heights*

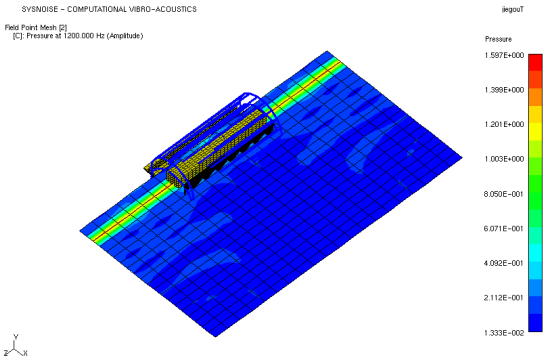
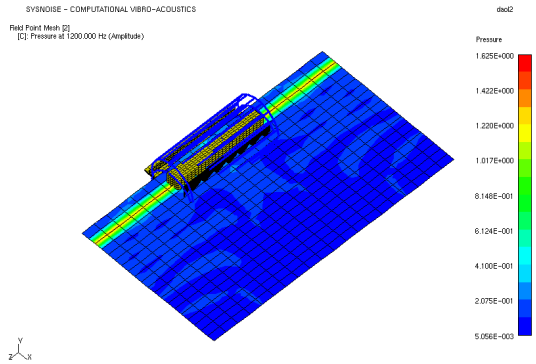
According to the sound pressure cloud pictures in Figure 5&Figure 6, when the sound barrier height is increased from 2.0m to 6.0m, the color of the sound pressure cloud pictures in the XZ field plane is gradually deepened, indicating that as the height increases, the noise reduction performance of sound barrier is gradually improved overall. In the trend, the sound pressure level in the direct shielding area of the sound barrier is significantly reduced and continued. The sound pressure level at the both sides of the sound barrier shielding area far from the sound barrier also gradually decreases but the amplitude is slightly smaller, and the sound pressure level at the both sides of the sound barrier shielding area near the sound barrier also gradually decreases but the amplitude is the smallest. Compared with the sound pressure cloud pictures in the YZ field plane , as the sound barrier height increases, the sound pressure level in the sound field distribution of the low spatial area at the railway boundary changed greatly and gradually decreases, and the sound pressure level in the sound field distribution of the high spatial area changed slightly.

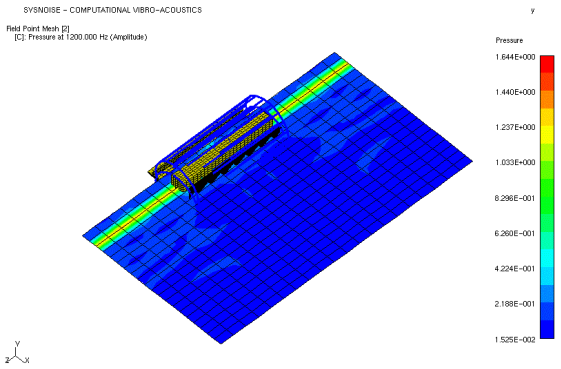


At the same time, although noise reduction performance of the sound barriergradually improves with the increase of the sound barrierheight, the degree of improvement has a big different indifferent height regions. When the the sound barrierheight is increased from 2.0m to 3.0m, the sound pressure cloud picturesin the XZ and YZ field points plane changedslightly, but the amplitude is small, indicating that in this height region, increasing thesound barrierheight has limited improvement in the noise reduction performance. When the the sound barrierheight is increased from 3.0m to 5.0m, the sound pressure cloud picturesin the XZ and YZ field points plane changedgreatly, and the dark sound shadow area is significantly increased, indicating that in this height region, increasing the sound barrier height can significantly improve the noise reduction performance of the sound barrier. When the the sound barrierheight is increased from 5.0m to 6.0m, the sound pressure cloud pictures in the XZ field plane does not change substantially, and the sound pressure cloud pictures in the YZ field plane changed slightly, indicating that increasing the sound barrier height can not improve the noise reduction performance of the sound barrier when the sound barrier height exceeds 5.0m.

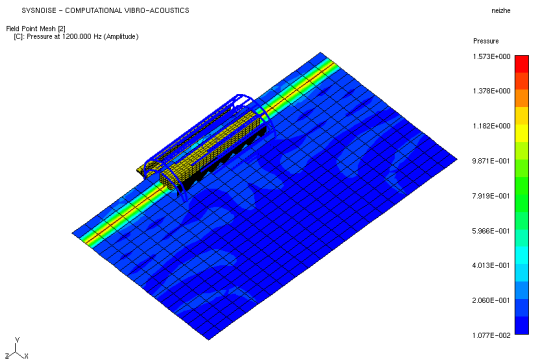
3.3 Analysis of noise reduction effect of sound barriers with different top structures



Based on the high-speed railway sound barrier model established above, the vertical, T-shaped, inverted L-shaped, Y-shaped and inward-folding sound barriers are simulated and analyzed under the dual sound source mode.The distribution of sound pressure in the XZ and YZ field points was extracted, and a sound pressure cloud with equivalent noise frequency of 1200 Hz was selected for comparison and analysis.

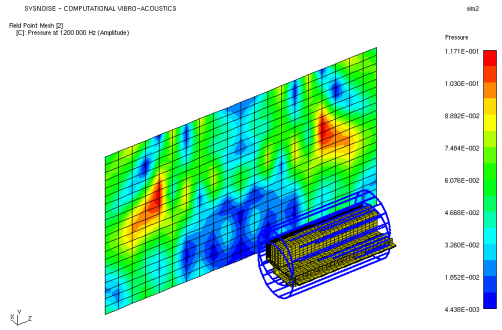


(a) Verticalsound barrier

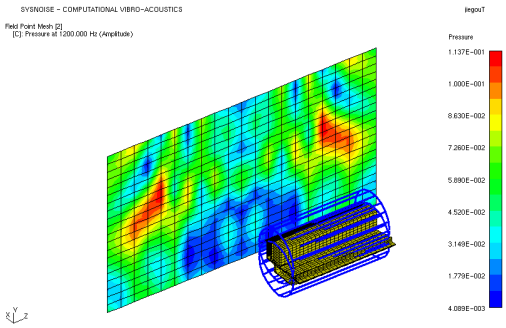


(b) T-shapedsound barrier

(c) Inverted L-shapedsound barrier



(d) Y-shapedsound barrier



(e) Inward-folding sound barrier

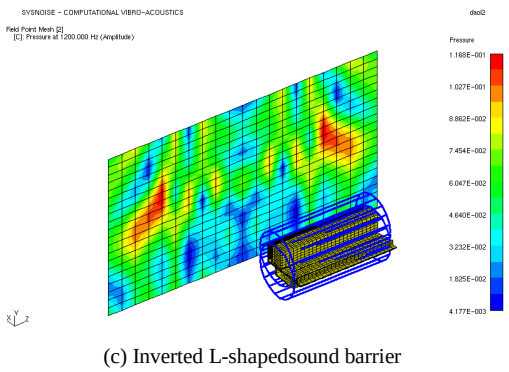


Figure7*Sound pressure cloud map of XZ plane at different frequencies of sound barriers with different top structures*

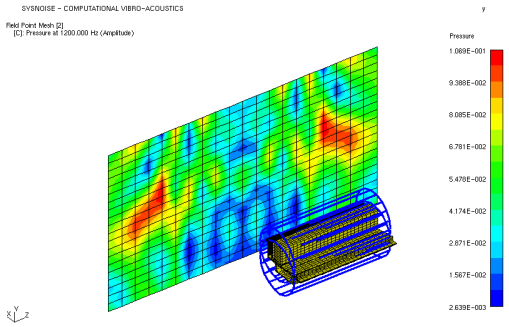
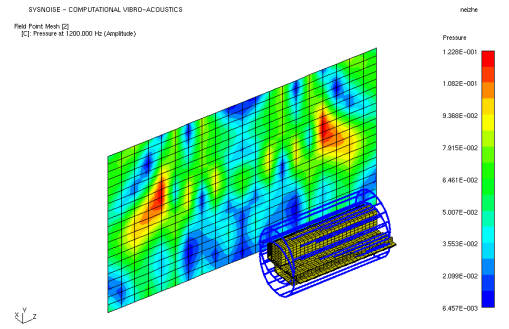


(a) Verticalsound barrier



(b) T-shapedsound barrier

(c) Inverted L-shapedsound barrier

(d) Y-shapedsound barrier

(e) Inward-folding sound barrier

Figure8*Sound pressure cloud map of YZ plane at different frequencies of sound barriers with different top structures*

The XZ and YZ plane sound pressure cloud diagrams at the equivalent frequency of different top-form sound barriers are shown in Figure 7 & Figure 8. It can be seen from cloud diagrams that different sound barrier structures have different sound pressure distributions in the plane of the field point.Compared with the sound pressure cloud diagram in the upright sound barrier, the sound field distribution in the plane of the XZ point is slightly different, but the sound pressure level is obviously lower when using other types of sound barriers with the top structure added.This shows that setting the top structure on top of the sound barrier can effectively improve the noise reduction performance of the sound barrier.

To further compare and analyze the sound pressure cloud diagrams of the T-shaped, inverted L-shaped, Y-shaped, and inward-folding sound barriers, it was found that the sound pressure distributions of the four kinds of sound barriers with the top structure in the XZ plane are quite different. Sound barriers have similar distributions of dark acoustic shadow areas and are significantly larger,

while dark sound shadow areas of sound barriers have similar distribution but relatively small areas.It shows that the noise reduction performance brought by different structural forms is quite different, and the diffraction acoustic energy dissipated by the T-shaped and Y-shaped top structures is greater than the inverted L-shaped and infolded top structures.

The sound pressure distributions and sound pressure levels of different types of sound barriers in the YZ field plane are also quite different. Compared with the upright sound barriers, the sound pressure distributions of the T-shaped and Y-shaped sound barriers in the YZ plane are similar. The inverted L-shaped and inward-folding sound barriers are quite different. The distribution area of the dark sound shadow area of the T- and Y-type sound barriers is significantly larger than that of the inverted L-shaped and inward-folding sound screens.When the top structure of the sound barrier is set, the wall folding structures on both sides of the shield have a certain shielding effect on the noise source, which can significantly improve the noise reduction effect of the sound barrier.Therefore, in acoustical design of sound barriers, it is preferable to arrange the folded wall structures symmetrically on both sides of the shield body.The sound pressure level distribution of different sound barriers in the YZ plane also shows some common features: the dark sound shadow area in the low space area has a large area, while the dark sound shadow area in the high area space has a small area. It shows that setting the top structure on the top of the sound barrier can effectively improve the sound field distribution in the low space area, but it has little effect on the high space area.

4Conclusions

Comparing the simulation results with the measured results, we found that the predicted noise level of the double sound source model is close to the measured one, while the calculated value of the single sound source model is significantly smaller than the measured results and the simulation results of the double sound model. Single sound source noise attenuation calculation results were significantly higher than the measured results.

Due to the fact that the sound barrier height is not a simple linear relationship with its noise reduction effect, considering the noise reduction performance and economic cost, we think that the suitable height of sound barrier of high speed railway bridge segment should be between 3.0m and 5.0m .

Through the simulation analysis of upright, T-shaped, inverted L-shaped, Y-shaped and internal folded sound barriers, it can be seen that providing the top structure at the top of the sound barrier can effectively improve the noise reduction performance of the sound barrier. Among them, the Y-type structure has the best noise reduction performance, followed by the T-type structure, and the inner and the inverted L-type structure have the lowest noise reduction performance.

Acknowledgments

This study received the funding support from National Science Foundation of China (Research on the theories and methods of structural optimization design of high-speed railway sound barriers under aerodynamic loading51878672/Investigation on the sound barrier dynamics and the line landscape design of the green line selection for high-speed rails Based on GIS51578553) and the Key Grant Science and Technology Research Planning Projects of The Ministry of Railway of Peoples Republic of China (2014G005-A;2013Z004-C; 2008G017-C).

Abstract: In view of the damage phenomenon of the clip SKL 15 of vossloh W300-1 fastening system, this paper makes an in-depth analysis on the field investigation, laboratory test, simulation analysis and field dynamic testing. There are 18 order polygons in the wheels of some EMU train, and the high frequency excitation of the wheel rail force generated by the polygon wheel is close to the natural frequency of the clip, and the vibration acceleration of the clip increases significantly. At the same time, the maximum stress of the clip appears at the support position, and the long-term effect produces fatigue crack, which leads to the stress concentration, the crack propagation and the instantaneous brittle fracture.

Keywords: High-speed railway; wheel/rail vibration; damage of fastening system; clip fractures; wheel polygonization; modal analysis

1. Introduction

The modern concepts regarding the transportation networks in countries consider as very important the railway transportation system. In many cases, railways are the most convenient, fast and safe transportation system, both for goods and for passengers. In fact, the main advantages of the train are related to costs, possibility to perform massive transports, energy consumption, environmental preservation and economic efficiency. These are current topics for transportation planning, infrastructural design and for scientific research [1]. The function of a railway infrastructure is generally to support and transmit the wheel loads from rail to the railway foundation with a reduction in pressure. Between different parts of the railway infrastructure, rail fastening system is one of the key players in railway noise generation. It is also a key element in providing consistent contact between the rail and sleepers. Due to their important role, these elements are usually inspected in regular maintenance inspections [2]. Vossloh W300-1 fastening system with clip SKL 15 is one of the main type of fastening systems in China. It had a good performance for years before the phenomenon of fastening clips fractures [3], shown in Figure 1.

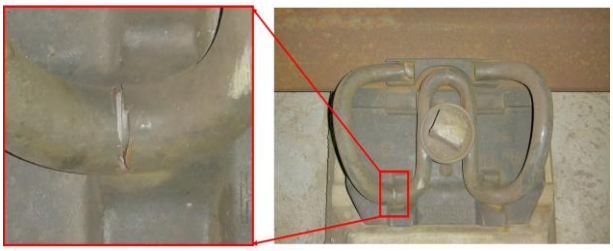

Figure 1 *Clip fractures of Vossloh 300-1 fastening system*

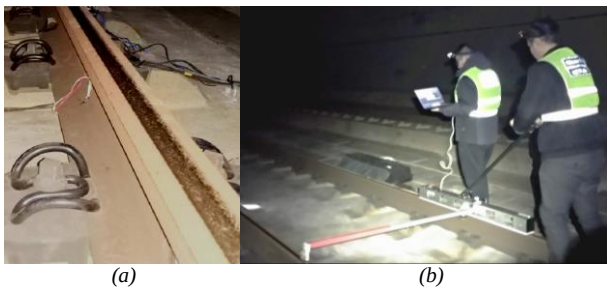
As crucial component to connect rails and sleepers to form a rail row, fastening system plays an important role in ensuring the stability and reliability of railway. The fractures of clip seriously affect the safety of the train driving, it is urgently needed to conduct a thorough analysis of the causes.

The damage mechanism of the rail fastening system has been studied and well addressed in some literatures. H. Guo believed that the main reason for the early fracture of the spring rods was carbon content of their raw material was lower than the standard required value to 60Si2MnA steel, which resulted in the hardness of the spring rods was lower than the technical requirement after heat treatment and reduced the fatigue properties of the spring rods heavily. Another reason for the shorter fatigue life was that there was net-shape ferrite structure at the local surface of the spring rods because of decarburization, which made fatigue cracking source generate easily [4]. D. Bartos [5] established the 3D solid FE model of SKL-1 clip, simulated the force in installation and operation process, analysed the spatial distribution of the stress and determined that the larger stress part of SKL-1 clip is the arc of the heel, which was the same as the field fracture position. S. Mohammadzadeh regards train axle load, driving speed and material fatigue parameters as random variables that conform to normal distribution or Weibull distribution. The dynamic model of vehicle track system based on multi rigid body dynamics and three-dimensional finite element model of clip are used to calculate the equivalent stress time history of the clip, and the linear cumulative loss of Miner is used. The injury theory is used to calculate the damage quantity, and the reliability of the elastic strip and the sensitivity of the random variable are studied under different service life in the process of crack generation [6]. S. Ahadi used the same method as S. Mohammadzadeh to calculate the equivalent stress time

history of the clip, and used the Paris formula of fracture mechanics to study the reliability of the projectile at different service life in the process of crack propagation [7]. Javad tests the plastic deformation and the change of the rail distance caused by the Vossloh clip and the Pandrol clip under the different driving speed and the train axle load through the laboratory test. The relationship between the cumulative change value of the gauge and the axle weight under different conditions is obtained. By comparing the limit value of the cumulative change of the gauge, the fastening system maintenance is determined [8].

In the present paper, the field investigation of the SKL 15 fracture of vossloh 300-1 was carried out firstly to find out the characteristics of fastening system damage. Then the internal performance test of SKL 15 including surface crack inspection, hardness, decarburized layer and metallographic structure were done. Thirdly, the natural frequencies analysis of SKL 15 were determined by modal test and theoretical simulation analysis. Fourth, the dynamic behaviour of SKL 15 used in operation high speed railway line was organized to find out the relationship between the dynamic behaviour and clip fracture. The conclusion of the influence of wheel/rail vibration on the damage of rail fastening system could be obtained.

2. Field investigation



Vossloh W300-1 fastening system with clip SKL 15 is one of the main type of fastening systems in China. It had a good performance for years, but some SKL 15 clips appear damage phenomenon in some sections of high speed railway lines in China. In view of the damage section of the SKL15 clip, the field investigation is organized.

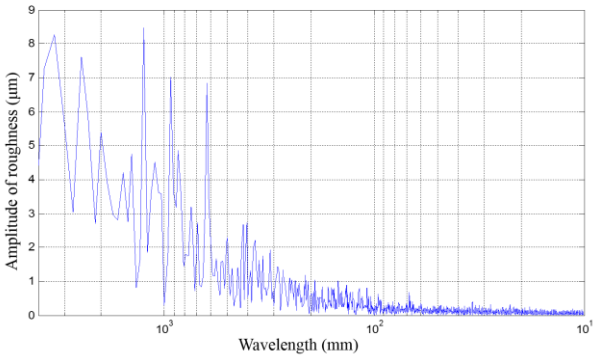
The fastening system installation in the investigation sections is well. Except for a few clips, most of the clips have no obvious corrosion appearance, shown in Figure 2, and some of them are checked out of the torque, it is in the normal range; the double block ballastless track is good, and there is no peeling between the bed plate and the lower base.

Figure 2 *The clip surface state in service lines*

The rail surface conditions and its investigation measurements for the clip damage section are carried out using CAT equipment shown in Figure 3. And the measurement results of rail roughness is shown in Figure 4. There is no obvious rail corrugation on the rail surface.

(a) *(b)*

Figure 3 *Rail surface condition (a) and Investigation measurements of rail surface (b)*



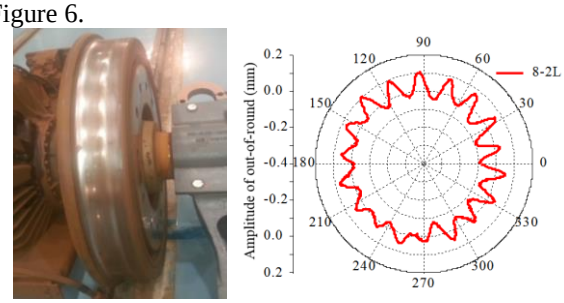


Figure 4 *Measurement results of rail surface*

The out-of-round of wheels investigation measurements are carried out using Miniprof in depot, shown in Figure 5. The test samples are 15 vehicles, which was selected by random.

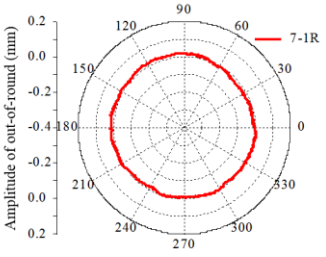

Figure 5 *Investigation measurements of out-of-round of wheels*

The investigation results illustrate that some wheels are out-of-round, but most of the wheels are well, shown in Figure 6.

(a)

(b)

Figure 6 *Measurement results of wheels (a) out-of-round wheel (b) no polygon wheel*

3. Internal performance test of clip SKL 15

In order to check the damage clip of SKL 15, the fracture position, surface cracks, hardness, decarburized layer, and the metallographic structure are checked for the broken and the unbroken clips respectively.

3.1. Fracture position and macroscopic analysis

Statistics on the fracture positions of 50 fractured samples found that the fracture positions of most clips are located between the support position of the heel and the tail of the side leg. The fracture position is different from that of the general fatigue tests (in 16Hz), which is illustrate in Figure 7.

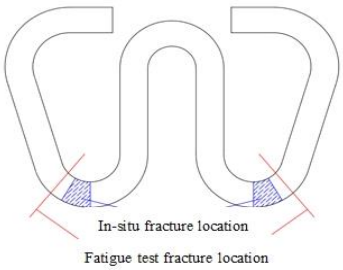

Figure 7 *Fracture positions of clip*

From the checking of the fracture zone, three zones can be found, that is the crack source zone, propagation zone and the instantaneous fracture zone. The crack of the fracture zones are all initiated at the inner surface of the clip arcs, and then propagate in a radial pattern into the inside of the clips and finally to form a fan-shaped propagation zone, which can be found in Figure 8. And from the macroscopic view, there are several crack source zones in the fracture zones of some clips.

Figure 8 *Macro characteristics of the fracture zone*

3.2. Surface crack inspection

Random extract 10 broken clips. Firstly, a solution is used to remove the anticorrosion layer on the surface of the fracture, and then treated with acid pickling, finally inspect the surface rust and scratch conditions. The inspection is shown in Figure 9.

Figure 9 *Surface crack inspection*

Through the surface status inspection for the fracture zone and the unbroken zone of the broken clips and for the unbroken clips, there is no obvious difference of the surface inspection results are found between the broken and the unbroken clips.

3.3. Internal performance detection

In order to further detect the internal performance of the clips, take samples at the middle part of the clip middle leg which is shown in Figure 10, and then inspect its hardness, decarburized layer, and the metallographic structure. The inspections of the hardness, the decarburized layer, and the metallographic structure are illustrated in Figure 11 to Figure 13 respectively.

Figure 10 *Sample location*

Figure 11 *Hardness inspection*

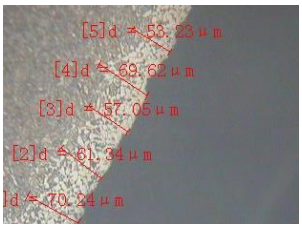

Figure 12 *Decarburized layer*

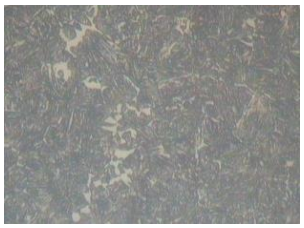

Figure 13 *Metallographic structure*

The inspection results of the hardness, the decarburized layer, and the metallographic structure are listed in table 1. It can be seen that the hardness, the decarburized layer, and the metallographic structure of the broken and unbroken clip are all within the standard range, no obvious abnormality are found.

Table 1 *Inspection results of the hardness, decarburized layer, and metallographic structure*

Items	Standard index	Results	Remarks
Hardness	400~460 HV	44.4HRC	430 to 440 HV
Decarburized layer	≤ 0.2mm	66.202μm	---
Metallogrphic structure	The metallographic structure should be a homogeneous tempered flexor and tempered soxhlet, a small amount of ferrite and a small amount of bainite is allowed in the heart.	The content of Ferrite is a bit high.	---

Through the inspection of the fracture location, the fracture zone characteristic, the surface cracks and the internal performance of the clips, the following conclusions can be drawn: (1) The fracture position of most clips are located at the support position of the heel, which is different from that of the general fatigue tests (in 16Hz); the fracture surface can be divided into three zones, that is the crack source zone, propagation zone and the instantaneous fracture zone.(2) there is no obvious difference of the surface inspection results are found between the broken and the unbroken clips.(3) The hardness, the decarburized layer, and the metallographic

structure of the broken and unbroken clips are all within the standard range.

4. Natural frequencies analysis of clip SKL 15

This section will research the natural frequencies of clip SKL 15 using the theoretical method and field test method.

4.1 Theoretical analysis

The space structure of the clip is very complex, it is difficult to get the analytical solution of its modal characteristics, and the finite element method (FEM) is usually used to analyze its modal characteristics. In order to accurately analyze the modal characteristics of the clip, the finite element model should meet the following conditions: (1) it can truly reflect the bending and torsional deformation of the clip; (2) the shape and size of the space structure can be accurately established; and (3) the boundary conditions under the actual state of the clip could be accurately simulated [9].

The software ANSYS is used to establish the theoretical analysis model of the clip. The bending and torsional deformation of the clip can be fully taken into account by the Timoshenko beam element. In order to accurately simulate the spatial structure shape of SKL15, a spatial structure model is established by picking up the precise position of the spatial coordinates of the center line, shown in Figure 14.

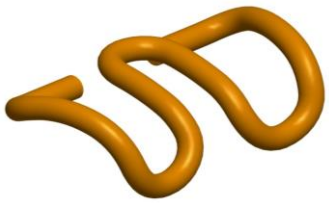

Figure 14 *Space structure of SKL 15*

The boundary condition of the clip assembly state mainly refers to the contact state between the clip and the other components after the fastening system assembly is completed. The accurate simulation of the boundary conditions is the key to the accuracy of the modal analysis. Therefore, the selection of the contact stiffness, contact position and contact area between the clip and the other contact components should be scientific and accurate in the simulation of the boundary condition.

The contact stiffness describes the proportional relationship between the contact pressure and the relative displacement. The classical Hertz contact theory can study the local pressure distribution of two contact objects on the contact surface and the stress and deformation caused by the pressure. Therefore, the classical Hertz contact theory can be used to solve the connection stiffness [10].

When the installation state of the clip is changed, the pressure of the clamp, the counterforce and the contact state all change accordingly. Therefore, according to the above analysis, the finite element analysis model of SKL15 is established. The contact and friction between the components of each assembly are simulated by the spring and damping element, shown in Figure 15.

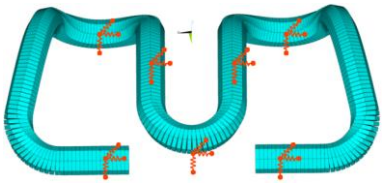

Figure 15 *FE model of SKL 15*

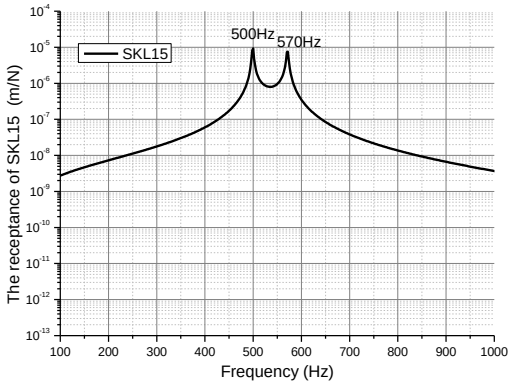
Based on the theoretical analysis model of SKL 15, the modal characteristics are analyzed using the ANSYS software. The displacement receptance of SKL 15 in the range of 0-1000 Hz is shown in Figure 16. And the corresponding modals and the maximum stress position of clip at 570Hz are shown in Figure 17.



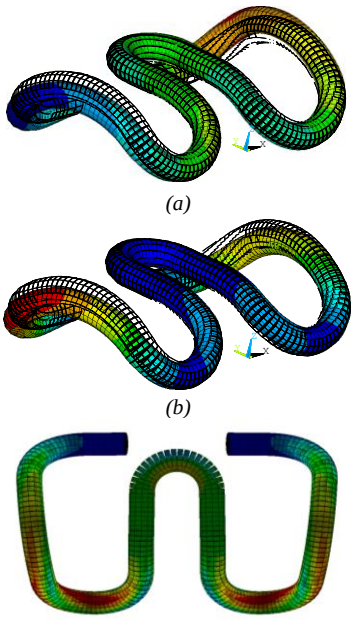


Figure 16 *Displacement receptance of SKL 15*

(a)

(b)

(c)

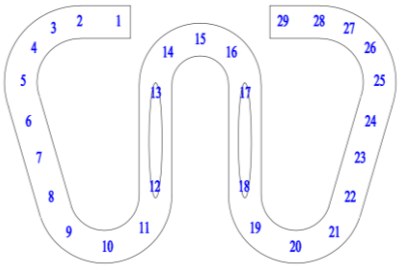

Figure 17 *Modal characteristics of SKL 15 (a) at 500Hz (b) at 570Hz (c) the maximum stress position of clip at 570Hz*

According to Figure 16 and Figure 17, the clip SKL 15 has two order modal characteristics at the assembly state in the frequency range of 0-1000Hz. The first order modal shape is the two limbs of the clip anti-symmetry valgus vibration at 500Hz, and the second mode vibration mode is the two limbs of the clip symmetric valgus vibration at 570Hz. The maximum stress position at 570Hz is at the supporting point of the clip.

4.2 Modal test of SKL 15

The method of hammering is used to test the mode of the clip with a total of 29 excitation points. The hammer

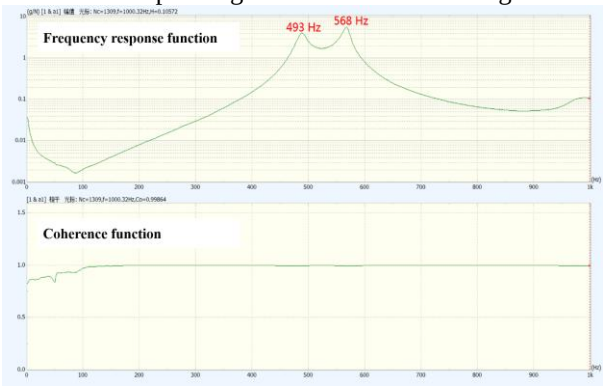
adopts the aluminum head to improve the bandwidth of the force spectrum, and each exciting point is hammered 3 times to get the average result in order to reduce the test error, shown in Figure 18.

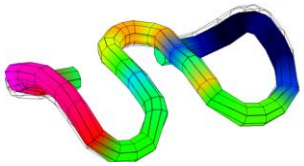
(a)

(b)

Figure 18 *Modal test of SKL 15 (a) excitation points (b) test process*

The test results of frequency response function and coherent function in the frequency range of 0-1000Hz with the standard assembly state are shown in Figure 19. And the corresponding modals are shown in Figure 20.





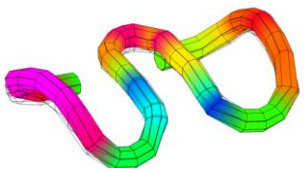


Figure 19 *Modal test results of SKL 15*

(a)

(b)

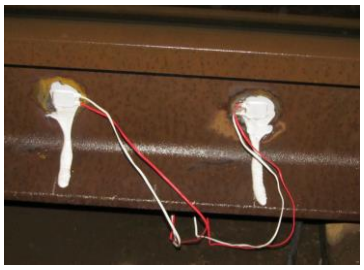

Figure 20 *Modal characteristics of SKL 15 (a) at 493Hz (b) at 568Hz*

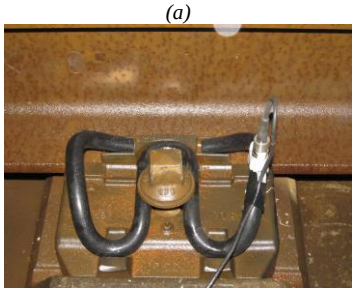
According to Figure 19 and Figure 20, the clip SKL 15 has two order modal characteristics at the assembly state in the frequency range of 0-1000Hz. The first order modal shape is the two limbs of the clip anti-symmetry valgus vibration at 493Hz, and the second mode vibration mode is the two limbs of the clip symmetric valgus vibration at 568Hz. The test results are same as the results of theoretical analysis.



5. Dynamic behavior test

5.1 Dynamic test

The dynamic tests include wheel/rail force and clip SKL15 acceleration. Wheel/rail force was measured by shear method using strain gauge, and SKL15 acceleration was measured by accelerometer with 1000g range. The wheel/rail force sensors were installed mid-span of rail, and the accelerometer was installed the clip, shown as in Figure 21. The speed of trains is 300km/h passed by the sensors.

(a)

(b)

Figure 21 *Installation of sensors (a) wheel/rail force sensor, (b) clip accelerometer*

5.2 Test results

The wheel/rail force of the train with polygon wheels at speed of 300km/h is shown in Figure 22.

Figure 22 *Wheel/rail force of train with polygon wheels at 300km/h*

It could be known from the time domain diagram, Figure 22, that the wheel/rail vertical force of 1st car to 7th car is not very different. The maximum wheel/rail force is 98kN of 1 to 7 cars. And the maximum wheel/rail vertical force of 8th car is 115kN, nearly increases 20%. The increase of the vertical force of 8th car is caused by the polygon of wheel.

Figure 23 is shown the clip acceleration of the train with polygon wheels at speed of 300km/h. It also could be known from the time domain diagram, Figure 23, that the

clip acceleration of 1st car to 7th car is not very different. The maximum rail acceleration is 1643m/s^2 of 1 to 7 cars. And the maximum clip acceleration of 8th car is 4766m/s^2, nearly increases 190%.

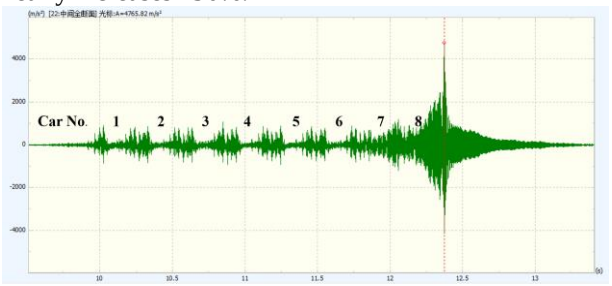


Figure 23 *Clip acceleration of train with 300km/h*

The wheel/rail vertical force of 1st and 8th car is analyzed via fast Fourier transform, shown as Figure 24. There are two obvious frequencies in 8th car, one is 517Hz, and the other is 613Hz. Because the only different of 1st and 8th car is the polygon wheel, so the two exciting frequencies of 517Hz and 613Hz is caused by the polygon wheel.

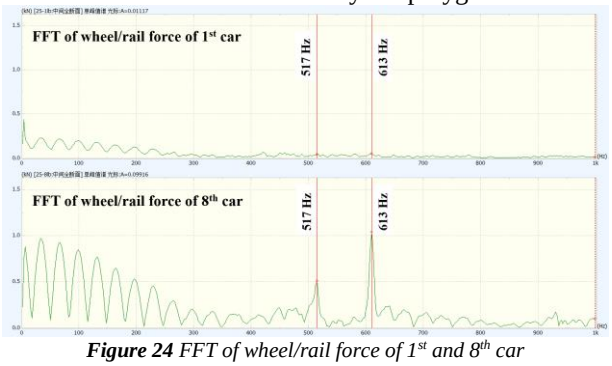

Figure 24 *FFT of wheel/rail force of 1st and 8th car*

The field test shows that when the high frequency excitation (517Hz and 613Hz) of wheel/rail force generated by the polygon wheel at 300km/h speed is close to the natural frequency of the clip SKL 15 (570Hz), the resonances of clip happened and the acceleration amplitude increases significantly. At the same time, the maximum stress appears at the support position of the clip, and the long-term effect produces fatigue crack, which leads to the stress concentration, the crack propagation and the instantaneous brittle fracture.

6. Conclusions

In view of the damage phenomenon of the clip SKL 15 of vossloh W300-1 fastening system, this paper makes an in-depth analysis on the field investigation, laboratory test, simulation analysis and field dynamic testing. The following conclusions can be drawn on the basis of the experimental and theoretical studies.

(1) Most of the damage of the clip SKL 15 occurs at the support position, which is different from the typical fracture position in the fatigue test, and there are three regions of crack source, fatigue expansion and instantaneous fracture.

(2) There is no obvious rust appearance in the appearance of the clip, and the hardness, decarburization and metallographic structure of the broken and unbroken clips are in the standard range.

(3) The natural frequency of the SKL 15 of vossloh W300-1 fastening system is 570Hz, and the maximum stress at 570Hz appears at the support position of the clip.

(4) There are 18 order polygons in the wheels of some EMU train, and the high frequency excitation of the wheel rail force generated by the polygon wheel at 300km/h speed is close to the natural frequency of the clip, and the vibration acceleration of the clip increases significantly. At the same time, the maximum stress of the clip appears at the support position, and the long-term effect produces fatigue crack, which leads to the stress concentration, the crack propagation and the instantaneous brittle fracture.

STUDY ON FUNCTIONAL ADHESION COEFFICIENT OF HIGH-SPEED WHEEL-RAIL ROLLING CONTACT

Q. Xiao [1,*], W.X. Jiang [1]

[1]Technology And Equipment Research Center of Rail Vehicle Operation And Maintenance,East China Jiaotong University,Nanchang,Jiangxi Province,China
[*] E-mail:jxralph@foxmail.com

Abstract:This paper adopted GPM-30 type rolling contact test machine, based on the changes of coarseness and hardness when the wheel-rail was under the circumstance of contacting surface, The main conclusions are:the adhesion coefficient of the lower wheel roughness is relatively high in the process of creepage from 0% to 5%. In the process of creepage increasing from 5% to 20%, the adhesion coefficient of the higher wheel roughness is relatively high;a functional model of high-speed wheel-rail rolling contact adhesion cofficient is built by experience formula and BP neural network.

Keywords:functional adhesion coefficient; creepage; wheel-rail system; rolling contact; roughness; adhesional tests; model optimization.

1. Introduction

The wheel/rail adhesion coefficienthas a direct impact on the special effects of wheel-rail rolling contact, followed by the changes of traction and braking of trains[1], also influencing the working quality and operating efficiency of train,therefore, the wheel-rail adhesion coefficient is indispensable in study of wheel-rail relationship.In Ohayama T[2~3], researchers adopted large size experimental sevices to analyse the adhesion coefficients under dry adhesion in different speed classes, find that the adhesion coefficient kept its numerical value and didn't seem to decrease, and the result was decentralized. Zhang Weihua,et al[4] commenced another adhesion experiment on the basis of rolling vibration test bench,acquring the complete relation of adhesion coefficient and creepage, fitting the finctional adhesion cofficient on the basis of water pollution inexperimental speed, but the influences of different surface in contact haven't been taken into account.Takaoka Y,et al[5] fitted the experience formulae showing the relation of adhesion coefficientand creep velocity, fitting the wheel-rail surface condition with related constant coefficient, which also limited the application of the formula. This paper adopted GPM-30 type rolling contact test machine, based on the changes of coarseness and hardness when the wheel-rail was under the circumstance of contacting surface, used the model of BP neural network to optimize the experience formulae of Japan Shinkansen "adhesion-creep velocity", the functional model of high-speed wheel-rail rolling contact adhesion cofficient is built.

2. Experimental scheme

2.1. Theoretical analysis

During the running of high speed train, the traction moment of the motor is transferred by wheel-rail adhesion force, the wheel-rail adhesion coefficientreflects the ability of wheel-rail to transfer the traction moment, and the ratio between the F_t , the maximum tangential and F_n,vertical static load between wheel and rail is defined as *f*, the wheel-rail adhesion coefficient:

$$f = F_t / F_n \tag{1}$$

The creepage can indicate the size of the creep:

$$\mu = \frac{\omega R - v}{v} \tag{2}$$

Where v is the line speed of the wheel to instantaneous; ω is the instantaneous angular velocity of the wheel.;R is the radius of the wheel.

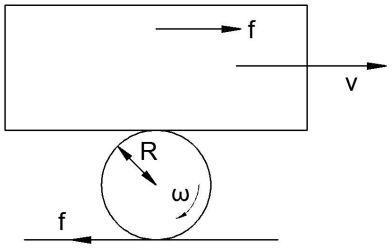

Fig. 1 *The schematic diagram of roller creep and traction transmission.*

As shown in Fig. 1, a single axis wheel rail instance model can be used to establish the following equation of motion and coefficient of adhesion:

$$J\frac{d\omega}{dt} = T - FR - B\omega \tag{3}$$

$$J\frac{d\omega}{dt} = T - FR - B\omega \tag{4}$$

$$F = fMg \tag{5}$$

Where J is the moment of inertia of the wheel($kg \cdot m^2$), w is the instantaneous angular velocity of the wheel($kg \cdot m^2$).,

Te is traction moment($N \cdot m^2$), *F* is adhesional resistance(*N*). *R* is the radius of the wheel(*m*),*B* is the viscous resistance, *M* is the axle weight(*kg*), *C* is the aerodynamic coefficient, *v* is the forward velocity of the car body($m \cdot s^{-1}$), *f* is the adhesion coefficient, and *g* is the gravity acceleration($m \cdot s^{-2}$).

2.2. Experimental parameters

2.2.1. Normal load

Simulation test method to the load calculation of the Hertzian simulation criteria[6], which simulate the wheel/rail between the maximum contact stress and the length of the contact spot half shaft is the same with the actual working condition and also is to satisfy the following two formulas:

$$(p_0)_{lab} = (p_0)_{field} \tag{6}$$

$$(\frac{a}{b})_{lab} = (\frac{a}{b})_{field} \tag{7}$$

Based on this formula, the calculation formula of literature [7] can be used to obtain the load required for the test:

$$P = \frac{(\alpha+\beta)_{field}^{\ 2}}{(\alpha+\beta)_{lab}^{\ 2}} \cdot P_{field} \cdot (K_d + 1) \tag{8}$$

Where α and β are the coefficient of correlation between the geometrical traits of the wheel and the wheel is the formula (9), (10) and (11).,K_d is dynamic load coefficient, the test takes 0.3.

$$\alpha+\beta = \frac{1}{2}(\frac{1}{R_{w1}} + \frac{1}{R_{w2}} + \frac{1}{R_{r1}} + \frac{1}{R_{r2}}) \tag{9}$$

$$\beta-\alpha = \sqrt{\begin{matrix}(\frac{1}{R_{w1}} + \frac{1}{R_{w2}})^2 + (\frac{1}{R_{r1}} - \frac{1}{R_{r2}})^2 \\ + 2(\frac{1}{R_{r1}} - \frac{1}{R_{r2}})(\frac{1}{R_{w1}} - \frac{1}{R_{w2}})\end{matrix}} \tag{10}$$

$$(\frac{\beta-\alpha}{\alpha+\beta})_{lab} = (\frac{\beta-\alpha}{\alpha+\beta})_{field} \tag{11}$$

Where R_{w1} and R_{w2} are the longitudinal and transverse principal curvature radius of the simulated wheel surface is pointed out for the rail contact.$R_{r1}$and R_{r2} are used to simulate the longitudinal and transverse principal curvature radius of the rail surface.

For example, It is known that the wheel diameter of the CRH3 high-speed train that is actually running in China is 860mm. Static wheel load P_{field}=*7619kg*, standard 60kg/m rail top surface arc radius is 300mm,the radius of transverse principal curvature is infinite, and the radius of longitudinal main curvature of test wheel is 30mm.,Test loads a *P=1379.6057N*.

2.2.2. Specimen Size

As shown in figure 1 for sample size and feeding way of figure, specimen diameter of 60 mm, inner diameter of 30 mm, including the simulation of wheel/rail contact line, and considering the surface roughness measuring 6 mm, as wheel sample.

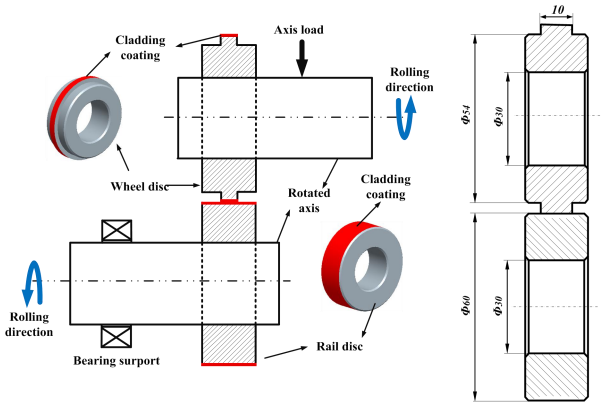

Fig. 2 *Specimen Size.*

2.2.3. Other parameters

The conversion formula of creep speed and creepage is:

$$s = \omega \times 2\pi R_w - (1-\mu) \times \omega \times 2\pi R_r \tag{12}$$

Where *s* is creep speed($m \cdot s^{-1}$), μ is the creepage, ω is the spindle speed for assembling the rail sample($r \cdot min^{-1}$), R_w is the upper sample (wheel) diameter (*m*), R_r is lower specimen (rail) diameter (*m*),in this experiment:

$$s = \mu \times \omega \times 2\pi R \tag{13}$$

In order to avoid loss of generality, the control spindle speed group was divided into 300r/min, 600r/min, 900r/min, 1200r/min, 1500r/min, and obtained discrete data of adhesion coefficientand creep speed under different conditions.

Measured by surface roughness meter horizontal contact surface roughness, measurement for contour arithmetic average Ra, sampling length is 2.5 mm, the average value of the measured values of the six points in the outer circle is evenly distributed.

3. Experimental results and analysis

3.1. adhesion coefficients - creepages characteristics at different speed levels

The adhesion coefficientin different speed grades under the creepage is shown in Fig. 4 on the clean surface condition. In general, every 300r/min on the adhesion coefficient; the average level under the same speed the adhesion coefficientis five a complete cycle of the waveform value; slip rate change in adhesion coefficientsharply change the 0% to 1% creep, every 0.25% creepage values of adhesion coefficient; coefficient of adhesion in the large changes in the 1% to 5% creepage changes, every 1% of the creepage values of adhesion coefficient; slip rate variation coefficient of adhesion in the relatively flat 5% to 20% creep, every 5%. The creepage values of adhesion coefficient.

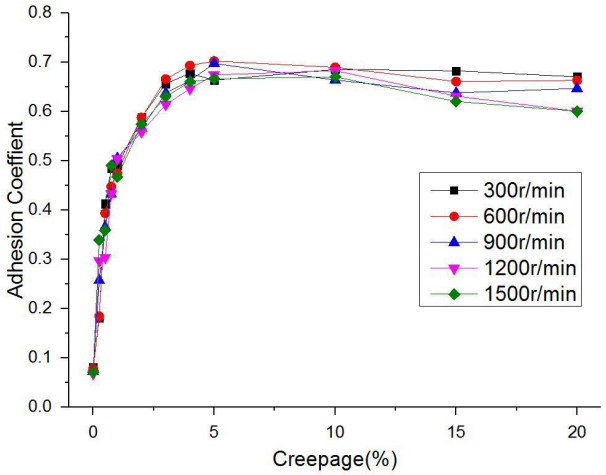

Fig. 3 *The adhesion coefficient- creepage characteristics of different speed levels.*

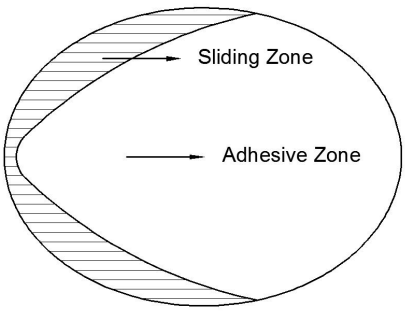
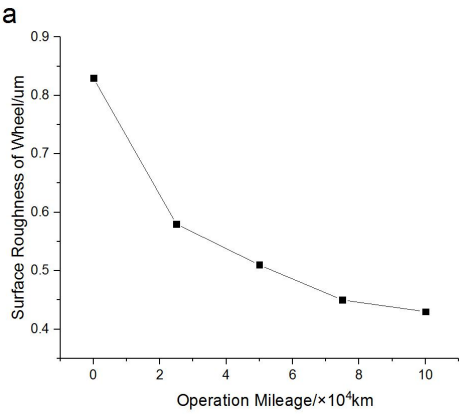
From figure 3, we can see that the adhesion coefficientincreases sharply as the creepage increases from 0% to 1%. In the case of 300r / min and 600r / min with lower speed grade, the adhesion coefficientincreases rapidly. The slope of adhesion coefficientis about 0.4 in the front segment, 0.9in the middle segment and 0.25 in the latter part. At the middle speed level of 900r / min, the front segment is about 0.7, the middle segment is about 0.4, and the latter stage is about 0.25; The slope of adhesion coefficientis about 0.95in the front section and 0.05 in the middle section under the working conditions of 1200r / min and 1500r / min with higher velocity grade. The latter segment is about 0.5. This is because the sliding zone in the contact spot, as shown in figure 5, develops with the creepage, and its proportion increases, resulting in an increase in the available adhesion. During the creepage increases from 1% to 5%. The slope of adhesion coefficientis obviously reduced because the contact spot is approximately elliptical and the area growth rate slows down when the sliding zone reaches the second half. When the creepage increases from 5% to 20%, the variation of adhesion coefficienttends to be gentle, which is due to the fact that the contact spot has been basically covered by the sliding zone, and the wheel / rail has entered a stable sliding state. The adhesion coefficientshows the maximum state, but because of a small amount of macro sliding, the overall trend is still slightly decreased, which is consistent with the results of the test conducted by Zhang Weihua, Southwest Jiaotong University[9].





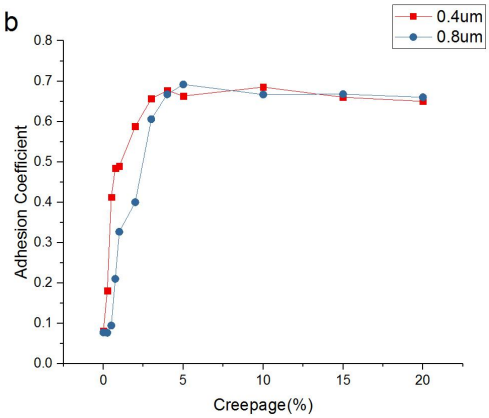


Fig. 4*. The sketch of wheel/rail contact patch*

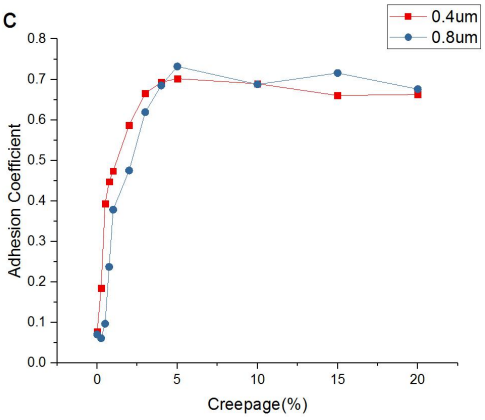
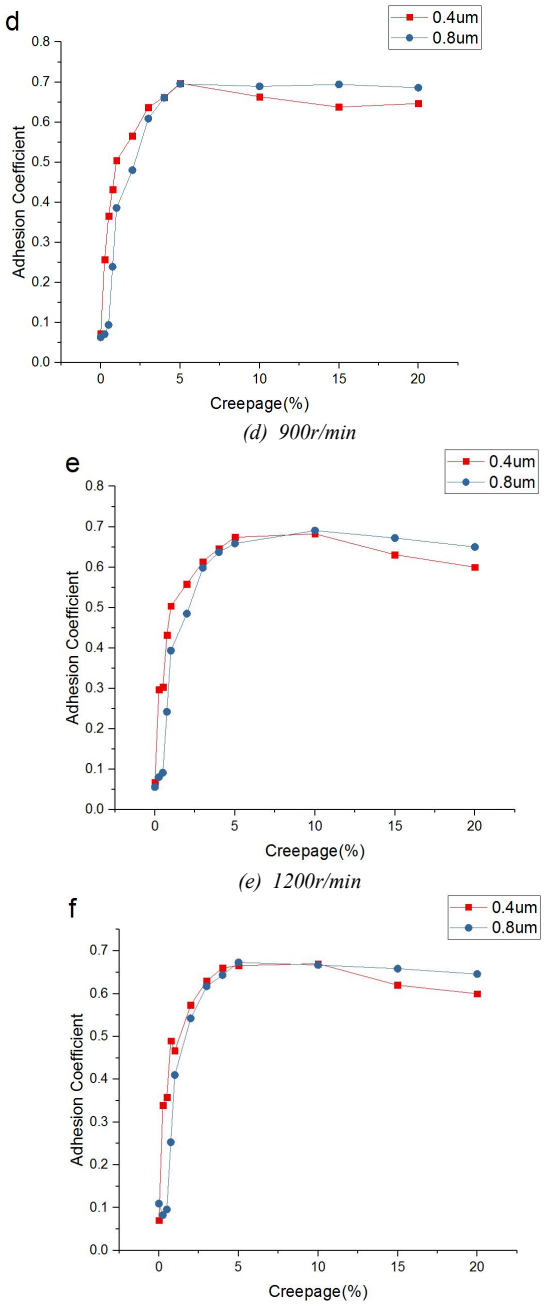
3.2. adhesion coefficients - creepages characteristics at different surface roughness of wheel



As shown in Fig. 5(a) the wheel roughness of CRH2 high-speed train with different mileage is actually operated on a Chinese line. According to the data shown, sandpaper is used to polish the wheel. The surface roughness of the rail specimen is kept unchanged when the wheel specimen is polished as 0.8um and 0.4um, respectively. The results are shown in figure 5(b-f).



(a) Wheel roughness under different operation mileages

(b) 300r/min

(c) 600r/min

(d) 900r/min

(e) 1200r/min

(f) 1500r/min

Fig. 5 *The adhesion coefficient- creepage characteristics of different wheel roughness and different speed levels:*

Fig.5 (b-f) shows that the adhesion coefficientof the lower wheel roughness is relatively high in the process of creepage from 0% to 5%. In the process of creepage increasing from 5% to 20%, the adhesion coefficientof the higher wheel roughness is relatively high, which is due to the fact that the actual contact surface area is smaller when the rough peak contact is higher.

4. Model optimization

4.1. The Function fitting by CFTool

There is a nonlinear relationship between the adhesion coefficientand the creepage. The general research is just analyzing and analyzing the influence trend of various factors on the adhesion coefficient. Little is known about the functional relationship between wheel rail adhesion coefficientand creepage. In this section, the BP neural network model is used to optimize the empirical formula of the adhesion coefficientcreep speed of Shinkansen in Japan, and a functional high-speed wheel rail rolling contact adhesion coefficientmodel is established. After obtaining instantaneous wheel pair speed and wheel speed, the corresponding real-time creepage can be obtained as a parameter basis for controlling wheel rail adhesion coefficient.

The empirical formula of the "adhesion coefficient- creep speed" of the Shinkansen of Japan[5] is as follows:

$$f(v) = a \cdot \exp(-3.6bv) - c \cdot \exp(-3.6dv) \qquad (12)$$

Where v is the creep velocity (m/s) and $f(v)$ is adhesion coefficients, and the coefficients a, b, c and d are determined by the contact surface condition.The empirical formula is fitted by two exponential functions, and combined with the formula (11), the formula may be changed to:

$$f(\mu) = a \cdot \exp(-b\mu) - c \cdot \exp(-d\mu) \qquad (13)$$

Where μ is the creepage.

In the third section, in order to compare the adhesion coefficientunder different working conditions, the average value of the adhesion coefficientis five complete cycles. This section is calculated by the Exponential function in Curve fitting tool of MATLAB. As shown in Figure 6, the fitting results of 0.4um, 600r/min and 0.8um and 600r/min working conditions are shown. The fitting coefficient and error analysis of each case are shown in Table 1.

4.2. The Function fitting by BP Neural Network

In practical application, the general error of the above calculation method will be larger. In intelligent algorithm BP neural network, we can input speed grade, adhesion coefficientcomplete waveform and wheel surface roughness, and the result is more precise. We can optimize the empirical formula based on the result.

BP network (Back-ProPagation Network), also known as the back propagation neural network, constantly corrects the weights and thresholds of the network through the training of sample data, so that the error function decreases along the negative gradient direction and approaches the desired output. It is a more widely used neural network model, which is mostly used in function approximation, model recognition and classification, data compression and time series prediction.

BP network is composed of input layer, hidden layer and output layer, hidden layer can have one or more layers, the three-dimensional input layer including slip, roughness and wheel speed grades; output layer the coefficient of adhesion;the hidden layer nodes determined by using the following empirical formulas (14) and (15) of the initial number of hidden nodes[10].

$$l = \sqrt{n+m} + a = 2 + a \tag{14}$$

$$l = 2n + 1 = 7 \tag{15}$$

Where n is the number of neurons for input layer, m is the the number of neurons for output layer, a is a constant between 1 and 10.

Therefore, the number of hidden nodes is 7 selected in this test.

The schematic diagram of its network structure is shown in Fig. 7,the specific parameters of the network training are shown in Table 2.

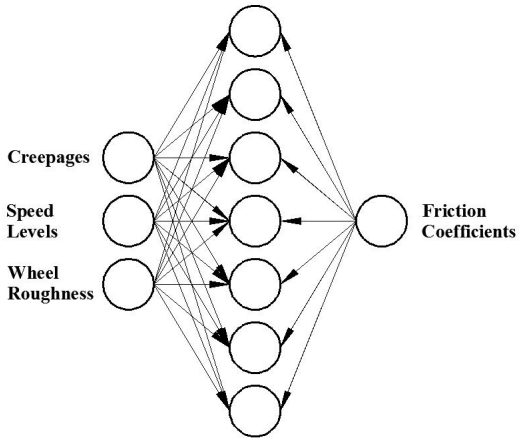

Fig. 7 *A schematic diagram of the structure of BP neural network.*

Tab. 2 *The specific parameters of the network training*

Parameters	**Values**
Maximum training times	5000
The number of neurons in the hidden layer	7
The learning rate of this improved neural network	0.035
Target error of training	6.5e-4

3/4 groups of datas were randomly selected as the training group, and the remaining 1/4 groups of datas were used as the validation group, and the fitting results of 0.4um, 600r/min working conditions are shown in Fig.8.

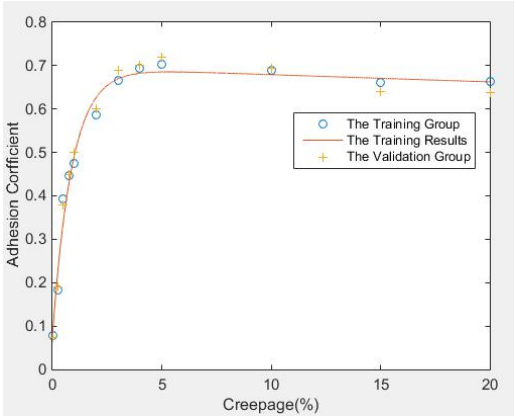

Fig. 8 *The relationship between creepages and adhesion coefficients based on BP neural network.*

In this case, the test results have good consistency as shown in the Fig.8,and when the creepage is between 1% and 5%, the training value should be increased by 7%.

5. Conclusion

The adhesion mechanism of wheel and rail is very complicated, which is influenced by many factors. This

paper mainly analyzes the influence of creepages, speed levels and wheel roughness on high speed wheel/rail adhesion coefficient, and then uses BP neural network algorithm to optimize the empirical formula of "adhesion coefficient-creep speed". The main conclusions are as follows.

(1)The adhesion coefficientincreases sharply as the creepage increases from 0% to 1%. In the case of 300r / min and 600r / min with lower speed grade, the adhesion coefficientincreases rapidly. The slope of adhesion coefficientis about 0.4 in the front segment, 0.9in the middle segment and 0.25 in the latter part. At the middle speed level of 900r / min, the front segment is about 0.7, the middle segment is about 0.4, and the latter stage is about 0.25; The slope of adhesion coefficientis about 0.95in the front section and 0.05 in the middle section under the working conditions of 1200r / min and 1500r / min with higher velocity grade. The latter segment is about 0.5. This is because the sliding zone in the contact spot, as shown in figure 5, develops with the creepage, and its proportion increases, resulting in an increase in the available adhesion. During the creepage increases from 1% to 5%. The slope of adhesion coefficientis obviously reduced because the contact spot is approximately elliptical and the area growth rate slows down when the sliding zone reaches the second half. When the creepage increases from 5% to 20%, the variation of adhesion coefficienttends to be gentle, which is due to the fact that the contact spot has been basically covered by the sliding zone, and the wheel / rail has entered a stable sliding state. The adhesion coefficientshows the maximum state, but because of a small amount of macro sliding, the overall trend is still slightly decreased.

(2)The adhesion coefficientof the lower wheel roughness is relatively high in the process of creepage from 0% to 5%. In the process of creepage increasing from 5% to 20%, the adhesion coefficientof the higher wheel roughness is relatively high.

(3)Using the model of BP neural network to optimize the experience formula of Japan Shinkansen "adhesion-creep velocity", the functional model of high-speed wheel-rail rolling contact adhesion cofficient is built.

Abstract: This paper presents a study on AE monitoring of switch rail wear for railway turnout based on a large number of field test. Meanwhile, Wigner-Ville high-order spectrum and data mining technology are employed for wear monitoring, and massive data with and without rail wear is acquired and characterized. Wigner-Ville high-order spectrum is applied to achieve the clusters features of switch rail wear by suppressing noise and realizing high time-frequency resolution of signals, and the subsequent collection of the acoustic emission signal can be classified and identified. The results clearly illustrate that the proposed method can monitor switch rail wear effectively.

Keywords: Signal-based wear monitoring; Railroad switch rail; Acoustic emission; Wigner-Ville high-order spectrum; Data mining technology.

1. Introduction

Turnouts are essential components of railway infrastructure, which provide flexibility to traffic operation. They are consisted of a switch panel, a movable-point crossing panel and a closure panel for high-speed railway turnouts. To enable the vehicle to change between tracks, the profiles of switch rails and crossing rails are designed to vary along the switch and crossing panels. This leads both to differences in rolling radius and to multipoint contact. The normal wheel-rail contact situations are disturbed when wheels transfer from stock rail to switch rail in the switch panel, or from point rail to wing rail in the crossing panel, sometimes resulting in severe impact loads [1]. Due to the lateral translation of wheelsets and varied rail profiles, dynamic vehicle-turnout interaction is a time variant process, even when discounting track irregularities, and is far more complex than on an ordinary track. These will ultimately lead to serious damage to the contact surfaces and to the transmission of noise and vibrations to the outside environment. In the case of a degraded turnout, severe wear causes major changes in the rail profile, thus having a significant effect on the running behavior of railway vehicles-this may include motion stability, riding comfort and derailment prevention [2, 3]. Railway turnouts contribute to largest part of reported faults and require more maintenance than other parts of the railway network, especially for turnout rail wear. According to statistics from maintenance databases in China [4], it is concluded that one of main reasons for reducing the service life of high-speed railway turnout is severe rail wear. Parts of high-speed railway turnouts changed the switch rails about every one and a half years, much less than design service life (5 years or 150 million tons of total passing weight). Furthermore, failure or disturbance of a turnout may lead to an indirect cost in the form of a traffic shutdown. The friction and wear of materials is is an important acoustic emission source, and sound waves caused by them reflect the essence.

Acoustic emission technique has been used for health monitoring for mechanical behavior and working condition of structure. Berkovits and Fang applied Acoustic emission technique to study fatigue crack characteristics of Incoloy 901, include initiation closure and propagation on smooth specimens. AE technique was applied to determine when and where a microcrack initiated on the specimens and the threshold stress intensity ranges were determined by combining AE tests and microscopic examination for crack initiation points [5]. Roberts and Talebzadeh used an advanced acoustic emission compact tension and system with accurate source location for the monitoring of T-section girder test fatigue crack propagation in steel and welded steel specimens. Located acoustic emission events were filtered for a narrow band containing the fatigue crack, and separated for different regions of the applied load range [6]. Warren and Guo used an acoustic emission sensor and signal processing software to study fatigue failure of the ground and polished AISI 52100 samples, and analytical approaches to determine contact stress and RCF life have been derived based on Hertz theory and kinematic analysis. The AE signals amplitude, absolute energy, and RMS increase sharply when fatigue occurs, while counts and average frequency decrease sharply with the onset of fatigue [7] Ramadan et al. applied acoustic emission technique to study the stress corrosion cracking of high-strength steel used in prestressed concrete structures, and the evolution of the acoustic activity recorded during the tests shows the presence of several stages related respectively to cracks initiation due to the local corrosion imposed by corrosives species, cracks propagation and steel failure [8]. McLaskey et al. introduced a novel method of acoustic emission (AE) analysis which isparticularly suited for field applications on large plate-like reinforced concrete structures, such as walls and bridge decks. Similar to phased-array signal

processing techniques developed for other non-destructive evaluation methods, this technique adapts beamforming tools developed for passive sonar and seismological applications for use in AE source localization and signal discrimination analyses [9]. Hensman et al. used acoustic emissions and Guassian processes to characterise and locate the damage events in complex strutures, and a method is proposed here for learning the relationship between time of flight differences and damage location using data generated by artificially stimulated acoustic emission (AE)-a classic problem of regression, and a structure designed to represent a complicated aerospace component was interrogated using a laser to thermoelastically generate AE at multiple points across the structure's surface [10]. Lu and Li utilized cement-based piezoelectric sensor (as AE transducer) and home-programmed DEcLIN monitoring system AE monitoring on mortar, and the broad band characteristic of cement-based piezoelectric sensor in frequency domain response benefited the analysis of frequency content of AE. Various evaluation methods were introduced and employed to clarify the variation characteristics of AE frequency content in each test [11]. Shokri and Nanni presented a novel technique to process multisensory AE data generated by the onset and propagation of cracks based on signal processing and sensor arrangement and is validated with experimental results from an in-situ load test, and the methodology is proposed to capture and locate events generated by cracks by considering the sources of uncertainty in the AE crack location process [12]. Masmoudi et al. applied acoustic Emission (AE) technique for the health monitoring of composite materials integrated by piezoelectric sensor, and A series of specimens of composite laminates with and without piezoelectric implant were subject to three-point bending in static and creep tests while continuously monitoring the response by the AE technique. The results showed the incorporation of piezoelectric sensor influences specially the fracture load and causes low degradation of mechanical properties of materials [13]. Xie et al. proved the validity of a nondestructive methodology for magnetic tile internal defect inspection based on acoustic resonance. The principle of presented methodology was to analyze the acoustic signal collected from the collision of magnetic tile with a metal block, and the separating part of the detection system was designed and discussed to accomplish the detection process and a simplified mathematical model is con-strutted to analyze the characteristics of the impact of magnetic tile with a metal block [14].

At present, the acoustic emission method has been introduced in relevant experimental researches for testing fractures in standard rails, which not only proved the feasibility of the acoustic emission method in testing rail fractures theoretically, but also further verified the effectiveness of the acoustic emission technology in testing rail surface fractures through wheel-rail testing equipment and on-site tests [15-17]. The above experimental researches focus on the acoustic emission source of rail surface fractures mainly and no any analysis on acoustic emission source of different fractures in rails has been provided. In order to make a further analysis on the acoustic emission source of fractures in rails, a model for rails and their internal fractures was established based on the finite element method in the researches [18-20], and in the meantime the acoustic emission source of fractures was set at reasonable positions of rails in order to simulate the expansion of fractures, the simulated signals, in relation to those obtained through tests, can provide uniform and ideal data for studying the characteristics of the acoustic emission source of fractures [21-22], however, the acoustic emission method aims to test the fractures in standard rails mainly and relevant researches on testing fractures in turnout switch rails, considering turnout switch rails have weak-constraint variable cross-sections without fasteners, their damage characteristics and the transmission of acoustic emission signals are far more complicated than those of standard rails.

Wear detection and monitoring during operation are complex and difficult tasks especially for materials under sliding conditions. In this work, acoustic emission signals generated by the wheel flange and switch rail contact at the field site to monitor the various phases of delamination wear, and data mining techniques are used to cluster and obtain the characteristics of acoustic emission signals for switch rail wear based on Wavelets and Wigner-Ville high-order spectrum.

2. Methodology

The wear and fracture of materials under a stress are an important mechanism of structural failure. Such source having direct relation to wear and fracture mechanism can be acoustic emission source, which causes mechanical vibration on the surface. The transient displacement on the surface can be transformed into electrical signals with an acoustic emission sensor. The charge signals of a turnout switch rail in service state are received by a PZT piezoelectric sensor for pretreatment. The Gaussianity of signal distribution is adopted for confirming whether the received signals are acoustic emission signals; In order to improve the efficiency of the signal analysis algorithm, 1/4 sub-band signals are selected as the characteristic signals through 20KHz highpass filtering and wavelet packet decomposition, and then a mass data can be recharacterised based on the modern signal processing technology and big data mining technology and through the modern signal processing technology and thus the time-frequency high-resolution characterisation of signals can be realised while restraining noise with Wigner-Ville four-order spectrum. Based on the high-resolution characterisation and noise restraint of acoustic emission signals, the big data are mined and clustered by taking the Wigner-Ville four-order spectrum as the characteristics of acoustic emission signals, and the new acoustic emission signals can be classified by taking the clustered mass data as the prior information.

2.1 Signal Pre-processing

An acoustic emission signal of a turnout switch rail fracture is similar to a transient impact signal, the emission of energy is transient, and therefore the acoustic

emission signal changes with the time. It is a nonstationary random signal since its probability density function changes with the time. Wavelet packet decomposition is helpful for characterising local signals within a time domain and a frequency domain at the same time, which can not only be adopted to describe the spectrum information of signals within a local time interval, but also to indicate the corresponding time domain information of frequency domain information. In order to improve the efficiency of the signal analysis algorithm, the acoustic emission signal can be decomposed based on the wavelet packet decomposition method. Given that a fundamental function $\psi(t)$ is, then make

$$\psi_{a,b}(t)=\frac{1}{\sqrt{\mathrm{a}}}\psi(\frac{t-b}{a}) \tag{1}$$

Where, both *a* and *b* are constants and *a>0*. It is obvious that $\psi_{a,b}(t)$ is obtained when the fundamental function $\psi(t)$ is shifted and then flexed. A family of function $\psi_{a,b}(t)$ can be obtained provided that *a* and *b* change continuously. According to the given square integrable signal $x(t)$, i.e. $x(t)\in \mathrm{L}^2(\mathrm{R})$, then the wavelet transformation of $x(t)$ can be defined as:

$$WT_x(a,b)=\frac{1}{\sqrt{a}}\int x(t)\psi^*(\frac{t-b}{a})dt=$$
$$\int x(t)\psi^*_{a,b}(t)dt=\langle x(t),\psi_{a,b}(t)\rangle \tag{2}$$

Where, *a* is the scale factor, *b* is the time shifting factor.

Make the spectrum function of the wavelet basis function $\psi(t)$. According to the property of Fourier transform, the spectrum function of the wavelet sequence $\psi_{a,b}(t)$ should be $a^{1/2}\psi(aw)\mathrm{e}^{-jab}$. It can be seen that the time factor *b* only indicates the change of signal phase in the frequency domain, while the scale factor *a* realises the frequency limit of the signal, i.e. the signal can be divided into different frequency band components. The higher the scale factor is, the lower the frequency will become and the narrower the frequency band will become. Provided that a *j* scale wavelet analysis will be made for a signal *f(t)* with a sampling rate $2f_s$, then $f(t)=\sum_{i=1}^{j}D_i+A_j$; Where the band range of A_j is $\left[0, f_s/a^j\right]$, the band range of D_i is $\left[f_s/a^i, f_s/a^{i-1}\right]$,$1\le i\le j$.

As shown in Eq. (2), the wavelet sequence function can be considered as a series of window functions, the local analysis on *f(t)* is made at time *b*. Suppose that the centre of the wavelet basis function $\psi(t)$ is t^* , the time window width is $2\Delta t$, then Eq. (3) will indicate the local analysis on *f(t)* within the following time window:

$$\left[at^*+b-a\Delta t, at^*+b+a\Delta t\right] \tag{3}$$

In a similar way, make the centre frequency of the spectrum function $\psi(t)$ of the wavelet basis function $\psi(t)$ be w^* and the band width be $2\Delta w$, then according to the property of Fourier transform, the frequency window in relation to the time window should be:

$$\left[w^*/a-\Delta w/a, w^*/a+\Delta w/a\right] \tag{4}$$

The low scale *a* is in relation to a high frequency signal, according to Eq. (3) and (4), a small time widow is used in the time domain for the wavelet transformation during the local analysis on the function *f(t)*, and big frequency windows are used in the frequency domain of them; While for the analysis on the low frequency signal in relation to the high scale *a* is quite the reverse. Because the wavelet has variable time / frequency windows, the wavelet transformation is characterised by good localisation in both time and frequency domains, which is quite suitable for analysing those signals with transient transformation.

2.2 Feature Extraction

The Wigner high-order spectrum is the extension of Wigner-Ville distribution, which, based on the good mathematical characteristics of Wigner-Ville distribution, is also provided with the advantages of high-order spectrum analysis. It, in essence, reflects the high-order spectrum characteristics of signals on time-frequency planes, i.e. the distribution of signal high-order domain energy on time-frequency planes. The Wigner-Ville high-order spectrum, being also provided with the capacity of high-order spectra in restraining Gaussian noises, keeps the high resolution characterised by the signal transformation domain and realises the synchronous high time-frequency resolution of signals.

The Wigner-Ville distribution and the Wigner-Ville high-order spectrum are defined as follows:

$$WVD(t,w)=\int_{-\infty}^{-\infty}x(t+\frac{\tau}{2})x^*(t-\frac{\tau}{2})e^{-iw\tau}d\tau \tag{5}$$

$$WVD_{Order}(t,w_1,\cdots,w_k)=\int_{\tau_1}\cdots\int_{\tau_k}x^*(t-\frac{1}{k+1}\sum_{m=1}^{k}\tau_m)$$
$$\prod_{i=1}^{k}x(t+\frac{1}{k+1}\tau_i-\frac{1}{k+1}\sum_{m=1}^{k}\tau_m)e^{-iw_i\tau_i}d\tau_i \tag{6}$$

When k=4, the Wigner-Ville four-order spectrum can be obtained.

The Wigner-Ville four-order spectrum selected as the basis for extracting the characteristics and cluster of acoustic emission signals of turnout rails is not only helpful for restraining Gauss background noises but also for keeping the high resolution of the signal time-frequency domain. When the Wigner-Ville four-order spectrum is used for processing the acoustic emission signals of rails, the “nice distinction” among different types of acoustic emission signals will not be “neglected” and “blurred”, on the contrary, the “nice distinction” among time domains can be put into a time-frequency domain for rearrangement, from this point of view, the Wigner-Ville four-order spectrum realises the effective amplification of the “nice distinction” among different types of acoustic emission signals, laying a solid foundation for the cluster analysis.

2.3 Data Mining

The big data mining technology, in essence, is the combination of signal processing and information processing technology. Information can be mined through signal processing. No any uniform methodology has been provided for big data mining, however, characteristic extraction, classification and clustering are important for the big data mining technology. In order to classify and cluster mass and nonisomorphic data, characterisation is necessary, which can even be deemed as a signal processing technology, see Fig. 1.

According to the fracture mechanics, it is no doubt that a "distinction" between different acoustic emission signals can be found in a time domain or a transformation domain. Characteristic extraction aims to extract this "distinction" precisely under strong background noises. Characterisation and cluster analysis are the core for acoustic emission signal processing, however characterisation is the foundation for cluster analysis. Theoretically, many methods in processing signals are helpful for characterising acoustic emission signals, but considering the strong background noises at railway turnouts, the Wigner-Ville four-order spectrum can be used to charactrising the acoustic emission signals of damaged turnout switch rails.

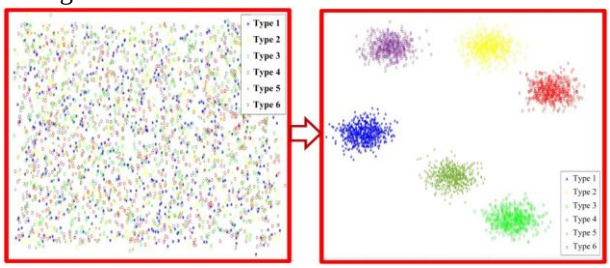

Fig. 1 Signal processing after data mining

Decomposing a set into some subsets according to a uniform standard is called "cluster analysis", each subset is called a cluster, "Birds of a feather flock together" is a typical application for cluster analysis. For cluster analysis, characteristic extraction is the foundation. The uniform standard of clustering comes from a certain transformation of characteristics. From the pure mathematical view, all clusters require the individuals of a subset to be limited within a similar tolerance, while strong subsets are quite different from each other. The acoustic emission characteristics of damaged turnout switch rails are distinguished according to the dynamic clustering method.

3. Acoustic Emission Characteristic

Acoustic emission is a common physical phenomenon. The range of acoustic emission signal frequency of different materials is wide - from the Hz class infrasonic frequencies, 20Hz~20KHz audio frequencies to MHz class ultrasonic frequencies; The amplitude range of acoustic emission signals is also wide - from microscopic 10^{-13}m dislocation motion to 1m magnitude seismic waves. A sound can be heard if the stress of acoustic emission meets the requirement. For most materials, the emission can be heard in cases of deformation and fracture, however many have very weak acoustic emission signal intensities that are hard to be heard directly, which can only be detected by sensible electronic instrument. The method for detecting, recording and analysing acoustic emission signals with instrument and testing acoustic emission sources with acoustic emission signals is called acoustic emission technology

3.1 Signal Acquisition

Acoustic emission sources generate elastic waves that can be transmitted to a tested surface through a certain medium, causing mechanical vibration on the surface. The transient displacement on the surface can be transformed into electrical signals with an acoustic emission sensor. The waveforms or characteristic parameters can be recorded and displayed after the acoustic emission signals are amplified and processed. The characteristics of the acoustic emission sources can be evaluated through data analysis and explanation. The characteristics of acoustic emission signals can be obtained according to the piezoelectricity energy method. The surface of a piezoelectric material generates polarization charge under an external force. The quantity of the electric charge is in proportion to the pressure. Piezoelectric crystals are characterised by low symmetry, the relative displacement of positive and negative ions in crystal cells being subject to deformation under the external force will make the positive and negative charge centres leave from each other, causing macroscopical polarization of the crystals. However the surface density of charge on a surface of a crystal is equivalent to the projection of the polarization intensity on the surface normal, therefore both ends of the piezoelectric material being subject to deformation under a pressure can generate contrary sign charge, whereas when the piezoelectric material polarizes in an electric field, deformation will be caused due to displacement of the charge center, as shown is Fig. 2.

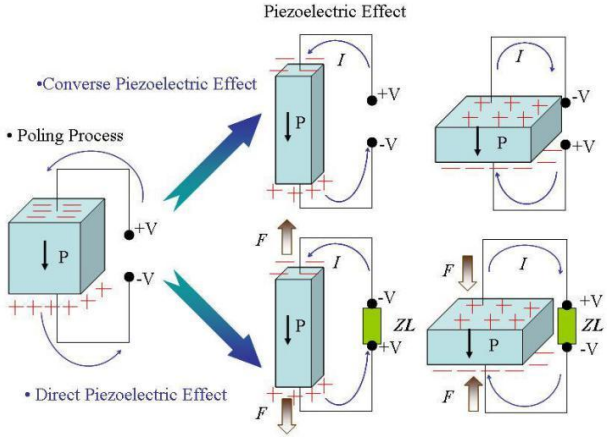

Fig. 2 Schematic of acoustic emission signals during piezoelectric energy test

PZT piezoelectric sensors are characterised by good electromechanical coupling property for realizing conversion between mechanical signals and electric signals. The voltage signals tested with PZT piezoelectric sensors can reflect the conditions of mechanical structures. For the constitutive relation equations, see Eq. (7).

$$\begin{bmatrix} s_1 \\ s_2 \\ s_3 \\ s_4 \\ s_5 \\ s_6 \end{bmatrix} = \begin{bmatrix} S_{11}^E & S_{12}^E & S_{13}^E & 0 & 0 & 0 \\ S_{12}^E & S_{22}^E & S_{23}^E & 0 & 0 & 0 \\ S_{13}^E & S_{23}^E & S_{33}^E & 0 & 0 & 0 \\ 0 & 0 & 0 & S_{44}^E & 0 & 0 \\ 0 & 0 & 0 & 0 & S_{55}^E & 0 \\ 0 & 0 & 0 & 0 & 0 & S_{66}^E \end{bmatrix} \begin{bmatrix} \sigma_1 \\ \sigma_2 \\ \sigma_3 \\ \tau_{23} \\ \tau_{31} \\ \tau_{12} \end{bmatrix} + \begin{bmatrix} 0 & 0 & d_{31} \\ 0 & 0 & d_{32} \\ 0 & 0 & d_{33} \\ 0 & d_{24} & 0 \\ d_{15} & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix} \begin{bmatrix} E_1 \\ E_2 \\ E_3 \end{bmatrix} \quad (7)$$

In this study, the characteristics of acoustic emission signals are tested through piezoelectric energy. A PZT piezoelectric sensor is installed at the base of a turnout switch rail, the acoustic emission signals of different damages to the switch rail can be acquired through and indoor test and an on-site test, providing a reference for the cluster analysis on acoustic emission signals of the damages to the switch rail. For the PZT piezoelectric sensor installed at the base of the turnout switch rail, see Fig. 3.

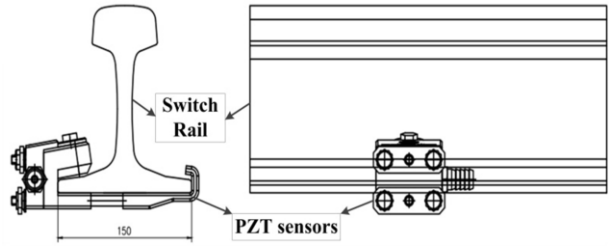

Fig. 3 Installed PZT piezoelectric sensor

3.2 Acoustic Emission Characteristic of Rail Wear

Turnouts are laid in marshalling stations with many passing trains. The stress environment of turnout rails is poor, and huge economic losses and casualties can be caused in case of switch rail wear. When wheel flange contacts with switch rail side and rail wear occurs, the time travel curve of acoustic emission signals will be received by the PZT piezoelectric sensor. The acoustic emission signal characteristics of the turnout switch rail fracture can be obtained according to the characteristic extraction method for acoustic emission signals mentioned in Section 2. The original acoustic signal of the switch rail wear can be found in both time (Fig. 4(a)) and frequency (Fig. 4(b)) domains.

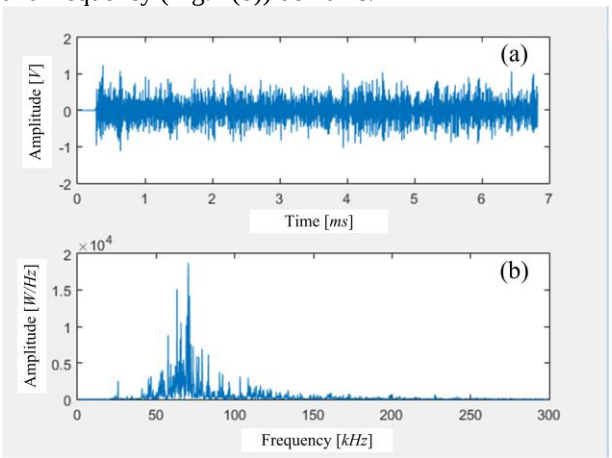

Fig.4 The original acoustic signal of the switch rail wears in time and frequency domains

It can be seen from Fig.4, the original acoustic signal of the switch rail wears in time domain is fluctuant, and there is no apparent frequency for original acoustic signal in frequency domain. However, there are some inapplicable signals for the switch rail wears and the original acoustic signal needs to be processed by data analysis.

The Gaussianity of signal distribution is adopted for identifying whether the received signals are acoustic emission signals; In order to improve the efficiency of the signal analysis algorithm, 1/4 sub-band signals are selected as the characteristic signals through 20kHz highpass filtering, and the acoustic signal after filtering of the switch rail wear can be found in both time (Fig. 5(a)) and frequency (Fig. 5(b)) domains.

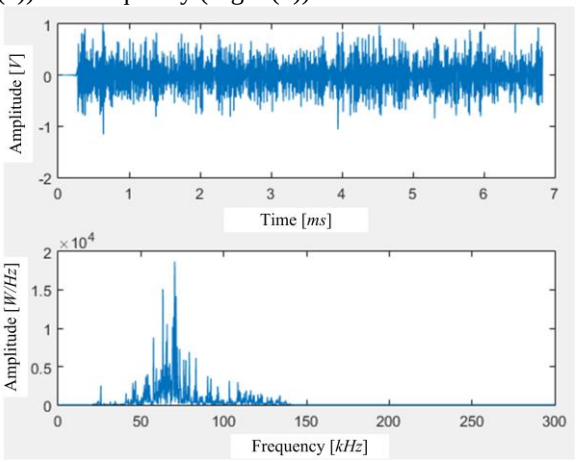

Fig.5 The acoustic signal after filtering of the switch rail wears in time and frequency domains

It can be seen from Fig.5, after signal identification and noise reduction, the acoustic signal of the switch rail wears in time domain changes and abnormal fluctuation has been eliminated. Meanwhile, the distribution in frequency domain has little change, especially for the frequency passing the target frequency.

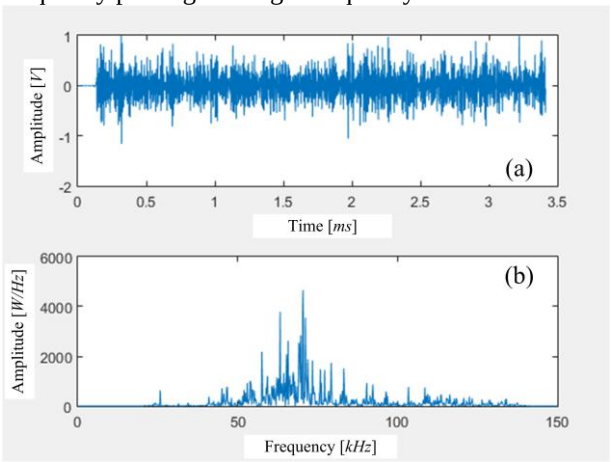

Fig.6 The acoustic signal after wavelet analysis of the switch rail wears in time and frequency domains

To obtain higher SNR (signal to noise ratio) accurate description for the switch rail wears in time and frequency domains, Mallat algorithm and Nquist sampling theorem of wavelet analysis is applied to

diagnose and filter the noise of acoustic emission signal, as shown in Fig.6.

Then, Wigner-Ville high-order spectrum is applied to describe the essential characteristics of acoustic emission signal for switch rail wear. The Wigner-Ville high-order spectrum for extracting acoustic emission characteristics is in Fig.7 and Fig.8. The acoustic emission characteristics can be used for data mining for wear monitoring of railroad switch rail.

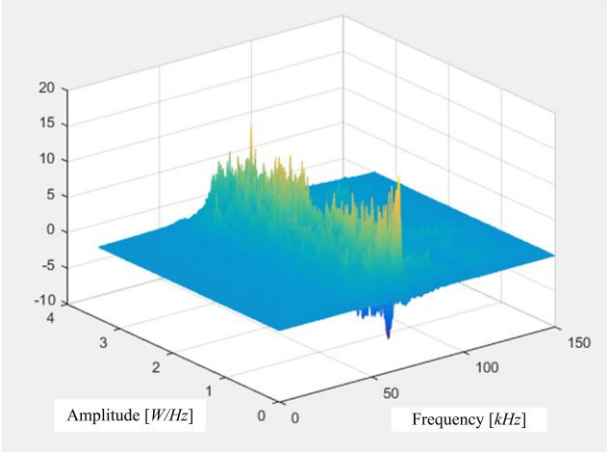

Fig.7 3D distribution for Wigner-Ville spectrum of switch rail wear

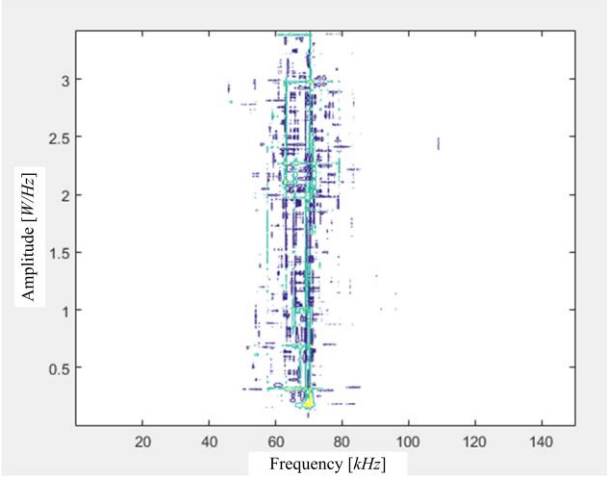

Fig.8 2.5D distribution for Wigner-Ville spectrum of switch rail wear

Factors such as the diversity of the acoustic emission source mechanism, the complexity of the sonic propagation route, the suddenness and uncertainty of acoustic emission signals as well as the severity of interference noises are of great challenges for acoustic emission signal processing and analysis. Moreover, though the Gauss noises have an impact when acoustic emission signals are acquired at turnout switch rail areas, the characteristic distinction among advantageous signals from different signal sources is minor, therefore a mathematical tool being quite available for restraining Gauss noises and amplifying the "nice distinction" among different types of acoustic emission signals is needed. In this study, the Wigner-Ville high-order spectrum is selected for extracting acoustic emission characteristics. As shown in Fig. 7 and Fig.8, the acoustic signal of the switch rail fracture can be found in both time and frequency domains. The amplitudes of the signal in the time and frequency domains are high within the time axis of 1ms ~ 4ms, indicating that the switch rail wear occurs within the time axis of 1ms ~ 4ms. The signal is "highlighted" at the point of around 70KHz in the frequency domain, which shows the acoustic emission signal characteristic in relation to the switch rail wear.

4. Conclusion

This paper, based on the Wigner-Ville high-order spectrum and big data mining technology, presents the method for extracting the characteristics of acoustic emission signals of turnout switch rail wear and analyses the characteristics of acoustic emission signals of damages such as turnout switch rail wear. A PZT piezoelectric sensor is installed on a turnout switch rail in an on-site test, when a switch rail wear occurs, the sensor can receive the energy signals. The Gaussianity of signal distribution is adopted for confirming whether the received signals are acoustic emission signals. Acoustic emission signals can be processed through through 20KHz highpass filtering and wavelet packet decomposition, and a sub-band signals are selected as the characteristic signals; The Wigner-Ville four-order spectrum is used for recharacterising mass data in order to realise bid data mining and cluster analysis, laying a foundation for monitoring turnout switch rail wear with the acoustic emission technology.

Abstract: An improved instantaneous frequency components separation method based on synchro-squeezed short time Fourier transform (SSTFT), which has inverse formula and is suitable for nonlinear unstable multi-component signal, has been presented. This approach could connect the extracted segment frequency curves into continuous ones, and reconstruct the IF components, with which we can study the signal's characteristics, fast and clearly. The results indicate that this method is accurate and effective. As an application, we studied the simulation signal and measured axle box vibration acceleration data of high speed railway, which could characterize the high-frequency percussion of the wheel-rail at the short wave irregularity point. Through the frequency curve, we reconstructed the vibration information and got the instantaneous frequency. Combined with the signal's characteristics both in time and frequency space, the on-site inspection and the feedback verified the correctness of the theory and the application value.

Keywords: synchro-squeezed short time Fourier transform; instantaneous frequency; rail corrugation; phase locked loop

1. Introduction

Instantaneous frequency (IF) is an effective description for the non-stable signal. It is widely used in signal processing. In 1937, Carson [1] came up with the idea of IF. He thought the frequency is the rate of change over the time. This gave us a new understanding of frequency. In 1948, Ville [2] provided the definition of the IF. Physically, the signal contains mono-component signal and multi-component signal. For the mono one, phase-difference is a revise of Fast Fourier Transform, and could only use for the signal which has linear phase due to its low noise resistance. The method of phase locked loop could resist the noise, but it couldn't show the IF precisely when the frequency changed fast. For the multi-component signal, in 1996, Shimon Peleg [4] proposed the processing method of polynomial phase transform for the multi-component signal. This is a reliable method for the signal with non-linear phase. Zero crossing method and Teager energy operator method [5][6] came with a list of formula. However, the low accuracy and low noise resistance are their weakness respectively. Norden E. Huang et al. [8][9], decomposed the signal into several Intrinsic Mode Function (IMF) with the method of EMD and EEMD in 1998. And use the Hilbert transform to extract the IF. Nevertheless, the algorithm contains heuristic and ad hoc elements that make it hard to analyse mathematically.

Short Time Fourier Transform (STFT) gives us a time-frequency analyse tool, However, it cannot meet the high-resolution requirement both in time and frequency domain. Thus, Daubechies et al. [6] constructed the wavelet transform. But the selection of the mother wavelet made it inconvenient. The method of EMD [8] and EEMD [9] avoid this problem effectively, but the mode mixing comes up on the time-frequency plane. These mixing modes could give us unreality information, which could get things into trouble. In 2010, Daubechies et al. came with a theory of synchro-squeezed wavelet transform (SST) [10]. SST, which has inverse transform, is a method combined with wavelet analysis and reallocation.

Inspired by SST and considered the widely use of STFT, Gaurav Thakur et al. proposed the algorithm of synchro-squeezed STFT(SSTFT) [11]. SSTFT is a method like SST and could make the frequency curve more clear on the plane. Besides, it eliminated the false information which comes with the mode mixing.

Here, we improve the curve extraction method after SSTFT. The original extracted frequency curves are piecewise curves. Then the inverse formula reconstructed the signal to time domain. The processing of simulated signal and measured signal of high speed railway axle box proved that our method does indeed succeed in extracting the instantaneous frequency.

2. Improved Synchro-squeezed STFT(ISSTFT)

SSTFT was described in the context of recovery of IF components [11] It is a combination of STFT and reallocation. But the original extracted frequency curves are piecewise curves. If the IF has a fixed relationship with time, we can't capture its information because the curve was separated by the threshold. Here we improve the algorithm, and the key steps are listed below:

1) Use STFT to get the time-frequency representation (TFR) W;
2) Synchro-squeeze W on the TF(Time-Frequency) plane;

3) Extract the frequency curve;
4) Connect the piecewise curves into continuous ones;
5) Combined with the inverse formula, reconstruct the signal in time domain.

The third step in detail is as follows:

i) Initialize $k = 1$;
ii) Find out (t_0, f_0), the maximum energy point on the TF plane, i.e. the instantaneous frequency of k-th components is $IF_k(t_0) = f_0$;
iii) Assign zero in the range $(t_0, f_0 - l)$ to $(t_0, f_0 + l)$, which l is an constant number;
iv) Assign $t_l = t_0 - 1$, $t_r = t_0 + 1$, $f_l = f_0$, $f_r = f_0$, for every $t > t_0$ and $t < t_0$:
   a) Find out the maximum energy point, which should be a bigger number then a hard threshold γ, from $(t_l, f_l - l)$ to $(t_l, f_l + l)$, if yes, $IF_k(t_l) = \tilde{f}_l$; Find out the maximum energy point, which should be a bigger number then a hard threshold γ, from $(t_r, f_r - l)$ to $(t_r, f_r + l)$, if yes, $IF_k(t_r) = \tilde{f}_r$.
   b) Assign zero in the range $(t_l, f_l - l)$ to $(t_l, f_l + l)$ and from $(t_r, f_r - l)$ to $(t_r, f_r + l)$;
   c) Assign $t_l = t_l - 1$, $t_r = t_r + 1$, $f_l = \tilde{f}_l$, $f_r = \tilde{f}_l$;
   d) Repeat a) - c);
v) $k = k + 1, k < n, n \in \mathbb{C}$;
vi) Repeat ii)-v).

The original process finished the reconstruction without 4). Due to the hard threshold γ, if we want to focus on the changing of the instantaneous frequency over a period of time, it could not meet our requirement for the reconstructed signal is discontinuous. This process is fast and effective only when we need the time-frequency information in a very short time. Whereas, it will bring a large calculation and is helpless for us to find the relationship with time. To make up this shortcoming, the fourth step connected the piecewise curves into continuous ones, and it in detail are as follows:

i) Initialize $j = 1$;
ii) Find out $curve_j$, which corresponding to the maximum energy point, the starting time and frequency are donated by t_0 and f_0, the ending time and frequency are donated by t_e and f_e;
   a) Find out the curves which have ending time less than t_0 in the leavings, connected $curve_j$ with which has an ending frequency nearest to f_0; Find the curves which have starting time bigger than t_e in the leavings, connected $curve_j$ with which has an ending frequency nearest to f_e; set the frequency is zero where the time is discontinuous;
   b) Update t_0, f_0, t_e and f_e,
   c) Repeat a) - b), till all the components have been extracted or t_0 equals 0, t_e equals the ending time of raw signal respectively;
iii) $j = j + 1, j < m$, where m is a changeable parameter.
iv) Repeat ii) - iii).

Remark. If there are two curves both have the same time distance and frequency distance with $curve_j$, the random selection has no influence on reconstruction.
According to SSTFT, the bandlimited signal could be reconstructed. After we got the signal in time domain, we can use it to get a clear time-frequency representation and instantaneous frequency or instantaneous amplitude. This is very helpful for the study of the relationship between frequency and time.

3. Numerical Experiments and Application

3.1. Instantaneous frequency for synthesized signal

We start by the synthesized signal of Figure 1 designed by

$$f(t) = f_1(t) + f_2(t),$$

where,

$$f_1(t) = \begin{cases} cos(2\pi(80 - t^{1.5})t) & t \in [0, 6) \ or \ t \in (7, 10] \\ 0 & t \in [6, 7] \end{cases}$$

and

$$f_2(t) = \begin{cases} e^{-0.3t} cos(2\pi(30 + t^{1.5})t) & t \in [0, 4) \ or \ t \in (5, 10] \\ 0 & t \in [4, 5] \end{cases}$$

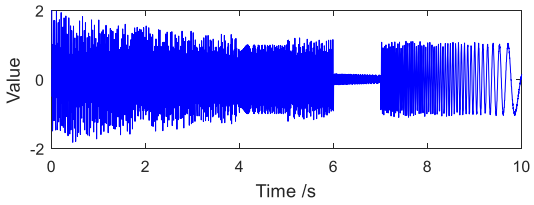

Figure 1 *Raw signal*

Figure 2 shows its TFD (time frequency distribution) obtained by STFT. TFD obtained by SSTFT is shown in Figure 3. Compared with Figure 2 we can see that the TFD obtained by SSTFT is clearer and preserves superb time-frequency concentration.

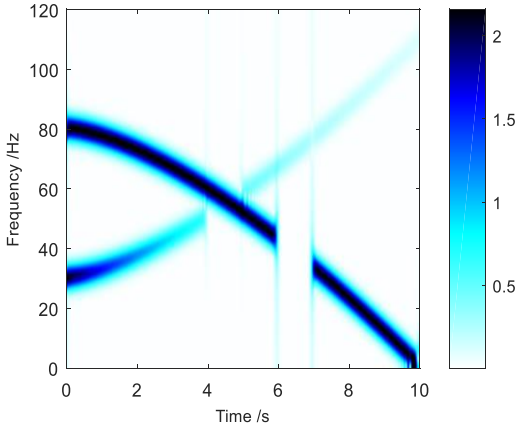

Figure 2 *The STFT representation of raw signal*

Due to the threshold γ, the frequency curves are discontinued and so does the reconstructed signal as a consequence. The first and third signal in Figure 4 belong to one signal, corresponding to the declining frequency curves in Figure 3, whereas they are separated between $t = 6s$ and $t = 7s$. The second and fourth signal in Figure 4 belong to one signal, corresponding to the increasing frequency curves in Figure 3, whereas they are separated between $t = 4s$ and $t = 5s$. The bottom signal in Figure 4

is the residual separated. The signals extracted by the ISSTFT are shown in Figure 5 and Figure 6, from which we can see that they are connected.

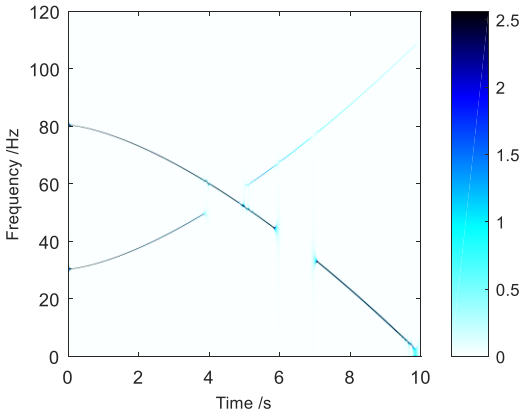

Figure 3 *The SSTFT representation of raw signal*

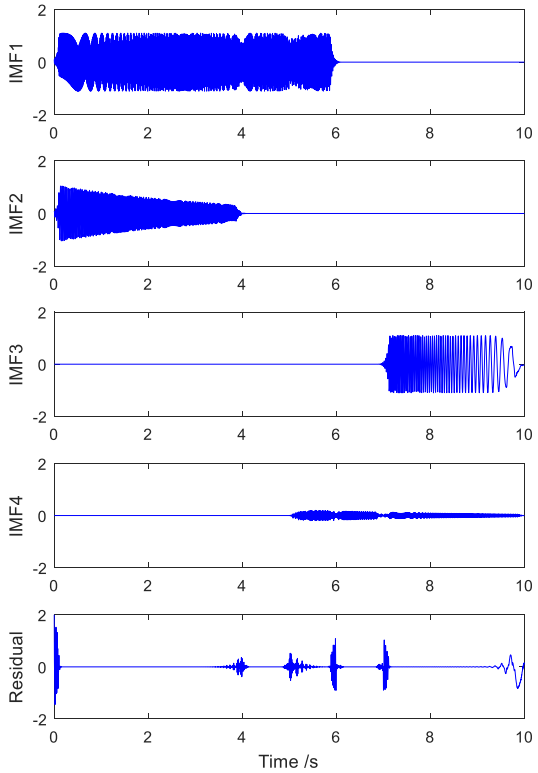

Figure 4 *The separated component and Residual after extracted*

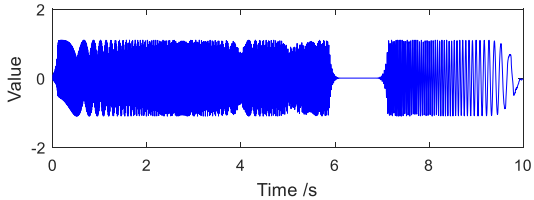

Figure 5 The first extracted component after connected

Figure 7 and Figure 8 are the instantaneous frequency of the first and the second component respectively in which the dash line is the analytical IF and the soiled line is the extracted IF by ISSTFT. The fluctuation around the beginning and the end are due to the boundary effect, which could be eliminated by extension. From Figure 7 and Figure 8 we can see that the extracted IF by ISSTFT could match the analytical IF exactly.

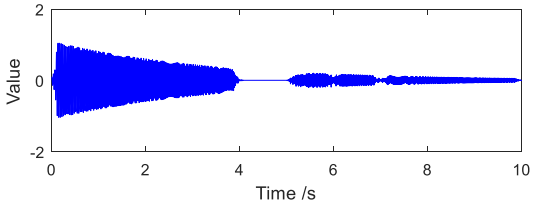

Figure 6 *The second extracted component after connected*

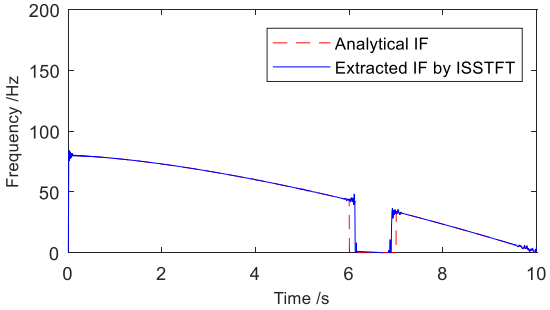

Figure 7 *The instantaneous frequency for the first component*

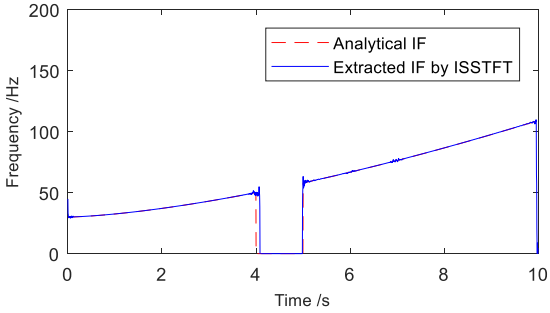

Figure 8 *The instantaneous frequency for the second component*

3.2. Comparison with EEMD

As a comparison, we choose the method of EEMD to separate the signal. Figure 9 shows the first to the third IMF separated by EEMD, an ensemble member of 50 is used, and the added white noise is each ensemble member has a standard deviation of 0.1. Figure 10 shows the Hilbert spectrum from the EEMD. From Figure 9, we can see that the first IMF contains some component belongs to the other one. So does the second and the third IMF. This phenomenon is due to the instantaneous frequency of the two components are closed to each other at some point. And the mode mixing comes up in Figure 10.

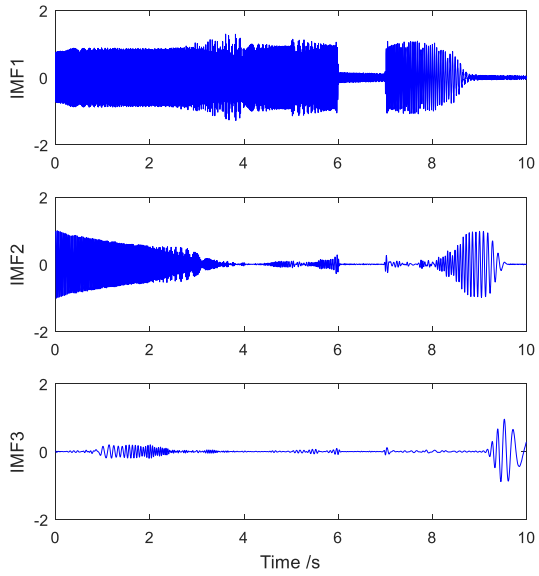

Figure 9 *The first and the second IMF separated by EEMD*

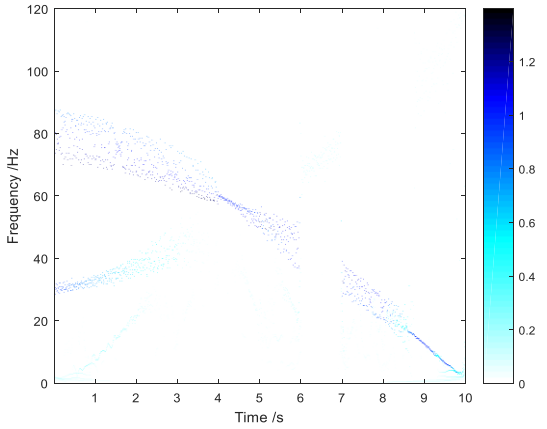

Figure 10 *The Hilbert spectrum from the EEMD*

3.3. Applying the ISSTFT to axle box acceleration of high speed railway inspection train

In this application, we illustrate the result on some real data, axle box acceleration of high speed railway comprehensive inspection train. The signal in Figure 11 was measured for $0.22km$, sampled at $2000Hz$ with speed $183km/h$. Figure 12 and Figure 13 are its TFDs obtained by STFT and ISSTFT respectively. Compared with each other we can see that the frequency curves in Figure 13 are more clearly. And there are some characteristic frequency between $K274+728$ and $K274+764$, as well as $K274+800$ and $K274+825$. Due to the threshold γ, the frequency curves are discontinued and so does the reconstructed signal, shown in Figure 14, as consequence. The bottom one in Figure 14 is the residual.

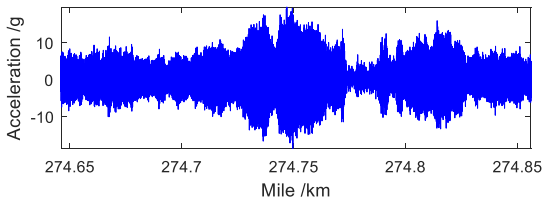

Figure 11 *Raw signal*

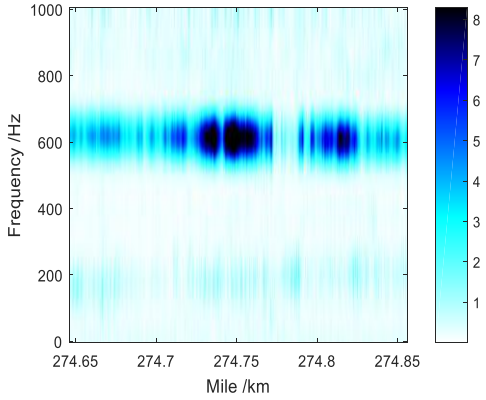

Figure 12 *The STFT representation of original acceleration signal*

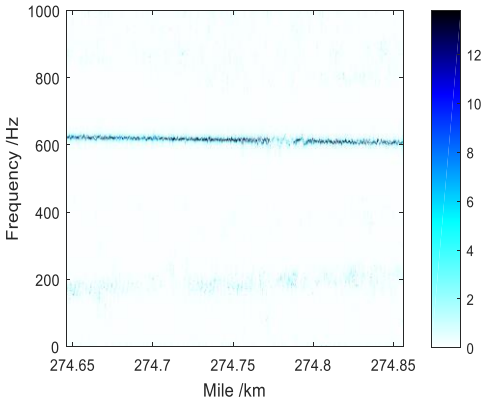

Figure 13 *The ISSTFT representation of original acceleration signal*

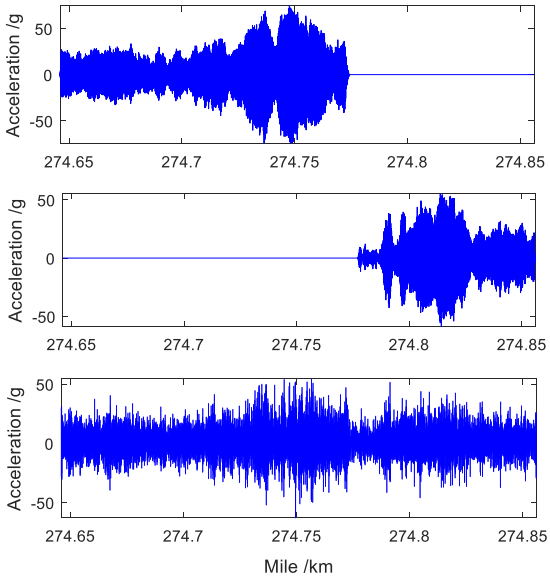

Figure 14 *The separated component after extracted and Residual*

The extracted component is shown in Figure 15.The IF of the continuous extracted component is shown in Figure 16. Figure 17 shows the instantaneous amplitude of it. After we connected the separated components, the reconstruction time is shortening. Through the Figure 16, we can see that the main frequency is $615Hz$, which corresponding to a wavelength $82.7mm$ at the speed of $183km/h$.

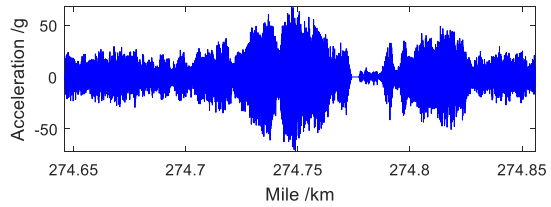

Figure 15 *The extracted component after connected*

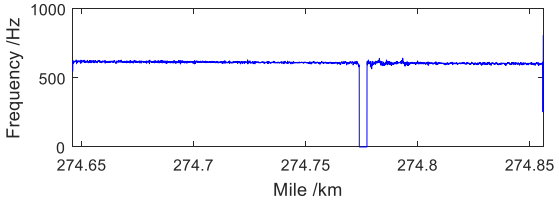

Figure 16 ***The IF for the separated component***

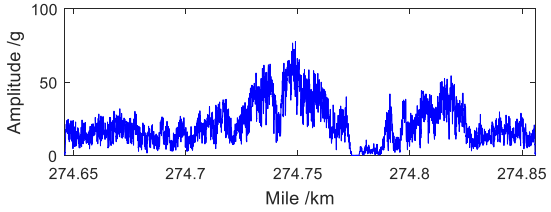

Figure 17 *The instantaneous amplitude for the separated component*

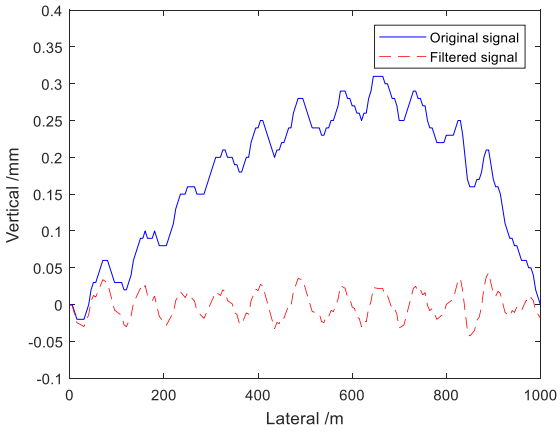

Figure 18 *The raw and filtered measurement of the rail*

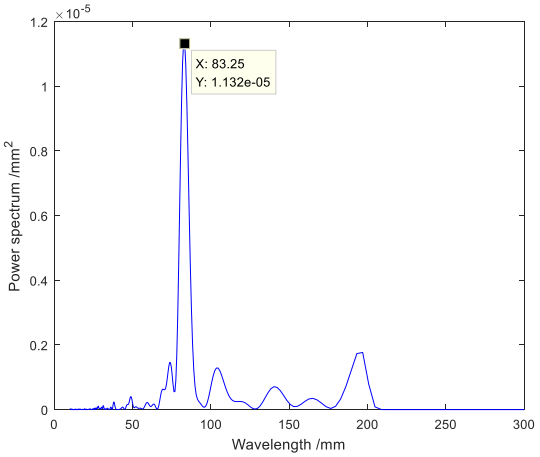

Figure 19 *The space spectrum of the filtered measurement*

In order to verify the conjecture, we inspected the rail under skylight. The detrended the roughness measurement of top-rail around $K274+750$ is shown in . Figure 18. Figure 19 shows its space power spectrum by FFT, which reveals the wave length $83.3mm$, in this rail section. This result proofs the correctness of the extract components and the usefulness in engineering.

4. Conclusions

An improved approach to compute the instantaneous frequency(IF) of a multicomponent signal has been presented. This procedure defines a high resolution time frequency distribution(TFD), which can help us extract the IF and get every component meanwhile. The simulation signal and the measured signal of axle box acceleration from high speed railway inspection train, both show its effectiveness. And the roughness measurement of top-rail verified the results of measured signal.

CHARACTERISTICS OF TANGENTIAL FORCE AT THE WHEEL/RAIL INTERFACE UNDER NON-STEADY SLIP RATIO

Daisuke YAMAMOTO [1]

[1] Railway Technical Research Institute, 2-8-38, Hikari-cho, Kokubunji-shi, Tokyo 185-8540, Japan

[*] E-mail:yamamoto.daisuke.55@rtri.or.jp

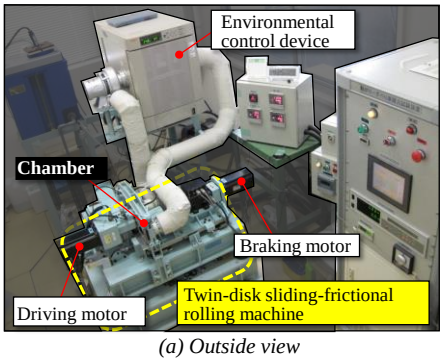
Abstract: This paper describes the tangential force characteristics under the steady/non-steady slip conditions based on the results of the experiments executed by using small cylindrical specimens. In the experiment, it's clearly that the characteristics under non-steady slip condition have large influence by the contact-patch and the surface properties. Especially it's showed that the tangential force coefficient in the case of the new specimen under the non-steady slip condition is small compared with that in the case of the used specimen under same condition. This means that the friction coefficient on the contact surface is not saturated due to low contact frequency.

Keywords: wheel/rail; contact-patch; tangential force; non-steady slip; fine unevenness; slip change rate; coefficient of friction.

1. Introduction

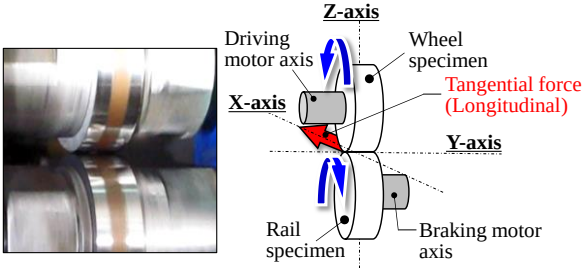
It's generally known that the tangential force characteristics of the wheel/rail interface has a large influence on the dynamics characteristics of railway vehicles, and many experimental and/or analytical researches were presented [1,2,3]. However, as the running distance of the railway vehicle increases, the wheel tread changes its shape from the initial cross-sectional one due to wear and re-profiling, etc. And the tangential force characteristics in this process are not known in detail. Therefore, in our previous studied, we paid our attention to fine unevenness and investigated the tangential force characteristics under steady slip conditions. In these papers [4,5], it was reported that the larger the fine unevenness is, the smaller the tangential force becomes, and this phenomenon becomes more outstanding if the humidity around the specimens is low.

On the other hand, when the railway vehicle is running powering or braking, the tangential force characteristics of the wheel/rail interface is under non-steady slip ratio conditions as well as under steady slip ratio conditions. However, in the experimental and/or analytical research [6,7,8] of the tangential force characteristics of wheel/rail under non-steady slip conditions, the relations among the contact-patch, the surface properties and the tangential force characteristics are not clear.



In this study, we paid attention to the difference in the contact-patch and the surface properties, in order to investigate the difference in the tangential force characteristics between steady slip conditions and non-steady conditions, and the tangential force measurement experiment is carried out using two small cylindrical specimens under environmental conditions, in control of temperature and humidity.

This paper described the difference in the tangential force characteristics between steady slip ratio conditions and non-steady slip ratio conditions based on the examination by the use of small cylindrical specimens. In addition, the difference in tangential force characteristics between the new specimen and the used specimen under non-steady slip conditions is presented.



2. Tangential force measurement experiments under the different slip condition

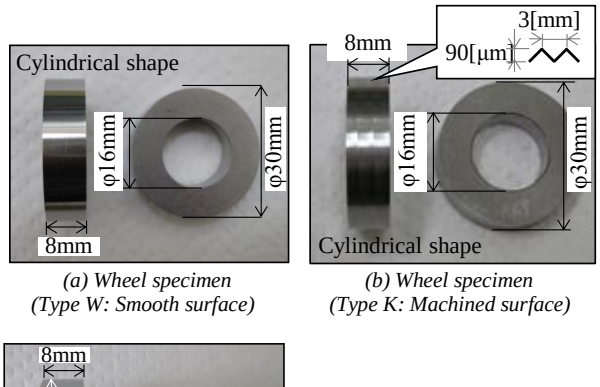
2.1. Experimental set-up

In order to investigate the tangential force characteristics of wheel/rail interface under the steady slip conditions and under the non-steady slip conditions, the measurement experiments of the tangential force was conducted using a pair of small cylindrical specimens. The same experimental device as is shown in Fig.1, i.e. Twin-disk sliding-frictional rolling machine equipped with environmental device in RTRI, used in previous

(a) Outside view

(b) Schematic figure of inside chamber

Figure 1 *Experimental set-up*



papers [4,5] was used. This experimental setup can measure the tangential force by keeping an accurate longitudinal slip ratio acting on the contact surfaces by means of a method of controlling the revolutions of two servo motors independently and keeping constant the environmental temperature and humidity conditions around specimens. Furthermore, a function of increasing a slip ratio bit by bit was added in this study.

The experimental setup and conditions were as follows; the rotational velocity is 100rpm, the vertical load is 450N (the contact pressure of the wheel/rail interface is about 1GPa), the attack angle between the specimens is zero, temperature around specimens is about 20℃, humidity around specimens is about 30%.

2.2. Specification of test specimens

The wheel specimen and the rail specimen were made from the actual wheel and the actual rail which is not heat-treated respectively. The maximum diameters of all the specimens are 30mm. Two types of contact surface of the wheel specimen are made, the smooth type and the machined surface type assumed to be after wheel re-profiling. In order to make the contact-patch between specimens elliptic, the shape of the contact surface of the rail specimens is made an arc of a radius of 300mm. Each cross-sectional shape and the specifications of the specimens are shown in Fig.2 and Table 1 respectively.

All specimens were used for the tangential force measurement experiment after drying them completely which were processed by performing ultrasonic cleaning for 15 minutes in state where they were completely dipped into the petroleum ether.

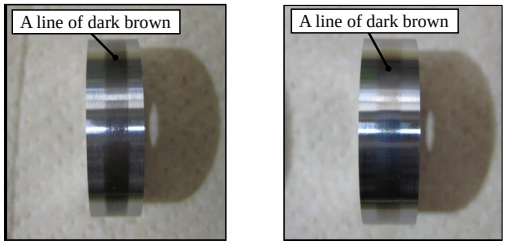
	Type K	Machined surface	3	90
Rail specimen	-	Smooth surface	-	Ra = about 0.4

2.3. The new specimens and the used specimens

It is considered that the surface properties of the tread are different between the wheel after re-profiling and the wheel without re-profiling after long run even though the cross-sectional shape of the wheel tread is the same. Therefore, in the case of the non-steady slip ratio condition, the tangential force measurement experiments were conducted for each of the smooth surface and the machined surface using two kinds of specimen, i.e. the new specimen assumed to be under re-profiling wheel tread condition as show in Fig.2(a) and the used specimen with dark brown material adhered to its surface assumed to be under after-long-run wheel tread condition as shown from Fig.3 to Fig.6.

- Firstly, rolling-sliding frictional force to the degree that it stops short of damaging the contact surface was applied until the tangential force coefficient reached its maximum completely. In this study, the slip ratio is invariably 0.3%. The experiment of Type W and Type K were conducted for about 17 minutes and about 25 minutes respectively.
- Next, the tangential force measurement experiment was conducted using the used specimen under non-steady slip ratio condition.



The condition of the contact surface and the cross-sectional shape of the used specimen are shown from Fig.3 to Fig.6 respectively. The cross-sectional shape of the used specimen is almost the same as that of the new specimen (see Fig.3 and Fig.5), and its contact surface is in state where dark brown material is adhered (see Fig.4 and Fig.6).

2.4. Conditions of slip ratio between wheel and rail

In the case of the experiments under steady slip ratio conditions, the experiments were carried out under the experimental conditions with its slip ratio kept constant as shown in 2.1. The slip ratio conditions are shown in Table 2.

In the case of the experiments under non-steady conditions, the experiments were carried out under the experimental conditions as described in 2.1 with the slip ratio increased bit by bit from 0.3% to 3.0%.

The specifications of the sweep of the slip change rate are shown in Fig.8.

Table 2 *Experimental condition of slip ratio*

	Range of slip ratio[%]	**Change time of slip ratio[sec.]**	**Equivalent slip change rate [%/sec.]**
Case 1	0.3 → 3.0	About 890	About 0.003

Case 3	0.3 → 3.0	About 8	About 0.34

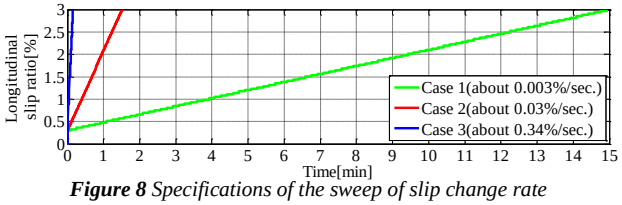

Figure 8 *Specifications of the sweep of slip change rate*

3. Experimental results of the tangential force measurement experiment

3.1. Steady slip ratio condition

The experimental results of the relation between the steady slip ratio and the longitudinal tangential force coefficient are shown in Fig.9. The vertical axis and the horizontal axis show the longitudinal tangential force coefficient and time respectively.

The experimental result of Fig.9 shows that the maximum value of the tangential force coefficient becomes large linearly as the slip ratio becomes large regardless of the cross-section of shape of the wheel specimen. The reason why the longitudinal tangential force coefficient becomes large is that the slip region in the contact-patch between specimens increases linearly [9]. On the other hand, the maximum value of the longitudinal tangential force coefficient in the case of the smooth surface is larger than that in the case of the machined surface under the same slip ratio conditions.

In order to investigate why the longitudinal tangential force coefficient in the case of the smooth surface is larger than that in the case of the machined surface, the theoretical value based on Kalker's rolling theory [10] is compared with the experimental results. Here, the contact-patch of the specimens is not elliptical because, strictly speaking, there is also fine unevenness on the contact surface of actual specimens. Therefore, based on the contact-patch strictly calculated taking the fine unevenness on the contact surface into consideration, the creep coefficients in the case of each surface are calculated using an easy estimation method by means of the Kalker's theory which we presented in our previous paper [11].

The tangential force coefficient estimated using the contact-patch calculated based on the cross-sectional shape of an actual specimen is shown in Fig.10.

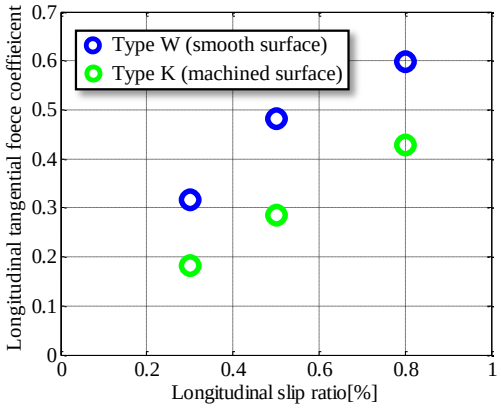
Here, the value estimated from Kalker's theory is the creep coefficient, which means the gradient of a graphical line representing the relation between the longitudinal tangential force and the longitudinal slip ratio where it is linear. The large gradient means that the creep coefficient is large, as is understood from equation (1).

$$T_x = C_{11} \times \nu_x \tag{1}$$

where T_x is the longitudinal tangential force; C_{11} is the longitudinal creep coefficient; ν_x is the longitudinal slip

ratio:

The tangential force under steady slip condition is almost the same as the values estimated based on Kalker's theory, as is shown by the estimated longitudinal tangential force coefficients in Table 3. These experimental results mean that the difference in the contact-patch of the wheel/rail interface, namely the difference in contact stiffness, has a large influence on the tangential force characteristics under steady slip ratio condition.



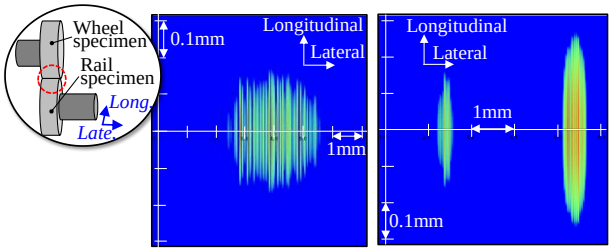


Figure 9 *Tangential force characteristics under steady slip ratio condition*

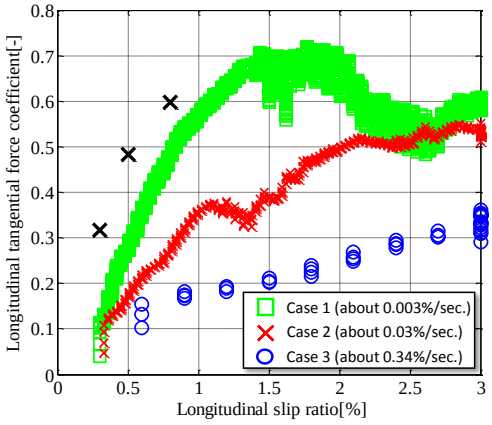
(a) Type W (Smooth surface) *(b) Type K (Machined surface)*

Figure 10 *Calculated contact-patch of test specimens*

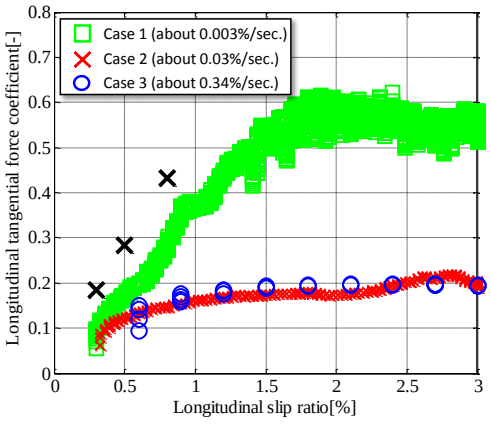
Table 3 *Estimated results of the tangential force coefficient*

Longitudinal slip ratio[%]	Longitudinal tangential force coefficient		
	Kalker's theory (Smooth surface)	Proposed method (Smooth surface)	Proposed method (Machined surface)
0.3	0.39	0.27	0.18
0.5	0.65	0.46	0.30
0.8	1.03	0.73	0.47



3.2. Non-steady slip ratio condition

Firstly, experimental result in the case of the new specimen is shown in Fig.11. The vertical axis represents the longitudinal tangential force coefficient, which is the longitudinal tangential force divided by the vertical load, and the horizontal axis represents the longitudinal slip ratio. The experimental result of the tangential force coefficient marked with × indicate those under steady slip condition.



The experimental result of Fig.11(a) and Fig.11(b) show that the tangential force coefficient increases as the slip ratio becomes large the same as under steady slip condition.

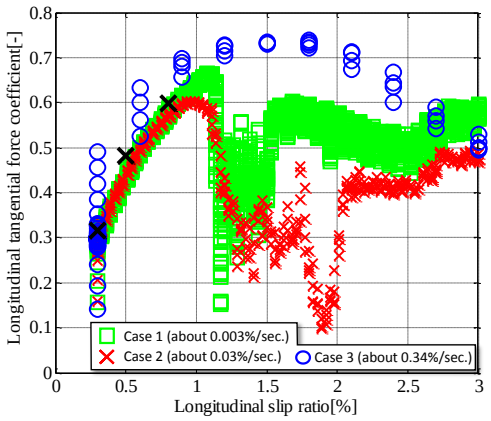
In the case of the smooth surface shown in Fig.11(a), although the longitudinal tangential force characteristics of Case 1 under small slip ratio condition are the same as those under steady slip condition, the tangential force coefficient is a little small. As the slip change rate becomes large, the gradient of the longitudinal tangential force coefficient becomes small bit by bit in the range of a slip ratio of less than 1%, and the longitudinal tangential force coefficient of Case 3 is saturated at about 0.3.

In the case of the machined surface shown in Fig.11(b), the longitudinal tangential force coefficient of Case 1 is a little small compared with that under steady slip condition, which is the same as in the case of the smooth surface shown in Fig.11(a). However, when the slip change rate becomes large, the longitudinal tangential force coefficient is saturated at about 0.2 uniformly. Although the cross-sectional shape of the specimens after the experiments is almost the same as the initial shape, dark brown material is formed on the contact surface of the specimens with its quantity increasing according to the duration of the experiment.

(a) Type W (smooth surface)

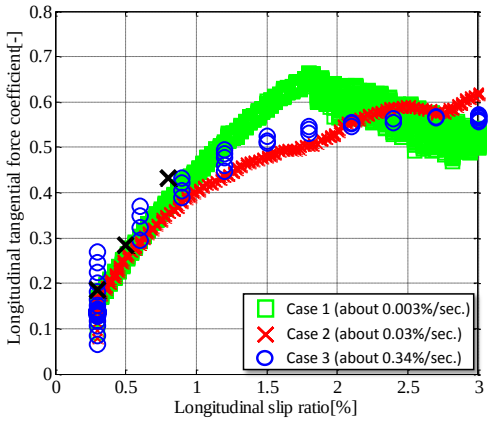
(b) Type K (machined surface)

Figure 11 *Tangential force characteristics of new specimen*



Next, the experimental results of the tangential force characteristics in the case of the smooth surface shown in Fig.12(a), the longitudinal tangential force coefficient of the used specimens is almost the same as that under steady slip ratio condition, these means that the slip change rate has a small influence on the longitudinal tangential force characteristics.

Although the longitudinal tangential force coefficient in the case of the machined surface shown in Fig.12(b) is



small due to a small contact-patch compared with that in the case of the smooth surface, this is the same tendency as that of the smooth surface shown in Fig.12(a). On the other hand, the dispersion of the longitudinal tangential force coefficients of Case 3 is large irrespective of the cross-sectional shape of the specimen in the range of a slip ratio of less than 1%. This is because the variation in the slip ratio is large due to the sparse sampling caused by the specifications of the measurement machine. In order to reduce the dispersion of the measured data, the longitudinal tangential force characteristics are evaluated by the gradient calculated using an approximate straight line, which passes through equalized longitudinal tangential force coefficients corresponding to every longitudinal slip ratio and zero point.

The relationship between the gradient of the longitudinal tangential force coefficient and the slip change rate is shown in Table 4. From the calculated result shown in Table 4, it is understood that in the case of the highest slip change rate condition, the gradient of tangential force characteristics under non-steady slip condition is as low as less than 10%, which is low enough, compared with that under steady slip ratio condition. Here, the fluctuation in the tangential force characteristics of Case 1 and Case 2 shown in Fig.12(a) is large in the range of a slip ratio of more than 1%. This is because a flat spot is formed on the contact surface in the process of the slip ratio increasing, and the longitudinal tangential force fluctuated discretely.

These experimental results mean that the longitudinal tangential force characteristics under non-steady slip ratio condition differ depending on the surface properties as well as the difference of the contact-patch.

(a) Type W (smooth surface)

(b) Type K (machined surface)

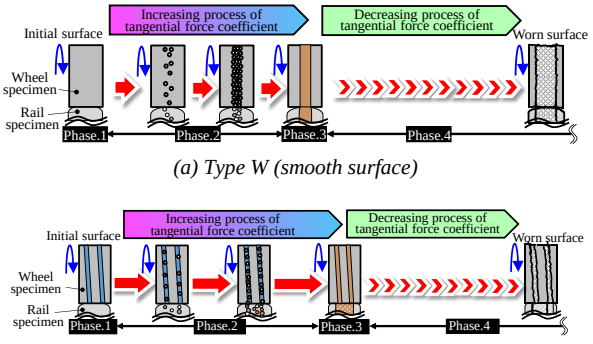
Type W(smooth surface)	0.92	0.92	0.97
Type K (machined surface)	0.50	0.50	0.54

4. The increase/decrease mechanism of the longitudinal tangential force coefficient

4.1. The change process of the longitudinal tangential force coefficient and surface properties

In order to understand the relation between the surface properties and the longitudinal tangential force characteristics, the change process of the contact surface between specimens is investigated in the course of the tangential force measurement experiment. Since the difference between the experimental results under steady slip ratio condition and those under non-steady slip ratio condition is only the formation speed of the surface properties, the experimental results under steady slip ratio condition are used for an example.



The time history of the measurement data of Fig.9 is shown in Fig.13, and the schematic figure of the process of the contact surface changing during the experiment is shown in Fig.14 respectively. Furthermore, the contact surface and the change process of the longitudinal tangential force characteristics during the experiment is as follows;

(a) Type W (smooth surface)

(b) Type K (machined surface)

Figure 13 *Time histories about tangential force characteristics under steady slip ratio condition*

(a) Type W (smooth surface)

(b) Type K (machined surface)

Figure 14 *Schematic figure of the process of the contact surface changing during the experiment*

Phase.1: The condition of the contact surface of the specimens before the experiment is the same as new specimens shown in Fig.2 in terms of its shape and color (silver).

Phase.2: When rolling-sliding frictional force is applied to the contact surface of the specimens, the contact surface changes its color to dark brown slowly, and accordingly the longitudinal tangential force increases.

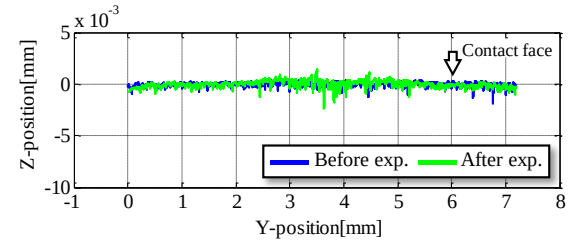
Phase.3: The dark brown on the contact surface becomes deeper, and the change in color becomes stable for a while. The longitudinal tangential force coefficient reaches a maximum value too, and is stable for a while. At this time, the contact surface is measured by the surface roughness measuring device, and the contact surface swelled approximately 1μm. The larger the slip ratio is, the shorter the length of time the longitudinal tangential force coefficient is kept stable.

Phase.4: The contact surface changes from dark brown to silver slowly. At this time, the longitudinal tangential force coefficient is a little small.

4.2. The increasing process of the longitudinal tangential force coefficient

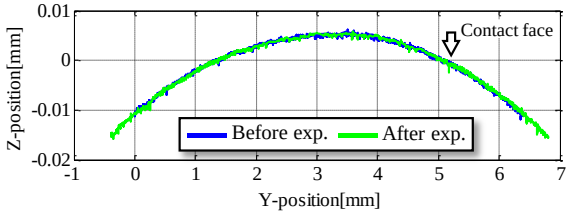
When the process changes from Phase.1 to Phase.2 as described in 4.1 the contact surface of the specimens is not greatly damaged in a short time because the rolling-sliding frictional force acting on the contact surface is small under small slip condition. Therefore, the minute metal powder which is exfoliated from the contact surface is trod down due to the rotation of the specimens because the condition is such that it is hard to drain from the contact surface. After this process, the minute metal powder change its color to dark brown bit by bit due to an oxidation phenomenon, and it's thought that the whole contact surface is covered with oxidized minute metal powder at Phase.3 and become dark brown.

On the other hand, the longitudinal tangential force coefficient gradually becomes large and stable as if its change followed the process in which the contact surface changes its color to dark brown. At this time, the cross-sectional shape of the specimens is almost the same as the initial shape of the specimens. According to the previous papers [12, 13], the process in which the friction coefficient on the contact surface increases was presented as follows;



When the contact surface is damaged by friction, the metal matrix emerges on the surface. The oxidation film which is produced through a process in which the metal matrix is combined with atmospheric oxygen appears on the surface. The friction coefficient of the contact surface becomes stable due to the lubrication effect of the oxidation film produced on the contact surface.

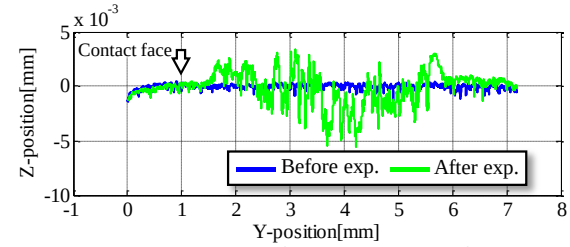
It is thought that the phenomenon characterized by an increase in the longitudinal tangential force coefficient during the tangential force measurement experiment is correspondent with the phenomenon described in the previous papers [12, 13]. This phenomenon, which can be explained by the above-mentioned analytical results and the knowledge of the previous papers, is because the rolling-sliding frictional force is applied to the contact surface repeatedly and it is characteristics of the minute metal powder to change its color to dark brown due to oxidation.



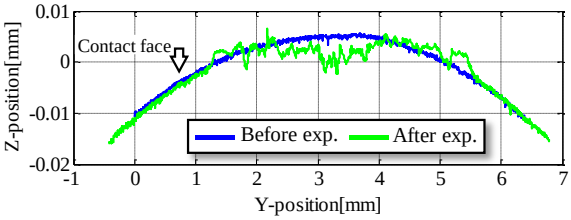
From the above, it's thought that the longitudinal tangential force coefficient, namely the friction coefficient on the contact surface becomes large because rolling-sliding frictional force is applied to the contact surface repeatedly, damage is done to the contact surface and the oxidation layer is formed on the contact surface.

4.3. Decrease process of the longitudinal tangential force coefficient

When the process changes from Phase.3 to Phase.4 as described in 4.1, the longitudinal tangential force coefficient becomes a little small and the color of the contact surface changes from dark brown to silver, which is especially prominent under large slip condition. The cross-sectional shape of the specimens 90 minutes later is shown, as compared with the initial cross-sectional shape of the specimens, in Fig.15 and Fig.16. Fig.15 shows that under 0.3% constant slip ratio condition, and Fig.16



(a) Wheel specimen of Type W (smooth surface)



(b) Machined surface type

Figure 15 *Cross-sectional shape of the specimens under 0.3% steady slip ratio condition*

(a) Wheel specimen of Type W (smooth surface)

(b) Rail specimen

Figure 16 *Cross-sectional shape of the specimens under 0.8% steady slip ratio condition*

shows that under 0.8% constant slip ratio condition respectively.

The cross-sectional shape of the specimens used under 0.3% constant slip ratio condition is almost the same as that of the initial specimens, and the contact surface is dark brown. However, the cross-sectional shape of the specimens used under 0.8% constant slip ratio condition is different from that of the initial specimens due to wear, and the contact surface becomes rough and its color becomes silver. The contact-patch in the case of the rough contact surface is small compared with that in the case of the smooth contact surface due to the small real contact area. For this reason, it is considered that the longitudinal tangential force coefficient of the specimen which was used for an experiment for a long time is a little small compared with the maximum value of the coefficient.

The above description deals with the case of the smooth surface, and, on the other hand, in the case of the machined surface the longitudinal tangential force coefficient does not become so small as that in the case of the smooth surface after the experiment under the same condition. This is because the contact-patch does not change greatly from its initial state, with the width of the unevenness nearly the same as that in its initial state despite the lowering of the height of the unevenness due to plastic deformation.

From these experimental results, it is considered that the reason why the longitudinal tangential force coefficient decreases is that the real contact area in the contact-patch becomes small due to the wear of the contact surface.

5. Influence of surface properties on the contact surface

5.1. Relationship between the coefficient of friction and the gradient of the longitudinal tangential force coefficient

In order to investigate, regarding the new specimens, the difference in the gradient representing the relationship between the longitudinal tangential force coefficient and the longitudinal slip ratio according to the slip change rate as shown in Fig.11 and Fig.12 which represent the experimental results, we consider a numerical analysis model in which the oxidation film formed on the contact surface in assumed to be the third body layer and the longitudinal spring element which transmits the tangential force acting on the contact surface is taken into consideration. The schematic figure is shown in Fig.17.

The longitudinal tangential force acting on the contact surface is defined as the vertical load multiplied by the coefficient of friction. Therefore, if the conditions regarding the slip displacement are the same what that the coefficient of friction is small means is that the longitudinal spring stiffness on the contact surface is small equivalently. Some literatures present the properties of the third body layer on the contact surface and its influence on the longitudinal tangential force characteristics with the aim of estimating the longitudinal tangential force characteristics of the contact surface with sand, water, ice, leaves, and dust on it by means of the numerical analysis.

According to the calculated results described in the literature [14], it was presented that the smaller the modulus of the transverse elasticity of the third body layer on the contact surface is, the gentler the gradient of the longitudinal tangential force coefficient is. Here, although the modulus of transverse elasticity described in the literature [14] is different from the longitudinal spring stiffness on the contact surface in dimension, these parameters can be compared with each other under the same slip displacement condition. From this point of view, it is considered that the gradient of the longitudinal tangential force coefficient is small because the traction force is small due to the small coefficient of friction on the contact surface. This consideration corresponded with the experimental results shown in Fig.11 qualitatively.

From these analytical results, the reason why the gradient of the longitudinal tangential force coefficient under the non-steady slip condition is different from Fig.9 is that the stiffness in the shear direction is different due to the difference in the coefficient of friction on the contact surface.

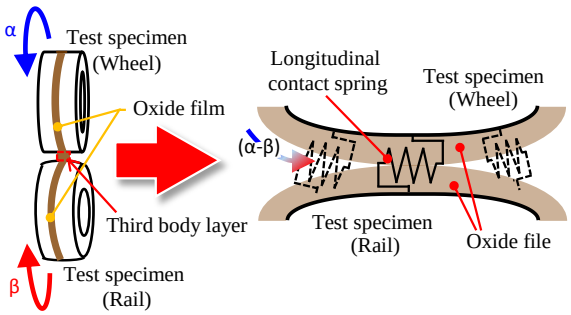


Figure 17 *Schematic figure of relation between third body layer of specimens and longitudinal equivalent spring assumed to frictional force*

5.2. *Dark brown material on the contact surface*

In order to investigate the influence of an increase in the dark brown material formed on the contact surface of the specimens, we conducted a tangential force measurement experiment under the steady slip condition as eliminating the dark brown material with the #240 abrasive cloth(see Fig.18). The dark brown material on the surface is eliminated as pushing lightly the abrasive clothe by hand onto the contact surface of the rotating wheel specimen.

The experimental result obtained from the wheel specimen with the smooth surface is shown in Fig.19. The longitudinal tangential force coefficient is represented on the vertical axis. And the longitudinal slip ratio is represented on the horizontal axis. The experimental

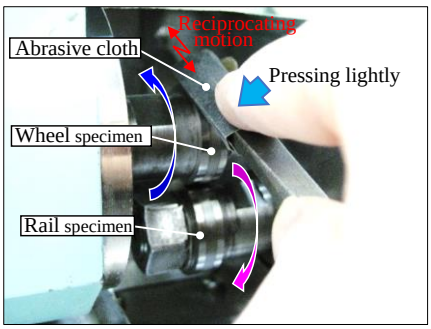

Figure 18 *The conditions of an experiment*

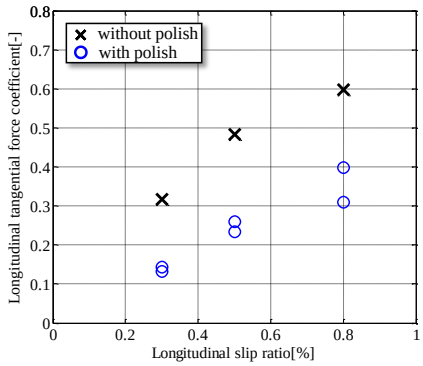

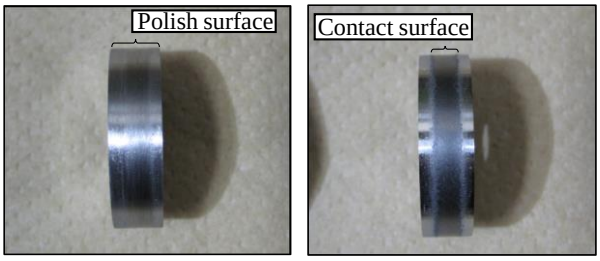

Figure 19 *Difference of tangential force coefficient with/without polish of Type W (smooth surface) new specimens*

results of the tangential force coefficient are marked with ○ when the contact surface is polished and with × when the contact surface is not polished under steady slip condition.

Although the longitudinal tangential force coefficient is a little small when the contact surface is polished compared with that when it is not polished, the longitudinal tangential force coefficient increases linearly as the slip ratio increases. At this time, the dark brown material is not on the contact surface of the wheel specimen as shown in Fig.20.

Since it has been found, from these experimental results, that the longitudinal tangential force coefficient in cases where minute metal powder is deposited on the contact surface is small compared with that in cases where the contact surface is clean, the experiment conducted with the contact surface polished cannot necessarily be expected to produce precise results. However, even when the dark brown material is not on the contact surface, it's considered that the coefficient of friction increases due to the rolling-sliding frictional force repeatedly applied on the surface.

(a) Wheel specimen *(b) Rail specimen*

Figure 20 *Contact surface of wheel specimen of Type W and rail specimen after polished experiment*

6. Conclusions

In order to investigate the difference in the tangential force characteristics of the wheel/rail interface between the case of the steady condition and that of non-steady condition, tangential force measurement experiments were conducted using small specimens under controlled environmental condition. As a result it is shown that the tangential force characteristics of small specimens under non-steady slip condition are greatly influenced by two factors, *i.e.* the contact-patch and the surface properties. The details of this study are as follows;

- In the case of the steady slip condition, the longitudinal tangential force coefficient is greatly influenced by the contact-patch, namely the contact stiffness.
- In the case of the non-steady slip condition, the longitudinal tangential force characteristics are influenced by the contact condition in addition to the contact-patch. Furthermore, the longitudinal tangential force coefficient obtained from the experiment on the new specimens is small without exception compared with that in the case of the steady slip condition due to low contact frequency.
- In the case of the non-steady slip condition, the longitudinal tangential force coefficient of the used specimens differs according to the contact-patch but it is not likely to differ according to the slip change rate. It is considered that this is because the coefficient of friction is saturated at a high value on the contact surface.
- In the case of the non-steady slip condition, as far as the used specimens are concerned, the difference in the gradient of the graphical line representing the relationship between the tangential force coefficient and the slip ratio, namely the difference in the creep coefficient, in the range of a slip ratio of less than 1% is as small as approximately 10% compared with the case of the steady slip condition as long as the slip change rate is less than 0.34%/sec..
- When frictional force is applied to the contact surface repeatedly, the longitudinal tangential force coefficient becomes large even with no dark brown materials on the contact surface. It is considered that this is because the coefficient of friction increases due to the damage and the formation of an oxide layer on the contact surface.

In future, in order to understand the tangential force characteristics of the actual wheel/rail interface, we have a plan to conduct tangential force measurement experiments using scale-up specimens under dry and wet conditions in the case of the large slip change rate.

Abstract: To obtain the wear rate function for wheel wear prediction, wear tests with scaled roller test rig are performed and the wear map was generated. The creep force, slip rate and contact area of the tests are calculated for the measured worn profiles using the multibody dynamics simulation under the test conditions and used to obtain the Tγ wear map for the wheel tread, throat and flange contact zones. The flange contact has the highest wear rate than the other two contact areas. The wear simulations with the wear maps obtained will enable accurate predictions of the wheel profile wear.

Keywords: Wheel wear; roller test rig; flange contact; multibody dynamics simulation; Tγ wear map.

1. Introduction

Prediction of wheel wear profile is crucial for estimation of re-profiling cycles as well as the change in the vehicle hunting and curve negotiation performances due to wear. Thus, many studies have been conducted to better understand wheel and rail wear properties. One method that has been widely used for the prediction of wheel and rail wear is the wear rate function expressed in terms of Tγ/A values, given by the creep force T, slip rate γ and contact area A in a contact zone [1, 2].

The wear rate function is usually identified using a two-roller wear test due to the simplicity in measurement, while limited studies have been carried out regarding the wear rate property for severe flange contact, where the Tγ/A value becomes higher than that of the tread contact due to the large creep force acting on a small contact area [3]. Unlike the two-roller wear test, the T, γ and A values are difficult to measure for a wheel due to the complexity in the contact geometry and presence of multi-point contact. Therefore, it is the objective of this study to evaluate the wear rate function of the wheel flange, throat and tread for the wear simulation using a scaled roller test rig and the multibody dynamics simulation.

2. Scaled roller test rig

2.1. Test specimen

A material of the specimens is AAR Class-C wheel steel (0.7%C). The hardness is HV 330. Figure 1 shows a micrograph. This material has a fine pearlite structure. Two wheel specimens and two roller specimens are used in the test. Class-C steel is not only wheel but roller. As illustrated in Figure 2, the wheel specimen is taken from the rim of an actual wheel. The roller specimens are taken from the forged material with oil quenching and tempering. Figures 3 and 4 present the dimensions and cross-sectional shapes of the specimens. The wheel specimens have the same profile as the Wide Flange type wheel in AAR standard with a scale ratio of 1:10. The wheel diameter is either 120 or 105mm and the thickness is 14.5 mm. The roller specimens have the same profile as the 136 RE type rail of AREA standard with a scale ratio of 1:10. The roller diameter is either 200 or 185mm and the thickness is 20 mm.

(a) Wheel

(b) Roller

Figure 4 *Brand new wheel and roller specimen profile*

2.2. Test conditions

In the test, as shown in Figure 5, each wheel specimen is in contact with a roller test specimen. The wheel specimen is driven by the roller specimen through contact. The vertical load is 3.12 kN, while the lateral force of either 1.3kN or 0.65kN is applied to the wheelset. This results in one side in contact with the tread only (hereinafter called inner side) and another side in contact with the throat and/or flange (hereinafter called outer side).

The revolution of the roller specimens is 300 rpm, while no lubricant is applied to the surfaces. Furthermore, an angle of attack is can be set by changing the yaw angle of the roller specimens.

These tests are stopped at rolling distance interval of 3.75×10^4 or 3.75×10^3 m to measure the weight of the specimen and the profile shape. The revolution, displacement, load, and torque are measured with a sampling time of 1 ms. Table 1 lists the test conditions. Table 2 gives the diameter of the wheel and roller specimens used in this test.

By adjusting the difference in the wheel and roller diameters, higher slip conditions were created as in Case 4 and 5, in which larger tangential forces are generated.

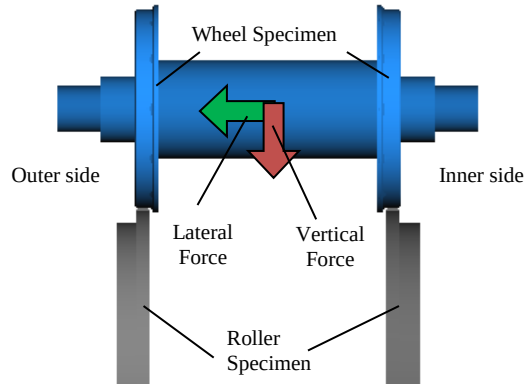

Figure 5 *Illustration of scaled roller test rig*

Table 1 *Test conditions*

	Revolution (rpm)		Vertical Force (kN)	Lateral Force (kN)	Attack Angle (deg)	Lubrication
	Wheel	Roller				
Case1	500	300	3.12	1.3	0	Dry
Case2				0.65		
Case3				0.65	0.5	
Case4				1.3	0	
Case5				1.3		

Table 2 *The diameter of wheel and roller specimens*

	Wheel Diameter [mm]		Roller Diameter [mm]

Case1	120	120	200	200
Case2				
Case3				
Case4		105		185
Case5				

2.3. Test results

Figure 6 presents the material loss of the wheel specimen for different rolling distances in Case1. The material loss of the wheel specimen increased approximately linearly with an increase in the rolling distance. It is clearly observed that the material loss of the outer wheel (i.e., a wheel subjected to flange contact) is larger than that of the inner wheel (i.e., a wheel subjected to tread contact only).

Figure 7 illustrates the measured wheel profiles in Case1. Figure 8 shows the vertical, lateral and longitudinal tangential forces as a function of the rolling distance in Case1. The vertical and lateral forces on the outer side are larger than those on the inner side.

In addition, a tangential force acts in opposing direction on the outer and inner sides due to the slip occurring in the opposing direction on the outer and inner wheels caused by the difference in rolling radii.

Figure 9 shows a comparison of the loss of material per unit traveled distance on the outer side for Cases 1, 2, and 5. From the figure, wear in Case 2 is smaller than that in Case1 due to the smaller lateral force applied in Case2 as shown in Figure 10. Wear in Case 5 is larger than that in Case1 due to the larger tangential force in Case5 as shown in Figure 11.

3. Evaluation of the wheel wear property

3.1. Evaluation method of wear property

To evaluate the wear property, the wear rate is defined by equation (1) [1].

$$K\left(\frac{T\gamma}{A}\right)=\frac{M}{DA} \tag{1}$$

where K is the wear rate; A is the contact area; T is the tangential force; γ is the slip rate; M is the material loss; and D is the rolling distance. In the two-roller test, the contact area A is calculated from the vertical force Fz obtained in the wear test using Hertzian contact theory. The rolling distance D is calculated from the diameter of specimens and rotations. The tangential force T is calculated from the torque applied to the specimen and the radius of the specimen. The slip rate γ is calculated from the revolution of the wheel and roller specimens and the radius of the specimens. The material loss M is calculated from the difference of the masses of the

specimens before and after the tests. However, it is difficult to accurately calculate each variable in flange contact for use of the wear simulation. In particular, the exact rolling radius at the flange cannot be obtained from the measurement. This mean that exact tangential force, slip rate and contact area cannot be obtained at each contact point. Furthermore, profile changes during the tests. Therefore, in this study, the tangential force T, contact area A, and slip rate γ at each contact point are calculated using the multibody dynamics simulation with the measured worn profiles under the same test condition as shown in Figure 12. This approach is used to evaluate the wear rate for the wheel.

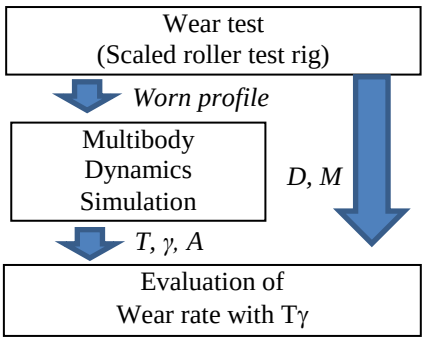

Figure 12 *Flow of evaluation of wear rate with Tγ*

3.2. Multibody dynamics simulation model and conditions

Tγ/A is calculated using the multibody dynamics simulation model with SIMPACK™, considering multi-point contact for the measured worn wheel and rail profiles in Figure 13. Table 3 lists the specifications of the simulation model. The longitudinal and yaw angular displacements of the wheelset model are constrained as in the test setup, while the roller model is allowed to rotate about its spin axis only and its rotational speed is prescribed by the driving constraint. Hertzian contact is assumed for each contact point in the simulation model and FASTSIM algorithm is used to evaluate the tangential creep forces [4]. Employing the measured profiles obtained at each measurement cycle, the wheelset-roller simulation is performed to obtain Tγ/A at each contact point. To evaluate the wear functions of the flange, tread and throat regions of the wheel separately, the wheel profile is divided into three regions based on the contact angle as shown in Figure 14. That is, in this study, any contact with a contact angle greater than 45 degrees is defined as a flange contact, and that less than 3 degrees as tread contact, as shown in Figure14. All other angles are classified as contact in the throat region.

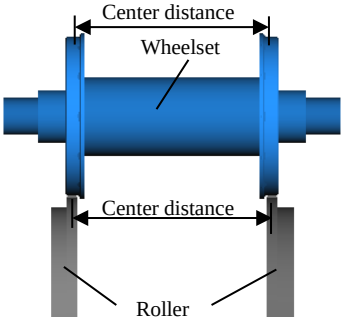

Figure 13 *Overview of simulation model*

Table 3 *Specification of simulation model*

Item			Value
Wheelset	Mass [kg/axle]		7.162
	Inertia moment [kg m^2]	Rolling	3.19×10^{-2}
		Pitching	6.62×10^{-3}
		Yawing	3.19×10^{-2}
	Center distance [m]		1.48
	Diameter [mm]		120 or 105
Roller	Mass [kg/specimen]		4.135
	Inertia moment [kg m^2]	Rolling	9.00×10^{-3}
		Pitching	1.78×10^{-2}
		Yawing	9.00×10^{-3}
	Center distance [m]		1.50
	Diameter [mm]		200 or 185

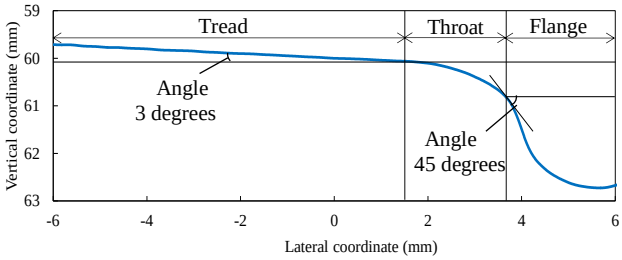

Figure 14 *Contact area of wheel profile*

3.3. Result of Simulation and wear property evaluation

Figure 15 shows the comparison of the tangential forces obtained from the simulation and the wear tests. From the figure, the tangential forces differ immediately after the start of the test (hereinafter called the initial state), but the tangential forces become steady afterwards. Such unsteady contact behavior in the initial state is not considered in the simulation.

Figure 16 shows the averaged values of the semi major and minor axis ratio a/b of the Hertzian contact areas in the tread, throat and flange regions, where a is the semi-axis in the longitudinal direction, while b is that in the lateral direction. These results were obtained for all the test conditions with measured worn profiles using the simulation. The tread contact area has the smallest a/b ratio, while the flange contact area has the largest a/b ratio, as expected. This result shows that the flange contact has sharper contact ellipse along the wheel rotation direction.

Using the loss of material due to wear measured by the test and the T, γ, A values obtained from the multibody dynamics simulation for each measurement interval, the loss of material per unit traveled distance and unit contact area ($\mu g/m/mm^2$) is plotted as a function of Tγ/A (N/mm^2) in Figure 17. Using the total material loss for a wheel, the material loss at each contact point is evaluated with the ratio of Tγ value at each contact point. Since the flange has larger material loss within small contact area, the wear rate defined by equation (1) results in considerably smaller than that of the tread and throat, and the wear functions of the flange and tread/throat are separated.

The wear rate function obtained by the two-roller wear test using the same materials [3] is also presented in this figure. It is observed that the flange and throat wear rates

are higher than that of the two-roller test results, while that of the tread is similar to the two-roller wear rate.

Next, to clarify the difference in wear property between the flange, throat and tread areas at the same Tγ/A, T/A and γ are compared at evaluation points a1 to a3 and b1 to b3 shown in Figure 17.

Figure 18 shows results of the comparison points a1 to a3, and Figure 19 shows results of the comparison points b1 to b3. From these figures, the flange and throat contact have larger T/A than the tread contact for the similar Tγ/A value, while the tread contact has larger γ than the flange and throat contact to have the similar Tγ/A value. This indicates that T/A value has a strong correlation to the wear volume rather than γ. Furthermore, smaller contact area in flange contact causes higher wear rate defined by equation (1).

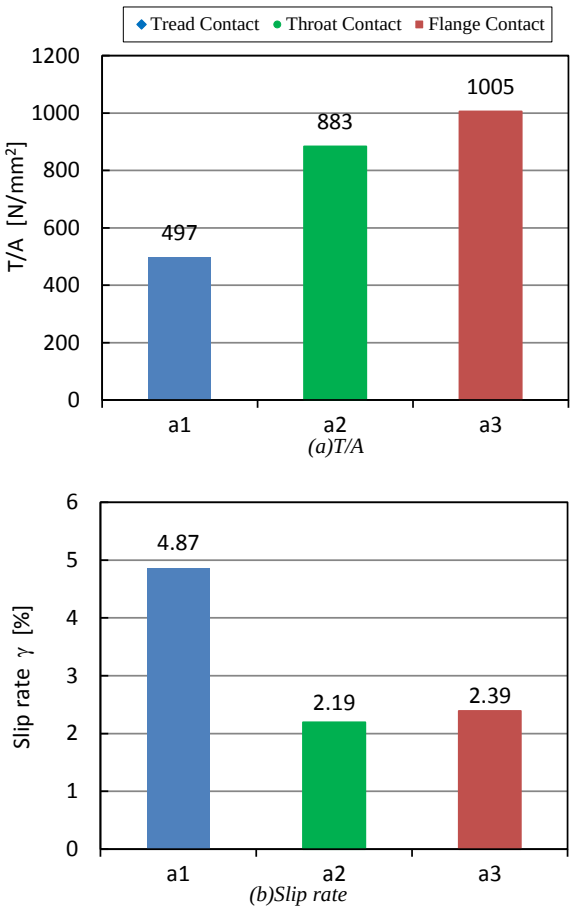

Figure 18 *T/A and slip rate of evaluation points (a1, a2, a3)*

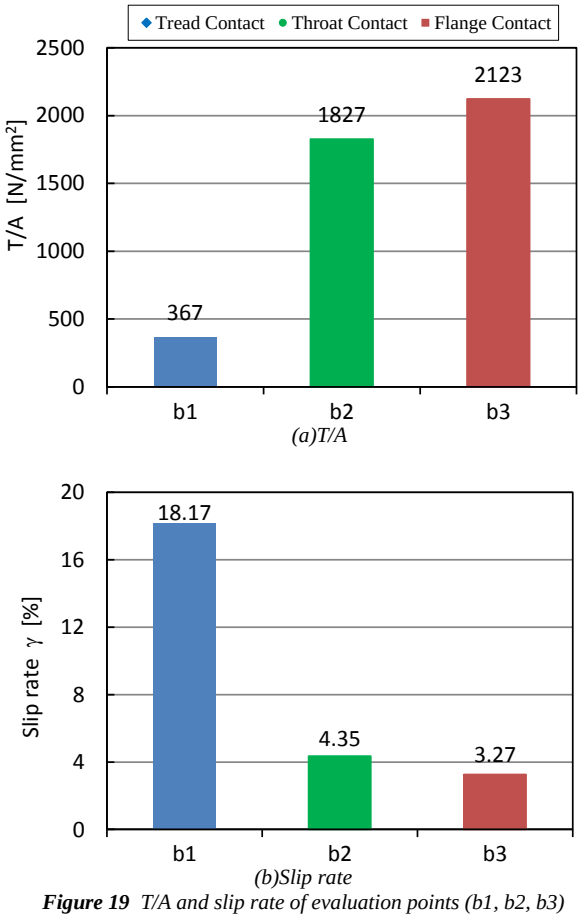

Figure 19 *T/A and slip rate of evaluation points (b1, b2, b3)*

4. Conclusion

In this study, the wear functions for the Tγ wear map are evaluated using the wheelset wear tests and multibody dynamics simulations. The wear test results show that the outer wheel specimens with flange contact have larger wear volume than the inner wheel specimens with tread contact. The wear functions for the flange, throat and tread area are obtained as different functions. The flange area has the highest wear rate and the tread area has the lowest under the loading condition considered in this study. The flange and throat area have larger T/A than the tread area at the same Tγ/A value, while the tread has larger γ than the other areas. This indicates that T/A has strong correlation to the wear volume, rather than γ. Furthermore, smallest contact area in flange contact causes higher wear rate defined by equation (1).

Abstract: In this paper, considering the vibration frequency of wheel/rail force and moment of rail inertia, the formula of rail bending wave velocity is derived firstly. Then two specific tests is designed to verify the influence of Doppler Effect to the dynamic test results in high speed railway lines of China. One dynamic test is designed by polygon wheel, and the other test is designed by rail corrugation. Last the conclusion of the Doppler Effect influence the dynamic test results could be made.

Keywords: Doppler Effect, wheel/rail dynamic test, rail bending wave, wheel/rail force, polygon wheel, rail corrugation, high speed railway

1. Introduction

Nowadays, high speed trains represent a real technology challenge to cover long distances in the less time possible. Transport security and quality require a proper and effective dynamic test to avoid related risks and to prevent incidents and accidents [1]. Dynamic tests generally include the foundation parameters of wheel/rail interface force, rail acceleration, rail seat force, sleeper acceleration etc., and the safety parameters of the derailment coefficient and rate of wheel load reduction could be obtained by the foundation parameters [2]. So the dynamic test play an important role in railway transport, especially in high speed railways.

The Doppler Effect is described by Christian Doppler in 1842. The Doppler Effect is the change in frequency or wavelength of a wave for an observer who is moving relative to the wave source. In classical physics, where the speed of source and the receiver relative to the medium are lower than the velocity of waves in the medium, the relationship between observed frequency f and emitted frequency f_0 is given by [3,4]:

$$f = \left(\frac{c + v_r}{c + v_s} \right) \cdot f_0 \qquad (1)$$

Where
c is the velocity of waves in the medium;
v_r is the velocity of the receiver relative to the medium; positive if the receiver is moving towards the source, and negative in the other direction;
v_s is the velocity of the source relative to the medium; positive if the source is moving away from the receiver, and negative in the other direction.

Based on the definition of the Doppler Effect, the velocity of the receiver and source relative to the medium is larger, the frequency change is more evident. The high speed train operation speed is 300km/h to 350km/h in China [5], and the sensors in dynamic test is fixed on the rail or wayside. That is to say, the receiver is stock-still relative to the rail and the source (train) is moving towards the sensors and then away from it with 300km/h to 350km/h. and the train operation speed relative to the velocity of waves in the medium (rail bending wave) cannot be ignored. So the Doppler Effect in dynamic test of high speed railway should be considered.

Doppler Effect in high speed railway is one of the most important phenomenon. Some investigators had research that in railway field. B. Barsikow and W.F. King III [6] described a technique that could avoid this Doppler effect of motion in railway noise measurement. The advantages of being able to measure narrowband spectra in the rest frame of a moving source are obvious, and they also describe array measurements of sound generated by a loudspeaker mounted beneath the middle of a coach on a test train. J. Brizuela et al. [7] presented a new inspection system for railway wheels using the Doppler Effect. The proposed system analyses the rail-wheel contact by frequency and phase shifts. Cracks on the wheel tread are determined while the train moves at a low speed. A special rail is used to propagate monochromatic surface waves. When a wheel on the measuring rail moves at constant speed, the received signal will present a regular frequency shift related with the movement speed. J. Dybala and S. Radkowski [8] presented a method for removal of signal's frequential structure disturbances related with relative move of vehicles and stationary monitoring station. For elimination of the frequential non-stationary of signals disturbance-oriented dynamic signal resampling method was used. They provided a test of two methods for defining the time course of local disturbance of signal's frequential structure: the method based on the Hilbert transform and the method of analytical description of signal's disturbance based on

the knowledge of a phenomenon that causes frequential non-stationarity of signals.

As was mentioned before, most of the Doppler Effect researches were focus on the acoustics and signal processing field. But there is a little research work on the effect of Doppler on railway vibration. So in this paper, considering the vibration frequency of wheel/rail force and moment of rail inertia, the formula of rail bending wave velocity is derived firstly. According to the formula of rail bending wave velocity and a given emitted frequency, the observed frequencies are obtained. Then two specific tests is designed to verify the influence of Doppler Effect to the dynamic test results in high speed railway lines of China. Last the conclusion of the Doppler Effect influence the dynamic test results could be made.

2. Rail bending wave velocity

There are two important waves in noise and vibration field, one is the longitudinal wave and the other is the bending waves. When the wavelength of bending is much larger than the section size of object, the bending wave exists in the vibration waves [9]. So the bending wave exists in the rail vibration waves.

In order to derivate the rail bending wave formula, the rail is simplified into the Euler beam [10]. The vibration mechanics of rail element are shown in Figure 1. Based on the Newton's second law, there is

$$\rho_L dx \frac{\partial^2 u}{\partial x^2} = -\left\{V + \frac{\partial V}{\partial x} dx\right\} + V \tag{2}$$

$$-M + Vdx + \left\{M + \frac{\partial M}{\partial x} dx\right\} = 0 \tag{3}$$

So

$$\frac{\partial M}{\partial x} = -V \tag{4}$$

where V is shear force, M is bending moment, and ρ_L is mass per unit length.

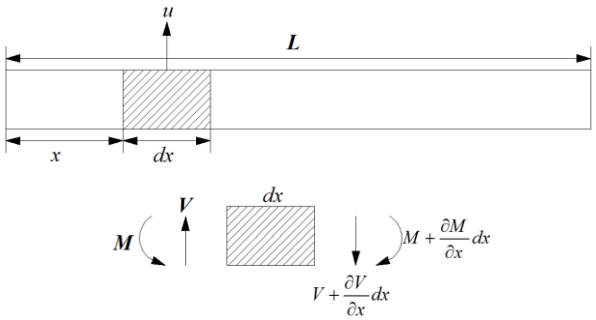

Figure 1 *Schematic diagram of rail element vibration mechanics*

Based on the Euler-Bernoulli beam theory, in symmetric plane, the curvature of bending beam and moment have the relationship as following:

$$EI \frac{\partial^2 u}{\partial x^2} = -M \tag{5}$$

Timoshenko had proved that the sign of $\partial^2 u / \partial x^2$ is always opposite to the sign of M [11]. That is to say, when the sign of $\partial^2 u / \partial x^2$ is positive, the sign of M is negative. When the sign of $\partial^2 u / \partial x^2$ is negative, the sign of M is positive.

So, there is

$$\rho_L \frac{\partial^2 u}{\partial x^2} = -\frac{\partial^2 \left\{ EI \frac{\partial^2 u}{\partial x^2} \right\}}{\partial x^2} \tag{6}$$

and

$$\frac{\partial^2 u}{\partial t^2} a + \frac{\partial^4 u}{\partial t^4} = 0 \qquad a^2 = \frac{EI}{\rho_L} \tag{7}$$

The bending wave numbers k_B could be obtained by solving the equation (7), and the velocity of bending wave c_B could be acquired from the bending wave numbers k_B, as the following:

$$c_B = \frac{\omega}{k_B} = \omega^{1/2} \{EI / \rho_L\}^{1/4} = \{1.8 c_L \cdot t \cdot f\}^{1/2} \tag{8}$$

Where

ω is angular frequency;
E is modulus of elasticity;
I is moment of inertia;
ρ_L is mass per unit length;
c_L is velocity of longitudinal wave;
t is the dimension of perpendicular to the direction of wave propagation;
f is the frequency.

According to the formula (8), the velocity of bending wave and frequencies are closely related. The longitudinal wave velocity of rail steel is about 5200m/s (c_L); and the height of 60kg/m rail is 176mm in China (t). So based on the parameters, the velocity of rail bending wave c_B is

$$c_B = \sqrt{1647.36 \cdot f} \tag{9}$$

3. Investigation of test train and track

In order to check the rail bending wave velocity formula and verify the Doppler Effect in railway vibration test, two specific dynamic tests are designed and carried out. One specific dynamic test is the high speed train with polygon wheels and there is no obvious rail corrugation in rail surface. The other specific dynamic test is the rail corrugation is existed and there is no obvious out-of-round in wheel surface.

Firstly, the wheel and rail surface are investigated using Miniprof to confirm the order of out-of-round of wheel and using CAT to confirm the roughness of rail surface.

3.1. Investigation results of test train

The test train includes 8 cars, 16 bogies, 32 wheelsets. Investigation measurements of out-of-round of wheels are carried out using the Miniprof in depot, shown in Figure 2.

Figure 2 *Investigation measurements of out-of-round of wheels*

The amplitude of out-of-round of wheel for 1st car to 7th car is very small and irregular along the circumferential direction. The maximum amplitude is only 0.05mm, the measurement results of 7-1R wheel is shown in Figure 3.

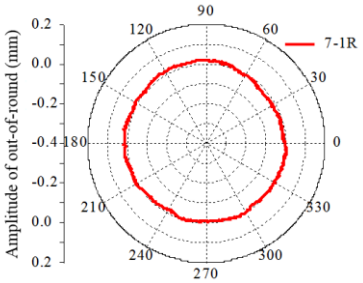

Figure 3 *Measurement results of 7-1R wheel*

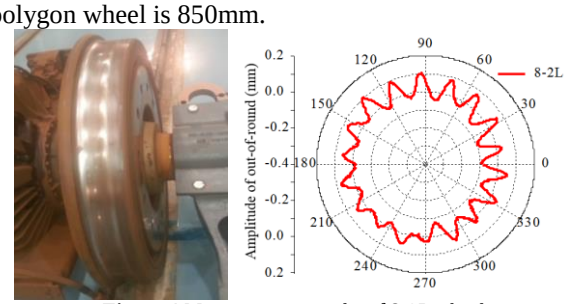
The amplitude of out-of-round of wheel for 8th car is very large and have the feature of 18th order polygon. The maximum amplitude is 0.15mm, the measurement results of 8-2L wheel is shown in Figure 4. The diameter of polygon wheel is 850mm.



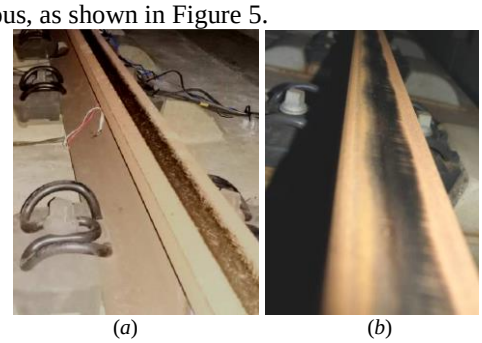


Figure 4 *Measurement results of 8-2L wheel*

3.2. Investigation results of test track

The test track is ballastless track with vossloh 300-1 fastening system. Two sections of track are chosen as the test track, one is that no obvious rail corrugation in rail surface and the rail corrugation of the other section is obvious, as shown in Figure 5.

(*a*) (*b*)

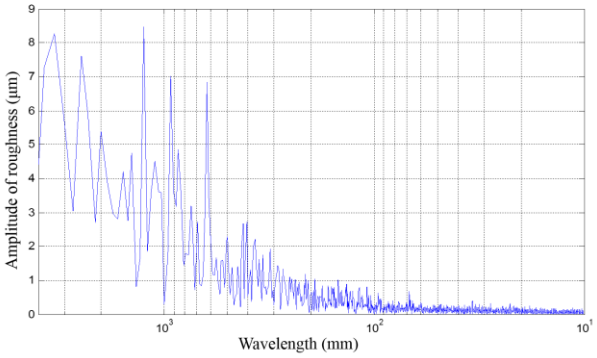

Figure 5 *Roughness of rail surface (a) no rail corrugation (b) rail corrugation*

The investigation measurements for these two track sections are carried out using CAT equipment shown in Figure 6.

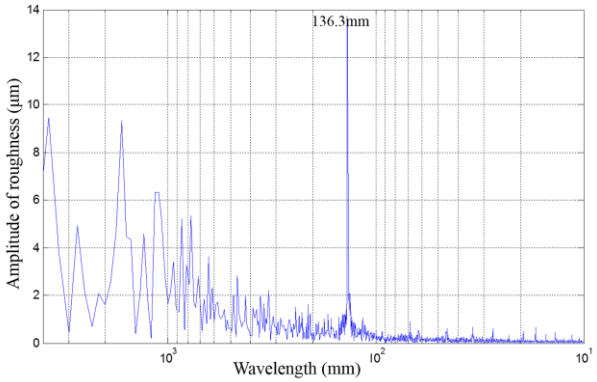

Figure 6 *Investigation measurements of rail surface*

Figure 7 shows the measurement results of rail roughness of two track sections. The rail corrugation wavelength is 136.3mm in the rail corrugation section, and there is no obvious rail corrugation feature in the other section.

(*a*)

(*b*)

Figure 7 *Measurement results of rail surface (a) no obvious rail corrugation, (b) rail corrugation section*

3.3. Test conditions

Based on the investigation results of test train and track, there are two combinations for test condition, shown in Table 1.

Table 1 *Test conditions*

Condition No.	Train	Track
I	18 order polygon wheel	No corrugation
II	No polygon wheel	Rail corrugation

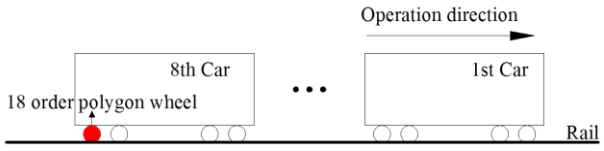
Test condition I is that the train with 18 order polygon wheel and no corrugation in rail surface; the test condition II is that there is rail corrugation in rail surface and no polygon wheel in test train.

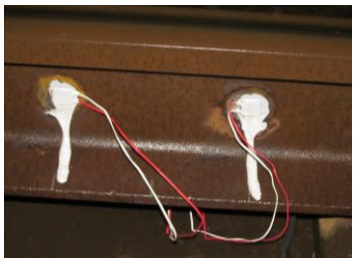
The purpose of test condition I is to verify the Doppler Effect of wheel/rail vibration by polygon wheels, and the

purpose of test condition II is to verify the Doppler Effect of wheel/rail vibration by rail corrugation.

4. Polygon wheel dynamic test to verify the Doppler Effect

The polygon wheel dynamic test is the test condition I, it is that the 8th car of train with 18 order polygon and the rail surface is well, shown as Figure 8.





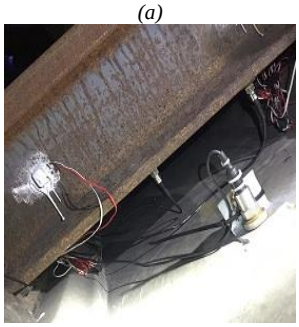


Figure 8 *Test condition I*

4.1 Dynamic test

The dynamic tests include wheel/rail force and rail acceleration. Wheel/rail force was measured by shear method using strain gauge, and rail acceleration was measured by accelerometer with 1000g range. The wheel/rail force sensors were installed mid-span of rail, and the accelerometer was installed the rail seat, shown as in Figure 9. The speed of test train is 300km/h passed by the sensors.

(a)

(b)

Figure 9 *Installation of sensors (a) wheel/rail force sensor, (b) rail accelerometer*

4.2 Test results

The wheel/rail force of the test train with speed of 300km/h is shown in Figure 10.

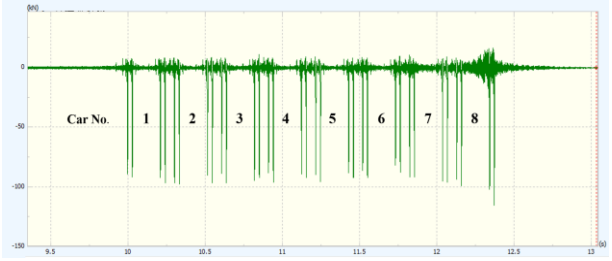

Figure 10 *Wheel/rail force of test train with 300km/h*

It could be known from the time domain diagram, Figure 10, that the wheel/rail vertical force of 1st car to 7th car is not very different. The maximum wheel/rail force is 98kN of 1 to 7 cars. And the maximum wheel/rail vertical force of 8th car is 115kN, nearly increases 20%. Except for the polygonal wheels of the 8th car, the other test conditions are the same, so the increase of the vertical force of 8th car is caused by the polygon of wheel.

Figure 11 is shown the rail acceleration of the test train with speed of 300km/h. It also could be known from the time domain diagram, Figure 11, that the rail acceleration of 1st car to 7th car is not very different. The maximum rail acceleration is 1151m/s^2 of 1 to 7 cars. And the maximum rail acceleration of 8th car is 1709 m/s^2, nearly increases 50%. It also illustrated the increase of the rail acceleration of 8th car is caused by the polygon of wheel.

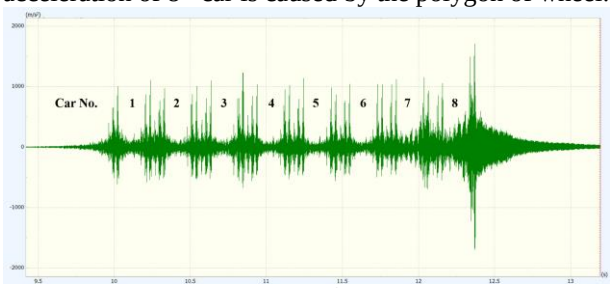

Figure 11 *Rail acceleration of test train with 300km/h*

The wheel/rail vertical force of 1st and 8th car is analyzed via fast Fourier transform, shown as Figure 12. There are two obvious frequencies in 8th car, one is 517Hz, and the other is 613Hz. Because the only different of 1st and 8th car is the polygon wheel, so the two exciting frequencies of 517Hz and 613Hz is caused by the polygon wheel.

Figure 12 *FFT of wheel/rail force of 1st and 8th car*

When the test train passes through the sensors with the speed of 300km/h, the excitation frequency of 18 order polygon wheel with a diameter of 850mm is 562 Hz, calculated by

$$f = \frac{n \cdot v}{\pi \cdot D} = \frac{18 \times 300}{3.6 \times 3.14 \times 0.85} = 562Hz$$

But there is no 562Hz in test results, instead of 517 Hz and 613 Hz. So the Doppler Effect should be considered. When the excitation frequency is 562Hz, the velocity of rail bending wave c_B is calculated by formula (9), as following:

$$c_B = \sqrt{1647.36 \cdot f} = \sqrt{1647.36 \times 562} = 962m/s$$

The velocity of rail bending wave is 962m/s, and the train speed is 300km/h (≈83.3m/s). So based on the formula (1), two frequencies could be obtained:

$$f_1 = \left(\frac{c_B}{c_B + v_s}\right) \cdot f_0 = \frac{962}{962 + 83.3} \times 562 = 517Hz$$

$$f_2 = \left(\frac{c_B}{c_B - v_s}\right) \cdot f_0 = \frac{962}{962 - 83.3} \times 562 = 615Hz$$

Based on the theoretical and experimental results, it could be concluded that it is consistency of results between the theoretical and experimental. And the Doppler Effect and the formula of rail bending wave are further verified.

5. Rail corrugation dynamic test to verify the Doppler Effect

The rail corrugation dynamic test is the test condition II, it is that the rail surface with 136.3mm wavelength of rail corrugation and the wheel of test train is well, shown as Figure 13.

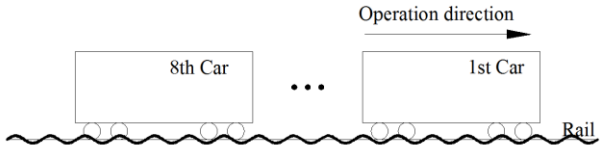

Figure 13 *Test condition I*

5.1 Dynamic test

The dynamic tests include wheel/rail force and rail acceleration. The sensors and installed positions are same as the test of polygon wheel dynamics, shown as in Figure 9. The speed of test train is 246km/h passed by the sensors.

5.2 Test results

The rail acceleration of the test train with speed of 246km/h is shown in Figure 14. A zone is the time of before the train put into the sensor position; B zone is the time the train put into the sensor position; and C zone is the time after the train pulled out of the sensor position.

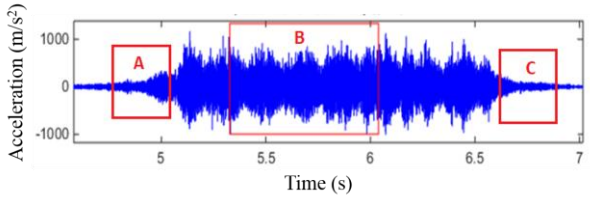

Figure 14 *Rail acceleration of test train with 246km/h*

The time domain diagram of A zone and its power spectral density is shown in Figure 15.

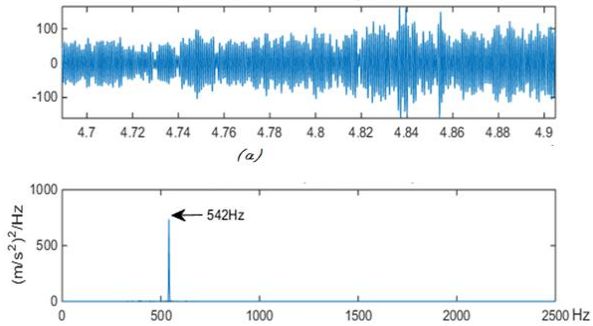

Figure 15 *Time domain of A zone and its power spectral density*

It could be known from the time domain diagram, Figure 15, which before the test train put into the sensor position, there is only one exciting frequency of 542Hz.

The time domain diagram of B zone and its power spectral density is shown in Figure 16. It shown that when the test train put into the sensor position, there are two exciting frequencies of 467Hz and 542Hz.

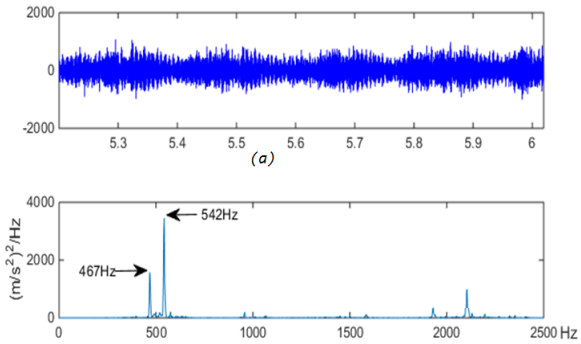

Figure 16 *Time domain of B zone and its power spectral density*

The time domain diagram of C zone and its power spectral density is shown in Figure 17. It shown that after the test train put out of the sensor position, there is also only one exciting frequencies of 467Hz.

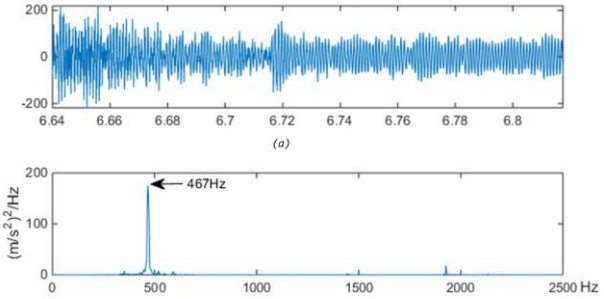

Figure 17 *Time domain of C zone and its power spectral density*

In the processing of the train passing by the test sensors, the three types of frequency are generated, as 542Hz; 467Hz and 542Hz; 467Hz. When the test train passes through the sensors with the speed of 246km/h, the excitation frequency of rail corrugation with wavelength of 136.3mm is 501 Hz, calculated by

$$f = \frac{v}{\lambda} = \frac{246}{3.6 \times 136.3} = 501Hz$$

But there is no 501Hz in test results, instead of 467 Hz and 542 Hz. So the Doppler Effect should be considered. When the excitation frequency is 501Hz, the velocity of rail bending wave c_B is calculated by formula (9), as following:

$$c_B = \sqrt{1647.36 \cdot f} = \sqrt{1647.36 \times 501} = 908m/s$$

The velocity of rail bending wave is 908m/s, and the train speed is 246km/h (≈68.3m/s). So based on the formula (1), two frequencies could be obtained:

$$f_1 = \left(\frac{c_B}{c_B + v_s}\right) \cdot f_0 = \frac{908}{908 + 68.3} \times 501 = 466Hz$$

$$f_2 = \left(\frac{c_B}{c_B - v_s}\right) \cdot f_0 = \frac{908}{908 - 68.3} \times 501 = 542Hz$$

Based on the theoretical and experimental results, it could be concluded that it is consistency of results between the theoretical and experimental. And the

Doppler Effect and the formula of rail bending wave are further verified.

6. Conclusions

In the present work, the formula of velocity of rail bending wave is derived firstly. Then two specific dynamic test is carried out to check the formula and verify the influence of Doppler Effect on the wheel/rail dynamic test. One dynamic test is designed by polygon wheel and the other test is designed by rail corrugation. The following conclusions can be drawn on the basis of the experimental and theoretical studies.

1. The velocity of rail bending wave c_B could be obtained by the formula as following:

$$c_B = \frac{\omega}{k_B} = \omega^{1/2}\{EI/\rho_L\}^{1/4} = \{1.8c_L \cdot t \cdot f\}^{1/2}$$

2. The polygon wheel dynamic test results are illustrated that the formula of rail bending wave is right, and the Doppler Effect could influence on the dynamic test results.

3. The rail corrugation dynamic test results are also illustrated that the formula of rail bending wave is well, and further verify the Doppler Effect could influence on the dynamic test results.

Wear problems of wheel/rail systems occurred on the Chinese high-speed railway network in the last decade are summarized and explained together with the corresponding experience of treating them. Focus is placed on uneven wear because absolute wear is not an urgent issue due to its very low wear rate for the Chinese high-speed railway systems. Two typical problems of longitudinal uneven wear, namely wheel polygon and rail corrugation, are introduced from aspects of characteristics, consequences, causes and initiation mechanisms. Afterwards, wheel hollow wear and flange/gauge side wear, as typical problems of lateral uneven wear, are discussed from the same aspects. Validated counter measures against all these problems are presented at the end together with further proposals under testing or consideration. The present work is mainly based on first-hand data collected from field observations, monitoring tests and dynamic measurements conducted in field.

Abstract: Dynamic equivalent conicity is defined as the equivalent conicity curve which changes with gauge and is also influenced by wheel and rail profiles. A fast algorithm is presented to calculate dynamic equivalent conicity in this paper, by combining wheel/rail profiles preprocessing and grading method, quasi-elastic modification and spline interpolation. The calculation procedures are introduced in this paper. A quasi-elastic method is used to modify the rigid contact calculation result. A wheel/rail maintenance strategy is proposed to provide technical support for wheel/rail system coupling maintenance on basis of dynamic equivalent conicity calculation result.

Keywords: Dynamic equivalent conicity, quasi-elastic modification, spline interpolation, rolling radius difference, vehicle hunting.

1. Introduction

The mileage of high-speed railways in China accounts for two-thirds of the world's total, and there are a large number of EMU train in operation with long operating hours. Hunting problem occurs at varying degrees of instability with some of them, including primary hunting which is reflected in low frequency vibration of the vehicle, and secondary hunting, namely bogie instability problem. A series of problems related to vehicles and rails caused by lateral instability increase the risk of derailment of vehicles and reduce the ride comfort, on the other hand, the cost of wheel and rail maintenance is increased and the overall economic benefit of the railway system is reduced.

Wheel/rail contact geometry has a great influence on vehicle stability, and it directly affects the vibration performance and critical speed of EMU trains [1-11]. Even small differences in wheel/rail profile and wheel/rail contact geometry could leads to dramatic changes in vehicle stability. Among so many parameters that characterize the relationship between wheel/rail contact geometry and vehicle dynamic response, equivalent conicity is widely used to characterize wheel/rail contact state in railway community due to its briefness, effectiveness and practicability. Low equivalent conicity could leads to the car-body hunting problem [2] and high conicity could leads to excessive bogie lateral acceleration [6,10], see Fig. 1.

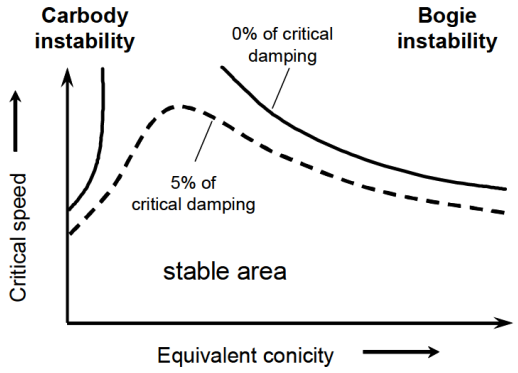

Figure 1 *Example of typical stability map*

In the actual application, wheel/rail contact geometry not only varies with the rail profile, but also related to the track irregularity, rail inclination, the vertical and lateral track layout error, and the elasticity of track basis. The literature [1,2,6,11] used equivalent conicity to analyze the influence of the wheel/rail contact geometry on the vehicle stability. But they only used standard gauge, influence of other gauge values on the equivalent conicity calculation is not considered. Luo Shihui's analysis shows that the gauge has a great influence on free wheelset and bogie hunting frequency [14]. Therefore, the equivalent conicity should be calculate with a continuously varying gauge in a certain range, an equivalent conicity curve changes with gauge which is called dynamic equivalent conicity should be obtained when characterizing the influence of wheel/rail contact on vehicle dynamic stability. The literature [15,16] has established the technical thresholds of dynamic equivalent conicity for different types of vehicles and different speeds.

Traversal algorithm is usually used to calculate dynamic equivalent conicity, that is, one equivalent conicity value is obtained with measured wheel/rail profile and gauge at each measurement. However, it takes a lot of computing time. Taking high speed railway line A for example, the line has a total length of 1319km, with a gauge acquisition frequency of 4 measurements/m and 5276000 measurements in total. 5 days could be cost if traversal algorithm is applied to calculate dynamic equivalent conicity, which is unacceptable.

Aiming at the bottleneck of computing time encountered by the traditional dynamic equivalent conicity calculation method, combined with wheel/rail profile preprocessing, quasi-elasticity modification and spline interpolation method, a new method for fast calculation of dynamic

equivalent conicity is studied and verified by measured data. A wheel/rail profile maintenance strategy on basis of dynamic equivalent conicity is proposed.

2. Data acquisition and preprocessing

Dynamic equivalent conicity could be affected by wheel profiles, rail profiles, gauge and other factors. Wheel profiles are measured by Miniprof, and rail profiles are obtained from continuous rail profile measurement system by combining laser triangulation measurement and image processing technique, and the entire profile is measured from rail bottom to top [17]. The gauge data is measured by the track geometry inspection system and associated with rail profiles by mileage.

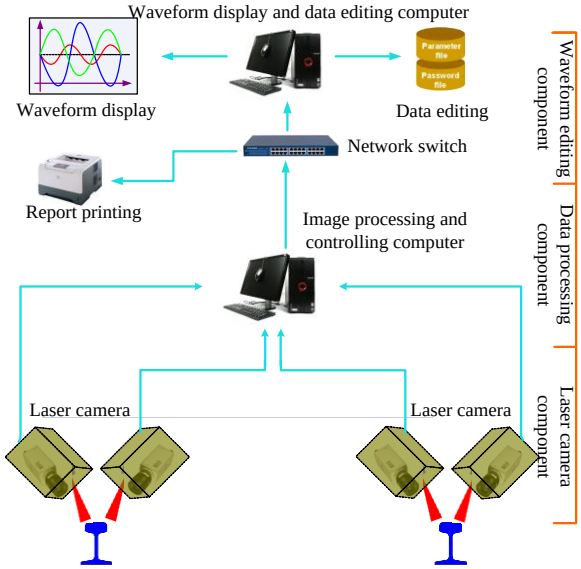

Figure 2 *Rail profile measurement system*

Rail profile measurement system includes three modules: Image acquisition, Image processing and Result display, see Fig. 2. The Image acquisition module obtains geometric shape of the measured object through position conversion between the global coordinate system, the camera coordinate system, and the image coordinate system. The Image processing module extracts the target curve of the rail profile by smoothing, segmenting, and thinning the rail profile image obtained by the image acquisition module. In order to avoid the interference of external light, a narrow-band filter device is used to obtain the optical section curve of the rail in a relatively simple environment, so that the optical section curve of the rail can be highlighted in the background of the image. In an ideal state, a single curve with one coordinate corresponding to one pixel can truly represent the shape of the rail. However, in actual situations, there exists a gray variation area of the optical section curve and the background, and due to the CMOS trailing effect and environmental noise, the obtained optical section curve is a gray belt. Therefore, in the target curve extraction process, the noise in the image is preprocessed firstly, and then the optical section curve is separated from the background, and it is processed into a rail profile curve with one pixel at each point finally.

Due to the inaccuracy of measurement tools and measurement methods, there are measurement errors in the measured wheel and rail profile data, which could affect the equivalent conicity calculation result. In order to eliminate the influence of non-smoothness on the calculation result of equivalent conicity, we propose a method for smoothing wheel/rail profile by combining the normal spacing calculation, Fast Fourier Transform(FFT), Inverse Fast Fourier Transform(IFFT) and boundary extension method. The method generally includes three steps:

1) Convert measured profile and standard profile to the same coordinate system. Use interpolation method to align the data points of the two curves. Then, subtract the two curves from the normal direction to obtain the normal distance curve.
2) Use Fast Fourier Transform (FFT), Inverse Fast Fourier Transform (IFFT) and boundary extension methods to filter and reconstruct the normal distance curve which is obtained in the previous step. Then, the smoothing of the curve is realized.
3) Superimpose the filtered data and the standard profile to reconstruct measured profile.

The method is used to process measured profile, and the result is shown in Fig. 3. After local amplification, we find that the reconstructed measured profile no longer contains “spikes”, so the smooth effect is ideal.

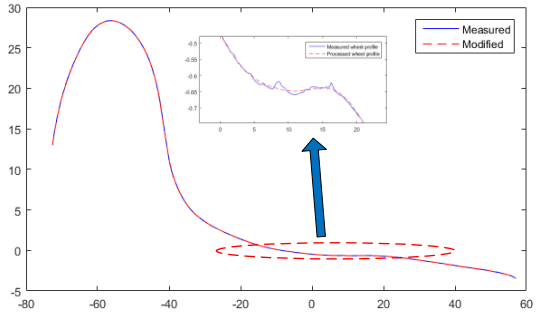

Figure 3 *Rail profile measurement system*

3. Equivalent conicity calculation and quasi-elastic modification

Wheel/rail contact geometry has a great influence on railway vehicle dynamic behavior. Equivalent conicity is an important parameter to characterize contact geometry. Harmonic linearization, equivalent linearization, and linear regression methods are usually used to calculate equivalent conicity. It is assumed that the left and right wheel/rail profiles are symmetrical, and the radii of the two wheels are exactly the same. Under these assumptions, the contact geometry function is symmetrical. The movement of wheelset could be periodic or random.

Quasi-linear contact model is proposed on basis of Klingel formula which calculates equivalent conicity by the wavelength of wheelset movement [18]:

$$\lambda = (\frac{2\pi}{L})^2 e_0 r_0 \qquad (1)$$

where L is the wavelength of wheelset movement, e_0 is the half distance between the centerline of the left and right wheels, r_0 is the wheel nominal rolling circle radius.

Assume that the rotational moment and lateral force at the wheel/rail contact patch can be ignored, then the Equation (2) of motion of a free massless wheelset with velocity v rolling in the x direction on a flat, perfectly rigid track could be derived. Assume that the wheelset's yaw angle ψ around the vertical axis is very small and the longitudinal and lateral wheel/rail creepage is zero, the wheelset's free-motion Equation (3) in the horizontal plane can be obtained:

$$\frac{e_0}{v}\frac{d\psi}{dt}+\frac{\Delta r(y)}{2r_0}=0 \tag{2}$$

$$\frac{1}{v}\frac{dy}{dt}-\psi=0 \tag{3}$$

where $\Delta r=r_1-r_2$ is the rolling radius difference of r_1 and r_2, t is time variable. After eliminating the time variable, the above equations can be rewritten as:

$$\psi\frac{d\psi}{dy}+\frac{\Delta r(y)}{2e_0r_0}=0 \tag{4}$$

$$dx=\frac{dy}{\psi} \tag{5}$$

By numerically integrating Equation (4), we can obtain the yaw angle ψ of the wheelset gravity center start from $y_{\min}$ ($\psi_{\min}=0$). Finally, the wavelength of wheelset movement L can be obtained by integrating Equation (6) from $y(0)=y_{\min}, y'(0)=0$ $(\psi=0)$. Then, equivalent conicity λ could be calculated through Equation (1).

$$\frac{d^2y}{dx^2}+\frac{\Delta r(y)}{2e_0r_0}=0 \tag{6}$$

In the actual operation, the shape of worn wheel profile varies according to different operation condition. Equivalent conicity calculation method described from Equation (2) to Equation (6) is a rigid contact algorithm, although the calculation is fast, it is sensitive to the changes of wheel profile, and the influence of contact deformation cannot be considered. The rolling radius difference curve is discontinuous, and the calculation error is large at those discontinuous points. The elastic contact model is able to take contact deformation into account and the calculation result is more accurate, but much more time it costs than rigid contact model. The quasi-elastic model is able to take deformation into account and produce a more accurate result in less calculation time.

The main idea of quasi-elastic contact is to calculate the minimum distance between wheel profile and rail profile at the contact area and calculate the deformation weight based on the minimum distance using the exponential weighting method. The contact point can be modified by combining the lateral distance information between the contact point and the point near it. The modified contact point is called the quasi-elastic contact point.

According to the principles of elastic mechanics and logarithmic strain, the deformation of the wheel and rail at the contact point is the largest, and the deformation is smaller when the distance is larger. Assume an exponential relationship between the contact surface distance and the deformation, the weight function can be expressed as:

$$\omega(s,q,p)=\exp(-\frac{d(s,q,p)}{\varepsilon}) \tag{7}$$

where $d(s,q,p)=q_z-p_z$ represents the vertical distance between point q of wheel profile and point p of rail profile. ε is the logarithmic strain. For wheel/rail contact problem, the range of ε is usually between $1.0\times10^{-5}\sim5.0\times10^{-5}$.

The modified lateral distance $\overline{s}$ is calculated with lateral distance s and weight coefficient $\omega(s,q,p)$ which is calculated according to Equation (7), see Equation (8).

$$\overline{s}=\frac{\int_{s_{\min}}^{s_{\max}}s\omega(s,q,p)ds}{\int_{s_{\min}}^{s_{\max}}\omega(s,q,p)ds} \tag{8}$$

The rolling radius difference curve is modified using quasi-elastic model, see Fig. 4, where the red line is the rigid calculation result and the blue line is the quasi-elastic calculation result. The Fig. 4 shows that the quasi-elastic calculation result is smoother, that is, the wheel/rail contact points changes more even along with the lateral distance.

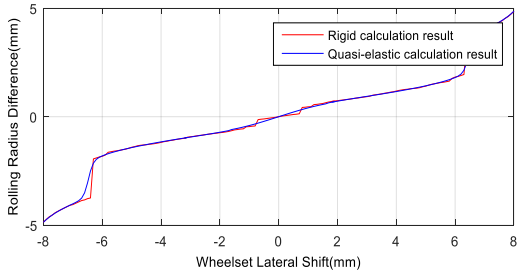

Figure 4 *Comparison of rigid and quasi-elastic contact calculation results*

4. Fast algorithm for dynamic equivalent conicity calculation

We find that worn wheel/rail profiles can be graded into several types. The same combination of wheel/rail type and gauge will result in the same equivalent conicity. From this point of view, we could see that there are a large number of duplicate calculations of the same combination of wheel/rail profile and gauge when using traversal algorithm.

Measured wheel/rail profiles are graded into several types, and each type of wheel/rail profile and gauge are combined and calculated to obtain the equivalent conicity curve which changes with gauge. These curves form a database with three-dimensional information for wheel/rail profiles and gauges that are required for dynamic equivalent conicity calculations. The database doesn't need to be recalculated, just need to be improved continuously.

When calculating dynamic equivalent conicity, we need to select the equivalent conicity curve which changes with gauge from the database according to the wheel/rail

profile type and measured gauge at the measurement point. Invokes the data of the selected curve from the database and uses the interpolation method to obtain the equivalent conicity at this measurement point. After traversing each measurement point, the dynamic equivalent conicity curve is obtained.

The dynamic equivalent conicity of high speed railway line A is calculated using the fast algorithm and traversal algorithm. The comparation of calculation time of these two algorithms are shown in Fig. 5. Comparing the results of fast algorithm and traversal algorithm, the error is less than 1%, and the calculation time is saved over 90%. The practicability and effectiveness of the method are verified.

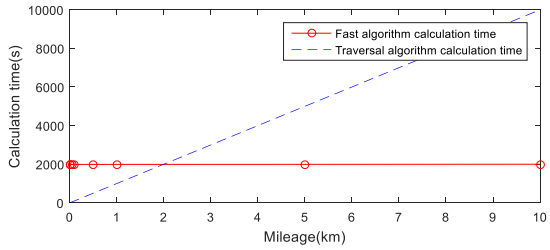

Figure 5 *Fast algorithm and traversal algorithm calculation time comparison*

5. Wheel/rail maintenance strategy

In the operation of some EMU trains in China, abnormal vibration phenomena have occurred with some of them. In order to ensure the comfort of the high-speed railway, it is necessary to analyze the abnormal vibration from the perspective of the wheel/rail matching and take effective maintenance measures. The literature [2,6] proposed different strategies from wheel/rail maintenance point of view to treat mismatch of wheel/rail profile. These methods are effective in controlling the abnormal vibration of EMU trains in particular sections. However, they do not specify which kind of equipment needs to be repaired when the wheel/rail matching condition reaches a quantitative index threshold, so it is not strong enough to form a maintenance proposal for the wheel/rail mismatch problem occurring in the entire high-speed railway network of our country from this point of view.

For a long time, wheel and rail maintenance activities have been carried out based on different principles under the guidance of their own departments. However, the wheel/rail maintenance strategy proposed from any single aspect may lead to the situation where the wheel/rail contact equivalent conicity is too low or too high. On basis of rapid calculation of dynamic equivalent conicity, we can use a quantitative index to measure the actual matching state of the EMU trains during the whole operation process and formulate the maintenance strategy based on the wheel/rail match condition, as shown in Fig. 6. For example, when a wheelset is matched with 80% of the rail profiles and their equivalent conicities exceed the threshold, it is considered that the wheelset must be repaired. Correspondingly, when 80% of the wheelsets are matched with a certain section of a railway line and their equivalent conicities exceed the threshold value, it is considered that the section needs to be repaired for rail gauge or rail grinding.

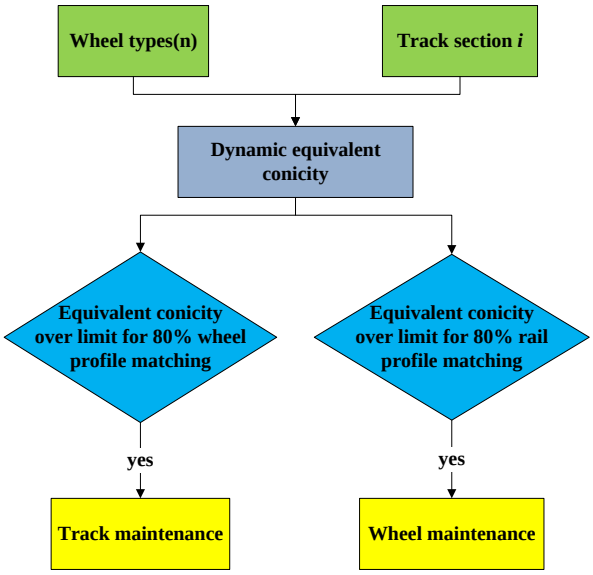

Figure 6 *Wheel/rail maintenance strategy*

6. Conclusion and discussion

The abnormal vibration of EMU trains which is a vehicle stability problem has drawn great attention. The contact geometry is fundamental to explain the dynamic running behaviour of a railway vehicle. Equivalent conicity is an important parameter to characterize contact condition, dynamic equivalent conicity takes into account the influence of actual gauge. Aiming at the calculation time bottleneck in the process of dynamic equivalent conicity calculation, combined with data pre-processing, wheel/rail profile grading, quasi-elasticity modification and spline interpolation method, a fast calculation method of dynamic equivalent conicity was proposed, and this method was used to calculate the dynamic equivalent conicity curve of high-speed railway line A. Measured data has been used to verify the practicality and reliability of the fast algorithm.

A wheel/rail maintenance strategy is proposed on basis of fast calculation of dynamic equivalent conicity. It is able to quantify the degree of wheel/rail mismatch, analyze the causes of wheel/rail mismatch, and then take corresponding maintenance measures to achieve the purpose of effectively controlling the abnormal vibration of EMU trains.

Abstract: Surface dents on rails may be caused by, for example, the drop of the freight goods and have a deep effect on the rail service life. This investigation aims at exploring the rolling contact fatigue of the rail materials after being impacted by hard bodies. The results show that the residual tensile stress, which is distributed on the shoulders of dent, decreases the RCF resistance of material around dent. Moreover, the unbalanced wear behaviour between two shoulders makes the situation even worse at one side of the dent. Crack propagates fast around the dent with white etching layer on the bottom of dent itself.

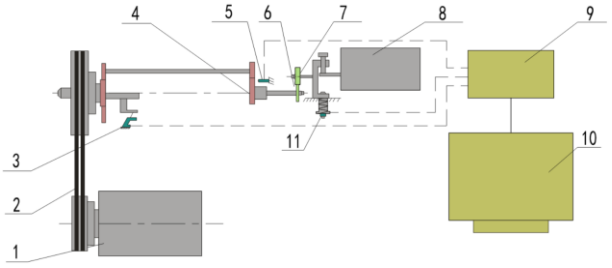
Keywords: rail material; dent; rolling contact fatigue; fatigue crack; propagation mechanism

1. Introduction

Wheels and rails present a number of different rolling contact fatigue (RCF) failures, such as corrugation, squats and head checks [1~3]. Squats are long cracks [4], which propagate at a small angle to the surface before branching upwards to form the spalling or downwards to cause a rail fracture. Head checks are a series of surface breaking cracks at the gauge corner of the rail [5], especially on the outer rail in curves. In previous works, many researchers have studied the RCF life of rail by means of various experimental and numerical methods. Ignesti et al. [6] and Innocenti et al. [7] established a development model for wheel and rail profile to predict their service lives. By changing the attack angle on wheel-rail surface, Huang et al. [8] found that the RCF cracks tend to grow in depth on the rail rollers while they are easy to become parallel to the surface on the wheel rollers. Based on the research of North American transit systems, Hernández et al. [9] claimed that rail base corrosion can shorten rail life from several decades to one year or less, compromising integrity and transit system safety.

Some of these RCF failures may be caused by subsurface-originated crack [10]. However, some pre-existing surface damage may be responsible for surface-originated fatigue failure. As well known, the railway usually operates under critical natural condition. The environmental factors such as the sand [11], leaves [12], and even the snow [13, 14] will influence the wheel/rail RCF resistance as well as their service lives. More in particular, surface damage can be caused by hard bodies coming from the unclosed environment. The hard body may stem from the drop of the freight goods such as the minerals, or the ballast rolled up by the passage of the trains. Once the hard body enters the wheel/rail interface and is crashed, the damage occurs both on the rail and wheel surfaces. Subsequently, in the service phase, this surface damage will change the contact condition and may affect the service life.

In the pioneer experiments carried by Gao et al. [15], the material around the dent was defined as two areas: trailing edge and leading edge. It can be noted that severe spall emerges on trailing edge of conic and diamond dents under oil lubrication. In his subsequent researches [16, 17], he evaluated the RCF life of rail material with different shapes of dents under various lubrication conditions. These tests showed that rail materials are relatively insensitive to the presence of surface dent when operating in their normal environment. Compared with trailing and leading edge, Seo et al. [18] found that the material in middle edge has a shorter fatigue life. In the meantime, he pointed that the RCF cracks would initiate and propagate when the diameter of dents reaches to a certain size. Using full scale experimental method, Stefano and Steven [19] pointed out that crack propagation of surface and sub-surface defects are not critical during the typical reprofiling interval.



Based on the previous research, the crack propagation mechanism with oil lubrication has clarified. However, under dry condition, the crack growth behavior around the pre-existing surface damage has not been clearly demonstrated. In this study, the residual stress distribution around the pre-existing surface damage after impacting was simulated in ABAQUS to make a contrast with experimental results. Then, the experiments for investigating the RCF behavior of the rail material around two kinds of dents were performed using a rolling-sliding wear testing machine. In particular, the factors influencing the crack initial and propagation was discussed.

2. Experiment details

2.1 Experimental machine

The objective of this study is to explore the effect of the rail dents subject to the rolling contact fatigue using a rolling-sliding wear testing machine, which is composed of a wheel specimen (lower roller) and a rail specimen (upper roller). The two rollers are powered and controlled by a DC motor through the transmission gears (Fig.1). The DC motor (1) drives the drive shaft through the belt (2) and transmits the power to the driven shaft through the transmission gears (4, 8). By changing the

transmission ratio of the transmission gear pairs, the upper and lower samples move at different speeds, which makes it possible to achieve various slip ratios at the wheel-rail contact interface. The upper specimen is fixed in a swinging bracket where a normal force (Maximum to 2000 N) can be applied and adjusted by a compressed spring; the normal force are measured by a force sensor. The tangential and normal forces in the wheel/rail interface are automatically measured by means of the torque sensor (3) and load sensor (11) (measurement error: ±5%). The signal collected by the sensors is fed back to the computer (10) through the controller (9) and the data can be calculate and saved in the computer.

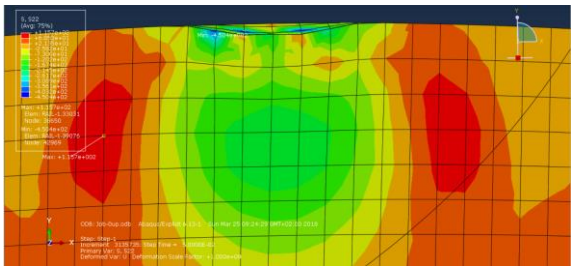
Fig.1: Schematic diagram of the machine.

2.2 Experimental parameters

The geometric sizes of wheel and rail rollers are determined by means of the Hertzian theory [20], as shown in Fig.2. The rail roller is cut from the railhead while the wheel roller is cut from the wheel tread. The material of rail roller is PD3 with the carbon content 0.65~0.75% in weight percentage and the carbon content of wheel material in weight is about 0.54%. The diameter of wheel/rail roller is 40 mm. Their chemical compositions in weight percentage are given in Table 1.

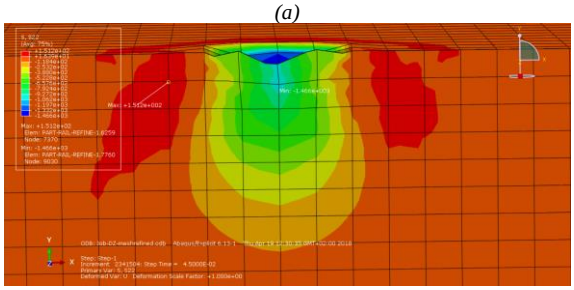
Table 1: Chemical compositions of wheel and rail rollers (wt %).

Roller	C	Si	Mn	P	S
Wheel	0.56~0.60	≤0.40	≤0.80	≤0.020	≤0.015
Rail	0.65~0.75	0.10~0.50	0.80~1.30	≤0.025	≤0.025



A normal force equal to 347 N is applied while the slippage ratio is 0.91%. The rotational speed of wheel roller is 200 r/min (about 0.42 m/s). After 5000 cycles, the contact zone of rail roller is impacted by two different hard bodies: steel ball (SB dent) and ballast from railway roadbed (B dent), respectively. Considering the size of dents referred in previous study [18], the weight of hammer is 5kg at an impact speed of 3.4m/s. The defected rail rollers are matched to non-defected wheels. For exploring the propagating behavior of fatigue crack around the dent on rail roller, the subsequent cycles are set to 48000, 72000, and 96000, respectively. On the contrary, the rail roller without dents also rotates for 96000 cycles under the same condition.

In this study, all experiments were carried out under the ambient environment (temperature: 20~23 ℃, relative humidity: 40~60%). The plastic deformation, surface damage and cracks were examined by optical microscope (OM) (OLYMPUS DSX510, Japan) and scanning electron microscope (SEM) (JSM-7001F, Japan). The residual stress at the edge of SB dent was tested by X-ray Residual Stress Analyzer (PULSTEC μ-X360n, Japan) to verify the accuracy of simulate results. The test rollers were cut longitudinally along the rolling direction. After polishing the samples to the roughness of 0.5 μm, the samples were etched by ethanol with 4% HNO_3 for analyzing with SEM.



3. Results

3.1 Residual stress

The steel ball and ballast are represented by spherical and regular tetrahedron, respectively. Both of them are considered as rig body with mass equal to 5kg and an impact speed of 3.4m/s. The simulated results of residual stress distribution (along Y axis) on rail material after impacting are shown in Fig. 3. The residual distribution on the profile of defected rail rollers shows the same trend: the stresses below the dents are dominated by compressive resistance while tensile stress is distributed on the shoulders of dent. Particularly, the maximum residual tensile stress locates on the subsurface material. The tested residual stress at the edge of SB dent is listed in Table. 2. Due to the fact that the stress along Y axis can not be detected by test machine directly, the simulate results are verified by comparing the stresses along the other axes.

(B)Simulate results	1648	1629	1466	151

3.2 Surface damage

Fig.3 shows an ascending trend of the wear loss of rail rollers with cycles rising. In particular, the impacted rail rollers always have a higher wear loss than those of non-impacted rollers. This can be due to the fact that the dents on the rail surface increase the contact pressure when the roller passes through the dent. The surface morphologies of rail rollers after different cycles are shown in Fig.4~6. The distribution of fatigue cracks on the non-defected rail surface is homogeneous and only short fatigue cracks and small spallings occur on the non-defected rail (Fig.4). Compared to a slight fatigue on the surface of non-defected rail roller, the surface damage around SB dents becomes severe and uneven. Along the direction of tangential force, the delamination usually emerges on the side of the SB dent where the tangential force firstly acts (Fig.5a). With the cycles rising, a large number of delamination gathers at this side and eventually a large peeling evolves (Fig.5b, c). Moreover, the damage gets extraordinarily serious around the B dents. Due to the irregular morphology caused by ballast, the stress may concentrate on the edge of dents (scratched by ballast). In the early stage, a large size of spalling appears around the dent (Fig.6a). With the surface materials spalling off, the surface damage is dominated by fatigue cracks (Fig.6b). And eventually, a long fatigue crack (Fig.6c) propagates on rail surface.

3.3 Subsurface damage

Fig.7 presents the fatigue cracks on profile of rail rollers. It is noteworthy that the damage behavior differs between the "shoulders" of the dent. On one side of dent, the material slips and accumulates in the dent due to the tangential force, while on the other side, the material spalls and is gradually removed (Fig.7a, b). Fig.8 shows the surface cracks on the defected and non-defected rail rollers. As it is shown after the final cycles, the length and angle of the crack are still larger than those on non-defected rails under the same condition (Fig.8), which means the dent conduces to the crack growth even it was worn off.

(b)

Fig.8 OM micrographs of fatigue cracks on the section of rail rollers after 96000cycles: (a) Rail roller with SB dent. (b) Rail roller without dent.

In order to reveal the differences of microstructures between the shoulders of the dent, SEM micrographs with high magnification were applied both on front and rear areas of dent. Figs. 9-11 highlight more details on these areas around the dents. Cracks firstly initiate and grow on one side of dent, and part of material around SB dents seems over etching, probably because the lattice was broken and becomes easy-etched. In addition, the residual stress resulting from impacting aggravates the lattice distortion and arranges the atoms on grain boundary in disorder, which makes the material easily erodible. Therefore, the critical strain release rate of the microstructure-broken material decreases and the crack easily propagates through it (Fig.9). As a result, the cracks around the SB dent are longer than that on non-defected rail.

Fig.9 also shows that a number of dark dots are present around the dents. On the contrary, just a few dark dots emerge on the rail roller without dents (Fig.10). Since the dark regions under electronic microscope represent the lower region of the profile after erosion, these dark dots might be the dislocation pile-up groups [21]. The dark dots gradually climb towards the surface and may connect the subsurface cracks. Thus, the dark dots provide a relatively weak-fatigue resistance area for crack growth (Fig.9b).

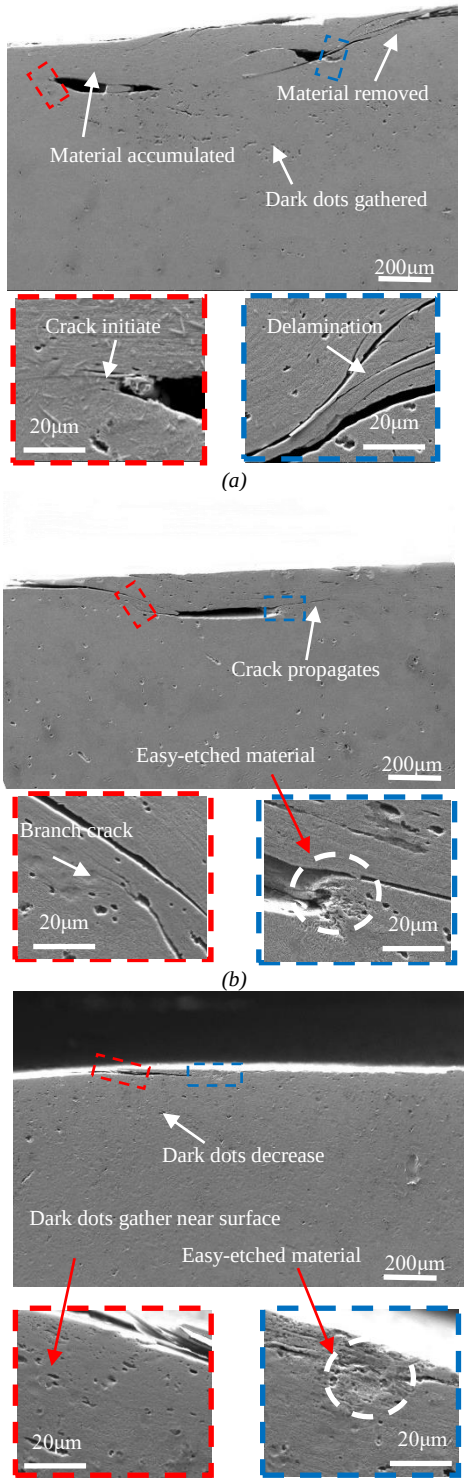

Fig.9 SEM micrographs of fatigue cracks on the section of rail rollers with SB dents: (a) 48000 cycles. (b) 72000 cycles. (c) 96000 cycles

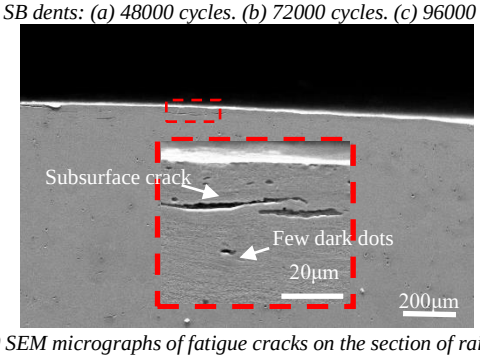

Fig.10 SEM micrographs of fatigue cracks on the section of rail rollers without dent

Fig.11 shows the crack propagation process during the evolution period of B dent with cycles rising. According to the difference of microstructure, the material around the dent can be divided into two areas: dense area and normal area. The dense area has a more compact microstructure than normal area. At the early stage, the cracks around the dent are short and easily spall. The cracks firstly initiate at the boundary of two areas and grow towards normal area, whereas, the crack on the other side of dent easily breaks and makes material remove fast (Fig.11a). With cycles rising, the dislocation pile-up groups climb toward the surface and the cracks growth around it, providing a relatively weak-fatigue resistance area for crack growth, resulting in a long crack around the dent (Fig.11b). Finally, when the dent is worn off, the crack stems from the edge of dent, propagates at a long scale and even braches in depth. Besides, the sharp edge of dent also leaves a large angle for crack starting growth (Fig.11c).

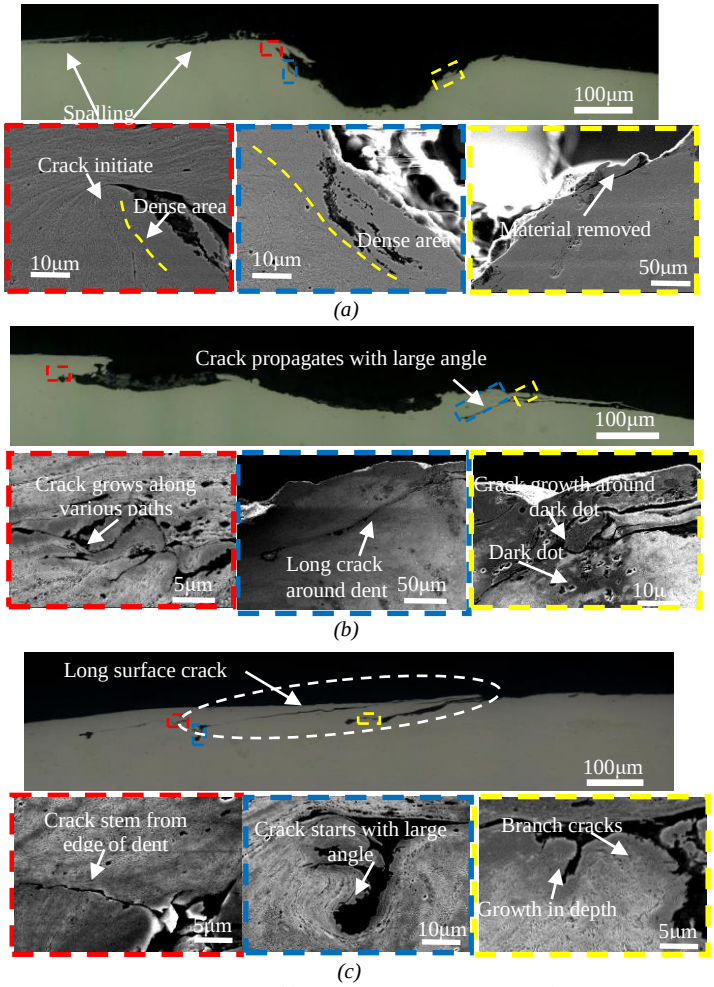

Fig.11 SEM micrographs of fatigue cracks on the section of rail rollers with B dents: (a) 48000 cycles. (b) 72000 cycles. (c) 96000 cycles

The length and angle of the crack on rail rollers after 96000 cycles are listed in Table. 3. The length and angle of crack both sharply increase when the rail rollers were impacted by hard bodies. The maximum length of crack around SB and B dent approaches 223 and 445 μm, which are 2 and 4 times larger than those on non-defected rail roller, respectively. In addition, the length of crack

around the B dent is much larger than that around SB dent.

Table 3: Statistic of surface cracks on rail rollers after 96000 cycles

Rollers	Max. length of crack/μm	Max. angle of crack/°	Ave. length of crack/μm	Ave. angle of crack/°
Non-defected	117.45	5.4	68.64	3.8
SB defected	223.14	8.1	187.39	6.2
B defected	445.18	12.8	227.58	10.5

4. Discussion

4.1 Wear behavior of the shoulders

As it is known, the length of crack is usually affected by the coupled factors: the wear and growth of crack [22]. On the one hand, the residual tensile stress increases the average stress of the cyclic stress [23]. This way, the cracks easily initiate and grow on the shoulders of dent, where the maximum tensile stress locates. Therefore, the length and angle of cracks on defected rail roller are both larger than those on non-defected rail roller because of the residual tensile stress after impacting. At the same time, the unbalanced wear loss between the two shoulders makes the crack growth differently. Fig. 12 shows the material accumulation and removal when tangential force acting on the shoulders of dent is present. Obviously, the material around the dent can be defined as two sections along the direction of tangential force: the front area and the rear area. In the edge of the front of dent, the tangential force compels the material slid and forms an accumulation layer. As it is shown, the tangential force can be divided into two components: the first one is the tensile force (vertical with respect to the dent bottom) which speeds up the cracks growth. The second one pushes the material slip into the dent. On the contrary, in the edge of the rear of dent, the sheer force, (also derived from tangential force) removes material at the edge of dent rapidly, and leaves a slope in the rear of the dent. The material is removed layer by layer when the tangential force is acting at the slope. As a result, the wear rate on the rear area is higher than that on front area and the damage on front area is much more serious than that on rear area (Fig. 5, 11).

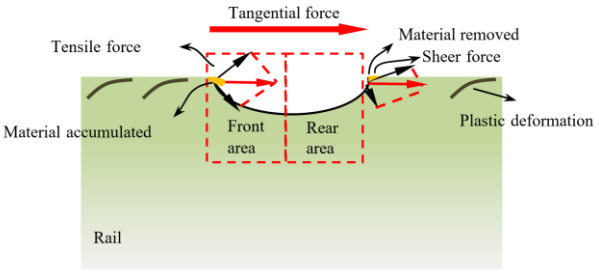

Fig.12. Force analysis around dent

4.2 Cracks on SB and B dent

The microstructure can be another factor influencing the crack propagation [24]. After etched by 4% HNO_3, the dense area can be found below the B dent (Fig. 11a). The OM micrographs show the dense area which is presumed to be white etching layer (Fig. 13). Furthermore, the nano-indentation hardness of this area is as high at 11.62 (±2.28) Gpa, which is in accordance with the white etching layer that previous papers referred [25,26]. The WEL may be caused by the radical friction between the sharp edge of ballast and rail material. On the one hand, the tensile stress is distributed on the subsurface of the shoulders, just at the boundary of WEL and normal material. On the other hand, the WEL, which mainly consists of martensite, has a different strain of pearlite under cyclic load. A hard material is usually less ductile than a softer one, producing initiation and acceleration in stress controlled crack growth. Therefore, the crack tends to initiate at the boundary of the WEL and pearlite (Fig.11a). Meanwhile, the crack grows in martensite through various paths because of the ductile of martensite, and eventually forms a long crack around the WEL (Fig.11b). While the dent is gradually wearing off, the crack continues growing and becomes a long surface crack. Otherwise, the irregular shape of ballast usually causes a sharp edge on the dent, which makes the crack starting growth at a large angle. Furthermore, the propagation mode of crack around the WEL is multiple: branching, converging, even propagating in depth (Fig.11). Therefore, the WEL and sharp edge of B dent makes the crack grow longer and deeper compared to that on SB dent.

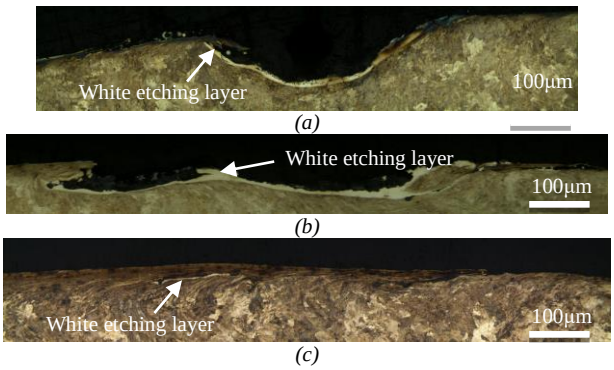

Fig.13 White etching layer on the bottom of B dent: (a) 48000 cycles. (b) 72000 cycles. (c) 96000 cycles

The factors accelerating RCF cracks propagation on the rail rollers are listed in detail in Table. 4. The dents brings Pre-exist tensile stress in the material and changes tangential force acting on the edge of dent (results in tensile force and deformation layer accumulation). Moreover, the radical friction between the sharp edge of ballast and rail material conducts WEL and sharp edge on B dent. These factors mentioned above all speed up crack growth, more and less. As the results, the crack gets easy to propagate in rail material when the rail is defected by hard body, especially for irregular ones.

Table 4: Factors accelerating RCF cracks propagation

Rollers	Pre-exist tensile stress	Tensile force	Deformation layer accumulation	WEL/ martensite	Irregular shape at edge of dent
Non-defected					
SB dent	×	×	×		
B dent	×	×	×	×	×

In summary, the appearance of dents influences the rolling contact fatigue by changing the distribution of

residual stress, wear behaviour on the shoulders of the dent, and the microstructure of the material around the dent. After being verified in full-scale experiments, the conclusions can be a reference to evaluate the performance of defected rail. Therefore, further study on the rolling fatigue of defected rail should be carried out under the full-scale condition.

5. Conclusion

The effect of surface dents on rolling contact fatigue of rail materials was investigated by observing the wear behaviour and crack propagate mechanism around the dent. The following conclusions can be highlighted:

1. No matter the type of surface morphology caused by hard bodies, the residual tensile stress is distributed on the shoulders of the dent and the maximum tensile stress locates on the subsurface, which promotes cracks initiation and propagation.
2. Due to the material accumulation on the front area and the material removed on the rear area of the dent, the damage on the front area is more serious than that on the rear area.
3. The WEL occurs on the bottom of B dent after impacting, resulting in a deteriorated fatigue crack on B dent compared to that on SB dent.

Abstract: A transient FE model of wheelset-rail rolling contact has been developed with ANSYS/Ls-dyna to simulate the high speed running of a free wheelset on a slab track section. Applying vibrations at passing frequencies of corrugation to the wheelset, significant coupling is found between the vertical and lateral wheel-rail interactions, while friction exploitation level dependent between the longitudinal and vertical. The resulting irregular wear calculated with implemented wear models of Archard, *Tγ* and Zobory increases in magnitude as the exploitation level increases, whereas its phase keeps stable except for approaching full-sliding in the presence of vertical or lateral vibrations.

Keywords: Wheel-rail rolling contact; tangential contact; high frequency dynamics; irregular wear; explicit FE method; high speed rail.

1. Introduction

Irregular wear such as rail corrugation and wheel polygonization has become a major problem worldwide. Its occurrence, development and influence, being easy to understand, are highly related to the dynamic wheel-rail interactions. Hence, the vehicle-track dynamics in the presence of irregularities has been studied intensively. To this end, frequency domain approaches were first developed in early days based on receptance and Fourier transformation [1~4], in which the coupling of the vertical, lateral and longitudinal dynamics was considered by cross-receptance [2, 4]. Such a model has to be fully linearized, the excitations were usually simulated with the moving irregularities (i.e. stationary loads), and only steady state solutions obtained. Thus, the approach is not suitable for transient analyses at irregularities, especially of short wavelength and large amplitude [5]. To improve the approach, the non-linear contact mechanics [4], the filter effects of wheel-rail contact [2, 6], and the moving load [7] have been included. Recent publications include [8-10].

The time domain approach, which can take into account nonlinearities, is widely employed today. In such an approach, vehicles are typically simulated as moving masses or structures of rigid bodies, springs and dampers, rails as either Euler or Timoshenko beams, truncated tracks as 1-3 layers with continuous or discrete supports, and normal wheel-rail interactions as Hertzian springs [11~16]. The formulae are usually derived using the Finite Element (FE) method, and for vibrations of rails modal decomposition or reduction is often employed instead of direct time integration to reduce the computational costs.

According to [5, 11], the modal reduction techniques are suitable for structures having a linear and time-invariant (i.e. steady state) behavior, and not sufficient for cases with irregularities, especially of short waves. More drawbacks of typical time domain approaches are: wheelset flexibility, continuum vibrations, rolling-sliding behavior, 3-D irregularities and finite contact patch are ignored; most models have only studied the normal (vertical) wheel-rail interaction [11,12,14~18], i.e., the coupling of the vertical, lateral and longitudinal interactions are ignored; the tangential interaction, if treated, is usually represented by steady-state rolling contact theories such as Kalker's linear theory and FASTSIM, Shen's and Polach's theories [13,19~21]; dynamic stresses cannot be obtained directly. These factors, however, become important in high frequency wheel-rail interactions and the resulting damage.

Recently, wheelset flexibility has been included in the time domain approach with eigenmodes derived from FE models in [17, 19], wheelset rotation was considered in [17], direct time integration was employed in [22, 23], CONTACT was embedded in a 2D model in [18], and multi-coaches or a train was modeled in [20]. Its further extension to include traction control [21] and gear transmission [24] has also been reported.

The transient wheel-rail rolling contact FE model, developed in the last decade [25, 26] and extended for high speed railways recently [27, 28], overcomes the aforementioned drawbacks. Flexibilities of wheel and rail are taken into account by mesh of solid elements, so that the coupling of the vertical, lateral and longitudinal wheel-rail interactions is included inherently. This work further develops the FE model to study the coupling in the presence of high frequency vibrations. Three non-linear wear models are implemented, instead of linear ones in many studies, to calculate the resulting irregular wear.

2. Modeling approach

2.1. Transient rolling contact FE model

Following the same approach in [25~28], a transient FE model illustrated in Figure 1 is developed for a Chinese high speed railway with ANSYS/Ls-dyna to examine the dynamic wheel-rail rolling-sliding at a speed up to 500 km/h. A whole wheelset that runs freely on a section of tangent slab track 15.2 m long is simulated, so that more realistic longitudinal and lateral creepages and spin can be considered simultaneously on both left and right wheel-rail contact (indicated as *L* and *R* in Figure 1). Vehicle components above the primary suspension are lumped into unsprung masses, and the slab track is composed of two rails, discrete fastenings, slabs and a continuous mortar layer. The wheelset and rail are meshed using solid elements (actual geometries considered), so that material non- linearity can be introduced conveniently. To simulate drive or braking, a time dependent torque (*M*) is further applied to the wheel axle at the position of drive gear.

In a simulation, the wheelset starts to roll from position *A* along the rails with specified translational and rotational velocities and creepages, and results in the solution zone *BC* (after the dynamic relaxation zone *AB*) are outputted for further analyses. An explicit time integration scheme is employed for solutions, so that a very short time step (10^{-8} ~10^{-7} s) is required due to its conditional stability, being suitable for analyses of high frequency dynamics.

With such a model the structural vibrations of the rails such as bending and torsion are considered together with their continuum vibrations and track resonances, and so are the wheelset and vehicle. Default values of parameters are given in Table 1. No lateral shift is considered for the wheelset. Boundary conditions are as follows: the longitudinal ends of the rails, slab and mortar layers are set to be symmetric planes; the bottom of the mortar layer is fixed; the fastenings can only move vertically. A 3D right-handed Cartesian coordinate system (*oxyz*) is defined, of which the origin is located in the initial position of the contact patch centre of the right wheel, as indicated in Figure 1. For more information about the approach, the readers are referred to [25~28].

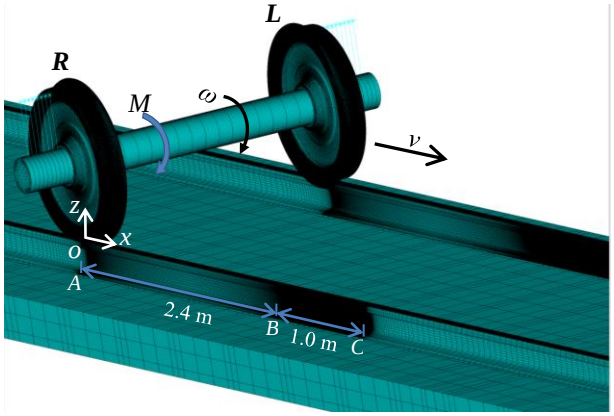

Figure 1 *The mesh of the transient wheelset-rail rolling contact FE model of a Chinese high speed rail. The minimum element size of 1.0 mm for detailed contact calculations, and the total nodes 2.91 M.*

2.2. Wear models

Wear models of Archard [29~31], *Tγ* [30~33] and Zobory [30, 34] are implemented into the transient FE model to calculate rail wear. Non-linear and empirical wear coefficients or rates reported in the literature are used, with which different wear regimes under dry conditions such as mild, severe and catastrophic [30~37] are considered. Assuming a uniform wear within the area represented by each node, the wear depth of surface (i.e. the surface height reduction by wear) is further calculated from material loss.

Table 1. *Default values of parameters involved in this work.*

Parameters		Values for each wheel
Rolling speed, v		300 km/h
Lumped sprung mass, m_c		8000 kg
Wheel diameter, ϕ		0.86 m
Wheelset mass, m_w		1172 kg (for wheelset)
Unsprung mass attached to wheelset	Drive gear, m_a	280 kg (for wheelset)
	Axle box, m_b	200 kg
Stiffness of primary suspension, K		880 kN/m
Damping of primary suspension, C		4 kNs/m
Stiffness of fastenings, K_f		22 MN/m
Damping of fastenings, C_f		200 kNs/m
Coefficient of friction		0.3
Wheel & rail material	Young's modulus, E	205.9 GPa
	Poisson's ratio, υ	0.3
	Density, ρ	7790 kg/m^3
	Damping constant, β	1.0 ×10^{-4} s
Material of pre-fabricated slabs	Young's modulus, E_s	34.5 GPa
	Poisson's ratio, υ_s	0.25
	Density, ρ_s	2400 kg/m^3
Material filled in slab gaps	Young's modulus, E_g	29.5 GPa
	Poisson's ratio, υ_g	0.25
	Density, ρ_g	2400 kg/m^3
Mortar material	Young's modulus, E_m	8 GPa
	Poisson's ratio, υ_m	0.2
	Density, ρ_m	1600 kg/m^3

2.2.1 Archard's model

With Archard's model, volume loss at a node $V_{Aw}(x, y)$ (unit: m^3) is calculated by

$$V_{Aw}(x,y) = k^A \frac{DF_N}{H} = \sum_{i=1}^{n_t} k_i^A \frac{s_i F_{Ni}}{H} \Delta t_W \qquad (1)$$

where, D and s_i are the sliding distance (m) and the sliding velocity (m/s) at the node, respectively, F_N the normal nodal force (N), H the Vickers hardness of the worn material taking as 2.94 Ga in consideration of hardness measurements in field, and Δt_W the time step (s); the subscript i corresponds to instant $i\Delta t_W$, and n_t is the number of calculated time steps. Two wear coefficients, namely k^{AL} and k^{AC} (dimensionless) shown in Figure 2, are employed on the basis of those published in [29, 30]. k^{AL} is defined by Equation (2), while k^{AC} is assumed to be constant in each interval of sliding speed, equalling to 35×10^{-6}, 65×10^{-6} and 35×10^{-6} separately.

$$k_i^{AL} = \begin{cases} (31+45s_i)\times 10^{-6} & (s_i < 0.2 \text{ m/s}) \\ (70-10\dfrac{|s_i-0.45|}{0.25})\times 10^{-6} & (0.20 \text{ m/s} \le s_i < 0.7 \text{ m/s}) \\ (40-30(s_i-0.7))\times 10^{-6} & (0.7 \text{ m/s} < s_i \le 1.0 \text{ m/s}) \end{cases} \qquad (2)$$

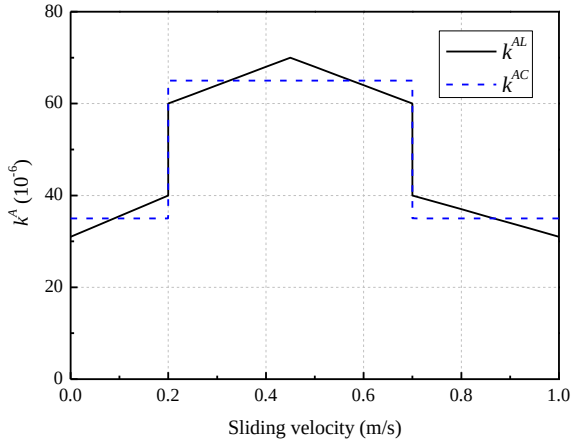

Figure 2 *Two wear coefficients employed for Archard's model*

2.2.2 Tγ model

With the dissipated energy based $T\gamma$ model, material loss at a node $m_{Tw}(x,y)$ (unit: μg) is calculated by

$$m_{Tw}(x,y)=\int_0^t k^T A v dt=\sum_{i=1}^{n_t} k_i^T A v_i \Delta t_W \tag{3}$$

where, A and v are the area represented by the node and rolling speed (m/s), respectively; the wear rate k^T (μg material loss/m rolled distance/mm^2 contact area) is a function of $T\gamma/A$,

$$k_i^T = k^T\left(\frac{T_i\gamma_i}{A}|_{(x,y)}\right)=k^T\left(\tau_i\frac{s_i}{v_i}\right) \tag{4}$$

where, τ is surface shear stress (MPa) at the node. Two wear rates k^{T1} and k^{T2} shown in Figure 3 are used in this work. k^{T1} was postulated from test results of R260 rail against R8T wheel under a pressure of 1500 MPa in [36], and k^{T2}, defined by Equation (5), is scaled from k^{T1}. Note that with respect to the test conditions in [36] the material pair of U71MnG rail against ER8 wheel used in Chinese high speed rails are similar, but the pressure level is significantly lower (~1100 MPa, see Figure 4), so that a scale of 0.55 is determined during calibration in section 3.1.2 (wear rates increase with pressure [37, 38]).

$$k_i^{T2}=\begin{cases}1.054\,\tau_i s_i/v_i & (\tau_i s_i/v_i<4.34)\\ 4.574 & (\tau_i s_i/v_i\geq 4.34)\end{cases} \tag{5}$$

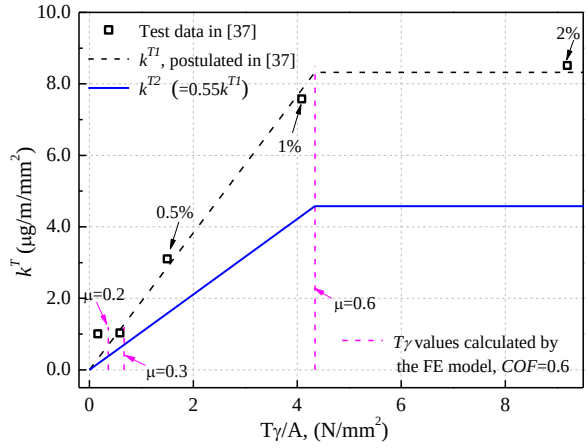

Figure 3 *Two wear rates employed for Tγ model*

2.2.3 Zobory's model

With the dissipated energy based Zobory's model, material loss at a node $m_{Zw}(x,y)$ (unit: g) is calculated by

$$m_{Zw}(x,y)=\int_0^t k^Z W dt=\sum_{i=1}^{n_t} k_i^Z F_{\tau i} s_i \Delta t_W \tag{6}$$

where, W and $F_{\tau i}$ are the frictional work (N m) and friction force (N) at the node, respectively; the wear rate k^Z (g/ N m) depends on energy flow density $F_{\tau i}s_i/A$ (N m/s mm^2).

$$k_i^Z=\begin{cases}4.78\times10^{-7} & (F_{\tau i}s_i/A<4.0)\\ 14.34\times10^{-7} & (F_{\tau i}s_i/A\geq 4.0)\end{cases} \tag{7}$$

2.2.4 Sliding velocity adjustment

It is shown above that wear transitions are included in all employed wear models. The transition at a $T\gamma/A$ of 4.34 in Figure 3 is believed to correspond to the onset of fully sliding [32], the shakedown limit [35], or both [33]. The saturation creepage, being 1~2% under the test conditions (see Figure 3), is often higher than 2% in field due to the existence of contaminants and complicated profiles/roughness [39-41]. In contrast, the calculated saturation creepage by the FE model is only 0.8% for the steady state rolling, in which contaminants and roughness are ignored and the coefficient of friction (COF) is set to be 0.6. To ensure the simulated results comparable to tests such as those in [36], s_i used in the wear models is corrected by assuming a saturation creepage of 1.45%, i.e.,

$$\gamma_i=1.82\gamma_{si} \quad \text{or} \quad s_i=1.82s_{si} \tag{8}$$

where, γ_{si} and s_{si} are the creepage and sliding velocity directly calculated from transient FE simulations. The vertical dashed lines shown in Figure 3 indicate the corrected $T\gamma/A$ of steady rolling cases with traction coefficients (μ) of 0.2, 0.3 and 0.6 (COF=0.6).

3. Results

Cases with and without forced vibrations are simulated to study the initiation of irregular wear damage such as rail corrugation. Without loss of generality, the vibrations are assumed to be sinusoidal. The velocity and COF are 300 km/h and 0.3, respectively, as listed in Table 1. Cases without vibrations are for validation of wear models and comparison. Note that the severity of these vibrations is determined with some arbitrariness on the basis of typical values observed or measured in field and those reported in literature.

3.1. Without vibrations

3.1.1 Contact forces and stresses

Contact results of a smooth case with default traction level (μ=0.1) are shown in Figure 4 as an example. It is seen that the contact forces and stresses are roughly constant in solution zone *BC*, i.e., stable rolling has been built up approximately after the dynamic relaxation zone *AB*, being in line with previous work. Furthermore, the vertical (contact) forces (*Fy*) of the two wheels coincide with each other approximately, and so are the longitudinal (contact) forces (*Fz*). In contrast, the lateral (contact) forces (*Fx*) caused by spin are in reverse directions. These suggest the validity of the transient

rolling contact FE model. For techniques required to reach an approximately stable rolling contact with the explicit FE method, the readers are referred to [28].

The maximum pressure or surface shear stress, shown in Figure 4(b), means the maximum value reached at a location during the simulated wheel passage. For clarity, Figure 4(b) only shows the results along a longitudinal line (y= –0.55 mm) on the right rail passing the location of maximum pressure in a contact patch, i.e. coinciding with the longitudinal axis of the elliptical contact patch in Hertzian contact. Hereinafter, this longitudinal line is referred to as the longitudinal axis, although the contact patch is not necessarily an ellipse.

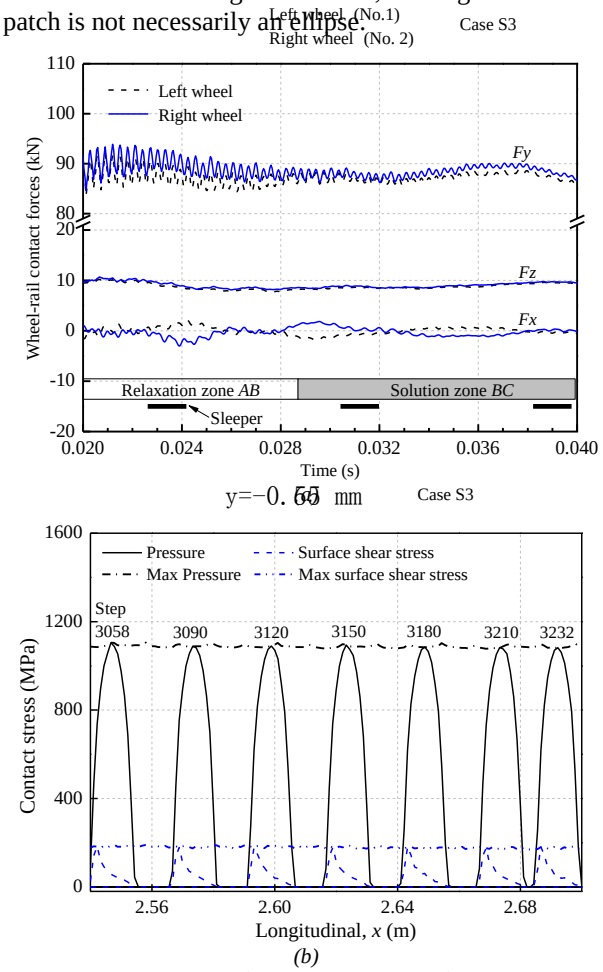

Figure 4 *Contact results of a smooth case with default traction level (μ=0.1): (a) Resultant contact forces, (b) Pressure and surface shear stress along the longitudinal axis of the right rail*

3.1.2 Wear model calibration

The three wear models explained in Section 2.2 have not been applied into transient wheel-rail rolling contact simulations, so that validity of their parameters suggested in the literature needs be examined first. To this end, a calibration against the measurements of rail wear over 3~7 years in [42] is conducted. The reported average wear rate is 0.0025~0.0043 mm/MGT on rail top of tangent tracks on Chinese high speed lines (running at 300 km/h), corresponding to a wear depth of $3.75\sim6.45\times10^{-8}$ mm every wheel pass (indicated by a grey box in Figure 5). During the calibration by trial-and-error, the wear transition intervals are assumed the same as those in literature, and the values of wear coefficient or rate are shifted or scaled carefully at intervals. A smooth case with μ=0.05 (a typical traction level on tangent tracks [27]) is simulated for the calibration. From the results shown in Figure 5 it is seen that the results of the three wear models agree well with the measurement when k^{AC}, k^{T2} and k^{Z} shown above (i.e. the calibrated ones) are used separately. Note that the result of k^{AL} almost coincides with that of k^{AC}, and the catastrophic wear regime is not considered because it hardly occurs in reality.

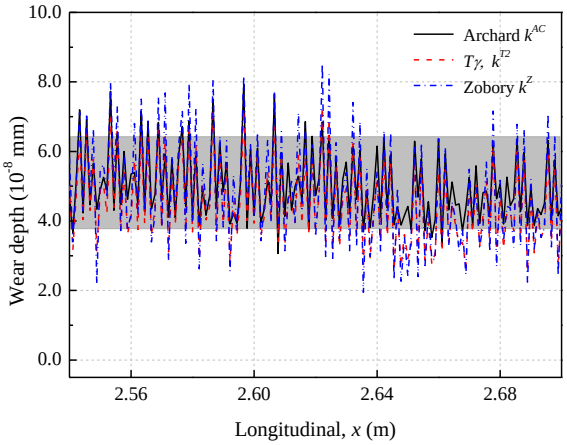

Figure 5 *The calculated wear distribution of a smooth case with μ=0.05 along the longitudinal axis of the right rail*

3.1.3 Wear under different traction coefficients

Figure 6 further shows variations of the predicted wear depth with traction coefficient, in which results of the three wear models are all plotted for comparison. The symbols represent the mean wear depth over the longitudinal axis section shown in Figure 5, and the error bars correspond to the fluctuation ranges in the same section. It is seen that the wear models, calibrated at μ=0.05 in Section 3.1.2, predict very differently for other traction levels, especially for high ones. E.g., the prediction of Archard's model is only 26% of that of Zobory's model at μ=0.3, whereas becomes the highest when μ<0.05. This difference should come from altered test conditions and varied approach for wear transition modelling in developing wear models. The platform at low traction levels (μ<0.05) in the Archard's prediction is in agreement with the test results in Figure 3 in trend.

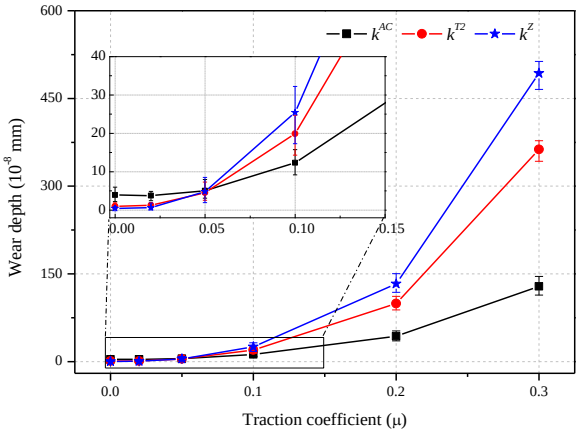

Figure 6 *Predicted wear depth under different traction levels (results along the longitudinal axis of the right rail)*

3.2. With forced vibrations

Harmonically varying loads are applied to the wheelset to simulate situations in which the eigenmodes related to rail corrugation are excited effectively. Rail surfaces are still assumed to be smooth as in cases shown above, i.e. the resulting irregularities have not formed. In other words, this intends to study the initiation of corrugation from vibrations. The frequencies of the varying loads are set as 1040 and 621.8 Hz, corresponding to the passing frequencies at 300 km/h of typical components of corrugation observed on the simulated Chinese high-speed railway (the wavelengths are 80 and 134 mm, respectively). Other parameters are kept the same as in cases shown above. Note that this work focuses on the consequences of the dynamic loads, no efforts are placed on their reasons, i.e., details of the excited eigenmodes are not considered, as will be seen later.

3.2.1 Vertical vibrations

A vertical varying load is applied to a section of axis at the right wheel (to be more detailed, to 20 nodes on a section 15.5 cm long). The variation starts at 0.025 s with a peak-to-peak amplitude of 40 kN and at a frequency of 1040 Hz. This simulates a moderate vertical vibration of one wheel (no contact loss occurs), and corresponds to the one-rail corrugation observed in field.

Figure 7 shows the calculated contact forces under μ= 0.1. It is first seen that the resulting variations of the vertical forces are not constant in magnitude over various periods, and the peak-to-peak magnitude is up to over 60 kN on the right side, while about 14.5 kN on the left, indicating the attenuation of the vibration during transmission, with approximately the same phase angle as on the right (after running-in). Furthermore, oscillations of the lateral and longitudinal forces also occur on the right side with the same frequency, and their peak-to-peak magnitudes are up to 3.3 and 6.4 kN, respectively. This indicates the coupling of the vertical, lateral and longitudinal wheel-rail interactions. On the other hand, peaks of the three forces usually do not occur at the same instants (phase lead or lag occurs at various periods), suggesting the significant independence of the vertical, lateral and longitudinal interactions. Oscillations of the lateral and longitudinal forces on the left side are not discussed further due to their negligible magnitudes. Considering the limited rolled distance of the wheelset, the influence of the discrete support of rail, being considerable as shown in Figure 7, is not further discussed in this work.

From the calculated wear shown in Figure 8, it is first observed that the three wear models predict very similar trends, but different magnitudes. Moreover, irregular wear results from the applied load, and its magnitude changes at various periods, being in good agreement with actual corrugation. Such a magnitude change, to the author's best understanding, may be owing to discrete supports of rail, composition of different vibrations etc, which is out of the scope of the present work. From Figure 9 it is further seen that the predicted wear pattern does not follow the variation of maximum (contact) pressure p_{max}, but that of the maximum tangential contact stress τ_{max}. This is understandable because wear is suggested to be related to friction in the wear models.

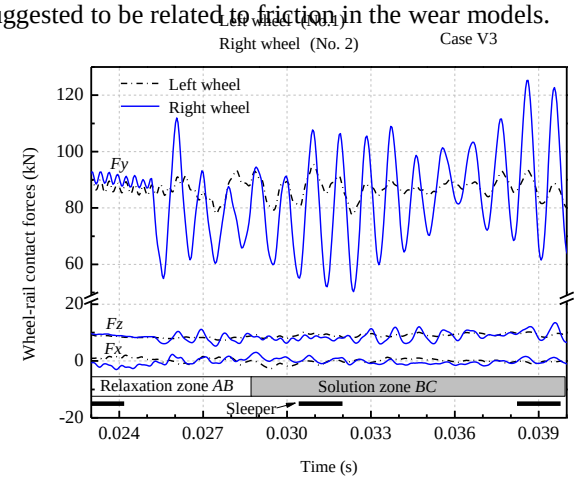

Figure 7 *Contact forces caused by the vertical varying load under μ=0.1*

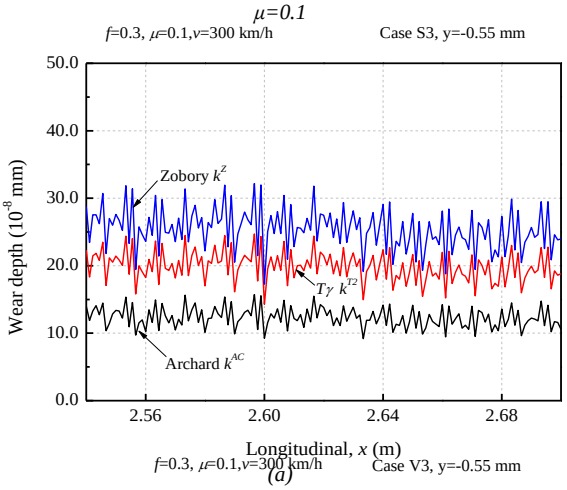

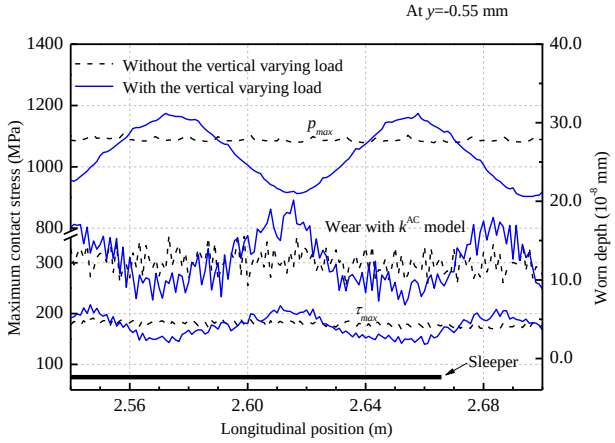

Figure 8 *Wear distributions along the longitudinal axis of the right rail (a) without and (b) with the vertical varying load*

Since the lateral shift of the wheelset is zero in this work, the normal force is approximately equal to the vertical force F_y, and the tangential or creep force (F_τ) are the resultant force of the longitudinal force F_z and the lateral force F_x. Considerable short-wave irregular wear existing in cases with and without the vertical varying load (see Figures 8 and 9) is a typical characteristic of transient analyses, i.e. completely steady rolling can hardly be reached due to continuum vibrations. Note that only results of Archard's model are employed for presentation hereinafter.

Fiure 9 *Wear and stress distributions along the longitudinal axis of the right rail without and with the vertical varying load*

The irregular wear caused by the vertical varying load, extracted by subtracting the predicted wear of cases without the load from that of corresponding cases with the load, are plotted in Figure 10. On the right side where the load is applied, the pattern of the irregular wear seems independent of the varying load if free rolling occurs (μ=0.0). This is mainly due to two reasons: i) the longitudinal and lateral forces are similar in magnitude and different in phase, so that the resultant creep force that determines the wear becomes complicated in pattern, ii) positive and negative peaks both exist in the longitudinal and lateral forces (i.e. the force direction changes), leading to two wear peaks in one period (as shown later in Figures 13 and 16). As the traction coefficient increases (μ=0.02~0.2), negative peaks of the longitudinal force gradually disappear and the lateral force gradually becomes negligible with respect to the longitudinal one, so that a distinct wear pattern corresponding to the applied load results. In such a case, the highest wear occurs slightly before the troughs of the vertical force, and the higher the traction coefficient, the closer to the troughs the highest wear, as shown in Figure 10(b). When friction saturates (μ=0.3), the pattern of the irregular wear becomes to follow that of the vertical force because full sliding always occurs, being nearly out of phase with respect to those in unsaturated cases (rolling-sliding occurs).

On the left rail, the periodic pattern of the resulting irregular wear is not as distinct as that on the right (see Figure 10) because of lower dynamic forces there (Figure 7). Moreover, the irregular wear is almost completely positive, especially under high traction coefficients, suggesting increased average wear on the left rail when the vertical load is applied on the right.

From these results it can be drawn that two kinds of corrugation may result from the applied vertical load. The first kind occurs under repeated applications of rolling-sliding wheels, in which the friction is unsaturated. The pattern of this kind may slightly shift longitudinally as the traction coefficient varies among different wheel passes. The second kind comes into being under the application of full sliding wheels, and its pattern is nearly out of phase with respect to that of the first kind. It can be imaged that corrugation would hardly occur if both rolling-sliding and full sliding wheels pass over a rail section, even though the vertical vibrations repeat completely in every pass. The possibility of corrugation occurrence on the left rail is much lower than that on the right where the dynamic load is applied. Figure 11 further shows the magnitudes of the irregular wear under different traction coefficients derived from the results in Figure 10. It is seen that the second kind of corrugation, if occurs, would grow much faster than the first kind. Note that the vertical force does not change with traction coefficient so that only one force result is plotted separately in Figures 10(a) and (b). The open symbols in Figure 11 refer to low possibilities of corrugation occurrence due to indistinct periodic wear.

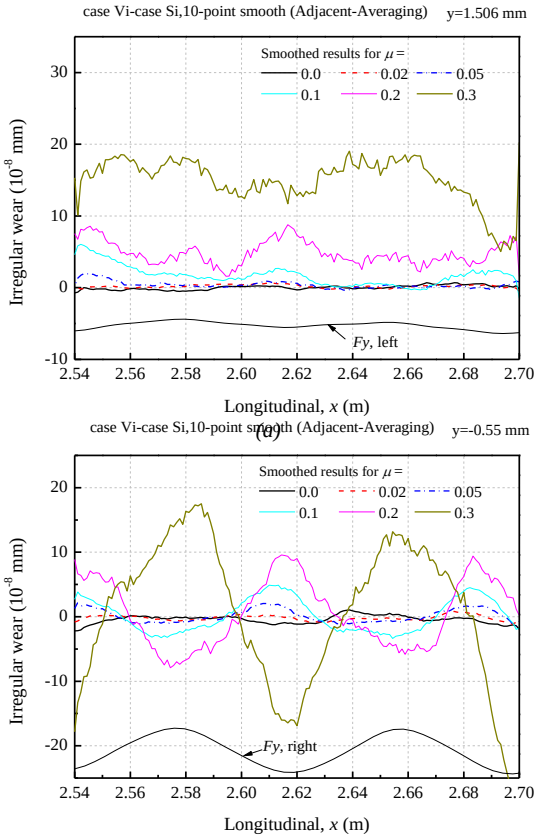

Figure 10 *Irregular wear along the longitudinal axes of (a) the left and (b) the right rails caused by the vertical varying load. 10-point adjacent averaging smoothing is applied to filter out the short-wave oscillations.*

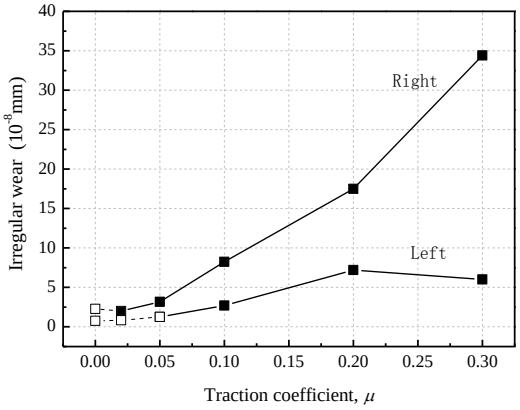

Figure 11 *Magnitudes of irregular wear caused by the vertical varying load under different traction coefficients*

3.2.2 Lateral vibrations

A lateral varying load starting at 0.025 s with peak-to-peak amplitude of 16 kN and at a frequency of 1040 Hz is applied to the left end of the wheelset axis to simulate a lateral vibration. The resulting lateral shift is about 0.8 mm in peak-to-peak amplitude, suggesting a negligible variation of the contact patch in lateral position (as will be seen later in Figure 13).

From Figure 12(a) it is seen that all contact forces show significant variations when the variation starts, especially the vertical and lateral ones. In the running-in stage, the dynamic forces on the left side where the load is applied are larger than those on the right, and then gradually become similar in magnitude, but still different from each other in trend or frequency components. The vertical and lateral forces on the left side are very similar in trend, but not the case on the right. For both sides, the variations of the longitudinal forces are low in magnitude and very different from the other two forces in trend. Furthermore, the longitudinal forces vary similarly under different traction levels before friction saturation, while become to follow that of the vertical contact force when friction saturates, as shown in Figure 12(b). Note that the vertical and lateral forces are not plotted in Figure 12(b) because they are independent of traction level.

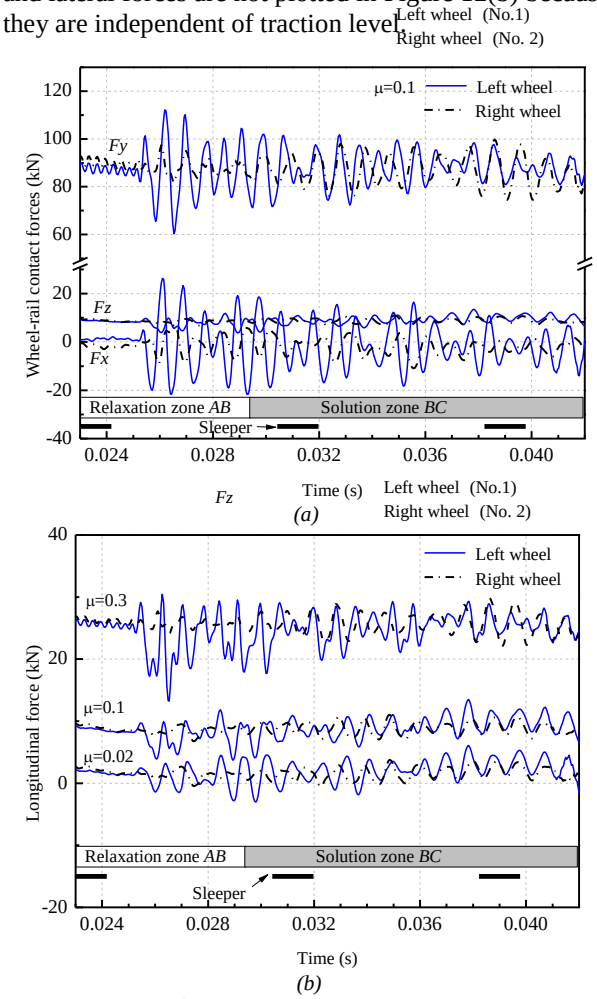

Figure 12 *Contact forces caused by the lateral vibration: (a) Results under μ=0.1, (b) Longitudinal forces under different traction levels*

Figure 13 shows the resulting contour of the irregular wear when μ=0.1. It is seen that the irregular wear on the right rail follows the applied load (with a wavelength of 80 mm), while a much shorter wavelength is observed on the left. This is mainly because on the left side the lateral force is larger than or comparable to the longitudinal force in absolute value at many instants (see Figure 12(a), i.e., the lateral force dominates or plays an important role in the resultant creep force there), resulting in wear peaks at locations where positive and negative peaks of the lateral force occur, as indicated in Figure 13(a). Meanwhile, the composition of the lateral and longitudinal forces also plays a role in the wear pattern on the left side. Such phenomena do not occur on the right rail due to low magnitudes of the lateral force there.

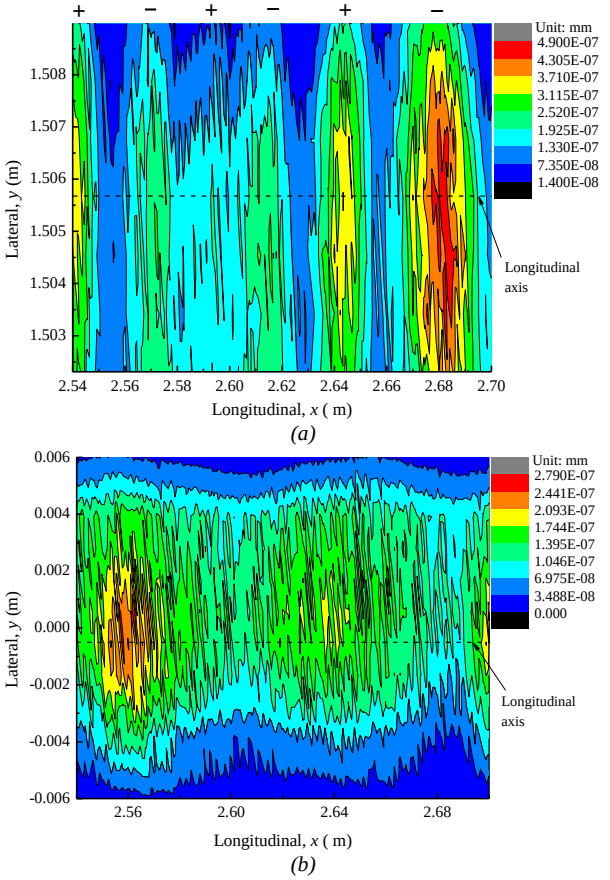

Figure 13 *Irregular wear caused by the lateral vibration under μ=0.1: (a) Left rail. (b) Right rail. Symbols + and – in (a) indicates the positive and negative peaks of the lateral force*

From Figure 14 it is further seen that the irregular wear pattern on the right rail is irrelevant to the traction level when friction exploitation is low, and becomes to follow the vertical force as friction saturates. Such a phenomenon is similar to that of the vertical loading shown above, and two kinds of corrugation as mentioned above are also expected, but the phase difference between the two kinds is smaller. Moreover, as the traction coefficient increases, the irregular wear first increases slightly in magnitude (the longitudinal force is smaller than the lateral force), then rise rapidly and finally become relatively stable again (saturation occurs). Note that completely positive irregular wear also occurs on the right side, suggesting increase of its average wear in the presence of the lateral vibration. The irregular wear on the left rail is not shown due to its complicated pattern.

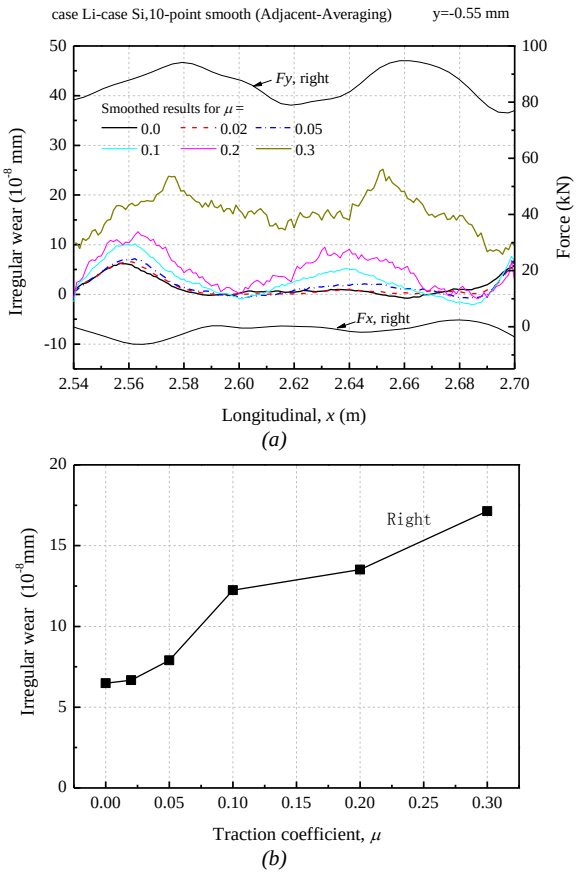

Figure 14 *Irregular wear on the right rail caused by the lateral vibration: (a) Distributions along the longitudinal axis and (b) magnitude variation with traction coefficient. 10-point adjacent averaging smoothing is applied*

3.2.3 Rotational vibrations

The torque *M* (see Figure 1) is set to vary with time to simulate a rotational vibration of the wheelset or the longitudinal interaction between wheel and rail. Before 0.01 s the torque is still assumed to be constant, then starts to vary with peak-to-peak amplitude of 3896.5 Nm (equivalent to a traction coefficient of 0.05) and at a frequency of 621.8 Hz (corresponding to a wavelength of 134 mm at 300 km/h). From Figure 15 it can be observed that the longitudinal forces significantly oscillate owing to the varying torque and their magnitudes gradually increase with time. This means that the frequency of the varying torque is very close to a rotational eigen-frequency of the system. In contrast, the vertical and lateral forces are not influenced considerably by the varying torque (not plotted in the figure).

From Figure 16 it is seen that the resulting irregular wear is more severe on the right rail than that on the left. This is because the drive gear through which the torque is applied is closer to the right wheel (see Figure 1). The wear peak indicated with "–" in Figure 16(b) is a consequence of a negative peak of the longitudinal force. As traction coefficient increases, the negative force peak gradually becomes positive, so that the corresponding wear peak disappears. In the meantime, the wear peaks indicated with "+" increase monotonically. Consequently, a wear pattern corresponding to the varying torque occurs at high traction levels. Furthermore, a phase shift of the wear pattern does not occur as friction approaches saturation, which is different from the cases with the vertical or lateral vibrations.

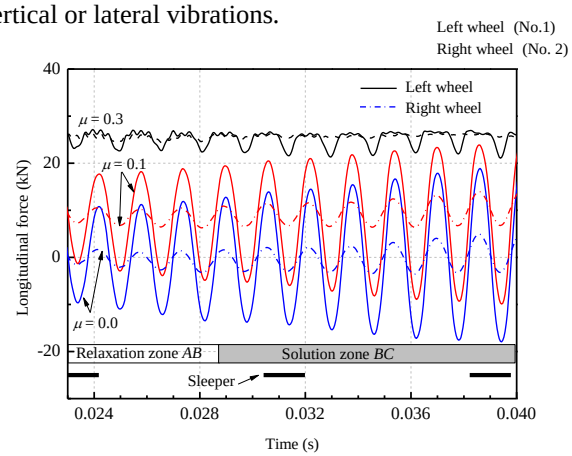

Figure 15 *Longitudinal forces caused by the rotational vibration under different traction levels*

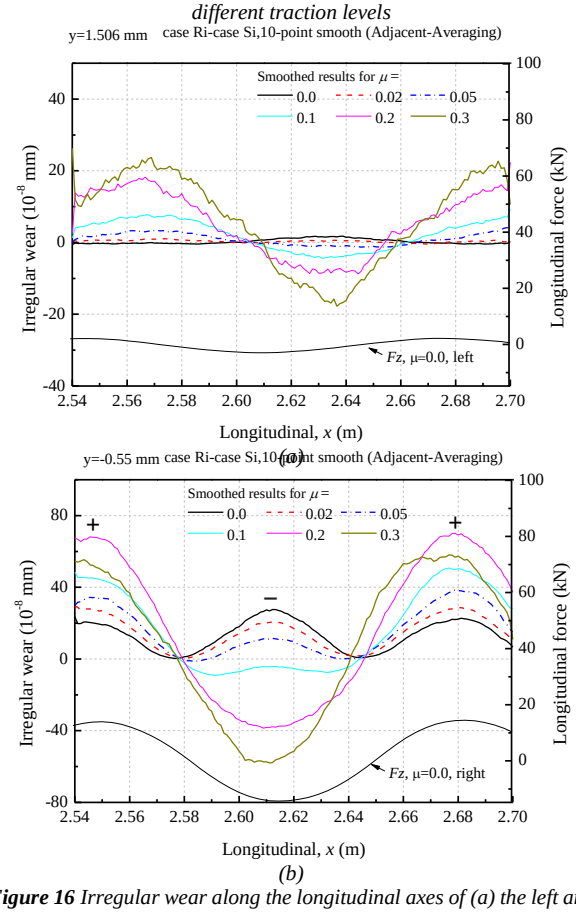

Figure 16 *Irregular wear along the longitudinal axes of (a) the left and (b) the right rails caused by the rotational vibration under different traction levels. 10-point adjacent averaging smoothing is applied*

4. Discussions

4.1. About the wear models

Wear models, usually developed based on low speed tests, are assumed to be applicable to high speed wheel-rail system in this work. Validity of this assumption was ever reported in [32], where the wear rate was found unchanged with the absolute velocity while maintaining the creepage or the traction load. Although the influence of pressure on wear is partly considered by shifting or scaling the tested wear coefficient or rate during the calibration (Section 3.1.2), the wear transition intervals, which are assumed to be the same as those in the literature, may also be dependent on pressure and on scales of test discs. These should further be studied in the

future. For the present work, however, the accuracy of the wear models is not dominant because the focus is placed on the irregular wear resulting from dynamic loads, not on absolute wear.

4.2. About the coupling and corrugation initiation

It has been shown that all three contact forces vary significantly when the vertical or lateral vibrations are applied, and the resulting vertical and lateral forces are independent of the traction level. In contrast, in the cases with the rotational or longitudinal vibration only the longitudinal forces vary significantly, while the vertical and lateral ones keep unchanged. Thus, the vertical and lateral wheel-rail interactions are coupled to a large extend, while the longitudinal interaction is relatively independent in rolling-sliding conditions (unsaturated friction), and becomes dependent on the vertical interaction when approaching full-sliding (friction saturates). Note that this is only valid for the simulated cases where the normal direction approximately coincides with the vertical direction, and the lateral and longitudinal forces are purely creep forces. If significant lateral shift of wheelset is considered, e.g. on curves, the lateral force may be composed of normal forces and creep forces, leading to more complicated phenomenon.

It is found that corrugation can hardly initiate from vertical, lateral and longitudinal vibrations under very low friction exploitation levels due to the indistinct\ complicated patterns and small magnitudes of the resulting irregular wear, especially considering the ever existing roughness/irregularities. Although higher possibilities of occurrence are expected with the increase of the exploitation level, the possibility for cases with vertical and lateral vibrations may further become low if the exploitation level varies between saturation and a sufficiently low value (due to the great phase difference between the two corrugation kinds mentioned above).

For the simulated cases without lateral shift, corrugation initiation from lateral vibrations is less likely with respect to that from vertical and longitudinal vibrations, because the irregular pattern does not correspond well to the vibrations due to the existence of negative force peaks. Of course, if a constant and sufficiently large lateral creep force exists in the meantime, e.g. during curving, the situation would be different because negative force peaks may disappear. Furthermore, one side vibrations would probably lead to asymmetric corrugation, i.e. one rail with severe corrugation and the other with light or no corrugation.

5. Conclusions

An explicit FE model of wheelset-rail rolling contact has been developed to study the coupling of the vertical, lateral and longitudinal wheel-rail interactions at a high speed and in the presence of high frequency vibrations. To calculate the resulting irregular wear, wear models of Archard, *Tγ* and Zobory are implemented and calibrated against field measurements of rail wear. From the presented results without lateral shift of wheelset, the following conclusions are drawn.

1) Wear predictions from the wear models are very close in pattern, but very different in magnitude.
2) In the presence of vibrations at 1040 and 621.8 Hz (passing frequencies of typical corrugation), the vertical and lateral interactions are found to be coupled to a large extent, while the longitudinal interaction is relatively independent under rolling-sliding and dependent on the vertical interaction when approaching full-sliding.
3) The magnitude of the irregular wear increases monotonically with the friction exploitation level.
4) With the increase of the friction exploitation level, the phase of the irregular wear caused by vertical or lateral vibrations are rather stable or changes slightly if only rolling-sliding contact occurs, and changes greatly when approaching full-sliding. For longitudinal vibrations, however, the great phase change does not occur.
5) Corrugation can hardly initiate under very low friction exploitation levels, and its initiation possibility and growth rate increase with the exploitation level; two kinds of corrugation with significantly different phases may separately occur under rolling-sliding and full-sliding conditions when vertical or lateral vibrations are present, but just one kind results from longitudinal vibrations; one side vibrations would probably lead to asymmetric corrugation.

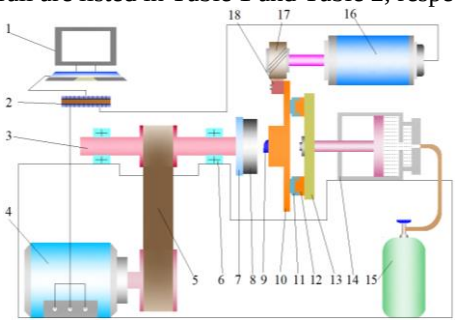
Abstract: Rail grinding technology is an essential part of rail maintenance. In this study, the influence of grinding pressure on the removal behaviours of rail material was investigated through a rail grinding simulation testing apparatus. The results indicate that with the grinding pressure increasing from 1600 to 2200 N, the grinding efficiency obviously increases, which is primarily illustrated by the rise of grinding depth and grinding amount. In contrast, the increase of grinding pressure causes the deterioration of surface quality of rail, which is evaluated with regard to the rise of surface roughness, surface hardness, residual stresses and the aggravation of surface burn. The wear pattern of abrasive grain in the rail grinding process primarily presents as macro fracture. Based on the experimental results, the grinding pressure is optimized considering the section radius of rail head.
Keywords: rail grinding; grinding pressure; material removal; grinding efficiency; surface quality

1. Introduction

With the rapid development of the railway towards high-speed and heavy-haul, rail defects, such as fatigue cracks, corrugation, pitting, and rail wear have become more serious [1,2]. These defects must be eliminated regularly to ensure the safety and stability of the trains. Rail grinding can not only effectively and economically remove these damages [3-5], but also can modify the profiles of the worn rails to keep good wheel-rail contact [6]. Moreover, the grinding scars on the rail resulting from the grinding operations have potential to slow down the generation and propagation of the fatigue cracks [7]. Therefore, rail grinding technology, as an essential rail maintenance measure, is widely used in the railway.

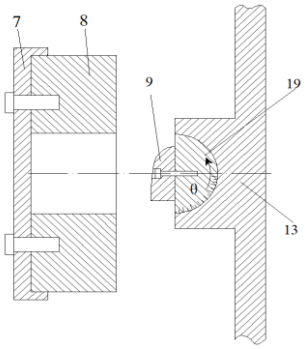
In essence, rail grinding is the process of removing rail material by the grinding wheels. There is complicated material removal and tribological behaviours on the interface between the rail and grinding wheel. The grinding efficiency and surface quality of rail are strongly influenced by many parameters. Many numerical and analytical models were established to simulate the rail grinding process. Zhi et al. [8] analysed the mechanism of material removal in the rail grinding process through the basic cutting theory of single grain. Zhang et al. [9] established a three-dimensional thermal model by simplifying the grinding wheel as a moving heat source, and the effects of grinding parameters on the temperature field of grinding rail were explored. Liu et al. [10] introduced a new analytical model to develop personalized rail grinding patterns by establishing effective grinding profiles per the area difference between the worn and target profiles. In recent years, many experimental studies were conducted to investigate the effects of grinding parameters on the grinding characteristics. Kanematsu et al. [11] developed new grinding stones and studied the effect of the grinding stone properties on the grinding efficiency. Gu et al. [12] investigated the effect of rotational speed of grinding wheel on the rail material removal behaviours. Uhlmann et al. [13] studied the influences of grinding parameters on the rail surface roughness and surface hardened layer depth. Lin et al. [14] measured the temperature of the interface between the rail and grinding wheel during the rail grinding process using a thermocouple, and explored the influences of grinding parameters on the temperature and surface burn of grinding rail. All experiments in these research studies were conducted on a friction testing machine which is composed of two fixed square rail specimens and a rotatable grinding wheel. These experiments have many limits to simulate the actual rail grinding conditions, because the experimental mechanisms and parameters are different from those of rail grinding operations in the field. In particular, the movement of rail grinding train along the rail in the rail grinding operations was not considered and the rail specimens were not designed based on the actual grinding rails.



In this study, the influence of grinding pressure on the removal behaviours of rail material was investigated using a rail grinding simulation testing apparatus. In particular, the section radius of rail head is taken into consideration. The results are of great significance to guide the selection of the grinding pressure in the rail grinding operation in the field.

2. Experimental details

A rail grinding simulation testing apparatus was developed to simulate the interaction between the rail and grinding wheel of actual rail grinding operation. Fig. 1 a shows the schematic diagram of rail grinding simulation testing apparatus. The apparatus primarily consists of a rotatable grinding wheel (8) driven by a DC motor (4) and a movable rail specimen (9) powered by a servo motor (16). Driven by the servo motor (16), the movable fixture (10) installed on the baffle (13) through guide (12) and slider (11) pairs can move at uniform speed through a gear (17)-rack (18) to simulate the movement of rail grinding train in the field. As shown in Fig. 1 b, the rail specimen (9) is fixed on a semicircular rotary fixture (19) that is installed in the semicircular groove of movable



fixture (10). The angle of the rotary fixture (19) relative to the movable fixture (10) can be manually adjusted to change the contact position of the rail specimen (9) and the grinding wheel (8). In the rail grinding process, the rail specimen contacts with the rotary grinding wheel under the push of the cylinder, and moves forward with the movable fixture at a certain speed. The rotational speed of the grinding wheel, the pressure applied on rail specimen, and the feed speed of rail specimen are controlled by a workstation.

As shown in Fig. 1 c, the rail specimen which also can be called half rail head specimen was directly cut from a rail head (U75V). The length of rail specimen is 800 mm and the chemical compositions and mechanical properties of U75V rail are listed in Table 1 and Table 2, respectively.

2#	3600	3	R80	1.6/1.8/2.0/2.2
3#	3600	3	R13	1.6/1.8/2.0/2.2

To simulate the interaction between the rail and grinding wheel as true as possible, the experiment parameters are set by referring to the actual rail grinding conditions. It is well-known that the vehicle speed of PGM-48 rail grinding train is from 1.6 to 16 km/h, and the rotational speed of the grinding wheel is 3600 r/min. This study comprehensively considers the performance of the rail grinding simulation testing apparatus and the actual grinding parameters, the feed speed of the rail specimen is set as 3 km/h, and the rotational speed of grinding wheel is 3600 r/min. The grinding pressure is characterized by the power of grinding motor whose power rating is 22 kW. It is necessary to calculate the experimental grinding pressure based on the principle of equal power. The power consumed during the rail grinding test is equal to that in the actual rail grinding operations.

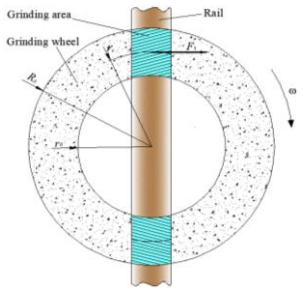
$$P_e = P_0\eta \tag{1}$$

Where, P_e and P_0 are the powers consumed during the rail grinding test and rail grinding operations, respectively. η is the power factor of the grinding motor which is about 0.83. The power consumed during the rail grinding test can be expressed as

$$P_e = F_t r_e \omega = \mu F_n \left(\frac{R_0 + r_0}{2}\right)\left(\frac{2\pi n}{60}\right) \tag{2}$$

Where, F_t is the tangential force in the grinding test that can be obtained by the normal force F_n. μ is the ratio of tangential force to normal force which is taken as 0.52 [15]. Fig. 2 shows the schematic diagram of grinding area.

As a result, the normal force which represents the grinding pressure in the rail grinding test is calculated as 1818 N. In addition, the rail head contains three arcs with different radius: *R*300 mm, *R*80 mm and *R*13 mm. To investigate the effect of the grinding pressure on the removal behaviours of rail material at different rail head positions, the experiments were carried out at these three section radius positions under four types of grinding pressure, which were 1600, 1800, 2000, 2200 N, respectively. The details of experiment parameters are listed in Table 3.



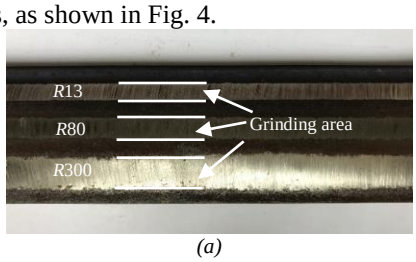


Fig. 2 *Schematic diagram of grinding area.*

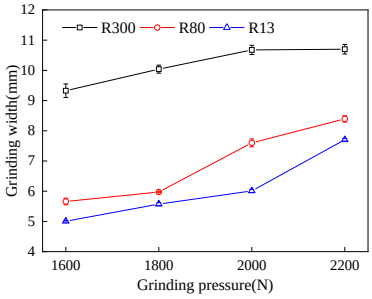
All experiments were conducted under dry and ambient conditions (ambient temperature: 18-23 ℃ and relative humidity: 50 to 70 %). The rail specimens were cleaned in ethanol to clean out the oil stains and rust on the surface before testing. The grinding width was measured by a vernier caliper and the hardness of rail specimens was measured using a Vickers hardness instrument (MVK-H21, Japan). The surface roughness of rail specimens before and after testing was examined through a profilometer (JB-6C, China). The surfaces of rail specimens were observed by a portable microscope (OLYMPUS BX60M, Japan), SEM (JSM-7001F, Japan), and white-light fiber interferometer (NPFLEX BRUKER, America). The surface of rail specimens and grinding debris were observed using OM (OLYMPUS BX60M, Japan), SEM and EDS (JSM-7001F, Japan).



3. Results

3.1. Grinding amount

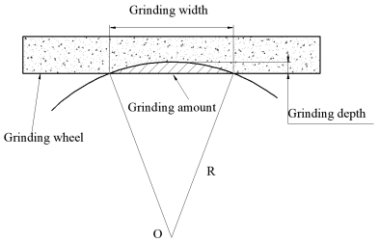
Fig. 3 a shows the rail specimen after grinding. It is clear that the grinding width is different at three types of section radius rail head. Bigger section radius rail head is found to presents wider grinding area, and the grinding width increases with the grinding pressure increasing from 1600 to 2200 N. Moreover, the corresponding grinding depth and grinding amount can be derived according to the geometric relations of these three variables, as shown in Fig. 4.

(a)

(b)

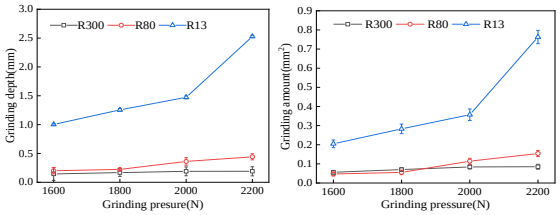
Fig.3 *Grinding width: (a) Grinding area. (b) Grinding width.*

As shown in Fig. 4 a, in the circular arc, the grinding depth can be deduced as



$$h = R - \sqrt{R^2 - (\frac{b}{2})^2} \qquad (3)$$

Where, h is the grinding depth, and R is the section radius (300 mm, 80 mm, 13 mm). b denotes the grinding width. Grinding amount is defined as the area formed by the rail profiles before and after grinding. Thus, the grinding amount can be expressed as



$$a = R^2 \times arcsin(\frac{b}{2 \times R}) - \frac{b \times h}{2} \qquad (4)$$

Where, a represents the grinding amount. The calculated results of the grinding depth and grinding amount are shown in Fig. 4 b and Fig. 4 c, respectively.

Obviously, the grinding depth and grinding amount increase with the increase of grinding pressure. Moreover, the grinding depth and grinding amount at bigger section radius largely outweigh those at smaller section radius.

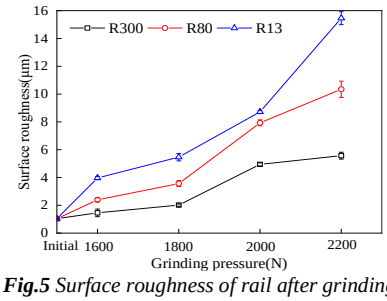
3.2. Surface integrity

Surface roughness of rail after grinding is one of the most important aspects to evaluate the grinding quality, which has a significant impact on the wheel-rail rolling contact. Obviously, the surface roughness of rail specimen is found to increase with the grinding pressure increasing from 1600 to 2200 N. In particular, when the grinding pressure increases to 2000 N, the surface roughness at *R*13 is close to 10 μm, which is the allowable maximum value of surface roughness in the rail grinding operations in the field. Moreover, when the grinding pressure increases to 2200 N, the surface roughness at *R*13 and *R*80 is over 10 μm. In this sense, the grinding pressure cannot exceed 2000 N at *R*13 and 2200 N at *R*80.

The results in Fig. 6 can further confirm the varying trend of surface roughness. It is clear that with the increase of the grinding pressure, the depths of grinding marks on the rail surface increase. When grinding at smaller section radius rail head, the depths of grinding marks are higher.



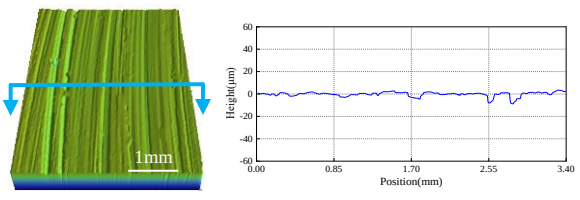


Fig.5 *Surface roughness of rail after grinding.*

(a)

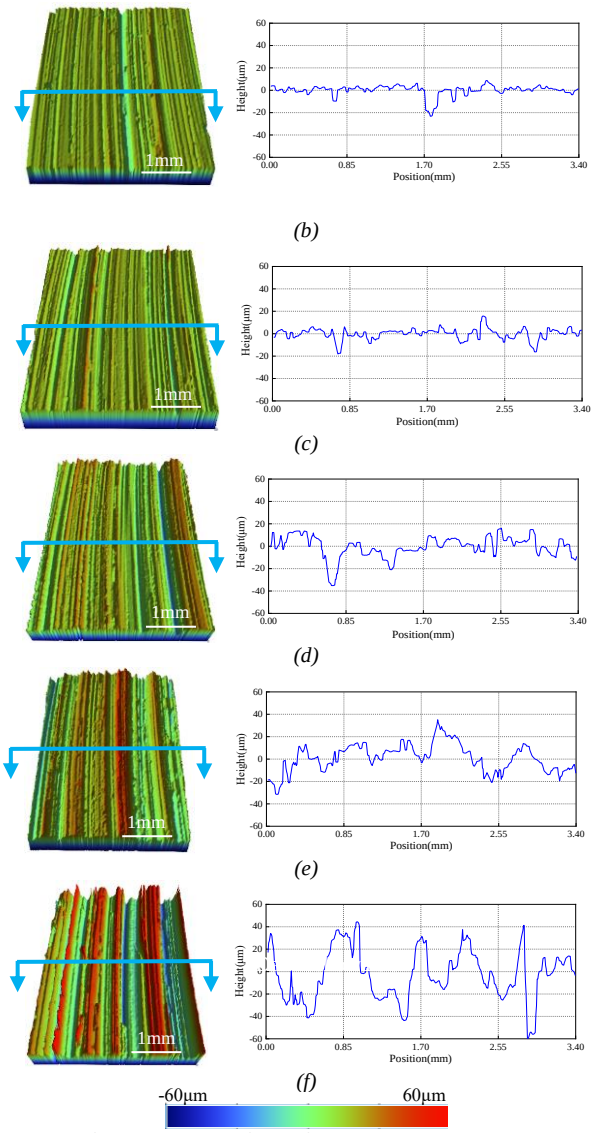

Fig.6 *Surface topography of rail after grinding: (a) R300, 1600 N. (b) R300, 1800 N. (c) R300, 2000 N. (d) R300, 2200 N. (f) R80, 2200 N. (e) R13, 2200 N.*

The surface morphologies of rails after grinding observed by SEM are shown in Fig. 7. The rail surfaces are found to be composed of three types of features: scratch, plastic flow, and flat. The scratch primarily includes the micro-groove and the ploughing. There is no visual crack on the rail surfaces. Obviously, with the increase of the grinding pressure, the rail surface presents more scratches and plastic flow but less flat. Moreover, more scratches and plastic flow appear at the smaller section radius rail head after grinding.

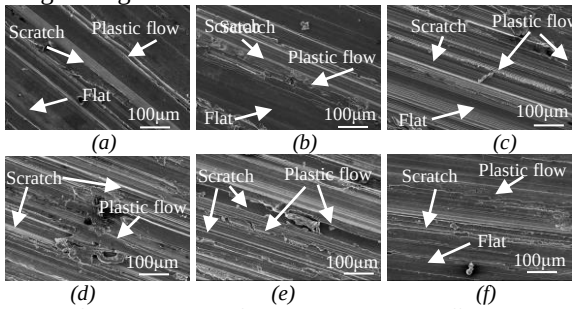

Fig.7 *Surface morphology of rail specimens under different grinding pressure: (a) R13, 1600 N. (b) R13, 1800 N. (c) R13, 2000 N. (d) R13, 2200 N. (f) R80, 2200 N. (e) R300, 2200 N.*

3.3. Surface burn

As well known, it is an essential method to judge surface burn according to the surface color, which is widely used in many grinding fields. OM observation in Fig. 8 shows that the rail surfaces after grinding usually present metallic luster. When the grinding pressure increases to a certain value, the rail surfaces start to appear light yellow burn or deep yellow burn. In addition, the smaller section radius rail head is more prone to appear surface burn compared with the bigger section radius under the same grinding pressure. In particular, when the grinding pressure increases to 2200 N at *R*13, the blue burn appears in the bottom of the groove as shown in Fig. 9.

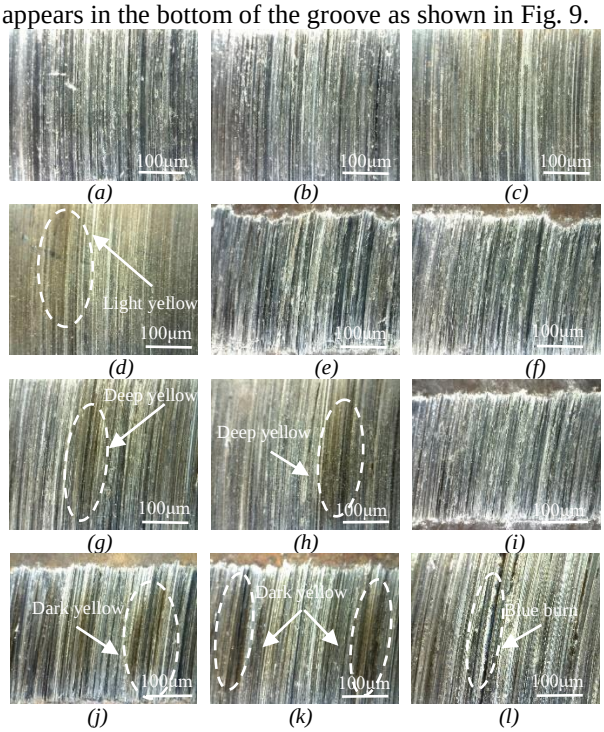

Fig.8 *Evolution of the surface burn: (a) R300, 1600 N. (b) R300, 1800 N. (c) R300, 2000 N. (d) R300, 2200 N. (e) R80, 1600 N. (f) R80, 1800 N. (g) R80, 2000 N. (h) R80, 2200 N. (i) R313, 1600 N. (j) R313, 1800 N. (k) R313, 2000 N. (l) R313, 2200 N.*

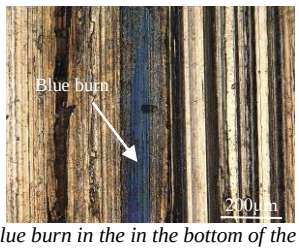

Fig.9 *Blue burn in the in the bottom of the groove.*

SEM micrographs of the sections cut from the rail specimens are shown in Fig. 10. When the grinding pressure increases to 2200N, 2000N, 1600N when grinding at *R*300, *R*80, *R*13, respectively, the plastic deformation starts to appear below the rail surface, and the white etching layer (WEL) starts to appear on the rail surface. Obviously, with the increase of the grinding pressure, the thickness of plastic deformation and the WEL increase. The plastic deformation is easier to appear at smaller section radius rail head under the same grinding pressure after grinding. In addition, it can be found in Fig. 11 that the thickness of WEL in the central region is higher than that in the marginal region. The

SEM micrograph of WEL exhibited in Fig. 12 shows that the plastic deformation emerges below the WEL.

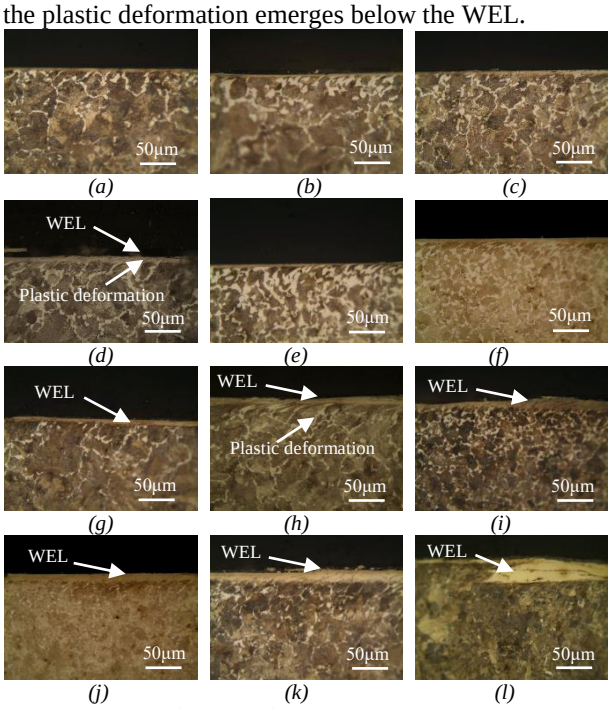

Fig.10 *Evolution of plastic deformation: (a) R300, 1600 N. (b) R300, 1800 N. (c) R300, 2000 N. (d) R300, 2200 N. (e) R80, 1600 N. (f) R80, 1800 N. (g) R80, 2000 N. (h) R80, 2200 N. (i) R13, 1600 N. (j) R13, 1800 N. (k) R13, 2000 N. (l) R13, 2200 N.*

Fig.11 *Variation of the thickness of WEL in the whole grinding area.*

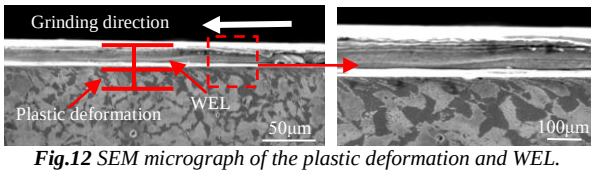

Fig.12 *SEM micrograph of the plastic deformation and WEL.*

The surface hardness under different grinding pressures are found to increases significantly after grinding as shown in Fig. 13. Obviously, the surface hardness increases with the grinding pressure. Moreover, the surface hardness of rail is higher when grinding at bigger section radius rail head.

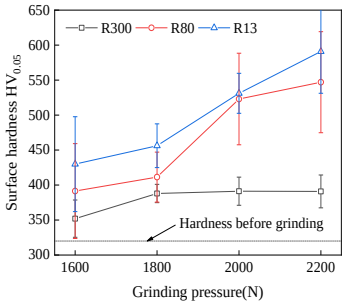

Fig.13 *Surface hardness of rail before and after grinding.*

The varying trends of the residual stresses perpendicular and parallel to the grinding scratches with the grinding pressure are shown in Fig. 14. It can be found that the rail surface before grinding presents residual compressive stress of -125Mpa. After grinding, the value of residual stress on the rail surface becomes positive, which indicates the residual tensile stress emerges. Moreover, the residual stress in the central grinding region is higher than that in the marginal grinding region. In particular, the residual stress parallel to the grinding scratches is lower than that of perpendicular to the grinding scratches. In general, the residual stress increases with the grinding pressure increasing from 1600 to 2200 N.

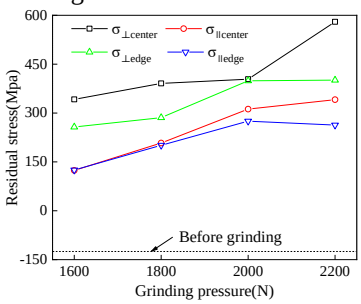

Fig. 14 *Residual stress of rail surface before and after grinding.*

3.4. Grinding debris and abrasive wear

The mechanism of material removal can be further explored by the morphology and composition of the grinding debris. The SEM micrographs of grinding debris are shown in Fig. 15. It is concluded that the grinding debris can be divided into three types of shapes: curled debris, lump debris, and spherical debris. The micrographs of curled debris and spherical debris are shown in Fig. 16. The surface of spherical debris consists of smooth cracks and irregular convex peaks. Moreover, the curled debris presents scale-like surface and smooth surface on its two sides. From the EDS spectrum of two types of debris in Fig. 17, it can be found that the spherical debris and curled debris have same chemical elements but differ in elements contents. Obviously, the content of oxygen in the spherical debris is higher than that of curled debris. Generally, with the increase of grinding pressure, the contents of lump debris and curled debris increases. Moreover, when grinding at smaller section radius rail head, the lump debris and curled debris is more.

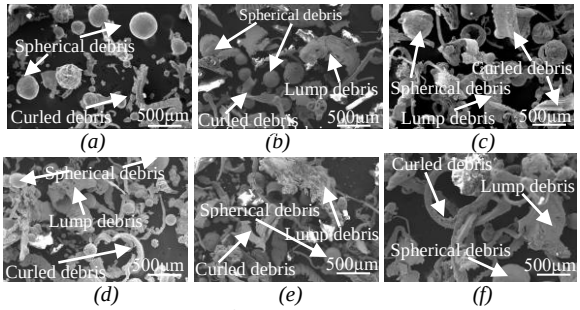

Fig.15 *SEM micrographs of the grinding debris: (a) R80, 1600 N. (b) R80, 1800 N. (c) R80, 2000 N. (d) R80, 2200 N. (f) R13, 2200 N. (e) R300, 2200 N.*

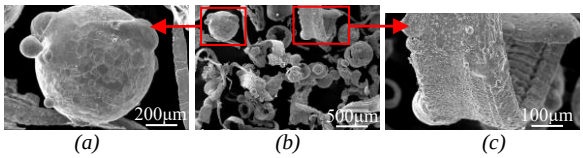

Fig. 16 *SEM micrographs of the spherical debris and curled debris: (a) Spherical particle. (b) Grinding debris. (c) Curled debris.*

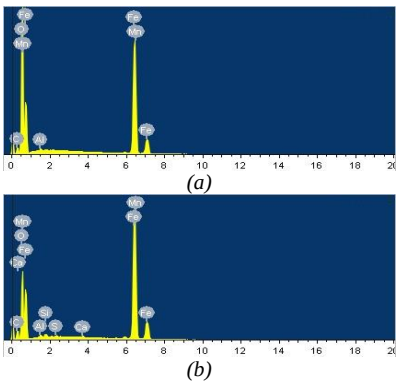

Fig. 17 *EDS spectrum: (a) Spherical debris. (b) Curled debris.*

SEM micrographs of the abrasive grains dropped from the grinding wheel are shown in Fig. 18. The main wear mechanism of abrasive grain is found to be macro fracture. When the grinding pressure increases to 2200 N at *R*80, the total break-out grain was found, which is shown in Fig. 18 d.

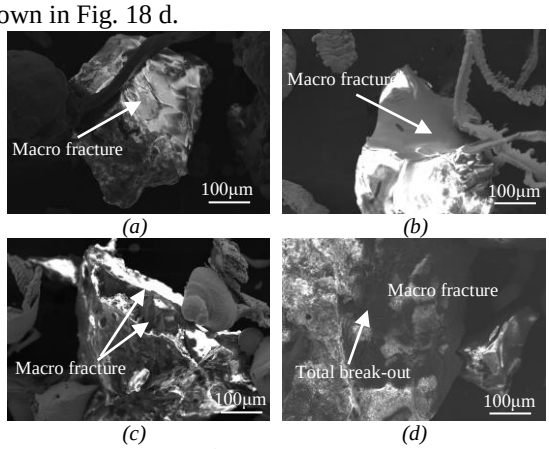

Fig.18 *SEM micrographs of worn abrasive grain: (a) R80, 1600 N. (b) R80, 1800 N. (c) R80, 2000 N. (d) R80, 2200 N.*

4. Discussion

There is complex material removal and tribological behaviours on the interface between rail and grinding wheel during the rail grinding process. The rail grinding simulation testing apparatus was developed in this study to simulate the interaction between the rail and grinding wheel based on the actual rail grinding conditions in the field. A series of experiments were conducted to investigate the effect of grinding pressure on the removal behaviours of rail material when grinding at three types of section radius rail head. Obviously, the grinding pressure not only affects the grinding efficiency but also affects the grinding quality.

The grinding width, grinding depth, and grinding amount all increase with the grinding pressure. Fig. 19 a shows the process of abrasive grain pressing into rail. When the grinding pressure increases, the pressure applied on single grain increases, which leads to the increase of cutting depth. Moreover, the number of grains involved in cutting also increases with the increase of grinding pressure. Thus, these two factors result in the significant increase of material removal amount. In addition, because the grinding width is smaller when grinding at smaller section radius rail head, the number of the grains involved in cutting is less than that at bigger section radius rail head under same grinding pressure. This also results in the big pressure applied on a single grain and further lead the grinding depth to increase. The increase of grinding depth caused by the increase of grinding pressure can also lead the rail surface roughness to increase as shown in Fig. 5. According to reference [15, 16], the grinding surface roughness is influenced by many factors and the relationship is expressed as

$$R_a = \frac{C_{Ra} v_\omega{}^a a_p{}^b f_a{}^c K_1 K_2 K_3}{v_s{}^d d_s{}^e b_s{}^f} \quad (5)$$

Where, υ_ω, υ_s, and a_p represents the feed rate of workpiece, rotational speed of grinding wheel and grinding depth, respectively. f_a, d_s and b_s are axial feed, diameter, and width of the grinding wheel, respectively. C_{Ra} is a coefficient related to the physical and mechanical property of ground workpiece, K_1, K_2, and K_3 are coefficients related to the grinding conditions. It can be found that the surface roughness increases with the grinding depth. As a result, with the increase of the grinding depth caused by the increase of grinding pressure, the surface roughness increases. The surface morphology of rail in Fig. 6 can further approve the change of surface roughness.

The grinding scratches and plastic flows in Fig. 11 were formed at the cutting stage. As shown in Fig. 19 b, with the grain moving forward, the rail material is cut from the rail surface and the material flows upheaved and stacked at two sides of the furrows [17]. Eventually, the residual stress parallel and perpendicular to the scratches is formed, as shown in Fig. 14. Residual tensile stress is harmful to the service life of the ground workpiece because they promote the formation and propagation of the fatigue crack [18]. The residual stress in the centre of grinding area is higher than that in the edge of grinding area, which is primarily because the cutting depth is higher in the centre of the grinding area due to the circular rail head. Generally, the residual stress perpendicular to groove is higher compared to the parallel direction, which is in agreement with the previous research study [19].

Generous heat is produced on the interface between the rail and grinding wheel in the process of rail grinding. With the grinding pressure increasing, the grinding temperature significantly increases [9, 14]. Excessive temperature can cause surface burn, and the colour of burn ranges from light yellow to blue with the temperature increasing, as shown in Fig. 8. The surface burns usually accompany the appearance of WEL. Moreover, there is plastic deformation parallel to the grinding direction underneath the WEL. The WEL on rail surface caused by the rail grinding can be pressed into deeper pearlitic matrix under the wheel-rail contact stress, which will results in severe and extensive cracks initiations [20]. Therefore, to avoid the appearance of surface burn, WEL, and exorbitant surface hardness, the grinding pressure cannot exceed 2000, 1800, and 1600 N when grinding at *R*300, *R*80, *R*13, respectively.

Debris formation is an essential component in the material removal theory. Actually, rail grinding is composed of many processes of slidings, ploughings, and cuttings accomplished by the abrasive grains on the end face of grinding wheel. Malkin [21] observed the debris and found that the debris is formed at the cutting stage and the shape and size were irregular which can be

attributed to the thermal effect during the grinding process. As shown in Fig. 19, the curled debris presents a scale-like surface and a smooth surface on its two sides, respectively. This can be well explained by the "card model" of Piispanen [22]. As shown in Fig. 19 c, the rail material in the first shearing zone was under large shear stress, and was cut to be a pile of cards when the grain cuts the rail material. With the grain moving forward, these cards slip along the grain surface. Thus, the debris surface contacting with grain is smooth and another appears scale-like. The lump debris is transformed from the curled debris, which resulted from the extrusion between the ground rail and grains. Fig. 17 shows that the chemical elements of spherical debris is same as that of curled debris but the content of oxygen is higher, which indicates the spherical debris is formed by the melted rail material. This melting process primarily occurred at the grinding point between the grain and the rail, in which the grinding temperature exceeded the melting point of rail material [23].

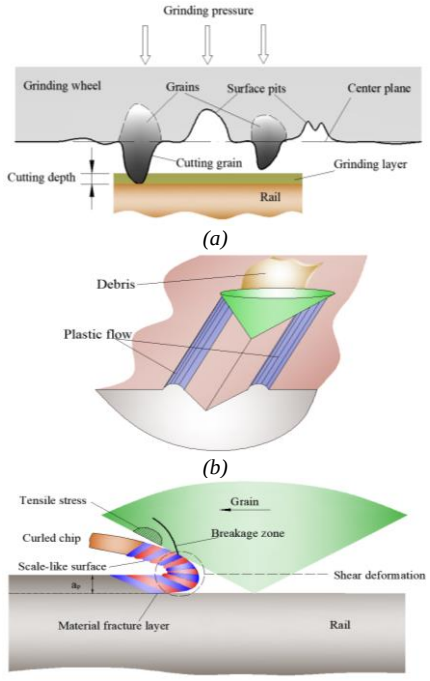

Fig. 19 *Mechanism of material removal in rail grinding: (a) Abrasive grain cutting. (b) Formation plastic flow formation debris. (c) Plastic flow of rail material.*

The wear of grinding wheel during the process of material removal plays a nonnegligible role in the economics of grinding [24]. It can be seen from Fig. 21 that the wear of grinding wheel is mainly caused by the fractures of grains. The reason of grain fracture is primarily concerned with the size and distribution of the stress on the grain [25, 26]. As shown in Fig. 19 c, the breakage zone of the grain is located on the point with maximum tensile stress [15]. On the one hand, this self-sharpening can increase the grinding capacity of the grinding wheel. On the other hand, the fracture of grain can make the grinding wheel surface more uneven which would result in higher surface roughness of the rail after grinding. Therefore, when the surface roughness is too large after grinding, the grain fracture can be taken into consideration apart from the grinding parameters.

In summary, the grinding pressure has a remarkable influence on the removal behaviours of rail material. It is of great significance to select the reasonable grinding pressure during the rail grinding operations in the field. Based on the results of grinding amount and surface quality of rail, the grinding pressure can be divided into three regions, which considers the differences of section radius. As shown in Fig. 20, in the region I, although, the surface quality of the rail is ensured, the grinding amount is sufficient. In contrast, in the region III, the grinding amount is enough, but the surface quality of the rail is worse. In the region II, the grinding amount and surface quality can be ensured simultaneously. In particular, the required grinding pressure is lower when grinding at smaller section radius rail head.

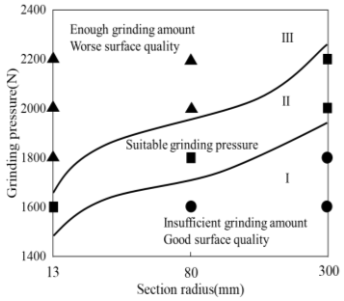

Fig. 20 *Division of the grinding pressure.*

5. Conclusion

1. A rail grinding simulation testing apparatus was developed to simulate the interaction between the rail and grinding wheel.
2. The grinding pressure has a significant effect on the grinding efficiency. With the grinding pressure increasing from 1600 to 2200 N, the grinding width, grinding depth, and the grinding amount all increase.
3. Surface quality of rail after grinding is significantly influenced by the grinding pressure. With the increase of grinding pressure, surface roughness, surface burn increase, which brings the rises of surface hardness, plastic deformation, WEL and residual stress of rail.
4. The formation of grinding debris is related to the grinding pressure. Moreover, the wear pattern of abrasive grain in the process of rail grinding primarily presents as macro fracture.

Abstract: Differences of wear volume, work hardening, plastic deformation and surface cracks between 5 types of wheel materials withU71MnG rail material were investigated by rolling friction and wear testing with a twin-disc test apparatus. The results show that harder wheel specimens tend to have better wear resistance and anti-fatigue performance. D2 and ER8C wheel specimens are proved to have superior comprehensive performance than ER8. Recommendations are given for wheel/rail material selection in high speed railways.

Keywords: friction and wear; hardness; wheel material; rail material

1. Introduction

The material selection and matching of wheel/rail is an important aspect of wheel/rail interaction. Reasonable matching of materials can balance the wear of wheel and rail, and reduce damage of both and improve their contact conditions. Thus, the service lives of both wheel and rail are prolonged [1~3]. In recent years, many scholars have carried out related research studies on wheel rail hardness and material matching [4~6], but there are few reports about specializing the wheel rail materials for high-speed railway.

With larger radius of track and smaller axle-load, the performance of wheel and rail material on high speed railway is quite different from that of conventional railway. In this study, rolling friction and wear testing which highlights the hardness ratio of wheel/rail materials were conducted on a twin disc testing apparatus and the featuring wear and RCF damages were analyzed. Recommendations based on these results are given to reduce the damage and wear of wheel and rail, and to promote the wheel/rail material selection in the operation.

2. Testing methods

2.1. Materials

The rail material used in this test is U71MnG which is a high speed rail for passenger dedicated line in China. The wheel materials include ER8, ER8C, ER9, SSWQ3R and home-made high speed wheel material D2, altogether 5 types of combinations. The wheel rail specimens were taken from the actual wheels and rail parts. The wheel specimen was taken from the rim of the wheel (near the tread), and the rail is taken from the railhead. The sampling position is shown in Figure 1. The micro Vickers hardness tester was used to measure the hardness of the contact surface for different wheel and rail specimens. The original hardness of the wheel/rail specimens and the hardness ratio (wheel over rail) of different test combinations is shown in Table 1. The hardness values of the ER8C, ER9 and D2 wheel materials are very close. Therefore, these 5 types of wheel materials can be basically classified to 3 hardness grades.

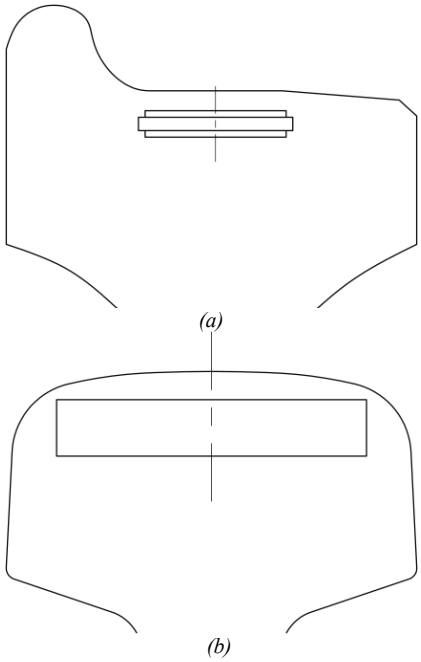

Figure 1 *Sampling position diagram of wheel and rail specimen: (a) Wheel. (b) Rail*

Table 1 *Hardness value of specimens and hardness ratio of the pairs.*

Rail material & Average hardness/$HV_{0.5}$	Wheel material & Average hardness/$HV_{0.5}$	Hardness ratio of wheel/rail specimens
U71MnG 281HV	ER8 277HV	0.96
	D2 288HV	1.02
	ER8C 290HV	1.03
	ER9 290HV	1.03
	SSWQ3R 328HV	1.17

2.2. Testing methods

Friction and wear testing of five types of wheel specimens (i.e. ER8, D2, ER8C, ER9 and SSWQ3R) with U71MnG rail specimens were conducted using a MJP-30A testing apparatus. The relative position and dimensions of the wheel and rail specimen are shown in Figure 2. The experiments parameters are listed in Table 2.

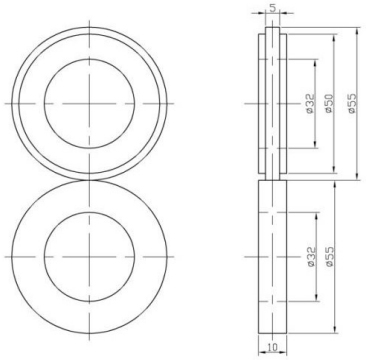

Figure 2 *Diagrams of wheel and rail specimen on twin disc apparatus.*

Table 2 *Testing parameters.*

Parameter	Value
Simulated axle load (t)	17
Main spindle rolling speed(r/min)	500
Slip ratio (%)	0.75
Vertical load(kN)	1.5
Hertz contact stress(MPa)	900
Total number of revolutions	50000
Friction condition	Dry

Specimens were all soaked in anhydrous ethanol and then cleaned by ultrasonic before and after the testing. Measurements of weight, hardness and roughness of each specimens were done after the cleaning. When the measurements were finished, specimens were then cut into cubes for surface and crack morphology observation under microscope.

3. Results

3.1. Friction coefficient

Fig. 3 shows the friction coefficient curves of the 5 testing groups (name after wheel material). As the revolution number growing, the friction coefficient between wheel and rail has experienced a certain process. In the early stage, the friction coefficient increases rapidly and reaches the peak shortly, then gradually stabilizes to a constant value. This actually represents the changing process from the running-in stage to stable wear stage. Finally, the friction coefficient between the specimens in the stable wear stage is concentrated in the range of 0.30~0.40. There is no significant difference among 5 testing groups.

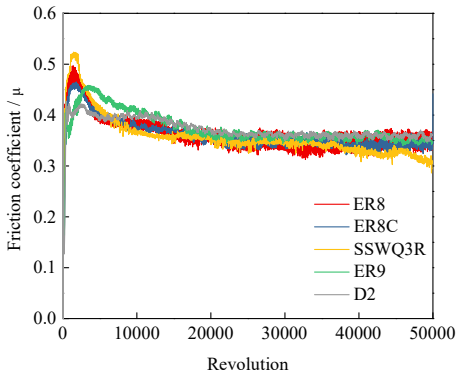

Figure 3 *Friction coefficient curves of the 5 testing groups.*

3.2. Wear

The wear volume of the wheel and rail specimen was obtained. Figure 4 is the comparison of the individual (columns) and system (line) wear of wheel and rail specimens from 5 groups. For wheel specimens, the wear of ER8 wheel specimen is the largest. SSWQ3R wheel specimen has the least wear volume, almost half of ER8. While the wear of ER8C and D2 and ER9 wheels are very close, ranking at the middle level. Apparently, the wheel with higher original hardness specimens tend to have smaller wear but the wear of rail in the pairs is higher after testing, except that the wear of rail specimen in the ER8 test group is higher than that in D2 test group. For D2 and ER8 test groups, although the hardness values of wheel specimens are higher than rail, the hardness ratios of which are 1.02: 1 and 1.03: 1, respectively. Wheel specimens tend to wear more seriously than rail. In the 5 test groups, the system wear of D2 test group is the smallest, and the ER8 test group is the largest.

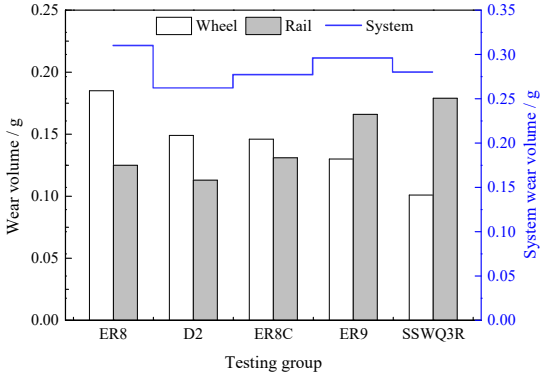

Figure 4 *Individual and system wear volume of wheel and rail specimens*

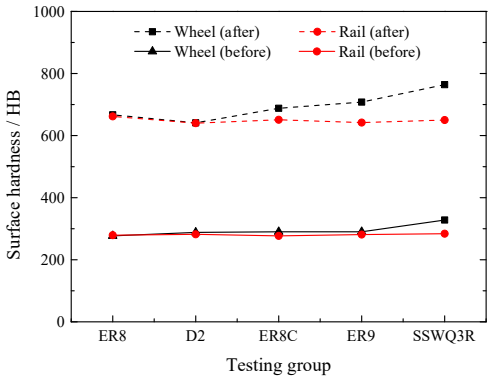
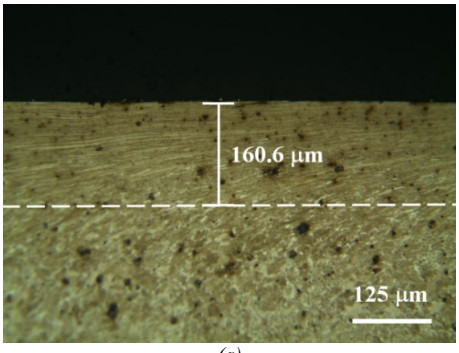
3.3. Work hardening and plastic deformation

The hardness values of wheel and rail specimens before and after testing (the solid line) (the dotted line) are shown in Figure 5. The surface hardness of rail specimens in different groups is almost the same regardless of testing, which means they had experienced a similar hardening process. For wheel materials, the maximum value was obtained on SSWQ3R after testing, and the hardness values of ER9, ER8C, ER8 and D2 decrease in turn. The post-testing hardness inherits from the pre-testing hardness. In addition, the hardness value of wheel specimen tends to grow faster than rail. The gap

between the wheel and rail is also enlarged with the increase of the original hardness of wheel specimen from ER8C to SSWQ3R. Thus, the gap between the wear resistance of 5 wheel materials is further amplified after the testing.





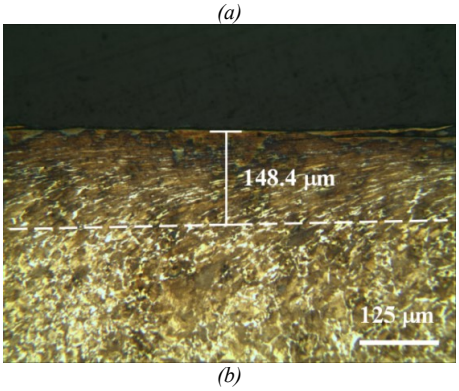


Figure 5 *Surface hardness of wheel and rail specimens before and after test.*

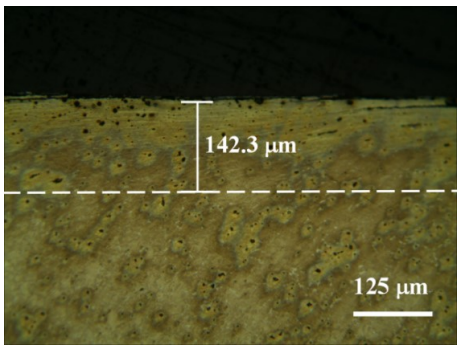

Fig. 6 shows the longitudinal section of wheel and rail specimens along the rolling direction. The surface structure of specimen is elongated under the joint action of vertical contact stress and longitudinal shear stress, forming a certain depth of deformation layer. Table 3 is a statistical comparison of the depth of the deformation layer on wheel and rail specimens from different groups. The depths of deformation layer on the rail specimens in different groups are very close, and the depth for wheel specimen is negatively correlated with the original hardness, which is related to its yield strength [7]. The depth of deformation layer for the ER8 wheel specimen is about 160μm, which is 1.5 times than that of the SSWQ3R material.

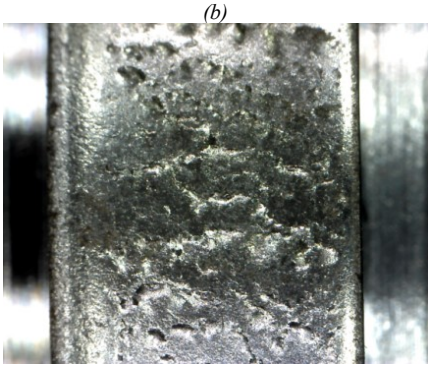
D2-U71MnG	148.8	122.5
ER8C-U71MnG	142.3	120.0
ER9-U71MnG	128.0	116.9
SSWQ3R-U71 MnG	104.7	124.1

3.4. Surface morphology and damages



The surfaces of wheel and rail specimens after testing are shown in Figure 7. It can be found from the images that the surface of the wheel specimen is filled with flake layer caused by contact fatigue and pits formed by cracking of the layer. The surface of wheel specimen is bright, but rough for the rail specimen, full of fine pits, abrasion marks and debris adhesion. The fatigue on the wheel surface is gradually weakened with the increase of its hardness. The crack length and the size of the flake layer on the surface of the ER8 wheel are significantly larger than that of the other wheel materials, and the state of the SSWQ3R is the best. Most rail specimens share similar macroscopic morphology, except that the rail specimen coupled with the SSWQ3R is worse.

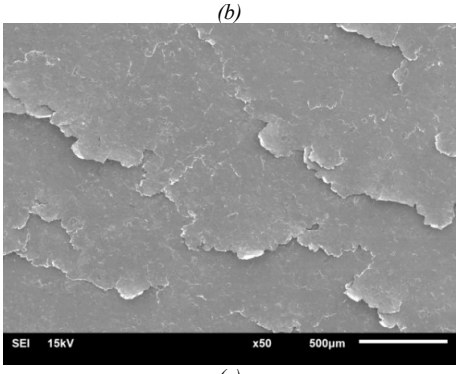
(f)

Figure 7 *Photos of wheel and rail specimens' surfaces after testing: (a) ER8. (b) D2. (c) ER8C. (d) ER9. (e) SSWQ3R. (f) Rail.*



SEM photos of wheel and rail specimens are shown in Figure 8. The wheel specimen shows typical fatigue wear characteristics, and the surface covers peeling lamellae. In the 5 types of wheel materials, the peeling lamellae of the ER8 material have the largest size. The higher the hardness of the wheel material is, the smaller the size of the peeling lamellae is. For rail specimen, the lamellae size is small, but shows considerable amounts. The local roughness on rail specimen is larger and the surface which has more debris adhesion. This can be observed in in Figure 7 f. The warped or open lamellae significantly increase the surface roughness to create cluster or granular debris, which may give rise to abrasive wear mode. The lamellae produced by the adhesion cause material loss, and accelerate the wearing process when the lamellae fall off and turn into abrasive particles. It can be seen that the size of the peeling lamellae has a great influence on the wear behaviour of the wheel material.

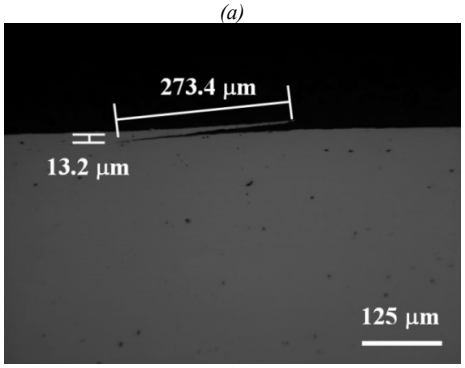
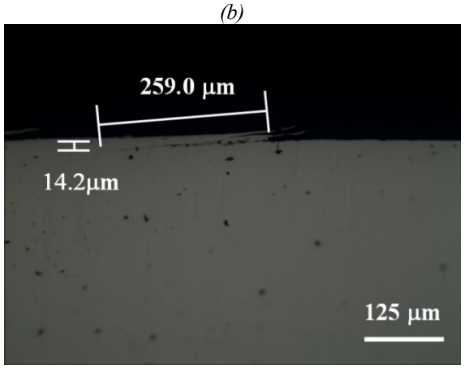
(e)

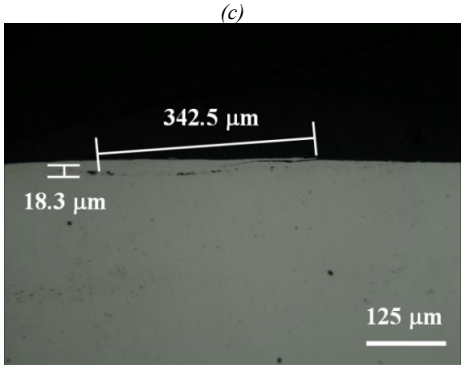


(f)

Figure 8 *Microscopic morphology of wheel and rail specimens: (a) ER8. (b) D2. (c) ER8C. (d) ER9. (e) SSWQ3R. (f) Rail.*



Sections of specimens are shown in Figure 9. The strip, which is about to be separated from the specimen, is the peeling layer in Figure 8, which is formed by the expansion of the surface crack. The crack length and depth of ER8, D2, ER8C and SSWQ3R wheel materials decrease in turn. In the 5 materials, the average crack length of the ER8 material is the largest, and the shortest cracks appear on SSWQ3R material, while there is no obvious difference for rail specimens. It is noteworthy that the maximum crack depth and the average crack depth of ER9 materials are larger than that of ER8C and D2 materials, which may be related to the its lower fracture toughness.



(a)

(b)

(c)

(d)

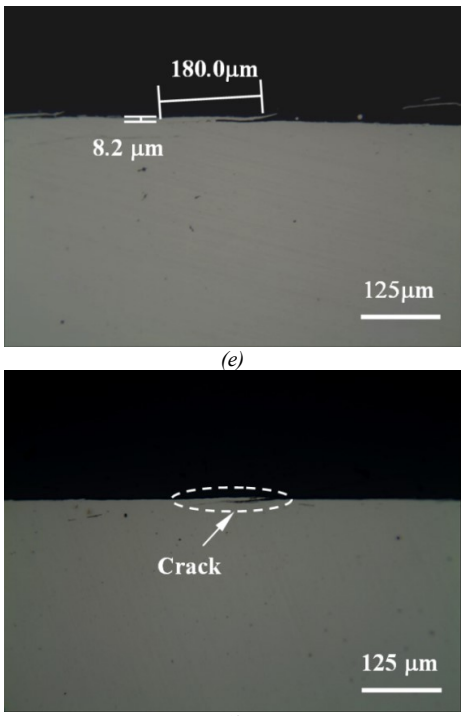


Figure 9 *Cracks on sections of wheel and rail specimens: (a) ER8. (b) D2. (c) ER8C. (d) ER9. (e) SSWQ3R. (f) Rail.*

The friction and wear process can be intuitively understood by collecting and observing the debris [8]. In the experiment, three groups of ER8, ER8C and SSWQ3R were selected, for they make a gradient of hardness ratio, to collect wear debris. SEM photos of the debris are shown in Figure 10. The size and thickness of the debris in the ER8 group are significantly larger than that of ER8C and SSWQ3R, which is corresponding to the characteristics of the peeling layer in Figure 8 and Figure 9. In the initial stage of wear, the bonding, pitting and micro furrow effect produced by the adhesion and oxidation wear make the surface roughness grow gradually, while the longitudinal shear force makes the plastic deformation and work hardening accumulate. When the deformation and hardening of the surface tissue developed to a certain degree, the fatigue wear characterized by lamellar exfoliation began to occur, the system gradually entered a stable wear stage with the continuous falling off of the lamellae.

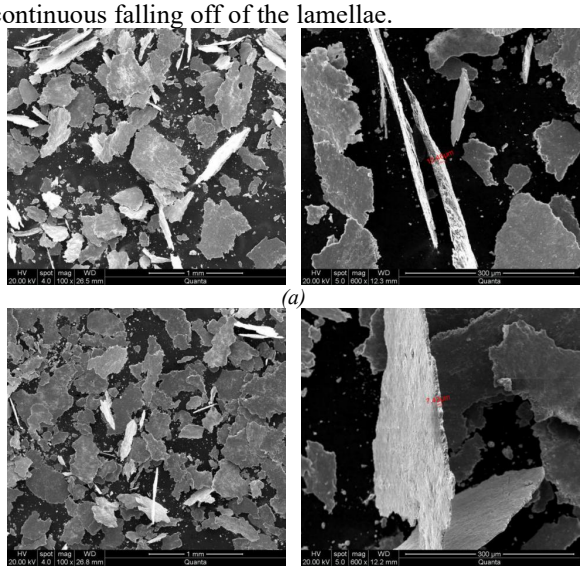

Figure 10 *SEM photos of wear debris from ER8, ER8C and SSWQ3R groups: (a) ER8. (b) ER8C. (c) SSWQ3R.*

4. Discussion

When the rail specimens are the same, the wheel specimen with higher original hardness has the smaller the wear amount. In addition, the harder wheel specimens tend to grow more through testing, it will also have smaller surface crack, peeling lamellae and depth of deformation layer (except for ER9), similar rules have also been found on rails [9, 10]. Therefore, harder wheel material has better resistance to wear and contact fatigue.

When it comes to system wear, D2 and ER8C test groups (with hardness ratio of 1.02:1 and 1.03:1) prevail among five groups. The individual wear volume of the wheel and rail specimen is more balanced in this pair. Their anti-fatigue performance is also better than ER8. Generally, D2 and ER8C are optimized choices considering both system wear and fatigue.

Rail specimens in ER9 and SSWQ3R groups have higher wear volume and poorer surface morphology than others. This adverse effect has also been found in other experiments. But in actual operations, the working frequency of wheel material may reach 100 times than rail. Even when the wheel and rail hardness is close, the wear of the wheel is always greater than the rail specimen, which may be related to the form of the movement mode of them. So the behaviour of wheel and rail materials in service remains to be studied, but it is certain that the original hardness of the wheel material in high speed railway should be set higher than the rail material.

5. Conclusion

(1) When coupled with same rail specimen, the harder wheel specimens are proved to have better wear resistance. The wear resistance of ER8 wheel material is the worst, while the performance of ER8C and D2 is similar, both prevail ER8. SSWQ3R has the least wear volume.

(2) Harder wheel specimens tend to have better anti-fatigue performance. SSWQ3R has smallest surface crack, peeling lamellae and depth of deformation layer, but ER9 show longer and deeper cracks on surface.

(3) D2 and ER8C (hardness ratios of which are1.03:1and 1.02:1) are optimized choices in 5 groups. The wear and contact fatigue of wheel specimens are lighter, and the wear of rail specimens is not serious.

(4) In order to reduce the wear and damage of the wheel material in operations, it is suggested that the wheel hardness should be harder than rail in the material

matching (i.e. hardness ratio of which shall be over 1:1) in high speed railway.

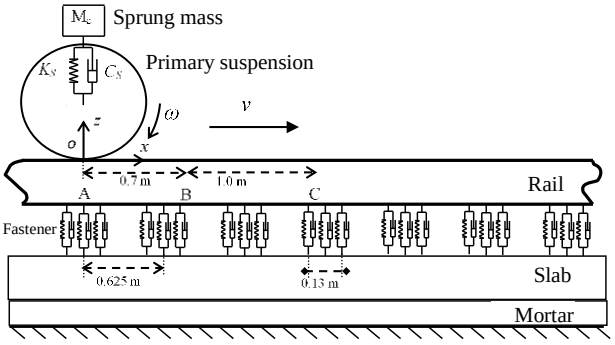
Abstract: Corrugation is widespread rail damage on metro lines, worsening the wheel-rail interaction significantly. Resilient wheels with a rubber layer between rim and web is widely recognized as a potential measure to relieve the influence of corrugation. This paper develops a three-dimensional transient wheel-rail rolling contact finite element model to study the influence of resilient wheels on the dynamic wheel-rail interaction under rail corrugation excitation. Comparisons indicate that resilient wheels can significantly reduce the dynamic wheel-rail force under short pitch corrugation excitation and the resulting axle-box acceleration in the vertical direction in a large frequency band.

Keywords: Resilient wheels, rail corrugation, wheel-rail interaction; FE method; dynamic characteristics

1. Introduction

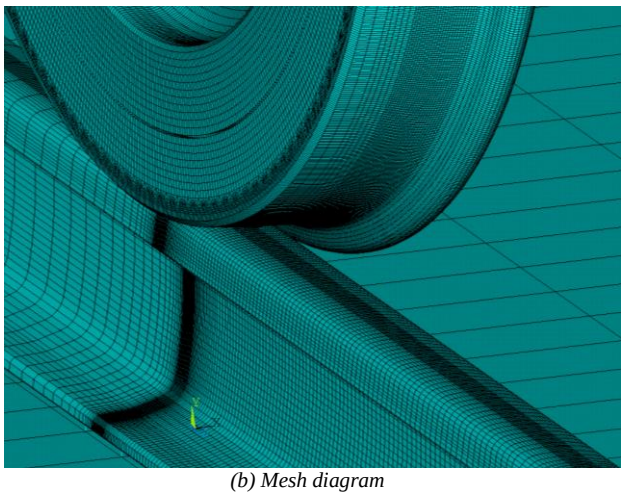
Rail corrugation is a common problem on many metro lines [1]. It can directly affect the force between the wheel and rail, leading to abnormal vibrations and noise [2] and affecting the running safety and ride comfort of trains. Resilient wheels with a rubber layer between rim and web can reduce the vibration and noise efficiently. It has been widely used in urban rail transit, especially on trams [3]. Resilient wheels were once installed onto ICE trains to treat the abnormal vibrations and interior noise caused by wheel polygons [4]. Koo D H tested the effect of resilient wheels on vibration and noise reduction on a metro line, and found that the resilient wheels can reduce frame vibrations by 7~10dB on straight lines [5]. Thus, resilient wheels have been considered as a significant measure by relevant departments in the industry to reduce vibrations and noise caused by corrugation. The core issue of this work is to reveal the influence of resilient wheels on wheel-rail interaction under the corrugation excitation through numerical simulations.

The short pitch corrugation on Chinese metros is typically 30~125 mm in wavelength [6], corresponding to passing frequencies of 180~930 Hz at 80~100 km/h. Such frequencies belong to medium and high frequency ranges, which are mainly determined by the flexibility of the wheel and the track [7]. For analyses of wheel-rail dynamic interaction, traditional mass-spring-beam models are often used in the literature [2, 4, 8, 9]. These models usually simplified a wheelset as a rigid body, and ignores its elasticity. Moreover, Hertzian contact spring typically used in the traditional model is generally derived in statics. Past research has shown that significant difference exists between the results of the simplified spring and those of more complicated models [10]. When resilient wheels are used, extra difficulties arises for the traditional approach used in modelling the rubber layer. Thus, the traditional dynamic modelling is not suitable for high-frequency wheel-rail interaction analyses, especially when the corrugation is present.



The rapid development of computers has made it possible to simulate transient wheel-rail rolling contact using FE method, with which real wheel-rail geometry and flexibilities can be taken into account easily together with surface irregularities, contact filtering and complex constitutive relationships [11, 12]. With the 3D transient wheel-rail rolling contact FE model, Zhao studied the high frequency wheel-rail interactions at squats [13]. Similar model has been employed to analyse the dynamic responses of a high-speed wheel-rail system at welds [14]. Yang further extended the model to calculate the impact vibrations and noise at insulated joints [15]. It has been found that the 3D transient FE model can effectively simulate the high frequency wheel-rail interactions.

In this paper, the transient wheel-rail rolling contact FE model is further developed to take into an account resilient wheel and employed to study its influence by comparing the dynamic wheel-rail forces under rail corrugation excitation with those with a ‘rigid’ wheel. Real wheel and rail profiles measured in field are introduced to reproduce numerically the wheel-rail rolling contact in the time domain, so that the nonlinear contact behaviour is considered.



2. Model approach

The 3D transient wheel-rail rolling contact FE model established with Ansys/Ls-dyna is shown in Figure 1. It simulates a metro system, in which a normal slab track composed of rail, fasteners, track slabs and mortar layer is considered. Considering the symmetry of the track, a half wheelset and a half track of 15 m length containing 25 sets of fasteners are built in the model. The bogie and the vehicle are, respectively, simplified as a rigid body connected to the wheel through the primary suspension

represented by using a spring and a damper. The wheel-rail contact is solved by a 'face-to-face' contact algorithm. Rail corrugation is applied onto the BC section before which the steady rolling is approximately built up. The parameters are shown in Table 1. For convenience, a Cartesian coordinate system *oxyz* is established, as shown in Figure 1(a), *ox* is along the wheel rolling direction, and the origin is set at the initial point A of the contact patch center.

(a) A schematic diagram

(b) Mesh diagram

Figure 1 *Three-dimensional transient wheel-rail rolling contact finite element model*

The wheel sections are shown in figure 2. The left figure is of a traditional 'rigid' wheel, and the right is of a resilient wheel designed compatible with the 'rigid' wheel, i.e. with the similar rim and web structures. The wheel diameter is 840 mm, and of straight web. The masses of the 'rigid' and resilient wheels are 328 kg and 393kg, respectively. For the resilient wheel, the rim is 202 kg, the web and the mounting ring 185 kg, and the rubber block 6kg.

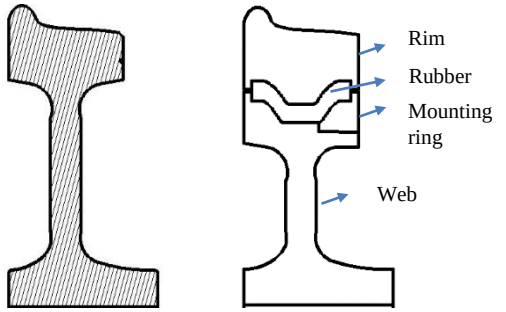


Figure 2 *The 'rigid' and resilient wheel sections.*

The rail is CN60 with a 1:20 cant. The wheel and rail are meshed with non-uniform solid elements (8-node hexahedral elements), as shown in Figure 1(b). A minimum mesh of 1 mm is used in the BC section, and is taken as large as possible for other areas to reduce the size of the model. The slabs and mortar layer are also meshed by the solid elements, and the primary suspension of the vehicle and the rail fasteners by distributed springs and dampers.

In a specific calculation, the static implicit solution of the wheel-rail system under gravity is solved first at point A. Then the displacement field of the implicit solution is taken as the initial state, with which the wheel forward and rotational speeds are applied as initial conditions of the following explicit simulation. The transition zone AB is designed to damp out the vibrations introduced by imperfect initial conditions. Transient responses of the wheel/rail interaction are solved by explicit time integration for a speed of 80 km/h. Boundary conditions are as follows: fixed constraints at the bottom of the mortar layer, symmetric on the symmetric plane of the system and at the longitudinal ends of the rail, slabs, and mortar layer.

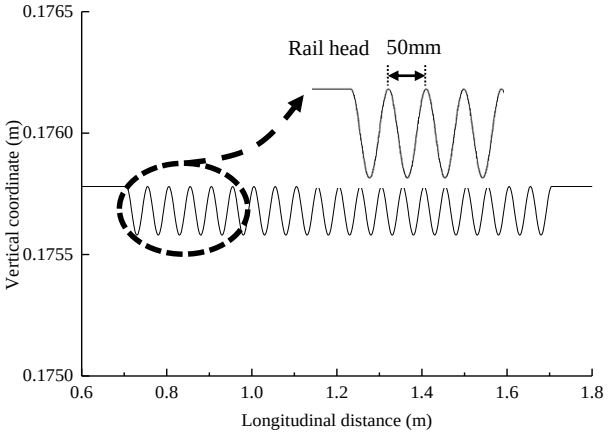

Table 1 *Values of the parameters in the FE model.*

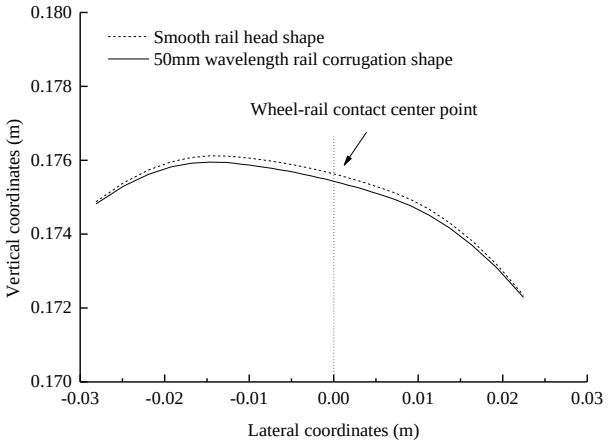
Parameters		Values
Sprung mass /(kg)		5000
Primary suspension	Stiffness /(MN/m)	1.38
	Damping /(kNs/m)	13
Wheel and rail material (steel)	Young's modulus /GPa	210
	Density /(kg/m^3)	7790
	Poisson's ratio	0.3
Wheel material (rubber)	Poisson's ratio	0.45
	Density	1200
	Rayleigh damping	0.01
Fastening	Stiffness /(MN/m)	40
	Damping /(kNs/m)	5
Slab	Young's modulus /GPa	36
	Density /(kg/m^3)	2400
	Poisson's ratio	0.24



Based on field observations of typical short pitch corrugation on metros, the wavelengths of 31.5 mm, 50 mm, 80 mm and 125 mm are adopted in the numerical simulation. Their wave depths are respectively 3.2 μm, 10 μm, 31.6 μm, 100 μm and 200 μm. Figure 3 shows a picture of rail corrugation on a metro line, in which its wavelength of 50 mm is marked. By modifying the coordinates of the involved nodes, the corrugation is applied in the BC section. For example, Figure 4 shows the geometry of applied corrugation with a wavelength of 50 mm and a depth of 0.2 mm. Clearly, the corrugation is simplified as the sinusoidal in shape.

Figure 3 *A corrugation with a wavelength of 50 mm occurred on a metro line.*

Figure 4 *Geometry of corrugation applied in the FE model with 50 mm wavelength and 200 μm depth.*

For the simulated speed of 80 km/h, the passing frequencies of the simulated corrugation are calculated as follows:

$$\lambda_1=31.5\text{ mm},\quad f_1=\frac{80/3.6}{0.0315}\approx 705\text{ Hz} \qquad (1)$$

$$\lambda_2=50\text{ mm},\quad f_2=\frac{80/3.6}{0.05}\approx 444\text{ Hz} \qquad (2)$$

$$\lambda_3=80\text{ mm},\quad f_3=\frac{80/3.6}{0.08}\approx 278\text{ Hz} \qquad (3)$$

$$\lambda_4=125\text{ mm},\quad f_4=\frac{80/3.6}{0.125}\approx 178\text{ Hz} \qquad (4)$$

3. Result analysis

3.1. Vertical dynamic contact force

The vertical dynamic contact force (VDCF) is significant consequence of wheel-rail interaction. The dynamic wheel-rail forces presented in the following are obtained by subtracting the wheel-rail forces under the smooth rail from those under the corrugation excitation. When the corrugation with 31.5 mm wavelength and 200 μm depth is present, the obtained VDCFs with the 'rigid' and resilient wheels are shown in Figure 4, in which the abscissa axis is the rolling distance of the wheel. Negative values mean load reduction with respect to the steady load on a smooth rail. It is seen that the peaks of the VDCF resulting from the corrugation significantly reduces when the resilient wheel substitutes the 'rigid' one. The maximum reduction is about 22%.

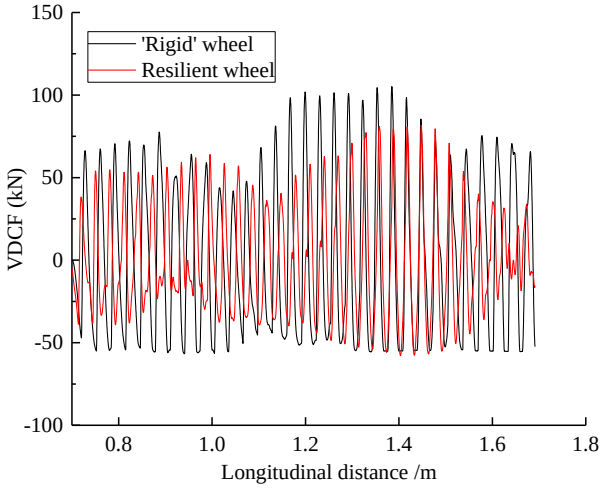

Figure 4 *The VDCF excited by corrugation with 31.5mm wavelength and 200μm depth*

The comparisons of the maximum VDCFs between the resilient and 'rigid' wheels are shown in Figure 5, in which the corrugation wavelength is changed while the depth is a constant of 200 μm. Obviously, the shorter the wavelength is, and the greater the maximum VDCF becomes. This is because the shorter wavelength means the higher corrugation passing frequency or the greater corrugation excitation frequency at the same speed, leading to stronger wheel/rail interaction. Note that such a trend will change when the wavelength becomes shorter than the contact patch, i.e. the contact filter effect. For the simulated system, the wheel-rail contact patch is about 16 mm long in the rolling direction under static load.

It is further seen from Figure 5 that the resilient wheel can effectively reduce the VDCF under the corrugation excitation with short wavelengths, while become insignificant or negligible under that with long wavelengths. This phenomenon is related to the corrugation excitation frequency and the radial decoupling frequency of the resilient wheel.

Figure 6 shows the variation of the maximum VDCF with the depth. The wavelength of the corrugation is 31.5mm. It is found that the maximum VDCFs increase with the depth for both wheel types, being easy to be understood, and the effect of the resilient wheel also become significant under deeper corrugation excitation.

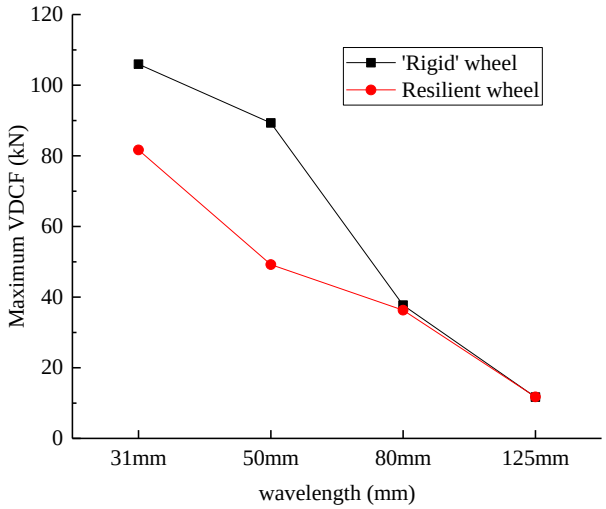

Figure 5 *Maximum VDCFs excited by corrugation of different wavelengths. The depth is 200 μm.*

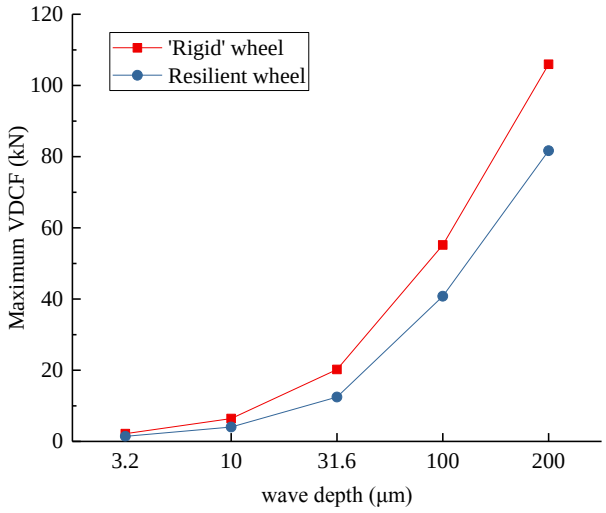

Figure 6 *Maximum VDCFs excited by corrugation of different depths. The wavelength is 31.5mm.*

Applying FFT transformation to the time-domain results, spectrum of the obtained VDCF are obtained. Figures 7-10 shows spectra of the VDCFs excited by rail corrugation of different wavelengths and 200 μm depth. In general, the peaks appear at the corrugation excitation frequency and its harmonic frequencies. The shorter the wavelength is, and the stronger harmonics are excited. However, the longer the wavelength is, and the lower the excitation frequency is. This will result in a denser harmonic wheel-rail force.

For the corrugations of 31.5 mm and 50 mm wavelengths, the resilient wheel can effectively reduce the wheel-rail force compared with 'rigid' wheel. At the corresponding corrugation excitation frequencies, the VDCF can be reduced by 22% and 35%, respectively. For 80mm and 125mm wavelengths, the VDCF of the resilient wheel at the corrugation excitation frequency is increased by 27% and 13%, respectively. This is related to the first-order radial resonance frequency of the resilient wheel (radial decoupling frequency), and its resonance frequency is 390Hz. For 31.5 mm and 50 mm wavelength corrugations, the excitation frequency is 709Hz, 444Hz respectively, higher than 390Hz. The rim and the wheel center are therefore decoupled largely by the rubber layer effectively, so the unspring mass is just the rim mass, resulting in a decrease in the VDCF as the resilient wheel is used.

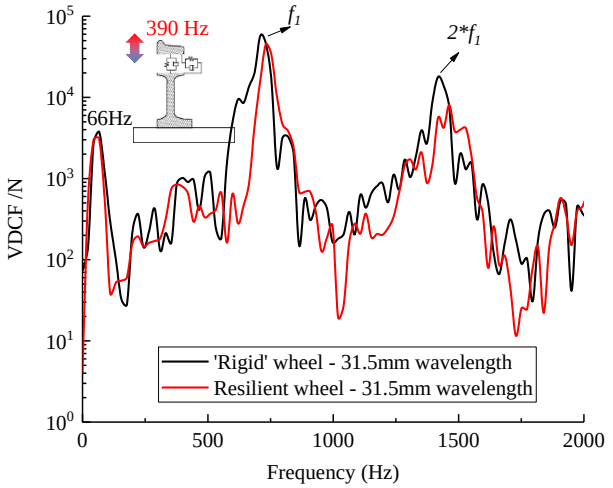

Figure 7 *Spectra of the VDCFs excited by corrugation with 31.5 mm wavelength and 200μm depth*

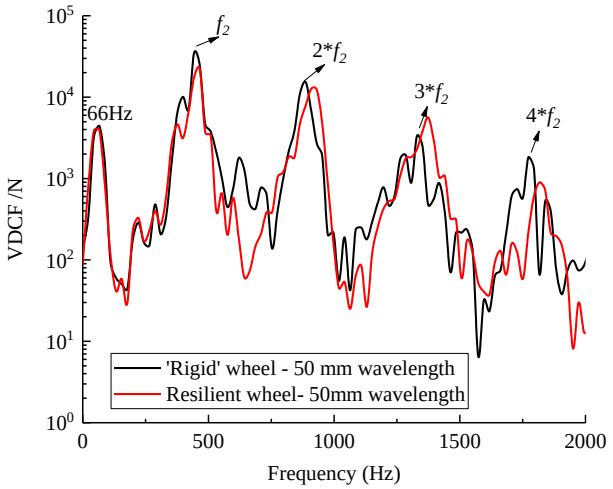

Figure 8 *Spectra of the VDCFs excited by corrugation with 50 mm wavelength and 200μm depth.*

For 80 mm and 125 mm wavelength corrugations, however, the excitation frequency is 288 Hz, 178 Hz respectively, being much lower than 390 Hz. This means that the rim and the web of the resilient wheel behaviour like one mass to a large extent. Due to the larger mass of the resilient wheel, the unspring mass is increased with respect to the 'rigid' wheel, so that increased VDCF is found.

Note that for all results shown in Figures 7-10, a peak exists near 66 Hz. This is caused by the resonance related to the vehicle mass and the wheel-rail contact stiffness. The resilient wheel can reduce the VDCF by 11%~18% at this frequency in different cases. This is mainly because the presence of the rubber layer in the resilient wheel increases the damping of the vehicle system and reduces the vibration of the vehicle system and the VDCF.

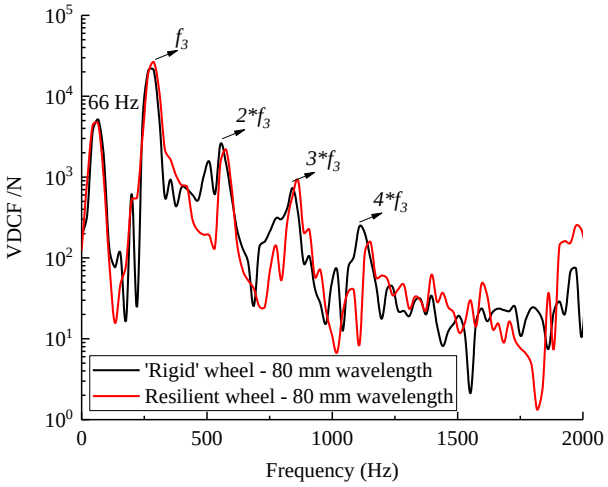

Figure 9 *Spectra of the VDCFs excited by corrugation with 80 mm wavelength and 200 μm depth.*

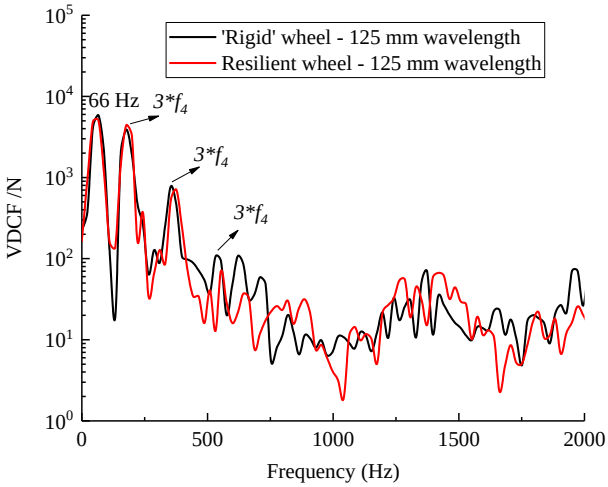

Figure 10 *Spectra of the VDCFs excited by corrugation with 125 mm wavelength and 200 μm depth.*

Figure 11 shows spectra comparison of the VDCFs under the corrugation excitation with different depths and a constant wavelength of 31.5mm. It is seen that the amplitudes increase in the whole frequency range as the depth rises, but the spectral characteristics are essentially unchanged. Furthermore, with respect to the 'rigid' wheel, the peaks at the corrugation excitation frequency are 20%~30% lower when the resilient wheel is used. Additionally, for the corrugation of 3.2 μm depth, the peak at the second-order harmonic frequency is no longer obvious.

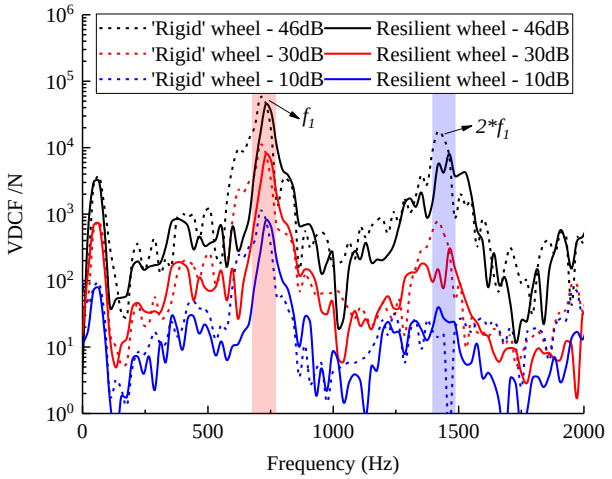

Figure 11 *Spectra of the VDCFs excited by corrugation of different depths. The wavelength is 31.5mm.*

3.2. Axle-box acceleration

Figure 12 shows the axle-box acceleration in the vertical direction(2000 Hz low-pass filtering), in which the abscissa is set as the rolling distance of the wheels. The corrugations with two different wavelengths are plotted, and the depth is 200 μm. It is seen that for the corrugations with two different wavelengths, the accelerations change periodically, similar to the corrugations. For the 31.5mm wavelength corrugation, the resilient wheel can effectively reduce the axle-box acceleration. The reduction of its maximum is about 20% compared with that of the 'rigid' wheel. For the 80 mm wavelength corrugation, however, the acceleration of the resilient wheel is even higher than that of the 'rigid' wheel, and the maximum value increases by 200%.

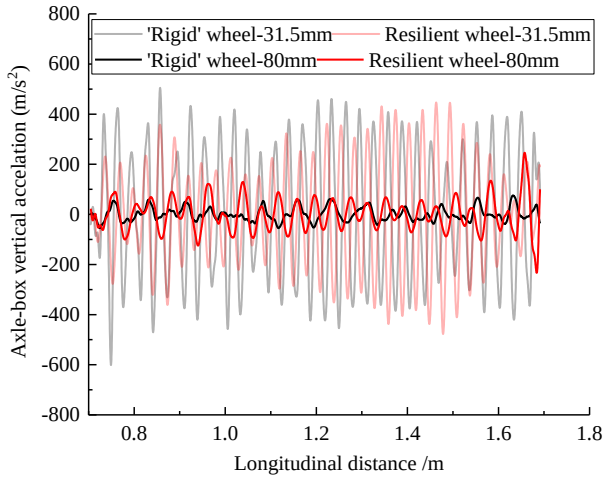

Figure 12 *The axle-box acceleration in the vertical direction (2000Hz low-pass filtering) excited by rail corrugations of different wavelengths. The depth is 200 μm.*

Figure 13 shows the spectra of the acceleration excited by rail corrugations of two different wavelengths, in which the depth is 200 μm. For 31.5mm corrugation excitation, the obvious peaks occur at the passing frequency for both the wheels. Other peaks correspond to axle resonances, such as 931 Hz and 1729 Hz for the 'rigid' wheel and 554 Hz and 1241 Hz for resilient wheel, as shown in the figure. The radial decoupling frequency of the resilient wheel is 390 Hz, and the theoretical vibration isolation

frequency($\sqrt{2}$*390 Hz) of the rubber layer between the web and the rim is about 550 Hz. So above 550 Hz, the resilient wheel reduces the vertical acceleration of the axle-box over most of the frequency band relative to the 'rigid' wheel. At the corrugation excitation frequency of 705 Hz, the resilient wheel reduces the axle-box vertical acceleration by 17%. Around the resonance frequencies of the resilient wheel axle, the vertical acceleration of the resilient wheel is higher than that of the 'rigid' wheel due to the influence of the axle resonance.

For 80mm wavelength corrugation excitation, the resilient wheel significantly reduces the axle-box vertical acceleration in most of the frequency bands above 550 Hz. It is worth noting that since the 80 mm wave excitation frequency is 278 Hz, which is lower than the vibration isolation frequency, the axle-box vertical acceleration of the resilient wheel is slightly increased at the corrugation excitation frequency. The maximum axle-box vertical acceleration of the 'rigid' wheel occurs at the corrugation excitation frequency. The maximum axle-box vertical acceleration of the resilient wheel occurs near the second-order harmonic frequency of 576 Hz of the corrugation excitation. This is mainly due to the fact that the axle of the resilient wheel has a resonant mode at 554 Hz, and the second-order harmonic wheel-rail force excited by 80 mm wavelength corrugation causes the axle to resonate, resulting in the maximum vertical acceleration of the axle-box and the axle-box vertical acceleration of the resilient wheel, shown in figure 12, higher than the 'rigid' wheel.

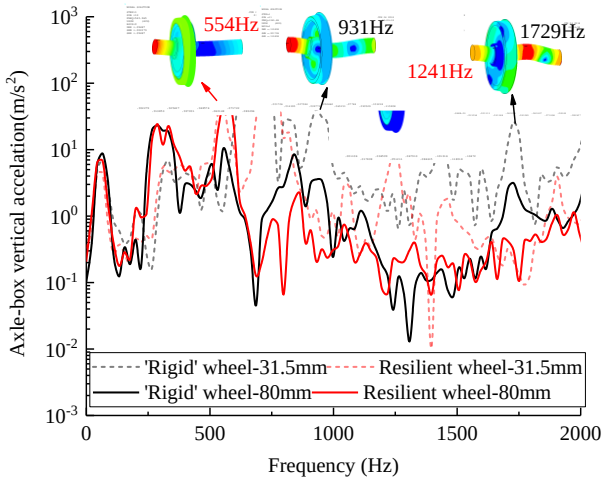

Figure 13 *Spectrum of the vertical axle-box acceleration excited by the corrugation of different wavelengths. The depth is 200μm.*

4. Conclusions

3D transient wheel-rail rolling contact FE models are developed separately for 'rigid' and resilient wheels to study the effects of resilient wheels on dynamic wheel-rail contact forces and axle-box accelerations excited by rail corrugation. Based on the results, the following conclusions are drawn:

(1) The developed models can reflect the harmonic excitations of the dynamic wheel-rail force caused by the corrugation.

(2) The resilient wheel can effectively reduce the dynamic wheel-rail force under rail corrugation excitation with wavelengths shorter than 80 mm. This is because the web mass is sprung due to the rubber layer when the excitation frequency is very high, while this effect gradually disappear with the excitation frequency decrease or the corrugation wavelength increase.

(3) The resilient wheel can reduce the axle-box acceleration in the vertical direction in a large frequency band above the vibration isolation frequency of the rubber. However, since the resilient wheel decreases the resonance frequency of the axle end, the axle-box vertical acceleration of the resilient wheels is larger than that of the 'rigid' wheels under longer wavelength corrugation excitation.

A METHOD TO GET PROPER VIRTUAL PENETRATION VALUE IN SEMI-HERTZIAN WHEEL/RAIL CONTACT PROBLEM

Bin Zhu*, Jing Zeng

State Key Laboratory of Traction Power, Southwest Jiaotong University, Chengdu, People's Republic of China

* E-mail: zhubin@my.swjtu.edu.cn

Abstract: In order to get a relatively accurate wheel/rail contact solution with reasonable time consuming, some so-called fast-accurate methods based on the concept of virtual penetration have been proposed. The normal solutions of the contact patch (shape and stress) are very sensitive to the virtual penetration value. When dealing with the non-Hertzian problems, there may be an incorrectness when the penetration is calculated from Hertzian contact parameters of a single point. This paper proposes a method to get a proper penetration by considering the change of local relative curvature of wheel/rail profiles based on semi-Hertzian method.

Keywords: Wheel-rail contact; fast contact algorithm; semi-Hertzian method; virtual penetration; contact stress distribution.

1. Introduction

Wheel/rail contact modelling is of great importance in the railway vehicle system simulation. It is closely related to vehicle system dynamics, wheel/rail wear simulation and rolling contact fatigue assessment. Although the finite element method (FEM) and CONTACT are considered precise, the slow calculation speed limits their application [1,2]. The widely used algorithm FASTSIM [3] is fast and performs well in vehicle system dynamics, but it cannot solve the stress and slippage distribution in the contact patch precisely when the contact patch is non-elliptical. In order to compromise calculation speed with precision, many fast-approximate algorithms have been proposed by Linder [4], Kik and Piotrowski [5,6], Pombo J etc. [7], Ayasse etc. [8], and so on [9-11]. Most of them are based on the concept of virtual penetration. In fact, the deformation of wheel and rail is very small, the virtual penetration is always very small too. In these methods, the shape, size, and normal force distribution of the contact patch are sensitive to this small value.

The virtual penetration is calculated from the Hertzian contact parameters of the initial contact point. If the material property of two contact bodies are uniform, the Hertzian contact parameters [12] are deduced by the relative longitudinal and lateral curvatures of contact bodies. The virtual penetration is considered to be related to the Hertzian parameter δ of the initial contact point, which is the rigid approaching displacement of two contact bodies in Hertz contact theory. The valued of penetration was taken by 0.55δ by Kik [5,6] and Linder [4] (also 0.5δ in some other publications). However, when the relative curvature is not a constant, the parameter δ of initial contact point cannot represent that of the whole contact patch. In this case, the virtual penetration may be incorrect. That would cause inconsistence of the applied normal force with the calculated resultant force.

In fact, the penetration is related to the curvature of the entire area of contact patch, however, the range of contact patch is based on the penetration. This leads to a logic infinite loop. It means that if the virtual penetration based on methods calculate the penetration from a single point, systematic error might occur in principle.

In this paper, a fast-iterative method to get a proper virtual penetration value is proposed, and a reliable value of virtual penetration can be obtained with good stability and speed. The wheel/rail contact is solved by using the semi-Hertzian method [8] with penetration calculated in the proposed method. Also, original semi-Hertzian method is performed to make a comparison.

2. Semi-Hertzian method and penetration compensation

2.1. Semi-Hertzian method

According to Ayasse, etc. [8], in wheel/rail contact pair, the curvatures of the wheel and rail are considered as a constant in the longitudinal direction, while the relative curvature in the Lateral direction is no longer a constant. It means that Hertzian [12] conditions are well satisfied only in the lateral direction. Then the semi-Hertzian method divides the contact patch into stripes along the longitudinal. The width of each stripe is short, so the curvature could be regarded as a constant. And the Hertzian theory could be used in each separated stripe. In this method, each stripe has its own independent local Hertzian parameters. The virtual penetration is calculated by the initial contact stripe (so called 'mother stripe'). Then, the lateral span of contact patch is decided by the intersection with the penetration gained in the previous procedure. Finally, the longitudinal span of each stripe is decided by the local penetration and the relative longitudinal curvature.

A brief introduction of derivation process of Semi-Hertz method developed is shown as follows. $A, B, m, n, r, \lambda, \delta$ are Hertzian parameters.

$$\begin{cases} A_i = 1/2(\rho_{iwyy} + 0) \\ B_i = 1/2(\rho_{iwxx} + \rho_{irxx}) \end{cases} \tag{1}$$

Where A and B are the longitudinal and lateral relative curvature respectively, i is the number of the

stripes, *x* and *y* represent the direction. ρ is the radius of wheel and rail profile. In order to make the penetrate intersection agree with the contact patch, the curvature is compensated:

$$\bar{A}_i = (n_i^2 / m_i^2)B_i \text{ and } \bar{B}_i = B_i \quad (2)$$

The stripe with the initial contact point is so called 'mother stripe'. The value of virtual penetration equals to the penetration h_0 at the mother stripe. The parameters in (3) are all in mother stripe.

$$h_0 = \frac{n^2}{r(1+\lambda)}\delta \quad (3)$$

The stripes are inside the contact patch if the following formula is satisfied. $h_i = h_0 - (z_{w,i} - z_{r,i}) \geq 0$

Then, the span of each stripe in the longitudinal direction is $\bar{a}_i = \sqrt{h_i / A_i}$.

The shape of the contact has been solved now. Kalker assumed pressure distributed parabolically in the contact patch. Apply this assumption in the longitudinal direction, the pressure distribution in a stripe is shown as following.

$$\sigma_z = \frac{2N}{\pi ab}\left(1-\left(x/\bar{a}_i\right)^2\right)\left(\bar{a}_i/a\right)^2 \quad (4)$$

Where *x* is the longitudinal coordinate, σ is the normal pressure distribution to agree with the Hertzian solution.

$$b = n\left(\frac{3}{2}N\frac{1-\upsilon^2}{E}\frac{1}{A+B}\right)^{1/3} \quad (5)$$

Finally, using equations (4)(5), one can define the pressure distribution as:

$$N_i(x) = \frac{4}{3\pi}\frac{h_i}{\bar{a}_i}\frac{1+\lambda_i}{n_i^3}\frac{E}{1-\upsilon^2}\left(1-(x/\bar{a}_i)^2\right)\left(\bar{a}_i/a\right)^2 \quad (6)$$

2.2. Compensation of penetration

When the lateral relative curvature of contact bodies changes sharply in the potential contact area, the local parameters δ_i of stripes differ from each other, and they all contribute to the virtual penetration. It means that the span of the contact patch in lateral should be clear, if the penetration was calculated without any feedback. It can be seen from (6), the normal stress is highly depended on the penetration value h_i. As a result, an overestimated penetration number leads to a larger integration of calculated normal stress than the applied normal force, vice versa. To get a proper penetration, a compensation coefficient is defined in this paper as following:

$$h_{0,i+1} = h_{0,i}Com \quad (7)$$

$$Com = \sqrt{P / \iint_A N(x,y_i)dxdy} \quad (8)$$

While the coefficient *Com* is small enough, the iteration will be stopped. Where Com: iterative coefficient, P: the applied normal load. Before solving the penetration, the local lateral curvature should be smoothed to avoid a sharp change of the contact patch shape. This procedure allows some freedom of the semi-Hertzian method and may influence the penetration estimating.

Tangential stress and slippage distribution inside the contact patch are computed based on the idea of Kalker's simplified method and its algorithm Fastsim. The algorithm flow is shown in figure 1.

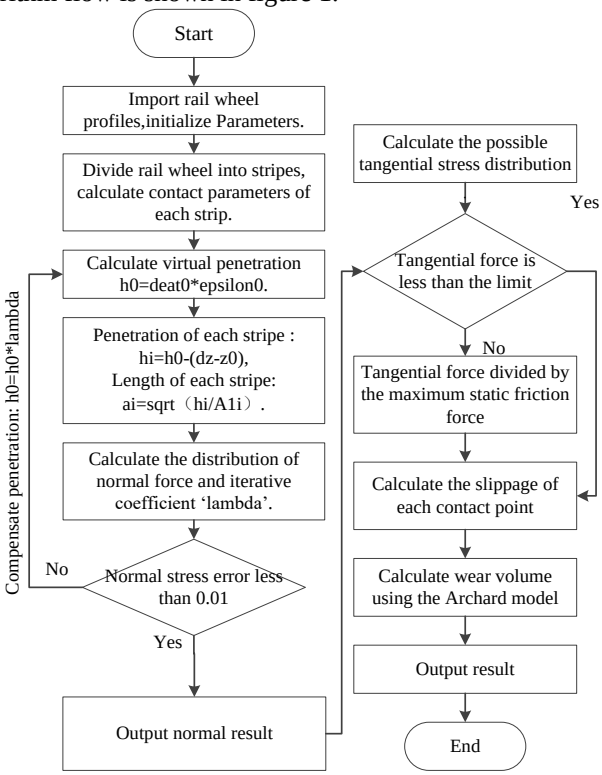

Figure 1. Algorithm flow diagram

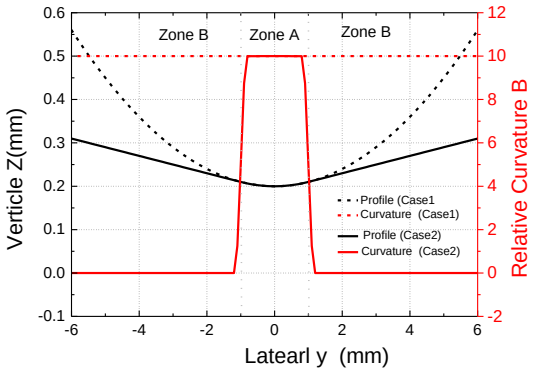
3. Case analysis

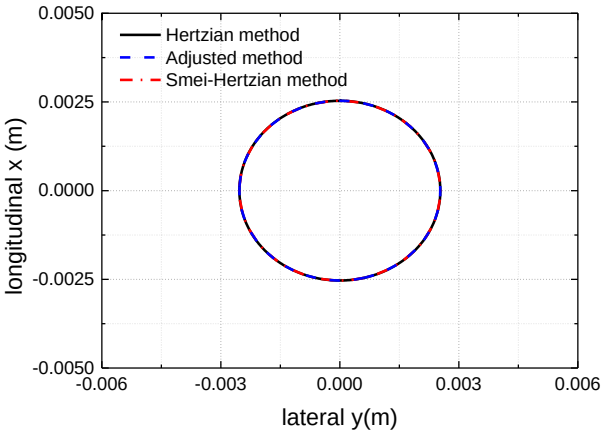
3.1. Normal solution

In this section, two imaginary models and a real wheel/rail contact pair will be compared in different methods, to analyse the influence of proper virtual penetration in terms of the normal stress distribution and contact shape. In this paper, the new method adjusts the virtual penetration based on the semi-Hertzian method, so it is to be called 'Adjusted method'. And the semi-Hertzian method without penetration adjusted is called 'semi-Hertzian method' in this paper.

3.1.1. Imaginary model analysis

Two Imaginary wheel/rail models with different profiles are compared to analyse the influence of the change of the lateral curvature to the normal solution.





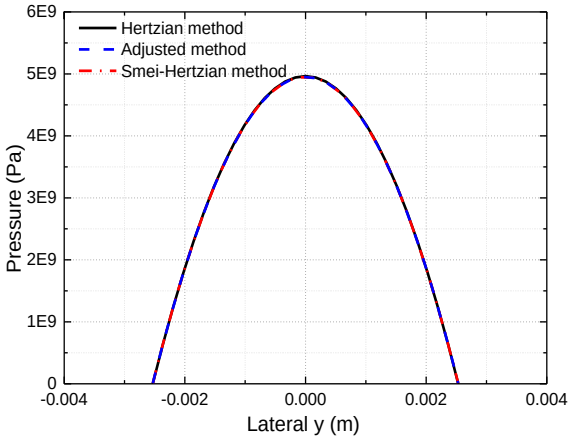


Figure 2. Imaginary model of wheel/rail profile and curvature

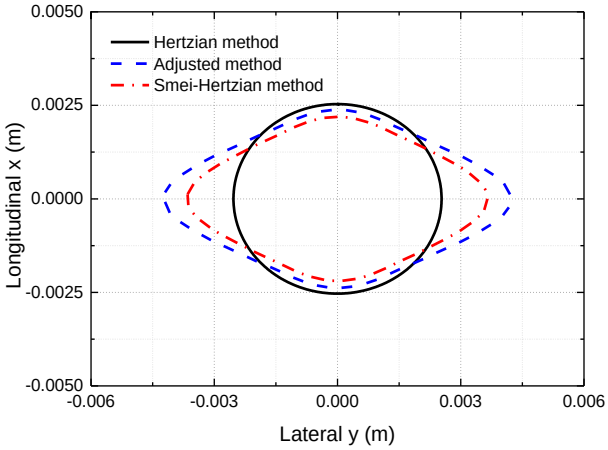
In the imaginary wheel/rail models, the rails are considered as flat surfaces, and the shape of rails are deduced by revolving the cross-section (figure 2, black lines) about the lateral direction. The cross-section of case 2 is described as a piecewise function. The lateral curvature is a constant ($10m^{-1}$) while $|y|<1mm$, otherwise it equals zero. In this case, if the lateral span of contact patch exceeds the $2mm$, the Hertzian theory cannot be applied, because the lateral curvature changes sharply at the points $|y|=1mm$. While the lateral curvature keeps invariability in case 1.

A normal force of $50kN$ is applied in both of the cases. The following shows some results. The black lines represent the solutions with Hertzian method. The blue dash lines and the red dash-dot lines are results with the Adjusted method and the semi-Hertzian method respectively.

(a) Contact patches of case 1.



(b) Normal stress distributions of case 1.

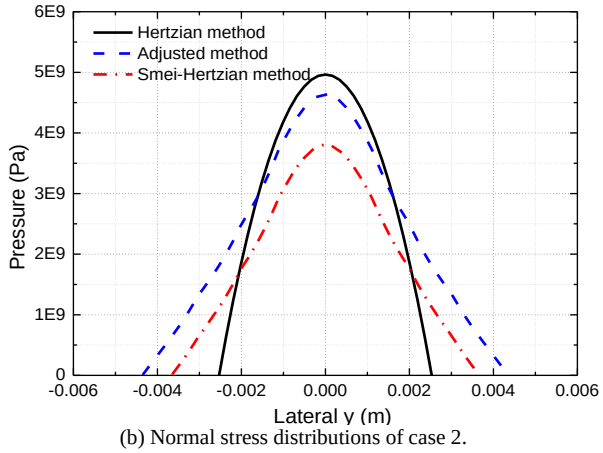


Figure 3. Comparison of different methods in case 1.

As can be seen form the figure 3, in the Hertzian case, the contact paths and normal stress boundaries with the Adjusted method and the semi-Hertz method both agree well with solutions of semi-Hertzian method. And the normal stress integration of the Adjusted and semi-Hertzian equals to $49.897kN$, which is a little smaller than the applied force ($50kN$), but it is acceptable with a relative error of 0.21%. This error is caused by the division of the stripes with a step size of $0.1mm$.

Figure 4 shows the normal solution of case 2. The shapes of contact patches of the Adjusted and semi-Hertzian method are similar and non-elliptical, but they are obviously different in size. The contact patch of the semi-Hertzian is included in that of the Adjusted method.

(a) Contact patches of case 2.

(b) Normal stress distributions of case 2.

Figure 4. Comparison of different methods in case 2.

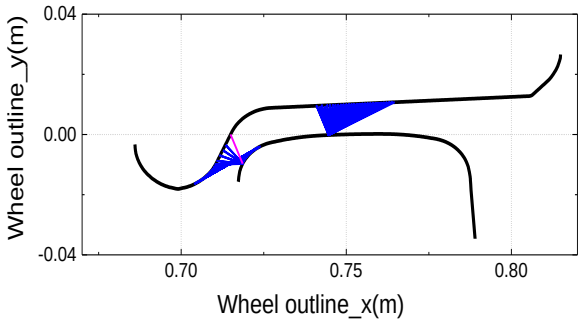
The Normal stress boundary in the lateral direction shows the same trend with the contact size. the boundaries of the Adjusted method and the semi-Hertzian method show similar shape but different magnitude. The Hertzian method gets the largest maximum stress and a narrow stress distribution span in lateral.

The result shows the normal stress integration estimated by the semi-Hertzian method equals $33.97kN$, which is 32.05% smaller than the applied force ($50kN$). The reason for this deviation is the improper virtual penetration. The virtual penetration is deduced by the Hertzian parameters of a single stripe (where y=0), which is acceptable when the contact curvature does not change much, such as case 1. Whereas, if the contact curvature changes dramatically, the Hertzian parameters of mother stripe may not represent the parameters of the whole contact patch. While, after two iterations, the normal stress integration computed by the Adjusted method is $49.40kN$. This number is much closer to the applied force, although the iteration process costs an additional 0.013 second, 2.97% of the total computing time in this case.

3.1.2. Application to measured wheel/rail geometry

In this section, a typical conical tread wheel for passenger train is studied. The wheel and rail are newly reshaped and measured. Their profiles and contact relation are shown in Figure 5. It is shown that the contact points mainly distribute in the centre of the tread and the flange area. In order to assess the contact patches when

the vehicle is under operation, a multiple body system model of vehicle is set up. A case of curve passing is simulated, in which a vehicle passes a 180*m* radius curve at speed of 45*km/h*.



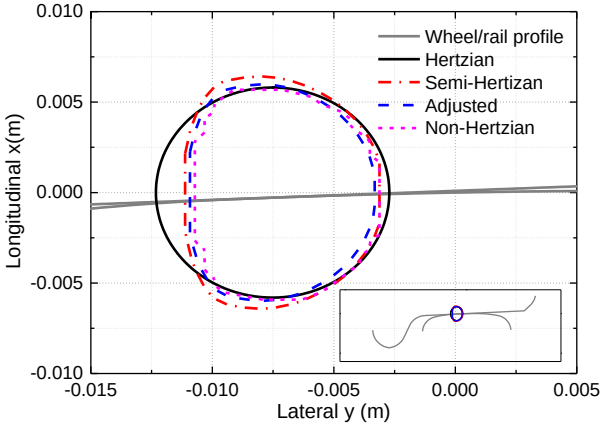


Figure 5. Measured profiles and contact relation.

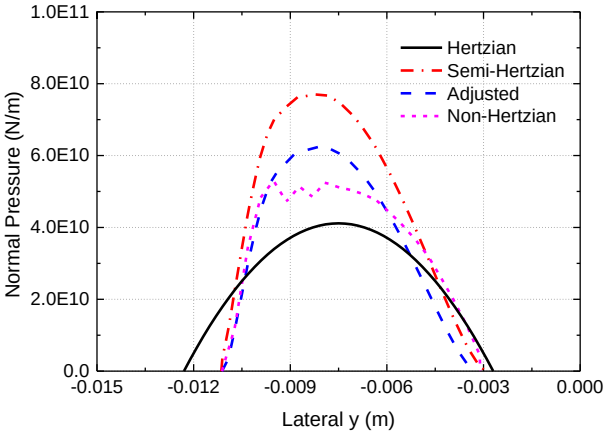

Figure 6. Two-point contact of the testing wheel and rail.

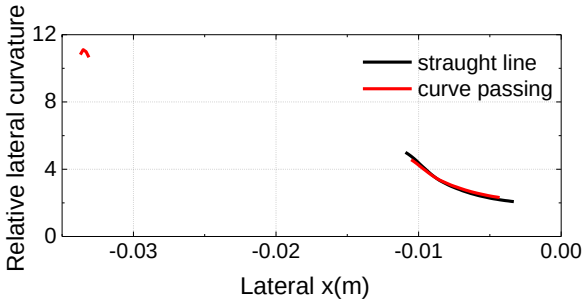
The non-Hertzian method [6] is introduced to be compared with the semi-Hertzian, Adjusted and the Hertzian methods.

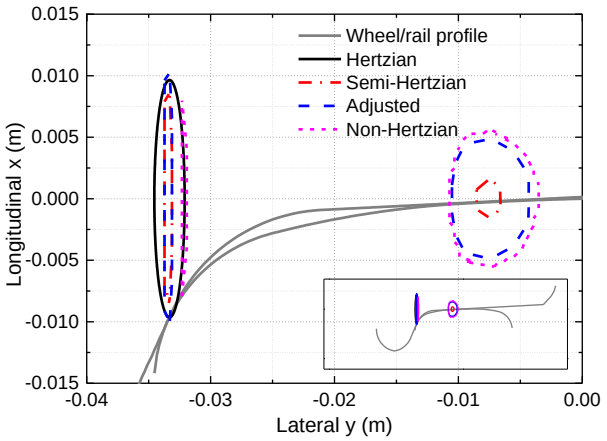
Two cases are selected to be studied during the procedure of curve passing. One is that before the vehicle entering the curve, the contact points mainly locate on the tread centre and the number of wheel/rail contact point is one. The other is that the flange contacts the inner side of the rail, resulting in two-point contact when passing the curve. The contact patches and normal stress are shown in figure 7 and 9.

(a) Contact patch.

(a) Maximum normal pressure distribution.

Figure 7. The contact patch and maximum normal pressure distribution, when the vehicle runs in a straight line.





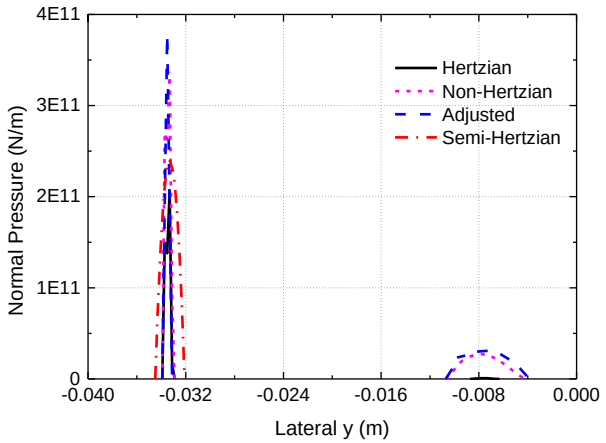


figure 8. Relative lateral curvature of two cases

In figure 7(a) and 9(a), for the wheel/rail profiles, the Y-axis stands for the vertical direction in the railway coordinate system. For the contact patch, Y-axis represents the longitudinal. Locations of the contact patches are illustrated in the windows at the bottom right corner of the figures.

In figure 7, the contact patch locates on the centre of conical tread and top of the rail, where the lateral relative curvature is smooth. The shapes of three non-elliptical methods are similar, they are consistent with the Hertzian method at the right side of the patch, but smaller than the Hertzian method at the left side. It is because that the lateral curvature on the left side changes more dramatically than that on the right side (figure 8). The size of semi- Hertzian method is a little larger than that of the Adjusted and non-Hertzian method.

(a) Contact patch.

(a) Maximum normal pressure distribution.

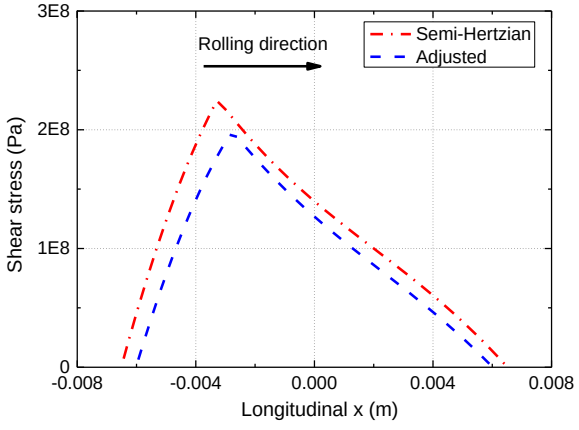

Figure 9. The contact patch and maximum normal pressure distribution, during curve passing.

Under curve condition, the Hertzian method cannot simulate two-point contact. The Adjusted method and the unadjusted non-Hertzian method are consistent with each other and differ from the semi-Hertzian method. And the resultant normal force calculated by the unadjusted non-Hertzian method is smaller than that with the Adjusted method by up to 78.87%. In this working condition, the size of contact patch and stress distribution of the semi-Hertzian method are underestimated due to the underestimated penetration. The primary cause of the problem is that the lateral curvature at the flange is much higher than the average value in the contact area, then a lower penetration was obtained, which is similar to case 2 in Section 3.1.1.

3.2. Tangential solution

The virtual penetration determines the normal solution directly, and the tangential is solved based on the normal solution. As a result, the tangential solution is influenced by virtual penetration estimating. In this section, the Adjusted method and the unadjusted semi-Hertzian method are going to be compared to discuss the influence of the penetration to tangential solutions.

The following solutions are based on a multiple body system simulation. The dynamic normal load on the wheel is 62.01kN, and the creepages are $\xi_x = 0.00239$ $\xi_y = 0.00195$ $\phi = -0.480$.

(a)

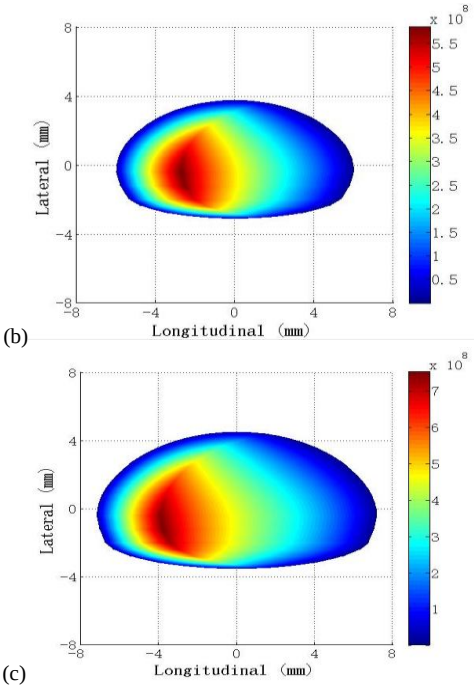

Figure 10. Shear stress distribution in contact patch. (a) The maximum shear stress alonge longitudinal. (b) (c) the shear stress estimeted by the Ajusted method and original semi-Hertzian method respectively.

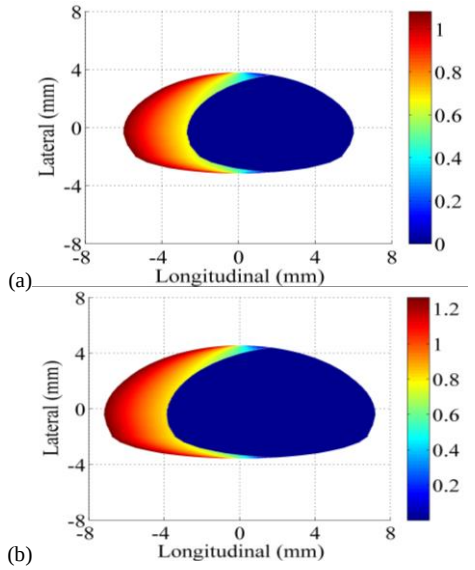

Figure 11. Slip rate. (a) for the Adjusted method and (b) for the original semi-Hertzian method. The Slip rate is defined as the ratio of the slipping speed versus wheel translational speed.

Seen from figure 10 and 11, the tangential solution shows a similar law with the normal solution, i.e. the shape of shear stress and slippage distributions computed with the original semi-Hertzian method and the Adjusted method are semblable. However, they are notably different in terms of size.

To assess the Adjusted method and the original semi-Hertzian method in terms of dynamics simulation, the relationship of creepage and creep force is studied.

In figure 12, the Adjusted method agrees well with the Hertzian + Fastsim method. In this working condition, creep force conducted by the semi-Hertzian method is notably lager than that of the other two methods because of an overestimated normal stress. This difference increases with the increase of the creepage. It is remarkable that although the contact shape and stress

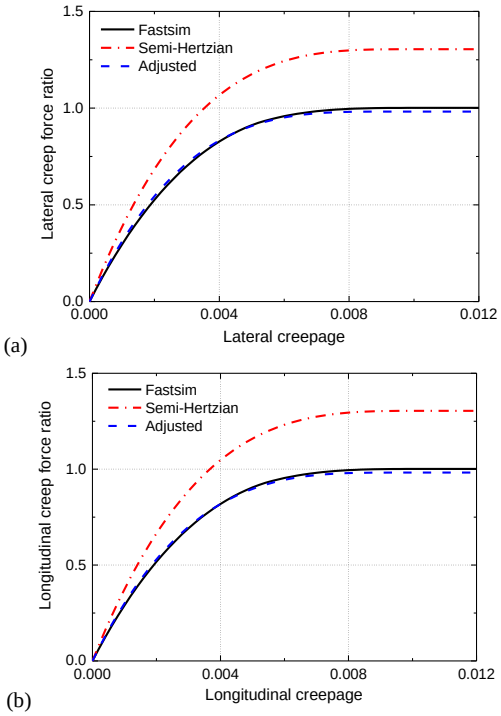

Figure 12. Curves of longitudinal and latera creep forces.

distribution of Hertzian + Fastsim and the Adjusted method are distinct, their creep curve coincident with each other very well.

4. Conclusions

Many fast-accurate wheel/rai contact models have been proposed to meet the requirement of calculation speed and precision in the vehicle system simulation. And many of these methods are based on the concept of virtual penetration. This paper illustrates the significant influence of the virtual penetration value to the contact solution and provides a fast-iterative method to get a relative proper virtual penetration value. The semi-Hertzian method with and without penetration adjusting are compared. The following can be concluded.

The contact patch is tightly related to the wheel/rail relative curvature. When the local curvature changes smoothly, it is acceptable to calculate the penetration from initial contact point. However, if the curvature varies considerably in the potential contact area, the penetration deduced from a single point may cause errors.

The shape of contact patches deduced from different penetration are non-elliptical and usually similar with each other. But the resultant force of the calculated normal stress is sensitive to the penetration because of the ellipsoidal distribution assumption.

The penetration also influences the tangential solutions. In terms of creep force, the Adjusted method coincides closely with the Hertzian + Fastsim method, although they are different in the stress distribution in the cases of the paper.

Although the proposed iterative method is efficient, additional time for computing the penetration should be spent. The further research will be focus on how to reduce the computing time.

Abstract: A comprehensive approach has been implemented in Sydney Trains railway network to control and minimize the rail degradation, especially squat defects. The popularity and severity of rail degradation were analysed, followed by the evaluation of different techniques in rail surface crack measurement. A detailed metallurgical examination on the ex-serviced rails was carried out to understand the mechanics of squat initiation and growth, and correlation between squat and presence of white etching layer on rail surface. The finite element modelling was introduced to investigate the wheel-rail contact with the consideration of white etching layer. A two-step of rail grinding strategy was proposed and commissioned.

Keywords: Squat; white etching layer; rolling contact fatigue; finite element modelling; metallurgical characterization.

1. Introduction

Squats are common problems in many railway networks across the world. They were first reported in the 1950s in Japan [1], and followed by European countries later [2]. In Australia they emerged on a heavy haul coal line in the mid 1990's and on the passenger network around 2000 [3]. Sydney Trains reported that the squats affect 18% of their rail system covering a wide spectrum of the infrastructure configures and traffic types on 2008 [4]. They affected more than 20km of track in Sydney Trains railway network on 2014 [5]. It is reported that squats affected 22% of its total track length of ProRail, Netherlands [6]. Squat-related costs are more than 5000 euro/km per year [7]. Total 30,000 incidents of rail replacements and welding repairs each year were implemented due to squats in another European railway network [8]. Consequently, squats exacerbate the deterioration of track and some vehicle components. Associated excessive noise and vibration have increased the complaints against the rail operators. The main risk with squat defects is that the cracks may turn down and grow into the parent rail at a transverse plane, with the possibility of a complete rail fracture failure if the squats are left untreated.

In order to implement more effective preventive and early corrective actions related to squat initiation or the early stages of squat growth, the root causes of squats in railway networks need to be determined. Many studies have been directed towards this goal, with squat formation examined and discussed with respect to a wide range of parameters. Squats occur mainly on tangent tracks and shallow curves, and on switch and crossing works, and are located in a seemingly random way. They occur on all types of track: ballasted and slab track; timber or concrete sleepers; passenger, freight or mixed traffic; high speed or conventional lines; Standard Carbon (SC) or Head Hardened (HH) rails [3,5,9,10]. It was expected that more squats occur near stations and signals where traction and braking efforts are high [9], and tangential force and wheel slip play the important roles in initiation and growth of squats. But controversial findings on this phenomenon have been reported by Sydney Trains [4]. Li et al proposed that squats grow as a result of plastic flow associated with high dynamic loads resulting from isolated irregularities on the rail [8,9,11]. A critical squat size of 6-8mm in both the rolling and lateral directions has been determined for preventive maintenance action [12]. In German railway, a squat of more than 30mm length need to be clamped by fish plate and impose a 120km/h speed restriction for single squat and 20km/h for multiple squats[5]. In terms of microstructure of rail steel, it has been proposed that minimal presence of pro-eutectoid ferrite in pearlitic rail steel increases fatigue life [13]. The sulphide inclusions (MnS) in rail material should be controlled as they facilitate the crack initiation and prorogation.

The area of squat initiation is still a matter of controversy. Research efforts have included possible relationships between the narrow and brittle white etching layers (WELs) observed on rail surfaces and squat formation in rails [14]. However, based on the literature, the nature of WELs and their formation mechanisms are not fully understood, as is their relationship to squat formation. WELs are believed to be created by either thermal martensitic phase transformation [2,4,15-18] and/or severe plastic deformation on rail surface [19-22], and squats can develop below them. Controversy continues partly

because, depending on the particular studies performed, the microstructures of WELs have been both identified and described differently as; martensite [2,4], nano crystalline Fe-C alloy [20]; deformed pearlite, nano-crystalline martensite, austenite and cementite [15]; and martensite and retained austenite [16,23].

Recently, Grassie [24-26] argued whether the rail surface defects were actually rolling contact fatigue (RCF) induced squats. He proposed the concept of "stud", which develops without severe plastic flow and associated with WELs at the top layer of rail under a lower borne tonnage. Although stud may show less tendency to cause rail fracture failure than squat, they also induce the rail surface degradation.

Rail degradation of the Sydney Trains railway network increased between 2002 and 2010, and was getting worse between 2010 and 2013, followed by an improvement after that. Previous understanding viewed squat development as benign. They form much quickly under relative low tonnages compared to the typical RCF defects, for example, a depth of millimetres within 10MGT [5]. Through extensive metallurgical examination of the ex-serviced rails, state of the art experimentation and advanced modelling, the current work focuses on rail surface degradation to understand the mechanics of squat initiation and growth, and relationship between squat and presence of WEL on rail surface. Track maintenance strategy against squat defects has been proposed and implemented.

2. Results and discussions

2.1. Squat popularity and severity analysis

A statistical-correlation analysis of squat defects was carried out to identify the squat occurrence and parameters of the vehicle - track system. The data of 7104 squat reports from 2002 to April 2015 was analysed, at which the ultrasonic technique was used to measure the squat. It has been found that the squat affected all of 43 tracks across the railway network. As shown in Figure 1, there is a significant increase of squat defects since 2010. It has been found that there are hot regions for squats; but squats occur on all types of track. There is no particular correlation with operations and geometries. The possible reasons for the sudden increase in squat development include (1) the introduction of "superseries" traction control and AC traction, which provide higher adhesion, resulting greater potential of wheel slip damage; (2) the introduction of wheels with a highly steering profile, which reduces wear but increases contact shear stress for squat formation; (3) the introduction of head harden rail (HH), which contributes to anti-wear performance but results in a lower resistance for squat growth; (4) the sharp corners and deep grinding scratches introduced by rail grinding, which might initiate fatigue cracks.

Under certain testing conditions squats can compromise ultrasonic rail testing and hide potential turning down defects as the longitudinal propagated cracks may shield the signals. Hence, MRX Rail Surface Crack Measurement System has been introduced to detect, measure and record flaws in tracks on and below the surface of rails. The capability of electromagnetic based walking stick was evaluated via field studies and extensive metallurgical work to determine crack depths for comparison with field measurement. It has been found that MRX Rail Surface Crack Measurement System could determine if cracks are present and if crack length is increasing or decreasing; however, the crack depth prediction often exceeded the measured values.

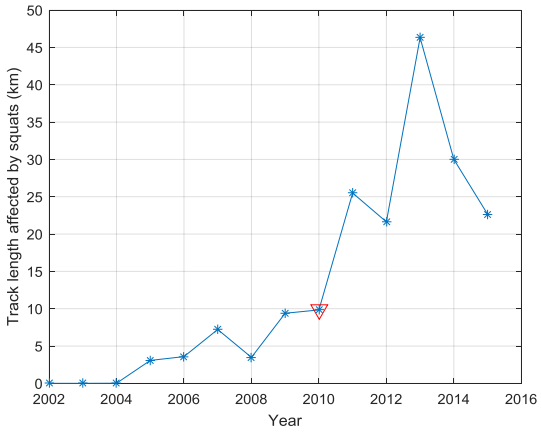

Figure 1 *Squat evolution with year*

2.2. Metallurgical examination of ex-service rail - correlation of squat and WELs on rail surface

An extensive metallurgical characterization has been conducted on the ex-serviced rail samples to investigate the origin and growth of squats. It has been found that WEL is present in most mild and moderate squats, up to 200 µm in thickness. High hardness (700 - 1200HV) of a WEL leads to brittle crack initiation. As shown in Figure 2, the cracks can initiate either from delaminated the edge of WELs island or from the transverse fracture of WELs island. Squat grows in a serviced rail under influence of repeated rolling contact between wheel and rail. Principle cracks grow into rail at the angle of 20^{o} - 30^{o} to the running surface. When principal cracks propagate to approximately 3-6 mm, sub-cracks branch from principal cracks and grow on multiple planes. Cracks can join and cause surface material to detach (spalling). In very rare case, cracks may turn down and grow at a transverse direction with the possibility of a complete rail fracture failure (TD, rail breaks).

Two distinguishable types of WELs were revealed [14]. The first one presents ultra-fine martensite and the other was characterised by both of retained austenite and martensite. WELs containing ultra-fine martensite were associated with a deformed subsurface pearlite structure and it was concluded that this type of WEL is induced by severe plastic deformation at wheel-rail interface. In contrast, the WELs containing both of significant amounts of retained austenite and martensite, were associated with undeformed pearlite in the underlying structure and it was concluded that this type of WEL is either thermally or thermomechanically induced.

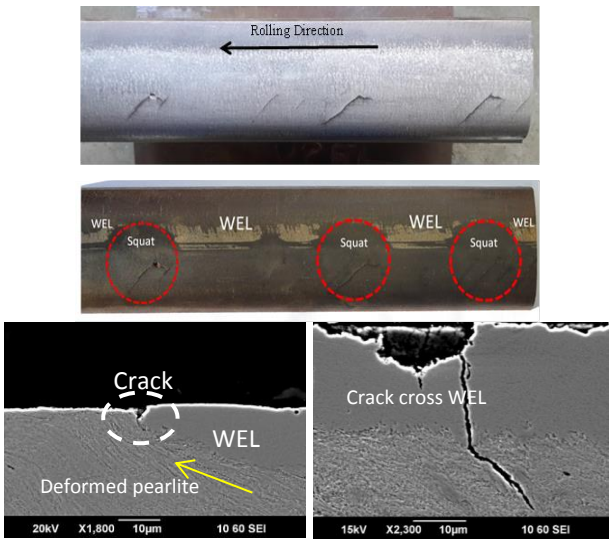

Figure 2 *Squat originates in the brittle WELs of ex-service rail [14]*

Synchrotron XRD results obtained from regions of squat defects themselves are consistent to that of WELs containing austenite and martensite in regions near the squats, which indicates a relationship between WELs and squat initiations. Occurrences of cracks extending from WELs down into the rail in squat regions were confirmed by microstructural observations, which is consistent with the premise that cracks in squats originate from an extension of cracks in WELs.

These results found that the brittle WEL plays a critical role on squat initiation. The popular existence of WELs on rail surface contributes to the formation of squats under a relative low tonnage. In addition to typical RCF initiated squat, the WELs associated with undeformed pearlite in the underlying structure supports the concept of stud. After initiation, squat grows due to rolling contact fatigue. Current rail grinding strategy needs to be revised to implement more effective preventive and early corrective actions to account for WELs associated squat initiation.

2.3. Nature and formation mechanics of WELs

In addition to metallurgical examination of the ex-serviced rails, state of the art experiments, including high pressure torsion, Gleeble thermal-mechanical testing, Leaking current Pulsed GTAW experiment, SEM, XRD, FIB and TEM, have been carried out to investigate the nature and formation mechanics of WELs in rails.

High pressure torsion experiment confirmed that WELs can occur under pure severe shear deformation without additional thermal input. Severe plastic deformation applied on rail material by repeated wheel/rail rolling contact can cause high decomposing of cementite lamella which results in the formation of very fine nano-sized structure WEL.

Gleeble thermo-mechanical simulation testing confirmed that martensite structure can be formed on rail steel at a temperature below the critical transformation point, 727 ^{o}C, when pressure is combined with the heating process. It has been found that WELs occur at temperatures as low as 550 ^{o}C under high pressure [27]. The flash temperature can be generated by micro wheel slip between wheel and rail [4]. Thermal phase transformation explains the sharp interface between the WELs and parent material.

It is interesting to note that WELs are not only detected on the running band area of the ex-serviced rail. This observation suggests that there is another cause of WELs formation. In electrified railway, arcing phenomenon (electrical leakage) occurs more often on the rails. Hence, WEL can occur when electrical current leaks between wheel and rail, which produces rapid heating followed by rapid cooling to the rail. Samples of rail material obtained from the ex-serviced rail were examined under different leakage current conditions in the lab, and followed by the detailed metallurgical investigation. It was confirmed that the temperature rise associated with the leakage current is sufficient to form white etching layers on the rail surface. Thus, arcing can be considered as another heat source in the rail head, rather than wheel slip, resulting in microstructural changes and white etching layer formation.

The understanding of three types of formation mechanics of WELs is of high importance as its perceived link with rail damage and the high cost of track maintenance procedures such as rail grinding designed to remove surface damage. Different track maintenance strategy is required to reflect the various types of formation mechanics of WELs.

2.4. Role of water on squat growth - evolution of rail surface degradation

Squats on open tracks, as opposed to track inside tunnels, have been reported by the railway networks across the world [4,28-30]. Theoretical research hypothesised that the hydraulic entrapment of water, possibly a liquid lubricant, is critical to crack propagation associated with squat growth [31-34]. The requirement for a fluid to crack propagation provides a rational to why squats vanish as soon as the railway enters a tunnel. Even though there were laboratory investigations to measure the role of water on squat initiation and growth [35,36], the metallurgical evidence from the ex-serviced rails damaged by the presence of water at wheel and rail contact interface is lacking.

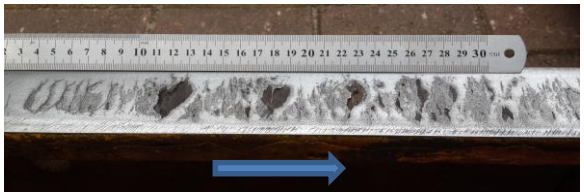

Figure 3 *Rail in Tunnel damaged due to water dropping from an air-conditioning system*

A shown in Figure 3, a localised section of rail was found to suffer severe surface damage associated with water dropping from an air-conditioning system located in a tunnel roof. This section of rail represented an ideal

controlled location for a detailed metallurgical investigation [37].

Figure 4 show the microstructure and crack development for dry contact of rail without suffering water dropping. It can be found that white etching layer / brown etching layer (BEL) up to 50 µm in thickness forms on rail in tunnel for dry contact condition. Water is not an essential condition for WELs formation. The deformed subsurface pearlite structure was found bellow WEL, which prove that squat initiation is associated with RCF and the presence of WELs on rail surface. In contrast, only thin WEL up to 10 µm in thickness are observed for wet affected rail as majority of WELs are removed by dynamic contact force between wheel and rail.

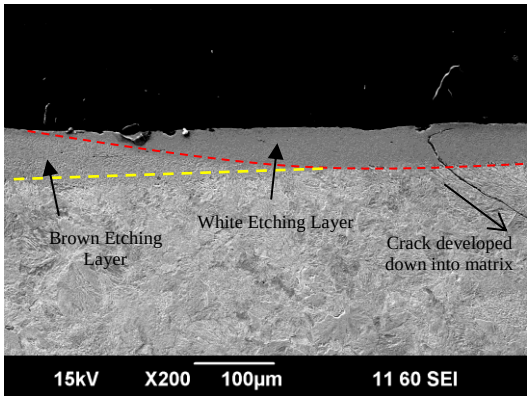

Figure 4 *Metallurgical observation of rail sample under dry contact.*

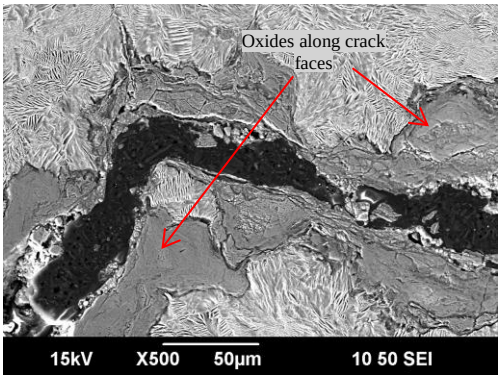

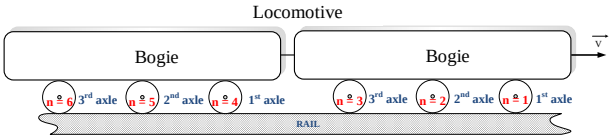

Figure 5 *Metallurgical observation of crack path for rail sample under wet contact.*

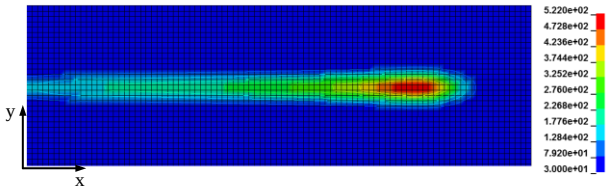
Figure 5 shows crack path for rail sample subject to wet contact due to water dropping from an air-conditioning system. The presence of significant amount of iron oxides inside crack suggests the existence of water, which is entrapped by wheel/rail interactions. When iron oxides are produced in steel material, the volume of original region is significantly increased. Hence, in addition to high pressure induced by hydraulic entrapment of water, the expansion in volume also causes high tensile stresses inside the crack faces. It is interesting to note the oxide along the crack faces is characterised by its undeformed microstructure, which means there was no friction between crack faces. Thus, it can be concluded that the crack growth was driven by tensile stress rather than shear stress. The presence of corrosive products including chlorine (Cl) and sulphur (S) elements inside the crack faces and tips can be a source of crack growth. It means that the mechanism of stress corrosion cracking (SCC) contribute in crack growth.



The above results prove the hypothesis of hydraulic entrapment of water on squat formation and to reveal the role of stress corrosion cracking on crack growth.

2.5. FE modelling of wheel-rail contact with the consideration of WEL

A 3D coupled thermal-mechanical FE model was developed to examine temperature rise due to high adhesion between wheel and rail [38]. The numerical model employed the moving heat source code developed by Goldak within ANSYS/LS-DYNA. The influence of multi-passes from multiple wheels attached to the locomotives on one point of the rail was also taken into account. The results indicated the flash temperature at rail surface can reach 626 ^{o}C after 6 wheel passes (one loco, two bogies, 6 axle wheels) as shown in Figure 6. Gleeble thermo-mechanical simulation testing confirmed that WEL can form at temperatures as low as 550 ^{o}C under high pressure [27]; hence, the rail surface flash temperature was sufficiently high to form the white etching layer.

(a) Practical scenarios of locomative (n: number of wheel pass)

(b) Temperature contours on the surface

Figure 6 *Coupled thermal-mechanical FE model to determine temperature rise on rail*

Different from the downscale setup in the previous simulations [39,40], full-scale dimension of an ANZR1 wheel and a rail section of 1500 mm long was considered in a 2D wheel-rail contact FEM to evaluate the presence of WEL on fatigue life as shown in Figure 7. In order to understand influence of the WEL geometry, six geometries with a/b varying between 2 and 12.5 based on reported WEL microstructures have been simulated. The typical WEL thickness is 200 µm. The proposed FEM model has provided a systematical investigation on stress/strain distribution and fatigue life of the WEL during wheel-rail rolling contact with the consideration the true geometry, the realistic wheel and rail contact, traffic condition and rail materials.

There is a good agreement between simulated residual stress and experimental measurements by synchrotron diffraction technique. WEL has much higher

compressive residual stress than rail matrix. The residual stress in WEL along rolling direction was dominant and it was in compression with a maximum magnitude up to 600~700 MPa.

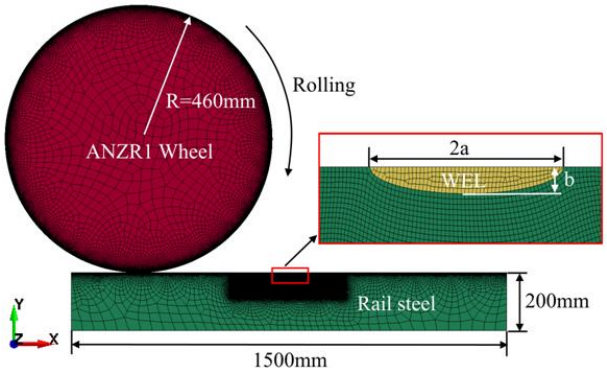


Figure 7 *Finite element simulations [41]*

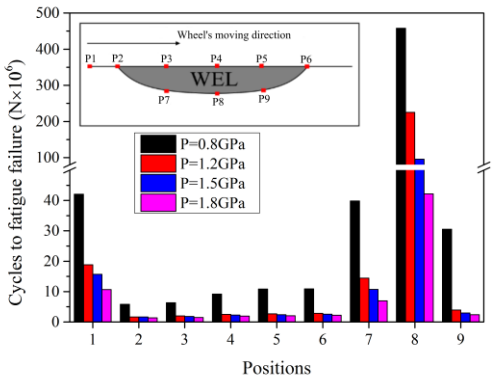

Figure 8 *Comparison of fatigue life at 8 different positions*

Compared with relative long fatigue life in rail matrix, the existence of WEL significantly reduces the life in service as shown in Figure 8. The shortest fatigue life occurred at the leading edge of WEL, followed by the middle of WEL and the trailing edge of WEL. It is interesting to note that the cracks will be initiated at the top surface of WEL rather than at the WEL and matrix interface. Loading pressure, friction coefficient and WEL geometry had a large influence on stress distributions in both rail matrix and WEL around the leading edge of the WEL. By contrast, slip ratio only had a minor influence. In addition, critical WEL geometry with a/b=5 (or α=22.6 °) has been found. Fatigue parameter of the WEL decreased quickly with a/b when it was less than 5 and then increased slightly when it was larger than 5. It also reveals that fatigue life of the WEL is reduced for high strength head-hardened (HH) rail compared with standard carbon (SC) rail.

2.6. Rail grinding strategy against squat

Squats have developed over the past 10 years and appear to have been getting worse in recent years. Traffic density, tonnage and speed have continued to increase, which has resulted in reduced available grinding windows. As shown in Figures 1 and 9, the increase in squat development coincides with an accumulated backlog of rail grinding (extended grinding interval and out of grinding cycle).

Rail grinding has proven reliable and effective for controlling wheel/rail contact stresses, reducing rolling contact fatigue defects and extending the life of rail [28,29]. Field work at Sydney Trains has clearly shown that surface lamination develops more quickly than that documented by most other railway networks. Grassie reviewed the surface initiated defects of the Sydney Trains network, and found that the surface lamination can develop to a depth of 2 mm within lower tonnage of 6 MGT of traffic, which equal 0.33 mm / MGT [5]. The Shinkansen's data is approximately 0.014 mm/MGT if the transverse crack were assumed to develop after 350MGT when the crack had reached 5 mm into the rail [28].The average rail life with preventive grinding and corrective grinding at Canadian Pacific Railway are 0.03 mm/MGT and 0.06 mm/MGT respectively [42].

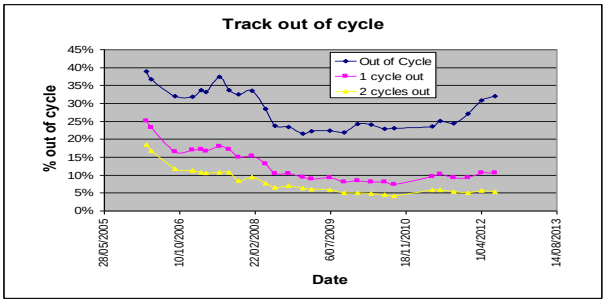

Figure 9 *Amount of track out of grinding cycle*

To address the deteriorated rail condition, a two steps preventive-gradual grinding approach has been recommended and commissioned into the track maintenance of Sydney Trains. Step1 is a transitional grinding in a progressive mode, which aims to address RCF problem and treat RCF affected track over a shorter grinding period with additional metal removal. The transitional grinding cycle needs to be short enough to cure the severe defects, and transfer to a preventive grinding regime from the deteriorated rail conditions within several cycles. Step 2 is a wear-like preventive grinding procedure, which aims to address squat problem by considering the competition of WELs formation and wear of rail. Metal removal at rail surface is suggested to follow a progressive mode with 0.05mm depth and around 10-15 MGT interval for each cycle

Two steps preventive-gradual grinding approach has contributed to control rail deterioration and minimize the risk of rail breaking. In 2017, the occurrence of broken rail has been significantly reduced, and a site monitoring was established to evaluate the long-term performance of new track maintenance strategy.

3. Conclusions

Through extensive metallurgical examination of the ex-service rails, state of the art experimentation and advanced modelling, we are researching rail surface degradation, especially squats in rails. Track maintenance strategy against squat defects has been

proposed and implemented. The major outcomes are summarized as follows:

A statistical-correlation analysis of squat defects helps to identify the popularity and severity of squat and parameters of the vehicle - track system. It has been found that there is a significant increase of squat defects since 2010. Increase in squat defects coincides with an accumulated backlog of rail grinding (extended grinding interval and out of grinding cycle). Squats occur on all types of track. There is no correlation with operations and geometries conditions.

A detailed metallurgical examination found that the brittle WELs play a critical role on squat initiation. The popular existence of WELs on rail surface contributes to the formation of squats under a relative low tonnage compared to the typical RCF defects in the Sydney Trains.

State of the art experimentation reveals the formation mechanics of WELs, including (1) severe plastic deformation; (2) flash temperature due to wheel slip; (3) leaking current between wheel/rail. Different track maintenance strategy is required to reflect the various types of formation mechanics of WELs.

Role of water on squat growth has been analyzed by metallurgical examination of rail in tunnel. It proves the hypothesis of hydraulic entrapment of water on squat formation from the ex-serviced rails and to reveal the role of stress corrosion cracking (SCC) on crack growth.

A comprehensive FEM modelling approach was introduced to investigate the wheel-rail contact, temperature rise at rail surface, and the contribution of WELs on fatigue life.

Rail grinding approach of removing a shallow depth of metal, typically of about 0.2 mm, by grinding at an interval of a few tens of MGT is not considered ideal. To address the deteriorated rail condition, a two steps preventive-gradual grinding approach is recommended and commissioned into the track maintenance of Sydney Trains. Step1 is a transitional grinding in a progressive mode, which aims to address RCF problem and treat RCF affected track over a shorter grinding period with additional metal removal. Step 2 is a wear-like preventive grinding procedure, which aims to address squat problem by considering the competition of WELs formation and wear of rail.

Abstract: Due to the change of wheel-rail contact parameters during the Electric Multiple Units (EMU) operation process, high-frequency abnormal vibrations occur in some vehicles. By coupling vibration test and modal test, it is proved that natural frequencies existing in the wheel-rail system are corresponding to those of the wheel polygon or rail corrugation frequency, and it is the main reason of the high-frequency abnormal vibrations. A wheel-rail dynamic monitoring system was established. This system uses ground wheel-rail force to monitor wheel polygons, uses axle box acceleration to monitor rail corrugation and the limit value of the methods also given.

Keywords: high-frequency abnormal vibration; dynamic monitoring system; mitigation measures; wheel polygon; rail corrugation; excitation resonance.

1. Introduction

The high-speed railway in China has been operating for nearly 10 years. Abnormal vibration in EMUs has always been a major problem that plagues the normal operation of passenger trains. In recent years some high-speed railways have abnormal vibrations such as component abnormal cracks that affect train operation safety. After investigation and analysis, it is found that the high frequency abnormal vibration is related to wheel polygons and rail corrugations. There are many studies on the causes of wheel polygons and rail corrugations. J. Kalousek [1-2] et al. began to study wheel polygons in 1992, and Frederick et al. [3,4] began to study rail corrugation in 1986. In recent years, many China scholars such as Jin Xuesong and Tan Licheng[5-7] have carried out a lot of research work on wheel polygon and rail corrugation phenomena. However, there are still many opinions about the occurrence and development mechanism of wheel polygonal wear, and no consensus has been reached[6]. In order to alleviate the high-frequency abnormal vibration caused by wheel polygon and rail corrugation as soon as possible, a dynamic monitoring system for wheel-rail should be established in time to quickly recognize the wheel polygon and rail corrugation phenomenon.

2. High-frequency Abnormal Vibration Phenomenon

During the inspection and maintenance, cracks phenomenon of brake disc bolts was found in an operating EMU. The abnormal vibration vehicle was tested by line vibration and measured by wheel static state. Simultaneously, the corresponding section of rail to the abnormal vibration was test static state. As shown in Figure 1, the results of line vibration test show that there is a significant peak frequency of fault brake disc around 514Hz and 843Hz. As shown in Figure 2 and Figure 3, the results of wheel-rail static measurement show that there are 26~28 orders polygon in the wheels of this type of EMU, and the 60mm~70mm wavelength of corrugation existing in the abnormal vibration section of the rail.

3. High frequency vibration causes analysis

3.1. Cause Analysis of abnormal Vibration of Brake Disc

As shown in Figure 4 and Figure 5, the hamper modal test on the complete state in the EMU is performed. The results are shown in Table 1. It can be seen that there is a natural frequency near 528 Hz and 852 Hz in the brake disc. After investigation, the EMU is mainly operated at two speed of 193km/h and 203km/h. As shown in Figure 6, there is a coincidence between the natural frequency of 528Hz and the wheel polygon frequency at this speed level, and the rail corrugation frequency coincides with the natural frequency of 852Hz. After turning on the wheel of the abnormal vibration EMU, the vibration data show that the peak frequency of 514Hz disappeared. And the peak frequency of 843Hz in the vibration data disappeared when the train passed through the non-corrugation section. The above phenomenon is a typical high-frequency abnormal vibration caused by wheel polygons and rail corrugations.

Table 1 *300-1000Hz brake disk modal test results*

Order		1	2	3	4
Brake disc	Frequency Hz	528	632	667	852
	Damping ratio %	2.45	3.281	1.525	0.549

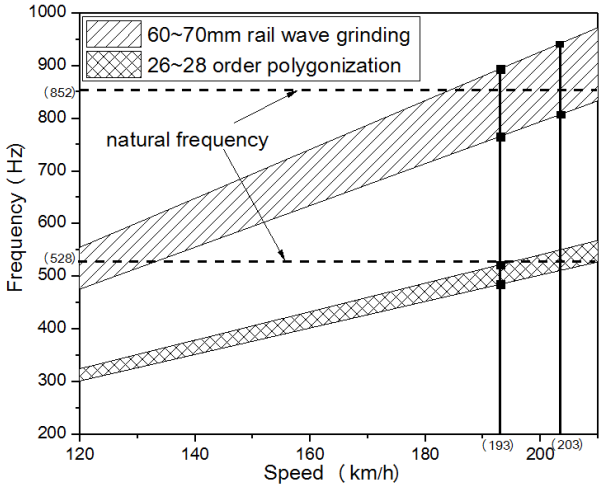

Figure 6 *Coincides between the wavelength frequency and natural frequency*

3.2. Natural Frequency Analysis of Wheel-rail System

In order to explore the reason why the wheel polygon and rail corrugation will occur, the component modal test and wheel-rail coupling vibration testing are used herein to

analyse the corresponding relation between the natural frequency of wheel, rail, fastener, rail board, etc and the wavelength frequency of wheel rail. Simultaneously, acceleration sensors are not only arranged at the positions such as rail, fastener, track board, etc in the fixed section of the track, but also arranged at the axle box, bogie, etc of the same type of vehicle that accident occurred for analysing the corresponding relation between the wavelength frequency of wheel-rail and the characteristic frequency of vehicle and track when the train passes the ground vibration measurement section.

(1) Analysis of Wheel-rail Modal Test

As shown in Figure 7 to Figure 9, the complete status hammering modal test on wheel, rail, fastener, track board is carried out, whose result is shown in Table 2. It can be seen that there is a natural frequency of wheel around 845Hz, which corresponds to that of rail corrugation. The natural frequencies of track boards exists near 530Hz and around 860Hz, which are corresponding to those of wheel polygon and rail corrugation respectively.

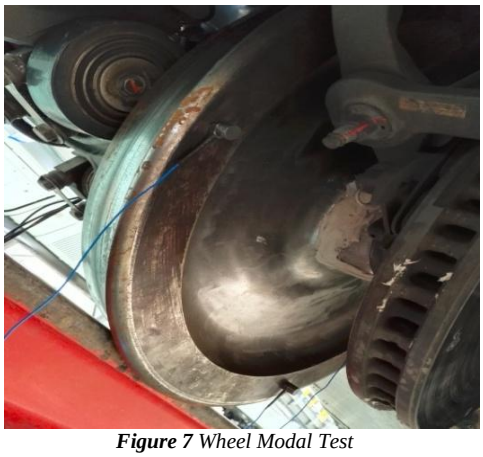

Figure 7 *Wheel Modal Test*

Figure 8 *Wheel-rail Modal Test*

Figure 9 *Modal Test of Fastener*

Table 2 *Main Modal Test Results of 300~1000Hz*

Orders		1	2	3	4
Wheel	Frequency Hz	346	384	648	845
	Damping ratio %	1.357	0.083	1.395	0.875
Rail	Frequency Hz	433	738	940	---
	Damping ratio %	0.761	0.074	0.767	0.507
Fastening	Frequency Hz	597	685	1124	---
	Damping ratio %	1.220	0.605	1.912	2.426
Track board	Frequency Hz	405	532	574	613
		671	766	803	864

(2) Wheel-rail Coupling Vibration Test Analysis

Axle box and bogie are bigger in mass and the modal test of hammering is not ideal, moreover, the boundary condition of the rail is difference between the modal test and the train passing. Therefore, the wheel-rail coupling vibration test is needed to analyse the characteristics frequency of the wheel-rail system.

Choose an abnormally vibrating vehicle, as shown in Figure 10, a laser pulse sensor should be installed under the vehicle, simultaneously, the reflector should be fixed on the track board at the ground measuring point. When the train passes the ground measurement point, the laser sensor is triggered to realize the wheel-rail synchronous coupling vibration test. As shown in Figure 11, an obvious peak frequency exists between the axle box and bogie around 530Hz, which corresponds to the wheel polygon frequency. Another obvious peak frequency exists near 750Hz to 870Hz, which corresponds to the rail corrugation frequency. Meanwhile, an obvious peak frequency of bogie exists near 550Hz, and this frequency is obviously amplified when it is transferred from the axle box to the bogie. The preliminary analysis suggests that there may be a natural frequency near 550Hz. As shown in Figure 12 and Figure 13, main peak frequencies of rail exist around 520Hz and around 870Hz, moreover, main peak frequency of track board exists around 500Hz.

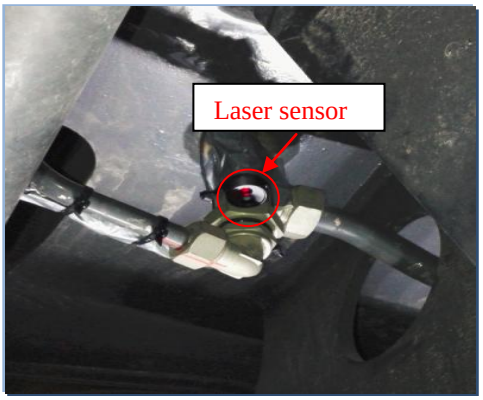

Figure 10 *Laser Sensor photo*

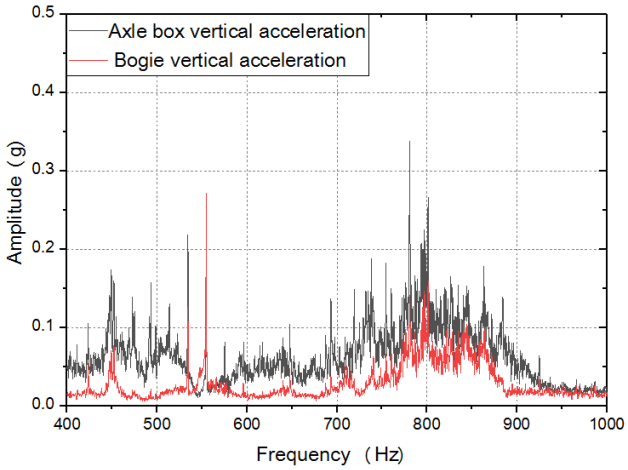

Figure 11 *Spectrum Diagram for Axle Box and Bogie*

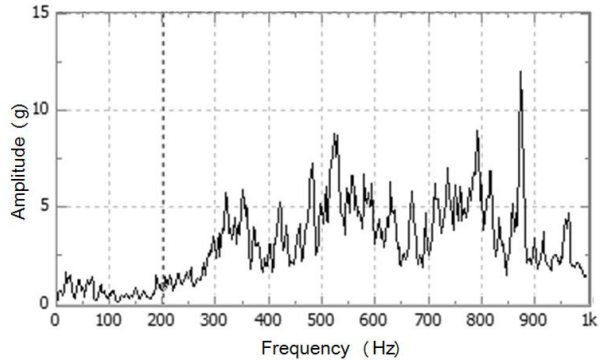

Figure 12. *Acceleration Spectrum of Rail*

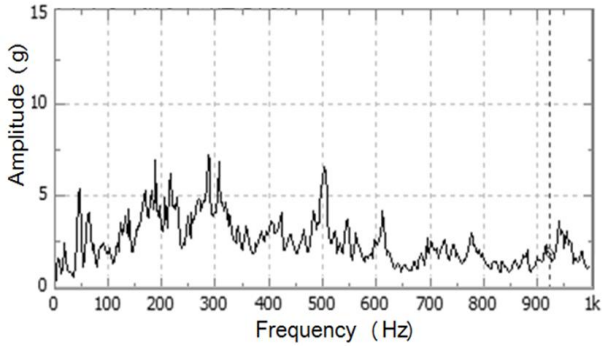

Figure 13 *Acceleration Spectrum of Track Board*

3.3. Comprehensive Analysis

The results of modal test and wheel-rail vibration test are summarized in Table 3. Because the boundary conditions for the modal test of wheel and brake disc are similar to that of vehicle running, the modal test result of wheel and brake disc can be used for comprehensive analysis. But the boundary condition of the rail is difference between the modal test and the train passing, so the rail modal test result can't be used for analysis. During the wheel-rail vibration test, the 550Hz frequency of the bogie may be related to its natural frequency, it can be used for comprehensive analysis. However, the frequency of the axle box and bogie at 750~870Hz may be related to the existence of light corrugation on the line itself. As there is no other vehicle data for comparison and elimination, the frequency is not used for comprehensive analysis. The peak frequencies existing at 520Hz and 870Hz of the rail and 500Hz of the track board are the common results derived from the comparative analysis on different types of vehicles, in a way, which can reflect its natural frequency, thus can be used for comprehensive analysis.

Table 3 *Summary of Test Results* *Hz*

Test Items	Name	Wheel Polygon 485~550	Rail Corrugation 766~940
Modal Test	Wheel	---	845
	Brake disc	528	852
	Rail	---	940
	Track board	532	766、803、864
Coupled Vibration Test	Bogie	550	750~870
	Axle box	---	750~870
	Rail	520	870
	Track board	500	---

The above frequencies which can be used for comprehensive analysis and the wheel polygon and rail corrugation frequency are summarized in Figure 14. It can be seen that the wheel polygonal frequency corresponds to the natural frequency of brake disc, as well as the vibration frequency of bogie, rail and track board. the rail corrugation frequency corresponds to the natural frequency of wheel and brake disc, as well as the vibration frequency of rail. In other words, there are natural frequencies in the wheel-rail system which corresponds to the wheel polygon frequency and the rail corrugation frequency.

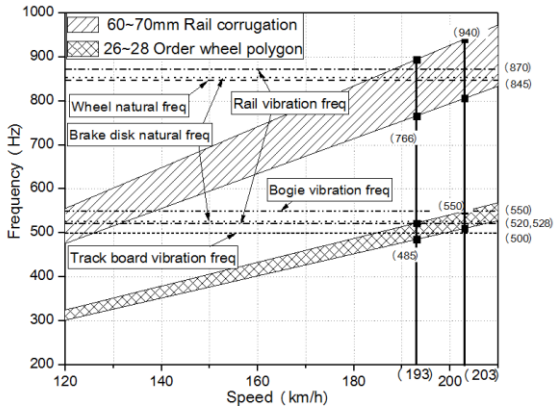

Figure 14 *Frequency Correspondence Analysis*

The coincidence of natural frequency and wavelength frequency is one of the main reasons for high-frequency vibration occurrence. Mitigating the impact of wheel polygon and rail corrugation on high-frequency vibration can be considered from two aspects: 1. Eliminating the excitation source, it can be achieved by wheel rotation repair and rail grinding; 2. Destroying the resonance of the wheel-rail system, it can be realized by means of cross-line running, variable speed running and mixed running of different models of vehicles.

Timely discover and eliminate the wheel-rail abnormal vibration at high frequency is prerequisite to guarantee the safe operation of the vehicle. Although the high-frequency abnormal vibration is an occasional event, but it is necessary to dynamically monitor its damage as it is destructive. The existing direct measurement method can't meet the detection demand due to its low efficiency[8], thus it is necessary to establish a complete

dynamic monitoring system, which can detect the rail corrugation through vehicles, and detect the wheel polygonal through ground measurement points.

4. Dynamic Monitoring of Rail Corrugation

As shown in Figure 15, a mass of measured data proved that there is a big difference between the acceleration signals of axle box when the vehicle passes through the rail corrugation section and the non-corrugation section. The axle box acceleration can be used to effectively identify the phenomenon and damage degree of rail corrugation. By comparing and analysing the measured rail corrugation data of different lines and the axle box vibration data of different types of EMU, the evaluation index Rc of rail corrugation was built by using vibration acceleration of axle box, for judging the condition of rail corrugation. As shown in Figure 16 and Figure 17, the dynamic monitoring system of rail corrugation is installed on the comprehensive detection train for regular dynamic detection on rail corrugation.

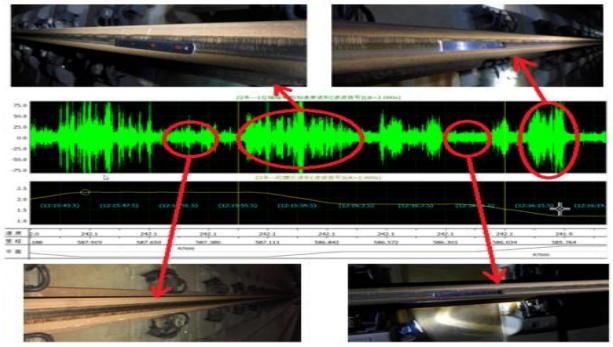

Figure 15 *Waveforms of corrugated and non-corrugated sections*

Figure 16 *Integrated testing vehicle inspection*

Rail corrugation index is R_C.

$$\text{—} \qquad (1)$$

R is the effective vertical vibration acceleration value of the axle box, and the formula is[8]:

$$- \qquad dx, \qquad (2)$$

Where y is the acceleration signal value; x is the signal sampling interval; L is the length of the analysis window.

R is the average effective value of the vertical vibration acceleration of the axle box. This value is obtained by testing the measured line rail by the integrated testing vehicle, and the rail is newly polished.

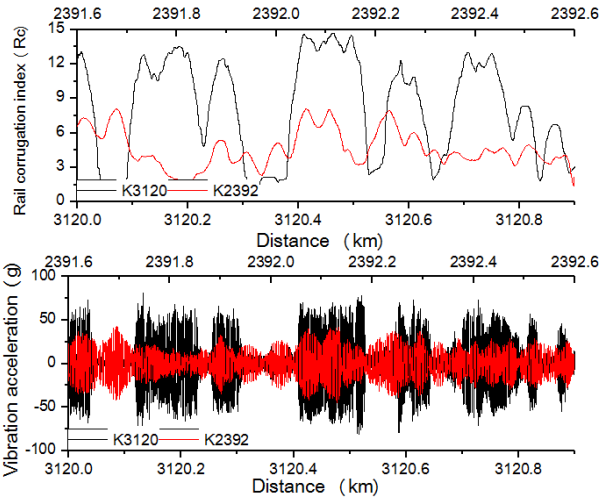

Figure 17 *Rail corrosion index comparison*

Compare the rail corrugation index with the actually measured rail corrugation conditions and get the limit of R_C:

If $15<R_C$, there is a deeper wave in the rails, and it is recommended that the rail should be polished immediately;

If $10<R_C\leq15$, there is corrugation in the rail, it is recommended that it should be polished as soon as possible;

If $5<R_C\leq10$, there is corrugation in the rail, it is recommended to observe regularly.

5. Wheel polygon dynamic monitoring

When there is a polygon in the wheel, it will inevitably produce a large impact of the rail. Therefore, the vertical force in the rail can be used to detect the wheel polygon. The vertical force can identify the order of wheel polygons and their harm degree. Figure 18 shows a monitoring system installed on a high-speed rail line. Through this system, the vertical force in each vehicle passing through the measuring point can be obtained. And the vehicle can be continuously tracked after the vehicle number identification is recognized. The alarm is achieved when the rail force exceeds the limit.

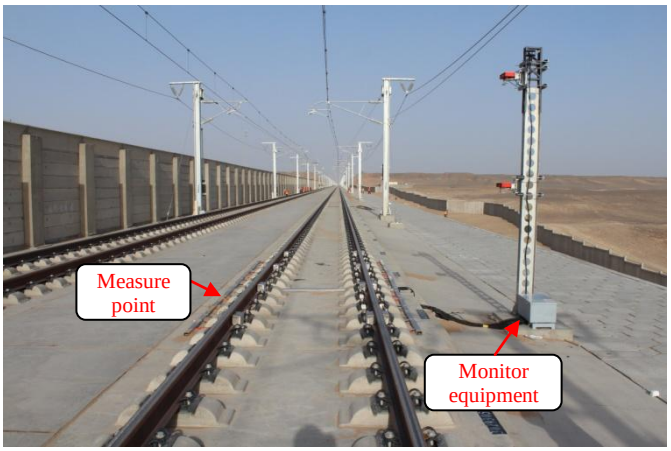

Figure 18 *High-speed rail ground monitoring system*

6. Conclusion

The modal test and coupling vibration test of wheel-rail system proved that there are natural frequency of wheel-rail system corresponds to the wheel polygon frequency and rail corrugation frequency, this is the main reason for the abnormal vibration at high frequency. Thus, high-frequency vibration can be effectively alleviated by eliminating excitation source and destroying the resonance of wheel-rail system. Meanwhile, the resonance of wheel-rail system may be related to the occurrence of wheel polygon and rail corrugation.

Timely detecting and eliminating abnormal high-frequency vibration in the wheel and rail are prerequisites for the safe operation in the vehicle. The direct measurement method can't meet the requirements of real-time monitoring. Through analysis the measured data, a wheel-rail dynamic monitoring system was established. This system uses ground wheel-rail force to monitor wheel polygons, uses vehicle acceleration to monitor rail corrugation and the limit value of the methods also given. The wheel-rail dynamic monitoring system can effectively identify wheel polygon and rail corrugation, which can effectively alleviate the high-frequency abnormal vibration problem in EMU.

Surface deformation 480
Surface quality 1191
Surface roughness 115, 639
Surface temperature 74
Surface texture 292
Switch 668
Switch panel 123, 648
Switches & crossings 196, 902
Synchrosqueezed short time Fourier transform 1141
Synchrotron diffraction 18

Tackiness 356
Tangential contact 681, 1181
Tangential force 1147
Telemetry system 1037
Temperature effect 163
Temperatures 1029
Test 633, 870
Test infrastructure 382
Test rig 993

Test track 567
Tgamma approach 181
The Green's function 147
The volume of sand 314
Thermal damage 245
Thermal effect 1096
Thermal martensite 921
Thermocouples 1029
Third body 208
Third body layer 431, 727, 1013
Torsion fatigue test 457
Torsional vibration 261
Track 130
Track damage 914
Track friendliness 81
Track impact Index 587
Track irregularities 767
Track short-wave irregularity 587
Track stress level 954
Trackbed 529
Traction 90, 208, 727
Traction/braking force 985
Traction coefficient 281, 292, 419, 727
Traction control 914
Traction enhancement 886
Traction force 624

Traction gels 1090
Traction-creep curve 720
Train-track interaction 228, 238
Tram-ways safety 1007
Transition zone 1
Transmission electron microscopy 18
Transverse crack 391
Transverse friction-coupled wheelset 503
Tread braking 163, 1029
Tri-axial stress analysis 844
Tribological testing 886
Tribometer 74, 208
Trolley for service applications 1007
Turnout 567
Twin-disc test 350, 838
Twin-disc testing 181, 610
Twin-disk 172, 292
Two-disk laboratory testing 383
Two-point cyclic rolling contact 938

Ultrasound 281, 518

Validation 870
Vanguard fasteners 1107
Vehicle dynamics 1043, 1147
Vehicle-track coupled dynamics 147, 962

Vehicle–track interaction 1
Vertical split rim 457
VFD pulsating torque 261
Vibration 818
Vibration acceleration frequency 50
Vibration analysis 856
Virtual measurement 333
Virtual penetration 1213
Viscoelastic layer 322

Wagon-track interaction 954
Water lubrication 115, 592
Wave interference 1066
