PREFACE

The 2024 European Conference on Computing in Construction was held as a mixed Conference from July 14 – July 17, 2024. The conference had 170 attendees that presented work and exchanged ideas in the areas of the conference. This book contains the papers that were submitted to the conference and were accepted after a rigorous peer-review process.

The EC^3 conference will be a core activity of EC^3. The conference organisation is managed independently by a group of volunteers. The present conference is the 6th annual event of EC^3.

The EC^3 2024 proceedings include an illustrated review of the program, the names of organizations and persons who contributed to the technical program. The peer review process consisted of two phases. Firstly, we received 55 optional abstracts that were reviewed by the respective area chairs. Following a rigorous full paper peer review process (with each full paper being reviewed by at least two reviewers drawn from the scientific committee of international experts, and final decisions being made collectively by the corresponding track and programme chairs, for two rounds of review), 131 outstanding full papers were ultimately included in the proceedings and presentation at the conference. The manuscripts were presented during 2 plenary sessions and 22 technical sessions, including topics that focused on:

- Blockchain & Distributed Ledger Technology
- Data Analysis, Simulation, & Resilience
- Data Integration Methods
- Data Sensing & Acquisition
- Education, Policy, and Standardisation
- Energy Modelling & Monitoring
- Product and Process Modeling
- Virtual and Augmented Reality

Please note: All EC^3 proceedings and session recordings are available at no cost from https://ec-3.org/publications/conference/. *All conference papers now have a unique DOI and are comprehensively meta-tagged to ensure easy discovery by commonly used search and indexing services.*

Additionally, the conference included four sessions dedicated to the technical committee work of the EC^3 and these included:

- Data Sensing and Analysis (DSA) Committee
- Modelling and Standards Technical (M&S) Committee
- Education (EDU) Committee
- Human Digital Interaction (HDI) Technical Committee

One further track allowed participants to communicate embryonic or thesis-related work through sessions dedicated to:

- Thesis-related work in the form of a Thesis-in-3 competition for students.

A day-long practical workshop for junior researchers on how to become an effective author of highly-ranked, peer-reviewed scholarly journal papers has been held by Prof. Mirosław J. Skibniewski. It conveyed the practical experience of a 30-year-long veteran editor-in-chief of a top-ranking international research journal focused on construction IT and related technologies.

During a dedicated session, PhD/Junior Researchers-Mentor round tables were conducted, with the scope of developing mentees' writing strength, clear goals, and personal growth.

In addition to the technical content, the conference also provided opportunities for fellowship and networking in informal events.

We would like to thank the EC^3 scientific community, including both academic and industry members for their contributions and support; the scientific committee (see specific acknowledgements below); Wahib Saif, Marta Boscariol, Dominik Hartmann for their invaluable support during the conference and the preparatory stages, and Sobia Bano for maintaining the conference website.

To all EC^3 2024 attendees: we sincerely appreciate your participation and involvement in this conference. We hope this experience provided opportunities to renew friendships and professional relationships, forge new ones, spark exciting new research ideas, and enjoy the scenery and surroundings in a beautiful setting!

Dr. Marijana Srećković, TU Wien, EC^3 Programme Chair, and Prof. Mohamad Kassem, Newcastle University, EC^3 Conference Chair.

EC3 SPONSORS:

We would like to thank our sponsors and academic partners for their generous contributions to the congress.

ACADEMIC PARTNERS:

EUROPEAN COUNCIL ON COMPUTING IN CONSTRUCTION

The **European Council on Computing in Construction (EC^3)** is a recently established society of construction professionals, academics, researchers and national Professional Bodies, aspiring to become the leading European forum in the area of information technology in construction engineering and management.

Role of EC^3

The **European Council on Computing in Construction (EC^3)** advances professional knowledge and improves engineering practice in the built environment by fostering research, education and policy in current and emerging computing and information technologies.

EC^3 is founded on the following four pillars and corresponding Technical Committees:

- DSA: Data Sensing & Analysis
- M&S: Modelling & Standards
- HDI: Human Data Interaction
- EDU: Education

EC^3 interacts strongly with other Architecture, Engineering, Construction and Facility Management (AEC/FM) societies in related areas, strengthen the collaborations between academia and industry in topics related to **EC^3**'s mission, spearhead research on such topics, identify and promote effective ways to advance the state of knowledge and the level of education and practice in these topics, assist in the making of policy, and support existing and new related specialty conferences and publications.

Technical Committees

The role of all technical committees is to:

- Gather, maintain and disseminate information on the application of the committee's area to AEC/FM
- Organise and support joint research activities in the committee's area
- Organise and support conference sessions, workshops, and meetings in the committee's area
- Disseminate innovation in the committee's area through position papers, white papers, grand challenges reports and policy work throughout the European spectrum
- Keep the SPAs aware of developments in the committee's area

Conference Committee:

Prof. Mohamad Kassem, Newcastle University (General Chair)
Dr. Marijana Srećković, TU Wien (Programme Chair)
Dr. Ranjith Soman, TU Delft (Dissemination Chair)
Dr. Athanasios Chassiakos, University of Patras (Publications Chair)

Acknowledgements

Conference host:

The European Council on Computing in Construction

The organisers would like to thank the Area Chairs and the Scientific Committee members for their contributions to the paper review and selection process. We would also like to thank the Technical Committee members for their invaluable contributions and hard work to deliver the other activities that took place in addition to the mainstream paper presentations.

Area Chairs:

Blockchain & Distributed Ledger Technology:

Dr. Jennifer Li, *Northumbria University, UK*

Data Analysis, Simulation, & Resilience:

Dr. Alessandro Carbonari, *Polytechnic University of Marche, IT*

Data Integration Methods:

Dr. Pieter Pauwels, *Eindhoven University of Technology, NL*

TABLE OF CONTENTS

Blockchain and Distributed Ledger Technology

BLOCKCHAIN-BASED COMMON DATA ENVIRONMENTS TO ADDRESS DATA AND INFORMATION FRAGMENTATION IN THE DUTCH CONSTRUCTION INDUSTRY

Rowan Kloosterman[1], Martijn Smits[1], Wasim Haji[1], Jennifer Li[2]
[1]Amsterdam University of Applied Sciences, Amsterdam, The Netherlands
[2]Northumbria University, Amsterdam, The Netherlands

Abstract

In the Dutch construction industry, the demand for advanced information storage and sharing is growing due to the complexity of construction projects. Limitations of traditional methods include lack of transparency and inefficient communication. Blockchain offers a promising solution by enabling decentralized storage and immutable recording of data increasing transparency and efficiency in the construction supply chain. Combining a Common Data Environment with the InterPlanetary File System – decentralized file storage and exchange, and a powerful tool for secure, efficient and reliable data management in construction – can emerge to improve cooperation between parties increasing effectiveness of projects.

Introduction

The construction industry is not known for being highly innovative. In general, construction companies struggle to keep up with the speed of technological developments and innovations (van Sante, 2016). A major obstacle to innovation and change in construction is the high degree of project-driven working and fragmentation (Nawi et al., 2014; Li, 2023). The different construction phases of a structure (vertical fragmentation), the specialized stakeholders (horizontal fragmentation) and the different, often complex projects create many challenges within the industry (Fergusson, 1993; Adriaanse, 2014).

While the application of Building Information Modelling (BIM) has become increasingly accepted in construction, making optimal use of it appears difficult (Canon, 2019). According to Koutsogiannis and Berntsen (2019), 95% of the data generated is lost between the parties involved and the different construction process phases. Construction information is rarely reliable and available, which is largely due to the limited connection between parties as a result of fragmentation (Adriaanse, 2014; Volker, 2019).

In the Netherlands, strong fragmentation and specialization perpetuate, with project-based approaches being the norm (Adriaanse et al., 2020). These characteristics present significant challenges, especially considering the growing amount of information generated throughout the life cycle of projects (Koutsogiannis and Berntsen, 2019). In practice, there often appear to be problems related to the availability and reliability of construction information, which has significant implications for the efficiency and effectiveness of construction projects (Chong et al., 2014). The transfer and preservation of construction information is a crucial part of the construction process and will become even more important in the future. Making and keeping information available and reliable is something that is a hot topic in many sectors. A development which is often associated with transparent and reliable exchange of data is Blockchain Technology (Puthal *et al.*, 2018).

The overarching objective of this study is to assess the viability of integrating blockchain with Common Data Environments (CDEs) to enhance the accessibility and dependability of building information within the Dutch construction sector. This focus is crucial as building information plays a pivotal role in streamlining construction processes across the life cycle of buildings in the Netherlands, ultimately fostering opportunities for long-term material reuse initiatives (Jaskula, et al., 2023).

The research question for this study is: "*How can the integration of blockchain and CDEs be leveraged to enhance the availability and reliability of building information in the Netherlands?*"

This paper reports on preliminary research focused on the exploration of information management within the Dutch construction sector. By examining local practices and challenges, this study allows researchers to contextualize and compare the findings in the Dutch context with research from other countries regarding information management in construction. This adds insights to the body of knowledge and facilitates the Netherlands in learning from other contexts, thus contributing to a broader understanding of information management practices in the construction sector.

In next section, the literature review introduces blockchain technology, and identifies challenges to current information management and CDEs in construction. The methodology explains the approach for the study centred on interviews and a use case evaluation, the results of which are then presented. The final two chapters bring discussion and conclusions of the study.

Literature Review

Blockchain technology

Many current database systems operate within a centralized architecture, where users have permission to modify data stored on the central server. A central authority manages the entire database, including access control and user authentication (Sarmah, 2018). Blockchain, often associated with cryptocurrencies such as Bitcoin, offers a decentralized approach. It is a type of Distributed Ledger Technology (DLT) that has the potential to spark a new industrial revolution (Perez, 2009). Unlike centralized systems, blockchain is managed and validated by a global network of peer-to-peer connected computers where no one individual or organisation has control over the data (Jena and Dash, 2021). This creates a digital database that is built, shared, validated and synchronized by participants eliminating the need for a central authority where everyone has access to the latest version of the ledger (Lashkari and Musilek, 2021). Transactions are sent to the network, validated by computer algorithms, and linked to previous transactions, creating an immutable chain. The distributed structure of blockchain and the confirmed guarantees of nodes make information almost impossible to manipulate, which increases trust between participants. This provides a solution to the limitations of traditional centralized systems (Bodkhe *et al.*, 2020).

Blockchains can be public or private. Public blockchains are open systems without authority; anyone can join and be granted full rights to participate (Guégan, 2017). The verifiability and transparency of information are central features as there are no access restrictions imposed. Public blockchains are not recommended for large or energy-sensitive domains. Private blockchains have limited access to the network and are shared privately between specific participants with communication protocols. Only pre-verified individuals meeting certain requirements are allowed to perform certain operations on the blockchain (Yang et al., 2020). Between public and private sits the consortium blockchain where only organizations or groups with the same goals can join (Jabbar et al., 2022). The degree of decentralization varies in DLT networks from full decentralization (e.g., Bitcoin) to lower decentralization with some form of hierarchy for direction and control (e.g., Hyperledger), depending on the specific application and parties involved (Hamilton, 2019).

Information management

Fragmentation in information management

Due to the dynamic and complex nature of construction, different professions and specializations have emerged, roughly divided into the well-known construction phases: initiators, designers, builders, maintenance parties (Nawi et al., 2014). In this subdivision, a clear structure is visible with strong separation between the different construction phases (Adriaanse, 2014). Within these phases, there is a high degree of specialization leading to many companies becoming involved in a construction project all having their own contributions and interests. In many cases, this leads to difficulties in communication and coordinating all the parties in the construction process (Chong et al., 2014; Di Giuda et al., 2020). Despite this high degree of specialization often presenting challenges, construction has proven to be a key piece in the overall development of society. Without the necessary infrastructure, many developments would have been much more difficult and society would be less developed (van Breugel, 2019). The construction industry exhibits considerable fragmentation as an inherent feature of its structure and mode of operation. It is often compared to an ‘archipelago’, consisting of several ‘islands’ that are highly distributed across three levels (Adriaanse, 2014) – vertical, horizontal and longitudinal. This complex structure leads to communication challenges between stakeholders, construction process phases and projects themselves (Dave and Koskela, 2009). This division results in significant challenges in communication and coordination among stakeholders (Fergusson, 1993).

CDEs for information management

The increasing complexity of construction projects, coupled with the need for real-time information sharing, underscores the necessity for digitalization in the construction industry (Agarwal et al., 2016). A CDE serves as a comprehensive data store for all project-related information, including geometric and semantic data, as well as documentation, throughout the construction project life cycle (British Standards Institution, 2013). By consolidating all information into one accessible location, the CDE acts as a central information management tool, facilitating efficient collaboration and communication among stakeholders (Preidel *et al.*, 2017). We consider whether the CDE can play a central role in integrating and managing information among stakeholders.

Efficient information management is paramount for project success due to the complexity and abundance of data generated during construction projects (Di Giuda et al., 2020). Defined by ISO 19650-1:2018, a CDE functions as an agreed-upon information resource for a project or asset, enabling the collection, management, and dissemination of information through a controlled process (ISO, 2018). It encompasses both a CDE solution, typically cloud- or server-based technology with database management features, and a structured CDE workflow that organizes information flow and management throughout the asset life cycle (BIM Dictionary, 2022).

Jaskula et al. (2022) outlines three levels of CDE maturity based on document management, life cycle functionality, security, and BIM integration. At its core, the CDE enhances information management by providing stakeholders with a unified platform for accessing, sharing, and collaborating on project data. This centralized approach fosters transparency, reduces errors, and improves decision-making, ultimately contributing to the overall success of construction projects. Cloud storage services such as Dropbox are categorized as Level 1 CDE due to limited integration with BIM technology and do not offer advanced management capabilities nor a high level of security. More advanced CDE tools such as Viewpoint, Asite, Procore, Deltek, or ProjectWise are considered Level 2 CDE for BIM because they offer BIM visualization and communication based on BIM formats such as BIM Collaboration Format (BCF) and Industry Foundation Classes (IFC) in addition to document management. Additionally, integrating technology such as the InterPlanetary File System (IPFS) could enhance the capabilities of CDE tools, potentially elevating them to Level 3 BIM integration. IPFS, with its decentralized and distributed file system, offers advantages such as increased data integrity, redundancy, and resilience against censorship. Platforms like Autodesk's BIM 360 or BIMcollab, integrated with IPFS, could offer Level 3 functionality for multidisciplinary real-time collaboration and document management, serving as a more comprehensive single source of truth throughout the life cycle of construction projects. However, this integration may still require further development and evaluation to ensure seamless compatibility and functionality within existing CDE frameworks (Jaskula et al., 2023).

IPFS as a solution to information management

While blockchain can store information, it is not a realistic solution for storing large amounts of building information (Kloosterman and Smits, 2023) for being prohibitively expensive and demands significant computational power. Therefore, current iterations of blockchain are not suitable for the collaboration and sharing of large amounts of data. This challenge can be addressed by integrating blockchain with IPFS (Steichen *et al.*, 2018), which allows participants to directly connect to each other without the need for a central server (Muralidharan and Heedong, 2019; Bennet, 2020). A major advantage is that IPFS allows flexible storage of large files. Each file uploaded to the IPFS network is encrypted into a cryptographic hash value referred to as a content identifier (CID). IPFS is considered a valuable addition because it can solve the problem of inefficient, bulky data storage in blockchain (Steichen *et al.*, 2018; Nyaletey *et al.*, 2019). In other words, users can choose to store design files or documents in IPFS and place only CIDs in blockchain transactions.

Implementation of the blockchain-IPFS CDE solution faces two challenges: (1) establishing the collaboration workflow of a CDE that integrates blockchain and IPFS, and (2) exchanging design information in such an environment. Regarding (1), limited studies have examined which CDE container(s) should use blockchain and the logic of collaborating in such a distributed environment (Ye and König, 2021). Regarding (2), in a blockchain network, users exchange information by proposing transactions and using smart contracts. But the data model of transactions and smart contracts that meets the requirements of CDE is not yet developed, which complicates communication between designers (Tao *et al.*, 2021). It is expected that these challenges will be addressed in due course within the research community; proposing solutions is outside the scope of this paper.

Methodology

To answer the research question, this study adopted an interpretivist philosophy and an inductive approach to data collection and analysis. The methodology can be seen graphically in Figure 1 below.

First, a literature review was conducted to understand the issues surrounding fragmentation in the Dutch construction industry, the nature of construction information and the opportunities offered by Blockchain.

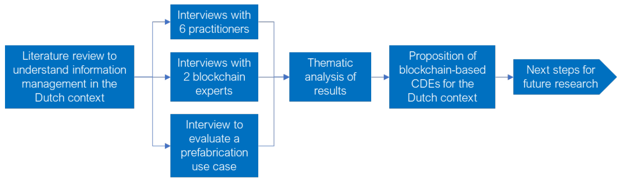

Figure 1: Methodology for the study

The findings of the literature review formed the basis of interviews with six industry practitioners (#1 to #6 in Table 1) and two blockchain experts (#7 and #8 in Table 1) contrasted with evaluation of a use case with a BIM Coordinator of a prefabrication project (#9 in Table 1) in the Netherlands. Finally, a validation interview took place with an academic with extensive knowledge of blockchain in construction (#10 in Table 1). The interviews with industry practitioners centred on investigating opportunities for enhancing communication and optimizing information utilization. Both positive and negative feedback were documented regarding various aspects including the availability and reliability of information, communication exchanges, and data storage. These insights are crucial for identifying areas for improvement and pinpointing specific pain points within current practices.

Table 1 presents the profiles of the participants, who were chosen based on their roles to ensure representation across different phases of construction projects. Conducted in Dutch, semi-structured interviews allowed for the organic evolution of topics and the emergence of new insights, with subsequent translation into English for analysis.

Table 1: Profile of Participants

ID	Function	Type of business	Subject
#1	Deputy director	Developer	
#2	Project leader	Architect	
#3	Managing director	BIM model elaboration	Data exchange and life cycle optimisation
#4	Project leader	Contractor	
#5	Project leader	Housing corporation	
#6	Transfer team leader	Housing corporation	
#7	Blockchain expert	Software developer	
#8	Blockchain expert	Knowledge organization	Blockchain
#9	BIM Coordinator	Prefabrication	Data generation and transfer
#10	Lecturer	University	Validation

Subsequent to the interviews, a use case was evaluated to examine the impact of using a single central source of truth on the availability and reliability of construction information with specific relevance to the Dutch context. The interviews with the blockchain experts also addressed these topics, but with a specific focus on the potential role of blockchain technology in transforming data exchange. The central question here was whether blockchain can add value to an alternative approach to data communication, addressing aspects such as information availability, reliability and storage in an innovative way. The use case was used to gain insights into whether working within a single network – such as a blockchain – has benefits for information exchange and availability. In fact, different departments within the company use the same information sharing system.

Upon collection of the data, thematic analysis was applied following Williams and Moser's (2019) three-step coding process. First open codes were identified, then refined into selective codes and finally themes were identified across the data. Table 2 shows the resultant themes along with analysis of positive or negative comments being made across the three sets of interviews.

Table 2: Evaluation of comments from the interviews

Themes	Current		Blockchain		Use Case	
	-ve	+ve	-ve	+ve	-ve	+ve
Availability	58	56	5	18	2	23
Reliability-Trust	60	67	6	44	3	25
Exchange-Communication	83	95	2	12	4	11
Storage	29	19	9	16	0	9
Construction information	133	130	23	68	1	19
Collaboration	51	76	5	16	4	25
BIM	58	87	2	16	1	6

Results of the interviews

The interviews were designed to explore three main aspects: the current situation, the potential added value of blockchain and a use case. Three sets of interviews were conducted with respondents from the construction industry, blockchain experts and as part of a case study.

The results, analysed thematically and summarized in Table 2, show the current situation around these topics is fairly even, with roughly equal numbers of positive and negative comments. However, when asked whether blockchain can add value, more positive statements emerged. This suggests that blockchain could be beneficial for these aspects. Furthermore, it was found that working within one network and with one source of truth produced more positive as well as negative expressions on the various topics. This indicates the potential of a blockchain-based structure to improve collaboration and information sharing.

Current situation with information exchange

The results of examining the current situation with information exchange show there is a clear need for available and reliable construction information. One crucial aspect that emerged from the interviews is the location where information is stored. Several stakeholders emphasized that construction work information is often stored on their own servers or systems, resulting in scattered and fragmented data storage. The interviews also revealed that just a shared storage location is not enough. Participant #2 said, "*That is the place where everyone leaves their information. In several projects, we have found this often acts as a kind of dumping ground for information. While anyone can put information there, there is often a lack of adequate version control and determination of relevance. Managing older data or directing that information is often neglected*". This makes it difficult to quickly access the information needed and forces parties to exchange information through external channels as indicated by participant #6: "*I get a very large information portion from the contractor through a USB stick*" (#6).

An adverse consequence of this information sharing is the challenge of identifying the most recent version of documents (e.g., drawings). "*The more information you have to share, the more mistakes are made*" (#2). This creates the risk of working with outdated or incorrect information, which can damage the reliability of construction work information. "*You will always have the customer or contractor working with a different system*" (#9). To address these issues, some stakeholders are already experimenting with software solutions that bring together construction work information in one central location. These CDEs are welcomed by respondents who recognize the benefits of centralized access to and exchange of information: "*You really need to have a place where the information is centralized, because it disappears everywhere. Everyone has different information and then what's the right version? You just lose that overview*" (#3). They believe such CDEs will improve the availability and reliability of construction information in the future: "*Of course, it would be much nicer if something from the contractor went directly into our system*" (#6).

These statements represent that the exchange and storage of construction information in construction could be significantly improved. Often, information is distributed to stakeholders in different ways, leading to ambiguity about the correct version. This leads to mutual consultation among stakeholders without everyone being aware, often resulting in parallel efforts and different versions of the 'truth'. According to respondents, the demand for a central source of information can yield significant gains in information management. Participant #6 indicated that a lot information is lost during construction and after handover. As a result, valuable data are missing during operation. Participants also indicated that there is no seamless connection between business information, with participant #6 indicating that it would be more efficient if the contractor could add information directly to the server. When asked whether applying blockchain in the Dutch construction industry can help improve information management and collaboration, there were mixed responses. Mainly, the lack of knowledge about blockchain and overall market adoption are mentioned as obstacles. Proper education about the possibilities can promote broader implementation. Participant #9 indicated that they are open to new technologies if they are beneficial for overall construction and information management in the different phases.

Added value through blockchain technology

The interviews with blockchain experts aimed to explore how blockchain can contribute to achieving more reliable and accessible information. A key focus was to identify the most appropriate form of blockchain for collaboration between different stakeholders. This involved asking about different types of blockchains (e.g., public, private, consortium), and examining the features most conducive to effective collaboration. In addition, the research assessed the impact of using blockchain in businesses by examining the potential benefits of blockchain adoption and identifying the challenges and adjustments needed when transitioning to a blockchain-based business model. Finally, they explored why blockchain, despite several years of existence, has not yet been fully utilized. Through these interviews, it was hoped the potential obstacles that may hinder implementation of blockchain in the Dutch construction industry could be better understood.

The results indicate that while storing large volumes of information on a blockchain is possible, it is also be prohibitively expensive and demands significant computational power. Therefore, it may be more practical to consider recording only the transactions associated with that information on the blockchain. *"The bitcoin-blockchain is extremely slow and poor to use for storing information. But it is very good at transferring values because it is so secure"* (#8). This approach can enhance the reliability of information without incurring excessive costs or energy consumption. Additionally, it is worth noting that the information is hashed, and the resulting hash code is processed through the blockchain, ensuring data integrity and security. Blockchain expert #8 expressed that "*you have to see the blockchain as the party that fixes the information that parties exchange with each other. A kind of notary*". This makes the implementation of a CDE a considerable necessity, as it promotes the availability of information for all parties involved. It ensures transparency and accessibility of information, which enhances collaboration and information sharing. The findings also highlight that blockchain is an additional layer within the ICT infrastructure because "*you actually have to really separate it from the database, it's just a different kind of technology*" (#8). It provides a secure and decentralized infrastructure for storing and verifying data, which promotes trust and transparency.

For collaborations involving stakeholders with hierarchical structures, private (consortium) blockchains are recommended by participant #8. This allows participants to work together within a shared network where specific roles and authority can be assigned as well as structured collaboration and decision-making giving parties "*the ability to share data among themselves. Moreover, it is configurable, so you can configure which parties specifically share data with each other. You have full control over this configuration*" (#7).

Based on these interviews, it can be said that the demand for structured and reliable information management is strong in the industry. The large-scale implementation of CDEs is lagging partly because of the lack of structure and control. This is where blockchain technology can add value. By capturing construction information using blockchain, it is possible to keep track of changes and other important issues. The ultimate goal with this is to roll out the large-scale application of central data management in construction.

Use Case: Prefabricated wall panels

To test an 'ideal situation' and focus on information exchange between cooperating departments within a single organization, a use case was evaluated. A factory specializing in the production of precast elements was chosen. As a modern method of construction, prefabrication has a more integrated supply chain than that of traditional construction sites (Ocheoha and Moselhi, 2018) and is, therefore, potentially more susceptible to adoption of blockchain in the near-term (Olawumi *et al.*, 2022).

The aim of the use case evaluation was to gain insight into how information is exchanged when internal stakeholders work together within the same network. This study focused specifically on the methods and processes used to share and communicate information among the departments involved and whether there is a 'Single Source of Truth' for all stakeholders to reliably access. The evaluation produced several results that highlight the benefits of working with a single source of truth. It was found to improve the reliability of information because all necessary data are stored in one central location, eliminating incorrect or contradictory information. This contributes to a higher degree of reliability and accuracy in the production process such that "*IFC is the digital source model of the prototype we make and with that we control the production*" (#9). In addition, working with a single source of truth adds value to the optimization and automation process. It streamlines information exchange and creates an efficient workflow. "*We have software that does our planning and also ultimately controls production. And through that system we have files for the lasers, for the plotter; files are generated*" (#9). By working with a centralized resource, processes can be automated and more emphasis can be placed on optimization and improvement of production. An additional advantage is that all employees and departments have access to the same data "*so we are working with the same source information*" (#9). Having the source information stored in one place with easy accessibility promotes communication and collaboration within the organization. Everyone can have access to the most recent and relevant data at any time ensuring better coordination and handling of tasks and processes. Information is no longer distributed through emails between internal stakeholders, but everyone knows where to find the information. This prevents duplication of information and ensures that the 'production model' is and remains the only source of truth. The downside of intensive use of the source model is that any changes made during the process must be updated in the model to avoid production errors, as many processes are based on the source information and automation. "*We aim to integrate as much information as possible into the production model that drives our production process. We want this to be the source of information*" (#9).

During the interview, it was noticed that company employees showed remarkably more mutual engagement than is common in the construction industry. This result can be attributed to the fact that they work together within one network or all work for the same company, which fosters a sense of belonging. As a result, all employees have a common interest in the final product, which differs from the usual fragmented nature of the construction industry in which individuals perform their own tasks.

Evaluation of this use case has shown that working with a single source of truth offers significant benefits, including improved reliability of information, availability of information, optimization of processes and a sense of belonging among employees and departments as they advance toward a common goal.

Discussion

This paper aimed to evaluate the use of blockchain in combination with CDEs to improve the accessibility and reliability of construction information in the Netherlands. The Dutch construction industry is known for its fragmentation and specialization, which poses challenges for efficient information exchange. Integrating blockchain with CDEs could help solve problems of information management essential for optimizing construction processes. The research question being answered was, "*How can the integration of blockchain and CDEs be used to improve the availability and reliability of construction information in the Netherlands?*"

The literature review highlighted the benefits of blockchain and CDEs, particularly in terms of reliability, accessibility and efficiency of information management. Blockchain is recognized for its ability to secure information and provide transparency without the need for trusted intermediaries (Lashkari and Musilek, 2021). The concept of CDEs is considered an effective way to centralize construction information and facilitate collaboration among stakeholders (Preidel *et al.*, 2017). The interviews showed current practices in construction often result in fragmented and piecemeal storage of information, leading to problems such as finding the most recent versions of documents and miscommunication between different parties. This highlights the need for centralized solutions such as CDEs to address these challenges.

The results show combining blockchain and CDEs offers a potential solution to the limitations of traditional centralized systems in the construction industry by making manipulation of information virtually impossible increasing trust between participants. This is valuable due to the complex and specialized nature of the construction industry, where different professional groups are involved in different phases of the construction process (Nawi et al., 2014). A centralized information management system can help consolidate information and facilitate collaboration and communication between stakeholders. However, it was found that storing information on a blockchain is not effective due to its latency and poor storage abilities. The combination of blockchain and a CDE was considered a potential solution to this with IPFS suggested to complement blockchain to help solve problems with inefficient data storage (Steichen *et al.*, 2018; Nyaletey *et al.*, 2019). This was supported by the findings from the interviews, though practical considerations are still to be addressed, such as the perceived high cost and energy requirements of storing large amounts of information on the blockchain requiring a targeted approach. A solution being, for example, capturing only transactions involving information on the blockchain with the actual information stored on IPFS.

The promising applications of blockchain in construction, particularly in improving efficiency, transparency and time savings, are a key finding of this research. Optimizing CDEs by further exploring and developing these areas for the Netherlands, innovative solutions can be developed that lead to more efficient, transparent and sustainable construction processes and projects. Moreover, it is important to research similar situations in other countries. This helps not only to understand the applicability and effectiveness of blockchain in different contexts, but also to identify global best practices. By making international comparisons and drawing lessons from different experiences, we can gain a deeper understanding of the potential impact of blockchain on the construction industry worldwide. This can ultimately contribute to a more informed and inclusive approach to the implementation of blockchain technology in the construction industry.

Conclusion

The Dutch construction industry, characterized by fragmentation, experiences challenges in communication and coordination of construction work information, with loss of valuable data. This research answered the question, "*How can the integration of blockchain and CDEs be leveraged to enhance the availability and reliability of building information in the Netherlands?*" Qualitative methods were used to examine construction information in the chain, as well as opportunities and limitations of blockchain.

The research findings emphasized the importance and issues surrounding availability and reliability of information in the construction supply chain, often associated with negative experiences. The lack of connection between companies, operating mainly on their own 'islands', leads to manual dissemination of information across stakeholders. This results in conflicting versions, miscommunication and lack of a clear source of truth.

Research on blockchain integrated with a CDE has provided insights on its potential and limitations. Although further research is required to explicitly answer the research question, it is suggested that integration of a CDE with blockchain could be a valuable approach. Blockchain is not suggested for storing large amounts of information, rather integration with IPFS for a CDE that acts as a central repository for all construction information, could see increased security and prevent manipulation of data. This enables reliable and immutable storage of information, which is crucial for the efficient and effective execution of construction projects.

The evaluated use case showed that using a shared network environment and working with a central source of truth brings several benefits in terms of optimization, efficiency and trust. This is because information is stored, managed and shared more efficiently within the network. The availability and reliability of construction information increases greatly when using a single source of truth. Because stakeholders know where information is stored, individual sharing is no longer necessary, which benefits information reliability and reduces the risk of miscommunication and duplicate versions.

One notable result is that stakeholders have more mutual trust and cooperate better when operating within the same network environment. This improvement comes from relying on each other's information within the same system, allowing individual goals to converge into a common interest. This highlights the importance of a shared platform and the potential of blockchain to enhance communication, trust and collaboration in the supply chain. In short, the study concludes that construction stakeholders benefit from available and reliable construction information, with blockchain serving as a valuable tool to achieve these goals.

As preliminary research, this study was limited regarding the number of stakeholders engaged and the use case evaluated. While the study gained insights from relevant perspectives, it is acknowledged that more engagement is needed. A wider range of stakeholders could provide a broader spectrum of insights and allow for a more comprehensive representation of diverse viewpoints in the Dutch construction industry. Extending the study to engage with a wider range of stakeholders across the project life cycle to gain a deeper understanding of the complex dynamics and challenges within the Dutch construction industry. The use case chosen considered information management at an intraorganizational level that arguably faces less challenges than at an interorganizational level, the latter will be included in the extended study. In addition, blockchain's technological elaboration and application alongside a central database will be explored.

Abstract

Blockchain offers a potential solution to enhance transparency and trackability in carbon management, but limited research exists on its implementation in the construction industry. This study proposes a blockchain-based approach for transparent and trackable carbon management in the construction supply chain to address concerns regarding data quality and confidentiality. A system was developed comprising off-chain carbon management and on-chain (public blockchain) storage, with technical highlights of: role-based access control for functionality, hierarchical hashing strategy for validation, and selective data disclosure before on-chain. The research's contributions include enhancing data quality and traceability for carbon assessments.

Introduction

The construction industry significantly influences global carbon emissions due to its energy-intensive processes, use of materials, and the operation of buildings (Sizirici et al., 2021). Carbon emissions from the construction supply chain, referred to as upfront embodied carbon, are estimated to account for around 30% of construction projects' whole life cycle carbon emissions (Gan et al., 2017). Therefore, how to manage and reduce carbon emissions from construction supply chains has become an urgent task in the construction industry. Although many practices and studies have been implemented to manage carbon emissions at the specific stage of the construction supply chains, it is still difficult to track carbon footprints along the supply chain. For one thing, the fragmentation of supply chains makes it difficult to gather consistent and accurate data on carbon emissions from each stage of the supply chain among multiple tiers of suppliers and subcontractors (Hijazi et al., 2021). For another, considering the wide scope of carbon emission data required during carbon assessment and tracking, stakeholders may find it difficult to access (Lai et al., 2023). In that case, the data transparency is very limited both for internal carbon management along the construction supply chain and external supervision for sustainability disclosure, which hampers the ability to track carbon footprints effectively.

As a promising technology, blockchain offers a possible and effective solution for the insufficient transparency and low trackability problems during carbon management along the construction supply chain (Turk et al., 2017). Blockchain technology is a decentralized and distributed ledger system that allows multiple parties to maintain a shared database without the need for a central authority. It is a chain of blocks, where each block contains a list of transactions or data (Hunhevicz et al., 2020). These blocks are linked together using cryptographic hashes, creating an immutable and transparent record of all transactions or data entries (Tao et al., 2022). With the help of blockchain, problems such as fragmentation, inefficient data-sharing, insufficient data transparency, and poor data trackability have been solved in many construction scenarios. Existing studies have explored blockchain's capability and feasibility in various construction scenarios, including construction payment transactions, construction information-sharing and collaboration during multiple project stages, and governmental supervision of construction work (Xu et al., 2023). However, there is limited research in the field of blockchain-based carbon management along the construction supply chain, especially focusing on the whole supply chain lifecycle and how to motivate all stakeholders to participate in such an innovative approach. During the interviews, it was noted that other challenges include concerns regarding data quality and sensitive information. Therefore, the two research questions in this research are:

(1) How can blockchain technology integrate with carbon management along the whole construction supply chain?
(2) How can carbon data quality and privacy be enhanced in the blockchain-based carbon management system?

This study aims to propose a blockchain-based approach for transparent and trackable carbon management along the construction supply chain for all stakeholders (suppliers, contractors, architects, and developers of the construction project) by developing a blockchain-based carbon management system. This approach covers all stages that will produce carbon emissions in construction supply chains (from material processing, transportation, and on-site construction activities), which is consistent with the A1 to A5 stages from the life cycle assessment identified in international standards.

Related work

Carbon management in the construction supply chain

Carbon emissions from the construction supply chain, referred to as upfront embodied carbon, are estimated to account for around 30% of construction projects' whole life cycle carbon emissions. Under the urgent trends of global carbon reduction, the importance of carbon management in construction supply chains is increasingly recognized.

A range of international standards have been developed and can be applied to assess and manage carbon emissions in the construction industry, including carbon assessment and management in construction supply chains. The European standard, EN 15978, is commonly recognized for the assessment of the environmental performance of new and existing buildings based on a life cycle approach. This standard specifies the calculation method and multiple carbon calculation stages based on Life Cycle Assessment (LCA) and other quantified environmental information based on the building level. Especially, A1 to A5 stages of product sourcing and construction stage identified in EN 15978 help assess carbon emissions from the construction supply chains, including sourcing, transportation, fabrication, and construction of all materials and products (British Standards Institution, 2011).

Moreover, multiple carbon certification schemes for construction materials and products have also been implemented in the construction industry, targeting to control and reduce carbon emissions at the start of construction supply chain management (A1 to A3 stages). For instance, the carbon reduction label managed by the Carbon Trust in the UK is one of the earliest certification schemes in the world. Under this scheme, organizations are required to report environmental claims and detailed carbon-proof data to get the certified label of products. Similar practices can also be found in The Singapore Green Building Product Certification (SGBPC), and the Construction Industry Council (CIC) Green Product Certification scheme in Hong Kong.

In academia, how to manage and reduce carbon emissions in construction supply chains to realize a green supply chain and improve its sustainability is also a hot topic. There are various research categories in the existing papers about carbon management in construction supply chains, including (1) green purchasing and procurement, (2) low-carbon design and manufacturing of construction materials and products, (3) green logistics, and (4) construction waste management. Green purchasing and procurement mainly focus on evaluation schemes and strategies for material and product selection along the construction supply chains. Bagul et al. developed a sustainable sourcing strategy for mega-construction projects using the analytic hierarchy process (AHP) technique and a multi-objective Goal Programming (GP) model, which has also been verified using a single construction megaproject case (Bagul et al., 2023). In the field of low-carbon design and manufacturing of construction materials and products, studies are focusing on how to design environmentally friendly construction materials and limit resource consumption during the production process of construction materials and products. For instance, Yang et al. developed a low-carbon design of an Ultra-High Performance Concrete (UHPC) by incorporating high-volume phosphorous slag (PS), which shows a promising approach to developing a cleaner building material with lower carbon footprints (Yang et al., 2019). Zheng et al. proposed a knowledge-based integrated product design framework to support low-carbon product development. Green logistics is another research field in carbon management along the construction supply chains. It aims to reduce carbon emissions during the delivery process of construction materials and products (Zheng et al., 2021). Chen et al. integrated building information modeling (BIM) and web map service (WMS) for the source selection of sustainable construction materials to reduce carbon emissions during the delivery (Chen et al., 2019). The carbon management of the recycling process of the construction supply chain is also studied in existing studies. Wibowo et al. proposed a measurement model to analyze the carbon reduction performance of recycled materials to support sustainable construction (Wibowo et al., 2017).

Blockchain applications in the construction industry

Blockchain is one of the most prominent types of distributed ledger technology (DLT) that allows all transactions to broadcast and operate on a distributed peer-to-peer (P2P) network without a centralized administrator. It enables the secure and transparent recording of transactions and data. The blockchain transactions are first grouped together, validated by particular consensus mechanisms (e.g., Proof of Work, Proof of Stake) among all nodes, and finally added to a block in a specific order. Since the newly generated block links to the previous block by unique a hashing index, it is difficult to modify once a block is added (needs to modify all previous block indexes and value if want to change one block), which ensures the integrity and trackability of the recorded data (Scott et al., 2021). Currently, blockchain's capability and feasibility have been discussed and validated in various construction scenarios, including construction payment and procurement, information-sharing and collaboration, construction supply chain management (including construction carbon management), regulations and compliance, and contract management (Li et al., 2021 a).

For construction payment scenarios, blockchain-based payment systems can enable faster payments by eliminating intermediaries and self-executing smart contracts. A distributed blockchain-based framework that does not require trust to automatically enforce the terms and conditions related to interim payments was proposed by Das et al., aiming to facilitate payment transparency, enforce conditions of interim payments, and automatically record payment cycles (Das et al., 2020). Similarly, to avoid the risks and disputes caused by slow payments among construction stakeholders, an autonomous payment administration solution integrating blockchain-enabled smart contracts and robotic reality capture technologies was proposed by Hamledari et al., which can automatically transfer cryptocurrencies by smart contracts after finishing phased work (Hamledari et al., 2021).

Blockchain technology has also been applied in the single stage or multiple stages of construction projects, such as design, construction, and maintenance, for information sharing and stakeholder collaboration to enhance construction data transparency, reliability, and trackability. For example, a blockchain-based prototype system was developed and evaluated to address the challenges of design liability control and information security during the construction design process (Pradeep et al., 2021). For the construction stage, a blockchain-based verification framework of adequate scaffolding was proposed for onsite inspections, aiming to make the onsite operations safer (Baek et al., 2020).

Among the above blockchain applications in the construction industry, blockchain-integrated construction supply chain management is one of the most popular research directions across multiple project stages. Recent studies have illustrated blockchain-enabled construction supply chain management via case studies. Wang et al. proposed a blockchain-based information management framework for precast supply chain information-sharing, real-time controlling, and status tracking, and a case study was used to validate the performance of the proposed framework (Wang et al., 2020). Moreover, Lu et al. developed a smart construction objects-enabled blockchain oracles framework to bridge the on-chain and off-chain worlds, which was examined in the context of off-site logistics and on-site assembly services (Lu et al., 2021). Some studies in this field also integrated blockchain with other digital technologies such as BIM and IoT to improve the performance of construction supply chains. For example, Wu et al. linked a permissioned blockchain to the Internet of Things (IoT)-BIM platform for off-site production management in modular construction by providing better information visibility, traceability, and a more collaborative working environment (Wu et al., 2022).

For construction carbon management, blockchain's potential to facilitate carbon data transparency and traceability has been examined in both carbon quantification and assessment. Rodrigo et al. explored the potential application of blockchain for accurate embodied carbon estimation in construction supply chains and developed a data model for the blockchain-based embodied carbon estimator for construction (Rodrigo et al., 2020). Recent literature has developed several theoretical frameworks for blockchain-enabled carbon management. For instance, Wang et al. proposed a conceptual framework integrating blockchain, supply chain, and environmental performance, which suggests using blockchain to enhance supply chain management and reduce carbon emissions (Wang et al., 2020). A blockchain-based identification and coordination framework was designed by Wang et al. based on a specific multi-tier supply chain for sustainable supply chain management, aiming to ensure compliance with sustainability standards in construction supply chains (Wang et al., 2023). Liu et al. proposed a conceptual framework integrating blockchain as a carbon management tool to achieve transparent carbon footprint disclosure during product certification and supply chain management (Liu et al., 2019). Moreover, Xu et al., developed a more detailed and implementable blockchain-based framework for the embodied carbon certification of construction materials and products, which was validated via real certification cases (Xu et al., 2024).

Some other blockchain-based applications in the construction field can also be found in construction supervision (Li et al., 2021 c), and contract management for solving contract disputes and claims (Li et al., 2021 b). In summary, blockchain technology has already been implemented in many construction cases with different objectives, such as increasing data transparency, enhancing mutual trust, and facilitating tracking functionalities. However, existing blockchain-integrated research mainly based on less decentralized solutions without transparency to the public, and there is limited research about sufficient transparency and traceability of upfront embodied carbon management among all stakeholders along construction supply chains.

Methodology

The research methodology employed in this study is based on the Design Science Research (DSR) method, which facilitates problem-solving activities as depicted in Figure 1. The research problems and objectives were identified through an extensive literature review of existing studies on carbon management in construction supply chains and blockchain-based applications, as well as through interviews conducted with stakeholders across the construction supply chain. Once the research problems were identified, the system framework and workflow of the blockchain-based system were developed. This entailed creating a model diagram that showcases the key components and a process diagram that illustrates the system workflows among different stakeholders. Subsequently, a system prototype was developed, tested, and demonstrated through a real-life case study, enabling the recording and tracking of carbon footprints along the construction supply chain. The final two steps of this study involve the evaluation of the system and its practical assessment through communication with relevant stakeholders.

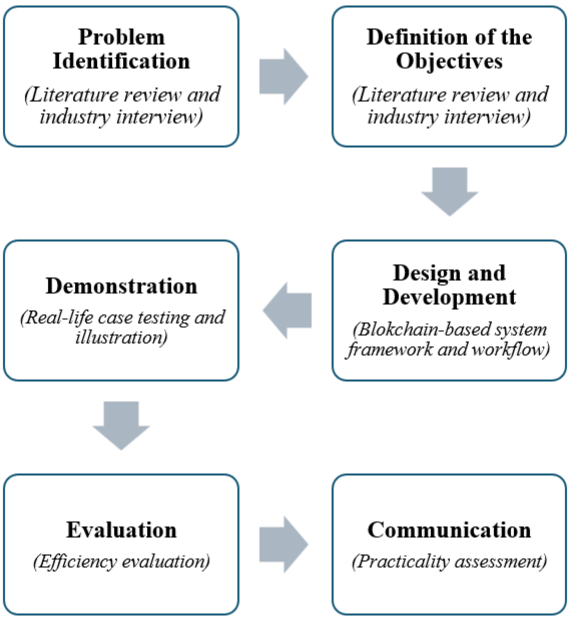

Figure 1: Research methodology in this study

System requirement analysis

Interview results for system requirements

We conducted interviews with one supplier, two contractors and one developer to gain insights into the industry practices related to embodied carbon practices. We also sought their opinions on the proposed blockchain-based carbon management system. The interview questions are provided below:

1. How does your company collect and store carbon-related information/data for a project? For instance, what types of data are collected, how is data collected from different parties, who is responsible for inputting the data, and how is the data stored?
2. Does your company have any concerns about using a blockchain-based carbon management system for tracking carbon-related data in the construction supply chain?

Based on the interviews, it is noted that only a few stakeholders have a practice of collecting and tracking embodied carbon data in their projects, such as having a centralized procurement system and an online centralized database for storing data. The stakeholders also expressed concerns regarding data quality and sensitive information (e.g., the design formula of the product, total quantity and inventory sources). Besides, they expressed expectations for the system to support data sharing throughout the project and industry (e.g., project emission factor), and facilitate the establishment of industry benchmarks.

System design

The research primarily focuses on the integration of blockchain technology with carbon management across the entire construction supply chain to enhance the quality and traceability of embodied carbon data for more accurate carbon assessments. In our blockchain-based carbon management system, the stakeholders involved are developers, architects, consultants (such as structural consultants and carbon consultants), contractors (such as foundation contractors and main contractors), and product suppliers (such as concrete and steel suppliers). The contractor and supplier are further categorized into general staff and senior staff for different roles in the system. The system framework is referenced in Figure 2.

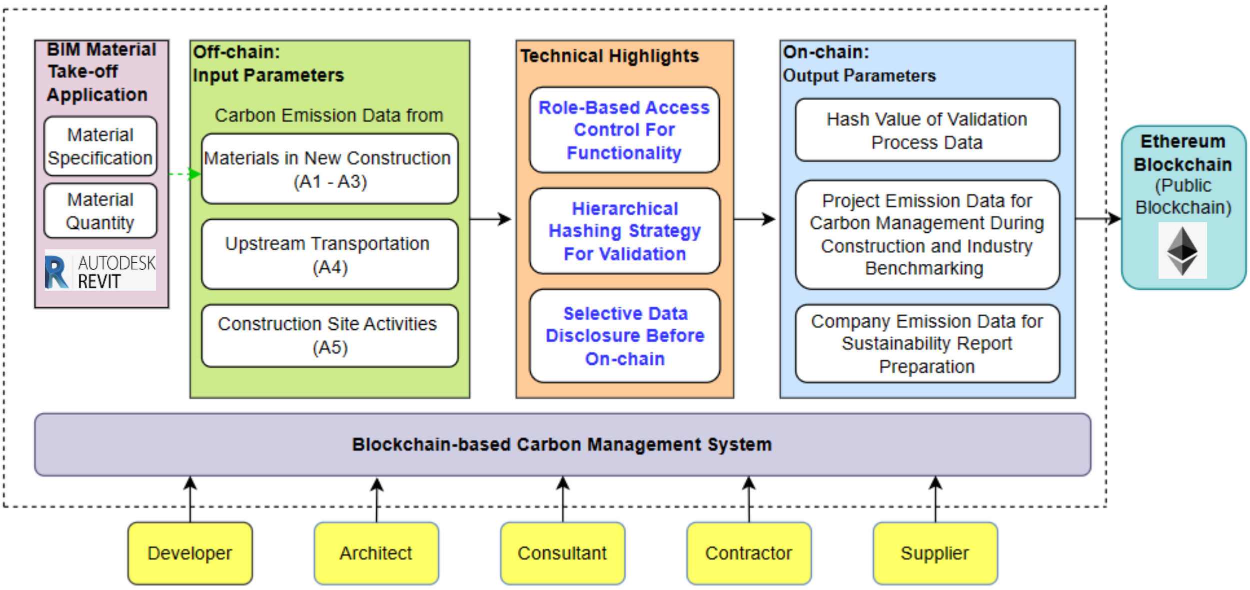

Figure 2: System framework

The proposed system framework provides the traditional off-chain carbon management functions, encompassing user registration and data input. Within this system, all stakeholders should register a unique account in the blockchain and carbon management system with their respective identities. Additionally, the architect creates a project account in the system. Under normal circumstances, the general staff of the contractors and product suppliers will be responsible for data input based on their respective roles in the project. Carbon data input parameters are divided into three groups based on the building life cycle: Materials in New Construction (A1 - A3), Upstream Transportation (A4), and Construction Site Activities (A5). These parameters include raw materials, origin, emission factors, material quantities, and transportation modes and distances. The BIM material take-off function is utilized to extract information for the input of A1 – A3, which covers material specification and quantity.

To make carbon footprints transparent, reliable, and trackable, the proposed blockchain-based system framework entails an on-chain smart contract and public blockchain storage for data recording and output. A decentralized database with self-executing smart contracts is utilized to store significant project information and carbon emissions data. In addition to the previously mentioned hash value of validation process data, the system also records and generates output data on a project basis and company basis. This includes details such as the project address, product emission factor, product quantity, monthly carbon emissions, total emissions in Materials in New Construction (A1 - A3), Upstream Transportation (A4), Construction Site Activities (A5), and the overall project emissions. These data serve various purposes, such as facilitating carbon management throughout the construction period, preparing sustainability reports, and establishing benchmarks. By storing data on the blockchain, it becomes immutable and can be easily shared with the project team and the public for enhanced traceability and transparency.

Technical Specification

There are three technical highlights of this carbon management system:

- *Role-Based Access Control For Functionality*: Every stakeholder has a clearly defined role and functionality within the carbon management system. The levels of power within the system, listed in descending order, are as follows: The Developer holds the highest level, followed by the Architect, Consultant, Contractor, and Supplier, while within each level, the Senior Staff holds a higher position than the General Staff. For example, in the context of the carbon management system being applicable to the industry rather than a single company, ensuring proper access control for individual and project accounts becomes crucial. Therefore, during user registration and project initialization, only the Architect has the authority to create projects in the system and to add, edit, or delete the accounts of Developers, Contractors, and Consultants. The Senior Staff, on the other hand, can add, edit, or delete the accounts of General Staff members. Furthermore, in the system view, the Contractor has the right to create and view all inputted carbon information, while the Developer is limited to viewing only the total carbon emissions data.
- *Hierarchical Hashing Strategy For Validation:* Data quality is a significant concern for stakeholders. In order to enhance the quality of carbon data, a validation process consisting of three hash values is implemented within both a company and a project team. The first value represents the original carbon data, the second value corresponds to the validation process executed by the first designated stakeholder (e.g., senior staff of the supplier reviewing and validating the input data provided by the general staff of the supplier), and the third value represents the validation process executed by the second designated stakeholder (e.g., after the senior staff of the supplier validates the input, the senior staff of the contractor further reviews and endorses the data). These three hash values, associated with the validation process data, are then stored in the blockchain.
- *Selective Data Disclosure Before On-chain:* Once the data has been validated, stakeholders who are concerned about sensitive data disclosure have the right to choose whether to disclose or encrypt the data before uploading it to the blockchain and sharing it with the public. For example, if the supplier has reservations about disclosing the product design formula, the senior staff of the supplier can opt to encrypt this information while disclosing other carbon data such as product specifications and emission factors.

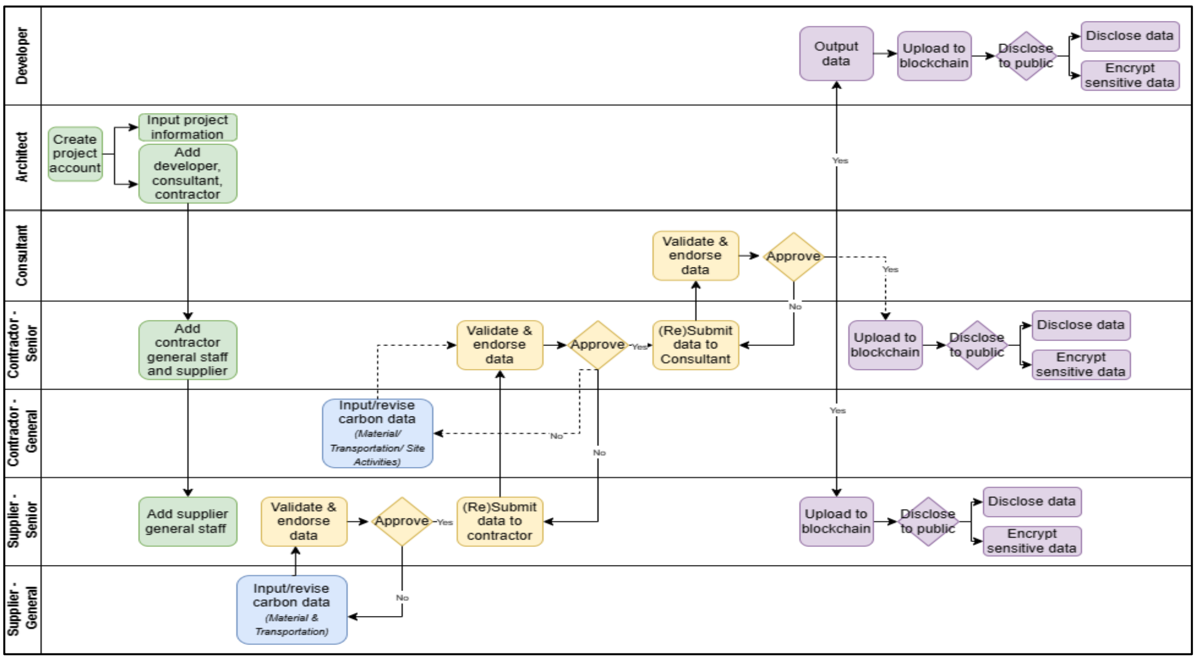

Figure 3: Operational Workflow (Green - User/Project Initialization; Blue – Data Input; Orange – Validation Process; Purple - Smart Contracts and Public Blockchain)

Operational Flow

In order to have a comprehensive understanding of the system, an operational workflow process is presented in Figure 3. Firstly, the architect initiates the creation of a project account and inputs the project information, as well as adds the relevant stakeholders (e.g., developers and contractors) within the project account. Additionally, the contractor adds the product suppliers, while the senior staff of the supplier/contractor includes their respective general staff in the project. Secondly, the general staff of product supplier and/or contractor input the carbon data into the information management system. Once the data is ready, their senior staff will review and validate the data before submitting it to the upper-level party for further validation. Thirdly, following the data validation process, the senior staff of the product supplier/contractor can choose specific data for encryption and subsequently upload it to the blockchain. This upload includes the three hash values associated with the validation process data, as elaborated in the previous section. Lastly, the developer possesses the final authority to select data pertaining to the total project and company emission for encryption and subsequently uploads it to the blockchain.

Implementation and results

System development

Figure 4 shows the system development details. First, a front end was developed for different users to collect carbon emission data via the web browser. A blockchain wallet tool called Metamask was used in this study to manage user blockchain accounts and provide methods to sign blockchain transactions during token transfer. At the backend, we use Alchemy to build the blockchain environment and provide the blockchain infrastructure. Considering this study aims to make carbon management along construction supply chains more transparent and directly assist with carbon data disclosure, Ethereum, a public blockchain platform, is thus used in this study to realize blockchain functions with smart contracts. For data storage, we use the integration of traditional databases and blockchain databases for safety and transparency. The traditional database is used to store original carbon emission data provided by all users. The blockchain transactions store and disclose all public carbon data transparently. At the same time, confidential carbon data for each party will also be stored on the blockchain after hash processing to satisfy the user's need to track their own carbon data through the blockchain-based carbon management system.

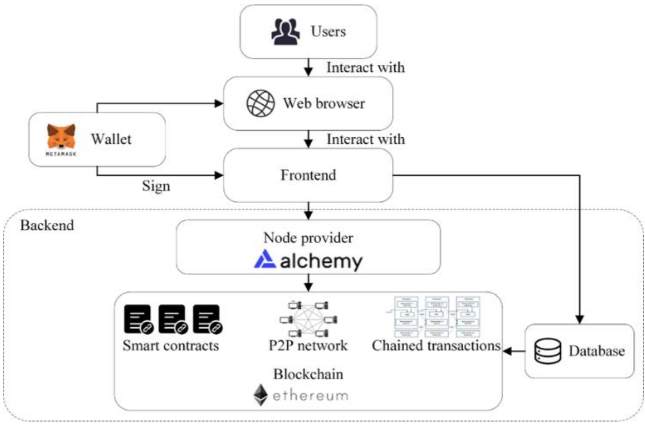

Figure 4: System development details

Result demonstration – User interface of input parameters

As mentioned previously, the DSR method is used as the research methodology in this study, consisting of six steps covering 1) problem identification, 2) definition of objectives, 3) design and development, 4) demonstration, 5) evaluation, and 6) communication. Based on the research progress, the study is currently at the stage of system design and development, with the user interface of input parameters being presented in this section. The input parameters consist of two main categories. The first category is the project information (e.g., site address, construction floor area) and project team information (e.g., names of stakeholders and their corresponding blockchain accounts), which are input by the architect. The second category is the upfront embodied carbon-related data, which covers the A1 - A5 modules of the building life cycle (from raw material extraction to the construction stage). This category is further divided into three groups based on the building life cycle and the parties responsible for inputting the data (i.e., product suppliers and contractors) for the substructure and superstructure stages. Figure 5 displays the extracted user interface of the input parameters.

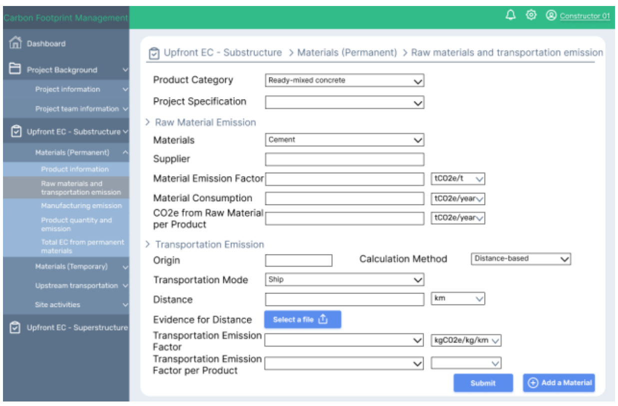

Figure 5: User interface diagram – carbon data related to raw materials and transportation emission

1. *Materials for constructing new buildings (permanent and temporary)*: This group includes emissions from raw material extraction (A1), transport to manufacturing (A2), and manufacturing (A3). The data includes product

information (e.g., product category and specifications), raw material emission data (e.g., emission factors, material consumption), transportation emission data (e.g., origin, transportation mode, fuel emission factors, and consumption), and manufacturing emission data (e.g., manufacturing process type and the fuel used).

2. *Upstream transportation and distribution*: This group includes emissions from A4 (transport to site) only, which refers to emissions from transporting products and materials from manufacturing plants to the project site. The input data is similar to the transportation emissions data in group 1 (e.g., transportation mode and distance).
3. *Construction site activities*: This group covers emissions during the construction of the building(s). The data includes emissions from fuel and energy-related activities (e.g., electricity, town gas, refrigerant, welding, and flame cutting) and waste generated during operations (e.g., landfill, public fill, metal, and timber recycling).

Conclusions

Carbon footprint management, especially carbon tracking, is complex along the construction supply chain due to the lack of accurate data collection and sufficient data transparency. Blockchain provides a potential and effective solution to enhance transparency and trackability issues in carbon management across the construction supply chain. However, there is limited research in the field of blockchain-based carbon management along the construction supply chain, especially focusing on the whole supply chain lifecycle and how to motivate all stakeholders to participate in such an innovative approach. Therefore, this study proposes a blockchain-based approach for transparent and trackable carbon management along the construction supply chain for all stakeholders by developing a blockchain-based carbon management system. The research methodology employed in this study is based on the Design Science Research (DSR) method based on (1) the literature review results of existing research about carbon management in construction supply chains and blockchain-based applications and (2) industry interview feedback from stakeholders along the construction supply chain. Based on the system requirement analysis results, a blockchain-based carbon management system is designed and developed, which consists of an off-chain traditional carbon management method and an on-chain (public blockchain) storage. There are three technical highlights of this carbon management system: role-based access control for functionality, hierarchical hashing strategy for validation, and selective data disclosure before on-chain. This research mainly contributes to enhancing the quality and traceability of embodied carbon data for more accurate carbon assessments by using blockchain during construction supply chain management. In the future, we intend to improve the system development and test the system by inviting more industry stakeholders to provide feedback.

Acknowledgments

The authors would like to thank Gammon Construction and Limited, China State Hong Kong for their support during the interviews. Also, the work described in this paper was substantially supported by a grant from the Research Grants Council of the Hong Kong Special Administrative Region (Project No. T31-603/21-N). Any opinions and findings are those of the authors and do not necessarily reflect the views of the Research Grants Council of the Hong Kong Special Administrative Region.

DIRECTIONS FOR RESEARCH ON INCENTIVISING AND GOVERNING THE INCREASE OF BIODIVERSITY IN CITIES WITH BLOCKCHAIN TECHNOLOGIES

Jennifer Li[1], and Theodoros Dounas[2]
[1]Northumbria University, Amsterdam, The Netherlands
[2]Antwerpen University, Antwerp, Belgium

Abstract

Biodiversity is crucial in sustaining all life on earth. However, extinction of species critical to the functioning of our global ecosystem is a direct threat to biodiversity. The built environment in its urban forms is one of the biggest causes of biodiversity loss through the exploitation of finite resources and land use on which it sits. In this paper we consider the application of blockchain to create new forms of incentivisation and governance for maintaining and increasing biodiversity in cities at the intersection of co-design, blockchain, biodiversity, and design and planning, and propose directions for future research on this topic.

Introduction

Biodiversity is "*the variety of life on Earth and the natural patterns it forms*" (Convention on Biological Diversity, 2009, para. 1). Such variety of species is critical to the functioning of the earth's ecosystem (Duffy, 2009). However, extinction of species is accelerating faster than ever in human history (WEF, 2020) threatening this variety. Biodiversity loss is reported as fourth in the top five global risks to humanity regarding likelihood and third regarding impact (WEF, 2020). Rockström *et al.* (2009) estimated three planetary boundaries (biodiversity loss, climate change, the nitrogen cycle) that sustain the Holocene and safe operating space for humanity are already exceeded. Global urbanisation, "*the process of anthropogenic transformation of wildlands to the built environment where people live and work*" (2021, p. 125), has accelerated these changes; since 1950, human activity has resulted in more energy use than the entire 11,000 years of the previous Holocene (Elmqvist *et al.*, 2021). As the planet deals with several crises centred on climate change, pollution, biodiversity loss (UN, 2023), and a clash between finite resources and an increasing population (Scheel *et al.*, 2020), a fundamental shift is essential in the relationship between humanity and nature to solve these problems (UN, no date). Being more sustainable is part of the solution, yet not enough is being done to prevent the disastrous impacts they bring (Abbass *et al.*, 2022).

The aim of this paper is to establish directions for research to investigate the extent to which blockchain technologies and smart contracts can be used to create new forms of incentivisation and governance for maintaining and increasing biodiversity in cities. The project will focus specifically on cities as the areas causing most of the biodiversity loss across the planet through urbanisation (Kirk *et al.*, 2021) and with a spotlight on the urban design and planning phase of the construction lifecycle where the decisions about biodiversity would have the most impact.

In the next section, the methodology for conducting the research for this paper is outlined, then literature on the role of design and planning in constructing the built environment is reviewed. Blockchain as a socio-technical system is presented with consideration to its possible use to govern and incentivise the increase of biodiversity in cities. This is done by analysing literature at the intersection of biodiversity, blockchain and construction through a socio-technical lens. Next, future directions for this research project are discussed before concluding the paper in the final section.

Methodology

In Figure 1 below, the three areas of research interest for this project are shown. There are existing studies at the intersections for two components (e.g., UB and BCT; UB and BE, BCT and BE). However, there is very little research sitting at the centre where all three interest areas intersect (i.e., UB, BCT *and* BE).

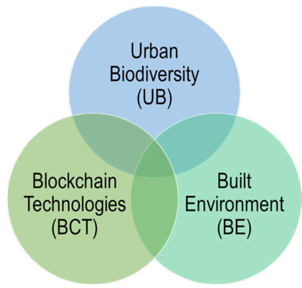

Figure 1: Intersection of research interests

To fill this gap, this paper took an inductive approach to conduct a traditional literature review to establish what is known at the intersections between two or three of the themes above. Given that there is little research at the intersection of all three, the paper suggests directions to fill this gap based on a synthesis of what is currently known.

Literature Review

The built environment's impact on biodiversity

The construction sector is responsible for constructing and maintaining the built environment necessary to maintain human life. However, it is also "*known to be the highest contributor*" to climate change (Oguntona and Aigbavboa, 2019, p. 513). Cities are essential to withstand the increase in population density but rapid expansion of urban areas are associated with resultant biodiversity loss (Uchida *et al.*, 2021). Through excessive resource use and adaptation of the land, construction can damage natural habitats jeopardising wildlife and plants. Thus, construction has a responsibility to protect sites and minimise damage to ecology. However, understanding of biodiversity in the sector is poor (Woodall and Crowhurst, 2003) and "*is often viewed as an afterthought or final addition once an urban development nears completion*" (Kirk *et al.*, 2021, p. 1). Biodiversity loss has critical consequences for the human race caused by current methods of production and overconsumption that could see the failure of food systems, collapse of healthcare systems and see whole supply chains disrupted (WEF, 2020). This creates an imbalance of the ecosystems that sustain clean air, water and all life on earth (WEF, 2020). The sector uses a substantial amount the world's resources from extracted materials, to global water and energy supplies, whilst being one of the highest contributors of greenhouse gasses (GHG) (Wieser *et al.*, 2019). It contributes heavily to the generation of waste and reduction of global ecological integrity, as well as buildings and infrastructure having a long-term environmental footprint (Oguntona and Aigbavboa, 2019). Cities are of strategic importance to the "*global governance of climate change*" and limiting global warning to only 1.5°C (Bulkeley, 2022, p. 266). It hinges on the ability to redress planetary limits and boundaries through reshaping urbanisation (Elmqvist *et al.*, 2021). An estimate puts global temperature increase at 4 degrees by 2100 if governments and the construction sector continue current policies and practices, thus, municipal level decisions are critical to limit the temperature rise to 1.5°C (Miller, 2020).

The role of design and planning in construction

Construction needs to be more sustainable utilising "*a sociotechnical approach, [that] underpins the principle of sustainable development*" (Medaglia and Damsgaard, 2020, p. 3). This can be done in part by moving toward a co-design approach that involves citizens in municipality-level decisions that feed into the design and planning phase of the project lifecycle. Such a concept gaining attention in the creation of the built environment is regenerative design. This positions citizens as both co-creators and contributors of earth's ecosystems moving beyond the current mindset of resource exploitation without consideration of the consequences (Wang *et al.*, 2023) where quality of life is put before economic growth (Axinte *et al.*, 2019). Camrass (2022) states that urban planners and designers are in a unique position to drive forward the regenerative agenda.

Miller (2020) writes about true democracy taking place in Canadian cities where citizens are regularly engaged with and are part of decision-making at municipality levels regarding urban planning. Joachain and Klopfert (2011) discuss two complementary currency programmes as policy instruments as follows: NU-Spaarpas was a loyalty card scheme in partnership with independent shops in Rotterdam, The Netherlands to promote greener consumption and behaviour from citizens. E-portemonnee based in Overpelt, Belgium focused on promoting sustainable behaviours by rewarding sustainable actions of citizens. This demonstrates the appetite and necessity for community engagement in promoting more sustainable practices in cities.

Blockchain

Blockchain is rooted in a desire to challenge central elites and associated power structures by offering a transparent, traceable, decentralised and distributed ledger (Ekblaw *et al.*, 2016) that can record anything of value (Mathews *et al.*, 2017). Its decentralised network of computers stores a common ledger and agrees on the truth of transactions recorded on the chain via an algorithmic consensus mechanism. Transactions are recorded on a chain of blocks where each one engulfs the previous blocks' cryptographic hash. It offers security and privacy based on its append-only nature while its immutability provides a single source of truth (Hijazi *et al.*, 2022).

Blockchain has been identified as a socio-technical system by several scholars (Shin *et al.*, 2022; Li, 2023; Selvanesan and Satanarachchi, 2023) who acknowledge society as central to its utility; consideration of this dimension key to its successful adoption. It gave rise to cryptoeconomics – applying cryptography to economic systems for new forms of organisational business models and commons frameworks (Brekke and Alsindi, 2021) – comprised of computer engineering, economics and game theory (Brekke, 2021). Smart contracts are programmable pieces of code that can run on a blockchain and self-execute based on pre-defined logic offering automation to create efficiencies and increase productivity without human intervention. They can facilitate the creation of powerful, domain-specific decentralised applications (Ye *et al.*, 2022). There is concern of the high energy consumption of blockchains, however, this is a misconception for it is applicable only to early blockchains that use the proof-of-work (PoW) consensus mechanism. Alternatives such as proof-of-authority, proof-of-burn, proof-of-capacity and others are very energy efficient (Lashkari and Musilek, 2021). For example, Ethereum originally ran PoW but changed to proof-of-stake in 2022 to consume 99.9% less energy equating to a megaton of carbon weekly (Kessler, 2022).

Blockchain as an incentive and governance tool

Several studies have considered blockchain for incentive and governance systems. Wang *et al.* (2023) discuss blockchain's potential to govern information, procedures, ownership and values of a regenerative built environment. Zhao *et al.* (2023) present a blockchain-based token incentive mechanism for environmental, social, and governance (ESG) performance to be used by organisations to attract investors, issue dividends, grant access to products and services, and allocate voting rights. The integration of blockchain, BIM, artificial intelligence, machine learning, building energy management systems and life cycle assessment is proposed by Desmond and Salama (2023) to manage energy usage of buildings. Incentives lie in the trading of stored energy, and smart contracts facilitate tax relief to buildings meeting sustainability objectives. Dounas *et al.* (2022) present a cryptoeconomics-based incentive system centred on architectural design governance connecting building performance and carbon reduction with financial incentives. Incentivising better than net-zero energy buildings are proposed by O'Reilly and Mathews (2019) by storing excess energy generated by solar panels and selling it as a commodity. This incentivises designers to optimise building performance and occupants to behave energy efficiently.

Beyond sustainability-related research, blockchain tokenisation can incentivise changes in human behaviour through decentralisation and offering multidimensional payment systems against today's one-dimensional monetary system (Hunhevicz and Hall, 2020). Hunhevicz *et al*. (2021) employ cryptoeconomics to incentivise lifecycle performance rewarding parties based on performance-based contracts. Green Coin, a blockchain-powered social currency, incentivises citizens to exchange urban waste via a tradable cryptocurrency that can be used in local shops in a Brazilian municipality (França *et al.*, 2020). It helps low-income families, supports awareness of correct ecological behaviours of citizens, reduces landfill waste, and improves health through reduction of fatal diseases such as dengue and zika. A survey on blockchain-incentivised applications across transport, energy and recycling in smart cities is presented in Kahya *et al.* (2021). Finally, in Marsal-Llacuna (2018), blockchain forms the basis of a governance and incentive system to facilitate prioritisation and submission of citizens needs to municipalities leading to the development of bottom-up, citizen-centric masterplans connected to urban codes (e.g., polices, planning, regulations).

Blockchain and biodiversity in research

There are few studies that focus on blockchain *and* biodiversity and none that intersects with construction. A blockchain-based biodiversity value chain is being developed to manage the unregulated exploitation of indigenous natural habitats (Bose *et al.*, 2019). Blockchain is used in food supply chains to conserve biodiversity through incentivising sustainable practices in agriculture and food waste (Kafi *et al.*, 2023). A literature review finds blockchain can support sustainable forestry, minimise illegal logging and help conserve biodiversity (He and Turner, 2022). The co-design of inter-species relations based on programmable cryptocurrency creates "*cities' transition towards Post-Anthropocene for cross-species bio-digital coliving*" facilitated by blockchain (Davidova and McMeel, 2020, p. 338). Beyond academic literature, Greener Tokens (2023) is an initiative that aims to connect companies to restorative finance (ReFi) to protect the Brazilian rainforest. They offer carbon emissions offsetting, ESG project management, and environmental consulting. They avoid greenwashing through their governance framework to ensure true protection of biodiversity. Funded by the Inter-American Development Bank (IDB), the design of digital tokens for a biodiversity innovation challenge aims to preserve natural capital and biodiversity in Colombia, Ecuador, Peru, and Trinidad and Tobago (IDB, 2023). Crypto Altruism (2023) discusses ways in which preservation of natural capital can be incentivised through tokenisation (e.g., carbon offsetting, fractional ownership, preservation of endangered species and the surrounding habitats). Token Kitchen is exploring the preservation of endangered African Forest elephants that support carbon capture and sequestration in the surrounding forests that incentivises locals by issuing tokens upon proof they are maintaining natural habitats (Voshmgir, 2021). Czura (no date) presents three applications: issuing Green Bonds to give investors more control over how their money is invested; TreeCycle that promotes eucalyptus tree planting in Paraguay where investors receive 40% of profits at harvest, 10% goes to local charities and 50% is reinvested into replanting; and the promotion of more sustainable supply chains (e.g., in aquaculture) with a blockchain-based trusted chain of provenance data.

Giving agency to nature, individuals and 'things'

Can blockchain give agency to nature, individuals and 'things' where a thing could be an inanimate object, a system or whole ecosystem? In Athens, Georgia in the United States, there is a 'Tree That Owns Itself' where it was gifted its ownership by the owner of the land upon his death (Figure 2).

Figure 2: A plaque to commemorate The Tree That Owns Itself, "For and in consideration of the great love I bear this tree and the great desire I have for its protection for all time. I convey entire possession of itself and all land within eight feet of the tree on all sides – William H. Jackson" (The Treeographer, 2018)

In a legal sense, the tree does not own itself but nobody disputed the self-ownership and so it was accepted. Upon the death of the Tree That Owns Itself, an acorn from the original tree was planted in its place where a new oak tree now stands; it is known as 'The Son of the Tree That Owns Itself' (The Treeographer, 2018). While this might be difficult to comprehend on a boarder scale, there is research ongoing that allows assets to own themselves in the form of no1s1, a blockchain-based project of a self-owned meditation pod at ETH Zurich facilitated by a decentralised autonomous organisation (DAO) (J. Hunhevicz *et al.*, 2021). The University of Edinburgh's BitBarista project is a coffee machine that accepts payment in bitcoin before administering a coffee to the user and pays people in bitcoin for servicing the machine (e.g., refilling water, cleaning). Individuals buying coffee answer questions about what they want such as high quality, low price, sustainable coffee and so on, the data for which determine the type of coffee BitBarista then automatically orders for itself (McMeel and Sims, 2020).

The challenge of giving agency to nature is that nature is limited in its ability to demonstrate intent. According to Schlosser (2019, p. 1), "*an agent is a being with the capacity to act, and 'agency' denotes the exercise or manifestation of this capacity*". Equally, an inanimate object such as a meditation pod is also limited in its ability to demonstrate intent given its lack of consciousness. The DAO is encoded with a set of rules determined by the creators of the pod (i.e., researchers at ETH Zurich). This is of course different to, for example, plants and animals that have inherent intent within the natural order of the ecological system around us, whereas with no1s1 and BitBarista, the logic is decided by the humans who created it, whose inherent intent is arguably different.

BitBarista is an example of "*devolved decision-making*" (McMeel and Sims, 2020, p. 215) that we could also call co-design where decisions are made based directly on users' wants, needs and means. This new form of business model can challenge existing hierarchical decision-making systems that typically benefit the few profiting from those decisions. Smart contracts and be explored for their ability to facilitate agency for nature and things; the challenge will lie in who is given the task and responsibility for establishing intent that is for the greater good and not the profiteering few.

Consolidation of the literature

Consolidating the above literature, the built environment is one of the biggest exploiters of the world's resources causing substantial biodiversity loss. Current efforts to reduce the negative impacts are insufficient. Therefore, new governance and incentive mechanisms are required to achieve lasting positive impact. Regenerative design aims to bring together different components of the urban ecosystem across the environmental, social and cultural domains with a view to leave the built environment in a better state than it was found. Blockchain could be a solution to bring these elements together as demonstrated by research and initiatives looking to leverage cryptoeconomics for behavioural change. The current efforts of applying blockchain to tackle issues of biodiversity focus on indigenous forests and habitats, and financial incentives, with very little focus on the urban complex of cities. The subsequent sections consider what can be done through this research project to address some of these challenges.

Future research directions

In this section, future directions for this research project are considered through the lens of the socio-technical framework as set out below. Then it considers initial gaps identified in the literature, and challenges and constraints that will form the focus of the future research before discussing the proposed outcomes.

A socio-technical perspective

A socio-technical framework for implementation of blockchain in construction will form the basis of the theoretical underpinnings for this research project. The framework (Li, 2023) consists of a set of tools and models to support analysis, understanding and implementation of blockchain in construction applications. Its four dimensions of technology, process, policy and society acknowledge the importance of technology whilst giving equal attention to the surrounding ecosystem ensuring any application is developed with a focus on meeting the needs at the social level where benefits are realised.

Technology considers the hardware, software, networks, infrastructure and technological integrations of blockchain-based systems; *process* considers how blockchain will integrate into existing organisational processes and the changes required to adopt blockchain at an enterprise level; *policy* focuses on the regulatory environment surrounding blockchain-based applications regarding standards, laws, compliance etc.; and *society* addresses the impact of blockchain applications on its users and the social environment where benefits will be realised.

Research on blockchain in construction has accelerated in recent years (Li and Kassem, 2021) to propositions of use cases across the built environment with plentiful proof-of-concepts and a handful of applications demonstrated in the 'real-world'. It is now time to focus the framework on achieving real change not just for the built environment, but for the betterment of humanity. In this paper, an initial evaluation of blockchain's ability to address the state of urban biodiversity is made. In later work, the framework in its entirety will be applied to better understand the challenges and provide solutions.

Technology: The literature reviewed in this paper has shown the potential of blockchain technologies to facilitate incentive and governance mechanisms that can be directed toward biodiversity. This has been shown by conservation of forests and biodiversity outside of the urban complex (e.g., He and Turner, 2022; Kafi *et al.*, 2023) plus establishment of the several tokens focused on biodiversity in the previous section. The next step is to consider the added complexities of biodiversity maintenance and increase in cities and evaluate how the use of blockchain and smart contracts can facilitate the integration of co-creation in the design and planning phase of constructing the built environment.

Process: From a process perspective, such a re-conceptualisation as co-creation requires re-thinking at several levels including citizen, municipal, and government as well as an understanding of incentives and governance models for urban planners, architects and designers. The organisations integrating blockchain technologies and implementing new business models will need to be aware of the implications blockchain has on existing systems and consider how existing processes will need to adapt or be replaced by new ones. The financial implications of new technologies and business models requires consideration so it is not a barrier to adoption, for this will be a challenge at all scales from micro to meso and macro.

Policy: Policy will be central to the blockchain-based maintenance and increase of biodiversity at the city scale. It is hoped the future findings of this research will inform policymakers on the benefits the application of blockchain can bring to the table. Part of the philosophy of an underpinning blockchain system is the rationale that policy and regulatory frameworks are partly shifted on-chain (i.e., to the computing protocol). As such, diligent care needs to be taken on forming the policies that drive the design of the blockchain and related smart contracts. A key question that would be interesting in the formulation of such policy is the governance rights that might be attributed to nature itself. Other researchers have raised the question as well. However, the use of a particular question as a case study might help us make inroads into forming such policy, even outside the blockchain frame. Beyond policy, of course, there is also the issue on how nature might be able to exercise such rights, so it is not only a question of agency but also of practical execution of such agency.

Society: Biodiversity has implications for humans that make up society. Unfortunately, the activities that we as humans have become accustomed to, to live comfortably and enjoy day-to-day living have negative effects on the environment and result in biodiversity loss. For blockchain as an initiative to incentivise and govern biodiversity maintenance and increase requires: a) acceptance of blockchain as a facilitator, and b) comprehensive participation of citizens in the co-design process to achieve this. This requires establishing what the role of citizens will be in maintaining and increasing biodiversity at the city scale. It is a departure from today's limited participation in municipal governance so will require adjustments from both citizens and municipalities.

Initial gaps in the literature

While there is literature on blockchain-based incentives and blockchain-based governance, the biggest gap lies in a general lack of research on biodiversity at the city scale facilitated by blockchain. While the initial motivation for this research lies with the increase of biodiversity without a specified utility, there might also be another unexpected shift that can directly benefit the economy and production of the built environment. This is the fostering of an environment where bio-based materials and bio-based processes for construction are being adopted within frameworks of the circular economy. An increase in biodiversity could be coupled with an increase of more readily available bio-based construction materials, directly contributing to the circular economy of the built environment, not only in the financial sense but also in the ecological sense (i.e., in a systemic change).

Challenges and constraints

While the challenges and constraints of blockchain-based governance and incentive mechanisms to maintain and increase biodiversity at the city scale are scattered throughout this paper, this section brings them together to concretise the focus of the wider research project going forward.

- Acceptance of blockchain as a viable solution is required, acknowledging that selling 'blockchain' as the underpinning technology is not the way to do this. The benefits brought about by building on blockchain platforms will offer new propositions, business models, and revenue streams that can be reaped not by marketing a blockchain-based application, but by promoting the benefits of the 'killer app' that will be the tipping point for blockchain applications.
- A change in current business models and levels of responsibility at government and municipal levels is required to embrace co-creation with citizens as a genuine and integrated piece of the solutions puzzle.
- A critical mass of participants is needed to make utilising blockchain technologies worthwhile where decentralisation of power (in this instance away from national and local governments) allows true democracy and a focus on the long-term impacts of the built environment.
- There is limited understanding of the importance of biodiversity across the general public. If citizens are asked to co-create new and rethink existing built environments, they must be aware of the importance of biodiversity, what it looks like and the different ways in which it can be achieved. This requires educating the public (i.e., through participatory action research) to highlight the benefits of bringing back biodiversity to cities such as improved physical and mental health, lower levels of pollution, better use of resources, and more sustainable urban environments.

Proposed outcomes

This research will create a framework to facilitate increasing biodiversity at the city scale. It will examine case studies from regions around the world that have high levels of biodiversity (e.g., Singapore, Brazil) either through protecting the natural environment or through rewilding back into cities. A set of detailed use cases for governance and incentive mechanisms of blockchain in construction will support the framework and an IT prototype will be created to demonstrate how blockchain technologies can enable this.

The outputs of this research will contribute knowledge to a new area of interdisciplinary research at the intersection of co-design, blockchain, biodiversity and design and planning in construction with a humanitarian focus.

Conclusions

Biodiversity is crucial to the survival of humanity and is central to the ecological systems in which the built environment exists. However, the built environment has evolved in recent decades to one that exploits natural resources and damages the environment without sufficient regard to the long-term effects. The aim of this paper was to consider the potential of emerging blockchain technologies to mitigate the negative impacts of the built environment at the urban complex where most of the damage is seen. As such our motivation lies in improving the performance of the built environment in issues of biodiversity, via the exploration of blockchain incentives and governance. We view biodiversity increase in the built environment as a public good, hence it has a very good alignment with the application of blockchain technologies as a socio-technical system for facilitation of governance and incentivisation.

Existing research has been conducted on blockchain as a facilitator of governance and incentive mechanisms showing its potential in changing user behaviours and organisational processes to create efficiencies and promote real democracy. This paper presents early plans for a research project that will create a framework and an IT prototype to utilise blockchain in maintaining and increasing biodiversity at the city scale. It will do this by conducing interdisciplinary research at the intersection of co-design, blockchain, biodiversity, and design and planning of the built environment.

Abstract

With the prosperity of the Web 3.0 era, the construction sector is turning to blockchain-based tendering to address stakeholder conflicts. However, bid rigging among suppliers and information asymmetry between suppliers and the general contractor (GC) potentially undermine the GC utility. To this end, we introduce contract theory into the blockchain-based tendering framework to augment the utility of GC. Simulation results indicate a potential 20.7% profit increase for the GC, due to fostering competition among suppliers, such as material delivery time, compared to traditional blockchain-enabled bidding processes.

Introduction

Construction projects typically require the procurement of materials, a process commonly facilitated via tendering. To select competent and qualified suppliers, the lowest price (Enshassi and Modough, 2012) and comprehensive bid evaluation (van der Meer et al., 2022) methods are primarily employed for their bid evaluation. Meanwhile, the mainstreaming tendering procedures are manual and e-tendering, respectively. However, several drawbacks, such as extremely time-consuming (Santoso and Bourpanus, 2019) and heavily reliant on the third party (Chen et al., 2016), remain in current tendering procedures, thereby posing motivation to augment the accuracy, automation, transparency, security, fairness, and efficiency in terms of the tendering procedures.

To this end, scholars have become increasingly interested in developing efficient and automatic tendering systems (Dong et al., 2023). In addition, in light of the tendering process being mainly used by governments and companies as a dominant procurement method (Mali et al., 2020), security issues are imperative to be resolved. Notably, given the legal and security issues and lack of transparency in the e-tendering process, the authors in (Torkanfar et al., 2023) developed a distributed e-tendering system via the integration of blockchain, public key infrastructure (PKI), and interplanetary file system (IPFS). Meanwhile, with the prosperity of the Web 3.0 era (Zhan et al., 2023), some scholars in the construction domain have attempted to implement blockchain technology into the tendering system to achieve a secure and fair tendering process (Zhang et al., 2023; Yutia and Rahardjo, 2019). In the recent past, a blockchain-based tendering system for construction projects has been proposed, which employs decentralized smart contracts to execute the tendering process, a decentralized storage system to exchange and store relevant off-chain documents, and a decentralized application to enhance interaction between the GC and suppliers (Ahmadisheykhsarmast et al., 2023).

Nevertheless, certain shortcomings persist within the blockchain-based tendering framework. In this framework, the selection of competent suppliers heavily relies on their submitted Request for Proposals (RFPs). In this way, the bidding initiative is not in the hands of GC, thus causing severe consequences, such as prevalent misconduct of bid rigging. In addition, suppliers' confidential information may also compromise the utility[1] of GC. For instance, in the United States, most participants reported experiencing or anticipating delays in the delivery of materials (Alsharef et al., 2021). Apart from this, some truck companies prioritize proximity orders and are reluctant to transport across state lines to avoid the risk of material delivery delays due to policy changes (Ren et al., 2023). Therefore, when facing concurrent material delivery orders, the priority level for delivering GC's material that GC is unknown. Since construction work requires the support of these upstream manufacturing plants and trucking companies in the supply chain, such information asymmetry issues between GC and suppliers might lead to delayed delivery and financial losses. Although penalty clauses are deployed when designing contracts to avoid material delivery delays, such as mandatory fines per day (Bergantiños and Lorenzo, 2019), the GC remains unable to control the risk of delayed material delivery during the supplier screening phase. Therefore, we aim to enhance existing blockchain-based tendering by considering two primary issues, ***i) GC does not completely possess the bidding initiative***, and ***ii) the information asymmetry between the GC and suppliers***.

Methodology

Regarding aforesaid issues, Nobel-winning contract theory (Li et al., 2024) excels in resolving information asymmetry and can transfer the initiative from suppliers to GC ingeniously. To this end, we propose a novel tendering framework that leverages blockchain technology and contract theory together, thereby ensuring a fair and transparent tendering process and optimizing the GC's utility. The proposed framework comprises several key Steps, as depicted in Figure 1. First, the GC will initiate a prequal-

[1]It is a measure of the benefit or value that an individual places on a particular choice.

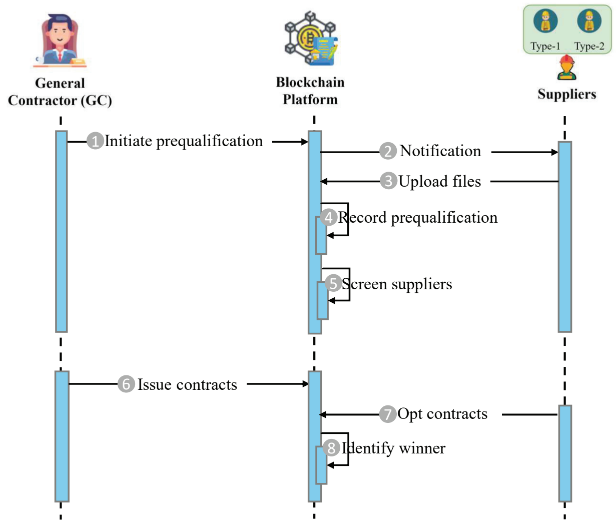

Figure 1: Sequence diagram of blockchain-based and contract theory-enabled tendering.

ification process to screen honest and qualified suppliers for participation in the tendering process. Suppliers will then upload their qualification documents as required by the GC for evaluation. Next, compiled smart contracts will be employed to screen suppliers according to predefined conditions. After that, a set of contract bundles will be designed and issued by the GC based on the contract theory for suppliers. Notably, the contract bundles will be selected by suppliers based on their actual confidential information (Bolton and Dewatripont, 2004). Subsequently, the smart contract will automatically identify the winning supplier based on previously defined metrics. Finally, the GC will sign with the winning supplier. In summary, our main contributions are summarized as follows:

1. To address the bid-rigging issue, we propose a blockchain and contract theory-based tendering framework. This framework enables the GC to take ownership of the tendering process while ensuring a fair and efficient tendering process for suppliers.
2. Under information asymmetry, we systematically model the tendering process of a blockchain-based construction project and formulate an optimization problem with the supplier's delivery time as the optimization variable. To address this problem, we employ contract theory to design a set of contract bundles that compel competition among suppliers under their confidential information.
3. The simulation and related numerical analysis results of the contract theory-based tendering model are presented. We compare the impact of different key parameters on the results and demonstrate the feasibility and effectiveness of the proposed model.

Blockchain-based contract theory procedure

To illustrate the blockchain and contract theory-based tendering framework, especially the connection between the blockchain and contract theory, we will delve into the details of our proposed tendering framework.

Algorithm 1: Blockchain-based contract theory

Input: timestamp, supplierAddress
Output: winning supplier, S_w

7 **if** *Invoke* ***SupplierSelectionContract*** **then**
    `// Use contract bundles in smart contract`
8   ContractBundle ⇐**T**;
9   Shortlist qualified suppliers;
10   Record selection results of suppliers;
11   Identify the winning supplier, S_w;
12 **end**

First of all, our proposed tendering framework, as depicted in Figure 1, which mechanism is analogous to the blockchain-based tendering framework proposed in (Ahmadisheykhsarmast et al., 2023). The critical difference is that we have integrated the contract theory into the blockchain-based tendering system, Steps 5-8 in Figure 1, and the detailed procedure is illustrated in Algorithm 1. Concretely, GC will first utilize blockchain to collect trustworthy data to evaluate the potential delivery time that suppliers can do (Lines 1-4 in Algorithm 1). Subsequently, as per evaluation results, GC will design contract bundles with the utilization of contract theory (Lines 5-6 in Algorithm 1). Then, the GC will code smart contracts as per calculated contract bundles (Lines 7-12 in Algorithm 1). Eventually, the GC will deploy the smart contract on the blockchain, thus enabling an autonomous and transparent tendering process, i.e., award the material delivery order to the supplier who opts for the strictest contract bundle, thereby effectively reducing the risk of delayed delivery.
It is worth noting that we utilize immutability and transparency two crucial properties of blockchain when designing the tendering framework. As for immutability, GC will trace the historical delivery data of the supplier by using smart contract ***DataCollectorContract***. Regarding transparency, our proposed framework will enable GC and suppliers to oversee the whole tendering process, i.e., the running process of smart contract ***SupplierSelectionContract***, including contract bundle selection and winning supplier identification. In addition, in light of our proposed tendering framework is enhanced as per (Ahmadisheykhsarmast

et al., 2023), thus it can be deployed on the Ethereum [2] as well.

In the remainder of this paper, we will present the mathematical model of blockchain and contract theory-enabled tendering process and numerical simulation comparison results to demonstrate the effectiveness of our proposed framework.

Contract theory model

Contract theory background

We consider K types of construction materials, collectively denoted by $\mathscr{M} = \{M_1, \cdots, M_k, \cdots, M_K\}$, to be tendered in the construction project. The execution sequence and interdependencies of various materials in the construction project implementation plan give rise to varying degrees of importance for different materials. We use δ_k to represent the importance of material M_k. Additionally, each material has a specific delivery time requirement to satisfy construction scheduling needs. While timely delivery of M_k is preferable, advance or delayed delivery may occur due to unforeseen circumstances. For ease of modeling, we assume that regardless of whether M_k is delivered early or late, the difference between the on-time delivery and both the earliest and the latest delivery times are identical.

In this paper, since the tendering process is similar for each material, we only consider the tendering process for M_k. As for tendering, the GC will solicit several suppliers to bid publicly for M_k. Without loss of generality from a mathematical perspective, we assume that GC calls only 2 suppliers to bid for M_k tendering, denoted as $\mathscr{S}_k = \{S_k^1, S_k^2\}$. Akin to (Doe et al., 2023), we can easily extend to a practical scenario where multiple suppliers together tender for M_k.

For simplicity, we will use S_1 and S_2 to represent two suppliers in the remainder of this paper. Each supplier can be denoted as S_n[3] and has a unique identity type, θ_n, corresponding to the material delivery time, which may influence by the count of concurrent delivery and delivery priority level for GC's material that suppliers possess. Due to privacy concerns, the exact identity type of the suppliers is unknown to the GC, resulting in information asymmetry. Thus, the GC can only stipulate the delivery time of M_k based on the public information submitted by suppliers, which we denote as T_k^{max}. However, setting the delivery time as T_k^{max} may not maximize the GC's utility, and arbitrary delivery time settings can result in supplier dissatisfaction. In a nutshell, under information asymmetry, it becomes challenging to maximize the utility of GC. Therefore, we have integrated contract theory with the blockchain-based tendering scheme proposed in (Ahmadisheykhsarmast et al., 2023).

[2]https://ethereum.org/whitepaper

[3]$n \in \{1,2\}$

Supplier model

For clarity exposition, we assume S_n with only two possible identity types, θ_H and θ_L. We define $\theta_H > \theta_L$[4], and each identity type corresponds to a different extent of advance delivery requirement with respect to T_k^{max}, represented by T_k^H and T_k^L, in which $T_k^H > T_k^L$. For the sake of modeling, we will drop the subscript k and use T_i to indicate advance delivery requirement, i.e., $i \in \{H, L\}$.
In addition, we assume that the tendering will use the comprehensive tendering method, a commonplace bidding model in the construction industry (van der Meer et al., 2022). As per our initial assumption, the GC follows Steps 1-4 of the framework depicted in Figure 1 to comprehensively evaluate and shortlist several suppliers. Subsequently, the GC implements Steps 5-8 to identify the ideal supplier using a multilateral contract theory-based (Bolton and Dewatripont, 2004)[5] tendering scheme. We assume that the average bid of selected suppliers in Figure 1 is $\bar{R}$. The utility function of S_n can be defined as follows:

$$U_{S_n} = \omega(\theta, \bar{R}) - \phi(T_i) - p(\delta_k) + r(\bar{R}), \qquad (1)$$

where $\omega(\cdot)$ represents the profit that S_n can earn for this project. $\phi(\cdot)$ denotes the cost function for the supplier to transport the construction materials. $p(\cdot)$ represents the penalty imposed on the supplier if they fail to deliver within the delivery time specified in the signed contract. Finally, $r(\cdot)$ represents the revenue generated by the blockchain platform for S_n.
As this paper adopts the comprehensive tendering model, the GC only needs to pay the successful bidder with $\bar{R}$. The difference in profit among suppliers is primarily determined by their identity type θ. Specifically, the better the delivery, the more intangible wealth the supplier will gain, such as a relatively high probability of getting the next order. Therefore, we define the profit function that S_n can obtain from the project as:

$$\omega(\theta_i, \bar{R}) = \theta_i \bar{R}. \qquad (2)$$

In light of the stricter delivery time requirement, i.e., T_i, the supplier will possess a lower concurrent delivery order or necessitate the supplier to set GC as a high priority, potentially impacting its profit. Therefore, we define the cost of S_n is related to T_i:

$$\phi(T_i) = \alpha(\bar{T} + T_i), \qquad (3)$$

where α is the coefficient of suppliers' cost, and $\bar{T}$ is the initial cost when suppliers' delivery time requirement is T_k^{max}.
The penalty function for construction material not delivered before the delivery time requirement imposed on S_n is related to the importance of the materials and the punctuality of delivery, which is defined as:

[4]Due to the θ_H type supplier with fewer concurrent delivery orders and will set GC's delivery order as the high priority.

[5]The multilateral contract theory is akin to the bidding process, where the winner takes all.

$$p(\delta_k) = P\delta_k \times \tau, \tag{4}$$

where $P\delta_k$ represents the penalty charged for the breach, in which P is a constant coefficient, and τ denotes the probability of a supplier breaching the contract.

The payoff function of operating a blockchain platform includes two main components: the revenue generated by the blockchain platform and the expenses required to operate it (e.g., human resources and hardware equipment). According to (Griffiths et al., 2017), the benefits derived from using a blockchain platform are typically associated with the project's bid $\bar{R}$. As a result, we define the blockchain payoff function as:

$$r(\bar{R}) = \Delta\bar{R} - C, \tag{5}$$

where $\Delta\bar{R}$ represents the reduced transaction cost generated by the blockchain, and C denotes the cost of operating the blockchain.

Following the above analysis, the utility function of S_n can be summarized as:

$$U_{S_n} = \theta_i\bar{R} - \alpha(\bar{T} + T_i) - \varphi + \rho, \tag{6}$$

For clarity, we use φ to denote $p(\delta_k)$, and ρ to represent $r(\bar{R})$.

General Contractor Model

The utility function of the GC is defined as follows:

$$U_{GC} = \pi(T_i) - \xi(\bar{R}) + p(\delta_k) + r(\bar{R}), \tag{7}$$

where $\pi(\cdot)$ represents the revenue function of the GC, and $\xi(\cdot)$ denotes the project funds that the GC pays to the supplier.

The revenue function of the GC is defined by

$$\pi(T_i) = \alpha' \ln(D + \varepsilon T_i), \tag{8}$$

where α' is a coefficient and D represents the revenue earned when the material delivery time is T_k^{max}. Also, GC can proactively control the delivery time of M_k earlier than the default delivery time setting T_k^{max}, so as to effectively reduce the risks of delayed delivery, thus we utilize εT_i to denote the additional revenue earned by GC.

The remuneration function paid by the GC to the supplier is defined as follows:

$$\xi(\bar{R}) = \beta\bar{R}, \tag{9}$$

where β is the project remuneration coefficient due to market fluctuations. In this article, assuming that the supply and demand in the market are in equilibrium, we set $\beta = 1$. In summary, the utility function of the GC can be expressed as:

$$U_{GC} = \alpha' \ln(D + \varepsilon T_i) - \bar{R} + \varphi + \rho. \tag{10}$$

Contract definition and problem formulation

Definitions of contract theory

Analogous to (Li et al., 2024), we assume that the GC faces competition from two risk-neutral suppliers[6] for an indivisible material supply order, without loss of generality and for the sake of simplicity. The cases with multiple risk-neutral suppliers can be studied similarly. As discussed earlier, each supplier S_n may have two identity type for supplying M_k, given by:

$$\theta = \begin{cases} \theta_H, & \lambda_n, \\ \theta_L, & 1 - \lambda_n, \end{cases} \tag{11}$$

where λ_n denotes the probability that the GC evaluates the identity type of S_n as θ_H, which can be determined by using empirical-based methods or data mining techniques. Consistent with (Bolton and Dewatripont, 2004), we assume that $\lambda_n = \lambda$, and all suppliers are identical ex-ante. Without loss of generality, we can restrict the GC to symmetric auctions where suppliers are treated equally.

During the tendering process, suppliers compete with each other to secure a contract and maximize their profits. In such a competitive scenario, suppliers take into account not only the contract bundles they choose but also the contract bundles that their competitors may opt for. To reflect this scenario, we present the types of contracts that the GC will offer during the tendering process in the following Definition 1.

Definition 1 (*Competed Delivery Time Requirement*)**.** *Suppliers' delivery time requirements will depend on their respective potential identity type, denoted by* $\mathbf{T} = \{T_{HH}, T_{HL}, T_{LH}, T_{LL}\}$.

To illustrate, T_{HH} denotes the contract variable designed by GC for S_n when the identity types of both suppliers are θ_H. Nevertheless, T_{HH} is a temporary variable set by GC during contract design, and the actual contracts issued are based on the potential identity type of each supplier. Consequently, in this study, only two types of contracts are issued by the GC, namely, T_H and T_L.

During the tendering process, suppliers have the freedom to choose either the same or different contracts. However, it is worth noting that their bid success rate may differ depending on the contracts they opt for. To provide clarity on this matter, Definition 2 is presented:

Definition 2 (*Bidding Success Rate*)**.** *Suppliers' probability of winning the material delivery order depends on their potential identity type, denoted by* $\mathbf{x} = \{x_{HH}, x_{HL}, x_{LH}, x_{LL}\}$.

For instance, x_{HH} represents the probability that supplier S_n wins the order when the identity type of both suppliers is θ_H.

[6] The supplier will be indifferent to risk when making decisions, i.e., the supplier is rational.

As there is only one indivisible construction project, the GC can only select one successful bidder among all suppliers. As a result, it is essential to ensure that the probability of successful bidding for all suppliers, who choose different types of contracts, must be less than or equal to 1. To formalize this requirement, Definition 3 is proposed:

Definition 3 (*Feasibility*)**.** *Supplier S_n has feasibility constraints on the probability of winning the order, i.e.,* $2x_{HH} \leq 1; 2x_{LL} \leq 1; x_{HL} + x_{LH} \leq 1$.

For example, x_{HH} represents the identity type of both suppliers as θ_H. In this case, x_{HH} is the bid success rate for both suppliers, and only one supplier will ultimately succeed in the tendering process, leading to the constraint $2x_{HH} \leq 1$.

With the previous definitions, we have established a mathematical framework for tendering scenarios. However, it is important to note that a rational supplier will only participate in a tendering project if it is profitable for them. Therefore, GC needs to design contracts in a way that ensures positive utility for suppliers. This idea is represented mathematically through Definition 4.

Definition 4 (*Individual Rationality, IR*)**.** *IR denotes that the GC designs the contract in a manner that S_n agrees to it only if there are guaranteed positive benefits.*

Considering the competition among suppliers, we redefined the utility function of S_n as:

$$U_{S(\theta_i,x_i,T_i)} = \sum_{j=H,L} \lambda_j(\theta_i \bar{R} x_{ij} - \alpha(\bar{T} + T_{ij}) - \varphi + \rho), \quad (12)$$

where $\lambda_H = \lambda$, and $\lambda_L = 1 - \lambda$. The physical meaning of (12) is that since there is only one indivisible material delivery order, the probability of S_n bidding success will depend on the contract chosen by other suppliers. Concretely, if the other supplier chooses the H-type contract with probability λ_H and the L-type contract with probability λ_L, S_n will have different probabilities of bid success, as defined in Definition 2. It is important to note that the effect of $\mathbf{x}$ is only on the supplier reward function. This is because the probability of receiving a reward for a successful bid is dependent on another supplier, even if they select the contract of their type and devote their best efforts.

Therefore, we can express the *IR* constraint as:

$$U_{S(\theta_i,x_i,T_i)} \geq 0, \quad i = H, L. \quad (13)$$

While the *IR* constraint ensures supplier participation in tendering, it does not guarantee that each supplier will choose the contract specifically designed for them, which would not maximize GC's utility. To ensure that each supplier selects only contracts suitable for their identity type, we introduce Definition 5.

Definition 5 (*Incentive Compatibility, IC*)**.** *IC denotes that suppliers can only maximize their benefits if they choose the contract that matches their identity type, i.e.,*

$$U_{S(\theta_i,x_i,T_i)} > U_{S(\theta_i,x_j,T_j)}, \quad i = H, L; j \neq i. \quad (14)$$

From (14), we can intuitively see that when a supplier chooses a contract that does not match its identity type, it will result in lower revenue. Therefore, a rational supplier will choose only the contract that meets its identity type, maximizing its benefits and satisfying GC's requirements.

Problem formulation

This paper proposes that the GC maximizes its profit by formulating a series of contracts. Specifically, the optimization problem of the GC is formulated as **P1**:

$$\textbf{P1} \quad \max_{\mathbf{T}} \quad \Pi_{GC} = 2 \sum_{i=H,L} \sum_{j=H,L} \lambda_i(\lambda_j U_{GC(T_{ij})}) \quad (15a)$$

$$s.t. \quad U_{S(\theta_i,x_i,T_i)} \geq 0, \quad i = H, L, \quad (15b)$$

$$U_{S(\theta_i,x_i,T_i)} > U_{S(\theta_i,x_j,T_j)}, \quad i = H, L; j \neq i, \quad (15c)$$

$$2x_{HH} \leq 1, 2x_{LL} \leq 1, x_{HL} + x_{LH} \leq 1, \quad (15d)$$

$$0 \leq T_{ij} < T_k^{max}, \quad i = H, L; j \neq i. \quad (15e)$$

The optimization objective of **P1** is to maximize the expected benefit of the GC. Constraint (15b) is the *IR* constraint on the supplier. Constraint (15c) represents the *IC* constraint on the supplier. Constraint (15d) is the feasibility constraint in the tendering process, and finally, constraint (15e) sets a limit on the material delivery time requirements of the supplier that should be met by the GC.

Optimal contract

Due to the presence of multiple non-convex constraints, solving **P1** is computationally intractable (Zhan et al., 2023). To overcome this issue, we aim to simplify **P1** by leveraging Propositions 1, 2, and 3, the detailed proof can be referred to (Bolton and Dewatripont, 2004).

Proposition 1. $x_{HH} = x_{LL} = \frac{1}{2}, x_{HL} = 1, x_{LH} = 0.$

Proposition 2. *If IR constraint of type θ_L hold, IR constraint of type θ_H will automatically hold.*

$$U_{S(\theta_L,x_L,T_L)} \geq 0 \Rightarrow U_{S(\theta_H,x_H,T_H)} \geq 0. \quad (16)$$

Proposition 3. *If IC constraint of type θ_H is binding, then IC constraint of type θ_L will automatically hold.*

$$\begin{aligned} U_{S(\theta_H,x_H,T_H)} &= U_{S(\theta_H,x_L,T_L)} \\ &\Rightarrow U_{S(\theta_L,x_L,T_L)} > U_{S(\theta_L,x_H,T_H)}. \end{aligned} \quad (17)$$

By using Propositions 1, 2, and 3, and temporarily relaxing constraint (15e), we can transform the intractable problem **P1** into a tractable one, denoted as **P2**.

$$\textbf{P2} \quad \max_{T_{ij}} \quad \Pi_{GC} = 2 \sum_{i=H,L} \sum_{j=H,L} \lambda_i(\lambda_j U_{GC(T_{ij})}) \quad (18a)$$

$$s.t. \quad U_{S(\theta_L,x_L,T_L)} = 0, \quad (18b)$$

$$U_{S(\theta_H,x_H,T_H)} = U_{S(\theta_H,x_L,T_L)}. \quad (18c)$$

By observing the two equality constraints in **P2**, we can obtain expressions for T_{LH} and T_{HH} in terms of T_{LL} and T_{HL}, respectively. Specifically, we have

$$T_{LH} = \frac{(1-\lambda)(\frac{1}{2}\theta_L\bar{R} - \alpha T_{LL}) - \alpha\bar{T} - \varphi + \rho}{\lambda\alpha}, \quad (19)$$

$$T_{HH} = \frac{\frac{1}{2}\theta_H\bar{R} + \frac{1-\lambda}{2}\theta_L\bar{R} - (1-\lambda)\alpha T_{HL} - \alpha\bar{T} - \varphi + \rho}{\lambda\alpha}. \quad (20)$$

For convenience, we define $T_{LH} = g(T_{LL})$ and $T_{HH} = f(T_{HL})$ and substitute these expressions into the objective function of the optimization problem. Hence, the optimal contract can be obtained by solving the following optimization problem, given by (21):

$$\begin{aligned} T_{ij}^* = arg\max_{T_{ij}} 2[&\lambda_H(\lambda_H U_{GC(f(T_{HL}))} + \lambda_L U_{GC(T_{HL})}) \\ &+ \lambda_L(\lambda_H U_{GC(g(T_{LL}))} + \lambda_L U_{GC(T_{LL})})]. \end{aligned} \quad (21)$$

First, we obtain the second-order derivatives of the optimization function with respect to T_{HL} and T_{LL}, respectively. Specifically, we have

$$\frac{\partial^2\Pi}{\partial(T_{LL})^2} = -\left[p_1\frac{(\varepsilon g'(T_{LL}))^2}{(D+\varepsilon g(T_{LL}))^2} + p_2\frac{\varepsilon^2}{(D+\varepsilon T_{LL})^2}\right], \quad (22)$$

$$\frac{\partial^2\Pi}{\partial(T_{HL})^2} = -\left[p_3\frac{(\varepsilon f'(T_{HL}))^2}{(D+\varepsilon f(T_{HL}))^2} + p_1\frac{\varepsilon^2}{(D+\varepsilon T_{HL})^2}\right], \quad (23)$$

where p_1, p_2, and p_3 are defined as $(1-\lambda)\lambda$, $(1-\lambda)^2$, and λ^2, respectively.

Then, since both second-order derivatives are negative, we can determine T_{ij}^* by taking the first-order derivatives of T_{HL} and T_{LL}. Specifically, we have

$$T_{LL}^* = T_{LH}^* = \frac{\frac{1}{2}(1-\lambda)\theta_L\bar{R} - \alpha\bar{T} - \varphi + \rho}{\alpha}, \quad (24)$$

$$T_{HL}^* = T_{HH}^* = \frac{\frac{1}{2}\theta_H\bar{R}}{\alpha} + T_{LL}^*. \quad (25)$$

Finally, we should also check whether T_{ij}^* satisfies constraint (15e) in **P1**. If this constraint is not satisfied, we can use various convex optimization tools such as Gurobi or CVX in Matlab to obtain the optimal solution.

Results

Comparison methods

To provide a comprehensive evaluation of our proposed blockchain-enabled and multilateral contract-based tendering scheme, we compare it with the following benchmark methods.

1. *Multilateral Contract in Complete Information Scenario* (Bolton and Dewatripont, 2004): This method assumes that the GC possesses complete information about the supplier's identity type and, as a result, designs contracts that can extract all the profits of the supplier. As such, we employ this method as an upper bound for performance evaluation.
2. *Bilateral Contract in Incomplete Information Scenario* (Doe et al., 2023): This method assumes that multiple material shipping orders are simultaneously available for the GC, enabling them to issue exclusive shipping order contracts to each supplier.
3. *Multilateral Contract without blockchain in Incomplete Information Scenario*: This scheme differs from the one proposed in this paper only in that it excludes blockchain; all other parameters remain identical.
4. *Traditional Tendering Scheme in Incomplete Information Scenario* (Ahmadisheykhsarmast et al., 2023): This scheme leverages the conventional tendering method employed in the construction sector to identify material suppliers for the GC on the blockchain platform.

For ease of reference in subsequent discussions, we refer to our proposed scheme and the four benchmark comparison methods as *Optimal contract*, *Complete contract*, *Bilateral contract*, *WoBC contract*, and *No contract*, respectively.

Experiment parameters

To indicate the high and low identity type of S_n with respect to M_k, we set θ_h and θ_L as 0.1 and 0.02, respectively. We categorize the importance levels of M_k into five categories, namely extremely low, low, medium, high, and extremely high, and represent them using $\{1, 2, 3, 4, 5\}$. We use key parameters with reference to studies involving blockchain-based construction payment management and blockchain-based tendering scheme (Ahmadisheykhsarmast et al., 2023; Griffiths et al., 2017; Bidhive, 2018; Brown et al., 2006).

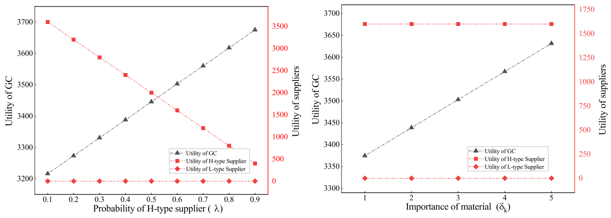
Discussion and result analysis

Contract analysis

In Figure 2, we depict the trend of utility changes for the GC, θ_L type supplier, and θ_H type supplier when varying key parameters. Notably, the utility of the θ_L type supplier remains at 0 for all four parameter variations due to the contract theory extracting the entire profit of the lowest-rated supplier, which aligns with previous research (Zhang and Han, 2017; Li et al., 2022; Doe et al., 2023).

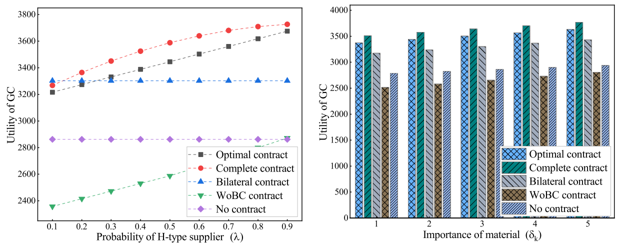
As shown in Figure 2a, when the identity types of θ_H increases, the utility of the GC also increases while that of θ_H type suppliers decreases. This result is intuitive as a higher λ value causes the GC to tailor contracts exclusively to θ_H type suppliers, extracting more profit.

Figure 2b reveals that when material importance δ_k increases, the GC's utility gradually increases. This outcome arises because heightened δ_k values necessitate a stricter delivery time requirement for materials, enabling the GC



(a) (b)

Figure 2: Contract-based tendering scheme for comparison of GC, θ_H and θ_L type suppliers' utilities as parameters vary.



(a) (b)

Figure 3: Contract-based tendering scheme for comparison with other four benchmark methods as parameters vary.

to extract more profit and thereby reduce risk. Notably, the utility of θ_H type suppliers remains constant across δ_k variations. This result stems primarily from the supplier's lead time increasing alongside δ_k. In other words, although the supplier's cost coefficient increases, the GC also obtains a more lenient delivery requirement, thereby reducing supplier delivery costs and leaving the utility of θ_H type suppliers unchanged.

Utility of GC

In Figure 3a, it is evident that the *Optimal contract*, *Complete contract*, and *WoBC contract* lead to an increasing trend for the GC's utility as λ increases. This result arises from varying the supplier's delivery time requirement as λ increases. In contrast, the *Bilateral contract* and *No contract* exhibit no change when λ increases since these methods do not affect the supplier's delivery time requirement. Specifically, in the *Bilateral contract*, the GC formulates designated contracts for suppliers with different identity types. Therefore, varying λ does not impact the supplier's delivery time requirement or the GC's utility. As for the *No contract*, it is intuitive that the supplier's delivery time requirement will not change irrespective of λ.

The reasons for the increase in GC's utility depicted in Figure 3b are similar to our analysis of Figure 2b, where an increase in δ_k leads to the extraction of more profit from the supplier by the GC. This increased profit stems from tailoring the contract to mitigate GC's own risk, resulting in an increase in the GC's utility as δ_k increase.

Based on the findings presented in Figure 3, we can determine the effectiveness ranking of the different contracts for GC's utility as follows: *Complete contract* > *Optimal contract* > *Bilateral contract* > *No contract* > *WoBC contract*. The *Complete contract* outperforms all other methods because the GC is aware of the supplier's identity type before contract formulation and can extract the maximum profit possible. Next, the *Optimal contract* generates more profit for the GC than the *Bilateral contract* by incorporating a competition mechanism during the contract formulation. Information asymmetry is the reason why the *No contract* method is inferior to the other three contract theory-enabled methods. Finally, the reason why the *WoBC contract* ranks last is that conventional tendering incurs an excessive amount of administration cost compared to the blockchain-based approach. Typically, administration costs range from 2% to 3% of the contract value (Bidhive, 2018; Brown et al., 2006), whereas blockchain cost remains fixed, which typically amounts to around \$750, including the cost of smart contract deployment and invocation, prequalification files submission, and evaluation and contract awarding, etc., for completing a tendering project on Ethereum. (Ahmadisheykhsarmast et al., 2023). Consequently, blockchain will generate more revenue as the contract value increases.

Conclusion

Considering information asymmetry and bid-rigging undermining the GC's utility, this paper proposed a blockchain and multilateral contract theory-based construction tendering framework. To promise the effectiveness of multilateral contract theory, the GC first utilized the blockchain to acquire trustworthy data. Then, with the utilization of contract theory, the GC can provide precise material delivery time via the smart contract for suppliers to opt for. The simulation results demonstrated that the proposed multilateral contract theory-based method improves the GC's profit by approximately 20.7% in comparison with the traditional bidding method, with only a 5% profit difference displayed compared to the performance-optimized upper bound complete information scenario, the ideal situation. Furthermore, the proposed framework benefits the scenarios where information asymmetry is prevalent, such as construction payment management and material transportation processes. In future work, we will take the continuity of different materials into consideration, and will not assume the tolerance for advanced and delayed delivery are identical since delayed delivery will cause more severe consequences.

EXPLORING TOKENIZED PRODUCT PASSPORT FOR CIRCULAR CONSTRUCTION SUPPLY CHAINS

Brandon S. Byers[1], Jens Hunhevicz[12], Meliha Honic[1], and Catherine De Wolf[1]
[1]ETH Zurich, Zurich, Switzerland

Abstract

A token is a cryptoeconomic entity on a blockchain that can be used to digitally secure, represent, and trade assets. Existing research does not sufficiently explore the use of tokenization as digital representations of physical construction assets within the context of circular supply chains. Thus, this research explores why tokenization for circular construction may be helpful by employing a mixed methods approach via quantitative and qualitative analysis of expert surveys and a technical review of tokens. The contribution proposes scenarios of tokenization's potential for blockchain-based product tracking and product passports for AEC.

Introduction

The built environment is facing two major transformations: a circular economy transformation and a digital transformation, and both are critical paradigms that can target enhancing sustainability (Çetin et al., 2021). Digitization for the architecture, engineering, and construction (AEC) industry is known to be slow because of general resistance to changing processes and adopting new technologies. Changing our built environment from a linear to a circular model is also inhibited by resistance to changing processes, resistance to upfront added costs, and information deficits (Byers et al., 2024).

In the built environment, implementing a circular economy primarily deals with the complexity of the supply chain. This includes the procurement and specification of materials, involving numerous participants, and the certification of material quality. Circular construction supply chain (CCSC) compared to typical construction supply chains also include connecting the materials from disassembly in one life cycle to a use case for additional life cycles as well as preserving information on the materials over time (Wijewickrama et al., 2021). Additional challenges include the presumed added costs of component reuse, though it appears this depends primarily on local regulation, culture, and precedent (Mollaei et al., 2023). Other challenges for reusing materials include product liability and the producer's responsibility for the circulation of the materials at the end of use, particularly if the original information on them is unknown (Farooque et al., 2019). Therefore, research is growing on how to track construction products over time, what information to track, and where to store it. Blockchain technology is considered useful for tracking and tracing information in supply chains and construction (Wang et al., 2020; Qian and Papadonikolaki, 2020). Though there is an overlap of tracking product information with the concept of Digital Product Passports (DPPs) European Commission (2022), there is insufficient work on their application for AEC. In particular, the use of tokenization to represent circular supply chain assets with a tokenized product passport (TPP) seems a promising concept. TPPs may help ensure data continuity and availability through multiple stakeholders and life cycles. Yet, this application is nascent and there is a gap in research and practice. Therefore, this research addresses the question: *why would tokenization be useful for product passports for a circular built environment?* The paper begins with a background on relevant concepts, states the methods used, analyzes survey responses, provides a technical review of token features, proposes resulting applications of tokens, and finally discusses existing challenges and future work.

Background

To contextualize the research objective of this work, some background is provided on product passports, blockchain tokens, and existing applications in both academia and industry.

Product Passports

Recent legislation in the EU pushes for Digital Product Passports (DPPs), which will be used to inform product supply chains and environmental impact (Çetin et al., 2023; Honic et al., 2024; European Commission, 2022). Within AEC, Material Passports (MP) are similar to DPPs and describe characteristics of materials in products regarding their constituents, recyclability, and reuse potential, which have been found to support circularity (Honic et al., 2021) and reuse (Byers and De Wolf, 2023). While MPs and building logbooks apply to the built environment, DPPs are a cross-sectoral concept shaped by the regulatory framework "setting eco-design requirements for sustainable products" of the European Commission (2022). A report from the Wuppertal Institute by Jansen et al. (2022) reviews 76 corporate, policy, and research initiatives for DPPs. Though several of these initiatives do look at buildings, many are focused on batteries, textiles, machinery, and automotive products and discuss the challenges of heterogeneous industries and stakeholders. Interestingly, nine of these implemented blockchains for immutability, transparency, and decentralization along the supply chain.

Blockchain Tokenization

Blockchain technology is a type of distributed ledger technology (DLT) that is run over a decentralized set of computer nodes and ensures secure and transparent peer-to-peer transactions without intermediaries. Blockchain's potential application for construction is well-researched (Li et al., 2019), including supply chain and lifecycle applications (Scott et al., 2021).

This paper concentrates on Ethereum, which is among the most widely used blockchains, chosen for its capabilities in handling smart contracts, offering distributed computing solutions, and having a robust developer community. Tokens can be programmed through smart contracts, which are executable code stored on the blockchain that can interact with and define transaction logic. Smart contracts are used to specify token features (e.g., destroyable, ownable, metadata, etc.), supply count, and transfer mechanisms. On a blockchain, tokens provide a critical role as a medium of exchange and a way to represent digital or real-world asset ownership. Tokens have already been integrated into various digital ecosystems (e.g., gaming, decentralized markets of digital goods, and real estate fractionalization) reshaping industries through innovative business models on new forms of ownership and transactions (Sazandrishvili, 2020).

Because tokens are produced through smart contracts and are customizable, token standards are used to ensure interoperability and secure implementation through standardized building blocks in the network. In the Ethereum ecosystem, this standardization happens through an Ethereum Request for Comment (ERC). An ERC is a proposed protocol for suggesting a new standard defining rules and specifications for tokens or smart contracts to be adopted by individual developers and projects. The most common token standards are ERC-20 and ERC-721. ERC-20 establishes a fungible token that is tradable and dividable into discretized shares. ERC-721 is a non-fungible token (NFT) that is tradeable, non-divisible, and used to represent unique values. Tokens often consist of links within the metadata to the storage of data too large to be stored on-chain as shown in Figure 1. A token, often constituted as a JSON-LD entity, combines principles of the semantic web with interoperability and is readable by both humans and machines.

The general benefits of tokenization are greater liquidity, global access, reduced intermediaries, faster transactions, increased transparency, and immutability. The associated challenges are legal, regulatory compliance and uncertainty, cybersecurity, and absence of public sector involvement (Tian et al., 2020; Sazandrishvili, 2020). This is similar to the report from McKinsey & Company that discusses the impact of tokenization including improved capital efficiency; democratization of access; operational cost savings; enhanced compliance, auditability, and transparency; and, cheaper infrastructure (Banerjee et al., 2023).

Tokenization Applications

In the context of using tokens within markets, Ferrara et al. (2022) states, "tokens of digital assets are indeed defined as digital objects in which the relevant information are stored to guarantee a single, unique matching between asset and token." The work proposed two processes for using blockchain in digital markets of physical assets: tokenization and legitimacy of ownership. Additional research from Weingärtner (2019) states the advantage of tokens is they facilitate the self-sovereignty of data and proposes three types: payment tokens (currency), utility tokens (rights or services), and assets or security tokens (represents a share).

A report from the consulting firm EY discusses tokenization of real-world assets for the transparency and improved traceability and trust in the chain of ownership. (EY, 2020). Tokens can be considered software with a unique asset reference connected to properties or legal rights. The report discusses three token standards and their ideal implementation: ERC-20 for transferring value between users, ERC-1400 for transferring asset or security tokens requiring a certificate, and ERC-721 for transferring ownership of a specific asset.

A recent position paper on the value of tokens for AEC provides a slightly modified token classification noting that the applications are either economic or technical: utility (governance), security (object representation), pegged (stablecoins), and direct (payments) (Kifokeris et al., 2023). The paper provides recommendations for a classification of tokenization opportunities by thematic area (e.g., circularity), and the associated benefits, challenges, issues, and opportunities.

Tezel et al. (2021) explored blockchain implementation in construction and suggested three primary supply chain management models: project bank accounts, reverse auction-based tendering, and asset tokenization for financing (crowdfunding). Wu et al. (2023) developed a prototype of an NFT-based construction waste material passport using a design science research approach. The prototype was built using Hyperledger, a private and permissioned blockchain. Additional research overlaps the concepts of smart construction objects and blockchain oracles for recording information around the construction processes on a blockchain (Lu et al., 2021).

Within the context of AEC, tokens have often been

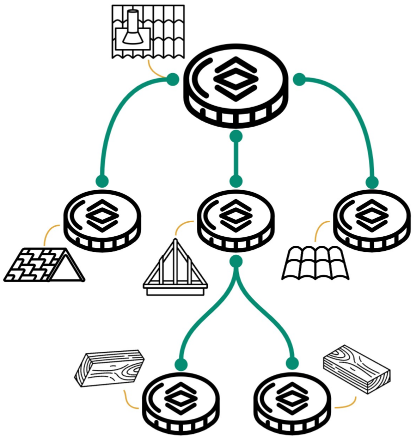

Figure 2: Visualization of Nested Token Hierarchy Representing Nested Component Assembly

proposed as an incentivization mechanism between stakeholders (Kouhizadeh et al., 2022). However, work from Dounas et al. (2021) proposed a system of organizing topology graph representation of a building as Ethereum tokens. Research from Hunhevicz et al. (2023) demonstrates a prototype of using tokens for Web3-based data access roles for material passports. Earlier work from 2019 proposes a framework for supply chain traceability based on tokenizing the bill of materials and component IDs (Dasaklis et al., 2019). Different tokens for source materials, elemental tokens, and compound tokens can be used to build up a tree structure of the data, emulating the similar hierarchy of assemblies in construction. Figure 2 symbolically represents this relationship of nested tokens for an assembly.

Boston Consulting Group and Arianee (2023) created a report on DPP tokenization that provided five main utilities: access to product information, a certificate of authenticity and ownership, a product lifecycle management tool, a customer relationship management tool, and a virtual replica of a physical object. Additionally, the three main proposed architectures are centralized DPPs, permissioned blockchain DPPs, and tokenized DPPs. Though in the short term, and for low-value products, tokenized DPP adoption is not as advantageous as other solutions, it is expected to provide much greater value in the long-term and for high-value products.

Methods

This paper is an exploratory paper on the overlap between tokenization and CCSC, therefore a mixed-methods approach was used including the exploratory data analysis of a survey of researchers and practitioners and a technical review of token features relevant to CCSC. The survey was issued to explore interest and elicit context on current challenges, perceptions, and suggestions for blockchain in CCSC. A more detailed description of the survey distribution and analysis is found in the respective section. In addition, technical standards were reviewed to better understand what features tokens can offer for product passports within AEC. Lastly, the mixed-methods approach combines the findings from each step into proposed scenario applications for tokenized product passports.

Survey on Exploring TPPs

Survey Approach and Overview

The survey distributed had 30 questions to gauge proximal knowledge on product passports for CCSC, technical requirements, and blockchain and tokenization applications. The survey was built online using Qualtrics and distributed via email through a convenience sampling of experts known by the authors with relevant experience in at least two of the three topics: sustainable construction, blockchain technologies, and circular economy. The submissions were analyzed anonymously using the language *R*. A total of 30 respondents completed the survey, though not all respondents answered every question. This paper shows the analyses of the most relevant questions for this work. The anonymized responses are a published dataset (https://doi.org/10.3929/ethz-b-000656624) and the code for the analysis can be found on github: https://github.com/cea-eth/TPP-EDA.

The format of the questions included five-point Likert-response, multi-select multiple-choice questions, and open-response questions. The open-response questions were analyzed using a natural language processing technique called latent Dirichlet allocation (LDA) for topic modeling. LDA is a generative probabilistic model for extracting similar topics over multiple documents (in this case, the documents are individual survey responses). The set of words for each extracted topic and the frequency of the topic are plotted and then interpreted by the authors for their meaning.

The respondents were asked to report in which countries they have projects. The highest reported country was Switzerland with 24% (nine responses), then the US tied with the UK with 13% (five responses), two responses in the Middle East, one response in Asia-Pacific, and the rest of the responses (n=16) were across Europe. About 40% of the respondents have 1-5 years of experience, about 23% have 5-10 years of experience, and 37% have greater than 10 years of experience. Of all the respondents, twelve work in academia, two for a government entity, and the rest within the private industry (in a combination of AEC firms, startups, and consultants).

Responses on DPP and Product Tracking

Of the 30 responses, four stated they were slightly familiar or not familiar with product passports, and two were left blank. Yet, 40% stated it is "Extremely Important" to track construction and building products over time, 40% stated it's "Very Important", and 13% stated it's "Moderately Important". The other two responses were blank.

Some of the questions asked were on potential issues related to data in the respondent's field and are displayed in Figure 3. The most striking results show a 100% positive

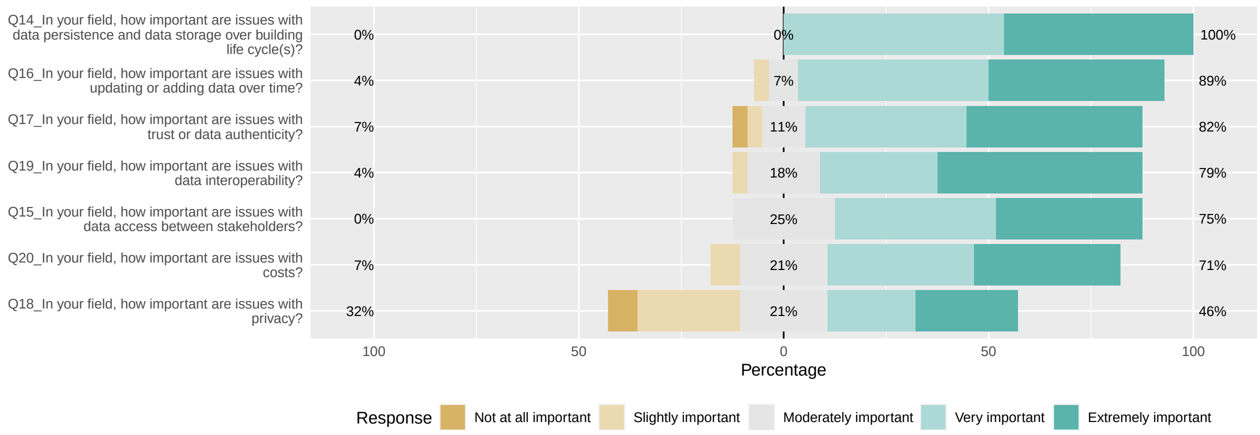

Figure 3: Responses on Importance of Issues on Data

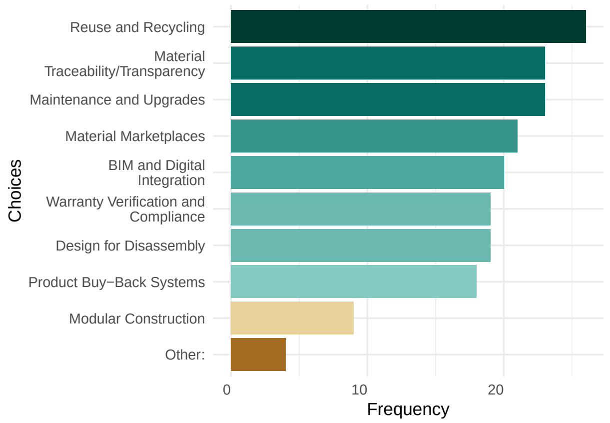

Figure 4: Responses on Ideal Use Cases for Product Passports

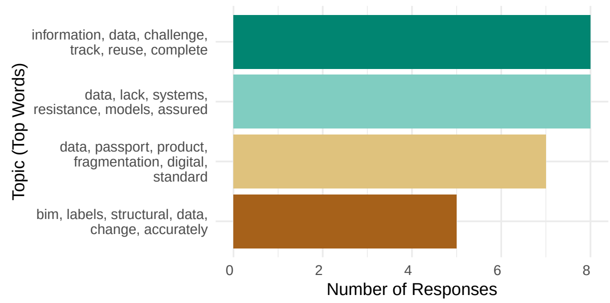

Figure 5: LDA Topics on the Challenges Inhibiting Product Passports for AEC

response for the importance of data persistence and storage over the building life cycle, and about one-third state issues with data privacy are only slightly or not important at all.

Among the various phases of the traditional product lifecycle, the three selected as having the greatest potential for implementing a product passport are B1-B3: Use, Maintenance, and Repair; B4-B5: Replacement and Refurbishment; and C1-C4: End of Life Stage. These responses are validated by another question on potential use cases for product passports shown in Figure 4.

The results from the LDA topic modeling on the problems and challenges inhibiting the use of product passports in AEC are shown in Figure 5. The y-axis shows the words in the topics produced from the model and the x-axis is their frequency found in responses. There are two topics on the challenges found eight times from the responses. The first topic is on the challenge of having complete information for tracking and reuse, the other major topic is on the resistance to data models and lack of assured data. Additional topics allude to challenges of product passport standardization and data fragmentation.

Responses on the Use of Blockchain and Tokenization

Figure 6 is a color-based correlation matrix from the Likert-based responses in the survey. The individual questions have been simplified to their topic and shown in the axes. A question has a perfect positive correlation with itself and is illustrated as dark green and a negative correlation is colored brown.

One of the questions asked the respondent how useful tokenizing product passports would be. The results from Figure 6 show that there is a slight positive correlation between tokenizing product passports and the questions asking about the applicability of blockchain and tokenization.

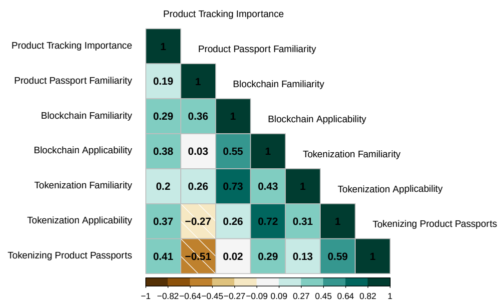

Figure 6: Correlation Matrix between Blockchain, Tokenization, Product Passports, and Product Tracking

Table 1: *Features of Tokens Relevant for Designing CCSC Systems*

Category	Token Features	Feature Description
Product Identification	Metadata Capacity	Amount of storage to hold product information
	Asset Linkage	Connecting the token to the product it represents
	Data Authenticity	Verification of unaltered product data
	Metadata Flexibility	Different types of data to be stored
Supply Chain Integration	Interoperability	Integration across platforms, actors, and file type
	Data Update Mechanism	Modifying data as the product moves or changes
	Queryable	Ease in searching for and retrieving token data
Lifecycle Management	Metadata Storage location	Considering on-chain or off-chain storage
	Composability	Combining and nesting tokens for assemblies or sub-products
Compliance & Privacy	Regulatory Compliance	Adhering to reporting regulations and other norms
	Data Privacy	Public or private chain for sensitive information
Business Proposition	Tradeability	Facilitating B2B/B2C transactions by token transfer
	Cost Efficiency	Evaluating overheads against its ROI
Product End-of-Life	Data Handling	Handling or burning of data at the end of its lifecycle
	Asset Linkage	Connecting the token to the product it represents

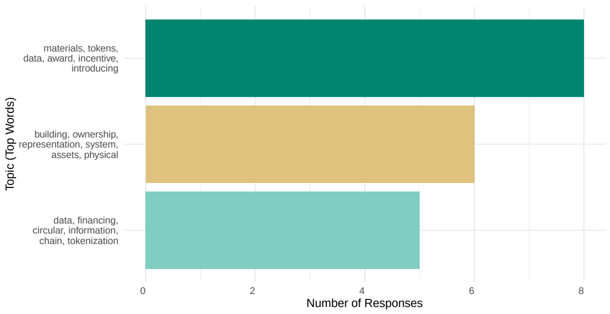

Figure 7: LDA Topics from the Potential Use Cases of Tokenization for AEC

Nevertheless, there is a slight negative correlation between the usefulness of tokenizing product passports and the familiarity level with product passports.

From the question of how might blockchain be used, the largest topic (n=13) extracted from the LDA was as the underlying technology for data transparency and tracking technology for building materials. From the question of how might tokenization be used for circular construction or circular supply chain management, only 19 responses were given as shown in Figure 7. Of those, the most frequent topic (n=8) discussed an application to introduce a system to award incentives for material information. Six responses discussed the topic of using tokens for ownership or representation of building assets. The third largest topic with five responses was on financing data for information in circular supply chains.

Review of Technical Token Features for CCSC

This section explores token standards for Ethereum and provides a table constructed from examined token standards that can be used to guide the applicability of a specific token for CCSC. Beyond ERC-20 and ERC-721, additional token standards have added functionality and potential relevance for this domain. Some are briefly listed below but this list is not exhaustive, which inspired the abstraction of token attributes from these ERC standards in Table 1.

- ERC-1155: Enables fungible and non-fungible tokens in one contract
- ERC-998: Composable NFTs that can own other NFTs and ERC-20 tokens
- ERC-6960: Dual Layer Tokens for asset classification, aiding in fractional and versatile ownership
- ERC-994: Delegated NFTs that register a geo-location of land and property
- ERC-5791: Physical-Backed Tokens representing physical item ownership and authenticity
- ERC-6551: Token-Bound Accounts are NFTs with unique Ethereum accounts for asset ownership and multi-chain application interaction
- ERC-5114: Soul-Bound Token, a non-transferable token permanently attached to a *soul* or address

Table 1 proposes features from various token standards that are relevant for applications to CCSC. The categories of token features should be considered by stakeholders interested in designing and implementing token-based systems. A similar classification approach was previously conducted on designing blockchain oracles for AEC (Dounas et al., 2023).

Resulting Scenarios

This section offers detailed scenarios for tokenized product passports, derived from a mixed-methods approach. The approach is a result from the analysis of token features, the review of relevant literature, and insights from the survey on blockchain's utility and use cases for CCSC. Tokens have broadly been shown to be used for asset representation, payment and incentive systems, or utilitarian and governance systems as defined in Kifokeris et al. (2023); Weingärtner (2019); Boston Consulting Group and Arianee (2023). The proposed scenarios examine the potential utility of tokens in CCSC by focusing on how tokens can serve as a means for representing objects. Proposing payment, incentive, or governance systems, although expressed from the survey results in Figure 7, is beyond the interest of this study.

These scenarios are not direct responses from the questionnaire but a synthesis of all results. Additionally, some token features are universally relevant for CCSC applications including Asset Linkage, Metadata Storage Location, Cost Efficiency, Data Authenticity, Composability, and Metadata Capacity.

Scenario 1) *Tokenize the Material DPP*: Drawing from industry proposals and the results from the survey, this scenario proposes a TPP system where each token acts as a representation for the DPP of the construction assets. The TPP can be connected directly to tracking hardware installed into the asset and used for streamlining compliance and transparency along the supply chain. Tokens could serve to create a unique digital identity for the provenance of each component, similar to Wu et al. (2023); Boston Consulting Group and Arianee (2023). According to DPP regulation, these tokens could facilitate accurate tracking and verification of the origin, composition, and recycling credentials of materials, which is essential for the integrity of a circular supply chain. Specific token features from Table 1 include: Regulatory Compliance, Queryable, and Interoperability.

Scenario 2) *Tokenize the Material Asset*: In this scenario, an asset tokenization platform for the CCSC can be developed for tokenizing the asset and supported by the results shown in Figure 7. Tokenizing a real-world asset reflects ownership within the real world and economic markets. Tokenized assets could allow the transparent traceability and management of material (EY, 2020) as well as their physical relationship to other materials (Dasaklis et al., 2019). An example of a preliminary implementation of this scenario and its integration with building modeling is proposed by Dounas et al. (2021). The token features from Table 1 important for this architecture include Tradeability, Metadata Flexibility, and Interoperability.

Scenario 3) *Tokenize the Material Ownership*: While the first scenario tokenizes the material information, the second scenario tokenizes the asset, and this third scenario utilizes tokens as a security for the ownership of the asset. This token security is a subset of asset tokenization that uses tokens to represent its value contractually, which can be reflected along the CCSC, particularly for material exchange, leasing, or purchasing in decentralized marketplaces (Hunhevicz et al., 2023; Ferrara et al., 2022). Though similar to the other scenarios, the financial and business considerations are more of an emphasis EY (2020); Boston Consulting Group and Arianee (2023). Using tokens as a mechanism for material asset securities also introduces new sustainable finance mechanisms for investing in circular economy solutions. Because of the legal and financial implications, the specific token features in the scenario include Regulatory Compliance, Tradeability, and Data Privacy from Table 1.

Discussion

One of the most interesting results from the survey is found in Figure 6, which shows a negative correlation between familiarity with product passports and the utility of tokenizing product passports. This implies either that those very familiar with product passports do not think there is much utility with TPPs, or that those who think there is high utility with TPP aren't very familiar with product passports. Nevertheless, there is a stronger positive correlation between TPP utility and those who believe tokenization has high potential for CCSC. These results align with Figure 7, where the most frequently mentioned topic was using tokens as incentives, not as representations of the asset itself. Although this supports the *direct* and *utility* cases found in Kifokeris et al. (2023), those cases are out of scope as this paper focuses on the *object representation* case.

Storing product passports on-chain ensures their accessibility and permanence for any stakeholder through time. This approach secures the data and also potentially enables new ecosystem interactions, such as unique wallets assigned to physical assets and the possibility for tokens to be held by non-human entities. The proposed scenarios for token usage are directional but grounded in existing research and survey findings. They require further development and verification through technical implementation and stakeholder engagement. Although this research primarily examines tokens on the Ethereum blockchain, other blockchains also employ tokens, which could be leveraged for DPP applications.

Challenges and Limitations

Blockchain in construction, in addition to product life cycle tracking, is a cyber-physical-social systems problem. To abate this challenge, the researched scenarios should be able to integrate first with existing systems for business-as-usual. Thus the use of a common data format and metadata schema is critical. Additionally, linking data in tokens to external servers is often critiqued because of the challenges associated with the maintenance of hosting externally.

This study is limited by not yet testing implementations of the proposed scenarios. For the survey, the respondents primarily work across Europe, with some in the UK and the US. Responses may vary based on geographical region. There is a natural selection bias from the method of approaching the respondents and cannot be taken as a generalizable state of knowledge. There are inherent limitations to using a questionnaire as it is more likely respondents will provide brief or no answers at all. The use of more exhaustive methods, like interviews or the Delphi method, may produce more informed responses.

Given the heterogeneity of experiences of the survey respondents, a deeper statistical analysis can be used for analyzing results. For instance, the results can be partitioned and analyzed separately based on the categories of responses (e.g., familiarity level with product passports, familiarity level with tokenization, or country of work).

Future Work

The survey included additional open-ended questions that were not covered in this study. Additional work can explore these other inputs from the respondents on hardware approaches, ideal stakeholders, and challenges and use cases. A few of the respondents noted the importance of analyzing the value-add of tokenizing product passports and an understanding of the environmental tradeoffs. These are valid concerns and though they are out of the scope of this study, stand as points for future work.

This work sets the exploratory and theoretical underpinning for future hypothesis development and research on qualitative implementation and quantitative testing of these new processes. Future efforts by the researchers will address the *how-to* for technical implementation and aim to quantify impacts. Further work will use a design science research approach for an exploration of TPP in a real building. The survey findings in this study will inform the goals and design of such a system.

Conclusions

This research investigated the application of tokenization for product passports in CCSC. The authors employ a mixed methods approach via a technical review and survey of experts to frame the potential value of tokenization in circular construction. The results extend the understanding of blockchain-based product tracking for AEC by focusing on the potential of using tokens for object representation of a product passport.

The academic literature confirmed general interest in blockchain and tokenization for product tracking, although with limited CCSC applications tested. Survey results supported the need for product tracking and blockchain for data transparency, while also noting challenges such as data gaps and system integration. Features extracted from various Ethereum tokens were explored for their potential relevance for product passports. Lastly, these results were combined for three proposed scenarios of tokenization within the CCSC: tokenizing the material DPP, tokenizing the material asset, and tokenizing the material ownership. Future research intends to expand upon this theoretical foundation by testing the specified scenarios. This study's findings suggest that tokens could serve as a comprehensive information repository, providing innovative application possibilities for CCSC.

Abstract

The digitization and automation of contracts within the built environment through blockchain has demonstrated potential. Nonetheless, the use of on-chain smart contracts can amount to substantial costs. This study proposes a blockchain-governed approach to individually assess whether and how to use blockchain for different components of contracts. We explain the rationale behind the concept and implement a pilot prototype of a performance-based, blockchain-governed contract. The results promise an alternative and more cost-effective approach to smart or intelligent contracts in the built environment, while still allowing for trusted verification of key contract parts through blockchain.

Introduction

Contracts are important to the collaborative built environment and for interactions between its actors. With the ongoing digital transformation, the digitization and automation of contracts is increasingly being discussed. In particular, blockchain technology promises to enable "smart legal", sometimes also termed "intelligent" contracts (Mason, 2017; McNamara and Sepasgozar, 2021; Allen and Hunn, 2022). Independent of the term, we refer here to the idea to encode contract terms in so-called blockchain smart contracts, which are scripts deployed on a blockchain that can then enforce interaction logic with any blockchain transactions, for example to execute a payment. Blockchain as an immutable ledger of peer-to-peer transactions ensures that contract terms are executed in a transparent and trustworthy manner without the need for a third-party institution. The applications of smart contracts for the built environment are diverse (Li and Kassem, 2021). Examples include the automatic execution of coded terms for contract management (Msawil et al., 2022), automated contracting for construction projects (Gupta and Jha, 2023), or performance-based contracts for lifecycle services based on IoT data (Hunhevicz et al., 2022).

Although a very promising technology for contracting, the use of blockchain smart contracts also creates challenges and risks (Mezquita et al., 2019). Most relevant to this study, their use can amount to substantial costs (Zou et al., 2021; Hunhevicz et al., 2022). As discussed later in this paper, potential solutions are to use a blockchain with low transaction costs or permissioned blockchains. However, we suggest that a more unexplored option is to decouple the functionality of smart contracts and use blockchain only for parts of a contract.

Therefore, we introduce the concept of "blockchain-governed" contracts in the built environment, and why it could be a way to reduce the costs associated with blockchain-based contract management with reasonable trade-offs. To do so, we first cover the necessary background in the point of departure, then introduce the concept of the chosen approach, and show an exemplary implementation of a performance-based contract. Finally, we discuss our contribution by comparing it to a previous on-chain implementation of a similar smart contract and point out limitations and further research.

Point of Departure

Smart Contract Components

As already mentioned in the introduction, smart contracts encode interaction logic with blockchain transactions. In simple terms, a smart contract performs tasks like *"if this happens on the blockchain, then execute this transaction logic"*. Smart contract can be abstracted into four key components (Hunhevicz et al., 2022), as shown in the upper part of Figure 1 and further described below. Although they can be combined into complex contract constructs, for the scope of this paper, we can focus on these components individually.

Identity: Blockchain identifies users with a pair of public / private keys. The public key serves as an address to identify a blockchain user on the network. The private key acts as a password to sign transaction to prove control of the respective address. Smart contracts require information about which public address is allowed to interact or is affected by the smart contract functionality.

Payment: Smart contracts can initiate payment transactions in native cryptocurrency or another token. They can also hold funds and act as bank accounts. Even if the functionality of a smart contract is not related to finance, smart contract functionality still involves a monetary fee to execute transactions. Therefore, for the scope of this paper, we refer to payments as any use of a token or cryptocurrency, both for contract payments or fees.

Data: Smart contracts can store and act on data. Depending on the blockchain, data is stored through available data primitives, for example, in the case of Ethereum, state vari-

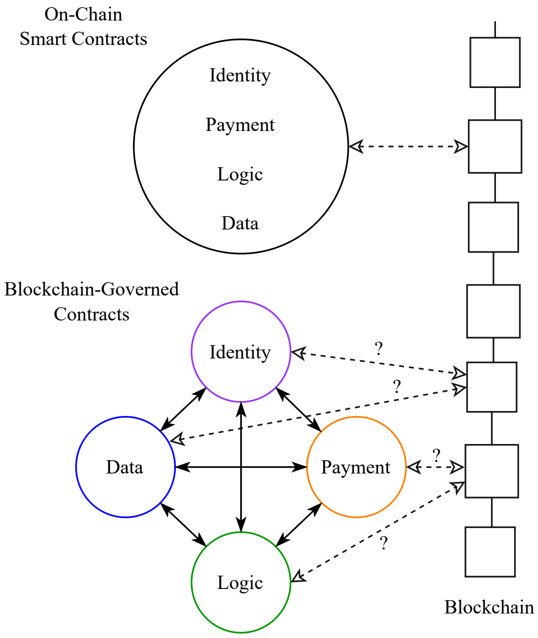

Figure 1: Smart contracts involve identity, payment, logic, and data; a blockchain-governed contract assesses individually whether and how to use blockchain for each category.

ables, arrays, structs, or mappings[1]. To add data to a smart contract, executing a transaction is required to pay the network for storing the data.

Logic: The key part of a smart contract is its logic related to transaction execution and interaction, possibly interacting with and connecting the other described components of identity, payment, and data.

Current Approaches to Smart Contracts

This section reviews current approaches to smart contracts and, where applicable, provides examples of research in the context of the built environment.

On-Chain Smart Contracts

In this paper, we refer to on-chain smart contracts as what is most often meant with the concept of blockchain smart contracts. They include all the above-introduced components in one construct. Once deployed on the blockchain, the logic is deterministic and fully transparent. Ethereum piloted the use of such Turing-complete smart contracts (Buterin, 2014). Several studies in the built environment use on-chain smart contracts, e.g. on Ethereum (Yang et al., 2020; Hamledari and Fischer, 2021; Hunhevicz et al., 2022).

Depending on the used blockchain, the speed of transaction execution can be slow and the associated transaction costs can amount to large sums (Zou et al., 2021). To reduce the costs associated with on-chain contracts, we identified two main options.

First, a blockchain with cheaper transaction costs can be used. For example, new generations of blockchain networks optimize and market themselves for high transaction throughput and low transaction cost, e.g. the Solana blockchain[2]. Moreover, existing blockchain networks, such as Bitcoin and Ethereum, promote the use of second-layer protocols to process transactions faster and cheaper (Gangwal et al., 2023). A potential trade-off to faster transaction can concern the security of the blockchain (Kiayias, 2016). Furthermore, transaction costs can also increase as a function of growing network usage. For now, we are not aware of much research discussing this approach in the built environment. Examples include Naderi et al. (2023) and Scott et al. (2024).

The second option is a permissioned blockchain, also known as a consortium blockchain, e.g. Hyperledger Fabric[3]. This type of blockchain is run by a set of trusted actors who operate the blockchain nodes. Permissioned blockchains offer high throughput and no transaction fees, as the consensus mechanisms are fast and overhead costs are typically paid and shared by the consortium. As a potential downside, permissioned blockchains rely on trusted actors to run the nodes, who have the ability to exclude transactions and users and even shut down the network at their discretion. Furthermore, ensuring the availability of nodes can be challenging over long time periods and changing stakeholders. Nevertheless, due to its project-based nature, a consortium approach is often considered in the built environment (Yang et al., 2020).

Off-chain Approaches to Contracts

A second way to reduce the costs associated with smart contracts involves moving parts of the smart contract off-chain, meaning not stored or implemented on the blockchain. One reason is that the transaction cost of an on-chain smart contract is typically determined by the transaction size and involved computation of a smart contract execution. Especially in the context of networks like Ethereum, moving data off-chain e.g. to external data networks like IPFS[4], is becoming increasingly common, also for applications explored in the built environment (Tao et al., 2021; Adel et al., 2023).

Another reason to research off-chain contracts is that some networks, e.g. Bitcoin, do not support Turing complete smart contracts. Therefore, different approaches are suggested to move data and logic off-chain, e.g. outsourcing to service providers (Wüst et al., 2019), trusted execution environments (TEEs) (Das et al., 2019), or off-chain schemas using blockchain as a state commitment layer and ownership control[5]. We are not yet aware of research in the built environment exploring such contract approaches.

Finally, governance platforms can facilitate trusted process execution through a blockchain-verified and secure semi-automated process (Dursun and Üstündağ, 2021). "Politea"[6] is an example for such a platform used as a pro-

[5] `https://rgb-org.github.io/`
[6] `https://proposals.decred.org/`

posal and payment system for the Decred blockchain contractors. Although no formal on-chain logic is utilized, it makes use of timestamps to allow for checking and re-evaluating the process in case of disputes. Timestamping is inherent to blockchains; each block and transaction has a timestamp for clear recognition. Using this mechanisms, data can be attached to a transaction to create a fingerprint for off-chain data as a proof of existence.

Motivation and Scope of This Study

The previous sections showed that there are different approaches to smart contracts. An alternative to on-chain smart contracts is moving parts or all of the contract components off-chain. We see these approaches as a viable alternative for smart or intelligent contracts in the built environment for the following reasons.

Known actors: Construction and the built environment rely on established processes. The decision to use blockchain involves a trade-off between trusting the technical system vs. trusting the involved actors (Hunhevicz and Hall, 2020). If actors are known and accountable, the cost premium of a fully decentralized on-chain smart contract may not be justified.

Time spans: Construction contracts usually span duration of several years of individual project phases, e.g., for design and construction. Even though such contracts can benefit from a blockchain approach, it might not be justified to pay for an on-chain contract that lasts as long as a blockchain exists.

Physical nature: Blockchain-based contracts need to rely on trusted feedback loops of physical processes and products. Although the logic of an on-chain smart contract is trustworthy, wrong input data could jeopardize a correct execution. A partial off-chain approach could be a practical middle ground with reasonable trust and transparency.

Trust in existing systems: The construction industry is known for slow technology adoption. In many cases, the possibility of traditional identity verification, FIAT payments, or the possibility for more data privacy has priority. A blockchain-governed approach could better consider these aspects than a pure on-chain smart contract.

Therefore, this study proposes the concept of ”blockchain-governed” contracts for the built environment, and pilots an off-chain governance system for an exemplary performance-based contract.

Blockchain-Governed Contracts

The term ”blockchain-governed” contract is proposed in this paper for contracts that use blockchain in one of the four components introduced (identity, payment, logic, or data), but at the same time also do not use blockchain with an off-chain approach in at least one category. As shown in Figure 1, such a blockchain-governed approach allows to individually evaluate for use cases whether and how blockchain is used for each component. Table 1 provides non-exhaustive examples of the differences between an on-chain and an off-chain approach for each component.

Proposed Off-Chain Governance System

To illustrate the concept of blockchain-governed contracts in the built environment, we propose an off-chain governance system for a contract in the built environment in Figure 2. The figure is organized in a matrix structure, with the four components of identity, payment, and logic arranged vertically, and the physical built environment, the off-chain governance system, and blockchain (on-chain) arranged horizontally. The proposed system is inspired by the aforementioned Decred governance system, which has been operational since 2017. Therefore, this system is already proven in the context of managing the development

Table 1: Exemplary differences in choosing an on-chain vs. off-chain approach for the four contract components. The proposed concept of blockchain-governed contracts could then use either option, but at least one on-chain, and one off-chain component.

	On-Chain	Off-Chain
Identity	To execute an on-chain transaction, actors need a blockchain address, e.g. for payments, logic execution, or storing data. Each transaction needs to be signed with the corresponding private key.	Traditional credentials such as username and password can be used as means of identification for off-chain contract applications, timestamping, or read-only functionality of blockchain state.
Payment	Cryptocurrency and tokens can be used as a means of payment. Execution guarantee, censorship resistance, and customization of the monetary asset can be advantages of using on-chain payments. Costs refer to network transaction costs.	Traditional third-party payment methods in FIAT currencies such as EUR can be linked to the contract, e.g. via application interfaces (APIs). Benefits include compliance with traditional systems and regulations. Costs relate to service fees.
Logic	On-chain logic provides several benefits, including direct interaction with the blockchain state (such as executing a payment), transparent and verifiable logic, and censorship resistant logic that cannot be changed unnoticed.	Off-chain logic can be transparent and verifiable by using accessible (public or distributed local) code repositories combined with timestamping. This enables the logic to be recalculated and verified. It may also be possible to use other approaches (e.g. TEEs).
Data	Data stored on a blockchain is transparent, immutable, and available as long as the blockchain exists. These characteristics ensure the data cannot be altered or deleted unnoticed.	Moving data to external storage locations can reduce on-chain computation costs. The smart contract can reference the data's location and timestamp to verify its authenticity.

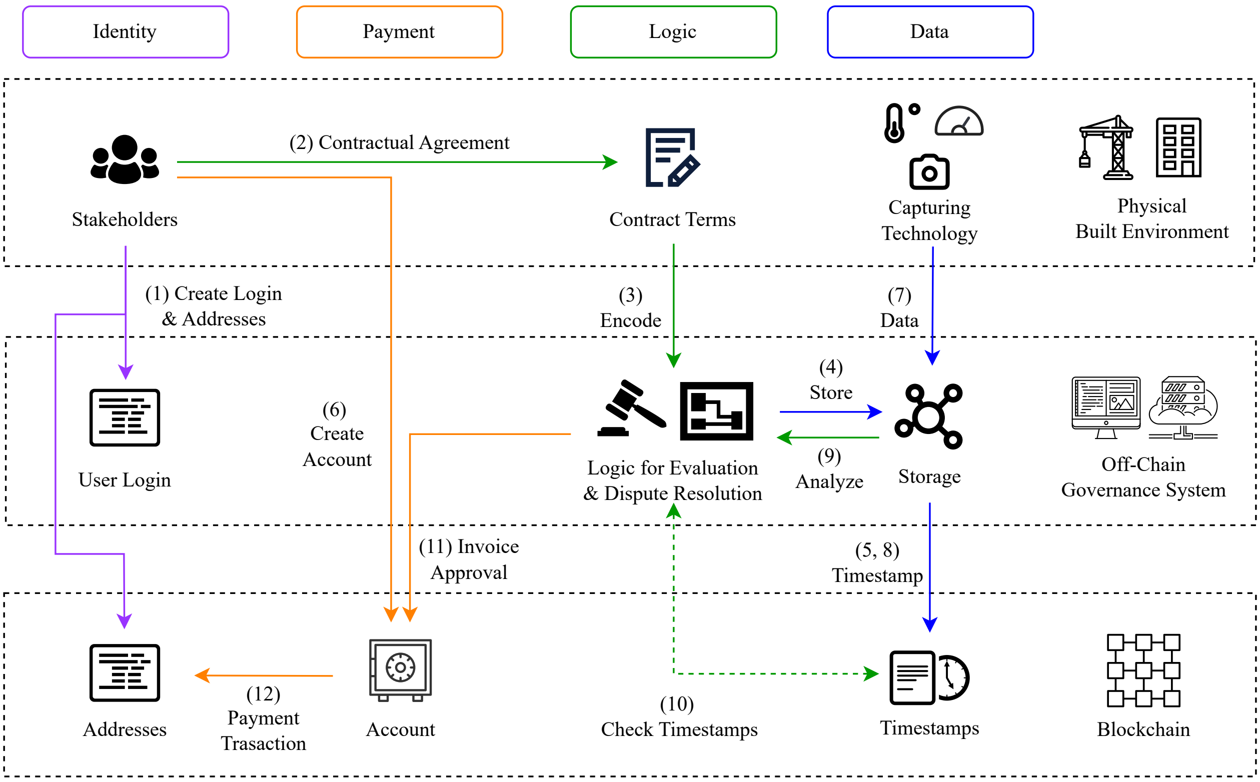

Figure 2: Exemplary blockchain-governed contract system for the built environment.

of the Decred ecosystem, making it a good starting point for investigating blockchain-governed systems in the built environment. In addition, it demonstrates the interaction between the different components using both on- and off-chain approaches.

A typical process would work as follows (see Figure 2): (1) All stakeholders create both login credentials for the governance platform, as well as an address so that the contract payout terms can be defined and encoded. (2) The parties negotiate the contractual agreement. (3) The contract terms are encoded. (4) The contract is stored in the off-chain governance database. (5) The contract is timestamped so that it can later be verified as authentic. (6) The responsible stakeholders create and fund the project account from which the payments will be released. (7) The required data is captured, streamed, and stored off-chain in the project database. All stakeholders should have a local copy, or at least access to the data. (8) The data is periodically timestamped so that it can be verified at a later time based on the locally stored copies. (9) At defined intervals, performance is automatically evaluated based on the input data and contract terms. All results are published transparently to stakeholders. (10) Stakeholders can confirm the evaluation. Only in the case of an error or disagreement, a dispute resolution process would start to verify the correct performance logic and data based on timestamps (dotted line in Figure 2). (11) If there is no disagreement, or after the dispute is resolved, the generated invoices are confirmed and signed by the necessary stakeholders. (12) Payouts are made in cryptocurrency to the defined addresses.

Implementation

We developed a pilot prototype to obtain first insights into the feasibility and challenges of the proposed blockchain-governed contract approach. After introducing the tested process, we outline for each component (identity, payment, logic, and data) the chosen approach for our prototype, in line with the proposed governance system in Figure 2.

Tested Process

The example follows the use case of a performance-based contract that rewards stakeholders for meeting the energy performance targets of operating a building. A similar process was implemented and evaluated in a previous study (Hunhevicz et al., 2022), allowing for a good comparison regarding process, cost, and efficiency. For the interested reader, the referenced study also gives more details on the rationale of performance based contracting.

Figure 3 shows the interaction between the technical parts implemented, as well as the stakeholders. The general idea is that a building owner initiates the use of a blockchain-governed contract to issue automatic payments to a contractor responsible for operating and managing the energy system. The exact logic of the contract is not important for the scope of this work; in this example we used historic temperature data from the NEST building at EMPA Dübendorf, Switzerland[7], issuing payments when the managed temperature stays within a defined range around the set-point temperature.

[7]https://www.empa.ch/web/nest/

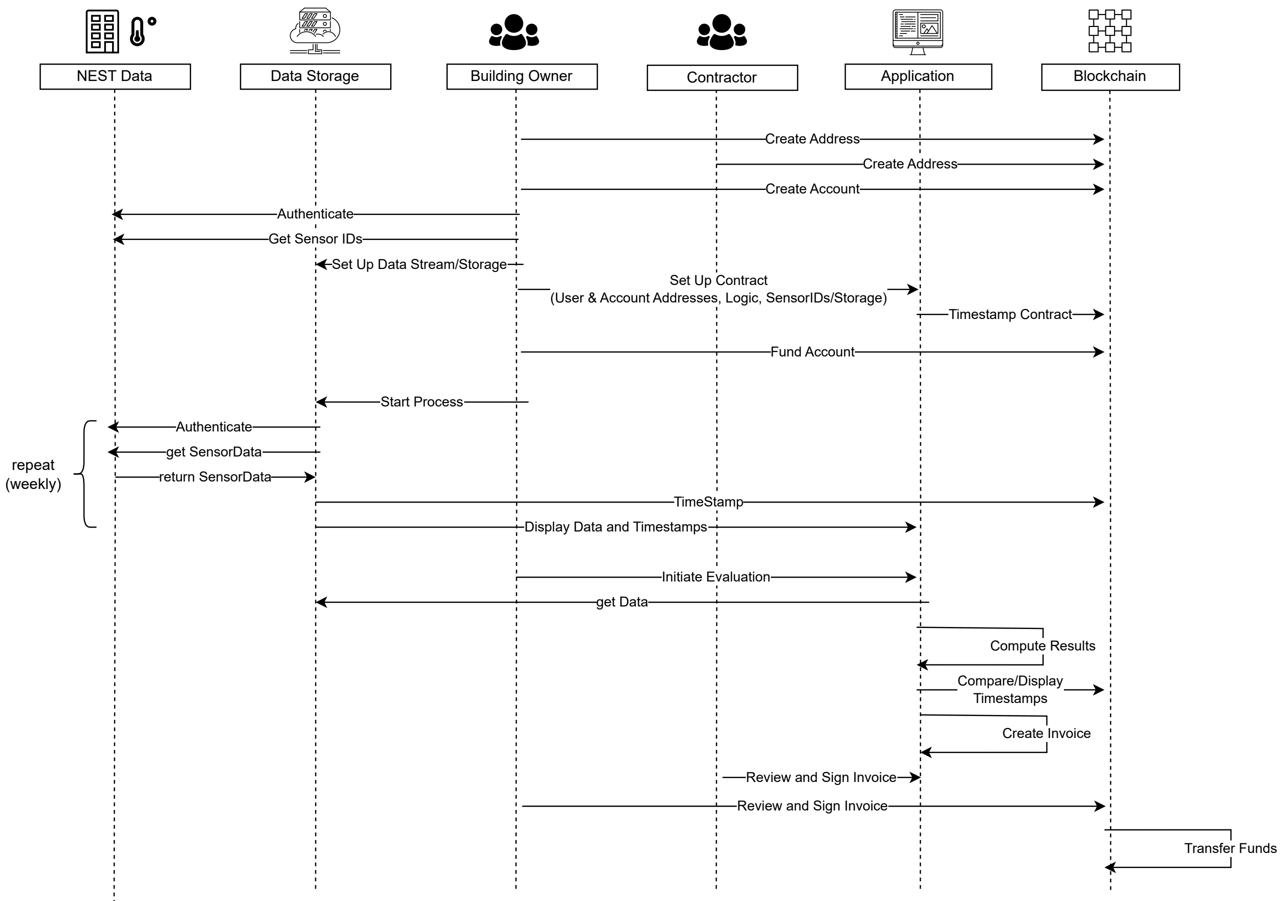

Figure 3: Implemented process of the temperature performance contract. In the tested process, both the owner and the contractor accept the evaluation and sign the invoice transaction.

Logic

The core of the prototype is a web application built with Next.js[8] that manages the main contract governance process. The stakeholders can define a new data set, as well as the contract logic with the main parameters of the contract (see Figure 4). In our case, we defined the sensor data set, the payout address, the set point temperature, the allowed deviation and threshold for penalties, and the payout amount of the performance based contract.

The contract will be time-stamped after its creation, anchoring the hash of the JSON contract file to the Decred blockchain (see Figure 4). We chose dcrtime[9], because the service is open source and freely accessible via API. Dcrtime timestamps approximately every hour, called anchoring. To indicate the status of the process, the application changes from "not timestamped", to "waiting for anchoring time", to "timestamped". Once timestamped, the digest can be retrieved from the application and checked for the timestamp and transaction hash on Timestamply[10]. In Decred's blockchain explorer[11], the transaction details can be displayed.

After a defined evaluation period, the results can be computed for the specified data set and defined contract logic. To make this evaluation trustworthy, the data and results are visualized in the application (see Figure 5). In case there are concerns about the validity of the process, the code and data can be checked against local copies or copies stored in an open source repository, and if needed, even redeployed and recalculated with the timestamped data and contract logic to check for authenticity.

Payment

Payouts are released from a separate project account, which is set up as a multi-sig wallet by the owner and contractor, meaning that both the owner's and contractor's blockchain signatures are required to move funds. This was implemented so that neither party could spend the funds without the other's approval. After calculation of the payouts, the invoice to credit the project account is automatically created based on the specified payout addresses. If both parties agree, they can import the proposed transaction to their respective wallets and sign for execution.

Identity

The above described web application requires a standard username and password for identity verification. However, the application could also have used blockchain-

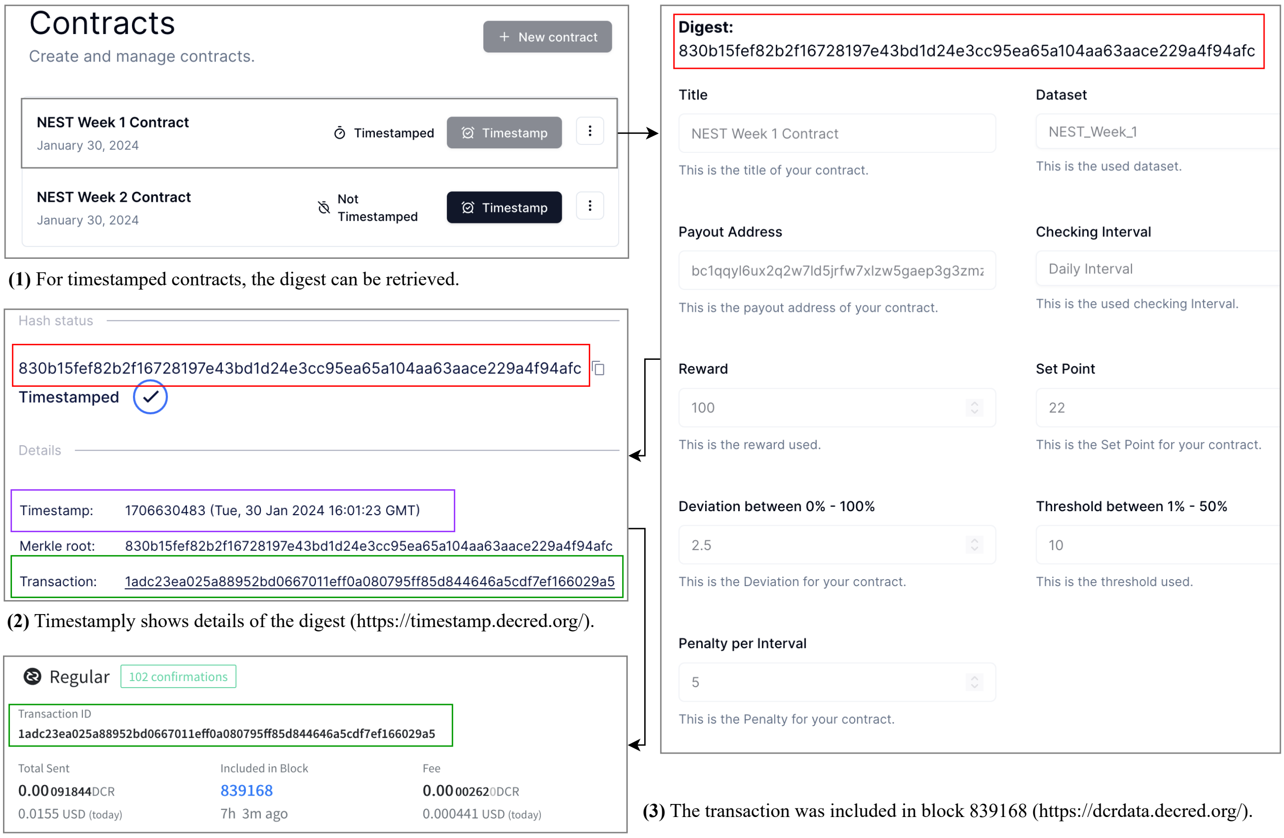
[11] https://dcrdata.decred.org



(1) For timestamped contracts, the digest can be retrieved.

(2) Timestamply shows details of the digest (https://timestamp.decred.org/).

(3) The transaction was included in block 839168 (https://dcrdata.decred.org/).

Figure 4: Contracts can be created in the application with the needed parameters for the evaluation and payout. After creation, they can be timestamped to ensure verifiability at a later point.

based access verification (Hunhevicz et al., 2023). This demonstrates that there can be different identity procedures within one blockchain-governed contract.

For the payouts, a blockchain wallet is needed. Since we chose the Bitcoin blockchain for payments, we used the Electrum[12] wallet to create the public/private key pairs, since it allows for easy multi-sig capabilities. The owner and the contractor each need their own wallet.

Data

Data is stored off-chain in a relational SQL database accessed by the application. In our example, the application used historical temperature tiime series of the NEST building from the ehub platform[13] through the available APIs. In addition to the main off-chain storage, the data is timestamped in weekly intervals, as introduced above for the contract logic (see also Figure 4). Therefore, the hashes of the data are stored on-chain on the Decred blockchain.

Discussion and Conclusion

This study is a first attempt to find practical alternatives to pure on-chain smart contracts in the built environment. The proposed decoupling and individual evaluation of whether and how to use blockchain for identity, payment, logic, and data was termed ”blockchain-governed contract”. The then proposed and evaluated exemplary contract governance system combines on- and off-chain approach, mainly using blockchain for proofing authenticity of data through timestamping, as well as payouts.

One of the most interesting consequences of this approach is that it forces an implementer to think about the individual parts of a contract and whether blockchain makes sense. With a complete on-chain approach, the entire contract is usually implemented on-chain, although only a subset would benefit from it. This means that blockchain could be used for only parts of a contract and that different parts of the contract may use different features of blockchain, possibly even different blockchains. For example, timestamping could benefit from the free services offered by e.g. the Decred dcrtime[14] library or Bitcoin's opentimestamps[15], while other features that require on-chain smart contracts could use a fast blockchain layer for high throughput and reasonable transaction costs. A more extensive and systematic analysis on when to use which blockchain would be interesting future research.

In addition, more work is needed to complete an implementation and validate it in a real-world contracting scenario. One of the missing pieces of the here tested system is the dispute resolution process, in case the parties do not accept the evaluation and payments performed.

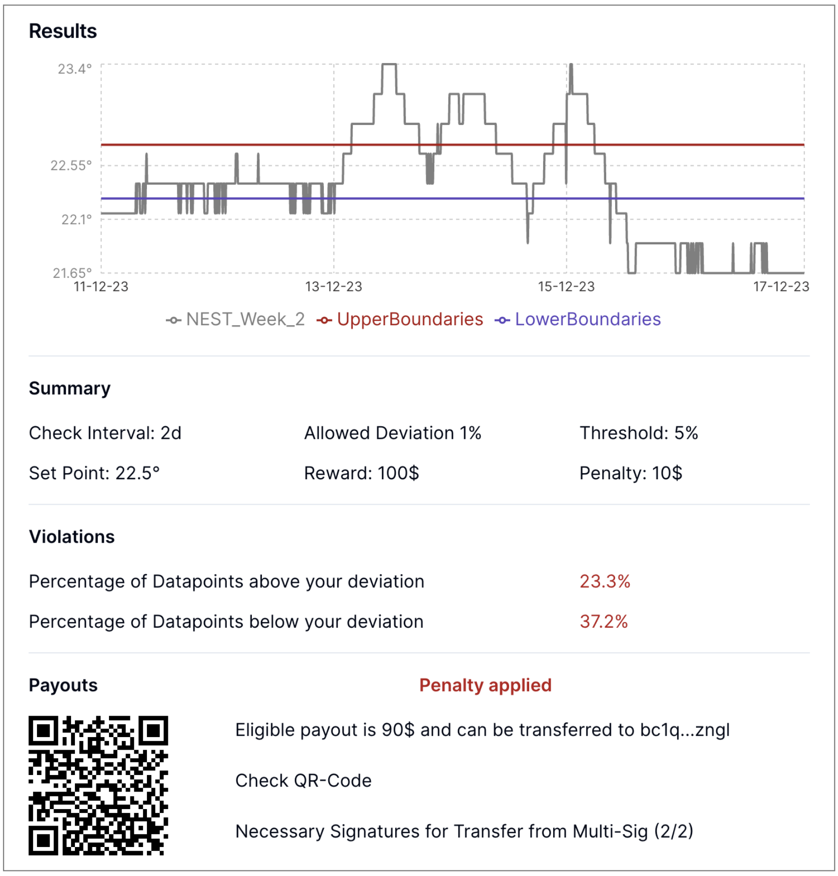

Figure 5: Evaluation of data in the application based on the contract terms and data set to calculate payouts. Authenticity of the data and contract can be checked against the timestamps. The invoice is created and needs to be signed by both the contractor and owner.

Other works have already proposed blockchain-based dispute resolution platforms for the built environment (Saygili et al., 2021; Son and Lien, 2022), which could serve as inspiration. We are confident that a suitable mechanism could be designed and implemented. Furthermore, while the proposed system seems like a reasonable approach, it is only one of many possible combinations between on- and off-chain for the different contract components as described in the departure section. Other combinations should be designed and tested for comparison.

A blockchain-governed contract approach appears to offer more flexibility and the potential for cost savings compared to an on-chain smart contract. In addition, we believe it could also improve the usability of smart contracts, since only parts of the contract require a blockchain, which is currently a mostly new technology unfamiliar to most stakeholders in the built environment. Complicated smart contract applications could be avoided. In our case, the proposed governance platform is similar to current web applications, except that payment execution requires a wallet. Another interesting observation is that a blockchain-governed approach requires more manual and human input than a full on-chain smart contract. In this sense, it can be considered less automated then previously proposed smart or intelligent contracts, but is potentially simpler and closer to existing practice. However, the verification process is likely to take longer to resolve than a fully transparent and deterministic on-chain approach, particularly in the event of a dispute. More detailed research is needed to evaluate user experience aspects, the industry requirements and readiness for different blockchain-governed smart contract platforms, as well as a quantitative comparison of cost and performance, e.g. under what circumstances the cost of on-chain smart contracts compared to a blockchain-governed approach is justified. Overall, a blockchain-governed contract approach seems a solution worth exploring in the built environment.

Abstract

Construction project governance (CPG) offers a strategic framework to guide participants through complex construction projects. Emphasizing the trust mechanism within CPG is crucial for managing inter-organizational relationships. Blockchain (BC) can serve as an enabler for trust-based CPG by facilitating and regulating relationships at the project level. Accordingly, this paper aims to identify CPG's trust requirements and assess the relationship between CPG's trust requirements and BC's characteristics through a state-of-the-art review. The results indicate that integrating BC's distinctive characteristics across project delivery can enhance CPG's trust requirements. This study presents comprehensive guidelines for developing a trust-based CPG model.

Introduction

Construction projects face temporal constraints, including limited duration, unique tasks, ambiguous hierarchies, diversity, and ad-hoc coordination (Sergeeva, 2019). These temporal aspects negatively impact long-term engagement, crucial for establishing trust among project stakeholders (Yan and Zhang, 2020). Trust describes relational aspects such as shared confidence and positive expectations that each organization will act in a mutually beneficial way (Li *et al.*, 2021). Trust between project stakeholders is one of the most critical factors for successful construction projects (Qian and Papadonikolaki, 2020). To establish trust, a comprehensive construction contract should clearly outline the requirements, obligations, and specifications of all project stakeholders. However, incomplete contracts arise during construction projects due to project stakeholders' bounded rationality and asymmetric information (Winch, 2010). As a result, continuous adjustment between project stakeholders is necessary throughout the project life cycle (Mansor and Rashid, 2016). As such, incomplete formal contracts with transactional relationships and informal agreements governing complex construction projects failed to ensure high trust at the project level, leading to issues like time delays, cost overruns, and compromised project quality (Liu *et al.*, 2022).

Construction project governance (CPG) offers new insights into the trust challenge from a broader perspective (Lin *et al.*, 2020). It aims to guide construction projects toward meeting stakeholders' goals by inducing collective behaviors through efficient regulation and principles (Müller and Martinsuo, 2015). Providing structures, processes, decision-making frameworks, and project management tools, CPG aligns objectives with each stakeholder's organizational governance models (PMI, 2017). However, the current CPG's rigid monitoring, strict contractual management, and rigorous audit mechanisms decrease communication, transparency, cooperation, and motivation, leading to low trust in construction projects (Lin *et al.*, 2020).

Blockchain (BC) has the potential to establish a trust-based CPG (Xu *et al.*, 2022). BC can facilitate the trust mechanism of CPG by directing network participants' behaviors through autonomous services and effectively governing relationships among BC network participants by enabling reliable information sharing (Lumineau *et al.*, 2021). As a digital ledger technology, BC chronologically records transactions across a peer-to-peer network (Das *et al.*, 2020). It provides real-time transmission for synchronized and immutable data through predetermined consensus algorithms, securing block-linked databases via cryptography and hashing algorithms (Perera *et al.*, 2020). However, existing research has not revealed the relationship between CPG's trust requirements and BC (Xu *et al.*, 2022). Therefore, this research aims to explore the trust requirements of CPG and assess the relationship between these requirements and BC characteristics through a state-of-the-art review.

Research Methodology

This study employed a state-of-the-art literature review to provide insights into current scientific advancements (Barry et al., 2022) and fresh viewpoints on the association between BC characteristics and trust requirements in CPG.

Table 1: Database, inclusion criteria, and search terms for a state-of-the-art review

Category	Details
Database	Scopus and Web of Science
Inclusion criteria	Academic journal papers
Search terms	(“trust” OR “governance” OR “relational governance” OR “relational norm” OR “construction”) AND “blockchain”

The Scopus and Web of Science academic databases were used to source high-quality scholarly articles. Details regarding inclusion criteria and specific search terms are outlined in Table 1.

Figure 1 outlines the methodology of the comprehensive review carried out in this study.

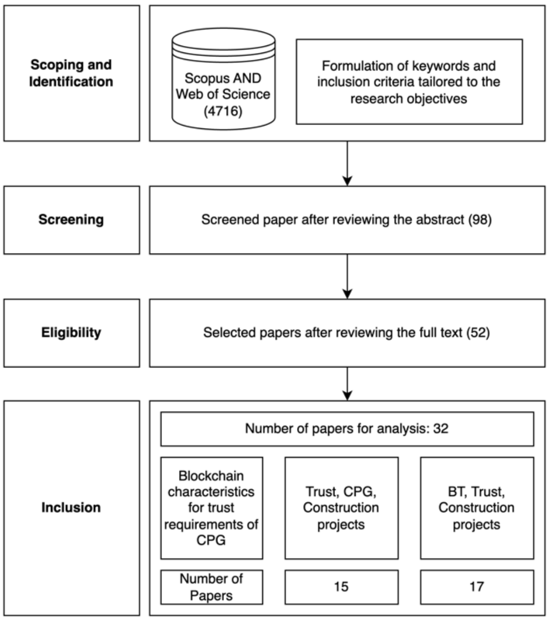

Figure 1: The state-of-the-art review process (devised by authors)

Specifically, the initial step involved a preliminary examination and identification of pertinent literature using specific keywords and inclusion criteria within the chosen database. The second step entailed a screening phase conducted through an abstract analysis. The final selection of 32 papers for in-depth analysis was made after an eligibility assessment based on a full-text review. Hence, the thorough review identified a gap in the existing literature, particularly its lack of exploration into the connection between BC characteristics and trust requirements of CPG.

Trust in Construction Project Governance

A common-pool resource is a shared resource that can be used without causing any harm under favorable conditions (Ostrom, 2019). A construction project can be regarded as a common resource scenario with a shared resource pool, decision-making rights, and risk/reward. Common-pool resource scenarios governed by a top-down governance approach exhibit multiple systematic failures (Hall and Bonanomi, 2021). However, the current CPG is biased towards top-down project governance using contractual project governance rather than bottom-up project governance. This top-down governance approach using rigorous monitoring processes and strict contract terms and conditions decreases trust at the project level (Sergeeva, 2019).

Additionally, according to agency theory and transaction cost economics, construction project stakeholders can be opportunistic, selfish, and possess bounded rationality in the common-pool resource contexts (Winch, 2010; Hall and Bonanomi, 2021). Trust is critical to limit these negative features of legally intertwined entities by facilitating mutual benefits, knowledge sharing, and emotional bonds (Laan *et al.*, 2012). As such, trust can improve project performance by achieving unique objectives within a set period and controlling uncertainty and fragmentation in complicated construction processes (Lu *et al.*, 2021b). In particular, trust is essential when uncertain situations and issues bearing risk occur. It can lead to a reliable relationship based on practical cooperation (Lakusic, 2021). However, fragmented construction processes, the temporality of projects, and project stakeholders' opportunistic behaviors hinder the establishment of trust in the construction project environments (Ke *et al.*, 2015).

Furthermore, self-organization explains the phenomenon where many agents interact with each other in a disordered complex situation but increase order and regularity through the interaction between spontaneous agents. Due to the uncertainties of the construction contract system, the agents participating in the construction project voluntarily form a self-organizing network to address these uncertainties (Steen *et al.*, 2018). Specifically, stigmergy is an example of self-organization involving indirect communication and learning processes through non-linear rules and methods. This provides a basis for understanding social agent interaction that induces complex patterns (Ramos and Abraham, 2004). Stigmergic principles need more flexible project governance structures and play an important role in building trust in construction projects by providing reliable coordination solutions and inducing collective actions within limited information-sharing environments (e.g., construction projects) (Dounas *et al.*, 2022).

Trust Requirements of Construction Project Governance

While agency theory and transaction cost economics as project governance theories provide the contexts of low trust in construction projects involving multiple project stakeholders, contingency and network theories provide the foundation for conceptualizing and understanding CPG's three trust requirements (mutuality, flexibility, and solidarity) derived from relational norms (Lu et al., 2015; Musawir et al., 2020):

- Mutuality: Willingness to mutually improve the current situation compared to the previous situation.

- Flexibility: Willingness to accept adjustments and modifications according to changed circumstances.
- Solidarity: Willingness to maintain and stabilize partner relationships.

Table 2 collates trust requirements underpinned by contingency and network theories, from the 15 reviewed papers on Trust CPG, Construction projects.

Contingency theory focuses on organizational effectiveness, described as the degree of alignment between the organizational characteristics and contingencies reflecting an organization's internal and external environment (Lizarralde *et al.*, 2011). Contingency theory posits that contingency variables (such as governance, size, culture, strategies, stakeholder motivations, or legal frames) align with the changing internal and external environment to improve organizational performance (such as time, cost, quality, scope, and benefit) and thus facilitate mutuality and solidarity (Deng and Smyth, 2013). The dynamic and flexible nature of contingency theory through its continual response to changing environments, suits the examination of various types of construction projects from diverse and complex backgrounds (Hanisch and Wald, 2012). However, construction project's temporality including limited duration, featuring ambiguous hierarchies, diversity, and informal coordination hinders the establishment of trust at the project level (Deng and Smyth, 2013). According to the contingency, CPG should highlight three relational norms: mutuality, flexibility, and solidarity among construction project stakeholders. These relational norms enhance trust by increasing responsiveness to the internal and external environments at the project level (Musawir *et al.*, 2020; Xu *et al.*, 2022). In addition to contingency theory, network theory emphasizes the efficiency of a network comprising multiple stakeholders participating in a construction project (Wang and Yin, 2023). Like the contingency theory, the network theory emphasizes flexibility, solidarity, and mutuality of relational norms as trust requirements through networking and a network's efficiency (Musawir *et al.*, 2020). Network theory is a subset of graph theory, which is the study of the properties of graphs and the mathematical definition of networks. In general terms, a graph is composed of nodes (objects that constitute the graph) and edges, representing the relationship between the nodes. Graph theory is used to analyze connected node data through various graph algorithms, such as basic statistics, graph data queries, visual exploration, and machine learning (Needham and Hodler, 2019). Similarly, network theory focuses on research into the connection patterns, network structures, node positions, and node outcomes of actors corresponding to the nodes in the graph. Accordingly, network theory is used in social science to study the characteristics of human society, such as group phenomena and human communications (Lu *et al.*, 2015b). Hence, network theory is widely used in project governance, requiring network thinking to study complex construction project networks (Li *et al.*, 2020). However, the non-linear execution of the construction project network, self-organization of multiple stakeholders within that network, and various emergent project situations can decrease network efficiency.

In response to these trust requirements, BC has been focused on as a potential solution to meet CPG's trust requirements (Lumineau *et al.*, 2021; Xu *et al.*, 2022).

Fundamentals of Blockchain Technology

BC consists of four fundamental technologies (Nawari and Ravindran, 2019; Perera *et al.*, 2020):

- P2P networks enable nodes to efficiently store, share, and manage files in a decentralized manner, enhancing speed and security in various digital services without requiring a central server.
- Hashing algorithms assure consistent outputs for identical inputs and resistance to reverse calculation, linking multiple transactions within a BC.

- Cryptography secures data in BC networks, employing either symmetric methods (fast but less secure) or asymmetric methods (more secure but computationally intensive).
- Consensus algorithms aim to maintain transaction orders even in adversarial environments by ensuring agreement among nodes on a single piece of data. These algorithms prevent malicious actions, addressing the Byzantine Generals' Problem, describing how Byzantine troops attacked a completely enclosed city.

Characteristics of Blockchain Technology in Construction Project Governance Contexts

A permissioned blockchain, known as a consortium blockchain, is appropriate for governance contexts in construction projects (Zhong *et al.*, 2020). A synthesis of literature from the 17 reviewed papers on BC, trust and CPG revealed the fundamentals of BC lead to six significant BC characteristics (see Table 3) in the permissioned BC contexts:

Table 3: The characteristics of blockchain in the construction project governance contexts

Characteristics	Details
Autonomy	Blockchain offers a range of autonomous services using smart contracts, which function as computerized protocols for business logics (Nawari and Ravindran, 2019).
Decentralization	Blockchain, as a digital ledger system, operates without a central administrator and a centralized data storage framework (Perera *et al.*, 2020).
Immutability	Once data are added in the blockchain networks, transactions on the blockchain cannot be canceled or altered (Das *et al.*, 2020).
Security	Blockchain protects data and prevents fraud by using public keys for network transactions and private keys for managing confidential information (Ciotta *et al.*, 2021).
Traceability	Every transaction on the blockchain is accurately recorded and timestamped, allowing network participants to access and track these records on any node (Msawil *et al.*, 2022).
Transparency	Authorized participants in the blockchain networks or channels have access to the same version of data (Teisserenc and Sepasgozar, 2021).

The Relationship Between Trust Requirements of Construction Project Governance and Characteristics of Blockchain Technology

There are strong relationships between CPG trust requirements and BC characteristics in construction project contexts characterized by a common pool resource and stigmergy (see Figure 2).

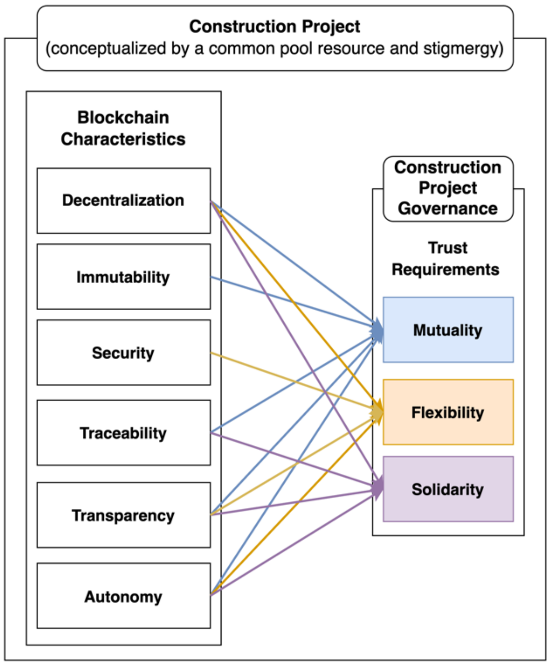

Figure 2: Blockchain characteristics and trust requirements of construction project governance (devised by authors)

First, decentralization, transparency, traceability, immutability, and autonomy are key factors that can enhance mutual relationships among project stakeholders. Decentralization can promote mutuality by creating interconnected networks that are directly operated by distributed entities without any central authority at the project level (Ciotta *et al.*, 2021). Transparency and traceability allow authorized project stakeholders to verify the actions of other network participants, thus promoting mutual trust (Das *et al.*, 2022). Immutability is also vital in mutual relationships, as it ensures that data is not altered or tampered with (Lu *et al.*, 2021b). Autonomy can positively impact mutuality by enabling transparent obligations and increasing the commitment of network participants through smart contracts with coded terms (Xu *et al.*, 2022). These transparent obligations and increased commitments align with the principle of mutuality (Nawari and Ravindran, 2019). Thus, blockchain technology can help establish mutual relationships that are based on a willingness to improve the current situation at the project level (Perera *et al.*, 2020). Second, decentralization, transparency, security, and autonomy can significantly improve flexibility in the context of CPG (Ciotta *et al.*, 2021). Compared to centralized systems, BC's decentralized architecture enhances flexibility in terms of response time against the risk of system failures or attacks (Fiorentino and Bartolucci, 2021). On the other hand, transparency and security enable reliable and secure information sharing, which positively impacts behavioral flexibility by allowing project stakeholders to respond quickly and efficiently to internal and external changes (Wang and Yang, 2022). Likewise, autonomy increases flexibility for data integration into a secure network by governing data access control within the construction project network (Msawil *et al.*, 2022). As a result, blockchain-enabled flexibility can help construction project stakeholders adapt effectively to any adjustments against rapidly changing external environments (Perera *et al.*, 2020).

Finally, decentralization, transparency, traceability, and autonomy are important factors that contribute to solidarity among stakeholders in construction projects (Xu *et al.*, 2022). Decentralization and autonomy enable the democratization of control in the CPG context, which promotes equal and participatory decision-making processes (Das *et al.*, 2022). This, in turn, leads to better solidarity through collaboration among project stakeholders (Perera *et al.*, 2020). For example, decentralized autonomous organizations and voting applications through BC ensure that stakeholders work together through a fair democratic system for collective decision-making (Nawari and Ravindran, 2019). Transparency and traceability are essential for promoting ethical practices and establishing an accountable cultural system in construction projects. This positive culture promotes solidarity from the project stakeholders at the project level (Li *et al.*, 2019). As a result, the strengthened solidarity positively impacts stakeholders' willingness to maintain and stabilize relationships (Yang *et al.*, 2022).

Hence, focusing on CPG trust requirements (mutuality, flexibility, and solidarity) through BC enables flexible bottom-up rather than top-down governance, enhancing trust at the project level (Xu *et al.*, 2022). Accordingly, the network-based bottom-up project governance through BC aligns with the stigmergy of construction projects as a common pool resource (Dounas *et al.*, 2022; Hall and Bonanomi, 2021).

Discussion

The first objective of this study was to explore CPG's trust requirements. The findings of this research indicated that mutuality, flexibility, and solidarity derived from relational norms are significant trust requirements in the CPG context. These results are aligned with those of previous studies about relational norms in the CPG context. For instance, Benítez-Ávila et al. (2018) argued that the CPG trust can be enhanced by mediating the effect of formal CPG designs and increasing project coalitions' capacity to coordinate tasks and reach high levels of cooperation. Similarly, mutual association through established normative practices and expectations in construction projects facilitates trust. The relational norms underpinning trust requirements yield positive outcomes and foster a high degree of trust by curbing opportunistic behaviors in CPG environments (Xu *et al.*, 2021). However, previous studies have failed to define CPG trust requirements and the theories underpinning them. The study highlights the importance of utilizing a flexible bottom-up project governance approach for construction projects conceptualized as a common-pool resource and stigmergy instead of top-down governance approaches. Additionally, the examination of contingency theory as a governance theory revealed that the current CPG system diminishes trust in construction projects due to its inability to swiftly adapt to rapid changes in the construction project's internal and external environments. Likewise, network theory suggests that traditional CPG systems fall short in facilitating effective communication among project stakeholders in the intricate networks of construction projects, which erodes trust. In particular, project clients and main contractors (Li *et al.*, 2020), dealing with intricate interests involving multiple stakeholders, prioritize efficient and rapid decision-making in CPG. They should also emphasize network-based project management, scrutinizing network connection patterns, structures, node positions, and outcomes within the multifaceted networks of construction projects.

Nevertheless, previous research on blockchain-based CPG tended to focus on the control aspects of CPG, which emphasizes the relationship between BC and the tools of control-based CPG: contract management (Kim *et al.*, 2022), procurement management (Gupta and Jha, 2023), project assurance (Lu *et al.*, 2021a; Das *et al.*, 2022) and quality assurance (Lu *et al.*, 2022) – to limit opportunism in the construction network. In response to the limitations of previous studies, this study aimed to assess the relationship between CPG trust requirements and BC characteristics. This state-of-the-art review introduces new knowledge to CPG research by identifying that BC's six distinctive characteristics can increase CPG's three trust requirements. According to Ostrom (2019), there are many instances of common-pool resource situations where top-down governance has led to significant and consistent failures. In response to this project governance challenge, the result theoretically presents a basis for establishing a BC-aided relational CPG that can guide the reliable coordination and collective behaviors of construction project stakeholders through the bottom-up approach. The relational CPG through BC leads to structural relationships between network participants, enhancing trust through collaborative project networks under uncertain project environments (Liu *et al.*, 2022).

However, developing relational governance under complex construction environments demands significant time investment and resource-intensive social processes from project stakeholders (Xu *et al.*, 2022). In response to these challenges, this study provided the practical trust-based CPG model through BC (see Figure 3). The

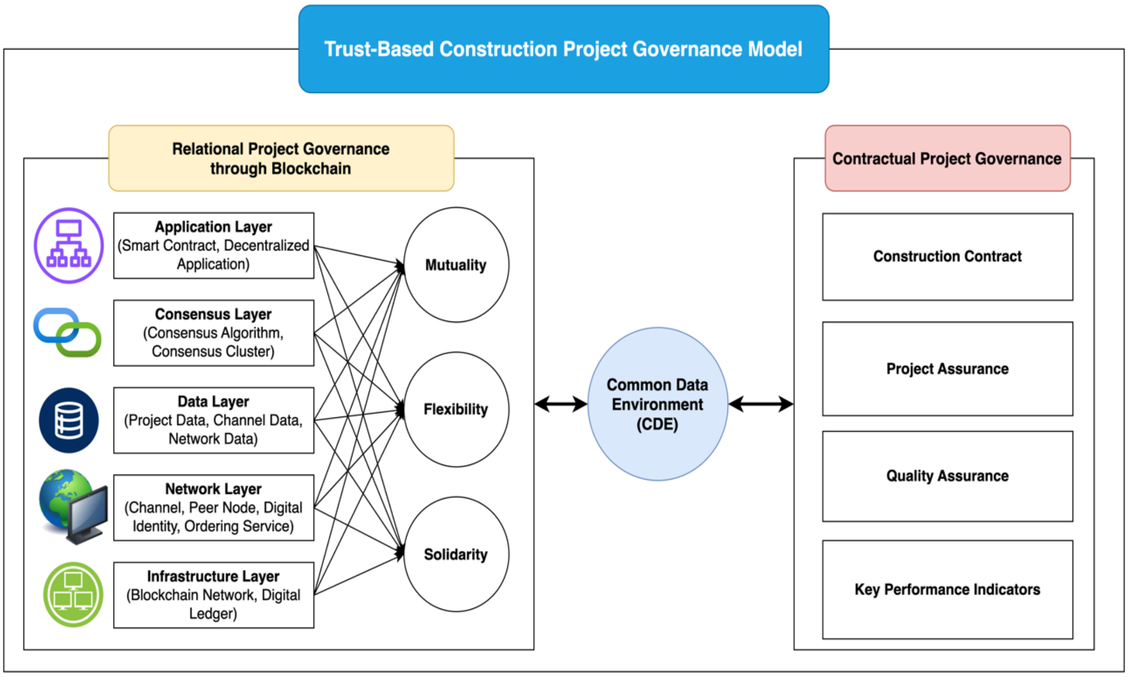

Figure 3: Trust-Based Construction Project Governance Model

findings indicate the possibility of developing a practical trust-based CPG model. Specifically, BC channels, nodes, orderers, and ledgers (Zhong *et al.*, 2020) can be configured, taking into account the unique context of each construction project. Additionally, a common data environment (CDE) can be used to connect existing CPG systems using construction contracts, project assurance, quality assurance and key performance indicators (KPIs). Trust among project stakeholders can be improved by securely storing, validating, and accessing project information using smart contracts. Ultimately, this trust-based CPG with BC can satisfy three trust requirements (mutuality, flexibility, and solidarity) of CPG. Therefore, this blockchain-enabled CPG, which is characterized by reliable decentralization, can efficiently govern and direct construction projects by enabling systematic self-organization and stigmagy environments. In particular, this system can provide novel insights allowing key project stakeholders (clients, main contractors, and consultants) to establish a trust CPG system while maintaining the existing governance system, including construction contracts and project assurance (Sergeeva, 2019).

Conclusions

This study, which adopted a state-of-the-art review, aimed to explore CPG's trust requirements and assess the relationship between CPG's trust requirements and BC's characteristics in construction projects distinguished by a common pool resource and stigmergy. The study revealed that CPG has three trust requirements: mutuality, flexibility, and solidarity. The distinctive six characteristics of BC; autonomy, decentralization, immutability, security, traceability and transparency can improve these trust requirements. Consequently, the findings bridge the knowledge gap concerning the trust requirements of CPG and their association with BC. The result theoretically lays the groundwork for establishing a BC-supported relational CPG, guiding stakeholder behavior in construction projects. The findings also indicate the potential for a practical, trust-based CPG model by using BC. This research serves as a foundational step toward achieving fully automated, trust-based CPG systems.

COULD GREEN BUILDING CERTIFICATION SYSTEMS BENEFIT FROM THE INTRODUCTION OF BLOCKCHAIN? A SYSTEMATIC REVIEW

Akman, Veysel Hüseyin*[1] ; Dounas, Theodoros [2]
[1]University of Warsaw, Poland; [2]University of Antwerp, Belgium

Abstract

We investigate the Green Building Incentive mechanisms to overcome identified barriers in adoption. With the aim of increasing the overall efficiency of the certification system, integration with the blockchain is proposed. Further, the blockchain concept and its applications are introduced. Blockchain-related incentive mechanisms and their intricate relationship with design and governance are also highlighted, through a systematic review. We conclude with the need for a stakeholder survey for the most suitable blockchain design and governance.

Introduction

The construction industry's impact on sustainability highlights the need for green buildings Jayakody and Vaz (2023). Measuring a building's sustainability performance becomes crucial as we strive to mitigate negative consequences. In response, several versions of the Green Building Certification System (GBCS) have evolved to measure a building's sustainability performance Braulio-Gonzalo et al. (2022). Despite its importance, barriers hinder the widespread adoption of green building certification Agyekum et al. (2019). In response, incentive mechanisms have been introduced, but their effectiveness still needs to be improved Olubunmi et al. (2016). Lack of sufficient motivation for green building certification drives exploration into innovative solutions, with blockchain emerging as a promising option.

Blockchain technology introduces a decentralized and secure way to manage records Turk and Klinc (2017). With their ability to represent various incentives, blockchain applications expand to the construction industry, offering viable solutions to the barriers encountered by GBCS . However, an effective application for GBCS requires careful consideration of BC design and governance Fan and Wu (2020).

This article explores the relationship between blockchain, governance, and incentives, examining their roles in potentially improving green building certification adoption. Investigating stakeholder perspectives becomes decisive because their preferences are the main driver for a tailored blockchain design in the green building certification area. This study reveals blockchain's potential to advance GBCS by promoting sustainability through efficient governance and alternative incentive mechanisms.

The article's structure is as follows: in the first section, we delve into green building certification and examine barriers to its adoption. Moving to the second section, we introduce blockchain technology and its application requirements. In the third section, we investigate the capabilities of blockchain in GBCS. Finally, we conclude by harmonizing key insights and proposing future research.

Methodology

To conduct a literature review and define the knowledge gap, we researched relevant articles in Google Scholar. We utilized Boolean operations to filter our search with the following keywords: "blockchain AND green building certification AND incentive mechanisms", "blockchain AND sustainable building AND financial incentives OR non-financial incentives", and "blockchain AND green building certification AND financial incentives OR non-financial incentives". These keywords were determined based on their relevance and incorporation with the key topics of research; blockchain, green building certification, and incentive mechanisms. We also applied the snowballing technique to improve the literature review's comprehensiveness. During the primary research, we identified two key articles and then extended the literature pool by systematically examining the references cited in these articles. This iterative process helped to collect broader relevant literature. Eventually, in our literature review process, we identified 82 relevant papers. These papers are examined to identify their alignment with the research objectives and key topics. Only articles published in English are taken into account. Articles published before 2000 are excluded from this study to provide a contemporary and relevant analysis. Relevant doctorate and masters' theses are also not included in the scope to focus and prioritize peer-reviewed research publications. For purposes of this research, we selected to present papers discussing the intersection of blockchain and green building certification systems, primarily focusing on the incentive mechanisms and their impact on sustainability and innovation in construction.

Why Green Buildings are Important?

The building sector is criticized due to its high energy and resource consumption. A recent study by Jayakody and Vaz (2023) stated that buildings constitute nearly 70% of the total energy consumption in the United States and around 35% globally. In addition to energy usage, buildings have a significant impact on other natural resources, contributing to 35% of greenhouse gas emissions, 50% of extracted materials, and approximately one-third of both water consumption and waste worldwide, as highlighted in another recent study by Braulio-Gonzalo et al. (2022).

The concept of green building has emerged as a response to the adverse impacts of construction on the three pillars of sustainability: environmental, social, and economic. It is a primary tool for advancing sustainability objectives within the construction industry as stated by Karji et al. (2021). Green buildings, alternatively called eco-friendly or low-energy buildings, are intentionally designed to alleviate stress on resources by limiting negative impacts on human health and addressing challenges like resource scarcity.

Green building contribution extends beyond environmental considerations; it is inherently connected to social sustainability. Green buildings support creating a healthy environment, fostering community, and boosting human productivity. As stated in Goh et al. (2020), they "complement their environmental impact, creating sustainable and livable spaces that promote a higher quality of life for individuals and communities."

Embracing green building practices has a substantial impact on all three sustainability pillars. Beyond the environmental and social perspectives, green buildings present economic advantages. Effective implementations result in cost savings throughout their lifespan and offer stakeholders the chance for increased profits. In essence, green building practices provide noticeable benefits both environmentally, socially and economically Olubunmi et al. (2016).

What is the GBCS?

Measuring the performance of development is fundamental for ensuring its contribution by establishing standards, aligning goals, and identifying successes and challenges. Braulio-Gonzalo et al. (2022) details that performance measurement optimizes resource allocation, supports the decision-making process, and exhibits the tangible impact of development initiatives.

Standards and frameworks used in the sustainability assessment are typically established by internationally recognized organizations such as ISO, GRI, etc. These institutions develop and define global standards that become laws or serve as the foundation for industry. Standards specify requirements in two ways: prescriptive standards provide methods of achieving objectives, while performance-based standards outline expectations for the desired outcomes Vierra (2016). To illustrate with energy consumption, prescriptive standards require using methods like efficient LEDs. In contrast, performance-based standards set a goal for energy deduction without specifying methods, allowing flexibility in solution.

GBCS emerged to establish standardized practices in construction, offering a common framework to evaluate and differentiate buildings that follow sustainability standards. Over time, these systems expanded to address not only environmental concerns but also social and economic, reflecting a broader understanding of sustainability as stated by Awadh (2017). While implementing these global standards locally, adjustments can be made according to local requirements. But yet, the overarching goal is to encourage and recognize practices that contribute to a holistic sustainability approach in building.

The Building Research Establishment Environmental Assessment Method (BREEAM) arose in the early 1990s as one of the first comprehensive green building certification systems in the United Kingdom. Following the success of BREEAM, other countries and regions established their own green building certification processes: LEED (Leadership in Energy and Environmental Design) in the United States, Green Star in Australia, and Estidama in the United Arab Emirates are a few examples which are extended their usage beyond the countries. All these initiatives have developed throughout time, adding social and economic aspects into their criteria to give a comprehensive approach to building sector sustainability Braulio-Gonzalo et al. (2022).

The functional benefits of green building begin with enhancing companies' competitiveness in the market. Tan et al. (2011) explored how green building certificates enhance contractors' competitiveness. The study revealed that "good corporate governance of environmental and social issues not only enhances companies' shareholder value but also safeguards their highly valuable reputations". It's crucial to emphasize that the advantages of these certificates go beyond contractors, benefiting all stakeholders at different levels. In addition to being a valuable marketing tool for developers, Vierra (2016) highlights the market desire for green building certification.

As mentioned, requirements of green building certification systems aren't universally applicable due to project dynamics, making one more suitable than another based on factors like location, budget, and goals. Selecting an appropriate certification system involves considering essential aspects such as cost, ease of submission, and building performance to determine the most relevant rating system and achievable certification level Vierra (2016). It's crucial to note that each green building certificate comes with distinct specifications, which may vary based on project requirements, whether for refurbishment, new construction, or specific needs. Obtaining green certification requires teamwork across various functions such as supply chain, planning, design, and manufacturing. Yet, the unique aspects of green construction and certification pose challenges, with cost as the main obstacle hindering broader adoption of these innovative practices, as highlighted by Agyekum et al. (2019).

Barriers to GBCS Adoption

Barriers to adopting sustainable practices exist across various dimensions, including economic, social, cultural, political, and systemic factors, as identified by Horner and Ryan (2019). Moreover, the type and intensity of these barriers vary among countries, contributing to distinctions in their quantity and severity Agyekum et al. (2019). Yet, it is essential to carefully analyze the requirements that provide guidance and an implementation plan for stakeholders. When examining current GBCS' characteristics, key requirements centered around energy efficiency, water preservation, minimum negative environmental impact, reliance on renewables and sustainable materials, and efficient space use.

Several studies have investigated the barriers hindering the widespread adoption of green building certificates. Fan and Wu (2020) identified obstacles as high upfront costs, limited access to capital, social and psychological barriers, and a lack of information, experience, and effective incentives. Another study by Karji et al. (2021) indicated common obstacles, including a lack of green building knowledge, high costs, insufficient incentives, lack of motivation, and insufficiency in policies and regulations. Similarly, Agyekum et al. (2019) highlighted various barriers highlighting regulatory deficiencies, inadequate training, developers' hesitation due to perceived additional costs, high investment cost barriers, and challenges in procurement and project-delivery mechanisms.

Considering local-level challenges, Shen et al. (2018) investigated barriers in Thailand using a Likert-scale survey among different stakeholders. The findings show social barriers, with the lack of owner motivation ranking as the major obstacle among all participants. Collectively, these studies underscore the multifaceted challenges impeding the widespread adoption of green building certificates, encompassing knowledge gaps, financial considerations, policy shortcomings, and social factors.

Furthermore, it is important to mention that traditional construction practices have been in place for many years. Transitioning from conventional to sustainable and digital methods will require significant time and changes across individual, organizational, and industry levels. For this reason, this transformation will not be without its hurdles Diyana et al. (2013) Li et al. (2019).

All stakeholders acknowledge the above-mentioned barriers, and as a response, various financial and non-financial incentive mechanisms have been introduced to motivate stakeholders. These incentives, typically offered by governmental entities, environmental agencies, and industry associations, are designed to encourage sustainable building practices and contribute to overarching sustainability objectives.

Incentive mechanism

An incentive mechanism is a structured strategy to encourage specific behaviors, actions, or outcomes by offering rewards or penalties. This concept has extensive application across several disciplines, leveraging components to drive individuals, organizations, or entities toward desired outcomes. In the context of green building, incentive mechanisms play a vital role in motivating developers to embrace sustainable construction Fan and Wu (2020). The eligibility of the incentive mechanism is mostly connected to the green building certification system because the incentive promoters are able to differentiate the project to award.

The Figure 1 illustrates the categorization of green building incentive mechanisms, highlighting their diverse nature and underscoring the necessity for a case-by-case approach. The literature created a spotlight on effectiveness. The reason for such a spotlight is that evaluating the efficiency of incentive mechanisms contributes valuable insights to understanding how different incentives influence stakeholders. The literature delves into the effectiveness of incentive mechanisms, often through case scenarios.

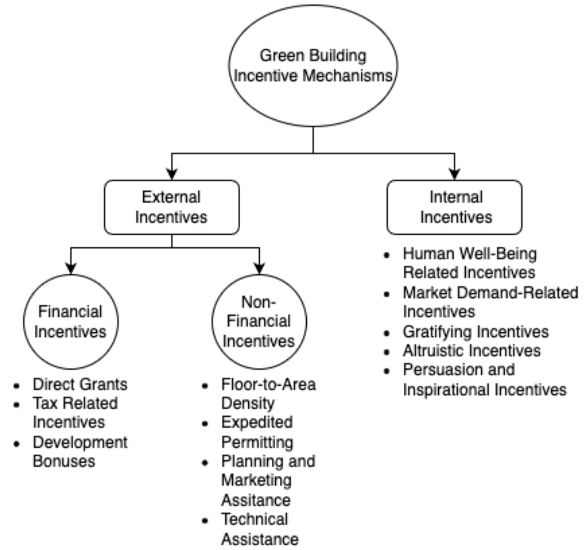

Figure 1: Categorization of Green Building Incentives adapted from Olubunmi et al. (2016)

The study conducted by Dounas et al. (2022) showcases the versatile usage of incentive mechanisms by proposing an innovative incentive model to reduce carbon and waste in the construction industry. It is highlighted that the proposed incentive model benefits environmental aspects and also enhances overall efficiency. Moreover, the research conducted by Sauer and Siddiqi (2009) compares the effectiveness of three different incentive mechanisms based on the production status offered by local government. By using regression analysis, the most preferred incentives are concluded as Gross Floor Area(GFA) concessions, administrative, and financial incentives. In another study, Agyekum et al. (2019) investigates the barriers to adoption in Ghana. The authors' findings show inadequate awareness of the benefits of green certification has the biggest impact on adoption in a developed country, Ghana. In a parallel study by Work (2007), the authors revealed that their findings point out that developers are aware of these incentives but don't always use them. The main reason is the timing of development decisions and the response time of local government don't always match together. Developers must take quick decisions, and governments prefer to move more slowly to see the outcomes.

Non-financial incentives have limited visibility in the literature compared to financial ones. Karji et al. (2021) connects this limitation to the poor impact of social incentives. Similar to the previously mentioned research, the root cause of the ineffectiveness of social incentives is the lack of information on the benefits of green building. It is possible to convey that recognition is elemental on non-financial incentives for governments and incentive receivers due to its ability to create public awareness.

On the other hand, Olubunmi et al. (2016) specifies weaknesses in the current green building incentive mechanisms, and in terms of the social effect of certificates, the authors criticize the close link between incentive mechanisms and third-party certification institutions due to the potential bias or inequity caused by economic relationship. Further criticisms of current green building incentive mechanisms are the lack of enforceability mechanisms, the absence of a mechanism to determine the optimal level and the non-transferability of incentives. But it is also mentioned that the production rate method gives limited information on real adoption rates therefore the outcomes are subject to discussion.

Fan and Wu (2020) conducted a cost-benefit analysis for incentive mechanism by using the Analytic Hierarchy Process. Based on outcomes, the authors proposed a hierarchy structure of cost and benefit criteria as actual and hidden. The high upfront cost of green building remains a major cost problem. Considering benefits, actual ones such as energy savings and GFA concession were deemed more important than hidden ones. However, it is crucial to note that stakeholders may not be aware of the proposed essence of hidden benefits like outdoor environment, productivity, and brand recognition, as mentioned, creating an opportunity for further research in the literature.

Considering the status of the construction industry, more adoption of green buildings is inevitably needed to increase sustainability performance. Incentive mechanisms play a vital on this as a main driver of stakeholder motivation. Research supports the feasibility of blockchain in incentive design, offering transparency and security to build stakeholder confidence. This decentralized and secure approach has the potential to generate economic benefits by cutting intermediaries, lowering transaction costs, and improving resource allocation within the incentive ecosystem, as stated by Fan and Wu (2020). Furthermore, side benefits due to the characteristics of blockchain may reveal new incentives and increase the overall effectiveness.

Blockchain

Definition and Basic Concept

Blockchain technology gained a reputation with the publication of "Bitcoin: A Peer-to-Peer Electronic Cash System" white-paper by an author under the name Satoshi Nakamoto Nakamoto and Bitcoin (2008). Fundamentally, blockchain is an unalterable distributed ledger allowing secure data transfer. Blockchain records data in groups on a peer-to-peer (P2P) network as detailed by Raj (2021). The name 'blockchain' is derived from two terms: 'block,' referring to the grouped data sets, and 'chain,' indicating that these data sets are securely linked using cryptographic principles.

In blockchain, transactions are a prominent feature that refers to an action that records the exchange of data or assets between parties. Once a transaction is completed, it leads to creating a new block with a time-stamp and linking to the preceding block to the end of the chain, as detailed by Natalia Maslova and CTP (2018). The information within each new block holds a secure, cryptographic summary of the one before it. This interconnectedness form enhances security naturally. Once data is added to the chain, it becomes immutable, making it impossible to alter or erase.

In a decentralized system like blockchain, consensus mechanisms are vital to ensure agreement among participants regarding transaction validity, thereby preventing system failures and keeping the whole system secure. Zhao et al. (2020) mentioned that besides security and continuity of the ecosystem, consensus mechanisms also significantly influence performance metrics such as scalability and block creation speed. In the consensus mechanism, the active participation of nodes in all roles is crucial to ensure system security, decentralization, and integrity Zhao et al. (2023). Roles and responsibilities within the ecosystem were outlined by Han et al. (2022) with broadcasting nodes participating in the verification, and spread of transaction records, while mining nodes actively execute the consensus mechanisms and support the block creation. Lastly, full nodes' responsibilities fall between the other 2 types.

It is important to highlight that executing consensus mechanisms comes with a cost, therefore, participants need to be compensated to maintain system continuity. Additionally, participants often prioritize actions that serve their own interests. In response to this challenge, incentive mechanisms are introduced to motivate cooperative behavior and maintain the security of the decentralized system, as elaborated further.

As we move towards the Blockchain 4.0 era, blockchain applications aim to enhance user experience and speed for creating advanced decentralized applications for all sectors. While blockchain technology has demonstrated transformative potential within the construction sector, its specific implications for green building certification systems warrant further investigation.

Blockchain Applications

Blockchain technology is widely adopted across numerous sectors, demonstrating its potential to transform traditional processes, promote sustainability, enhance effectiveness, and drive innovation. The finance sector was among the first to embrace blockchain technology, but its applications extend to sectors rapidly such as construction, energy, crowdsensing, and supply chain management, as detailed by Xu et al. (2017).

For instance Zhang et al. (2020) proposes a blockchain-based certification system to address inefficiencies regarding to centralization in China's renewable energy certificate process, emphasizing intelligent and automated processes facilitated by blockchain technology. The studies conducted by Marques et al. (2023) Delardas and Giannos (2023) also delve into the application of blockchain in the energy sector, aiming to enhance efficiency and effectiveness. The research conducted by Wei et al. (2020) explores decentralized crowdsensing architectures via blockchain, focusing on security enhancement, privacy protection, and incentivization mechanisms. Simulation of the proposed model confirms its feasibility, showing that the proposed incentive mechanism effectively encourages participation.

The research conducted by Wei et al. (2023) focuses on addressing technical information exchange barriers in the supply chain, which lead to substantial energy consumption. By leveraging blockchain for data management and government incentives, the paper investigates strategies to improve the sustainability of supply chains. The research proposes practical measures and introduces a data governance platform to foster eco-friendly supply chains, drawing insights from government involvement and behavioral theories.

In the built environment, distributed ledger technology offers promising applications across several domains. Li et al. (2019) categorized these domains as smart energy, smart cities and the sharing economy, smart government, smart homes, smart transport, Building Information Modelling (BIM) and construction management, and innovation in business models and organizational structures. The majority of the cited articles in this paper discuss the application of blockchain technology in the various domains of built environment. Also, studies like Smajgl and Schweik (2022) bring a further looking perspective and anticipate that blockchain technology will bring significant changes into the existing socio-economic framework, influencing the governance aspects and expanding the boundaries of solutions created in sustainability.

While numerous studies demonstrate the advantages of blockchain technology across different domains, its specific application in green building certification systems remains relatively unexplored. Understanding the governance and design principles of blockchain applications is crucial, particularly within green building certification systems, where tailored approaches are needed to address adoption and sustainability challenges effectively. The following chapter will delve into the governance and design considerations specific to blockchain technology in the context of green building certification, underscoring the dynamic and versatile nature of blockchain technology in diverse contexts.

Blockchain Governance and Design

The close connection between blockchain governance and its design arises from the foundational principles of technology. Design encompasses the underlying architecture, consensus mechanisms, and smart contracts that shape how the system operates. These design choices directly influence how governance is implemented within the blockchain network. Governance rules are often encoded in smart contracts, automating and enforcing predefined rules without the need for centralized control. As mentioned before these choices and rules also determine performance, including scalability, efficiency, etc. of the application, as further detailed in Han et al. (2022).

De Filippi et al. (2020) emphasizes that blockchain governance relies heavily on incentives coded into the protocol and game-theoretic principles align with community priorities. The goal of good governance is to align diverse stakeholders toward a common understanding and agreement. Effective governance can increase the reliability and overall success of domain by ensuring that created financial and non-financial incentives match desired behaviors and encouraging community adherence to shared standards.

Therefore, introducing blockchain into a specific domain requires a deep understanding of both design principles and governance requirements to achieve effective application. A holistic approach is essential to ensure that the blockchain solution aligns with the required outcome and goals of the application.

Blockchain Related Incentive Mechanisms

Incentives are vital in blockchain systems to motivate participants and align their interests with the collective goals of the system. Incentives support positive behavior, discourage malicious activities, and foster an active and engaged community within the decentralized networks. Well-designed incentive mechanisms not only drive the desired behavior but also play a pivotal role in shaping the governance structures that govern the decision-making processes of the blockchain protocol. Thanks to the inherited features of blockchain, participants can be motivated in several forms of incentives.

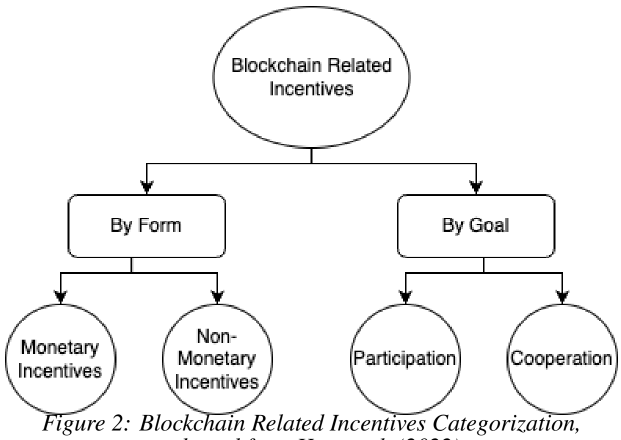

Figure 2: Blockchain Related Incentives Categorization, adapted from Han et al. (2022)

The Figure 2 illustrates the high-level classification of blockchain-related incentives based on the form and goal of the incentives in the literature. Monetary incentives are designed to regulate system entities economically, motivating participation with financial rewards. Non-monetary incentives, like credit-based and reputation-based systems, foster trust among entities, while gamified incentives leverage individuals' preferences for enjoyable experiences to guide their behavior within the system. Tokens and badges are commonly used in gamified mechanisms as incentives for system engagement as ticket.

In terms of goals, incentive mechanisms can be categorized as encouraging participation to maintain system sustainability and promoting cooperation among entities. The participation goal addresses nodes' selfish nature by providing incentives for their involvement, which is crucial for ensuring security and decentralization. On the other hand, the cooperation goal acknowledges the fact that selfish nodes may deviate from system design, posing threats to the system. To mitigate, introducing incentive mechanisms becomes essential, fostering cooperation through adherence to system protocols and discouragement from initiating attacks.

In conclusion, the multifaceted nature of blockchain, with its diverse array of incentive mechanisms, creates opportunities for various benefits within the ecosystem. By strategically aligning incentives with the goals and form, blockchain not only addresses the rational and profit-driven behavior of nodes but also promotes the safety, sustainability, and decentralization of the system. In essence, blockchain's innovative approach to incentives unlocks opportunities, driving positive contributions and reinforcing the resilience of various domains implemented.

Blockchain for GBCS

There is a growing need for a more comprehensive and digital green building certification system to address the challenge of inadequate motivations hindering widespread adoption. Blockchain, with its inherited features, has the potential to bring more integrity to certification practices. By leveraging its capabilities, blockchain has the potential to bolster the credibility of certificates while streamlining verification procedures.

Blockchain has been already implemented as a transformative factor in certification processes, providing a streamlined and reliable method to verify accomplishments. Fowler (2017) suggests that blockchain integration in certification processes holds promise for lowering costs associated with advancement in measurement methodologies to meet evolving quality standards. In the article by Woo et al. (2020), the authors support the idea of blockchain-enabled GBCS and target the high cost associated with the current systems. Their research proposes a blockchain-based framework for measurement, reporting, and verification as a cost-effective alternative.

Pu and Lam (2023) discuss the advantages of blockchain-enabled certification systems and highlights that GBCS is a particularly suitable domain to apply. Firstly, blockchain's ownership or identity management capabilities provide a secure way to verify the identity of individuals or entities involved in green building projects. Secondly, the provenance tracing capacities of blockchain ensure transparency in the supply chain, allowing stakeholders to trace the origin of materials used in construction. Lastly, ownership transfer mechanisms can streamline the transfer of green building certifications between different parties, enhancing overall efficiency in the certification ecosystem.

Introducing blockchain into the GBCS may enhance the certification system by providing both monetary and non-monetary benefits. Therefore, stakeholder dynamics play a vital role in blockchain design, particularly for incentive mechanisms and their effectiveness. Each stakeholder in the green building certification process has unique priorities and motivations as detailed in Mulligan et al. (2014). Building owners seek cost reduction and streamlined processes, while architects focus on sustainable building design principles. Certifying bodies prioritize integrity and credibility through incentive mechanisms. Regulatory bodies may enforce compliance with incentive requirements or promote adoption by implementing new incentives, depending on the ecosystem dynamics.

Dynamic Alliances, as described by Grover et al. (2021), refer to collaborations formed by entities with mutual interests and goals in a given domain. Dynamic Alliances aim to create a collaborative environment that allows parties to leverage strengths, optimize resources, and accomplish common objectives. The authors suggest that integrating blockchain into governance ecosystems of dynamic alliances would bring notable benefits. Integrated Project Delivery (IPD), a project management approach tailored to the construction industry, has governance characteristics and principles that resonate with Dynamic Alliances. In this context, the research by Hunhevicz et al. (2022) proposes using blockchain for IPD using in a common pool resources scenario. Likewise, the authors suggest that blockchain implementation will leverage the governance of the domain. This suggests that the governance structures and incentive mechanisms inherent in blockchain implementation can effectively align with the principles of collaboration, trust, and accountability within green building certification systems.

In conclusion, the alignment of blockchain's governance with those observed in Dynamic Alliances and IPD highlights the importance of carefully balancing stakeholder interests in design and governance decisions. Tailoring design and governance decisions to the diverse motivations of stakeholders ensures that incentive mechanisms effectively encourage collaboration, trust, and accountability within the green building certification ecosystem. In the context of GBCS, blockchain implementation can optimize collaboration, streamline processes, and foster innovation, thereby advancing sustainability goals within the construction industry.

Conclusion and Future Work

In overview, the construction industry encounters challenges including issues with information exchange, materials procurement, high costs, and trust, limiting its ability to achieve better sustainability performance. Blockchain technology holds promise in addressing these challenges by its decentralized and secure nature. Our literature review acknowledges the potential of blockchain in the construction industry to enhance sustainability performance. However, practical implementations are currently constrained, indicating a gap between theoretical recognition and widespread adoption.

To address this gap, we propose a comprehensive survey targeting diverse stakeholders involved in green building certification. This survey aims to explore stakeholders' motivations to participate in GBCS and assess their receptiveness to various incentive mechanisms and receptivity toward blockchain. The survey results are expected to close the gap between theoretical discussions and practical implementations of blockchain in green building certification. Also, these findings may support decision-making processes, driving refinements in certification practices toward greater sustainability.

Throughout the literature review, it is identified that the integration of blockchain technology promises to enhance transparency, efficiency, and trust in certification processes. Moreover, such a system has the potential to create a range of diverse incentives, including both financial and non-financial, which may be novel to the construction sector. In light of survey findings, this integration holds promise for promoting the adoption rates of GBCS by tailoring design and governance preferences to stakeholders. In conclusion, while the potential benefits of blockchain for GBCS are recognized, the dynamics of GBCS need to be thoroughly comprehended. The identified literature gap calls for a survey with GBCS stakeholders to investigate their motivations and preferred incentives. The outcomes of such a survey inform the governance and design choices of the best-suited blockchain technology for widespread adoption in green building certification.

Abstract

Poor installation and misaligned supply chain incentives can impact the energy performance and user comfort of External Thermal Insulation Composite System (ETICS) panels. This paper investigates a combined IoT-blockchain solution to create trusted traceability of the process, together with performance-based incentives based on sensor data about the panel state. The system is implemented on the University of Brescia prototype, an experimental test house. The results demonstrate the feasibility of an integrated system of smart contracts, IoT sensors and a digital twin for visualization. The work provides insights into an IoT-blockchain solution applied to a real-world use case for supply chain process improvement.

Introduction

Tracking of the state of health, inspection, and commissioning of installed components in the built environment has traditionally been a manual process. Tracking of progress depends on visual inspections, checklists, and logs to report deficiencies. Traditional practice relies heavily on inspectors' personal judgment and observational skills (Boschè et al., 2015). More recently, a huge body of work has emerged for automated monitoring of operation-level construction progress, using technologies such as laser scanning, computer vision and/or Building Information Modeling (BIM) for many applications, for example mechanical, electrical and plumbing systems or concrete floor flatness.

Another large field of research is the automated commissioning of buildings to show that they follow the promised energy performance (Panteli et al., 2020). Related research for facility management focuses on the real time monitoring through visualization at building and city scale, energy performance analysis, and energy benchmarking (Tomašević et al., 2015). Using these solutions, facility managers can retrieve energy-related information from the Building Management System (BMS) and view the BIM information using web-based energy management platforms (McGlinn et al., 2017). This allows facility managers to better visualize indoor environmental conditions such as temperature and humidity and make adjustments to improve user comfort (Marzouk and Abdelaty, 2014).

Other energy related solutions include the energy performance analysis based on real time data. Typically, energy analysis is based on mathematical simulation methods in the 3D environment; however, there is often a gap between predicted and actual building performance. Moreover, the likelihood for performance disparity increases in cases of complex, high-performance features which are difficult to model and simulate. However, one promising solution to improve accuracy of prediction versus performance is to use technologies to enable real time data as calculation input for the energy analysis (Yilmaz et al., 2023).

Despite advances in these research areas, solutions for progress tracking and commissioning technologies often mirror the fragmentation found in the greater industry (Hall et al., 2020). The proposed solutions tend to be oriented around individual project temporal phases: installation, inspection, and commissioning. Solutions are developed in isolation for tracking the installation, automating the inspection, or checking the commissioning. By contrast, much less research looks at integrating these activities with an object- or component-oriented perspective.

Monitoring these activities at the component level has several advantages. It avoids misaligned incentives where firms attempt to push risk down the supply chain. Better supply chain management of the digital asset can occur across the lifecycle and enable new incentive systems and business models for management of the asset, including opportunities for sustainability (e.g., circular economy), productivity (e.g., better collaboration, streamlined value chain) and/or security (e.g., the Hackett fire in London) (Watson et al., 2019).

Industry 4.0 for Lifecycle Traceability

The concept of "industry 4.0" is used to describe digital technologies and automation to create interconnected, intelligent, autonomous, and self-learning cyber-physical systems (Lasi at al, 2014). In the Architecture, Engineering, Construction, and Operations (AECO) industry, the term "Construction 4.0" is emerging (Klinc et al., 2019; FIEC 2015; Sawhney et al., 2020; Garcia de Soto et al., 2019). While Construction 4.0 encompasses many concepts and technologies, multiple sources mention the combination of BIM, Internet-of-Things (IoT) sensors, and distributed ledger technologies (DLT, also referred to as blockchain) as a favorable combination to enable supply chain traceability and data integration (Ye at al., 2018; Kinnaird and Geipel, 2017). BIM allows designers and builders to design, visualize, and coordinate construction systems with greater efficiency using three-dimensional digital models and processes.

BIM have proven that generation of large data sets in the AECO industry is possible. It has triggered a change towards digital working practices across stages of the design, construction, and operations process.

IoT refers to a network of sensors and connected devices that can be used for real-time feedback. To reduce the gap between the digital and physical world digital twins can act as (often) visual representations of information based on sensors for real-time representation of the physical world. For example, Zhai et al. (2019) finds that sensors in the construction process, in tandem with BIM, can help to address problems of inconvenient data collection, lack of automatic decision support, and incomplete information.

DLT and associated blockchain technologies can be an important enabler for more transparent and streamlined traceability in the AECO industry (Li et al, 2020). DLT enables direct peer-to-peer transactions of value and the immutable and trusted storage of data. These properties facilitate the building of trust between transacting parties and devices and can decrease the settlement time of transactions and reduction of costs associated with intermediaries (Viryasitavat at al., 2018). In addition, newer implementations of blockchain allow the execution of code protocols, often called smart contracts (SCs). SCs can encode business logic for value transactions and data handled on the blockchain to create automated workflows. Since these code protocols live on a blockchain, they benefit from the immutability and transparency of the system and hence it is ensured that they execute exactly as specified. Two studies critically analyzed blockchain for construction applications, concluding that the technology indeed has real world potential beyond the hype (Hunhevicz and Hall, 2020; Perera et al., 2020).

Supply chain traceability has been identified by several studies as one of the most promising ones for the application of DLT (Hunhevicz and Hall, 2020; Perera et al., 2020; Li at al., 2019). The opportunity is best described by Qian et al. (2020), who conclude that "blockchain technology is a key technology in Construction 4.0 that can bring the cyber (digital technologies) and physical (social capital) closer together by transforming trust to support various ecosystems of construction supply chains that shape and produce the built environment." However, overall there is a need to further investigate how the combined use of DLT, IoT and BIM should be implemented to create a system of trusted life cycle traceability and incentives.

Scope and Methodology

The goal of this research is to develop a tracing and performance monitoring system, leveraging combined use of new Industry 4.0 technologies, in particular BIM, IoT and blockchain. The innovation hereby lies in applying blockchain to the complete life cycle, beyond track and trace of just one supply chain stage. Furthermore, there is an opportunity to couple the performance evaluation through sensorized components with the benefits of trusted blockchain traceability and payments.

Research Setting

To achieve this goal, the study works with the supply chain for the retrofitting process using an External Thermal Insulation Composite System (ETICS). ETICS panels are widely used in retrofitting intervention to enhance the energy performance of the existing building. Correct installation of ETICS is important for a functioning insulation system to achieve the planned energy performance, having a direct impact on the cost of operation and comfort of inhabitants.

However, the current installation of ETICS is subject to repeated failure. ETICS represents an exemplary case for the often-present life cycle related issues in the construction supply chain. The success of the ETICS installation depends on different contractors that need to do their due diligence to deliver the final expected performance. The contractor is incentivized to maximize their profit during installation by taking "shortcuts" to save on material or time. Failures during production or installation manifest often, but they are not discovered until the operations phase because ETICS panels remain hidden behind the façade until the failure is propagated to the surface. This time discrepancy makes it very hard to investigate the exact cause of failure, as well as to hold the responsible parties accountable. The installing parties may pass blame to others, may have gone bankrupt, or the warranty time may have already expired.

A careful tracing and performance evaluation of ETICS panels over the course of their life cycle could benefit 1) the environment through emission reduction and recyclability of the material related to the concept of circular economy, 2) the operational efficiency through cost reduction both in heating or cooling losses and warranty claims, and 3) health and safety of both workers and occupants of the retrofitted building.

Implementation of a BIM-IoT-DLT approach is particularly suitable for the ETICS case study because: 1) it has a specific product focus that can be tracked, inspected, and commissioned; 2) the supply chain of ETICS panels has been repeatedly identified as a typical example where stakeholders misbehave at different working steps for their own benefit, to the detriment of the overall system performance. DLT can provide the trusted traceability to ensure accountability regarding correct production, commissioning, and installation, and incentivize correct installation through performance-based payments.

Case Study Description

This study uses the so-called "University of Brescia (UniBS) Prototype" as a research case study. The UniBS was built to investigate different improvement potentials around the lifecycle performance of ETICS. The physical prototype consists of a small demonstrator-house realized at the experimental facilities provided by Ente Sistema Edilizia (Building System Institute) Brescia, within a collaborative framework involving both the academia and industry. The research program was managed with the support of an industrial manufacturer Weber Saint-Gobain. The driving force from academia was the eLUX lab– "Energy Laboratory as University eXpo" at the smart campus of the University of Brescia in Italy, led by the Department of Civil, Environmental, Architectural Engineering and Mathematics and the Department of Information Engineering.

UniBS is equipped with detailed network of IoT to provide real time data on the ETICS performance. The UniBS prototype served as the test platform, applying the developed technical system throughout the life cycle of the prototype, from construction to operations.

The next section of the paper further specifies the role of the investigated ETICS supply chain workflow in the UniBS prototype, and the implemented blockchain process. The results section then gives details on 1) the transaction and SC design logic and implementation of the DLT-based system for the case study, and 2) the connection of the DLT SC with the digital twin and the IoT system for performance evaluation.

Blockchain for ETICS supply chain tracking

The main two value propositions of DLT in this prototype are 1) the transparency and immutability it can provide to track the ETICS panels and associated transactions in the supply chain, 2) workflow automation throughout the supply chain process for the execution of the performance-based incentive payments. The first one is important to establish a trusted database that can hold parties accountable for their actions, as well as assurance that data integrity is maintained. The second one can then create (semi-)autonomous workflows and automatic triggering of payments without any intermediary. Below we outline the investigated workflow of the ETICS panels, and afterwards give more details on the implemented blockchain process.

Investigated Workflow

Figure 1 pictures the overall workflow logic of the ETICS value supply chain for the UniBS Prototype with its involved stakeholders. To implement blockchain for the UniBS Prototype, the supply chain was simplified regarding both the number of actors and the workflow steps. The real supply chain is more extensive, nevertheless, this approach can showcase most important aspects to investigate a blockchain implementation. The considered actors involve the supplier of the ETICS panels, a contractor responsible to install the panels on the construction site, as well as the building owner.

Moreover, there is an actor introduced called "Oracle". The term oracle usually describes an external source of information that is needed to feed information to blockchain based SC. For the UniBS Prototype, the Oracle is a placeholder name for actors that will take the role of verifying various aspects regarding the energy performance-based contract. In the example of this paper, to feed the verification data of the installation steps (Figure 1; (7)) the Oracle is a trusted human third-party actor, while for the commissioning (Figure 1; (10)) the Oracle consists of the sensor network. To have both a human actor and sensors as an Oracle can also showcase these two possibilities in comparison. Having said that, not all SCs used in the prototype need input from external sources. Some of them only rely on the information saved on the blockchain itself. For example, accessibility features and users' roles, as well as the prescribed supply chain flow and the actual state of each panel can be described and checked on-chain. More information on the different SCs implemented in the prototype is given in the next section.

Implemented Blockchain Process

The blockchain-based process follows the defined workflow of the panels as defined in Figure 1. The smart contract logic controlling the access rules and the sequence of actions is then based on the "state" of panels. For example, the workflow starts with registering panels through the supplier once they are produced (Figure 1; (1)). The state is then "produced". This indicates to the SC that the next step needs to be selling the panels to the owner with a subsequent payment (Figure 1; (2), (3)). The workflow goes on to ship the panels to the construction site (Figure 1; (4)), where the contractor will receive and install them (Figure 1; (5), (6)). At this point, the SC only allows the payment and subsequent use of the panels in the state "installed" if all the installation checks are

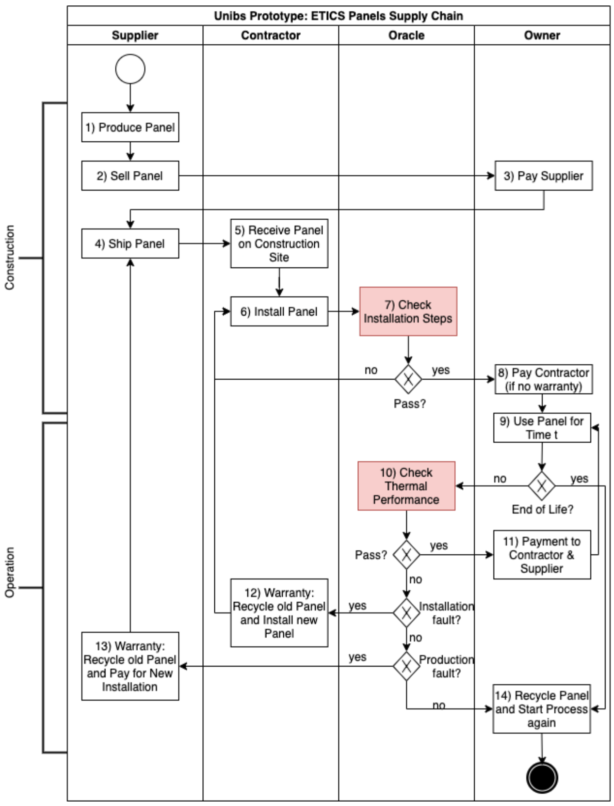

Figure 1: Flow chart of the ETICS Panels Supply Chain in the UniBS Prototype.

successful. This ensures verifiability and certification of the installation steps. For the use phase, the SC request for each time interval t the sensor data to check the thermal performance of the ETICS system (Figure 1; (9), (10)). If the situation is as expected, a payment to both the contractor and the supplier is automatically triggered (Figure 1; (11)) and the procedure repeats until the end of life of the panel is reached (Figure 1; (14)). In case the thermal performance of the ETICS is not as expected, the SC logic runs through the various causes, while considering the installation certification. In case it is an installation fault, the warranty and reinstallation of the panels needs to be performed through the contractor (Figure 1; (12)). In case of a production fault, the warranty to install a new ETICS panel needs to be paid by the supplier (Figure 1; (13)).

Overall, the proposed workflow acts as an energy performance smart contract (EPSC) and extends the liability of the supplier and contractor into the operational phase. Stakeholders get paid as usual to cover their immediate expenses, but only receive profit if the solution performs well during operation through an automated and continuous revenue stream. The blockchain smart contract gets funded up front by the owner and therefore acts as an escrow. If the solution does not perform well, the stakeholders will receive less or no profit. This should act as an incentive to collaborate and integrate across the life cycle phases. If behaving honestly, all participants can benefit from such a solution. The supplier has data available on where the panels are installed and how they perform. The owner gets assurance on the production an installation quality, as well as automatic warranty claims based on real-time sensor data. The contractor can benefit from the constant additional revenue streams but could also be held accountable for mistakes and warranty claims. Through the transparent installation certification, the contractor can also proof later that the installation was correct, but maybe a production error.

Implementation and Results

Transaction, SC Design and DLT-based system

The core of the implementation of the ETICS DLT-based system consists of a set of SCs supporting trust-demanding tasks developed for the Hyperledger Fabric permissioned blockchain infrastructure. Since not every task and data can benefit from on-chain execution, we defined a rule-based approach to identify these trust-demanding tasks and data objects. In general, these tasks identify critical activities in the workflows, with associated data objects, as explained above. A Private permissioned blockchain was chosen because it offers privacy and all parties are known (Hunhevicz and Hall, 2020). However, a permissionless blockchain could also be utilized, provided that appropriate encryption measures are implemented for the data written on it.

The Hyperledger Composer, a rapid prototyping environment running on top of Hyperledger Fabric, was used as development environment. The main concepts of a Hyperledger Composer project are *participant*, *asset*, *transaction* and *event*. An asset is anything, whether physical or virtual having some value in the considered domain. A participant is a role of the workflow who participates in the operations on the ledger. A transaction is an operation submitted by a participant to modify the ledger. It may consist of modifying the amount of an asset and it may raise events. A transaction typically modifies or creates some contents of the Hyperledger world state. Implementing a Hyperledger Composer project (M.M.S. et al., 2019) consists of creating three main files. A model definition (with extension .cto) file describes the business domain. It is written in a specific notation, called Composer Modeling Language, in which resources like participants, assets, transactions and events are declared. A JavaScript file, in which transactions declared in the .cto file are implemented as functions, describes the way assets are processed. Finally, a file containing a list of access control rules defines the rights (e.g., Read, Create, Update) assigned to each participant to operate on the ledger. These files form the so-called Business Network definition. For example, the following shows both the definitions of the Owner participant and the *Building* asset in the model definition file:

```
participant Owner extends Company {
o String name
        o String contactInfo optional
}
asset Building identified by buildingID{
o String buildingID
--> Design[] referencesToDesign
}
```

Here, the definition of the *Owner* participant extends the *Company* super-type. The resource has all properties and fields specified by the super-type and may add additional properties from its own definition. The definition of the *Building* asset includes the identified attribute *buildingID*. A resource definition specifies a set of relationships to other types that are not owned by the resource but that may be referenced from it. In this example, *Building* references a set of objects of *Design* type.

In our implementation, the participants can make an authentication on the ledger and perform the operations they are authorized to by the access control rules. The assets are the objects that the transactions operate on. We developed two kinds of transactions. The first one updates the ledger world state. The second one permits to create instances of assets (e.g., to insert a new panels installation on the ledger).

```
async function terminatePosing( tx ) {
    const NS = 'com.biz.eticssample';
    const factory = getFactory();
    const dateTime = new Date();
    const panRegistry = await getAssetRegistry('com.biz
.eticssample.installations');
    const instConfirmation =
factory.newResource(NS, 'instconfirmations', tx.id);
    instConfirmation.EndingDate = dateTime;
    instConfirmation.anchorsPattern = tx.anchorsPattern;
    instConfirmation.building = factory.newRelationship(
NS,'building',tx.building);
```

```
instConfirmation.contractor = factory.newRelationship(NS,'contractor',tx.contractor);
    await panRegistry.add(instConfirmation); }
```

The above function *terminatePosing* defined to process a transaction, exemplarily showing transaction execution. This transaction is declared in the model definition file and represents the corresponding workflow task. It permits to a contractor to create an *installationConfirmation* object sets its properties (i.e., date and time, pattern used for panel anchors, references to the building and to the contractor), and to add it to the ledger. The parameter *tx* is an instance of the *terminatePosing* function.

SC, IoT and DT for Commissioning of ETCIS Panels

The proposed system leverages IoT sensors to continually gather data on the condition of panels throughout their operational lifespan, enriching the Digital Twin (DT) model of the building. This integration allows for real-time monitoring of ETICS health. BIM is employed to facilitate intuitive visualization for building managers. Moreover, it serves as a proactive tool, triggering alarms promptly in response to any detected anomalies or critical events, with respect to the expected behavior. To assess the performance of the ETICS system during the operational phase, it is important to have a base for comparison (expected values). Therefore, an energy model was used to simulate the thermal behavior of the system. The purpose is to provide a predictive model of the energy flow that is transferred from inside (where a heating system in winter set up the temperature to 20°C) to the external, passing through the ETICS consisting of the materials EPS and glass wool. The model allows to calculate the expected temperature in the interface between the wall and the insulation layer defined by the boundary conditions through the heat transfer equations implemented in the dynamic simulation (Energyplus).

The temperature profile in the wall has been then defined in the calculation model and depicted in Figure 2. The sensor for measuring temperature and relative humidity should be properly installed in the interspace between the thermal layer and the wall. The calculated value can be then compared to the temperature measured by the sensors. Based on this method, it is possible to assess the deviation of the predicted value compared to the temperatures measured by the sensors on the control walls (north, west), as well as the temperatures on the failing walls (south, east).

The deployment of a distributed monitoring system could make the analysis of the energy efficiency and the maintenance state of an installed thermal insulation system. Such a system should be able to monitor in real-time several parameters from which can be inferred key performance indexes (KPIs) about the status of the building thermal coating. In particular, the monitoring system should be able to identify the following conditions: i) partial detachment of the insulation panel; ii) change in the energy efficiency of the coating detected by the temperature in the interface between the wall and the insulation panel and due to water infiltration for example. The monitoring system should be easy to install, low-cost and robust since it must be installed on the external wall.

Battery-operated devices are preferred to cabled ones, because they are easier to install. In addition, the monitoring system should have a lifetime comparable with the installation to monitor, i.e. approximately around 10/20 years. Thus, the system should be formed by devices with low power consumption, to guarantee a useful lifetime. Given these considerations, the monitoring system exploits the Wireless Sensor Network (WSN) approach for extensive monitoring of the parameters. Each of the monitoring points is composed of a wireless sensor, able to collect the parameters using transducers. Each of the sensors should monitor the temperature and the relative humidity (used to estimate the efficiency of the ETICS), and the 3-axis acceleration (used to estimate the partial detachment of the ETICS). The estimation of energy efficiency requires the estimation of the external and internal temperature and relative humidity. The block diagram of the sensor board is shown in Figure 3. Each sensor board is composed of three types of transducers: a temperature sensor, a 3-axis

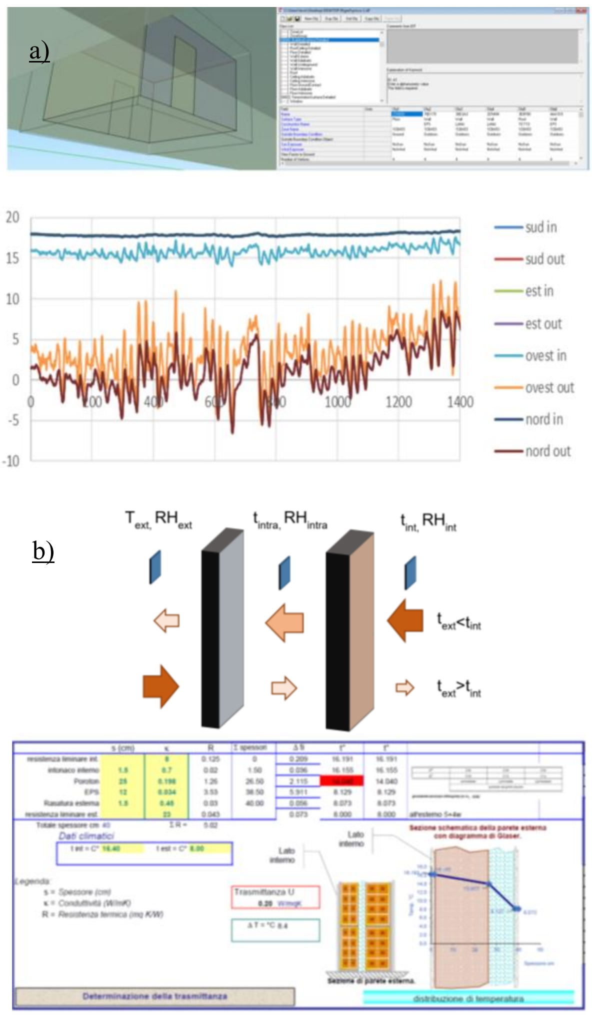

Figure 2: Calculation Method: a) Energy model of the test house b) Assessment of the expected sensor values.

accelerometer, and a relative humidity sensor. The data generated by the transducers are acquired and processed by the Micro Controller Unit (MCU). The data are temporarily stored in the MCU and, when possible, transmitted to a remote gateway through a Bluetooth Low Energy (BLE) modem. The MCU is also responsible for the optimization of the energy consumption of the entire board, through the adoption of proper low-power policy. All the peripherals of the board, including the transducers and the BLE modem, are turned off and the MCU itself remains in deep sleep mode until a data transmission is scheduled. The wake-up of the sensor board is obtained using the wake-up peripheral of the MCU. Each of the boards has been programmed to wake up every 3 hours, to reduce energy consumption. After the wake-up, the MCU acquires the data from the transducers and transmits the data through the BLE modem. The BLE protocol defines several communication modes, which require a data exchange with the local network coordinator. Such communication modes are not suitable for applications with strict requirements on power consumption. BLE provides a communication mode that does not require any interaction with the network coordinator: the advertising. Advertising packets are sent by a BLE node to advertise its presence to the coordinator. An advertise packet contains the Universally Unique Identifier (UUID), which identifies the sending node, and up to 37 bytes that can contain custom data. In the current case, the custom bytes are used to transmit the transducers' data, i.e. temperature, relative humidity, and 3-axis acceleration. The prototype of the sensor has been realized using the CC2650 Sensor Tag prototype board produced by Texas Instruments. Each of the boards is equipped with a high-performance ARM Cortex-M3 CC2650 wireless MCU, a 9-axis movement transducer (3-axis accelerometer, 3-axis gyroscope, 3-axis magnetometer), and a humidity transducer, able to monitor both relative humidity and temperature. The complete list of transducers used in the prototype and their main characteristics are summarized in Table 1.

Table 1: List of the transducers used by the prototype of the sensor board.

Sensor Type	Measurand	Bit resolution	Device
Movement	3-axis Acceleration, 3-axis Magnetometer, 3-axis gyroscope	16 bits	MPU9250
Humidity	Relative Humidity, temperature	16 bits	HDC1000

Each of the sensors installed in the interspace between the insulating layer and the wall represents a node of a Wireless Sensor Network (WSN). Each of the sensors transmits asynchronously the data acquired from the transducers one time every three hours toward the network coordinator, i.e. the GW in Figure 4. The WSN can be composed of a variable number of nodes. Since a connectionless transmission is used, there is no limit to the maximum number of nodes composing the WSN. The maximum number of nodes composing the WSN depends on the radio coverage and the computational resources of the GW itself. Approximately, is required a GW per each installation. The data acquired by the GW are then transmitted using HTTP RESTful services, through the public network, to a remote server for data processes (the data flow is shown in figure 4).

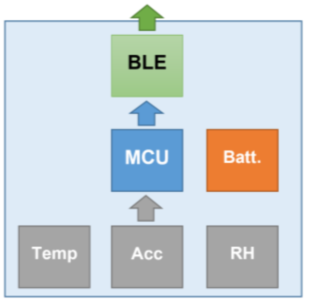

Figure 3: Block diagram of the sensor board. Relative Humidity (RH); Bluetooth Low Energy (BLE); Micro Controller Unit (MCU).

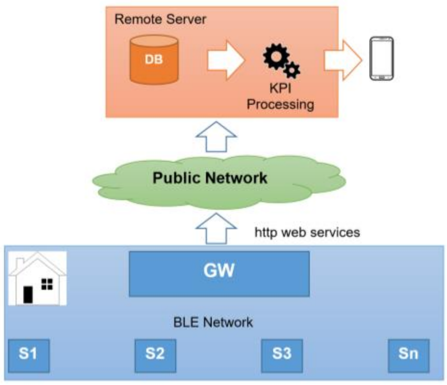

Figure 4: The architecture of the data analysis system.

A NoSQL DB (based on InfluxDB) is used to store the stream of data generated by the sensors. Computational resources are used to process the KPIs using the data stored in the DB. The data and the processed KPIs can be visualized using a dashboard, realized using the Grafana Framework. An example of the dashboard is shown in Figure 5. The proposed system can be easily scaled to process the data coming from different installations. The data from the sensors can be used to inform about the energy performance of the refurbished building and provide insight into discrepancies between the expected performance after the retrofit and the actual situation. The energy model of the building can be used to calculate the expected energy consumption and the temperature measured by the sensor can be used to calculate the energy flow for transmission.

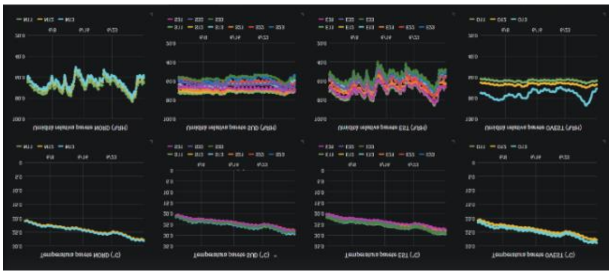

Figure 5: An example of the dashboard used to present the sensor data.

If the values are aligned, a discrepancy in consumption in winter could be related to the ventilation losses and to occupants' behavior for improving IAQ (indoor air quality) to the detriment of the energy saving. On the contrary, if the temperature is lower than expected and the ETICS is not properly insulating, it is possible to activate a detection procedure to understand if an issue is in progress for example for an infiltration which reduces drastically the insulation effect of the material. The experimental information model has been also used as an ideal Digital Twin of the test house working on the data mapping on the walls of the temperature distribution. Through VPL (Visual Programming Language) the sensors created into the information model for the different walls have been connected to the measures database of the value gathered from the sensors and the spread radius of the temperature variation have been visually approximated based on theoretical models since the empirical experience is not possible to exploit (Figure 6). However, the analysis of the data monitored showed that a difference of temperature due to the gradient distribution of the wall is detectable.

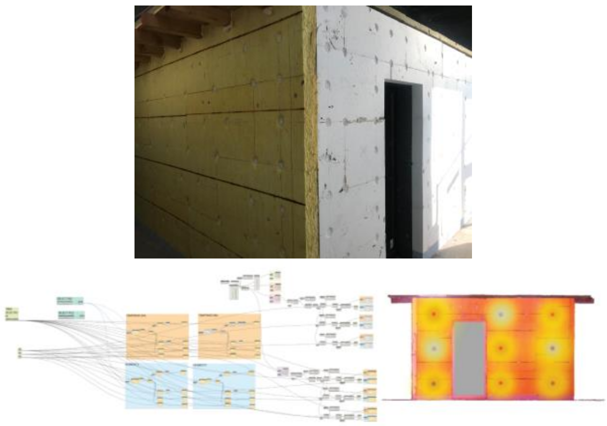

Figure 6: Test house before the installation of the finishing layers when it is possible to see the two target insulation materials, VPL model, and simulation of the spread radius of the temperature variation.

The data coming from the sensors, distributed on the walls, were collected and the difference of temperatures at different installation heights is used to define a sensor-based thermography of the situation of the walls (Figure 7).

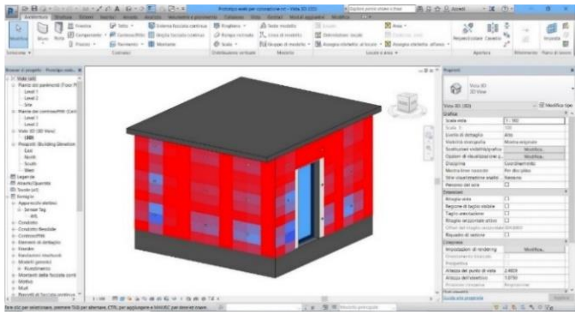

Figure 7: BIM based thermography related to the measured temperatures.

Conclusions

This study demonstrates the significant potential of blockchain technology in the AECO industry, particularly in addressing the challenges of traceability and transparency in supply chain scenarios where trust cannot be guaranteed. Our study focuses on the supply chain of ETICS panels for retrofitting existing buildings, which has been shown to suffer from misaligned incentives throughout the commissioning, installation, and operation of the panels.

Blockchain can provide trusted and transparent tracking of panels for accountability between supply chain actors and can use smart contracts to create performance-based incentive payments for a well-functioning system. For the necessary performance assessment, the sensor enabled IoT solution can provide real-time information over the entire building lifecycle, including the operations and maintenance (O&M) phase.

Our work explores an exemplary implementation of such a combined blockchain-IoT solution, focusing on a lifecycle perspective rather than just parts of the supply chain. We contribute to the emerging number of blockchain-IoT studies that implement energy performance smart contracts (e.g., Hunhevicz et al., 2022). Although the technical implementation and validation was performed on a test building, we believe it can provide valuable insights and inspiration for real-world implementation. Future research could extend to an actual construction project to further assess the cost and performance of the engineered system, compare between different available technical solutions, and evaluate the requirements and impact to industry beyond the focus on technology. Nonetheless, our findings demonstrate how the synergy between blockchain technology and sensor-based solutions can help shape the future of sustainable and resilient construction practices.

Abstract

Time performance management is a core contractual mechanism that contributes to the success of construction projects. However, its interdependent processes face underlying challenges. Hence, this paper aims to build a conceptual framework of how Hyperledger Fabric can contribute to addressing challenges encountered in practice. The results reveal that existing digital solutions implemented on construction projects can act as software oracles for Hyperledger Fabric blockchain and the contractual logic can be converted into smart contract functions at the process level. The paper acts as a point of departure to develop a proof-of-concept for practical adoption within the context of FIDIC Red Book 2017.

Introduction

The delivery of large construction projects hinges on contractual governance (Zhang et al., 2023) and interdependent contractual mechanisms (Chen et al., 2018). The logical execution of those contractual mechanisms is operated by a construction contract administration (CCA) system. Among the various elements of the CCA system, time performance management is a core mechanism that contributes to the success of construction projects (Hetemi et al., 2020) and benefits all organisations involved (Maylor et al., 2023). Yet, time performance management continues to be perceived as fraught with challenges (Abdul-Malak and Mehdi, 2020). One main reason for this is that it is underpinned by interdependent processes with each process having its own underlying challenges (Farghaly et al., 2024).

To this effect, a host of research efforts have attempted to tackle an array of inherent challenges associated with each process through the adoption of advanced digital technologies. For example, some studies developed AI-based solutions to improve schedule generations (Soman and Molina-Solana, 2022). Another strand focused on enhancing progress reporting (El-Omari and Moselhi, 2011; Hamledari et al., 2017). In addition, attempts at improving the related claims management process were made (Palaneeswaran and Kumaraswamy, 2008; Ali et al., 2020). Furthermore, improving the analysis of schedule delays has occupied a considerable space in the extant literature (Bhih and Hegazy, 2021; Guévremont and Hammad, 2018). Despite their empirically validated benefits, those research efforts tend to treat their respective process as independent from the other processes. In addition, they tend to be rooted in the perspective of a single organisation (centralised) while overlooking the nexus of autonomous agents involved in the CCA process.

With the advent of Hyperledger Fabric (HLF, 2023), a permissioned blockchain, this overlooked perspective and its associated aspect can be tackled. A number of studies have proposed HLF-based solutions to tackle inherent challenges of contractual processes in construction projects while taking into account the inter-organisational perspective. Proof-of-concept-based studies have focused on financial management (Elghaish et al., 2022; Cheng et al., 2023), document and records management (Das et al., 2022), quality management (Sheng et al., 2020), and other relevant processes (Zhong et al., 2022). Yet, this emergent research line has not advanced the interplay between HLF and the processes associated with time performance management. In addition, while it encapsulates the inter-organisational perspective it tends to focus on developing the HLF-based solutions without rooting them in a defined contractual governance (Msawil et al., 2022). This is, of course, often due to a deliberately limited research scope. As a result, it can be argued that interested scholars and practitioners have remained uninformed of the practical and applicable alignment between this advanced technology and current contractual practices, on the one hand, and existing digital solutions implemented on construction projects, on the other hand. This argument is echoed by Çıdık and Boyd (2022).

Hence, this paper proposes an HLF-based conceptual framework for enhancing contractual time performance management. The framework attempts to integrate existing digital solutions of relevant processes into a single digital platform, while grounding the framework within the context of the FIDIC Red Book (RB) 2017 (FIDIC, 2017) - a standard contract model devised by the International Federation for Consulting Engineers (FIDIC) and it is widely adopted worldwide for infrastructure projects procured through the design-bid-build route.

Conceptual background

The conceptual background first formulates the research problem in the form of challenges. Subsequently, it summarises existing HLF-based solutions developed for various CCA processes before justifying the research need.

Challenges facing time performance management

Both scholars and practitioners continue to regard time performance management mechanisms to be fraught with challenges regardless of the form of contractual governance adopted. Table 1 consolidates relevant identified challenges based on analysing literature against the various processes associated with this contractual mechanism. From an inter-organisational perspective, it can be inferred that the persistence of such current challenges hinders efficient and effective management of time performance, which can result in financial losses to all involved organisations (Elazouni et al., 2023). In addition, such challenges damage the business relationship to varying degrees (e.g., due to unsettled time extension claims, legal disputes) (Jelodar et al., 2016). These challenges highlight the need for developing an innovative solution to achieve an efficient and effective time performance management from an inter-organisational perspective while respecting contractual governance. In this paper, it is argued that such an innovative solution can be realised through the adoption of Hyperledger Fabric (HLF), a permissioned blockchain protocol, and its associated smart contract technical functionality.

Hyperledger Fabric-based applications for CCA

HLF is a digital implementation protocol that was specifically devised to execute permissioned blockchain-based business processes. Accordingly, studies have justified the suitability/applicability of HLF as a permissioned blockchain to the managerial and contractual processes of construction projects (Tao et al., 2021; Elghaish et al., 2020). HLF blockchain-governed transactions are executed through a 'chaincode' that contains 'smart contract' functions (HLF, 2023). At its core, a blockchain-based 'smart contract' can be described as a logical structure of a programming code that implements the business logic of a contractual process (Mason, 2021). Feeding the required input data into smart contract functions can be achieved by several methods: it may be from previous transactions immutably stored in the HLF blockchain (Sheng et al.et al., 2020); from so-called 'oracles' based on hardware, software, or human agnets (Lu et al., 2021); or a combination of these methods (Mason, 2021).

In the research stream that concentrates on blockchain applications in the construction project management (CPM) sphere, a broad range of HLF-based solutions has emerged. Among this growing stream, only a limited number of studies can be mapped to the particular contractual processes/mechanisms of CCA (Msawil et al., 2022). These are presented in Table 2.

Table 2 is evidence that these identified CCA process challenges can be resolved by the HLF-based application's unique features (authorised accessibility, symmetric information, digital security, immutability, process streamlining, and simultaneous traceability of performed contractual obligations).Yet, the potential applicability of HLF to improve processes involved in the contractual time performance management in particular has not been unearthed, at least in the context of a defined contractual governance. In general, it is recognised that contextualising innovative digital solutions within existing practices can act as an enabler to their possible adoption in construction (Çıdık and Boyd, 2022).

Project 'legal' governance	Zhong et al. (2022)	Proposing an HLF framework to automatically monitor and record environmental pollution.	Hardware (Internet of Things (IoT) sensors)

Hence, this paper attempts to tackle the preceding formulated problematisation through the development of a conceptual framework. To this effect, it is conceptualised by converting the processes associated with time performance management under FIDIC RB 2017 into HLF-based technical architecture (on-chain) linked with available software implemented on construction projects (off-chain). Together with the analysed studies, the proposed conceptual framework paves the way forward to advancing the understanding of the potential applicability of HLF to improving time performance management as a practical/ particular instance of the wider CCA system.

Contractual derivation of the framework

This section derives the various processes and subprocesses associated with contractual time performance management. The derivation is based on analysing relevant contractual sub-clauses of FIDIC RB 2017 as an application context. Figure 1 shows the resulting analysis of the processes and subprocesses along with three forms of their contractual interdependencies: explicit, implicit, and absent. Due to limited space, the illustrated processes and subprocesses are briefly explained herein as deduced from their corresponding sub-clauses at the contractual process level.

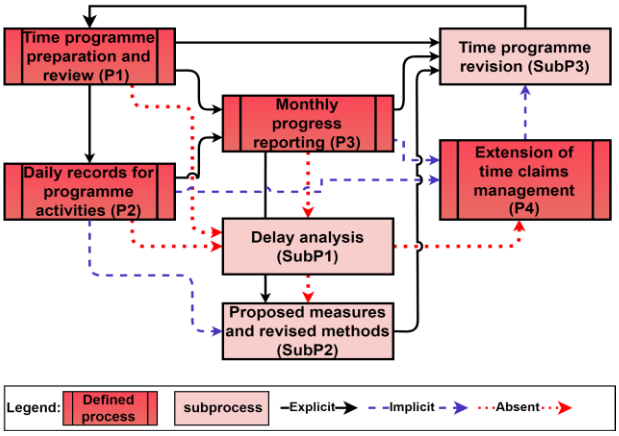

Figure 1: Key processes and subprocesses and their interdependencies

Time programme preparation and review (P1): this is derived from sub-clause 8.3 [Programme]. It places an obligation on the Contractor to prepare and submit the time programme to the Engineer, taking into account a wide range of factors and aspects.

Daily records for programme activities (P2): this is based on sub-clauses 6.10 [Contractor's Records] and 4.4.2 [As-Built Records]. It places an obligation on the Contractor to prepare and keep daily progress and as-built records for each activity shown in the programme to feed data into P3.

Monthly progress reports (P3): this is extracted from sub-clause 4.20 [Progress Reports] wherein a relatively long list of requirements is placed on the Contractor to prepare the monthly progress reports and submit them to the Engineer. Among other aspects, the requirements include a comparison of the actual and planned progress based on the programme update.

Under both P2 and P3, if a delay event that impacts the time performance occurs due to the Contractor's own cause, then the Contractor needs to propose [mitigation] measures to recover such time impacts. Such a Contractor's delay can be detected from the daily and monthly records and can be achieved through subprocess 1 (**SubP1**).

Delay analysis (SubP1): the contractual analysis of FIDIC RB 2017 did not reveal an explicit method of delay analysis. It recommends seeking advice from legal experts on the selection of an appropriate delay analysis method in line with the governing law of the Contract [project] and including it in the particular conditions.

Proposed measures and revised methods (SubP2): this can be considered as an undefined subprocess and it is inferred from sub-clauses 4.20 [Progress Reports] and 8.7 [Rate of Progress]. Any such measures and methods should be immediately incorporated into the programme to enable instant fulfilment of obligations and protection of rights of all involved organisations. Hence, it is logical to include this contractually inferred subprocess therein to place an emphasis on its role in closing the interdependence loop and linking the earlier processes to SubP3.

Time programme revision (SubP3): as a result of any changes to the initial programme that may result from (**P3**) and/or the adoption of measures/ methods under (**SubP2**), the Contractor shall revise the programme accordingly as a self-performed contractual obligation based on sub-clause 8.3 [Programme] or Engineer's instructions under 8.7 [Rate of Progress]. The revised programme becomes the programme for the subsequent period.

Under the aforementioned relevant processes and subprocesses, if a delay event occurs which is not a Contractor's responsibility, then the Contractor is entitled to an Extension of Time (EoT) as a contractual remedy.

Extension of time claims management (P4): this process is derived from sub-clauses 8.5 [Extension of Time for Completion], 20.2 [Claims for Payment and/or EoT], and 3.7 [Agreement or Determination]. It involves multi-sequential stages that hinge on the coordination and control-related obligations performed mainly by the Engineer and Contractor (with a minor involvement on the Employer's part). As evident in Figure 1, this process is contractually disconnected from the other processes, despite the very practical fact that its successful execution is influenced by information contained in (**P1, P2, P3, SubP1, Sub2, and SubP3**) and its outcome necessitates revising the programme. The authors emphasise here that this apparent 'disconnect' has been disregarded, as a critical review of the drafting of FIDIC RB 2017 is beyond the scope of this paper.

Based on the analysis above, it is self-evident that the means of improving contractual time performance management of FIDIC RB 2017 rests in addressing these processes and subprocesses. Yet, integrating them simultaneously while providing trust at an inter-organisational level and respecting the contractual governance is argued to have remained elusive. The following section presents an attempt to tackle this elusiveness.

The proposed HLF-based chained time performance management framework

This section presents the proposed conceptual framework by drawing on the tabulated HLF-based studies summarised in Table 2. As Figure 2 shows, the proposed concept connects the three involved organisations represented by human agents in a distributed manner around the notion of 'chained time performance management'. According to HLF design philosophy, each organisation is represented as a digital node and authorises its own human agents and software to act as peers on HLF network.

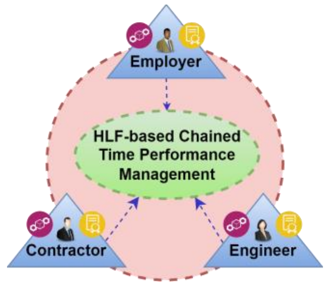

Figure 2: The multi-organisations connected to chained time management performance

Figure 3 shows the three key components of the framework and their digital relationships. In what follows, the key components along with their digital flow are described.

Off-chain: this component represents a construction contract environment where scheduled activities take place at a construction site, human agents perform contractual tasks, and software-based tools are implemented to aid human agents. In addition, it includes the defined contractual governance that regulates the interactions among the involved organisations. Of particular relevance to the current conceptual framework are human agents (human oracles) entrusted with performing a variety of contractual tasks and digital solutions (software oracles) implemented at the project level. The former includes project managers, project controls engineers, and quantity surveyors. The latter can include scheduling software (e.g., Microsoft Project and Oracle Primavera P6), BIM-based solutions, AI-based tools, and electronic document management systems. Both oracles interact with each other in a dynamic manner with human agents entrusted with data inputs while digital solutions entrusted with generating outputs. In this conceptual framework, it is proposed that both oracle types can act as dynamic data pipeline that feed required data variables of blockchain-based smart contracts through middleware.

Middleware: this component acts as a digital bridge between the off-chain oracles and the on-chain side. It performs a range of digital operations including invocation, queries, and updates. This component hinges on database servers and Application Programming Interfaces (APIs). It serves multiple technical functions. First, it enables human agents to interact with the HLF blockchain. This interaction can be to invoke a smart contract function by entering the required data variables or to query the blockchain ledger. Second, it enables available digital solutions (software oracles) to trigger a smart contract function in response to the occurrence of an event or query the blockchain ledger at regular coded intervals (e.g., each 24 hours) or invoke a specific function when pre-defined conditions are met based on programmed conditional statements. In addition, this set of middleware serves to return results retrieved from the ledger (on-chain) to human agents at both the project and inter-organisational levels. Furthermore, the database

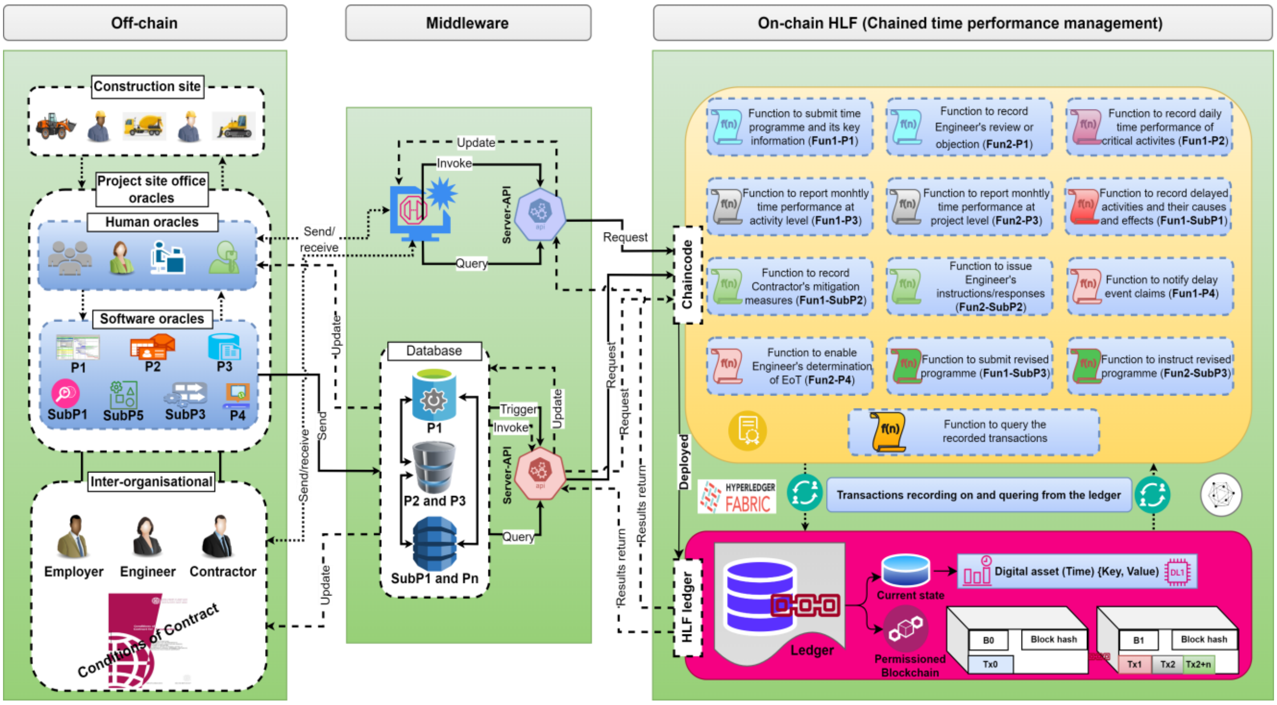

Figure 3: HLF-based chained time performance management framework

updates itself for subsequent digital operations (e.g., automatic invocation). Due to limited space, the solid and dotted arrows shown in Figure 3 conceptually show those digital operations. The detailed rules of the conceptualised operations and their interdependencies along with the server selection are currently under development.

On-chain HLF: the design of this component follows the HLF design philosophy. It includes a single channel that represents 'chained time performance management'. Authorised peer nodes at both the project and inter-organisational levels as well authorised software oracles are given access to the channel. On each authorised peer node, both the ledger and chaincode are deployed.

- **The chaincode**: the chaincode contains a set of the application-based smart contract functions coded to represent the contractual logic (see the previous contractual derivation of the framework) under each process or subprocess. In this paper, this set is called application-based smart contract functions which differs from system-based smart contract functions (e.g., initialise the ledger). Currently, the parameters that reflect the contractual logic of the relevant sub-clauses of FIDIC RB 2017 are being defined and analysed. To automatically execute a coded contractual task, the coded parameters inside a given smart contract function will receive data variables either from human agents or software agents or both, through middleware. If the received data variables meet the coded conditions, then the smart contract function executes a transaction that is immutability recorded on the blockchain. Subsequently, the various cumulative transactions can be queried by human agents or software agents to monitor the time performance and to automatically trigger specific action as coded.
- **The ledger:** the ledger consists of two interconnected parts: the blockchain and the current [world] state. The blockchain stores and processes all valid transactions whereas the current state shows the latest value of the defined asset (see the explanation below).

In addition to the preceding chaincode and ledger, the conceptual framework recognises the other digital HLF components (e.g., certificate authorities, endorsement policy, system-based chaincode, and identifying an ordering service for validating transactions and ordering blocks). For clarity and simplicity, those digital components are not shown in Figure 3.

Conceptual explanation of the proposed framework

This paper proposes a novel approach to managing time performance of construction projects in line with the objective ontology of FIDIC RB 2017. The proposed framework argues that time can be represented as a single digital asset in line with the philosophy of blockchain technology. To this effect, the contractual time is argued to be an asset owned by the Employer and it is allocated to the Contractor with the aim of using it to complete the construction project. The Engineer has a dual role in managing this asset: to monitor the Contractor's contractual state of time at defined intervals as stipulated in the Contract [project] data and to determine when the Contractor needs an increase in the allocated time (e.g., in case of a delay event which is not a Contractor's responsibility). This establishes an interdependent proactive approach to time performance management whereby all the processes and subprocesses are digitally connected through the adoption of an HLF-based solution.

Accordingly, this proposed approach chains and integrates the peers and their respective organisations enabling them to have complete status of time performance at any given moment with a history of fulfilled and remaining contractual obligations.

In addition, the human and software oracles providing input data are both identified in the recorded transactions based on HLF certificate authorities. On the part of human oracles, this increases the level of due-diligence and accountability in respect of data inputs. The need for increased due-diligence assessment fundamentally stems from the prospective awareness that a ‘smart contract’ function cannot be invoked without the input of all required data variables while taking into account that there will be neither an opportunity to change any input data nor to revoke recorded resultant transactions due to immutability. This awareness will substantially reduce erroneous data inputs and, hence, increase the likelihood of keeping the permissioned blockchain input error free. With this in mind, the data variables can be obtained from available digital solutions as software oracles.

It is envisaged that existing digital solutions can act as software oracles to feed smart contract functions with required data variables. However, an unintended limitation of current available digital solutions is that they tend to treat their digitalised processes as being independent which are in fact interdependent. Hence the proposed framework integrates those solutions (deployed off-chain) with their corresponding channel (on-chain ledger and smart contract functions) through APIs and databases that can technically be developed. In turn, smart contract functions are interconnected on the HLF platform with the capability of calling each other as well as calling APIs to obtain and feed data from the relevant processes of the ‘chained time performance management’.

The logical flow of this proposed approach follows contractual processes described in FIDIC RB 2017 with slight adjustments in terms of interdependence. This logical flow chains the entire associated processes from the commencement date of the Contract (i.e., project) to the date of completion in the form of a defined digital asset that represents the contractual time. The state changes of the defined asset are automatically and immutability recorded on the ledger through a series of digital transactions. As an example, the progress reporting process (**P3**) can be linked to the EoT claims management (**P4**) process through their respective smart contract functions supported by blockchain-governed API servers. With this linkage, as soon as the update of a given activity on the programme shows a negative float (i.e., delay) of a pre-defined numeric value while following a programmed delay analysis (**SubP1**) to detect the allocated delay responsibility, the ‘notice’ of EoT claim can be triggered through a smart contract function. As a result, the EoT claim management process automatically starts if that activity is not the Contractor’s responsibility. If, on the other hand, the delay is the Contractor’s responsibility then **SubP2** (see above) is invoked. With those interdependent processes and subprocesses being digitally executed, the relevant information flow coupled with the contractual obligations are captured and recorded in HLF-based transactions while being visible and immutably traceable at the inter-organisational level.

Discussion

In developing the notion and its conceptual framework, a number of findings emerged. In contrast with earlier HLF-studies, the conceptual framework highlights the possibility of enhancing the management of time performance by capitalising on HLF capabilities and connecting them with human and software oracles. It proposes a set of smart contract functions to enable the execution of various contractual processes and subprocesses as derived from FIDIC RB 2017.

Deploying and operating those prospective smart contract functions on an HLF-based platform can mitigate a number of inherent challenges. With reference to Table 1 above, examples at the project level include misapplication of related sub-clauses (Ch-2), missing contractual obligations (Ch-12), inaction due to optimism bias (Ch-13), and missed time-bar (Ch-14). Challenges addressed at the inter-organisational level include distortion of information (Ch-6), information asymmetry (Ch-10), avoidance of discussion and poor communication (Ch-15), and difficulty with establishing continuous reasoned causation (Ch-19). For both levels, it can be posited that the net foreseeable result is enhanced control and coordination of contractual obligations and information in respect of time performance management.

Evidently, with minor adjustments to the existing contractual logic of FIDIC RB 2017 at the contractual process level in terms of connection, the notion of ‘chained time performance management’ can be realised. For example, such adjustments may involve explicitly connecting the EoT claims management process with the other processes while defining a delay analysis protocol in the particular conditions of a construction contract. Yet, these adjustments should be coordinated and cross checked across the whole Contract to avoid unintended consequences. Prospective adopters can seek contractual and legal advice to verify and validate such adjustments before scaling the proposed framework into technical development and production.

Conclusions

This paper presents a conceptual framework for enhancing contractual time performance management from an inter-organisational perspective while respecting contractual governance. With available digital solutions linked to HLF as a digital core coupled with minor adjustments to contractual logic, a way to enhancing contractual time performance management can be built in a single digital environment.

This paper has implications for practice and research. In practical terms, it establishes an adaptable conversion path from practical problems associated with contractual time performance management to an HLF-based framework. This path may help interested practitioners adapt the approaches presented herein to other mechanisms of FIDIC RB 2017 and other standard contract models. Along the same line, it highlights the possibility of using existing digital solutions, implemented in practice, as software oracles to leverage advanced HLF-based solutions. Theoretical contribution to the body of knowledge was realised in two ways. First, in advancing the case of blockchain in CCA and construction at large by proposing an adaptable HLF-based framework for time performance management. Second, by offering an application reference within a defined contractual context that can be further validated by academic researchers.

Further work is currently being carried out to develop and refine the application framework. This includes: (*i*) defining the parameters of the proposed smart contract functions, (*ii*) coding the smart contract functions using a suitable programming language, and (*iii*) developing API rules and their technical requirements. Accordingly, the framework will be instantiated through the demonstration of a proof-of-concept on an infrastructure project to realise the notion of 'chained time performance management' for large construction projects.

Abstract

Existing challenges in policy, practice, and digital innovation, and their integration into Circular Economy (CE) result in a complex undertaking. Currently, not many frameworks for the digital optimization of a building's End-of-Life (EoL) and its related processes exist. This paper explores the digitalization of the EoL process with blockchain technology, by analysing an applied use case of a closed loop reuse product in Austria. A blockchain-based solution designed to enhance the verifiability of the reuse process is proposed, by introducing a privacy-preserving zero-knowledge proof application which can increase, among other things, transparency, and trust to promote CE.

Introduction

The transition towards a Circular Economy (CE) represents a paradigm shift from traditional, linear economic models towards ones that are restorative and regenerative by design (Bocken et al. 2016; Kirchherr et al. 2023). This shift is underpinned by the integration of digital technologies, which play a pivotal role in enhancing the sustainability and efficiency of various sectors, from waste management to construction (Kamble et al. 2018). The End-of-Life (EoL) process of products and materials is a critical aspect of the CE and gets increasingly important due to resource shortages and CO_2 emissions benchmarks (Gervasio & Dimova 2018) for certification of buildings (e.g. DGNB), also required for compliance with the EU Taxonomy (2024) for buildings. With the gradual digitalization of EoL processes (Dodampegama et al. 2024) a fundamental database can be created to promote recycling, reuse, and reduction of construction demolition waste (Papamichael et al. 2023), contributing to the conservation of resources and the mitigation of environmental pollution.

Studies like Pagoropoulos et al. (2017) emphasize the role of digital technologies, including Big Data and IoT, in advancing CE. Additionally, in the construction sector, digital platforms for Circular Economy are aimed at integrating digital technologies and data management to optimize resource use, addressing the industry's challenges (Kovacic et al. 2020). Findings from Çetin et al. (2022), highlight the potential of digital twins and scanning technologies in supporting CE strategies despite existing challenges. These insights underscore the digitalization's crucial role in advancing CE, calling for continued exploration and application of digital solutions.

This paper explores the digitalization of the EoL process with blockchain technology by analysing a use case of a closed-loop reuse-product, applied in Austria. This blockchain-based solution is designed to enhance the digital perspective of the reuse process, by introducing a verifiable certification concept. This concept ensures the correctness of provided claims without breaking privacy for the involved stakeholders, with zero-knowledge proofs. In this way the solution increases, among other things, transparency and trust to promote CE implementation.

Literature Background

Circular Economy

Kircher et al. (2017) present a comprehensive definition of CE derived from extensive literature review. They define CE as an economic system that shifts away from the EoL concept by prioritizing reduction, reuse, recycling, and recovery of materials throughout the production, distribution, and consumption processes. This operates at various levels including micro (products, companies, consumers), meso (eco-industrial parks), and macro (city, region, nation, and beyond), facilitated by innovative business models and responsible consumer behaviour. Consequently, there are diverse interpretations of CE and circularity (Kirchherr et al. 2017; Alhawari et al. 2021), all aiming at incorporating strategies for smarter product use (refuse, rethink, reduce), longer product lifetimes (reuse, quality, repair), and material circulation at the EoL (recycling, cascading), necessitating new business models for implementation (Brändström & Eriksson 2022).

In Architecture, Engineering, and Construction (AEC), the building life cycle comprises four stages (EN 15978:2011): production, construction, use, End-of-Life including deconstruction/demolition, transport, waste processing, and disposal. Currently, the EoL phase of the buildings' life cycle remains the least sustainable (Charef 2022). Defining End-of-Life within the CE context in AEC poses challenges due to the lack of clear standardization and regulation across different countries, and essential prerequisites for digitalization including the use of Building Information Modeling (BIM). The disconnection between BIM tools and EoL tools hampers comprehensive considerations of this phase (Akbarieh et al. 2020). The built environment represents a significant, yet poorly documented stock of material resources (Heisel & Rau-Oberhuber 2020). Absence of guidelines for material and component databases impedes conclusions drawn from EoL considerations, which should ideally be integrated into the design phase. Adopting circular design strategies (e.g., design for deconstruction, disassembly, adaptability, and flexibility) alone does not reduce environmental impact unless integrated and considered during the design phase to manifest in whole buildings' life cycle. Moreover, EoL asset management necessitates extensive data, requiring new workflows, processes, and business models (Charef 2022).

The digital potential within the reuse process, highlights how advancements in Artificial Intelligence and BIM are unlocking new possibilities for effective reuse strategies in the construction sector (Khosrowshahi, 2017). Initiatives like the EU-funded RRReMaker project, employ Artificial Intelligence for design for deconstruction, aimed at resolving current problems when planning with reuse components and their associated uncertainties such as quality etc. Simpler versions of digitalization are online platforms for reuse (e.g. Harvest Map; Concular), which are increasing in number and significance, and facilitating material reuse, especially with the goal of shifting the paradigm of this topic in society. The success of these platforms depends on the provision of comprehensive and detailed information about available materials, their provenance in combination with material condition (Veit et al. 2014).

The legal framework for CE in Austria is mainly regulated in the Austrian Waste Management Act (AWG 2002), which introduces a waste hierarchy. In addition, the Austrian standard *Dismantling of buildings as standard method for demolition* (ÖNORM B3151:2022) is applied on a voluntary basis, and gives a guideline on how to proceed in the building's EoL: demolition typically follows the reverse sequence of construction, focusing on maximizing reuse, preparation for reuse, or recycling of materials resulting from the process.

The digital potential within the reuse process, highlights how advancements in Artificial Intelligence and BIM are unlocking new possibilities for effective reuse strategies in the construction sector (Khosrowshahi, 2017). Initiatives like the EU-funded RRReMaker project, employ Artificial Intelligence for design for deconstruction, aimed at resolving current problems when planning with reuse components and their associated uncertainties such as quality etc. Simpler versions of digitalization are online platforms for reuse (e.g. Harvest Map; Concular), which are increasing in number and significance, and facilitating material reuse, especially with the goal of shifting the paradigm of this topic in society. The success of these platforms depends on the provision of comprehensive and detailed information about available materials, their provenance in combination with material condition (Veit et al. 2014).

Closed Loop in CE

The closed-loop system is an integral part of the CE, and it stands in contrast to the traditional linear economy, which follows a *take, make, dispose* (EMF 2013) model of production. By maintaining the utility and value of products through multiple life cycles, closed loop systems can significantly reduce environmental impact by lowering the demand for resource extraction and minimizing waste. Moreover, closed loop practices can lead to economic benefits by reducing the raw material procurement and waste disposal. Socially, they can contribute to job creation in the refurbishment and maintenance sectors (Zhang et al. 2024).

Braungart et al. (2008) differentiate between *cradle-to-grave* flows of materials and cyclical, *cradle-to-cradle* flows, whereby Stahel (1982; 1994, p.179; 2010) refers to *closed loop systems* instead of cyclical systems, introducing herewith two essentially different types of loops within a closed loop system (1) reuse of goods and (2) recycling of materials. Referring to the aforementioned authors including McDonough & Braungart (2002), Bocken et al. (2016, p. 309) define two cardinal strategies for the cycling of resources: 1) *slowing resource loops* - By crafting durable goods and implementing strategies like product-life extension, such as service loops for repairs and remanufacturing, the lifespan of products is prolonged, leading to a reduction in the rate of resource consumption; 2) *closing resource loops* - Recycling closes the loop between post-use and production, establishing a circular flow of resources.

In a closed loop system, the End-of-Life concept is replaced with restoration/refurbishment; products must be designed with their next use in mind. This means that once the initial use of a product is completed, it can be disassembled and the materials can be used again in their original form instead of being downcycled into lower-quality applications (Braungart et al. 2007).

However, the transition to a closed loop system is not without challenges. It requires a paradigm shift in design philosophy, a move towards business models that can support product life extension, and the development of markets for secondary materials. It also depends on the establishment of effective collection and processing systems that can support the return of used products for remanufacturing or recycling (Korhonen et al. 2018; Figge et al. 2023).

Expanded from Bocken et al. (2016, p. 309), for the purpose of the presented research, Figure 1 shows a circular life extension of a good/product in CE where the left section (black) demonstrates a system focused on waste recycling. The complete picture however, which

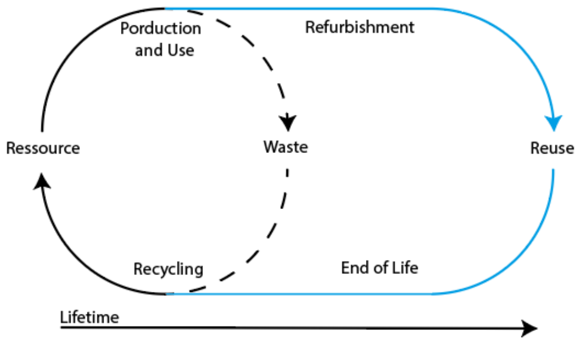

Figure 1: Closed Loop in CE

includes the right side (blue), reveals a fully realized CE that emphasizes keeping goods/products in use for as long as possible (extending the life span) through refurbishment and therefore in a closed loop system. The concept begins with resource extraction and product use, followed by product recycling at the end of its life. The expansion into refurbishment aims at slowing down the resource loop, hence promoting reuse and reducing the dependence on new resources.

Blockchain in EoL

Blockchain technology, synonymous with Distributed Ledger Technology (DLT) and initially introduced through Bitcoin (Nakamoto, 2008), has gained momentum across various sectors. Although the term was originally coined to describe Bitcoin's data structure, it now encompasses the underlying technology that permits decentralized state synchronization. This encompasses not only account balances, as with Bitcoin, but also a range of data types where the current state is critical for all participants. DLT's utility is further enhanced by Smart Contracts (Szabo 1997), with Ethereum blockchain (Buterin et al. 2013) emerging as the standard-bearer for Smart Contracts (SC) execution.

Blockchains, particularly in their original iterations like Bitcoin and Ethereum, operate as open networks with public data visibility. In contrast, private blockchains, which are generally permissioned and limit data access to known participants, are considered more appropriate for corporate use (Wüst et al. 2017). However, the efficacy of private blockchains has been questionable, potentially due to the absence of a "network effect." A hybrid approach that utilizes SCs on public networks alongside private databases interfacing through standardized protocols may offer a resolution.

Several studies illustrate blockchains potential to boost the life cycle approach within the AEC sector (Scott et al. 2021). Blockchain can ensure comprehensive traceability of materials and energy, aiding in the prediction of recycling and reuse outcomes for materials utilized in construction (Shojaei et al. 2021). The technology can also enhance the transparency and reliability of data in Environmental Product Declarations - EPDs (Rangelov et al. 2021). It facilitates end-to-end lifecycle assessment by documenting the metadata of raw materials, thereby verifying their provenance from source to construction site (Shojaei 2019). Copeland and Bilec (2020) have integrated RFID, BIM, and blockchain to specify components with a verifiable data trail throughout their lifecycle, and explored the integration with a crypto-economic incentive model for asset recycling. Additionally, blockchains can be employed for post-occupancy evaluations, with BIM serving as the repository and blockchain as the validator for built environment assets (Di Giuda et al. 2020).

Methodology

The presented research follows an integrated research approach, which, in a first step, was based on a comprehensive literature review, secondly on conducted and evaluated interviews with key stakeholders operating in AEC and EoL. These findings laid the groundwork for the following use case analysis of a reuse product in a CE closed loop, as outlined in the literature background. Furthermore, an important element of this ongoing research within the realm of the DiCYCLE project, is the integration of a blockchain into the framework of the presented use case called re:parkett. To create the presented use case, a workshop was conducted, where the details of the individual process steps were documented, and the current challenges in CE were discussed. The latter were the starting point for the applicability of our framework. The focus was on ensuring that the “executed” process was true to the “planned” process enabling herewith transparency and authenticity verification of the reuse product. In addition, a proposal for the creation of CO_2 certificates for the reuse product is laid out, adding also economic value, based on the partially required CO_2-audits for buildings. The aim is therefore to enable the creation of an unfalsifiable proof that the parquet flooring has been reused and is a closed loop product as shown in the case of re:parkett.

Use Case re:parkett

The starting point for re:parkett was the dismantling of significant areas of parquet flooring at the former Vienna Directorate and subsequently the requirements of a new project that needed installation of approximately 1200 square meters of parquet flooring for a building contractor in St. Pölten, Austria. This resulted in the novel idea of mechanically processing and further refurbishing individual parquet strips for reuse in new building projects.

In collaboration with a floor manufacturer, this concept transitioned into an implementation phase focused on product development. The objective was set to install 500 square meters of the reuse product by the end of 2022. A key aspect of this activity was the partnership with a floor laying company, which played a crucial role in both the dismantling and installation processes, thereby closing the loop of the product cycle. To ensure a systematic approach to the dismantling process, all three involved companies (the “circular design” company responsible for the assessment and collection of reusable parquet flooring, the manufacturer of flooring and the parquet floor layer) aimed at developing a manual that would integrate a standardized harvesting process into their business models. By April 2022, the first sample of the processed parquet was showcased publicly, signalling the readiness for market introduction. Efforts to expand distribution channels across various regions are ongoing, reflecting a scalable model for the adoption of sustainable practices in construction and renovation projects. This use case exemplifies the potential of collaborative innovation in promoting CE principles within the AEC industry.

Use Case Analysis & Discussion

In the research project DiCYCLE, a systematic approach to reprocessing harvested parquet floors has been developed, encompassing several key steps, as shown in Figure 2. The process is divided into four levels, with transport, deconstruction, manufacturing and certification. It initiates upon receiving an order, where builders, flooring layers, or flooring owners seek out the services of a company skilled to perform dismantling, recovery, or reprocessing of used/old parquet flooring. The second step involves a detailed and professional inventory of an existing or potential repository, with an assessment of the current condition of parquet flooring. Hence, an expert determines data regarding quantity, quality, and other features of the parquet, which are documented in a data sheet. Additionally, external parties can submit their own data sheets of potential repositories of reusable parquet flooring to the online platform/database (e.g. Harvest Map) of the “circular design” company which is then further checked and processed.

A crucial decision is made based on the collected information: whether to renovate the parquet flooring on-site, dismantle it for reuse, or dispose of it. In scenarios, where on-site renovation is deemed feasible, sometimes there might be a shift into dismantling and processing of flooring into a reuse product, due to previously false classification or the parquet owner’s change of plans. However, in some cases this leads to improper dismantling by untrained individuals due to time or budget constraints, potentially reducing the amount of material available for reuse.

In the “circular design” company’s database (Harvest Map) all relevant data on the dismantled parquet flooring regarding, quality and quantity is collected. However, the following step, which should entail an automatic digital data transfer between the “source database” and the manufacturer responsible for the refurbishment of the reusable parquet flooring, is currently missing due to the absence of a suitable implementable solution.

Going further into the process the manufacturer after receiving data regarding quality and availability of the flooring area, integrates this information into its own Enterprise Resource Planning (ERP) system, which is then utilized to determine the market demand for the product, as well as production plans and associated sales activities.

To summarize, the final decision on demolition or delivery to the manufacturer, is based on all previous steps in the laid-out process by the “circular design” company. For existing buildings, demolition is initiated, or the inventory in stock is delivered to the manufacturer for further processing. The dismantled product is then handled in the manufacturer's own production facility deemed at restoring/refurbishing the product, eventually ending up either being stored in the manufacturer's own warehouse or sold directly to the customers on demand, depending on the sales planning and production capacities.

In addition to all these steps, there is currently an ongoing effort to create a CO_2 certificate in the form of an EPD for the finished reuse product. This initiative aims to quantify the environmental impacts across all process steps, potentially offering the certificate with the floor delivery, or positioning the closed loop product on the market with its environmental background information. As mentioned, the schematic process is illustrated in Figure 2, providing an overview of the approach adopted in the DiCYCLE project.

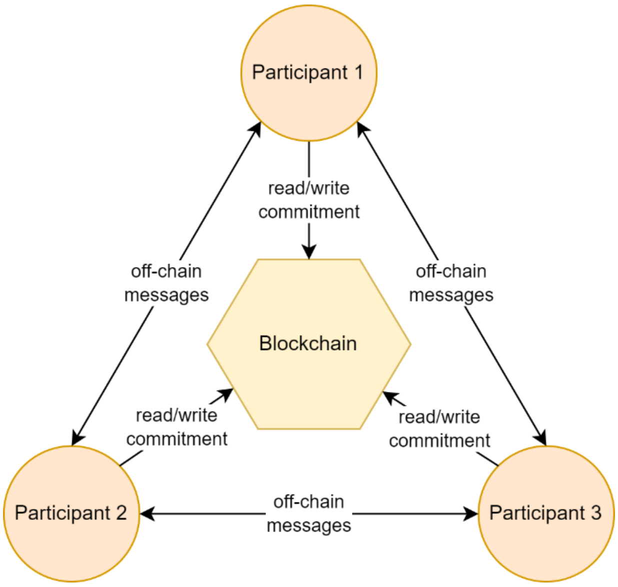

Figure 3: Overview of interactions on the blockchain

Blockchain application

Based on findings from the projects BIM.design & FMChain and the ongoing research presented here, we developed a system architecture for the use of blockchain to address challenges in the EoL process. The proposed framework allows for sustainable documentation of essential steps and data in the EoL value chain and ensures verifiable compliance to process models.

The first use of blockchain technology in the field of business process management mapped processes models entirely on blockchains by translating models to Smart Contracts (Weber et. al. 2016, García-Bañuelos et. al. 2017, López-Pintado et. al. 2019). This initial approach of mapping all data (including actors, gateways, etc.) on the blockchain is problematic for several reasons: Generally, when implementing processes, which involve multiple stakeholders, two fundamental obstacles occur. Firstly, basic privacy requirements of companies are violated: companies generally want to avoid having their own data associated with their business processes (e.g. supply chain data, production process data, etc.) to be openly visible to third parties. This was also reaffirmed by our interview partners in our requirements analysis for our use case. Furthermore, storing data on a blockchain is also unattractive due to high transaction costs. This is especially true for so called public blockchains, like Bitcoin or Ethereum. These are, as the name suggests, visible and open to be used by everyone. However, this is also a disadvantage, since the limited possible number of transactions per second can result in high transaction costs for participants. Private blockchains, i.e., blockchains that cannot be viewed by everyone and are operated by a small number of participants, have this limitation to a much lesser extent, but have other disadvantages, such as missing network effects; and also lack the capability for public verification (Carminati et. al. 2018, Marangone et. al. 2022).

In summary, as little data as possible should be stored on the blockchain but enough to fully exploit the capabilities of this technology. The data on the blockchain should also meet the privacy requirements.

With that in mind, Figure 3 shows our developed framework and how participants interact with the blockchain and each other. The main communication between the individual participants takes place off-chain, i.e. using peer-to-peer communication channels. The interaction with the blockchain is limited to commitments that represent irrevocable statements. These need to be transparent and verifiable for everyone and are therefore stored on the blockchain. These statements include only a fraction of the data that is held by the individual participants. A zero-knowledge proof (ZKP) ensures the relation between the commitments and the private data as well as the correct execution of state updates. The private data hence becomes immutable and tamper-proof.

To harness these privacy and security features in our framework we model use cases as a choreography of message exchanges. Figure 4 displays the message exchanges of an End-of-Life value chain, based on our use case re:parkett in a simplified form as a BPMN choreography diagram. Each box represents a message exchange task and displays the two stakeholders in terms of sender and recipient, as well as the conducted action. This modelling method results in a clear definition of the order in which stakeholders are involved and the information being shared between them. The interaction with the blockchain is limited to essential commitments

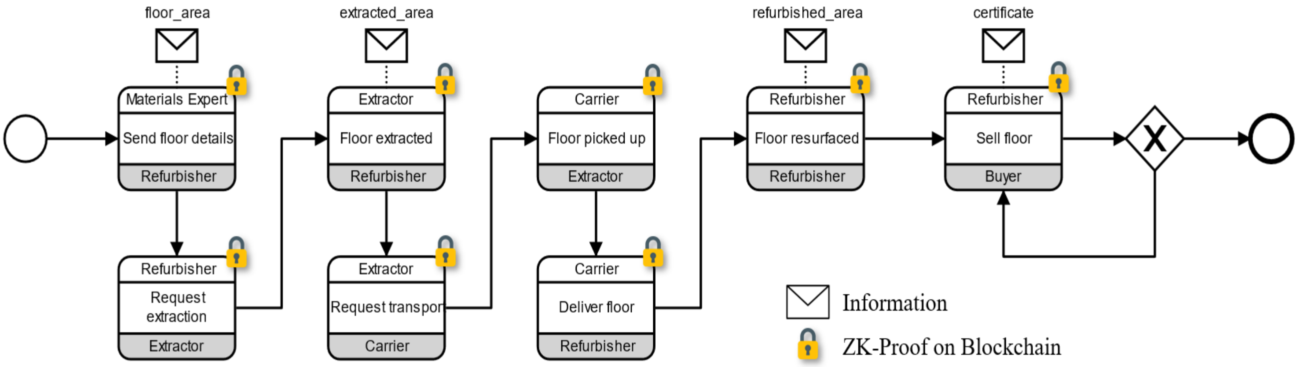

Figure 4: BPNM choreography diagram for re:parkett

and associated ZKPs (illustrated as padlocks in Fig. 2 and Fig. 4), verified with a smart contract on the blockchain. This facilitates immutable and public-verifiable assignment of data, without revealing any additional or non-disclosable private information.

A Zero-Knowledge Proof (ZKP) is set up as an interaction between a prover and a verifier. The prover's goal is to convince the verifier of the correctness of a computation without revealing the complete set of inputs (Goldreich and Oren 1994; Tomaz et al. 2020). ZKPs therefore provide the fundamentals to secure authentication and privacy protection in blockchain transactions, by creating a platform for stakeholders to interact without disclosing sensitive data (Meralli, 2020; Čapko et al. 2022).

While ZKPs were envisioned as multi-round interactive protocols, current variants are non-interactive i.e., only a single message is exchanged between the prover and the verifier. This property allows ZKPs to be included in blockchain transactions. Furthermore, zk-SNARKs, a highly efficient non-interactive variant with small proof sizes, enable storage and verification on the blockchain (Partala et. al. 2020).

Our framework utilizes this technique to ensure the correctness of private processes on a public blockchain. More specifically, participants signal the completion of a choreography tasks by sending off-chain messages to each other. Furthermore, they commit to those messages by sending a transaction consisting of a reference to the message and the process state together with a ZKP to the blockchain. A Smart Contract verifies the correctness of the ZKP and only updates the process state in case of success. The ZKP ensures that only transitions defined in the model can be executed, that only the permissioned participants can trigger a transition, and that the passed information satisfies some predefined rules. For example, in the case of the re:parkett use case, only the *Extractor* may complete the *Floor extracted* task by sending a message to the *Refurbisher*. Furthermore, although not shown in the figure, the value of *extracted_area* needs to be smaller or equal to the *floor_area* value that was provided by the *Materials Expert* in the first task.

Applied to the whole re:parkett use case the framework allows to create a certificate of provenance. A reference to the state in the SC proofs the validity of the certificate, as only conforming process updates can be submitted to the blockchain and hence the claims of the certificates must be correct. In case of re:parkett the certificate ensures that the amount of floor certified as recycled cannot exceed the amount identified by the expert.

The example demonstrates that our framework is highly suitable for many supply-chain use cases in AEC. By adopting our approach of tracing goods, it becomes feasible to comply with privacy requirements and legislation, while increasing the level of trust and security for digital processes in CE.

Conclusion

In this paper, we have explored the integration of blockchain technology into EoL processes within a CE framework, using a specific case study of a closed-loop reuse-product in Austria. The application of a blockchain-based solution has demonstrated substantial potential to enhance challenges regarding transparency, authenticity and trust through verifiable, privacy-preserving mechanisms, specifically zero-knowledge proofs.

Our research confirms that digital technologies, like blockchain, are vital for advancing CE by ensuring transparent and reliable data throughout product and material lifecycles. Implementing our blockchain framework in parquet flooring reuse demonstrates effective digital strategies for real-world CE challenges. This enhances environmental sustainability and creates economic value by potentially generating CO2 certificates (e.g. possibly published on a token, referring to CO2 emissions of a product or part of a product), herewith aligning with EU Taxonomy compliance. The findings support stronger integration of digital tools in CE processes, especially in the building sector, for resource efficiency improvements.

Ultimately, this paper calls for ongoing research and collaboration across sectors to refine and expand the use of digital solutions in promoting sustainable practices within the circular economy. This will not only enhance environmental outcomes but also foster economic resilience and social well-being.

Data Analysis, Simulation and Resilience

A COMPARATIVE ANALYSIS OF MULTI-TARGET FEATURE SELECTION METHODS IN DATA-DRIVEN MODELS FOR BUILDING ENERGY AND THERMAL PERFORMANCE PREDICTION

Esther Borkowski, Xiaojun Fan and Arno Schlueter
Architecture and Building Systems, Institute of Technology in Architecture, ETH Zurich, Zurich, Switzerland

Abstract

Building energy management increasingly utilises Machine Learning (ML) to use data from sensor-rich environments. A significant challenge in this context is managing high-dimensional data, which can affect model performance. This study addresses this by applying multi-target feature selection, an underexplored method that reduces dimensionality by analysing inter-feature relationships. From 182 features, two were key for developing three ML models predicting the energy and thermal performance of the HiLo living lab. These models achieved a robust fit with an average Root Mean Squared Error (RMSE) of 0.18 kW and 1.03 °C, demonstrating multi-target feature selection's effectiveness in enhancing building performance predictions.

Introduction

Buildings, accounting for 36% of global energy consumption, play a key role in the transition towards a more sustainable energy grid (United Nations Environment Programme, 2021). With the projected increase in the electrification of many end-use sectors and the broader integration of renewable energy sources, the focus shifts from supply-side to demand-side flexibility in grid operations. This shift is crucial for buildings to contribute significantly to decarbonisation targets by managing their energy consumption and generation dynamically, a concept known as energy flexibility (Li et al., 2022).

In this evolving landscape, buildings are expected to provide nearly half of the flexible demand capacity by 2030. This transformation is accelerated by the 'Internet of Things', which has increased the use of sensors in Heating, Ventilation and Air-Conditioning (HVAC) systems in buildings, resulting in the generation of vast amounts of data (Kathirgamanathan et al., 2019). However, these data are often high-dimensional, which creates challenges for Machine Learning (ML) algorithms due to the presence of irrelevant, redundant or noisy features that can slow down the learning process and degrade performance. Feature selection is recognised as a crucial method for reducing dimensionality. It involves choosing a subset of relevant features based on certain criteria, thereby simplifying model interpretation and decreasing memory usage, computational costs and learning time (Hashemi et al., 2021). Furthermore, should these models be applied in real buildings, the careful selection of sensors through feature selection would necessitate only essential sensors. Such efficient sensor usage would enhance economic viability and conserve critical raw materials, thereby supporting resource efficiency and circularity in buildings by reducing sensor network requirements.

In feature selection, a distinction is made between single-target and multi-target data. While single-target data involves predicting one output per sample, multi-target data consists of samples with multiple outputs, where the correlation between features and these outputs determines feature relevancy. This distinction directly influences the choice and application of feature selection methods. According to Hashemi et al. (2021) and as shown in Figure 1, feature selection methods can be broadly categorised into search methods and supervision methods, with search methods being often designed with single-target problems in mind.

On the other hand, supervision methods can address both single-target and multi-target feature selection. Within supervised ML algorithms, multi-target feature selection methods can be further divided into binary transformation and algorithm adaptation. Binary transformation initially converts multi-target data into several independent single-target data and then evaluates features for each target separately. However, this method may overlook the correlations between different targets (Masmoudi et al., 2020). In contrast, algorithm adaptation is specifically designed for multi-target data and aims to preserve and utilise these inter-target relationships.

Recent years have seen the development of various single-target feature selection methods, with numerous studies evaluating their application in ML models related to building controls (e.g. Olu-Ajayi et al., 2023; Kathirgamanathan et al., 2019; Zhang and Wen, 2019). Yet, real-world complexities often require addressing multi-target problems, especially in buildings where simultaneous prediction of multiple targets is common. Despite their significance, multi-target feature selection methods have received limited attention in research, both generally and within the built environment. While some studies have explored binary transformation for multi-target issues, to the best of the authors' knowledge, research on algorithm adaptation in this area is notably lacking. This study set out to fill this gap by comparing multi-target feature selection methods, with a particular focus on algorithm adaptation in data-

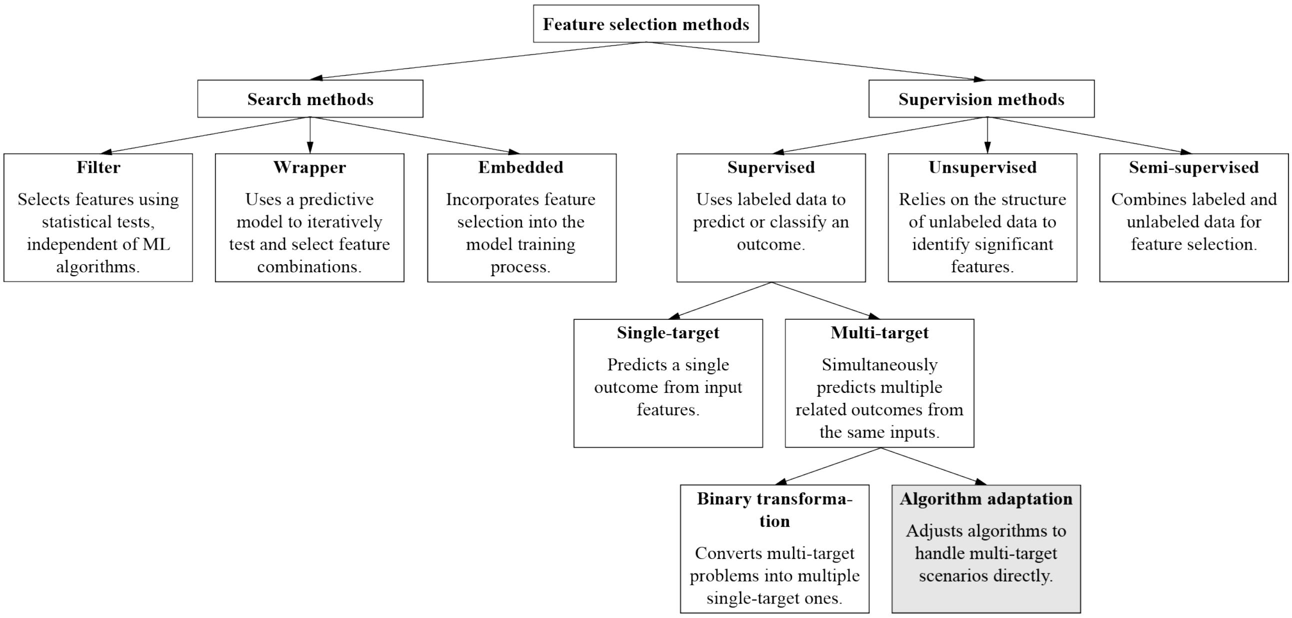

Figure 1: Categorisation of feature selection methods, highlighting the method used in this study. Based on categorisation by Hashemi et al. (2021).

driven models for accurately predicting building energy and thermal performance.

To achieve this aim, investigations have been conducted on data from the HiLo living lab in Dübendorf, Switzerland, as can be seen from Figure 2 (Block et al., 2017). Designed with the guiding principle of 'high performance, low emissions', HiLo features innovative building systems, such as Thermally Activated Building Systems (TABS) embedded into lightweight concrete structures. These TABS use a hydronic pipe network integrated into HiLo's structural components to transform the internal ceilings of two of its offices into radiant surfaces for heating and cooling (Lydon et al., 2019). Utilising concrete's thermal properties for heat storage and thermal inertia, TABS facilitate a time shift of peak heat load and a time lag of sensible heat transfer from the concrete to the interior air. These characteristics make TABS particularly effective for enhancing building energy flexibility (Arteconi et al., 2014).

Figure 2: Exterior view of HiLo from the southwest. Photo: Roman Keller.

However, controlling TABS in heavyweight concrete structures, which typically exhibit extended time constants, presents significant challenges as the regulation of heat output's timing and amount often becomes complex (van der Heijde et al., 2017). In response, this research project investigates the use of TABS in lightweight concrete structures, as exemplified in two of HiLo's offices. To model one of these similarly designed offices, i.e. Office 1, a data-driven (black-box) approach was selected due to its computational efficiency and accuracy against a more resource-intensive physics-based (white-box) model.

This study's central focus is applying multi-target feature selection during data pre-processing. This step was instrumental in accurately predicting two key aspects: (1) the thermal power of the TABS to ensure optimal control over the timing and amount of heat output and (2) the indoor air temperature in the office to maintain it within comfortable ranges. By comparing various multi-target feature selection methods, the study aims to identify the most influential sensors within HiLo's extensive sensor network. The aim is to develop a model that predicts TABS thermal power and indoor air temperature and aligns closely with the measured data. Achieving this aim is expected to provide valuable insights into improving building energy efficiency and occupant comfort and enhancing the methodological tools available for built environment research.

Methods

This section details the study conducted at the HiLo living lab, which was used to assess the effectiveness of multi-target feature selection methods in predicting the thermal power of the TABS and the indoor air temperature in

HiLo's Office 1.

Dataset

The study utilised a comprehensive dataset from HiLo, which is equipped with over 1,500 data points. For this study, a subset of 184 sensors was selected based on their relevance to predicting the cooling performance of the TABS in HiLo's Office 1. These sensors recorded data at ten-minute intervals for two summers (i.e. from 1 June to 31 August 2022 and from 1 June to 21 August 2023), covering a range of parameters from environmental conditions to HVAC system performance metrics. This dataset was then used to study the effect of 182 input variables on two key output variables: the TABS's thermal power and the office's indoor air temperature. Data extraction and analysis were conducted using Python, with libraries such as scikit-learn, pandas and matplotlib.

Data pre-processing

Data pre-processing is crucial for ML algorithm performance, as it addresses raw data imperfections and irregularities, such as high dimensionality and missing data (Olu-Ajayi et al., 2023). Therefore, data were pre-processed in this study to ensure dataset quality and avoid difficulties during model development. The process involved seven main steps:

1. **Data splitting:** Initially, the dataset was divided into features and targets, followed by splitting these into training and testing subsets for model evaluation.
2. **Biased reduction:** To prevent model overfitting and ensure accuracy, features strongly correlated with targets were removed, reducing the feature count to 162.
3. **Constant feature removal:** Non-variable features were eliminated for lacking predictive value, narrowing down the dataset to 106 features.
4. **Redundancy elimination:** Highly correlated features with a Pearson correlation above 0.9 were identified, and duplicates were removed to prevent multicollinearity, leaving 73 features.
5. **Missing data imputation:** Missing values, often a result of communication errors, were imputed using the K-Nearest Neighbours (KNN) algorithm to maintain dataset integrity.
6. **Cyclical feature encoding:** Cyclical aspects like time and solar position were encoded using sine and cosine transformations, leading to 97 features in the dataset.
7. **Supervised learning transformation:** To effectively model the TABS response, 12 lagged observations spanning a two-hour window were included to capture immediate past effects, expanding the feature set to 1,261.

Feature selection methods

The feature selection process leveraged the algorithm adaptation method, employing three ML models to determine the most predictive features:

- **Random Forest (RF):** This model combines multiple decision trees to form a more robust and accurate prediction. It is particularly adept at handling large datasets with complex relationships between features.
- **Gradient Boosting Machine (GBM):** Employing a stage-wise additive model, this technique progressively builds a model to optimise a loss function, which makes it effective for both bias reduction and variance control.
- **Support Vector Regression (SVR):** SVR applies the principles of support vector machines for regression purposes, hence providing a flexible approach to capture both linear and non-linear relationships within the data.

These models were selected due to their ability to handle diverse data characteristics and provide comprehensive insights into feature relevance.

Given that each of these models has its inherent method of assigning feature weights, which can differ significantly in scale and interpretation, feature weights were normalised to ensure comparability. This normalisation process adjusted the feature weights from each model to a common scale, thereby allowing for a direct and meaningful comparison of feature importance across different methods.

The effectiveness of each model in feature selection was then assessed based on these normalised weights, along with the impact on model performance and the computation time. The comparison aimed at identifying the most effective feature selection method for the HiLo dataset.

Model development

This study used the scikit-learn library to implement the three ML models listed above: RF, GBM and SVR. These models were chosen because of their performance in various prediction tasks, especially in scenarios involving complex and high-dimensional data like the real-world data in this study. The development process focused on optimising the predictive performance through strategic feature selection and iterative model tuning. Standard hyperparameters from scikit-learn were used due to the study's exploratory nature.

The process to determine the optimal feature set for each model involved systematic experimentation. Starting with the most predictive feature for the thermal power of the TABS and the most predictive feature for the indoor air temperature of Office 1, features were added incrementally – first in pairs, then in larger groups of ten and eventually by hundreds. This approach allowed testing all features up to the entire dataset of 1,261 features. Duplicate features were carefully removed to ensure a balanced emphasis on feature importance.

Model evaluation

The model's performance was assessed primarily using the Root Mean Squared Error (RMSE) metric, where a lower RMSE value indicates better model performance with fewer errors in prediction (Naser and Alavi, 2023).

For predicting the thermal power of the TABS (0-1 kW range) and the indoor air temperature of Office 1 (22-28 °C range), RMSE values up to 0.3 kW and 1 °C, respectively, were considered indicative of satisfactory model accuracy. This evaluation ensured that the model was not only accurate but also reliable and applicable in practical settings.

Results analysis and discussion

The study conducted with data from the HiLo living lab revealed that only a selected group of features significantly influenced the prediction of the thermal power of the TABS and the indoor air temperature in Office 1. The feature selection methods used – RF, GBM and SVR – differed in identifying these influential features. Notably, RF and GBM models assigned high importance to a few features, whereas the SVR model distributed importance more evenly across a broader range of features, as shown in Figures 3 and 4. Descriptions of the symbols for the top predictive features are provided in Table 1.

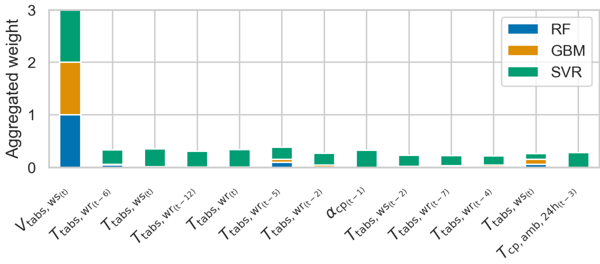

Figure 3: Aggregated weights of top six features for predicting TABS thermal power across RF, GBM and SVR models.

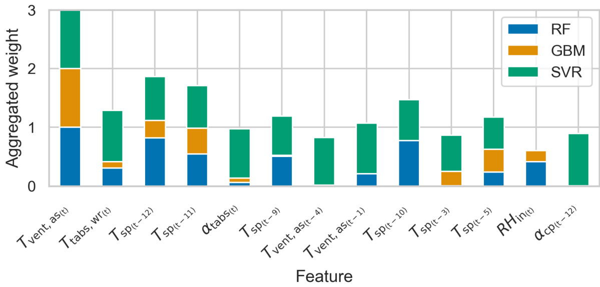

Figure 4: Aggregated weights of top six features for predicting indoor air temperature across RF, GBM and SVR models.

Despite methodological differences, all models consistently recognised two features as most important for their predictions: the supply water flow rate of the TABS at the current time step, $V_{tabs,s_{(t)}}$, for predicting the TABS's thermal power, and the air supply temperature of the ventilation system at the current time step, $T_{vent,s_{(t)}}$, for predicting the indoor air temperature. Beyond these top two features, the divergence in feature selection became more apparent. For instance, when predicting the indoor air temperature, RF and GBM models identified the zone regulation's setpoint temperature at various preceding time steps as the next two most important features. RF focused on the measurements twelve and ten steps prior, $T_{sp_{(t-12)}}$ and $T_{sp_{(t-10)}}$, whereas GBM focused on the measurements eleven and five steps prior, $T_{sp_{(t-11)}}$ and $T_{sp_{(t-5)}}$. In contrast, the SVR model yielded a different pair of features as most influential: the circulation pump's valve opening percentage twelve steps before the current time, $\alpha_{cp_{(t-12)}}$, and the water return temperature of the TABS at the current time, $T_{tabs,r_{(t)}}$.

Table 1: Top feature symbols and descriptions without time-lag notation.

Symbol	Description
$V_{tabs,s}$	Supply water flow rate of TABS
$T_{tabs,r}$	Water return temperature of TABS
$T_{tabs,s}$	Water supply temperature of TABS
α_{cp}	Valve opening of circulation pump
$T_{amb,24h}$	24h average of ambient temperature
$T_{vent,s}$	Air supply temperature of ventilation
T_{sp}	Setpoint temperature of zone regulation
RH_{in}	Indoor relative humidity

This variance in feature selection could be attributed to the inherent characteristics of each model. RF and GBM, both being ensemble tree-based models, tended to focus on similar aspects of feature interaction and non-linear relationships. On the other hand, SVR's unique approach, particularly its sensitivity to data characteristics, led to a distinct interpretation of feature importance.

These differences also slightly influenced model performance. As Figures 5 and 6 illustrate, RMSE values remained relatively stable across varying feature counts and models, which may suggest that the models' reliability was not heavily dependent on the feature count or selection methodology. Overall, all models demonstrated a strong fit to the data, with average RMSE values of 0.18 kW for thermal power and 1.03 °C for indoor air temperature across various feature counts and selection methods.

A closer examination of the RMSE values for TABS's thermal power prediction revealed that they remained relatively constant, regardless of the number of features added, as detailed in Table 2. Including just the top two features yielded RMSE values of 0.15 kW for RF, 0.13 kW for GBM and 0.14 kW for SVR, closely aligning with the overall average. This suggests that more features did not necessarily improve RMSE. Interestingly, expanding the feature set to four or six initially degraded prediction ac-

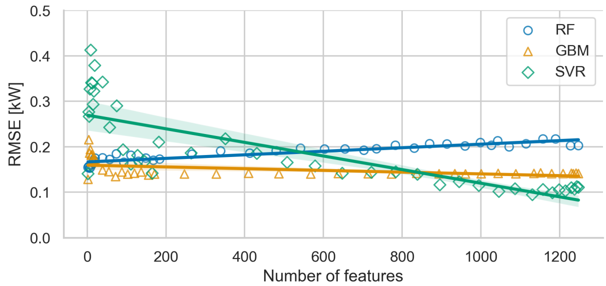

Figure 5: RMSE comparison for TABS's thermal power prediction across RF, GBM and SVR models and varying feature counts.

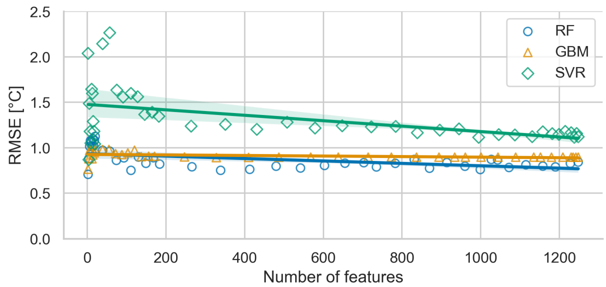

Figure 6: RMSE comparison for indoor air temperature prediction across RF, GBM and SVR models and varying feature counts.

curacy, followed by a slight improvement. However, even with the full feature set, RMSE values were 0.20 kW for RF, 0.14 kW for GBM and 0.11 kW for SVR, which indicated minimal gains from adding more features. This pattern suggests that optimising predictions for TABS's thermal power and indoor air temperature in HiLo's Office 1 might not require more than two important features, which demonstrates effectiveness in feature utilisation from an RMSE standpoint.

Table 2: RMSE comparison for TABS's thermal power prediction [kW] across RF, GBM and SVR models with top two, four and six features and overall feature average μ.

Model	Feature count			
	2	4	6	μ
RF	0.15	0.16	0.15	0.19
GBM	0.13	0.22	0.19	0.15
SVR	0.14	0.28	0.27	0.19

RF and GBM models showed a similar trend for indoor air temperature predictions to those observed for the TABS's thermal power predictions. Starting with the top two features provided better-than-average results, with an RMSE of 0.87 °C for RF and 0.91 °C for GBM. This performance diminished with the inclusion of four or six top features, then slightly improved again as more features were considered. This pattern, however, diverged for the SVR model. With only the top two features, the SVR's RMSE was 2.04 °C, which improved to 0.87 °C with the four top features but worsened again with six. As detailed in Table 3, the fluctuations observed with the SVR model underscore the distinct feature selection strategies inherent to each model. With its unique handling of features, the SVR model underscores the critical influence of feature selection methodology on model performance. This variability further accentuates the need for model-specific feature selection to enhance predictive accuracy and reliability.

Table 3: RMSE comparison for indoor air temperature prediction [°C] across RF, GBM and SVR models with top two, four and six features and overall feature average μ.

Model	Feature count			
	2	4	6	μ
RF	0.71	0.88	1.01	0.87
GBM	0.76	0.88	0.97	0.91
SVR	2.04	0.87	1.49	1.32

The runtime analysis complements these findings. As depicted in Figure 7, the runtime increased significantly with the addition of more features, underscoring the need for a careful balance between computational efficiency and model accuracy. The comparative analysis of RMSE and runtime suggests that a model with two features provided an optimal balance between accuracy and efficiency. Using two features, the runtime was 0.14 seconds for RF, 0.56 seconds for GBM and 0.63 seconds for SVR. This indicates that SVR was 77.77% slower than RF and 11.23% slower than GBM, a significant efficiency loss that could be disadvantageous in more complex modelling scenarios. This balance was consistent across different feature selection methods, offering a practical and robust solution for predicting TABS thermal power and air temperature in the given context.

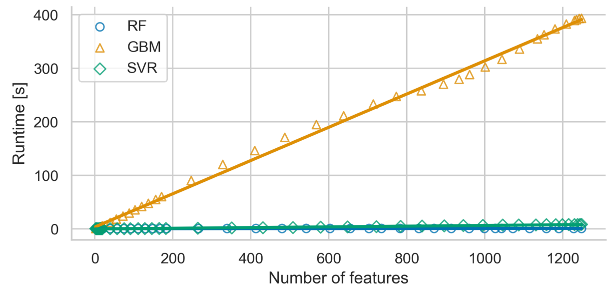

Figure 7: Runtime comparison across RF, GBM and SVR models and varying feature counts.

The overall performance metrics of the models, characterised by average RMSE values of 0.18 kW for thermal power and 1.03 °C for indoor air temperature across various feature counts and selection methods, indicate a robust fit to the dataset. This alignment is further evidenced by Figures 8 and 9, which compare the model's predicted outcomes against the measured data for TABS thermal power and indoor air temperature in HiLo's Office 1. These comparisons span a one-week period in mid-August 2023 within the test set, with each model iteration using the top two features identified by the respective feature selection method.

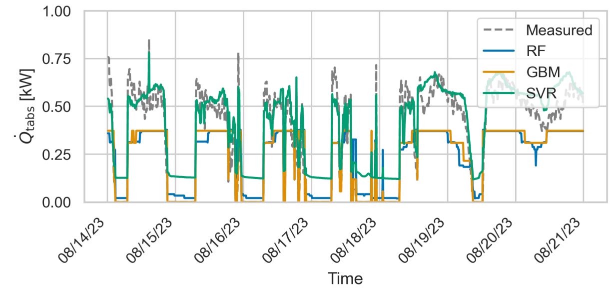

Figure 8: Comparison of predicted and measured TABS thermal power across RF, GBM and SVR models for one week in the test set.

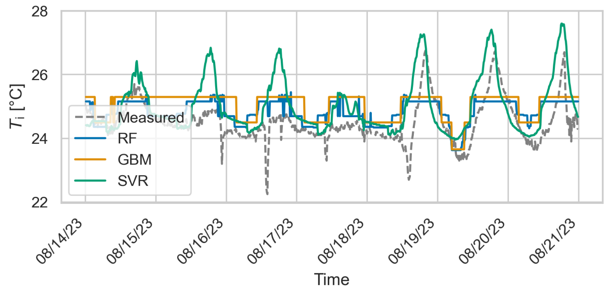

Figure 9: Comparison of predicted and measured indoor air temperature in Office 1 across RF, GBM and SVR models for one week in the test set.

The figures highlight the differences in the algorithms of RF, GBM and SVR models, despite utilising the same features. RF and GBM models yielded more constant outcomes, while the SVR model, characterised by greater variability, performed better at capturing peak values. This was particularly noticeable on the weekend, as indicated in the last three days of the graphs. A plausible explanation for this divergence could be SVR's sensitivity to extreme values (peaks) that arose from its objective to minimise the error within a certain threshold. This inherent sensitivity allowed SVR to better capture and predict extreme values or peaks in the data, leading to its observed variability but effective handling of peaks.

The analysis underlines the importance of model selection based on specific use cases, which factor in considerations such as prediction accuracy, computational efficiency and the ability to manage peak values. While RF and GBM showed higher accuracy and faster execution with the top two features, they did not match SVR's capability in considering peak values. This capability to accurately predict peak values might be crucial for certain applications and emphasises the need to choose models that align with particular performance criteria and application-specific requirements.

Conclusions

This study set out to evaluate how effectively multi-target feature selection methods, through algorithm adaptation, identify influential sensors to enhance building performance predictions. Employing a data-driven approach, the research focused on modelling and predicting the thermal power of the TABS and the indoor air temperature, using a subset of features from the extensive sensor network in the HiLo living lab.

The key findings highlighted that while RF and GBM models prioritised a similar set of features, the SVR model demonstrated a preference for a different subset. Despite these variations, the comparative analysis of the RMSE metric and the computational runtime suggested that models incorporating just two features achieved an optimal balance between accuracy and effectiveness. This balance is particularly crucial in real-time building control applications where both precision and computational speed are essential.

However, the study faced several limitations. First, while the focus was on balancing model complexity and effectiveness, further refinement through hyperparameter tuning or exploring other ML algorithms could enhance performance. Additionally, the inherent differences in how each feature selection method evaluates and ranks feature importance might have impacted the model's ability to generalise across different scenarios.

Despite these limitations, this research underscores the advantages of algorithm adaptation in multi-target feature selection, particularly its ability to leverage inter-feature relationships. This is crucial for complex building systems like TABS, where the interactions between different features significantly impact the system's performance.

Looking ahead, this study opens avenues for future research. A direct extension could utilise the findings to explore the energy flexibility potential of the TABS within HiLo's lightweight concrete structures. This would contribute to a more nuanced understanding of energy flexibility in building systems and its implications for sustainable building operations.

On a broader scale, future research should delve into other multi-target feature selection methods, exploring their strengths and weaknesses in different contexts. Such studies would enrich the toolbox of ML techniques available for building energy management, paving the way for more intelligent control strategies. This would be a significant step toward advancing smart building technologies, which align with global efforts to reduce energy consumption and carbon emissions in the built environment.

Acknowledgments

The data used in this study were collected and made available by the Swiss Federal Laboratories for Materials Science and Technology (Empa) with the support of the Swiss Federal Office of Energy (SFOE) and the Swiss National Science Foundation. It was partly financed by Mitsubishi Electric R&D Centre Europe B.V. [contract numbers EMPA NEST2019 / TT 2019-124, ETH ID No 16234, ETH ID No 20500, ETH ID-No 23035] and the SFOE [contract number SI/502623-01].

DETECTION AND CLASSIFICATION OF CONSTRUCTION OBJECTS BY USE OF MACHINE VISION AND DEEP LEARNING

Nicolas Nicolaou, and Symeon E. Christodoulou
Department of Civil and Environmental Engineering, University of Cyprus, Nicosia, Cyprus

Abstract

This research paper focuses on the detection and classification of objects at construction sites and analyzes the utility and potential of such detection and classification activities in the construction industry. Object detection and classification are performed by applying technologies such as machine vision (MV) and deep learning (DL) to image processing and/or in combination with object segmentation and labeling. These activities have varied applications at construction sites, including but not limited to: (1) the monitoring of workers and machinery for productivity measurement and for the prevention of accidents and collisions; and (2) the monitoring and classification of procured and installed construction materials for the evaluation of work progress. This serves as a valuable, low-cost measurement tool in the context of the management and monitoring of construction projects.

Introduction

The construction sector, even in modern times, faces numerous perennial problems and challenges related to the effective management and monitoring of construction projects.

Some of these challenges are, for example, associated with safety and health on construction sites. Despite significant progress achieved through the introduction of regulatory frameworks and legislation, a considerable number of occupational accidents are still recorded today. These accidents are not exclusively personal but are often linked to the reckless use of mechanical equipment and vehicles, as well as insufficient coordination, organization, and monitoring at construction sites. Therefore, a system using machine vision (MV) and deep learning (DL) technologies could, in this case, detect a worker in a restricted zone of the construction site, or determine whether the worker is wearing appropriate safety equipment or, even better, continuously appraise the ergonomic risks to workers (Lambrides and Christodoulou, 2023). Additionally, the system could be used to ensure the proper operation of mechanical equipment in designated areas and the maintenance of safe distances by the working personnel at the construction site.

Another critical issue commonly encountered at construction sites is resource management and construction progress monitoring. Delays, particularly in large construction projects, often occur due to material shortages and insufficient logistics in material delivery. Conflicts and construction delays are also frequent occurrences. Therefore, a mechanism based on the aforementioned technologies could be employed to monitor the transport of construction material to sites and visually document the construction process. This visual documentation can be valuable for reference and analysis.

In light of the aforementioned and other challenges faced by the modern construction industry, the use of machine vision and deep learning technologies is imperative. These technologies enable the automation of numerous technical processes on the construction site while facilitating the monitoring and resolution of various problems within it.

Literature Review

In recent years, a significant number of research studies has been conducted on the use of machine vision (MV) and deep learning (DL) technologies for detecting and classifying construction elements at construction sites. This trend began in the early 2010s, with works on the automated generation of parametric BIMs (Brilakis et al., 2010), and despite the significant improvements in relevant applications, there is still room for further development.

The article by Czerniawski and Leite (2020) introduces the automation of digital modeling of existing buildings through reality capture devices and computer vision algorithms. The goal is to facilitate the use of digital building representation technologies, promoting new forms of simulation, automation, and information provision. The research results suggest that achieving a more complete semantic coverage of building infrastructures will require a revision and intensification of relevant efforts.

Nath and Behzadan (2020) propose the validation of a genetic adversarial network (GAN) based on a deep convolutional neural network (CNN). The research involves photos taken, trained, and tested at the construction site from two internal datasets to increase image resolution when generating missing pixel information. Results demonstrate that using GAN-enhanced images can further improve the average accuracy of pre-trained models for object detection while maintaining overall processing time for real-time object detection.

In a subsequent work, Paneru and Jeelani (2021) provided an up-to-date and categorized overview of computer vision applications in construction by examining recent developments in the construction sector and the challenges that future research must address to maximize the benefits of computer vision. The authors focus on specific areas considered most likely to benefit significantly from computer vision, such as safety management on construction sites, progress and productivity monitoring, and work quality control.

One year later, Duan et al. (2022), focused on developing a large-scale image dataset specifically collected and processed for construction sites, named SODA (Site Object Detection Dataset). This dataset includes 15 types of objects categorized into mechanical means, materials, and labor personnel. Specifically, 20,000 images were collected from various construction sites, considering different construction site conditions, weather conditions, construction phases, and shooting angles. After careful examination and processing, 19,846 images were selected, containing 286,201 objects accompanied by corresponding labels from predefined categories.

An analysis conducted indicated that the developed dataset is advantageous in terms of diversity and volume. Further evaluation using two widely accepted object detection algorithms based on deep learning (*YOLO v3 / YOLO v4*) demonstrated the dataset's effectiveness in visualizing typical construction scenarios, achieving a maximum mean Average Precision (mAP) of 81.47%. This research contributes a large-scale dataset for the development of deep learning applications in object detection within the construction industry. It serves as a reference point for the further evaluation of corresponding algorithms in this field.

In their work, Wang et al. (2022) proposed a new semantic method aiming to extract information by integrating deep learning object detection and image captioning. This method explores important information from construction images or videos. In the proposed approach, object detection serves as an encoder to extract features of construction objects and the holistic image. By adopting this method, semantic information from construction images can be presented to project managers as a valuable tool for making crucial decisions on the construction site.

In the research work of Hou et al. (2022), a multi-object detection method based on the improved *YOLOv4* model is proposed to overcome the problem of low detection accuracy. Research results indicate that the average accuracy (mAP) of the improved *YOLOv4* model for many objects can reach 97.03%, which is 2.16% higher than that of the original *YOLOv4* detection network. At the same time, the detection speed reached 31.11 fps, a decrease of 0.59 fps, a result quite satisfactory for real-time detection data.

Zhou et al. (2022) propose an object detection method based on an improved *YOLOv5* model with high sorting accuracy of construction waste. It involves creating a dataset from images of construction waste taken in situ at construction sites. This improved model was trained, validated, and tested based on the collected images and compared with other conventional models such as *Faster-RCNN*, *YOLOv3*, *YOLOv4*, and *YOLOv7*. The *YOLOv5* model recorded an average accuracy (mAP) on the test dataset of 0.9480, indicating better performance than other conventional models in object detection.

In a recent research paper by Jog et al. (2022), full-scale validation experiments of a multi-object location tracking method for its application to resource tracking in large-scale, congested, outdoor construction sites are presented. The validation stage involved testing under harsh conditions on various large project sites. This research paper describes the process of data collection and testing, as well as the measurements and results obtained. The validation showed that the new vision tracking provides a good solution for tracking different entities in large and congested construction sites.

Research Methodology

The research work discussed herein focuses on the automated detection and classification of construction objects, and the applied research methodology was based on utilizing the Python programming language along with machine vision and deep learning technologies. In the realm of these technologies, several terms are often used interchangeably, yet they entail distinct tasks and methodologies. Classification entails assigning predefined labels or categories to input data based on their inherent features or attributes. Its primary objective is to categorize input instances into one of several predetermined classes, such as determining whether an image depicts a cat or a dog. On the other hand, the term "prediction" encompasses various interpretations, but within the domain of object classification, it involves assigning a probability score to each class to indicate the model's confidence level in its classification decision. Detection, meanwhile, pertains to the identification and localization of specific objects or phenomena within an input scene or data stream. It focuses on discerning the presence and position of objects of interest within images, videos, or sensor data, often using bounding box annotations. However, recognition, frequently conflated with detection, refers to the process of identifying and comprehending objects or patterns within an image or scene. Unlike detection, recognition entails a more profound analysis of visual content, which may include grasping the context, identifying specific object features or traits, and drawing higher-level associations or inferences based on observed patterns.

The goal was to create software, or leverage existing tools, capable of learning a series of construction objects present at a construction site. Subsequently, the software should successfully detect and classify these objects using either images from a dataset or random images. To achieve this objective, *ImageAI* (v.3.0.3) was employed. *ImageAI* (Moses, 2018) is an open-source Python library that simplifies machine vision and deep learning tasks. It is built on other libraries such as *TensorFlow* and *Keras*. From the array of tasks offered by *ImageAI*, specific codes related to image classification and object detection were utilized - activities directly aligned with the focus of this research. For each of the two tasks, a code was used for custom model training process based on the custom classes, resulting in the creation of a model. Additional codes were employed for result extraction, verification of the resulting accuracy-performance, and broader evaluation of the respective trained models, primarily through the utilization of unseen data.

Furthermore, a dataset was created for each task, incorporating photos of all the examined objects. These data resulted from a combination of my own photos from construction sites, ready-made datasets from Kaggle, which is a platform for data science and machine learning competitions, and generally photos obtained by Google Images search service. In the context of this research, the decision was made to initially explore two distinct classes to clarify the operational mode and compatibility of *ImageAI* with the research goals. These objects were the 'column' and the 'excavator'. However, at a later stage, seven more classes (totaling 9) were added to the detection, as follows: 'beam', 'masonry', 'slab', 'window', 'person', 'safety helmet', and 'reflective jacket'. The choice of some of these object classes relates to the intent of using developed algorithms and trained models for use in health & safety applications at construction sites.

Image Classification Framework

For this task, a set of 6000+ images of the object classes to be examined was collected. Initially, a general folder was created, which contained two additional folders named 'train' and 'test,' respectively. Within each folder, a subfolder was created for each prediction object. The training photos, used to train the classification model, and the corresponding test photos, used to evaluate it, were placed in these subfolders.

In the 'train' folder/dataset, 500 photos were included for each object, while in the 'test' folder/dataset, 200 photos were included. This dataset was then utilized in the training code, where various tasks were performed, including the selection of the algorithm. *ImageAI* offers the option to use four different algorithms for training custom image classification models (*MobileNetV2*, *ResNet50*, *InceptionV3*, and *DenseNet*), each with different speed and prediction accuracy characteristics.

Additionally, other parameters such as 'batch_size' (the number of images the network will process simultaneously) and 'num_experiments' (the number of network training iterations on all training images) were set in this code. For the purposes of this work, the MobileNetV2 algorithm was chosen due to its fastest prediction speed in compare with other algorithms.

Upon each execution of training code, the model with the highest accuracy was generated and stored in the dataset folder. Additionally, the other parameters mentioned above were systematically varied during each run to elucidate their impact on the accuracy of the respective model. This measure was undertaken to facilitate the incremental enhancement of the model, which became evident with each successive iteration. In this context, accuracy represents the percentage probability that a detected object belongs to a specific class. The accuracy is calculated using the following formula:

$$\text{Accuracy} = \frac{\text{Number of Correctly Classified Images}}{\text{Total Number of Images}} * 100$$

This percentage reflects the model's confidence in the correctness of its prediction. Higher percentage probabilities generally indicate that the model is more confident in recognizing a particular class of object in the image.

At a later stage, this model was employed in another code, where its effectiveness in predicting the examined and subsequently trained objects was evaluated using both trained and random photos. A schematic overview of this methodology is depicted in Figure 1.

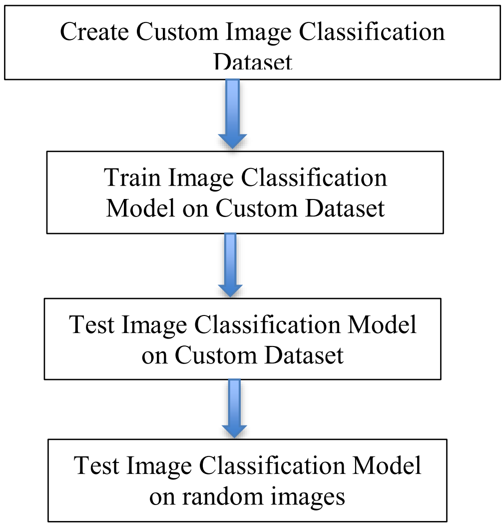

Figure 1: Image Classification methodology flowchart

Object Detection Framework

For this task, a set of 2700+ images was collected for the examined classes. Initially, a general folder was created, which included two subfolders named 'train' and 'validation,' respectively. Within each of these folders, two additional subfolders were created. The first, named 'images,' contained photos of the examined objects without separating them based on the object they depict. The second, named 'annotations,' contained the corresponding assignments for these classes, in txt format.

To create the assignments, an open-source graphic annotation tool for images, Labelimg, was employed. The process involved creating bounding boxes and labels in each photo and assigning them to each of the examined objects for the purpose of learning object detection. As part of this activity, 300+ photos were collected for each object, with 70-80% stored in the 'train' folder for training the detection model and the remainder in the 'validation' folder for evaluating the model's performance during training.

This dataset was then input into the training code, where, among other tasks, algorithm selection was performed. *ImageAI* provides the option to use two different algorithms to train custom image object detection models, namely *YOLOv3* and *TinyYOLOv3*, each with varying speed and accuracy characteristics for prediction. In this code, additional parameters such as 'batch_size' and 'num_experiments' were set, as previously explained.

During the training process for object detection, the initially used model did not include specific objects such as those found at construction sites. The model training with additional, construction site objects enriches the utilized pre-trained model and facilitates its use on construction-related image detection applications. Additionally, the option for training using a pre-trained *YOLOv3* model was specified. For the purposes of this work, both algorithms were employed. Future work shall aim the incorporation of newer releases of YOLO models (e.g., *YOLOv8*) and training datasets (e.g., *SODA*).

Each time the code was executed, the model with the highest accuracy in terms of mAP50 (mean Average Precision at 50%) was generated and stored in the dataset folder. Additionally, the other parameters mentioned above were systematically varied - in conjunction with the practical application of non-maximum suppression (NMS) - during each run to elucidate their impact on the accuracy of the respective model. During the training of each model, in addition to mAP50, additional metrics such as precision, recall, and mAP50-95 were obtained. However, these metrics were not automatically saved. Precision is a measure of the accuracy of a model's positive predictions and is derived from the following relationship:

$$Precision = \frac{True\ Positives}{True\ Positives + False\ Positives}$$

On the other hand, recall, also known as sensitivity or true positive rate, is a term used to evaluate the performance of a classification or object detection model and is calculated as follows:

$$Recall = \frac{True\ Positives}{True\ Positives + False\ Negatives}$$

By using these two terms, it is possible to calculate the F1 Score, another widely used metric for evaluating classification models. The formula for the F1 score is:

$$F1\ Score = 2 * \frac{Precision * Recall}{Precision + Recall}$$

The term 'mAP' (mean Average Precision) is a metric that assesses the precision-recall tradeoff of a model. It evaluates how well a model performs at different confidence levels in its predictions. Specifically, 'mAP50' evaluates the model's precision and recall at a specific 50% Intersection over Union (IoU) threshold. Higher mAP50 values indicate better performance, with a maximum value of 1.0 representing perfect precision and recall at the specified IoU threshold. IoU is a metric that measures the overlap between the predicted bounding box and the actual location of the object. A 50% IoU means there is at least a 50% overlap between the predicted and actual contexts. This evaluation system is commonly used in assessing object detection models, including those trained for custom object detection tasks. At a later stage, this model was employed in another code, where its effectiveness in detecting the examined and subsequently trained objects was evaluated using random photos. A summary flowchart of this methodology is presented in Figure 2.

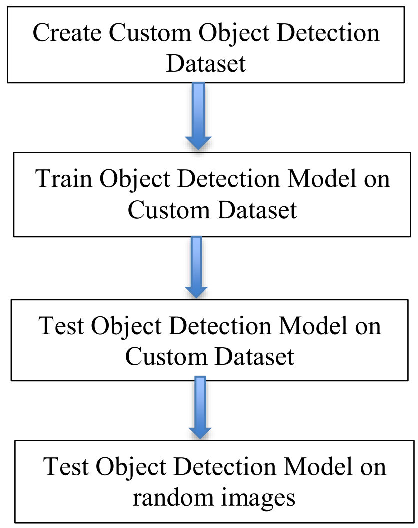

Figure 2: Object detection methodology flowchart

Additionally, the capability was provided by creating a Python code in combination with trained detection models to identify health and safety issues in photographs from construction sites, specifically printing a relevant warning message for the absence of part or all of the necessary safety equipment (protective helmet and reflective jacket) in case a person is detected in those areas.

Case Studies, Findings and Discussion of Results

In the pursuit of fulfilling this work's objectives, a series of tests were conducted through the execution of custom training Python programming language codes, as described. Throughout these tests, specific parameters were systematically varied in each training code, including the dataset itself, to generate two models - one for each task - with the highest accuracy and optimal performance. These models aimed to best fulfill the intended purpose for which they were created.

The final analysis results for the nine classes described in the previous stage are as follows. For image classification, considering the case of nine classes, a *MobileNetV2* model achieved an accuracy of 81.06%. This relatively high accuracy indicates the near certainty of the model in the correctness of its predictions, specifically in successfully predicting the nine trained classes in any given photo. This result was further validated by the model's performance on various photos, consistently yielding generally high probabilities for correctly predicting the depicted object. The model was tested on both trained and random images, and during the conducted tests, no significant change in performance was observed between these two categories of images. It is thus evident that the model's performance was proportional to its accuracy rate. Some example results are provided below.

The figure below presents the outcomes of a random image illustrating various objects at a construction site, including columns, beams and slabs. Utilizing the aforementioned image classification model, a probability of 52.24% was assigned to the depiction of a beam in the photo, 26.02% for column and 21.38% for slab. Predictions for the remaining classes were notably low, aligning with expectations given that only these three classes were prominently featured in the image under examination. The difference between the three main predicted classes is based mainly on the extent of viewing each class from the angle of the photo. This result affirms the high predictive capability of the trained model.

```
beam : 52.2404
column : 26.02
slab : 21.3805
masonry : 0.1741
person : 0.1149
Safety_Helmet : 0.0305
excavator : 0.0174
Reflective_Jacket : 0.0142
window : 0.0081
```

Figure 3: Result of random image in image classification (example 1)

Figure 4 displays corresponding outcomes from a random photo depicting masonry and window, which are equally positive. In this photo the prediction percentage is relatively high and almost equal between the two mainly predicted classes and very low for the rest classes that are not represented. Similar results were obtained for the rest of the classes among random photographs with the characteristic of combining several classes in the same examined image with the results being generally satisfactory as can be seen in Figures 5 & 6.

```
window : 50.7926
masonry : 44.4139
Safety_Helmet : 1.6045
Reflective_Jacket : 1.513
person : 0.6469
beam : 0.5646
column : 0.315
slab : 0.1471
excavator : 0.0023
```

Figure 4: Result of random image in image classification (example 2)

The image in Figure 5 depicts a female worker at a construction site, with appropriate personal construction protection gear. The results of the applied model to this case confirm the successful prediction of the three main classes that appear in the photo in question, with the corresponding prediction percentages showing significant

```
Reflective_Jacket : 49.1006
person : 38.3086
Safety_Helmet : 12.3392
excavator : 0.2281
beam : 0.0159
masonry : 0.0066
slab : 0.0006
window : 0.0003
column : 0.0001
```

Figure 5: Result of random image in image classification (example 3)

fluctuations. Specifically, a higher percentage was given to the reflective jacket class (49.10%), with the person class following (38.31%) and the safety helmet class registering a significantly lower percentage (12.34%) among these three classes.

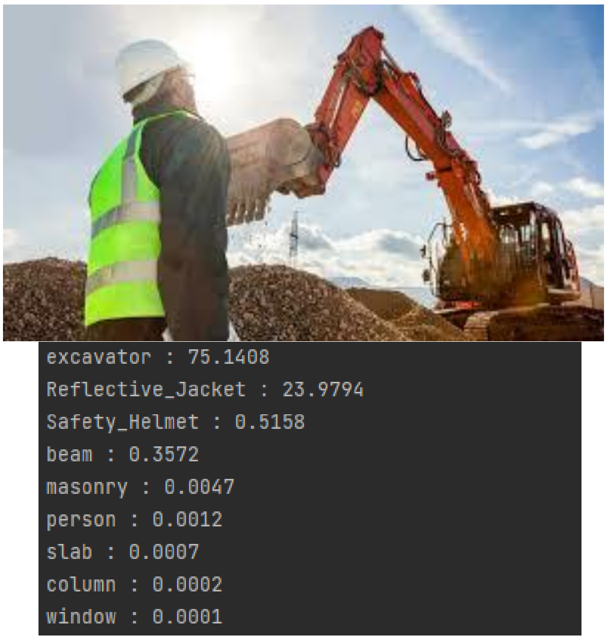

Figure 6: Result of random image in image classification (example 4)

Similarly, Figure 6 shows the results for an image showing a worker with appropriate personal protection gear near an excavator. The trained model correctly identified the existence of the excavator and the safety vest but not the worker and the safety helmet. One possible explanation for the very low prediction rates of the mentioned existing classes in the respective photograph is the intense lighting precisely at the point where the safety helmet is located, along with the posture of the human figure.

Frequently, models such as the one developed for image prediction encounter challenges related to their real-world effectiveness when presented with random images or images combining the examined objects. For instance, a model may perform well on the trained dataset but struggle to generalize its effectiveness to new, random data. However, as previously mentioned, no such phenomena were observed for this particular model.

Accordingly, for object detection, a *YOLOv3* model with an average accuracy (mAP) of 67.41 % was achieved. This figure indicates the relatively average to good accuracy of the specific model in terms of detecting and successfully classifying the objects under study in examined photographs, however efforts are being made to enhance the performance of this model to achieve even higher success rates. This result was further validated by the model's performance on various photos, where several satisfactory results were observed in terms of the true positive detection and classification of objects. The *YOLOv3* model was tested on both trained and random images, and during the conducted tests, no significant change was observed in terms of the model's performance between these two categories of images. Therefore, in this case as well, it is evident that the performance of the model is proportional to its accuracy rate. Some example results are provided below.

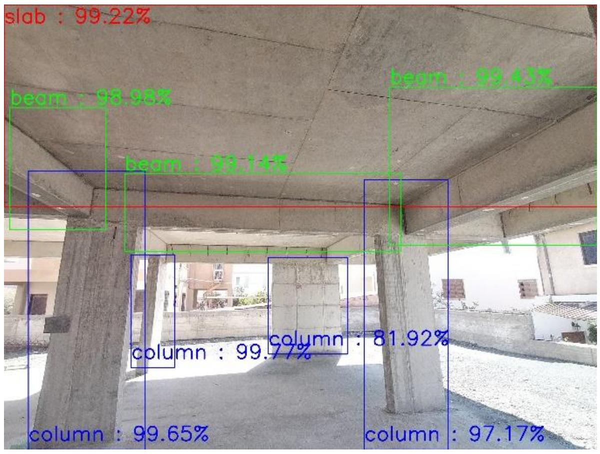

Figure 7: Result of rabdom image in object detection (example 1)

The figure above displays the outcomes of a random image depicting various objects on a construction site, including columns, beams and slabs. Utilizing the aforementioned object detection model, several load-bearing elements were detected with a probability of successful classification exceeding 81% affirming the high performance of the trained model. However, some other objects that would be expected to be detected by the model were not detected. These objects may have been influenced by the phenomenon of occlusion due to the relative angle of the photograph's capture. Nevertheless, the results largely coincide with those obtained using the classification model, which is deemed satisfactory. Additionally, Figure 8 demonstrates corresponding outcomes from a random photo of a worker on a construction site with appropriate personal protection measures. From the results of the model for this case, it emerged the successful detection of the three main classes that appear in the photo in question, with the corresponding confident scores showing very high (>96%) as in the case of the classification model for the same photo, the results of which were previously presented.

Figure 8: Result of random image in object detection (example 2)

Equally satisfactory results were obtained from tests conducted on other random photographs depicting the examined classes, as evident from Figures 9 & 10. The photo in question, presented in Figure 9, shows that using the model, masonry and a window were successfully detected with a confidence score exceeding 94%. Therefore, the behavior of the model under these conditions is considered satisfactory.

Figure 9: Result of random image in object detection (example 3)

Furthermore, in Figure 10, an example is provided depicting multiple objects (of those under examination), with the detection model yielding satisfactory results for most of them and moderate results for a single class (person). However, a better performance of the detection model is observed in the said image compared to its classification counterpart (Figure 6), as noticeably higher prediction rates are evident.

Figure 10: Result of random image in object detection (example 4)

Using the same detection model, results were obtained from other construction site photographs, with an additional capability introduced: the detection and notification of safety and health issues concerning the necessary and recommended personal protective measures on the construction site. Specifically, if a person was detected in these photographs without either or both of the reflective jacket and safety helmet, a corresponding warning was issued, as demonstrated in Figure 11.

Figure 11: Result of random image in object detection (health & safety example)

In conclusion, Figure 12 presents the confusion matrix of the detection model examined in the study. In a confusion matrix, each row represents the actual labels depicted in the validation set images, while the columns represent the corresponding labels predicted by the detection model. From the presented matrix, it is observed that some classes are positively evaluated due to a high number of true positive detections (e.g., excavator, window, etc.), while others are characterized as moderate to negative. The results of the matrix are to some extent expected, as the examined detection model did not achieve particularly high levels of accuracy. However, an NMS implementation with value equal to 0.4 led to an increase in the overall accuracy of the model in terms of F1-Score by approximately 30%. Essentially, the matrix provides insights into which classes the model struggles to predict accurately and can guide further improvements in the model, such as fine-tuning class-specific features or collecting more diverse training data for those classes. Therefore, there is room for significant future improvements.

Complete Confusion Matrix:

	column	excavator	beam	masonry	slab	window	person	Helmet	Jacket
column	349	0	111	10	67	3	3	0	0
excavator	0	76	0	0	0	0	3	0	0
beam	144	0	223	6	51	7	3	1	0
masonry	5	0	6	130	5	4	6	1	0

Jacket	0	0	0	1	0	0	85	70	65

Figure 12: Results of confusion matrix based on object detection model

Conclusions

The utilization of artificial intelligence, particularly technologies such as Machine Vision (MV) and Deep Learning (DL), in the construction industry is deemed imperative. The applications and benefits that can arise from these technologies are crucial, especially during the transition to a new era fraught with challenges. The real-time application of MV and DL can enhance the monitoring of safety and health issues on construction sites, extending to the broader and more essential oversight of labor management, mechanical equipment, vehicles, and materials, all while considering the relatively low costs resulting from the use of these technologies.

The present study focused on the automated detection and classification of construction elements at construction sites using the *ImageAI* library, built on the foundation of Python's *TensorFlow* and *Keras* libraries. The entire process was based on the integration of Machine Vision and Deep Learning technologies, combined with a dataset collected for the objects under consideration. The extracted results were analyzed in relation to the accuracy of the corresponding models from which they were derived. As part of future work, the following actions are to be taken to enhance the performance and accuracy of the relevant models based on *ImageAI*:

- Improvement of the annotation functions for bounded frames and labels, using advanced rendering practices in conjunction with the practical application of non-maximum suppression (NMS).
- Use of a balanced dataset with respect to all examined objects to prevent overfitting and the memorization of specific objects by the trained model for each activity.
- Exploration and testing of other custom activities offered by the *ImageAI* library for accuracy and usefulness, particularly by using video streams of related content.

A COMPARATIVE STUDY OF DEEP LEARNING MODELS FOR GRANULOMETRY IMAGE BASED ESTIMATION OF CONCRETE AGGREGATE

Benjamin Pasquier and Houda Chabbi Drissi
iCoSys - Institute of Artificial Intelligence and Complex Systems
HEIA-FR, HES-SO Haute école spécialisée de Suisse occidentale

Abstract

Obtaining the granulometry is the starting point of our pipeline for automating the calculation of concrete properties using images. For this reason, we focus on developing the best deep learning model that can compute aggregate gradation and can generalize to images obtained from different aggregate producers. We investigate two established approaches: Convolutional Neural Networks (CNNs) and Vision Transformers (ViTs). Our analysis includes a dedicated CNN model trained from scratch, alongside pre-trained CNN and ViT models adapted through transfer learning.

To evaluate the performances and the generalization ability of the models, we use three different datasets: two publicly available and one of our own. Our analysis shows that transfer learning followed by fine-tuning on ViT_16 outperforms the other models, on both classification and regression tasks, with smaller errors and greater generalization capabilities.

Introduction

Deep learning applied to images is successfully used for prediction in many fields. Our aim is to use images of aggregates and a deep learning model to predict the properties of concrete. Our assumption is that such a model, trained on a dataset of aggregate images and corresponding concrete property data, would extract meaningful features from the visual representations of aggregates. These features can then be used to predict concrete properties such as compressive strength and workability.

The most influential factor on the properties of concrete mixtures is the type of used aggregates and their granulometry. Therefore, we propose to build a system that uses aggregate images as the foundation for the predictive final system, which will then use additional inputs to predict concrete properties based on the aggregate size distribution, as shown in Figure 1. Integrating this model with a camera system observing the aggregate conveyor belt during concrete production allows for real-time granulometry determination through image analysis. Leveraging this real-time information, the entire system can then continuously estimate key concrete properties enabling real-time monitoring of the mix design and ensuring consistent concrete quality.

We are interested in concrete mixes in which recycled or

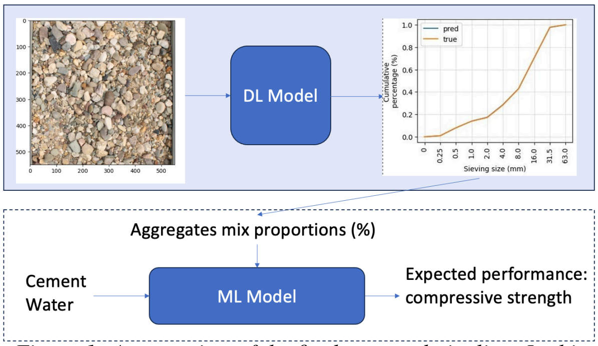

Figure 1: An overview of the final expected pipeline. In this paper, we are interested in finding the best DL model for the granulometry task.

natural aggregates may be present in varying proportions. Therefore, we seek for a model that can accurately and automatically extract granulometry distribution from aggregates images. In addition, this model should have a strong generalization capability, adapting to new images and new particle size distributions of natural or recycled aggregates, without the need to explicitly specify the aggregate type.

To carry out our study, we compare the performances of different deep learning architectures for granulometry estimation, first as a classification task, then as a regression task. To obtain a deep learning model, two main approaches can be considered: either build an own network and train it, or take advantage of generalist pre-trained models to perform the desired downstream task using transfer learning. The latter leverages knowledge from large datasets to improve efficiency and performance on new tasks. In our evaluation, we take AggNet, a specialized Convolutional Neural Network (CNN) model (Coenen et al., 2022) on the one hand, and perform transfer learning on pre-trained CNN models from different families on the other: MobileNetV2 (Sandler et al., 2018), ResNet50 (He et al., 2015) and finally the Vision Transformer (ViT) model ViT_16 (Dosovitskiy et al., 2020), a recent architecture using self-attention mechanisms (Vaswani et al., 2017).

In addition to leveraging transfer learning to enhance the performance of pre-trained models, we use hyperparameter optimization techniques to refine the predictions of these models. ResNet50 and MobileNetV2 are two popular deep learning CNN models that has been shown to be effective for a wide range of tasks and are relatively easy to train and fine-tune. ViT_16 is a vision transformer (ViT) that also shown to be state-of-the-art for image classification. ViT architecture models are interesting in this study because they are expected to allow a better accuracy and generalize better than CNNs (Maurício et al., 2023).

The paper is organized as follow: the next section reviews related works. Then, the two following sections introduce our methodology and our experimental setup to carry on the study for classification and regression tasks. Before concluding, we present the results of our experiments.

Related Work

Classification and granulometry tasks to determine the distribution of particle is very important not only for estimating concrete properties but for ore field in general. To avoid the need for costly manual techniques such as sieving, work has been carried out to automate the process by analyzing images of aggregates or ores. Since the emergence of deep learning, research has embraced CNN as a primary approach. A comprehensive survey on ore image processing using deep learning can be found in WANG Wei and Hao (2023), which highlights similarities to approaches employed for aggregates. The application of deep learning for aggregates can be divided into two main categories: those that start from scratch by building their own models, as seen in Lau Hiu Hoong et al. (2020), Qin et al. (2023) or Coenen et al. (2022), and those that leverage existing pre-trained models and employ transfer learning techniques to adapt them to specific tasks, such as Olivier et al. (2020). In addition to this distinction, there is another categorization based on the image processing strategy employed. The first one is to classify individual aggregate images as described in Sun et al. (2022), while the second way is to regress from images of aggregate mixtures to granulometry distributions.

In the first category, the authors of Lau Hiu Hoong et al. (2020) propose a customized Residual Network (ResNet) model and a dataset of 36'000 images of individual grains. They achieve a classification accuracy of 97% (brick, ceramic, stone, etc.). They also proposed a segmentation method to predict the nature of each grain in an image of a multi-grain sample. In Qin et al. (2023), the study is based on the concept of instance segmentation, using a specialized neural network model (AS Mask RCNN) to detect and classify individual aggregates within mixed aggregate images. The results of their study indicate that the AS Mask RCNN model achieved an accuracy of over 89.13%. The approach requires a dataset made up of images and their segmentation masks for each aggregate to be provided for each image. All these papers demonstrate the relevance of using deep learning models when calculating granulometry based on the segmentation of individual aggregates.

In the second category, where classifying and regressing are used without segmentation, deep learning has also been successfully used. In Olivier et al. (2020), the authors use the CNN architecture VGG16 Simonyan and Zisserman (2015) with transfer learning to predict the ten size fractions considered for an ore. The obtained results show the effectiveness of a CNN in predicting the size distribution of ore, with a mean model error of -0.012 and a standard deviation of 0.107. Coenen et al. (2022) presents a deep learning model, AggNet, for real-time determination of concrete aggregate grading curves. They propose a dedicated CNN network model with multi-scale feature extraction to handle diverse particle sizes and showed good results on a classification task with an accuracy of 95.5%, which is the best according to our knowledge.

We are interested in the second category of approaches because of their simplicity and industrial applicability. Once trained, these models dispense with the need for labor-intensive data preparation, allowing for direct estimation of aggregate granulometry from images. The main difficulty lies in preparing a dataset of varied aggregates images with their size distribution. Authors of AggNet published their dataset Coenen (2022) which we rely on as it meets our needs: each aggregate image is associated with its particle size distribution. We use this model as a reference for our analysis to study how it generalizes to our own dataset and to compare it to our approach which is based on adapting pre-trained models. In Coenen et al. (2023), the authors propose to use vision transformers and developed again their own model based on this architecture. They demonstrate the technical feasibility and interest of this approach. However, we believe that we can leverage the feature extraction capabilities of the pre-trained models (CNN or ViT), acquired through training on vast image datasets, and tailor them to our downstream tasks of classification and regression.

Methodology

As said in the previous sections, we compare four neural network architectures for estimating the granulometry of aggregates from images. We separate this task into two sub-tasks: the first one aim to classify the aggregates images toward the corresponding DIN 1045-2 Deutsches Institut für Normung (2008) standard granulometry class and the second one aim to directly estimate the mass percentage for each bin size considered. To perform this comparative study, we use three different datasets, two are publicly available and one is own-made.

Data

We use two publicly available datasets that contain image samples of natural aggregates: the Visual Granulometry dataset (Coenen, 2022) and the Deep Granulometry dataset (Coenen, 2023). The first one is designed for a classification task and the latter for a regression task. The Visual Granulometry dataset contains 900 images of aggregates along with their corresponding DIN 1045-2 standard granulometry class. There are nine classes in the standard (see Figure 2), each representing a grading curve, i.e. the size distribution of the aggregates. For each class, two samples of 5 kg of aggregates were produced and mixed to obtain a total of 50 images per sample, and 100 images per class.

The Deep Granulometry dataset contains 1650 images of coarse aggregate samples with different particles sizes ranging from 0.1 mm to 32 mm. Each image is accompanied by the mass percentage of each particle size bin considered, following 33 different granulometries (11 per largest grain size).

We then use a custom dataset with our own data that we use only for evaluation purposes, in order to measure the generalization of the trained models. This dataset contains 174 images of both recycled or natural aggregates from seven different sources, i.e. seven different granulometries, in an unbalanced fashion. For the classification task, we assign the DIN 1045-2 class to each of these granulometries by minimizing the mean squared error between them and the granulometry of each class. As shown in Figure 2, our grading curves can be far from the standard classes, therefore the assignation is not exact but still allows us to evaluate the model on our own data for a classification task. As two granulometries fall in the same class, we have only 6 of the 9 DIN 1045-2 classes that are represented. For the regression task, we simply report the mass-percentage for each size bin considered in the Deep Granulometry dataset.

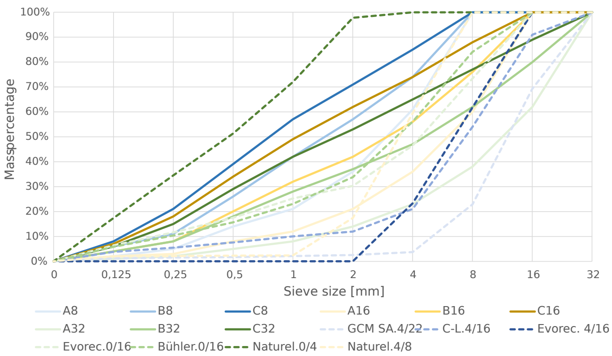

Figure 2: Grading curves of the DIN 1045-2 standard classes (solid lines) and those of our sources (dashed lines).

Since the two publicly available datasets contains images rectified by homography that were taken with a ground sampling distance (GSD) of 0.125mm, we also rectified our images in a similar way. However, as the setup was not exactly the same for all taken images, 80 of images have been cropped manually and can therefore present some deformations due to the perspective. In addition, the GSD of our images is not exactly equal to 0.125mm. These variations in our own dataset will serve to assess the generalization capabilities of the models we test. The Table 1 summarizes the size and characteristics of the two datasets used.

Neural networks

Classification, i.e. classifying images of aggregates towards the right DIN1045-2 standard class, is the first task we consider. We assume that this task is simpler than the regression one which consists of predicting the real percentage for each size bin considered. Therefore, we evaluate three CNN-based models, namely ResNet, MobileNetV2 and AggNet, as well as one ViT model. The AggNet model is a dedicated CNN model for granulometry estimation and the source code of its architecture has been made available by the authors (Coenen, 2022). The remaining three models are pre-trained models that we adapt to the granulometry estimation task using transfer learning. We then adapt and evaluate the two best performing classification models on the regression task, i.e. estimating the mass percentage for each size bin considered.

Transfer learning

As the state-of-the-art computer vision models are composed of millions of parameters, they need to be trained on large datasets. In order to adapt these models on a new task, it is often recommended to use the weights of a pre-trained model instead of training the model from scratch and risking to overfit the data. This can be done by freezing the weights of the pre-trained model and adding a new fully connected layer on top of it, which will be trained on the new task. This process is called transfer learning. In this study, we freeze the weights of the pre-trained model feature extraction layers, using it as a feature extractor, and train a new fully connected layer on top of them, as shown in Figure 3.

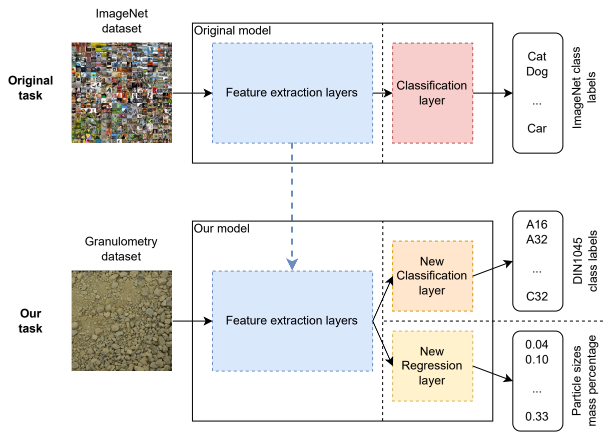

Figure 3: An overview of the transfer learning process used in this study. Feature extraction layers of the pre-trained model are frozen and new trainable classification or regression layers are added on top of them. Top image from (Deng et al., 2009).

To perform our comparative study, we use transfer learning on three pre-trained models, namely ResNet50, MobileNetV2 and ViT_16, all originally trained on the ImageNet (Deng et al., 2009) dataset.

Training

The network parameters θ are learned by optimizing a loss function $\mathscr{L}(\theta)$, which differs depending on the network task. The loss function is computed for each batch of data and the network weights are updated according to the gradient of the loss function with respect to the weights. The compared classification networks aim to classify images of aggregates towards M classes, where M is the number of DIN 1045-2 standard classes. To do so, they are

Table 1: *Summary of the datasets used.*

Dataset	Task	Size	Images size	Particles size	Nb. of classes / size bins
Visual Granulometry (Coenen, 2022)	Classification	900	2200x3000px	0-32mm	9
Deep Granulometry (Coenen, 2023)	Regression	1666	2200x3000px	0-32mm	33
Own	Both	174	1072x1472px	0-32mm	6 / 7

trained by minimizing the well-known cross-entropy loss function, defined as

$$\mathscr{L}_{CE}(\theta) = -\sum_{i=1}^{M} y_i \log(\hat{y}_i) \tag{1}$$

where y_i is the ground truth label for the i^{th} class (either 0 or 1) and $\hat{y}_i$ is the predicted probability for the i^{th} class.

For the regression task, we aim to predict the mass percentage of the M size bins considered. Therefore, the networks are trained by minimizing the Kullback-Leibler divergence, which is the same loss used in (Coenen et al., 2022). It is defined as

$$\mathscr{L}_{KL}(\theta) = \sum_{i=1}^{M} y_i \log(\frac{y_i}{\hat{y}_i}) \tag{2}$$

where y_i is the ground truth mass percentage for the i^{th} size bin and $\hat{y}_i$ is the predicted mass percentage for the i^{th} size bin.

For training, we systematically perform early stopping to avoid overfitting and use the Adam optimizer (Kingma and Ba, 2017) to optimize model weights. In order to obtain the best performances, we then perform different optimizations and evaluate their impact on a validation set before selecting the best model.

– **Data augmentation :** As the dataset used for both classification and regression are relatively small (900 to 1666 images), we perform data augmentation to allow models to generalize better and avoid overfitting on training data. This data augmentation is performed during the training, on the fly, so that it is highly unlikely for the model to see the same image twice. We test two kind of data augmentation:

1. A tuned augmentation by evaluating the model many times on different combinations of geometric transformations, such as rotation, shift, zoom or shear.
2. The augmentation proposed in paper (Coenen, 2022), performing geometric and radiometric (e.g. hue shift) transformations.

We compare the best tuned augmentation to the one proposed in (Coenen, 2022) and keep the one that performs the best on the validation set.

– **Hyperparameter tuning :** We then tune the hyperparameters of the models in order to optimize their performances. This is done by evaluating many times the model on different combinations of hyperparameters, which are the batch size, the neurons number in the fully connected layers, the dropout rate and the learning rate. We keep the combination of hyperparameters that gives the best performances on the validation set.

– **Fine-tuning :** Finally, we perform a final fine-tuning by unfreezing the weights of the pre-trained model feature extraction layers and continuing the training for a few epochs. We then evaluate if this fine-tuning improves the performances of the model on the validation set.

Experimental Setup

In order to evaluate the performances of the different models, we use an identical experimental setup for all of them. We first split the dataset into a training and test set with a ratio of 80% and 20% respectively, the latter being only used for the final evaluation of each model. Before training, the training set is further split into a training and validation set with the same ratio, allowing us to select the best model according to different configurations and to ensure its good generalization. The Table 2 summarizes the number of images used for training and evaluation for each task.

Table 2: *Number of images used for training and evaluation for each task. Evaluation is both performed on the Deep or Visual Granulometry (V/DG) datasets and on our own dataset.*

Set		Classification	Regression
Training		720	1326
Evaluation	V/DG	179	340
	Own	174	174

As the architecture of the three pre-trained models we consider are designed to take images of 224x224 pixels as input, all the images are cropped to be squared and then resized to this size. For the AggNet model, images are simply down-sampled to 550x750 pixels, keeping their original size ratio.

Figure 4 summarizes the training and evaluation procedures. More details for each task we consider are given in the next sections.

Classification task

For the classification task, we train and evaluate respectively four models : ResNet50, MobileNetV2, ViT_16 and AggNet. Hyperparameter tuning, data augmentation tuning and fine-tuning are only performed on ResNet50 and MobileNetV2, as ViT_16 showed already good performances without doing so (see section *Results and dis-*

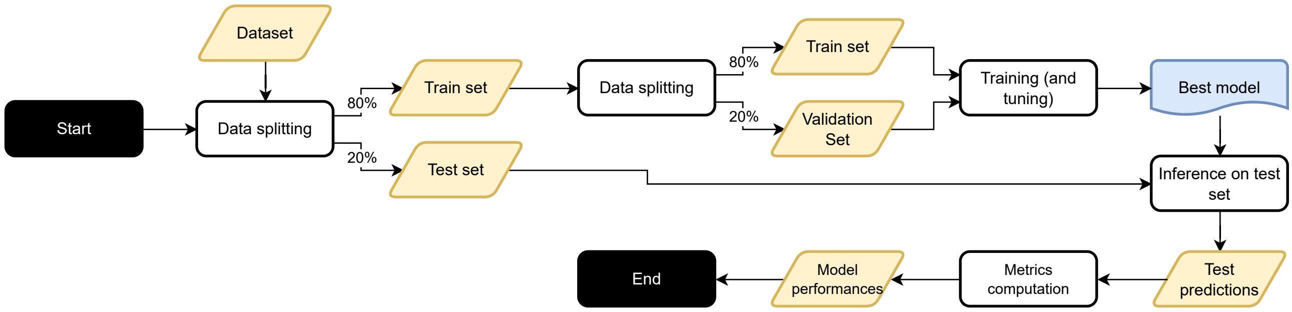

Figure 4: Training and evaluation procedure for each model architecture we compare, on both classification and regression tasks.

cussion) and as the authors of the AggNet model already performed these optimizations.
To evaluate their performances, we use the accuracy metric, defined as

$$Accuracy = \frac{\text{Number of correct predictions}}{\text{Total number of predictions}} \quad (3)$$

We also compute the confusion matrix, that allows us to see which classes the evaluated model confuses the most. It also allows us to quickly calculate other metrics per class, such as the precision, recall and F1-score.

Regression task

For the regression task, we only train the two best performing models on the classification task, namely ViT_16 and AggNet (see section *Results and discussion*). This time, we also perform hyperparameter tuning, data augmentation tuning and fine-tuning on ViT_16 in order to obtain the best possible model and see if it can outperform AgGNet. Training configuration for AggNet model is once again taken from (Coenen, 2022), while the best configuration we find for ViT is the following :

- **Tuned hyperparameters** : batch size of 64, dropout rate of 0, hidden size of 512 and learning rate of 0.007
- **Tuned data augmentation** : horizontal and vertical flip, shift range of 0.1, zoom range of 0.3 and fill mode on reflect.
- **Fine-tuning** : learning rate of 0.0001.

To evaluate the performances of each model, we use the mean absolute error (MAE) metric and the root mean squared error (RMSE) metric, defined as

$$MAE = \frac{1}{N}\sum_{i=1}^{N}|y_i - \hat{y}_i| \quad (4)$$

and

$$RMSE = \sqrt{\frac{1}{N}\sum_{i=1}^{N}(y_i - \hat{y}_i)^2} \quad (5)$$

where N is the number of predictions, y_i is the ground truth mass percentage for the i^{th} image and $\hat{y}_i$ is the predicted mass percentage for the i^{th} image. These metrics are calculated for each size bin and then averaged to obtain a single measure of model performances.
We compute the RMSE along with the MAE because the RMSE penalizes more the large errors than the MAE, and thus gives us an other important information about the model performances. We use the RMSE instead of the MSE because it is more interpretable as it is in the same unit as the ground truth mass percentage vector.

Results and discussion

We first discuss the results obtained by the different classification models, before focusing on the results obtained by the two best performing ones on the regression task.

Classification

Table 3 summarizes the performances in terms of accuracy obtained by each compared models on the two test datasets. While they all performs significantly better on the Visual Granulometry dataset, the ViT_16 outperforms the other models with respective accuracies of **97%** and **34%** on both datasets. As neither hyperparameter tuning nor data augmentation tuning were performed on ViT_16, we can assume that even better performances could be obtained by doing so. This shows how powerful transformers can be on various tasks, including computer vision tasks. The AggNet model is also performing very well on the Visual Granulometry dataset Coenen (2022), which coincide with the results reported in Coenen et al. (2022). All the models show a low accuracy on our own dataset, with accuracies ranging from 26% (AggNet) and 34% (ViT_16), showing a poor generalization of the model on the classification task.

Table 3: Performances of the different classification models on the two test sets, i.e. the Visual Granulometry (VG) and our own dataset.

Model	**Accuracy**	
	VG data	**Our data**
ResNet-50	0.85	0.30
MobileNetV2	0.87	0.29
ViT_16	**0.97**	**0.34**
AggNet	0.94	0.26

Figure 5 shows the confusion matrix obtained by the ViT_16 model on our own dataset and help to understand why models are under performing on it. As it shows high

Table 4: *Regression results on the Deep Granulometry dataset with both models. Errors are computed for each grain size bins considered and then averaged.*

Grain size bins [mm]		**0.25**	**0.5**	**1**	**2**	**4**	**8**	**16**	**31.5**	**63**	**Avg.**
AggNet	MAE [%]	0.22	1.23	1.36	0.67	1.65	1.61	1.73	1.69	0.21	1.15
	RMSE [%]	0.28	1.56	1.78	0.86	2.11	2.18	2.61	2.72	0.47	1.62
ViT	MAE [%]	0.13	0.88	0.86	0.46	0.51	0.98	0.94	0.49	0.04	**0.59**
	RMSE [%]	0.18	1.20	1.29	0.66	0.73	1.59	1.61	1.02	0.14	**0.93**

accuracy on Visual Granulometry data, we do not present here the confusion matrix obtained on this data. On our own data, ViT_16 frequently misclassifies B16 as A32 or A16, and A32 as A16, likely due to the fact that our data samples do not exactly follow the particle size distribution of the classes defined by DIN 1045. For better performances, we should add more classes instead of simply assign our sample to one of the standard classes. Analyzing ViT's regression performances on our data might be more revealing, as it predicts continuous values of the real granulometry instead of inferred discrete classes.

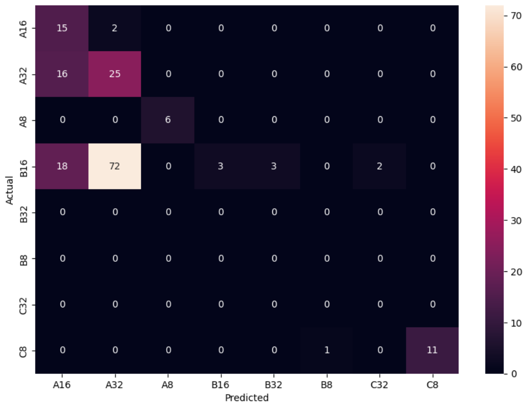

Figure 5: *Confusion matrix obtained on our own dataset with the ViT_16 model.*

Regression

Since the best models on the classification task on Visual Granulometry data are the ViT_16 and AggNet models, we only train and evaluate these for a regression task.

Table 4 first shows the results obtained by both models on the Deep Granulometry dataset (Coenen, 2023). The ViT model therefore fares better than the AggNet model, with an average MAE of **0.59%** versus 1.15%, i.e. half as much. The obtained RMSE with both models also confirmed this observation. As far as errors by size are concerned, the ViT model seems to have more difficulty in predicting proportions for sizes from 0.5mm to 1mm and from 4 to 31.5mm, as does the AggNet model. It shows that either some sizes are more difficult to differentiate than others, either the data is much more varied in certain bin sizes than others.

The worst respectively the best predicted grading curves by ViT on this first dataset are shown in Figure 6, along with the ground truth. We see that the model achieve to predict the perfect grading curve in some case, and to predict a grading curve that is still very close from the ground truth in the worst case.

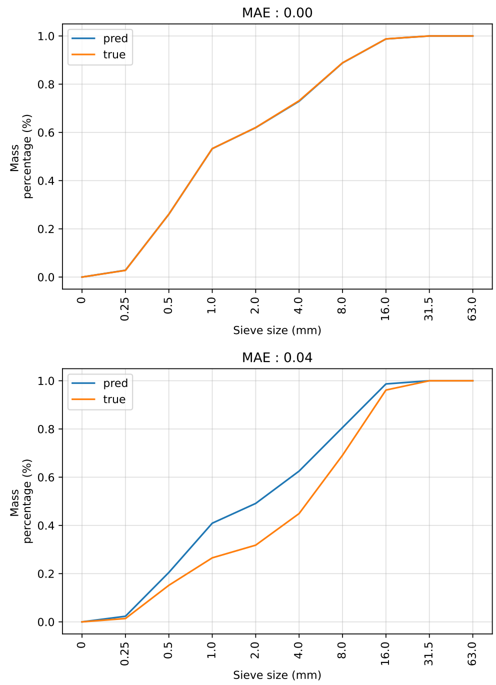

Figure 6: *Best (top) and worst (bottom) predicted grading curves (in blue) by ViT on the Deep Granulometry dataset, along with the ground truth (in orange)*

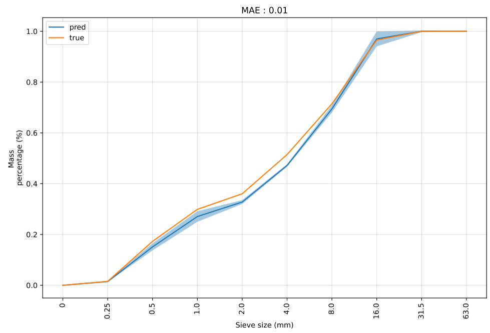

Figure 7: *ViT worst resulting grading curve (in blue) obtained by averaging predictions of a same aggregates mixture on the Deep Granulometry dataset, along with the ground truth.*

If we average predictions over samples following the same grading curve, we obtain a new prediction that is much closer to the ground truth even in the worst case, as shown in Figure 7. This shows that in a real setup where many images of the same mixture of aggregates are taken, we can predict a much more precise granulometry by averaging the predictions made by the model.

Table 5 then shows the results obtained by both models on our own dataset. The results are significantly worse than those obtained on the Deep Granulometry dataset, with an

Table 5: Regression results on our own dataset with both models. Errors are computed for each grain size bins considered and then averaged.

Grain size bins [mm]		0.25	0.5	1	2	4	8	16	31.5	63	Avg.
AggNet	MAE [%]	6.06	9.0	7.22	4.64	9.46	9.87	9.04	13.33	0.41	7.67
	RMSE [%]	10.01	9.45	7.88	5.44	10.15	12.07	11.66	15.63	0.71	9.22
ViT	MAE [%]	6.35	4.57	4.14	5.00	8.47	11.87	9.53	10.82	0.18	**6.77**
	RMSE [%]	10.22	5.28	4.98	6.21	10.76	13.82	11.44	12.97	0.29	**8.44**

average MAE of **6.77%** for the ViT model and 7.67% for the AggNet model. While these errors are similar, ViT is still able to generalize better that the AggNet model. This overall increase in errors can be explained by the difference in particle size distributions between the two datasets. Indeed, the granulometries of our dataset are significantly different from those of the Deep Granulometry dataset. As the models are trained on the latter, it is very likely that they will have difficulty generalizing to other data. In addition, some images in our dataset have not been rectified by homography, this difference in images may therefore also have an influence on model performances.

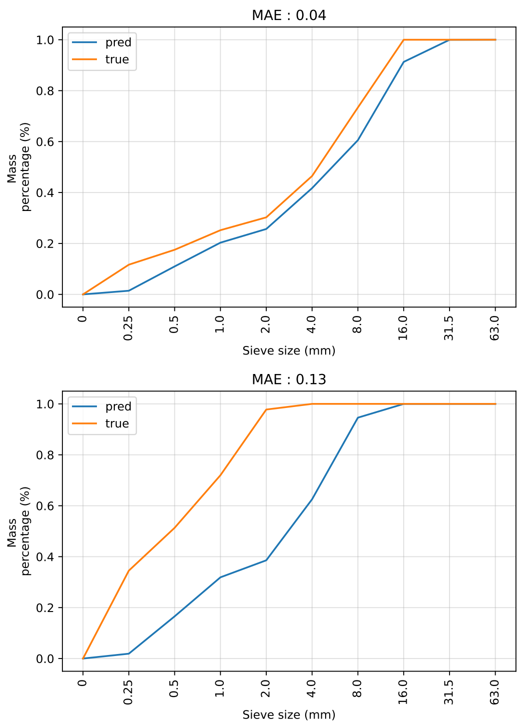

Figure 8: Best (top) and worst (bottom) predicted grading curves (in blue) by ViT on the Deep Granulometry dataset, along with the ground truth (in orange)

The worst respectively the best predicted grading curves by ViT on our dataset are shown in Figure 8, along with the ground truth. This time, we see that the model may struggled to predict a grading curve close from the ground truth, especially when aggregates follow a granulometry far from the ones the model was trained on. These results indicate that we may need aggregates training data that follows a wider range of granulometries in order to increase the generalization of the model. We can still note that for different but close granulometries, the model is able to make prediction with few errors, which is encouraging. If we average predictions over samples following the same grading curve, we achieve to reduce the MAE but still remains relatively high (11%) in the worst case, as shown in Figure 9. The need for more varied training data therefore remains.

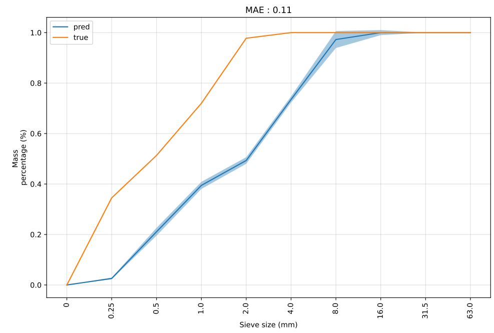

Figure 9: Worst resulting grading curve (in blue) obtained by averaging predictions of a same aggregates mixture made by ViT on our own dataset, along with the ground truth (in orange).

Conclusion

The result of our study shows that using the dedicated CNN AggNet model of Coenen et al. (2022) for the task of classification and calculation of the distribution of aggregates from their images is a better approach than performing transfer learning on the most popular pre-trained CNNs that we used: ResNet50 and MobileNetV2. On the other hand, our tests show that applying transfer learning on a pre-trained model based on transformers (ViT_16) allows to achieve better results on the two considered tasks. Iman et al. (2023) positions transfer learning as a valuable technique to unlock the full potential of deep learning. In our case, where the images are very specific and different from datasets of the pre-trained models, the smaller AggNet model, using multi-scale feature extraction layers, effectively handles the diverse aggregate sizes compared to the generalist pre-trained CNNs. This specialization likely contributes to its better performance. Similarly, ViT_16 excels in this task due to the inherent ability of transformers to capture both local and global interactions within the image, potentially explaining the advantage of ViT over AggNet.

To evaluate the generalization ability of each model, we employed our own dataset for testing. This dataset differs from the publicly available one used to train and evaluate the models in two key ways. Unlike the public dataset, it includes both natural and recycled aggregates and it presents different aggregate size distributions. Again, we obtained better results with ViT_16, which reinforces the idea of deepening this approach to improve its adaptability to datasets that do not perfectly follow the granulometry of the training data. While the current results of this generalization are not optimal, we believe incorporating a subset of our own data into the training set has the potential to significantly improve model performance.

Therefore, our next future task is to enlarge our own dataset in order to cover a greater variety of grading curves. Besides, our dataset is currently imbalanced, and we aim to achieve a balanced distribution with at least 100 images per class. While this imbalance was not a disadvantage for the present study (used for testing only), it needs to be addressed to determine the best strategy for ViT_16 generalization. We will explore two options: fine-tuning the model on a subset of our own data or reapplying transfer learning with hyperparameter tuning incorporating this subset into the training dataset. Our goal is also to identify the optimal dataset size that maximizes the generalization performance of the ViT model for granulometry estimation.

Acknowledgments

We are thankful to Daia Zwicky, Julien Ston and Sonia Anselmina from iTeC institute of HEIA-FR (Institut des Technologies de l'Environnement Construit) for the preparation of our own dataset.

This research was partially supported by a grant of the Programme de recherche HEIA-FR / Smart Living Lab (AGP:119149).

MACHINE LEARNING MODEL PREDICTION OF PROJECT SUCCESS

K. Moravej, S. L. Laroche, and S. M. Musick
Canadian Nuclear Laboratories, Chalk River, Canada

Abstract

Managing projects can be challenging with institutionalism and enterprise environments. Artificial Intelligence can be used to augment decision-making by enhancing the understanding of "drivers" enabling project performance. Research was performed to determine if a supervised machine learning (ML) model could predict the project's performance at fiscal year end, utilizing mid-year information. Enterprise Data, from annual performance data was used to train and evaluate several ML models. The results are promising, and indicate the potential of identifying projects that require monitoring at mid-year. Organizations could use a similar methodology to support decision-making and focus on the highest-value projects with predictable outcomes.

Introduction

The tendency for an organization to manage projects with the determination to drive successful outcomes can be challenging with institutional dynamics and enterprise environmental factors. Decisions to initiate, continue, or stop projects are frequently based on short-sighted assumptions, such as flawless implementation of processes and "as planned" project execution. These assumptions often result in risks that are realized where projects require longer durations to complete and at higher costs, a study found up to a 38% extension in schedule duration and an increase in the original budget of up to 45% (Chandrasekaran, et al., 2021).

To help mitigate these risks, new and evolving tools, approaches, and methodologies are being applied to enable decisions earlier. One such tool is ML. When augmented with an organization's Enterprise Data, ML will enhance the project teams' awareness and understanding of the "drivers" enabling project performance.

An agile organizational change management approach is critical to the success of implementing any ML model. Primarily, this approach is directly associated with the tendency of an organization to have complex data environments that do not readily lend themselves to direct integration between systems with the ever-changing enterprise environment, (Bou Hatoum, Nassereddine, Musick, & El Jazzar, 2023). However, it is essential that the exhaustive amount of data being generated daily throughout the project lifecycle is captured using a holistic framework that enables collaborative access by decision makers (Hatoum, Piskernik, & Nassereddine, 2023).

The development of new tools for project management is evident as industry continues to invest in projects with only 35% of these projects being considered successful (Nieto-Rodriguez & Viana Vargas, 2023). Projects management activities continue to rely on traditional tools, such as spreadsheets and slides. Artificial Intelligence (AI) can be used to leverage the existing information in enterprise systems to reveal trends earlier and enable better selection and prioritization of projects.

A Gartner Survey reported that 37% of organizations had implemented AI in some form by 2019, increasing 27% from the previous four years (Costello, 2019). This increasing trend to use AI has continued with the availability of commercial off the shelf items that integrate AI into their service offerings.

In this project, the application of ML in project management was investigated. A research initiative was undertaken to determine whether a supervised ML model could accurately predict the probability of project success. This research aimed to illustrate that organizations could enhance their project management methodologies by integrating their own model designs with existing approaches. The initiative utilized Enterprise Data, incorporating annual project performance data from almost 700 projects over a five-year period. These projects were labelled with binomial project identifiers, such as "On Track" or "Monitor Performance", determined from prescribed cost and schedule performance indices success criteria ranges. The outcomes from the labelling effort were then used to train the ML model algorithms.

This research sought to determine how the trained model classifies each project, by evaluating the explain-ability of the ML model. These results furthered the understanding of the behavior of ML models and revealed that after six months, cost and schedule performance indices were lead indicators in predicting project success.

The ML model, designed under this research initiative, provided advanced insights into project performance ahead of project completion. This additional insight provided management with additional information to determine if the project should proceed, and a firm foundational technique that other organizations can use to leverage ML. Once implemented, organizations would be able to weigh project benefits while supporting decision-making process through the gating and sanctioning process, focusing on the highest value projects with predictable outcomes.

Objective

This project aims to explore the feasibility of designing a supervised ML model capable of predicting the project's status at the end of the fiscal year, utilizing the information accessible during the mid-year point. To achieve this objective, the following steps were taken:

- **Data Source:** Identify and extract relevant data sources from the company's database.
- **Data cleaning and Processing:** Evaluation, cleaning, and preprocessing of the extracted data to prepare it for ML model training.
- **Model Training and Evaluation:** Training, tuning, and evaluating ML models using the prepared dataset.

Data Sources

The identification of suitable enterprise data is a critical step when starting to develop the ML model. A complete understanding of the data is important in determining what is possible or not based on the data available and its quality.

A review of historical project data identified three types of data sources to serve as project information with similar characteristics. These data sources were Project Data (including Earned Value Management System (EVMS) Data), Milestones, and Deliverables. The Milestones and Deliverables datasets are crucial tools for project management as they contain information about each project's ability to achieve the desired outcomes. The enterprise data was consolidated into a single location, or a dataverse, as shown in Figure 1. This process required the careful integration of data from all sources, rigorous data cleaning, and preprocessing steps to remove irrelevant data points. Data consistency was ensured across all sources by standardizing the data format and aligning the data fields.

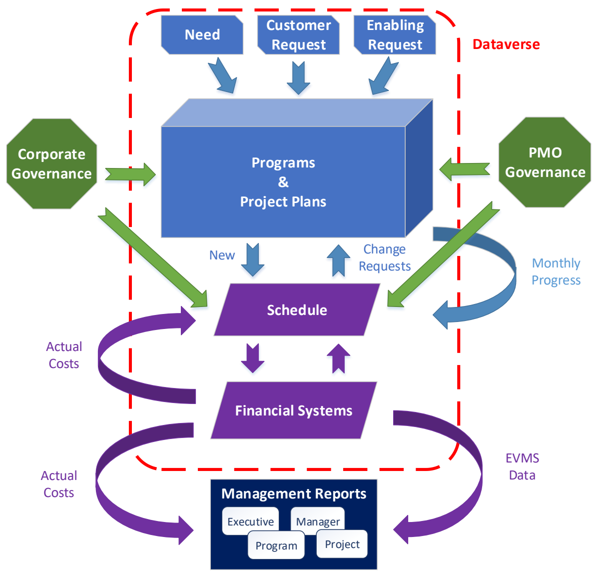

Figure 1: Dataverse contents

The extracted dataset consisted of nearly 700 projects spanning a five-year timespan, with multi-year projects included for every year of their duration. Figure 2 illustrates the number of projects for each fiscal year.

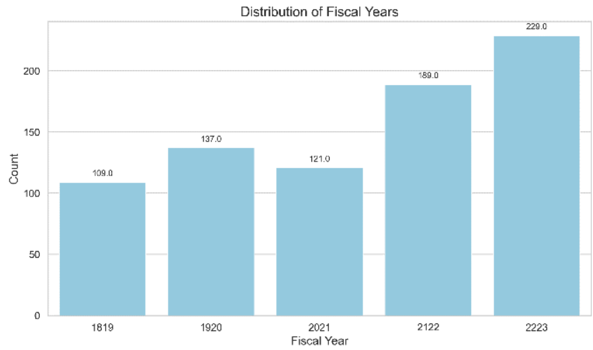

Figure 2. The number of projects for each fiscal year. The horizontal axis represents the fiscal year, where, for example, "1819" corresponds to the fiscal year 2018-19, and "2223" corresponds to the fiscal year 2022-23.

Table 1 summarizes the types of information available for each project and included free text, categorical, and numerical. This project information served as input to the ML model after appropriate pre-processing and is referred to as project input or indicators in this paper.

Table 1: Information available for each project.

Free Text	Categorical	Numerical
WorkPackage_Title Project Description Project Objective Background Tasks details Milestone details Deliverable details Etc.	fiscalyear Program, Program Manager Theme_Name, SubTheme_Name Project Lead Principal Investigator planned employees actual employees Etc.	BurdenedCost April-March EVBurdened April-March PVBurdened April-March ACBurdened Etc.

Data cleaning and Processing

The resulting structured dataset was designed for ML by ensuring the data was well-formatted, consistent, and complete. All dataset fields were retained during this phase to determine which fields should be used as inputs for the ML model. This decision ensured that all potentially useful information was available for analysis and optimization of the ML model's performance. Several appropriate feature engineering and pre-processing techniques, such as normalization, scaling, encoding of categorical data (Müller & Guido, 2016), text preprocessing, and topic modeling (Tong & Zhang, 2016) using natural language processing (NLP) were implemented.

Project Success Indicators

Labelled data is required to train a supervised ML model. To classify the projects, a success metric was established and each project tagged with the appropriate label. The project data could be classified as either "On Track" or "Monitor Performance".

The criteria for labelling the dataset were determined based on Project Management Office governance and annual Cost and Schedule Performance Indices, SPI, and CPI. These indices were used to label the historical project performance data which could then be used to train the supervised ML model. Table 2 shows the metric used for labeling the projects. For example, if the project's CPI at the end of the fiscal year is 0.98, that project is labeled as "On Track," and if the CPI at the end of the year is 1.25, the project is labelled as "Monitor Performance." The same idea has been applied to label each project based on the SPI metric. This approach provided two labels for each project: one based on the CPI and the second one based on the SPI performance.

Table 2: The CPI and SPI thresholds for labelling projects.

Metric	Threshold	Label
CPI & SPI	0.95 ≤ metric < 1.2	On Track
CPI & SPI	metric < 0.95, metric ≥ 1.2	Monitor Performance

Model Training and Evaluation

Given that CPI and SPI are distinct variables driven by dynamically different factors, two separate models were created. The first model was formulated to predict the CPI label at the end of the year, while the second model concentrated on predicting the SPI label. The input parameters for both models remained consistent with only the target variable being different between the two models. For the SPI model, the target variable is the SPI label, while for the CPI model, the target variable is the CPI label.

To ensure a fair evaluation of our model's performance post-training, the data was divided for each model into a training dataset (75%) and a test dataset (25%). This dataset split was organized to preserve a similar ratio of monitor performance and on-track instances in both the training and validation sets. Subsequently, the ML model underwent training using the training set and performance evaluation using the test datasets—essentially, unseen data—during the training phase. This approach serves as a reliable indicator of the ML model's effectiveness and performance.

Multiple ML models have been trained to investigate their performances on our dataset. In this paper, the Decision Tree (Charbuty & Abdulazeez, 2021), Random Forest (Parmar, Katariya, & Patel, 2019) and XGBoost (Chen & Guestrin, 2016) models were used to evaluate the suitability.

The hyperparameters of each model were tuned using the K-Fold cross-validation technique (Gupta, Gupta, Kumar, & Sardana, 2021). K-Fold cross-validation is very important in ML development and hyperparameter tuning, especially when dealing with a small dataset. This method improves model performance and robustness while optimizing hyperparameters for better generalization. We adjusted the hyperparameters of our models using the F1 score which is defined as:

$$F1 = 2 * \frac{(Precision * Recall)}{(Precision + Recall)} \quad (1)$$

where, precision measures the proportion of true positive predictions out of all positives and recall measures the proportion of actual positives correctly predicted by the model. Precision and recall are defined as:

$$Precision = \frac{TP}{TP + FP} \quad (2)$$

$$Recall = \frac{TP}{TP + FN} \quad (3)$$

where,

- *True Positives (TP)* are the number instances that are correctly predicted as positive by the model.
- *False Positives (FP)* are the number of instances that are incorrectly predicted as positive by the model when they are actually negative.
- *False Negatives (FN)* are the number of instances that are actually positive but are incorrectly predicted as negative by the model.

These metrics are determined by comparing the actual and predicted labels generated by the trained model.

Model evaluation and comparison

Recall was prioritized for the Monitor Performance class when evaluating the performance of each model. This prioritization is because the primary goal is to identify and flag all projects belonging to this class, while being less concerned if some flagged instances designated as Monitor Performance, turn out to be On Track. Table 3 summarizes the performance of different models on our dataset for CPI label prediction, and Table 4 summarizes the performance of different models for SPI prediction.

Table 3: The performance of different models on test data set for CPI label prediction.

	Monitor Performance			On Track		
	Precision	**Recall**	**F1**	**Precision**	**Recall**	**F1**
Decision Tree	0.69	0.69	0.69	0.56	0.57	0.56
Random Forest	0.74	0.85	0.79	0.72	0.57	0.64
XGBoost	0.74	0.77	0.76	0.66	0.62	0.64

Table 4: The performance of different models on test data set for SPI label prediction.

	Monitor Performance			On Track		
	Precision	**Recall**	**F1**	**Precision**	**Recall**	**F1**
Decision Tree	0.72	0.58	0.64	0.51	0.66	0.57
Random Forest	0.80	0.79	0.79	0.69	0.70	0.70
XGBoost	0.76	0.77	0.76	0.65	0.63	0.64

Table 3 and Table 4 show that for both CPI and SPI, the Random Forest model outperforms other models, reasonable in both Recall and Precision metrics for the 'Monitor Performance' class. XGBoost also demonstrates reasonable performance, with its results closely aligning with those of the Random Forest Model.

The models were also compared in terms of computational costs and the results are summarized in Table 5. The models were trained and tested on a Windows laptop with an 11th Gen Intel(R) Core(TM) i5-1145G7 processor running at 2.60GHz and 16.0 GB of RAM. Table 5 shows that XGBoost is the most expensive one during the training phase and Random Forest is the most expensive one during the test phase.

Table 5: The computational cost of different models.

	Train time (s)	Test Time (s)
Decision Tree	0.003	0.0004
Random Forest	0.266	0.022
XGBoost	0.495	0.008

Performance Factor Importance

This initiative aimed to investigate how the trained Random Forest model classifies each project and determine which project input/performance indicator holds the highest contribution or importance in the prediction of the Random Forest model. This approach is known as feature importance (Menze, et al., 2009) in the ML community. Figure 3 shows the top ten project indicators in terms of importance in the prediction of Random Forest Model.

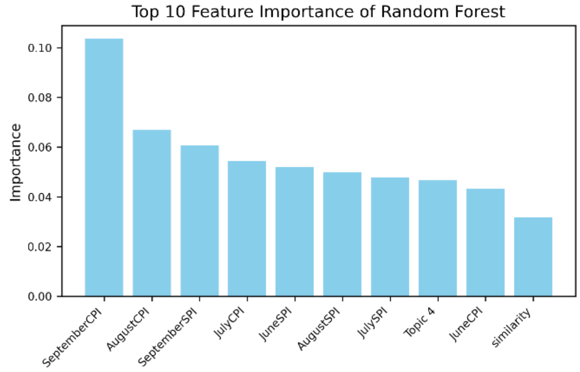

Figure 3: Importance of Performance Indicators for CPI model.

Figure 4 displays the top 10 project inputs in terms of their importance and impact on the Random Forest ML model for predicting the CPI label. This assessment revealed that mid-year cost performance holds the highest significance. Schedule performance had a comparatively lower significance, which can be attributed to the flexibility in the delivery approach, allowing for adjustments to recover the schedule.

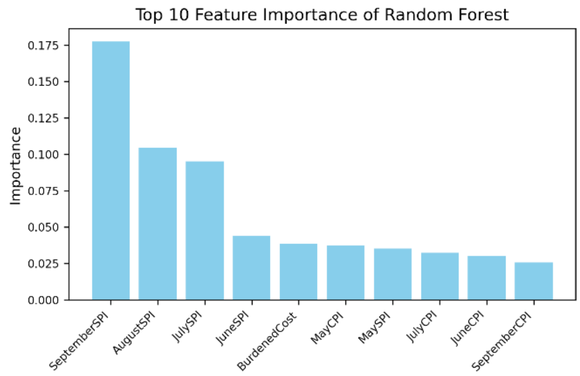

Figure 4: Importance of Performance Indicators for SPI model.

Figure 4 illustrates the top 10 project inputs in terms of their importance and impact on the Random Forest ML model for predicting the SPI label. Results showed that mid-year SPI is more important than other project inputs. Following September, August, and July SPI, Burdened Cost and mid-year CPI emerge with the highest importance.

Methodology for Implementation

Two separate models were designed and optimized, one for CPI and one for SPI, to predict the project status at the end of the fiscal year, utilizing information available at mid-year. Both the CPI and SPI models independently labeled each project, resulting in two labels for each project: one based on outcomes from the Cost model and another from the Schedule model (refer to Table 6). Subsequently, the results were consolidated into a single outcome per project for review by the project team and decision-makers. The classification methodology used is outlined in Table 6.

Table 6: Labelling methodology based on the outcome of CPI and SPI models.

CPI Model Label	SPI Model Label	Resultant
On Track	On Track	Project on Track
Monitor	On Track	Monitor Cost Performance
On Track	Monitor	Monitor Schedule Performance
Monitor	Monitor	Project at Risk

Conclusions and Discussion

In this project, multiple ML models were developed to predict the project's status at the end of the fiscal year based on the information available at mid-year. The results are promising, and testing the models indicates that we can potentially identify projects that need monitoring at mid-year. However, it is important to acknowledge that, due to the complexity of factors affecting project management, achieving perfect precision and recall with such an application is inherently impossible. This highlights the need for a balanced approach in interpreting and applying the model's predictions in practical scenarios.

The ML model designed under this research initiative, provided advanced insights into project performance ahead of project completion. This additional insight provided management with additional information to determine how to proceed with the project, and a firm foundational technique that other organizations can use to leverage ML. Once implemented, organizations would be able to weigh project benefits while supporting the decision-making process throughout the gating and sanctioning processes while focusing on the highest value projects with predictable outcomes. Using a ML model as part of enabling a more powerful framework for monitoring project performance, the following prospective outcomes can be inferred:

- Stabilizing a central dataverse to house all project performance data is critical to enabling a ML model for projects of any scale or complexity.
- Ability for a more robust determination on which projects should proceed during the gating and sanctioning process from a fulsome understanding of the true as-is condition based on current performance and the potential for a project's future success.
- Project teams will be able to more readily see and understand where and how their optimism bias is impacting the overall performance of the project.
- Actionable forecasted intelligence on where the project team's efforts should be focused to correct the predicted outcome.
- Business decisions can be made with greater confidence while projects are evaluated more closely earlier on.

These findings from this research furthered the idea that organizations can use ML to support project management activities with project outcomes and can be predicted after capturing six months worth of project performance data. Further, cost and schedule performance indices were viable leading indicators in predicting project success when utilizing the earned value management system.

Despite the simplicity of this model, it is anticipated and expected that the subsequent steps and implementations for leveraging ML within an organization would be dramatic and exponential. The foundational needs and designs required to establish this simplistic model will enable many future avenues to explore to further enhance predictable project execution.

Acknowledgments

The authors would like to acknowledge the support during the execution building, testing and documenting the results from the ML model from Ashlea Colton, Catalina Anghel, Larkin Mosscrop, Jesse Rhodes and Bryan Simpson.

SCALABILITY IN BUILDING COMPONENT DATA ANNOTATION: ENHANCING FAÇADE MATERIAL CLASSIFICATION WITH SYNTHETIC DATA

Josie Harrison[1], Alexander Hollberg[1], and Yinan Yu[1]
[1]Chalmers University of Technology, Gothenburg, Sweden

Abstract

Computer vision models trained on Google Street View images can create material cadastres. However, current approaches need manually annotated datasets that are difficult to obtain and often have class imbalance. To address these challenges, this paper fine-tuned a Swin Transformer model on a synthetic dataset generated with OpenAI's DALL-E and compared the performance to a similar manually annotated dataset. Although manual annotation remains the gold standard, the synthetic dataset performance demonstrates a reasonable alternative. The findings will ease annotation needed to develop material cadastres, offering architects insights into opportunities for material reuse, thus contributing to the reduction of demolition waste.

Introduction

Demolition waste from construction and renovation activity is a growing problem internationally, making up 25%-30% of all waste generated in the EU (Anastasiou et al., 2014). There is a general consensus that current practices have room for improvement for diverting and recovering materials from demolition waste (Kabirifar et al., 2020).

Recovering demolition waste is not a common activity in many countries because there remain limitations that practitioners currently face. Not having insight into the availability of which specific materials will be available and at what time is often identified as a top barrier (Akanbi et al., 2020). The planning of projects that could use recovered materials typically begin several years before the actual construction begins. A material cadastre that maps detailed building material information for every building at the scale of a country with an estimate of when the materials could become available would significantly alleviate the current time window bottleneck.

Because of the significant potential of this solution, several researchers have turned their attention to developing city-scale material cadastres with computer vision models trained on images of building exteriors (Raghu et al., 2023; Arbabi et al., 2022). A top pain-point in developing these models is acquiring the training data necessary for machine learning (ML). For deep learning models, some practitioners say that the size of training data should be 10x the number of weights in a network (Baum and Haussler, 1988)—often leading to six figure digits and more.

Additionally, because the type of material is not known before the GPS coordinates are requested to collect training data, this process can lead to some materials (i.e. classes) having higher counts than other classes—also known as class imbalance. ML practitioners try to avoid class imbalance because a ML model will place importance on a class that has a higher chance of occurring in the training data. For example, if brick is the most common material in the training data, then the model is likely to predict brick when deployed in a real-world situation. This effect can be negligible if brick actually is the most common material in a city, but it is preferable to assume equal class counts since the true distribution of materials in a city is unknown.

The scale achieved by previous studies has been at the scale of a city; however, the blue sky vision for a tool like this would be at the scale of a country. This would mimic current practices of sourcing materials while staying within the bounds of maximum distance for a recovered material to travel before its sustainability benefits become negligible (Ginga et al., 2020). There is some truth to the logic that if a model works at the scale of a city then it should have similar performance at the scale of a country; however, previous studies have identified that several problems can arise when scaling an image classification task (Maggiori et al., 2017; Perronnin et al., 2010; Hendrycks et al., 2022). For example, wood siding can take on different colours and textures in different cities since it is often a regional material, but an image classification model may struggle to perform well if it hasn't been trained on wood with a particular colour. Because it's impossible to foresee all potential quirks that may arise with a given use case, it's important to move beyond proof-of-concepts at the scale of a city and demonstrate that the model maintains reasonable performance at the scale of a country.

Furthermore, it would be desirable to test an image classification model's performance on residential and office interiors since this layer of a building typically has a high rate of change, resulting in a potentially high yield of reusable renovation waste. However, obtaining large and diverse datasets of building interiors can be challenging because of privacy concerns, data access limitations, and the labor-intensive process of data collection and annotation. As a result, public datasets for this task are limited in size, diversity, and representativeness, which may not fully capture the complexity and variability of real-world interior environments. Addressing the scarcity of this type of dataset could unlock an important layer in the quest for creating country-wide material cadastres.

Therefore, the aim of this paper is to investigate the potential of using synthetically generated images to augment and extend previous research done to classify façade materials in Google Street View (GSV) images. More specifically, the research questions that this paper addresses are:

1. What are the impacts on an image classifier's performance when correcting the class imbalance of a manually annotated dataset with synthetic data?
2. Is the error distribution of an image classifier trained exclusively on synthetic data comparable to a classifier trained on manually annotated data when both are evaluated on a manually annotated test set?
3. Does a model trained and tested only with synthetic data have a similar error distribution to the manually annotated dataset?

The results from these research questions make several contributions to the field of urban mining for material cadastres. To the authors' best knowledge, no previous studies have utilized synthetic images that mimic GSV images for augmenting and extending an image classification model to detect façade material. As a result, we present a novel approach to reduce the amount of time needed to develop a training dataset for the classification of façade materials, as well as provide an indication of the potential to use synthetic images to create datasets that would otherwise be difficult to obtain. Additionally, we present two methods to decrease errors in the current approaches: utilizing a higher resolution model by reducing the problem space and augmenting a manually annotated dataset to correct class imbalance. The workflow developed in this research can be extended to detect façade materials that have no manually annotated training data and the workflow can be used to improve performance of the current state-of-the-art for this specific use case.

Background

Material stock datasets

In 2023, researchers from ETH Zurich published the first urban-scale ground truth dataset—hereon referred to as the Urban Resource Cadastre (URC) dataset—to detect façade materials in Tokyo, New York City, and Zurich (Raghu et al., 2023). The researchers collected this data by first identifying GPS coordinates of interest, requesting the corresponding GSV image for these GPS coordinates, and manually annotating all resulting images. This dataset contains 971 annotated 400x600 pixel images with the labels 'brick', 'stucco', 'rustication', 'metal', 'siding', 'wood', 'null' (for images with no façade), and 'other' (for façade material that did not belong to any of the other labels). However, the authors noted that collecting this type of dataset can easily become a time-consuming process.

Generating images for training data

In recent years, there were significant developments with synthetic images generated for the purpose of training downstream models. Research in this area is often fueled by use cases where acquiring more data is time/cost prohibitive, it is necessary to mask personally identifiable information for privacy, or it is not possible to collect data at all (Man and Chahl, 2022). There exists a wide variety of generative text-to-image models; however, it has recently been accepted that diffusion models outperform previous text-to-image generative models. Inspired by non-equilibrium thermodynamics, diffusion models replicate the diffusion process observed in physics by teaching a deep learning model to add and reverse noise in images (Sohl-Dickstein et al., 2015).

The lack of diversity within a synthetic dataset is a known limitation associated with generating images for training models. To overcome this, He et al. (2023) used "language enhancement" to add variety to the prompts given to the generative model while also using a filter to discard images that didn't resemble the target image. The "language enhancement" involved using a simple keyword-to-sentence Natural Language Processing (NLP) model based on the T5 model (He et al., 2023) to make sentences from keywords. This method to diversify the generated output is prone to straying far from the desired image, however. To counteract this effect, He et al. (2023) proposed a "CLIP Filter" that leveraged CLIP zero-shot classification confidence. However, the authors aimed to create a fully automated process, which could be excessive for use cases where there is enough value in just generating synthetic images alone—which is this paper's use case.

Façade materials with high reusability potential

At this point, it becomes apparent that we should justify the selection of specific façade materials for the synthetic generation of images. For example, there exist buildings built with ETFE plastic bubbles, but since these projects are rare, their inclusion in a training dataset would confuse a ML model. While research in the area of the reusability potential of specific building materials is rather sparse, Icibaci (2019) and Iacovidou and Purnell (2016) identified stone with lime-based mortar, curtain walls, and concrete panels as materials with high reusability potential—hereon referred to as the High Reusability Potential (HRP) labels.

Image classification

Originally developed for NLP tasks (Vaswani et al., 2017), vision transformers (ViTs) are deep learning models that take an image separated into patches (with its positional information saved), encode these patches into a memory, and compare that memory with a target value (Dosovitskiy et al., 2020). The memory is created with 'attention', which maps all the patches to each other to establish relative importance between them all (Vaswani et al., 2017). The Swin Transformer is a variant of the ViT methodology, which has shown to outperform many other models on image classification tasks while also being conscious of computational efficiency (Liu et al., 2021).

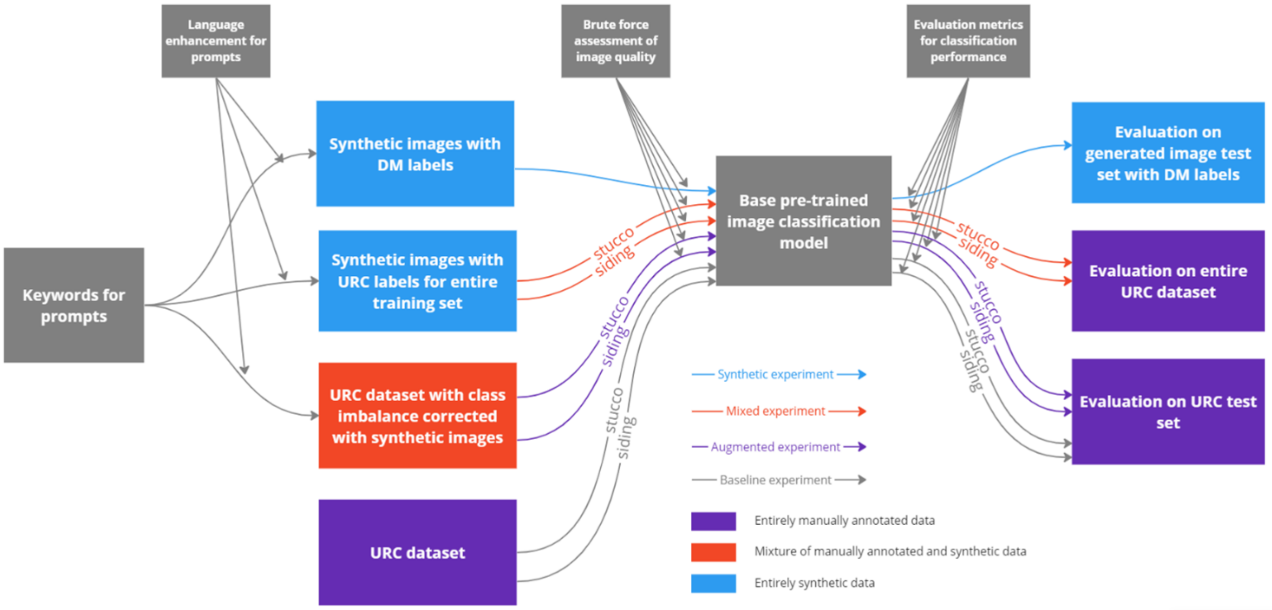

Figure 1: Workflow showing all four experiments: baseline, augmented, mixed, synthetic with sub-experiments for stucco and siding.

Experiment

Workflow

The workflow shown in Figure 1 assembled all materials and methods together into four experiments. There are three main experiments compared to a baseline experiment: augmented, mixed, and synthetic. For each experiment, a pre-trained image classification model was fine-tuned with the respective dataset, with synthetic images first passing through a brute-force image quality evaluation. After model training, the predictions were evaluated on the experiment's test dataset. The synthetic experiment's test set is entirely synthetic while the other three experiments use a manually annotated test set.

Materials

Drawing on previous research, four datasets (baseline, augmented, mixed, and synthetic) were collected for the purposes of training an image classification model to replicate previous work and to also train a model on unseen labels. The baseline, augmented, and mixed datasets used the URC labels, while the synthetic dataset used the HRP labels. For the augmented, mixed, and synthetic experiments (shown in Figure 2), varying amounts of 512x512 pixel synthetic images were generated. This resolution was suitable for image classification models that can be trained on consumer-grade hardware.

For the baseline, augmented, and mixed experiments, the number of labels was reduced to three to create sub-experiments: null, other, and one label of interest in order to reduce the parameter space of the image classification model. 'Stucco' and 'siding' were isolated as two labels of interest because 'stucco' had a similar class distribution as the 'null' and 'other' labels, and because 'siding' had a high class imbalance in the original dataset. Therefore, there were two sub-experiments for the baseline, augmented, and mixed eyxperiments using two sets of labels:"null, other, stucco" and "null, other, siding". As mentioned earlier, the URC dataset came with class imbalance, so the augmented experiment corrected this class imbalance with synthetic images. The mixed experiment used only synthetic images for training while leaving the entire URC dataset as the test dataset. Finally, the synthetic experiment trained and tested entirely on synthetic images using the HRP labels: 'stone', 'curtain wall', and 'concrete panels'. The synthetic experiment dataset size was made to match the mixed stucco experiment's dataset set to maintain comparability.

Methods

There are several open source versions of diffusion models that are capable of creating synthetic images; however, the effort required to get them into an operational state can often be time-prohibitive while also requiring intensive hardware. For that reason, OpenAI's DALL-E 2 model was chosen to generate images because it is the most effective to leverage with just a simple API request. A portmanteau of the famous surrealist artist Salvador Dalí and the Pixar character WALL-E, DALL-E takes in a user defined text prompt to create highly realistic images. The DALL-E 2 text-to-image generation model was trained on 650 million images (Ramesh et al., 2022); however, OpenAI does not disclose the source of training data for any of their models (Jiang et al., 2023). To reduce this dependency on an external organization, it would be ideal to develop an open source model in-house, however.

A limitation of generating synthetic GSV images was the inability for DALL-E to create believable images with more than one façade material. Other researchers found similar difficulties when requesting more than three components with descriptions about shape or colours (Marcus et al., 2022). Additionally, it was possible to utilize

Figure 2: Class distributions for the different datasets.

a higher resolution image classification model by reducing the label set to one material of interest combined with the ‘null’ and ‘other’ labels. For these reasons, it was decided to generate images with one label. Since this paper’s use case would not require predicting several labels in real-time, it is proposed that the implementation would require several models with each model focusing on one label (as well as the non-buildings and other materials).

As mentioned earlier, there was enough value in creating the synthetic images alone to not utilize a fully automated filtering process. Therefore, a brute force version of this process was suitable. This brute force method shown in Figure 3 involved generating a collection of prompts from keywords, generating a few hundred images by randomly sampling a prompt from the collection, manually removing irrelevant images from the final dataset, and taking note of the few prompts that were likely to produce the best images. The remaining dataset was generated using this final collection of ‘high batting average’ prompts.

To achieve a classification model that can perform at the scale of a country, it is desirable to encourage diversity in the synthetic images by injecting additional keywords into the prompt. For this experiment, the facade material label was given possible synonyms, a time period when the façade material was likely to be common, and cities where the facade material can be found. However, these keywords could be extended to any aspect of a building, such as type, size, or neighbourhood density. For example, ‘siding’ was assigned the synonyms ’shiplap’, ’feather edge’, ’fiber cement’ and the time period ’20th century’. For all labels in the augmented and mixed experiments, the original URC dataset cities (New York City, Zurich, and Tokyo) were used as keywords. For the synthetic experiments, the cities ’Vancouver’, ’San Francisco’, and ’Amsterdam’ were chosen arbitrarily but would benefit from additional cities in future experiments.

For the image classification task, it was decided to use a Swin Transformer model pre-trained on the ImageNet-21k dataset to maximize comparability to previous studies and to leverage a well-known image classification model. A pre-trained image classification model is trained on a large generic dataset with the intention to later ’fine-tune’ the ’head’ of the model on tailored datasets. This method generally improves accuracy and reduces the need for a large tailored dataset. The ImageNet-21k dataset is commonly used for pre-training because it is 14 million images with 21,000 labels and contains a variety of natural images. Raghu et al. (2023) achieved a macro-averaged F1 score of 0.93 by applying the pre-trained Swin Transformer v2 model to the URC dataset. However, the authors used the model version with a resolution of 192 pixels, which was not adequate for the synthetic image dataset. It was seen that the synthetic images struggled with creating the same texture detail as real images, and this data loss was compounded when used with a low-resolution model. This is akin to taking a photocopy of a photocopy. Therefore, the experiments in this study use the Swin Transformer v2 model with 384 pixel resolution.

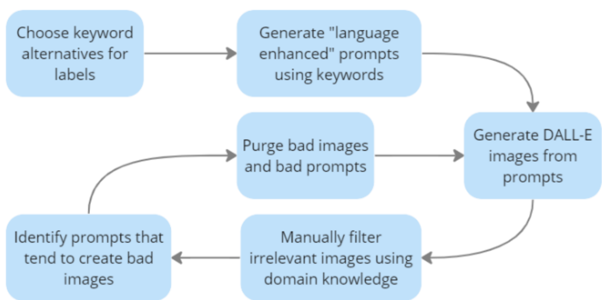

Figure 3: Brute force method to filter irrelevant synthetic images from accepted images.

To provide a quantitative and objective measurement of the image classification performance, it was decided to calculate the weighted F1 score, precision, recall, as well as create a receiver operating characteristic (ROC) graph and confusion matrices for each experiment. The confusion matrix is a grid of all target labels with the y-axis representing the true test values and the x-axis representing the predicted test values. In this way, it’s possible to index how many samples were predicted for a specific label: the first cell in the grid shows the number of samples predicted as 'null' were correctly classified. It is not possible to decide which dataset performed the best by looking at these confusion matrices, however, so quantitative metrics were calculated: precision and recall.

$$precision = \frac{tp}{tp + fp} \tag{1}$$

$$recall = \frac{tp}{tp + fn} \tag{2}$$

Precision (1) refers to the likelihood that a prediction will be correct, while recall (2) refers to the likelihood that all samples will be correctly classified. In its basic binary form, the precision is the true positives (tp) divided by all samples marked as positive ($tp + fp$) (2). Similarly, the recall formula (2) divides the true positives (tp) by the sum of true positives and false negatives ($tp + fn$). The F1 score (3) provides a harmonic mean of both precision and recall.

$$F = \frac{2 * precision * recall}{precision + recall} \tag{3}$$

When working with multi-class problems, it is necessary to choose an averaging mechanism for the F1 score, precision, and recall metrics. The 'weighted' average is recommended for imbalanced classes because it assigns different weights to each class based on their prevalence in the dataset. This prevents the dominant class from strongly influencing these metrics.

Lastly, the ROC curve graph was created to visually compare the performance of all four experiments. In this study's context, the ROC curve can be used to visualize the characteristics of the performance; at what threshold between the true positive rate and false positive rate the model becomes uncertain about its predictions.

Discussion and result analysis

Image generation

As with many NLP models, the generated prompts contained a fair amount of hallucination; however, these nonsensical prompts surprisingly created some of the best images. For example, a successful prompt for the 'stone' label was, "The construction of building made of stone is in the medium of the Artistic Gymnastics." It was valuable to refrain from editorial oversight of the initial prompts to allow for spontaneity in the generated images. Because of this, the resulting datasets had more diversity than if one prompt created all the synthetic images.

Some labels had a higher number of generated images flagged as irrelevant than other labels, with an average of 24% of all images being flagged as irrelevant. In most cases, the irrelevant images featured materials different from the target label. For example, the 'stucco' label often created images showing metal, siding, or rustication, which resulted in 45% of all 'stucco' images being flagged as irrelevant. In some cases, the generative image model created images with no building shown at all.

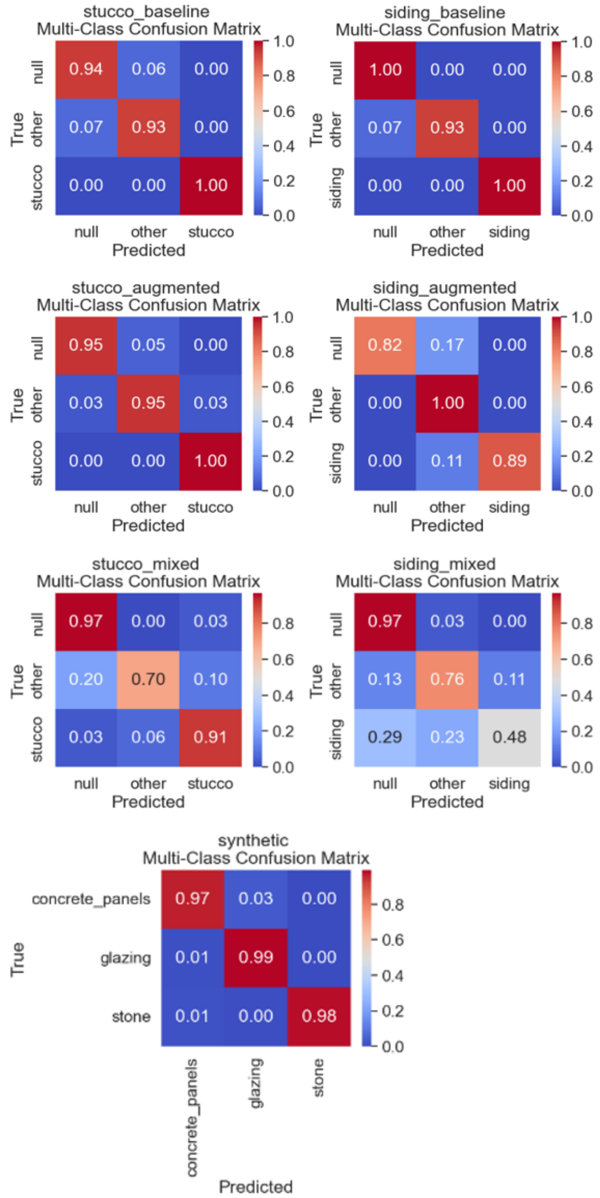

Figure 4: Confusion matrices for all experiments.

Image classification

By reviewing the confusion matrices, ROC curve graph, and bar graph comparing F1 scores, precision, and recall, we are able to achieve a nuanced and holistic evaluation of the image classification results in the context of the research questions.

The confusion matrix compares the number of true labels versus predicted labels. To aid in comparability and interpretability, the numbers of each row in the matrix were normalized to a percentage scale of 0% to 100%. The set of confusion matrices (Figure 4) show which labels perform the worst and best for each experiment and whether any degradation of performance is acceptable. Comparing the augmented stucco experiment to the baseline, it can be seen that the augmented dataset offered a slight advantage for the 'null' and 'other' labels, while maintaining perfect

performance for the 'stucco' label. When using the mixed dataset, there was decrease in performance (100% of true 'stucco' samples predicted as 'stucco' versus 91% of true 'stucco' samples predicted as 'stucco'). Moving to the siding experiment set, the augmented siding experiment had a decrease in performance (as opposed to the augmented stucco experiment). This is likely because the 'siding' augmented class had a higher proportion of synthetic to manually annotated images, which triggers the question that there might be a threshold where the ratio of synthetic to manually annotated images hinders performance. The mixed siding experiment showed further degradation with only 48% of predicted 'siding' samples matching the true 'siding' label. This may have been caused by the size of the mixed siding dataset (248 training samples and 62 testing samples for each class), which was half the size of the mixed stucco dataset (596 training samples and 149 testing samples for each class). Lastly, it is no surprise that the synthetic experiment achieved near perfect results since the model had no way to test its performance on 'in the wild' images. Comparing the synthetic experiment results to the mixed experiment offers insight into the possible ways a model trained and tested on purely synthetic data might degrade when brought into a real data scenario.
The ROC curve graph is helpful in comparing each experiment's discrimination capability between different classes. A model with a curve that hugs closely toward the top left corner suggests high performance in sensitivity and specificity, while the straight, black, dotted line represents the performance of a random classifier. A model with a ROC curve too close to this random classifier line indicates that the model is essentially predicting a class at random.

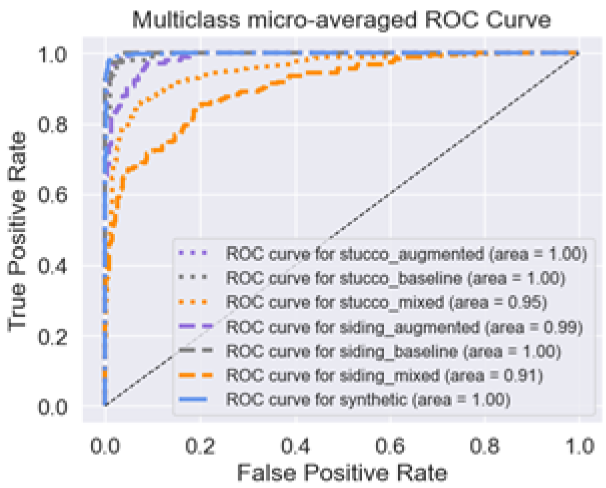

Figure 5: ROC curve graphs comparing the stucco and siding sub-experiments.

From the ROC curves (Figure 5), it can be seen that there are a few experiments that achieved both high sensitivity and specificity across all thresholds, indicated with an Area Under the Curve (AUC) value of 1.00: both baseline experiments, the augmented stucco experiment, and both synthetic experiments. The two mixed experiments achieved AUC values of 0.95 and 0.91 for stucco and siding, respectively, which is generally considered quite a good score. Since those ROC curves are positioned well above the random classifier line, it can be interpreted that these mixed models achieved a meaningful separation between true positives and false positives.
Evaluating the weighted precision, recall, and F1 score of the four experiments provides a global view of the overall performance of each experiment. A higher precision indicates a lower rate of false positives, a higher recall indicates a lower rate of false negatives, while a higher F1 score indicates a balance between precision and recall.
The bar graphs showing the weighted F1 score, precision, and recall (Figure 6) further supports the observations that models trained with some augmentation can increase performance and models trained with synthetic images maintain reasonable results on a manually annotated test dataset. The highest performing experiments were the synthetic experiment and the baseline siding experiment, achieving a value of 0.98 for all three metrics. Although the confusion matrices differed slightly, the baseline stucco and augmented stucco experiments achieved the same score of 0.96 for all three metrics. The augmented siding experiment performed slightly worse than the baseline siding experiment with a value of 0.91 for F1 score and recall (and a value of 0.93 for precision). This further supports the finding that too much augmentation can degrade performance. Although the mixed experiments had a decrease in metrics, the mixed stucco experiment maintained a reasonable performance with the values 0.86, 0.87, 0.86 for F1 score, precision, and recall. The mixed siding experiment showed further degradation with values 0.72, 0.75, 0.74 for F1 score, precision, and recall. However, the training and testing sets were half the size of the mixed stucco experiment, which could have influenced performance.

There were several key findings from this study; some that offer an improvement over the state-of-the-art, and some that provide a nuanced analysis into the trade-offs made when training a model on synthetic images. In terms of overall improvement, this study achieved a higher F1 score, precision, and recall than the state-of-the-art by utilizing a higher resolution model (Swin Transformer v2 at 384 pixel resolution) and reducing the problem space to three labels (null, other, and a label of interest). This study achieved a 0.98 weighted F1 score, 0.98 recall, and 0.98 precision on the baseline siding experiment while the state-of-the-art achieved 0.93 macro F1 score, 0.91 recall, and 0.96 precision (Raghu et al., 2023). For marginal improvements, it was found that augmenting a dataset with 27% synthetic data (for the 'stucco' class) offered a slight improvement over the baseline. This had the opposite effect when using a dataset with 80% synthetic data (for the siding class). As for the possibility to train a model on entirely synthetic data, the performance was generally worse than the baseline, but still a reasonable performance with the mixed stucco experiment capturing 91% of true posi-

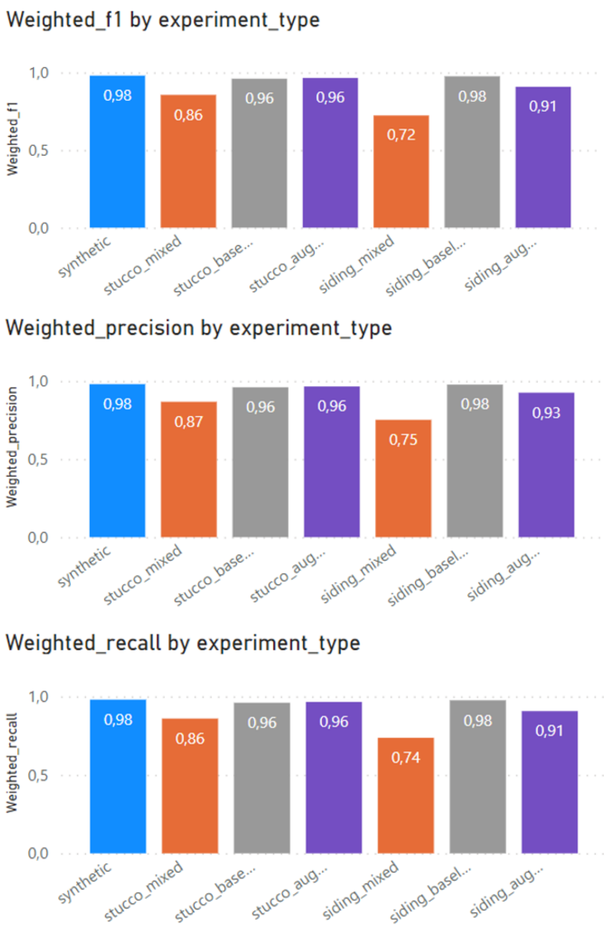

Figure 6: Weighted F1, precision, and recall for all experiments.

tives in the confusion matrix, achieving an AUC value of 0.95, and scoring 0.87 for precision and 0.86 for the F1 score and recall. The results from the mixed siding experiment may have been adversely affected by the size of the dataset (62 samples for test and 248 samples for training); potentially signaling a need to have a larger dataset when training on synthetic images. The near perfect results of the synthetic experiment show that it is possible to train a model on synthetic images for a new label set, but demonstrates the value of testing a model on manually annotated images.

Conclusions

Recent advancements in text-to-image generation have made it feasible to train image classification models on synthetic images, addressing previous challenges of data scarcity and enabling scalability to a national or global level for façade material identification. In this study, we explored the potential benefits and trade-offs that could be made when using varying amounts of synthetic images for training a classification model, as well as proposed an improvement in overall performance with a higher resolution model. The research contributes a novel approach in urban mining for material cadastres by utilizing synthetic images to augment and extend an image classification model for detecting façade materials, offering a potential solution to reduce training dataset development time and address data scarcity challenges while improving current approaches' performance. This, of course, comes with caveats: the text-to-image prompts should trigger diversity in the generated images, the model should be at least 384 pixel resolution, the problem space should be reduced to three labels (null, other, and label of interest), the synthetic training data should be large enough, and it is worthwhile to still manually annotate a test set to develop an intuition for the types of errors that will happen. The results from this study are limited to replicating GSV images for the study's specific set of labels and would not necessarily guarantee reasonable performance for synthetic images of building interiors or niche facade materials (such as ceramic tile cladding). Access to a high-performance GPU (an nVidia GeForce RTX 3070 8GB GPU) enabled utilization of the pre-trained Swin Transformer v2 384 pixel resolution model, which may not be possible to train on a CPU alone. Additionally, there could be privacy concerns associated with remotely compiling building material inventories, particularly regarding historical (materials that should not be moved from their location) or high-security façade materials (materials that may reveal structural vulnerabilities).

These limitations indicate future research that could progress the field of urban mining for material cadastres further. While this experiment achieved good results mimicking GSV images, it would not be safe yet to conclude that any type of building image could be replicated with synthetic images. Therefore, it would be valuable for future work to explore applying the workflow to interior office and residential synthetic images. For the resolution of synthetic images, there was a considerable difference in performance when moving from the 192 pixel model to the 384 pixel model resolution, which begs the question whether generating higher resolution images and training with an even higher resolution model may increase performance further. When generating the synthetic images, a brute-force method was used to separate irrelevant images from the training set because it was suitable for this use case; however, an automatic filtering method would greatly reduce the time needed to prune the output of the generative model. Further studies using synthetic images could benefit material cadastre research by unlocking building interior datasets, by increasing performance of image classification models even more, and by reducing the time needed to filter synthetic images. Developing a robust image classification model that has proven reliable performance in detecting building materials in a wide variety of contexts, scales, and building layers would be an important milestone in the goal to develop country-wide material cadastres for reusable demolition and renovation waste.

Abstract

Ensuring that a building can be safely evacuated in emergencies necessitates using various specialized simulators for prediction, including earthquake propagation, safe evacuation route planning, etc. However, there is no common vocabulary nor standardized approach for integrating diverse building simulation models, hindering their direct integration in an unified collaborative simulation. This is a crucial limitation because no single simulator alone can accurately predict evacuation scenarios in the building industry. We propose the concept of Building Simulation Identity Cards (BSIC) that characterizes and integrates properties of specialized simulation models and demonstrates its role in collaborative simulations for emergency evacuation.

Keywords: Collaborative Simulations, Building Simulation Identity Cards, BIM, Emergency Evacuation

Introduction

Disasters, whether resulting from human activities or natural phenomena, pose a significant risk to life and property, even when they can be anticipated. Emergency evacuation, as a primary safety measure, involves the organized movement of people from disaster areas to safe zones. This practice has been extensively studied and implemented to mitigate the devastating consequences of such events (Yueming & Deyun, 2008).

Emergency evacuation simulations in buildings involve technological innovation, safety engineering, and collaborative planning. As our urban landscapes continue to expand and undergo transformation, safety and resilience in built environments become increasingly important. Research in the field of effective emergency evacuation gained momentum in the 1980s after nuclear incidents at Three Mile Island and Chernobyl (Battegazzorre et al., 2021; Johnson Jr & Zeigler, 1986). These incidents served as evidence of the inability of many emergency authorities to handle such catastrophic events. The subsequent development of specialized simulators has become indispensable for forecasting evacuation scenarios, encapsulating essential information such as geometry, behavior, occupant characteristics, environmental conditions, assessment of structural integrity under seismic conditions, identification of potential challenges through physical simulations, and estimation of evacuation time, among others.

However, despite the availability of powerful, specialized simulators, there is not a single simulator that can account for the highly diverse range of scenarios that users may need to make predictions about. For example, consider a prediction scenario for an earthquake event. An evacuation planning simulator alone often does not consider elements such as structural failure resulting from earthquake loading or considerations of lighting, electricity, weather, and time of day.

In response to these challenges, our study selectively focuses on specific simulations, including: (a) earthquake propagation within the building, (b) development of secure evacuation routes, (c) geometric modeling of the building structure, (d) assessment of structural integrity of the building under seismic conditions, (e) identification of potential challenges in evacuation through physical simulations, (f) estimation of evacuation time, and (g) analysis of occupant movement pattern to ensure the effectiveness of results.

Addressing the aforementioned challenge involves integrating specialized simulators effectively within a collaborative simulation, or so-called co-sim (Gomes, Thule, Broman, et al., 2018; Hansen et al., 2024; Thule et al., 2019) framework to ensure the validity, reliability, and formal verifiability of co-simulation results.

Toward achieving a comprehensive solution, our study introduces a novel concept, the Building Simulation Identity Cards (BSIC) which is aimed at addressing inconsistencies during the integration of simulation models, ensuring that different modules or components can interact correctly, proposed as a comprehensive research agenda and vision for the community. In this paper, we will introduce and outline the development of the BSIC concept, drawing inspiration from key technological initiatives in other industries such as manufacturing, automobile, and aviation, where similar approaches have proven successful in enhancing operational efficiency and interoperability between simulation models.

The process for the development of BSIC involves the creation of standardized ontologies and meta-models to characterize building simulators, which will incorporate available information regarding the simulation model across various aspect (Aßmann et al., 2006; Mahdavi et al., 2023). It involves creating standardized interfaces, frameworks, and algorithms to facilitate their integration into collaborative simulations (Hansen et al., 2022) . An example of this approach is the Model Identity Card (MIC) that has been developed for characterizing simulators in the automotive industry (Sirin et al., 2015).

Attached to the emergency evacuation planning domain, The BSIC concept will incorporate Functional Mockup Interface (FMI) (Schwan et al., 2017) and co-simulation theory and frameworks. This ensures the standardized storage and sharing of simulation model information, including interfaces, input/output parameters, methods, and usage data. This integration will enhance collaboration and knowledge transfer between simulation models, promoting interoperability and mitigating existing barriers.

BSIC will serve as a novel BIM-based solution for harmonizing the properties and attributes of various simulation models employed in the context of emergency evacuation. BSICs act as standardized profiles for simulation models integrated with BIM standards (Eastman, 2011). In this framework, the present study will address the following research question:

RQ: How can the integration of two independent simulation models be systematically achieved to facilitate the co-simulation process in the building sector for emergency evacuation planning in case of earthquake?

By leveraging BSIC, we have a potential avenue for improved collaboration and communication among stakeholders, researchers, and practitioners involved in emergency evacuation simulations. In this paper, we introduce the concept of BSIC as a solution to the challenge of the integration of specialized simulators including earthquake analysis and emergency evacuation simulator for predictive simulations in case of emergency evacuation planning from buildings.

Related Work

There are several research studies focused on emergency evacuation simulation within buildings. (Gelenbe & Desmet, 2013) used graph theory to identify critical positions for emergency evacuations in buildings. In another study. (Forssberg et al., 2019) aimed to improve the reliability of evacuation design assessments by analyzing the variability in pre-movement times during building evacuations. (Mirahadi & McCabe, 2021) proposed the utilization of Dijkstra's algorithm to identify the most secure path-planning strategy for evacuations, particularly in the context of fire emergencies. The model establishes a risk factor for each compartment, taking into account factors such as fire location and potential blockages. By employing a modified version of Dijkstra's algorithm, the model calculates the path with the lowest risk. (Kirby et al., 2015) in their study, they used AnyLogic software to create an evacuation simulation model, demonstrating the importance of data on optimal staff, materials, space, and time resources required for evacuation planning. Additionally, (Chu et al., 2019) in their study investigated the emergency evacuation simulation and management optimization in urban residential communities. A framework was developed for data acquisition, scenario development, evacuation simulation, and emergency management analysis.

In parallel, collaborative simulations (co-sim) have emerged as a topic of increasing interest in the building industry. (Alfalouji et al., 2023) investigated the integration of multiple tools for co-simulation of buildings and smart energy systems. This method has significant potential in advancing building envelopes due to its ability to accommodate complex control strategies and sequences.

Framework for co-simulations for building

By pursuing our aim in this paper, the Building Simulation Identity Card (BSIC) concept is developed to overcome challenges in integrating and orchestrating specialized simulators in a collaborative simulation framework. In this light, we propose a roadmap for BSIC development inspired by major technological initiatives, i.e MIC, to characterize simulators in the automotive industry.

In order to address occupant safety challenges in buildings, a design and engineering team develops a comprehensive digital model of the building, very often incorporating BIM-based programs such as Revit. Subsequently, the structural engineer analyzes the building for potential failure and risk under earthquake loading (Smith, 2016) using the BIM model in a structural integrity simulator. The earthquake loading is sourced from another plateform, e.g., PEER Ground motion data base (PEER-Center, 2013). The data from this simulator needs to be integrated into the evacuation planning simulator. The data may include information about the occupants, output from the structural integrity simulator, and available evacuation routes. Taken together, the purpose of conducting these simulations is to plan the evacuation of people from the building in the event of an earthquake. Yet, neither of the two aforementioned simulators can independently execute such a scenario. Therefore, running a co-simulation is imperative to obtain the desired results. However, the lack of a common vocabulary for integrating different simulators poses a high risk of simulation model integration failure. The framework for co-simulations for emergency evacuation planning from buildings is represented in Figure 1. The evacuation planning engineer uses BSIC to gather the structural integrity simulator output, which serves as input for the emergency evacuation simulator. This process involves manual implementation, where a structural engineer formulates the BSIC for the structural integrity simulator. Subsequently, an evacuation planning engineer utilizes this BSIC as input for the emergency evacuation simulator.

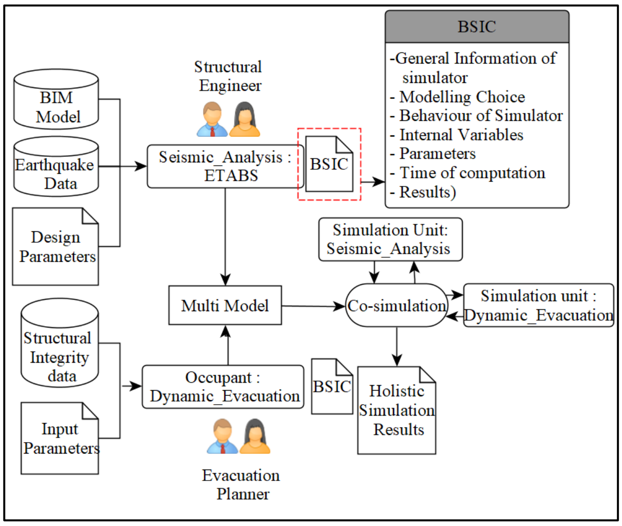

Figure 1: Framework for co-simulations for emergency evacuation from buildings.

In co-simulation, the process begins by defining the connections between simulation unit instances at the system modeling level. These simulation units interact through designated interfaces, known as ports. For instance, in the seismic analysis and dynamic evacuation simulation unit, there is a float output port. The framework also incorporates the Functional mockup interface (FMI) (Palmieri et al., 2020), a common interface standard crucial for co-simulation. FMI provides a standardized approach for encapsulating simulation functionalities, enabling seamless transfer of inputs between simulation units. In assosiation with Functional mockup units (FMUs), which are standardized models for exchanging simulation data, multi-model facilitates the transfer of input to each simulation unit at the current time step. Subsequently, within each simulation unit, the time step for the next major iteration is calculated and used in the multi-model (see next sectoin for multi-model). Each simulation unit advances in a time step until it reaches the point where the maximum shear and moment causing structural failure of the beam are obtained. A collaborative simulation using this multi-model is finally executed by a Co-sim Orchestration Engine (COE), which will act as the central control unit, coordinating interactions among simulation instances. This process is done manually as a part of proof of concept.

Building Simulation Identity Card (BSIC)

We develop BSIC that represents key attributes of simulation models, including general information about the simulator, modeling choices, its behaviour, internal variables, parameters, and simulation results, which serve as the basis for input for other simulators. As presented in Table 1, these attributes are part of the proof-of-concept study, and a more detailed formalization of the BSIC will be undertaken in future research.

Table 1: Classification of attributes used to formulate BSIC.

Attributes	Description
Information	Name , Purpose, description, run time & version of simulation model
Modelling Choice	Modelling field, model dimension and time scale
Required Simulation tool	Name , version and alternative simulator tool
Behaviour	Behaviour specification, analysis type
Interface	Nature, domain , sub-domain
Internal Variables	Type, description, value, unit
Parameters	Classification, quantity, scale
Simulation Results	Time step, accuracy, outputs

Multi-model

FMUs and their interdependencies establish the framework known as a multi-model system. The concept of multi-modeling involves the integration of diverse simulation models to analyze complex systems (Fishwick et al., 1994). This enables communication among different simulators and provides information that cannot be obtained through the use of a single model. This approach allows for a more comprehensive analysis of the system's overall dependability and performance under various scenarios, such as emergency evacuation planning from buildings. For instance, in the context of emergency evacuation planning scenarios, multi-modelling allows the integration of structural integrity and emergency evacuation models. Each model represents a different aspect of the case, facilitating a more holistic understanding of the system as a whole.

In this study, we develop a multi-model that uses BSIC to aid in the solution of potential inconsistencies in the creation and combinations of specialized simulation models. Figure 2 shows the multi-model for co-simulation of emergency evacuation planning incorporating structural integrity.

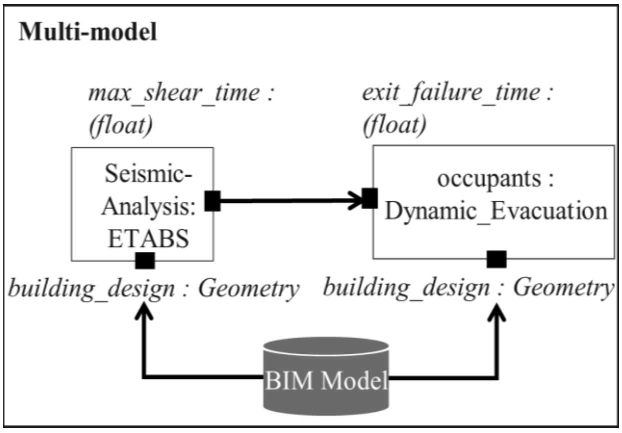

Figure 2: Emergency evacuation planning multi-model.

Proof of concept demonstration

In this section we present a proof-of-concept demonstration of an evacuation scenario that integrates an earthquake simulator and occupant egress simulator. The structure under examination is intended to be simple in terms of geometry, a single-story building featuring two rooms measuring 20 by 30 feet each. The building has been modelled using Autodesk Revit software. The structure has one normal exit, referred to as Evacuation Point (E.P)1, and an emergency exit labelled E.P2. The primary evacuation route is E.P1, which is used by most occupants during normal times. In case E.P1 is inaccessible, individuals will use E.P2 as an emergency exit. The total area of the building encompasses 1200 square feet, accommodating 20 individuals. Figure 3 represents the floor plan of the building.

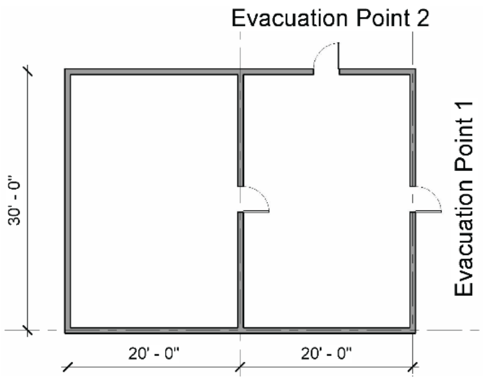

Figure 3: Building floor plan.

A comprehensive structural analysis of the building was conducted, revealing a fundamental time period (Çelebi, 2007) of 0.84 seconds. ETABS software was used for a comprehensive analysis of structural stability and earthquake impact (Guleria, 2014). The time history of the 1989 Loma Prieta earthquake (PEER-Center, 2013) served as a reference for this analysis. The structural analysis revealed the maximum stresses experienced by structural elements at t=5 sec, with corresponding shear and moment recorded. During this critical instance, the shear and moment data suggest a potential beam failure above E.P1. This is because the design shear and moment capacity of the beam is less than the shear and moment caused by the applied loads. Subsequently, these findings were transcribed into the BSIC (see the next section), forming the basis for input in an emergency evacuation analysis. To facilitate evacuation analysis, a dedicated agent-based simulator was employed using the Python language.

Results

The ETABS analysis provides critical information regarding the structure's seismic response. This is represented through a comprehensive time history plot, illustrating the dynamic movement of the structure's floors. The plot represents base shear over time, describing the structure's response to seismic forces. Figure 4 represents a time history plot illustrating the seismic response of the building under earthquake loading, indicating a peak base shear of -78 kips occurring at t = 5 seconds in X direction. This plot is utilized to analyze the behavior of the building under seismic loading (Rathod & Gupta, 2020).

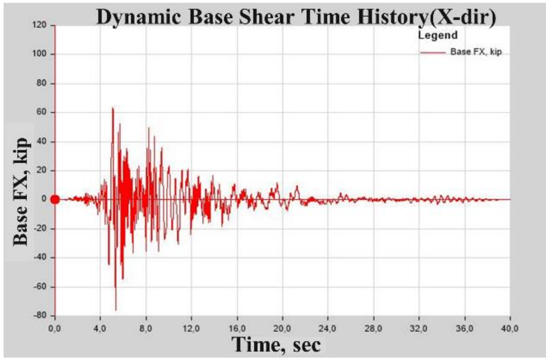

Figure 4: Dynamic base shear time history plot (X-dir) for the building under earthquake loading.

The analysis results indicate that at t = 5 seconds, the structural beam above E.P1 experience maximum stress. At this point, the stress level has reached a critical level, which indicates a potential vulnerability in the structure. It's important to note that the beam above E.P1 may fail due to a critical stress condition, leading to its blockage.

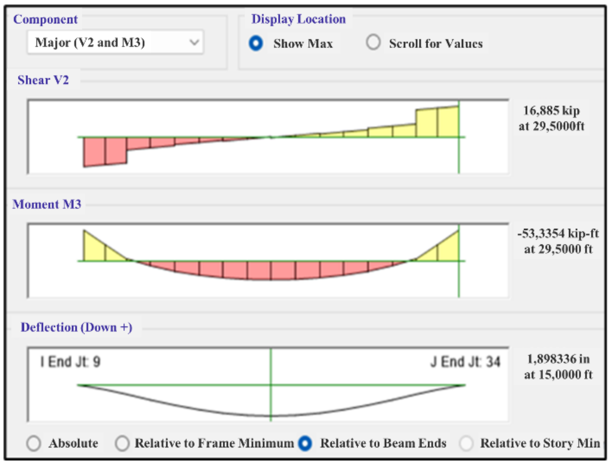

Figure 5: Screenshot of the ETABS tool showing the maximum moment and shear diagram for beam above E.P1 at t=5 sec

The seismic forces during the earthquake event have created conditions where the moment and shear forces acting on the beam above E.P1 exceed its design structural capacity. This ultimately leads to beam failure. Figure 5 illustrates the moment and shear diagram for the beam under consideration subjected to earthquake loading. Figure 6 illustrates the lateral displacement of the structure in the X-dir, providing a visual representation of structural deformation under earthquake loading. The displacement in the X-dir is more than in the Y-dir. Notably, the lateral displacement of the structure at t=5 seconds exceeds the allowable limit of H/500 (Abd Samat et al., 2017), reaching 0.6 inch. This will cause structural failure starting from the beam above E.P1.

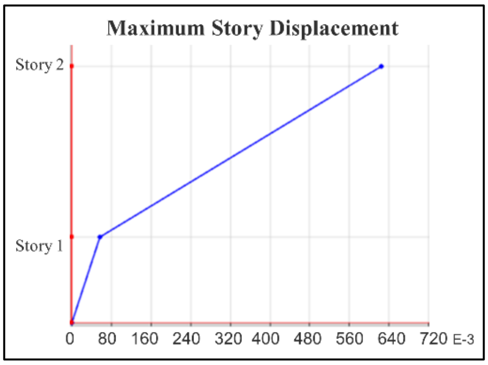

Figure 6: Lateral story displacement in X-direction.

The integration of outcomes derived from the seismic analysis simulator into the evacuation planning simulator has been executed manually, serving as a proof of concept. This process is represented in the sequential diagram illustrated in Figure 7. A master algorithm is utilized by a Co-sim Orchestration Engine (COE), such as the Jacobi algorithm, which performs a simulation step by initiating the advancement of all FMUs in time, retrieving the necessary outputs, and setting the necessary inputs (Gomes, Thule, Larsen, et al., 2018). The simulation follows a series of iterative steps until a termination condition is met, typically determined by the maximum timestep specified by the user. The procedural sequence can be described as follows: The COE initiates the simulation cycle by dispatching inputs to all FMUs. Subsequently, the COE retrieves the next time step from each FMU. Advancing the simulation, the COE progresses the state of each FMU's simulation to the minimum (earliest) time reported by the respective units. Finally, the COE consolidates the output data generated by all FMUs.

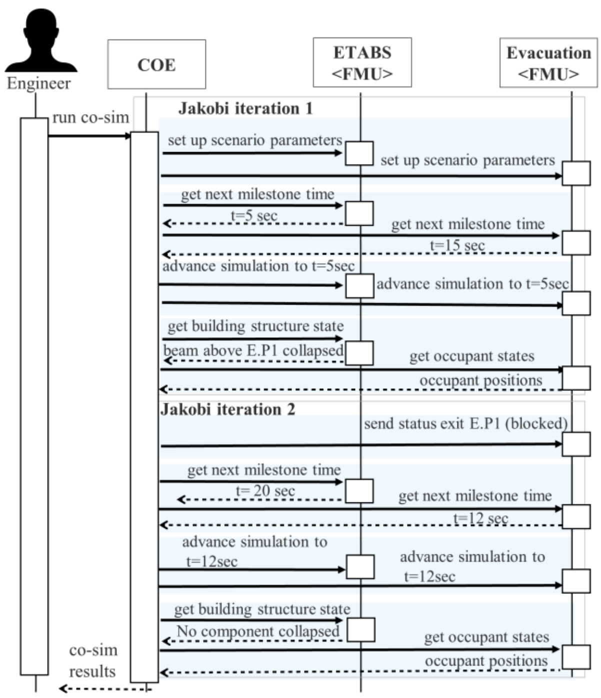

Figure 7: Sequence diagram for co-simulation in Emergency evacuation planning

BSIC used in co-sim process for structural integrity simulation is represented in Figure 8. It reflects a understanding of simulation model characteristics. It provides general information about the simulation model, such as its name, purpose, and the simulator employed for execution. Additionally, it covers details related to the modeling and behavior of the simulation model. The BSIC also encompasses variables and parameters that are necessary for the design of the simulation model. Finally, it presents the results obtained from the simulation model.

Subsequently, the BSIC information is then integrated into simulation model for evacuation analysis. The latter is executed by developing Python code that establishes a comprehensive and integrated approach. This approach will accommodate the seismic activity and emergency evacuation scenarios within our model.

SeismicAnalysis_ETABS	
Attributes	**Description**
General Information	
Name of Simulation Model	SeismicAnalysis ETABS
Simulation purpose	Earthquake analysis
Description	This simulation model serves the purpose of providing information on the maximum stresses occurring at a specified time and location
Simulation run time	Varies based on the complexity of the model
Software/language used	ETABS (Extended Three-Dimensional Analysis of Building Systems)
File format name	.e2k, .edb, .f2k, .exr, .DXF/.DWG, CIS/2, IFC, .igs, .stl, .obj, .xlsx, .docx, .accdb
Modelling Choice	
Modelling Field	Structural Engineering
Model dimension	2 rooms (20x30x11)
Applied Earthquake	Loma Prietan1989
Time scale	Time-dependent analysis capturing seismic events
Behaviour	
Behaviour specification	Material nonlinearity, geometric nonlinearity, and boundary condition nonlinearity considered
Analysis type	Dynamic Time-History Analysis for seismic response
Internal Variables	
Time History	X and Y-direction
Base Shear X-direction	56Kips
Base Shear Y-direction	78Kips
Damping	0.5%
Parameters	
Spectral Acceleration (X-dir)	0.78g
Spectral Acceleration (Y-dir)	0.75g
Concrete compressive strength	4000psi
Poission´s ratio	0.2
Results	
Time of max response	5 sec
Fundamental time period	0.82sec
Design moment	-52kips-ft(top), 27kip-ft(bottom)
Shear capacity	11.95kip
Moment at beam due to E.Q loading	-53-3kip-ft
Moment at beam due to E.Q loading	16.9 kip
Lateral displacement (allowable H/500)	0.26 in
Lateral displacement at E.Q loading (X-dir)	0.6inch
Lateral displacement at E.Q loading (Y-dir)	0.57inch

Figure 8: BSIC for structural integrity simulator

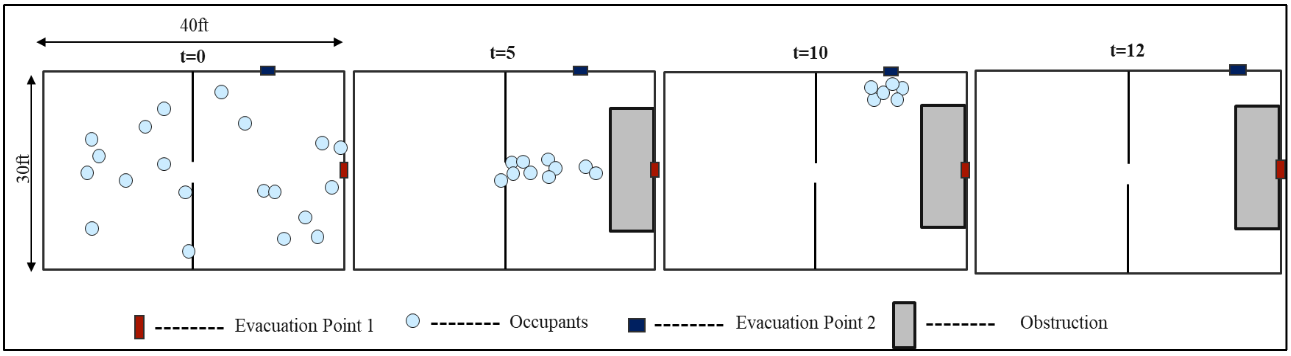

Figure 9: Emergency evacuation scenario w.r.t time.

Agent-based simulation is employed to predict the evacuation of people within the building during a seismic event. Figure 9 illustrates thse flow of people towards the primary exit, also known as E.P1, at times t = 0 and t = 5 sec. However, in the event of a structural failure occurring at evacuation point 1 at time t = 5 sec, the primary exit becomes obstructed by rubble. As a result, people will move towards E.P2, identified as the secondary exit. The figure illustrates that at t = 12 sec, all the occupants have evacuated the building safely.

The dynamics of the evacuation rate, as derived from the data collected during the evacuation simulation, are depicted in Figure 10. Notably, the rate of evacuation increases significantly when a large number of people are at an evacuation point at the same time. In the observed time frame from t = 0 to t = 5 seconds, there is a noticeable upward trend in the cumulative departure of occupants from the building.

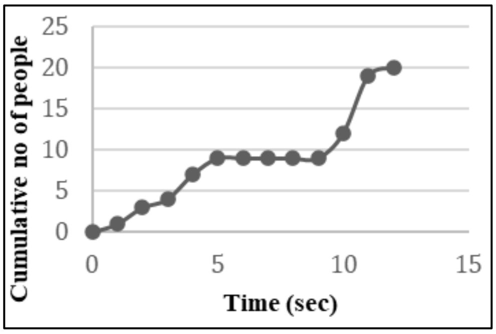

Figure 10: Cumulative number of people leaving the building.

Conversely, between t = 5 seconds and t = 9 seconds, a consistent evacuation rate is observed. This stabilization corresponds to occupants redirecting their movement towards E.P2 following the closure of E.P1. At t=12 seconds, where the graph reaches its peak, all 20 occupants have noticeably vacated the room.

Figure 11 represents the concise BSIC version of the dynamic evacuation simulation model, summarizing crucial information about the simulator used, its inputs, and outputs. It provides a comprehensive understanding of the simulation process, including different attributes of simulation model. This BSIC will prove valuable in the iterative development of the structural integrity simulator and in designing additional simulation models for co-simulation purposes.

BSIC: Dynamic_Evacuation	
Attributes	**Description**

Modelling Choice	
Modelling Field	Evacuation Planning
Model dimension	2 rooms (20x30)
Time scale	Discrete
Behaviour	
Behaviour specification	Individuals exhibit dynamic movement, responding to room structures and obstacles, with a focus on reaching evacuation points.
Analysis type	Real-time Visualization
Evacuation Strategy	Dynamic pathfinding based on real-time structural information.
Internal Variables	
Description	Instances representing individuals spped and obstacles in the simulation
No of structural component failure	1
Speed of occupants	3ft/s
Parameters	
Name	Room width, room length, no people, speed, total time
Description	Parameters defining the simulation environment, evacuation points, number of people, and speed
No. of occupants	20
No. of evacuation points	2
Model dimension	2 rooms (20x30x11)
Results	
Time step	1 sec
Time of structural failure	5 sec
Evacuation Success Rate	100%
Total evacuation time	12 sec

Figure 11: BSIC for emergency evacuation simulator

Discussion

To address the issues related to the combination of a specialized simulation model for information storage and sharing, we demonstrated the first proof of concept of BSIC. For conducting emergency evacuation simulations from a building in case of an earthquake, the provided proof of concept serves as a foundational framework for co-simulations. To improve emergency evacuation planning, integrating data from diverse simulations is imperative, e.g., understanding earthquake propagation, managing dynamic crowd flows during egress, and creating building structure models are crucial components. Furthermore, emergency evacuation planning should consider assessing structural integrity during earthquakes, estimating evacuation time to prevent injuries and analyzing occupant movement patterns.

In this study, we used a seismic analysis simulator to determine if the structure would fail during an evacuation due to earthquake loading. Then the data from the seismic analysis simulation model is integrated with an evacuation planning simulation model to understand the significance and usability of BSIC in combining diverse simulation models.

The integration process between simulation models is executed manually, creating the challenge of automating the co-simulation process, which needs consideration. This includes the implementation of ETABS and the dynamic evacuation simulator as proper FMUs integrated into a COE, and the processing of inputs and outputs for seamless communication between the two simulators. An intricate issue in automating the process concerns the sequential aspects of simulation data. The ETABS simulator focuses on the structural time scale, whereas the dynamic evacuation simulator focuses on crowd behavior dynamics. Future studies will focus on running this co-simulation process automatically.

Furthermore, the integration between specialized simulation models not only highlights the interaction between seismic analysis and the evacuation planning simulation model but also emphasizes the practical application of BSIC in enhancing the understanding of the emergency evacuation planning process.

BSIC outlined in Figure 8 and Figure 11 represents a limited understanding of Seismic analysis and evacuation planning simulation model properties. BSIC is used for classifying analysis modelling, including input/output parameters and quality expectations. A comprehensive BSIC at full scale will be developed in a future study.

Conclusion

Our study, focused on improving collaboration and integration among simulators for predictive simulation during emergency evacuation planning from buildings in earthquake scenarios, has yielded significant insights into co-simulation complexities. The efforts were put in place to answer the research question projected in the introduction.

We first introduced and configured the concept of BSIC to facilitate the co-simulation process for independent simulation models. Then, we utilized BSIC for integrating specialized simulators into emergency evacuation prediction scenarios. Our study achieved significant progress by surpassing the limitations of individual simulators through the successful implementation of a standardized and shared vocabulary.

We implemented BSIC in emergency evacuation predictions by standardizing model representation, ensuring an accurate representation of various factors from both seismic analysis and emergency evacuation simulation models.

This addresses challenges related to a lack of common terminology and interface inconsistencies during the integration phase of a simulation model, whether performed manually or facilitated by software. Through standardized interfaces and frameworks, BSIC facilitates informed decision-making for design teams, enabling effective collaboration in the integration of seismic analysis and evacuation planning simulators.

This research lays the foundation for future investigations, where we aim to further consolidate data from various simulation models, building upon the capabilities of BSIC to achieve a comprehensive understanding of the emergency evacuation planning process. In this regard, BIM will play a crucial role in emergency evacuation planning by facilitating realistic scenario modeling, aiding in the planning of evacuation routes, assessing potential damage, and effectively allocating resources (Stančík et al., 2018). BIM's ability to create a digital replica of real-world structures and environments, complete with intricate details, provides a strong foundation for disaster preparedness. In the next stage, our project focuses on how and in which way integration of BIM with specialized building simulators should be developed to use extensive datasets, offering insights into complex details related to structural integrity and evacuation planning.

CAN MACHINE LEARNING AUTOMATE CARBON CLASSIFICATION OF MATERIALS WITHIN A BUILDING INFORMATION MODEL?

Abdulkadir Adeola Abdulrahman[1], Rogage Kay[2]
[1,2]Northumbria University, Newcastle, United Kingdom.

Abstract

Buildings account for an estimated 35% of the UK's total greenhouse gas emissions. Assigning carbon data to building designs can aid contractors in sustainable material selection. Authoring inconsistencies in building data mean addition of environmental data is difficult and expensive. Machine learning enables classification of materials at a scale manual approaches cannot match. A machine learning approach is documented for classifying building products that enables automatic augmentation of environmental data from carbon databases. Our findings provide foundational research on automating data authoring, that can reduce costs and simplify processes associated with adding environmental assessment data to building designs.

Introduction

In June 2019, UK parliament made a legally binding commitment to bring all Greenhouse Gas (GHG) emissions in the UK to Net Zero by 2050 (Department for Business, Energy & Industrial Strategy, 2019). The construction sector is a major contributor to the UK's carbon footprint and is responsible for 50% of all extracted materials and 35% of GHG emissions (Rogage et al., 2019). Construction activity accounts for around 50m tonnes of CO2 emissions, over half of this is linked to construction products and materials (Government Commercial Function, 2022). Modern approaches to collecting information about buildings across the supply chain offer unprecedented data resources for analysing and improving processes. Building Information Modelling (BIM) is an established term within academia and across the sector that is defined as a process for collaborative processing and management of design and construction information (Tallet et al., 2021). Whilst in its essence BIM is an information management approach, it is more specifically associated with standardised schemas and classification systems that enable interoperability and automated data processing. Cavalliere et al. (2019) stressed carbon management in construction is becoming an increasing priority as buildings make up such a high percentage of GHG emissions. Frameworks such as the Leadership in Energy and Environmental Design (LEED) (2024) and Building Research Establishment Environmental Assessment Method (BREEAM) (2024) certifications, enable contractors to calculate and certify embodied carbon impact when selecting building materials. Whilst calculating embodied carbon of buildings is not the aim of our research, our findings could link to existing frameworks such as LEED and BREEAM as part of the calculation method for the material selection process. Tools are needed that accurately classify materials within BIM and match them up to associated suitable carbon database items in order to optimise carbon management strategies (Cavalliere et al., 2019).

Whilst several classification systems exist, often product material data is unclassified or classified using non-standard approaches, making it difficult to automate assigning carbon information to products. This research explores a Machine Learning (ML) approach to address the problem of assigning carbon information to products. We seek to understand the potential for ML to accurately identify material descriptions in BIM data, so information from carbon databases can be automatically augmented to building products. Our developed approach uses text and sentiment analysis, and classification techniques in order to match BIM material descriptions with those found within carbon databases. A comprehensive literature review of classification algorithms using BIM data and carbon management provides the foundation for developing the ML approach. We then select and evaluate a number of algorithms for classifying BIM data against carbon impact categories in the Inventory of Carbon Energy (ICE) (Circular Ecology, 2020) database. We propose a novel application of ML techniques for predicting and classifying incomplete or inaccurate BIM data.

Related Work

BIM has rapidly become an indispensable approach in AEC industries for creating digital representations of building designs (Basbagill, 2013). A BIM consists of any elements that represent assets within a building such as doors, windows, walls etc. Consistent and accurate classification of BIM elements including materials, remains an ongoing challenge for AEC professionals. Honic et al. (2019) found that inconsistent data and a lack of cooperation among different stakeholders, created a barrier to automation of data related to recycling of building materials. Manual classification of BIM elements can be time consuming, ineffective and create inconsistencies within data. An automated classification approach utilising ML could significantly enhance accuracy and efficiency when applied to element classification of BIM data.

Studies have highlighted ML’s utility for accurately classifying heritage buildings (Bassier et al., 2017), maintenance issues (McArthur et al., 2018), wall and door elements (Koo et al., 2021) and quantifying environmental impact assessments (Cavalliere et al., 2019; Xu et al., 2022). Deep Learning (DL) is a subcategory of ML that uses historical experience as the basis for future predictions. DL specifically has shown promise as an accurate way of classifying complex BIM elements based on geometry (Koo et al., 2021; Rogage and Doukari, 2024). One area in which ML algorithms have been applied to BIM is in assessing embodied environmental impacts of building designs. Basbagill et al. (2013) and Cavalliere et al. (2019) offer examples of this application using Life Cycle Assessment (LCA), continuous BIM-based assessment and an automated LCA approach. Xu et al. (2022) proposed an innovative BIM-integrated LCA for prefabricated buildings as an automated way of performing the embodied carbon assessment process. All three studies demonstrate the potential of ML/BIM combination in mitigating environmental impacts while optimising building design performance. ML algorithms have also been successfully utilised with BIM for classification of maintenance issues and enhanced data collection, according to an approach devised by McCarthy et al. (2018) utilising ML visualisation techniques in BIM to classify issues while increasing data collection rates. Zabin et al. (2022) conducted an in-depth literature review pertaining to applications of ML to BIM projects and highlighted its capacity for automated quality control and error detection. Koo et al. (2021) introduced an automated approach for accurate classification of BIM elements using 3D geometric Deep Neural Networks (DNN) as walls and door elements. Rogage and Doukari (2024), further demonstrate use of 3D geometric DNN for classifying a further range of products. These studies demonstrate the promise of ML with BIM for improving accuracy and efficiency of classification of elements within BIM. However, consideration must be made regarding possible challenges or restrictions associated with its usage; including issues surrounding data quality, privacy concerns and interpretability (Zabin et al., 2022).

Recurrent Neural Networks

Here we consider ML models for classifying BIM data. Recurrent Neural Networks (RNN) are a type of artificial neural network that use layers to process data. RNN with Long Short-Term Memory (LSTM) architecture comprises three layers: input; recurrent; and output (Nosouhian et al., 2021). RNN input layers (shown on the left of figure 1) accept input sequences such as time series data or natural language text as vectors; then feed these vectors one at a time into their networks for processing. A type of RNN called LSTM units can store long-term memory, which enables them to comprehend text sequences better by capturing context and semantics (Kaur and Mohta, 2019). An RNN's recurrent layer serves to maintain its memory of previous inputs and generates outputs based on each cell taking an input and producing an output, along with updating their hidden state, each time step based on current and previous hidden states - thus giving rise to RNNs' ability to recall past data inputs (Kaur and Mohta, 2019). Within each layer are nodes or neurons, represented by circles in figure 1, which perform simple operations and pass signals to other neurons. Connections between neurons are represented by lines, the strength of connections determined by weights. Signals travel through the network from left to right via these weighted connections. As data passes through each layer, the network learns patterns and extracts meaningful features. An RNN's output layer (shown on the right of figure 1) takes the final hidden state from its recurrent layer and generates its output; it could take the form of either a simple feedforward layer, or it could employ complex features like softmax layers for classification tasks (Nosouhian et al., 2021). This output produces the network's predictions or classifications based on what it has learned. In many applications, neural networks contain multiple hidden layers to solve increasingly complex problems. The number and arrangement of layers and neurons can be modified to suit different tasks. One of the primary strengths of RNNs lies in their capacity to handle variable-length data sequences efficiently, due to using identical weights across time steps of sequence processing allowing it to process sequences of various lengths without disrupting operation of the network.

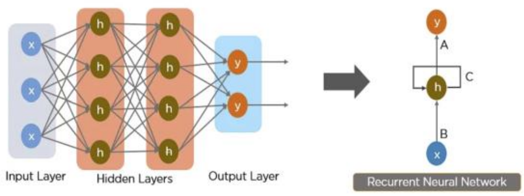

Figure 1: Deep Learning architecture (Badhan et al, 2024)

Figure 2 demonstrates how RNNs process sequential data. RNNs are commonly used for natural language processing tasks where the order of inputs is important, such as text classification. We can think of this grid as representing a sequence of inputs an RNN would read, from left to right and top to bottom. Each cell contains a token or word from the sequence. As the RNN processes each step, it considers both current input and information from the previous step, represented by the cell to the left. This looping, recurrent structure allows RNNs to connect previous information to later inputs in a sequence. The network develops an internal state capturing features of the entire sequence processed so far which is passed from each cell to the next. By reading the sequence from this grid in order, an RNN would build up understanding of word patterns and relationships over multiple time steps. This visualisation conveys how RNNs can process variable-length sequential data by sharing parameters across every step. The 2D array representation provides a simple way to conceptualise how RNNs flow information through a network from start to end of a sequence, capturing context at each point to help classify or generate sequential outputs.

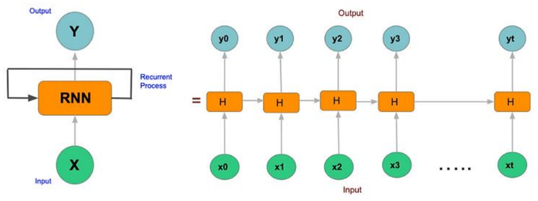

Figure 2: RNN architecture (Nagesh, 2020)

Naive Bayes

Naive Bayes methods are a set of supervised learning algorithms based on applying Bayes' theorem with the "naive" assumption of conditional independence between every pair of features given the value of the class variable (Qiang, 2010). Naive Bayes is a probabilistic classification algorithm that calculates the probability of an instance belonging to a class based on the probabilities of its features. It uses Bayes' theorem:

$$P(y|x) = \frac{(P(x|y)\ P(y))}{P(x)} \qquad (1)$$

Where:

P(y|x) is the probability of class y given the features x.
P(x|y) is the probability of features x given class y.
P(y) is the prior probability of class y.
P(x) is the probability of features x.

Naive Bayes estimates probabilities P(x|y) and P(y) from a training dataset. During prediction, it calculates the probability of each class label for a new instance and assigns it to the class with the highest probability. The model assumes features are independent, meaning the presence or absence of one feature does not affect the presence or absence of others. This assumption simplifies calculations and allows the model to handle high-dimensional feature spaces efficiently. Despite its simplicity, naive Bayes performs well in text classification tasks, such as spam detection and sentiment analysis. It is computationally efficient and can handle large datasets. However, it may not perform well when the independence assumption is violated or when there is a lack of sufficient training data.

Random Forest

Random Forest is an ensemble learning method that combines multiple decision trees to make predictions (Wang and Wang, 2021). It randomly selects subsets of training data and features to train each tree. The final prediction is made by aggregating predictions of all trees, either through majority voting for classification or averaging for regression to improve prediction performance. The algorithm is illustrated by creating multiple decision trees, each trained on different subsets of data and features, and then combining their predictions. Random Forest is widely used for its effectiveness and ability to handle high-dimensional datasets.

Figure 3 shows three decision trees each making independent classifications. Branches of Decision Tree-1 and Decision Tree-2 represent two individual decision trees classifying an input sample and arrive at a "Result". These predictions are combined through majority voting. Majority voting is the process of having each tree "vote" for a class and selecting the class receiving the most votes overall. This aggregation helps to reduce variance and prevent overfitting compared to a single decision tree. By growing many decision trees on randomly sampled subsets of training data and combining their results, Random Forests are able to capture relationships any individual tree may miss. This ensemble approach typically yields better generalisation performance than a single estimator. This ensemble technique is effective for both classification and regression tasks.

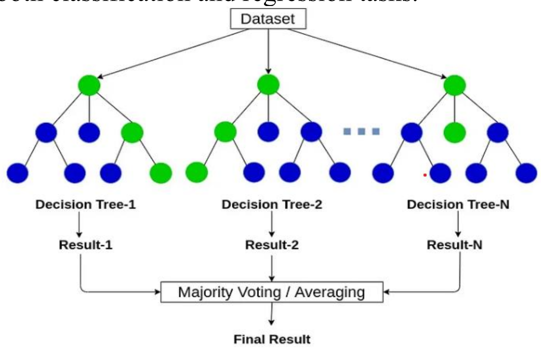

Figure 3: Random Forest structure (Zhu and Spachos, 2021)

Simulation and Experiment

Methodology

The data science pipeline and methodology is shown in figure 4. This approach involves selecting data, then cleansing and preparing data using feature extraction with consideration to the model to be employed. Data exploration precedes model construction to comprehend the significance of various features, the relationships among features, data distribution patterns and hypotheses formulated about them. A model is then built with the aim of producing inferences or future event predictions from it or discovering a "root cause" behind an already observed event; its results are then assessed and presented upon evaluation.

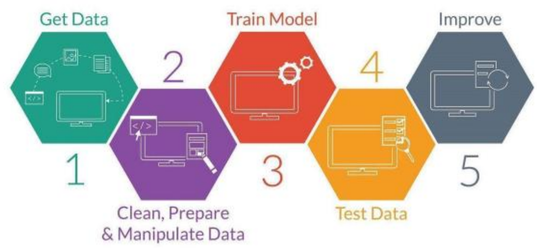

Figure 4: Machine Learning workflow (Muhammad, 2022)

Data Sources

The first data source contains approximately 10,000 material descriptions extracted from the ICE database (Circular Ecology, 2020). These include detailed information on embodied carbon and energy of various construction materials, reflecting their significant influence in the construction industry. The second data source encompasses BIM data, including labels and classifications for different building products. The ICE database was selected for its comprehensive coverage and credibility in documenting embodied carbon and energy of construction products. This dataset is split into two parts: one containing detailed material descriptions, and the other consisting of material names or labels. Material descriptions provide extensive information about each building material, including its embodied carbon, which is crucial for the analysis.

Exploring the Data

Data exploration began with data cleaning and preparation. The BIM dataset comprised 11,488 rows with four columns covering Family, IFC Type, Material Types and categories such as "ICE Category" (this is the category the model will predict to automate the mapping of BIM data directly into the ICE database). Table 1 provides a dataset sample. After a preliminary study of the data, it became apparent two columns: Family and IFC Type; were not relevant because they are both classified in generic terms which are applicable to all material that falls under the general family representation respectively, so they were removed from the dataset entirely leaving only the Material and ICE Category columns.

Table 1: Sample data from the BIM dataset

IFC Type	Material	ICE category	ICE Material
Air Terminal	Air Terminal - Diffuser Body	NaN	NaN
Air Terminal	Air Terminal - Perforated Plate	NaN	NaN
Air Terminal	Aluminium - Koolair	Aluminium	NaN
Air Terminal	Aluminium	Aluminium	NaN
Air Terminal	Anodised Aluminium - Koolair	Aluminium	NaN

Further visualisation of the data (figure 5) revealed an uneven distribution of building materials. More specifically, certain samples had significantly more entries than others indicating an uneven representation in the data and potentially leading to biased predictions and reduced accuracy when training ML models. To address this challenge, data balancing was employed; an approach in which samples from each category are adjusted to create an even distribution for more accurate predictions through ML models trained on representative samples of data. There are various strategies available for balancing data, including oversampling and undersampling (Bonatti and Kirrane, 2019). Oversampling involves increasing the sample population from minority classes while undersampling involves decreasing it; both strategies aim to achieve an even distribution across categories. This study used oversampling, specifically the Synthetic Minority Over-sampling Technique (SMOTE), to balance data (Chu et al., 2016). SMOTE involves creating artificial samples in minority classes by interpolation among existing ones; thus ensuring each minority class receives enough samples, leading to more balanced distribution of data. By using SMOTE to balance data, the model was then trained on a more balanced distribution of materials within the dataset for more accurate predictions and vital insights for sustainable building practices.

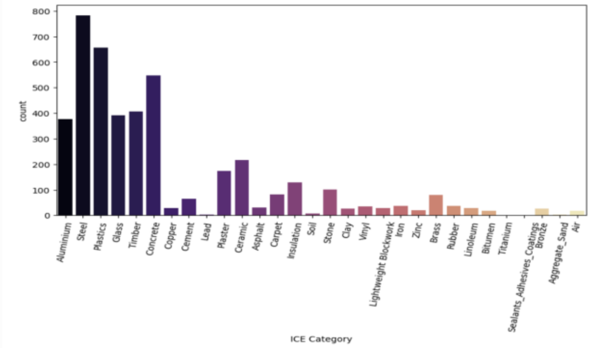

Figure 5: Dataset Distribution

A Bag of Words function was introduced to search and verify the presence of specific materials in the database, offering insights into their carbon footprints. This method represents each document as a vector of word frequencies, without regard to order or structure of words (Anello, 2021). This serves as indicators for classification of building materials, assisting in the ML process for accurate categorization and analysis. Use of these datasets allows for a detailed examination and understanding of the relationship between material properties and their environmental impact. This concluded the data preparation and manipulation stage ready for the final stage of training the model.

Model Development

The ML model was developed using three algorithms: RNN with LSTM, Random Forest, and naive Bayes. The combination of these algorithms offers a comprehensive approach to the classification of building materials, leveraging strengths of each to enhance overall effectiveness and reliability of the model in classifying building materials based on their carbon impact, as per the ICE recommendations.

Model Training

In this project, a common technique for training network parameters and performing classification was employed: splitting available data sets 80/20 on a train/test split. This strategy is known as train-test split and commonly utilised within ML to assess model performance. At this phase of training, the model was trained on its training set by using an optimization algorithm to adjust network parameters and minimise its loss function. Alpaydin (2020) defines loss function as measuring the difference between predicted output of the model and actual output and an optimization algorithm can adjust these network parameters so as to decrease this difference as much as possible. Once the model is trained and evaluated on its test set, the next stage is to improve the model. Cross-validation is used for measuring generalisation ability, testing the model on new data allows for a more accurate representation of its performance on unseen sets of information and provides an opportunity to improve the model. Hyperparameter tuning was conducted to improve the Random Forest classifier model. The number of estimators was set to 400, and the criterion for measuring the quality of a split was chosen as "entropy". The random state was also fixed to ensure reproducibility of results. This careful selection of hyperparameters aims to optimise the model's performance by adjusting its complexity and learning capacity. For the Bidirectional LSTM model, specific architecture choices such as embedding dimension, number of LSTM units (16), and use of dropout for regularization indicate a tuning process aimed at balancing model capacity with the need to avoid overfitting. While the description doesn't detail an iterative search over a range of values, these choices reflect considerations typical in model tuning, focusing on optimising the network's structure for the task at hand. The metrics used to evaluate the accuracy and completeness of the model's predictions are Precision, Recall, and F1 Score.

Precision is the ratio of true positives (correct predictions) to the total number of positive predictions. It measures how precise the model is in identifying relevant cases. A high precision means that the model has a low rate of false positives (incorrect predictions).

Recall is the ratio of true positives to the total number of actual positive cases. It measures how well the model can recall or retrieve all relevant cases. A high recall means the model has a low rate of false negatives (missed predictions).

F1 Score is the harmonic mean of precision and recall. It balances both metrics and gives a single score that reflects overall performance of the model. A high F1 score means the model has both high precision and high recall. From table 2, Random Forest model has the highest scores across all metrics at 99%. This means the Random Forest model is the most accurate and complete in its predictions, compared to the other two models. Both naive Bayes and RNN have a Precision of 98%, Recall of 97%, and an F1 Score of 97%. These scores are slightly lower than the Random Forest model, but still very high and impressive.

Discussion and result analysis

Multiple experiments using the RNN (LSTM), naive Bayes, and Random Forest models to classify building materials into various ICE categories were conducted. Training the model involved using datasets of building material data before testing its performance on test sets. A subset of building material data were manually classified with corresponding ICE categories before comparing accuracy between each classification method. Results of the experiment demonstrated high levels of accuracy on their test sets, achieving 97%, 98.38%, and 99.59% (See table 2) respectively. During data preprocessing, the dataset was simplified by removing columns ('IFC Type', 'Family', 'ICE Material') not directly relevant to the primary goal of predicting the 'ICE Category' from the 'Material' description. This decision represents a targeted form of feature selection, focusing the model's learning on the most relevant data available. The strategy adopted for imputation was straightforward yet effective: rows with missing 'ICE Category' values, which are critical for supervised learning, were dropped. This approach ensures the models are trained on complete records, enhancing the reliability of their predictions. However, it's important to note that this method of handling missing values might not be suitable for datasets where such omissions could lead to significant loss of valuable information. In those cases, more sophisticated imputation techniques might be necessary. It is crucial to note that these results, while promising, require further validation to ensure their reliability and applicability in real-world scenarios. The comparison with manual classification methods, although indicative of potential efficiency gains, should not overshadow the importance of accurate and safe classification of building materials. Table 2 shows how each model performed using different evaluation metrics.

Table 2: Model comparison Between Random Forest, naive Bayes and RNN results

	Precision	Recall	F1 Score
Random Forest	99%	99%	99%
Naive Bayes	98%	97%	98%
RNN	98%	97%	97%

Table 3 shows the first 5 rows of materials predicted using the RNN model. This means that the RNN model has successfully classified the building materials in the ICE Category based on what the model understands from the training dataset. This was the first model developed, while it successfully predicted the materials, the accuracy of its prediction could not be confirmed as this model does not suppose the confidence level measure.

Table 3: RNN Prediction

Material	ICE Category
Air Terminal - Diffuser Body	Air
Air Terminal - Perforated Plate	Air
ConnectorSolidMaterial	Concrete
Duct_Afkast	Steel
Duct_Udsugning	Brass

Table 4 shows the first 5 rows of predictions with their confidence level by the naive Bayes model. The results show the model has classified some materials such as “Air Terminal - Diffuser Body” and “Air Terminal - Perforated Plate” under the “Air” category correctly, with high confidence levels of 18.05 and 17.53 respectively. However, the model has made errors, such as classifying “Connector/Solid/Material” and “Duct_Lining/lining” as “Linoleum”, with low confidence levels of 3.43 each. These materials are likely made of metal or plastic, not linoleum, which is a type of flooring material. Similarly, “Duct_Airseal” is categorised as “Steel” with a confidence level of 9.05, which may not be accurate if the duct is made of another material.

In ML, confidence level is a measure of how likely a prediction is to be correct. It is usually expressed as a percentage between 0 and 100, where higher values indicate higher confidence. In the case of the naive Bayes prediction in table 4, where the model predicts that a building material belongs to the “Air” category with a confidence level of 18.05, it means that the model got 18.05% vote after splitting the total available percentage to the possible materials, materials with the highest vote gets predicted and the higher the percentage the better chance of the prediction being accurate (Srivastava et al., 2018).

Table 4: Naive Bayes prediction

Material	ICE Category	Confidence Level
Air Terminal - Diffuser Body	Air	18.05%
Air Terminal - Perforated Plate	Air	17.53%
ConnectorSolidMaterial	Linoleum	3.43%
Duct_Afkast	Steel	9.05%
Duct_Udsugning	Linoleum	3.43

Table 5 below also depicts the first 5 rows of material predictions and their confidence level by the Random Forest model. This model performs best although with 1% margin, and higher confidence level out of the models explored. The confidence level is calculated by taking the proportion of votes from the decision trees that agree on the same label. For example, if 100 trees are in the forest, and 96 of them vote for the “Air” category for the “Air Terminal - Perforated Plate” material, then the confidence level is 96/100 = 0.96 or 96%.

Table 5: Random Forest prediction

Material	ICE Category	Confidence Level
Air Terminal - Diffuser Body	Air	99.25%
Air Terminal - Perforated Plate	Air	96.00%
ConnectorSolidMaterial	Concrete	69.75%
Duct_Afkast	Steel	89.00%
Duct_Udsugning	Steel	77.75%

The models demonstrated impressive performance because of the focused feature set. By concentrating on the 'Material' descriptions as the primary input feature and carefully preprocessing this text, the models could learn effectively from the most relevant data. Also, by addressing class imbalance through resampling techniques such as SMOTE or direct resampling helped mitigate biases and improve model performance across less represented categories. Finally, optimised model configurations including deliberate setting of hyperparameters and model architecture choices, such as number of estimators in the Random Forest and structure of the LSTM network, contributed to the fine-tuning of each model's ability to capture the nuances of the dataset.

Conclusions

The contribution of this project lies in its exploration of ML techniques for automating classification of building data with carbon information. Whilst LCA tools and frameworks enable the calculation of embodied carbon, they rely on parametric modelling for environmental assessment, however, its application within BIM has been relatively underutilised and, more importantly, does not exist within commercial software packages used in BIM (Alwan et al., 2021). In the absence of this data, we offer an automated technique for classifying BIM products so that environmental assessment data within carbon inventory databases can be augmented to models, thus removing the need for authors to manually generate this data at design stages.

Our approach offers a foundation upon which further research can develop model accuracy and further validate the results. It demonstrates the potential of ML in automating classification tasks, which could lead to significant productivity gains in the construction industry. However, we acknowledge that our results are a preliminary step in this direction and that further research is needed to refine these techniques, improve accuracy, and fully realise their potential. Future research in this area should focus on enhancing the validation processes for ML models in construction, ensuring that they not only achieve high accuracy in controlled tests but also maintain this accuracy in practical applications. Further work is also required to investigate the integration of additional variables and data sources to enrich the models and capture a more comprehensive range of factors affecting building material classification. By advancing these aspects, subsequent studies can build upon our findings, contributing further to the knowledge and application of ML in construction and ensuring that the transition towards automated processes prioritises safety, accuracy, and reliability.

Limitations and Further Recommendations

Although this project demonstrated the efficiency of using ML to classify building materials into different ICE categories, some limitations must be acknowledged within its research design. Performing the study on a larger dataset would improve generalisability and make networks more resilient against fluctuations. Additionally the quality of data used for training and testing the ML models could be improved. Accuracy depends heavily on input quality; any errors or inconsistencies could compromise network performance significantly.

This study concentrated on classifying building materials based on their carbon impacts according to ICE. While this approach is instrumental in understanding and mitigating the environmental footprint of construction materials, it's important to acknowledge that this focus on carbon impacts alone presents certain limitations. For instance, the classification does not account for other environmental aspects such as the life cycle impacts of materials beyond carbon emissions, which can also be significant in sustainable construction practices. Future studies might expand the scope to include a more holistic environmental assessment of building materials, encompassing a broader range of environmental metrics beyond just carbon impacts.

It is also recognised that our proof of concept prototype solution utilised the UK based ICE database for linking product data to carbon calculations via materials. The embodied carbon coefficients of building materials, vary from country to country. To address this, further validation is required to assess the generalisability of the solution on databases focusing on other countries such as Öekobaudat (Federal Institute for Building, Urban and Spatial Research, 2024), Gabi (Sphera, 2024) and Bauteilkatalog (2024).

Future Work

Future work could include expanding the study to cover other properties of building materials such as durability, strength and cost. Several other ML techniques can also be evaluated in order to determine which algorithm best predicts the materials. By employing ML techniques to predict these characteristics of materials used in construction projects, more informed decisions could be made regarding selection and usage for more sustainable and cost-effective outcomes. More research could also focus on creating ML models specifically tailored for sustainability in construction industry applications, by including sustainability criteria into ML model development processes.

Acknowledgements

The datasets used within this study were provided by xbim Ltd who provided access to the ICE data alongside industry BIM data. The proprietary aspect of the ICE dataset means that it cannot be made available for further analysis by researchers outside the research team. Additionally, whilst the BIM data provided by xbim Ltd was anonymised, we were not authorised to make this dataset public. We would like to thank xbim Ltd for providing access to both datasets, and time to support the researchers in better understanding the data, without their support this project would not have been possible.

ENHANCING RFI ANALYSIS IN CONSTRUCTION PROJECTS: A COMPARATIVE STUDY OF TEXT CLUSTERING METHODS AND VISUALIZATION TECHNIQUES

Neziha Yilmaz[1] and Esin Ergen[1]
[1]Istanbul Technical University, Istanbul, Turkey

Abstract

The Request for Information (RFI) is a vital communication tool in construction projects, aiding teams in addressing queries and navigating challenges. Unstructured RFIs hinder manual analysis for extracting hidden knowledge. Prior research in RFI analysis employed NLP and text clustering and often relied on a single clustering method. This paper performs a comparative analysis using diverse clustering methods (LDA, NMF, and K-means) and visualization techniques to determine the most suitable methods. The study offers project managers and quality engineers an effective tool for extracting hidden knowledge in RFI.

Introduction

The construction industry heavily relies on efficient information management throughout the project lifecycle, generating a substantial volume of information in various formats (Al Qady and Kandil, 2014). Approximately 80% of corporate information is embedded in project documents, and challenges arise as professionals spend considerable time searching for and reading documents (Abbaszadegan and Grau, 2015). Insufficient information or delays in information exchange can lead to significant issues at construction sites (Abdirad et al., 2022).

Manual knowledge extraction from text documents is time-consuming and error-prone (Khuzaimah and Hassan, 2012), prompting researchers to adopt advanced Natural Language Processing (NLP) and text mining techniques, including sentiment analysis, semantic analysis, and clustering methods (Afzal et al., 2023; Jallan et al., 2019; Gheeseewan and Pudaruth, 2020).

In compliance and quality assurance, the Request for Information (RFI) document is a crucial text document in construction. It serves as a performance indicator and is analyzed conventionally through manual methods or text mining to extract insights and lessons learned (Herrera et al., 2019; Kim et al., 2022). Extracting insights and lessons learned from RFIs facilitates the early identification of potential issues, project uncertainties, and risks (Lee and Yi, 2017), allowing for timely corrective actions to be implemented in the early stages. Moreover, uncovering hidden information within RFIs enables the identification of the root cause of nonconformance. In the literature, Koc et al. (2024) have investigated the impact of non-conformities on project costs using machine learning methodologies. Similarly, the envisioned approach in this study is to extract insights from RFIs and utilize them to predict potential non-conformities for corrective and preventive action development. This approach fosters a culture of quality and compliance while mitigating reworks over time. Clustering the RFI texts to determine topics is the first step for utilizing RFI to predict unconformity and uncover hidden information within RFI texts. Exploring the effectiveness of various text topic modeling algorithms is crucial due to the unique characteristics of RFI texts. For instance, RFIs and responses, typically one to seven pages long and containing 20 to 5000 words, may be stored in unstructured format within a CDE. These texts often contain a mix of uppercase and lowercase letters, spelling errors, abbreviations, and inconsistent terminology (such as "frame" versus "beam" or "drawing" versus "CAD"), necessitating preprocessing techniques. Given their intricate details, RFI texts require micro-level clustering focus.

While some publications focus on text clustering and visualization techniques for RFIs (Lee and Yi, 2017; Afzal et al., 2023), they have utilized a single clustering method, lacking a comparison with other methods and determining the preferred visualization technique for experts. To address these gaps, this paper performs a comparative term analysis of RFI text using various clustering methods, namely Latent Dirichlet Allocation (LDA), Non-negative Matrix Factorization (NMF), and K-means, and visualization techniques (i.e., pyLDAvis, scatter plots, word cloud, and bar charts). The study involves expert interviews to determine the most suitable clustering and visualization methods for RFI clustering analysis. The research contributes to the limited comparative studies on text clustering and visualization of RFIs, offering a valuable tool for project managers to grasp RFI status.

Literature Review

Text-based data clustering methods are important for diverse applications in the construction industry. Moreover, text mining plays a crucial role in the quality management of construction engineering, involving tasks such as text cleaning, text segmentation, and semantic network analysis on unstructured data within text collections (Wang et al., 2018). The construction sector benefits from the interactive utilization of user-centric dictionaries, sentiment analysis based on word clusters, and the automated extraction and clustering of relevant terms for dictionary generation (Kohita et al., 2020; Alshari et al., 2020). These approaches ensure the construction industry's access to comprehensive and industry-specific term dictionaries, facilitating effective text analytics and knowledge management.

RFI texts, rich in information about project history and design functionality, offer detailed insights into potential quality issues in the construction site, allowing for a comprehensive focus on field operations. Traditionally, extracting insights from RFIs involved manual data mining and content analysis (Bhat et al., 2017; Afzal et al., 2023). Several studies in the literature focus on classifying RFIs. Dantas Filho et al. (2016) revised constructability concerns for evaluating RFIs in residential projects, introducing categories such as Design Correction, Divergence of Information, Design Change, Design Failure, Validation Information, and Design Verification. Morales et al. (2022) analyzed 2690 RFIs from 17 projects using statistical classification methods to associate RFIs with BIM usage. The RFIs were classified, such as alternative design solutions, approvals, clarifications of information, and other categories. Subclassifications include conflict RFIs, incorrect RFIs, insufficient RFIs, and questionable RFIs. Ham and Yuh (2023) used 872 BIM RFIs to classify them based on their purpose across four completed projects and 12 construction sites.

However, existing studies generally focus on the manual classification of RFIs, and a limited number of studies have concentrated on extracting important terms from RFIs via text clustering methods (Lee and Yi, 2017; Afzal et al., 2023). Lee and Yi (2017) used topic modeling to predict uncertainty in RFIs, focusing on the pre-bidding stage. Yet, this study did not consider the construction phase, although numerous RFIs are typically created as projects progress. Afzal et al.'s (2023) study proposes an innovative approach using the LDA algorithm to extract patterns from RFIs, offering valuable insights for the construction industry but lacking a critical comparison of clustering and visualization techniques.

LDA is an unsupervised generative probabilistic model commonly used for text topic modeling for uncovering hidden topics within a collection of text documents (Buntine et al., 2004; Lee and Yi, 2017; Afzal et al., 2023). LDA was used for text clustering in annual reports of construction companies (Jagannathan et al., 2022), focusing on macro-level clustering to identify key concerns related to understanding corporate and industry strategies. Lai and Konstanta (2019) also investigated job descriptions, which are relatively short, for building permits using LDA. In another study, LDA was used for clustering on-site inspection text, and this data is entered within constrained timeframes of on-site inspections, thus including typos and variations in upper/lower case (Lin et al., 2020). Lastly, construction-defect litigation cases were clustered using LDA, and in this type of text, many words are used interchangeably, for example, grading versus slope (Jallan et al., 2019).

On the other hand, NMF is a linear algebraic model. Unlike other topic modeling approaches, NMF utilizes matrix factorization and multivariate analysis to generate coefficients rather than probabilities for each word, associating them with specific topics (Naik, 2016; Jagannathan et al., 2022). NMF effectively reduces the dimensionality of large datasets by finding a low-rank approximation of the original data matrix, capturing essential features while discarding noise and irrelevant information (Lee et al., 2012). However, NMF works better with shorter texts, such as tweets or titles, and smaller datasets (Egger and Yu, 2022). Previous studies in non-construction contexts, particularly analyzing large text streams and review data, have demonstrated varying performance between LDA and NMF, with one algorithm often outperforming the other (George and Vasudevan, 2020).

K-Means is another unsupervised learning algorithm that groups data into n clusters with equal variance by minimizing the inertia or sum-of-squares within each cluster (Wu, 2012). K-means efficiently process large datasets by grouping data points into clusters based on similarities (Farhang, 2017). However, the initial selection of cluster centers in advance can impact the outcome (Rana et al., 2011). Additionally, K-means are sensitive to noise and outliers, potentially compromising clustering accuracy (Kaur & Aggarwal, 2017). In the literature, Liu et al. (2021) investigated the reasons for pipeline incidents and contributory factors using the K-means clustering method.

Application of text mining and visualization techniques, including sentiment analysis, semantic analysis, content analysis, and clustering methods, is crucial for unlocking insights and analyzing construction issues in RFI documents. These techniques extract meaningful knowledge from unstructured data, providing valuable insights for addressing construction challenges. However, previous studies have not determined which of these methods is the most suitable for analyzing RFI texts.

Methodology

Data Collection and Pre-Processing

The project's unique characteristics and phases (i.e., pre-bid, design, or under construction) can significantly alter the terms and topics within RFI texts. Using a common RFI dataset from various project types might lead to overlooking project-specific hidden information. Therefore, this study analyzed the RFI documents of a single project, which is an airport project. The RFIs were retrieved from a common data environment (CDE), which has streamlined the RFI handling process by enabling online communication and ensuring tracked information (Afzal et al., 2023).

During the data preparation phase, if an RFI conveyed multiple topics, these were treated as separate data instances (i.e., RFI texts); for example, a clarification topic might be observed at multiple points in a structure but communicated through a single RFI. Each clarification point is treated as an individual RFI text in this case. Additionally, an RFI should be evaluated in conjunction with its responses, as submitting an RFI triggers opinions and additional inquiries from multiple parties, and the responses should provide information about the RFI topic. A subject stored as 4-5 distinct RFI documents in CDE was considered a single RFI text to maintain the RFI context. Consequently, 288 RFI texts were extracted, representing different disciplines and locations within the structure. A similar number of RFI documents (243 RFI data) were analyzed in another study

(Lee and Yi, 2017). To ensure the extraction of pertinent and meaningful information from the RFI dataset while minimizing irrelevant or confounding data, the following pre-processing steps were employed: (1) lowering case, (2) removing punctuation, (3) stop words removal, (4) filtering out alphanumerical patterns, (5) removing currency symbols, (6) copyright symbols removal, (7) tokenization, and (8) lemmatization.

Text Topic Clustering

Despite preprocessing efforts, not all obtained words (terms) hold equal significance on the RFI topic. Therefore, to prioritize terms based on their weights, the "Term Frequency-Inverse Document Frequency" (TF-IDF) stands out as the most representative weighting method for word prioritization (McArthur et al., 2018). TF-IDF considers the frequency of words across different documents and their frequency within each document. If a word occurs frequently in a document but is rare in the general collection, its importance within the document increases (Christopher et al., 2008). This situation forms the basis for using TF-IDF to reduce common words, focus on significant terms that differentiate documents from others, and extract key terms based on TF-IDF scores. Then, RFI texts were transformed into a TF-IDF matrix. Subsequently, this TF-IDF matrix is processed using four different clustering algorithms, and distinct key terms are identified.

Evaluation of Topic Clusters and Visualization Techniques

Identifying themes for each topic involves subjective human interpretations, necessitating domain knowledge from the building and construction industry (Lai and Kontokosta, 2019). To highlight the importance of domain experts, Lai and Kontokosta (2019) stated that they plan to gather a panel of experts, including architects and contractors, to further validate the topic model. Therefore, the efficacy of clustering methods and visualization techniques for complex RFI data analysis was assessed through expert evaluation by three quality engineers with over five years of experience. The following question was posed to the experts, "How successful are text clustering algorithms' outputs in understanding an RFI text's content (topic) and determining the keywords that reveal its content?". Similar questions are included in measurement tools, such as The Usability, Satisfaction, and Ease of Use (USE) and The System Usability Scale (SUS), which are commonly used in assessment of prototype, process, and model evaluation studies (Lund, 2001; Brooke, 1996). Results from each algorithm were evaluated on a 5-point Likert scale, ranging from most to least useful, practical, and applicable (i.e., successful).

Additionally, engineers were presented with visualization techniques tailored to each algorithm's output, rated on a 5-point Likert scale. This comprehensive approach identified the most advantageous clustering methods and visualization techniques for analyzing RFI texts.

Findings

All clustering algorithms were applied to the same dataset, forming 10 clusters with 20 distinct key terms. The researchers systematically named the topics to enhance clarity and facilitate interpretation. Tables 1-3 briefly list these keywords into topic clusters.

Within the framework of these three distinct clustering methods, certain pivotal keywords have undergone encryption due to privacy issues. This encryption is necessary because it includes project names, places, people involved, and contract details. For reference, this encryption scheme adheres to the following mapping: A*: (5 characters), B*: (5 characters), C*: (5 characters), D*: (6 characters), E*: (7 characters), F*: (8 characters), G*: (5 characters). Additionally, words with two or three characters have been included in the analysis. These short words hold significance for experts involved in the project and dealing with RFIs, serving as a distinctive feature of a known phenomenon within the project.

Evaluation of LDA Clusters

LDA is a probabilistic model where each word in a specific document can be associated with multiple topics. LDA considers each document a mixture of different topics and assumes that each word has a probability distribution among the topics in the document. Therefore, a word can be associated with multiple topics. The list of the 10 topic sets was obtained from the LDA model in Table 1 and the top 20 keywords with the highest weights that characterize each topic.

Table 1: Partial List of RFI Topics in LDA Clustering Method

Topic	Keywords
0	detail, attach, beam, see, column, connection, level, information, lift, steel
1	subrfi, rfi, A*, date, doc, response, damper, fire, room, rficir
2	ceiling, type, bracket, shutter, roller, camera, height, case, width, custom
3	lock, door, cut, provision, button, require, room, water, out, contact
4	door, schedule, use, cylinder, requirement, fire, confirm, attach, lock, handle
5	fire, report, foundation, contractor, stair, document, structural, provide, wall, include
6	change, rfi, frame, relate, B*, instruct, prab, draw, acm, core
7	lamella, sensor, dual, bliptrack, wifisensor, gate, strip, lift, type, installation
8	comment, mount, request, draw, area, equipment, revise, elevation, update, change
9	prab, show, acm, connection, sounder, design, accord, heating, floor, draw

The explanation of each topic is provided as follows:

Topic 0_Structural Details: Discusses details, attachments, beams, columns, and steel lift information.

Topic 1_RFI and Document Handling: Involves submissions, responses, dates, documents, and fire related topics.

Topic 2_Ceiling and Custom Design: Focuses on ceiling types, brackets, shutters, roller cameras, and custom designs.

Topic 3_Door and Water Requirements: Covers door related discussions, schedules, cylinders, and water requirements.
Topic 4_Door Scheduling and Confirmation: Focusses door scheduling, usage requirements, and confirmation processes.
Topic 5_Fire Safety and Foundation: Relates to fire reports, foundations, contractors, stairs, and structural documents.
Topic 6_Change Requests: Centers on changes, RFIs, frames, instructions, and core design.
Topic 7_Sensor Installations: Discusses lamellas, sensors, dual systems, WiFi sensors, gates, and lift installations.
Topic 8_Comments and Revisions: Involves comments, mounting requests, drawing areas, equipment revisions, and elevation updates.
Topic 9_Prab Design and Heating: Focuses on designs, connections, sounder designs, heating, and floor drawings.

Evaluation of NMF Clusters

NMF decomposes the given data matrix into the product of two lower-dimensional non-negative matrices. In text analysis, one matrix represents the distribution of topics across documents, and the other represents the distribution of words across topics. Due to this decomposition, a word in NMF can possess non-zero weights in multiple topics, resulting in the occurrence of the same keyword across different topics.

The list of the 10 topic sets was obtained from the NMF model in Table 2 and the top 20 keywords with the highest weights that characterize each topic.

Table 2: Partial List of RFI Topics in NMF Clustering Method

Topic	Keywords
0	subrfi, A*, doc, date, response, rfi, C*, mep, pdf, sprinkler
1	door, lock, leaf, cylinder, hardware, bk, closer, handle, schedule, D*
2	rficir, A*, shaft, doc, fcu, date, group, air, return, near
3	drawing, prab, td, acm, wall, structural, str, floor, foundation, design
4	opening, beam, existing, fit, slope, routing, pipe, designer, existing, solution
5	subrfi, A*, damper, control, supply, power, sys, date, doc, td
6	bracket, color, ral, camera, drawing, custom, shop, colour, commented, schedule
7	beam, level, connection, lift, steel, attached, E*, load, column, imd
8	total, gh, lcp, dcl, belongs, area, toilet, principle, room, follow
9	ceiling, shutter, roller, casing, height, mm, large, lamella, type, leeuw

The explanation of each topic is provided as follows:
Topic 0_RFI and Sprinkler Systems: Addresses RFIs, documents, responses, MEP, PDFs, and sprinkler.
Topic 1_Door Hardware and Schedules: Focuses on doors, locks, leaves, cylinders, hardware, and schedules.
Topic 2_RFICIR and Air Return: Discusses RFICIR (indicated the RFI which is in circulation among different stakeholders), shafts, documents, FCUs, dates, groups, air, and near returns.
Topic 3_Drawing and Structural Design: Involves drawings, walls, structural elements, floors, foundations, and designs.
Topic 4_Opening Solutions: Addresses openings, beams, existing structures, fits, slopes, routing, pipes, and design.
Topic 5_RFI and Damper Control: Covers RFIs, dampers, control, supplies, power systems, dates, and documents.
Topic 6_Brackets and Color Design: Focuses on brackets, colors, cameras, drawings, custom designs, shops, and schedules.
Topic 7_Beam Connections and Steel: Discusses beams, levels, connections, lifts, steel attachments, and columns.
Topic 8_Total Area and Ceiling Design: Addresses total areas, belongings, toilets, principles, rooms, and designs.
Topic 9_Design and Casing: Discusses specific design elements, ceiling shutters, roller casings, large lamellas, and leeuw types.

Evaluation of K-means Clusters

In addition to LDA and NMF, in the K-means model, each cluster is defined by the similarity of documents in the feature space. If a particular keyword is relevant to documents in multiple clusters, it can appear in the top keywords for each cluster.

The list of the 10 topic sets was obtained from the K-means model in Table 3 and the top 20 keywords with the highest weights that characterize each topic.

Table 3: Partial List of RFI Topics in K-means Clustering Method

Topic	Keywords
0	door, schedule, switch, bar, push, frame, ral, alarm, need, F*
1	door, lock, cylinder, leaf, bk, hardware, closer, D*, provision, handle
2	drawing, wall, attached, prab, td, acm, document, information, design, rfi
3	fit, opening, routing, existing, slope, pipe, changed, possible, beam, order
4	convector, size, card, reader, cad, lift, send, signal, riser, inspection
5	subrfi, A*, doc, date, rfi, damper, control, response, td, supply
6	beam, opening, existing, solution, ipe, steel, level, connection, attached, E*
7	ceiling, total, shutter, mep, roller, height, lighting, final, casing, type
8	rficir, A*, shaft, doc, fcu, date, group, rfi, air, near
9	lamella, mm, panel, cps, plate, new, G*, circuit, solution, damper

The explanation of each topic is provided as follows:
Topic 0_Door Schedules and Bar: Involves door schedules, switches, bars, pushes, frames, and alarms.
Topic 1_Door and Hardware: Focuses on doors, locks, cylinders, leaves, hardware, closers, and provisions.
Topic 2_Drawing and Design: Discusses drawings, attached documents, information, and design-related topics.

Topic 3_Fit and Routing Solutions: Addresses fits, openings, routings, existing structures, slopes, pipes, changes, and possible orders.

Topic 4_Convector Size and Lifts: Involves convector sizes, cards, readers, CAD, lifts, signals, and risers.

Topic 5_RFI and Supply Control: Covers RFIs, documents, dates, responses, and damper control.

Topic 6_Beam Solutions and Steel: Discusses beams, openings, existing structures, solutions, IPE, steel, levels, and connections.

Topic 7_Ceiling and Lighting Design: Focuses on ceilings, total areas, shutters, MEP, rollers, heights, lighting, final casings, and types.

Topic 8_RFICIR and Lamella Design: Addresses RFICIR, shafts, documents, FCUs, dates, groups, air, near returns, and lamella designs.

Topic 9_Circuit and New Solutions: Discusses specific elements like circuits, new panels, plates, and innovative solutions.

Comparison of All Clusters

Upon reviewing the results, the observed behavior can be attributed to the inherent differences in the assumptions and structures of the three clustering algorithms (LDA, NMF, and K-means). Each algorithm assigns unique topics based on its approach to modeling the connections between RFI documents and words, albeit with some word overlaps. For instance:

- LDA Topic_0, NMF Topic_7, and K-means Topic_6 share five common keywords (beam, level, connection, steel, attach (LDA) / attached (NMF&K-means)).
- LDA Topic_1, NMF Topic_0, and K-means Topic_5, with different weights, share 6 common keywords (subrfi, doc, date, response, rfi).
- LDA Topic_2, NMF Topic_9, and K-means Topic_7, with different weights, share 6 common keywords (ceiling, shutter, roller, case (LDA) / casing (NMF&K-means), height, type).
- LDA Topic_4, NMF Topic_1, and K-means Topic_1, with different weights, share 4 common keywords (door, lock, cylinder, handle). Additionally, leaf, hardware, bk, and closer are common only in NMF Topic_1 and K-means Topic_1.
- LDA Topic_9, NMF Topic_3, and K-means Topic_2, with different weights, share 4 common keywords (draw (LDA) / drawing (NMF&K-means), prab, acm, design).
- Although LDA exhibits similar topics, as seen in the examples above, it diverges with some topics (e.g., LDA Topic_8).

Table 4: Expert Evaluation of RFI Clustering Methods

	Expert #1	Expert #2	Expert #3	Mean
LDA	5	4	5	4,67
NMF	3	5	4	4,00
K-means	3	4	4	3,67
Mean	3,67	4,33	4,33	

The scale for understanding an RFI text's content (topic) and determining the keywords was defined as 1: very unsuccessful and 5: very successful (Table 4).

From the experts' perspective, LDA is more successful than the other two clustering algorithms in clustering RFIs. LDA can create more distinctive topics and provides a focus on micro-level clustering rather than generating general topics. When considering the characteristic features of RFIs compared to other text data used in the construction sector, such as their lengthiness, noisiness, inclusion of typos, combinations of upper- and lowercase letters, and utilization of variable terms for a single concept, the obtained results are consistent with the literature.

Ratings assigned to NMF and K-means models, except for Expert #2, are identical. This topic similarity has led to experts giving similar ratings, as these models create quite identical topics. None of the experts gave a rating below three because clustering algorithms are generally not used in current RFI analyses. Therefore, a clustering study of this kind is perceived to positively impact on understanding the RFI text's content (topic) and determining the keywords that reveal its content. In summary, even the model with the lowest score (K-means) demonstrates average success in the clustering RFI text data.

Comparison of Visualization Techniques

Multiple visualization techniques are employed in clustering problems. The pyLDAvis, specific to LDA models (See Figure 1(a)), is a Python package that empowers users to visualize LDA models effectively. This interactive tool provides features like hovering and clicking for in-depth data exploration. Essentially, pyLDAvis is a critical tool for gaining insights into the topics generated by LDA models and their distribution across documents.

The second method involves scatter plot visualization. For this method, the t-SNE (t-Distributed Stochastic Neighbor Embedding) algorithm was applied first (See Figure 1(b)). t-SNE is a dimensionality reduction technique designed to visualize high-dimensional data compactly by preserving pairwise distances between data points as much as possible in a lower-dimensional space. In essence, t-SNE rearranges data points from a high-dimensional space to a lower-dimensional one, emphasizing the preservation of relationships among similar points.

The third method visualizes topics with word clouds (See Figure 1(c)). Word clouds are highly preferred for identifying and highlighting key themes and subjects within a textual corpus.

They facilitate a quick and effortless analysis of crucial keywords in a dataset by visually displaying frequently occurring words, where the font size is directly proportional to their frequency of occurrence. These word clouds represent a set of words visually, with the most frequent words appearing larger in size and color. They are typically arranged in a circular or elliptical pattern.

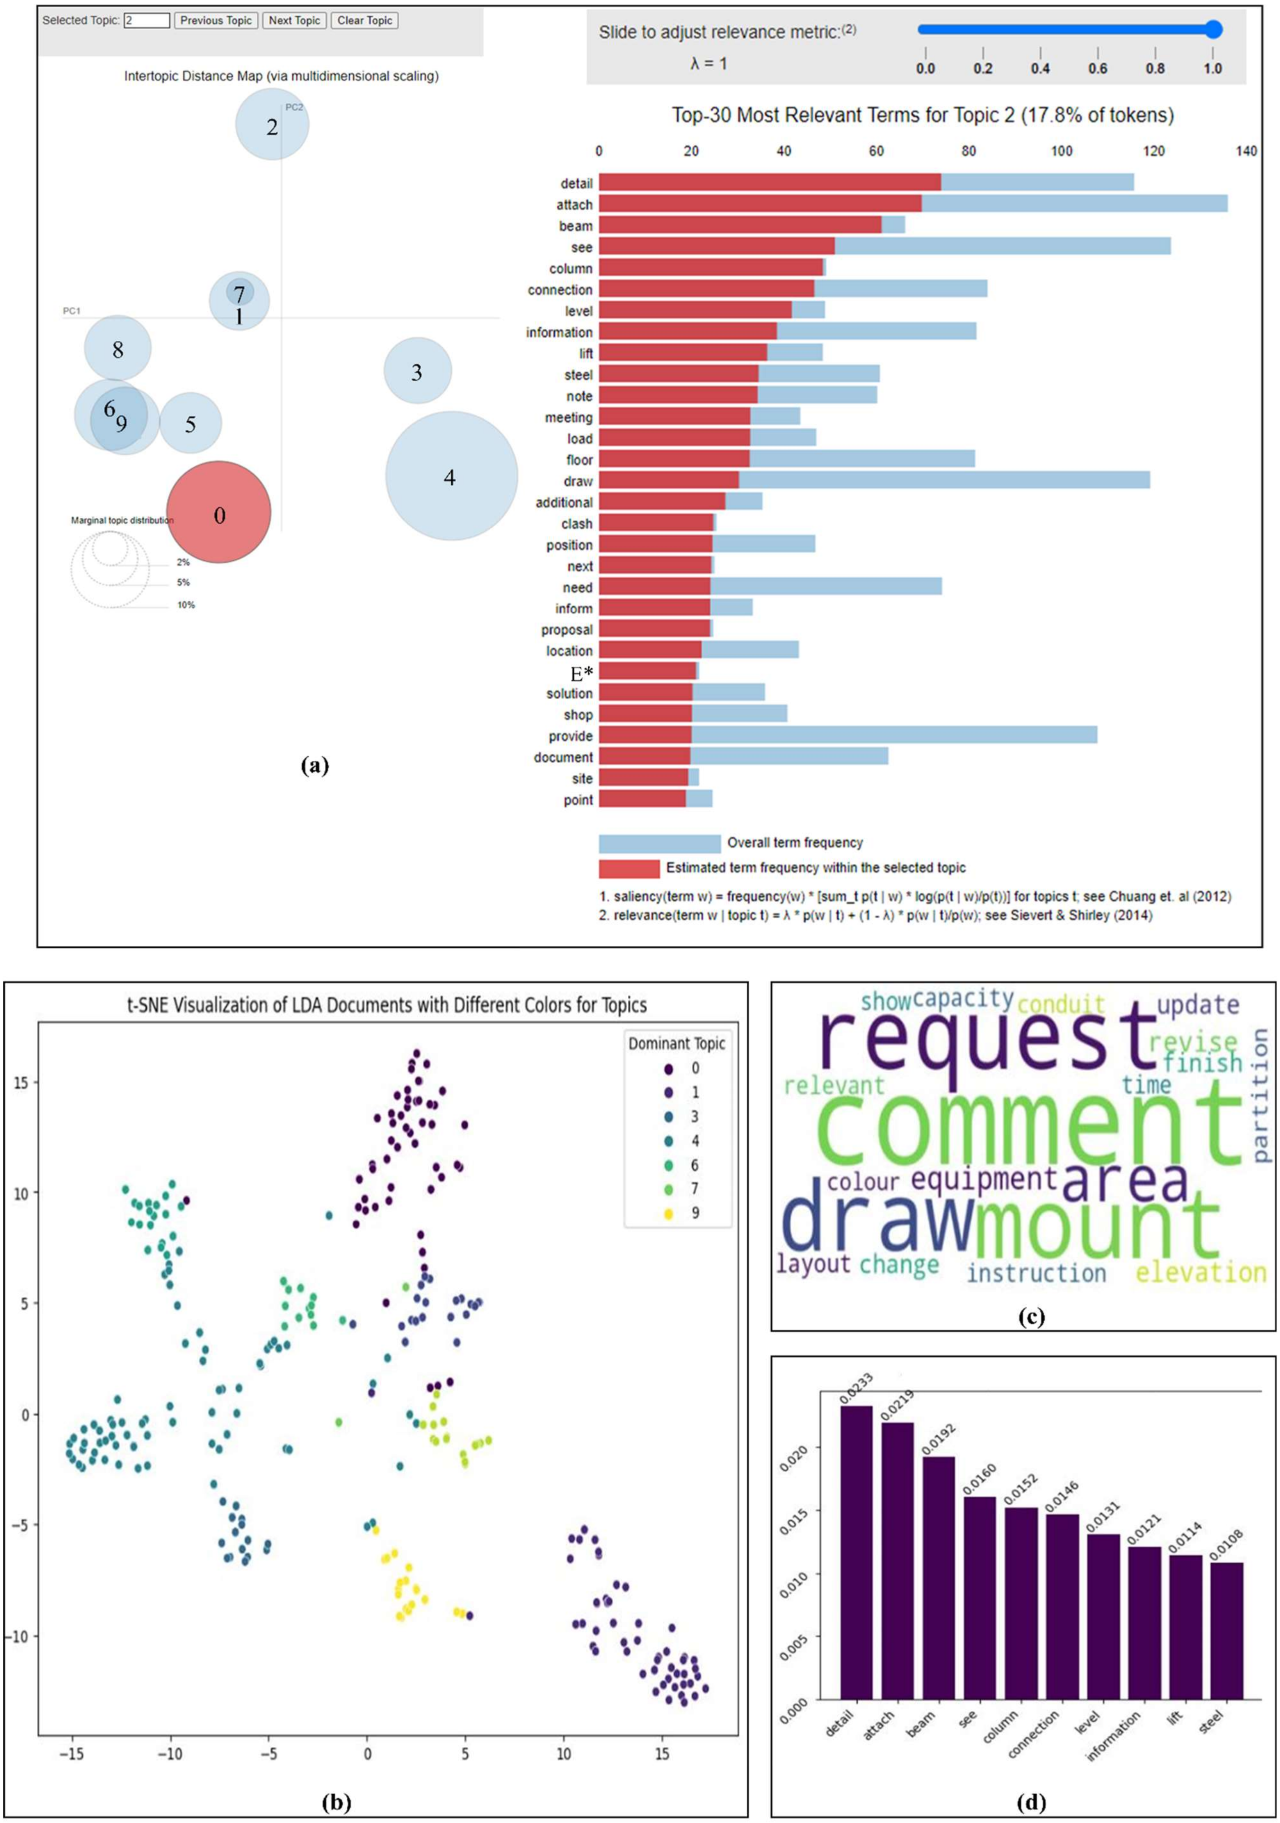

Figure 1: RFI Clustering Visualization Methods (a) pyLDAvis; (b) scatter plot; (c) word cloud; (d) bar charts

The final method utilizes bar charts (See Figure 1(d)). Bar charts are employed in statistical studies for simplicity, interpretability, distribution insight, representation of topic data, and space efficiency. This study applied visualization techniques, including scatter plots, word clouds, and bar charts, to LDA, NMF, and K-means, while pyLDAvis was exclusively used for LDA.

The experts evaluated the outputs of each model with each visualization method and were asked to rank their preferences for visualization tools used for analyzing topics and keywords. Table 5 shows the experts' preferences for visualization techniques regarding RFI topics and keywords.

Table 5: Expert Evaluation of RFI Clustering Visualization Methods

	pyLDAvis	scatter plots with t-SNE	word clouds	bar charts
Expert #1	1	4	3	2
Expert #2	1	4	2	3
Expert #3	1	4	3	2

The most preferred visualization method was identified as pyLDAvis. The experts deemed its ability to filter topic clusters with their keywords rapidly and provide interactive access to be the most useful, practical, and applicable.

Two experts ranked word clouds and bar charts second, providing data on keyword weights. While word clouds offered insights into keyword weights through font sizes, experts found the provision of numeric data more practical.

The scatter plot was evaluated as the least preferred visualization method because of its perceived lack of user-friendliness for quickly analyzing topics despite providing insights into the proximity or overlap of topic clusters.

Conclusions

In this study, 288 RFI texts retrieved from an airport project were analyzed with three different clustering algorithms (LDA, NMF, and K-means), and the results of these algorithms were compared. The generated clusters and keywords were presented using four visualization methods (pyLDAvis, scatter plots, word cloud, and bar charts). In the final stage of the study, with expert opinions, the most preferred algorithm (LDA) and visualization technique (pyLDAvis) were determined. The results of this study provide crucial insights into determining the most effective clustering algorithm and visualization technique for analyzing RFI texts in the literature. Moreover, the findings of this study can benefit project managers and quality engineers for rapidly and effectively analyzing RFI topics to develop proactive measurements for non-conformities before they arise on the construction site.

In the future, comparative analyses can be conducted by increasing the number of RFIs and including different types of projects. Furthermore, the topics in this study's results can be extended by processing them as metadata in RFI texts and analyzing them with machine learning algorithms. While the results of this study play a role in the prior work for visualizing RFIs on the BIM model, visualization and 3D querying practices within the scope of BIM are left for future studies.

EXPLORING CAUSAL LOOPS IN RESILIENT MAINTENANCE OPERATIONS OF BUILT ASSETS: A LITERATURE REVIEW

Fereshteh Ahmadi[1], Pablo Martinez[1], Barry Gledson[1], SeyedReza RazaviAlavi[1]
[1] Northumbria University, Newcastle, UK

Abstract

Maintenance operations account for a significant portion of project lifecycle costs and are subject to disruptions. A potential solution to this problem is to develop resilient strategies to cope with disruptions, ensuring safe and reliable operation of assets. This paper intends to develop a causal loop diagram to depict system downtime causes among resilient maintenance operations of built assets and represent the complex nature of relationships between maintenance outcomes and disruptions. As a result, root causes of major disruption events to maintenance operations of built assets are mapped to inform technological advances that support predictive maintenance such as simulations.

Introduction

The operation and maintenance (O&M) phase is the "longest and costliest phase" of an asset's lifecycle (Chen and Tang, 2019), which can account for up to 80% of the total cost of the asset (Cavka et al., 2015). The cost of maintenance itself can constitute 25% of the overall operation and maintenance cost (Navas et al., 2020). Therefore, improving maintenance operations can significantly reduce the total cost of built assets. 'Maintenance operations' refers to what maintenance activities should be carried out on the asset, when and how the demand for this operation is activated (Gits, 1992). In this study, maintenance operations refer to activities to be undertaken to ensure the acceptable level of functionality of an asset. Maintenance operation is a complex process due to the requirement of incorporating a variety of disciplines, knowledge, human resources (e.g., maintenance crew), tools (diagnostics and predictive technologies), information technology systems (hardware and software), financial resources and physical resource (e.g., spare parts) (BS EN 15341:2019). This complex process can be affected by different sources of uncertainty and disruptions consequently leading to significant financial losses, threatening survival of asset and unserviceability of the assets (Osei-Kyei et al., 2021). In this regard, with the increase of disruption events (man-made and natural disasters) (Dianat, et al., 2021) there is an immediate need for a resilient strategy to improve responsiveness of the asset to the unexpected events and disruptions (Ali et al., 2017). As Hosseini et al. (2016) stated, improving resilience of systems significantly raised for researchers and industries. However, literature shows that there is a lack of clarity in the maintenance operation resilient definitions, concepts, and strategies (Ali et al, 2017, Burroughs, 2017). Simulation is one of the effective methods for modelling maintenance operations and analyzing the efficiency of various scenarios for improving resilience in response to disruptions. It can model the complexity and uncertainties of maintenance operations in a risk-free environment, allowing organizations to observe a system's behavior under various circumstances. The necessary first step to developing a decision-making model for this purpose is to look at the dynamic behavior of system and potential root causes of disruptions to analyze their interactions with each other and on the system and how they work to create the phenomenon (Dianat et al., 2021). In addition, there are some causes whose sources are independent of the system itself; however, the impacts of them amplify disruptions in the system. These interactions can be illustrated via causal loops using system dynamics (SD). The SD shows how components interact throughout the system by going beyond events and searching for behavior patterns (Khorshidi et al., 2023). It also captures, simulates, and estimates the effects of policies, parameters, and components that change dynamically over time on the whole system (Khorshidi et al., 2023) and demonstrates them in a causal loop diagram (CLD).

Methodology

This study is informed by a deductive approach where the qualitative data (pre-existing theory) is analyzed to anticipate certain core concepts. Thereby, an extensive literature review is conducted to identify root causes of disruptions to maintenance operations. In order to make full sense of the findings, a start list of priori categories was generated in line with previous research using the research questions (mentioned below). Data was deductively analyzed to develop clusters of disruption sources (internal to the organization, external to the organization but internal to the network, and external to the organization). Thereafter, a system dynamics approach was used to develop a novel causal loop diagram (CLD) for demonstrating the causality (causes and effects) and interrelationships between identified disruptions, their variables, and sources. CLD is one of the SD modeling that represents the complex and nonlinear relationships between components and can be developed through gaining knowledge about a system as well as discussing and brainstorming with experts (Khorshidi et al., 2023). The CLD helps the user communicate the feedback structure (root causes of a problem) and underlying assumptions (Sushil, 1993). According to Sterman (2000) CLD can *"1) quickly capture your hypotheses about the causes of dynamics, 2) eliciting and capturing the mental models of individuals or teams; and 3) communicating the important feedback, you believe are responsible for a problem."*

Research questions:

1) What are the root causes of major disruptions to the maintenance operation of assets?

2) How do the identified events impact the maintenance operations (e.g., what aspects of maintenance operation are affected)?

3) How can the resilience of maintenance operations be improved (e.g., what capabilities are required to be improved to reduce the impact of disruptions)?

Literature review

Maintenance operation resilience

Resilience is the ability of a system to absorb, resist, adapt, and recover from disruptions (Osei-Kyei et al., 2021 and Durán et al., 2020) without interrupting the full performance of the system. If a system is substantially affected, its resilience gives it the ability to fully recover its function in the shortest possible time (Hosseini et al., 2016). In this paper, resilience of maintenance operations refers to the ability of the asset to continue its operations while subjected to disruptions. Bukowski and Werbińska-Wojciechowska (2021) developed a resilient-based maintenance support system with four subsystems including monitoring, responding, learning, and anticipating (as shown in Figure 1) to minimize the consequences of disruptions. The main task of the monitoring phase is to detect disruptive events. The response to disruptive events should be authorized, effective, and analyzed after the disruption. However, as resources (e.g., information, maintenance crew, materials, and tools) in organizations are not infinite, responses can only be prepared for a limited number of disruptive events or situations that occur frequently (Bukowski and Werbińska-Wojciechowska, 2021). The learning subsystem is based on the organization's behavior and actions in specific situations. The primary purpose of learning is to improve the organization's ability to respond, monitor, and anticipate disruption as well as changing values and criteria in the organization if required. The final phase is anticipation. The key purpose of this phase is to think and imagine outside the event horizon, conceive different possibilities, and predict what can happen in the future.

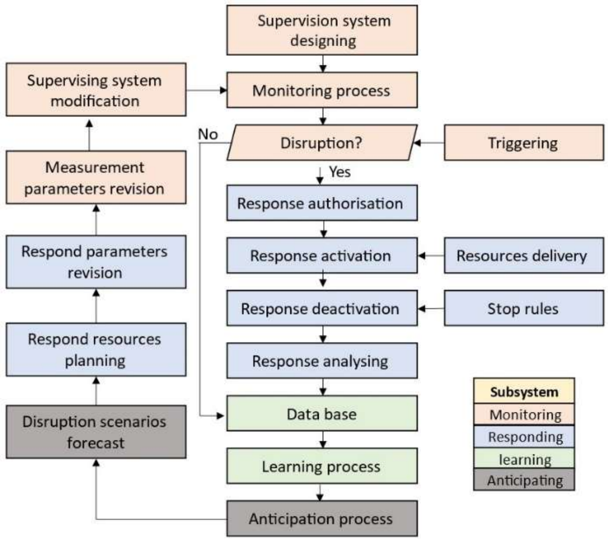

Figure 1: A functional diagram of a maintenance support system (after Bukowski and Werbińska-Wojciechowska. 2021)

Sun et al. (2022) examined another framework which is a resilience-based approach to maintenance asset and operational cost planning comprising three principal capacities: absorption, adaption, and restoration. As shown in Figure 2, 'Absorption' (R0) is the capacity of a system to withstand a disruption, absorb its consequences, and return to its original state. The strength of the absorption capacity is based on the structure of the system and the intensity of the interruption. A system with higher absorption capacity requires less effort to recover from a disruption (Sun et al., 2022). 'Adaption' (R1) is the ability of a system to recover a certain amount of lost performance without the need for external maintenance actions (Abimbola and Khan, 2019). And 'restoration' (R2) is the phase in which the system is restored to a new equilibrium state which can be lower, equal, or greater (green dotted line) than its original state by employing external maintenance actions.

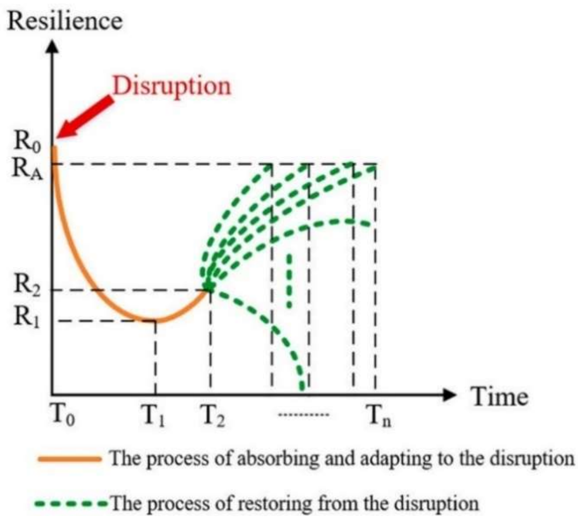

Figure 2: The resilience behaviour of a system subject to disruptions (after Sun et al., 2022)

Shekarian and Mellat Parast (2021) defined four resilience enhancers (flexibility, agility, collaboration, and redundancy) and examined the effect of each enhancer on five types of disruptions to a network (demand, supply, process, control, and environmental disruptions) and realized that adopting appropriate enhancers has great impacts on organizational performance while being affected by disruptions. To improve resilience in an organization, all the affective variables are required to be identified. In this regard, disruptions and their root causes to the maintenance operations categorized are discussed below.

Disruption to maintenance operation

Sources of disruptions to a system can be categorized into three types: 1) internal to the organization, 2) external to the organization but internal to the network, and 3) external to the network (Shekarian and Mellat Parast, 2021, Sun et al., 2022). Shekarian and Mellat Parast (2021) defined five types of disruptions to a network including process and control risks (internal to the firm), demand and supply risks (external to the firm but internal to the network) and environmental risks (external to the network) and classified supply chain disruptions into these categories as shown in Figure 3 below.

The following section discusses the sources of disruptions to the maintenance operation of built assets based on the identified categories discussed.

Maintenance process risks: process risks involve potential deviations from producing the desired quality and quantity at the right time (Shekarian and Mellat Parast, 2021). Root causes of maintenance operations process risks can be referred to lack of maintenance crews or skilled workers (e.g., labor strikes), lack of spare parts (caused by deficiency in inventory management and logistic network), adequate budgetary resources for maintenance costs, lack of diagnostic and preventive technologies tools, and interruptions to information communication technology (ICT). For example, cyber-attacks are one type of ICT disruption. In recent years, the development of digital platforms for the operation and maintenance of assets to exchange and store data has benefited organizations but it has also made them more vulnerable to cyber-attacks (Ghadiminia et al., 2022).

There are some additional sources of process risks depending on the maintenance approach adapted in the organization, such as failure in the data transmission network (failures in sensors and IoT networks), breakdown of external or internal IT infrastructure, insufficient maintenance records, inaccessibility to data in real time, and lack of decision support systems.

Control risks: "control risk or network risk involves the assumptions, rules, systems, and procedures that govern how an organization exerts control over its processes" (Shekarian and Mellat Parast, 2021). Various maintenance approaches, including corrective maintenance (unscheduled and event-driven tasks) and proactive maintenance (time-based or planned preventative maintenance, and condition-based maintenance) have different maintenance standards, regulations, and legislation (Miles et al., 2019). However, many maintenance standards have been developed in a way that they provide a common ground for a harmonized maintenance approach (Miles et al., 2019). These legislation and regulations outline the general requirements for defining all types of maintenance (e.g., EN 13306), present general recommendations for the technical documentation of maintenance (e.g., EN 13460), provide generic descriptions of maintenance process (e.g., EN 17007) among others but they lack local legislation to mitigate health, safety, and environmental (HSE) risks (Miles et al., 2019). On the other hand, compliance with such requirements is typically governed and managed by experienced system experts in the organization; therefore, lack of interorganizational policies to embed these rules is another source of control risk. Other examples of sources of this type of risk are lack of safety policies and asset management policies.

Demand risks: this type of risk involves any possible gap between actual and anticipated demand and any potential disruptions in the flow of material and information within the network or between the focal firms and the market (Shekarian and Mellat Parast, 2021).

Demand forecasting is a challenging task as the demand is intermittent and lumpy. From maintenance operations perspective, unanticipated demands (e.g., skilled workers), high demand services, uncertain maintenance demands, and insufficient information for forecasting demands are examples of demand risks.

Supply risks: these risks entail: 1) failure to supply spare parts in terms of time, quantity, and quality; and 2) disruptions to the flow of products and information within or outside the organization. Turan et al. (2020) stated that unavailability of spare parts accounts for up to 80% of all system downtime in the maintenance operations. Sources of supply risk associated with maintenance operations can be referred to insufficient logistics networks (failures in nodes (facilities) or links), poor inventory planning, and lack of outsourcing and globalization.

Environmental risks: these are risks external to the organization and are beyond the control of organizations. One of the examples of sources of environmental risk is natural disasters. As a result of climate change, natural disasters, such as floods, have occurred more frequently and intensively in the past decades (Song et al., 2016 and Feldmeyer et al., 2020). In fact, a 2% rise in the annual incidence of natural disaster was documented during the past 15 years and built assets are one of the most vulnerable areas to be affected by natural disasters (Bang and Burton, 2021). Other examples include war, epidemics (e.g., COVID-19), and political instability.

In addition to the previously described disruptions, evaluating 'co-occurring' or 'compounding failures' (when two or more sources of disruption occur

Supply chain sources of risks				
Internal to the firm		External to the firm but internal to the supply chain network		External to the network
Process risk	Control risk	Demand risk	Supply risk	Environment risk
Machine failure	Lack of collaborative planning	Volatile demand	Outsourcing and globalisation	Natural disaster
Labor strike	Asset management policy	Market changes	Sudden hike in costs	Terrorism and war
Product quality problem	Safety stock policy	Innovation competitors	Supplier commitment	Political instability
Equipment unreliability	Batch size or order quantity policy	Unanticipated demand	Supplier insolvency	Social and political grievance
Operator unavailability	Transportation management policy	Unusual customer payment delays	Variability of replenishment lead time	Technology changes
Bottleneck or inflexible process		Competition changes	Supplier quality problem	Diseases or epidemics
Breakdown of external or internal IT infrastructure	Asymmetric power relationships	Forecasting errors	Supplier bankruptcy	Economic downturn
			Sudden supplier demise	
Reliability of supporting communication system	Poor visibility along the supply chain	Insufficient information from customer order	Poor logistics performance of suppliers	
			Capacity fluctuations or shortage in supply market	

Figure 3: Supply chain sources of risks and disruptions (after Shekarian and Mellat Parast, 2020)

concurrently) and 'cascading failures' (when a disruption happens after the initial failure (horizontal-correlated cascading failures) or when a disruption can cause failure at the upper layers of the system (vertical-correlated cascading failures) (Moffatt et al., 2021) is crucial because they have high impacts on the maintenance operations and are more difficult to fix.

Due to the variety of sources of disruptions to the maintenance operations, developing strategies to mitigate disruptions by making the maintenance operations more resilient and responsive is crucial. Access to reliable and quality data is critical for achieving this aim and developing a simulation-based decision support system.

Technologies and disruptions

There are two types of disruptions to maintenance operations: 1) 'anticipated' disruptions, like demand risks, which can be predicted based on historical data related to their nature, range, and frequency, and 2) 'unanticipated' disruptions like environmental disruptions, which are not dependable or consistent with historical data (Tsiamas and Rahimifard, 2021).

In recent years, integrating BIM (building information modeling), GIS (geographic information system), IoT (Internet of Things) and computerized maintenance management system (CMMS) such as IBM Maximo, ARCHIBUS, EcoDomus, FM Systems, AssetWorks, or eMaint among others has supported maintenance operations by improving decision-making (Ma et al., 2020). These approaches use asset life-cycle data and maintenance records to detect possible failures (Moradi et al., 2021). For example, BIM can be used to minimize maintenance processes and supply disruptions by providing equipment location data, equipment maintenance data, cost data, and historical maintenance records. Also, it can be adopted to deal with control disruptions by increasing collaboration between participants and identifying potential risks. IoT and machine learning tools can be adapted to minimize supply and maintenance process disruptions, as they can predict when an asset or equipment requires maintenance actions (before breakdown point) and provide an accurate assessment of equipment health conditions based on data collected by sensors (Shamayleh et al., 2020).

Digital twins, through the synergy of several technologies including IoT, artificial intelligence (AI) and BIM integrate multi-source data into one single system to support decision-making for maintenance processes. AI can be adapted to improve maintenance demand planning with identification of demand pattern, market trend, and efficient forecasting. However, in order to take advantage of AI, clean and quality data, sufficient technological infrastructure, resource availability, and area experts are necessary. This will include supplying spare parts.

Results and discussion

The initial contribution to this research is to define the sources of disruptions to the maintenance operations and propose a classification based on these criteria. The classification includes 'Internal disruptions' (process risk, control risks), 'External to the organization but internal to the network' (demand risks, supply risks) and 'External disruptions' (environmental risks) to the maintenance operations. The connections between sources of disruptions and their root causes to improve organizational responses are mapped. To achieve this, SD is adapted due to its capability of capturing the dynamic behavior of complex systems and depicting the dynamic interactions of maintenance operations in different areas such as economic, risks, humanity, environmental, and supply chain. Causal loop diagrams in SD are employed for developing a hypothetical and knowledge based CLD (see Figure 4) to demonstrate maintenance operation system structure, complexity, and feedback processes.

In CLD, each box is a variable and causal relationships between each variable are represented as arrows with polarities (positive and negative signs). In this context, a positive sign means that a change in one variable led to a change in the same direction, and a negative sign led to a change in the opposite direction. The causal loops can be positive (reinforcing) or negative (balancing). "A positive loop is associated with exponential growth. However, a

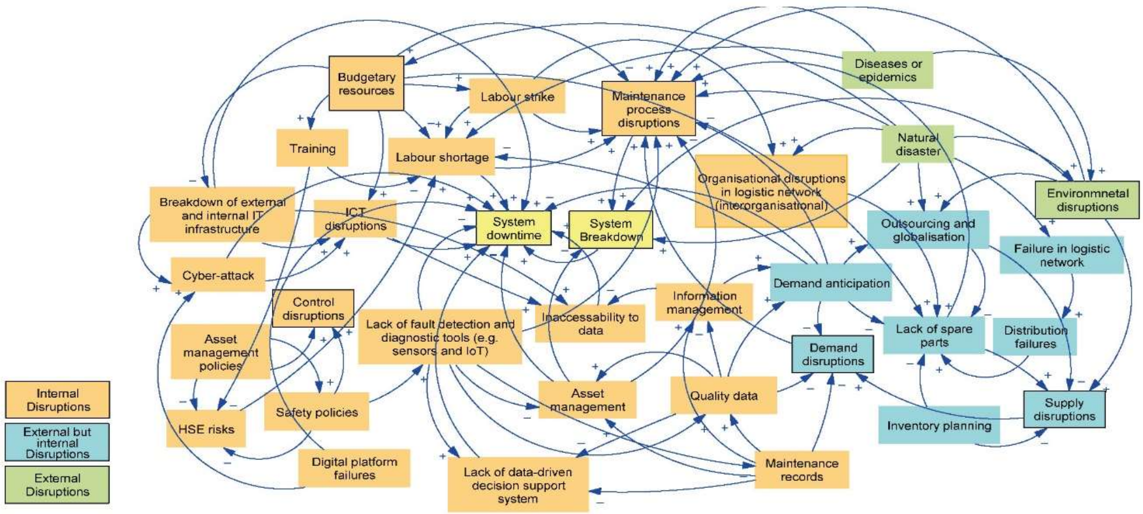

Figure 4: Causal loop diagram - root causes of disruptions to the maintenance operations.

negative loop tends to reach a balance point" (Khorshidi et al., 2023). Color coding is adapted to distinguish different types of disruptions (internal, external, external but internal) and their interconnected factors.

The advantage of CLD is that it can connect non-linear relationships between different sources and varieties and present casualty of system breakdown or system downtime. As it can be seen in Figure 4, the relationship between maintenance process disruptions and training is not a linear relationship. For example, budgetary resources have a positive impact on training; the higher the budget, the more training is conducted. So, training has a negative impact on maintenance process disruptions through budgetary resources, which is a dynamic variable.

The proposed CLD requires it to be tested empirically and validated by experts in the future. Once the CLD is validated, it can be transformed and formulated for the model and run for results. By adopting simulation, different recovery strategies on maintenance operations performance affected by disruptions can be analyzed. To achieve this, different scenarios in terms of the presence or absence disturbances and presence or absence of a mitigation strategy can be examined. The impact of mitigation strategies will be analyzed in regard to time and cost of recovery.

The CLD aims to provide a base for the development of accurate simulation models in the context of maintenance disruptions. In this context, the CLD can be used to ensure that the all the relevant and impactful data on the simulated variable is considered in the simulation. For example, let's envision creating a simulation model that aims to determine the impact of disruptions on 'spare parts supply chain'. Following the CLD across the multiple links that connect 'Supply Disruptions' with the rest of the variables, one can ensure that all the relevant variables are included in the model. On the first instance, 'outsourcing and globalization', 'logistic networks', 'lack of spare parts', 'inventory planning' and 'environmental disruptions' are connected, then the variables linked to those need to be considered and so on. With the CLD in mind, a comprehensive list of variables required to accurately simulate an outcome from a major disruption is given. However, the importance and impact of each variable on the outcome is not provided on the CLD and simplification of simulation models from the initial list of variables is a work in progress.

Conclusion and further study

This study presents a review of the literature to explore potential root causes of disruptions to the maintenance operations of built assets to improve maintenance operations resilience. Due to the dynamic nature of this system, system dynamics theory is used to demonstrate relationships and feedback loops between related factors to enhance understanding of the system complexity and non-linear causality. It also shows the need of multidisciplinary resilience approaches (current research gap). As a result, academics and practitioners are better equipped with the technological advances that support predictive maintenance, such as simulations, for improving resilience of maintenance operations in the practices. It is mentionable that practices required some practical changes for adopting resilience policies that necessitated a rethinking and adaptation of new governance approaches.

The limitations for this study are: 1) there is not much available literature about disruptions to maintenance operations as well as improving resilience in maintenance operations (research gap); and 2) the literature review is secondary data, not primary data: therefore, quality and accuracy of data is limited.

By understanding the current gaps, future research will develop a digital simulation-based decision-support system (based on the proposed CLD) to improve resilience of maintenance operations of built assets. Survey research including expert interviews will be conducted to 1) analyze the intensity and frequency of experienced disruptions in the medium-to-large size organizations, 2) explore organizational mitigation plans to recover from the disruptions, 3) evaluate the efficiency of the mitigation strategies adapted, 4) evaluate resilient capabilities in the organization absorption, adaption, and restoration.

Also, given that most of the research has focused on the pre-disruption stage, future studies are recommended that also investigate the post-disruption stage and its management.

DEVELOPMENT OF SIMEC-OPT FRAMEWORK FOR OPTIMIZING GLAZING PARAMETERS ENHANCING RESIDENTIAL BUILDING THERMAL COMFORT AND ENERGY PERFORMANCE

Bhavya Gonuguntla, Tripti Singh Rajput, Omprakash Ramalingam Rethnam, and Albert Thomas
Indian Institute of Technology Bombay, Mumbai, India
Corresponding author, e-mail address: albert@iitb.ac.in

Abstract

While glazed buildings have become a symbol of modern construction with their aesthetic appeal, there is a lack of research specifically focusing on the influence of glazing parameters on energy consumption and occupant comfort in residential buildings, especially in tropical climate zones. The study is focused on developing a simulation-based framework for optimizing the glazing parameters of multi-storied residential buildings in Indian climate zones to enhance thermal comfort and energy performance using a baseline model in Mumbai, India. Optimal configurations, identified through the study, suggest potential improvements of up to 30% in energy efficiency and 8% in thermal comfort compared to a baseline design considered in the study. The findings aim to inform architects, builders, and policymakers about tailored glazing configurations in various Indian climates.

Introduction

As global carbon emissions attributed to buildings reach nearly 42 percent, the emphasis on sustainable and energy-efficient building design has become paramount (Architecture 2030, 2023). The key to achieving sustainability in the building sector is the exploration of energy consumption patterns so as to take up energy-conserving measures for the same. An assessment by the Bureau of Energy Efficiency (BEE) shows that in India, lighting and air conditioning use 80 percent of the energy in commercial buildings, whereas fans, lighting, and refrigerators use maximum energy in residential buildings (Kaja, 2015). The energy demands of a building are significantly influenced by its envelope which serves as the primary connection between the external environment and the interior spaces. The architectural world is witnessing a surge in the popularity of providing more glass as a major material in the building envelope (Ayyad, 2011). Glass offers transparency and a sleek, contemporary look that enhances the architectural appeal of structures. Glass allows natural light to enter buildings, positively impacting occupant well-being as exposure to natural light has been linked to improved state of mind, increased alertness, and enhanced productivity (Golmohammadi et al., 2021). As countries such as India experience urbanization and economic growth, there is a desire to shift to contemporary architectural styles that incorporate more glass in the envelopes. However, when it comes to building energy efficiency, the choice and application of glass can significantly influence the outcome. One of the primary challenges with glass in tropical climates is excessive heat gain. Tropical climates typically experience intense and prolonged sunlight which can lead to a greenhouse effect inside buildings, causing them to overheat. This, in turn, requires more energy for air conditioning and cooling, leading to increased energy costs and carbon emissions (Sayed and Fikry, 2019). Hence, the performance of selected glass is of paramount importance in controlling energy consumption.

The process of selecting glass has become increasingly intricate due to the wide array of glass options available, ranging from performance-oriented attributes to aesthetic considerations. Usta and Zengin (2022) performed energy modeling for an office building, considering four distinct types of glazing, to assess the influence of various window glazing properties on the building's energy performance while maintaining consistent indoor thermal and visual comfort conditions. The findings of the study demonstrated that the utilization of appropriate glazing materials could lead to a substantial reduction in energy consumption, specifically about 25% (Usta et al., 2022). Though the study showcased significant improvement in energy consumption, the lack of validation of the model raises concerns about the reliability of the simulated results. Further, the methodology outlined in the study appears to have a limited scope regarding glazing variations as it considers only four types of glazing models. Khalaf et al. (2019) investigated the impact of façade and shading systems on the energy performance of school buildings in Istanbul, emphasizing the need for a balance among lighting energy, heating, and cooling energy. The authors presented a case study comparing traditional clear double-layer windows with various glazing and shading alternatives and revealed a significant energy consumption reduction when using proper glazing and shading systems. However, the authors overlooked the user comfort and the potential effect of glazing and shading type on the productivity of students (Khalaf et al., 2019). Kumar et al., (2018) investigated the thermal performance of commercial and residential buildings constructed with various building materials and window glass types in five different climatic zones of India. The findings demonstrated that, among the eighty building models analyzed, the building featuring a mud brick wall and south-facing bronze-reflective glass windows exhibited the most significant energy savings in terms of minimizing heat gain. While this study made valuable strides in understanding energy efficiency in residential buildings, it beckons further considerations to understand the broader impact of glazing choices. With the increasing prevalence of remote work, residential spaces have become multifunctional and serve as both living and working areas, enhancing the significance of factors such as productivity and comfort in residential buildings. While the above studies make significant contributions to the aspect of energy efficiency, the impact of different glazing options on occupant comfort in residential environments remains underexplored. ASHRAE (American Society of Heating, Refrigerating, and Air-Conditioning Engineers) defines thermal comfort as the conditions in which occupants of a space feel satisfied with their thermal environment (ASHRAE Standard 55). Further, due to the intricate nature of building models, computer simulations emerge as an efficient, comprehensive, and highly accurate method. Naji et al., (2021) used a multi-objective optimization approach using TRNSYS (Transient System Simulation Tool) and EnergyPlus to enhance the envelope components of prefabricated houses across six distinct climate zones in Australia. Optimization with multiple objectives involves the simultaneous consideration of conflicting goals, such as minimizing energy consumption while maximizing occupant comfort. This requires evaluating trade-offs between different design options to identify the most optimal solution that satisfies multiple criteria. The authors in this study considered energy efficiency, thermal comfort, and daylight illuminance as objectives. The results demonstrated significant improvements in various aspects of building performance compared to a baseline design. Compared to a baseline design, the life cycle cost of the optimal solution was reduced by 27-31%, indicating cost savings over the building's lifespan. Further, thermal discomfort hours were reduced by 6-55% (Naji et al., 2021). In a similar study by Ran et al. (2023), DesignBuilder was used, which employs a non-dominated sorting genetic algorithm (NSGA-II), to optimize building energy, comfort, and cost. The optimal solution reduced energy use by 21.1%, and improved thermal comfort by 32.4%, but increased initial investment cost by 35.3% for a reference building in Beijing. However, the above studies focus on various construction aspects, such as building materials, orientation, and insulation, rather than explicitly addressing the direct impact of glazing types. The studies also oversee the importance of validating building models with real-time data to authenticate consumption patterns and occupant behavior. Bridging this gap in literature would provide valuable insights for architectural regulations and building design, especially in the context of Indian climate zones. India is a vast country with different climate patterns and temperature ranges, from the tropical conditions in the south to the colder climates in the north. With residential buildings already accounting for a significant portion of India's energy consumption i.e., 20.4% projections suggest that by 2032, this percentage will increase sevenfold to reach 36.5% emphasizing the need for more sustainable practices in residential buildings (BEE, 2021). Addressing this need, the study is focused on the selection of optimum glazing type and Window-to-Wall ratio (WWR) that help build energy-efficient and thermally comfortable residential buildings.

Methodology

The study employs a simulation-based framework – SIMEC-Opt, illustrated in Figure 1, to find the optimum glazing configuration that reduces heat gains and improves thermal comfort. The building is modeled in DesignBuilder, including detailed information regarding materials, characteristics of HVAC systems, schedules, and occupant behavior. Further, to understand the impact of glazing, an essential aspect involved the identification of glazing properties that will define glazing configurations. Glazing parameters such as U-value and Solar Heat Gain Coefficient (SHGC) are defined from glass types available in the Indian market. Next, optimization is carried out with the objectives of minimizing electricity consumption and maximizing thermal comfort by considering varied glazing options, and WWR to identify optimal combinations for different climate zones. The climate of India has been classified into five climate zones by BEE (BEE, 2021). BEE, in its Handbook of Replicable Residential Designs, has identified five representative cities corresponding to these climate zones. The five climate zones and their associated cities are detailed in Table 1. These 5 cities have been selected as they are a fair representation of the climate characteristics of the zone and have a high residential development potential in the coming years (Handbook of Replicable Residential Designs, 2021). Weather data files are obtained from climate.onebuilding in the EnergyPlus Weather (EPW) format. These EPW files provide comprehensive meteorological data necessary for building energy simulations, including parameters such as temperature, humidity, wind speed, solar radiation, and precipitation (climate.onebuilding).

Table 1: Climate Zones of India and their representative city

Climate Zone	City
Hot and Dry	Aurangabad
Temperate	Bengaluru
Warm and Humid	Bhubaneshwar
Composite	Lucknow
Cold	Srinagar

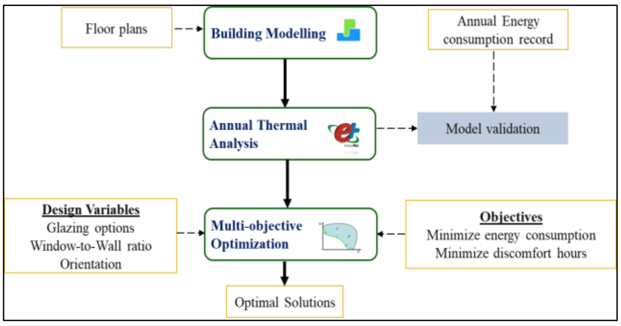

Figure 1: SIMEC-Opt Framework

Energy consumption is quantified by assessing the building's annual lighting, cooling, and heating demands, while thermal comfort is evaluated by calculating annual discomfort hours. Discomfort hours refer to the duration of time during which the indoor environmental conditions within a building fall outside the range considered comfortable for occupants. The criteria are often aligned with industry standards for acceptable indoor temperature and humidity levels. Discomfort hours in DesignBuilder are aligned with ASHRAE Standard 55, which defines the conditions for thermal comfort in indoor environments (DesignBuilder Software Ltd).

Modelling

Model Description

DesignBuilder is chosen as the tool for modeling and analysis in this study as it offers flexible geometry input, extensive material libraries, and load profiles and utilizes EnergyPlus as its simulation engine (DesignBuilder Software Ltd). Using the original drawing files, a residential quarter is replicated in the DesignBuilder software. This building with its actual glazing configuration and WWR, serves as the base model for this study, representing a typical apartment complex in India. In practical applications, the number of windows and building materials differ across geographical locations. Since the present research is designed to assess the impact of various glazing systems, the same building model is employed across all locations, ensuring consistency and comparability in the study. The building was originally located in Mumbai, a city characterized by warm and humid climate conditions, as per the BEE classification (BEE, 2021).

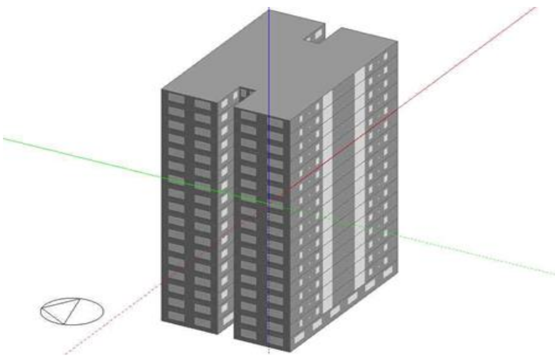

Figure 2: Model of the building

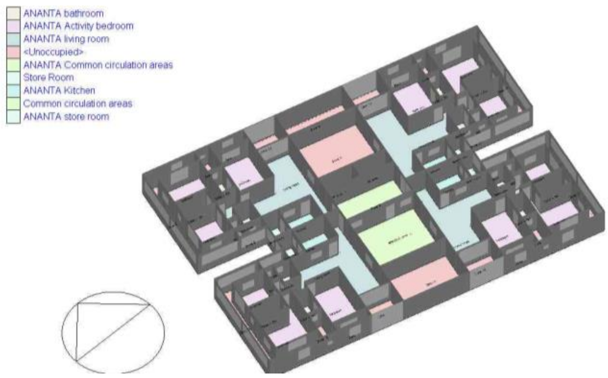

Figure 3: Floor plan of the building

Table 2: Specifications of the building envelope

Component	Layers	Material	U-value (W/m^{2}K)
External Wall	3	1.25 cm cement plaster + 22.5 cm brick + 1.25cm cement plaster	2.192
Internal Wall	3	1.25 cm cement plaster + 20 cm brick + 1.25cm cement plaster	2.335
Roof	2	1 cm RCC + 1 cm lime concrete	2.939
Floor	1	10mm ceramic tiles + 50 mm cement screed + 150 mm concrete floor slab	2.562
Glazing	1	Single clear glass 6 mm	5.88

Table 3: Zone-wise HVAC details of the building

Zones	Ventilation	Lighting	Cooling	Heating
Bedroom 1	Mixed mode	On	On	On
Bedroom 2	Mixed mode	On	On	On
Bedroom 3	Mixed mode	On	Off	Off
Living Room	Mixed mode	On	Off	Off
Kitchen	Mixed mode	On	Off	Off
Storeroom	Mixed mode	On	Off	Off
Bathroom 1	Mechanically ventilated	On	Off	Off
Bathroom 2	Mechanically ventilated	On	Off	Off
Bathroom 3	Mechanically ventilated	On	Off	Off

The building comprises a total of sixteen floors, with each floor accommodating four individual units. These units are equipped with three bedrooms, a kitchen, a store room, three bathrooms, and a living room. Additionally, the ground floor of the building is designated for parking. A visual representation of the building and the floor plan for each level is provided in Figure 2 and Figure 3, respectively. Detailed specifications of the building's envelope and the U-value of components are outlined in Table 2 (ECBC, 2017). The model is equipped with two-pane sliding windows (50% openable area) of aluminum frame and single-glazed clear glass of 6 mm thickness with SHGC of 0.88 and a U-value of 5.8 W/m^{2}K.The HVAC systems in each zone within the apartments are outlined in Table 3. The building follows a specific operational schedule for each zone, considering that occupants are outside and have office working hours starting at 9 am to 6 pm hence occupants are considered active at the house only in hours other than office hours on weekdays and active all day on weekends (Rethnam and Thomas, 2023).

Model Validation

To validate the model, the monthly electricity consumption data for the building is collected from the regional Estate office and then compared with the simulated energy consumption for the Mumbai location. DesignBuilder uses detailed information about the building, including its geometry, materials, HVAC systems, schedules, occupant behavior, and weather data for the required location to simulate annual building performance. The actual annual energy consumption for the building is given to be 223922 kWh, while the simulated value stood at 210065.6 kWh, resulting in a difference of 6.2%, which lies in the acceptable range of error for building energy simulation models (Xu et al., 2017).

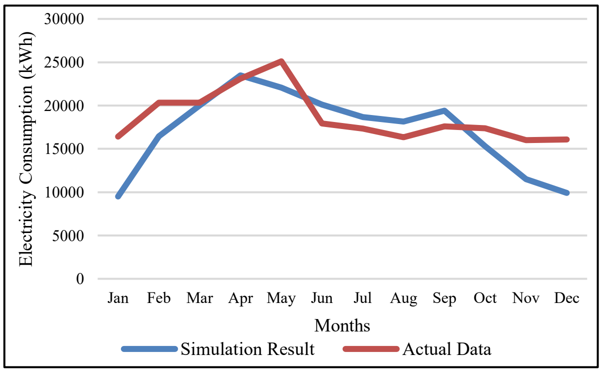

Figure 4: A graphical comparison of monthly total energy consumption between simulated and actual data

Figure 5 below provides a graphical representation of the monthly comparison between simulated and actual energy consumption (kWh). Furthermore, discomfort hours are also calculated by DesignBuilder, in compliance with ASHRAE guidelines, by running detailed energy simulations. The software considers various factors such as indoor temperatures, humidity, airspeed, and other environmental conditions over a year. It uses this data to quantify the duration of time when indoor environmental conditions deviate from the ASHRAE-defined comfort range. Annual discomfort hours of the building are determined to be 1048.46 hours out of 8760 hours annually after the model validation.

Optimization Configuration

Furthermore, the validated model of the building is again simulated for annual energy performance and thermal comfort with initial glazing configuration and WWR for all the representative cities. To find the best design options in each climate zone, the optimization is carried out in the next step considering design variables, glazing configuration, and WWR. Glazing options are provided in Table 4.

Table 4: Glazing types involved in parametric analysis

Glazing options	SHGC	U-value (W/m^{2}K)
Glazing 1	0.24	1.6
Glazing 2	0.53	1.8
Glazing 3	0.34	1.8
Glazing 4	0.3	3.7
Glazing 5	0.14	3.6
Glazing 6	0.41	4.8
Glazing 7	0.47	5.7
Glazing 8	0.69	5.7
Glazing 9	0.49	5.8
Glazing 10	0.58	5.70
Glazing 11	0.42	4.60
Glazing 12	0.34	4.00
Glazing 13	0.45	5.30
Glazing 14	0.33	5.00
Glazing 15	0.44	5.80
Glazing 16	0.38	1.70
Glazing 17	0.59	5.40
Glazing 18	0.29	1.70
Glazing 19	0.21	1.70
Glazing 20	0.38	5.70

For WWR, the range is set from a maximum of 80% to a minimum of 20%, with steps of 5% increments. This means that WWR values are considered at 80%, 85%, 70%, 75%, and so on, down to 20%. The in-built module "Optimization" of DesignBuilder is utilized for conducting multi-objective optimization in this study. Further, objective functions, which quantify the goal as minimizing energy consumption and minimizing discomfort hours, are defined. The optimization process involves an advanced evolutionary algorithm, NSGA- II (Non-dominated Sorting Genetic Algorithm II). As depicted in Table 5, a Simulated Binary Crossover (SBX) with a crossover probability of 0.9 and a mutation probability of 0.1 is used in the optimization process, which includes a population size of 100 individuals. Selection is done using a Binary tournament, and optimization is carried out for a 1000-generation termination criterion to reach optimal design solutions. Finally, NSGA II finds a set of Pareto-optimal solutions in a Pareto front (where no solution is better than the other), which represent trade-offs between conflicting objectives, energy consumption, and discomfort hours (Singh Rajput and Thomas, 2023).

Table 5: NSGA II parameters

Parameter	Value
Population size	100
Crossover Type	Simulated Binary Crossover
Mutation probability	0.1
Crossover probability	0.9
Selection process	Binary Tournament
Termination criterion	1000 generations

Results

Baseline configuration simulation results

Table 6: Baseline configuration simulation details

City	Electricity Consumption (kWh)	Discomfort Hours (hours)
Aurangabad	166638.50	828.55
Bengaluru	142195.60	1181.64
Bhubaneshwar	210194.40	1012.73
Lucknow	184967.80	1033.54
Srinagar	117669.62	1346.13

Table 6 showcases the simulation outcomes for the annual energy performance and thermal comfort, considering the initial glazing configuration and WWR for the representative cities across the five climate zones in India. In the base case simulation results, Bhubaneshwar has electricity and discomfort hours similar to Mumbai's. It could be attributed to the fact that they both belong to warm and humid climates. Bhubaneshwar also has the highest electricity consumption and discomfort hours, followed by Lucknow, which has a composite climate. Srinagar is last, followed by Bengaluru, which has a temperate climate.

Optimization Result

The optimization analysis aimed at minimizing the annual electricity consumption (in kWh) and minimizing the annual discomfort hours (in hours) involving design variables, WWR, and various glazing options, for each representative city, led to a specific number of iterations to find optimal solutions as detailed in Table 7.

Table 7: Number of iterations and optimal solutions of each representative city

City	Iterations	Number of Optimal Solutions
Aurangabad	196	19
Bengaluru	242	62
Bhubaneshwar	200	30
Lucknow	213	32
Srinagar	242	54

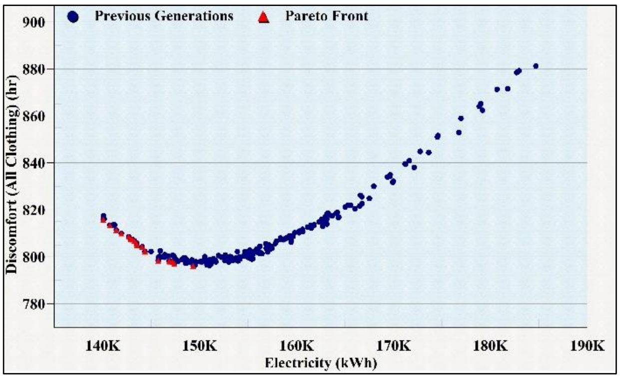

Figure 5: Pareto graph result of Aurangabad

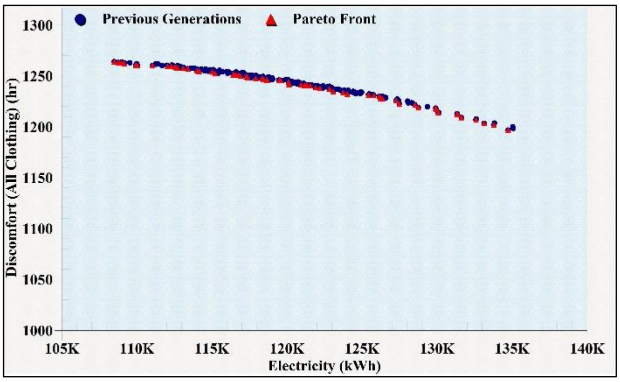

Figure 6: Pareto graph result of Bengaluru

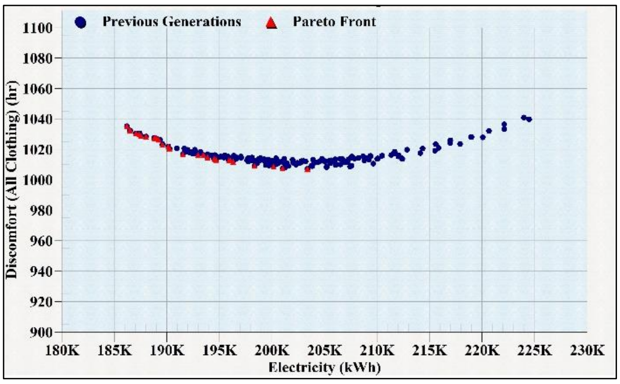

Figure 7: Pareto graph of Bhubaneshwar

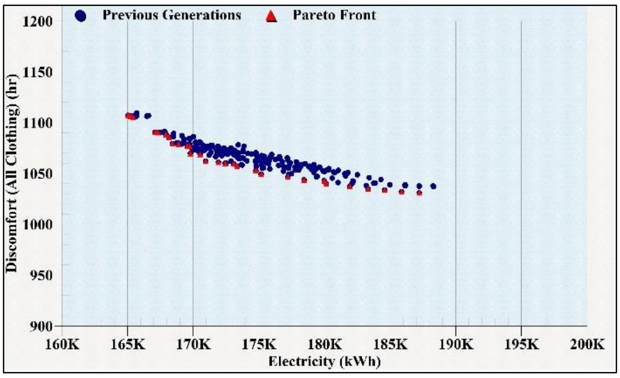

Figure 8: Pareto graph of Lucknow

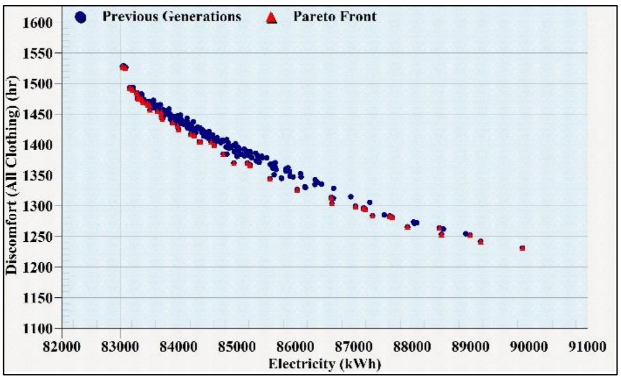

Figure 9: Pareto graph of Srinagar

The Pareto-front graph of the optimization analysis of each city is presented in Figure 5, Figure 6, Figure 7, Figure 8, and Figure 9. The optimization results illustrated a trade-off relationship between electricity consumption and discomfort hours. The electricity consumption and discomfort hours of optimal solutions of each city are compared with the values of the respective city baseline configuration which is equipped single clear glass of 6 mm and 30 % WWR. Aurangabad demonstrated a 10% to 16% reduction in electricity consumption and a 4% reduction in discomfort hours. However, for Bengaluru, this reduction ranged from 5 to 24%, while discomfort hours showed no potential for improvement. In Bhubaneshwar, optimal solutions lead to a 3 to 11% reduction in electricity consumption and a minimal change in discomfort hours. Lucknow, on the other hand, experienced a decrease in electricity consumption by up to 11% and also showed negligible potential for improvement in discomfort hours. Srinagar displayed up to 30% reduction in electricity consumption and up to 8% decrease in discomfort hours. Overall, the results indicated significant improvements in some cities, while others showed minimal enhancements compared to the baseline scenario. Comparable to outcomes of research conducted in Dubai on a two-story building, wherein double glazing resulted in a 9.3% reduction in energy consumption, the results of Aurangabad's (hot and dry climate) energy saving resonate closely (Abdeen et al., 2024).

The optimum solutions with minimum electricity consumption and minimum discomfort hours for each city are illustrated as a decision matrix in Figure 10. Along the top horizontal axis, WWR ranges from 20 to 80 with increments of 5. On the bottom x-axis, cities representing distinct climate zones are listed. The y-axis denotes glazing types numbered from 1 to 20. In this matrix, each block represents possible glazing configurations with different glazing types and WWR. Notably, blocks highlighted in brown signify the optimal configuration of glazing type and WWR for each respective city. These configurations strike a balance between reducing electricity usage and minimizing discomfort hours, tailored to the specific climatic conditions of each location. In Aurangabad, which represents a hot and dry climate, optimal configurations commonly included Glazing 5, 19, and 1. WWR for Glazing 5, which has the lowest SHGC, ranged from 20% to 80%, and for Glazing 1 and Glazing 19 ranged from 20% to 35%. with WWR ranging from 20% to 40%. Bengaluru, representing a temperate climate, tended to favor Glazing 18, Glazing 5, and Glazing 3, with recommended WWR falling between 20% to 80%. Bhubaneshwar, representing a warm and humid climate, showed optimal solutions with Glazing 5 and WWR varying from 20% to 75%. Lucknow, representing a composite climate, tended to benefit from Glazing 2 over all the WWR and from Glazing 1, and Glazing 16, with WWR between 20% to 40%. In Srinagar, representing a cold climate, optimal configurations include Glazing 2 for Glazing 16, and Glazing 17, with WWR ranging from 20% to 80%.

Discussion

The results suggested specific recommendations for different climatic zones regarding the selection of glazing properties. In hot and dry climates, and warm and humid climates, glazing with lower SHGC values and moderate U-values to minimize solar heat gain. Composite climates are recommended to have a mix of U-values and SHGC values when choosing glazing, demonstrating the need for a balanced approach in composite climates. In cold climates, the glazing options with lower U-value and relatively higher SHGC are found to be suitable. This is

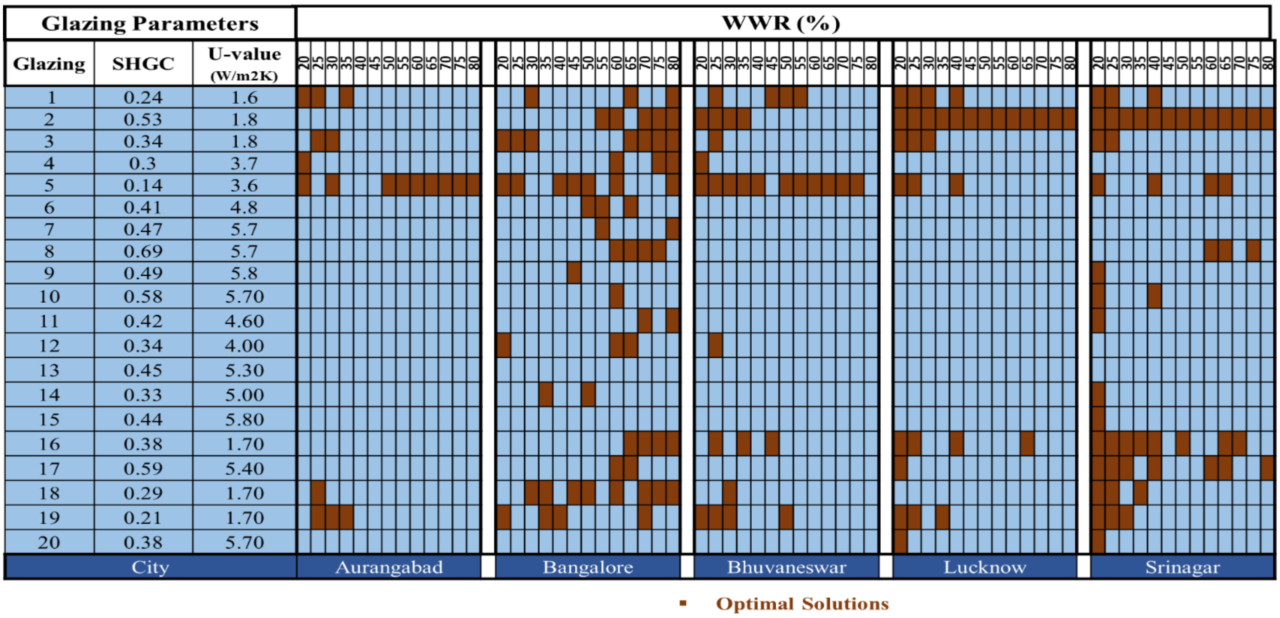

Figure 10: Decision Matrix of glazing solutions for minimum electricity consumption and maximum thermal comfort

because the total heat gain through the glazing of the building is given by relative heat gain (RHG), which combined accounts for both conductive and radiative heat transfer. Conductive heat transfer depends on the temperature difference between the building's interior and the outside environment and is influenced by the U-value. Radiative heat transfer is related to the amount of solar radiation entering the building and is influenced by the SHGC of glass. In tropical climates where temperature differences are minimal, conductive heat transfer plays a minor role, making SHGC more critical than U-value. Conversely, in colder and temperate climates such as Srinagar and Bengaluru, the U-value of glazing options becomes a more critical factor in reducing heat loss. The results also recommend relatively higher SHGC for cold climates so as to facilitate passive heating. The decision matrix derived through the optimization analysis can serve as a valuable guideline for updating building codes, standards, and sustainability regulations. By promoting the adoption of energy-efficient building envelopes tailored to local climatic conditions, policymakers can support the transition towards more sustainable and resilient built environments.

Conclusions

This study aimed to establish a simulation-based framework, SIMEC-Opt for optimizing glazing parameters in Indian residential buildings, employing a validated model of a residential building across diverse climate zones in India. By performing optimization analysis in the study, glazing configuration and WWR as design variables, the best solutions were identified, revealing the potential for significant improvements in both energy efficiency and thermal comfort. Across representative cities in different climate zones, the study demonstrated reductions in electricity consumption ranging from 3% to 30%, coupled with improvements in discomfort hours of up to 8%. Discomfort hours showed minimal variation across a few climate zones, suggesting that factors such as air velocity, ventilation, and occupant preferences may be more influential in analyzing thermal comfort.

The SIMEC-Opt framework represents a significant advancement in the field of building optimization, particularly concerning the selection of glazing parameters to enhance energy efficiency and thermal comfort in residential buildings. Through its simulation-based approach and multi-objective optimization algorithm, SIMEC-Opt offers a systematic and comprehensive methodology for identifying optimal glazing configurations tailored to specific climate zones. By considering a wide range of glazing options and window-to-wall ratios, SIMEC-Opt enables architects, builders, and policymakers to make informed decisions that maximize energy savings while ensuring occupant comfort across diverse environmental conditions. The framework's novel features, including its focus on Indian residential buildings and its consideration of multiple performance metrics, contribute to its effectiveness and relevance in addressing the pressing challenges of sustainable building design and construction.

While the study takes into account the diverse climate zones within India, it's important to note that building characteristics, energy consumption patterns, and occupant behavior also exhibit variability across different regions. The study's findings may be specific to certain typologies of residential buildings reducing the generalizability of results. Factors such as cost, government policies, local building laws, and technological feasibility may also influence the practicality of adopting the recommended solutions. The optimization framework primarily focused on glazing configurations and window-to-wall ratios, neglecting other critical building components such as walls and roofs. Though the narrow focus of the study confined to glazing allowed for a detailed examination of the unique characteristics and effects of glazing on building performance, integrating the wall and roof materials into the analysis can provide a more holistic understanding of building performance. While the study focused on representative cities across different climate zones in India, the underlying principles and optimization approach are transferable to similar climatic regions worldwide. As such, the recommendations can inform building design and retrofitting projects in various geographical contexts, contributing to global efforts to mitigate climate change and reduce energy consumption in the built environment.

Abstract

Drawing on insights from computer graphics, this study introduces the Crack Boundary Point Rendering Network (CBPRN), an innovative high-resolution (HR) image segmentation framework designed to improve UAV-based bridge crack inspections. We developed an edge-guided branch and an uneven sampling strategy, enhancing detail preservation on crack boundary areas effectively. Through comprehensive ablation experiments, the efficacy of the CBPRN was validated, demonstrating its superior performance with remarkable outcomes: a processing speed of 13.45 FPS and mIoU, mBA, and Dice scores of 87.23%, 93.56%, and 89.59%, respectively, for images beyond 2K resolution. The CBPRN establishes a new standard in HR crack image segmentation.

Introduction

The emergence of surface cracks can effectively reflect the recent load-bearing status of bridges and provide a strong reference for traffic management departments to make reasonable maintenance decisions, thus preventing potential catastrophes (Manjunatha et al., 2023, Park et al., 2019). Therefore, accurate and efficient crack detection is crucial for ensuring the bridge's safety during its service life. In recent years, advancements in crack detection technology, driven by digital image processing algorithms, have seen rapid progress. This development has markedly enhanced efficiency and reduced the high costs traditionally associated with manual inspection methods (Çelik and König, 2022). Presently, extensive research has been undertaken by researchers in the field of crack detection utilizing image processing methods (Munawar et al., 2021, Ren et al., 2020). Within this domain, deep learning (DL)-based crack segmentation algorithms have garnered significant interest over classification and object detection algorithms. This preference is due to the segmentation algorithms' superior ability to accurately delineate the contours and shape characteristics of cracks with pixel-level precision.

A considerable amount of research based on DL for crack segmentation has been conducted, with some advanced algorithms reporting an impressive mIoU of over 93% on certain open-source crack datasets (Yang et al., 2023, Ali et al., 2021). However, it is noteworthy that these studies and their corresponding algorithmic improvements have primarily focused on identifying the main body of cracks while neglecting the recognition of fine-grained representations at crack boundaries. This oversight is significant because the quality of mask boundaries plays a crucial role in image segmentation; precise object segmentation directly benefits various downstream applications, such as damage quantification and assessment (Liu et al., 2023, Li et al., 2017). To comprehend the limitations in achieving fine-grained representations at crack boundaries, a critical analysis of the supervisory principles governing these segmentation algorithms is required, with a particular focus on the Mask Intersection-over-Union (Mask IoU) loss function (Cheng et al., 2021). This loss function, a benchmark in model training, guides models in predicting masks at pixel wise. Under the supervision of Mask IoU loss, models strive to maximize the overlap between the predicted mask and the actual mask. However, this loss evaluates all pixels equally, both internal and boundary pixels, making it less sensitive to the boundary quality of coarser cracks. As the crack size increases, the number of internal pixels grows quadratically and can far exceed the linearly increasing number of boundary pixels. This discrepancy leads to ambiguous segmentation effects in crack boundaries, especially at higher image resolutions where the difference between crack boundary and main body pixels is more pronounced. This trend is problematic for the industry's shift towards HR imaging for crack detection, as it can significantly affect segmentation results and impede accurate structural safety assessments. Therefore, a systematic study of the fine-grained recognition of crack edges is necessary to address this challenging issue.

To this end, this study introduces the Crack Boundary Point Rendering Network (CBPRN), which enhances three key components of traditional point-based rendering architecture, enabling the rendering head to fully utilize its advantages in refined segmentation of cracks. The network architecture is illustrated in Figure 1. Initially, an edge-guided branch based on a super-resolution encoding architecture was designed, ensuring that details of crack boundaries and related tiny crack information are adequately preserved in the deep semantic feature maps used as a source for refined rendering. For the second improvement, an uneven sampling strategy focusing on boundary areas was developed for the rendering-based prediction head, allowing the network to concentrate computational power on challenging areas like crack boundaries. Overall, these two improvements fully leverage the advantages of graphic rendering methods in the fine-grained segmentation of crack images. The CBPRN achieves a good balance between computational resource consumption and practical deployability while providing crack image outputs with precise boundaries, which is significant for accurate structural safety assessments of bridges.

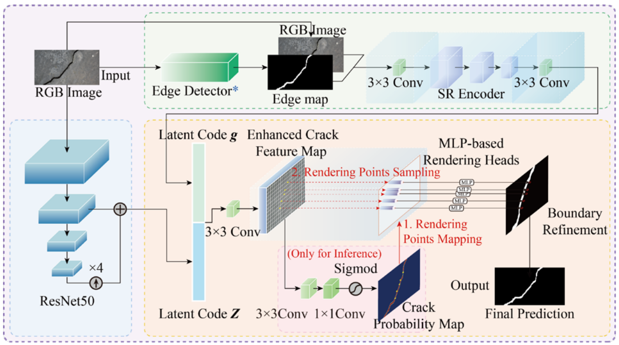

Figure 1: Visualization of boundary region-guided sampling with different dilation coefficients during the training phase

Methodology

The CBPRN proposed in this study consists of three main components: a coarse crack segmentation feature extraction backbone, an edge-guided branch, and a point rendering-based fine-grained prediction head. The coarse crack segmentation feature extraction backbone is built on a ResNet50-based encoding architecture, designed to perform coarse-grained feature extraction from high-resolution crack images. The edge-guided branch comprises a fixed-parameter edge detector and a super-resolution image encoding architecture, which guide the edge details in high-dimensional implicit features for coarse-grained crack features. The fine-grained prediction head based on point rendering primarily aggregates the implicit crack features outputted from the first two components and restores the fine-grained edge details of the cracks through point-by-point refined rendering based on the shared-weight multi-layer perceptron (MLP). Figure 1 visually presents some algorithmic details and computational logic of the proposed CBPRN. The edge-guided branch and the fine-grained prediction head constitute two innovative enhancements to the original PointRend architecture, respectively, and are detailed in the following subsections.

Edge-guided Branch

To ensure that the deep semantic feature maps of cracks sufficiently retain the details of crack boundaries and minute cracks for refined rendering, this study customizes an edge-guided branch in addition to the coarse crack segmentation feature extraction backbone. In fact, previous research has utilized guided image filtering (He et al., 2012) for boundary guidance in natural scene image segmentation, an effective edge-preserving smoothing operator based on guided images. However, edge recognition methods based solely on morphological operations are easily disturbed by environmental noise like cracks and struggle to accurately extract edges of small-sized cracks. To address this, the authors retain the fixed-parameter guided image filtering operator while introducing an encoder designed for super-resolution reconstruction tasks, aiming to eliminate noise interference in the boundary feature map while enhancing the representation of minute crack boundary features. This super-resolution encoding architecture, as shown in Figure 2, is primarily constructed using three residual modules. To improve the extraction performance of tiny crack details, the authors incorporate a transformer module in each residual module (b1, b2, b3), hoping to model long-distance dependencies for crack pixels scattered across the global view through the inherent self-attention mechanism of the transformer.

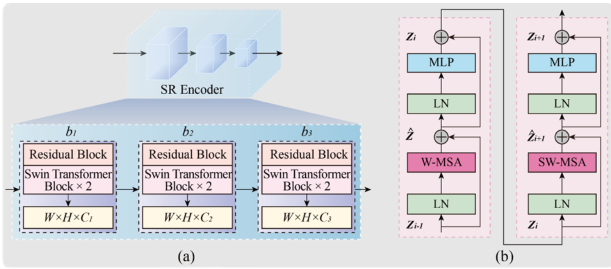

Figure 2: Details of the super-resolution reconstruction encoding architecture and some internal components in the edge-guided branch, (a) implementation details of the super-resolution reconstruction encoding architecture, (b) implementation details of two consecutive Swin Transformer blocks

Fine-Grained Prediction Head Based on Point Rendering

Inspired by refined rendering methods in computer graphics, the authors propose a crack fine-grained feature prediction decoding architecture based on point rendering. It is important to note that the principle of boundary refinement rendering point sampling remains consistent with the original PointRend architecture (Kirillov et al., 2020), ensuring computational efficiency during the training phase while enabling the trained model to perform effective end-to-end inference. Therefore, two different point sampling methods are designed for model training and inference.

For the training phase: due to the availability of precise pixel-level labels for effective supervision of prediction results, selecting boundary points for adequate sampling based on these refined pixel-level labels is a more accurate and computationally efficient method compared to the original approach in PointRend, which involved boundary prediction based on the most uncertain points. Therefore, during the training phase, boundary information is directly extracted from the refined pixel-level labels of crack images to guide the selection of sampling points. Specifically, an edge detection algorithm is used to extract the edge areas of the crack labels, and some of the sampling points, originally uniformly distributed across the background and the main body of the crack, are concentrated in these extracted edge areas. It is important to note that to prevent a decline in model performance due to an imbalance in the ratio of positive to negative samples during training, and to ensure efficient training, the total number of sampling points per image is set to $N = \frac{H\times W}{20}$. These sampling points are randomly distributed in the crack body, crack boundary, and background areas in a ratio of 0.3:0.4:0.3. Figure 3 visually demonstrates the sampling strategy for the rendering points used in training the model. Ultimately, all the sampling points identified on the labels are mapped onto the corresponding enhanced crack feature maps for model training.

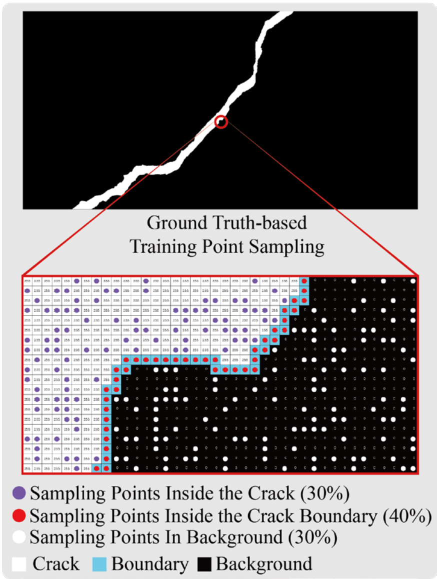

Figure 3: Visualization of the sampling points selection strategy in the training phase for the point rendering-based prediction head

For the inference phase: Refined labels, which are the ultimate prediction results, are not available at the beginning of the inference phase, hence the sampling method used during the training phase cannot be applied. To effectively focus computational resources on accurately predicting minute cracks and crack boundaries, this study proposes a boundary-guided rendering point sampling strategy based on a probabilistic heatmap. Specifically, two convolutional modules are added to the enhanced crack feature map to generate a refined crack pixel probability heatmap. Rendering points are guided by identifying pixels with high uncertainty in predicted values on the probability heatmap. Based on the probability, pixels on the heatmap can be roughly divided into three areas: pixels with probabilities close to 0 and 1 represent background and crack body, which are easily recognized by the network; pixels with probabilities around 0.5 represent areas of minute cracks or boundaries that are difficult for the model to determine with certainty. During the inference phase, for pixel areas on the probability heatmap with probabilities close to 0 and 1, the corresponding background and crack labels are directly used to represent the final prediction values, eliminating the need for further refined rendering. However, for pixel areas with probabilities around 0.5, refined rendering is required to further refine these ambiguous predictions. The refined rendering points are uniformly distributed in these hard-to-identify pixel areas. It is important to note that the probabilistic heatmap is used instead of the coarse segmentation results from the original PointRend architecture because the enhanced crack feature map used to obtain the heatmap is unified in size according to the second block of ResNet. It retains more details of minute cracks with only one downsampling compared to the original coarse segmentation and requires less computational resources than coarse segmentation. To visually represent the refined rendering point sampling method during the inference phase, Figure 4 displays a visualization of a randomly selected probabilistic heatmap example. On the heatmap, probabilities in the background and main body of the crack are concentrated near 0 and 1, respectively, while in the boundary area, due to issues like manual annotation errors and insignificant color differences, the probabilities of pixels fluctuate around 0.5. This study sets the probability range for these hard-to-identify pixels between 0.3 and 0.7, and in the subsequent refined rendering phase, only samples with probabilities between 0.3 and 0.7 undergo refined inference. The parameter settings for sampling points during the training and inference phases will be detailed in subsection 3.3.2.

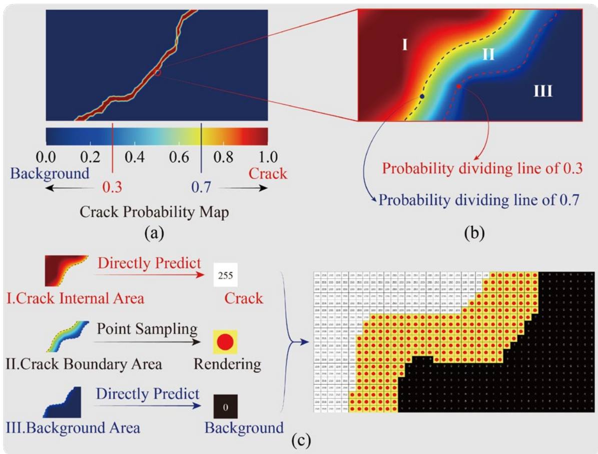

Figure 4: Visualization of the sampling points that require refined rendering during the inference phase

Experimental Setup and Results

Dataset

The CFD (Shi et al., 2016), Crack500 (Yang et al., 2019), and Deepcrack537 (Zhou et al., 2022) were chosen for model training. The crack images in these three datasets almost encompass most crack forms in engineering structures and include crack samples collected under different lighting conditions, which is beneficial for enhancing the model's robustness. Importantly, these three datasets all have finely annotated pixel-level labels, which are helpful for accurately evaluating the advantages of the algorithm proposed in this study in terms of boundary refinement segmentation. It is noteworthy that before training the model, images from the three datasets were uniformly resized to 256 × 256 pixels to facilitate uniform training input and save computational resources required for training. In total, 1200 resized crack images from the three open-source datasets were used, including 900 training samples, 150 validation samples, and 150 test samples.

Furthermore, a total of 60 crack images were collected in the urban area of Changsha, as shown in Figure 5, to test the segmentation performance of CBPRN on HR crack images.

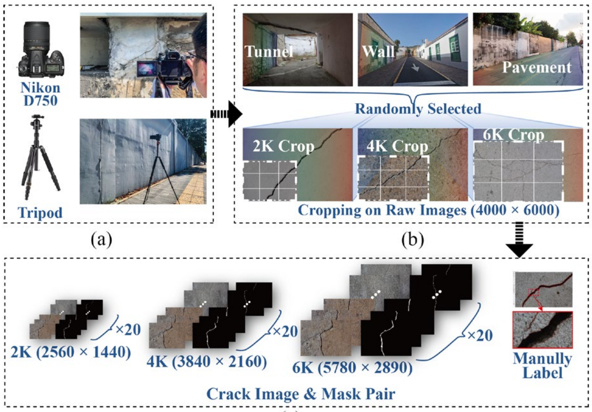

Figure 5: Details of establishing the high-resolution crack image dataset with pixel-level annotations

Implementation Details and Metrics

Training Hyperparameters: The experiments were conducted on a system equipped with an i9-9820X CPU and two NVIDIA RTX 3090 Ti GPUs, running Ubuntu 20.04, and the network model was implemented within the PyTorch framework. The total number of iterations was set to 1000 epochs, with a batch size of 16. The initial learning rate was set at 0.01, using a warming-up strategy for the first 100 epochs followed by a poly learning rate decay strategy with a decay rate of 0.9. Additionally, to ensure the global optimum of the loss function can be obtained during training, Adam optimizer, which combines the advantages of momentum and RMSprop, was used with a momentum of 0.9 and a weight decay of 1×10^{-4}. With these parameters, the preliminary model trained on the low-resolution open-source crack dataset was further fine-tuned using field-collected crack images.

Evaluation Metrics: Two common metrics were chosen for quantitative assessment of the experimental results: mean Intersection over Union (mIoU) and Dice Similarity Coefficient (Dice). Additionally, to highlight the performance of the proposed method in boundary areas, Mean Boundary Accuracy (mBA) was used as an additional evaluation metric. The core concept of mBA involves calculating the IoU between the Ground Truth (GT) and the predicted mask within the boundary area (Cheng et al., 2020).

Ablation Study

Ablation study for the point rendering-based prediction head: To fully illustrate the advantages of performing fine-grained crack mask using the point rendering method, a performance comparison was first made between the proposed decoding architecture and the traditional decoding architecture based on multiple convolutional layers and upsampling operations. The relevant experimental results are listed in Table 1. From the first two rows of Table 1, it can be seen that the point rendering-based decoding architecture has achieved improvements in mIoU, Dice, and mBA compared to the traditional decoding architecture, with the most significant improvement observed in mBA, reaching 86.78%. This is because the MLP in the point rendering-based decoding architecture is position-sensitive, calculating the prediction value for each pixel independently. Therefore, it can flexibly capture details and spatial relationships in crack images. In contrast, the traditional upsampling-based decoding architecture is limited by discrete feature sampling and struggles to capture local crack details.

After demonstrating the superiority of the proposed decoding architecture, parameter performance experiments need to be conducted to obtain the optimal parameters matching the model architecture. Since the training and inference stages use distinct fine-grained rendering point sampling methods, as described in Section 2.2, the following two sets of parameter performance experiments are conducted to obtain relatively optimal point sampling parameters for both the training and inference processes.

Point sampling study in the training phase: It is necessary to emphasize again before conducting parameter experiments that the regions most likely to have erroneous predictions are mainly concentrated at the boundaries and their adjacent areas, because these regions often have colors and contrasts similar to those of nearby cracks in RGB images. However, if the training point sampling is carried out as shown in Figure 3, where only a one-pixel-wide edge area is used for boundary guidance, it may not be possible to avoid the biasing guidance caused by the subjective nature of human annotation, resulting in errors between the true boundary and the labeled boundary. To avoid the negative impact of erroneous guidance on the model during training, it is necessary to expand the guided boundaries. Specifically, in this study, simple morphological operations were used, with the outermost pixels of the crack label as the center of dilation, and dilation operations were performed with the same dilation factor towards the background area and inside the crack. Considering the image size and the average pixel width of cracks in the training dataset, four different edge dilation coefficients were used to expand the boundary region. As shown in Figure 6, the widths of the expanded boundary regions (yellow outlined areas) after dilation are 1, 3, 5, and 7, respectively. The total number of sampling points on each training image is $N = \frac{H \times W}{20}$, distributed randomly in the background, expanded crack edges, and inside the cracks at proportions of 30%, 40%, and 30%, respectively.

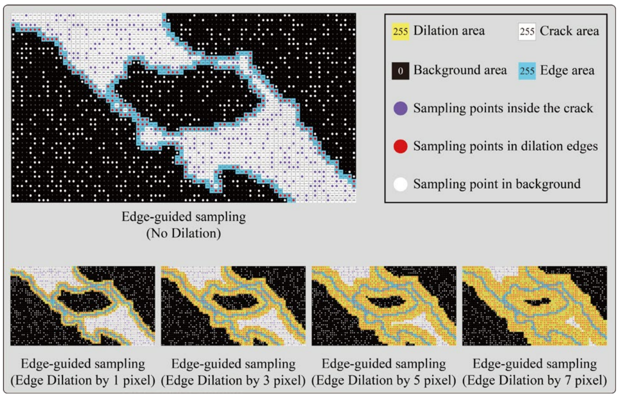

Figure 6: Visualization of boundary region-guided sampling with different dilation coefficients during the training phase

The set No.2 to set No.5 in Table 1 provide statistics on the performance of the model, which was trained in the training phase using four different widths of expanded boundaries for guiding sampling points. It can be observed that the model performs best when the dilation coefficient is 2 (corresponding to a boundary region width of 5), with mIoU, mBA, and Dice reaching 86.49%, 90.52%, and 88.54%, respectively. This best performance occurs due to the fact that the manual labeling bias range in the crack training dataset used in this study falls within this interval. Combining the experimental results in Table 2 with the visual effects of the probability heatmaps in Figure 4, the following conclusions can be drawn: dilation coefficients that are too low (0 or 1) or too high (3) result in improved performance compared to no dilation, but they respectively lead to insignificant improvements due to the inability to fully encompass error boundaries in the sampling region or the dispersion of computational resources beyond the error interval. Specifically, when the dilation coefficient is 0 or 1, the dilated boundary region is not sufficient to encompass the bias generated near the boundary during manual labeling. When the dilation coefficient is 3, the crack's main region and too many background regions without artificial labeling errors are included as ambiguous boundary regions requiring fine sampling. These unnecessary simple sample regions take away computational resources that should belong to the ambiguous boundary regions, thereby reducing the model's learning and representation capabilities for ambiguous boundary regions, resulting in a very limited improvement in recognition accuracy brought by boundary-guided sampling.

Point sampling study in the inference stage: In order to effectively improve the model's fine-grained inference performance in the boundary regions while saving computational efficiency, it is necessary to determine reasonable probability intervals for areas with uncertain prediction results concentrated around 0.5 on the probability heatmaps. A larger probability interval implies the need to sample more probability points for fine-grained rendering, which increases precision but significantly increases computational redundancy in the inference process. Conversely, a too small probability interval, while speeding up inference, may lead to ineffective fine-grained rendering of many tiny cracks and boundary details, seriously affecting the final recognition accuracy.

Specifically, two probability parameters need to be set: the critical probability value α between background pixels and boundary regions on the coarse prediction probability map, and the critical probability value β between boundary regions and crack pixels. For the critical probability value α between background and boundary regions, this study sets three different probability parameters: 0.2, 0.3, and 0.4. Similarly, for the critical probability value β between boundary regions and crack pixels, three different probability parameters are also set: 0.6, 0.7, and 0.8. By defining these nine different probability interval ranges based on the two types of critical probability values, the boundary regions are categorized. Table 2 provides statistics on the inference results of the models that use these 9 different probability intervals for sampling on the test dataset.

From Table 2, it can be seen that the models from Set No. 4, 5, and 6 (i.e., background region probability range between 0 and 0.3) achieved relatively better accuracy than other models. This is because, compared to the sampling groups with the background region probability range set between 0 and 0.4, the sampling methods under these three parameter settings encompass a wider background sampling area, which is more helpful in repairing some tiny crack details that were not detected in the background. At the same time, the sampling groups with the background region probability range set between 0.0 and 0.2 classified too many pixels originally belonging to the boundary region as background pixels, causing ambiguous boundary regions to be unable to achieve precise boundary detail repair due to insufficient sampling points, thus resulting in relatively lower mBA.

In addition, by comparing the model performance from Set No. 4 to 6, it can be observed that when the critical probability of crack internal area is set to 0.7, the model's inference accuracy is the highest, with mIoU, Dice, and mBA reaching 87.23%, 93.56%, and 89.59%, respectively.

Finally, the sampling parameter configuration set by Set No. 6 is adopted as the optimal inference stage sampling parameters to control the model's subsequent experiments.

Performance Comparison between CBPRN and the Traditional PointRend Model

Considering that the CBPRN is built based on the original PointRend model and is specifically designed for crack segmentation, with the main improvement being the introduction of a fine-grained boundary point rendering sampling method based on the fine-grained probability heatmap in the inference phase. In order to further demonstrate the effectiveness of this approach, which involves fine-grained point sampling guidance based on the probability heatmap in the inference phase, in comparison to the traditional approach of fine-grained point sampling guidance based on coarse segmentation, this section compares the segmentation results of the original PointRend using different sources of coarse segmentation on high-resolution images collected in Section 3.1 with the corresponding results obtained by the method proposed in this study.

Specifically, the authors selected five mainstream deep learning segmentation architectures with varying levels of segmentation accuracy, including FCN-18, UNet, DeepLabV3+, PSPNet, and RefineNet, as the generating networks for the coarse segmentation required when the original PointRend architecture performs predictions. In contrast, the method proposed in this study uses probability heatmaps proposed based on enhanced crack features extracted by the encoder and the boundary guidance branch to perform boundary point sampling guidance for the fine-grained prediction head based on point rendering.

It is worth noting that all coarse segmentation architectures and fine-grained segmentation networks were trained with default optimal parameters in the same deep learning framework with the same configuration. Additionally, when using the trained coarse segmentation models for prediction, all high-resolution images were proportionally scaled down to have a long edge of 900 pixels to avoid issues related to GPU memory overflow caused by excessively high original resolutions.

The experimental results are shown in Table 3. From the table, it can be observed that there are significant differences in the prediction results generated by different coarse segmentation mask generation architectures, with differences in mIoU, mBA, and Dice ranging from 2.92%, 3.06%, to 2.36%, from the lowest accuracy of FCN-18 to the highest accuracy of RefineNet. However, after applying the original PointRend model for the refinement process, the differences between the fine-grained prediction results become less pronounced, with mIoU, mBA, and Dice for all five experimental groups fluctuating within the intervals of 83.30±0.09%, 87.14%±0.16%, and 85.27±0.06%, respectively. These results indicate that the PointRend refined segmentation method is indeed independent of specific coarse segmentation masks and exhibits good robustness to coarse-grained features from different coarse segmentation architectures. However, when comparing the final experimental results with the best-performing coarse segmentation results based on RefineNet within the PointRend group, it can be observed that the method guided by probability heatmaps further improves the segmentation accuracy. It can be noted that among the three improved metrics, mBA shows the most significant improvement, which is more than twice the improvement in mIoU and Dice, reaching 6.27%. This outstanding robust performance is largely attributed to the introduction of the edge-guided branch in the feature extraction stage of this study, which preserves sufficient information about small cracks and crack boundaries in the enhanced crack features used to generate probability heatmaps. This enables the pixels in these detail areas to be detected during inference and finely represented through point-wise dense rendering. Additionally, it should be noted that CBPRN, by avoiding the guidance of coarse segmentation from external sources and based on a customized non-uniform inference point sampling method, surpasses the original PointRend in inference speed by more than twice on average, achieving 13.45 FPS. To further demonstrate the effectiveness of the above conclusions, Figure 7 provides visualizations of the test results for five randomly selected high-resolution crack images collected in the field. It is evident that the inference model guided by probability heatmaps proposed in this study outperforms any fine-grained rendering method guided by coarse segmentation masks in terms of crack edge recognition accuracy and sensitivity to tiny cracks.

Conclusions and Future Work

In this study, a HR crack image fine-grained segmentation architecture named CBPRN is proposed. For the first time, rendering techniques from computer graphics are introduced into HR crack image segmentation tasks. Through three customized improvements, the originally designed point rendering technique for natural scene objects is adapted to effectively perform crack segmentation with fine-grained boundaries. The proficiently trained CBPRN attains a remarkable inference speed of 13.45 FPS, yielding mIoU and mBA scores of 87.23% and 93.56%, respectively, along with a Dice score of 89.59%. This performance was demonstrated on crack images exceeding 2K resolution, thereby establishing CBPRN as the current state-of-the-art benchmark in this domain.

In future, the implementation of model pruning and quantization techniques will be advanced to facilitate the lightweight deployment of CBPRN on the UAV, aiming to provide bridge maintenance departments with a more reliable and secure method for conducting bridge crack detection in practical engineering scenarios. Additionally, this method can be adopted to the hydropower projects, similarly to detect the defects of dam structures.

Table 1: Performance comparison of traditional decoding architecture and the proposed point-rendering-based fine-grained prediction head in models trained with different parameterized feature point sampling strategies

Set No.	Decoding architecture	Sampling point extraction method for the training phase	Dilating coefficient	Width of the boundary area after dilating	IoU(%)	mBA(%)	Dice(%)
1	Traditional convolution and upsampling operations	Uniform sampling	/	/	85.54	88.67	87.31
2	Fine-grained prediction head based on point rendering	Boundary guided sampling	0	1	85.98	89.60	87.76
3			1	3	86.12	89.94	88.03
4			2	5	86.49	90.52	88.54
5			3	7	85.76	89.09	87.50

Table 2: Comparison of inference performance obtained by different boundary probability ranges

Set No.	Probability range for background area	Probability range for boundary area	Probability range for crack internal area	IoU(%)	Dice(%)	mBA(%)
1	（0.0,0.2）	（0.2,0.6）	（0.6,1.0）	86.53	90.69	88.58
2	（0.0,0.2）	（0.2,0.7）	（0.7,1.0）	86.98	92.47	89.12
3	（0.0,0.2）	（0.2,0.8）	（0.8,1.0）	86.49	90.52	88.54
4	（0.0,0.3）	（0.3,0.6）	（0.6,1.0）	86.78	91.12	88.80

EARLY DESIGN STAGE MULTI-OBJECTIVE OPTIMIZATION FOR THERMAL REFURBISHMENT OF BUILDINGS: A CASE IN ISTANBUL

Damla Kömürcü[1], and Ecem Edis[2]
[1,2]Istanbul Technical University, Istanbul, Turkey

Abstract

To improve the energy efficiency of the large existing building stock, there is a need for decision-support to determine optimal solutions considering different objectives. In the study, it is aimed to find appropriate optimization methods through their hyperparameter optimization that will support designers at the early design stage of a building refurbishment project for environmental and economic sustainability. For this, NSGA-II, NSGA-III, C-TAEA, RVEA were investigated with a case study on residential buildings. The first three methods were observed to give limited renewal proposals, while RVEA provided diversified renovation scenarios with its models' features open to preference related to this.

Introduction

In energy efficient buildings, it is important to achieve simultaneously high performance in all aspects, even when dealing with conflicting goals. Studies for comfortable and energy efficient buildings address various objective functions such as energy consumption, thermal comfort and economic benefit indicators as single, multi or many objective/s. In addition, the differences in building functions (e.g., housing, office), decision variables (e.g., building form parameters, envelope) or constraints (e.g., budgets, thermal comfort conditions) in the optimization studies have resulted in datasets with a wide variety of features (Motlagh et al., 2021). Optimization methods suitable for problems with such different characteristics have also varied.

In comparative evaluation studies conducted to find the appropriate optimization method for the problem at hand, different methods have yielded superior performance results. To find the optimal design solutions for a passive building with a green roof for instance, six optimization algorithms [Multi-Objective Evolutionary Algorithm based on Decomposition (MOEA/D), Non-dominated Sorting Genetic Algorithm (NSGA)-II, NSGA-III, Multi-objective Particle Swarm algorithm (MOPSO), multi-objective dragonfly algorithm (MODA), Multi-objective ant lion optimization algorithm (MOALO)], were compared and MOALO algorithm was reported to lead to the best pareto front (Lin et al., 2021). In another study on minimizing the building energy consumption, CO_2 emission, and indoor thermal discomfort degree, an Adaptive Evolutionary Algorithm based on Non-Euclidean Geometry for the Many-Objective Optimization (AGE-MOEA), compared to the other four popular multi-objective optimization methods [NSGA-II, NSGA-III, MOEA/D, Constrained multi-objective optimization (C-TAEA)], was found to identify a set of pareto optimal solutions with a maximum optimization rate of 13.43% (Shen and Pan, 2023). A study to optimize the life cycle performance of the building on the other hand, compared NSGA-II, NSGA-III, and C-TAEA; and C-TAEA was the best bringing a reduction for the life cycle carbon emissions by 34.7%, for the life cycle costs by 13.9%, and for the indoor discomfort hours by 26.6% (Chen et al., 2023). In a study to be a reference for retrofit planners, the comparison of NSGA-II, MOPSO, MOEA/D, and NSGA-III showed that NSGA-III derives a comprehensive set of trade-off alternatives from possible retrofit scenarios (Son and Kim, 2018).

This study, therefore, aimed to find appropriate multi-objective optimization methods to support decision-making at the early design stage for thermal refurbishment through the building envelope to improve the energy efficiency of existing buildings considering both economic and environmental sustainability dimensions, which are sometimes conflicting. For this purpose, the optimization results of different methods were evaluated comparatively taking existing residential buildings in Istanbul as a case. In the paper, the information related to the application is given in the 'Methodology' section, and the detailed results are given in the 'Result and Discussion' section.

Methodology

The study consisted of three main steps: (1) case study and the multi-objective optimization problem definition, (2) optimization method selection, and (3) optimization study and evaluation of results (Figure 1). The studies carried out in these steps are explained in the following subsections.

Step 1: Case study and the multi-objective optimization problem definition

For the case study, the data given in Cetiner and Edis' (2011) study was decided to be used. That study was carried out to develop an environmental and economic sustainability assessment method regarding the improvements at the scale of building elements to reduce the use phase heating energy consumption of existing residential buildings in Istanbul (Cetiner and Edis, 2014). Environmental and economic sustainability scores were calculated based on the gain rate calculated by comparing the results of refurbished buildings with that of the base existing building condition obtained by EnergyPlus and SimaPro tools. Production, construction, and use periods were considered as building life cycle stages. For these phases, the environmental impact was calculated based on emissions and solid/liquid waste; the economic impact was calculated considering the cost based on the required water, material, energy (heating, cooling, transportation, and application), labor, and equipment. Design variables and objective functions, and their value ranges are given in Table 1. The distribution of the whole data by building age and by the element that would be thermally refurbished concerning their economic and environmental sustainability scores are given in Figure 2.

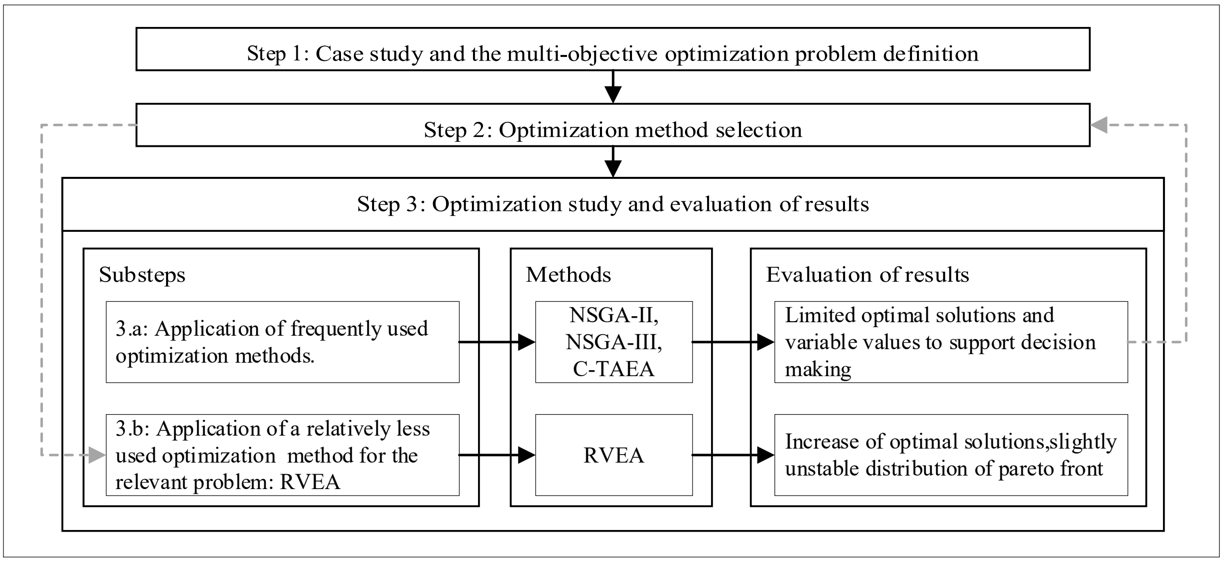

Figure 1: Research framework

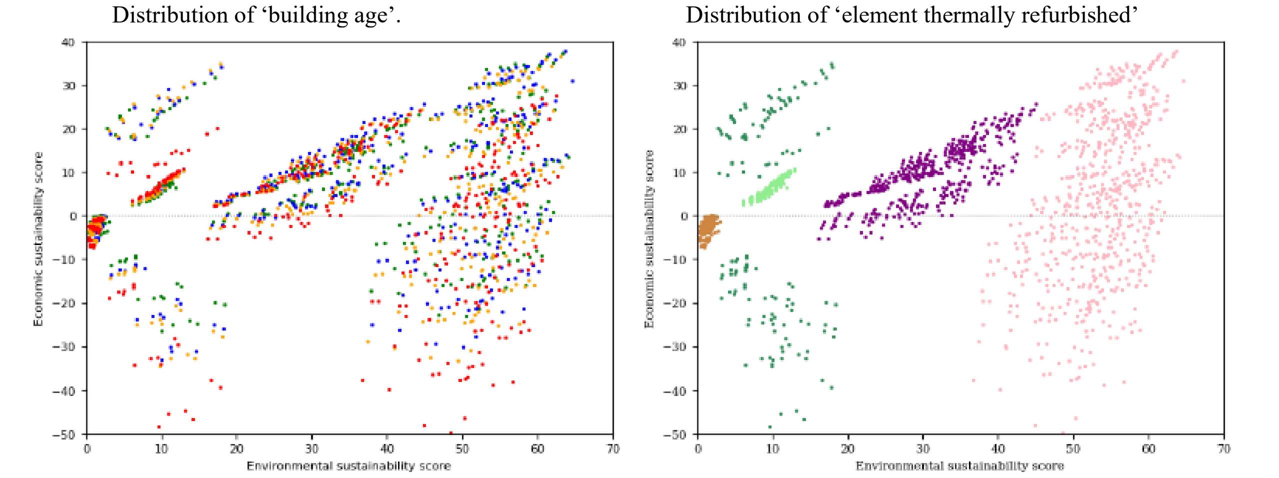
Table 1: Design variables and objective functions, and their value ranges

	Variables- level 1	Variables- level 2	Ranges
Building	Building age	-	15, 20, 25, 30
	Plan type- floor area	Rectangular plan	ca. 230 sqm, and ca. 420 sqm
		Square / close to square plan	ca. 210 sqm, and ca. 400 sqm
	Orientation	Rectangular plan	Long sides facing East and West, Long sides facing North and South
		Square / close to square plan	Main orientations only
Envelope	Window-to-wall ratio	-	10%, 20%, 30%
	Window frame materials/ glass and glazing type	-	Wooden/ clear single glass, PVC/ clear double glass
	Element thermally refurbished - Insulation material and window frame (if specified) used	Floor over unheated spaces (uninsulated in base cases)	EPS, Stone wool, XPS
		Roof (uninsulated in base cases)	Glass wool
		Exterior wall and projected floor (uninsulated in base cases)	EPS, Stone wool, XPS
		Window frame (wood frame with clear single glazing in base cases)	Wood frame/double glazing, PVC frame/double glazing
		All of the abovementioned elements	
		Group 1 (wood frame with clear single glazing in the base cases)	EPS and wood frame/double glazing, EPS and PVC frame/double glazing, Stone wool and wood frame/double glazing, Stone wool and PVC frame/double glazing, XPS and wood frame/double glazing, XPS and PVC frame/double glazing
		Group 2 (PVC frame with clear double glazing in the base cases)	EPS and PVC frame/double glazing, Stone wool and PVC frame/double glazing, XPS and PVC frame/double glazing
Objective functions	Environmental sustainability score		(0, 65)
	Economic sustainability score		(-50, 38)
	Total sustainability score		(-39, 102)



Colors used for 'building age'

15 years old | 20 years old | 25 years old | 30 years old

Colors used for 'element thermally refurbished'

Floor above unheated spaces roof | Roof | Exterior wall and projected floor | Window frame and glazing | All elements mentioned on the left side

Figure 2: Distribution of the data by building age and element thermally refurbished

The multi-objective optimization study aimed to maximize environmental and economic sustainability scores for the two-objective functions; and, to maximize the total sustainability score (sum of environmental and economic sustainability scores) added to them for the three-objective functions. For the purpose of supporting the designer at the early design stage, building variables (building age, plan type, and orientation) were used as controlled variables in the study. This setup brought a total of 24 data sets with a population size of 75 for each.

Step 2: Optimization method selection

First, the methods that were observed to be frequently used in the literature were selected for the application. After the application of methods, the results were observed to be insufficient in terms of decision support performance. For this reason, another research study was conducted to select another optimization method suitable for this problem.

NSGA-II and NSGA-III are among the most frequently used methods in the studies (Pan et al., 2023; Hashempour et al., 2020; Shi et al., 2016). NSGA-II is a method that was designed based on a genetic algorithm, and a modified mating and survival selection calculation is applied, additionally (Deb et al., 2002; Blank and Deb, 2020). NSGA-III, developed from NSGA-II, specializes in many-objective optimization (Deb and Jain, 2014; Jain and Deb, 2014). C-TAEA, one of the state-of-the-art methods, is also increasingly used in studies and shows competitive performance in comparative evaluations of algorithms (Chen et al., 2023; Zhan and Huang, 2024; Picard and Schiffmann ,2021; Tian et al., 2021; Tian et al., 2022; Chen et al., 2024). It utilizes convergence-oriented archiving (CA) and diversity-oriented archiving (DA). Driving the population to the feasible area and approaching the Pareto front is primarily the responsibility of CA as the main force. To explore the area of CA development, DA is used as a supplement. The evolutionary state of CA and DA was used to select mating parents during reproduction (Li et al., 2019). For the optimization study, these three methods were selected considering their frequently usage.

Following their application and the assessment of their results, Reference Vector Guided Evolutionary Algorithm (RVEA) was then selected to be assessed as an alternative method. In RVEA method application, a scalarization approach known as angle penalized distance (APD) is proposed to measure the distance of the solutions to the ideal point and the closeness of the solutions to the reference vectors; this could be used as a diversity measure or a degree of satisfaction to the preferences (Cheng et al., 2019). An adaptation strategy is to adjust the distribution of reference vectors dynamically according to the scales of objective functions.

Step 3: Optimization study and evaluation of results

In the optimization applications with the selected methods, the pymoo framework was used (Blank and Deb, 2020). As aforementioned, due to the need for a new method search and application in relation to the limited number of refurbishment scenarios obtained with the initially selected methods, this step consisted of two sub-steps, which are detailed below. In each of these sub-steps, hyperparameter optimization and evaluation of the obtained optimal solutions in terms of decision support were carried out.

3.a: Application of frequently used optimization methods

In the study, NSGA-II method was used for two-objective functions. NSGA-III and C-TAEA methods were used both for two and three-objective functions.

The hyperparameter values that control the optimization process were selected based on the performance evaluations made in other studies. The hyperparameters evaluated in this study and their values and explanations are as follows:

- Das-Dennis and Riesz s-Energy options were selected for hyperparameter optimization for the reference directions (ref_dirs), which need to be defined for models with three-objective functions. These reference directions consist of a set of predefined reference points to guide the evolutionary search, and help to produce diverse and well-distributed solutions on the Pareto front. While Das-Dennis requires the use of more structured point sets and dimensions, Riesz s-Energy was developed to solve this problem (Ma et al., 2021).
- Termination Criterion (n_gen) is the parameter that determines when to terminate an algorithm run. For the hyperparameter optimization study, 250, 500, 1000, and 1500 values were studied (Rohit et al., 2021; Blank and Deb, 2020).
- Crossover operators were used to generate the offspring for all optimization models in the study (Katoch et al., 2021). For this purpose, Simulated Binary Crossover (SBX) was applied. SBX is a real-parameter recombination operator, and the spread of offspring solutions is determined by the operator's parameter in relation to their parent solutions (Deb et al., 2007). For all optimization studies related to this operator, the probability of SBX is set as 0.5 for two objectives, and as 1 for three objectives (Deb et al., 2007; Blank and Deb, 2020). For the hyperparameter optimization study, mutation probability (mut) values of 0.1, 0.2, and 0.3 were studied by keeping eta value constant at 30.
- Random sampling was used for unbiased representation of populations (Blank and Deb, 2020).

For all optimization studies, hyperparameters were optimized for the dataset that had 15-year-old buildings with rectangular plans of ca. 230 sqm, where long sides were facing east and west. Hyperparameter search space and settings selected accordingly are given in Table 2. For the first group of methods, mostly, values that will take less calculation time have been chosen because different parameter configurations did not produce any change in the results. NSGA-III produced mostly the same solutions as other methods, but for certain datasets, they were less than others. Therefore, hyperparameter setting determination criteria for this method were decided to be as giving the optimal solutions being the same as the optimal solutions obtained in all other methods.

Following the hyperparameter optimization, optimization studies were done for all data sets with the selected hyperparameter values. These optimization studies done with the selected methods led to limited optimal solutions and limited design scheme proposals to support decision-making (Figure 4), and these are given in detail and discussed in the 'Results and Discussion' section.

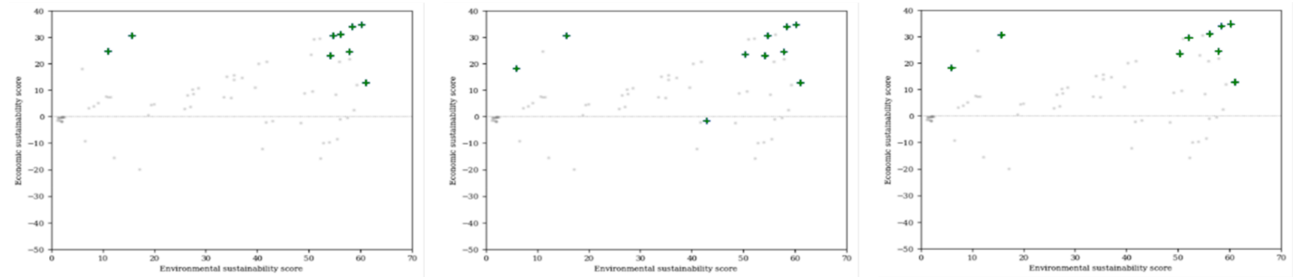
Table 2: Hyperparameter search space and parameter values selected from it for optimization models (Note: values shown in bold provided better results, others made no difference in solutions with different settings)

Objective numbers and optimization methods		Hyperparameter search space, and the parameter values chosen for the related methods.		
		Generation	Mutation	Reference direction
		250, 500, 1000, 1500	0.1, 0.2,0.3	Das-Dennis, Riesz s-Energy (energy)
2 objectives	NSGA-II	250	0.1	-
	NSGA-III	250	0.1	energy
	C-TAEA	250	0.1	energy
3 objectives	NSGA-III	250	**0.1**	**energy**
	C-TAEA	250	0.1	energy
	RVEA	**500**	**0.2**	**energy**

3.b: Application of a relatively less used optimization method: RVEA

Because of the limited optimal solution obtained in the previous step, RVEA, in which the Pareto front result can be determined depending on the user preference, was chosen to be used.

The hyperparameter search space and parameters were chosen the same as in the application of previous methods. Compared to the results of all previous optimizations in this study, changes in the hyperparameter settings were observed to have a significant impact on the Pareto front distribution for RVEA. In response to this, hypervolume (mean and standard deviation) and Pareto front were used as criteria for the hyperparameter value selection in the RVEA application. The Pareto front was evaluated by expecting to have a distribution that is concentrated as close to the ideal point as possible depending on the objective functions without any outlier in the distribution. Regarding this, hyperparameter value settings and corresponding hv values (mean and standard deviation) obtained by RVEA are given in Table 3 and three Pareto front graphs obtained by specific hyperparameter settings are given in Figure 3. Considering pareto front, n_gen is more effective during hyperparameter optimization, since it operates for the optimization of the distance of the solutions to the ideal point and the closeness of the solution for APD in RVEA. Additionally, compared to the other methods in Step 3.a, an increase in optimal solutions was also observed. Yet, the Pareto front distribution was slightly unstable.



Hyperparameter settings: n_gen: 500, mut:0.2, ref_dirs: energy	Hyperparameter settings: n_gen: 1000, mut: 0.3, ref_dirs: energy	Hyperparameter settings n_gen:1500, mut:0.1, ref_dirs: das-dennis

Figure 3: Pareto front obtained by RVEA with specified hyperparameter settings for the dataset that had 15-year-old buildings with rectangular plans of ca. 230 sqm, where long sides were facing east and west only

Table 3: Hyperparameter value settings and corresponding hv values (mean and standard deviation) obtained by RVEA

n_gen	mut	ref_dirs	hv(mean)	hv(std)
250	0.1	das-dennis	3.349152	0.0
		energy	3.349152	0.0
	0.2	das-dennis	3.349152	0.0

Results and discussion

The optimization methods applied within the scope of the study gave different results in terms of the diversity and stability of optimal solutions.

The first group of methods that is commonly used in literature, together with the dataset with a limited Pareto front solution caused by the data distribution depending on the objective functions in this study, gave very precise results that did not show any difference with different hyperparameter values in the optimization of the methods. The Pareto front obtained by this first group of methods resulted in two optimal solutions for each of the 24 datasets one of which is shown in Figure 4, and these results provided only three design options as presented in Figure 5.

These design options were all for the building envelopes with a 10% window-to-wall ratio (WWR) and wooden window frame, except for an option with a 20% WWR, and only the renewal by thermally refurbishing 'all elements' came up for all. When evaluated through the graph, it can be concluded that these methods give accurate results regarding the optimum renewal solution. However, those results provided no other alternative solutions for refurbishment projects for instance with a limited budget where an option for renewing a single building element would therefore be more preferable. This situation was considered to be an issue that would limit the designer’s decisions considerably.

To obtain more alternative design options, the use of RVEA, where user preferences are effective, has been tried. The optimum results obtained with that method not only include the Pareto front but also include feasible options further inside of the periphery (Figure 4). Results were obtained above the average of the economic sustainability score, and the environmental sustainability score ranged from a minimum of 3 to a maximum of 64.

Regarding the decision-support for the designer at the early design stage, optimal solutions obtained by RVEA provided diversified thermal refurbishment options. Design schemes corresponding to these optimal solutions given in Figures 5 and 6 show that:

- Renewal through all elements was the most proposed design by RVEA, same with the first group of methods because this option was the only one where the corresponding results for the values regarding the economic sustainability scores are the highest (Figure 2). Yet, depending on the budget, options for thermally refurbishing an individual element (i.e., ‘roof’, ‘window’, or ‘exterior wall and projected floor’) came up too.
- Options for 10% WWR and wooden frames were recommended more frequently. However, when the WWR of the building with a wooden window frame increased to 20% or 30% and refurbishment of all elements was preferred, replacing wood with a PVC frame was the only recommendation.
- More options were proposed for rectangular planned buildings than square alternatives.

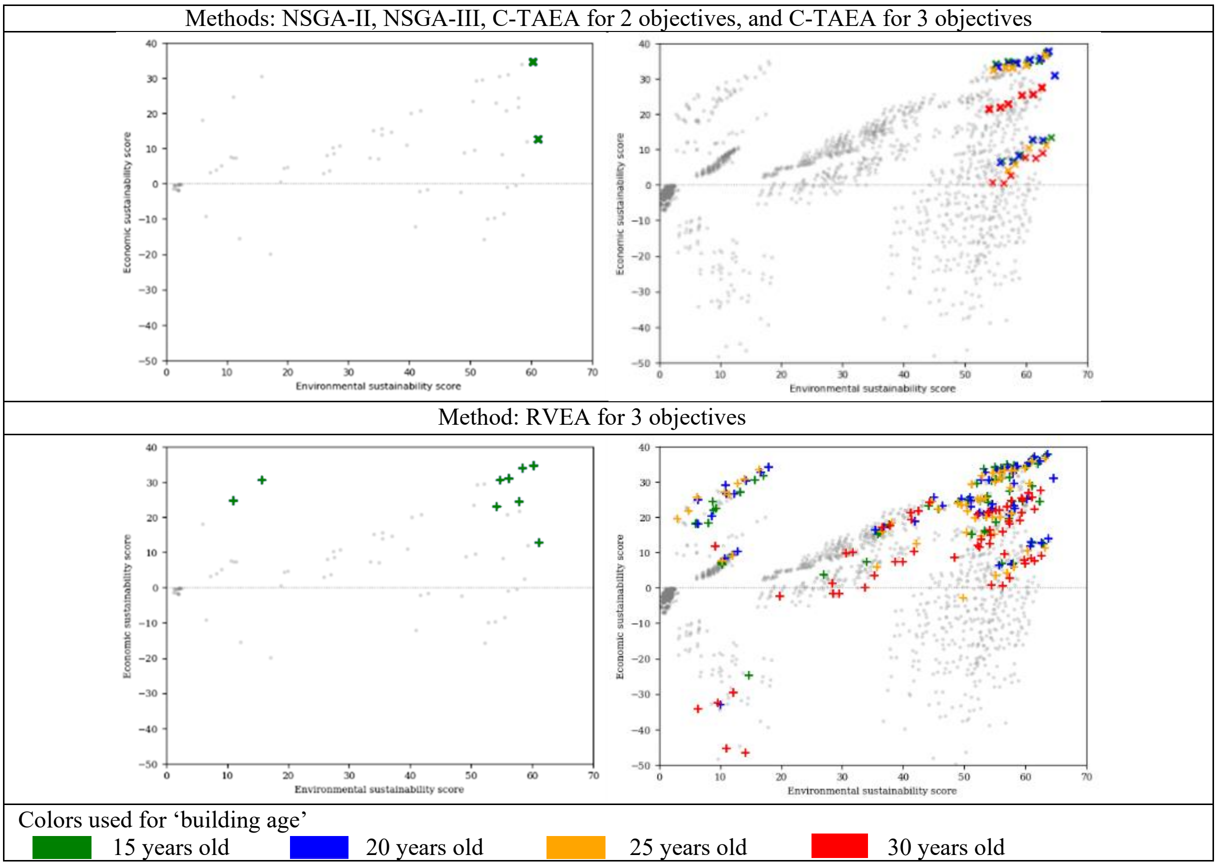

Figure 4: Optimal solutions for the dataset that had 15-year-old buildings with rectangular plans of ca. 230 sqm, where long sides were facing east and west only (left), and all optimum solutions obtained with all sets colored according to building age (right)

Window-to-wall ratio	Window frame materials/ glass and glazing type	Element thermally refurbished - Insulation material and window frame (if specified) used															Optimization methods

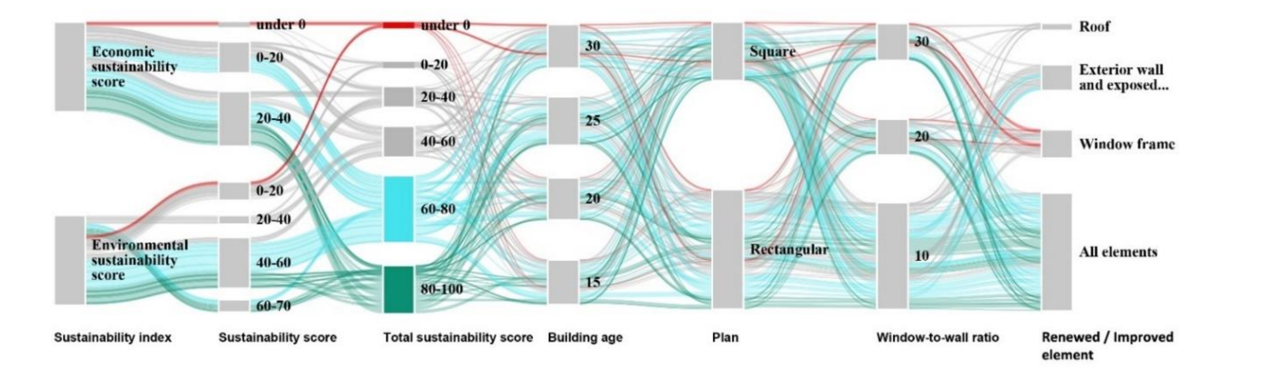
15 years old (green) 20 years old (blue) 25 years old (orange) 30 years old (red)

Symbols used for ‘plan type’
▯ Rectangular plan ■ Square / close to square plan

(n=…): the number of data sets for which the corresponding configuration is recommended
*: Group 1 methods include those used for 2 objectives (i.e., NSGA-II, NSGA-III, C-TAEA), and 3 objectives (i.e., C-TAEA).
**: the related design schemes are optimum options for 18 datasets with NSGA-III for 3 objectives.

Figure 5: Variable values corresponding to optimal solution



Colors by ‘Total sustainability score’

	Score between ‘80-100’		Score between 60-80
	Score between ‘0-60’		Score under 0

Figure 6: Optimum design scheme with RVEA (colored depending on the value of ‘Total sustainability score’)

- For 30-year-old buildings, designs for 20% and 30% WWRs have been less commonly recommended even with RVEA.
- In addition to XPS, which was the only insulation material recommended by the first group of methods, EPS has become a frequently recommended option with the use of RVEA in the cases of replacement of all elements for all building ages and in all plan types. However, it was not recommended in the case of the replacement of any single element.
- There were some solutions which RVEA gave as the optimal solution to maximize objective functions, but they correspond to low economic values (values specified as under 0 in Figure 6), and therefore they can be considered incorrect. These were the options in which the window frames of 30-year-old buildings with 20% and 30% WWR were renewed in by wooden window frames. These options were clustered in a corner opposite to the ideal point completely.
- Regarding the refurbishment option of renewing the floor above the unheated spaces on the other hand, which are clustered far from the ideal point similarly, no suggestions came up.

Conclusion

The objective of this study was to find appropriate multi-objective optimization method(s) to support decision-making during early design for building thermal refurbishment through the building envelope. In this manner, four evolutionary algorithm methods were compared for a case in Istanbul, Turkey concerning residential buildings.

As a result of the studies conducted on the dataset used, NSGA-II, NSGA-III, C-TAEA methods brought limited solutions that were highly close to the Pareto front; and, setting the hyperparameters differently didn't change or expand these limited solutions in almost all individual optimization cases. The reason for this is due to the characteristics of the dataset studied: the distribution of the data in a way that the Pareto front does not spread widely and the fact that the dataset is in a discrete distribution. As a solution to these undesirable situations from the decision support perspective, RVEA, which allows user preferences to bring alternative design schemes, was evaluated. As a result, RVEA provided more solutions in number and variety of designs with reasonable stability regarding the study related to hyperparameter optimization.

Further research is planned on the application of optimization methods to other problems to evaluate the effect of problem characteristics on optimization performance.

Abstract

Building energy simulation models have strong energy prediction capabilities but suffer from high computational costs, which could be reduced through surrogate modeling approaches. Existing surrogate models predict energy consumption on an annual resolution, however, for strategizing net-zero measures, granular predictions are necessary. This paper evaluates the ability of four state-of-the-art machine learning algorithms to predict building energy consumption on an hourly basis. The results indicate that Random Forest Regression is the most suitable predictive model due to the high R^2 value of 0.94. The proposed framework can be further expanded to test net-zero energy retrofits at minimal computational costs.

Introduction

The operation phase of buildings accounts for nearly 30% of global emissions (IEA 2021) which necessitates the need for innovative strategies for reducing emissions. The International Energy Agency estimates that in the next 30 years, global building floor area will grow by 75%, with around 80% of the increase in emerging markets such as India. The building sector in India accounts for over 30% of total electricity consumed (BEE 2018) and the commercial building sector in India consumed 8.31% of end-use electricity in the year 2021 (MoSPI 2022). Previous studies on energy consumption show that the availability of an accurate building energy forecasting system can save about 30% of the total energy consumption in buildings (Olu-Ajayi et al. 2022). Hence, predicting the energy consumption pattern of buildings is of significance to multiple stakeholders as it can help improve buildings' energy efficiency and aid in energy conservation measures for buildings.

Building energy simulations for energy prediction are typically done by creating a prototype building model using an energy modeling tool such as EnergyPlus, developed by the U.S. Department of Energy based on the proposed design inputs (Chan et al. 2022). Data-driven approaches using surrogate machine learning (ML) based models help overcome the challenges of building an energy simulation approach, which requires high computational costs for performing the energy simulations. The ML models identify the relationship between input features impacting building performance such as weather parameters and output variables such as energy consumption. Such a trained ML model develops the capability to predict the energy consumption of buildings eliminating the need for multiple energy simulation runs for varying simulation scenarios (Olu-Ajayi et al. 2022).

The development of a surrogate ML model consists primarily of four steps: data collection, data preprocessing, model training, and model testing. Data collection involves collecting available past data, such as weather data and energy consumption data of buildings. Data preprocessing is done by integrating the required data into a comprehensive dataset, which will be used further for model training. The model training step involves developing and deploying a suitable ML model for energy prediction studies. Model testing involves using standard model evaluation measures to check the accuracy of the prediction model (Amasyali & El-Gohary, 2018).

Energy prediction using machine learning models is commonly done using algorithms such as regression models and artificial neural networks (ANN). Some of the commonly employed regression models in energy prediction include multiple linear regression (MLR), polynomial regression (PR), and random forest regression (RFR) (Sun et al. 2020). In a study based out of buildings in Italy, multiple linear regression is used as a decision support tool for assessing the preliminary energy demand. This was used as an alternative to assessing energy demand by building energy modeling. The correlation of the results shows that the MLR model can predict the buildings' heating, cooling, and total energy demand with a high degree of reliability (Ciulla et al. 2019). Meanwhile, the polynomial regression model is more flexible than multiple linear models as it can fit data in a wide range of curvature, making it suitable for problems where the relationship between input and output variables is non-linear, as in the case of building energy loads. In a study conducted on 17 buildings in Europe, polynomial regression was used to predict the heating demand based on climatological conditions and the architecture of the building. The results showed that the polynomial regression model prediction is best suited for predicting fast, early-stage energy consumption (Tiberiu 2012).

Another ML model that can capture non-linear relationships between input and target variables is Random Forest Regression. In a study conducted on a dataset of 5 existing buildings from a building data genome project (Miller et al. 2017), short-term energy consumption in hourly resolution is predicted to propose effective solutions to help buildings' owners and facility managers understand building energy consumption patterns for enhancing energy efficiency in buildings. The RFR model was selected for the study as it can reduce predictive error while solving regression problems, and it considers all decision trees in the prediction correlation (Pham et al. 2020). The results from the study showed that RFR is an effective technique in predicting hourly building energy consumption, which helps stakeholders take adequate steps to reduce the energy consumption of buildings.

Artificial neural network (ANN) is also a commonly used ML model for predicting the energy consumption of buildings besides RFR. In a study of 243 commercial buildings in Southeast Asia, the cooling loads of buildings obtained from the physics-based building energy model were compared to an ANN model. ANN was used due to its ability to solve non-linear problems dependent on numerous variables. The features for developing the ANN model were general building information, building envelope, and internal loads. The results showed that the cooling load prediction by the ANN model agrees well with the physics-based building energy simulation at a fraction of the time required for the latter (Ngo 2019).

Overall, existing studies have largely focused on predicting the 'annual' energy consumption of buildings, and energy prediction for 'hourly' resolution and 'one-year' time horizon has not been addressed thoroughly. The current studies are also limited to using meteorological information from a single climatic zone, and the impact of variation of varied climatic conditions on energy consumption is not explored in detail. Hence, this study aims to address this critical gap by identifying the best ML model for predicting building energy consumption in hourly resolution under varying climatic conditions for an annual time horizon. The developed framework is expected to reduce the computational effort required by a traditional building energy modeling approach for hourly energy predictions, even under varying climatic conditions, by eliminating the need for multiple energy simulation runs. This approach can further be used in optimization studies to inform design strategies, such as renewable energy generation, that support the transition to net-zero energy performance for existing buildings.

Methodology and Experiment

A four-stage methodology to identify the best predicting ML model for hourly energy consumption is proposed as follows:

Stage 1: Generating hourly energy simulation using Energy Plus

Stage 2: Compiling dataset for ML training

Stage 3: Developing ML Model and evaluating

Stage 4: Predicting energy consumption using ML model

The flow chart of the hourly energy prediction framework is given in Figure 1 below.

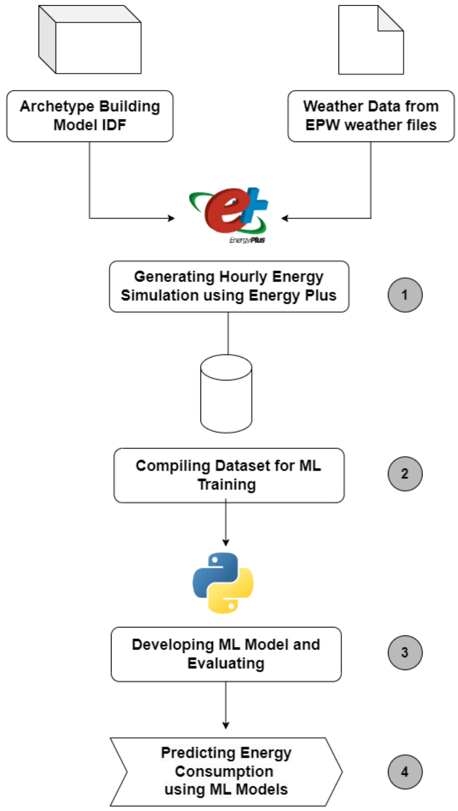

Figure 1 Framework for hourly energy prediction

Stage 1: Generating Hourly Energy Simulation Using Energy Plus

The dataset used for ML training is the collection of meteorological data from weather files and hourly building energy consumption data generated from energy simulations. The process is explained in detail below.

Hourly building energy consumption data based on annual simulation of a standard reference building model is used for the ML model development. A validated prototype reference commercial building model, based on a previous study of 230 commercial buildings in India (Bhatnagar et al. 2019), is adopted to simulate hourly energy consumption, and the archetype-building model used for this study is shown in Figure 2 below.

Archetype Building Model

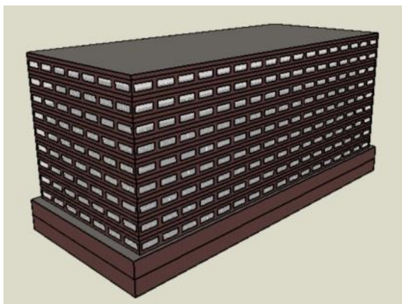

Figure 2 Archetype reference commercial building model for an 8-hour working schedule

Building features of the archetype reference building used in this experiment are mentioned in Table 1 below.

Table 1 Archetype reference building features

Feature	Value
Total floor area (m2) (excluding basement)	31,381
Percent of conditioned Area (%)	76
Basement floor area (m2)	7,689
Floor Area	3,487
Number of floors	9
Building shape	Rectangular
Aspect ratio	2.3
Window-to-wall ratio	30%
Window U-factor (W/m2-K)	2.05
Window SHGC	0.27
Exterior wall	Brick wall (200mm width) with plaster
Exterior wall U-factor	1.46
Roof	Roof tile + Concrete (200 mm) + Expanded polystyrene (50mm) + Plaster
Roof U-factor	0.64
Average lighting power density (W/m2)	Office: 8.32; Basement parking: 1.81
Daylighting controls	No
Occupancy controls	No
Exterior Light (kW)	8.12
Cooling type	Screw Chiller
Distribution and terminal	Variable air volume AHU with motorized dampers
COP	5.6
Supply Fan Fan Power (W/l/s)	1.25
Economizers	No
Energy recovery	No

Weather data

The weather data in 'epw' format, developed by the U.S. Department of Energy, is used for this study. Representative cities used for this study are shown in Table 2. The input variables (X-variables) used for ML model development, are listed in Table 3. The weather file input parameters are also taken as per studies conducted previously. In addition to the weather parameters, occupancy fraction is also considered as one of the input variables for energy consumption prediction as the occupancy schedule has been shown to significantly influence energy consumption (Li et al. 2018).

Table 2 Representative cities for ML model development

Sl No:	Climatic Zone	Representative City
1	Hot-Dry	Ahmedabad
2	Hot-Humid	Kolkata
3	Temperate	Bengaluru
4	Composite	Lucknow

Table 3 List of input variables for ML model development

Sl.No.	Input Variables (X)	Variable Name
1	Dry bulb temperature	X1
2	Dew point temperature	X2
3	Relative humidity	X3
4	Global horizontal radiation	X4
5	Direct normal radiation	X5
6	Diffuse horizontal radiation	X6
7	Wind direction	X7
8	Wind speed	X8
9	Occupancy	X9

Stage 2: Dataset for ML Training

The simulation software 'EnergyPlus,' version 8.7, developed by the U.S. Department of Energy, is used to generate hourly energy consumption for an annual simulation with 8,760 hourly energy data points. Out of the total 8,760 data, an 8-hour working schedule, from morning 09:00 to evening 17:00, is considered. The days considered were from Monday to Friday, excluding 10 public holidays. The resulting dataset has 2,000 hourly data points of input (X-variables) and output variables (Y-variable) as given in Table 4.

Table 4 Data points considered based on an 8-hr schedule

Climate Zone	City Name	Total Simulation Data	Data points based on 8-hr schedule
Hot-Dry	Ahmedabad	8,760	2,000
Hot-Humid	Kolkata	8,760	2,000
Temperate	Bengaluru	8,760	2,000
Composite	Lucknow	8,760	2,000

Stage 3: ML Model Development and Evaluation

The dataset is further split into training and test sets. The 'X-variables' and 'Y-variables' from the dataset are split in an 80:20 ratio for all the subsequent ML models used to develop a predictive model. Four different ML algorithms, such as MLR, PR, RFR, and ANN, are used to investigate the best-performing model in predicting hourly energy consumption. MLR, PR, and RFR algorithms are developed using the 'scikit-learn' library, and the ANN model is developed using the 'tensorflow' library with Python as the programming language. ML model development is given in more detail in the subsequent sections.

Multiple Linear Regression

From the 'scikit-learn' Python library, the 'LinearRegression' function is imported. The split dataset is further given as input to the linear regression function. The 'predict' function is then used with the test set of 'X-variables' to predict the hourly energy consumption.

Polynomial Regression

Similar to the multiple linear regression, 'PolynomialFeatures' and 'LinearRegression' functions are imported from the 'scikit-learn' library. The training dataset for 'X-variable' is then transformed using 'fit_transform'. The 'predict' function is further used with the test set of 'X-variables' to predict the hourly energy consumption.

Random Forest Regression

For RFR, the 'RandomForestRegression' function is imported from the 'ensemble' module from the 'scikit-learn' library. The 'RandomForestRegression' function is then called on the split dataset with 'n_estimators' defined as 10 and 'random_state' set as 0. The 'predict' function is further used with the test set of 'X-variables' to predict the hourly energy consumption.

Artificial Neural Network

ANN model differs slightly from the other three models used. For ANN, the 'Tensorflow' python library is used for analysis. A multi-layered feed-forward ANN model with one input layer, one hidden layer, and one output layer is used based on trial and error for prediction accuracy. The number of 'epochs' is set as 100. The 'predict' function is further used with the test set of 'X-variables' to predict the hourly energy consumption.

Following the ML model development, model performance evaluation techniques are further deployed on each ML model to select the best predicting model. The model performance evaluation is conducted separately for the four representative cities.

Stage 4: Energy Prediction using ML Model

Some of the standard model performance evaluation metrics used for evaluating the test set prediction results are coefficient of determination (R^2), Mean Squared Error (MSE), Mean Bias Error (MBE), Root Mean Squared Error (RMSE), and coefficient of variance (CV) (Sun 2020). All these model performance parameters are estimated based on the equations below, and the results are discussed in further sections.

The coefficient of determination (R^2), as mentioned in Equation 1, measures how close the predicted value is to the actual value, with a value of 1 indicating a perfect fit.

$$R^2 = 1 - \frac{\sum_{i=1}^{n}(PEi - AEi)^2}{\sum_{i=1}^{n}(AEi - \overline{AEi})^2} \quad (1)$$

The Mean Squared Error (MSE), mentioned in Equation 2, calculates the variance between actual and predicted values.

$$MSE = \frac{1}{n}\sum_{i=1}^{n}(AEi - PEi)^2 \quad (2)$$

The Root Mean Squared Error (RMSE), in Equation 3, represents the square root of the quadratic mean of the differences between predicted and expected values.

$$RMSE = \sqrt{\frac{1}{n}\sum_{i=1}^{n}(AEi - PEi)^2} \quad (3)$$

The Mean Bias Error (MBE), mentioned in Equation 4, is the average error or bias of each value between the actual and predicted values in the sample space.

$$MBE = \sum_{i=1}^{n}\frac{(AEi - PEi)}{n} \quad (4)$$

The Coefficient of Variation (CV), mentioned in equation 5, indicates how well a model approximates the real data points, which measures the model's degree of predictability.

$$CV = \frac{\sqrt{\frac{\sum_{i=1}^{n}(PEi - AEi)^2}{n-1}}}{\overline{AEi}} * 100 \quad (5)$$

where PEi is the predicted energy, AEi is the actual energy at the hour 'i', $\overline{AEi}$ is the mean of actual energy, and n is the total number of samples.

Based on the results obtained from the model performance evaluation conducted for each representative city, the best predicting ML model is selected for further scenario analysis.

Scenarios considered using the best predicting ML Model

The best ML algorithm, selected based on model performance evaluation, is further deployed in two different scenarios. The two different scenarios considered in the study are explained below.

Scenario 1

In Scenario 1, the X and Y variables from all four representative cities are considered and combined to train the ML model. The combined dataset, which contains 8,000 data points, is then split into an 80:20 ratio. The hourly energy consumption of the building using the test set is then predicted.

Scenario 2

Scenario 2 demonstrates the energy forecasting capacity of the ML model for a dataset it is not trained with. In this case, the data points from three climatic zones were used, and the combined dataset contained 6,000 data points. In this study, the training set included X and Y variables of Ahmedabad, Lucknow, and Bengaluru, and the hourly energy consumption of Kolkata is predicted.

Results and Discussion

The experiment to predict the hourly energy consumption using ML models was conducted and the results are given and discussed as follows.

Model Performance Evaluation

The results of the model performance evaluation conducted for the four ML models MLR, PR, ANN, and RFR using Lucknow's dataset are shown in Figure 3 and Table 5 below. Similarly, the model performance evaluation is conducted for the Kolkata, Ahmedabad, and Bengaluru datasets, and the results are shown in Table 6 to Table 8, respectively.

Table 5 Model performance evaluation for Lucknow with MLR, PR, ANN, and RFR models

Model performance	R^2	MSE	RMSE (%)	MBE (%)	CV (%)
MLR	0.89	1169.6	34.20	-1.27	9.6
PR	0.83	1857.6	43.10	-4.58	10.9
ANN	0.88	1296.2	36.00	-3.20	10.1
RFR	0.94	636.39	25.22	-2.88	9.7

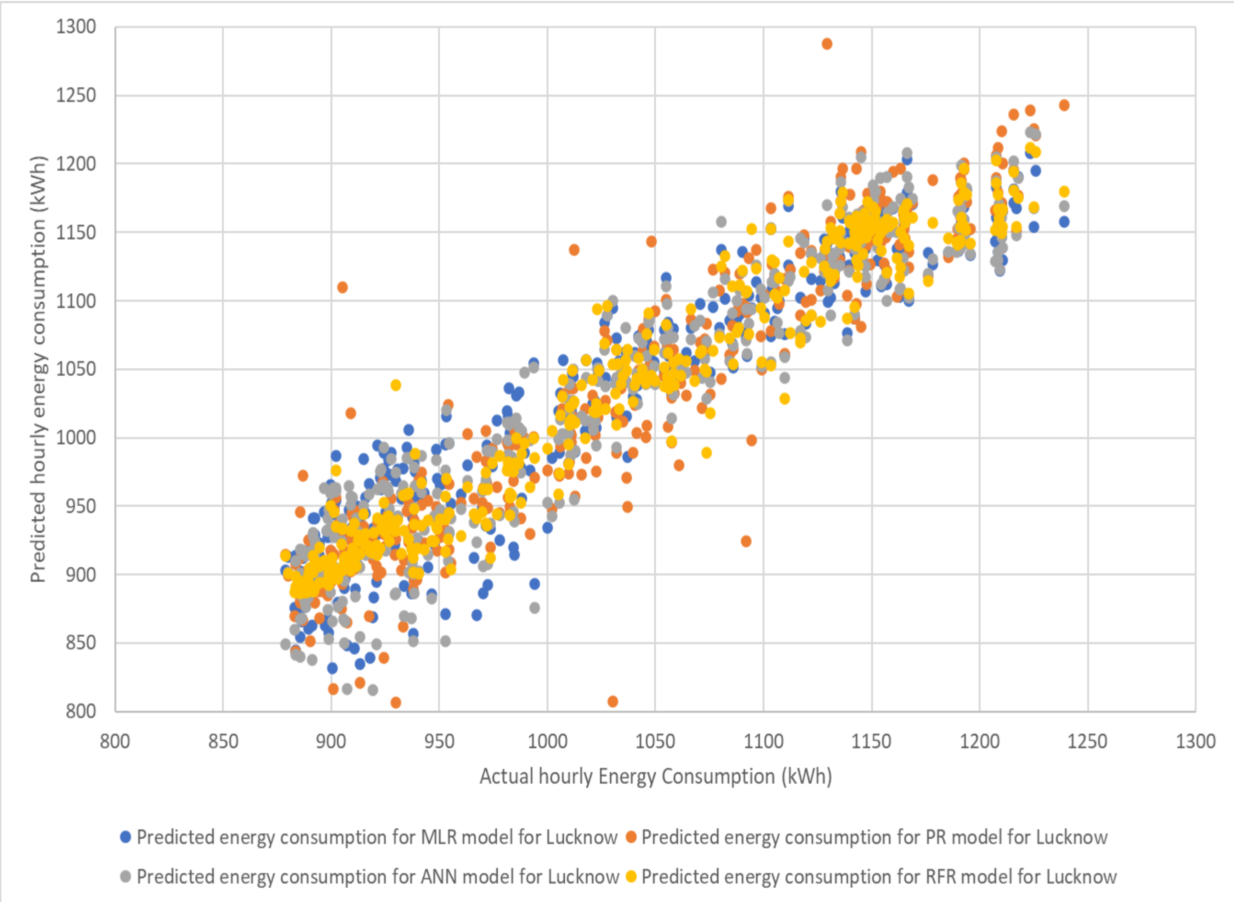

Figure 3: Graph showing the predicted vs actual hourly energy consumption for the four ML models tested for Lucknow

Table 6 Model performance evaluation for Kolkata with MLR, PR, ANN, and RFR models

Model performance	R^2	MSE	RMSE (%)	MBE (%)	CV (%)
MLR	0.86	1208.1	34.75	1.72	8.9
PR	0.56	4055.1	63.67	4.31	10.4
ANN	0.82	1574.4	39.67	7.54	9.7
RFR	0.91	748.4	27.37	1.55	8.8

Table 7 Model performance evaluation for Ahmedabad with MLR, PR, ANN, and RFR models

Model performance	R^2	MSE	RMSE (%)	MBE (%)	CV (%)
MLR	0.75	1637.88	40.47	5.80	7.0
PR	0.42	3846.89	62.02	-1.02	9.3
ANN	0.75	1667.55	40.83	-5.89	8.0
RFR	0.88	739.46	27.19	1.69	7.4

Table 8 Model performance evaluation for Bengaluru with MLR, PR, ANN, and RFR models

Model performance	R^2	MSE	RMSE (%)	MBE (%)	CV (%)
MLR	0.61	559.18	23.64	1.110	3.4
PR	0.25	1071.9	32.73	-1.105	4.6
ANN	0.50	709.73	26.64	-3.126	3.9
RFR	0.70	434.28	20.83	1.904	3.4

The graphs shown in Figure 3, represent predicted and actual energy consumption for the four ML models MLR, PR, ANN, and RFR for the city of Lucknow. The X-axis represents actual hourly energy consumption and the Y-axis represents predicted hourly energy consumption in kWh. In the case of the RFR model, in Figure 3, the predicted energy consumption closely follows the actual energy consumption. However, in the case of MLR, PR, and ANN, the predicted energy consumption shows variations. In some instances of MLR, PR, and ANN, the predicted energy consumption value is higher than actual energy consumption. Thus, the RFR model shows better performance when compared to MLR, PR, and ANN.

The results observed from Table 5 to Table 8 show that the RFR model outperforms other models due to its high R^2 values and lower MSE, RMSE MBE, and CV values. Hence, the RFR model is chosen as the prediction model for further scenarios 1 and 2.

Energy Prediction Results for Scenario 1 and 2

Scenario 1

Hourly energy consumption is predicted using the RFR model, trained with the dataset of all four representative cities combined. The results are shown in Table 9 below.

Table 9 RFR model performance in the test phase of scenario 1

Scenario	Training points	R^2	MSE	RMSE (%)	MBE (%)	CV (%)
I	6,400	0.90	837.8	28.94	2.21	8.70

The performance evaluation of the test data in the test phase of scenario 1 gives an R^2 value of 0.90 and a CV value of 8.70%, indicating that the RFR model is reliable for hourly building energy prediction (Yang et al. 2015).

Further, to understand the results figuratively, Figure 4 shows the predicted versus actual hourly energy consumption for the test data of scenario 1. The scatter plot is generated from the test set of scenario 1, i.e., with 1600 data points (20% of 8000 data points) combined from all four cities. The concentration of the scatter plot points along the 45-degree line indicates a high degree of correlation between actual and predicted values.

Further to test the hourly energy prediction capability of the RFR model with changing weather conditions scenario 2 was conducted and the results are given in the following section.

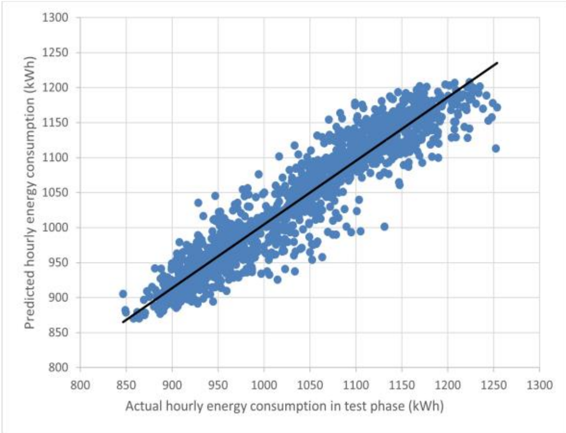

Figure 4: Scatter plot of predicted vs actual hourly energy consumption in the test phase of scenario 1

Scenario 2

Hourly energy consumption is predicted using the RFR model trained with a dataset of three cities: Ahmedabad, Bengaluru, and Lucknow, and the energy consumption of Kolkata is predicted. The performance of the RFR model is given in Table 10.

Table 10 RFR model performance in test phase of scenario 2

Scenario	Training points	R^2	MSE	RMSE (%)	MBE (%)	CV (%)
II	4,800	0.80	1825.1	42.72	8.96	8.80

The model performance evaluation shows an R^2 value of 0.80 and a CV of 8.80%. The results indicate that the prediction accuracy of the RFR model for scenario 2 is less than that for scenario 1. To understand the results figuratively, Figure 5 shows the predicted versus actual hourly energy consumption for test data of scenario 2.

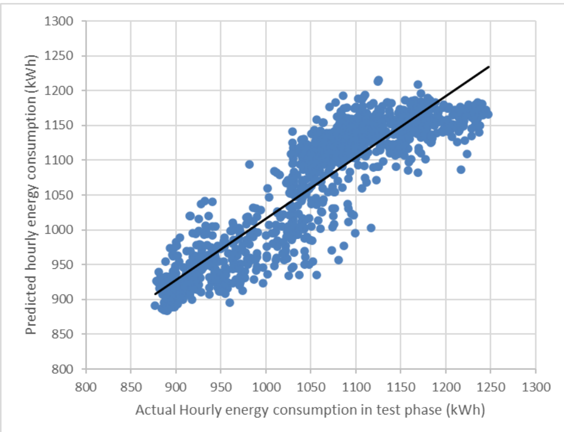

Figure 5 Scatter plot of predicted vs actual hourly energy consumption in the test phase of scenario 2

The graphs generated for the test data set of scenario 2 predicted from 1200 data points using the weather file of Kolkata to generate the scatter plot. Although the scatter plot concentrates along the 45-degree line, the distribution is not uniform, like in scenario 1. The observation is as per expectation because the ML model was tested for a dataset it was not trained with. However, the results are promising since MBE falls within the permissible limits of 10% and CV less than 30% (Yang et al. 2015). This shows that there is scope for further evaluating the use of ML models such as RFR for predicting energy consumption for hourly resolution under changing climatic conditions.

Scenario 1 and Scenario 2 results indicate that the RFR model is a suitable ML model for predicting energy consumption on an hourly basis due to an R^2 value of more than 0.8 in both cases and CV values of less than 10%. The RMSE value is 42.7% in scenario 2, while that in scenario 1 is 28.9%. This indicates a greater spread of the data points in scenario 2 from the mean value Figure 5, corresponding to scenario 2, also indicates the same. The MSE and MBE values for Scenario 2 are also greater than Scenario 1, indicating greater prediction accuracy in Scenario 1.

Conclusions

The study was conducted to demonstrate ML models' capability to predict commercial buildings' energy consumption in hourly resolution for annual time horizons under varying climatic conditions. An archetype reference commercial building model for an 8-hour working schedule representative of the Indian office buildings was used for this study. A methodology was also developed to generate a dataset and predict hourly energy for changing climatic conditions. Four ML models were used: MLR, PR, RFR, and ANN. The model performance evaluation on these four models identified RFR as the most accurate predictive ML model for hourly energy predictions. Thus, the RFR model was used for further evaluation in Scenario 1 and Scenario 2. Scenario 1 was conducted to test the holistic prediction capability of the RFR model and the results of Scenario 1 indicate that the RFR model is suitable for hourly energy prediction. Scenario 2 was conducted to check the capability of the ML model to predict hourly energy consumption for test data for which it was not trained. Model performance evaluation results for scenario 2, although less accurate than scenario 1, are promising. This indicates that there is scope for using ML models such as RFR for predicting hourly energy consumption and changing weather conditions.

The comparison of Scenarios 1 and 2 results indicates that the relationship between input weather features and building energy output needs further study. Further studies in this direction can consider ensemble-based methods, which combine the output of multiple machine-learning algorithms to enhance the prediction performance of a single data-driven model. Commonly used ensemble methods such as bagging, boosting, and stacking may be deployed to improve the hourly energy prediction for changing weather conditions such as the one considered in this experiment in scenario 2. This will further aid in improving the efficiency of building operation systems and support the transition of existing buildings to achieve net-zero energy.

CONSTRUCTION DATA SPACE FOR BUILDING PERMIT MANAGEMENT

Gonzalo Gil[1], Francisco Javier Diez[1], Ricardo Romero[1], Ignacio Lazaro[1] and Izaskun Fernandez[1]
[1]Tekniker, Basque Research and Technology Alliance (BRTA), Eibar, Spain

Abstract

Building permit management involves complex compliance checking processes that today are mainly performed by sharing documents between stakeholders and reviewing them manually. This causes long delays in obtaining building permits. Based on the DigiPLACE Reference Architecture Framework for digital construction platform, this paper presents the DigiChecks Framework, a novel approach to digitize and automate building permit management based on the orchestration of compliance checks and a data space, a distributed and open infrastructure for interoperable, trusted, and sovereign data sharing between platforms of different stakeholders. The DigiChecks Framework reduces data sharing and compliance checking efforts, while it ensures strict compliance with existing regulations.

Introduction

The management of building permits is a process that requires numerous compliance checks based on the information shared between different stakeholders, including architects, engineers, construction companies, subcontractors, designers, certification companies, suppliers, and public authorities. The current low level of digitization in the construction sector leads to resource-consuming compliance checks, based mainly in documents sharing and manual review. This causes considerable delays in obtaining building permits.

The challenges in digitizing and automating the management of building permits are significant (Beach et al., 2013). Among all of them, the following three stand out.

1. For different countries, but also regions or municipalities, there is a need to verify compliance with different regulations (Rezgui et al., 2011).
2. To check compliance, coordination issues should be tackled by combining building data stored in different proprietary formats (Rezgui et.al., 2013).
3. The reluctance to share data needs to be avoided by providing control over the data (Jarke et al., 2019).

To address these challenges, based on the DigiPLACE Reference Architecture Framework (RAF) (David et al. 2021), this paper presents the DigiChecks Framework, a novel approach to digitize and automate compliance checks by combining an orchestration of compliance checks and a data space. The orchestration provides a modular and scalable approach to manage the different compliance checks to be performed based on current regulations. The data space, following the path for the digital transformation of the construction sector (Buhler et al., 2023), facilitates the necessary collaboration between stakeholders through an open and distributed infrastructure for interoperable, trusted, and sovereign data sharing between their different platforms.

The rest of the paper is structured as follows. First, the related work is presented. Second, based on observed needs concerning building permit management, the main principles of the DigiChecks Framework are stated. Third, based on the related work and considering the main principles of the DigiChecks Framework, the conceptual architecture of the DigiChecks Framework is described. Fourth, the DigiChecks Data Space which, as part of the DigiChecks Framework, provides an open and distributed infrastructure to enable the collaboration between platforms based on interoperable, trusted, and sovereign data sharing, is detailed. Finally, conclusions about this work are drawn.

Related Work

The DigiPLACE RAF sets common guidelines for building digital platforms for the construction sector. Considering them, the DigiChecks Framework proposes a novel approach to digitize and automate compliance checks by combining an orchestration of compliance checks and a data space. In what follows, the DigiPLACE RAF and the work carried out on the definition and design of data spaces is described.

DigiPLACE Reference Architecture Framework

The RAF is based on two guidelines: “Interoperability and Common Processes” and “Data Control”. They are described below.

“Interoperability and Common Processes” is divided into data interoperability, data and process management and governance. Data interoperability establishes the definition of data vocabularies based on open standards, common data formats and models, and standardized data access. Data and processes management sets the collaboration between stakeholders through common data environments and data lifecycle management based on digital twins. Governance proposes open accessibility to standards and community engagement to improve them. Figure 1 represents this.

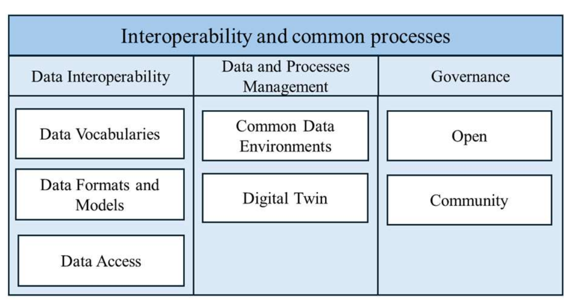

Figure 1: Interoperability and Common Processes

“Data Control” is divided into data security, data ownership, data trust and data availability and sustainability. Data security covers the security of the data, data sovereignty and data sharing within data spaces. Data ownership sets compliance with the GDPR, the ownership of the data and data transparency. Data trust encompasses data certification and value. Finally, data availability and sustainability establish compliance with FAIR principles as well as the sustainability of the data. Figure 2 represents this**.**

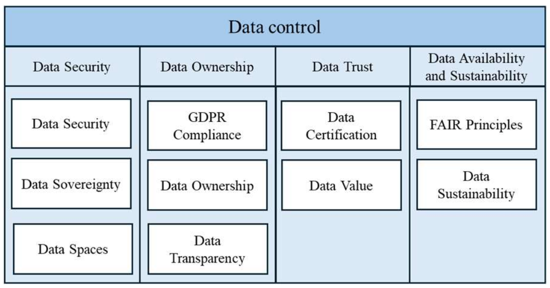

Figure 2: Data Control

Data Spaces

Nowadays, different initiatives are working worldwide on the definition and design of data spaces: The OPENDEI project, the Data Spaces Business Alliance (DSBA), GAIA-X and the International Data Spaces Association (IDSA) stand out. This large number of initiatives makes it difficult to clarify which building blocks are needed to build a data space and the technical components required to support them.

Recently, the design principles for data spaces resulting from the OPENDEI project (Nagel and Lycklama, 2021) and the common framework proposed subsequently by the DSBA (Gronlier et al., 2021) agree on the building blocks required to build a data space. These are detailed in Figure 3.

Figure 3: Data Space Building Blocks

In this context, GAIA-X and IDSA are positioned as the reference initiatives for the specification of the technical components that must be developed to support these building blocks. While GAIA-X defines the GAIA-X Technical Architecture 23.10 (GAIA-X European Association for Data and Cloud, 2023), a set of technical components for a governance framework for a federated infrastructure of services that complies with European standards and values of digital sovereignty, IDSA defines the IDSA Reference Architecture Model (RAM) 4.0 (International Data Spaces Association, 2023), a set of technical components for an interoperable, and sovereign data sharing framework between services.

On this basis and considering that the data space building blocks meet the DigiPLACE RAF core guidelines to build digital platforms in the construction sector, we consider the GAIA-X Technical Architecture 23.10 and the IDSA RAM 4.0 as the technical foundations to build the DigiChecks Data Space that acts as the core of the DigiChecks Framework.

DigiChecks Framework Principles

For the design of the DigiChecks Framework, a review of the main needs concerning building permit management has been made. These needs are summarized below:

1. Automated compliance checking cannot be achieved with one-step solution, but by combining multiple tools in the form of services provided by different organizations that gradually makes compliance checking more mature.
2. The wide variety of existing processes, tools and contexts means that there will be no one-size-fits-all solution, but a solution that enables the interaction with multiple services.
3. Individual services communicating with each other need a common language so that they can understand each other. The common language should follow a formal, explicit specification of a shared conceptualization.

These needs lead to the following three principles of the DigiChecks Framework.

1. The framework is a distributed infrastructure, rather than a centralized, monolithic application.
2. The framework is an open infrastructure with a modular and scalable approach, where services can be included and swapped easily.
3. The framework uses a shared set of conceptual information models that align with existing domain ones. Information models are formalized based upon open and widely accepted standards.

DigiChecks Framework Conceptual Architecture

Considering the three principles of the DigiChecks Framework, the DigiChecks Framework Conceptual Architecture is build based on the following four architecture principles:

1. The DigiChecks Framework Conceptual Architecture is a modular and distributed architecture in which the components have the flexibility to be deployed across multiple platforms managed by different stakeholders.

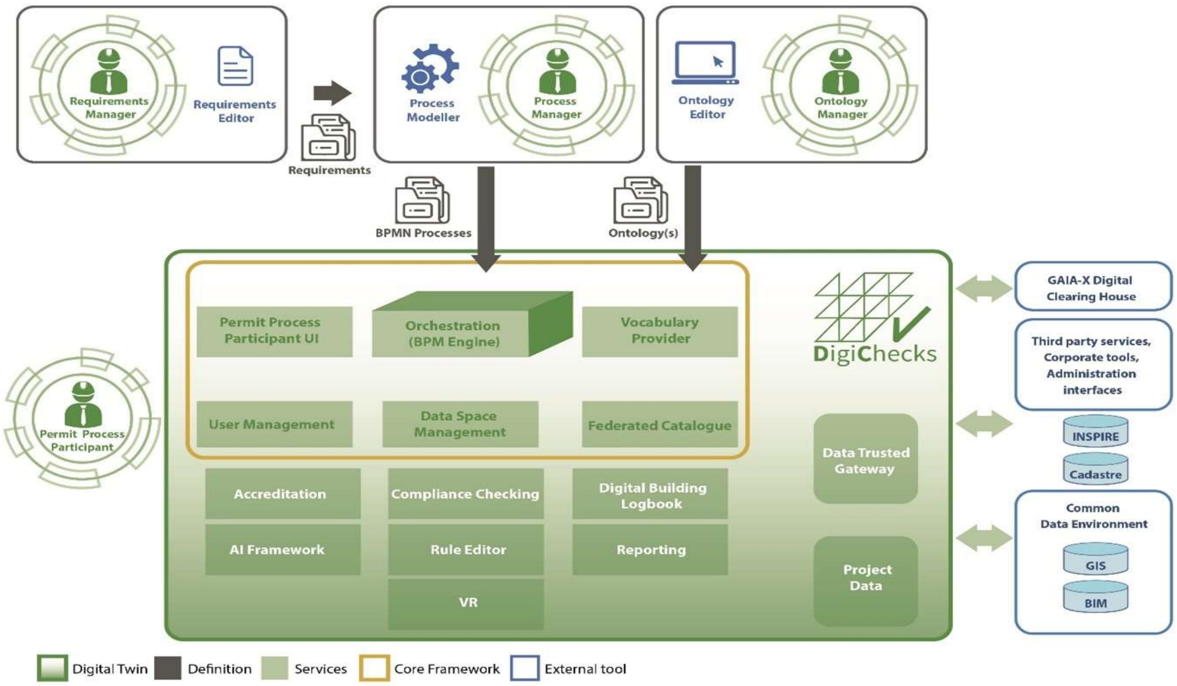

Figure 4: DigiChecks Framework Conceptual Architecture

2. The DigiChecks Framework Conceptual Architecture is based on the DigiChecks Data Space to enable the collaboration between the platforms od different stakeholders based on interoperable, trusted, and sovereign data sharing.
3. The DigiChecks Framework Conceptual Architecture provides Core Components that play an essential role in the orchestration of compliance checking processes and the management of the DigiChecks Data Space.
4. The DigiChecks Framework Conceptual Architecture can be extended with new components that provide additional functionalities for specific use cases.

Considering these four architecture principles, Figure 4 represents the DigiChecks Framework Conceptual Architecture. It can be divided into three main blocks:

- **Design tools:** They are services that support the definition of the main elements involved in the building permit management.
- **Core Framework:** It consists of unique services that provide core functionalities to manage building permits.
- **Digital Twin:** It is composed of the Core Framework and additional services that provide specific functionalities that in conjunction with the Core Framework enable the performance of modular and scalable compliance checks.

All these main blocks and their components are further described below.

Design Tools

The Design Tools are divided into the Requirements Editor, the Process Modeler, and the Ontology Editor.

The **Requirements Editor** assists the *Requirements Manager* in the definition of the requirements to be involved in compliance check processes. These requirements can be defined manually or extracted from structured documents and defined in a structured format.

The **Process Modeler** enables the *Process Manager* to define the processes in a Business Process Model and Annotation (BPMN) 2.0 standard format, defining who is responsible for the process, what requirements must be checked, and the data required to do so, what tasks and when must be performed and how they must be performed, either manually or automatically against and specific service.

The **Ontology Editor** supports the *Ontology Manager* to design the necessary semantic information model in form of ontology to represent the data to be shared in the DigiChecks Framework.

Core Framework

The Core Framework is divided into the Orchestration, the User Interface, the User Management, the Data Space Management, the Vocabulary Provider, and the Federated Catalogue.

The **Orchestration**, which is a Business Process Model (BPM) Engine, is the core component in charge of managing the full process of turning a BPMN process in an executable version. It orchestrates and manages the state of the tasks required.

The **User Interface** offers to the *Permit Process Administrator* a user interface to manage and monitor the processes and workflows of the defined permitting processes. Also, provide specific forms and screens to enable the *Participant* to provide the necessary information for any step in the permitting process, be able to see at any time the status of the process, to provide manual inputs and get the final resolution approval or rejection.

The **User Management** enables administrators to manage the access of users to the different services that compose the DigiChecks framework.

The **Data Space Management** provides the services required to manage the DigiChecks Data Space. These are the Dynamic Attribute Provisioning Service (DAPS) and the Clearing House. The DAPS ensures trusted data sharing within the DigiChecks framework. The Clearing House provides a service to log data transactions. As they are part of the DigiChecks Data Space, they are further described in the following Section.

The **Vocabulary Provider** manages the semantic information model designed through the Ontology Editor to ensure interoperable data sharing within the DigiChecks Framework. As part of the DigiChecks Data Space, it is further described in the following Section.

The **Federated Catalogue** provisions a catalog of services that have been certified according to European guidelines of digital sovereignty. As part of the DigiChecks Data Space, it is further described in the following Section.

The Digital Twin

The Digital Twin is composed of several services. Among others, the Compliance Checking, the Rule Editor, and the Interfaces with External Tools stand out. They are described below.

The **Compliance Checking** ensure the adherence of digital permitting processes to expert system rule-driven systems. It plays a crucial role in maintaining regulatory compliance and enforcing predefined rules and standards. By allowing operators to introduce and update rules, Compliance Checking empowers organizations to adapt their processes dynamically and stay aligned with evolving regulations.

The system leverages advanced algorithms and automation to evaluate the current state of the permitting process against the established rules. It constantly monitors and verifies whether the process complies with the required criteria, minimizing the risk of non-compliance and associated penalties. This automated approach significantly reduces the burden of manual verification, enabling organizations to streamline their operations efficiently.

The **Rule Editor** enables *Rule Managers* to define, in an easy-to-use graphical interface, the rules to be executed by Compliance Checking services to validate compliance with specific requirements.

The **Interfaces with External Tools** integrate external third-party services, corporate tools, and data sources with the DigiChecks Framework through the DigiChecks Data Space. Within this category are the Data Trusted Gateway and Project Data. While the Data Trusted Gateway is a generic integration component, the Project Data is specific to manage the Common Data Environment (CDE) supporting the integration of Building Information Model (BIM) and Geographic Information System (GIS) data.

It should be mentioned that several external data sources are of interest for automating the management of building permits. Cadastre and Inspire Geoportal external databases are integrated in the DigiChecks Framework to provide Industry Foundation Classes (IFC) models and other relevant geographical information. Also, the Common Data Environment (CDE) is integrated into DigiChecks Framework to provide building data involved in the compliance checking services and to supply advanced visualization of the BIM models through external services and tools such as navigate on the building model pieces or parts, or by enriched 3D visualizations.

DigiChecks Data Space

Based on the GAIA-X Technical Architecture 23.10 and the IDSA Reference Architecture Model 4.0, Figure 5 represents the DigiChecks Data Space. It can be divided into the technical components required for the role of the Core Participant and the role of the Intermediary that is provided in the DigiChecks Framework through the Data Space Management component within the Core Framework. These roles are described below.

Intermediary

Intermediaries act as trusted entities which assume a central role that creates benefit for Core Participants in the DigiChecks Data Space ensuring interoperability, providing trust, and creating new business models.

The technical components assigned to this category are the GAIA-X Digital Clearing House (GXDCH), the Federated Catalogue, the DAPS, the Vocabulary Provider, and the Clearing House.

The **GXDCH** operates and runs the services of the GAIA-X Framework. The GAIA-X Framework sets the rules that define whether organizations and the services they provide comply with European standards and values of digital sovereignty.

The services of the GXDCH are operated by GAIA-X Federators. Therefore, they are not really provided within

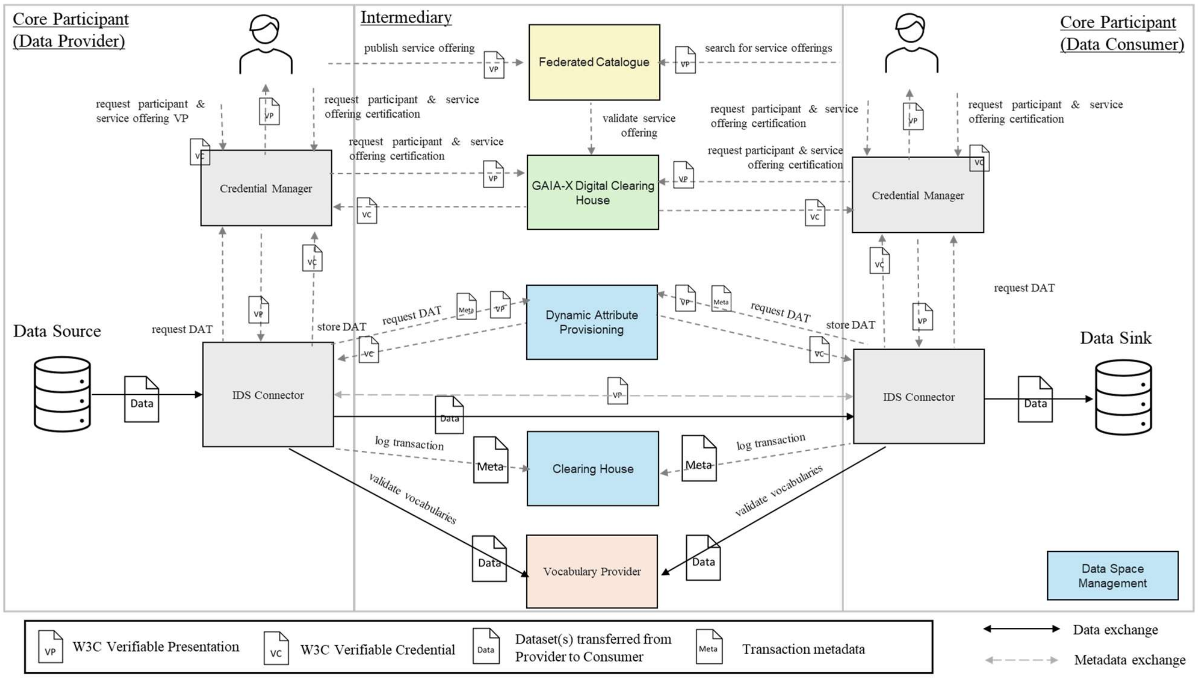

Figure 5: DigiChecks Data Space

the DigiChecks Data Space. These services are accessible to anyone to automatically verify compliance with the GAIA-X Trust Framework and obtain GAIA-X compliance attestations.

It is important to mention that the GXDCH relies on a user-centric and self-sovereign approach for identity management called Self-Sovereign Identity (Maier and Pohlmann, 2022) that is based on W3C recommendations of Decentralized Identifiers (DIDs)[1] and Verifiable Credentials (VC)[2]. Based on the information provided by Core Participants, the GXDCH verify compliance of either the organization or the services they provide with the GAIA-X Trust Framework. If satisfied, the GXDCH issues to the Core Participant a VC containing the GAIA-X compliance attestation. This VC is self-managed by the Core Participant. To enable other services to validate the integrity, the authenticity, and the validity of the issuer of the VC, the VC contains a cryptography proof.

The goal of the **Federated Catalogue** is to enable Core Participants within the DigiChecks Data Space to find best-matching service offerings, which comply with European standards and values of digital sovereignty.

To publish service offerings, the Federated Catalogue requests and validates VCs attesting compliance of the organization providing the service and the service itself with the GXDCH. To search for service offerings, it controls the access to the services available in the Federated Catalogue to organizations which comply with the GXDCH.

The **DAPS** sets the rules that define how an IDS Connector, the technical component of a Core Participant responsible for data sharing, manages data control. In other words, it states the level of trust of an IDS Connector. The IDS Connector is further described later.

As the trust level is higher, the requirements are higher, from a basic trust level where only interoperability is guaranteed, to higher levels that implement secure communication protocols, usage control etc.

As the level of trust can change in an operational environment over the time, once an IDS Connector is initially manually certified and deployed, the DAPS sets the operational trust level considering the one initially certified and operational environment data.

The DAPS, as the GXDCH, relies on DIDs and VCs. Therefore, it issues VCs that attest the trust level of an IDS Connector. This VC is self-managed by the Core Participant. It is used by the IDS Connector to access to other IDS Connectors.

The **Vocabulary Provider**, as part of the Data Space Management, hosts, maintains, and publishes the semantic information model that is designed using the Ontology Editor, describing the relevant concepts (e.g., “building”, “office space”, “toilet space” and “size”) shared by IDS Connectors in the DigiChecks Data Space to manage building permits in the construction domain. Furthermore, it implements Shapes Constraint Language

[1] Decentralized Identifiers (DIDs) v1.0 (w3.org)

[2] Verifiable Credentials Data Model v2.0 (w3.org)

(SHACL)[3] validations that are required by the IDS Connector to verify whether the expected data is received.

It is important to mention that the Vocabulary provider only includes the model. It does not include its instantiation (specific data) and therefore doesn't provide information about specific instances. The instances should be managed and provided by Core Participants through the IDS Connectors.

The **Clearing House**, as part of the Data Space Management, records all the relevant information related to data sharing between the IDS Connectors of Core Participants. This includes contract agreements and data usage information for clearing, settlement and billing services.

Core Participant

A Core Participant can be assumed by any organization that provides or consumes data within the DigiChecks Data Space. Roles assigned to this category are the Data Provider and the Data Consumer.

To share data between the Data Provider and the Data Consumer, both uses a software component that is compliant with the IDSA RAM. This is the IDS Connector. To manage the VCs issued by the GXDCH and the DAPS, the Data Provider and the Data Consumer use a software component called Credential Manager.

The **IDS Connector** is the technical component responsible for interoperable, trusted, and sovereign data sharing between Core Participants within the DigiChecks Data Space.

To enable a modular and scalable development of the services, the DigiChecks framework is based on a microservices approach (De Lauretis, 2021). For a system that provides a specific service, while the user interface layer enables participants to manage the service itself, the IDS Connector provides those layers to share data within the DigiChecks Framework in an interoperable, trusted, and sovereign way. Figure 6 represents these system layers.

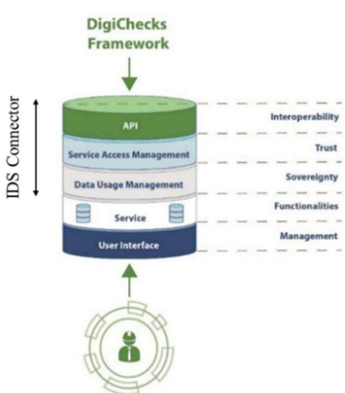

Figure 6: DigiChecks Framework Microservices System Layers

The Application Programming Interface (API), the Service Access Management and Data Usage Management layers are described below.

The API ensures interoperable data sharing. To this end, it implements the Dataspace protocol v1.0 (International Data Spaces Association, 2024) and several Data transfer protocols.

The Dataspace protocol is a set of specifications that define the interfaces, protocols, and schemas to expose a data catalog, to negotiate contracts and access negotiated data. To describe the data catalog, the Dataspace protocol proposes the Data Catalog Vocabulary (DCAT)[4]. It is a vocabulary designed to facilitate interoperability between data catalogs. It should be noted that DCAT is domain-agnostic. To provide a domain-specific description of the data, DCAT is extended with domain-specific vocabularies, which are provided by the Vocabulary Provider. Once negotiated data is accessed, data sharing is delegated to data transfer protocols.

Data transfer protocols are traditional protocols, such as HTTP or MQTT, that will be used for data transfer after data access. They are also integrated with the Vocabulary Provider. As the Vocabulary Provider implements SHACL validations, it can be ensured that the expected data is received.

The Service Access Management ensures trusted data sharing. It controls the access to the IDS Connector based on the VC that attests the level of trust of a requesting IDS Connector. For authentication purposes, it validates the integrity, the authenticity, and the validity of the issuer of the VC. For authorization purposes, it analyses the attributes of the VC.

The Data Usage Management ensures sovereign data sharing. Data sovereignty is referred as the self-determination of organizations regarding the usage of their data (Jarke et al., 2019). To grant data sovereignty, the IDS Connector implements Distributed Usage Control (Gil et al., 2023). It is a particularization of Usage Control for data sharing scenarios that extends Access Control to control what must happen to data through its life cycle (Jung and Dorr., 2022).

The **Credential Manager** abstracts Core Participants from the complexity of managing VCs.

On the one hand, it provides Core Participants with the interfaces to request the certification of the organization itself and the services it provides to the GXDCH, store the VC attesting the result and retrieve them.

On the other hand, it provides the IDS Connector with the interfaces to store retrieved VC from the DAPS and retrieve them for authentication purposes.

Conclusions

This paper addresses the main challenges regarding the automated management of building permits. These are the lack of standards between regulations in different

[3] Shapes Constraint Language (SHACL) (w3.org)

[4] Data Catalog Vocabulary (DCAT) - Version 3 (w3.org)

countries and regions and municipalities, interoperability between data in different formats and the control of the data.

Considering the DigiPLACE RAF, which sets the common guidelines for building digital platforms for the construction sector, and with the aim of addressing the challenges identified, this paper presents the DigiChecks Framework, a novel approach to digitalize and automate building permit management that combines an orchestration of compliance checks and a data space. While the orchestration provides a modular and scalable approach to verify different compliance checks depending on existing regulations, the data space facilitates the collaboration between stakeholders through interoperable, trusted, and sovereign data sharing between their different platforms. Thus, the DigiChecks Framework reduces data sharing and compliance checking efforts, while it ensures strict compliance with existing regulations.

Future Work

The conceptual architecture of the DigiChecks Data Space, which is the main development within the DigiChecks Framework and the focus of this paper, is based on existing standards defined by GAIA-X and IDSA. In this regard, the defined technical components are built from open-source tools that have already been developed following these standards or from new tools developed from scratch. The application of these tools to real-world scenarios presents two major challenges. First, as data spaces is a novel concept, these standards are continuously evolving. As the piloting stage approaches in the DigiChecks project, there is a need to make decisions on the versions of the standards to be used for two main purposes. For those tools already developed, to select the version to be used. For those new tools required, to select the version to be followed in the development. Second, different pilots lead to different requirements. Although existing tools are developed to be 100% agnostic to the use case requirements, the truth is that they should be adapted in about a 10% to the use case. This may lead to weaknesses in our approach that should be addressed by providing extensions to existing tools. For example, in the case of the IDS Connector, specific data transfer protocols may be required for the different pilots. If they are not implemented on existing tools, they must be implemented on top of an existing tool.

Having said that, at the end of the piloting phase, with the tools already selected and adapted, the DigiChecks Data Space technical architecture is expected to be published considering the version of the standards followed, the tools selected, the specific challenges addressed for their application in real-world scenarios and how they have been addressed.

Abstract

This study addresses neighborhood-level sustainability in urban development as a critical lever in Germany's energy transition goals. It explores identifying reference districts through Geographic Information System (GIS)-based machine learning (k-means algorithm) and public data, utilizing clustering methods to analyze spatial and socio-infrastructural metrics. The methodology yields significant insights into district definition and characterization, integrating technical and human understanding of urban dynamics. The findings highlight the importance of attribute selection in neighborhood classification and extend beyond mathematical validation to include social context comprehension. The developed technique is applied to a case study involving the city of Aachen.

Introduction

In the energy transition, particularly within the building sector, renewable energy systems are crucial for a climate-neutral energy supply, with heating and hot water consumption constituting a significant portion of Germany's building energy use (BMWK-Bundesministerium für Wirtschaft und Klimaschutz, 2022). The traditional, fossil-based energy infrastructure often limits the implementation of innovative, demand-driven thermal solutions (Acksel et al., 2017). District solutions are pivotal in optimizing energy potential and achieving economies of scale through sector coupling (Reicher et al., 2020). This approach integrates energy-saving strategies, efficiency, and renewable use, considering building characteristics, user behavior, and technical infrastructures (Többermann and Yu, 2021).

However, municipalities' current practices in urban-scale energy system planning are fragmented, often leading to slow and inefficient implementation (Boenigk et al., 2019). To address this, the paper advocates for establishing 'reference districts' as a means to streamline and standardize energy solutions, facilitating their application within and across various municipalities. Therefore, the paper discusses the challenges in defining district boundaries, especially in existing, evolving neighborhoods, and proposes using GIS and machine learning techniques on public datasets to identify and classify districts based on diverse attributes. This approach aims to enhance the scalability and effectiveness of energy solutions within existing infrastructures.

The concept of a neighborhood or district, lacking a universal definition, is interpreted variably across urban planning, cultural, and social perspectives (Feldmann, 2009). In urban planning, districts are defined by physical attributes such as building density, types, ages, and locations, including aspects like energy-efficient urban aggregation (Reicher, 2013; Reicher et al., 2020). Socially, they are important spaces for daily life, social interaction, and identity formation, embodying a range of physical to historical dimensions, thus influencing individual and communal life (Schnur, 2008). Neighborhood sizes vary, ranging from large housing estates to small settlements, with manageability and social identification as key criteria, typically not exceeding 20,000 residents (Bundesinstitut für Bau-, Stadt- und Raumforschung, 2012; Mehnert and Kremer-Preiß, 2014). Neighborhood attributes encompass a diverse spectrum including functional, spatial, socio-demographic, technical, economic, cultural-historical, and legal aspects, with differentiating factors such as natural boundaries, architectural typology, social structure, and community spaces (Malottki et al., 2013).

In case of newly planned districts, specific demarcation and energy zoning are simple, as they are planned in advance and meet current energy standards. In the case of existing districts, however, the question of boundaries arises because they are continuously developed, changed, and have grown over time. The question is, how can boundaries be defined in order to utilize energy potential in the context of the district?

For the practical application of district energy solutions, it is vital to recognize the diversity among district types. This paper puts forth a strategy for establishing neighborhood boundaries by employing georeferenced information combined with machine learning techniques on accessible datasets. Such techniques enable the amplification of energy solutions in pre-existing infrastructure, by creating reference districts defined by specific attributes. These can range from singular features like the type of buildings to an amalgamation of several traits. Consequently, this aids in the convenient replication of district energy solutions in comparable neighborhoods, resulting in a wide spectrum of reference districts, each marked by its distinct set of characteristics.

Related Research

This literature review explores statistical approaches, machine learning, and GIS in urban planning, emphasizing their role in energy evaluation and spatial analysis. It covers various approaches to mapping urban energy properties, classifying urban areas, and developing tools for sustainable urban development, highlighting the advancements and applications of these technologies in urban morphology analysis.

In the field of urban energy evaluation, several key projects and methodologies have emerged. The UrbanReNet project by Dettmar et al. (2020) systematically mapped the energetic properties of urban areas, analyzing prototypical elements of urban architecture and spaces for energy and structural values. This approach, combining urban morphology and land use, allows for a representation of Germany's building stock. It integrates qualitative and quantitative methods for evaluating energy generation, storage, and networking, leading to the development of mathematical models and software tools for neighborhood-level energy supply concepts.

GIS-based analyses have been pivotal in understanding energy dynamics in urban areas. März (2016) employed GIS-based multi-criteria decision analysis to locate neighborhoods at risk of energy poverty, focusing on space heating. Alpagut et al. (2021) and Quénéhervé et al. (2018) used GIS to optimize land use for solar production and its local energy impact.

In identifying and classifying settlement areas, Jochem et al. (2018) utilized geo-based vector data and machine learning to classify residential settlements in Afghanistan, while Gonzalez et al. (2020) applied deep learning to identify urban building typologies. Arribas-Bel et al. (2021) and Perez et al. (2020) explored urban cluster analyses using modified DBSCAN and Bayesian Networks, respectively, to analyze building types and urban functions.

Regarding city planning and administration, considering neighborhood dynamics, Photis (2012) developed the SPiRAL algorithm for redistricting electoral districts. López-Moreno et al. (2022) introduced a GIS-based approach for classifying residential areas in Madrid, aiding in energy-efficient urban renewal strategies. Similarly, Kelm et al. (2019) applied a semi-automatic approach using official geobase data in North Rhine-Westphalia (NRW) to create block structures for city planning and administration, demonstrating the growing importance of technology and data in urban planning and energy management.

Our methodology's choice of attributes for analysis was guided by this literature review on urban neighborhood characteristics, which highlighted key socio-infrastructural and energy-related factors to include in our study.

Methodology

Data Sources

In the process of identifying various reference districts in Aachen, NRW, a robust data foundation is essential. To conduct a comprehensive analysis, various public data sources were utilized in this study, with the main focus on the city of Aachen, located in western Germany. An overview of the freely available data sources used can be found in Table 1.

A central dataset titled ALKIS Real Estate Cadastre provides detailed information about plots and buildings in NRW. According to the Surveying and Cadastre Law of the state of NRW (VermKatG NRW), it offers extensive information about the structure and identification of plots and buildings. The cadastre, in which these data are recorded, offers a wealth of information, including geometric and geographical data, usage, size, and development of each plot.

Additional datasets were sourced from the OpenGeodata.NRW portal, which includes, among others, information on general and psychiatric hospitals, was last updated in June 2023. Complementarily, locations of childcare centers (KiTas) and schools were also incorporated into the analysis, as they represent crucial social spaces within a neighborhood.

Energy-related data, such as the location of renewable energy sources or potential areas for renewable energy installations, is sourced from the Energieatlas NRW. It is collected and provided by the State Agency for Nature, Environment, and Consumer Protection of NRW.

The Approach

In this section of our study, we describe the methodology adopted for analyzing reference districts through a bi-fold approach focusing on socio-infrastructural factors and energy sources. The objective was to leverage the clustering of various public datasets to gain insights into neighborhood structures.

Multiple variables are considered to provide a comprehensive view of the various characteristics and dynamics within a neighborhood. This is achieved by first creating a so-called feature matrix. A feature matrix is a table where each row corresponds to an object (in this case, a building), and each column represents a feature or characteristic of that object (e.g., the distance to churches). In this context, the features represent urban planning factors. Each entry in this matrix denotes the value of the corresponding building feature. Once the feature matrix is established, a clustering algorithm can be applied. The first clustering process aims to identify districts that show similarities in terms of the features captured in the matrix. After the initial clustering, in which districts are identified, the dataset is enriched with additional information regarding the building type and specific and absolute heating demands from the Wärmekaster NRW dataset. Each district is characterized by the total amount of contained buildings, the distribution of building types, and the district's aggregated heating demand. Districts with similar feature values are grouped into the same cluster, resulting in a reference district, while those with significantly different values are classified into different clusters. This approach enables a multidimensional examination of the neighborhoods, allowing us to uncover hidden relationships and patterns between neighborhoods that might be overlooked in isolated analyses. Two different feature sets are considered and are described in the following sections.

Table 1: Overview of the utilized freely available data sources

Dataset	Description	Source
ALKIS Real Estate Cadastre	Buildings, Plots	Bezirksregierung Köln (2024)
Geoportal.NRW	Locations of Hospitals and Schools	Lanuv NRW (2024b)
Wärmekataster	Building Category, Building Type, Heat Demand	Lanuv NRW (2024c)
Open Street Map	Streets, Religious Institutions, Parks, Supermarkets, Car-sharing, Restaurants	OpenStreetMap Contributors (2024)
Solarkataster	Locations of Rooftop and Open-space PV	Lanuv NRW (2024a)
Energieatlas NRW	Biomass, Wind power plants, Hydropower plants, Lignite, Natural gas, Sewage gas, Mineral oil, Hard coal, Mine gas, Landfill gas	Bezirksregierung Köln (2024)

Socio-Infrastructural Approach

Various socio-infrastructural data were analyzed to examine a neighborhood's social structure. These will be described in the following.

In this study, building density is understood as the distance between individual buildings, which can provide insights into population density and the intensity of residential developments in a neighborhood. Typically, buildings in urban areas are constructed in close proximity to each other, whereas in rural areas, the distance between buildings tends to be greater and more variable. For instance, town or terraced houses often exhibit uniform distances from one another.

Considering the distance of buildings to religious institutions might reveal social and urban structural patterns. This concept dates back to ancient and medieval times, when churches, temples, and even city halls evolved as focal points of urban planning (Kaupp (2022)).

Furthermore, green spaces enhance the quality of life for adjacent residents, offering areas for both social interaction and individual recreation. It is anticipated that the proximity to parks influences the likelihood of residents utilizing these areas for leisure activities, potentially shaping local social and cultural boundaries.

In the state of NRW, according to the statewide hospital plan, accessibility to hospitals within a 20-minute drive should be guaranteed for 90% of its citizens (Ministerium für Arbeit Gesundheit und Soziales des Landes Nordrhein-Westfalen, 2023). In this context, the question arises whether the location of buildings and, thus, their proximity to hospitals plays a role in defining neighborhoods. Consequently, distance was selected as a relevant attribute for investigating this relationship. Additionally, the locations of schools and childcare centers might play a role in the social delineation of neighborhoods. Children often attend the school or childcare center closest to their residence. Areas with such facilities are typically characterized by family-friendly infrastructure, including playgrounds and similar amenities. Hence, the distance to playgrounds is also considered a parameter for investigation.

Moreover, local businesses could influence the character of neighborhoods. The distance to restaurants, for instance, might indicate the liveliness of an area. Accordingly, distances to restaurants and supermarkets were included in the study.

The spatial proximity to office buildings can indicate places of work and potentially offer new urban planning insights. Office buildings, often part of non-residential structures, tend to concentrate in specific areas along with other non-residential structures.

Furthermore, the structure of districts is often shaped by the traffic route network. Examining this factor could reveal how street layouts influence the formation of neighborhoods. In urban areas, car-sharing services are increasingly spreading. Analyzing the locations of such car-sharing facilities could provide indications of neighborhood boundaries.

In calculating distance as a feature, the shortest distance to the destination, for example, the nearest school, was determined. For streets with a speed limit of 50 km/h, the shortest orthogonal distance from a building to the street was chosen as the feature.

Table 2: Clustering attributes for Socio-infrastructural approach

Building density	Car-sharing	Religious institutions
Office buildings	Residential buildings	Childcare centers
Playgrounds	Restaurants	Supermarkets
Schools	Parks	Hospitals
Roads (max. 50 km/h)		

The complete set of attributes relevant to the Socio-Infrastructure Model is detailed in Table 2.

Energy Approach

In addressing the energy aspect of our study, we focus on the significant shift from fossil fuels to renewable energy sources, a strategic move by the Federal Government to counteract climate change. This transition is particularly pertinent in NRW, Germany's most populous state, which boasts a wide array of energy sources. These range from traditional fuels like lignite and mined gas to innovative renewable technologies, including biomass and photovoltaic (PV) energy generation. The pivot towards renewable sources signifies the phasing out of fossil fuels, underscoring the need to ensure continuous access to energy sources for the future. This is vital for maintaining an efficient energy supply chain. The crux of our energy approach is the development of an urban model designed to map out the distribution of various neighborhoods based on energy sources within urban settings. A key aspect of this model involves analyzing the proximity of buildings to diverse energy carriers, thereby identifying potential areas for the integration of renewable energy solutions based on the density of energy sources. By mapping the city's proximity to these energy sources, our model not only highlights Aachen's current energy infrastructure but also provides a blueprint for enhancing renewable energy uptake. This approach aligns with national efforts to transition towards a more sustainable and environmentally friendly energy mix, reflecting a commitment to reducing carbon emissions and combating climate change. The following attributes were considered for the clustering:

- Roof-surfaces PV
- Open-space PV
- Wind power plants
- Hydroelectric power plants
- Sewage gas
- Biomass availability

Integrating these two approaches enables us to construct a multidimensional description of urban neighborhoods, highlighting both challenges and opportunities in socio-infrastructural development, energy efficiency, and renewable energy utilization. Subsequently, districts from both approaches are enriched with data on building types and heating demand, resulting in a comprehensive dataset encompassing all identified districts and their attributes. An extra clustering step is then conducted to define reference districts, enabling the assignment of district types from the social infrastructure and energy perspectives.

After careful consideration of various algorithms, the k-means clustering method was chosen based on its efficiency in processing large datasets and its simplicity in implementation. Furthermore, the main hyperparameter k, the number of clusters, is highly interpretable, allowing expert knowledge to inform the algorithm tuning process. While DBSCAN was considered for its density-based clustering capabilities, it is earmarked for future work; however, it was discarded for the first proof of concept due to its complex parameter tuning.

Further, to evaluate the effectiveness of the k-means algorithm in producing meaningful clusters, we employ the Silhouette method. The Silhouette method is a popular evaluation technique, offering a quantifiable measure of cluster cohesion and separation, providing a robust justification for the selected number of clusters compared to other methods like the Elbow Method. It provides a succinct graphical representation of how well each object has been classified. The Silhouette score ranges from -1 to +1, where a high value indicates that the object is well-matched to its own cluster and poorly matched to neighboring clusters. This method is particularly useful in determining the optimal number of clusters and in assessing the quality of the clusters formed by the algorithm. A hyperparameter study was conducted using the Silhouette method for k-values ranging from 6 to 70. The minimum number of clusters was determined based on the number of the seven main administrative districts in the city of Aachen. The choice of the upper limit of 70 was also informed by the results of the Social Development Plan of the city of Aachen (Stadt Aachen, 2020).

Through this methodological approach, we aim to achieve a robust clustering of the given data to find definable reference districts, providing valuable insights into the underlying patterns and relationships within the dataset.

The study used the High-Performance Computing Cluster (HPC) at RWTH Aachen University for intensive computations. Due to QGIS's limitations in processing large datasets and tuning hyperparameters, it was replaced by Python for analysis, while QGIS was used only for visualization. The research employed Python libraries like scikit-learn for machine learning, GeoPandas and Pandas for data management and feature selection, and Fiona for loading geo-referenced data.

Results

Socio-infrastructural Approach

The methodology focussing on the socio-infrastructural attributes enabled us to delineate 54 unique districts, each representing a specific typology. The resulting cluster map can be seen in Figure 1. It can be observed that the larger clusters tend to be near and around the city center, which can be explained by the higher density of social infrastructure in the historical urban core.

Our analysis revealed significant differentiation among the clusters, particularly in terms of their spatial distribution and proximity to key urban infrastructures. For instance, significant variations were observed when examining the distribution of average distances of all clusters to residential buildings. Some clusters were characterized by notably shorter distances to residential areas, suggesting a predominance of residential use within those districts. This observation hints at the potential functional specialization of neighborhoods, where some are more residentially-focused while others may serve different urban functions.

Further examination of the average distance to religious in-

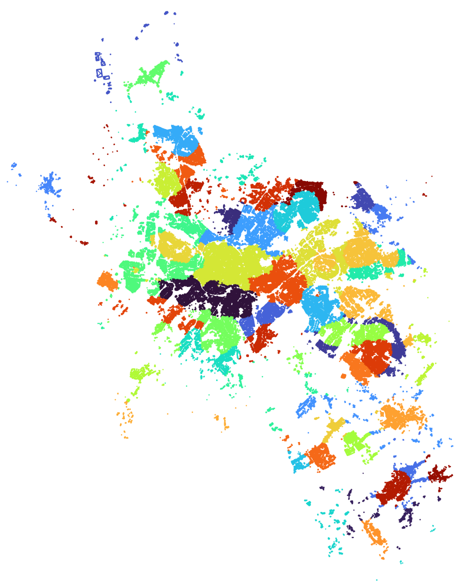

Figure 1: Clustering result of the Socio-Infrastructural-Model: 54 districts were identified

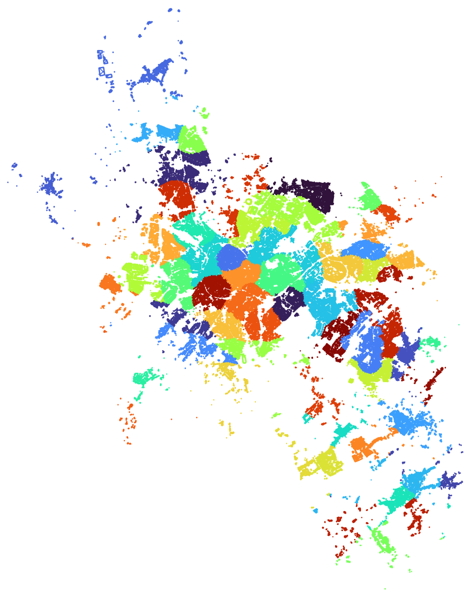

Figure 2: Clustering result of the Energy-Model: 58 districts were identified

stitutions across clusters also highlighted distinct patterns. Certain clusters demonstrated closer proximity to these institutions, reflecting their potential role in the social and cultural fabric of those neighborhoods. This differentiation in proximity to key urban elements underscores the diverse character of urban districts and their unique contributions to the city's overall structure.

Additionally, the analysis of the distribution of average distances for various attributes revealed nuanced differences between clusters. While some attributes showed a relatively linear distribution across clusters (e.g., distance to healthcare facilities), others exhibited significant variability (e.g., distances to childcare centers).

The observed variation indicates that specific urban characteristics might play a more significant role in distinguishing neighborhood types. There's a notable disparity in the number of buildings per cluster; for instance, clusters in the city center encompass over 6000 buildings, whereas those on the city's outskirts may have as few as 65 buildings. Additionally, there's a trend where the proportion of non-residential buildings in a cluster tends to rise with its distance from the city center. Meanwhile, the heating demand seems to be proportional to the cluster size.

Energy Approach

While looking at the different locations of energy resources in the city of Aachen, a total of 58 different clusters were found, with a Silhouette value of 0.38. Figure 2 shows the different clusters based on the location of various energy sources.

The clusters, each representing a unique combination of energy source proximity, were visually represented to provide insights into the spatial distribution of energy infrastructure across the urban fabric. This visualization underscores the variance in access to different energy sources across neighborhoods, such as biomass producers and PV installations. This examination revealed notable differences in how closely neighborhoods are situated to renewable energy sources, highlighting areas with potential for further development of sustainable energy solutions.

In particular, the study found varying degrees of proximity to biomass energy producers and rooftop PV systems across the clusters. Some clusters demonstrated close proximity to biomass sources, suggesting an emphasis on bioenergy utilization, while others were characterized by greater distances, indicating potential areas for increased biomass energy integration. Similarly, the examination of distances to PV installations provided a snapshot of the penetration of solar energy within urban areas, identifying clusters that could benefit from enhanced solar energy deployment.

In contrast to the first method, the range of building distribution per identified cluster is significantly narrower, with the highest count being 2334 buildings and the lowest at 70. Additionally, the total heating demand correlates less with the number of buildings and more with the types of buildings present. The distribution of building types per cluster also exhibits a less steep gradient compared to that observed in the first approach.

This clustering analysis sheds light on the intricate relationship between urban form and energy infrastructure, offering a foundation for targeted urban planning and energy policy development. By pinpointing districts with specific energy characteristics, policymakers and planners can tailor strategies to optimize energy efficiency and expand renewable energy use within urban ecosystems. This approach not only contributes to the sustainability of urban areas but also supports broader goals of energy transition and climate change mitigation.

Reference Districts

Integrating districts from socio-infrastructure and energy methods into a unified clustering process resulted in the identification of six unique reference district types. These types were defined by key characteristics: the total number of buildings in each cluster, the variety of building types, and the total aggregated heating demand. This comprehensive overlay of districts from both methods facilitated their categorization into one of the six reference types, as depicted in Figure 3. The clustering effectiveness, measured by the Silhouette score, was 0.433 for k=6.

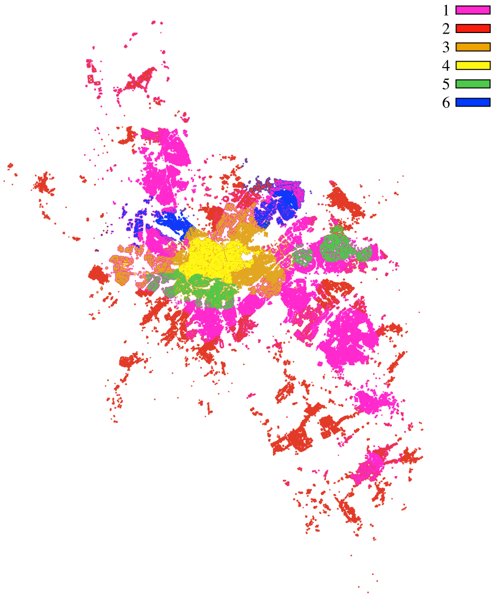

Figure 3: Results of the Reference Districts Clustering: Overlay of Socio-Infrastructural and Energy Model Districts

On the map, it is clearly visible that the reference district types form an orbicular pattern around the city center. Table 3 summarizes the mean distributions of each building type and specific heating demand for the six reference district types.

Cluster number four represents Aachen's urban center and is the city's most densely populated region, which is evident from the high number of buildings in this reference district. Characterized predominantly by large multi-family housing (BMFH), this cluster has the highest specific heating demand among all clusters, significantly exceeding others. In contrast, cluster two, encompassing the city's outskirts, has the lowest heating demand. Clusters one and six share striking similarities, not only in residential building distribution but also in heating demand and location, as depicted in Figure 3. However, there are significant differences in their absolute heating demands. The total demand of cluster six is nearly 1.5 times higher than that of cluster one.

A detailed examination of Table 3 highlights the primary emphasis of the clustering process. It shows that each identified reference district type is predominantly characterized by a single building type.

Discussion

The clustering approach uses a feature matrix aimed at a holistic approach, considering multiple attributes simultaneously. In this study, while defining two base models for identifying typological neighborhoods using public datasets, it was crucial to select relevant attributes, as irrelevant ones could distort outcomes. Selecting specific attributes for clustering still remained a subjective challenge. The approach incorporated biases related to socio-infrastructural aspects to provide insights into patterns that may be prevalent across other communities within NRW and thereby acknowledging the influence of preconceived constructs of the attributes. The results demonstrated that not all attributes cluster effectively, with some showing little variance across neighborhoods, highlighting the need for careful attribute selection in urban area analysis due to the dynamic nature of urban development and infrastructure changes. Additionally, increasing dimensions complicated clustering without compromising quality, often resulting in indistinct clusters.

The chosen k-means algorithm necessitates predefining the number of clusters (k), with determining the ideal number being a significant challenge. Computation efficiency requires setting a specific range for k, as demonstrated in the Aachen case study. However, estimating this range becomes increasingly complex for larger or more diverse geographical areas, such as the whole state of NRW, which encompasses multiple cities and rural areas, the latter being outside the scope of this study. The utilization of the

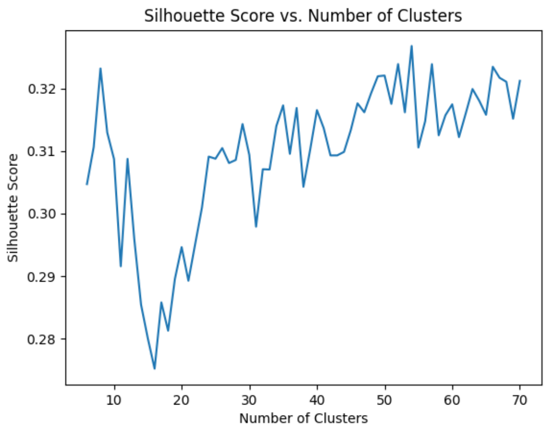

Figure 4: Silhouette score for k-means clustering of Socio-Infrastructural-Model for different k

Silhouette score to identify the optimal 'k' for k-means clustering was a critical component of our analysis. This evaluation method, grounded in mathematical principles, provides a quantifiable measure of cluster coherence and separation. However, it is essential to note the distinction between the mathematical assessment of cluster quality and the perceived social characteristics of neighborhoods. While the mathematical evaluation offers a systematic ap-

Table 3: Mean distribution of cluster attributes: Single-Family-Dwelling (SFD), Big-Multi-Family-House(BMFH), Terraced House (TH), Multi-Family-House (MFH), Non-Residental Buildings (Non.-Res), specific heating demand (demand)

proach to determining cluster quality, it may not capture all aspects relevant to interpreting these clusters effectively. Moreover, it was observed that the graph displayed comparably high Silhouette scores with significantly fewer clusters (Figure 4). This phenomenon suggests that a more compact cluster formation can provide a similarly coherent and well-separated structure as configurations with a larger number of clusters. This finding is particularly illuminating, as it implies that optimal clustering does not necessarily equate to maximizing the number of clusters but rather to identifying a configuration that balances cluster coherence with the complexity of the model. This discrepancy underscores the importance of not solely relying on quantitative metrics for interpreting cluster results. An understanding of the urban structure, historical developments, and other pertinent factors should also be incorporated. Such a holistic approach ensures that the interpretation's significance is not merely confined to numerical values but is enriched by a comprehensive context of neighborhood structures.

Conclusion and Future Work

This study yielded significant insights into the feasibility of neighborhood classification studies while highlighting opportunities for future research. It showcased an innovative approach to urban planning and energy management by integrating socio-infrastructural and energy data to identify reference districts within Aachen, NRW. The cluster analysis conducted for Aachen revealed specific structural and characteristic patterns within its neighborhoods. By employing clustering techniques on public datasets, the research illuminated the complex interplay between urban form, energy infrastructure, and social dynamics, contributing valuable insights into sustainable urban development and the energy transition. The methodology demonstrated the potential of using machine learning and GIS technologies to dissect and understand the multifaceted characteristics of urban areas. However, the study also highlighted several challenges, including the subjectivity in selecting clustering attributes, the difficulty in managing and integrating large and diverse datasets, and the computational demands of processing extensive urban data. Applying the same analysis to the entire state of NRW would likely yield different results due to its diverse composition of cities, rural areas, and villages, each with unique structures and attributes, requiring spatial understanding and various validation methods. Investigating various validation methods could also comprehensively assess cluster result quality. A systematic examination of the weighting of individual characteristics may enable a more nuanced, context-specific classification, acknowledging the varying impacts of different features on neighborhood formation. These challenges underscore the need for further refinement of the methodology and the exploration of more advanced machine learning techniques to enhance the precision and applicability of the findings. Additionally, integrating socio-economic or environmental indicators could better represent neighborhood characteristics and contribute to developing more comprehensive models. Including the performance and impacts of energy producers on the power and heating networks and building energy inputs in the study of energy neighborhoods could offer a more holistic view.

METADATA EXTRACTION OF RFIs USING NATURAL LANGUAGE PROCESSING AND MACHINE LEARNING ALGORITHMS

Ceyhun Ozogul[1], Esin Ergen[1]
[1]Istanbul Technical University, Istanbul, TURKEY

Abstract

Accurately assigning metadata of RFIs plays an important role in the analysis and management of RFI documents. However, these metadata are manually entered in the RFI management system, which results in loss of time and incorrect entries. This study aims to demonstrate that metadata of RFI documents can be extracted and assigned automatically using natural language processing and machine learning algorithms. To achieve this aim, the performance of Naïve Bayes and K-Nearest Neighbor algorithms are evaluated and compared. The results show that machine learning models perform well in automatically extracting the metadata of RFIs and, the performance of machine learning models for each label varies. The findings of this study can be used to develop an artificial intelligence based RFI management system by integrating natural language processing and machine learning models into the system.

Introduction

In construction projects, documents such as drawings and specifications may not address all aspects of the structures to be built or may contain deficiencies, uncertainties, and overlaps. These issues need to be clarified through Request For Information (RFI) documents (Shim et al., 2016). Hanna et al., (2012) defines RFI as " *a formal written procedure initiated by the contractor seeking additional information or clarification for issues related to design, construction , and other documents*". RFIs are a communication tool between the design team and the construction team (Bhat, 2017). Even though it holds significance, RFI, as a communication channel, is frequently perceived negatively within the project (Aibinu et al., 2019). This is due to the effort involved in initiating an RFI, as well as the process of reviewing and generating responses (Afzal et al., 2023). The response time for RFI can become critical and have a negative impact on progress in the field (Kelly and Llozor, 2020). Moreover, a delay in responding to the RFI, or the absence of a response altogether, can lead to a sense of frustration and mistrust among project team members (Philips-Ryder et al., 2012; Afzal et al., 2023).

Utilizing common data environments, such as Aconex and Procure, assists in overcoming the challenges associated with Request for Information (RFI) management. These platforms facilitate online communication and provide a means to track information effectively (Das, Tao and Cheng 2020; Afzal et al., 2023). However, metadata, which is a classification output, is typically entered manually into common data environments and the users are reluctant to fill out the related metadata, since this process requires additional time and effort. This results in inaccurate or incomplete metadata, which is problematic because metadata holds significant importance when analysing the unstructured RFI text data to obtain valuable insights and lessons learned to manage future projects in a more effective way. The erroneous metadata entry directly impacts the data quality, consequently influencing the outcomes of analysis studies.

This paper proposes to use Natural Language Processing (NLP) and machine learning models to automatically extract discipline code, which is one of the RFI metadata. To achieve this, NLP processes were applied to the RFI documents and Naïve Bayes (NB), K-Nearest Neighbor (KNN) algorithms were used to classify the RFI documents according to their disciplines. This approach enables extraction of the metadata of RFIs in an automated way. It reduces the time required for filling out the metadata of RFIs and results in effective management and analysis of RFIs by reducing erroneous or incomplete metadata.

Literature Review

Automatic extraction of metadata from documents is associated with the automatic classification of documents. Documents can be classified according to their metadata by using NLP and machine learning models. In the early 2000s, studies were conducted on the automatic extraction of metadata from texts in different domains, such as marketing, information-document management, educational sciences (Paik et al., 2001; Han et al., 2003; Yılmazel and Finneran, 2004). In these studies, rule-based methods were combined with NLP. Later, with the increase in the processing power of computers, machine learning models have been integrated with NLP instead of rule-based approach to automatically extract metadata.

Valdez et al. (2016) developed a natural language processing-based ontology for extracting metadata from texts in the biomedical domain. In addition, a natural language processing-based ProvCaRe-NLP tool was developed to perform clinical text analysis and information extraction. Some other studies used NLP and ML on metadata stored in a computerized maintenance management system (CMMS). Zhang et al. (2020) employed the information contained in failure notifications to forecast failure codes and assess the precision of the labels. Texts are converted into word counts after NLP preprocessing. The SMOTE (Synthetic Minority Oversampling Technique) algorithm is utilized to balance the classes. In the final stage, one of the eight supervised machine learning models that are used in the classification problem, such as Support Vector Machine (SVM), NB, or Logistic Regression (LR), was applied.

Arif-Uz-Zaman et al. (2017) sought to enrich the metadata in a Computerized Maintenance Management System (CMMS) by classifying downtime notifications as either resulting from a failure or indicating no failure. In this study, the vectors obtained after applying NLP operations to the text data are used as input for SVM and NB algorithms. The SVM algorithm is noted to achieve the highest performance.

Tanguy et al. (2020) applied the SVM algorithm to categorize fault notifications in their study. The study demonstrated that incorporating all 3-character substrings along with word stems resulted in a slight enhancement compared to using only words. This improvement is likely attributed to the inclusion of abbreviations, compound terms, and alternative writing forms.

Deloose et al. (2023) have made a recent contribution to the study of CMMS metadata, in which natural language processing techniques and artificial models are utilized to forecast and rectify CMMS metadata. The performance of shallow machine learning models and deep machine learning models using multiple labels were compared. Random forest algorithm (RF), which is a shallow machine learning model, and Recurrent Neural Networks (RNN), which are deep learning methods, gave better results than other algorithms. It was also identified that the RNN algorithm performed slightly better than the RF algorithm.

In the field of construction management, studies on automatic classification of documents focuses on the accident analysis/occupational safety management, contract management, building information modeling (BIM), and facility management. In the studies related to the accident analysis and occupational safety management, accident reports were analyzed and the performances of machine learning models in the automatic classification of accident reports were compared. Tixier et al. (2016) used Stochastic Gradient Tree Boosting (SGTB) and Random Forest (RF) algorithms. The SGTB algorithm performed better than the RF algorithm. In Goh and Ubeynarayana (2017), the performances of six different machine learning models were compared, and the SVM algorithm showed the best performance.

In the area of contract management, studies involving automatic classification were conducted using NLP and ML (Yilmaz and Dikbas, 2013; Yilmaz, 2013; Candas, 2022; Eken, 2022). In Yilmaz and Dikbas (2013), dispute decision documents were classified using four machine learning algorithms. The algorithm with the highest accuracy was decision tree (DT). Eken (2022) conducted classification work to automatically review construction contracts. Five different machine learning algorithms are combined with different vectorization techniques. Models that perform well were selected and combined with ensemble learning. Candas (2022) conducted research on the multi-obejctive semantic analysis of construction contracts. NLP and machine learning algorithms were applied for the purposes of the automatic classification of contract clauses according to departmental relevance and accurately predicting the presence of ambiguity in contract clauses. The SVM and DT algorithms demonstrated the best performance.

The classification studies were also carried out for analysis of RFIs, but these classification studies were mostly performed manually (Tilley et al.,1997; Morales et al., 2022). In their studies on the analysis of RFIs, the researchers manually classified RFI documents under three main headings according to type, cause, discipline.

The manual classification of texts is acknowledged as time-consuming and error-prone. The process of manually categorizing thousands of RFI documents inevitably prolongs the time required to finalize the analysis. Additionally, misclassifications significantly impact the accuracy and reliability of the analysis outcomes concerning RFI documents. Consequently, the adoption of an NLP-based approach to analyze RFI documents offers potential benefits, such as shorter analysis times and more precise analysis results.

Methodology

Python programming language, Natural Language Toolkit and Scikit-learn library were used for natural language processing and machine learning methods applied to RFI documents. The original dataset is the RFI documents extracted from the common data environment of a project. In order to improve the quality of the original dataset, RFI documents with a lot of noise and very short descriptions were excluded. The metadata to be automatically retrieved from the RFIs was the selected as discipline (i.e., architectural, electrical, mechanical, and structural). The dataset comprises 25 RFI documents for each discipline. In total, 100 RFI text documents were analyzed. The RFI documents retrieved in .pdf format and each RFI document was turned into .txt format.

Implementation workflow for automatic extraction of RFI discipline metadata is shown in Figure 1. It has three main steps: Label assignment, NLP and machine learning. In the first step, each RFI document was labeled in terms of discipline. In the second step, NLP techniques were applied. NLP techniques were performed using the Natural Language Toolkit (NLTK) in Python. These blocks, also known as modules in NLTK, aid in tasks such as tokenization, stemming, lemmatization, and data classification. First, RFI documents were tokenized. Tokenization involves breaking a sequence of text into smaller units, referred to as tokens. These tokens can vary in size, ranging from individual characters to entire words

(Manning et. al., 2009). Second, punctuation marks and stop words were removed from each RFI document. Punctuation removal is often performed to diminish the dimensionality of the data and to eliminate elements that may not carry significant semantic meaning for certain NLP tasks. Thirdly, stop word removal was performed. It is a common preprocessing step in NLP where frequently occurring words, known as stop words, are removed from a text corpus. These words are often common (i.e., 'the', 'a', and 'in') and do not contribute significantly to the understanding of the content. Finally, RFI text data was converted into vectors via vectorization process. Vectorization techniques transform text data into a form that a computer can make sense of. In this study, Bag of Words (BOW) vectorization technique, one of the mostly used vectorization techniques (Qader et al., 2019), was used. BoW was utilized to represent text based on the number of word occurences, using a fixed-length vector created from a vocabulary. The BoW technique was implemented using the Scikit Learn Python library.

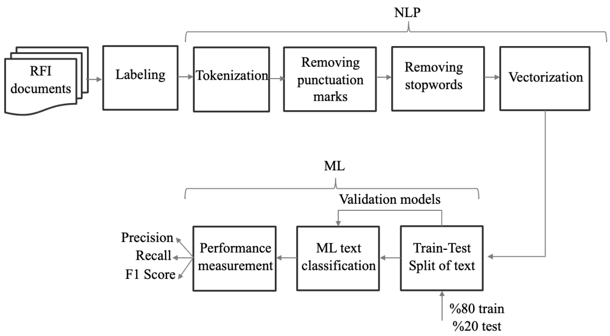

Figure 1: Implementation workflow for automatic extraction of RFI discipline metadata

In the third step, machine learning algorithms were applied. The automatic extraction of metadata from RFI documents is a classification problem. Therefore, supervised machine learning models need to be trained, and two classification algorithms, Naïve Bayes and K-Nearest Neighbor, were selected. Bayes' rule is used to calculate the probabilities of the classes. The NB algorithm is based on Bayesian Decision Theory (Alpaydin, 2014) and the NB model is the most widely used Bayesian network model in machine learning. The term "naïve" is used because the NB algorithm is based on the assumption that attributes are conditionally independent of each other (Russell and Norvig, 2010). It is extensively used in text categorization tasks, including document classification and spam e-mail detection.

The K-Nearest Neighbor classifier categorizes the input into the class with the highest frequency among the k neighbors of the input. Each neighbor holds an equivalent vote, and the class with the highest count of votes among the k neighbors is chosen. Ties are resolved arbitrarily or through a weighted vote. Typically, k is chosen as an odd number to reduce ties, especially when confusion occurs between two adjacent classes (Alpaydin, 2014).

First, the data was split into 80/20, where the first percentage represented the proportion of data allocated to the training set, and the second percentage represented the testing set. Validation was performed before testing the model within training set. The selected algorithms are trained to automatically extract RFI discipline metadata. Then the KNN and NB algorithms were trained and tested by using the output of the vectorization process.

Traditionally, two metrics are commonly used for measuring the performance of machine learning models: Precision and Recall. Precision measures the proportion of truly relevant documents in the result test. Recall measures the ratio of all relevant documents in the corpus that are included in the result set. It is possible to achieve a balance between precision and recall by adjusting the size of the returned result set. The F1-Score is the harmonic mean of sensitivity and recall (Russell and Norvig, 2010).

Precision, recall and F1Score values are calculated by substituting the parameters shown in Table 1 into the equations (1) to (3).

$$Precision = \frac{TP}{(TP+FP)} \quad (1)$$

$$Recall = \frac{TP}{(TP+FN)} \quad (2)$$

$$F1Score = \frac{2\ x\ Precision\ x\ Recall}{Precision+Recall} \quad (3)$$

Table 1: True and false positives and negatives

	Relevant	Irrelevant
Retrieved	True Positives (TP)	False Positives (FP)
Not retrieved	False Negatives (FN)	True Negatives (TN)

Findings

In the BoW vectorization process, word counts were performed for each discipline and they are used as input when applying the BoW technique. Twenty most common words related to the architectural discipline were determined and used in the vectorization process. The first five most repeated words out of the 20 most common words are given in Figure 2.

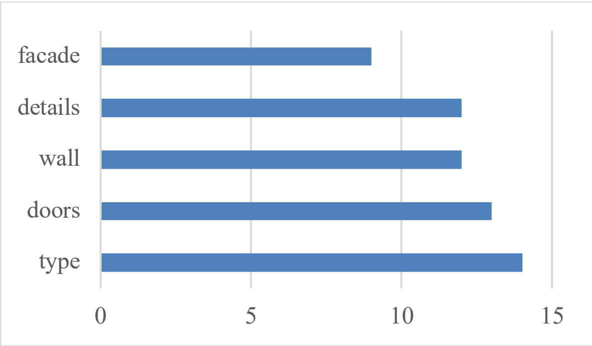

Figure 2: First five most common words in RFI documents related to the discipline of architecture

Similar to the architecture discipline, twenty most common words related to structural, mechanical and electrical disciplines were identified. The first five most repeated words out of the 20 most common are reported in Figure 3 to 5 for structural, electrical, and mechanical disciplines respectively.

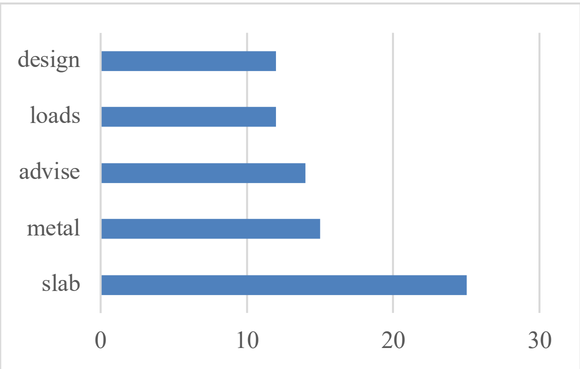

Figure 3: First five most common words in RFI documents related to structural discipline

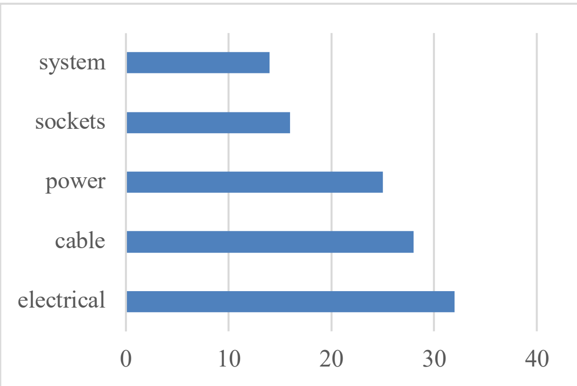

Figure 4: First five most common words in RFI documents related to electrical discipline

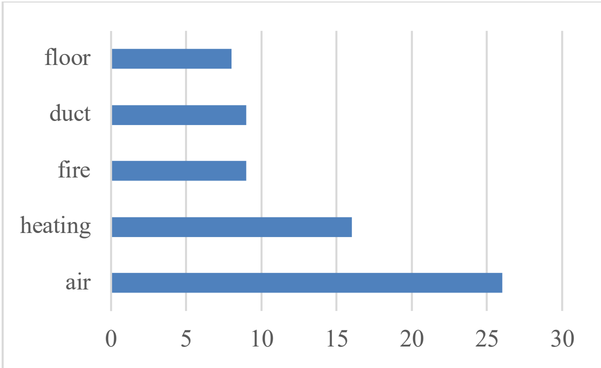

Figure 5: Some of the most common words in RFI documents related to mechanical discipline

After the vectorization process, the NB and KNN models were trained. %80 percent of the data was used for training and %20 percent for testing. The content of the eighty percent training set was changed ten times and validation work was carried before the test phase. At different iterations, the performance fluctuation of the trained algorithm was checked. The performance result of the trained NB algorithm is shown in Figure 6. After ten iterations, the Average Precision, Recall, and F1 Score values are approximately 85%, 82% and 82% respectively. The NB algorithm proves to be highly successful in automatically extracting the discipline metadata of RFIs.

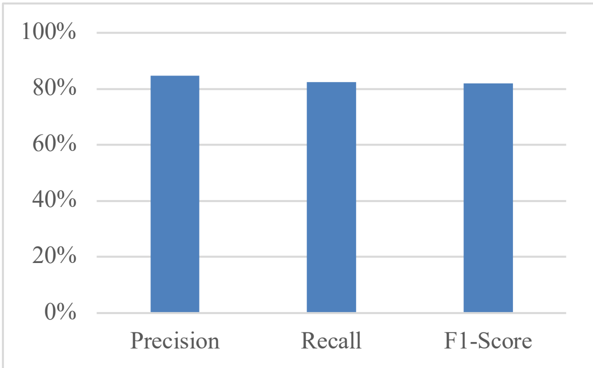

Figure 6: Performance results of the NB algorithm

The tuning of the hyperparameter k corresponding to the number of nearest neighbors is important for enhancing the performance of the KNN algorithm.

The performance results for different k numbers are determined and compared as shown in Figure 7. The results illustrated that KNN demonstrated the best performance when k was set to 5. Precision, Recall and F1 Score values are approximately %75, %60 and %62, respectively.

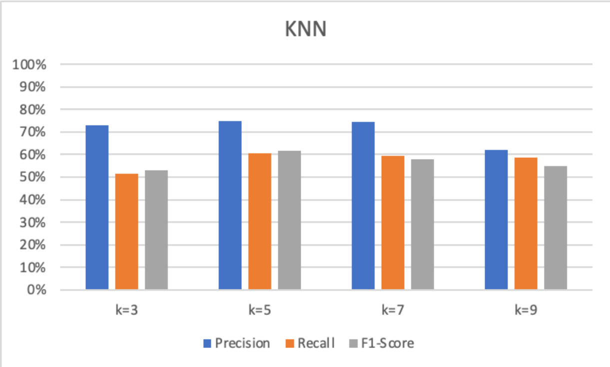

Figure 7: Performance results of KNN algorithm for different k values

Comparative performance results of NB and KNN algorithms are given in Figure 8. NB algorithm showed much better results than KNN algorithm according to precision, recall and F1-Score criteria. Overall, the findings have illustrated that one of the metadata of RFIs, which is discipline, can be successfully extracted automatically.

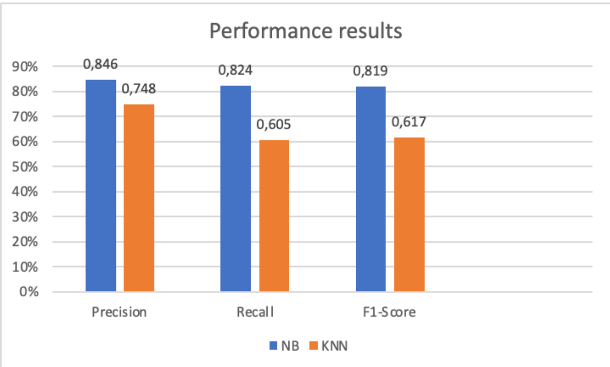

Figure 8: Comparative performance results of the algorithms

Conclusion

In this study, an NLP and machine learning-based model is developed to automatically extract the discipline, which is one of the metadata of RFIs. The performances of the two machine learning models, NB and KNN algorithms, are compared. The average precision of the NB algorithm is around 85%, while for the KNN algorithm, it is approximately 75%. In the case of KNN, it was demonstrated that the KNN algorithm gave better results for k=5.

The model proposed in this study has the potential to prevent time losses during the manual entry of metadata for RFIs in the common data environments, and it can contribute to a reduced number of incorrect entries.

An artificial intelligence based RFI management system can be developed by integrating NLP and machine learning models into the system. As a result, RFI management systems will be more effectively used. The utilization of emerging technologies and data-driven analytics can be harnessed to augment the RFI analysis process, leading to improvements in overall project efficiency (Afzal et al., 2023).

In future studies, we plan to conduct a more comprehensive analysis by expanding the dataset and diversifying the algorithms. In addition to training shallow machine learning models, it may be beneficial to explore the development of deep learning models.

DEVELOPMENT OF NATURAL LANGUAGE APPLICATION FOR CONSTRUCTION SITE PROCESSES SAFETY SUPPORT

Alessandra Corneli1, Francesco Spegni1, Berardo Naticchia1 and Leonardo Messi1
1DICEA, Polytechnic University of Marche, Ancona, Italy

Abstract

Efficiency in safety management at construction sites is an extremely present issue despite the many technological advances that could represent valuable means of support. This is because safety is a complex, multifactorial field in which the human factor plays a central role. It is precisely for the latter reason that finding systems that integrate technology into processes in as natural a way as possible is a challenge to be met. In this context, this research aims to develop a Digital Twin that takes use of Natural Language Processing for supporting safety during construction site operations through communication improvement.

Introduction

Construction is a complex process that requires decisions at every stage. Decision makers are inevitably influenced by past experience, situational knowledge, and other human factors. This often results in operational inefficiencies or safety and environmental problems (Saini et al., 2022). Safety management on construction sites has always been a critical issue in the construction sector since, as is well known, among all industries this is the one with the highest number of fatal accidents even today (Mihic et al., 2019). In this context, the support that could be given by innovative technologies still fails to be incisive (Yap et al. 2022). What makes it extremely difficult to go to work on incorporating new technologies into safety management worksites is that it is a complex issue. The explanation for this lies in multiple factors (Giri, 2020):

- the construction site is a workplace that evolves (rapidly) over time.
- construction procedures are not as precisely defined as operations within factories.
- the centrality in many cases of workers in implementing safety procedures and thus the human factor (Haupts et al., 2019).
- health and safety risk assessments, especially in the drafting of safety plans, which often use standard prescriptions instead of identifying, on a site-by-site basis, the main critical issues.

All of this contributes to the fact that what happens on a construction site, including from a safety management perspective, is difficult to predict in advance and therefore needs appropriate tools. This complexity has also led over time to a misguided approach of focusing on certain types of hazards while neglecting an integrated approach (Mihic et al., 2019).

This has resulted in the paradigm recently promoted for the management of domains characterized by high complexity, namely the concept of digital twin (DT) (Saini et al., 2022). Due to the characteristics of real-time interaction and self-evolution, DT is considered the best technology that can contain all the required information (Zhao et al., 2019). One aspect that is often overlooked in DT development, however, is the circularity of information that on the one hand is collected from the real environment but on the other hand should return to it so that the agents involved can learn about the information and possibly self-correct. This approach from a safety perspective is called safety II. In order, however, to communicate the information needed for safety management on the job site, one aspect to consider is that this information be easily usable and integrated into the processes. The use of natural language represents an optimal method of communication on the construction site for the purpose of human-machine interaction that is as natural as possible. The innovation proposed in this research concerns the integration of several innovative technologies (localization using UWB and RTK sensors, natural language, BIM approach for representing the built environment) in order to develop an application to support safety in construction processes. One of the innovative aspects is the use of NLP in spoken form, as opposed to the more widely used automatic text analysis, is the communication improvement on the construction site. This together with the early detection of dangerous situations through the development of DTs represents a method to apply a safety II approach with the aim of guiding workers toward recommended attitudes rather than pursuing an exclusively prescriptive approach.

Literature review

The construction industry is recognized for its dynamic and complex nature. Safety planning in construction environments is therefore challenging. Moreover, due to the lack of standardization of production processes it is very complicate to incorporate new methods and technologies into workflows without disrupting the entire industry. Among new technologies, BIM is the most cited approach in the literature. This is usually used in conjunction with other innovative technologies or the basis for others (e.g., AR) (Khudhair et al., 2021). This is also because if BIM means IFC this represents only a part of all the knowledge underlying the processes of the construction industry, namely the objects of which a building is composed. Missing from this representation are a number of crucial parts including the representation of processes, workings, economic aspects and temporal aspects. Furthermore, in the construction industry textual information (including BIM) is the dominant data type that exists in every stage of construction management, with over 80% of it being unstructured (Shamshiri et al., 2024; Wu et al., 2022). This information format is not very convenient to use on the construction site. It is precisely this high percentage of written text in construction management that has caused much research over the years to introduce natural language as a tool for handling this amount of data. Some approaches to Natural Language Processing (NLP) involve its use for interpreting documents. In (Fang et al., 2020) they developed a novel approach for classifying text contained with safety reports specifically in the case of near misses using NLP specifically to gather information in a smart way. Similarly (Baker et al., 2020) test two state-of-the-art deep learning architectures for NLP, providing a method for identifying (after training) the textual patterns. Again, the application of NLP is focused on automation in document interpretation. (Martinez et al., 2020)'s retrieval systems have been proposed for retrieving accident cases and supporting health and safety plan preparation. (Tian et al., 2023) have developed an information retrieval system that can answer questions about the best procedures to follow regarding safety during operations. Shamshiri et al., 2024 highlight how the use of NLP applications interests' safety management much more than the other domains of interest. Despite this, most text classification and information extraction applications have been widely used for the specific task of construction site accident and injury reports.

However, one aspect lacking in safety management is communication, and so natural language voice interaction (rather than written) could be a real breakthrough in workplaces where the use of paper and digital texts is not very smooth. There are two different types of interactions that can be imagined on a construction site between human agents and a Vocal Virtual Assistant (VVA). The first one requires the user to begin an interaction (passive VVA). The second one requires the system to monitor the human and artificial agents on the construction site, and proactively sends voice commands or requests to specific human actors on the field (pro-active safety VVA).

In the present work we focus on pro-active safety VVAs because assuming that workers would actively begin an interaction with a safety VVA would be equivalent to assuming that they continuously have a high degree of awareness level for safety hazards on their working environment. Unfortunately, field experience and the vast literature on construction site risk management and hazards teach us that repetitive and tiring tasks such as those characterizing the construction industry induce the workers to lower their safety hazards awareness levels. This motivates the development of a methodology for implementing an efficient pro-active safety VVA that would either provide useful safety hints to the workers on site or ask questions that aim to raise the level of attention of the worker potentially at risk.

Methodology

In Fig. 1 a methodology is introduced for driving the integration of the required technologies (see Fig. 1). The methodology spans two of the main stages of a construction project, viz. system set up and construction phase. During system set up, the first step concerns the digital representation of agents that are relevant for safety reasons (workers, vehicles, equipment, ...). Next, a connection between the real environment and the digital environment is established and maintained along time installing and configuring a network of sensors capable of localizing the described agents in the construction site (the technology for the sensor network is chosen based on the specific construction site, and especially it depends on whether it is outdoor, indoor, or mixed). In the Natural Language Processing step, the NLP microservice of the platform is fed with a set of sentences that should be recognized or reproduced by the platform itself in order to interact with the workers when it is needed. The construction phase is divided in two main steps: construction site monitoring and interaction. The former observes the positions of the agents in the construction site and detects whether some of the rules should be activated. The latter takes care of the voice interaction with the worker following the specific rules that are activated during the monitoring step, if any.

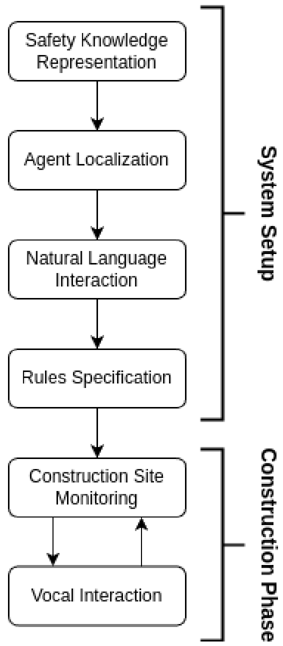

Figure 1 - Methodology

Safety knowledge digital representation

Construction site safety management is a complex issue because it requires the knowledge and integration of different information. Indeed, aspects that are part of safety concern workers, equipment, operations, hazards and spaces to name a few. Multiple efforts to represent aspects concerning safety can be found in the literature. From methods to classify hazards (Mihic et al., 2018; Fang et al., 2020; Johansen et al., 2023) to integrations with existing built classification such as IFC (Farghaly et al., 2022) contexts (Doukari et al., 2024; Gao et al., 2022) and rules (Shen et al., 2022).What is clear from these studies, however, is that to create an ontology that can collect everything that is needed for construction site safety monitoring is almost impossible.

This is because the domains to which the various parts to be taken into account refer are very different, and in the perspective of digitization of construction these differences become even more evident. In fact, if one thinks of BIM as a building model this involves a digital transposition of information based on objects, not on processes and workings that for example are central to making reasoning in the field of safety.
For this reason, the method chosen to deal with knowledge was to integrate different representations. The ontology that was taken as the basis is the one presented by (Zhang et al., 2015). Since the primary focus in this work is on monitoring resources (workers and machinery) in the chosen ontology we focused on the structure of resources not using the other parts for the time being. A handbook from the National Institute for Insurance against Accidents at Work (INAIL, 2019) was referenced to identify which components within the classification made sense to consider. This manual was compiled following the 2016 earthquake that struck central Italy. In the aftermath of that tragic event a very large number of construction sites were opened at the same time and in areas (urban centers, often including historic ones) that provided even more risks and aspects to be taken into account. In light of the great turmoil for reconstruction that is still unfinished today these guidelines identify the necessary human resources, machinery and equipment for each job. These items were used to fill within the system the categories identified by the chosen ontology.
As for the spaces that refer to the different construction site areas, we chose to model them with a BIM authoring software and then export information in IFC. The construction site layout is a mandatory document in Italy forming part of the safety documents. In this first implementation of the system, a single construction site layout was modelled with BIM and inserted into the DT platform to be used as a basis of the spatial reasoner. The site spaces planned for machine allocation, maneuvering, material storage, and different work areas were modeled in BIM as IFCSpace to identify their geometry and dimensions in digital space. In subsequent developments of the system, it could be envisaged to have more than one BIM model of the construction site with identified spaces and their changes in the duration of the construction.

Agent localization

Agents' localization on the construction site for the purpose of which the installation of a sensor network is planned. The real-time localization system has the task of attributing spatial coordinates to any entity, equipment or person, moving around the construction site.
The first requirement of the network for agent localization in order to be effectively implemented is high-precision localization capabilities in both open and closed environments for work taking place outside buildings and inside. The second one is real-time data sending to a platform for DT management.
The technologies selected for tracking are Ultra Wide Band tags for indoor and GPS-RTK for outdoor (Corneli et al., 2023). The two technologies can also be integrated into one tag which would allow both technologies to be exploited simultaneously in the case of mixed indoor/outdoor environments. As for UWB technology this involves the use of battery-powered mobile tags (to be provided to workers and attached to machinery) and requires the placement of anchors and gateways, two powered components. For this reason, UWB technology is intended for use in indoor environments where wiring the system is not an added risk to the worksite compared to outdoor environments. The accuracy for UWB localization is 10 cm.
On the other hand, for outdoor use, the technology used is GPS-RTK, which provides an accuracy of 1,5 cm. This can be implemented through an antenna inside the tags, which are provided to personnel and hooked onto the machinery. In both cases, localization information is sent by the sensor network to the Digital Twin Platform by means of intermediary service implementing a publish-subscribe information exchange pattern. This is often the case of services such as MQTT or SignalR.

Natural Language Interaction

The vocal interaction is a natural means of communication among agents in the construction site. Technological advancements in recent years make feasible to apply vocal interaction using natural language even on miniaturized and wearable devices. Cloud computing and high speed internet allows to displace the task of "reading" a given sentence or recognizing a vocal interaction on remote computers that are likely to have higher computing capabilities than those on the construction site. Neural networks allow to automatically transcribe the voice input onto its textual representation with high accuracy.
In our methodology, a pro-active safety VVA contains a collection of sentences that can be reproduced to specific group of people on the field, under suitable conditions. Each sentence is a template, mixing raw text with expressions that are computed if and when the sentence is reproduced. For instance, take the following sentence:

{{ A.name }}, you are in danger: equipment {{ B.name }} is too close!

In it {{ A.name }} and {{ B.name }} denote expressions that should be evaluated in order to deduce, respectively, the name of the worker at risk and the name of the equipment that represents a danger for the worker. A sentence with expressions in double curly braces is called an open-sentence, while sentences that do not contain expressions in curly braces are called closed-sentences. The key difference between the two kinds is that the latter can easily be converted to an audio file passing it as input of one of the several available text-to-speech AI driven cloud services, while the former need a pre-processing stage responsible for replacing the expressions with meaningful pieces of text. How this pre-processing phase happens is explained in the last stage of the methodology. The fact that sentences contain parameters allow the system to be more explicit and address specific workers calling them by name or referring to their close context.

This contributes in increasing the level of awareness in workers that perhaps do not even notice that their context is changing around them in a way that is becoming too risky to continue their task.

Parameters in template sentences are associated with one among three types of entities from the selected safety ontology: Human Resource, Equipment, or Space.

In general, the Safety Manager can devise sentences that aim to:

- raise the level of awareness in workers that are closer to dangerous or risky areas, equipment, or materials
- ask the worker for confirmation that he/she is wearing the required personal protective equipment (PPEs) or had the proper training;
- ask the worker to stay out of a delimited area.

It is evident that such goals can only be achieved by a pro-active safety VVAs.

Rules Specification

In order for the VVA to exhibit a pro-active behavior, the Digital Twin Platform must have the tools to express how to react when agent positions change, possibly denoting a risky situation on the field. To this aim, the methodology provides a stage for specifying rules that will activate the vocal interactions of the system with the workers on the field. In this stage the Safety Manager can model the configuration of agents locations that will initiate a vocal interaction of the Digital Platform, and what workers should be involved in the interaction. To this aim, each rule allows to specify two core pieces of information: a preconditions; an NLP sentence; one or more workers. The precondition expresses under what circumstances the rule should trigger a vocal interaction (Fig. 2). The NLP

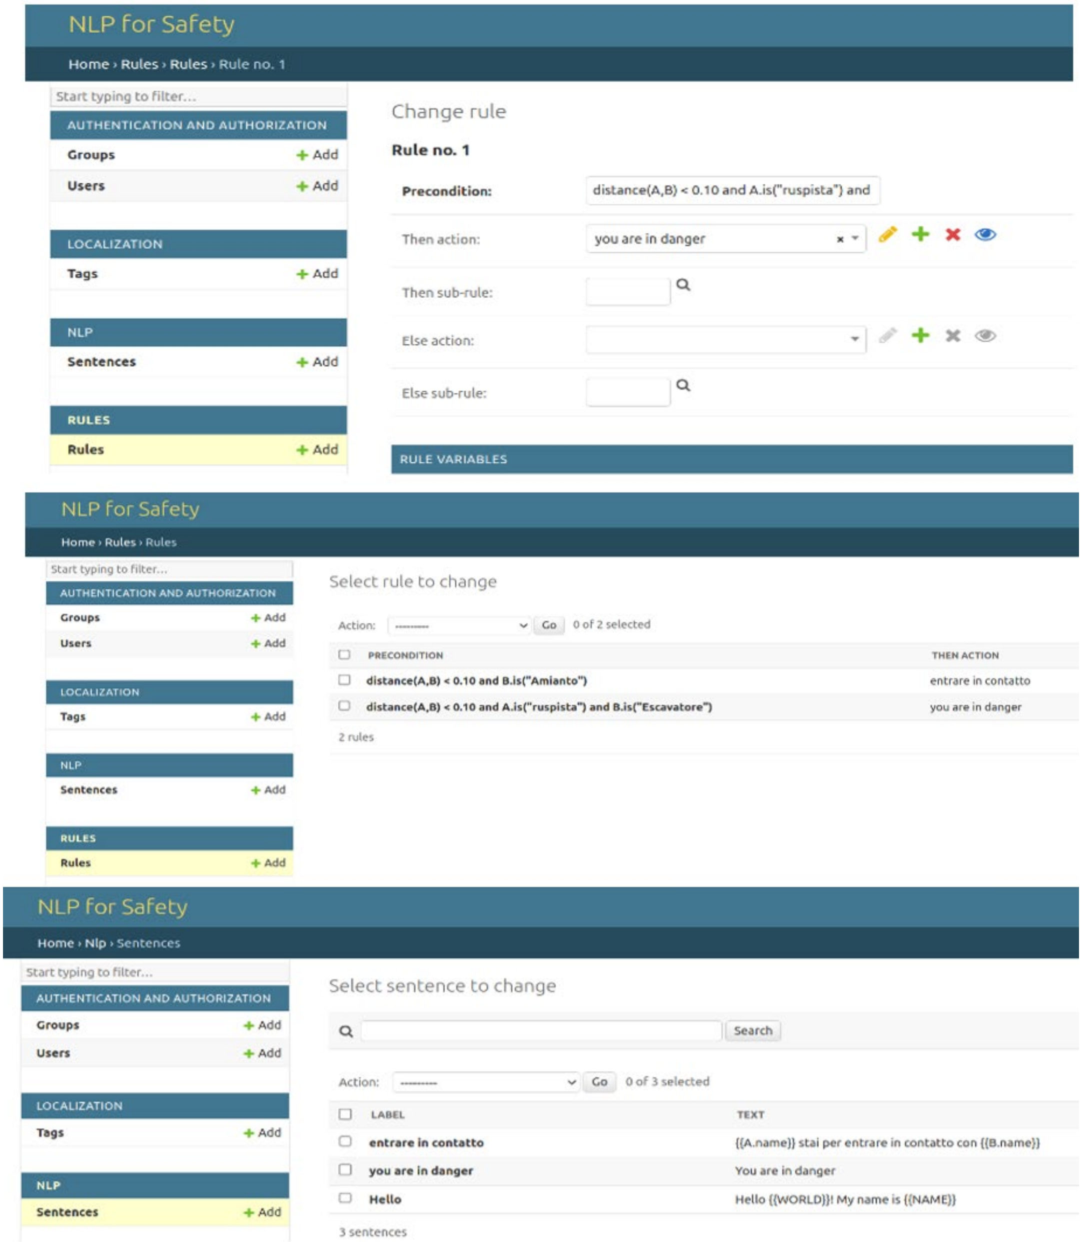

Figure 2 - NLP implementation: from above 1. rule definition; 2. rule-vocal action combination; 3. vocal action composition.

sentence specifies what audio message the Digital Twin Platform should send to the workers.
The rules preconditions are boolean formulas that can contain:

• variables;
• rational numbers;
• boolean operators (and, or, not);
• arithmetic operators (+, -, *, \);
• comparison operators among rational numbers (>, <, ==, !=); and
• function names.

From a formal point of view, the rule precondition is a first-order, existentially quantified, boolean formulas over rational numbers. An example of rule precondition is the following:
\exists A:Human Resource, \exists B: Equipment. (B.identifier == "BridgeCrane" and distance(A,B) < 0.5 and A.identifier == "BridgeCraneOperator")
The intended meaning of such a precondition is to detect when any worker qualified as a bridge crane operator is "close enough" (less than 50 cm) to the controller of the bridge crane on the construction field.
The target of the rule, i.e. the recipient of the vocal message, can be the involved worker, in case the aim of the Safety Manager is to raise the attention of the worker itself, or it can be the Safety Manager, in case she/he wants to be notified of certain relevant events happening on the construction field.

Construction Site Monitoring and Vocal Interaction

Construction Site Monitoring constitutes of a digital process continuously receiving updates concerning the agents locations on the field, and at each location update all the rule preconditions in search for those rules that should be considered enabled.
In order to detect that a rule is enabled, the Construction Site Monitoring contains a pattern matching logic searching for agents in the construction site that are compatible with the variables required by each rule, and selecting only those configurations of agents that satisfy the rule preconditions. Each configuration of agents that satisfy a rule is called an environment satisfying that rule. Note that the same rule can be satisfied by several environments, meaning that the same rule can generate multiple vocal interactions targeting different agents at the same time (for instance, to raise their attention or to ask for confirmation about the task they are executing on the field).
The latter stage, Vocal Interaction, involves generating an audio file whenever a rule is found enabled during the Construction Site Monitoring stage (Fig. 2). In case the NLP sentence associated with the rule is an open-sentence with parameterized expressions in it, the Vocal Interaction stage receives from the Construction Monitoring Site stage the environments satisfying the rule, and by binding the parameters of each such environment to the open-sentence a closed-sentence is obtained and converted to an audio file using text-to-speech cloud services. Finally, such audio file is routed to the workers associated with the enabled rule. It should be specified that rule activation has no effect on the environment except for voice interaction.

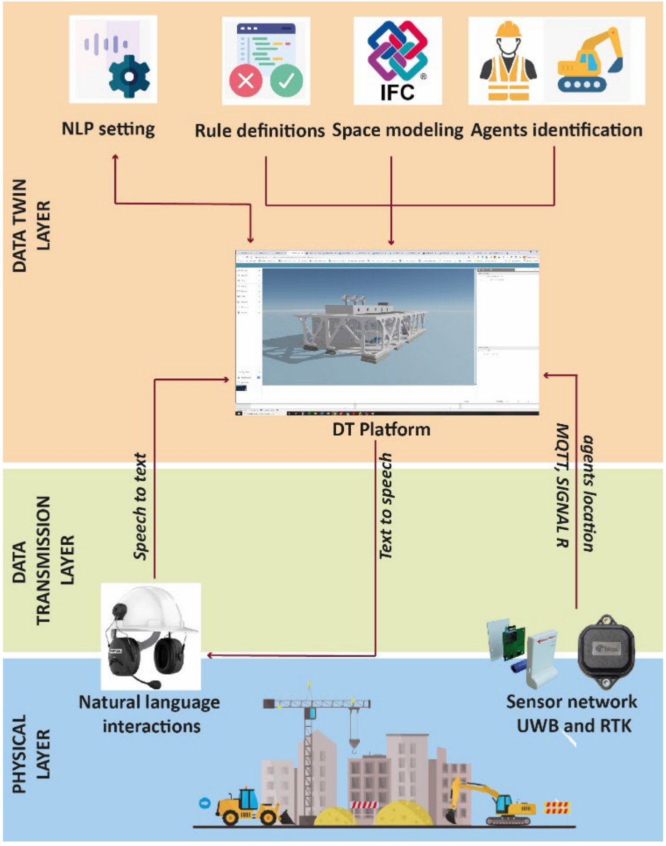

Figure 3 - System Architecture

System architecture

The architecture of the proposed system is shown in Fig. 3. The physical layer, typical of any DT, is represented in our case by the construction site, including resources (workers and machinery), definition of spaces and hazards. The connection between the real world and the digital world is represented by the Data transmission layer. In this DT it is not possible to speak only of Data acquisition layer because the system focuses on communication at the construction site through natural language. Therefore, the data transmission layer has on the one hand the task of acquiring data from the construction site through a sensor network, on the other hand, the information from the reasoning part applied to the data is poured back into the construction site through voice interactions performed by the system.
From data transmission layer we move to what we have called DT layer. In this layer of the system there are several components. Into the DT platform goes all the relevant information for site management and it is the platform that invokes the natural language micro-service. The necessary information also already covered in the methodology concerns the definition of the resources involved (workers and means), the rules to be applied and the spaces. The latter are the spaces of the construction site thus work areas, material storage areas, machinery maneuvering spaces, internal roadway areas, etc.

Application development

A simulated construction site has been recreated in order to test a prototype implementing the proposed methodology. The experiment was conducted within the DC3 laboratory of the Polytechnic University of Marche. The laboratory is equipped with a bridge crane and the agents in the simulated construction site were monitored using an UWB sensor network composed of five UWB anchors mounted along the perimeter of the laboratory and seven UWB tags attached to the agents moving in the simulated construction site. The gateway of the UWB sensor network published the coordinates of every tag once per second on a configured MQTT broker, while the web application subscribed the topics of the same broker in order to receive the most updated position for each tag and store it on the database. To enable audio and vocal interaction with the VVA each worker was equipped with a Bluetooth headset and a battery powered Raspberry PI mini PC connected to a local Wi-Fi internet connection. A web application implemented the aforementioned architecture to drive the Safety Manager along the steps of the proposed methodology. The basic entities at the core of the Digital Twin data-model are Equipment, Protective Equipment, Space, and Human Resource. On a different entity type named Construction Site, the Safety Manager creates instances representing each construction site he/she is managing, specifying for each the relevant attributes such as an identifying label, the location of the construction site itself, the date when the works began and the date when they are supposed to end.

Finally, entity type Item collects instances of each family of equipment, protective equipment, space or human resource, and put it in relation with the specific construction site. For example, two entities named “Jane Doe” and “Tom Cobley” respectively can be linked at a single entity labeled “Scraper operator” of type Human Resource, and at the entity of type Construction Site with label “Gotahm City Central Hospital”. This example clearly identifies two (working) agents in a specific construction stie. They can also be linked to two different entities of type Human Resource, such as “Team A” for “Jane Doe” and “Team B” for “Tom Cobley”. As a different example, the Safety Manager may add an entity of type Item named “Parking Area” that is linked to an entity of type Space labeled “Team A Working Area”, while a second Item may be labeled “Warehouse” and be linked to an entity of type Space named “Team B Working Area”. In the web application, an entity of type Tag is stored on the database for each of the UWB tags, together with their relevant data, viz. the tag identifier, a label for it, the last known position, and the time when the position was detected by the UWB sensor network. Each Tag entity is linked to the entities of type Item mentioned earlier. The next task of the Safety Manager is to model the sentences the VVA should pronounce. Here is the list of template sentences and questions used for our simulated construction site:

S1: {{ A.name }}, the bridge crane requires the following personal protective equipment: {{ PPEs }}. Can you confirm you are wearing all of them?

S2: {{ A.name }}, it appears you are operating on the Bridge Crane {{ B.name }} as though you are not assigned to this task. Are you sure you are allowed to do it?

S3: Watch out {{ A.name }}! You are in danger because the crane is above you

S4: {{ A.name }}, it appears you are working outside the area you are assigned to.

Finally, the Safety Manager can specify the rules that defines the set of events triggering a sentence or a question. Rules are formalized as a logic precondition, associated with a sentence that is to be spoken by the VVA.

Rules are associated with typed variables and the following sentences have been associated to actual implementations:

- distance : it takes two 3-dimension coordinates and computes the linear distance between them
- above : it takes two 3-dimension coordinates and computes the linear distance on the XY plane, thus checking if one of the objects is close or above the other

Below are examples of rules tested in the simulated environment:

- R1: \exists A:Human Resource, \exists B: Equipment. (B.identifier == “BridgeCrane” and distance(A,B) < 0.5 and A.identifier == “BridgeCraneOperator”)
- R2: \exists A:Human Resource, \exists B: Equipment. (B.identifier == “BridgeCrane” and distance(A,B) < 0.5 and A.identifier != “BridgeCraneOperator”)
- R3: \exists A:Human Resource, \exists B: Equipment. (B.identifier == “BridgeCrane” and above(A,B))
- R4: \exists A:Human Resource, \exists B: Space. (B.identifier == “Team A Working Area” and A.identifier == “Team B”)

Rules are associated to sentences as follows: (R1, S1), (R2, S2), (R3, S3), and finally (R4, S4).

The most expensive task of the implemented system, in computational terms, is the construction monitoring phase, re-evaluating rules preconditions in search for environments satisfying the rules themselves and required in order to transform open-sentences onto closed-sentences ready to be reproduced on the workers’ headsets.

Results

In order to carry out an initial verification of the proposed framework, three tests were planned:

- TEST 1: identification of interference risk situation between overhead crane and worker and subsequent voice warning;

Figure 4 - DC3 lab tests, from left to right: test 1, test 2 and test 3.

- TEST 2: verification of possession of the qualifications for handling a construction site machinery (represented by the overhead crane) and vocal communication of any non-possession of the above requirements;
- TEST 3: verification of possession of permits to access areas of the construction site.

Figure 4 and 5 show the setting of the tests performed. In the first scenario, the hook of the overhead crane from which the load was hung was instrumented. The worker, on the other hand, was instrumented with a badge attached to the vest. The minimum distance below which the system sent a warning was set equal to 50 cm, and the warning sent to the worker via Bluetooth earpiece said "Alessandro (worker name) you are about to make contact with the overhead crane (equipment). In the second case, the worker (who always wears the sensor) holds the remote control of the bridge crane, which is also instrumented with a sensor for tracking. In this case, the minimum distance at which the warning starts is 20 cm, and the warning received by the worker is "Alessandro you are/are not in possession of a license to drive the overhead crane." Finally in the last case tested, the cones are instrumented with UWB sensors to detect location and the worker also has the sensor for location. In this case the area identified by the cones is connected with an area defined in BIM for which access rules have been introduced in the system. In the latter test in case the worker sensor overlaps with the identified area, the system reports "Alessandro you do not have permission to access this area."

Conclusions

Safety management at construction sites is a complex problem in which recent technologies still struggle to establish themselves. In addition to reasons such as the economic investment required and the low perception of the usefulness of the proposed innovations, there is also the fact that changing processes or standardizing them in an industry that has never worked on rationalizing procedures is seen as a difficulty in addition to the others already mentioned. For this reason, Safety II proposes an approach to safety that, rather than imposing standard procedures, strives to find ways to make them follow naturally and integrated into operations. With this in mind, this research work aims to integrate natural language within processes through collaborative monitoring techniques. Initial tests have demonstrated the feasibility of the system and the effective development of this initial integration.

The next steps involve studying the best tool for voice communication on the construction site. A helmet with integrated headphones could be a solution whose feasibility should be investigated. Further testing should also be done at construction sites since an important limitation of the proposed approach could be the noise present at the construction site, which could adversely affect message comprehension. Finally, a systematization of knowledge about safety could be implemented for the purpose of testing the scalability of the system to all site operations. Another main limitation of the current research lays in the non-optimized implementation of the rule engine, that at the moment is based on Python and capable of handling only small construction sites. Nevertheless, state-of-the-art and freely available SAT-solvers such as Chaff or Z3 are highly optimized to handle existentially quantified first-order boolean formulas over rational numbers and find environments that satisfy them in systems made of thousands of actors, thus making the methodology feasible even for real-world scenarios.

Abstract

Despite numerous existing vacant industrial buildings and vast unused brownfield land, new production settlements are rarely integrated within existing structures. This paper presents the RE:STOCK INDUSTRY framework, aiming to develop a method for assessing the reuse potential of industrial structures, focusing on vertical expansion and circular economy principles. Utilizing scanning and photogrammetry data, a novel AI method will generate as-built FEM models for structural analysis and prediction of retrofitting measures under vertical expansion. An augmented reality app will aid visualization and decision-making on-site. Innovatively combining AI, computational structural design and AR, the project advocates sustainable reuse, reducing reliance on recycling or disposal.

Introduction

Industry accounts for 30% of Austrian economic growth (Bolen, 2022), with over 1,000 new industrial enterprises annually (Statistik Austria, 2022a). There are more than 82,200 industrial and warehouse buildings, with over 1,000 new construction permits granted each year (Statistik Austria, 2022b,c). The significant land sealing resulting from horizontal production and storage processes is a problem: Austria has approximately 20,000 hectares of unused, derelict industrial and commercial areas (Enzinger, 2017), and up to 6,000 commercially or industrially pre-used buildings with potential for reuse (Janitsch, 2022). Companies and municipalities that want to relocate businesses are faced with the challenge of securing space for the expansion or relocation of production, warehousing and logistics (Lasi et.al, 2014, Vajna, 2014), but too rarely integrate these into existing buildings. Cost- and time-efficient concepts for integrating new production and logistic uses into existing buildings and solutions for vertical production processes must also be developed to relocate production back to Europe while minimizing new land sealing.

The potential of a building for reuse and vertical upgrading depends heavily on the actual condition of the load-bearing structure, as it must be able to cope with the new loads and space requirements. Information on the material and structural composition, the condition, the pollutant and contaminant content, and, consequently, the effective load-bearing capacity and serviceability of the existing structure for conversion and new use is often lacking. In addition, most building owners do not see their existing building stock as a valuable material resource bank: existing structures are usually demolished and rebuilt, which increases the volume of waste and landfill, leaves valuable substances unused and results in increased resource and energy consumption.

The current challenge in evaluating the existing structural stock regarding its reuse capability is to accurately digitize, model and analyze the actual structural building stock and make it accessible to the life cycle-oriented economy. The creation of digital analytical as-built models using the finite element method (FEM) for structural analysis of existing structures is currently a predominantly manual, time-consuming, and error-prone process.

This paper deals with the question: "Which methods and technologies are suitable for digitally recording and documenting the structural properties and material composition of the existing building stock and evaluating its reuse, modernization and upgrading potential for vertical industrial uses from a circular economy perspective?"

The research is conducted within the research project RE:STOCK INDUSTRY, funded by the Austrian Research Promotion Agency FFG. The overall goal of the project is to reuse the existing load-bearing structures of industrial buildings in a targeted manner for new settlements, expansions, or conversions instead of resorting to recycling or disposal processes. Through innovative vertical production concepts and their integration into structural analysis, new soil sealing is to be avoided and the service life extended by reusing the building structure. In the research, missing automated methods for scan to FEM using artificial intelligence (AI) algorithms will be developed and innovative approaches for vertical retrofitting of industrial buildings and customized concepts for vertical production and storage processes in existing buildings researched. An interactive augmented reality (AR) application will enable the visualization of reuse concepts with real-time feedback directly at the construction site and it will aim at motivating planners and building owners to upgrade instead of demolishing and new construction.

This paper presents the RE:STOCK INDUSTRY methodology and framework. The paper is structured as follows: A state-of the art review presents existing work on Scan to FEM, Vertical production, Re-use assessment models and AR technologies for retrofitting purposes. The next section describes the research design and methodology followed by the presentation and description of the RE:STOCK INDUSTRY framework. Within the conclusion potentials and challenges of the research are discussed and future research steps highlighted.

State-of-the-art

Scan to FEM

Structural analysis models are essential for the reuse of industrial buildings. The level of knowledge about the load-bearing capacity and serviceability of existing buildings is currently achieved through extensive plan studies, former available structural calculations, and on-site inspections, followed by the creation of simplified digital twins or 2D plans. Digital as-built building modeling often focuses on scan-to-BIM approaches. Researchers are investigating the reconstruction of 3D building models for material quality analysis (Paral et al., 2021), structural analysis (Alfio et al., 2022) or reconstruction from point cloud data (Poullis, 2013). However, methods for the parametric representation of 3D models for FEM analysis out of scans are lacking. Scan to FEM is often investigated in architectural cases for historical buildings (Alfio et al., 2022, Barazzetti et al., 2015). Others include manual identification of properties for a procedural model to reconstruct geometric structures from point clouds (Funari et al., 2021), estimate elastic parameters of beams from point clouds (Riveiro et al., 2018), or detect cracks in reinforced concrete to ensure stability (Yu et al., 2021). Automatic methods for the recognition of cylinders in point clouds for the reconstruction of plants (Liu et al., 2013), FEM mesh structures for the numerical analysis of tunnels from point clouds (Cui et al., 2023), or the assignment of a B-spline representation to a point cloud for the purpose of FEM analysis (Xu and Neumann, 2020) are being investigated. Semi-automated methods for converting point clouds to BIM and using them for structural analysis (Rolin et al., 2019) or machine learning for monitoring the structural condition of buildings (Mishra, 2020) are used. The combination of point clouds with image data allows parts of point clouds to be segmented and classified as known classes of structural elements (Barrile et al., 2019). Most of the existing methods require manual intervention or work semi-automatically.

Vertical production

A third of Vienna's added value comes from production. STEP2025 addresses the future of the productive sector and advocates sufficient space for trade and industry (Rosenberger et al., 2017). Vertical production, involving the multi-storey use of buildings for the production of goods, can reduce the space required for trade and industry and requires efficient material flows across several levels (Hompel et al., 2018). VERTICALurbanFACTORY explores stacked functions and vertical production for efficient space utilization (Haselsteiner et al., 2019). Haselsteiner et al. (2020) show utilization scenarios for different building types to implement vertical production. Vertical production and logistics solutions are already established in densely populated regions such as Singapore and Hong Kong (Kuznetsova et al., 2018, Low et al., 2015). Vertical production concepts are being investigated in algorithmic optimization of material flows in a layout (Ahmadi et al., 2017, Karateke et al., 2022). Others are researching adaptive reuse of industrial buildings regarding critical factors (Vardopoulos, 2019) or for residential purposes (Glumac and Islam (2020). The integration of 3D utilization concepts into structural analysis can be enabled by spatial zoning methods, reaction grammars and parametric planning methods (Claessens et al., 2020, Boonstra et al., 2020, Reisinger et al., 2022). To the best of our knowledge, a methodology that considers the effects of multi-story production in structural analysis has not been widely researched.

Re-use assessment models and resource passports

The uncertainty in predicting the future use of materials and buildings is a challenge in circular economy approaches (De Wolf et al., 2020). BIM4eco is developing a web tool that automatically imports BIM information of a building model in early phases into a life cycle assessment program, records it component by component and calculates environmental impacts (SOLID, 2022). Reuse-Life Cycle Assessment (Escamilla, 2023) analyzes the potential for reducing the environmental impact of reusing materials in buildings. In Build-Re-Use (Lead AEE, 2022), basic principles for the construction and dismantling of buildings with short utilization cycles - supermarkets, office buildings, interim buildings, sanitary facilities - are developed. The buildings are constructed with reusable components and can be dismantled and returned after use. Gebäudepass (Umweltbundesamt, 2013) is developing the basis for the standardization of building passports as building material information systems. M-DAB (2019) uses BIM-based digital technologies to digitize, analyze and sustainably manage the city's material resources. BAMB, (2020) aims to involve the construction industry in the circular economy and increase the value of used materials. PlattformCB'23 (2023) has created a guideline for the circular economy, circular tenders, and future reuse.

Existing digital material register platforms (Madaster, 2024, Concular, 2024, Rosen, 2024, EcoDesign Circle, 2023) document the products and materials used in buildings in terms of quality and quantity and enable the creation of building resource passports. The focus is on circularity, the environment, life cycle assessment and financial evaluation. Raw material utilization is mapped in Madaster and status descriptions are possible in the form of certificates and archive documents. The RhinoCircular (Heisel, 2021) and Phoenix (EPFL, 2024) tools deal with structural components and parameters relevant to the circular economy. There are few approaches for documenting and assessing the load-bearing capacity and serviceability of existing buildings for new use. Re-use assessment and documentation methods often focus on materials, elements, compounds, and chemical constituents. Structural aspects are neglected, and the focus is primarily on recycling and deconstruct ability. RE:STOCK INDUSTRY is investigating ways of evaluating and documenting structural information relating to the reusability of the building.

Augmented Reality for retrofitting measures

One of the main advantages of AR is situated visualization, where the simulated content is closely linked to the environment and decision-making processes are supported by facilitating the calculation and understanding of domain knowledge (Martins et al., 2022). In the construction industry, AR is used in education for on-site training (Tan et al., 2022) and quality testing of HVAC systems (Schranz et al., 2021). GAMMA AR (Gramma, 2024) is used for construction site monitoring and documentation with BIM. The combined use of BIM and AR is gaining increasing interest. AR enables the display of BIM elements directly in the building to make annotations or show hidden installations (Chai et al., 2019, Urban et al., 2019, Hugo Silva et al., 2021). When displayed on AR glasses, the addition of AR data enables hands-free exploration of the built structure. The use of AR for interactive finite element analysis has also been investigated (Huang et al., 2017, Huang et al., 2023). The research methods in which conversion and retrofitting options of buildings can be visualized as scenarios on site within AR are sparse.

Research Design and Methodology

The research objective is to develop a framework for the end-to-end digital recording, modeling, and analysis of the load-bearing stock of industrial buildings for circular re-use and vertical expansion. The potential for reuse, modernization and upgrading in vertical extensions, considering circular economy aspects, should be determined, and recorded by documenting structure-specific information in resource passports and material registers. Through efficient visualization stakeholders should be able to foresee vertical retrofitting possibilities including modernization measures directly on the construction site and to have an assessment model which evaluates the planned retrofitting measures in comparison to demolition and new construction through ecological and economic assessment.

Figure 1 shows the research design of the project for the method and framework development. The data collection and method development are based on industrial buildings in steel and reinforced concrete skeleton construction, as 80% of the industrial building stock consists of these types of structures. Ten buildings in Austria with different geometries and structural systems are defined as use cases. The existing buildings will be captured using scanning and photogrammetry, on-site inspections by experts with knowledge of deconstruction and structural retrofitting and supplemented by the analysis of planning documentation. During the inspection, contaminated elements and damages will also be digitally recorded and localized.

In the first step, two novel methods for automated generation of the analytical as-built FEM model by coupling point clouds and image data with AI algorithms will be researched and developed: a.) Reconstruction of the parametric FEM model from 3D point clouds by heuristic optimization methods. The reconstructed model will contain information on the geometry, material and condition of the existing structure. A digital process enables the integration of additional information on damage assessment, detailed material properties such as material grades and contaminants. b.) Development of a deep neural network (DNN) for the automated recognition of structural joint connections from geometric and image data. Real as well as synthetic data from existing use cases and BIM models will be used to train the DNN.

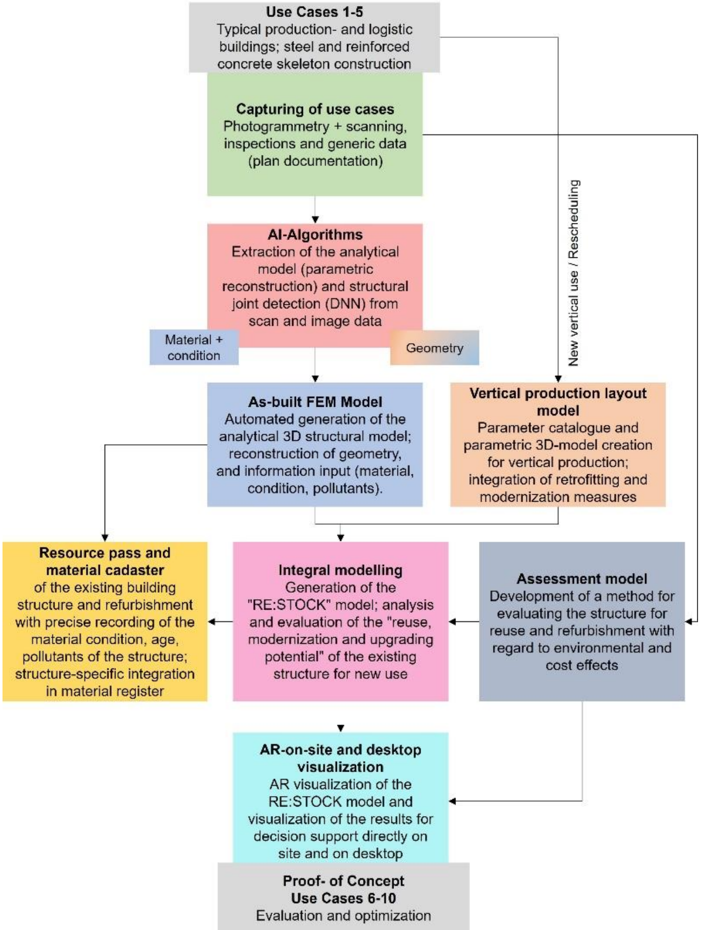

Figure 1: The research design and methodology of RE:STOCK INDUSTRY

Furthermore, vertical production and modernization concepts for integration into structural analysis processes are researched to quickly determine the load-bearing and strengthening capacity of the existing building for new use: By analyzing use cases, best practice, literature and interviews, requirements and processes for vertical production, the dependencies with the supporting structure and modernization concepts for vertical strengthening are defined, documented in a catalog of requirements and transferred into parametric planning rules. Developments from the authors previous research (Reisinger et al., 2022), in which a concept for the integration of 2D horizontal production processes into structural design was developed, serve as the basis for the development of the parametric RE:STOCK model, which couples the as-built FEM model with 3D vertical production concepts.

To integrate circular economy aspects into the analysis of existing structures two methods are being researched: a) Development of a method for evaluating the reuse and retrofitting of load-bearing structures. Clear evaluation criteria for reuse and retrofitting, such as environmental and cost effects, quality, functionality, and technical feasibility, are defined and integrated into existing methods of ecological and economic life cycle analysis in order to take specific reuse requirements into account. The aim is to use the RE:STOCK model to compare the existing structure including retrofitting with demolition and new construction scenarios and to compare their environmental impacts and costs. b) Development of a method to efficiently document the digitized inventory and retrofitting planning in building resource passports and material registers. This is done by analyzing available databases and cadasters and standardizing data and interfaces with the RE:STOCK model. As a result, detailed structural information such as material composition, quantity, load-bearing capacity, condition, year of construction and pollutant content can be efficiently recorded.

Finally, a method for integrating AR technology as a visual decision support tool for planners and clients into the early retrofitting process will be researched. The aim is to visualize the effects of reusing the structure, the vertical strengthening and the ecological and economic evaluation feedback directly on the construction site. The proof-of concept will be conducted on real use cases and validated with experts.

RE:STOCK INDUSTRY framework

The RE:STOCK INDUSTRY framework will integrate all of the aforementioned research developments into a digital platform to guarantee a holistic planning process and decision support tool for early re-use, expansion and retrofitting processes. The framework aids to automatically generate accurate FEM models of the building structure inventory from point clouds and photogrammetry data and document the structure-specific information in resource passports. A computational tool, the RE:STOCK model, will generate re-use plans of the existing structure for vertical upgrades and evaluate them from a circular economy perspective. By linking an AR method to the integral RE:STOCK model, the visualization of possible expansion and reinforcement measures will be displayed directly on site in the existing building.

Figure 2 shows the framework of RE:STOCK Industry and the most relevant developments with the parametric *RE:STOCK Model (6)* as the central part:

1 and 2 - Scan Data to as-built FEM Model: An as-built FEM model will be generated out of received point clouds and photogrammetry data and enriched with the exact geometry and material properties. Optimization-based techniques will be used to reconstruct the main shape of vertical and horizontal structural elements and their parameters (e.g. size, thickness). The elements will be initialized by heuristic search for vertical and horizontal point beams and the parameters of the model will be optimized to fit the scanned point cloud. Deep learning will be used with geometry and image data to classify the joint connections of the structural elements and describe their properties in relation to the connected elements. The neural network will be trained with real and synthetic data from existing use cases and BIMs. The recognized joint connections and status descriptions will be added to the parametric model to enable the structural analysis in the as-built FEM model. The proposed algorithms will significantly accelerate the as-built analysis of skeleton constructions. This model can be used not only for traditional structural analysis but also for cycle-oriented documentation and evaluation of the re-use capability of the structure.

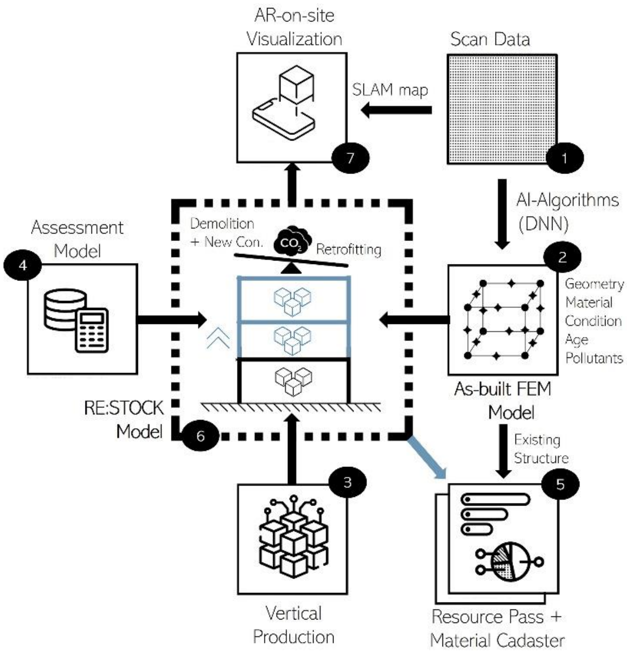

Figure 2: The RE:STOCK INDUSTRY framework

3 - Vertical Production: The goal is to create a 3D-layout generator for vertical production planning. Requirements and processes for vertical production as well as modernization concepts for structural vertical upgrading are defined, documented in a catalog of requirements and transferred into parametric planning rules. Parametric methods from the previous developed 2D production layout generator (Reisinger et al., 2022) are used to develop the vertical 3D layout model. For the integral RE:STOCK model, the as-built FEM model is extended with the vertical production layout model through parametric and generative design methods.

4 and 5 - Assessment Model and Resource Pass + Material Cadaster: The interfaces to existing material registers and resource passports are examined so that relevant structural information from the RE:STOCK model can be transferred and recorded in material passports and building cadasters. An ecological-economic method will be developed to evaluate the reusability of the structure in terms of retrofitting vs. demolition/new construction. For this purpose, qualitative and quantitative sustainability principles (life cycle assessment, circular construction, adaptability, preservation of existing buildings, CO2 storage capacity, reusable structure, legal and technical feasibility) are defined. The method integrates ecological and economic life cycle analyses to determine the gray energy of the existing building, CO_2 savings through structural preservation, and the evaluation of retrofitting measures to promote reuse instead of demolition/new construction. Argumentation aids and proposed solutions. such as CO_2 pricing and climate impact costs, will be included, so that not primarily the option with the lowest costs is chosen.

7 - AR-on-site Visualization: For this purpose, the RE:STOCK model will be integrated into a specially developed situated AR application. On site, the model will be aligned with the real building by locally comparing the initial point cloud scan - from which the RE:STOCK model was generated - with the sparse point cloud provided by the AR device. The registration between original scanned point cloud and the point cloud provided by the AR device will be achieved using iterative closest point algorithm (Besl and McKay, 1992). Once the RE:STOCK model has been aligned with the real building, the AR view is correctly updated in perspective as the user walks around using Simultaneous Localization and Mapping (SLAM).

Conclusion

The presented digital framework for the circular reuse of existing industrial building structures for vertical production addresses industrial companies, builders and architects, production and structural engineers or life cycle management stakeholders. By digitally capturing the structural stock and assessing and visualizing the retrofit potential using the AR visualization approach, stakeholders should be motivated to reuse the building stock as it is, increase its value through vertical retrofit measures and extend the life of their buildings. The research promotes vertical production and logistic processes, optimizes operations and resource utilization, and maximizes business efficiency and productivity. The automation and standardization of the data basis for the structural stock of industrial buildings is essential for the long-term optimization and permanent monitoring of building waste management, whereby the central linking and provision of structural data with building geometry information plays a key role for numerous other fields of research and applications. The methods to be developed aim to avoid manual, error-prone processes in inventory recording and modeling as well as lengthy iterations in interdisciplinary planning processes. Integral analysis and evaluation can be expected to lower the inhibition threshold for stakeholders to make changes and investments in their buildings and production facilities. The methods will enable sustainable structural modernization under vertical use and lead to an extension of the building's service life and avoidance of soil sealing. Land recycling enables the resettlement and return of production companies from surrounding areas and abroad. By upgrading populated areas, economic added value is achieved, and social structures and workplace situations are expected to be improved. The methods should reduce the ecological impact by up to 50% and waste volumes by up to 70%, this will be examined in a case-study of real industrial buildings.

In the context of the presented study several limitations need attention in future scientific research. The framework's applicability is currently focused on the specific building type of industrial skeleton construction and the geographic region of Austria, necessitating further research to evaluate its generalizability across diverse contexts and construction practices. Furthermore, the framework relies heavily on emerging technologies such as AI, AR, and novel structural analysis methods, whose interoperability and integration into existing systems need to be fully explored. The quality of input data—scanning, photogrammetry, material properties, and structural details—directly influences the framework's output accuracy, highlighting the need for rigorous validation and sensitivity analyses in future. Economic viability, encompassing lifecycle cost analysis need to consider dynamic market conditions, which poses to be challenging. Regulatory, legal, and policy barriers present additional impediments to practical adoption, which highlights the importance of in-depth analysis and close work with municipalities to identify ways for regulatory reform and policy advocacy. A holistic environmental impact assessment extending beyond the CO_2 emissions and waste reduction of the structural system but to include environmental impacts of the whole building systems as facades and built in components will be crucial for understanding the full environmental footprint. The project solely focuses on the resource efficiency of the structure to avoid CO_2-equivalent emissions; however, energy efficiency is not addressed. Lastly, the technological and methodological advancements proposed necessitate a change in traditional practices among stakeholders in the planning and construction industry. The adoption of such new technologies and methods is influenced by behavioral factors, including perceived utility, ease of use, and cultural aspects and will be respected in user studies with practitioners and students on real use-cases.

With a focus on industrial and logistic buildings, the results of this project will be also beneficial for numerous planning areas that require (automated) recording and evaluation of existing buildings for new use in long term.

Acknowledgments

The authors would like to acknowledge the support by the Austrian funding institution FFG (Österreichische Forschungsförderungsgesellschaft) for the research project "RE:STOCK INDUSTRY" within the "Kreislaufwirtschaft" (3rd call for tenders) programme. We would particularly like to thank our project partners.

AUTOMATED ON-SITE HAZARD IDENTIFICATION USING DIGITAL AND THERMAL IMAGERY

Mohamad F. Abbas[1], Bahaa Eddine Mneymneh[1], and Hiam Khoury[1]
[1]American University of Beirut, Beirut, Lebanon

Abstract

A major component of construction safety management processes entails identifying potentially on-site hazardous areas. However, traditional methods are manual, labor-intensive, and time-consuming. In an attempt to automate hazard identification, researchers have used digital imagery and computer vision at large but failed to explore thermal imaging analysis. As such, this paper introduces an automated vision-based hazard identification approach using both digital and thermal imagery. Several experiments were conducted and results highlighted the effectiveness of analyzing both digital and thermal images to reduce false positive detections and rapidly identify on-site hazardous areas.

Introduction

The construction sector has always been responsible for a high rate of fatal injuries. As such, regular safety inspections are of paramount importance and help management ensure that safe work practices are being maintained on jobsites. However, current inspection methods still rely on safety officers patrolling the site and identifying unsafe conditions, or on the workers' capabilities in identifying hazards. The former method is manual, labor-intensive, and time-consuming, while the latter approach is considered inadequate and not very dependable. Therefore, there is a need to automate construction safety inspections. Initial research efforts have targeted automating the safety inspection processes and monitoring the site conditions and construction personnel using digital imagery and computer vision (Yang et al. 2010, Brilakis et al. 2011, Park and Brilakis 2012). Other studies have focused on actively detecting PPE-wearing from digital images and videos using computer vision (Shrestha *et al.* 2015, Park et al. 2015, Abbas et al. 2016, Mneymneh et al. 2017, Mneymneh et al. 2018, Mneymneh et al. 2019, Nath et al. 2020, Yang et al. 2020). In a nutshell, extensive work has been done in the past years targeted at automating safety inspection processes while building on recent developments in the field of computer vision (Guo et al. 2021, Maali et al. 2024).

In an attempt to further automate safety inspection processes, several other research efforts evaluated the applicability of Unmanned Aerial Vehicles (UAV) or camera-equipped drones in construction safety (Gheisari et al., 2014, Abbas et al., 2016, Mneymneh et al. 2016, Melo et al. 2017, Kim et al. 2019, Martinez el el. 2020, Maali et al. 2024). Results revealed the importance of adopting drones in safety applications as they can provide safety personnel with real-time visual access to jobsites. However, no prior work has analyzed thermal imagery or coupled it with digital imagery to identify construction hazardous areas. Therefore, the objective of this paper is to enhance construction safety inspections by developing an automated vision-based hazardous identification system using both digital and thermal imagery. As such, real-time images and videos of indoor construction sites are captured using digital and thermal camera-equipped drones or UAVs.

Methodology

The hazardous situations considered in this study were extracted from a previously published survey conducted with construction personnel (Abbas et al. 2018). It was found that the top ranked hazardous situations are unprotected openings, fire, steel grinding, and steel welding. Only fire, steel grinding, and steel welding were considered in this study as the exact location of openings can be obtained from the as-planned drawings. It is worth noting that the routine activities of steel grinding and welding can be safely conducted. However, they may pose risks if adequate precautions are not observed and appropriate protective gear is not utilized. Hence, detecting these activities serves as the initial step towards implementing necessary health and safety measures.

Given the nature of the aforementioned three hazardous scenarios, it was decided to opt for digital imagery analysis using object detection and color-based segmentation as well as thermal imagery analysis. It is worth noting that the latest deep learning vision algorithms commonly used for object detection and segmentation (e.g. Faster RCNN, Mask RCNN, YOLO, etc.) were not adopted in this study, as they require voluminous training data and huge computational power. In this case, simplicity, interpretability, and computational efficiency were prioritized. As such, the chosen vision tools applied on digital imagery were the cascade object detector and RGB-CIE color-based segmentation. Besides, these can be complemented by a thermal imaging analysis to enhance the overall results.

A cascade object detector based on HOG features was used to detect objects having an appearance that does not change significantly (Alionte and Lazar 2015). This technique involves training the detector by creating a database containing images of relevant objects from several angles and views. The detector then uses a cascade classifier to decide whether the window sliding over a certain image contains the object of interest. In this research work, the cascade object detector is used to detect hazardous areas displaying repeating patterns.

On the other hand, the potential hazardous scenarios of fire, grinding, and welding have particular colors that differentiate them from the background. For this reason, color-based image segmentation was used to detect the presence of these hazards. The segmentation was performed using both RGB and CIE LAB color spaces. The acceptable interval of color values that represent each hazard was obtained following several trials and experiments. In other words, hazardous pixels were extracted from real positive images, and their color ranges were identified. If the number of detected hazardous pixels in any image is greater than a significant threshold specified according to the image resolution, then the developed software reveals a hazardous situation detection. This procedure was applied to fire (orange), steel grinding (bright yellow), and to steel welding (bright white).

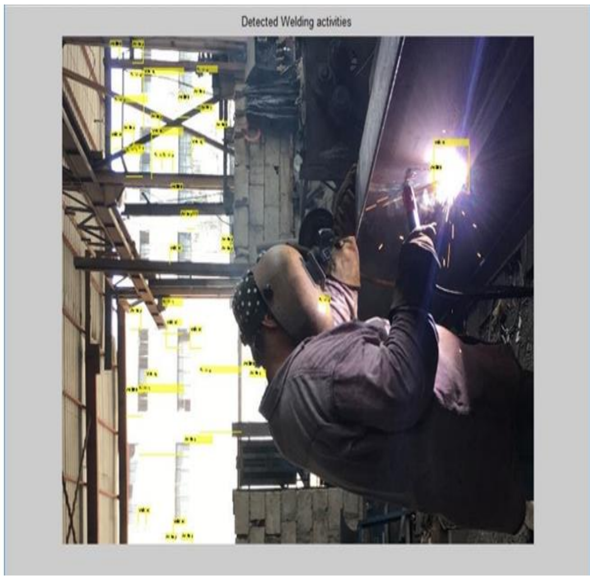
In addition, all considered hazardous scenarios are known to generate high heat when occurring. As such, analysis of thermal images captured by a heat camera was deemed necessary in order to confirm the presence and the detection of high heat hazardous scenarios. In general, heat cameras or thermal imaging cameras are devices that usually detect infrared radiation above 9,000 nanometers and create images of that radiation.

Experiments and Results

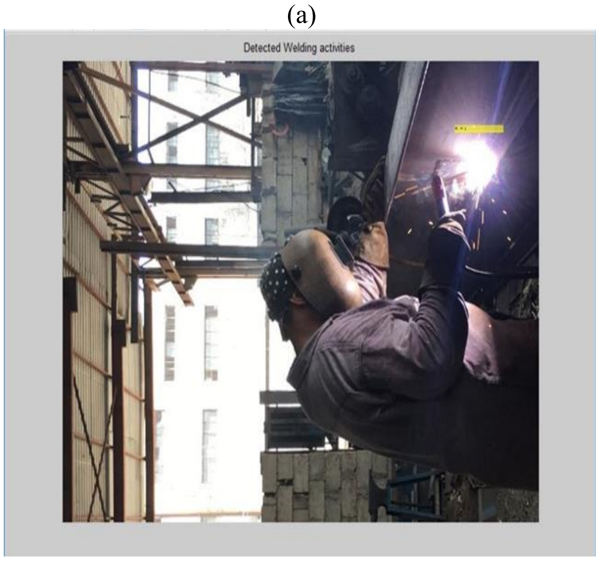
In order to test and demonstrate the feasibility and performance of the three proposed methods, numerous experiments were conducted in several indoor environments under different scenarios. In this case, standard resolution images and videos (640x480p) were captured from different construction sites and construction-like environments using digital and thermal camera-equipped drones.

The first experiment involved training a cascade object detector for the welding activity. The cascade detector is designed to detect objects according mainly to the shape, features, and the contrast difference between the object and its background. Generally, welding is characterized by an approximately circular shape and a white color but may be captured by cameras in other random shapes due to reflectance. When training the detector, it is important to include challenging negative images having shapes similar to welding, including bright windows and light reflections, to reduce the chance of false positive detections. To assess the quality of training images, two detectors were trained, whereby the first was trained with a random set containing non-challenging negative images, and the second was trained with a set of negative images captured from real construction sites and locations where welding activities may occur. Both detectors were trained with a number of stages equal to 7 and a false alarm rate equal to 0.05. Results highlighted the importance of carefully selecting the negative instances to avoid false positive detections, as tests conducted using the first detector revealed a large number of false detections captured in the background (Figure 1a). False negative detections were greatly reduced when using the second detector, as shown in Figure 1b.

One major limitation of the proposed algorithm is that, in case of the presence of objects that reflect sunlight, it may detect this reflection as a welding activity due to the resemblance of shape and shining light between the two. Furthermore, fire and steel grinding have various irregular shapes while the cascade object detector works best when used to detect objects with fixed shapes. Therefore, in order to address the aforementioned limitations, another vision tool was tested which is color-based segmentation.



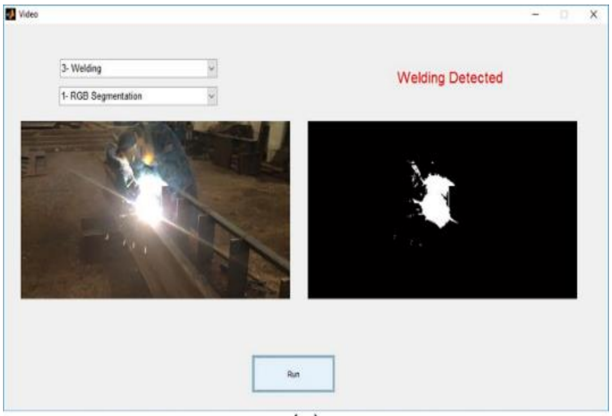
(a)



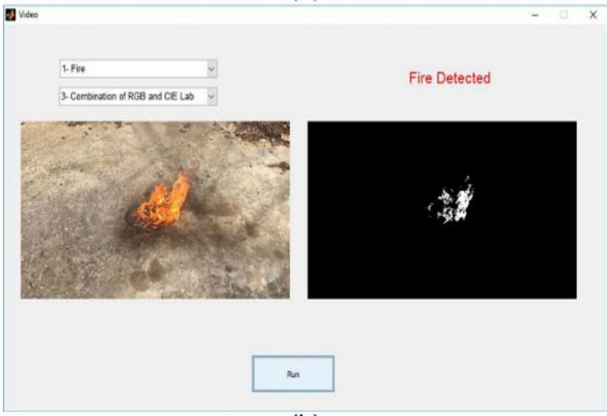
(b)

Figure 1: Cascade object detection examples: (a) welding detection using random training images and (b) welding detection using challenging training images

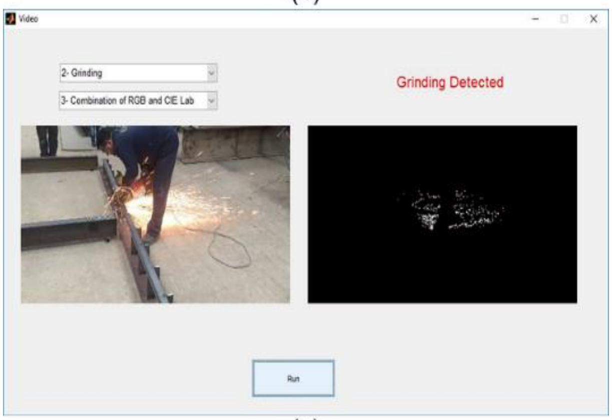
Color-based image segmentation was implemented using the RGB color space, CIE Lab color space, and a combination of both. In this case, the acceptable color ranges need to be pre-defined and calibrated according to the used digital camera for all three color segmentation tools and while considering the three hazardous situations. To test the proposed algorithms, a video-based graphical user interface was implemented whereby the user is first prompted to choose among the three hazardous scenarios then select a particular color segmentation algorithm to test. Figure 2 displays examples of true positive detections for all hazardous cases.



(a)



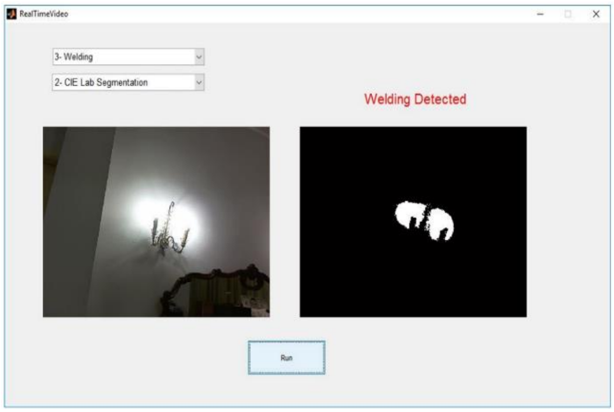
(b)



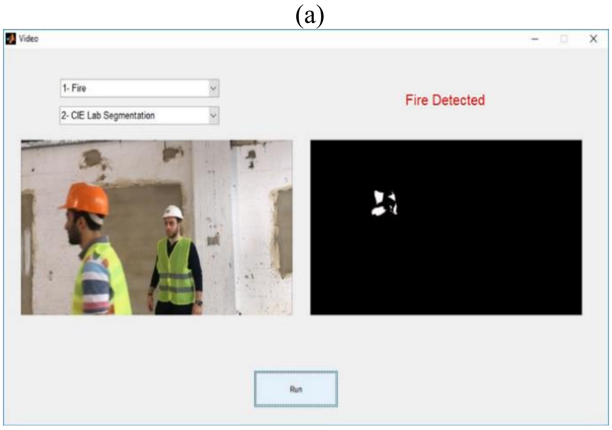
(c)

Figure 2: True positive detections using color-based segmentation: (a) welding, (b) fire, and (c) grinding

Although color-based segmentation was tested on negative images and displayed convenient true negative detections, false positive detections may occur when an object satisfying the algorithm conditions exists. For example, objects displaying a bright white color may be mistakenly classified as welding (Figure 3a) and objects displaying a bright orange color can be wrongly classified as fire (Figure 3b). The same is true for grinding whereby objects displaying a bright yellow color are falsely detected as grinding.



(a)



(b)

Figure 3: Examples of false positive detections using color-based segmentation: (a) welding and (b) fire

One way to enhance the performance of this tool is to benefit from the variation of the shape of the hazardous activities from one frame to another. The intersection of positive pixels in two consecutive frames can be obtained by multiplying their binary matrices. If the ratio of intersected positive pixels over the minimum number of detected positive pixels in both frames is less than a reasonable value, then the change of shape is considered significant and a positive detection occurs. This value was obtained following several trials performed on fire, welding, and grinding videos, and was set equal to 0.4. Experiments conducted highlighted the ability of this frames intersection method in accurately detecting hazardous situations while reducing the occurrence of false positive scenarios (Figures 4, 5, and 6).

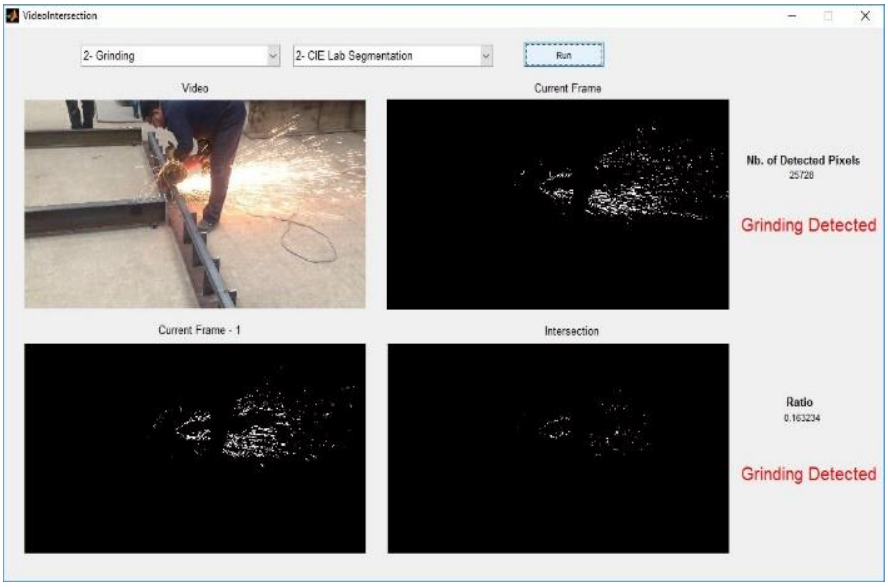


Figure 4: True positive detection of grinding using the frames intersection algorithm

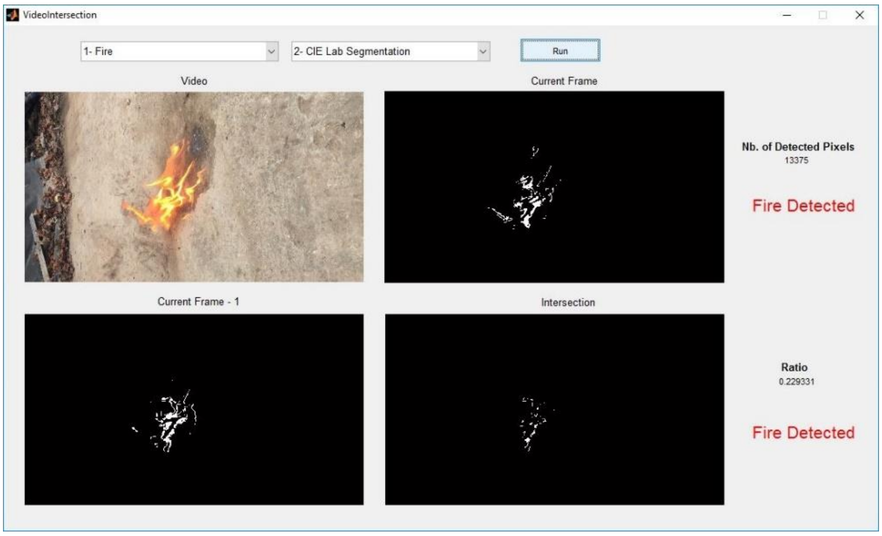

Figure 5: True positive detection of fire using the frames intersection algorithm

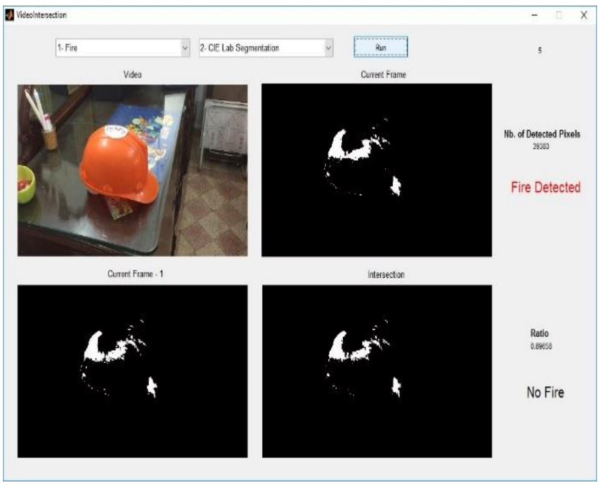

Figure 6: True negative detection of fire using the frames intersection algorithm

Accordingly, this frames intersection tool can potentially reduce false detections resulting from static objects that may have similar color properties of fire (i.e. orange hardhat placed on ground, signs and cones), and are no longer detected as fire since they do not vary remarkably from one frame to another (Figure 6). However, this tool can exhibit some limitations whenever an object having color properties that match one of the pre-defined hazardous situations is actually moving on a construction site (e.g. mobile construction worker wearing an orange hardhat). In this case, the ratio of intersection pixels between two consecutive frames might be lower than the threshold and a false detection may then occur. A false detection can also occur if the camera itself was moving. It was thereby decided to opt for thermal imaging analysis to reduce false positive detections whenever a high heat scenario is not witnessed.

As a matter of fact, the hazardous scenarios of fire, grinding, and welding are known to generate high heat when occurring. Therefore, the analysis of images captured by a thermal imaging camera may then be applied to confirm the presence and detection of high heat hazardous scenarios. Accordingly, several non-processed 14-bit TIFF still images of fire, grinding, and welding scenarios as well as random negative images were captured from several construction sites using the Flir Vue Pro heat camera. These images were then assessed using the software 'Flir ResearchIR' and processed and analyzed later on in order to detect whether the hazardous or high heat scenarios are indeed occurring or not. It was found that the maximum heat values for negative instances did not exceed a value of 9,200 nm (Figure 7), while images containing the three hazardous scenarios (i.e. fire, grinding and welding) displayed high heat values ranging between 12,000 and 16,000 nm (Figure 8).

Figure 7: Heat values for negative images

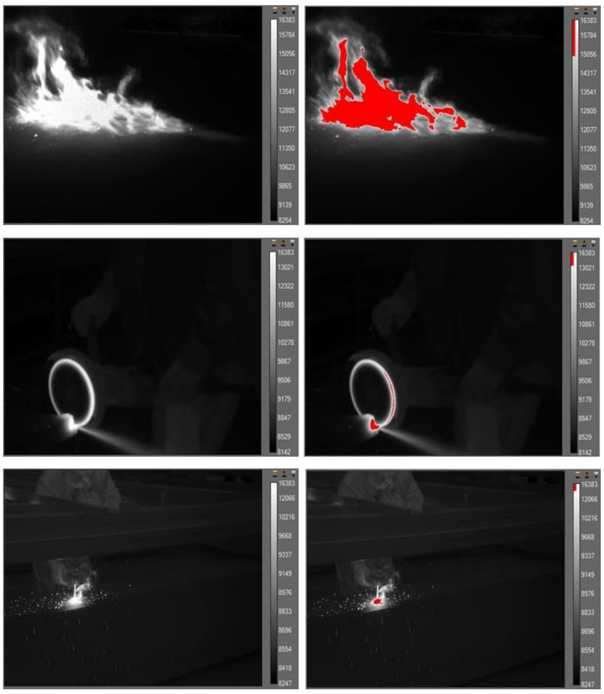

Figure 8: Heat values for positive images

Figure 9 displays an example of a fire thermal image where a high heat was detected.

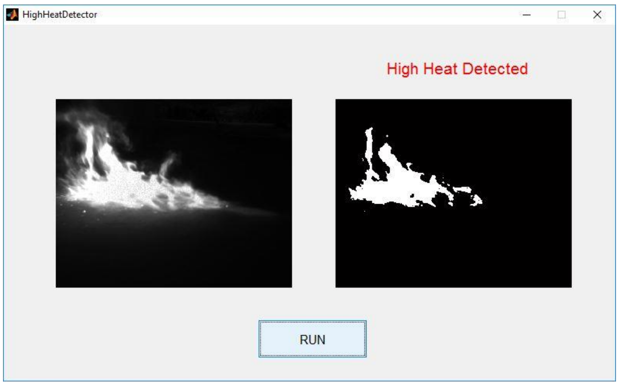

Figure 9: Detection of high heat using thermal imaging

The results in Figures 8 and 9 further highlight the potential of thermal imaging in recognizing high heat-related scenarios on jobsites and can, as such, complement the object detection or color-based segmentation algorithms and reduce false positive detections. For instance, in the case of the indoor light in Figure 3a, only a thermal analysis can confirm a non-welding case since the light with its circular shape and color properties can be mistakenly detected as welding when using the cascade object detector and color segmentation respectively. Similarly, orange objects found on construction sites (e.g. hardhat, cone, sign, etc.) may satisfy the color segmentation algorithm's conditions and can be falsely detected as fire if exposed to certain lighting situations. In this case, capturing and analyzing thermal images of these objects can greatly deny the presence of a high heat scenario and, in turn, eliminate the false positive detection resulting from the color segmentation tool. Figure 10 shows an example of a thermal image captured from a construction site that contains an orange hardhat and displays, as a result, no high heat.

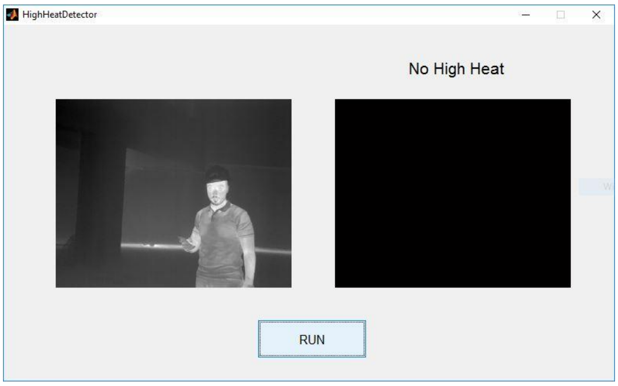

Figure 10: No detection of high heat using thermal imaging

It is worth noting that not only thermal imaging analysis is capable of complementing the two other vision tools but these latter tools can also complement the thermal imaging analysis, as it might be hard to differentiate among the three hazardous scenarios when similar heat values are registered under certain circumstances. Therefore, all three presented tools can complement each other to accurately identify and visualize each of the three hazardous scenarios. Table 1 summarizes the best use for each of the investigated methods for the hazardous scenarios.

Table 1: Summary of Hazardous situations and investigated detection methods

Hazard	Cascade Object Detector	Color Segmentation	Heat Analysis
Welding	Detection	Detection	Reduce False Positive Detections
Grinding	Not Analyzed	Detection	Reduce False Positive Detections
Fire	Not Analyzed	Detection	Reduce False Positive Detections

Conclusion and Future Work

Construction is one of the most dangerous industries whereby many hazardous tasks and conditions occur, which may pose injuries, risks and fatalities to the construction personnel. Thus, safety inspections must be carried out to maintain a safe construction environment. Many research efforts have targeted automating the safety inspection processes using digital imagery but failed to do so using thermal imagery. Hence, this study presented an automated vision-based hazardous identification system using both digital and thermal imagery. The results, obtained from several experiments conducted on construction sites, highlighted the effectiveness of analyzing both digital and thermal images to reduce false positive detections and rapidly identify on-site hazardous areas, in particular fire, grinding and welding scenarios. More specifically, the cascade object detector worked best with certain shapes. Color-based segmentation using RGB or CIE LAB color spaces, coupled with the proposed frames intersection method proved effective in detecting hazardous situations and reducing the number of negative detections. On the other hand, high heat scenarios were accurately identified using thermal imaging, thereby eliminating false positive detections when using the other vision tools.

Future work aims at enhancing and fully automating hazard identification on construction sites. This will be achieved by: (1) detecting a larger set of potential hazardous scenarios besides the three presented ones, (2) acquiring thereby a larger training data set and resorting to deep learning vision tools for analysis, (3) experimenting further with thermal imaging, (4) adjusting the implemented algorithms to read data from the construction tasks' schedule and accordingly detect the associated risks or possible hazardous scenarios, and (5) rapidly locating workers and alerting them of a nearby hazardous area, activity or scenario.

Data Integration Methods

ADDRESSING THE CONCEPTUAL CHALLENGES IN THE PROCESS OF UPDATING THE GEOMETRY OF DIGITAL TWINS OF BUILT ASSETS

Iryna Osadcha[1], Andrius Jurelionis[1], Vishal Singh[2]
[1]Kaunas University of Technology, Kaunas, Lithuania
[2]Indian Institute of Science, Bangalore, India

Abstract

Maintaining up-to-date Digital Twin information for building or infrastructure assets is critical to its effective use. The virtual model, which reflects the real geometry of an asset, serves as an essential component of the Digital Twin and requires continuous reliability assurance and high fidelity. However, the link between physical structures and their digital counterparts remains under-researched due to the complex nature of construction and the associated technical and conceptual challenges of updating geometric data. This paper aims to identify and systematically analyse these conceptual issues in order to formulate a comprehensive framework that can be applied in practice. Design Science Research (DSR) methodology is used as a basic approach, resulting in the formulation of a theoretical framework. This framework will be further applied to specific case studies to improve the understanding of when, why, and how geometry updates affect the short- and long-term performance of the Digital Twin.

Introduction

The adoption of Digital Twins for buildings is rapidly increasing in the construction industry. Although Digital Twins are primarily used for large and complex structures, advances in data capture and modelling technologies, particularly real-time data collection, are extending the applicability of Digital Twins to a broader range of assets. Regardless of the specific application, the architecture of a Digital Twin is typically complex, involving a physical object, its corresponding virtual model, data capture and processing tools, and a continuous exchange of information between the physical entity and its virtual counterpart (Boje et al., 2020). Ideally, Digital Twin allows the state of a physical object to be tracked and managed based on its virtual model, including real-time monitoring of its condition and prediction of its future states and behaviour based on simulation at different scales and time intervals. To ensure optimal Digital Twin performance, accurate data analysis and simulation results, it is essential that the high fidelity of the Digital Twin is assured and that it contains all the necessary spatial information (Lu et al., 2020). This information does not need to be exhaustive but should be sufficient for specific needs.

Considering the evolution of the Digital Twin concept since 2003, when the vision of applying a digital model of a physical process or object was first proposed, the Digital Twin paradigm was generalised to a cyber-physical system and began to contain a virtual component (Grieves, 2003). As technologies evolved, the complexity and functionality of Digital Twin started to grow, leading to the evolution from a digital model reflecting only a physical object to a digital shadow with unidirectional automatic data flow and further evolution to Digital Twin with bidirectional automatic data flows (Fuller et al., 2020).

To date, several taxonomies describe the maturity level and the analytical or intelligent capacity of Digital Twin (Agrawal et al., 2022). By applying these taxonomies to the Digital Twin of a built asset, it is possible to define general characteristics and requirements for the components of the virtual model. For example, based on a hierarchy proposed by Gartner (Gartner, 2013) and describing different levels of digital analytics capabilities (descriptive, diagnostic, predictive, and prescriptive), at the lowest level (descriptive), building geometry data can be organised as a database or common data environment containing all relevant information such as 2D drawings, images, visualisations, component specifications, etc. starting from the design stage and further accumulated according to the life cycle stages, but without generation a comprehensive 3D model. This method of data organisation is acceptable but inefficient, as it requires extensive human involvement in data analysis and management, and significantly limits the capabilities of Digital Twin in terms of simulation and task automation.

As the level of Digital Twin automation improves, the need for a 3D model increases. However, for some tasks, such as simple visualisation, it may be sufficient to have only 2D data on the building geometry. Simultaneously, considering Digital Twin as a complex of interconnected systems that collect and analyse data on the current state of the building based on information from different sources (building technical systems, structural health monitoring systems, indoor climate control, etc.), a 3D model of the building geometry becomes not only a visualisation, but also a component involved in data analysis, simulation, and prediction. The role of the geometry of a 3D model becomes even more important in the event of a breakdown or emergency, speeding up the process of identifying the location of the problem, its repair, and the analysis of the consequences.

The geometric representation of a building is the basic component of the Digital Twin's virtual counterpart. With a high level of maturity, accuracy, and comprehensive semantic data, it becomes a valuable resource for various applications, including analysis, simulation, and forecasting. At the same time, the challenge of maintaining the geometry of a virtual building model, particularly on a global scale (not just its local elements), remains under-studied. This problem is compounded by the frequent and incorrect interchangeability of BIM and

Digital Twin terminology in the construction industry, often oversimplified to 'as-built' geometry.

Certainly, several factors contribute to the gaps in Digital Twin geometry updating research. First, the geometry of a building is typically complex, including structural and non-structural components, openings, and highly ornate elements. Additionally, in most cases, the geometry of a building remains unchanged for a long period after its construction stage, unless there are major renovations, reconstructions, emergencies affecting the geometry of the building, or the detection of deformations due to external factors. This stability means that changes to building geometry information during the operational phase are rare, reducing the attractiveness of investing in this technology. However, when updates to the geometry become necessary, the costs and technical requirements associated with this process can be significant. In addition, updating geometry is a very case-specific process, depending on the type of building, the stage of the life cycle, the required frequency of updates (regular, periodic, one-off), the source data available (relevance to the BIM model) and the type of data collected (static, dynamic, multi-source, real-time). Consequently, the approach to updating geometry will be customised to meet these specific requirements.

When the geometry update process is considered from a system thinking perspective, it becomes clear that there are conceptual challenges that go beyond the consideration of tools, equipment, and technical methods. These challenges include a deeper understanding of the geometry update process itself, its purpose, timing, and the critical elements of the building involved. It also involves recognising the impact that maintaining the current state of the geometric model has on the overall performance of the Digital Twin. This is particularly important in the context of the rapid development of advanced technologies that enable optimised and enhanced data collection and processing techniques. In this scenario, a technology-driven approach carries inherent risks, where new technology is seen as the driving force, and the challenge is to identify the appropriate problem to address (Agrawal et al., 2022). These risks include the potential disruption of existing processes in the pursuit of optimisation. There is also the possibility that optimisation will remain elusive due to fundamental constraints, resulting in the technology's potential not being fully realised. There are also risks associated with implementation costs, such as time, financial resources, and potential productivity reductions. In this scenario, the process of updating geometry should adopt a problem-solving approach that involves identifying current needs or problems and then finding appropriate technologies to address them. In certain situations, it may also involve aligning both approaches to achieve the desired outcome.

The objective of this study is to develop a comprehensive framework for identifying critical areas, referred to as 'hot spots', within the geometry update process. The framework operates at two levels: the entities that undergo update and the updating process itself. It also includes the main components involved, such as physical and virtual parts, and data. This framework aims to facilitate the analysis of hot spots during the planning phase of the Digital Twin geometry update process, with the ultimate goal of devising a more efficient set of actions. Additionally, the framework is intentionally designed to be sufficiently abstract, ensuring its flexibility and applicability across various real-world scenarios.

Background and context

In addressing the main conceptual challenges of updating the geometry of the Digital Twin, it is essential to consider the complexity of the Digital Twin, not only from a technological perspective but also in terms of conceptual complexity (Singh, 2016). This must include consideration of the diversity, fragmentation, and interdisciplinary nature of the knowledge associated with the Digital Twin. To date, there is no universally accepted definition of a Digital Twin that fits all construction projects. The concept of a Digital Twin covers a wide spectrum, ranging from a basic digital representation of a building to a sophisticated model that incorporates various engineering systems, data inputs, and predictive capabilities (Agrawal et al., 2022). Moreover, due to the complexity of real-world scenarios, often characterised by numerous unknown variables, it is reasonable to expect that a virtual model will never perfectly mirror real-world asset behaviour. To address this, it is important to assess the components of a Digital Twin, including its subcomponents and related requirements, the connection between the physical object and its virtual counterpart, as well as the supporting system that facilitates their interaction. The aim is to identify both functional and non-functional requirements as well as the desired performance metrics. As the subcomponents of the physical and virtual models require different levels of support within the system (such as software, hardware, data traffic protocols, etc.), it is worth identifying in advance generic requirements for their evaluation with further adaptation to the specific needs. The general directions outlined in Figure 1 should be considered independently of specific case applications.

The fuzziness around the concept of a Digital Twin includes various classifications related to its level of maturity, autonomy, adaptability, data and process standardization, cost-effectiveness, and the balance between computational load, execution time, and efficiency. Agrawal et al. (2023) proposed that a Digital Twin can play multiple roles, including an observer (performing tasks such as representation, visualization, description, sensing, etc.), an analyst (performing analysis, monitoring, pattern recognition, interpretation, prediction, etc.), a decision maker (engaged in optimization, simulation, forecasting, planning, etc.), and an action executor (responsible for actuation, communication, control, etc.). However, when it comes to

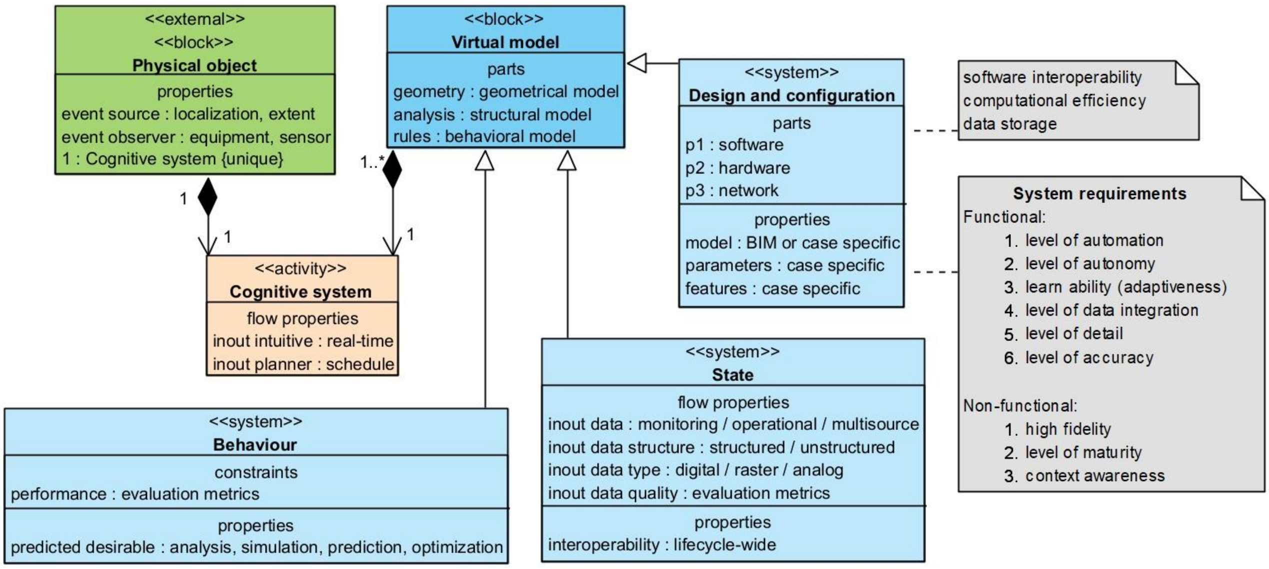

Figure 1: Digital Twin Component Model

deciding whether to update the geometry of the virtual model, it may not be wise to rely entirely on the Digital Twin itself, even though the system may typically operate at the agent level (as a decision-maker or action executor) for other tasks. Nevertheless, the Digital Twin can generate new data through analysis and simulation and serve as a valuable source of information for assessing the need to updating process (Gabor et al., 2016).

In many cases, there is no need for ongoing and constant updates to the geometry of the building model. Changes to the physical structure typically occur in specific, localised areas rather than affecting the whole building. As a result, it is not necessary to remodel the geometry of the entire building regularly, but only to address specific areas (Kaiser et al., 2022). Considering the Digital Twin as the data source in this scenario, changes in the building geometry can be analyzed in two different ways. First, point anomalies can be detected, where individual data instances are identified as deviating from their expected normal state. Second, contextual anomalies can be detected when a data instance is considered anomalous within a specific contextual scenario. In this case, the data instances under consideration could be information obtained from wireless sensor networks (WSNs) responsible for real-time monitoring of the building's condition. These sensors, such as inclinometers, accelerometers, or strain gauges, can detect and signal changes in the structures of the building in real-time. Simultaneously, for this approach to be effective, it is essential to establish the criteria for normal operating conditions that can be derived from historical or simulation data relating to the behaviour of the building over time.

Research Methodology

The Design Science Research (DSR) methodology was chosen as the basic approach for developing the framework (Singh et al., 2020). DSR is designed to methodically generate knowledge about a specific problem and its potential solutions within a research context. Figure 2 illustrates the steps of the methodology and provides a detailed description of the process. These steps include theoretical analysis techniques to identify the problem and define research objectives, followed by iterative design and development of the framework. In addition, the methodology outlines steps for future research efforts aimed at validating the developed approach and assessing its practical applicability.

During the initial phase of the theoretical research, a systematic literature review was conducted with the following objectives (Osadcha et al., 2023):

- analyse the relationship between Digital Twin, BIM, and the building lifecycle, focussing on updating building geometry data.
- examine the prevalent equipment and techniques used to collect, process, and integrate building geometry data.
- explore key areas where the geometry of building models is of significant importance, such as structural health monitoring applications, prefabricated construction, and simulations of building responses to extreme events.

Furthermore, latent semantic analysis was employed to investigate the potential integration of sensing technologies, specifically Radio-Frequency Identification (RFID), as an additional tool for capturing building geometry data in conjunction with conventional techniques such as laser scanning, photogrammetry, and regular sensors. Additionally, practices for maintaining the accuracy of model geometry in other industries and manufacturing sectors were explored. Based on the results of the theoretical research phase, the main conceptual challenge has been identified, and the current state of

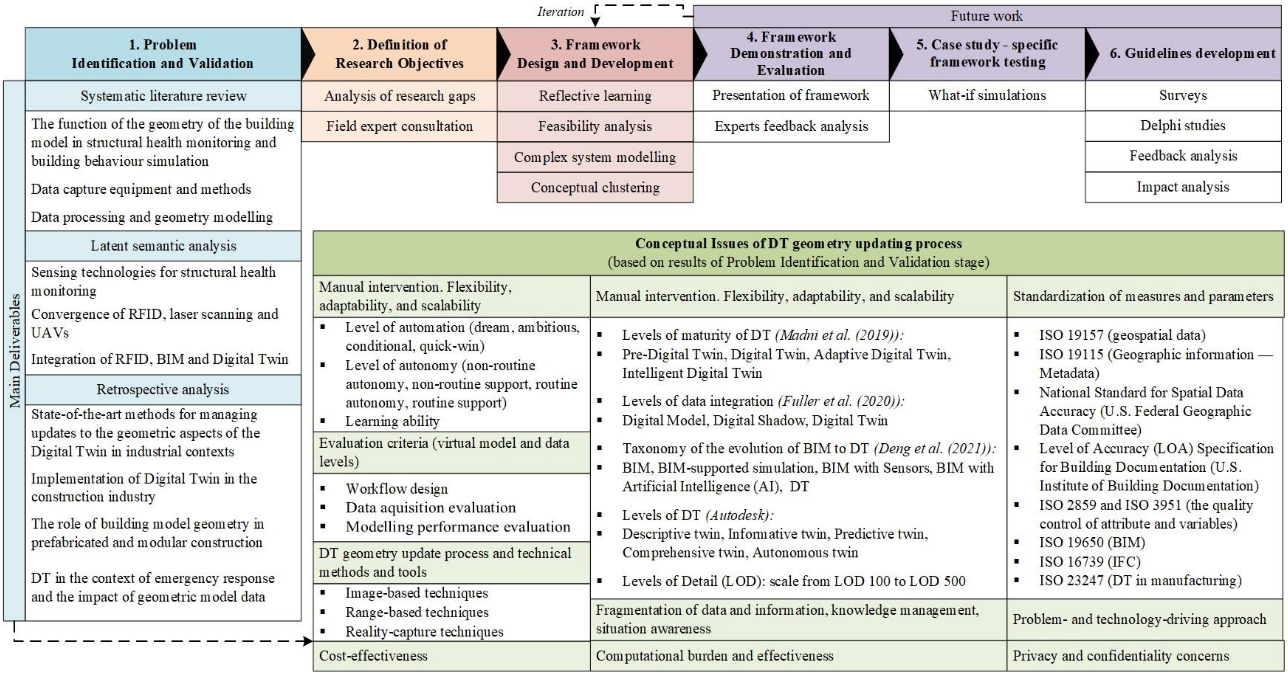

Figure 2: Research methodology stages

knowledge on these issues has been assessed to provide a basis for the development of a framework.

Results and Findings

From the standpoint of modelling cyber-physical systems, the Digital Twin of a building is a scientific model, i.e. it describes and reflects the behaviour of an existing physical object, as opposed to an engineering model, which defines what the behaviour of a physical object should be once it has been created (Lee, 2018). It is crucial to highlight that models are unable to comprehensively represent all of the properties and characteristics of complex physical objects. Therefore, the list of properties of interest must be established beforehand and assumptions about the behaviour of the model should be made. A scientific model is considered complete when it encompasses all of the properties of interest of the physical object; i.e., what is true of the physical object is also true of the model. Using this logical framework for the Digital Twin of a building, we solely focus on the virtual component of the model, particularly its geometric aspect. This means that all the geometric properties of the building should be reflected in its virtual model. To achieve this, the geometrical imperfections of the model should be reduced to a tolerable point so that the model can reflect the physical object as fully as possible while maintaining an acceptable level of computational burden. Considering that we are not taking into account the particular Digital Twin at this stage, the levels used to describe the geometric model should be sufficiently abstract to cover as many variables as possible. In this stage, the aspects related to the updating of the geometry of a virtual model are examined from two perspectives: the entity level, which deals directly with the geometric model, its sub-components and functions, and the process level, which addresses the procedures related to its updating. It is worth noting that this approach focusses only on the geometric part of the Digital Twin and its subcomponents, as well as the process of updating and maintaining the current state of geometrical data, without reference to the dependencies between the geometry of the virtual model and other Digital Twin components, data, outcomes, or services. This allows narrowing the scope of the problems to be considered and generalising these problems at the level of geometric information only, since the other components of the Digital Twin and their interaction with the geometric model can be diverse and specific to each individual building asset. Furthermore, it is advisable to extend this approach to the levels of interaction between the geometric model of the building, its data and other components of the Digital Twin, and to verify the performance of the Digital Twin as a function of the faithful geometric model.

Digital Twin geometry update at the entity level

At the entity level, the main components of the geometric model are defined, including its geometric and semantic information, as well as the relationships between these components (e.g., Figure 3). Consequently, the components of the physical building can be represented as basic geometric shapes, complex geometric shapes, or higher-order primitives, depending on the scale of the updating and the geometric parameters of the building.

Constructive Solid Geometry (CSG) and Boundary Representation (B-rep) are the primary methods used for geometric modelling. CSG is an appropriate choice when localised geometry updates are required and when the shape of the physical object is relatively simple, i.e., it can

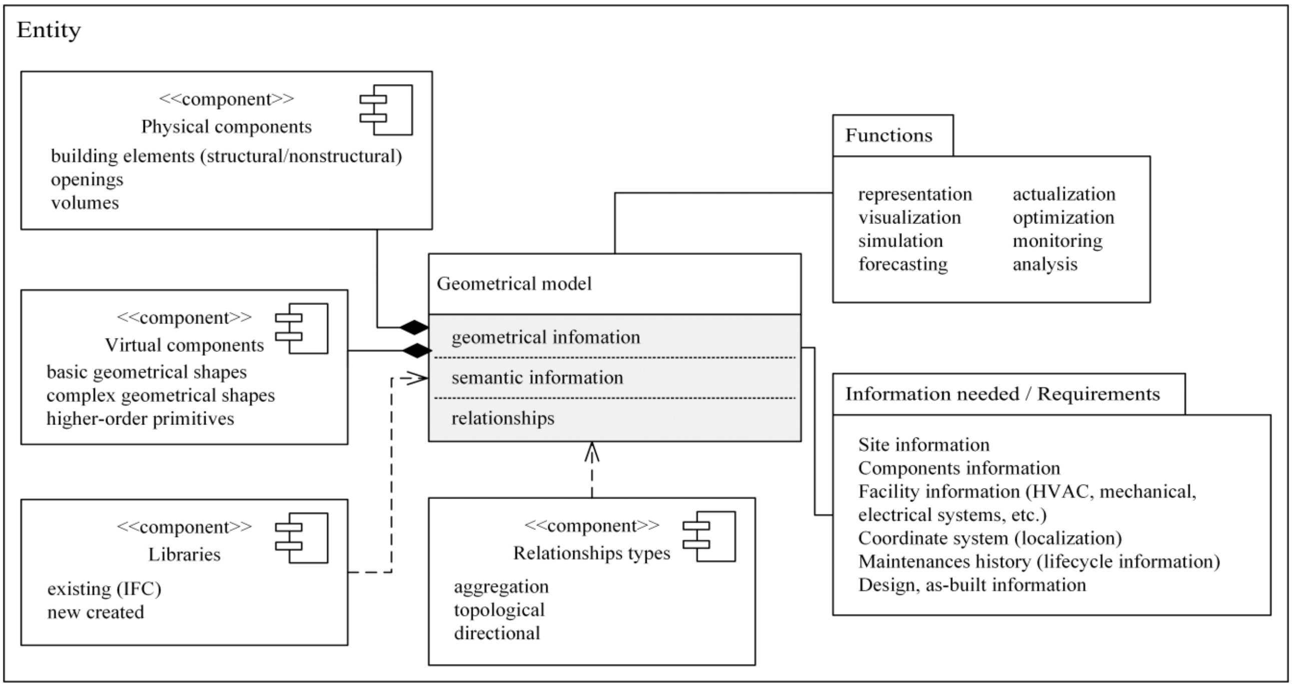

Figure 3: Geometry update process at entity level

be described using basic geometric primitives. Conversely, B-rep is a better solution for describing free-form or complex geometry. Unlike CSG, B-rep is a surface-based method that uses planar and curved surfaces to represent physical objects, making it more suitable for modelling complex architectural geometry. Although this approach is more accurate, it requires more computing power.

Semantic information in a virtual model should accurately capture the attributes associated with geometric shapes. In many cases, these attributes are determined using the Industry Foundation Classes (IFC) scheme (Masood et al., 2020). For geometric entities not covered by the IFC, it is possible to develop custom libraries or use alternative classifiers such as Unified construction classification systems (UniClass) or Construction Classification systems (OmniClass). In most cases, the BIM model serves as the basis for Digital Twin which provides support for applying IFC schema. At the same time, BIM is by nature object-oriented, and consequently, the relationships between objects are predominantly formed through parametric modeling. Non-parametric modeling techniques, such as triangular meshes, can be used as complementary tools at certain stages of the update process, particularly during point cloud processing.

Digital Twin geometry update at the process level

Figure 4 shows the main components and stages involved in the process of updating the geometry of a Digital Twin. Currently, there is no ready-to-use method for automatically updating the geometry of a Digital Twin. Although some aspects of this process can be partially automated, it remains overall complex and heavily relies on manual intervention. Building geometry data collection techniques can be categorised as either contact or non-contact. Contact techniques involve direct measurements using sensors, measuring tapes, or similar equipment. Non-contact methods include image-based techniques such as photogrammetry or videogrammetry using UAVs, range-based techniques such as laser scanning or laser measuring, and geodetic measurements using total stations, theodolites, levels, and the Global Positioning System (GPS). To achieve comprehensive coverage of building geometry data, a combination of these techniques is often necessary. To date, laser scanning and photogrammetry are the most widely used technologies, with other techniques typically serving as complementary approaches.

The data collected for updating geometry is typically in the form of a point cloud, except for WSNs and data from traditional measurement equipment. As a result, there are many techniques for the segmentation and classification of point clouds, including the most used methods such as Random Sample Consensus (RANSAC) and region-growing techniques. Point cloud segmentation and classification have traditionally relied on manual or semi-automated methods. However, there is a growing trend toward the adoption of deep learning-based approaches to automate the detection and classification of objects within point clouds, as well as the use of RFID tags to facilitate the identification of building elements within raw data.

Although deep learning methods have not yet achieved high levels of performance on large point clouds, especially compared to convolutional neural networks (CNNs) designed for image processing and applicable to photogrammetry data, there is potential for improvement. The challenges arise from limited training data and labelled datasets. However, by using synthetic data and adopting semisupervised learning architectures, these methods are likely to advance soon. In the context of

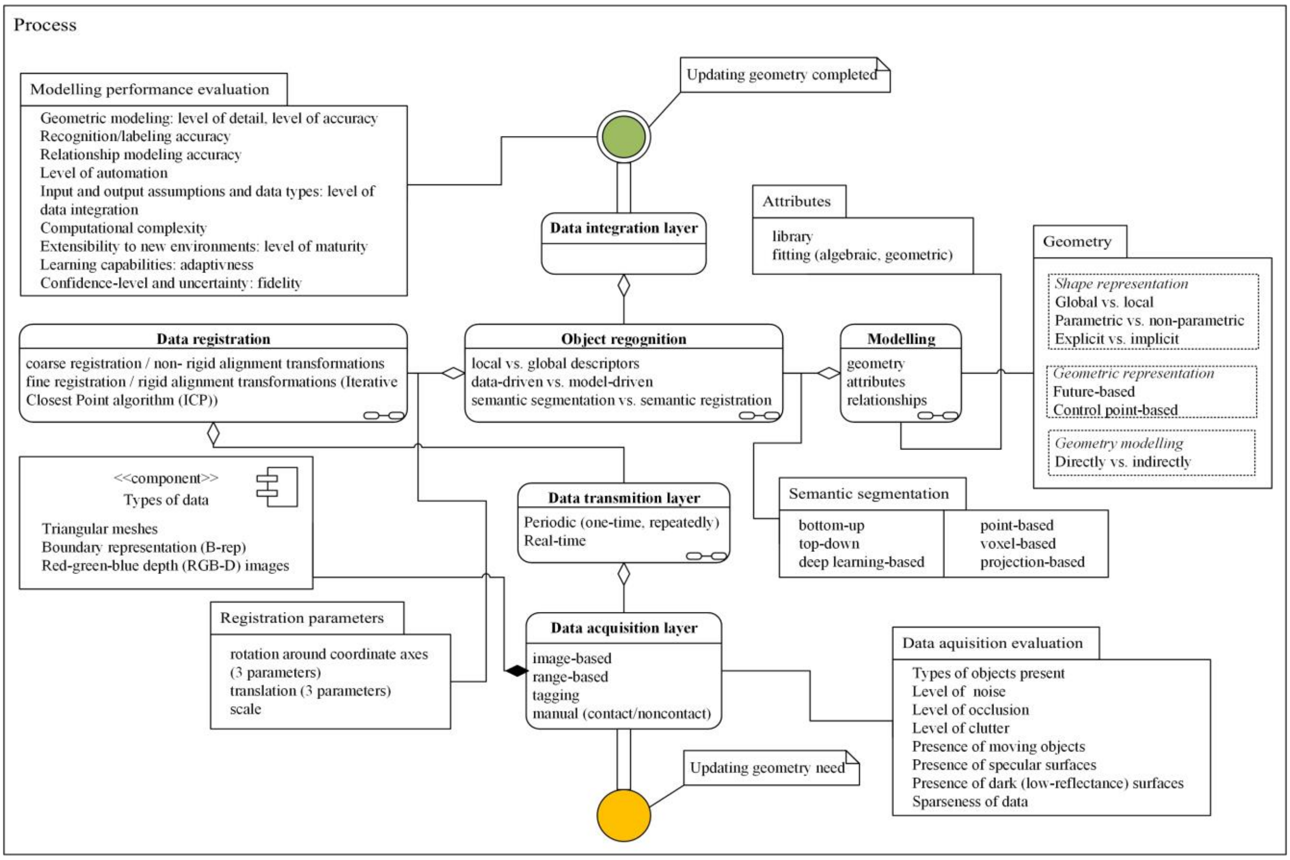

Figure 4: Process-level building geometry update

updating geometry, it is important to acknowledge that existing data processing methods are evolving rapidly, particularly with the increasing prevalence of deep learning techniques. This evolution will lead to greater automation in the short term, even for real-time data scenarios. Therefore, during the framework design the focus was shifted away from specific current technical methods and moved to the broader aspects of the process and the underlying patterns.

To develop a framework for updating the geometry of a Digital Twin several aspects were considered. This includes technical and conceptual aspects of the process, extending to the level of component entities and data (Hribernik et al., 2021). Based on theoretical research outcomes, a comprehensive roadmap for updating the geometry of a Digital Twin has been developed (Figure 5). This roadmap addresses critical research questions, including the reasons for updating, the timing of updates, and the methods involved in the updating process. It also involves identifying the current state-of-the-art, distinguishing between problems and technology-driven approaches, recognising potential knowledge gaps and associated challenges, and establishing a future research objective within this context.

Discussion and Future Work

When dealing with a complex cyber-physical system such as a building and its Digital Twin, predicting the system's behaviour when one of its components is modified can be challenging. Therefore, it is essential to assess the potential impact of changes on overall performance. These changes can occur at several levels:

1. Physical level:
   - Changes in the physical geometry of the building that are not reflected in the Digital Twin.
   - Discrepancies in the geometry of the Digital Twin, including noise, redundancy, and temporal elements, are not presented in the actual building.
2. Digital Twin data level:
   - Changes (systematic errors) in WSNs or other types of data.
   - Changes in computational capabilities from the hardware perspective.
3. Digital Twin virtual model level:
   - Immediate response: real-time updates of semantic information based on real-time data.
   - Planned response: scheduled update geometric information using 3D data capture techniques.
   - Validation: assessing how changes to the model's geometry affect other Digital Twin components, such as potential collisions with other systems (HVAC, electrical, plumbing, etc.).

Furthermore, when considering the process of updating geometry from a more systematic perspective, it is important to recognise that certain solutions aimed at maintaining data integrity may require significant

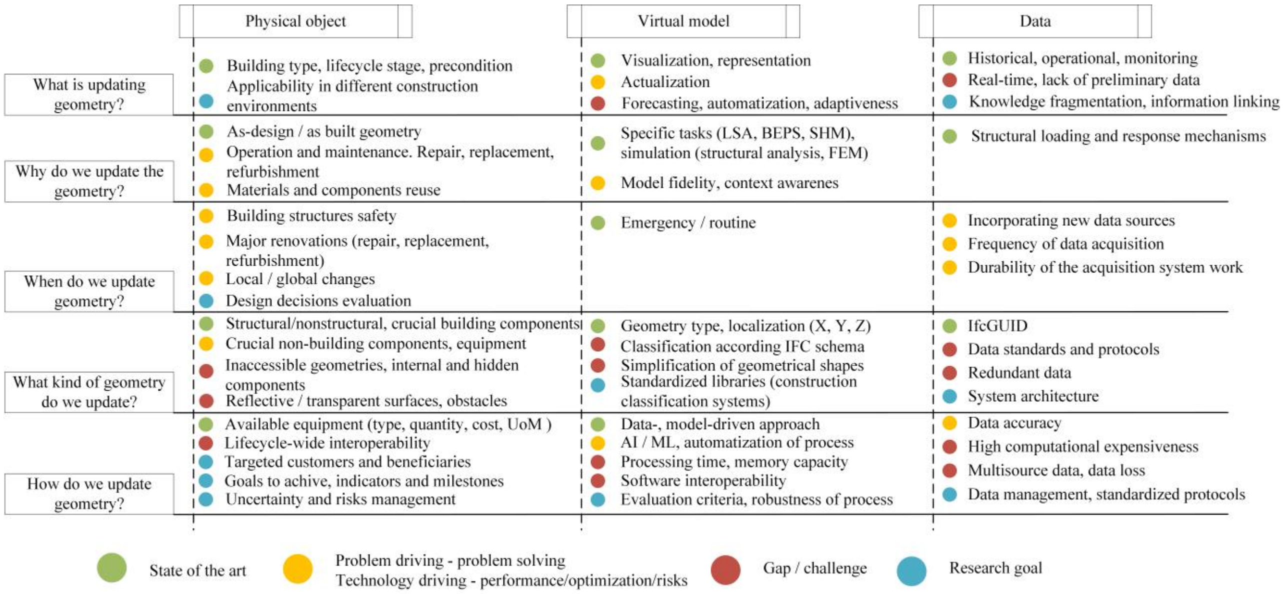

Figure 5: The roadmap for the process of updating the geometry of the Digital Twin and future research directions

investment in terms of cost, time, and effort. In other words, why do we update the geometry and what is the cost of this process in terms of benefits and risks? This requires a methodical approach to the implementation and execution of these solutions (Singh, 2016). For example, some cases may require periodic updates of geometry according to a predetermined schedule (buildings under environmental or man-made influences, unique structures (supertall, asymmetric, free-form buildings, heritage objects, etc.)). On the other hand, there are situations where a one-off effort is sufficient, such as updating the geometry in response to unexpected events that affect the physical structure. Moreover, it is crucial to acknowledge that certain decisions or actions may be irreversible and have both positive and negative effects on system performance. In such cases, alternative scenarios, including the consequences of not updating the geometry at that time, need to be considered. Developing a robust risk management system, such as a data integrity backup solution, can also be a valuable strategy in these scenarios (Reinbold et al., 2022).

Another aspect that deserves attention is the conceptualisation of the Digital Twin not as a static entity, but rather as a dynamic collection of interconnected systems that are continuously evolving. Typically, a combination of approaches is used, including both system- or model-based methods and data-driven approaches (Singh et al., 2020). This integration of approaches involves using knowledge from the original model, its constituent parts, and their technical specifications (e.g., building engineering systems specifications) and operational data generated throughout the lifecycle of the building. In this context, it is crucial to analyse the impact of planned interventions, such as the integration of new geometrical data, to prevent the disruption of existing processes and non-value-added activities that may result from a lack of awareness of the current situation or poor planning. To address these challenges, based on the analysis of the hotspots outlined in the roadmap, critical areas that require focused attention for further research can be summarised as follows:

- Identification of key scenarios for implementing the geometry update process.
- Investigation of the evolution of Digital Twin throughout the building life span and the role of influencing the geometry of the virtual model during this process.
- Addressing data interoperability issues both at the software level and in the broader context of lifecycle-wide interoperability of building information.

Conclusions

The concept of a Digital Twin is constantly evolving, and its role in the construction industry will grow significantly in the coming years. Advances in technology and the need to improve sustainability in construction will drive further digitisation. Maintaining the accuracy of a Digital Twin's geometry is a critical aspect of this evolution. It serves not only as a visual representation of a building but also as a valuable source of information for various tasks such as Building Energy Performance Simulation (BEPS) and Life Cycle Assessment (LSA). These types of analysis rely heavily on building geometry data. Without established frameworks or systematic solutions, the process can become intuitive and rely on subjective judgment. An incomplete evaluation of this process can result in missed opportunities to enhance the capabilities of the Digital Twin. Therefore, it is essential to develop a methodological approach to ensure that the geometry of the Digital Twin remains up-to-date.

Most existing publications address the geometry update process primarily from a technical perspective, discussing various data collection and processing options. However, the geometry update process is highly case-specific, which complicates the search for a universal solution, and this is one of the limitations of the current work. It is not possible at this stage to consider all the potential factors that may arise during the process. However, an analysis of Digital Twin update geometry from two angles, entity/process levels, and main components (physical, virtual, data), has resulted in the development of a roadmap that provides insights into the current landscape, identifies potential challenges, and outlines future research directions. Even at this stage, the roadmap can serve as a source of information for planning and implementing the process of updating the geometry of the Digital Twin. It provides a basis for understanding the underlying complexities and issues that may arise during the process and need to be addressed.

LEVERAGING CLASSIFICATION KNOWLEDGE FOR IMPROVED DATA ACCESSIBILITY IN DIGITAL CONSTRUCTION

Jakob Martin[1,2], Klaus Linhard[2], Cornelius Preidel[1,2]
[1]Munich University of Applied Sciences, Germany
[2]Institute of Applied Building Informatics (iabi), Munich, Germany

Abstract

While the prevalent use of complex structures such as Industry Foundation Classes (IFC) in digital building models has good reasons, it also limits the easy accessibility of data and hinders a common understanding of building structures across different projects or companies. This paper presents an approach to how existing classification systems can effectively improve common understanding by representing and collecting classification rules in the machine and human-readable IDS format of buildingSMART. The formally mapped classification rationale serves as a common starting point for stakeholders, capturing and consolidating classification knowledge from project or company-specific models and breaking down technical barriers to using digital models. This initiative contributes to a more collaborative and standardized digital construction industry and promotes better data understanding and knowledge sharing between stakeholders.

Introduction

The digitization wave sweeping across the construction industry necessitates the adoption of highly structured and complex data formats like the Industry Foundation Classes (IFC) to encapsulate the rich, multi-dimensional information inherent in construction projects. (Zhang et al., 2014) However, a significant barrier arises as stakeholders, particularly those with varied disciplinary backgrounds, grapple with these complex data structures. The pressing need is to ensure the most straightforward entry point for all stakeholders into the digital realm, promoting wider adoption and effective utilization of digital methods. (Opoku et al., 2023)

Classification systems stand as a pivotal element in bridging this complexity gap. Essentially, classifications are systematic arrangements in defined categories based on shared characteristics, as ISO 14177 (International Organization for Standardization, 1994) outlines. These systems, utilized across diverse application areas and disciplines within the construction industry, provide a familiar framework for engineers working with them for decades. The essence of classification lies in its ability to streamline information retrieval, enhance communication, and promote standardization, which is fundamental in handling complex data structures inherent in digital construction models.

State of the Art

The evolution of digital construction methodologies, particularly Building Information Modeling (BIM), has catapulted the significance of classifications to a new level. (Wu and Zhang, 2019) BIM, with its ability to create rich, multi-dimensional digital representations of physical and functional characteristics of assets, necessitates a structured approach to information management. Here, classification systems serve as the backbone for organizing this voluminous data in a structured, accessible, and interoperable manner (Beetz, 2018). In the digital realm, classifications have evolved to serve as a categorization tool and a medium to enhance information flow, accessibility, and collaborative engagement. They are now employed to structure the data within digital models, facilitating more straightforward navigation, interpretation, and utilization of the information. For instance, in terms of model structuring, they aid in structuring digital models. This enables stakeholders to navigate and interact with the model contents through a familiar classification view and simplifies the engagement with complex data structures like the Industry Foundation Classes (IFC). In the context of information retrieval, classifications speed up the retrieval of pertinent information. Organizing data systematically and predictably becomes crucial for decision-making and coordination among various project stakeholders. When considering interoperability, classifications enhance this by offering a standardized framework. This facilitates efficient information exchange amongst numerous software applications and platforms typically employed in a project. Lastly, there's a shift in modern digital construction methodologies towards knowledge capture. More than ever, there's a focus on capturing and formalizing the knowledge of how components are classified. This pivotal change facilitates a shared understanding and consensus on classification standards throughout the industry.

In practice, there are two different ways of classifying components of a digital construction model: (1) Rule-based Classification and (2) Attribute-based Classification.

Attribute-based Classification describes a process in which the model authors manually add attributes to the components to assign the component according to a classification. This pragmatic approach is confirmed by its implementation in industry practices and standards, such as the guidelines of BIM Deutschland (BIM Deutschland, 2024). This initiative makes key recommendations for the use of BIM in Germany. It emphasizes the need for defined attributes to be added and maintained across all service phases for Level of Information (LoI), exemplified by the requirement to add attributes for classification according to DIN 276 manually. This customization provides flexibility in classification as attributes can be tailored to suit specific project needs. It also facilitates intuitive classification based on observable or measurable characteristics. Despite its practical application and advantages, this method involves significant manual effort, which can be cumbersome, time-consuming, and prone to errors. Additionally, a coherent understanding of the classification scheme among all stakeholders is required to ensure consistency. The manual addition of attributes leaves the underlying rationale for classification with the human operator devoid of formalization. This tacit knowledge remains unshared and unstandardized across the industry, highlighting the necessity of initiatives like BIM Deutschland in guiding the industry toward standardized practices.

Rule-based Classification is a methodology that leverages static filter-like rules within native software tools. Users implement rule logic to filter components based on inherent information. This mechanism automates the classification process, ensuring consistency and efficiency while reducing the manual effort required. However, it presents limited flexibility in adapting to varying classification needs, and the logic may become complex and challenging to manage with evolving project requirements. (Bloch and Sacks, 2018) A notable shortfall of this approach is the lack of formalization of the underlying rationale for classification, making it difficult to capture and share classification knowledge across the industry. This mechanism can also be used to harmonize different types of content from other authoring tools. For example, exterior walls that have different characteristics (e.g., name or specific property) in various models can be identified as such. Prominent examples of rule-based classification in practice are seen in tools like *Solibri Office* and *BIMcollab Zoom* (Solibri, 2023; BIMcollab, 2023) (see Figure 2). In *Solibri Office*, classifications are facilitated through predefined rules, allowing users to filter and organize model components efficiently. Similarly, Smart Views in *BIMcollab Zoom* enable users to create custom views based on rule logic, aiding in the classification and visualization of model components. Figure 1 shows how users can define these rule-based classifications within *Solibri Office*. These examples showcase the practical utility of rule-based classification but also underline the inherent limitations in flexibility and formalization of classification rationale, underscoring the necessity for exploring alternative or supplementary methods to encapsulate classification knowledge in a more standardized, shareable format.

When examining the two prevalent classification methods, each brings distinct advantages. Rule-based classification stands out for its automation and consistency, offering a quicker and more standardized way of categorizing items. Conversely, attribute-based classification shines in its flexibility and intuitiveness, enabling more customized classifications.

Delving into the disadvantages, rule-based classification reveals certain limitations. Its adaptability to varying classification needs is initially restricted, posing a challenge in dynamic projects. As these projects evolve, the rule logic might become complex, cumbersome to manage, and potentially decelerating the classification process. Most notably, the absence of clarity in the rationale behind classifications obstructs the sharing and standardization of classification logic across different projects or teams, impeding collaborative endeavors and industry-wide learning.

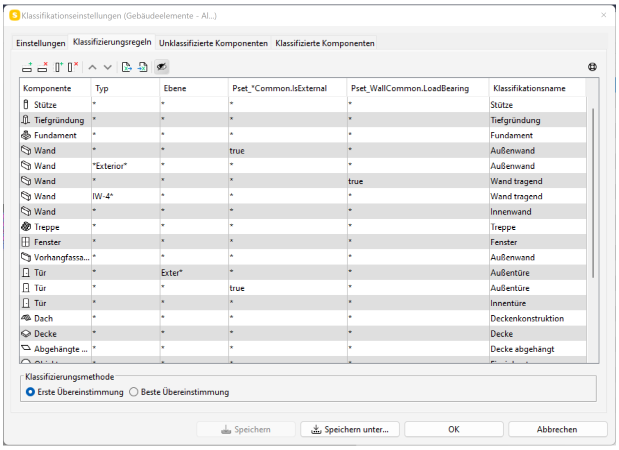

Figure 1: User interface in Solibri Office, in which a user can build up classification rules line by line

On the flip side, attribute-based classification carries its own set of hurdles. It demands manual effort in classifying items, which can be time-intensive and error-prone, particularly in large-scale projects. Additionally, a coherent understanding of the classification scheme among all stakeholders is requisite to maintain consistency, a demand that could be challenging in diverse teams or multi-stakeholder projects. Like its rule-based counterpart, attribute-based classification falls short in elucidating the reasoning behind classifications, leaving the understanding of classification logic unshared and unstandardized across the industry. This shortfall again hinders knowledge sharing and collaborative efforts.

Both methods share a common pitfall: the ambiguity in the reasoning behind classifications. This ambiguity stifles the sharing and understanding of classification logic across the industry, pinpointing an area ripe for further exploration.

In summation, while each classification method boasts its unique strengths, they both encounter significant challenges, chiefly in elucidating the reasoning behind classifications to foster knowledge sharing and industry-wide standardization. This exposition underscores the need for a refined classification approach that combines the strengths of rule-based and attribute-based classifications while alleviating their weaknesses, paving the way for enhanced sharing and understanding across the digital construction domain.

Approach

The potential benefits of formalizing this classification knowledge in a shareable, neutral format are manifold.

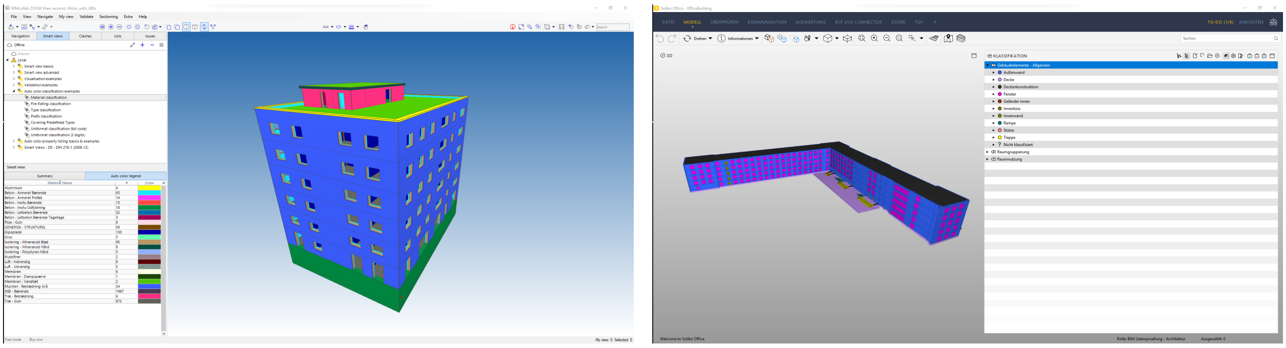

Figure 2: Showing Smart Views in BIMcollab Zoom (left) and Classifications in Solibri (right)

Firstly, it provides stakeholders with valuable insights, enabling a more comprehensive understanding and agreement on classifying components. This mutual understanding is crucial for harmonizing different stakeholders' perspectives. Additionally, a significant benefit is the reduction of manual work. By utilizing existing information about components for automated classification, the process becomes more efficient and consistent, minimizing the chances of errors that come with manual classification. A key advantage is the encapsulation of rule logic into a standardized format. This encapsulation creates a common language that explains the reasoning behind each classification, making it much easier to manage and share across various projects and teams. Overcoming the typical constraints associated with traditional classification methods, this approach fosters better collaborative engagement. A standardized format serves as a common ground, encouraging dialogue and cooperation among stakeholders, which is vital for the success of digital construction projects. Moreover, streamlined data management is a significant outcome of this approach. It simplifies the classification process and creates a more organized digital environment, making navigating and interacting with digital models easier. Often, the rationale behind a component's classification is inherently depicted by the existing information about the component. The prevalent constraints can be overcome by identifying and encapsulating this rule logic into a standardized format, paving the way for enhanced collaborative engagement and streamlined data management in digital construction. By extracting and formalizing this rule logic into a standardized form, we can transcend the current limitations, unlocking a new horizon of collaborative engagement and streamlined data management in digital construction. Through this endeavor, we aspire to intertwine the existing classification systems with complex data structures, simplifying the digital landscape for all stakeholders and nurturing a more collaborative, efficient, and user-centric digital construction ecosystem.

Standardized Formats for Formalizing Classification Knowledge

It is worth investigating existing standards that can efficiently encapsulate and share classification rule logic to formalize classification knowledge within the digital construction domain. Among the many available formats, mvdXML and Information Delivery Specification (IDS), both by buildingSMART International, emerge as suitable candidates owing to their structured frameworks and widespread recognition in the industry (Tomczak et al., 2022). A summary of the different pros and cons for our use case is shown in Table 1.

mvdXML (buildingSMART, 2016) is a technical schema accompanying Model View Definition (MVD) to formalize and validate data exchanges in construction projects. MVD is used to specify subsets of the Industry Foundation Classes (IFC) schema to facilitate interoperability in specific use cases. It can also be leveraged to formalize classification knowledge, aligning it with established industry standards. mvdXML provides a structured framework with an added validation layer, ensuring the encapsulated classification rule logic adheres to the predefined standards. Employing mvdXML to formalize classification knowledge could align the classification logic with established industry standards, promoting consistency and interoperability. Furthermore, the validation feature of mvdXML could be instrumental in maintaining the integrity of classification logic over time.

Information Delivery Specification (IDS) (buildingSMART International, 2023a) is a relatively newly introduced schema specifying a construction project's information delivery requirements. It serves as a blueprint, outlining the nature, format, and extent of information to be exchanged amongst stakeholders at various stages of a project lifecycle. By doing so, IDS augments the clarity, consistency, and efficiency of information exchange, minimizing misunderstandings and errors that could potentially derail a project.

The primary intent of IDS is to facilitate the precise articulation and fulfillment of information requirements. It acts as a bridge, ensuring that the information generated and consumed across different phases of a construction project is aligned with the defined standards, thereby promoting interoperability and collaborative engagement.

Suggested Methodology

mvdXML offers a broad framework for formalizing and validating data exchanges in construction projects across

Table 1: Comparison of mvdXML and IDS for Formalizing Classification Knowledge

	mvdXML	**IDS**
Pros	+ Powerful, structured framework for formalizing data exchanges. + Supports detailed specification of data subsets in IFC for interoperability. + Built-in validation ensuring adherence to industry standards. + Potential for aligning classification logic with established standards.	+ Simplified and straightforward encapsulation of classification rule logic. + Quickly adopted standard by buildingSMART, ensuring industry recognition. + Compatible with existing IDS editors for authoring and editing. + Facilitates interactive exploration and application of classification logic. + Supports regular expressions (RegEx) for the specification of values
Cons	– Complexity and detailed structure may challenge users. – Many features may be redundant for classification, adding to the complexity. – Low market penetration given that it was introduced years ago.	– Lacks built-in validation mechanism. – May require additional effort to capture more complex classification logic. – No existing tools for interpreting IDS in the proposed manner (before demonstrator development).

various use cases of the IFC schema. In contrast, the Information Delivery Specification (IDS) is limited to specific aspects of mvdXML, focusing on clearly articulating information delivery requirements throughout a construction project's lifecycle. While mvdXML is versatile enough to encompass the functionalities of IDS, the latter's targeted approach promises to be more user-friendly and streamlined for its intended purpose.

Despite its robustness and comprehensive technical schema, the mvdXML standard has specific challenges that could hinder its prompt adoption of our suggested approach. A primary concern is its current market penetration, which is not as widespread as desired, potentially limiting its immediate usability and acceptance for formalizing classification logic. Furthermore, the high complexity of mvdXML poses a steep learning curve for stakeholders, especially those new to digital construction standards, which could deter them from adopting this standard for classification logic formalization. On the other hand, the IDS standard, with its simplified approach, presents a lower barrier to entry, making it a more attractive option. Despite these concerns, the potential of mvdXML in this domain is acknowledged, and a comparative analysis with IDS in future studies could provide a nuanced understanding of their respective merits and limitations in formalizing classification knowledge.

Our proposed method utilizes the Information Delivery Specification (IDS) format without altering or extending its existing structure. The key idea is to employ a slightly different interpretation of certain aspects of the IDS for a distinct, constructive purpose.

The IDS file format, grounded in a standardized XML schema, is a robust mechanism for detailing information requirements for elements within Industry Foundation Classes (IFC) files. An IDS file comprises two main sections: a Header containing general metadata about the file and a list of Specifications detailing the information requirements for IFC elements.

Each Specification within an IDS file is divided into three components: Metadata, Applicability, and Requirements. Metadata provides contextual information about the Specification, Applicability defines the scope of elements the Specification applies to, and Requirements outline the actual information requirements for the objects in question.

Both the Applicability and Requirements components use a mechanism known as Facets to specify their content. In the context of IDS, Facets describes potential information an element in the IFC model might have. Six precisely defined Facet Parameters are used to make these requirements machine-interpretable, namely:

- Entity Facet
- Attribute Facet
- Classification Facet
- Property Facet
- Material Facet
- PartOf Facet

Traditionally, the IDS specification is divided into two main parts: the 'Applicability' part, which outlines the specific components the specification applies to, and the 'Requirement' part, which outlines the information requirements for those components. Our methodology retains the conventional use of the 'Applicability' part but adopts a different interpretation of the 'Requirement' part. Instead of seeing the facets defined in the 'Requirement' part as information requirements, we suggest interpreting them as classification logic. This subtle shift in interpretation allows an IDS specification to be seen as one or many applicable classification rules. These rules, encapsulated in the 'Requirement' part, apply to the components specified in the 'Applicability' part.

Figure 3 shows an example of this. In this example, the characteristics for identifying load-bearing external walls are defined in the 'Applicability' part, and then two classification requirements are listed in the 'Requirement' part. According to the introduced logic, all identified building components in a model should now be classified as *"buitenwanden; niet constructief, massieve wanden"* according to the Dutch NL-SfB 2005 and as *"332 - Nichttragende Außenwände"* according to the German DIN 276 (BIM Loket, 2023; DIN, 2018).Since an entry is stored in the buildingSMART Data Dictionary (bsDD) (buildingSMART International, 2023b) for the Dutch classification, a corresponding URI can also be stored here, which links the resulting classification to the entry.

This novel methodology facilitates the systematic classification of components based on established logic, nurturing a more structured and insightful representation of model data. The transparency of the classification logic further improves understanding and consensus among different stakeholders, fostering a more collaborative and efficient digital construction ecosystem.

Utilizing the existing IDS format in such an innovative way aligns with the industry's ethos of leveraging established standards to foster interoperability and knowledge sharing while paving the way for enhancing the practicality and usability of digital models in construction projects.

Results & Test Cases

This section examines the practical application and feasibility of the proposed methodology using selected test scenarios. The aim is to gain insights into how the approach performs when applied to real cases. For this preliminary investigation, we have focused on the example of the national classification system DIN 276 to assess its applicability and robustness. This decision marks our first effort to validate the proposed method and illustrate its feasibility straightforwardly.

IDS Authoring & Demonstrator

Creating IDS files is a crucial part of this process, and having accessible tools significantly aids in this endeavor. One significant advantage of authoring the IDS according to the suggested approach is the compatibility with existing IDS editors, whether commercial or open-source. As the IDS specification is not changed or expended, any compatible IDS editor can create, author, or edit the suggested classification logic.

For this research, the open-source *xBIM IDS Editor* (Benghi, 2023) was used to create the IDS files.

Given the absence of existing tools capable of interpreting the IDS as per our suggested methodology, a demonstrator was developed utilizing *ifcopenshell* (Krijnen, 2023) and the *IFC.js* (Viegas, 2023) viewer components. This demonstrator allows stakeholders to interact with IDS files alongside IFC files. In this setup, users can conveniently load IFC files with one or multiple IDS files, and the encapsulated classification logic is automatically applied. Consequently, users are presented with the classification systems and the corresponding classification items, alongside the count of components identified as classified components according to the rules contained. Users can interactively navigate the model by clicking and highlighting the objects based on their classification.

This demonstrator serves as a practical illustration of the utility and effectiveness of our proposed approach, facilitating an interactive exploration of classification systems and the underlying classification logic within the digital construction models. In its current form, the viewer implemented acts more like a substitute, given the lack of existing implementations capable of interpreting the IDS as per our methodology. However, a far more impactful use case for the resulting IDS would be its integration into any platform users utilize to visualize, create, or edit digital building models. Such integration would significantly enhance the user experience by allowing the contents to be immediately structured according to the classification logic represented in the IDS files. This showcases the potential of integrating the existing IDS format for classification purposes and demonstrates a path toward fostering a more collaborative and insightful interaction with digital construction data among stakeholders. Through this hands-on evaluation, the proposed methodology has showcased promise in bridging the complexity associated with digital construction models, paving the way for broader adoption and effective utilization of digital methods in the construction industry. The resulting demonstrator is shown in Figure 4.

At this point, it should be added that the resulting classification results can also be fed back into an IFC model, as the IFC schema provides explicitly for this. However, it should be noted that this content only reflects the classification results but not the classification logic itself. If there are changes in the IFC model, the logic stored in the IDS would have to be applied again, and the classification contents stored within the IFC model would have to be updated. The resulting classification data can also be added to the IFC file on demand as part of the prototype development. For example, these contents can be displayed with Solibri Office as shown in figure 5.

The entire development of the Prototype Framework and the generated IDS files are open source and can be reused (iabi, 2023).

Use Case: DIN 276

The German DIN 276 standard is a vital guideline in the construction industry for structuring and managing costs in construction projects (DIN, 2018). It categorizes costs systematically, aiding in accurate budget planning and risk reduction by standardizing cost estimation and allocation. This standard ensures financial discipline, transparency, and effective communication among stakeholders in German construction projects. We have translated significant

```xml
<ids>
  <specification name=”LoadBearing External Walls” ifcVersion=”IFC2X3 IFC4”>
    <applicability>
      <entity>
        <name pattern=”IFCWALL|IFCWALLSTANDARDCASE”/>
      </entity>
      <property name=”IsExternal” datatype=”IfcBoolean” value=”TRUE” propertySet=”Pset_WallCommon”/>
      <property name=”LoadBearing” datatype=”IfcBoolean” value=”FALSE” propertySet=”Pset_WallCommon”/>
    </applicability>
    <requirements>
      <classification uri=”https://identifier.buildingsmart.org/uri/nlsfb/nlsfb2005/2.2/class/21.11”
                value=”buitenwanden; niet constructief, massieve wanden”
                system=”NL-SfB 2005”/>
      <classification value=”332 - Nichttragende Außenwände”
                system=”DIN 276”/>
    </requirements>
  </specification>
</ids>
```

Figure 3: Example IDS File containing classification logic - this example is for illustration purposes and is not directly usable as IDS because it was simplified

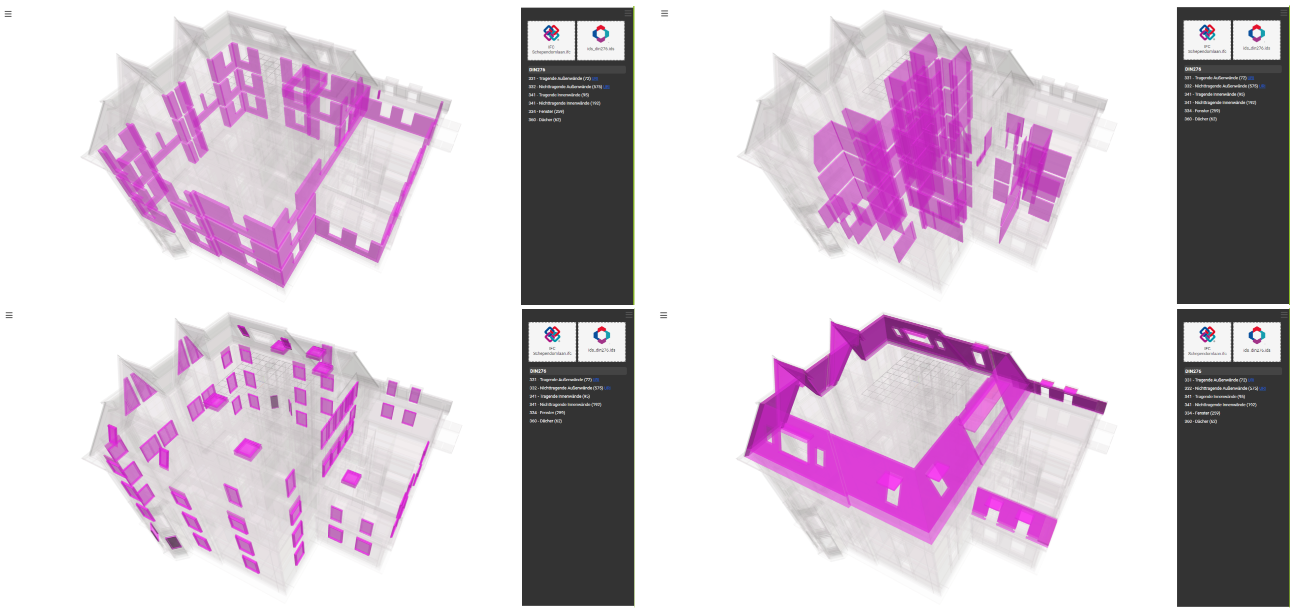

Figure 4: Resulting framework Demonstrator showing different resulting classifications processed using the IDS-representation of the German DIN 276

parts of the DIN 276 structure into IDS for demonstration purposes using the approach presented in this paper.

The resulting IDS can be used in the prototype framework to classify and structure any IFC model, showing the resulting structure on the fly. Figure 4 shows different classification results that have been successfully applied using the rules contained in the IDS. On-demand, the resulting classification can also be written back into the IFC file as references *IfcClassificationReference* objects.

Conclusions & Outlook

The exploration into formalizing classification knowledge via the IDS format reveals a promising avenue toward bridging the intricacies of digital construction data with the practical necessities of industry stakeholders. This methodology not only leverages an established standard but also proposes a nuanced interpretation that aligns classification logic with the inherent structure of construction components. The resultant framework demonstrates a tangible step towards a more collaborative, efficient, and user-centric digital construction ecosystem. The success of the applied test cases underscores the methodology's potential to facilitate more intuitive interaction with complex data structures, thereby fostering a broader understanding and engagement across disciplinary bounds.

However, our approach is only a first step and has a whole

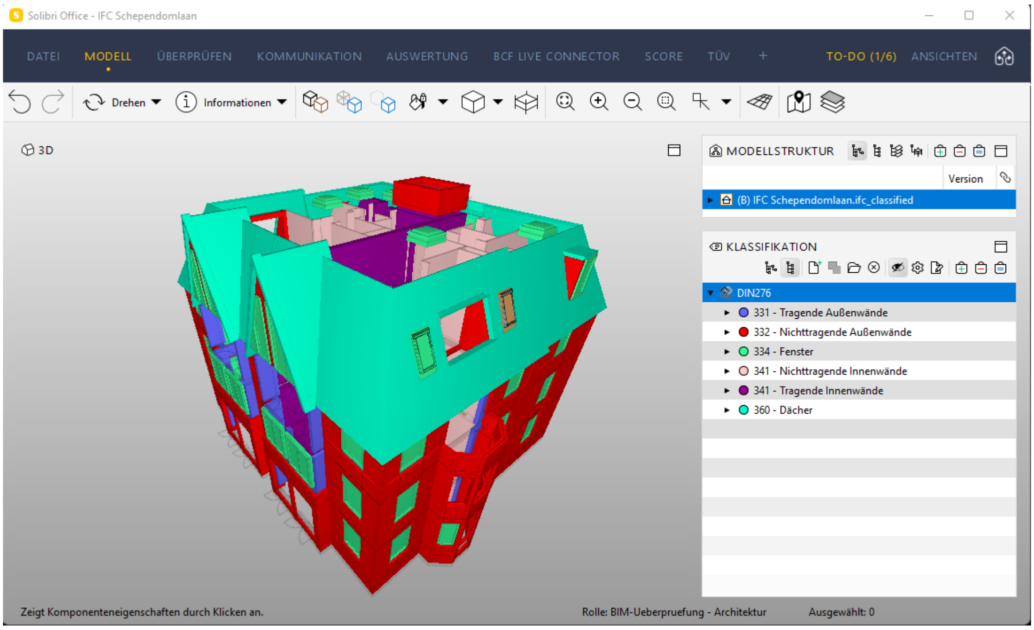

Figure 5: Resulting classification shown in Solibri Office

series of limitations that require consistent further development and refinement:

Exploration of Complex Classification Systems: In our contribution, we have initially converted elementary parts of DIN 276 as a first step to test the basic concept. Of course, there are other national or specialized classification systems worth translating into IDS to make them easily applicable to the masses. Our future research will examine more complex classification systems such as Uniclass and Omniclass. These systems are designed for more complicated and global classification requirements and will be essential for expanding the scope of our study.

Dependence on correct model content: The accuracy and precision of model content remain critical to the successful application of any classification system, underscoring the need to improve modeling procedures continuously. The effectiveness of classification systems depends mainly on users' consistent and accurate maintenance of attribute data. Our approach does not change this, but this is not the intention because, at this point, it is the task of model quality assessment and assurance mechanisms to ensure the appropriate quality.

Conversion of Native Classifications: Regardless of official classification systems, a lot of valuable classification knowledge is deeply embedded in native software solutions and remains inaccessible without targeted and sometimes laborious extraction processes. This represents a significant obstacle to using this knowledge across different systems. Classification knowledge currently only contained in systems such as Solibri Classifications and BIMcollab Smart Views needs to be extracted and converted into an open format such as IDS. This will enable wider sharing and application of this knowledge, overcoming the limitations of proprietary systems and improving interoperability and collaboration across digital construction platforms.

Our work represents an initial step towards potential improvements as we explore automated classification and model validation. It introduces possibilities for further research in model semantics, knowledge extraction, and sharing classification knowledge. Future efforts can focus on refining these methods to enhance their practicality and efficiency:

Automatic Derivation of Classification Logic: A proactive examination of existing models with classification attributes could be undertaken to derive classification logic from these models automatically. Utilizing Artificial Intelligence (AI) and Machine Learning (ML) techniques, the underlying classification logic within these models could be extracted and formalized into IDS files. This automated extraction of classification knowledge could potentially unveil a rich repository of classification logic, making it available for users across different platforms.

Model Validation: The established classification logic can be employed in its original intent, as per IDS, for validating models. This validation ensures that models adhere to defined classification schemes, enhancing the quality and consistency of digital construction data.

Semantic Enrichment of Models: The classification logic could also serve as a mechanism for semantically enriching models. When a component is identified under a specific classification, this logic could provide instructions on the data placeholders or specific values the component should possess. This semantic enrichment facilitates a more detailed and nuanced representation of construction components, enriching the digital construction model.

Community-Driven Evolution: Encouraging a community-driven evolution of this methodology could foster a collaborative environment for continuously refining and expanding the classification logic. Engaging with industry experts, academia, and software developers could collectively advance this approach, aligning it more closely with real-world needs and emerging industry standards.

The envisioned enhancements and the community-driven evolution of this methodology highlight the potential of this approach in addressing the present challenges and adapting to the evolving needs of the digital construction landscape. Building upon the established standards and engaging with the broader community could significantly contribute to the ongoing digitization efforts within the construction industry, making digital construction models more accessible, understandable, and usable for all stakeholders involved.

Acknowledgments

The authors gratefully acknowledge the support and resources that made this research possible. This work has been carried out mainly within the framework of the openDBL project, which has received funding from the European Union's Horizon Europe research and innovation program under grant agreement No 101092161. We are deeply grateful for this fundamental support. Furthermore, our thanks also go to the NEMETSCHEK Innovation Foundation, whose financial contributions have been an essential basis for the progress of our research and, thus, of crucial importance.

Abstract

In response to the EU's Green Deal and its emphasis on sustainable construction, this study introduces an innovative framework for the AECO industry aimed at overcoming the prevalent challenge of fragmented and non-standardized product data exchange processes. By integrating Information Delivery Specification (IDS) and buildingSMART Data Dictionary (bSDD), the proposed framework enhances the accuracy and efficiency of product data exchange. This approach addresses current inefficiencies in the sector and aligns with sustainable objectives by ensuring consistent, up-to-date information, thereby facilitating better adherence to safety, budget, and regulatory standards.

Introduction

The Architecture, Engineering, Construction, and Operations (AECO) sector critically relies on accurate and timely product data, from design specifications to material properties (Tulke and Schumann, 2018). This data is essential to ensure projects are executed smoothly, remain within budget, and comply with safety and regulatory standards. However, the sector faces significant challenges:

Fragmentation of Product Data: Varied and non-standardized data from manufacturers often lead to delays and inaccuracies in project execution.

Lack of Standardization: The absence of a unified approach in data provision hampers efficient data retrieval and application.

These challenges become more pronounced with the implementation of the European Union's Green Deal, which underscores the need for sustainable construction and stringent environmental standards (European Commission, 2023; Schunz, 2022). The Deal necessitates immediate access to detailed, accurate product data to ensure compliance. Moreover, the push towards a circular economy emphasizes the importance of understanding building materials' origin, composition, and recyclability, where data discrepancies can result in non-compliance and potential legal or reputational damage. This context sets the stage for our research, highlighting the need for a standardized and efficient method to query and retrieve product data, a crucial element for operational efficiency and reliability in the AECO sector. At the same time, a persistent challenge within the sector has been the non-uniform manner in which product data is provided by manufacturers, owing to a lack of industry-wide standardization (Kebede et al., 2022; Lucky et al., 2019). This fragmentation obstructs efficient data retrieval and utilization, inevitably leading to delays and inaccuracies in project execution. The research gap thus emerges from the necessity of a streamlined, standardized method for querying and retrieving product data from manufacturers.

State of the Art

In the dynamic domain of digital construction, the seamless exchange of product information between manufacturers and core stakeholders such as contractors, designers, and engineers is fundamental. This exchange profoundly influences various stages of the construction process, facilitating informed decision-making, accurate cost estimation, and adherence to compliance norms, among other critical facets (Aranda-Mena and Wakefield, 2006). The information regarding products is especially crucial during distinct phases such as the planning and design, tendering, procurement, construction, and operational maintenance phases. During the planning and design phase, engineers and architects heavily rely on product information to make critical design decisions, ensuring that the selected products align with the project's objectives and compliance requirements (Yogana and Latief, 2021). The data aids in evaluating the compatibility of products with the design intent and making necessary adjustments to the design. As the project transitions to the tendering stage, acquiring precise product data is indispensable, empowering contractors and planners to craft accurate bids. They necessitate detailed specifications, pricing, and the availability of products to devise competitive yet realistic tenders. A significant aspect of the tendering process is the comparative analysis of products from different manufacturers. This step helps ascertain the most suitable options in terms of cost and functionality. Procurement is the next critical phase, where accurate product data is vital for making informed purchasing decisions. At this juncture, a bulk of comparison between different manufacturers' products is carried out to secure the best value and ensure project continuity. Once the construction phase commences, access to product information is essential to ensure that suitable materials are utilized per the specifications. It also aids in addressing any on-site challenges that may arise related to product installations. Post-construction, during the operational maintenance phase, having a repository of product information proves invaluable for facility management and maintenance activities. It aids in ensuring that the products used are serviced or replaced following the manufacturer's guidelines. Traditionally, obtaining product information has been a manual process, relying on product data descriptions typically provided in PDF format by manufacturers due to industry norms. Although functional, this method is time-consuming and prone to data inconsistencies, mainly when product specifications are updated.

Platforms for the distribution of product data

In the evolving landscape of the AECO industry, the emergence of platform providers for product data has become notable. Acting as intermediaries, these platforms house various manufacturers' product data, providing a centralized hub for stakeholders to efficiently access and compare product information. Such platforms include BIMobject (BIMobject AB, 2023) and Cadenas (CADENAS GmbH, 2023).

These providers endeavor to bridge the gap between product manufacturers and various industry stakeholders, including contractors and designers, positioning themselves as intermediaries that provide access to product data that is more about availability than immediate, customizable retrieval. Such platforms are particularly valuable during phases like tendering and cost calculation, where precise product specifications are paramount. However, the adoption of these platforms presents significant challenges. The utility of such a platform is contingent upon its widespread acceptance by multiple product manufacturers, as navigating various platforms not only complicates the workflow but also introduces inefficiencies. Therefore, for contractors and other stakeholders to reap the full benefits, a unified system is essential to streamline processes and enhance efficiency across the board.

A more pressing concern is the redundancy inherent in these systems. Product manufacturers, in their typical operations, maintain detailed specifications within their proprietary databases or systems. The introduction of intermediary platforms necessitates the replication of this data onto the new platform. This duplication poses several risks:

Inconsistencies: There's always the potential for discrepancies between the data in the manufacturer's primary system and those copied onto the intermediary platform.

Data Asynchronicity: The delay between updates in the manufacturer's system and their replication on the platform can result in stakeholders accessing outdated information.

Maintenance Overhead: For manufacturers, managing and updating product data in two places can be resource-intensive and error-prone.

While these platform providers aim to streamline processes and enhance accessibility to product data, they inadvertently introduce complexities and potential data integrity issues. It underscores the need for more integrated solutions to address these challenges, ensuring stakeholders have access to consistent, up-to-date product information without the pitfalls of redundancy.

Digital labeling and classification systems

In contrast to dedicated platforms that aim to host all the information, other approaches aim to link the connections between the required data and the manufacturers' data and manage these links. A prominent example is the *UniversalTypes*, developed and owned by *ProMaterial* under the aegis of buildingSMART International (buildingSMART International, 2023c). This initiative was developed to standardize and harmonize the characteristics and properties of products in a catalog and thus significantly improve the real-time sale of building products and materials.

Initially published as a publicly available specification in the buildingSMART Data Dictionary (bSDD), the language of UniversalTypes is envisioned to be standardized and maintained for general use. Unlike previous systems that were confined to proprietary platforms, UniversalTypes is integrated with the bSDD, enabling it to leverage a wider industry acceptance and providing a robust foundation for data harmonization across the construction sector. This integration is illustrated in our study's Figure 2, where UniversalTypes are referenced as a classification system within the bSDD framework (buildingSMART International, 2024).

ProMaterial offers a dedicated platform that utilizes UniversalTypes to streamline online sales processes. Within this platform, products can be explored using specific properties defined as UniversalTypes, such as the manufacturer's product number, Data-provider product ID, and various product dimensions and material properties. These properties are essential for designers during the design phase, allowing for an in-depth analysis and comparison of products from different manufacturers.

Moreover, ProMaterial extends its functionality by providing developer documentation for API development, facilitating advanced queries and interactions with the UniversalType Center for more customized workflows. This integration enhances the efficiency and accuracy in data retrieval and analysis, making it a valuable tool for planners' workflows and embodying modern digital construction industry processes.

In summary, the classification part of UniversalTypes represents a robust approach that not only uniquely identifies individual features but also complements other classification systems. It is showcased by its integration into the bSDD, enhancing its utility and reach. However, the reliance on a dedicated platform for providing this information highlights a business case that inherits the limitations of proprietary platforms, posing challenges for achieving a truly open, vendor-neutral solution.

Product Data Templates (PDT)

A Product Data Template (PDT) is a standardized format that outlines essential and optional product attributes, such as fire rating and color, according to established product standards. PDTs offer a unified method for handling construction product data, simplifying the process for manufacturers to keep product details up-to-date. The ISO standard 23387:2020 establishes guidelines for data structures that describe construction-related entities, promoting efficient digital information exchange and operational enhancement (International Organization for Standardization, 2020b). ISO 23387:2020 is a consistent further step after ISO 23386:2020 that includes a definition of characteristic structures (International Organization for Standardization, 2020a). PDTs are supposed to maintain data consistency across a product's lifecycle and are designed to be machine-readable for easy data exchange.

A Product Data Sheet (PDS) is created when manufacturers input data into a PDT using specialized software, detailing a construction product's technical and performance characteristics according to various regulations and requirements. As a product's identifiable document, a PDS ensures the supply chain can access up-to-date and accurate information from a trusted source. Unlike static formats like PDFs, PDSs support automation by integrating with various manufacturer systems, such as Product Information Management (PIM), Digital Asset Management (DAM), or Enterprise Resource Planning (ERP), to keep data fresh. They can act as a single source of truth for automatic updates across these systems.

PDTs can potentially improve data management in construction, but they come with challenges. The complexity of PDTs, particularly their integration with the IFC schema, creates a steep learning curve that can discourage smaller firms or those without technical expertise. The specificity of PDTs to IfcTypes can also be restrictive, lacking the flexibility to handle unique data needs and sometimes leading to inaccuracies requiring manual correction. Moreover, PDTs' reliance on the IFC schema can be limiting if the IFC schema has no prominent role in the project or undergoes changes, necessitating updates to the PDTs. Integrating PDTs into existing systems not designed for them can be complex and costly. PDSs, while designed to be a standardized source of information, face issues with data consistency, mainly when multiple parties contribute to project-specific PDSs.

Filling out PDSs can be time-consuming for manufacturers, particularly for those with a wide range of products or frequent updates. Despite these obstacles, the industry is working towards improving these systems to leverage their benefits in the digitally evolving construction sector fully. The transition involves overcoming the initial difficulties associated with adopting new technologies.

Formulating requirements for successful and efficient product data exchange

The AECO sector is at a pivotal juncture where the need for accurate product data intersects with the drive for sustainable construction mandated by the EU's Green Deal. Despite the potential of existing systems like native Product Data Platforms or Product Data Templates (PDTs), their adoption faces significant hurdles. The complexity of these systems, their integration challenges, and the need for consistent, up-to-date data underscore the necessity for a more streamlined approach to product data exchange. The industry's reliance on fragmented and non-standardized data hinders project efficiency and poses risks to compliance with emerging sustainability regulations. As the sector grapples with these challenges, it becomes clear that a new paradigm is needed to address the limitations of current methodologies and set clear, actionable requirements for a robust data exchange framework. To transition from the current state of disparate data practices to a future of streamlined and standardized data exchange, the following requirements must be met: Firstly, it is imperative to have a standardized data format. A universally accepted data format ensures seamless product data integration into the myriad software tools and platforms employed across the sector. Moreover, the systems utilized by various stakeholders, be they architects, engineers, or contractors, must be interoperable. This interoperability ensures smooth data exchange devoid of any compatibility hiccups. The integration of open APIs and dedicated tools can further smoothen this process. For widespread adoption, platforms or tools designed for data exchange must feature an intuitive user experience, easing the transition for all involved parties. Additionally, these platforms should allow stakeholders to retrieve specific data subsets efficiently, negating the need to sift through entire datasets. Another cornerstone of this endeavor is real-time data access. Stakeholders should always be working with the most recent information available.

Approach & Methodology

To enable the information orderer and provider to communicate information and requirements directly, this study proposes using the newly introduced Information Delivery Specification (IDS) standard from buildingSMART in conjunction with data dictionary services, e.g., buildingSMART Data Dictionary. The main objective of this study is to optimize the information exchange between the two main stakeholders in this process, especially in phases such as the tender: the information receiver and the sender. Therefore, the central idea is to rely on existing standards and describe a process as simply as possible, allowing as few obstacles as possible between these stakeholders.

buildingSMART Data Dictionary (bSDD)

The buildingSMART Data Dictionary (bSDD) serves as a fundamental source for ensuring data consistency and interoperability between different software platforms and actors in the AECO industry. Although there are several organizations that see establishing such sources as their task (see, e.g., the BIM Portal of the Federal Government (BIM Deutschland, 2023)), in our approach, bSDD provides the standardized terminology and data structures. These structures can be referenced in the Information Delivery Specification (IDS) to effectively communicate the data requirements and ensure that the exchanged product data is correct and commonly and uniformly understood within the industry, particularly between the purchaser and supplier.

As demonstrated in Figure 2, we explicitly utilize references from bSDD to establish this connection and ensure uniformity across the data exchanged. This us-

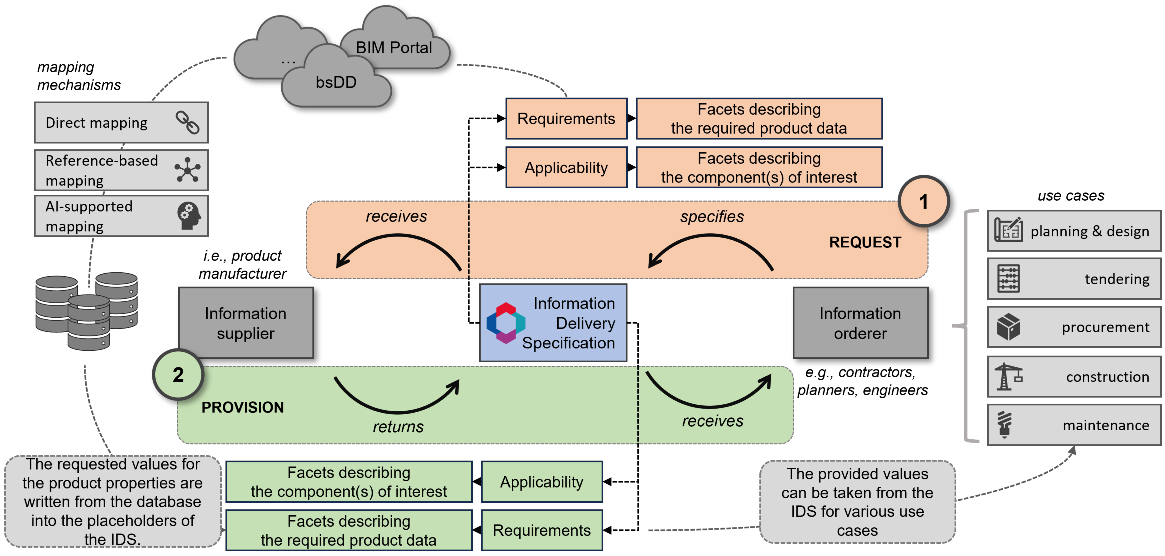

Figure 1: Schematic representation of the suggested methodology and process between the actor that orders and that provides the information

age highlights how bSDD's standardized terminology and data structures are critical in supporting the IDS's role in enhancing interoperability and clarity in communication among stakeholders.

Information Delivery Specification (IDS)

Information Delivery Specification (IDS) (buildingSMART International, 2023b; Tomczak et al., 2022) is a rather newly introduced XML-based tool to specify a construction project's information delivery requirements. It serves as a blueprint, outlining the nature, format, and extent of semantic information to be exchanged amongst stakeholders at various stages of a project lifecycle. By doing so, IDS augments the clarity, consistency, and efficiency of information exchange, minimizing misunderstandings and errors that could potentially derail a project. The primary intent of IDS is to facilitate the precise articulation and fulfillment of information requirements. It acts as a bridge, ensuring that the information generated and consumed across different phases of a construction project is aligned with the defined standards, thereby promoting interoperability and collaborative engagement. However, the structure of the format itself offers a variety of possibilities for further application areas that the introduction can open up. In addition, the format is getting a lot of attention, and many software vendors are implementing the standard. This momentum can be used to exploit the widest possible application of the format.

The following methodology has been proposed to achieve this objective and is shown schematically in figure 1:

1. Information Request

To begin with, the required product information must be collected using the IDS format. For this purpose, the features of IDS are used as follows:

- The *Applicability* elucidates which components need certain information and why. It specifically identifies which components are affected and should be considered. In this section, additional facets can add more details to describe the components, and some settings can be established as defaults. Additional design specifications could need to be set in advance during the planning phase. A more detailed description of the affected component could help identify it during the operating phase.
- The *Requirement* section further refines this by detailing the exact nature of the information needed. This can be an attribute according to the IFC schema or a user-defined property, i.e., a property in a property set with its required data type.

For the definition of the different pieces of information, a special characteristic of IDS can be used to give more robustness and reliability to the whole process: Each piece of information can be additionally provided with a URI, which refers to an external resource, e.g., to the bSDD. Similarly, other sources can be used as reference systems for attributes and properties, such as the BIM Portal in Germany (BIM Deutschland, 2023). The BIM Portal in Germany, managed by BIM Deutschland as of 2023, functions as a central resource for promoting BIM standards and practices. It offers detailed guidelines, best practices, and tools to streamline BIM adoption, supporting governmental and industry-wide efforts to enhance interoperability and efficiency in construction projects through digitization. In this way, a reference to a source can be established, which can be used for a common understanding of the same information if required. This could involve mapping to national classifications, UniversalTypes, and other standards recorded in the bSDD or any other source of information. An example of an IDS capturing requested information for external doors is shown in figure 2.

```
<ids>
  <specification name=”Example for doors” description=”Requesting Door Properties” ifcVersion=”IFC2X3 IFC4”>
    <applicability>
      <entity name=”IfcDoor”/>
      <property name=”IsExternal” datatype=”IfcBoolean” value=”TRUE” propertySet=”Pset_WallCommon”/>

</ids>
```

Figure 2: Example IDS file containing an information request for product manufacturer data for doors - for illustration purposes, the IDS has been greatly simplified and can therefore not be directly used as such

This formulated IDS can now be used as an information request and, as such, be sent to one or more information providers - i.e., product manufacturers eligible to deliver the requested information. This can happen precisely when the information is imperative, for instance, during the tendering phase.

2. Information Provision

Upon receiving the IDS-based query, a manufacturer deciphers the request, mapping it to their specific product specifications. The bSDD and, where needed, other standards like UniversalTypes aid this mapping. By doing so, the manufacturer can access its databases, where the most recent and reliable data about products is maintained. This prevents inconsistent or outdated data from being returned, and no middleman is required, which is a great help regarding liability issues. Subsequently, the manufacturer responds with the solicited information formatted in IDS. This returned IDS, while preserving its original format, now contains the values for each piece of requested data.

The planner, upon receiving the populated IDS along with the requirement specifications, has two potential courses of action:

- Manually incorporate the provided data. Given that the IDS already dictates applicability, the planner is guided on where to position the product data.
- Opt for a fully automated data integration in the model.

Using the BCF API Standard to foster the workflow

Applying the BCF API specification, as outlined by (buildingSMART International, 2023a), is recommended to facilitate prompt data exchange. Particularly, the BIMsnippet object within the BCF API framework is optimally designed for exchanging subsets of information, utilizing a harmonized schema. Particularly, the BIMsnippet object within the BCF API framework is optimally designed for exchanging subsets of information, utilizing a harmonized schema. A BIM snippet is a partial model referencing a schema, ensuring structured standards for its content. The Information Delivery Specification (IDS) XML schema is integrated with our proposed methodology. The IDS XML schema is integrated with our proposed methodology. Moreover, the pertinent attributes defined in the BCF standard are selectively employed for initiating and

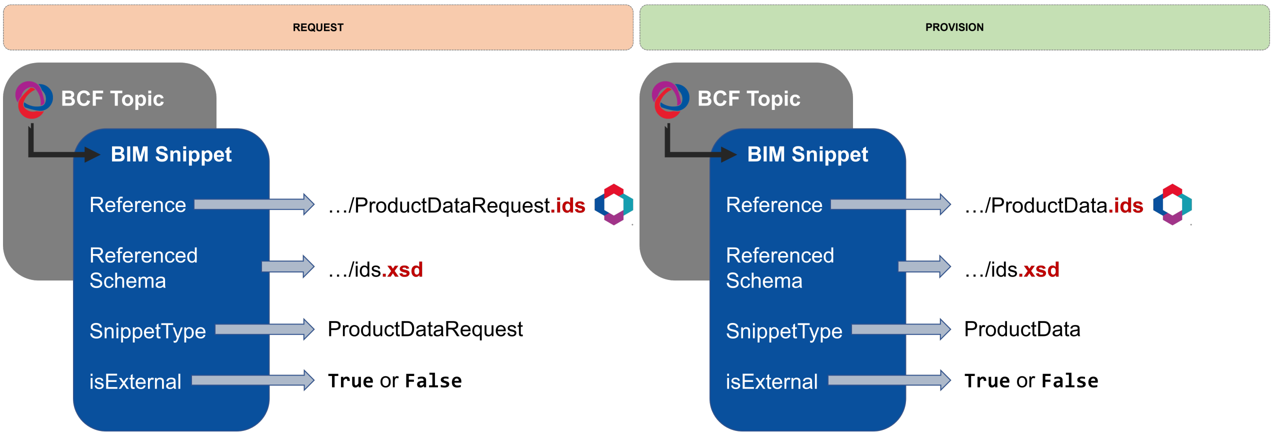

Figure 3: Schematic representation for the use of the BIMSnippet object for the BCF API for the mapping of the data request (left) and the data provision (right)

fulfilling data requests. Figure 3 illustrates the foundational principle for requesting and providing entities. The widespread adoption of the BCF API across software vendors significantly attests to its efficacy in streamlining this workflow. By employing this proposed workflow, a product manufacturer can establish a BCF API server as an access point for stakeholders seeking information. In this process, an information requester initiates a new BCF topic, embedding the request details as IDS within the BIMSnippet objects. Conversely, the supplier responds to the request by filling the same BCF topic with a BIMSnippet object that holds the information provision as IDS. This way, the request workflow can be largely automated and scaled if needed.

As an example, if multiple manufacturers are queried simultaneously via the BCF API, a mechanism for multiple suggestions could be conceived. This would allow planners to receive and compare various data samples simultaneously. Based on this comparison, the planner could decide what product to choose. To confirm that all data have been received and entered in the model as required, it can be checked very easily with the original IDS that was used for the request at the beginning - according to the original purpose of IDS, it also serves for model checking and can also be used for this purpose.

Adopting this methodology is anticipated to engender a more seamless and efficient data exchange within the AECO sector, thereby enhancing collaborative efforts and augmenting the quality of project outcomes.

Test Case: Requesting manufacturer properties of a door

To test the viability of our proposed approach in a simple test use case, we set up a common use case together with a manufacturer of door products as it is often encountered in practice: The correct specification of doors is a crucial element to ensure safe, user-friendly, and efficient buildings. At this, the key factor is the correct definition of requirements at each door aligned with local standards and regulations. Architects and planners often lack the knowledge to do this properly and are often exposed to the risk of missing important security-related features. The process proposed in this paper helps to enhance this task. In collaboration with the door manufacturer, we used our framework so that a planner generates a specification request (IDS) containing the requirement definitions, formulating a typical information request for a set of doors, mirroring common industry practices. The receiver is a domain specialist who adds the specific values to the request and sends it back to the architect. This roundtrip is repeated along the planning stages multiple times with different requirements, data, and stakeholders. The requested and transmitted response information from the product manufacturer is shown here in Table 1, together with the URI for the mapped source, e.g. bSDD:

Table 1: IDS Exchange for Door Specification with iterative planner and manufacturer responses, including URIs

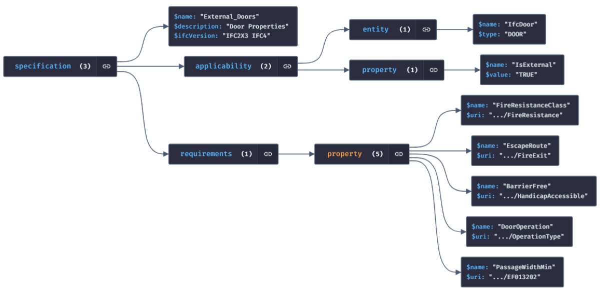
Information	URI	Responses
FireResistanceClass	🔗	T30
EscapeRoute	🔗	RW DIN 179
BarrierFree	🔗	True
DoorOperation	🔗	A (Automatic)
PassageWidthMin	🔗	900mm

The resulting IDS files for information request and provision are shown in Figure 4 - to enhance understanding further, it is shown as a graph-based illustration.

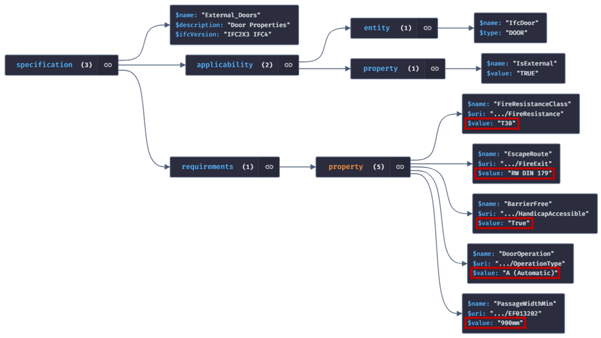
Conclusions & Outlook

The proposed method of utilizing IDS alongside bSDD and other data dictionaries presents a novel pathway toward overcoming the long-standing challenge of standardized product data provision within the AECO industry. This approach promises enhanced data accuracy and availability and fosters a collaborative ecosystem among the various stakeholders, driving the industry toward a more integrated and efficient future.

Building upon the presented research, several avenues emerge for further investigation:



Query of features in an IDS specification



Providing features by assigning values (marked red)

Figure 4: graph-based representation of a (left) query and a (right) response based on IDS-XML

Industry Adoption Analysis: Investigating the barriers to, and facilitators of, widespread adoption of this standardized data provision method within the AECO industry.

Integration with Existing Systems: Exploring this method's compatibility and integration possibilities with existing industry data management and project management tools.

Exploratory Prototype Development: In our study, we have outlined a conceptual framework designed to standardize and streamline product data exchange within the AECO industry. Moving forward, the next phase of our research will focus on evolving this conceptual framework into a more tangible model that can be rigorously tested and validated. This will involve developing an initial prototype for a broader spectrum of product data queries and processes. The prototype will be designed to demonstrate the practical applicability of our framework in real-world scenarios, allowing us to assess its effectiveness and make iterative improvements based on feedback from industry stakeholders. This progression from a conceptual framework to a prototype is crucial for bridging the gap between theoretical research and practical implementation. It will provide valuable insights into the challenges and opportunities associated with deploying such a system on a larger scale, thus paving the way for widespread adoption in the industry.

Limitations and Future Research Directions

While our current framework focuses primarily on model-based workflows typical of the AECO industry, a significant portion of the sector still operates without such models, particularly in managing existing, non-digitized assets. Given this gap, an important question for future research arises: how can the framework we propose be adapted to support non-model-based workflows effectively? This question is crucial as it aims to extend the benefits of standardized product data exchange to broader contexts within the industry, ensuring inclusiveness and broad applicability. Answering this question involves exploring methods to generalize the principles of our framework to support workflows that do not rely on structured digital models, thus expanding the scope of its utility and impact.

Additionally, it is important to note that the current implementation of IDS is limited to alphanumeric information exchanges and does not support the transfer of geometric data. While this is acceptable as an initial step, further investigation is needed since some product information exchange might also rely on geometric data, not just characteristics.

This endeavor lays the groundwork for a series of potential advancements in addressing the product data provision challenge, pushing the frontier of information management within the AECO domain.

Acknowledgments

The authors gratefully acknowledge the support and resources that made this research possible. This work has been carried out mainly within the framework of the openDBL project, which has received funding from the European Union's Horizon Europe research and innovation program under grant agreement No 101092161. We are deeply grateful for this fundamental support. Furthermore, our thanks also go to the NEMETSCHEK Innovation Foundation, whose financial contributions have been an essential basis for the progress of our research and, thus, of crucial importance. Additionally, the authors extend their sincere thanks to dormakaba Deutschland GmbH for their practical contributions to this study.

A KNOWLEDGE GRAPH MODELING APPROACH FOR AUGMENTING LANGUAGE MODEL-BASED CONTRACT RISK IDENTIFICATION

Chunmo Zheng[1], Yinqiu Tang[2], and Xing Su[1]
[1] Zhejiang University, Hangzhou, China
[2]PowerChina Huadong Engineering Corporation Limited, Hangzhou, China

Abstract

Contract risk identification is essential for preventing disputes and losses in construction industry. Large language models (LLMs) have impacted various natural language processing tasks, offering a promising avenue for automating contract review without extensive data processing and feature engineering. However, LLMs still has difficulty in recalling facts while generating knowledge-grounded analysis, especially when related to complex domain knowledge. This paper introduces a Knowledge Graph (KG) modeling approach to enhance the LLM-based automated contract risk identification. A case study demonstrates that our approach exhibits enhanced performance on risk identification tasks compared to non-augmentation scenario.

Introduction

Legal issues, such as disputes, claims, and litigation, frequently occur in construction industry, due to the growing size and complexity of construction projects. The use of natural language in contracts has been identified as the leading cause of such issues (Zait & Zarour, 2018). Specifically, semantic vagueness and ambiguities in contracts can lead to disagreements and misunderstandings between parties, resulting in conflicts or disputes (Mahfouz et al., 2018).

Natural Language Processing (NLP) techniques offers a promising tool to automate contract text processing, thus reducing human errors and increase efficiency. NLP has demonstrated its potential in various automated text processing tasks within the construction industry, including automated contract reviewing (Lee et al., 2020), automated compliance checking (Salama & El-Gohary, 2016) and similar case retrieval (Zou et al., 2017). These techniques can be broadly categorized into rule-based, machine learning-based and deep learning-based methods. However, two limitations have been frequently highlighted in the current literature. First, existing methods rely on sufficient high-quality annotated data to perform the domain-specific tasks, which is highly data-dependent and lack in scalability. Second, current approaches are facing the criticism of only predicting fragmented risk labels without an interpretable risk reasoning.

To mitigate the aforementioned problems, researchers have proposed using large language models trained on a massive amount of unstructured data to facilitate the legal and contractual reasoning tasks. For example, LLMs have begun to reshape the practice of legal services among professionals (Fernandez, 2023). Many argues that the model's ability to learn new tasks from limited data would significantly reduce the human labor in data annotating and feature engineering. However, it still faces many challenges when adapting LLMs to downstream contract risk reasoning. They may struggle with domain-specific knowledge and may not be able to provide explanations from expert perspective, along with factual errors.

Existing works have shown that retrieving structured triple-formed knowledge from KGs can significantly improve LLM's performance on knowledge-intensive reasoning. KG is a data structure designed to accumulate and represent real-world knowledge, where nodes represent entities of interest and whose edges represent various relations between these entities (Hogan et al., 2021). The explicit knowledge representation of KGs can be provided as external knowledge to guide LLMs towards more robust and interpretable knowledge reasoning process (Yang et al., 2024).

Motivated by the identified challenges and existing KG-augmented LLMs solutions, this paper proposes a nested knowledge graph (KG)-enhanced LLM method for automated contract risk identification. A comprehensive framework of developing the ontological layer and instance layer of contract KG is introduced. The nested KG can capture the intricate and interconnected relation within contract clauses, which provide structured and accurate external knowledge for LLMs. Our approach shows improved interpretability of the generated content, and also sheds a light on the integration of LLMs and KGs in automated contract review systems and other knowledge-intensive domain reasoning tasks.

Literature Review

NLP-assisted contract management and the role of prior knowledge

NLP techniques have been widely used in addressing legal issues in construction projects (Hassan et al., 2021).

In contract review, many researchers perform the detection of requirement clauses or poisonous clauses. Lee et al. (2019, 2020) use NLP and semantic syntactic rules in both risk-prone clauses extraction and contractor-friendly clauses detection, achieving the F-score of 81.8% and 80%. Machine learning-based NLP is employed to detect risk-prone paragraphs in contract, achieving an accuracy of 94% (Chakrabarti et al., 2018). Additionally, many studies have also used machine learning algorithms to classify contract clauses into different categories to facilitate contract review process. The categories include requirement or non-requirement clauses, different categories of construction projects or different categories of risks (Candaş & Tokdemir, 2022; Hassan & Le, 2021).

Turning to automated regulation text processing, automated compliance checking aims at detecting the violation with construction laws or regulations. Semantic text classification in unstructured provisions is the first step to perform the automated compliance checking task (Beach et al., 2020). Salama et al. (2016) used a hybrid approach combining semantic analysis and machine learning to classify clauses, achieving a recall of 100%. Zhou and El-Gohary (2016) introduced a rule-based NLP method to classify environmental requirements, alongside a machine learning-based approach for regulatory codes classification.

These studies reveal that NLP techniques have achieved a promising performance in the contract document analysis. However, owing to the unique and complex nature of contract terminologies and semantic patterns, it is difficult for generic NLP models to produce equally reliable performance in construction contract domain without a proper adaptation (Hassan et al., 2021). A few recent studies have attempted to settle these issues by integrating domain-knowledge into the NLP models with the help of semantic representations such as taxonomy, ontology and KG (Lee et al., 2019; Xu & Cai, 2019; J. Zhang & El-Gohary, 2016). These studies have shown an impressive performance, highlighting the importance of integrating domain-knowledge in the future NLP-assisted contract analysis.

Knowledge representation of domain knowledge and the issue of complex knowledge modeling

Semantic web technologies enable the representation of machine-readable data on the web (Kumar, 2019). It is widely adopted in the Knowledge Representation (KR) of domain knowledge by defining domain concepts, enhancing domain information integration and performing logical reasoning (Li et al., 2022). Ontology is one of the fundamental concepts in semantic web technology. It provides a conceptual model to describe a set of concepts in a domain (S. Zhang et al., 2015). Many researchers have developed construction domain ontology for efficient knowledge management, compliance checking, risks or conflicts detection (Zhong et al., 2019; Z. Zhou et al., 2016).

Ontology can function as formal representation to create knowledge graphs (KGs). Recent years, KG has been appeared as a major trend in KR technique to serve many industrial applications (Fang et al., 2020). It presents knowledge in the form of labeled directed graph. Each entity is considered as a node and they are linked via edges which represent relations between entities. The basic unit of KG can model binary semantics with RDF triple (Duan et al., 2017).

In real world knowledge of many domains, especially contract domain, there are always additional information conveying conditional, temporal or provenance information that are beyond the modeling ability of a triple. Modeling and extracting such metadata are beneficial for efficient domain knowledge management. Semantic legal metadata extraction is also crucial for interpreting legal provisions (Sleimi et al., 2019, 2021).

Data modeling solutions for RDF metadata include standard reification, singleton property and RDF-star (Hartig & Thompson, 2021). They are able to represent additional contextual information attached to individual triples (Orlandi et al., 2021). The metadata representation in the graph structure have also been explored. Temporal KG and event KG associate triples with time or site hyper-edges, where an event triple is considered as a semantic unit (Lv et al., 2022; Park et al., 2022).

Contract KG modeling approach

Motivated by the challenges of representing complex knowledge in contract, we introduce the nested KG framework. This framework defines a triple in knowledge graphs as head and tail nodes connected by a relationship edge, while allows nodes to appear as either a single node or a fact node. A fact node is a nested entity which contains a triple inside. This allows a triple to be treated as a node, so that further constraints or statement can be link to the triple. The symbolic definition of this framework is given in Table 1. h, r, t denotes the head entity, relation and tail entity respectively. E, F, R refers to the collection of single entity, fact (nested entity) and relation. Single entities and facts can be interlinked with each other to form nested triples, namely entity-to-entity, entity-to-fact and fact-to-fact triple.

Table 1: Definition of nested triples

Triple	Definition
T_{E2E}	$T_{E2E} = \{(h, r, t) \mid h, t \in E, r \in R\}$
T_{E2F} /T_{F2E}	$T_{E2F} = \{(h, r, t) \mid h \oplus t \in \{E, F\}, r \in R\}$
T_{F2F}	$T_{F2F} = \{(h, r, t) \mid h, t \in F, r \in R\}$

By expanding the concept of entities and triples in knowledge graphs to multi-layer nested structure, the knowledge representation framework can capture deeper semantics and interconnected facts. When dealing with the complex relations in contract context such as conditional, temporal and compound relations, our framework is able to incorporate not only the scattered concepts, but relations among the concepts.

Principally, the nested structure can be infinitely nested, in order to represent more complex semantics. However, it is important to note that there exists the trade-off between expressivity and scalability of knowledge graph, where the more complex nested layer will limit the graph scalability.

Ontology layer development

In this section, a contract ontology based on the nested knowledge graph framework is developed to represent contractual knowledge. As shown in Figure 1, the ontology provides a hierarchical conceptual schema for modeling contract semantics.

contractual relations can either be conditional relations or temporal relations in the contract. Based on this, we can extract the contract rules as, for example, <Statement, if-then, Event> or <Event1, withinPeriodOf, Event2>.

Instance layer extraction

For representing the contract knowledge graph instances, RDF-star language is chosen for its efficiency in representing nested data structures efficiently and directly, without introducing redundant nodes.

Figure 2 illustrates the procedure of constructing nested knowledge graph from sample construction contract

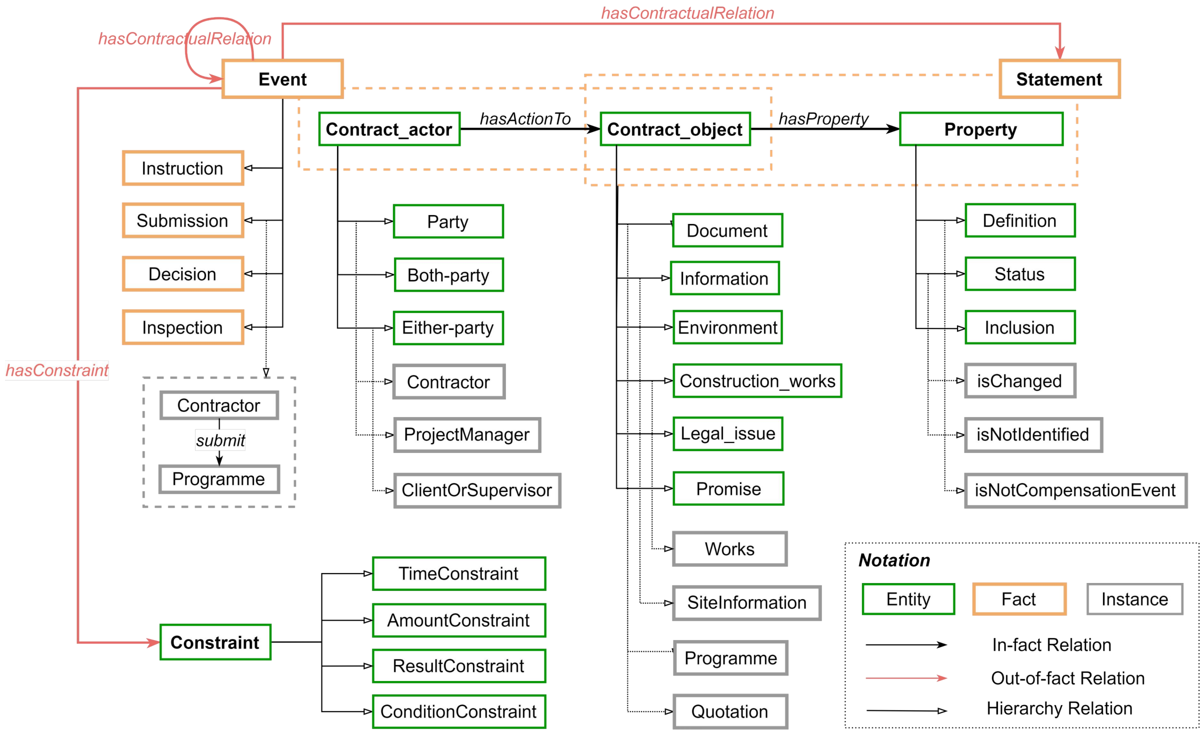

Figure 1: Ontological layer of nested contract KG

The core entities in the ontological layer of nested contract knowledge graph contains “Contract_actor”, “Contract_object”, “Property” and “Constraint”. “Contract_actor” and “Contract_object” class can be joined by the “hasActionTo” relation to form the basic “Event” class fact: <Contract_actor, hasActionTo, Contract_object>. For example, <Contractor, submit, Programme> is an instance of “Event” class, and more specifically, it is under the “Submission” subclass. Similarly, the description of the property of certain product is called a “Statement”. The fact <Programme, hasProperty, isNotIdentified> is an instance of “Statement” class.

In the contract clauses, a “Event” always has many constraints. The “Constraint” class can be attached to the “Event” class as <Event, hasConstraint, Constraint>. In real instances, the relation and tail entity should be replaced by specific constraint types such as <Event, hasTimeConstraint, beforeCompletionDate>. Finally, we have the “hasContractualRelation” edge to connect a Event and a Statement, or connect two Events. The

clause. First, entity extraction is performed by linking the identified entities to the predefined ontology classes. For example, “Contractor” and “Project Manager” belongs to Party class, while “Proposal” belongs to Document class. Accordingly, two Fact is recognized as (Contractor, make, Proposal) and (Project Manager, accept, Proposal), denoting two events in the contract. Finally, temporal relation “within two weeks of” is used to link the two facts and form the knowledge representation. The final RDF-star representation is shown in the rectangular box.

Following the ontology and construction workflow defined above, we can also develop automated approach to facilitate the knowledge graph construction. Given the in-context learning ability of LLMs, recent studies proposed using ontology prompting to generate structured knowledge representation. Motivated by such efforts, our instance development method adopts a semi-automated construction following knowledge representation from unstructured text[1]. This can reduce the intensive human efforts from constructing a knowledge graph to an acceptable level of manual intervention.

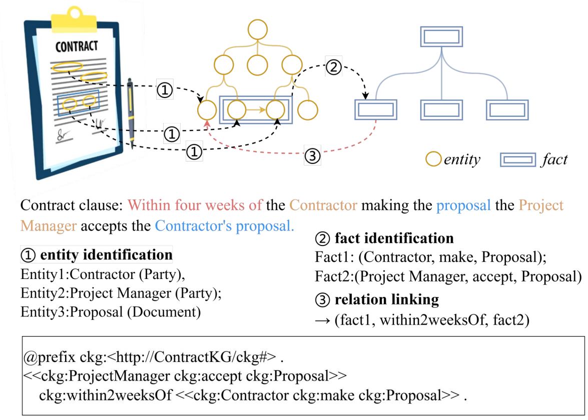

Figure 2: Schematic diagram of constructing nested KG from contract

Nested Contract KG query

The nested contract KG query allows the entity-level knowledge retrieval from the constructed domain knowledge database. This section will briefly introduce the construction of domain knowledge base and the contract knowledge query. The ontological layer of contract KG was created in Protégé, and the instance layer was stored in RDF-star language as a turtle file. The classes and instances were then imported into graph database such as GraphDB or Neo4j. Therefore, the query can be performed through SPARQL or Cypher language.

In practice, standard form of construction contracts (SFCCs) serves as a standard for regulating the responsibility and roles for stakeholders. They are the important knowledge for understanding and reviewing the contracts. We present sample queries of the SFCC KG as in Figure 3. In the first query in (a), contractor may want to know all of the time constraints for submitting documents. Through graph database, the documents and corresponding time period for submitting will be returned both in RDF and graph view. We can also explore interlinked concepts in the graph database. As shown in (b), we can perform a more complex query related to conditional relation of two "Event" class. A triple will be retrieved to indicate what a party should do in this case.

Q (TimeConstraint): What are the time constraints for documents that Contractor is responsible for submitting?

```
PREFIX ckg: <http://ContractKR/ckg#>
PREFIX rdfs:<http://www.w3.org/2000/01/rdf-schema#>

SELECT ?o ?b WHERE {
BIND (<<ckg:Contractor ckg:submit ?o>> AS ?a)
?a ckg:hasTimeConstraint ?b .
}
```

(a)

Q (Behavior): What should parties do if quotation for an acceleration is accepted?

```
PREFIX ckg: <http://ContractKR/ckg#>
PREFIX rdfs:<http://www.w3.org/2000/01/rdf-schema#>

SELECT ?c WHERE {
BIND (<<ckg:QuotationForAnAcceleration
ckg:hasProperty ckg:isAccepted>> AS ?a)
?a ckg:if-then ?c .
}
```

(b)

Figure 3: Demonstration of query in contract KG

Augmenting LLMs with contract KG on automated contract review

In this section, we propose the overall framework to integrate nested knowledge graph in automated contract review using natural language prompting.

Figure 4 illustrate our contract KG-enhanced LLM contract review framework. The aim is to retrieve external knowledge in the nested contract KG for augmenting contract analysis task. Given a contract clause c, a set of natural language query $Q = \{q_1, q_2, \ldots, q_n\}$ will be generated, and subsequently transformed into SPARQL query $S = \{ s_1, s_2, \ldots, s_n \}$. External explicit knowledge $K = \{ k_1, k_2, \ldots, k_m \}$will be retrieved in RDF-star format and feed back to LLMs. The final prompt $P = \{r|c,\ k\}$ is designed to generate corresponding risk analysis result with the initial contract clause input and the retrieved knowledge.

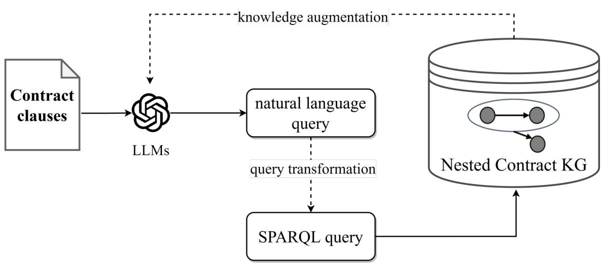

Figure 4: Contract KG-augmented LLM contract review pipeline

Specifically, in the first query generation stage, the language model is prompted to analyze the review task and output relevant queries based on the given contract clauses. The prompt is designed for asking the questions such as "What terms in this clause need further clarification?" and "What knowledge about the clause is required to determine the risk?". The output should be querying property of certain terms, constraints of contract

[1] https://bratanic-tomaz.medium.com/constructing-knowledge-graphs-from-text-using-openai-functions-096a6d010c17

events as external knowledge of the contract context. In this stage, we aim to stimulate the in-context learning ability of LLMs for identifying what external knowledge is needed in the context, to bridge the knowledge gap with experts. In the query transformation stage, the natural language to SPARQL query translation requires LLMs to map the concept in natural language query to classes in the defined knowledge graph. Multi-hop query can also be included in order to respond to the natural language query. After the knowledge retrieval from nested contract KG, the triple-formed knowledge and the initial contract clause will be input for prompting LLMs to generate the final result. This whole process performs in a retrieval-augmented fashion, providing external knowledge for the automated contract risk identification.

Case study

In this section, we validated our approach on contract clauses collected from international construction projects. The contract was thoroughly reviewed by contract experts, and the sample clauses-review pair was given as the gold standard, as shown in Table 2. The sample clause was input for risk identification and analysis in the standard LLM review (baseline) and KG-enhanced LLM contract review pipeline (our method), respectively. In the baseline setting, only contract clause was input for LLMs to identify the potential risk, while our method also provided the final output according to the process described in Figure 5. The evaluation process was manually conducted by domain experts, measuring both the risk label and the accuracy of the risk analysis.

The baseline output and the process of our approach is shown in Table 3. All the content was generated using gpt-3.5-turbo, which is a natural language understanding and generating model provided by OpenAI[2].

Table 2: Contract clause review case overview

Project clause& review demonstration
Contract clause: (a) Contract clause: The amount of the Advance Payment shall be twenty five (25%) of the Supply Price and shall be amortised proportionately against amounts recovered through interim applications for payment throughout the progress of the Supply, starting with the first Interim Payment after the Order Date. The currency shall be the same as the Supply Price. (b) The Employer shall pay the Advance Payment after: (i) receiving the Performance Bond in accordance with Clause 4.3(b), and (ii) receiving the Advance Payment Guarantee in accordance with Clause 4.3(b), provided, however, the Advance Payment shall be made within fifteen (15) days of the later of (i) and (ii). (c) The Supplier shall ensure that the Advance Payment Guarantee is valid and enforceable until the entire Advance Payment has been adjusted by the Supplier, but its amount shall be progressively reduced by the amount adjusted through proportional deductions from Interim Payment amounts paid for the Equipment under Clause 11.5 (Schedule of Payments) …
Risk review: No risk. The amount of Advance Payment is quite generous to the Contractor, which is much higher than the common practice of 10%. Requiring Performance Bond or Advance Payment Guarantee prior to paying the Advance Payment is reasonable practice to protect the interest of the Employer. The requirements for proportional deductions from Interim Payment and validity period are also common practice, which reminds the Contractor of updating the guarantee if necessary. It would be better if the contract could stipulate the Contractor's right when the release of the Advance Payment is delayed by the Employer.

[2] https://platform.openai.com/docs/models/overview

Table 3: Knowledge-enhanced LLM contract review

Automated risk analysis demonstration
Baseline output Risk. The clause introduces financial risk for the Contractor because the Advance Payment is tied to the provision of a Performance Bond and an Advance Payment Guarantee, which can be costly and administratively burdensome. Additionally, the Advance Payment must be repaid through deductions from interim payments, which could affect the Contractor's cash flow. The obligation to maintain the Advance Payment Guarantee until the Advance Payment is fully adjusted adds further financial strain and administrative responsibility on the Contractor.
Natural language query Explain Advance Payment Guarantee. [Q1] What is the condition of making advance payment? [Q2]

SPARQL query
Q1:
SELECT ?p ?actor1
WHERE{
ckg: advancePaymentGuarantee ckg:hasProperty ?p .
?actor1 ckg:submit ckg: advancePaymentGuarantee}
Q2:
SELECT ?actor2 ?c1 ?c2 WHERE{
BIND (<<?actor2 ckg:make ckg:advancePayment >> AS ?e)
?e ckg:hasTemporalConstraint ?c1 .
?e ckg:hasConditionalConstraint ?c2}

Retrieved knowledge from nested KG A1: ckg: Employ ckg:submit ckg: advancePaymentGuarantee . ckg: advancePaymentGuarantee ckg:hasProperty ckg: amountequalToAdvancePayment . ckg: advancePaymentGuarantee ckg:hasProperty ckg: currencyequalToAdvancePayment . A2: <<ckg: Employer ckg:receive ckg:PerformanceBond_and_ advancePaymentGuarantee >> ckg:within14days << ckg: Employer ckg:make ckg:advancePayment>>
KG-augmented output No risk. The clause matches the standard provision regarding the advance payment being conditional on receiving the Performance Bond and Advance Payment Guarantee. The payment timeline of 15 days, as opposed to 14 in the standard form, is slightly longer but does not significantly alter the contractor's obligations or risks. The requirement for the

Advance Payment Guarantee to be valid until the advance is fully adjusted is also standard, ensuring the employer's risk is mitigated without imposing unbalanced obligations on the contractor.

As shown in Table 3, the baseline output using standard prompting stated that the contractual risk lies in the precondition of providing performance bond and advance payment guarantee before advance payment, posing an unbalnaced obligation to the contractor. However, it is an unfounded claim as employer make payment based on receiving advance payment guarantee. Such hallucination arises due to the absence of knowledge related to relevant contract terms and provisions. In the retrieval process, the regulation of advance payment guarantee and constraints of making advance payment was retrieved as the standard provision. After knowledge-augmentation, the model answers “No risk”, with an explanation that objectively analyze the contract provision in comparison to the standard provision. The answer aligns with the expert review and showcases a more coherent and interpretable reasoning in the perspective of a contract expert.

Discussion

In this paper, we introduce the automated contract review method enhanced with contract knowledge graph. This method suggests integrating LLMs and KG to achieve a more interpretable and trustworthy automated contract review process. Although it is a feasible solution, there are some unsolved challenges and future promising directions that we would like to discuss here.

Firstly, there are also other approaches to augment LLMs, such as retrieving knowledge from websites and tools. They can enhance LLMs with real-time information or mathematics ability, which can be combined with domain knowledge graph for comprehensive knowledge augmentation.

Secondly, the current process is conducted semi-automatically, while further study is required for higher level and more accurate automation of ontology construction and query mapping. This might involve ontology learning and searching for the relevant reasoning path in KGs. It is noted that although achievements have been made in ontology extraction, current methods still struggle with complex multi-layer extraction, making human intervention for nested knowledge graph construction inevitable at the moment. The trade-off between expressivity and scalability should also be considered. More accurate and comprehensive knowledge representation comes with higher human intervention.

Thirdly, the current evaluation metrics does not consistently align with expert evaluations concerning the accuracy and coherence of risk reasoning output. This is because the existing benchmarks focus on the tasks where model learn by fine-tuning on task-specific data. Under the LLM era, constructing a benchmarks for construction contract risk analysis will be of great importance.

Conclusion

This paper presents a novel framework for augmenting large language models with structured domain knowledge to improve automated contract risk identification. A knowledge graph modeling approach is developed to capture the complex and interconnected relationships within contracts, along with the contract ontology and RDF-star representation. A framework that integrates knowledge from knowledge graph into the LLM reasoning pipeline using natural language prompting is also proposed. The case study demonstrates improved performance with our knowledge augmentation method on automated contract risk identification task.

THE ANATOMY OF AN ARCHITECT'S ARGUMENT: FORMALLY CAPTURING SOCIALLY-ORIENTED DESIGN INTENTIONS IN THE BUILT ENVIRONMENT

Yazan N. H. Zayed[1], Anna Elisabeth Kristoffersen[1], Gustaf Lohm[1], Aliakbar Kamari[1], and Carl Schultz[1]
[1]Aarhus University, Aarhus, Denmark

Abstract

Sustainability is a large driving factor in today's society. This work focuses on assessing aspects contributing to the social sustainability of buildings. Social aspects encompass, for example, well-being and the building's impact on the occupants regarding qualities such as air quality, visual and thermal comfort, and privacy among others.

We introduce *"ProFormalize"*, a formalization framework, for capturing the structure of design arguments regarding social intentions. Moreover, presenting the formalization of design intentions and activities obtained through case-study focused interviews. In addition, the organization and formalization of design arguments are presented as preparation for software implementation.

Introduction

Building designs are often full of intentions and visions for how the building should be experienced and perceived by its users. These intentions are typically tied together with the physical aspects of the building in the form of different design choices. Examples of this can be that building users feel at home and relaxed in specific areas of the building because the area contains lounge furniture of good quality, or the building users feel a sense of ownership towards the building because they feel that the used decorations and artworks represent them. These intentions are introduced by different stakeholders through the design phases, based on the different perspectives added by stakeholders to the project (Entwistle, 2022). Throughout the changing stages of the building design process, the responsibility shifts between stakeholders (Säwén, 2023), which often leads to the risk of losing design intentions due to different stakeholders' focuses, and that these intentions are often implicit and not explicitly stated in the project documentation.

To effectively address this problem, we present the initial work of developing a formalization framework for design intentions regarding social aspects. The two main research questions in this work are:

RQ1 How can socially-oriented design arguments be captured in the digital representation of buildings?

RQ2 How can socially-oriented design arguments be represented in a way that prepares such kind of data to be implemented in software?

To address these questions, we present the first proof of concept of our framework, and the main contributions are:

C1 Setting up the overall workflow of our formalization framework *"ProFormalize"* in the form of four activity stages (elicitation, organization, formalization and implementation), and the corresponding output of each stage. This contribution is presented in "The formalization framework - ProFormalize" Section, and it addresses RQ1.

C2 Formalization of a selection of socially-oriented design arguments and presenting them in the form of First-Order-Logic (FOL) formulas and Abstract Syntax Trees (ASTs) in order to be used in further software implementation. This contribution is presented in "Analysis of case studies" Section, and it addresses RQ2.

Background

Sustainability is a large driving force in today's society and is influencing decisions and practices across numerous industries. One of these industries is building and construction, where sustainability is commonly addressed based on a large range of building certification systems (Jensen et al., 2018). Existing building certification systems consist of varying criteria, which are related to each of the three pillars of sustainability: environmental, economic and social sustainability (Jensen et al., 2018).

Out of these three pillars, the social pillar is the least developed and the most vaguely defined (Bebbington and Dillard (2009); Boström (2012); Kristoffersen et al. (2024)). The existing definitions and approaches towards social sustainability do not offer neither a widely accepted definition nor a universally accepted list of included aspects (Bebbington and Dillard (2009); Boström (2012); Kristoffersen et al. (2024)).

However, through our recent extensive survey on social sustainability, we have determined that there exists an agreement that social sustainability is focused on humans, and that definitions often include aspects such as, but not limited to, the forming of social networks, health, safety and justice (Kristoffersen et al. (2024)). This lack of a commonly agreed-upon definition can lead to a hollow shell concept of social sustainability due to its large adaptability to different contexts.

Instead of using the term *social sustainability*, it has been proposed to use the term *social values* followed by the specification of which exact value and to whom (Kristoffersen et al. (2024)). The research presented in this paper,

therefore, embraces this word choice to describe the effects on socially-oriented design intentions.
By doing that, we encourage a higher degree of transparency towards what effects are experienced in a building, and thus avoid obscuring these effects within the concept of improving social sustainability.

The formalization framework - ProFormalize

In this section we introduce our overall formalization framework "ProFormalize", and we explain the core purpose of, and activities within, each stage, as well as how the stages connect to each other. We give particular focus to how we formalize socially-oriented design intentions following our so-called "three-level approach".

Deriving the "anatomy" of architect arguments

A socially-oriented design intention argument represents a design activity that is intended to evoke a certain feeling of the occupants regarding their presence in the building or to improve their experience and perception of a specific social intention in that building.
This shows a **causal logical relationship** between "building elements" and "social intentions", that is, the design activity that architects decide to implement, influences socially-oriented design intentions and contributes to the occupants experience in the building. This relationship is illustrated in Figure 1.
For example, "installing artwork in the workplace will increase the sense of belonging to the workplace". This is a socially-oriented design intention argument. The underlying structure of this argument can be derived as follows:
The argument addresses a specific social intention which is the ultimate goal that the architect is trying to accomplish, that is, evoking a sense of belonging to the workplace among building occupants. The other part of the argument defines a design activity that is implemented in order to achieve the mentioned socially-oriented design intention, that is, installing artwork.
This anatomy of design arguments produces our "three-level argument structure", which is a core foundation of how we formalize socially-oriented architectural arguments by making them unambiguous, precise, and explicitly integrated into the digital representation of buildings.
Through the three-level approach, we define three levels of formalization; *the goal level*, *the domain level* and *the product level*. This approach is inspired by the work of Lauesen (2002), where the author introduced the *goal-design scale* that consists of four levels of requirements: *the goal level*, *the domain level*, *the product level* and *the design level*.
In our work, we focus on social intentions in the context of the built environment, that is among others, the set of emotions, behaviors, functions and experiences that people have in buildings.
The goal of this approach is to formalize the socially-oriented design intention arguments of architects and other early design stakeholders about the impact of different arrangements of objects and building elements on the social aspects experienced by building occupants.
Such aspects include sensory aspects (visibility, hearing, etc.), behavioral (movement, functions, etc.), emotional (excitement, privacy, inspiration, etc.).
We define the arguments of interest in our work as the arguments that contain information about both social intentions and the building elements used to affect them.
Consider the following arguments:

1. Installing LED lights in the working area would reduce energy consumption.
2. Organizing regular meetings with the business owners would increase the sense of belonging to the workplace.
3. Installing pieces of art in the workplace would increase the sense of belonging to the workplace.
4. Organizing regular meetings with the owners would improve business performance.

Based on the definition of arguments of interest in our work we can classify the above arguments as follows:
The first argument contains information about a type of building element (the LED lights) but the intended goal is not related to a social aspect but rather environmental and economical, hence this argument does not fit our formalization approach.
The same is true for the second argument as well, where the intended goal is related to social aspects, however the way to achieve this goal is not related to the arrangement of building elements.
The third argument is the one that fits our formalization approach. In this argument, the intended goal is to increase the sense of belonging to the place, which is a social intention, and the proposed way to achieve that, is to install pieces of art, which are building elements.
The fourth argument does not fit our formalization approach, as it does not contain any information about how a certain arrangement of building elements would achieve a social intention.
From the above definition, there are at least two basic levels of formalization that should exist for each design intention argument. These two levels are *the social intentions level* and *the building elements level*.
We use these two basic levels to form a reasonable way to initiate the structure of our formalization approach. The social intentions level is called *the goal level*, and the building elements level is called *the product level*.

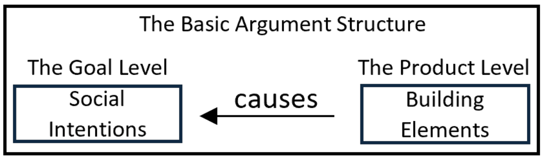

Figure 1: The causality between the two building blocks of the basic structure of a design argument: social intentions and building elements

This provides the basic structure of the formalization approach, that is to classify parts of the arguments into these two levels. The first one includes information about building elements such as walls, doors, slabs, lighting, art, furniture, etc. The second one includes information about the ultimate goal to be achieved which must be a social intention representing the feelings, emotions and behaviors of building occupants.

We argue that there is an implicit reasoning between these two basic levels of formalization, and we should introduce an intermediate level. This would be the smallest number of categories that we can work with in order to introduce a universal formalization approach that can handle a wide range of design intention arguments.

This intermediate level represents the stage between how building elements are arranged and the emotional and the behavioral experience is perceived by building occupants. It explains how changes in the design and in the arrangement of building elements will go through their senses and impact their interaction with their surroundings.

For example, considering the third argument again, "installing pieces of art in the workplace would increase the sense of belonging to the workplace". It is not enough to install pieces of art for the building occupants to have a sense of belonging to the workplace. Although the argument fits the basic approach criteria, it is important to explain how installing this art would create this experience. Where should the building occupant stand in the room to see the art and be triggered by it? What if the building occupant is visually impaired, does not that limit the area of the room from which the art is visible?

These are valid questions, and they help explain the flow of the design argument. Such questions and more are answered with the addition of the third level, *the domain level*, which has information about the sensory experience of the occupant and the functional spaces in the building.

To summarize, *the goal level* contains information about the social intention that is under consideration, and **why** architects are implementing a certain design activity. *The domain level* explains **how** the effect is going to be achieved and *the product level* explains **what** building elements are being used and controlled to achieve the goal of the socially-oriented design intention.

The workflow of ProFormalize

Figure 2 shows the four stages of the workflow and the corresponding output of each stage.

The work in this study is data-driven and case-study-based. The cases are selected related to EU funded project (Probono) of buildings located at Aarhus University Campus, and they are:

1. The Library basement.
2. The basement floor of the Molecular Biology Department.
3. Human Resources Department.
4. Center of Education Development.
5. Institute of Advanced Studies.
6. University Startup Hub (The Kitchen 2.0).

In the following, the four stages of the framework from Figure 2 are elaborated.

Stage (1) Elicitation of socially-oriented design intentions from existing projects through semi-structured interviews. The elicitation of design intentions was conducted through semi-structured interviews with early-design stakeholders, in this case, an architect who has been involved in the six projects mentioned above. The interview was planned based on the guidelines and insights by Robson and McCartan (2016) as well as Kvale and Brinkmann (2015). The interview was planned to have a narrative and anecdotal approach. This is done to encourage the interviewee to focus on what has actually happened and been done and not on what the interviewee wished for or would like to have done (Blommaert and Jie, 2020).

The interviewer developed an interview guide and updated herself on projects connected to the interviewee before the interview was conducted. A generic excerpt from the interview guide is presented in Table 1.

The approach utilised in practice in the interview has similarities with an unstructured interview since the interviewee was allowed to follow his train of thought and move freely between talking about different building projects and social intentions. In cases where the interviewee strayed away from the focus point of the interview, the interviewer utilised one of the prepared questions from the interview guide to reestablish the focus of the interview.

Table 1: Interview Guide

Question type	Question examples
Main Questions	• Which building and design projects have you been involved in? • Can you tell me a bit about the thought behind the project?
Elaborating Questions	• What was the intention? • How was the intention integrated into the project? • Has the intention been successful? • Is the intention adding the expected value to the building? • Have you gotten any response from the users?

The interview language was selected based on which languages the participants in the interview understand, and which working language the early-design stakeholders use. Whenever possible, the interviews were conducted in the same language as the main working language of the interviewee, to encourage the interviewee to use the phrases which were included in the project during the early design stages. The interview was recorded using a voice recorder on the interviewer's phone. This was done to let the interviewer and interviewee focus on the dialogue without slowing down or pausing the interview to take notes. The recording was transcribed in the interview language, either Danish or English, by first using Microsoft Word's

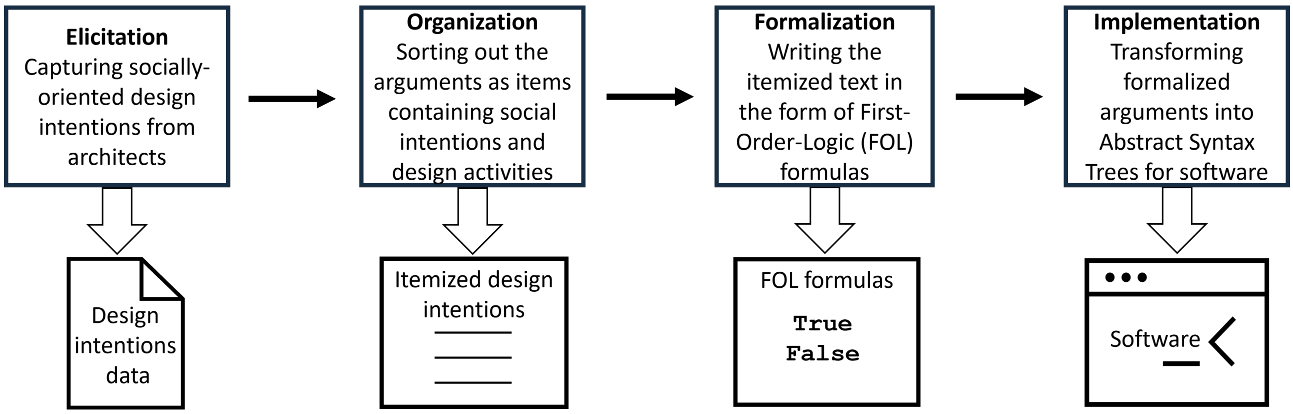

Figure 2: The workflow of ProFormalize

transcribe function, after which the interviewer edited the transcript to remove the errors originating from the transcription's automation.

Stage (2) Organization of the design intention arguments and sorting them out by identifying socially-oriented design intentions and their corresponding design activities to achieve those intentions.

In this stage we categorized the transcription from the elicitation stage into items containing two parts: **the socially-oriented design intentions** and **the design activities**.

This was done by following the four sub-stages: Identification of intents, translation, systematization/ input of data and validation.

The identification of intents was performed by reading the transcribed interview, and marking when the interviewee states a socially-oriented design intention or of an architectural or design-oriented decision. The essence or key points of the intent were then translated into English by the interviewer if the interview was conducted in Danish. After this, the intention was added to the database of the collected intentions, which is managed in an Excel sheet.

The database contains information about in which building the intention was implemented, the activity used to implement the intent, in which interview the intent was identified, and a timestamp referring to when in the interview the intent was mentioned. The references to which interview and the timestamps were recorded to make a direct connection between the database entries, the transcription and the interview recording. The identified and translated intents were sent for approval and review from the interviewee to ensure that the English translation of the intent represents and encompasses what the interviewee meant.

Stage (3) Formalization of the itemized design intention arguments.

In this stage, architects design arguments were represented explicitly, including the categories of targeted building occupants, their senses that the design activity is trying to evoke and the surrounding environment or situation.

The core of this level is to systematically identify implicit and ambiguous aspects of each design intention argument and systematically decide how to disambiguate them.

In order to do that, each statement was manually translated into first-order-logic formulas based on the three-level approach presented in "The formalization framework - ProFormalize" Section. This makes particular aspects of the argument explicit such as occupant sense-experience, the surrounding environmental conditions, etc.), moreover, natural language concepts are expressed as predicates and terms, and combined into formal logical statements.

In addition, qualitative spatial prepositions are grounded with definite interpretations that at the same time allow architects to adjust them based on their reasoning.

Hence, this approach provides architects with a structured form of building blocks to present their arguments in a valid way and shows them what different terms they can use in each level.

The three levels of formalization are defined as follows:

The goal level contains predicates about **social intentions**. Those predicates refer to the aspects that affect the experiences and the feelings of building occupants. The goal level is the only level that can take such predicates, as it is the level that represents the objective of the design activity and describes the accurate intention behind that activity.

The domain level contains predicates about **building occupants and their senses**, this level takes predicates from two major categories which are:

1. **Spatial artefacts**, those are regions of empty space that contain important semantic value because they represent the space in which an object can be seen, heard, used, etc. For example, the movement space of a room, which is the space where people can move within a room, or the visibility space and the hearing space of humans, they refer to the region of empty space where humans can see or hear the visual or acoustic effect of a building element, respectively. (Bhatt et al. (2010)), (Bhatt et al. (2012)).
2. **Spatial prepositions**, those are the terms that represent the direction, orientation, or position information of spatial artefacts and building elements, such as in front of, between, near, inside, directed at, etc.

The product level contains predicates about **building elements** that are going to be used or arranged in a specific way to affect a specific social intention.
Figure 3 demonstrates this structure and presents some examples of each predicate category.
Stage (4) Implementation of the formal design arguments as Abstract Syntax Trees for software development.
In this final stage we performed a direct one-to-one translation from the formulas into first-order abstract syntax trees to be used in software implementation.

The Goal Level	The Domain Level			The Product Level
Social value predicates	Spatial artefact predicates	Spatial preposition predicates	Building occupant predicates	Building element predicates
privacy()	visible_space()	inside()	occupant()	art()
curiosity()	hearing_space()	between()	student()	wall()
belonging()	function_space()	near()	elderly()	use_art()
.	.	.	.	.
.	.	.	.	.

Figure 3: Predicate rules of the three-level approach

Analysis of the case studies

In this section, we discuss in more detail the case study that is the focus of this research, which originates from a project conducted at the building housing the Department of Molecular Biology at university campus (institution name removed for blind review). The building houses students, researchers and other university employees. Most of the collected intents focus on how the students use and feel in the building, since students are the primary users of the areas which the interviewed architect has focused on.

Elicitation

The elicitation of socially-oriented design intentions has been conducted through semi-structured interviews in accordance with the description of the Elicitation stage in the Section "The Workflow of ProFormalize". The intentions were collected through three interviews over 14 months.
The interviewee in all the interviews was the same architect, who has been participating in the planning and implementation of the intentions into the building. The first two interviews were conducted in Danish as sit-down interviews with only the architect and the main interviewer participating. The third interview was conducted walking through the Department of Molecular Biology at the university, where the architect showed the building and the activities tied to the socially-oriented design intentions.
The interview was conducted by the same main interviewer as the previous two, with a secondary interviewer joining the interview with the goal of documenting design choices through pictures and indications on a floor plan drawing. The interview was conducted in English to accommodate the secondary interviewer. The result of this stage forms the basis for the identification, organisation and processing through the following steps.

Organization

The organization of the data consists of identifying socially-oriented design intentions in the transcribed interview, and presenting the intentions in an organized manner that can serve as a stage towards concertising the intents.
The dark red points on the floor plan shown in Figure 4 represent the locations of socially-oriented design intention items which were collected through the on-site interview and have been transcribed and organised. These points are explained in Table 2 and presented in Figure 5.
The dark blue points on the floor plan represent the locations of socially-oriented design intention items that have not been transcribed or organised yet, this includes wall art (a and c), changing wall colours (b), and specific furniture (d and e).

Figure 4: Floor plan of the basement of the molecular biology building, showing locations of organised design intention items (dark red) and the not yet organised items (dark blue)

Formalization

The three levels are represented as first-order-logic formulas, this is explained through the following example of a design intention argument about the case study of the molecular biology building: *"A delimited area of the basement in the building is being equipped with real, one-of-a-kind artworks, the intention with this space is to make an area where the students feel inspired, and actually want to be sitting"*.
Based on the three-level approach we can classify the following parts of the argument as follows:

1. The social intention under consideration is *"sense of inspiration"*, this represents *the goal level*. And this is the intention behind the architect's design decision.
2. The way to achieve the goal is to place the artworks in the area to be visible by the students, this represents *the domain level*.

Table 2: Items of design intentions and design activities

Id	Socially-oriented design intention	Design Activity
*DI*1	The art is growing and developing when you look at it and creating a space where the students feel inspired and actively want to sit.	Installing art consisting of four lamps emitting different light of different temperatures and intensities.
*DI*2	Creating an area where the students actively want to sit.	Installing a sofa that is adapted to the room size, taking accessibility into consideration.
*DI*3	Creating an area where the students actively want to sit.	Installing sockets on the sofa which are directly integrated through a conscious design choice in the sofa.
*DI*4	Creating a subspace within a larger area and providing a feeling of coziness.	Using high contrast colors of the sofa and the wall between the general area and the subspace.
*DI*5	Draw attention and encourage mobility and inspiration to explore the building.	Painting a line of color wrapped around the corner.
*DI*6	Draw attention and encourage mobility and inspiration to explore the building.	Installing a contrasting color expanding into the hallway.

3. The building elements that are under consideration are the *"artworks"*, they represent *the product level*.

The goal level formula: increasing their sense of inspiration of the occupant P in room R:

$$sense\_of\_inspiration(P,R)$$

The domain level formula: the occupant P must be inside the visible space of the artwork A to see it:

$$occupant(P) \wedge inside(P, visible\_space(A))$$

The product level formula: using artwork A in room R:

$$art(A) \wedge room(R) \wedge use\_art(A,R)$$

As our approach is based on case studies of actual buildings, this approach is under constant development and there might be a need to add more levels to achieve a different level of detail, but for the current moment, as it is unnecessary to add more levels, we use this three-level approach, and we could represent different design arguments in a reasonable way.
In the previous example, 6 predicates and 1 function have been used, this is explained as follows:

1. A predicate named "art" is used to define an artwork as a building element. It takes 1 argument, which is the variable representing the artwork.
2. A predicate named "room" is used to define a room in the building. It takes 1 argument, which is the variable representing the room.
3. A predicate named "use_art" is used to specify which art piece is used where. It takes 2 arguments, the first is the piece of artwork, and the second is the place where this art is installed.
4. A predicate named "occupant" is used to define a general building occupant. It takes 1 argument, which is the occupant.
5. A predicate named "inside" is used as a spatial preposition to describe that an element is inside a specific space. It takes 2 arguments, the first is the element itself and the second is the space that the element is inside.
6. A function named "visible_space" is used to represent the space from which a specific element is visible. It takes 1 argument, which is the element for which the visible space is needed.
7. A predicate named "sense_of_inspiration" is used to describe that an occupant has a sense of inspiration regarding a specific building element. It takes 2 arguments, the first is the occupant and the second is the building element.

There is also a term named "Var" that takes one argument only and it is used to represent a building element or an occupant as variables.

Implementation

In the implementation stage, we transform the formalized first-order-logic formulas into abstract syntax trees as a preparation for the software stage. In the abstract syntax tree representation, there are the following elements:

1. **Logical expressions**, that evaluate to either *true* or *false*. This includes logical operators (*and, or, not*) and predicates (*Pred*).
2. **Terms**, that includes functions (*Func*) that is applied to other terms and they evaluate to a new term, and variables (*Var*) that are used to represent different terms.

Figure 5: Images demonstrating the design intention arguments illustrated in Table 2

The following is an example of the abstract syntax tree of the domain level:

```
And(Pred("occupant", 1, [Var("P")]),
 And(Pred("building_element", 1, [Var("A")]),
     Pred("inside", 2,
       [Var("P"),
       Func("visible_space", 1, [Var("A")])])
))
```

Discussion and conclusions

In this paper we presented the initial stage of "ProFormalize", a formalization framework to capture socially-oriented design intentions in buildings.
The underlying structure behind architects socially-oriented design intention arguments was derived and the three-level structure was presented.
In the subsequent phase of this work, the implementation stage of the proposed framework will be further developed. One potential service that this framework provides is to query about socially-oriented design intentions that are related to specific building elements, and vice versa.
Figure 6 shows a floor plan of the basement floor of the molecular biology department highlighting a selected path that an occupant might take to reach their working area. Along the shown path, the occupant passes through several locations where architects have implemented certain design activities using various building elements in order to improve or add a specific feeling or experience.
For example, in design intention (DI5), the architect argue that painting a line of color around the corner will draw attention and encourage occupants to move around the building and explore it. This location is highlighted with the blue point with coordinates (13,3) in the floor plan.

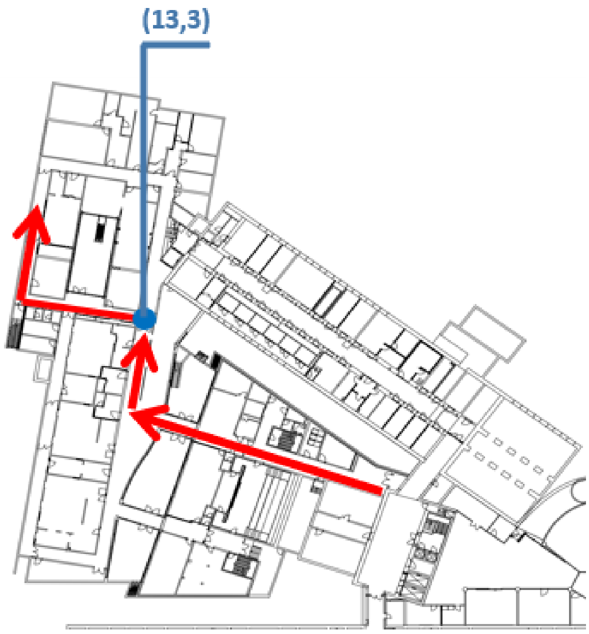

Figure 6: The floor plan of the basement of the molecular biology department, showing a selected walking path of a building occupant and the location of DI5

As an implementation of the framework, the following query example is presented:

```
>>>relation(DI5,building_element).

building_element = wall3265
building_element = paint4873
```

The predicate "relation" is referring to the relationship between building elements and design intentions. The goal of this query is to list the building elements that are used to achieve design intention 5 (DI5), those elements are listed using their unique ids as (wall3265) and (paint4873).
Another query example is to list the design intention items that are affected by a specific building element.
The following query lists the design intention items that are affected by the sofa with the unique id (sofa0012).

```
>>>relation(DI,sofa0012).

DI = DI2
DI = DI3
```

In addition, the user can query about the design intentions that will be experienced according to the argument.

For example, the path shown in Figure 6 is defined as the line segments connecting the set of 2D points:
Path = [(0,0),(10,1),(10,3),(13,3),(13,5)], then the following query can be implemented:

```
>>>social_intention(Path,DIs).
[(at((13,3)),social_intention(inspiration),id(DI5))]
```

The "social_intention" predicate takes two arguments, one is the selected path represented as the set of points and the second argument represents the design intentions that are located along the path.
The output of the predicate will be a list of elements, where each element contains a point, a social intention represented using the "social_intention" predicate, and the design intention represented using the "id" predicate.
This provides architects a way to find out which building elements affect a specific socially-oriented design intention, and reduces the risk of losing some intentions when changing the use or arrangement of the building elements through different phases of the design process.
Additional querying services might also include the visualization of the functional space of certain equipment or service areas such as printing facilities, storage rooms, working stations, among others. This space represents the area from which this equipment or service zone can be used safely, efficiently, privately, etc.
This framework was developed based on case studies of actual buildings that are mainly used by students or employees of an educational institution. Further applicability of this framework include governmental buildings (e.g., offices) and the scale of applications could be expanded to cover multiple buildings located in a close area up to a neighborhood.
The main limitation of this work was the limited amount of collected socially-oriented design arguments. As part of the future work, more locations are planned to be visited and more interviews are planned to be conducted with architects who are working on relevant projects concerning the addition or improvement of social criteria in buildings.

Abstract

Integrating building performance analysis and life cycle assessment in design requires accurate material databases interfacing different analysis engines. However, mappings of databases developed for different purposes are missing. We evaluate whether beyond material name or ID, density can be used as a mapping parameter between environmental, energy, daylight, and structural databases in two cases in Switzerland and Sweden. In total, 16 out of 19 materials could be confidently mapped based on the information available. The variability of the mapping parameter, density, was ±15 % for structural materials, and up to 64 % for insulation materials. The lasting contribution of this work is a consistent methodology for mapping between material databases.

Introduction

To deal with the major environmental impact of the construction industry, the life cycle impact of buildings needs to be considered and reduced during their design (Röck et al., 2020). This needs to be done without overlooking the functional performance of the buildings (Khoshnava et al., 2020). This calls for the integration of environmental Life Cycle Assessment (LCA) and functional Building Performance Analysis (BPA), including structural analysis, approaches into holistic assessment workflows (Säwén, 2023). Such workflows should be introduced in early design stages to achieve the maximum benefit to the final performance of the design (Hollberg et al., 2018; Meex et al., 2018).

For this purpose, several tools both for BPA (Säwén et al., 2022a) and LCA (Säwén et al., 2022b) have been developed. These tools are usually adapted for use with specific material databases. For instance, the BPA toolset Ladybug Tools includes the EnergyPlus database for thermal material properties (Sadeghipour Roudsari and Pak, 2013), whereas the parametric LCA tool Bombyx provides access to the Swiss KBOB database (Basic et al., 2019).

However, including a multitude of analysis methods during design processes quickly becomes time consuming for the designer (Purup and Petersen, 2020). First, they need to develop the geometric model for architectural purposes. Then, they need to adapt this model for each specific analysis mode considered. This includes identifying the associated material properties relevant to each analysis mode. In early design stages the extensive semantic information provided by Building Information Modelling (BIM) workflows, including material data, is usually not available (Cavalliere et al., 2019). This means the analysis process often becomes time- and resource-consuming enough that the analysis is entirely left out, or at best, carried out on a qualitative basis (Jusselme et al., 2020).

One avenue to streamline this process of modelling and data collection, is to make available a *single point of contact* in terms of material properties. By this we mean, as shown in Figure 1, that instead of selecting material properties individually for each analysis module, the material of each building component is selected only once in the user interface. Then, the material properties associated to each analysis module provided by the given analysis workflow are directly linked. In the analysis step shown in the figure, the various models necessary can then be generated based on a consistent material selection.

There are three main benefits for the designer with this approach. Firstly, the modelling and analysis process is greatly accelerated by only selecting the material once. Secondly, the risk of operator error in terms of selecting incorrect materials, or making incorrect mappings between similar materials with different properties, are sharply reduced as the number of operation required are reduced. Thirdly, the widespread use of such a consistent database would make the comparison between different studies achievable, a task which is currently difficult even within a specific analysis domain (Emami et al., 2019).

However, for this to be possible, the mapping of databases developed for different purposes is needed. The designer needs to be able to retrieve trustworthy data for a range of widely used building materials. Such a mapping does not currently exist in the market. This gap has been pointed out in number of research efforts. To bridge it, Fenz et al. (2021) developed an ontology for materials used in renovation and adapted it for use with Industry Foundation Classes (IFC), i.e., a BIM workflow (Theißen et al., 2020). Li et al. (2020) similarly define an ontology aimed at the materials design industry. Hong et al. (2019) instead propose that automated web crawling techniques could be applied to collect consistent material data and avoiding duplicated efforts by collecting data at different points in the design process.

While these studies provide useful starting point for a consistent ontology for material properties, and consistent

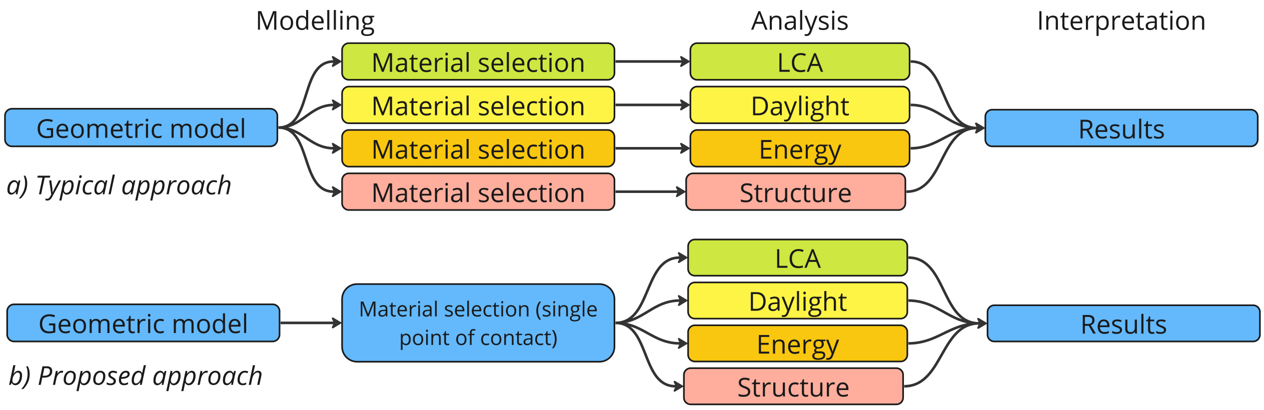

Figure 1: Typical and proposed methods of adding material data to a geometric model.

methodologies for collecting them, no studies known to the authors provide a hands-on approach for actually combining specific databases for LCA and BPA data relevant in the early design stages. We approach this by posing the following research question: *how can material databases developed for different analysis purposes be mapped using material names or IDs and density as mapping parameters?* This question is investigated through two cases, the addition of BPA data to the generic Swedish Klimatdatabas, and the holistic evaluation of an earthen house in Switzerland using KBOB, EnergyPlus, and Eurocode databases for LCA, energy, and structural analysis.

Methods and materials

The overarching method was collecting material data from a variety of sources and intended for different analysis methods, and mapping the data for each material using the density, ρ [$\mathrm{kg\,m^{-3}}$] as a mapping parameter. Both of the case studies are included in an overarching project to study the possibility of developing globally relevant databases for life cycle building performance data as compared to using locally defined databases. The specifics of each case study are described below.

Case study 1: Climate database in Sweden

The aim of the case study carried out in the Swedish context is to create a database which supports a parametric life cycle building performance assessment workflow. This workflow should contain LCA modules as well as BPA modules implemented in the parametric framework Grasshopper® (GH) (Robert McNeel & Associates, 2022).

The workflow is visualised in Figure 2. After geometry is modelled, material data is collected in a single point of contact within the GH interface. Data is collected for the three analysis modules, the analysis is carried out, and the results displayed and exported in the GH interface.

The database used for the climate assessment is the climate database (Klimatdatabas) of the Swedish National Board of Housing, Building and Planning (Boverket) (Boverket, 2023), which is available in Swedish and English. It includes the environmental impact I_{KDB} for the LCA modules A1-A5 [$\mathrm{kg\,CO_2\,eq.\,kg^{-1}}$] (Hollberg, 2016), which is mapped to geometry using the conversion factor density ρ [$\mathrm{kg\,m^{-3}}$] to transform volume of material first to mass of material and then finally to global warming potential. The data included refers to generic materials, not specific products.

There are no standardised databases for energy and daylight material information in Sweden. Instead, data was collected from a variety of sources. The following parameters were collected:

- Thermal conductivity λ [$\mathrm{W\,m^{-1}\,K^{-1}}$]
- Density ρ [$\mathrm{kg\,m^{-3}}$]
- Specific heat c [$\mathrm{J\,kg^{-1}\,K^{-1}}$]
- Roughness [-]
- Thermal absorptance α_t [-]
- Solar absorptance α_s [-]
- Visible absorptance α_v [-]

For the purposes of this article, the thermal conductivity λ and solar absorptance α_s are used for demonstration.

The climate database under consideration currently contains 171 opaque materials. Based on being representative, 10 materials from a variety of categories were selected for evaluation in this study. The mapping process, exemplified in Figure 3 for the case of "Structural steel, all sorts, primary material" in Klimatdatabas, was performed in two steps:

- Mapping of material names or IDs
- Mapping using parameter value (ρ [$\mathrm{kg\,m^{-3}}$])

The mapping of material name or IDs was done manually, by finding identical or near-identical labels for the materials included in the compared databases. When several candidate materials were present, for instance steel materials

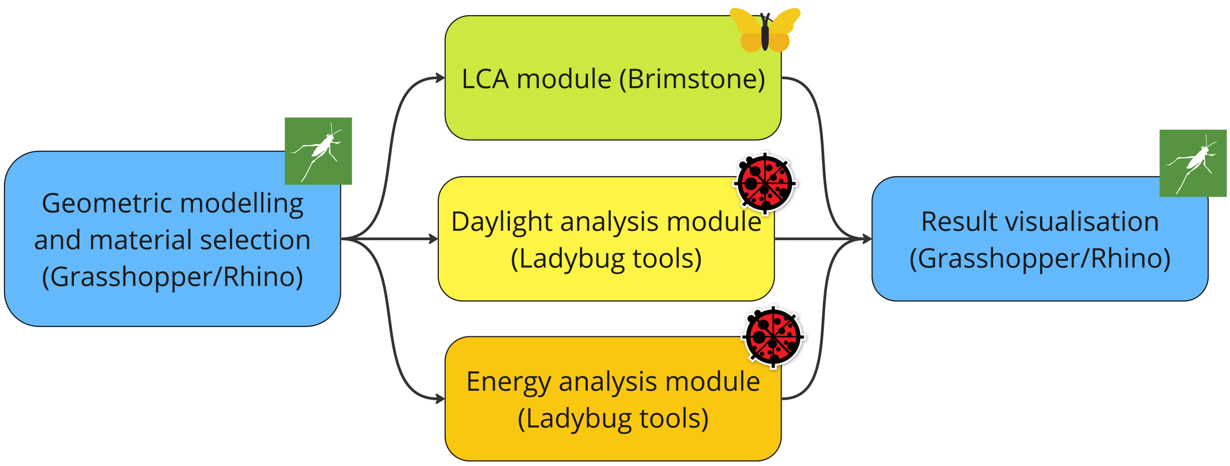

Figure 2: Workflow for parametric life cycle building performance assessment.

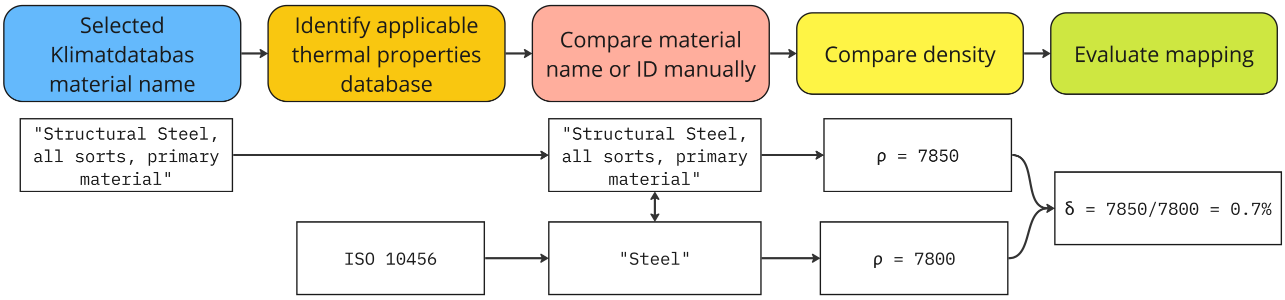

Figure 3: Example of mapping process for material "Structural steel, all sorts, primary material" in Klimatdatabas (Boverket, 2023) to thermal properties database (Pinterić, 2021).

with different structural performance, the material with the closest density was selected. Once the mapping was made, parameter values were collected and the precision of the mapping evaluated using the name or ID and density as comparative parameters to make sure that consistent data was collected.

Case study 2: Earth building in Switzerland

The aim of the Swiss case study is to combine database for an unconventional construction technique: using earthen materials. Earthen materials can be used in a variety of techniques, such as earth bricks or rammed earth, as shown in Figure 4, where rammed earth was used to build a school in the centre of Zurich. In addition to the LCA and BPA modules, the workflow of this case study integrates a Finite Element Modelling (FEM) module in GH, based on the Karamba plugin (Preisinger, 2013).

The FEM database for structural analysis is based on Eurocode materials, such as EN 1992-1-1 (European Committee for Standardisation, 2014) for concrete or EN 338 (European Committee for Standardisation, 2016) for timber. The mechanical properties of the materials are matched to the LCA and BPS database using the conversion factor density ρ [kg m^{-3}]. Although earthen materials are missing from the FEM database, the workflow in GH provides the ability to create bespoke isotropic or orthotropic materials. Assuming isotropic linear behaviour,

Figure 4: Umbau Schulpavillon Allenmoos II: school with rammed earth walls in Zurich © Boltshauser Architekten

the mechanical properties of the earthen materials are derived from the average values given in the RILEM State of the Art report (RILEM TC 274-TCE, 2022). The following parameters were collected:

- Young's modulus E [MPa]
- In-plane shear modulus G_a [MPa]
- Transverse shear modulus G_t [MPa]
- Density ρ [kg m^{-3}]
- Tensile strength σ_t [MPa]

- Compressive strength σ_c [MPa]
- Coefficient of thermal expansion α [°C^{-1}]
- Strength Hypothesis: Mises, Rankine or Tresca

The LCA database used for the Swiss context is provided by the Swiss Federal Conference of Public Project Owners for the Coordination of Construction and Building Services (KBOB, 2023). This database, available in German and French, provides information on materials, building services and systems, and transport. The Life Cycle Impact Assessment (LCIA) methodology calculates the Global Warming Potential (GWP) of materials, including manufacturing (A1-3) and disposal (C3-4). Energy consumption is assessed according to the Swiss standards SIA 2032 (Société suisse des Ingénieurs et des Architectes (SIA), 2020) for energy efficiency and embodied energy of buildings. This LCA database includes earth materials such as rammed earth, earth bricks or earth plaster. Rammed earth is taken as a reference for earth materials in the KBOB database.

The BPS database follows the EnergyPlus data developed by the US Department of Energy's Building Technologies Office (US DOE BTO, 2023). Although there is a mud material in the database suitable for modelling soils, a bespoke earth material is created against a monitored earth building (Estève-Bourrel et al., 2023).

Once the custom materials have been created and integrated into their respective database, and material names or IDs translated from French and German to English, the mapping procedure is carried out in the same way as in case study 1, using a single contact point in GH. In addition to earth materials, conventional materials such as concrete for the slab or timber for the roof are also considered.

Results

Case study 1: Climate database in Sweden

As seen in Table 1, all the materials presented were possible to map to materials in relevant databases for thermal properties, whereas consistent databases for data relevant for lighting simulations are harder to find. As seen in Figure 5, the mapping using the density ρ as a mapping parameter was generally successful, with a divergence of $\pm$15 % for most materials, notwithstanding EPS with a divergence of 36 %.

It should be noted that when collecting the data, no single database could be identified which collected all the relevant information. Instead, data was collected from varyingly from ISO standards (Pinterić, 2021), online resources (The Engineering ToolBox, 2009; Svenskt trä, 2003), and material manufacturers (Vitro Glazings, 2020; Eco Merchant, nd).

Case study 2: Earth building in Switzerland

In the case study 2, the earth building, the densities of the materials considered have a variability of less than 10%. The KBOB LCA database suggests a range in the density

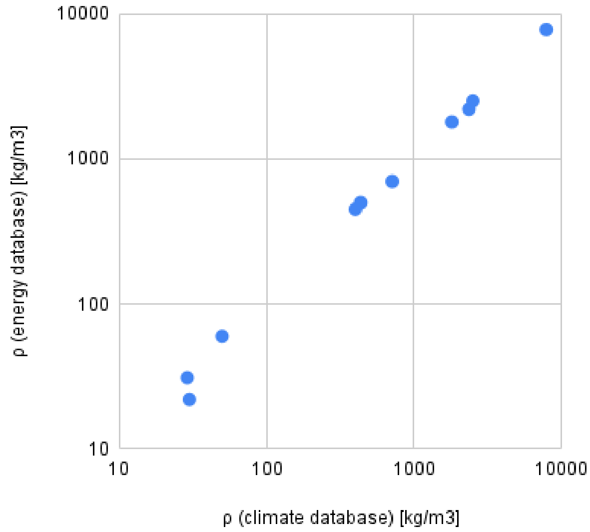

Figure 5: Overlap of parameters in baseline database and comparison database in case study 1 (Swedish climate database). X axis shows the density in the climate database for all materials, and Y axis shows the density in the respective energy databases.

of mineral wool and cellulose fibres, with values ranging from 32 to 160 $\mathrm{kg\,m^{-3}}$ and 35 to 60 $\mathrm{kg\,m^{-3}}$ respectively, which can create a greater disparity in the correct matching of densities, see Figure 6. The fact that the materials are also matched on the basis of their names or IDs confirms that they match correctly.

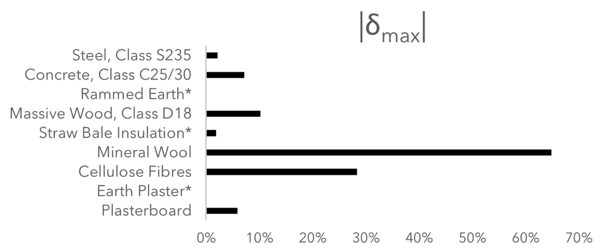

*Figure 6: Maximum absolute difference $|\delta_{max}|$ between the densities of the materials considered for the three studied databases (KBOB, EnergyPlus and Eurocodes). *bespoke material*

It is worth noting that the non-conventional construction materials chosen for this case study, shown in Table 2 such as rammed earth, straw bale or earth plaster, are included in the KBOB LCA database, but are absent from the EnergyPlus and Eurocode databases. The creation of these bespoke data is therefore based on scientific literature. The RILEM State of the Art book (RILEM TC 274-TCE, 2022) provides mechanical and thermal values for earth materials, including density matching the value in the KBOB database. The thermal characteristics were then checked against a monitored earth building. The thermal properties of straw bale were derived from experimental tests (Czajkowski et al., 2022).

Table 1: Excerpt of material mapping in case study 1 (Swedish climate database). I_{KDB} is the environmental impact (A1-A5 modules), λ is the thermal conductivity, and α_s is the solar absorptance. ρ_c is the density defined in the climate database, ρ_e is the density defined in the energy database, and ρ_d is the density defined in the reference data used for daylight material data. δ refers to the difference (in percent) between the ρ_c and ρ_e.

Material ID	I_{KDB}	ρ_c	λ	ρ_e	α_s	ρ_d	δ
Structural steel, all sorts, primary material	3.4	7850	50	7800[a]	0.65	7820	0.7

Discussion

Compared to creating different models for each analysis mode, the creation of a single model which interfaces with several analysis engine would speed up the analysis process by greatly reducing the time needed for modelling and data collection. However, this hinges on the use of one database which can be used to define material properties for a variety of analysis methods. The currently available databases with life cycle impact data generally only include this data as well as conversion factors such as density to be able to map it to geometric data. This is true also in the case for the two climate databases considered in the present study: the Swedish Klimatdatabas, and the Swiss KBOB.

This means data needs to be collected from other resources to add the information needed for holistic life cycle building performance analysis including energy, daylight, and structural analyses, etc. We investigated the extent to which these resources could be mapped to the climate databases using the density as a quantitative and the resource name or ID as a qualitative parameter.

We found that the mapping to publicly available databases for energy analysis could be done based on the name or ID for most typical construction materials like concrete and steel. However, there was a variation in density ranging between $\pm$15% for most structural materials, and up to 64 % for insulation materials. This means there is an uncertainty in terms of how well the material properties are actually matched. Future work could delve into explaining these discrepancies in a deeper examination of the databases, or alternatively, evaluate what kind of uncertainties are acceptable when making design decisions based on the analysis results. It would also be relevant to study the impact of the need for translation between databases defined using different languages.

Further, we found that some important materials in the sustainable transition are missing even in widespread material databases like the ones offered by ISO (ISO 10456 regarding the hygrothermal properties of building materials and products (Pinterić, 2021)) and EnergyPlus (US DOE BTO, 2023). This includes wood materials like glulam and earthen materials like rammed earth and earth plaster, data for which instead needs to be collected from specific material manufacturers, which risks a bias. We also found that while energy data is accessible for most materials, data necessary for daylight analyses like reflectances/absorptances are more obscure and also require the use of data from specific manufacturers.

The method of using the density as a mapping parameter in addition to the name or ID of the specific resource appears useful based on our study, but it adds a layer of uncertainty to an already highly uncertain situation in the early design stages. This situation could be improved through a collective effort to improve climate databases by adding information needed also for other analysis modes. Alternatively, databases for structural, energy, and daylight analyses could be updated to also include climate information relevant to the local context. However, the constant evolution of life cycle data as more ecological approaches are adopted, and life cycle assessments are carried out in greater detail, mean that any such database needs to be in constant flux and requires regular update as new life cycle information is retrieved.

One limitation of our study is of course that only a few materials were selected for analysis. In future work, a wider overview of materials, in different national contexts, could be provided. In such an overview, the deeper analysis of the risk for false positives would be beneficial, especially if transitioning from manual to automatic mapping meth-

Table 2: Mapping of materials in case study 2 (earth building in Switzerland). I_{KBOB} is the environmental impact (A1-3; C3-4 modules), C^{bio}_{KBOB} is the biogenic carbon in the material, ρ_{KBOB} is the density defined in the climate (KBOB) database, ρ_{E+} is the density defined in the energy (EnergyPlus) database, ρ_{EU} is the density defined in the structure (Eurocode) database. $|\delta_{max}|$ refers to the absolute difference (in percent) between ρ_{KBOB}, ρ_{E+} and ρ_{EU}.

Material ID	I_{KBOB}	C^{bio}_{KBOB}	ρ_{KBOB}	ρ_{E+}	ρ_{EU}	$\|\delta_{max}\|$

ods. Another important future work is cross-referencing of a number of available databases for improved robustness. Further, it should be noted that different parameters were collected in the different case studies based on their respective purpose. The overlap of the case studies is the evaluation of name or ID and density as mapping parameters.

Since the only parameters mapped were the name or ID and the density, there is a great risk of misidentifying some materials, leading to incorrect data mappings. One potential way of overcoming this would be comparing further data attached to each resource, such as the material description commonly provided. To investigate such qualitative parameters, natural language processing (NLP) methods could be applied to compare great amounts of textual data.

We acknowledge that the proposed method only resolves the issue of selecting consistent material data for an existing geometric model for use with a variety of simulation tools. Further work is needed to streamline the workflows which generate each necessary analysis model from this single geometric model with added material data.

Conclusion

In the present study, the mapping of life cycle data from the Swedish Klimatdatabas and the Swiss KBOB database to databases for energy, daylight, and structural material properties was investigated. This was done by comparing the names or IDs and densities of materials to check whether the materials could be mapped.

A divergence of ±15 % was detected for structural materials, whereas the divergence of up to 64 % was detected for insulation materials. This indicates that while the mapping using the proposed methodology is possible, it introduces a great uncertainty in terms of the material properties.

We propose the development of robust, nationally and internationally relevant material databases including life cycle information along with energy, daylight, and structural material properties. The mapping of materials used when developing such databases could include the material name or ID, the density, and other parameters. These databases need to be periodically updated and revised as the life cycle impact of materials is improved through the sustainable transition of the production industry. The benefit of the use of such a holistic database is reducing modelling and analysis time, avoiding user errors, and allowing direct comparison between analyses, by only selecting material information once as shown in Figure 1.

In future work, we propose that the applied methodology of matching materials through resource name or ID and density is further tested by comparing several available databases, and by testing it in different national contexts.

Abstract

Network availability and quality is vital for using robotics, real-time digital twins or augmented reality in construction. This paper explores using semantic web models to perform radio propagation calculations for construction sites. We have created an ontology describing and linking data to calculate how building element installation affects attenuation losses. Our findings enable to predict network quality in the context of construction progress to ensure network performance and coverage for mobile construction robotics. Hereby, network optimisation tasks can be automated or planned in time for re-adjusting antenna positions and orientation.

Introduction

The construction sector faces major challenges in creating affordable housing and modernising infrastructure despite rising material prices and a shortage of skilled workers. To meet these challenges, it is necessary not only to optimise the design of buildings but also to dramatically increase the productivity of construction processes. In the methods commonly used in practice, team productivity is strongly influenced by effective communication in coordinating construction activities and fast access to information (Ahsan et al., 2009). Nowadays, this means that a stable network connection is of great benefit. Network availability and quality are crucial to further digitalising the sector and enabling the use of digital twins and robotics, which have increased productivity in other sectors.

Construction activities can be monitored by various sensors, including laser scanners, depth cameras, ground penetrating cameras, RGB cameras, radio frequency identification, inertial measurement units, global navigation satellite systems, and wireless sensor networks (Rao et al., 2022). These sensors are also needed for mobile robots to operate safely on construction sites - especially to provide situational awareness in human-machine collaboration. The success of construction robotics will depend not only on the capabilities of each machine but also on the ability to share observations and, thus, context. This is highly dependent on a robust and high-performance network infrastructure.

Common, widely used wireless network technologies, such as WLAN (e.g. IEEE 802.11), have range, throughput, jitter, latency and reliability limitations that significantly hinder construction automation. Additionally, a lot of devices do not back up Quality of Service (QoS) functionalities. A promising approach to overcome this is the introduction of 5G technologies in the form of campus networks for construction sites. For example, the reliability and low latency promised by 5G networks play an important role in autonomous and remote-controlled construction machinery (Lee et al., 2022). In general, high latency is detrimental to real-time robot control.

While the capabilities of 5G networks can potentially improve network quality and coverage on construction sites, these environments present specific challenges. Unlike fixed factory floor deployments, environmental factors on a construction site are permanently changing. Therefore, networks must be able to adapt and move as construction progresses. Otherwise, limited network performance and connectivity results (Din and Bernold, 2017). As with other wireless radio networks, the quality of 5G networks depends on the characteristics and design of the antenna and the propagation of radio waves. Factors such as propagation losses, including path loss, reflection, diffraction, refraction and scattering, can limit the effectiveness of radio networks (Erunkulu et al., 2020).

Predicting network quality at specific locations on a construction site by estimating the loss of signal strength, considering construction progress, building information, and antenna configuration could significantly contribute to digitalization and automation in construction. The knowledge gained could, for example, influence the navigation preferences of mobile robots to avoid areas with poor network quality.

More promisingly, it could be used to optimise a network setup, where antenna settings, position and orientation can be adjusted based on construction progress. Recent antenna technologies such as Massive Multiple Input Multiple Output (MIMO) allow software-optimised radio, such as beamforming optimizations. Concepts like O-RAN and SD-RAN enable applications to steer RAN so that fewer physical positioning adjustments are required. Still, such applications require exact information about site topology and progress.

To enable this, the proposed network quality prediction requires harmonising and linking data that do not originate from the same source system and cannot currently be put into a machine-readable context. Linked Data and Semantic Web technologies are ideal for linking such heterogeneous data from different knowledge domains. In addition, there are already approaches for Building Information Modeling (BIM) and construction process modelling in the form of Linked Building Data (LBD) ontologies, ifcOWL (Pauwels and Terkaj, 2016) and the results of the Internet of Construction (IoC) project (Brell-Cokcan and Schmitt, 2024). Therefore, the approach described in this paper investigates the development and use of a semantic data model using an ontology to represent the data required for the calculation of radio wave propagation.

State of the Art

Fundamentals in Radio Wave Propagation

Radio waves are electromagnetic waves. As such, they are affected by reflection, refraction and absorption phenomena when propagating through matter. Commonly, the propagation of an electromagnetic wave is described with the wave equation:

$$\begin{aligned} E(x,t) &= E_0 \cdot e^{-i\left(\omega t - \frac{\omega}{c} x n\right)} \mid \text{with } n = n' + i \cdot n'' \\ &= E_0 \, e^{-\frac{\omega n''}{c} \cdot x} \cdot e^{-i\left(\omega t - \frac{\omega n'}{c} \cdot x\right)} \end{aligned} \tag{1}$$

where the first term gives the exponential decay of the wave's amplitude with propagation for $n' > 0$. For the intensity $I(x)$ holds

$$\begin{aligned} I(x) &= \frac{1}{2} \varepsilon_0 c \cdot |n| \cdot |E(x)|^2 \\ &= \frac{1}{2} \varepsilon_0 c \cdot |n| \cdot E_0{}^2 \cdot e^{-\frac{2\omega n''}{c} \cdot x} = I_0 \cdot e^{-\alpha \cdot x} \end{aligned} \tag{2}$$

where α is the attenuation coefficient, and the last identity is known as Beer-Lambert's law. The intensity of the transmitted radio wave is related to its power by multiplication with the unit area $I \cdot 4\pi d^2 = P$. Typically, the transmit power of an antenna is given in the unit dBm. This is equivalent to the power ratio of the signal power in reference to $P_0 = 1\,\text{mW}$ on a $\log_{10}$-scale as in equation 3.

$$P\,[\text{dBm}] = 10 \cdot \log_{10}\left(\frac{P_{RX}\,[\text{mW}]}{1\,\text{mW}}\right) \tag{3}$$

On the same logarithmic scale, the received signal strength P_{RX} at the distance d can be expressed as the sum of the transmit power P_t of the transmitting antenna, its respective antenna gain G_{TX}, the propagation losses along the path between the transmitter and the receiver TL, and the gain of the receiving antenna G_{RX} on the logarithmic scale.

$$P_{RX}\,[\text{dBm}] = P_t\,[\text{dBm}] + G_{TX}\,[\text{dBi}] - TL\,[\text{dB}] + G_{RX}\,[\text{dBi}] \tag{4}$$

The antennas' gain and transmit power are adjustable properties, whereas, for propagation losses, the environment plays a crucial role. Propagation loss describes the reduction in signal strength when an electromagnetic wave traverses a medium capable of absorbing or dispersing a portion of the wave energy. In a simplified model, the total propagation losses can be considered as the sum of the free space path loss (FSPL), reflection loss (RL), and attenuation by penetrating building elements (PL).

$$\text{TL}\,[\text{dB}] = \text{FSPL}\,[\text{dB}] + \text{RL}\,[\text{dB}] + \text{PL}\,[\text{dB}] \tag{5}$$

FSPL refers to "the loss between two isotropic radiators in free space, expressed as a power ratio". The Friis transmission equation (Friis, 1946) can be written as

$$\text{FSPL}\,[\text{dB}] = 20 \log_{10}\left(\frac{4\pi d f}{c}\right) \tag{6}$$

where d denotes the distance between the transmitter and receiver and f the frequency.

Reflection losses describe the signal lost when an object's surface reflects a fraction of incoming radio waves. The reflectance is a material property and depends strongly on the frequency of the incident radio wave and the angle under which the wave hits the surface.

$$P_r = R(f) \cdot P_{in} \tag{7}$$

Lastly, and especially in the construction environment, penetration loss or attenuation occurs when radio waves penetrate building elements since most real-world materials are dielectric materials characterised by permittivity, permeability, and conductivity. To quantify the impact of material properties on wave propagation, we follow the calculations in ITU (2023) and consider the attenuation distance Δ where the amplitude of the electromagnetic field vector has fallen by a factor $\frac{1}{e}$:

$$\Delta = \frac{1}{k_0 \sqrt{\eta'}} \sqrt{\frac{2\cos(\delta)}{1-\cos(\delta)}} \tag{8}$$

In equation 8 η' denotes the real part of the complex relative permittivity $\eta = \eta' + i \cdot \eta''$. The permittivity of the material is then $\varepsilon = \eta \varepsilon_0$. Since the angle of the loss tangent $\delta = \arctan\left(\frac{\sigma}{\varepsilon\omega}\right)$ relates the conductivity σ with the permittivity, the attenuation distance also depends on these properties of the material and the frequency of the wave. In the limit of a good conductor, the attenuation length simplifies to

$$\Delta_{conductor} = \lim_{\sigma \to \infty} \Delta = \frac{1}{k_0 \sqrt{\eta'}} \sqrt{\frac{2}{tan(\delta)}} \tag{9}$$

whereas for a nearly perfect dielectric, it becomes

$$\Delta_{dielectric} = \lim_{\sigma \to 0} \Delta = \frac{1}{k_0 \sqrt{\eta'}} \frac{2}{tan(\delta)} \tag{10}$$

The attenuation distance is related to the attenuation rate as shown in equation 11.

$$A\left[\text{dB}\,\text{m}^{-1}\right] = \frac{20 \log_{10}(e)}{\Delta} \tag{11}$$

As suggested by ITU (2023), we use equations 9 and 10, to express the attenuation rates for conductors and approximately ideal dielectric materials as functions of η' and σ resulting in

$$\begin{aligned} A_{conductor} &= 20 \log_{10}(e) \sqrt{\frac{\pi}{\varepsilon_0 c_0{}^2}} \cdot 10^9 \cdot \sqrt{\sigma f\,[\text{GHz}]} \\ A_{dielectric} &= \frac{20 \log_{10}(e)}{2\varepsilon_0 c_0} \cdot \frac{\sigma}{\sqrt{\eta'}} \end{aligned} \tag{12}$$

Both σ and η' depend on the frequency and can be characterised as follows:

$$\eta' = af^b \quad \text{and} \quad \sigma = cf^d \tag{13}$$

To calculate the total amount of propagation losses, the derived attenuation rates have to be multiplied by the distance the wave travels within the material. Since building elements often consist of several layers of materials, these calculations need to be done for all layers. The thus found value for the expected signal strength can be compared to the RSSI value that can be found in the network statistics of each connected device that fulfils the IEEE standards 802.11 or 802.15.4.

Research on building materials affecting radio wave propagation

Current research on the electromagnetic behaviour of building materials is mainly conducted at the city scale or focuses on the finished building and how the choice of materials affects the signal quality. Exemplary approaches focus on the use of blueprints (Seidel and Rappaport, 1994) and the 3D geometry of the building (Ullah et al., 2020) for ray tracing simulations. Similarly, empirical studies of building penetration losses indicate the effect of façade material, structure and thickness, radio parameters such as frequency, signal strength, incidence angle and the incident field's polarisation. A study by García Sánchez et al. (2022) focused on the impact of building penetration losses at 3.5 GHz across various facade types, examining factors such as the incidence angle, polarization, and material effects within 5G systems. Their findings included an attenuation variation of up to 8 dB based on the incident angle. An example of a compilation of such studies can be found in (ITU, 2021). Like Yamamoto et al. (2019), we relate the received radio signal strength at a dedicated measurement point to the distance between the transmitting antenna and the receiver. Yet, in contrast, in construction, considerations about the propagation losses that affect the radio signal along its path through physical objects need to be included. While only applied studies are available for many phenomena such as scattering, and therefore no values exist that can be meaningfully transferred to individual components and their materials, the necessary characteristic values for permittivity and conductivity are collected in ITU-R P.2040 (ITU, 2023). Therefore, in this paper, we concentrate primarily on mapping these values.

Linked Building Data

Linked Building Data (LBD) leverages Linked Data principles (Heath and Bizer, 2011), connecting information relevant to applications in the Architecture, Engineering and Construction sectors. World Wide Web Consortium (W3C) standards such as the Resource Description Format (RDF) (Lassila et al., 1998) are used. LBD benefits interdisciplinary collaboration (Pauwels et al., 2017) and interoperability (Beetz, 2009). To promote data accessibility, the W3C Linked Building Data (LBD) Community Group has focused on developing modular approaches in recent years(Rasmussen et al., 2020). For material properties, the Digital Construction Building Material (DICBM) ontology, developed by Valluru et al. (2020), is a modular framework to improve the management of building material information within the BIM collaboration process. This ontology encompasses components such as MaterialDefinition, LayerSet, Layer and MaterialProperty. However, it does not include properties for describing the electromagnetic behaviour of construction materials. In contrast to materials, radio antennas and their properties have been completely absent and, therefore, cannot currently be modelled in the LBD context.

Methodology

Scope and competency questions

Calculating values to dynamically predict network quality and coverage on construction sites is mainly related to antennas, their properties, the site topology, and the building plan, including geometry and used materials. Moreover, the construction process, which involves scheduled and performed progress and auxiliary elements such as formwork or scaffolds, needs to be included as changing spatial conditions. As there is not yet the possibility to model and link all the needed data in RDF, an ontology is created to introduce the necessary classes and properties while connecting them to existing approaches from the linked building data domain, as the ontology complements and extends these when possible. The methodology deployed is described by Noy and McGuinness (2001). According to their guide, the first step is to clarify the focus and scope of the new ontology. Three questions regarding the scope (SQ) are defined and answered for that purpose.

SQ1: What domain is covered by the ontology?

The ontology covers radio network modelling and signal strength predictions for construction sites.

SQ2: What is the purpose of the ontology

The ontology should enable the calculation of the Received Signal Strength Indicator (RSSI) calculation to predict radio networks' relative signal strength at any spot on a construction site. Therefore, it is necessary to be able to save and link data relevant to radio propagation of the frequency used connected with the building information modelling and construction process data. It should enable the simulation of wireless communication networks with respect to changing spatial conditions of the construction site and propose possible adaptations to the nomadic network infrastructure.

SQ3: What questions should the ontology answer?

The ontology should be able to answer questions about the topology-related setup of the wireless network infrastructure and its current configuration. It should help assign and query values for building materials describing their type permittivity and conductivity to query and calculate propagation losses dynamically and independently of the deployed radio frequency.

Competency questions (CQ) were developed according to the scope specification. These competency questions are technical-functional, describing what queries should be able to be answered when data is instantiated using the ontology. These queries are not intended to directly answer questions about the expected network quality, as this requires complex calculations. Our goal is to prove that context-enriched values can be retrieved to calculate or simulate approximate values incorporating dynamic construction process information. The CQs are shown in Table 1.

Table 1: Defined competency questions (CQ).

No.	Questions
CQ1	What are the characteristics and position of the transmitting antenna?
CQ2	What are the characteristics and position of the receiving antenna?
CQ3	What building elements that interfere with radio wave propagation are expected to be realized at a given time?
CQ4	What is the material composition of the building elements in question?
CQ5	What are the materials' type, permittivity and conductivity properties concerning radio waves?

Reusing existing ontologies is one of the core principles of Linked Data. Our investigation into existing ontologies that predict radio propagation within construction sites reveals a lack of developed approaches. Therefore, the competency questions cannot be answered with any existing solution known to us. However, for concepts that describe the building elements and the construction process, there are ontologies that we consider to be applicable and mature. These can be built upon and incorporated to achieve greater interoperability. Table 2 gives an overview of the reused or linked ontologies.

Table 2: Overview of the connected ontologies.

Name	Main classes and purpose
bot	*bot:Zone*, *bot:Element*, *bot:Interface* Ontology describing topological concepts of a building (Rasmussen et al., 2018)
ifc	*Ifc:Root* Web Ontology Language (OWL) representation of the IFC schema (Pauwels and Terkaj, 2016)
ioc	*ioc:process* Ontology developed within IoC to describe processes (Kirner et al., 2024)
opm	*opm:PropertyState* An ontology for describing properties that change over time (Rasmussen et al., 2020)
qudt	*qudt:Quantity*, *qudt:Unit* A unified model of measurable quantities and units (QUDT.org, 2015)

The Construction Site Network Ontology (CNO)

The **CNO** ontology is designed as an application-level ontology. It is intended to be used in combination with the LBD ontologies (Oraskari et al., 2021) and *ifcOWL* (Pauwels and Terkaj, 2016) to add construction context, as well as the Internet of Construction Process Ontology (ioc) (Kirner et al., 2024), which enables dynamic scheduling and status information of construction processes. The main classes of the **CNO** ontology describe the missing dynamic data needed to calculate the expected signal strength according to the radio propagation fundamentals. Specifically, these are *cno:Antenna*,*cno:Obstacle* and *cno:Material*. Most proposed additions are object and data properties that extend or link existing classes like *ifc:IfcMaterial* to add metadata relevant to radio propagation.

cno:Antenna

The major new concept to add is the *cno:Antenna*. Simplified, the antennas are subdivided into *cno:Transmitter*, which describes the main antenna and *cno:Receiver*, in this case, the antennas of the devices in the network. Antennas must have object properties that describe the relevant properties. In this first draft, these are limited to position and direction, power, gain, and frequency. As antennas for wireless communication are quite complex, these properties will be extended in future iterations.

cno:Obstacle

An object that leads to reflection and propagation losses caused by its dielectric properties is described with the class *cno:Obstacle*. Although the focus is clearly on the building elements, obstacles, such as formwork, can also be auxiliary or temporary objects of the construction process. In addition, cars or construction machinery are relevant. For building elements, position and rotation can be queried via LBD geometry descriptions or data from the *ifcOWL* instances. Geometry information in conjunction with antenna position and properties can be used to calculate FSPL or coarse reflection effects (see equation 6).

cno:Material

For the object propagation loss, the material composition of the building elements is decisive. Real-life building elements rarely consist of a single material. The *ifc:IfcMaterialLayer* instances can provide material, layerthickness, and direction. Therefore, we propose extending *ifc:IfcMaterial* via *rdfs:subclassOf* with *cno:Material* to add metadata regarding the relevant material type (*cno:Conductor* or *cno:Dielectric*). The values needed to calculate the attenuation rate according to equation 11 are linked as *cno:hasRelativePermittivityFrequencyCoefficient*, and *Exponenet* as well as *cno:hasConductivityFrequencyCoefficient* and *Exponent*. They can be retrieved from Table 3 of ITU-R P.2040-3 (ITU, 2023). The model from which these equations were deduced is only valid in a certain frequency spectrum, so a *cno:FrequencyRange* must also be attached to each material.

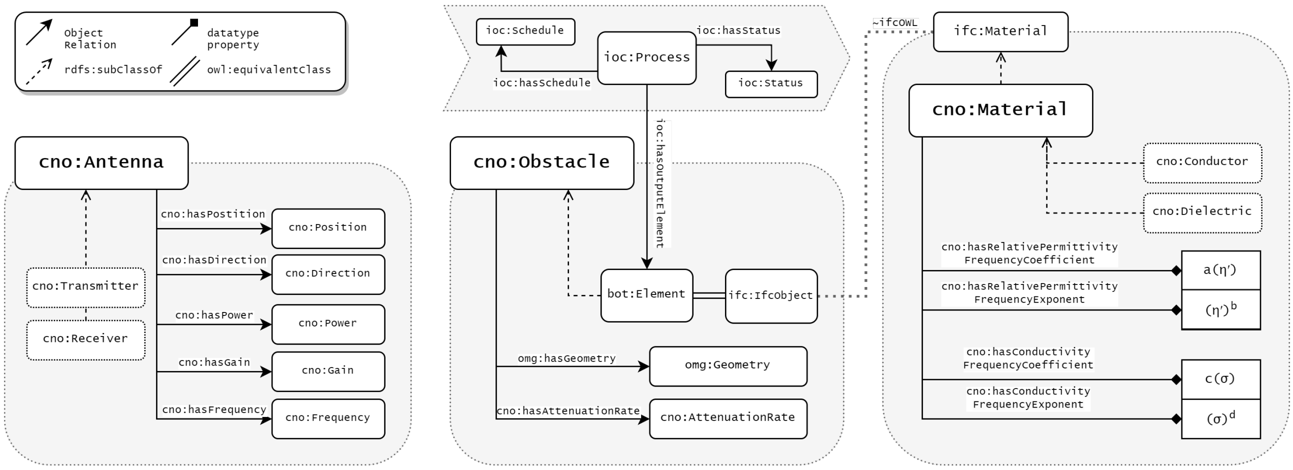

*Figure 1: Main concepts and properties of the **CNO** ontology.*

All classes and properties presented aim to enable the calculation of attenuation rates in a construction site context. For object propagation losses, they can be added to a *cno:Obstacle* with the help of *cno:hasAttenuationRate*. This should be a dynamic, time-stamped value enabled using the OPM ontology's *opm:CurrentDataState* class. This is considered a main improvement over static material bound values found throughout the state-of-the-art. On the one hand, depending on the composite material, the number of layers is due to changes in the course of the construction process. On the other hand, as shown in equations 8, attenuation rates also depend on frequency, which is not necessarily static, depending on the network setup deployed.

Properties of the ontology

The ontology described here represents a first draft of an OWL-based ontology describing radio networks on construction sites. In its current state, the ontology consists of twelve classes, six object properties, and six data-type properties. Figure 1 shows the basic concepts, as well as object and datatype properties proposed.

Evaluation and use-case

A dataset derived from the operational 5G network on the reference site Aachen Melaten was created to evaluate the ontology presented. This does not aim to validate whether the calculated values are precise but to prove that the established competency questions can be answered. Therefore, a dataset created with the help of the CNO ontology provides the data required to predict signal strengths in a dynamic construction site environment.

Due to scientific comparability, a known BIM model, the duplex[1], is used as a source of building information. It is converted to RDF and extended by *ioc:processes*, which describes, using *ioc:Schedule* that a certain building element is expected to be erected at a given time.

The modelled scenario consists of the transmitting antenna, an AW3374-T0-F (1) mounted on a Liebherr L1-24 tower crane, and a Milesight UR75 5G Router (2). The Router is mounted on a Heros 224 mobile AGV from Innok Robotics. A multilayer outside wall of the BIM model is chosen as the element of interest (3). Figure 2 shows the scenario and its components.

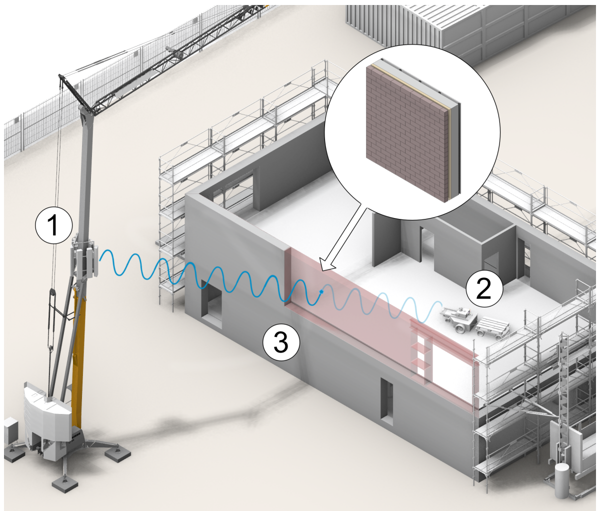

Figure 2: Scenario on the reference construction site in Aachen.

The Antenna and its properties were modelled manually. While values like gain or direction are among the characteristics provided by the antenna's manufacturer, power and frequency are subject to the network setup. It is to be noted that these values are linked to the antenna to simplify the data model and queries. Practically, the radio in use determines these values. The antenna position is designed as a dynamic feature to enable nomadic network setups in reaction to progressing construction processes. The resulting triples added to the graph are shown in figure 3.

[1]https://portal.nibs.org/files/wl/?id=O9inoVWDytV4P3UTS7ildqhVKcTyVlcs

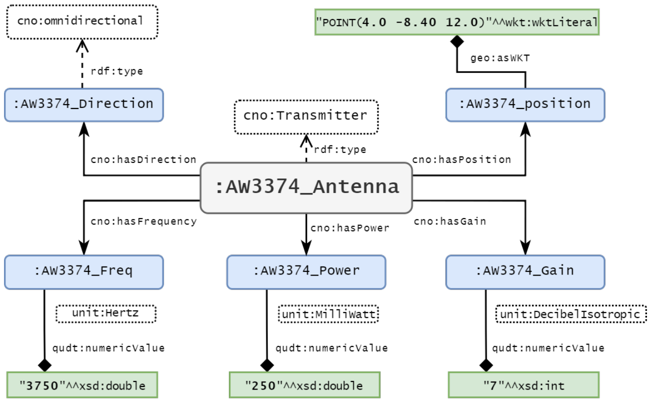

Figure 3: Example for an instantiated cno:Antenna including metadata.

CQ1-2 can be answered by querying the depicted instances in addition to a receiver that is modelled accordingly. Listing 1 presents a query retrieving the transmitter, frequency, and receiver positions. Querying for *opm:CurrentDataState* ensures that the currently valid value is retrieved, which implies the dynamic characteristics of the proposed approach.

Listing 1: SPARQL Query for CQ1

```
PREFIX cno: <http://w3id.org/cno#>
PREFIX qudt: <http://qudt.org/schema/qudt#>
PREFIX unit: <http://qudt.org/vocab/unit#>
PREFIX geo: <http://www.opengis.net/ont/geosparql#>
PREFIX opm: <http://www.w3id.org/opm#>

SELECT ?f ?posTX ?posRX WHERE
   {?Transmitter a cno:Transmitter;
      cno:hasPosition ?posTXState;
      cno:hasFrequency ?fstate.
   ?fstate a opm:CurrentDataState;
      qudt:numericValue ?f;
      qudt:unit unit:Hertz.
   ?posTXState a opm:CurrentDataState;
      geo:asWKT ?posTX.
   ?Receiver a cno:Receiver;
      cno:hasPosition ?posRXState.
   ?posRXState a opm:CurrentDataState;
      geo:asWKT ?posRX.}
```

Retrieving the cartesian coordinates of the transmitter and receiver and the transmitter frequency enables us to calculate the free space path loss as in equation 6.

$$\mathrm{FSPL} = 20\log_{10}\left(\frac{4\pi \cdot 21\,\mathrm{m} \cdot 3.75\,\mathrm{GHz}}{c_{air}}\right) = 70.37\,\mathrm{dB} \qquad (14)$$

To answer CQ3, the process model linked to the building model must be queried. The structure of the query depends on how detailed the process model was created. In its most simplistic form, a *ioc:Process* is created for each *bot:Element*, which describes the "finalization" of said element. The object property *ioc:hasOutputElement* describes that the instantiated Process creates the linked element. Finally, a schedule is added to that process via *ioc:hasSchedule*. To keep it simple, the schedule is only connected to *xsd:datetime*, which expresses the scheduled end time of the process with the help of *prov:endedAtTime*. Querying elements that are the output of processes with this schedule metadata and using a SPARQL Filter for the timestamp will retrieve the necessary building element IRIs.

All values from Table 3 of ITU-R P.2040-3 are collected in a JSON file to include the relevant material properties for radio wave propagation to the data model. Hereafter, material aliases are added to map the materials from the Table to materials in the IFC. Depending on which authoring software is used, these can differ slightly. The Duplex was modelled with Revit, so exemplarily, "Brick" needs to be mapped to "Masonry - Brick". Finally, a Python script queries the data model for IFC materials, locates the materials via the aliases in the JSON file, and updates the graph with the needed material properties. An excerpt of the resulting database is depicted in figure 4. It shows the process logic on the top, LBD element and *ifcOWL* structure, and two of the material layers on the bottom. For enhanced readability, we refrained from labelling *ifcOWL* object properties.

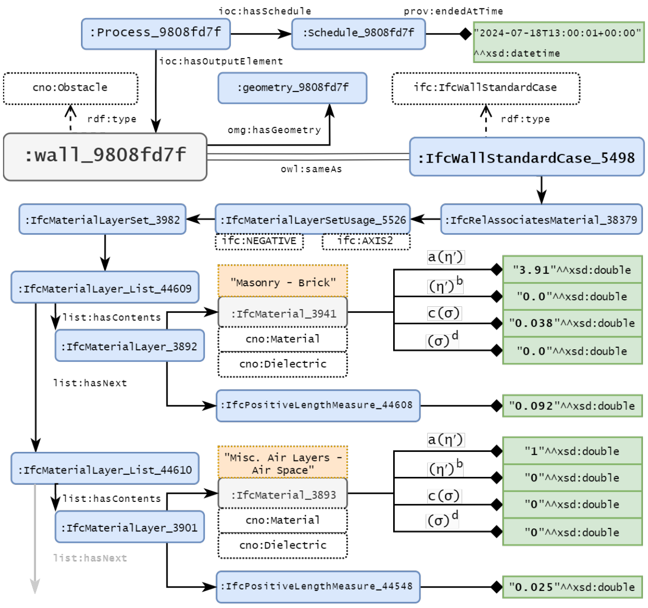

Figure 4: Excerpt of the data model extended with the help of the cno classes and properties.

Querying the database to answer QC4-5 mainly involves traversing the *ifcOWL* structure, which is complex. While for many use cases, the LBD ontologies and, most specifically, *props* in combination with geometry is more than sufficient, we need the full expressiveness of the IFC data model here. RDF lists need to be processed when navigating via *relAssociates* to the material layers. This is best done by using the SPARQL 1.1 property path features. Listing 2 shows a query realising this. The asterisk in *list:hasNext** shows that we follow this property to the end of the list via a path of "zero or more occurrences".

Listing 2: SPARQL Query for CQ5-7

  ?IfcMatLayer ifc:material_IfcMaterialLayer ?Mat.
  ?Mat rdf:type ?MatType;
      cno:hasRelativePermittivityFrequencyCoefficient ?a;
      cno:hasRelativePermittivityFrequencyExponenet ?b;
      cno:hasConductivityFrequencyCoefficient ?c;
      cno:hasConductivityFrequencyExponent ?d.}
```

This query returns the sequence of materials in the layered element. The direction, axis and thickness of each layer describe the geometric properties. The material properties introduced in the cno ontology contain the values to be inserted into the required propagation loss equations. These depend on the type of material, either a *cno:Conductor* or a *cno:Dielectric*. For the first layer queried, "Masonry - Brick" (see figure 4), we calculate:

$$\begin{aligned} \eta' &= 3.91 \cdot 3.75\,\text{GHz}^{0.0} = 3.91 \\ \sigma &= 0.0238 \cdot 3.75\,\text{GHz}^{0.16} = 0.81\,\text{S}\,\text{m}^{-1} \\ A_{dielectric} &= 1636 \cdot \frac{0.03}{\sqrt{3.91}} = 24.33\,\text{dB}\,\text{m}^{-1} \end{aligned} \tag{15}$$

Multiplying the calculated attenuation rate by the layer thickness of 0.092 m gives an attenuation of about 2.23 dB. This process must be repeated for all 6 layers of the component, resulting in a calculated propagation loss of 20.61 dB and an average attenuation rate of 49.4 dB m^{-1}. While this value is consistent with the approximate values found in the literature, it should be noted that this calculation is highly simplified. On the one hand, the layered wall has a stud metal layer, which can significantly affect propagation due to its conductive behaviour. On the other hand, we do not consider other effects, such as Snell's law or additional reflections that are relevant here.
To complete this proof of concept, the transmitting and receiving antenna gain is taken from listing 1. Focusing on the FSPL and the element propagation loss, combining the values to get the total propagation loss and inserting it into equation 4, we can calculate the received power in dBm and thus the expected RSSI (see equation 16).

$$36.98\,(\text{dBm}) + 9\,(\text{dBi}) - 90.97\,(\text{dB}) + 5\,(\text{dBi}) = -39.99\,(\text{dBm}) \tag{16}$$

Conclusions and Outlook

Construction sites differ from other production environments due to the ever-changing site topology, leading to restricted radio network connectivity and performance. To address this, an ontology is designed and developed that introduces and links concepts relevant to radio wave propagation with existing building and construction process modelling approaches. These concepts have been developed with respect to both the scientific fundamentals and the material properties available in official reports. To test the usability of the approach, a sample data set describing the 5G installations of the reference construction site in Aachen and a BIM model enriched with scheduling was generated and queried. The values obtained could be used in simplified, basic equations to determine the network quality, thus demonstrating that the approach makes it possible to link the necessary variables with the construction process context.
The described use case can prove that the necessary data can be retrieved to perform basic estimations. For this, the developed ontology as open and extensible data standard the facilitates access to information independent of software vendors, ensuring accessibility and interoperability. However, the ultimate goal is to feed more complex simulation environments to enable accurate network quality estimation for network optimization. To achieve the required accuracy, the ontology will need to be extended to include material properties such as albedo, roughness, or refractive index to allow for the calculation of effects such as reflection, refraction, and scattering, which were beyond the scope of this work. Future research will aim to validate more complex, construction context-dependent simulations with precise measurements in real-world scenarios. In this way, further insights will be gathered to create a network infrastructure that can adapt to the evolving construction environment by predicting network coverage and quality, thus driving innovation in the construction industry, such as digital twins and construction robotics.

REVOLUTIONISING INDIAN HIGHWAY PROJECTS: UNLEASHING THE POWER OF DATA INTEGRATION WITH CUTTING-EDGE DATA LAKE

Chenchu Murali Krishna[1], Kirti Ruikar[2], and Kumar Neeraj Jha[3]
[1]Indian Institute of Technology Delhi, New Delhi, India
[2]Loughborough University, Loughborough, United Kingdom
[3]Indian Institute of Technology Delhi, New Delhi, India

Abstract

Indian highway projects grapple with multifaceted delays, from contractual hurdles to legal complexities. Addressing this, the National Highway Authority of India (NHAI) embraces a cloud-based Data Lake, ushering in a "Fully Digital" paradigm. This advanced tool, validated through a literature review and NHAI stakeholder interviews, forecasts and manages delays systematically. The study reveals NHAI's adept integration of Data Lake technology across project phases, offering tangible solutions and underlining the transformative potential for data-driven decision-making in highway infrastructure projects. Recommendations advocate wider adoption, continual development, and prioritising education and research in delay management, heralding a new era of operational efficacy.

Keywords: Construction Delays, Data Lake, Highway Projects, Delay Management.

Introduction

In the realm of constructing India's expansive road network, measuring approximately 5.89 million kilometers, the continuous challenge of ensuring the timely completion of highway projects stands as a significant obstacle (Ministry of Road Transport & Highways Year End Review, 2022). This herculean task encounters numerous hurdles ranging from unpredictable weather conditions and complex land acquisition processes to bureaucratic permissions and the looming threat of supply chain disruptions. A study by the National Cooperative Highway Research Program (NCHRP) reveals that a staggering 40 per cent of projects experience delays, leading to escalated costs, compromised quality, and a noticeable decline in public satisfaction. These delays not only inflate project budgets and diminish quality but also erode trust among the public. Traditionally, project managers have relied heavily on their expertise and intuition to anticipate and manage potential delays. Yet, this conventional approach often falls short of identifying hidden delays until they materialise (Tripathi *et al.*, 2023). The imperative arises for a paradigm shift toward a more data-centric approach to delay management.

In this era of data innovation, data lakes have emerged as critical components for managing enormous quantities of structured and unstructured data efficiently. Functioning as a centralised repository, a data lake allows for the storage of data in its original format. It facilitates detailed analysis through an array of data mining and machine-learning techniques (Mathis, 2017). This seismic shift towards data lakes provides a transformative solution for highway project delay management, moving away from the traditional, manual forecasting techniques that are time-consuming data gathering and inherent to inaccuracies.

Data lakes are preferred over traditional approaches like data warehouses and data marts due to their unmatched flexibility, scalability, democratised access to data, and cost-effectiveness (Hai *et al.*, 2023). Unlike rigid data warehouses that require predefined schemas, data lakes store raw data in its original form, accommodating diverse data types seamlessly (Singh *et al.*, 2022). Scalability is another key advantage, enabling data lakes to handle the growing data volumes of highway projects seamlessly. This scalability, coupled with the lower total cost of ownership, makes data lakes an attractive option for organisations and innovation by providing a centralised repository for organisational data, unlike data marts tailored to specific domains (El Haddadi *et al.*, 2020). Additionally, data lakes facilitate advanced analytics techniques like AI and Machine learning, empowering organisations to extract actionable insights from their data. The decision to prioritise data lakes over well-defined data structures and explicit information requirements reflects a strategic choice to embrace technologies such as UML, graph databases, and ontologies (Sawadogo, 2019; Singh and Ahmad, 2019; Nambiar and Mundra, 2022). A comprehensive comparison of these technological options is shown in Table 1, highlighting the unique strengths and advantages that data lakes offer in meeting the evolving demands of construction big data challenges in the digital age.

In the dynamic landscape of highway construction, where the precision of timing and meticulous management of resources is paramount, the integration of data lakes emerges as a pivotal element for advancing project efficiency (Nargesian *et al.*, 2018). This advanced system empowers project managers to aggregate and scrutinise data from a myriad of sources, encompassing historical project data, predictive weather analytics, and real-time insights from sensors strategically deployed at construction sites. The advent of machine learning algorithms within these data lake frameworks acts as a formidable guard against potential delays. These algorithms are adept at identifying complex patterns, recognizing trends, and discovering connections within the vast pool of integrated data, offering not only the ability to forecast delays but also the means to proactively prevent them (Gudivada *et al*., 2017). Imagine a scenario in highway construction where delays are not merely managed but actively prevented (Durdyev and Hosseini, 2020). This scenario is made possible through the seamless integration of varied data sources, all housed within the secure confines of a data lake, orchestrated by the strategic application of machine learning algorithms. This not only underscores the role of data lakes as mere storage facilities but elevates them to the role of architects in a data-centric revolution in highway project management. This paradigm shift underscores the narrative that progress in the construction sector transcends the traditional reliance on physical materials, pivoting towards the strategic leverage of data. As the industry leans into this transformative approach, it stands to redefine delays not as mere hurdles but as opportunities to refine resource allocation, boost quality, and uplift public satisfaction.

Table 1: Comparison of the different technologies with Data Lake

S. No.	Database	Stores Raw Data	Structured Data Support	Schema Flexibility	Horizontal Scaling	Querying & Analytics	Why Data Lake is Preferred
1	Data Lake	✓	✓	✓	✓	✓	Flexibility in storing raw data in its original format
2	Data warehouse		✓		✓	✓	Structured storage for consistent querying and reporting
3	NoSQL Databases	✓	✓	✓	✓	✓	Flexibility in schema and scalability for diverse data types
4	Object Storage	✓			✓		Scalability and cost-effectiveness for storing large objects
5	Unified Modeling Language					✓	Conceptual modelling and communication in software development
6	Graph Databases				✓	✓	Ability to model relationships between entities effectively
7	Ontologies					✓	Explicit representation of domain knowledge and relationships

Data Lake Implementation at NHAI

The NHAI has introduced a data lake, marking a significant step forward in managing highway projects. This innovation brings enhanced efficiency, transparency, and the ability to make decisions based on data. The development involved careful planning and implementation, beginning with the initial phase of recognising the essential need for a centralised data repository. This necessity arose from the complexities involved in managing highway projects. Consequently, NHAI decided to establish a cloud-based data lake, laying the foundation for a revolutionary digital infrastructure. In collaboration with technology partners, the NHAI initiated the design of a data lake's architecture, focusing on ensuring scalability, reliability, and the capacity to handle various data types (Khine and Wang, 2018).

The selection of cloud infrastructure from premier providers like AWS or Azure was made to establish a strong foundation for the platform's operations (Sharma, 2018). The development phase involved dedicated teams working diligently to realise the data lake's vision, integrating it effectively with existing systems such as project management and GIS for a smooth transition. Stringent testing measures were put in place to maintain the utmost standards of data integrity, security, and efficiency. This included thorough user acceptance testing with participation from stakeholders across different functions, ensuring it meets the changing requirements of NHAI. Additionally, detailed training programs were organised for end users such as contractors, engineers, project directors, and regional officers, enabling them to utilise the data lake fully in their daily activities.

The data lake was smoothly incorporated into the NHAI's pre-existing workflows, replacing manual procedures with automated systems. This enhancement significantly improved efficiency and accountability across various operations. The integration encompassed project documentation, communications, workflow monitoring, timelines, notifications, and financial transactions related to projects, and all facilitated through the data lake interface. This allowed stakeholders to make well-informed decisions based on up-to-the-minute data insights. Furthermore, the compulsory inclusion of drone surveys for every project enabled thorough monitoring and analysis, substantially strengthening NHAI's capability in managing projects. The data lake serves a broad array of end users, including contractors, engineers, project directors, regional officers, and headquarter staff. Each group of stakeholders enjoys access to customised features and functionalities designed to meet their unique requirements, thereby empowering them to make decisions rooted in data, which in turn promotes project success and organisational development.

NHAI data lake architecture

The data lake architecture employed by the NHAI is designed to efficiently handle large volumes of diverse data, facilitating data-driven decision-making and operational efficiency within the organisation. It consists of key components such as the ingestion layer, storage layer, processing layer, catalogue and metadata management, governance and security, analytics and visualisation, and finally sharing and collaboration components. The simplified breakdown of the key components is as follows:

Data Ingestion Layer: This layer focuses on collecting data from various sources, including internal databases, APIs, and external sources like documents and images. It ensures the seamless ingestion of structured and semi-structured raw data types relevant to NHAI's operations (Singh and Ahmad, 2019).

Data Storage Layer: Once data is ingested, it is stored in a distributed file system, such as Hadoop Distributed File System (HDFS) or cloud-based storage solutions like Amazon S3 or Azure Blob storage. This ensures secure and efficient storage of data, enabling accessibility for further processing and analysis (Inmon, 2016).

Data Processing Layer: In this layer, tools and frameworks like Apache Spark, Apache Flink, or Apache Beam are utilised to process and transform raw data into usable formats. Batch and stream processing techniques enable real-time or near-real-time data processing, enhancing NHAI's analytical capabilities (Sharma, 2018).

Data Catalog and Metadata Management: NHAI's data lake architecture incorporates a metadata management system to catalogue and organise the vast amount of stored data. This metadata provides valuable information about the structure, format, and lineage of the data, facilitating easy discovery and understanding of available datasets (Madera and Laurent, 2016).

Data Governance and Security: Data governance policies and security measures are integral components of NHAI's data lake architecture. Access control mechanisms, encryption, data masking, and compliance with regulatory requirements ensure the privacy and security of sensitive information stored within the data lake (Abraham *et al*., 2019).

Data Analytics and Visualisation: NHAI's data lake enables data analytics and decision-makers to perform advanced analytics and derive insights from the stored data. Tools like Apache Hadoop, Apache Spark, or specialised analytics platforms facilitate data analysis and visualisation through dashboards or reports, empowering informed decision-making (Nagel *et al.,* 2021).

Data Sharing and Collaboration: NHAI's data lake architecture includes features for sharing data and collaborating with internal and external stakeholders. This may involve providing APIs for accessing data, implementing data-sharing agreements, enabling secure data exchange protocols, and fostering collaboration and knowledge sharing within the organisation (Couto and Ruiz, 2022).

Data lake for delay management

In the domain of highway construction, the data lake emerges as a powerful tool for effective delay management. Acting as a centralised repository, it adeptly accommodates structured and unstructured data of any magnitude, enabling the integration and analysis of information from various sources, such as construction sites, traffic sensors, and weather reports. This versatility makes the data lake a crucial component in effective delay management, which is evident in its diverse applications (Edison and Singla, 2020).

Primarily, the real-time monitoring capabilities of data lakes empower project managers to gather instantaneous data from varied sources ranging from sensor metrics and weather projections to traffic dynamics and social media updates (Gorelik, 2019). This comprehensive data snapshot enables proactive decision-making, allowing project managers to discern potential delays and take corrective measures promptly. Secondly, through the lens of predictive analytics, data lakes craft models that discern trends in historical data, translating them into actionable insights for anticipating and mitigating future delays. For instance, a meticulous analysis of past weather patterns facilitates pre-emptive measures against weather-induced schedule disruptions (Nambiar and Mundra, 2022).

Furthermore, data lakes facilitate a detailed optimisation of resource allocation by identifying areas of underutilisation or excess usage. This optimisation strategy not only streamlines project timelines but also acts as a strong deterrent against delays. Additionally, these reservoirs of information play a pivotal role in root cause analysis by storing and examining historical data on previous delays. Armed with this knowledge, organisations can effectively implement measures to minimise and prevent similar delays in future projects. Additionally, data lakes transcend their role as mere repositories by fostering collaboration among project stakeholders. By providing a centralised hub for project-related data, they facilitate seamless communication and collaboration across diverse teams, ensuring alignment toward common project objectives (Hagstroem *et al.*, 2017; Chomo, 2019).

In summary, data lakes serve as invaluable assets in the ongoing effort to minimise delays in highway construction projects. Through the integration and analysis of data from diverse sources, project managers gain deep insights, enabling them to make informed decisions and proactively guide projects toward successful completion. This fusion of big data within the data lake seamlessly addresses the complexities of highway construction delay factors, showcasing a nuanced alignment between the features of the data lake and the diverse challenges encountered in construction projects, as illustrated in Table 2.

Methodology

This study was conducted within the framework of the NHAI and involved a diverse group of stakeholders. The study aimed to understand the subjective experiences and interpretations of these stakeholders' concerning delays in highway projects. By adopting a collaborative approach, the research sought to generate knowledge that reflects the multifaceted perspectives of those involved, thus acknowledging their crucial role in shaping the findings. The methodology of the study was structured into four stages, designed to align with the research objectives. The investigation utilised both secondary and primary data sources. Initially, the research identified the problem of project delays through an extensive literature review, the author's direct involvement with highway projects, and informed discussions with experts.

Table 2: Matrix that maps delay management features for highway projects against common causes of delays

Cause of delay	Delay management features			
	Real-time monitoring	***Predictive analytics***	***Resource Allocation & optimisation***	***Collaboration***
Poor planning and scheduling of the project	✓			✓
Site clearances	✓			✓
Land acquisition and rehabilitation issues	✓	✓		✓
Weather and force majeure-related delays	✓	✓	✓	✓
Project changes and redesigns	✓	✓	✓	✓
Permit and approval delays	✓	✓		✓
Stakeholder conflicts	✓	✓	✓	✓
Poor resource management	✓		✓	✓
Inadequate project monitoring	✓	✓		✓
Poor communication between construction parties	✓			✓

This phase of the research identified 182 publications related to project delays and data lakes, with 56 unique articles remaining after duplicates were removed. These articles, dating from 2006, were sourced from databases such as Scopus, Elsevier, and Web of Science. Following the identification of delays, theoretical propositions were formulated to address these delays, based on analysis of the initial data. Qualitative data was collected through semi-structured interviews with six stakeholders, including deputy managers experienced in data lake-integrated projects, two project managers and two senior research followers actively involved in data lake-related projects. Table 3 shows the details of the interviewers. These interviews aimed to gather insights on the identified causes of delays, the theoretical propositions, and the impact of data lake processes and technologies in mitigating these issues. Interviewees are chosen for their efficacy in eliciting information about non-observable phenomena. The final stage involves formulating recommendations and conclusions derived from the content analysis of the collected interview data. This comprehensive approach, integrating data, information, and knowledge through the prism of a data lake, has the potential to revolutionise the landscape of effective data utilisation in highway construction projects, leveraging the vast reservoir of big data available, paving the way for a revolution in the field.

Table 3: Details of the Interviewees

Parameters	Stakeholders					
	Expert 1	Expert 2	Expert 3	Expert 4	Expert 5	Expert 6
Designation	Deputy Manager	Deputy Manager	Project Manager	Project Manager	Senior Researcher	Senior Researcher
Experience (Years)	18	20	15	15	4	3

Propositions

The theoretical propositions of this study are drawn from a thorough review of the literature, focusing on the attributes of a data lake anticipated to contribute significantly to the mitigation of project delays. The study primarily explores the implementation of a data lake in the context of Indian highways, aiming to quantify its advantages vis-à-vis the prominent causes of delays. However, the study's scope is limited to examining a data lake's potential to improve communication, information flow, and coordination among project stakeholders.

The study proposes further investigation into how a data lake can enhance communication and collaboration in highway projects (Nargesian *et al.*, 2018; Giebler *et al.*, 2019). The existing literature research lays a robust foundation for the formulation of key propositions, integral to guiding interview questions design and subsequent data collection:

1. *Proposition 1*: Implementation of a Data Lake in highway projects enhances data visualisation and construction process comprehension, thereby mitigating delays in progress payments and expediting client decision-making.
2. *Proposition 2:* Adoption of a data lake in NHAI projects facilitates effective delay management while fostering improved communication and coordination between the client and other stakeholders.

These propositions serve as the compass for the study, directing the formulation of insightful interview questions and the meticulous collection of data from pertinent stakeholders. This approach allows for a detailed exploration of the benefits and challenges inherent in implementing a data lake within the context of Indian highways, unravelling the untapped potential of data integration for practical usage in highway construction projects.

Interview Analysis

Proposition 1: Implementation of a Data Lake in highway projects enhances data visualisation and construction process comprehension, thereby

mitigating delays in progress payments and expediting client decision-making.

The efficacy of a data lake in highway construction projects is evident in its ability in visualising diverse datasets and operational aspects. Consolidating all data into a singular repository provides a comprehensive overview of project status, progress, and performance, enabling stakeholders to make data-driven decisions. Addressing concerns outlined in prior research such as Keane and Caletka (2015) and Du *et al.* (2018) pertaining to insufficient information about construction progress and communication gaps among stakeholders causing delays in progress payments and decision-making, the content analysis of interviews underscores the substantial benefits that implementing a data lake brings to the fore in managing delays and enhancing decision-making processes.

The content analysis of interviews highlights that implementing a data lake in highway projects brings significant advantages for managing delays and improving decision-making. Data visualisation enables quick identification of concerns and prompt corrective actions. Access to centralised data facilitates decision-making based on real-time insights. However, successful implementation requires understanding the data and selecting meaningful metrics. Transparent processes and workflows within the data lake enhance utilisation and support process improvement. It is important to note that implementing a data lake alone is not sufficient; it requires a comprehensive approach to leverage its benefits effectively.

The interviews emphasise that the implementation of a data lake in highway projects significantly bolsters delay management and decision-making processes. The key insights derived from the content analysis illuminate critical considerations:

1. *Strategic Metric Selection for Visualization*: Based on the input from deputy manager-level stakeholders and project managers who have experience with data lake-integrated projects, it is unanimously agreed that selecting meaningful metrics for data visualisation is critical. This strategic metric selection ensures that the visualised data is relevant and resonates with its audience, which is crucial for effective decision-making. Strategic metric selection in data lake is key for enhancing business performance through a data-driven approach. Metrics related to operational efficiency, data integration, and business analytics are essential for effective visualisation (Laurent *et al.*, 2020; Barbierato *et al.*, 2021; Kumar and Chundi, 2023).
2. *Expedited Decision-Making Process:* The consensus among interviewees highlights that the implementation of data lakes significantly accelerates the decision-making process by offering streamlined access to comprehensive and centralised data, fostering a culture of prompt and well-informed decisions. Beyond speeding up decision-making, data lakes bring technological advantages by improving flexibility and scalability, democratising data access. They also transform the business paradigm by addressing big data challenges and driving digital transformation, ultimately enhancing business intelligence. By providing a centralised repository of virtually inexhaustible raw data for analytical activities, data lakes enable enterprises to profoundly improve their decision-making processes and business intelligence, thereby transforming their overall business paradigms (Terrizzano *et al.*, 2015; Johny and Pillai, 2022).
3. *Visualisation of Project Status and Impact of Delays:* The interview findings highlight the significance of visualising data pertaining to schedule overruns and activity delays to enhance decision-makers' understanding of project status, with projection of the completion schedule offering insights into the impacts of delays and enabling proactive mitigation efforts. Data lakes at NHAI play a vital role in democratising data access and supporting divers' analytics tasks within enterprises. The data lake structure comprises five layers, enabling effective visualisation of project status by integrating multiple time series data sets. The adaptability of data lakes is exemplified by the NHAI dashboard, which positions stakeholders of data lakes as invaluable tools for the visualisation and analysis of project statuses (Fang, 2015; Mathis, 2017; Kumar and Chundi, 2023; Schneider *et al.*, 2023).
4. *Process Establishment and Improvement:* Interview data affirm that data lakes play a pivotal role in facilitating the establishment and documentation of processes and workflows within NHAI. This analysis helps in identifying areas that need improvement, resulting in greater efficiency in overall processes. Additionally, data lakes enable the use of advanced data-driven analysis techniques, which significantly aid enterprises in optimising the NHAI business operations. This not only captures key process parameters but also serves as a foundation for rigorous analysis. The insights derived from this analysis become instrumental in identifying areas for improvement, ultimately leading to enhanced overall process efficiency (Nagel *et al.*, 2021; Schneider *et al.*, 2023).

In conjunction with the literature review propositions, the synthesis of interview findings underscores that the implementation of data lakes in highway projects has the potential to be a game-changer in decision-making through data visualisation. However, it is imperative to acknowledge that successful implementation necessitates not only adequate resources for maintenance and development but also the addressing of a discernible skill gap in data lake expertise. The collaboration and knowledge-sharing among industry professionals, as underscored by senior research follows actively engaged in data-lake-related projects, emerge as critical components for establishing best practices and standards in data implementation and data lake utilisation. The call to allocate resources for ongoing support, encompassing infrastructure, data integration, quality management, and governance, resonates as a strategic imperative for organisations venturing into the realm of data lake implementation in highway construction projects.

Proposition 2: Adoption of a data lake in NHAI projects facilitates effective delay management while fostering improved communication and coordination between the client and other stakeholders.

In delving into the realm of effective data utilisation within highway construction projects, insights obtained from interviews with key stakeholders underscore the crucial role of a data lake in enhancing communication dynamics. The literature, supported by expert opinions, emphasises the importance of seamless communication to prevent delays, with inadequate exchange leading to suboptimal designs and planning (Saini, 2015).

Interview analysis highlights the significant impact of a data lake on communication between clients and stakeholders, serving as a keystone for real-time updates, meticulous tracking of communication flows, and seamless access to relevant information within a centralised platform (Malacarne *et al.*, 2018). This data lake design intricately reflects all communications within stakeholders' dashboards, ensuring immediate action based on document flow, approval status, and remarks of respective officers. This creates a harmonised and transparent communication channel that fosters enhanced coordination, mitigating delays attributed to internal or coordination factors. The implementation of a data lake in highway projects not only improves communication but also streamlines decision-making processes, leading to more efficient project management and ultimately, successful project completion.

In essence, the interview analysis manifests in phrases that unveil the data lake's diverse role:

1. *Improving Communication between Clients and Stakeholders*: The interviews with key stakeholders, including deputy manager-level experts in data lake-integrated projects, project managers, and senior research fellows deeply entrenched in data lake-related endeavors, yielded profound insights into the enhancement of communication dynamics between clients and stakeholders. A pivotal observation emerged: the strategic design of the data lake serves as a communication nexus, seamlessly reflecting all relevant interactions within stakeholders' dashboards. This design ensures not only visibility but catalyses immediate action on requests, leveraging the dynamic flow of documents, approval statuses, and remarks from respective officials.

   The real-time updates from the data lake proved instrumental in transforming project dynamics. Stakeholders, armed with instantaneous information on project status, documentation details, and approvals, navigated a landscape of enhanced coordination. This, in turn, emerged as a powerful countermeasure to delays induced by internal factors or coordination challenges. The interviews underscored a paradigm shift in communication dynamics, where the data lake became a pipeline for real-time collaboration and coordination, moving projects towards streamlined efficiency and reduced delays.
2. *Central Repository for Documents and Information:* In illuminating insights drawn from interviews with key stakeholders, the data lake emerges as a central repository for approved requests, project documents, drawings, notices, and more. According to the perspectives gleaned from two deputy manager-level stakeholders intimately acquainted with data lake integration, two project managers, and two senior researchers who are deeply entrenched in data lake-related projects, the data lake's role as a document repository is pivotal. This repository function, as articulated by the interviewees, not only ensures the organised storage of essential documents but also stands as a safeguard against human errors. The availability of information within this consolidated data lake reduces the likelihood of oversights and inefficiencies, contributing to smoother functioning. Importantly, the improved accessibility to this repository acts as a catalyst, streamlining processes and, consequently, playing a significant role in the reduction of delays within the context of highway construction projects. The consensus among these key stakeholders underscores the transformative impact of a data lake as more than just a repository—it is a dynamic facilitator that not only safeguards against errors but actively contributes to the efficiency and agility of project processes, aligning seamlessly with the overarching goal of minimising delays in highway construction projects.
3. *Facilitating Prompt Resolution of Requests:* In the interview analysis, stakeholders with expertise in data lake-integrated projects unanimously highlighted the data lake's instrumental role in expediting request resolutions and curbing delays. The real-time updates afforded by the data lake emerge as a cornerstone for well-informed decision-making, providing up-to-date insights that prove pivotal in navigating project intricacies. The synergy of improved coordination and communication, facilitated by the data lake, contributes substantially to the efficiency of project management. This integrated approach ensures not only the prompt resolution of requests but also an overarching enhancement of project efficacy through streamlined communication channels and data-driven decision-making.

Conclusions and Recommendations

The research, centered on leveraging data lakes to streamline Indian highway projects, crystallises into two pivotal propositions. The first proposition underscores the transformative impact of visualising data within construction endeavors through data lake implementation. This strategic utilisation addresses delays in progress payments and decision-making with unprecedented efficacy. The second proposition underscores the instrumental role of data lakes in elevating communication and coordination among project stakeholders, thereby enhancing overall operational efficiency in delay mitigation. The study unequivocally concludes that data lakes represent a potent solution, offering substantial potential to rectify delays by optimising data management, communication, and coordination.

In extrapolating these findings, the imperative for the NHAI becomes evident. Prioritising two key domains data governance and skilled professionals emerges as the strategic pathway to maximise data lake utilisation.

1. ***Data Governance***: Effective data governance is essential for optimising the use of data lakes. To achieve this, organisations should first establish a clear data governance framework by setting clear goals, such as ensuring data quality, securing sensitive data, complying with regulations, and forming a cross-functional team to oversee policy implementation (Gillan, 2021). It is also important to maintain detailed documentation and manage metadata to keep data easily accessible and understandable. Implementing role-based access controls and maintaining audit trails helps protect sensitive information and monitor data usage. Organisations should classify data based on sensitivity and handle it, accordingly, applying necessary security measures for highly sensitive data. Managing the data lifecycle by setting policies for data retention, archiving, and deletion, and conducting regular audits ensures data remains compliant with legal and business requirements (Brous *et al.*, 2016). Continuous monitoring, measuring effectiveness, and adapting governance practices as necessary will maintain the data lake as a secure, compliant, and efficiently managed resource. This approach empowers organisations to fully leverage their data lakes while ensuring data security and compliance (Duzha *et al.*, 2023).
2. ***Skilled Professionals***: To effectively manage data lake systems in the construction industry, professionals require a combination of technical skills and soft skills. Technical skills encompass knowledge of data platforms like data warehouses and data lakes, proficiency in data management tools such as Delta Lake and Snowflake and understanding of data processing strategies like those in Hadoop (Kaur *et al.*, 2023). Additionally, soft skills like effective communication and presentation are vital for managing both data and human resources within construction teams. Professionals in the construction industry must possess skills in sensor data analytics and data science, including machine learning. Understanding data analytics applications across various construction phases is crucial. A methodology integrating Building Information Modelling (BIM) and Business Intelligence (BI) tools enables collaborative data management. The adoption of information communication technology (ICT) facilitates decision-making and project management (Huang *et al.*, 2012). Managing data lakes requires proficiency in data platforms, management tools, and processing strategies. Investing in skilled professionals is crucial for deriving insights and optimising operations. The NHAI recognises the importance of this and focuses on recruitment, retention, and training programs. Collaborative efforts with academia and industry experts further contribute to bridging the skills gap and fostering innovation within the construction industry. This holistic approach ensures that data lake systems are managed efficiently, driving progress, and enhancing the construction sector's competitiveness.

By focusing on these strategic imperatives of data governance and skilled professionals, NHAI is poised to unlock the full potential of their data lake. This approach not only facilitates effective analysis of highway data but also enhances operational efficiency and safety measures across the expansive highway network.

REAL-TIME ASSESSMENT OF REGULATORY COMPLIANCE OF CONSTRUCTION SITES

Nicholas Nisbet[1 2], Zijing Zhang[1], Selçuk Çidik[1]
[1]University College London, London, UK,
[2]AEC3 UK Ltd

Abstract

Previous work on automatic compliance checking has targeted static descriptions of the built environment represented in Building Information Models. In contrast, this work examines the potential of semantic mark-up to capture and then apply health and safety regulations to live construction sites. There are significant differences in what constitutes a testable metric and what constitutes a fact when considering process rather than product compliance. Extensions to the RASE approach are defined and demonstrated to accommodate these differences. This leads to extending the concept of 'decidability' with considerations around the relative 'timeliness' of information.

Introduction

Previous work has applied the RASE method to building regulations and other static assessments of building proposals. The paper examines how automated compliance checking of construction site processes differ from the compliance checking of facility models. The attention on wellbeing, health and safety in construction (WHS) is widening from retrospective consideration of reconstructions of past accidents and near-misses scrutinized in enquiries and hearings (Pirzadeh et al., 2017). Besides safety, compliance requirements provide rules that may be best assessed live, rather than retrospectively. Thus, WHS presents a suitable case to develop theory and practice on automated compliance checking for processes in construction work.

There has been an increasing use of contemporaneous and real-time monitoring of construction activity on site (Cheng et al., 2013). This can support the immediate triggering of alarms and warnings about safety due to the proximity of incompatible entities, such as heavy plant and operatives. One source of the rules for such triggering is the legislation and regulations defining safety compliance. These rules can be checked against real-time construction activity data and static information about construction sites, such as project planning and resourcing (PERT) plans, 3D and 4D models and methods of work statements. This paper examines examples of real-time information sources and safety regulations to propose how semantic mark-up based on the RASE methodology (Nisbet et al. 2008) can be adapted to provide machine-operable rules that can be evaluated continuously for automated compliance checking for construction processes. RASE is a mark-up approach that highlights the logical structure and metrics in documents, as illustrated below.

Previous work

There has been previous work on rules about construction sites, dynamic assessment in other sectors, rule capture and the representation of time in predicate logic.

Many recent works have focused on 'prevention through design' looking for design features in static BIM models which may indicate specific hazards that may need consideration during construction planning (Johansen et al., 2023; Schwabe et al., 2019; Tekbas et al.,2020; Yuan et al., 2019). Shen et al. (2022) used the term 'dynamic' to refer to the importance of the sequence of processes anticipated when following work procedures. The target of the rule checking was a '4D' BIM description and narrative. Rules were obtained by transcribing knowledge onto a product/activity/location template along with the hazard and solutions. Queries were accepted in free text with NLP being used to map terms to the template. Bao et al. (2022) used a static BIM model and additional safety measures inserted automatically by third-party software. Scripts detected topological adjacency information. Sequencing was obtained from the project PERT (program evaluation and review) plan. Rules were translated into SQL (structured query language) expressions. The outcomes were alerts within the BIM authoring platform with recommendations for improvements prior to construction commencing.

Continuous real-time assessment of dynamic construction sites is being considered as an aspect of digital twins (Li et al., 2021). Teizer et al. (2022) proposed a combined view seeking to ensure safety through (a) design and construction planning, (b) risk detection and (c) learning and feedback. The choice of rules to be applied was left open.

Pradhananga (2015) explored the tracking of heavy plant using GPS and the visualization of those tracks around work, hazard, material, travel, loading and dumping zones. Zones could be taken from GIS (geospatial information system) or BIM (building information modelling) information or deduced from the behaviour of vehicles. Productivity was measured by repetitive cycle times. Speed and proximity were detected as leading indicators for hazards. Xu (2023) developed a fuzzy-logic tree combining live monitoring weather, location and worker IoT feeds to generate a continuous feed assessing worker well-being and risk. Rules were acquired by agreeing decision tables and fuzzy logic tables of risk and association. Other sectors have similar needs but within a static built environment and with static operational patterns. For example, Yang et al., (2023) examined vehicle conflicts at airports. The work deduced rules from safety critical correlations between vehicle speeds, accelerations and convergence. Li et al. (2022) combined engineering and soil monitoring values to alert possible construction risks, using SPARQL (RDF query language) applied to the combined data sets. Nisbet et al (2023) has raised concerns concerning the use of SPARQL.

RASE is a mark-up approach to identify the logical structure and semantic metrics in normative text, by identifying sections and phrases as Requirements, Applicability, Selections or Exceptions. RASE has been applied to static rule situations such as comparing building proposals against planning (zoning) and building control (technical) regulations (Beach et al., 2020 and 2023). RASE has been shown to be able to generate propositional and predicate logic statements (Nisbet et al., 2022). RASE was selected for its 'no-code' approach offering transparency to both inspectors and constructors.: mark-up can be added, reviewed and, if necessary, improved, by domain experts. This 'white-box' approach is in contrast to conventional translation and programming which remains opaque to domain experts.

Whereas most discussions of propositional and predicate logic assume a static context, built around the present tense, rules about live environments may need to consider 'temporal logic' capturing the sequence of the processes of interest. This has extensive literature, given its importance in legal and contractual and computational analysis, summarized in Lamport (1994).

There are two candidate modes for temporal logic, one based on representing events, and the other based on representing intervals. Temporal logic can be expressed in predicate logic by considering the role of four verb tenses. Ploug et al. (2012) summarised previous work including Prior and Kripke who proposed four tenses P "It has at some time been the case that …" F: "It will at some time be the case that …" H: "It has always been the case that …" and G: "It will always be the case that …" which can be combined to generate more complex tenses. In order to integrate event-based view into predicate logic the operators 'before' and 'after' can be used to relate two disjointed predicate statements.

In summary, literature has focused on identifying invariant rules on facility designs and construction plans that must be true continuously but has not addressed the dynamic narrative around events on construction sites and the means to capture and apply such rules. There is a gap in the literature related this real-time assessment of construction process compliance.

Method

Given the uncertainties and lack of previous work, a design science research approach has been taken to explore and iterate towards a plausible approach. This allows the solution space to be explored without necessarily discovering all the limitations of the solution. Part of that solution space includes the use of existing ontologies around safety and built environment.

This approach was supported by a workshop invitation issued by the Health and Safety Executive (HSE), a UK regulatory body, as part of their 'Discovering Safety' programme. The HSE encouraged the engagement of three commercial solution providers each addressing live construction site information, and the lead author as an information integrator.

The following section examines some relevant theory and ontology resources. The next section then looks at the preparatory work applying RASE semantic mark-up to Clause 22 of the UK Construction (Design and Management) Regulations 2015 (C(D&M) 2015), prior to considering specific information sources. This paper then reports on experiments to examine information sources around some specific scenarios, how these map to target ontologies and how these information resources can be continuously tested. Each experiment iterated progressively towards an improved rule representation and a rule-engine to test its utility.

Theory

This section examines theory and ontology for safety compliance checking of construction processes including for the target model, for dictionary resources and for rules.

Ontology for construction processes including health and safety

Both IFC (ISO 16739-1, 2024) and classification standards (ISO 12006-2, 2015) use a four-layer model for the descriptive and narrative representation of the built environment. The top-most layer describes the built environment in terms of named locations and spaces. These spaces are defined and supported by physical objects. These physical objects are affected by processes, activities and events. The processes are supported by resources including actors and construction aids.

This suggests that a tabular representation (Figure 1) can be used to track all the activities and timings (3) happening on the construction site with associated locations (1), products (2) and actors (4).

1: Location		2: Product		3: Activity			4: Actor	
Name	Description	Name	Description	Name	Description	Date and Time	Name	Description
S1	Site	B1	Facility	45246	Shift	16/11/2023 08:00	-	-

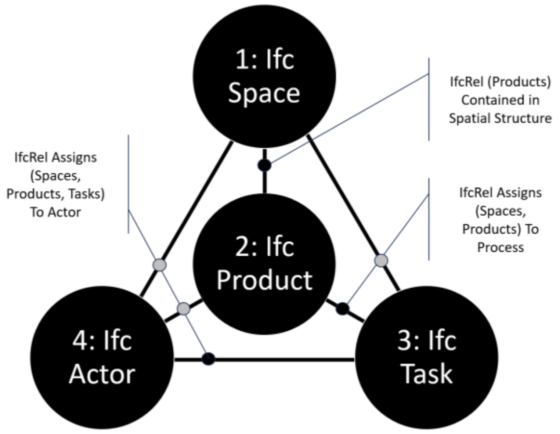
Figure 1: Tabular information model and sample

In situations where there are multiple information sources available, a unifying ontology may be needed. IFC offers a comprehensive descriptive and narrative schema. Typical BIM models provide the physical product and some spatial location entities. To consider the dynamics of a construction site activity, tasks, events and actors are included in addition. Figure 2 shows the four IFC entity types in a tetrahedral arrangement. All six possible inter-relationships are provided by three IFC objectified relationship entities. The ability to sequence activity is also illustrated in the sample.



```
#11 = IFCSPACE(...  , 'EX1', 'Excavation 1', $, #91, $, $, .ELEMENT., .EXTERNAL., $);
#12 = IFCMEMBER(... , 'SP2', 'Excavation support', $, #92, #93, $);
#13 = IFCTASK(...   , 'SH3', 'Shift 3', 'Work shift', 'SH3', '', 'Shift start', .F., $);
#14 = IFCACTOR(...  , 'SE4', 'Site engineer 4', 'Engineer', #94);

#21 = IFCRELCONTAINEDINSPATIALSTRUCTURE(... , (#12),    #11);
#22 = IFCRELASSIGNSTOPROCESS(...            , (#11), $, #13, $);
#23 = IFCRELASSIGNSTOPROCESS(...            , (#12), $, #13, $);
#24 = IFCRELASSIGNSTOACTOR(...              , (#11), $, #14, $);
#25 = IFCRELASSIGNSTOACTOR(...              , (#12), $, #14, $);
#26 = IFCRELASSIGNSTOACTOR(...              , (#13), $, #14, $);

#26 = IFCRELSEQUENCE(...                    , #13,      #15, 0, .FINISH_START.);
```

Figure 2: IFC ontology and sample

Some information sources may lack structuring so consideration can be given to automated or manual RASE mark-up of diary and monitoring entries (Figure 3) either to read directly, obtain tabular information or generate IFC data. Figures 3, 4, 5 and 6 show Requirements in blue with underlining, Applicability in green with dashed underlining, Selection in purple with dotted underlining and Exceptions in orange with double underlining.

Figure 3: Narrative text with RASE as an information model

UK BSI PAS 1192-6 (2018) offers a model of safety risks. The comparability of risks in a shared risk register is supported by the consideration of likelihood and consequence. Likelihood is considered as the outcome of the effects of physical product (P), process activity (A) and spatial location (L). This 'PAL' model omits the consideration of the actors responsible for or engaging in activities so as to shift the emphasis away from operator error and towards systemic factors. This is intended to make safety risk information more shareable, generalisable and reviewable. Regulatory considerations often additionally address actor roles so that responsibility and accountability can be assigned when compliance is assessed. Uniclass (2023) tables can be used to classify the locations (SL), products (Pr), activities (Ac), roles (Ro) and also the resulting risk (RK).

Ontology for dictionaries

Previous work has shown that dictionaries can be used to relate concepts from different domains, including relating names, descriptions and classifications and properties, or concepts from natural language and specific data schemas (ISO 12006-3, 2022). Nisbet et al. (2024) showed how ordinary text and tables can be marked-up to serve as dictionary resources.

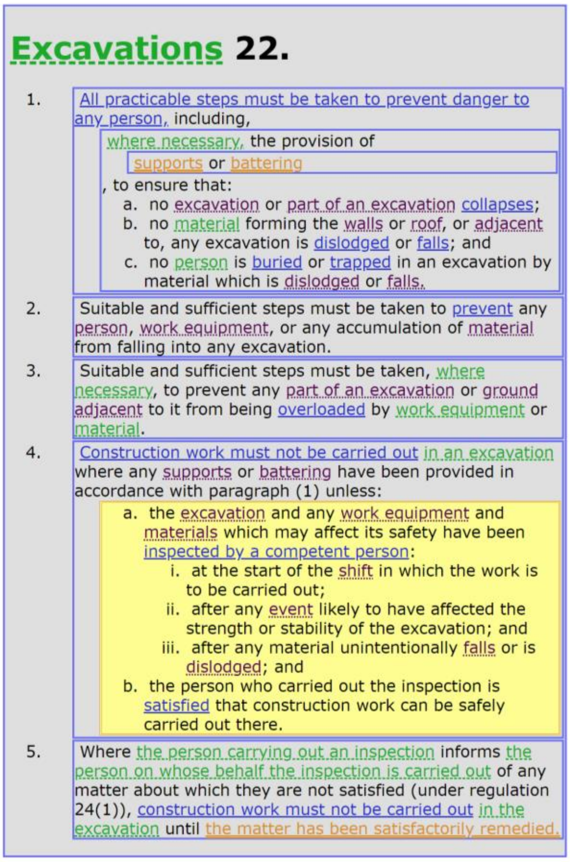
Ontology for normative knowledge

RASE captures the ontology of knowledge embodied in First Order Logic. This can be summarized as an executable tree hierarchy of logical operators applied to objectives and testable metrics. Normative knowledge as a logical statement of how the world is required to be, may be wrapped in deontic logic around duties and obligations which are usually handled externally by administrative or operational action. In the current example the action may include 'enforcement' by the HSE authorities.

Preparations

EU UK legislation and secondary legislation and regulations are publicly accessible. An example is EU Directive 92/57/EEC (EP 1992) which is implemented in the UK as the C(D&M) 2015 regulations that are applicable to most construction activity. These regulations comprise clauses 1-15 concerning the allocation of responsibilities and roles, and clauses 16-39 which define 'general requirements for all construction sites'. Clause 22 considers the steps expected for the safe execution of excavations. Sub-clause 22(1) is problematic in that it refers to 'all practicable steps' and the ill-defined qualification 'if necessary'. This sub-clause will be considered in the Discussion section. The text of clause 22 is available as HTML and has been marked up with RASE (Figure 4) using 'AEC3 Require1' (AEC3, 2024).

Sub-clause 22(4) is a particularly significant clause in that it explicitly bans construction work within excavations unless certain conditions are met. The Requirement is that no construction activity is carried out. This has Application to excavation locations but only if a Selection from supports and battering (sloping sides) is present. A substantial Exception then identifies the events which should trigger an inspection and satisfaction. Whilst most of the events are discrete and independent, the inspection and satisfaction are related and dependant to those events. This relationship is not captured by the visible mark-up. However, each RASE mark-up can contain metadata which can be made visible when a mouse hovers over the mark-up ('mouse-over event'). Previously this metadata has given each mark-up an identifier 'id' and the naming of the RASE class 'Type'. Optionally metrics can have 'Property', 'Comparator', 'Target' and 'Unit' added to deconstruct any numeric metric. Optionally sections can have a 'Outcome' to record where any intermediate outcome is of interest. In HTML each piece of metadata is stored as an attribute on the tags, prefixed with 'data-rase' which combines the convention for extensions to HTML markup with a RASE specific identifier.



Excavations 22.

1. All practicable steps must be taken to prevent danger to any person, including,
where necessary, the provision of
supports or battering
, to ensure that:
a. no excavation or part of an excavation collapses;
b. no material forming the walls or roof, or adjacent to, any excavation is dislodged or falls; and
c. no person is buried or trapped in an excavation by material which is dislodged or falls.

2. Suitable and sufficient steps must be taken to prevent any person, work equipment, or any accumulation of material from falling into any excavation.

3. Suitable and sufficient steps must be taken, where necessary, to prevent any part of an excavation or ground adjacent to it from being overloaded by work equipment or material.

4. Construction work must not be carried out in an excavation where any supports or battering have been provided in accordance with paragraph (1) unless:
a. the excavation and any work equipment and materials which may affect its safety have been inspected by a competent person:
i. at the start of the shift in which the work is to be carried out;
ii. after any event likely to have affected the strength or stability of the excavation; and
iii. after any material unintentionally falls or is dislodged; and
b. the person who carried out the inspection is satisfied that construction work can be safely carried out there.

5. Where the person carrying out an inspection informs the person on whose behalf the inspection is carried out of any matter about which they are not satisfied (under regulation 24(1)), construction work must not be carried out in the excavation until the matter has been satisfactorily remedied.

Figure 4: RASE markup of Clause 22

One way of understanding this complexity of related events is to ask what it is that potentially fails. It is not the individual events, nor the excavation but the sequence of events and inspections – the timeline – that passes or fails. Some metrics depend on the state of the excavation, in terms of the presence or absence of 'work', 'supports' and so on. Based on the work on 'temporal logic' discussed in the literature review section, it is necessary to record that certain events such as 'inspections 'and 'satisfactions' are not only required but must be in a specific relationship to the events and states, specifically coming later in a timeline.

This means that the requirement for inspection is actually for a 'subsequent inspection' and the requirement for satisfaction is actually for 'subsequent satisfaction'. The 'subsequent' test is in each case relative to a previous entry in the timeline. This can be achieved by adding an additional item of metadata 'Reference' which can ensure that the test for an inspection is applied, not to the whole timeline (has there been an inspection ever?) but to the timeline since the triggering event (has there been an inspection since that triggering event?), and similarly can ensure that the test for 'satisfaction' is applied, not to the whole timeline (has there been a satisfaction event ever?) but to the timeline since the inspection event (has there been satisfaction since that inspection?).

With this addition, the marked-up regulation can be reported back, for example as a conceptual graph (Solihin et al., 2015) of distinct metrics as seen in figure 5.

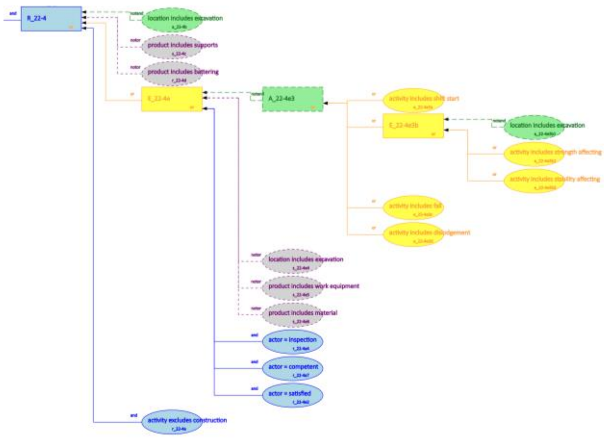


Figure 5: Reflection of Clause 22(4) as a conceptual graph

Reviewing the list of metrics, it is clear that some terms need synonyms. These can be plain language synonyms, or can relate the terms to the table headings (Figure 1) or IFC concepts (Figure 3). Such synonyms can be provided for locations, products, activities and roles. Within a specific project, there may further synonyms, for example 'SE1' may be synonymous with 'Simon Engineer' or 'se1@enginering.com'. Both the general and the project dictionary can be held as RASE documents (figure 6), or in a database service.

eng-GB: Site engineer	**eng-GB: Site engineer**

Figure 6: Example dictionary entry

Experiments

Two scenarios were investigated. In each, the site diary and site monitoring data streams were available as separate timelines. These were provided by the participants as anonymised examples based on actual site data. The site diary is maintained by the site supervisor, logging the significant events. Many site-based ('field') and construction management solutions offer applications to support this activity, including AI-supported voice-and video recording. Site monitoring is dependent on the use of electronic tagging of individuals via their construction hard-hats and vehicles via secure attachments. The specific application used also supported the representation of polygonal safety zones defined from 4D BIM or other inputs.

Some safety issues were detectable by considering a data stream alone. In experiment 1, site monitoring can create a timeline where checking Clause 22(4) can detect if work is being conducted in an excavation. There is a vehicle incursion into the excavation zone, which is detected by the site monitoring. This is event is defined as potentially affecting the stability of the excavation, but work continues, so immediately the rule-engine reports that the site is non-compliant because although a visit by the site engineer has been detected, no acceptance can be sensed (Figure 7).

In experiment 2, the number of aspects that can be checked for compliance expands considerably by combining data streams. In this second scenario, a shift starts, there is a fall of earth and so supports are installed. Supplying the rule-engine with a combined data stream from the site diary and the site monitoring highlights that the excavation was compliant up until the supports were installed but before the excavation had been inspected. Once inspected and approved, the excavation reverts to being compliant (Figure 8).

Overall, two experiments using the live collation of information were used to assess the compliance of a construction site. Alerts have been generated when the excavation is in a non-compliant state. Any alert can be supplied to the site supervisor, site engineer and/or the operatives concerned. These alerts are exactly defined by the sense of the original regulatory text, and potential remedies are suggested.

Figure 8: Non-compliance detected and resolved from combined sources (experiment 2)

Temporary non-compliance (in the examples a matter of minutes) may be felt to be too strict. There is no guidance or common knowledge as to what period of time is reasonable before compliance is to be re-established. Reasonableness will depend on what action is attached to the lapse. If an alert sounds on a mobile device, then 5 minutes might be appropriate. If a siren or alarm sounds, then a longer period may be more appropriate.

Discussion

This paper has addressed the question of how rules for the continuous assessment of safety compliance within a site context can be obtained and made operable explicitly and without specific coding. The experiments have shown that some clauses of the C(D&M) 2015 regulations can be assessed in 'real-time', but others may be problematic as they lack 'decidability' due to the temporality of the evaluated processes.

Decidability

Zhang et al. (2022) identified four kinds of ambiguity in normative text which pose obstacles for decidability in automated compliance checking. These are (1) intentional, (2) grammatical, (3) tacit knowledge and (4) domain-specific. A dictionary can hold the collective tacit knowledge, domain-specific mappings and agreed analytic tools to address these obstacles (Beach et al., 2023). In addition, some C(D&M) clauses are ambiguous if taken as metrics defined by examination of the information sources, but if read as objectives, defined by satisfying subsequent clauses, these can be evaluated. We can distinguish testable metrics from objectives, even if their appearance in source regulations appear similar. Previous assumptions about the exclusion of clauses by consideration of the internal characteristics have been replaced with criteria relating to this external context.

Table 1: Obstacles to decidability

Obstacle	Description (and resolution)	*C(D&M) 2015 examples*
Grammar	Two or more possible parsings (resolved by mark-up).	*'work equipment or material'* *(see 22(3))*
Ambiguity	Two or more assessment methods (resolved in dictionary).	*'adjacent'* *(see 22(1))*
Subjectivity	No common assessment method.	*'practicable'* *(see 22(1))*
Objective	Dependant on following sections and metrics (resolved by mark-up or omission).	*'danger'*
Temporality	No information or authority available.	*(see 22(1))*

Thus, decidability is dependent on managing grammar, ambiguity, subjectivity and additionally 'objectives' and 'temporality' (Table 1). Grammatical ambiguity can be resolved by domain experts when performing the RASE markup. In the example it could be that either all material or only work material is meant. Other ambiguities need to be resolved by developing the intermediate dictionary so that there is a common and singular matching of regulatory and descriptive/narrative models, for example 'adjacent' is untestable unless the dictionary provides a plausible distance. Subjectivity, for example 'practicable', arises where perceptions can differ completely between applicant and inspector. This identification of sections as objectives can be resolved by mark-up or its omission. On the other hand, 'temporality' depends on the distinction between leading and live indicators of the state of the construction site as opposed to trailing outcomes such as 'buried or trapped' in clause 22(1c) (Table 2).

Table 2: Safety and compliance indicators

Category	Description	*Safety examples*	*C(D&M) 2015 examples*
Leading indicators	Predictive metrics	*Safety management underway*	*Clauses 1-15*
Live indicators	Direct metrics	*Inspections and satisfactions*	*Clauses 16-35*
Trailing indicators	Outcome metrics	*Safety records and evidence*	*Clause 22(1c)*

Leading and live indicators may be available from documentation or from contemporaneous recordings by sensors and participants. These sources can be combined in a unified information model accessible to a rule engine.

Trailing outcomes are frequently referred to in the first sub-clause in each C(D&M) clauses 16-35. The construction of such sentences gives them a similar appearance to 'actual' requirements, the difference being that the value of the individual metrics is knowable only in retrospect. These can be handled either by deliberately not marking them up or by developing a 'Future World Assumption' (FWA) that requirements and exceptions may be taken as positive but applicability and selections may be taken as negative, at least until they become knowable.

Within in the DRSM (design science research method) framework, the evaluation of the user acceptance of the outcomes is postponed until the artefact has been developed. Such evaluation would need to take into account a number of different organisation contexts into which a live compliance checking system could fit, such as private to the constructor, private to the inspectorate or accessible to both the constructor and inspectorate.

Conclusions

Automated compliance checking has previously been focused on static descriptions of a facility. This work has shown that the RASE methodology can be extended to capture the expectations for dynamic contexts such as construction sites, especially the relative timing of separate requirements. Using a suitable ontology to track real-time events can structure the increasing availability of real-time information on construction sites so as to support the continuous assessment of compliance, such as safety compliance. Definitions of compliance may mix leading, live and trailing metrics which can affect the 'decidability' of those rules. The decidability of individual metrics within regulations depends on addressing ambiguity, subjectivity and especially the 'temporality' of information availability. Whilst the other barriers can be resolved (as listed in Table 1), the use of metrics having trailing 'temporality' can only be resolved by treating these as 'objectives'. This represents a contribution to the real-team process compliance checking in construction.

A limitation of this work has been the limited choice of clauses as examples, and the limited number of information sources used. Further research could be less selective about the clauses considered so as to confirm the completeness of the approach used here. Other leading and real-time information sources, such progress charts, could be integrated.

Further work is being proposed to broaden the number of use-cases supported by the mark-up of construction regulations. This could include decision support tools and educational and training experiences.

Acknowledgments

This work has been conducted with the support of AEC3 UK Ltd who provided the 'AEC3 Require1' application, ASITE Ltd who provided sample anonymised site diary information and Wearable Link Ltd (trading as PLINX) who provided sample anonymised site monitoring logs, whilst collaborating with the UK HSE.

Abstract

A Digital Building LogBook/Passport (DBL/DBP) is a repository for static ”as built” and dynamic ”Key Performance Indicators (KPIs)” throughout the life cycle of the buildings. This ongoing research uses the semantic mapping approach to analyse and compare the current recommended DBL/DBP models to identify the similarities/differences between them. The findings of this investigation show that due to the lack of comparison studies on DBL/DBP models in academic literature, the similarity percentage between proposed categories and elements is very low, and a knowledge-based method would be needed that makes the comparison not straightforward. In particular, the lack of metadata caused an increasing uncertainty percentage of elements. The focus of this paper is on assessing the DBL/DBP models (comparison of categories and elements, metadata evaluation), further work is needed to develop an integrated model.

Introduction

Buildings account for 40% of total energy consumption in the EU and are a major contributor to greenhouse gases (GHG) and energy consumers globally (Koltsios et al., 2022). Current European regulations aim to achieve the Paris Agreement as a nearly zero operating energy target in buildings (Ahmed et al., 2022). Net-Zero energy buildings are defined as a building or construction that has a zero-net consumption of energy or zero carbon emissions over a set period (Sartori et al., 2012) and are classified into four types: zero-energy sites, zero-emissions buildings, zero-energy sources, and zero-cost energy buildings (Ahmed et al., 2022). Space heating, hot water production, lighting, and the operation of various electric appliances, all use operational energy and account for the majority of total life cycle energy use (Vourdoubas, 2017).

Collecting Net-Zero emission building data in a single repository facilitates monitoring of greenhouse gas emissions across the entire life cycle of constructed assets within global, regional, and national frameworks (Society, 2020). Implementing a unified repository enables the thorough tracking and analysis of emissions data, hence facilitating the identification of patterns, trends, and areas that require improvement. Decision-makers can then use this information to guide the creation and application of strategies and policies to help the built environment reach Net-Zero emissions targets.

Building LogBooks and Passports

Töpfer (1997) introduced the first definition of a Building LogBook (BL) as a tool to improve the transparency of technical properties, standards of building services, quality of use, and operation costs of buildings by communicating comprehensive information to clients and buyers of the new property, developers, and real estate agents. The term ”Building Passport (BP)”, has now replaced the Building LogBook. A BP is a simple format for presenting both the ”birth certificate” and ”health certificate” of a building. The birth certificate specifies the key performance elements of the building to operate sustainably during the design process or after the first year of operation (Virta et al., 2012). The ”health certificate” compares the building's operation to previous years' operations and provides a short and long-term repair and retrofitting plan (Virta et al., 2012). The Global Alliance for Buildings and Construction (GlobalABC) defined the BP as a repository for all construction types and real estate activities throughout the life cycle. It will be able to create and update itself, feed on data from various data sources (e.g., Internet of Things (IoT), and Digital Twins (DT)), and enable effective virtual representations of physical assets UNEP (2020).

Semantic mapping analysis is the process of calculating the relationships between texts based on the semantic similarities methods. These methods combine automatic and knowledge-based measurements, to determine similarities and differences between phrases and sentences based on their meaning (Chandrasekaran and Mago, 2021).

This paper provides an overview of current BP/BL models to identify their main differences and similarities with semantic methods (see Experiment section), which are the fundamental basis to assess the potential for creating a single integrated model. Understanding the variation between models helps in fully comprehending the primary (minimum, lowest common denominator) BL/BP data elements, by examining element commonality and similarity. It also enables the development of a fully comprehensive model that covers all elements of all BPs. Both models help to organize data in a way that reflects the relationships among different pieces of information that can be understood by both technical and non-technical users, which is crucial for effective decision-making and system development.

This paper only explores approaches currently available from the literature, and hence the effort required to integrate these data sources. The resulting integrated model is aimed to be used by various use cases, who will be able to develop a sub-set (view) on the model that contains only the data that they require, and hence identify how to source the required data in the different passport contexts and countries, greatly reducing the time for data discovery and integration.

Experiment

Current DBL/DBP initiatives

Numerous research initiatives received funding through the European Horizon 2020 program to encourage increased energy renovations across the European Union. EU Commission study (EU) proposed a DBL data model to enhance energy efficiency and sustainability (Dourlens-Quaranta et al., 2020). As part of the iBRoad project, Libório et al. (2018) proposed a BL data model to support the implementation of a building's renovation road map for single-family houses based on occupant needs and preferences. As part of the ALDREN project, Sesana et al. (2020) proposed a tailored conceptual building Renovation Passport model to understand the state of the non-residential buildings and inform building owners about the technical energy performance status. Within the X-tendo project, a BL model that can be attached to the EPCs to inspire the next EPC generation was proposed (Toth et al., 2021). The EUB SuperHub project proposed a DBL model to achieve the EU's sustainable buildings (Malinovec Puček et al., 2023). The DBL report used the existing European INSPIRE initiative and proposed the DBL semantic data model (van der Ende et al., 2023). A green Building Renovation Passport (UKGFI) was proposed to enable data for energy performance estimates and retrofit assessments in (Small-Warner and Sinclair, 2022). THE BIM4EBB[1] developed an interoperable BIM-based toolkit for efficient building renovations. The BIM4Ren[2] proposed workflow for the renovation process and information requirements.
The GlobalABC proposed the main contents of BP based on the integration of Woningpas[3], the Building Renovation Logbook initiative, Ukraine[4], and the Building data Collection initiative (UNEP, 2020). Miller (2016) developed a BP to capture building energy efficiency data on residential buildings. Within the chronicle[5] project, a DBL framework is developed to achieve sustainability targets and long-term maintenance and renovation plans. National initiatives such as Madaster[6], Passeport Efficacité Énergétique[7], PAS-E[8], BASTA Logbook[9], Property Logbook[10],and Building Renovation Logbook[11], do not provide an official data model. The initiatives that provided the data model are listed in Table 1.

Previous Attempts at Integration

Although the approach of integrating BL/BP models was not addressed before, various Energy Performance Certificate (EPC) integration initiatives exist ((EPC and BP are the sources of a building's operation consumption and energy performance)). Serna-GonzÁLez et al. (2021) proposed a harmonization EPC data model by combining models from Italy and Spain. The Hale Studio tool was used to map the target data model to the source data model(Serna-GonzÁLez et al., 2021). Popa et al. (2022) created an integrated EPC model from England, France, Scotland, and Ireland to determine a dwelling's energy performance rating. Pouliot et al. (2018) used the Open II (Open Information Integration) tool to compare the geospatial standards from syntactic, structural, and semantic points of view. The Hale Studio [12] and OpenII [13] are powerful data transformation and harmonization tools, which don't include functionality for comparing and identifying similarities between texts.

Semantic similarity

Semantic similarity is a technique for assessing the degree of semantic equivalence between two texts, providing a quantified measure of similarity instead of a binary determination of whether they are similar or dissimilar (Chandrasekaran and Mago, 2021). Existing methods for short text similarity calculation can be roughly divided into two categories: word-level semantic-based and semantic modelling-based (Yang et al., 2021).
word-level semantic-based: The similarity of two short texts is calculated by aggregating the similar words in both texts, including knowledge-based and corpus-based methods.

- **Knowledge-based methods:** This method uses the shortest path method (Yang et al., 2021), Lexical (Farias et al., 2016), and syntactical similarity (Costin and Eastman, 2019), with the knowledge-based approach to computing the semantic similarity between two short texts (Chandrasekaran and Mago, 2021). This approach allows for a representation of human common sense and demonstrates improved performance compared to other methods (Yang et al., 2021). The main drawback of shortest path and lexical, respectively, is that the texts must be synonymous, and the lexical technique only considers zero and 100% similarity. The syntactically similar measure quantifies the similarity of two text strings for approximate string matching or comparison. For example, the

[11]https://eeplatform.org.ua/
[12]https://wetransform.to/halestudio/
[13]https://sourceforge.net/projects/openii/

strings ”Sam” and ”Samuel” are similar and have the same character sequence (Pradhan et al., 2015).

- **Corpus-based methods:** This method extracts the context information of words from large corpora and then induces the distributional properties of words (Yang et al., 2021). It does not capture the semantic relationships between words. It treats each term in isolation, without considering synonyms, related terms, or context.

Semantic modelling-based: Semantic modelling-based methods model a text as a whole to obtain the semantic vector and calculate the similarity of two short texts by performing algebraic operations on the obtained vectors (Yang et al., 2021).

- **Explicit Semantic Representation:** ESR models focus solely on word-level representations, overlooking the valuable information conveyed by syntax (Yang et al., 2021).

Methodology

To evaluate the potential of combining existing BP towards creating a comprehensive passport model, their similarities and differences in elements (attributes) classification, and metadata availability need to be investigated. The overall approach is organized as follows:

Step 1: Identify LogBooks/Passports. This included a comprehensive literature review, using the following search terms in the Google Scholar engine in all fields of the publications, such as titles, abstracts, keywords, and the entire text of the papers: ”LogBook”, ”Building LogBook”, ”Building Passport”, ”Material Passport”, ”District LogBook”, ”Building Renovation Passport”, ”Green Building”, ”Building Certificate”. Publications from 2000 to 2023 in the form of journal and, conference papers were searched, with language limited to English to allow for semantic matching.

Step 2: High level comparison. The papers that provided information about the BP structure and classification were selected and reviewed to identify the detailed data model presence that could be used for comparison, and the presence of metadata describing the model. Following this stage, BPs with sufficient detail for semantic comparison were selected. To enable the comparison process, a single BP was selected, to be the model to which all other models will be compared.

Step 3: Detailed data model comparison for the selected BP

- **Format, type, and level of classification investigation:** This step involved understanding how different elements in the models are classified (grouped), the types of classifications used, and the hierarchical classification level.

- **Manually Transfer Models into Excel:** The models were initially in PDF format, and for the initial comparison, each model was manually entered into a distinct Excel sheet. This involved taking each element in the model and manually typing it out into the corresponding sheet. A sheet was created for each classification identified above, with a column created for the elements from each BP.

- **Exclude the dynamic data:** To evaluate the infrastructural elements of BP and due to the different natures of static and dynamic data, the dynamic elements were excluded.

- **Import into a Database:** SQL (Structured Query Language) is commonly used for querying relational entities (Date, 2011). Each sheet model in CSV format was imported into a database; i.e. one entity (table) was created for each classification for each BP. This enables semantic comparisons to be performed using Transact-SQL queries.

Step 4: Semantic comparison. The similarities and differences between the classifications and elements of each model by the other models were examined. The knowledge-based and syntactical methods were used to conduct a more detailed semantic comparison of the category and element at the static information level. The LIKE query was executed to model the syntactical method, which allows finding all textual elements similar to the source element. This method is acknowledged as a semi-automatic method in this paper. The following is the comparison process:

- **Identifying the elements with similar terminology:** A semi-automatic method was used to find textually similar element names.

- **Identifying the elements with similar meaning but different terminology:** A knowledge-based approach was used to find the elements that did not share the same terms but were similar in meaning. Where available, metadata was used where this was not available a comprehensive exploration of the documentation was undertaken to confirm any interconnection between the data element names.

- **Identifying the elements with similar terminology potentially different meaning:** As above, after using the semi-automatic method, a knowledge-based approach was used to review and clarify the elements, using metadata and BP documentation where possible.

- **Identifying the elements with uncertain meaning:** A final category of elements are those where the meaning is uncertain and where the documentation and metadata do not provide sufficient clarity to match the elements.

Step 6: Key information comparison. The main BP content proposed by the GlobalABC UNEP (2020) was compared to categories and elements of identified models to assess their similarity.

Step 7: Similarity methods comparison. The average similarity percentage was examined to determine whether semi-automatic or knowledge-based approaches performed better.

Step 8: Statistical analysis. Aggregating all of the outcomes above, the similarity percentage between categories and elements was calculated to assess how much information could be collected from each model. Elements with a high level of certainty were chosen for analysis, while those with unclear meanings were excluded. It is important to note that elements lacking consistent terminology; i.e. where meaning was uncertain, have been removed from the analysis.

Results

Analyzing BL/BP models

A total of 7 BL/BP data models were identified and summarised in Table 1. They have a different number of categories that provide different information. The first column of the Table 4, Table 5, Table 6, Table 7, and Table 8 provides the category description.

Table 1: Summary of Identified BP

Source	Summary	Metadata Available	Number of Categories	Total Number of elements
EU	Proposing a DBL model to achieve energy efficiency and sustainability	Partial	7	76
X-tendo	Proposing a DBL model to inspire the next generation of EPCs information	No	7	173
EUB	Proposing a data structure for DBL to achieve energy efficiency and sustainability	Partial	7	167
ALDREN	Proposing a Building Renovation Passport (BRP) model to understand the technical energy performance status of non-residential buildings	No	5	66
iBRoad	Proposing a framework for managing energy performance, executed maintenance activities, and building plans	Partial	4	73
UKGFI	Proposing a green BRP model to improve energy efficiency	No	8	75
DBL report	Proposing a semantic DBL data model	Partial	7	86

Performing semantic comparison

A preliminary comparison was performed to select a more complete model regarding the building's fundamental elements. EU and X-tendo models provided more information on the buildings, and EU was selected as a starting point. In the semi-automatic part, a script with the LIKE operator was executed per category, and the identified elements with the same input terms were displayed in the results. Similar results were then imported into the repository, which was used for the next comparisons. This process was repeated for each model until it reached the final one, allowing all models to be compared. It is important to note that some steps were iterative since previously analyzed information had to be reanalyzed several times along the line, as the need to understand the problem better increased in subsequent rounds. The following are some illustrative examples of the comparison process.

- **elements with similar terminology:** The ”Floor area” element in the EU model's *Building descriptions and characteristics* category, was identified as a match by the automated checking process to the ”Total floor area (unheated and heated area)” in the EUB model's *General Building Information* category, ”Floor area” in the X-tendo model's *Building descriptions and characteristics* category, ”Net floor area” in the iBRoad model's *General and administrative information * category and ”Floor area and building volume” in the UKGFI model's *Building type* category.

- **elements with dissimilar terminology but similar meaning:** The ”Building information model/Design and plans of the building” element in the X-tendo, EU model's *Building descriptions and characteristics* category, could be assumed to be similar to the ”Layout of the whole building for multi-unit properties (i.e. block of flats, terrace housing) ” in the UKGFI's *Building type* category, and ”3D model/Architectural plans” in the EUB model's *Building Documentation BIM* category. One of the main limitations of an automated approach is identifying similarities, where there are no identical terms between models.

- **elements with similar terminology but uncertain meaning:** The ”Address” has been considered in the EU and X-tendo models's*Administrative* category, which is undefined and is related to the building owner's address, occupier address or the building's address. The meaning of the ”Storage” element in the X-tendo model's *Building descriptions and characteristics* category, and the ”Energy supply and storage” in the UKGFI's *Building Services* category are unclear.

- **elements with uncertainty meaning:** The meaning of ”Renewable energy systems” in the EU model's *Building descriptions and characteristics* category, ”Any existing and planned local energy schemes” in the UKGFI model's *Building Service* category, ”Optimizing self-consumption of locally generated energy” in the ALDREN model's *Technical system* category, and the ”isDescribedByNativeGIS” in the DBL report's *Location* category, are unclear. In the EU and X-tendo models, the ”U value of different components” is proposed as an element in the ”Building Performance” category, although its meaning and definition are unclear.

- **elements with uncertainty metadata:** The description of ”Ventilation systems” or ”Cooling systems” in iBRoad model's *Building construction information* category is "Description of the building ventilation systems" and "Description of the building cooling systems", which do not encompass the essential requirements that should be incorporated into it.

duplicated elements: The "Safety Manual" proposed in the EU model includes building operations and maintenance, and security procedures, whereas the " Maintenance records and information" element, also has been proposed by EU, X-tendo, UKGFI, and iBRoad models. The "Building pictures" in the EUB report's *Building Documentation BIM* category was repeated in the EUB report's *General Building Information* category.

Our results demonstrated that significant progress in defining a comprehensive BL/BP model has been made, though there is still a lack of interoperability between elements, data consistency, metadata availability, and information exchange.

Comparing some key information

The percentage of similar elements proposed by more than 3 models is 6 %, and the similarity percentage between elements is low (See section Statistical analysis), making it challenging to identify the key elements. Table 2 compares the main content proposed by GlobalABC and identified BP models (categories and elements). As can be seen, in some cases, the contents are similar to the group of model elements (e.g., Building description, Technical features, Use and operation). In these cases, similar elements were found using the knowledge-based method in addition to the semi-automatic method. The semi-automatic method was used to find similar elements to the *Contracts*, *Material inventory*, *Building description*, *Operation*, *Energy Performance Certificate*, and *Maintenance*. The knowledge-based was performed to find similar elements to the *Identification of buildings*, *Identification of the plot*, *Material inventory* and *Technical features*. The models did not include the *Environmental performance and carbon footprint*, *Surfaces*, *Dismantling and recycling strategy*, *Results of user satisfaction survey* and *Certificate* elements. The EUB model only incorporated the *Proof of maintenance* (as the maintenance report element), *Design documents* (as the Architectural plans and As-built plans), and *Operational cost*.

Comparing similarity methods

Table 3 compares the semi-automatic and knowledge-based methods. The similarity was calculated by the average number of similar certain and uncertain elements (elements were unclear or did not have similar words but were similar in their meaning) by the total number of its elements. The semi-automatic method performed better for the X-tendo and EUB models, while the others were processed using the knowledge-based approach.

Table 2: Comparison of some key information

Content	EU	X-tendo	EUB	ALDREN	iBRoad	UKGFI	DBL report
Identification of plot and plot-related characteristic	**Element:** Building owner	**Element:** Buiding owner	**Element:** Building owner	**Element:** Owner name		**Element:** Owner's details	**Element:** Owner

Table 3: Comparison of similarity methods

	X-tendo [%]		EUB [%]		ALDREN [%]		iBRoad [%]		UKGFI [%]		DBL report [%]	
Source	Semi-automatic	Knowledge-based	Semi-automatic	Knowledge-based	Semi-automatic	Knowledge-based	Semi-automatic	Knowledge-based	Semi-automatic	Knowledge-based	Semi-automatic	Knowledge-based
EU	37	4	20	6	0	4	1	4	0	10	6	3
X-tendo	-	-	16	4	1	2	0	4	1	5	2	1
EUB	-	-	-	-	2	4	1	7	0	6	2	3
ALDREN	-	-	-	-	-	-	1	5	1	6	3	11
iBRoad	-	-	-	-	-	-	-	-	0	6	2	4
UKGFI	-	-	-	-	-	-	-	-	-	-	0	2

Performing statistical analysis

The similarity percentage of classifications for each model to the other models was calculated by the average number of similar categories divided by the total number of categories in the model. The EU model with 57%, X-tendo with 57%, and EUB with 51 % were the most identical to the other models. ALDREN with 40%, iBRoad with 35%, DBL report with 25%, and UKGFI with 10 % were in the subsequent ranks. As can be seen in Table 4, Table 5, Table 6, Table 7, and Table 8, the "Building Documentation BIM" category is not included in the other models, or the "Envelope" category of the ALDREN model is relevant to the "Building construction" category of iBRoad. The location element has been considered in the other models but not in a separate category; ALDREN's model is the only one considered a category for location.

Table 4 demonstrates the similarity percentage of EU elements to the X-tendo, EUB, ALDREN, iBRoad, UKGFI, and DBL report models using the semi-automatic and knowledge-based methods. It was calculated by the number of similar elements with clear meaning in the EU model by the total number of its elements. Table 5, Table 6, Table 7, and Table 8 shows the similarity comparison for the other models. As can be seen, the overall matching percentage in terms of category and elements, with X-tendo and then EUB, is significantly higher than with the other models. The low percentage of similarities arises from diverse elements incorporated within the same categories across different models. For example, "Building age" is part of the iBRoad "General and administrative information" category, while the "Year Built" is included in the EU "General Building Information" category.

Table 4: EU similarity comparison with X-tendo, EUB, ALDREN, iBRoad, UKGFI, DBL report

Discussion

The BL/BP is a summary of all the key information about the building, including the original design, commissioning, and handover details, and information on its management and energy performance, the material used, sustainability performance, indoor environmental quality, and potential energy throughout the building life cycle (Small-Warner and Sinclair, 2022).

The main purpose of our approach was to evaluate the differences and similarities between the data models that underpin each BP and assess whether semi-automated or knowledge-based approaches would be useful to create an integrated data model of the various BP. This work showed that the currently proposed BL/BP models, firstly have different categories (groupings or classifications of elements) which, when examined in detail, overlap in some cases and are not aligned with the proposed categories by GlobalABC (UNEP, 2020). This adds a layer of complexity to the potential for automated integration, which is further complicated by the fact that elements (attributes) within each classification sometimes overlapped or were included in different groupings in the different BP. Underpinning the automation challenges are gaps in the lack of an agreed and standardized conceptual BL model accompanied by detailed metadata, which would provide clear element definitions, including the data type, and sufficient data descriptions. This could be further complicated when it is considered that not all these BP originals in English-speaking countries - and local terminology - and translations- could cause additional issues. Methodologically, the use of text-based comparison (LIKE) for matching could also introduce false positives (See section Step 4 for examples) and manual checking was required to validate the results. The approach of selecting a single model (EU model) towards full integration of models available from the literature, was however very beneficial as it was avoided.

The comparison results showed that although the most common categories are Administrative information, Building Identification, Building performance, and Building operation (Table 2), the similarity percentages between elements are low (Table 4, Table 5, Table 6). There is a lack of clear consensus regarding the Building geometry category, suggesting the need for further discussion. The similarity percentage between models on Building equipment information (e.g., Heating, Cooling, DHW, etc) is low, which is substantial in proposing the integrated model. The models made no distinction between Building and Building unit elements, which are required for creating an integrated mode. The EUB model incorporated the EPBD indicators (Energy Performance Building Direction) [14], however further discussion is required to distinguish between EPBD and integrated BP elements. The categories in the integrated BP model must be harmonized according to the proposed GlobalABC report's categories. Although the static information was examined, the EUB model only included the KPI indicators. This indicates that identifying real-time data and considering the Building Automation System (BAS) in the integrated model requires significant effort.

Overall, therefore, it can be concluded that to develop an integrated model an extensively manual process will be required, starting from creating digital versions of PDF models and moving from there. Indeed, the automated SQL comparisons did not prove reliable enough to even be a first pass for the approach, given that in 32 cases similar terminology was used with different meanings, so false positives were observed (Section Methodology- Step 4). An extensive effort to identify key information in an integrated model is required due to the 42 elements shared by more than 3 models.

Conclusions and further work

The BL/BP is a repository for the comprehensive collection of the most important performance characteristics and technical data feed in from various data sources (e.g., Internet of Things(IoT)) and should enable effective virtual representations of physical assets (Tharma et al., 2018). The overall purpose of this specific task of our ongoing research was to examine both the parallels and distinctions of the current recommended BL/BP models in terms of their element's contribution to the physical, energy performance characteristics, and technical data of a building using semantic similarity methods. The results showed that, while great progress has been made, the similarities between proposed models are quite low, and a knowledge-based strategy would be required. The outcome of the process above will be an integrated UML and physical data model that will allow users to trace back each element to its source or sources (BP or EPC) and make a connection between different entities. Users of this integrated model will thus be able to select the required subset of elements from the full model (as a view) and easily understand whether such data is available from data currently collected by BP or EPC. Future work will also entail the integration of the BP identified above with EPC models. These provide the necessary energy consumption information and may help achieve Net-Zero carbon objectives.

GRAPH-BASED DIGITAL DECISION SUPPORT SYSTEMS: INTRODUCING BTWIN, A TOOLKIT FOR PERFORMANCE-BASED BUILDING MANAGEMENT

Angelo Massafra[1], Ugo Maria Coraglia[1], Giorgia Predari[1], Riccardo Gulli[1]
[1]Alma Mater Studiorum University of Bologna, Bologna, Italy

Abstract

The digitization of the AECO industry is increasing the need for digital decision-support systems (DDSS) in building management. Despite technological progress, developing such systems still demands significant resources. In particular, integrating diverse building data remains a challenge. Addressing this, the paper introduces BTwin, a toolkit designed to simplify the prototype development of DDSSs supporting decision-making in performance-based building management. This software library facilitates linking data from multiple sources into graph networks, like building information models and time series databases, providing a low-code and open-source framework for creating user-friendly web applications using connector logic.

Introduction

The built environment strongly impacts global energy consumption and produces high environmental emissions. Although it sits at the crossroads of many EU policies, it is still affected by a persistent challenge of limited innovation, which is probably the primary impediment to its digital and ecological transformation.

To face these challenges, in recent years, the Architecture, Engineering, Construction and Operation (AECO) sector has started its digital transition, pushed by the emergence of cutting-edge technologies, including Artificial Intelligence (AI) (Zhang et al., 2022), Building Information Modeling (BIM) (Deng et al., 2021), Internet of Things (IoT) (Mannino et al., 2021), Building Performance Simulation (BPS) (de Wilde, 2023), and Digital Twins (DT) (Lu, 2022). Notably, DTs have risen prominently, serving as a catalyst for developing digital decision support systems (DDSS) to enhance decision-making in built asset management, leading to the spread of performance-oriented applications for multiple uses, such as space usage monitoring, analysis of energy needs, reporting of energy and water consumption, estimation of emissions due to building usage, as well as analysis of indoor environmental quality regarding thermal, visual, acoustic comfort, and air ventilation (Petri et al., 2023).

Despite their rapid growth, DTs are still in their infancy and require, on the one hand, prototyping and technical development and, on the other, further conceptualization (Boje et al., 2020). The lack of standardized definitions, the heterogeneous and vast amount of data and data sources, and the not scientific approach that usually characterizes built asset management (Abuimara et al., 2021) hinder the organic development of such technology and, more in general, of DDSSs, limiting the possibility of easily transforming building data in usable knowledge.

Developing such systems poses a resource-intensive challenge, with economic, financial, and cultural benefits that are sometimes difficult to comprehend during the conceptualization phase (Ma et al., 2022). These challenges are highlighted by the AECO sector's lack of data integration, marked by the presence of numerous data silos belonging to various stakeholders and created using distinct languages and frameworks, leading to significant data interoperability issues (Merino et al., 2022). These digital solutions require high expertise from many domains to enable secure and streamlined data flow, reliable and scientifically valid information generation, and user-friendly, accessible and usable knowledge to non-digital experts. The scientific community, therefore, is called first to theorize these systems and second to prototype solutions demonstrating the tangible benefits of such technologies.

In order to respond to these needs, this paper introduces BTwin, a software toolkit designed for simple and cost-effective prototyping of DDSSs for building management. The toolkit allows for semantically linking building data from diverse sources (like BIM, BPS, meters, and sensors) within graph networks and visualizing it organically through interactive dashboards, offering a low-code and open-source solution for prototyping web-based DDSSs. Implemented on JSON-LD (JavaScript Object Notation for Linked Data) principles, BTwin structures data within graphs by following the axioms and meanings defined in a federated ontology. After linking data, the toolkit enables the creation of web applications that extract data from graphs using user-executable queries through a graphical user interface (GUI). It then presents this data in various formats, informing the application user about the key performance indicators (KPIs) that characterize building performance. The software library performs these tasks in Python, a programming language known for its simple syntax, making it extremely popular for various software projects.

In this article, after discussing the state of the art in developing graph-based DDSSs in the AECO sector, the theoretical framework that supported the development of the tool is presented. Furthermore, the toolkit is applied to a simplified case study to demonstrate its applicability and provide some examples of its use.

Related work and background

Knowledge graphs

When people express their thoughts to other people in the places where they work, they, consciously or unconsciously, create graphs. It means identifying specific objects and labelling the relationships between them to explain a problem, share a concept, or explain a domain, in other words, to transfer knowledge.

Such graphs can be produced either by humans or computers. Those intelligible to computers typically comprise nodes (or vertices), denoting entities and subjects, alongside edges representing the connections between these nodes (relationships or links). Both nodes and edges can be characterized by semantic attributions and property descriptions (Paulheim, 2016).

Accordingly, organizing domain concepts and information in knowledge graphs (KGs) allows for, first, assigning semantic and ontological meaning to data, as well as enabling semantic query, extraction and analysis of data from complex data structures; second, proficient visualization and, therefore, comprehension of a knowledge domain and its segmentation into knowledge sub-domains.

Beyond these capabilities, KGs also excel in analyzing extensive datasets entrenched in diverse formats. Moreover, if coupled with semantic web technologies (Pauwels et al., 2017), KGs can allow fast accessibility to information on the web, an issue that has become a priority for modern DDSSs.

Ontologies and schemas for data representation

Understanding the terminology used in a KG is crucial for systematically organizing and sharing the knowledge it contains in a universally comprehensible manner. In KGs, organic information description can be achieved through ontologies, formal, shared, and explicit representations of a domain's conceptualization, crafted to ensure that all information is clearly defined for logical reasoning.

Recently, the surge in digital tools within the construction sector has led to the definition of various ontologies to describe the AECO world and its subdomains (Pritoni et al., 2021). Among the most used ontologies and data schemas, the following are considered relevant to this research: Industry Foundation Classes (IFC); Building Topology Ontology (BOT); Brick Schema; Semantic Sensor Network Ontology (SSN); the Sensor, Observation, Sample, and Actuator (SOSA) ontology, and the Energy Management Key Performance Indicator Ontology (EKO).

IFC, the open BIM standard supported by buildingSMART, is the most recognized schema for BIM data. Its integration with semantic web technologies is allowed by the IFC web ontology language (ifcOWL) (buildingSMART International, n.d.). The Building Topology Ontology (BOT) is a simplified ontology proposed by W3C that exclusively addresses the core building concepts revolving around the building's topology, including physical and conceptual components and their relationships (Rasmussen et al., 2017). Brick is an open-source schema that standardizes the semantic descriptions of buildings' physical, logical, and system assets and interrelationships. Its primary focus is on smart building applications and equipment representation (Balaji et al., 2018). SSN describes sensors and their observations, features of interest and samples, procedures, and actuators. It is often used to describe BAS data with semantic tags (Compton et al., 2012). SOSA, instead, redesigns SSN to provide a lightweight, general-purpose specification for modeling the interactions between entities involved in observations, actuation, and sampling (Janowicz et al., 2018). Finally, EKO enhances multi-level energy management and energy performance information exchange (Li et al., 2019).

Graph-based approaches for digital twins

In the contemporary landscape, graphs have assumed a pivotal role across many data-driven applications, also influencing the AECO sector (Lygerakis et al., 2022).

Various researchers have introduced and tested the use of KGs to develop digital systems for building operations, contributing to forming a solid approach to the subject, although relying on various technologies and data schemas. For instance, Merino et al. experimented with using KGs to deliver the DT of an educational building aimed at fault detection and diagnosis of HVAC systems for facility management purposes (Merino et al., 2022). In their study, these authors mainly leveraged IFC and Brick schemas for data representation and a data lake architecture for data storage. Chamari and colleagues, instead, explored the integration of BMS, IoT, and BIM via KGs, utilizing IFC and Brick within RDF graphs (Chamari et al., 2022). They proposed a hybrid approach for managing time series data, which was stored in a JSON-based MongoDB to overcome the limitations of graphs in handling time series with millions of data points. Differently, Hosamo et al. conducted interesting work on DT for fault detection and comfort optimization, integrating BIM, sensor time series, and maintenance records. Although the research refers to BOT, SSN, and Brick schemas, they used a custom ETL (Extract, Transform, Load) process to enable condition monitoring and predictive operation (Hosamo et al., 2023). Another significant example is the work of Ramonell and his team, who proposed a system for data integration within DTs, leveraging property graphs in Neo4j (Ramonell et al., 2023). This approach allowed for mapping semantic information according to different ontologies, keeping the graph as the interoperability backbone of the systems.

All these contributions, which propose hybrid strategies to enhance BIM-based KGs with time-series data, underscore the significance and utility of such technologies in modeling building knowledge, highlighting both potentials and limitations. However, an aspect not covered in the mentioned articles is the Return on Investment (ROI) for developing these applications. Indeed, it remains a challenge to ascertain whether the benefits of developing such complex systems can be financially justified for the administrations that adopt them, especially considering that substantial funding programs are usually behind these research initiatives. Consequently, leveraging the theoretical frameworks established in these studies and the insights derived from these pioneering explorations, this paper seeks to introduce a toolkit designed to streamline the initial prototyping process of such digital environments. The goal is to make the process more cost-effective and accessible to research and development groups of smaller scale or with limited resources, thus promoting wider adoption and innovation in this field.

Materials and methods

Ontology definition

BTwin assumes that a building can be represented as a graph composed of nodes (subjects) and edges (predicates). To define organically information, nodes are designated to classes (and subclasses), whereas edges are associated with types of relationships, following the ontology depicted in Figure 1. This federated ontology, designed by leveraging BOT, IfcOWL, Brick, SSN, SOSA, and EKO, integrates these already established ontologies within a unified and extensible ontological model.

At the foundational level, the federated ontology employs the BOT's zones (i.e., 'bot:Building', 'bot:Site', 'bot:Storey', and 'bot:Space'). These objects establish a hierarchy necessary for representing the building's spatial configuration. BOT serves as the backbone, allowing for the detailed specification of physical locations and the inclusion of elements (such as sensors) within spaces. BOT is also used to model 'bot:Interface' elements resembling interface elements bounding the spaces (e.g. walls, floors, roofs, windows and doors).

Interlaced with BOT is IfcOWL, which is used in the ontology to map the properties of spatial elements as 'ifc:Property' within 'ifc:PropertySet', instrumental in providing detailed descriptions of element properties and their attributes. Moreover, IfcOWL allows for the representation of sensor elements, considered as physical electronic devices, using the 'ifc:Sensor' class.

Enhancing the ontology is Brick. The Brick framework enables classifying sensor elements as 'brick:Sensor'. While there seems to be an overlap with 'ifc:Sensor', Brick sensors are denoted as 'brick:Point', which are input points symbolizing the value captured by a device or instrument engineered to detect and measure various variables. This indicates that a single IfcSensor device can embody multiple points (thanks to the 'brick: hasPoint' relationship). For instance, a 'brick:HumiditySensor' and a 'brick:TemperatureSensor' points may continuously provide data to an 'ifc:Sensor' device. The link between sensors and spaces is given by the relationship' brick:hasLocation'. Additionally, Brick facilitates the organization of spaces into zones utilizing the 'brick:Zone' class, which can encapsulate groupings of rooms such as energy zones or fire compartments. Furthermore, the relationship 'brick:hasLocation' establishes semantic interoperability with the BOT spatial hierarchy, thereby enriching the data model with spatial context and associations.

The ontology further incorporates the SSN and SOSA ontologies through the 'sosa:Observation' and 'sosa: ObservableProperty' classes. These are pivotal for modeling the data generated by sensors (thanks to the

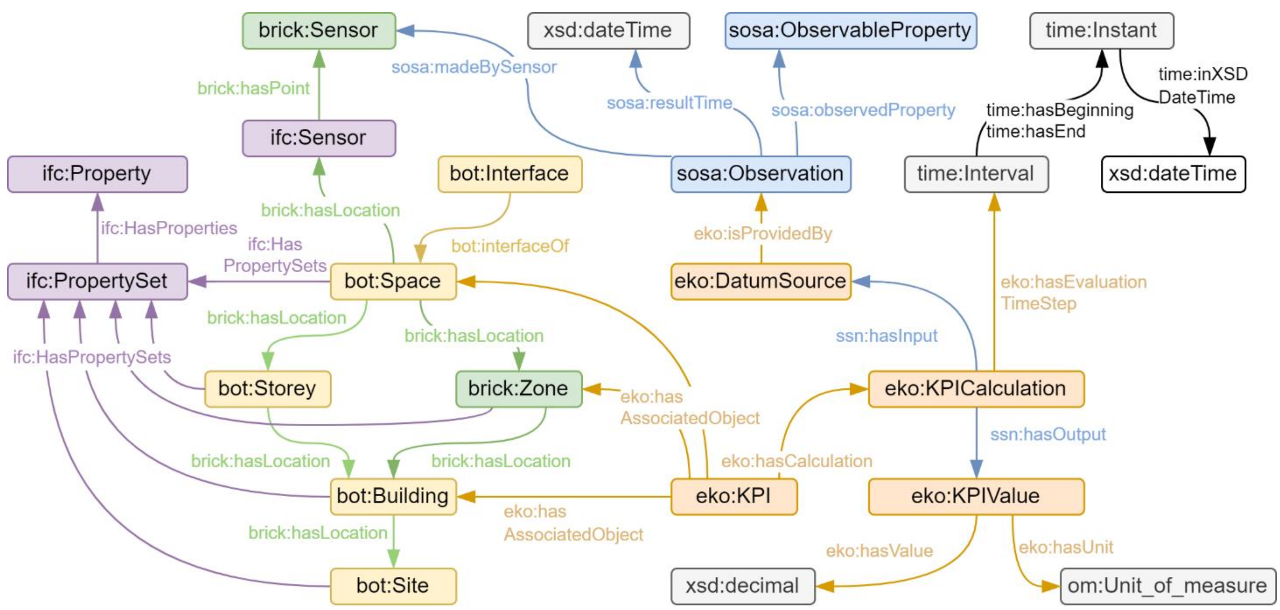

Figure 1: The federated ontology supported by BTwin.

'sosa: madeBySensor' relationship) and the observational processes in a semantically rich context.

EKO, which includes classes such as 'eko:KPI', 'eko:KPICalculation', and 'eko:KPIValue', is instead used to describe the performance aspects of spatial elements. These classes are used to define, calculate, and store the values of performance metrics, which are crucial for evaluating building performance. The 'eko: hasAssociatedObject' relationship provides the necessary linkages between performance-related and spatial concepts. Additionally, this part of the ontology integrates time-related classes, such as 'time:Instant' and 'time:Interval', to represent temporal aspects, which are essential for capturing the dynamics of sensor performance data and observations over time.

Data format

The federated ontology is enhanced with a distinct syntax employing JSON-LD to illustrate entities and their interconnections in graphs. JSON-LD is a streamlined format for Linked Data, leveraging the prevalent JSON structure to enable JSON data to function seamlessly globally. It significantly improves the ease with which data can be read and written by humans, offering a clear advantage over other formats like the EXPRESS format used in IFC. Due to its extensibility and adaptability, this data model allows the serialization of data and the creation of graph-based data models. Additionally, it is lightweight, rendering it suitable for data exchange within web environments and the development of web APIs and applications.

Specifically, BTwin adopts the JSON-LD format to represent static elements, whereas it sources dynamic data, like sensor observations, from databases tailored for time-series data (e.g., SQL or MongoDB), which are more adept at managing large data volumes than graph databases. Within the JSON-LD data format, each building element corresponds to a JSON object. This JSON object functions as a dictionary, possessing a unique identifier, the indication of its class within the ontology, and the relationships with the other objects within the KG. In BTwin, this data format can be read and transformed into a KG using specific functions that leverage the NetworkX library, a Python package that provides a comprehensive set of tools for creating, manipulating, and analyzing graph networks.

Figure 2 presents an example of a JSON-LD syntactic description in BTwin. The 'context' section enables the mapping of terms used in the document to Internationalized Resource Identifiers (IRIs) to provide precise meanings. In this part, reference ontologies (such as Brick and BOT) are mentioned, as well as the keys used in various JSON dictionaries to describe the objects. On the other hand, the 'graph' section describes the nodes that form the graph and maps the existing relationships between them ('relationships' keys).

The example in Figure 2 shows the topological structure of a sample building through BOT. This structure comprises <storeyX>, defined as a 'bot:Storey' and representing a level within the building, and by <space1>, which is a 'bot:Space' located on <storeyX>. The Brick Schema is employed to standardize descriptions of sensor data, with <sensor1> being an 'ifc:Sensor' situated in <space1>, and having a temperature 'brick:Point' connected to <temperaturePoint1>. Moreover, IFC is used to model the properties of spatial entities, i.e., <PSet_SpaceThermalRequirements1> is depicted as a set of thermal requirements for <space1>, including a property about the temperature setpoint for winter. The interconnections between the elements, given by the 'relationships' key, are essential for decoding the spatial hierarchy and placing sensors within the building.

Figure 2. Example JSON-LD representation.

Toolkit architecture

BTwin consists of a Python library dependent on other reference libraries widely supported by the programming community. Leveraging the principles of linked data and using a hybrid approach for integrating KGs with time-series data allows for fast prototyping of DDSS dashboards. A

s stated, this software library employs a data format based on JSON-LD. This format can be parsed and converted into network graphs by relying on specific functions integrated with the NetworkX library.

Using the so-called 'connector' logic, the tool organically integrates with external libraries and BIM formats, promoting scalability and modularity in the data modeling steps. Alternatively, for simpler cases, static graph data can be modeled directly within BTwin without the use of third-party software.

Table 1 below shows the alignment of the federated ontology adopted by BTwin with some of the classes of the BIM formats supported by the toolkit: IFC, Autodesk Revit, Topologic, and EnergyPlus' Input Data Format (IDF). The representation of such formats in KGs is obtained through the use of connectors that rely on IfcOpenShell, Autodesk Revit APIs, Topologicpy, and Eppy, respectively.

For example, the connector with Topologic allows the representation of Topologic elements directly within graphs (e.g., Topologic cells are transformed into nodes labelled as 'bot:Space'). Similarly, the connector with EnergyPlus, developed in BTwin by integrating the APIs of the Eppy library, enables the linking of simulation results to the spatial elements whose behavior is simulated (provided that the zones in the IDF have the same name as the zones in the KG), as well as the calculation of energy-related KPIs. Additional connectors allow for interfacing with Autodesk Revit, using the APIs provided by Autodesk, and IFC, using IfcOpenShell. These connectors are useful for extracting the properties of spatial elements within BIM models and associating them with the graph nodes. Furthermore, compatibility with Arduino for modeling sensor data has been tested, and preliminary experiments have been conducted with ChatGPT APIs to enable the extraction of information from graphs using textual prompts and interpreting it through OpenAI's Large Language Models (LLMs).

For better computational efficiency, dynamic data, such as sensor readings, are not stored in graphs but in more streamlined formats within dedicated databases, such as SQL. These databases employ a straightforward schema that includes only the sensor's unique identifier, the timestamp, and the recorded value. The connection to the time-series data is established via a link to the brick:Sensor's UID. An illustrative example of tabular time series data is depicted in Table 2. This approach enables time-series databases to handle and store many records efficiently. Meanwhile, the graph database maintains relationships among static elements separately, allowing for the processing of time-series data solely when computing KPIs.

Once the static and dynamic data are interconnected using this hybrid approach, the toolkit enables various functions for querying, aggregating, processing, and visualizing the data stored within the KG. In particular, the visualization module relies on Plotly and Dash libraries for the creation of web dashboards. The results are web micro-applications that can be easily published on the Internet using solutions such as Docker and AWS, following, for instance, methods similar to the one demonstrated by (Betti et al., 2022).

Table 1: BIM formats supported by BTwin and class alignment.

BTwin	IFC	Autodesk Revit	Topologic	Energy Plus
bot: Building	IfcBuilding	Building	Cell Complex	Building
bot: Storey	IfcBuilding Storey	Level	-	-
bot:Space	IfcSpace	Space	Cell	Space
brick: Zone	IfcZone	Zone	Cluster	Zone
bot: Interface	IfcWall, IfcRoof, IfcSlab, IfcDoor, IfcWindow	Wall, Roof, Floor, Door, Window	Face, Aperture	Surface

Table 2: Example of a time-series data

Timestamp	Value	brick:Point UID	Unit
2023-11-15 10:00	18.3	tempPointX	°C
2023-11-15 10:15	18.6	tempPointX	°C
2023-11-15 10:30	18.8	tempPointX	°C

Demonstration

This section applies the toolkit to develop a sample application for monitoring indoor environmental quality parameters, namely temperature, humidity, and illuminance. For illustrative purposes, a fictional case study is employed to demonstrate a potential workflow. This hypothetical building comprises four spaces: three square offices, each with dimensions of 5x5 meters and a height of 3 meters, and an adjacent corridor measuring 15x2 meters with the same height. This setup creates a data-sharing environment that, through a user-friendly interface, enables the evaluation of the number of hours during which the setpoints for temperature, humidity, and

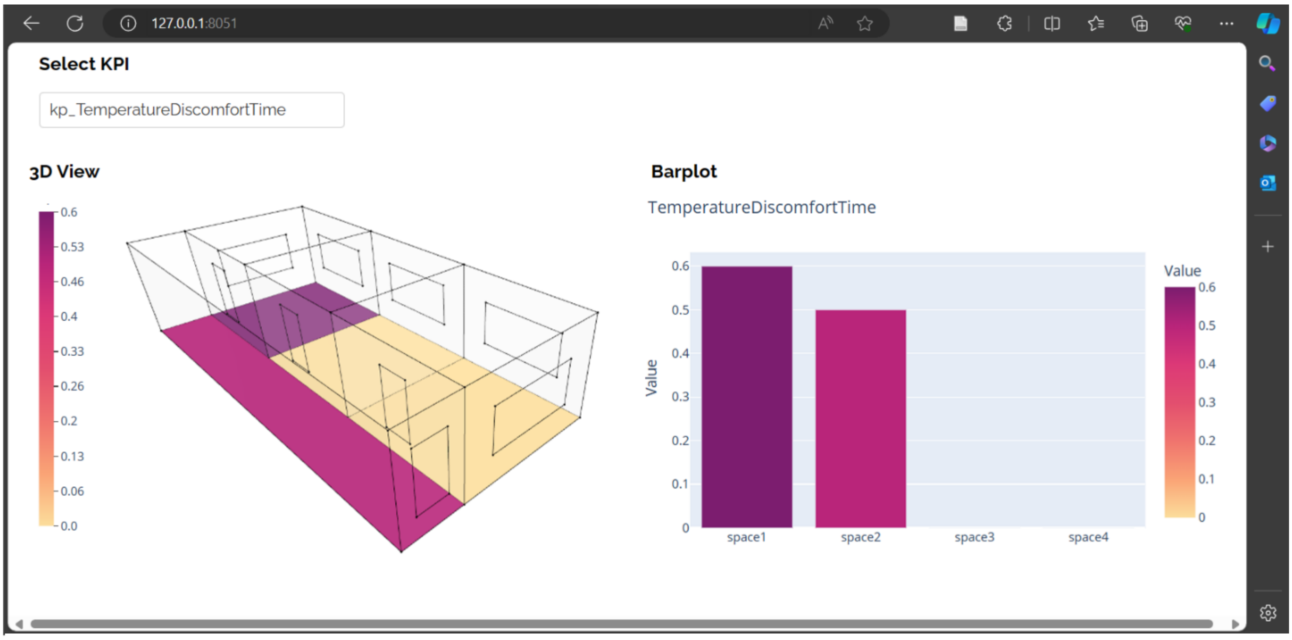

Figure 3: A dashboard developed for the sample application.

lighting are not met in these four spaces. The assessment is based on fictional measurements recorded on a winter day, as shown in Figure 3.

The architecture of the prototype DDSS is shown in Figure 4, while the main steps followed for the application's implementation are listed below.

1. First, the spatial hierarchy of the building was modeled. In particular, Topologic was used to create the case study's BIM model and the connector between Topologic and BTwin was used to transform it into JSON-LD format. The Topologic model also served for 3D visualization within Plotly.
2. Subsequently, sensor elements were added to the JSON-LD as 'ifc:Sensor' and 'brick:Sensor' elements. Moreover, relationships between these and the spatial elements were established.
3. Once all the spatial and sensor elements were identified, the properties of the spatial elements were added to the JSON-LD document. For each space, attributes related to target values of environmental comfort, defined in the KG as properties of the spaces grouped within property sets, were added. The values of the added properties were set, for example, at a minimum value of 20°C for temperature, a range between 30% and 60% for humidity, and a minimum value of 250 lux for lighting.
4. Thanks to NetworkX's connector, a KG containing the spatial elements, sensors, and property sets was created starting from the JSON-LD data. It is depicted in Figure 5.
5. Then, the data related to the measurements taken by the sensors was formatted in a MySQL database according to the notation in Table 2. For each space, temperature, humidity, and illuminance observations were recorded once per hour over a 10-hour working day in winter, resulting in 120 records.
6. Information was then extracted from the KG and MySQL to calculate the internal environmental comfort KPIs, space by space. These KPIs indicate the number of hours in which the target comfort values were not met. After being calculated, such KPIs were connected to the node representing the evaluated space in the KG for each space.
7. Thanks to Plotly's connector, a dashboard was created through Dash to display the KPIs on the geometries of the building's 3D model, previously created in Topologic, within graphs and tables (Figure 3).

From a methodological point of view, the following process can be repeated for different information uses, such as analyzing the energy needs of spaces, detecting indoor air quality, monitoring space usage, and so on.

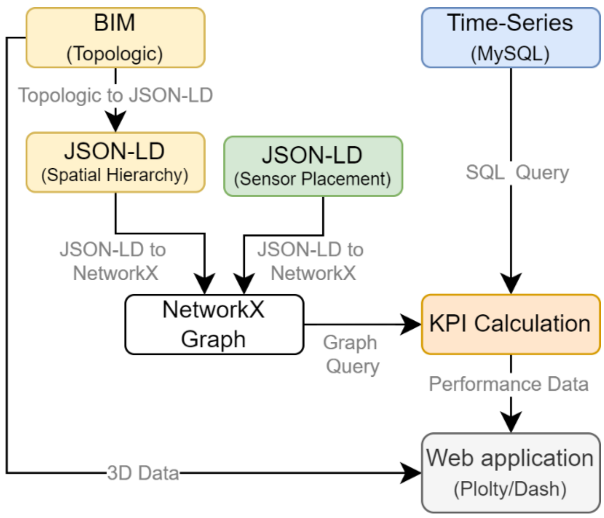

Figure 4. The system architecture of the prototype DDSS.

Conclusion

The AECO sector is currently experiencing a digital revolution, resulting in an increased need for instruments that facilitate decision-making in the realm of building management. Despite technological strides, a scarcity of these tools persists, primarily due to the substantial technical and economic investments required for their creation.

To provide a solution for streamlining the prototyping process of web-based DDSSs and address the gap in data integration in the AECO sector, this article presented BTwin, a software library designed for low-code development of DDSSs aimed at building performance-based management. The article, serving as a whitepaper for BTwin, provided the theoretical background of the toolkit, describing the axioms, concepts, and principles on which it is based. Additionally, it offered demonstrations using a simple fictional case study building to illustrate an example of its application.

This open-source toolkit, developed using a JSON-LD format and several Python functions, features a range of methods designed for semantically integrating building data from various sources, such as BIM, BPS, meters, and sensors, within KGs. It also enables data visualization through interactive dashboards, facilitating the monitoring and analysis of building performance-related aspects in a user-friendly manner. This approach could enable developers to easily create DDSS prototypes, allowing stakeholders to quickly preview dashboards during the development processes of these digital systems and provide feedback from a user-centered design perspective, thus ensuring tools tailored to actual needs. Moreover, its human-readable design makes it valuable for students and learners in the fields of BIM, DT, and KGs.

The toolkit is currently in development, with plans to expand its capabilities. Future enhancements will involve the integration of additional connectors to align the JSON-LD format with more complex data structures, such as gbXML (Green Building XML), to ensure compatibility with widely used BIM and web data exchange standards. Experiments will be conducted to utilize BTwin's KGs in more robust databases than NetworkX, such as Neo4j or MongoDB, and to incorporate real-time time-series databases. Moreover, special focus will be placed on refining the interfaces to simplify user access to data within the KG, enabling data queries through textual prompts. This feature will be developed utilizing Large LLMs like ChatGPT, which are experiencing rapid growth in the industry. Ultimately, future versions will demonstrate the tool's application in more complex real-world case studies, guiding the presented approach towards a DT perspective.

Abstract

Digitalisation supporting a more sustainable, efficient, and waste-friendly built environment is key. The requirements for this go far beyond the development of digital tools. The ability to collect, track, exchange, and trace data throughout processes is decisive. Digital Building Permit (DBP) and Digital Building Logbook (DBL) share these assumptions. However, a mutual realisation is lacking, and intuitions point to attaining added value. This vision motivates the research. Action research was elected to diagnose and discuss the viability of the vision and the associated challenges. Contributions demonstrate soundness and provide relevant insights into twin paths involving both concepts.

Introduction

Before becoming real and usable, buildings and civil engineering works need to be strategically defined, technically detailed, and constructed. This sequence of events is how, iteratively, construction "ripens and materialises" the idea and the object to be built. The underlying processes involve the production of large amounts of information. Digitalisation defies the transition from paper documentation to digital documents, metadata, and models (International Standards Organization, 2018). However, the EU Industrial strategy for construction (European Commission, 2021b) and the Green Deal requirements (European Commission, 2019) entail improvements at efficiency and sustainability levels, scoping the processes themselves as well as their outcomes (Papadaki *et al.*, 2023). To attain the proposed objectives, data-driven concepts with interfaces steeped by digital sobriety assumptions (Péréa, et al., 2023) must be positioned at the centre of the concerns.

Building permitting constitutes the authority of the local administration based on applying the measures laid down by law, aiming to secure the safety, sustainability, and compliance of buildings with the regulations (Fauth *et al.*, 2024). Digital Building Permitting (DBP) includes using digital data as input and output and digital tools to support or automate checking to tackle current limitations derived from analogue documents and processes (Malsane *et al.*, 2015). Several stakeholders structure building and infrastructure cadastral data for different purposes (Buchholz and Lützkendorf, 2023). Some data derives from national or local regulations and are kept by public authorities or private agents, from promoters to owners and users. Several gaps and inefficiencies are observed due to the wide range of processes and the often practised siloed and analogue approaches (Gómez-Gil, *et al.*, 2022). DBLs aim to collect, store, and link buildings' relevant data, fostering data transparency and increasing data availability on buildings-related properties to a broad range of market players (Dourlens S., et al., 2021). Several studies and projects are being developed to define and structure reference architectures and features to deploy DBPs and DBLs. However, little research exists seeking overlaps, potential relationships, challenges and added value from mutual developments and implementation.

This study builds upon previous research on DBP (such as Noardo *et al.*, 2022) and DBL (such as Mêda *et al.*, 2022) to focus on the abovementioned aspects. Stanford Center for Integrated Facility Engineering (CIFE) horseshoe and Action Research constitute the framework, anchored in a focus group. The focus group gathered experts on DBP and DBL to assess the relationship further and discuss the common elements. The first outcome is the answer to the research question: To what extent should DBP and DBL be considered related concepts? A second outcome involves identifying mutual challenges and processes with outlined associated requirements.

The article is organised as follows: The present Introduction section portrays the topic, the motivations for the work, the scientific approach, and the organisation. Second, the Research Design and Methods are presented, detailing the characteristics of the focus group from which most results stem. Follows the Diagnosis, where a brief overview of DBP and DBL is performed supported by scientific research and grey literature. This part includes a summary of the concerns, setting the bridge to the Action section, where the focus group contents are presented, namely, quantitative results from surveys and qualitative thoughts shared. Then, the Analysis and Discussion section proposes a framework with links, assessing and clustering the practical challenges and requirements of a common approach. Examples of processes and impacts on stakeholders' practices are debated. Finally, the Conclusions present the main remarks, elaborating on limitations and future directions.

Research Design and Methods

This research aims to demonstrate if DBP and DBL are related concepts. As part of the process, commonalities and requirements are evidenced, as well as clustering challenges at the implementation level. Given its potential to structure a transdisciplinary research process, the CIFE

Horseshoe Framework (see Figure 1) was selected as the guiding framework (Kunz and Fischer, 2007).~

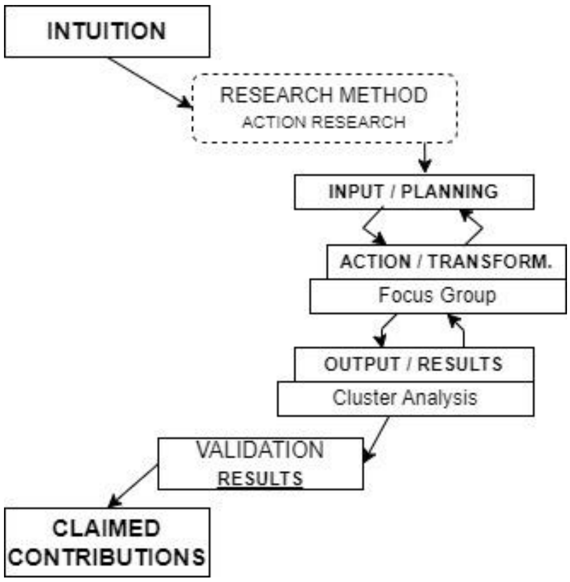

Figure 1: Research design using action research as the main method and The Stanford CIFE Horseshoe framework

The author's intuition establishes that DBP and DBL are related concepts. This relationship, which might seem obvious, does not have expression in the literature, nor is it a consensus among experts and industry stakeholders working on the associated topics and processes. Action research adopting a critical and pragmatic paradigm to investigate the intuition and propose improvements is used (Fellows and Liu, 2022).

The planning stage comprises DBP and DBL diagnosis anchored by relevant scientific and grey literature. The action stage involves a focus group in the form of an online workshop to discuss the alignment of the concepts and collect and explore qualitative and quantitative data on the requirements and challenges. The option for a focus group with selected experts was because it is the most suitable method to encounter the topic as this state. Following (Eeuwijk and Angehrn, 2017), it helps to identify and clarify shared knowledge among groups and communities, which would otherwise be difficult to obtain with a series of individual interviews.

Eighteen professionals were engaged, and the participation criteria were based on the sound knowledge/expertise on at least one of the concepts under discussion. In terms of background, the group had different origins from engineering (22,2%) and architecture (27,7%) practice to academia (27,7%) and geospatial sciences (11,1%). Regarding professional experience, 22,2% work between 15 and 20 years and 77,8% for over 20 years. The structure follows the characteristics addressed by (Jain, 2023), pursuing several iterative steps.

The outputs and research contributions comprise the discussion of all impressions and the analysis of the two surveys (see Figure 2) performed during the workshop. Cluster analysis (Romesburg, 1984) of all elements leads to the primary challenges and requirements and a proposal for a framework linking DBP and DBL.

Diagnosis

Digital Building Permit (DBP)

The process of issuing a permit for a building, independently of the phase, is a crucial milestone for any construction process. Despite being a small part of the mentioned life cycle, all relevant laws and regulations that ensure construction quality, user safety, environmental safety, etc., are enforced (Bloch and Fauth, 2023). The dependency of the legal framework and governmental processes makes the building permit process overly complex, prone to errors, non-transparent, and unpredictably lengthy (Ataide, *et al.*, 2023). Due to these characteristics, building permit issuance can be somewhat different in terms of process, information, and moment(s) during the construction process life cycle, among others. Some researchers have devoted their efforts to the topic of automated code compliance checking, for example (Bloch, *et al.*, 2023; Fischer *et al.*, 2023), which is one of the essential steps within a permit, mainly exploring the potential of using the BIM methodology (Amor and Dimyadi, 2021). Complementary to and following the international push for digitalisation, others have been looking to the building permitting process to identify ways to become more efficient and transparent through the use of digital tools (Bloch and Fauth, 2023; Fauth and Seiß, 2023; Krischmann, *et al.*, 2015).

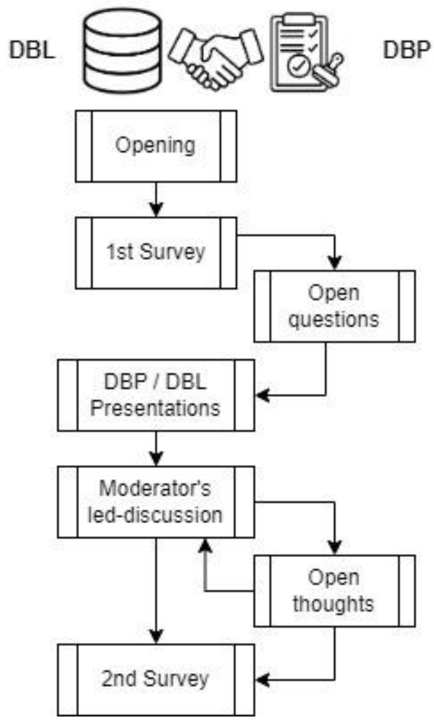

Figure 2: "DBL meets DBP" workshop – action structure

To support a digital transformation in the building permit domain, a basis of knowledge was needed, including not only the technological aspects of supporting industry in the development of the systems infrastructure but also the involved procedures, legislation on different levels and the involvement of various organisations (Fauth *et al.*, 2024). The DBP gained a specific space and attention under the EUnet4DBP initiative (Noardo *et al.*, 2020). Requirements and reviews were developed to clarify, provide awareness, identify common data and processes, and forecast common frameworks for DBPs (Noardo *et al.*, 2022; Fauth *et al.*, 2024).

Presently, there is the notion that DBP can represent a wide variety of building permitting processes running from early design phases to the handover and the commissioning of the building or infrastructure. Notwithstanding, almost all actions are driven by regulatory obligations and led by public authorities or designated bodies, meaning that similarities exist in how the process should run despite the differences in information requirements and compliance checks. The processes tend to be narrow regarding time frame, and DBP efficiency and accomplishment are linked to this objective. Finally, the issuance of a permit relies on information that is collected and structured for this specific purpose. Despite the issuance of the building permit, the storage of the information used for the process and the building permit report itself should be stored and kept during the life cycle of the construction. For example, a building usually changes during its life and most likely needs other building permits. It would be highly beneficial to have the necessary information directly by hand.

Digital Building Logbook (DBL)

An enormous amount of information is generated and used during a construction life cycle (Espinoza-Zambrano, *et al.*, 2023). However, this information is often collected in isolation, meaning that it is searched and managed to serve the purpose of a defined stakeholder in a given temporal moment of that life cycle. Other stakeholders must do the same for their specific objectives, searching for and managing the same or different information. According to (Miller *et al.*, 2014), this way of doing things leads to several gaps. Additionally, the process is highly error-prone and inefficient, diluting most of the benefits of information use. The proposal for the new Energy Performance of Buildings Directive (EPBD) (European Commission, 2021a) calls attention to the importance of effectively collecting and managing this data. The DBL concept was introduced as the common repository for all building relevant data, setting links to relevant existing databases, documentation, records and processes (Dourlens S. *et al.*, 2021).

Several recent studies have contributed to improving and clarifying the understanding regarding the DBL concept (Mêda *et al.*, 2021; Gómez-Gil, Espinosa-Fernández and López-Mesa, 2022; Alonso *et al.*, 2023). Most research works individually focus on specific aspects of the DBL, from the processes level to the data sources and functionalities, digital technologies or event contributions to progress indicators associated with the environment. Despite the wide range of discussed aspects, the DBL is broader and, as a result, also its challenges and added value. This wide range of aspects makes it very difficult for many stakeholders to understand the benefits when they are out of their scope of action or boundaries. Developing a business process modelling notation (BPMN) associated with the DBL life cycle was vital as a kick-off to detail the associated main processes (Mêda *et al.*, 2022). The objective was to set a background that enabled further granularity at process, data, and relationship levels.

The vision of the processes and their evolution throughout the construction process life cycle feeds the intuition of the potential relationships with DBP. Complementary, the outcomes from the most recent study on DBL technical guidelines (Grow, 2023) presented a proposal for DBL components where data from regulatory steps is to be collected and managed.

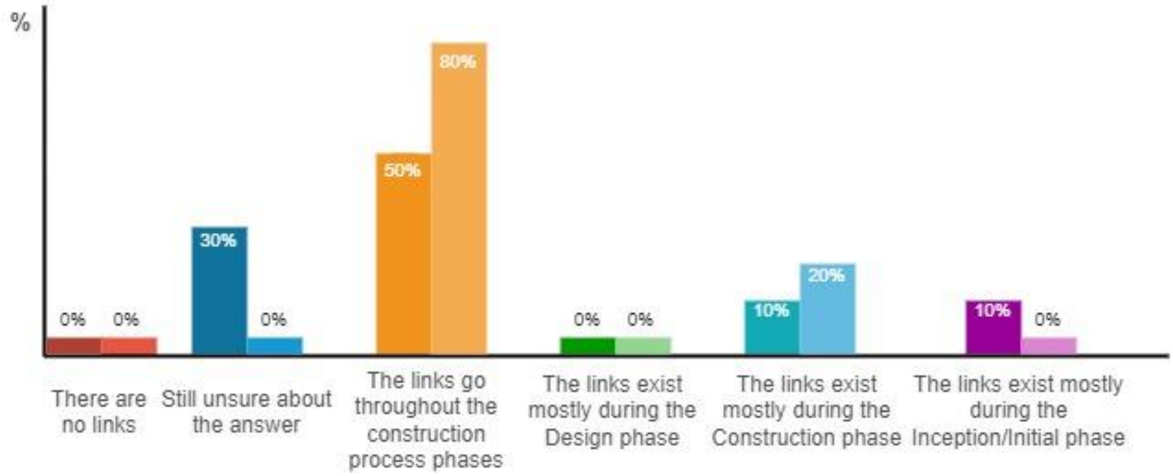

Figure 3: Focus group perception on the existing links between DBP and DBL

Action – Focus Group Workshop

A ninety-minute session was structured to accommodate several activities: two surveys, open questions, presentations, and moderators-led discussions and thoughts on challenges and priorities for future actions, all contributing to the research objectives. The two surveys were placed at the beginning and end of the session to collect quantitative data on the perception of concepts, their relationship, and how the visions evolved (see Figure 2). Figure 3 provides an overview of the respondents' visions and how they shifted during the session regarding the relationships between DBP and DBL. Darker colours (the left ones) represent the results from the first survey, and the lighter ones are the results from the second.

Interestingly, the answers point to evident links between the two concepts despite the fuzziness of the first survey on how they materialise during construction. In the second survey, most identify links throughout the construction process phases. It is one of the aspects worth further discussion.

The presentations mainly used contents already detailed in the diagnosis section. The objective was to harmonise the knowledge level regarding DBP and DBL. Several topics were raised during the discussion. Notwithstanding and for the purpose of the research, it is relevant to stress the shared thoughts associated with "Information Requirements", "Common Processes", and "Stakeholders".

When asked to share thoughts regarding the information requirements of DBP and DBL, many stated that DBP will have most of the requirements defined by regulations. At the same time, DBL seems to be more open regarding requirements. Depending on the evolutions and business models, a more risk-driven approach might be applicable. Given the wide range of situations these concepts can cover, defining a minimum set of information requirements was mentioned as needed, followed by mechanisms to assess the reliability of the information presented. The discussion also approached the existing knowledge and standards developed for Building Information Modelling (BIM). In this respect, it was found relevant to try "not to reinvent the wheel" and, in opposition, make all efforts to use the existing standards related to information requirements as they are or with updates.

A general consensus was observed regarding the existing links with Geographic Information Systems (GIS) when debating the common processes. A large majority of the participants shared that despite the wide range of processes surrounding permits, "DBP itself can be an integrated part of the DBL process". This declaration was a surprising insight, considering the objectives. To conclude, it is worth highlighting that it is assumed that DBP and DBL hold and deal with General Data Protection Regulation (GDPR)-sensitive data. Due to that, both concepts need to consider the processes to ensure GDPR compliance as part of their reference architectures.

To finalise, some thoughts were shared on the stakeholders' engagement: the awareness needs, the training, and the competencies to understand, proficiently apply and operate the technologies and processes surrounding DBP and DBL. Similarly, the previous knowledge and experiences with BIM implementation

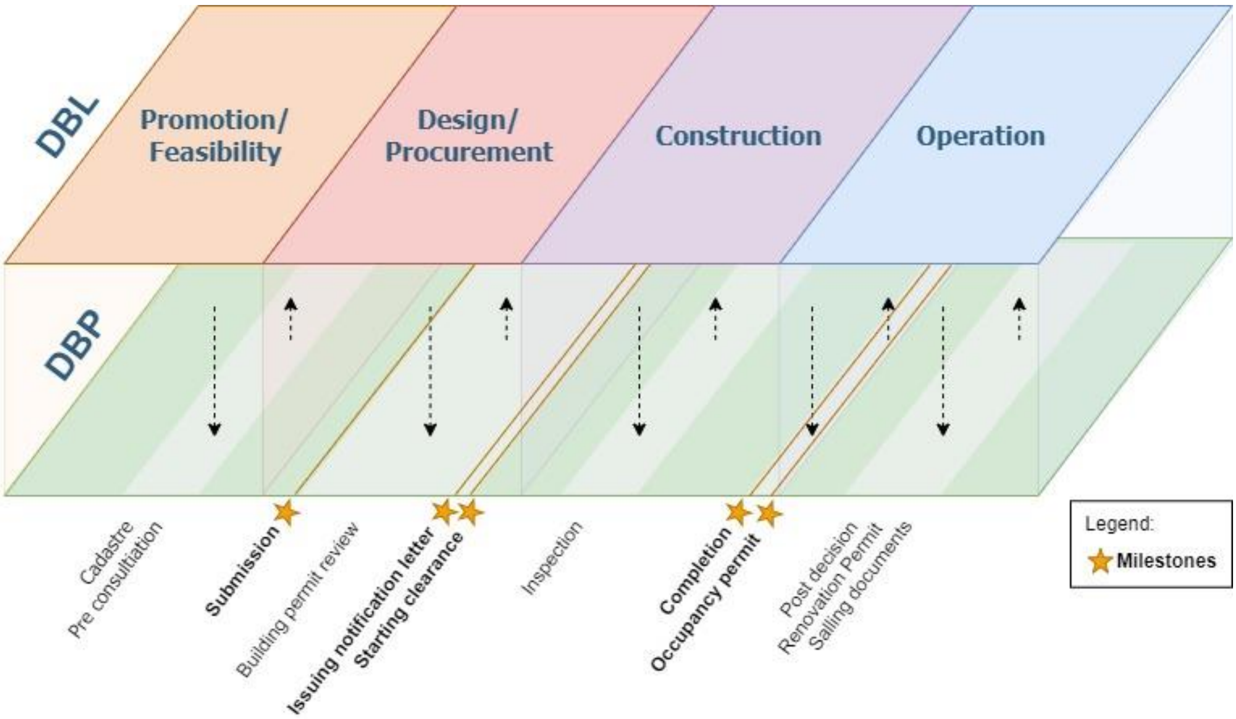

Figure 4: Process-related links between DBP and DBL

were highlighted as relevant to allow shortcuts and anticipate barriers.

Analysis and Discussion

Processes and Phases

It is possible to state that building permit processes are highly country- or even municipality-dependent. Despite this fact, there is the notion that building permitting is associated with verification, meaning that it occurs at a specific moment and often as a milestone belonging to the construction life cycle. In contrast, the processes involving the materialisation of the building logbook are more continuous. Assuming that DBL can work as a Digital Twin enabler, the concept will surpass the construction process life cycle itself, serving the purposes of the construction life cycle. Considering all the visions and statements, it is clear that DBP and DBL are related concepts, and several links throughout the construction life cycle may exist depending on the range of the building permitting processes.

Figure 4 envisages the links between DBP and DBL, using background knowledge from targeted research performed by (Fauth *et al.*, 2023) and (Mêda *et al.*, 2022) and the concerns expressed during the focus group.

Figure 4 presents a high-level framework proposal on how to merge DBL and DBP processes, establishing the data flows between both. Considering previous research, a broad vision of this permit process was considered from the building permit side, where these are required at several moments throughout the life cycle. In this respect, it is worth highlighting the cadastre evaluation and pre-consultations with the authorities to prepare a building application in the early phases and before design. The application adjustments during the review, including compliance checking and authorisation for construction, occupancy permit, and permit prior to a renovation intervention (similar to cadastre pre-consultation when there is a pre-existence and when the permit process starts again).

Looking in detail at one of the possible examples and seeking increased granularity, it is possible to pinpoint a situation during the design phase where the information requirements for the building permit (for example, building permit review performed by the Municipality) will need to be considered for the design development. All elements should be developed or deployed as part of the DBL. Depending on the type of automation, the elements can be sent via DBL or the communication can be enabled with the DBP system, which is managed by the authority. After the analysis, the building permit or the correction notice is sent using the established communication mechanism (as previously and in the opposite direction). The records are kept, and all relevant stakeholders are informed of the results (depending on the individual authorisation). The elements must be centralised or stored in a distributed ledger, depending on the system's architecture.

Requirements and Challenges

As described, the thoughts shared during the focus group were prosperous. They allowed the identification and clustering of common requirements and challenges. Eleven aspects were considered the most relevant to prioritise in terms of what concerns the challenges. Relations to BIM, awareness, training and knowledge, and related services, meaning additional services linked with DBL, and services that must be organised to feed DBP and/or DBL, were identified as the aspects where requirements exist at process, stakeholder and data levels. A second group of challenges was identified, comprising process and stakeholder requirements. These involve governance (existing standards, regulations, use of open standards and BIM, challenges in terms of revising and setting new legal diplomas), the identification and establishment of mechanisms linking existing databases, implementation costs, and all the environment associated with data security and accessibility. One challenge was identified with data and stakeholder requirements related to establishing common terminology for DBP and DBL. Data framework and Information reliability challenges were identified in association with the data level. Finally, the challenge associated with the maintenance of data and curation of the systems throughout the building life cycle was identified as bearing requirements at the process level. Figure 5 overviews the challenges and associated requirements clustered from the focus group inputs.

Conclusions

This research proves that DBP and DBL are related concepts and have several potential interconnections throughout the construction life cycle. Nevertheless, it is paramount to stress that DBP is more time-framed (specific processes). In contrast, DBL is more continuous through the construction life cycle. Combining the findings with previous outcomes, it is worth mentioning that there are no time lags between DBP and DBL as this is deployed together with the idea, and DBP will interact, depending on the range of processes, through the life cycle. This vision is supported by the evidence that the concepts partially share information requirements, relationships with databases, data security and reliability concerns, governance, and curation care (Figure 6).

DBP and DBL can be set as independent systems. However, given the overlaps in their scope and for the sake of digital sobriety, it is relevant to consider a shared landscape for terminology and datasets. This aspect should encompass other systems and concepts. Additionally, it is worth highlighting that the efficiency and complete accomplishment of the objectives of both concepts might be disturbed if there is the need to feed each one manually with data from the other.

From a strategic viewpoint, there can be several benefits from the synergies and proper links and data sharing between DBP and DBL. The implementation challenges will be higher due to the coordination needs from a systems architecture perspective. However, several savings can be achieved in awareness, training, and getting the confidence of stakeholders for use. As discussed, several stakeholders' activities might overlap, meaning adoption can become more straightforward by working correctly with the synergies.

This study's limitations are related to the defined scope and level of granularity. Nevertheless, this was set intentionally to set the background for future and more in-depth research activities. This research focused on specific dimensions, such as processes, data, technologies, solutions, and stakeholders' needs, setting assumptions to work further on the articulation between DBP processes and DBL.

As studies point to the integration between BIM and GIS, DBP and DBL, which are still in their infancy, should benefit from a joint endeavour, contributing to the accomplishment of digital twin transition goals for the built environment and effectively raising most relevant stakeholders into the Construction 4.0 dimension. If building permitting is a critical process in the construction life cycle, using and producing building-related data. Logbooks aim to be golden thread enablers, and complete data traceability implies embedding the digital processes for building permitting as part of the digital logbooks' framework.

LEVERAGING GRAPH BASED SEMANTIC ENRICHMENT FOR ENHANCED AUTOMATED CODE-CHECKING

Tanya Bloch[1], Jiabin Wu[2], Maen Alnuzha[1] and André Borrmann[2]
[1]Technion Israel Institute of Technology, Haifa, Israel
[2]Technical University of Munich, Munich, Germany

Abstract

Despite advances in BIM technology, achieving a comprehensive machine-readable design representation for Automated Code Checking (ACC) remains a challenge. We propose decomposing regulatory checks into sets of semantic enrichment tasks, each tailored with a suitable solution. We demonstrate this approach with a case study on Israeli regulations for security rooms, focusing on two distinct semantic enrichment tasks. We use the Girvan-Newman algorithm to isolate single apartments in a floor plan. A GNN then categorizes security rooms based on the ratio of supporting walls, according to the ranges defined in the regulations. The approach paves the way for a highly automated ACC methodology, with potential implications for diverse regulatory contexts.

Background

The conventional approach to ACC involves two pivotal tasks: the translation of human-written text into machine-readable rules and the establishment of a machine-readable representation of the building design. The ability to translate regulatory documents into hard-coded rule sets is limited due to ambiguous, subjective, or vague regulatory statements, requiring manual interpretation and contextual knowledge (Nawari, 2019; Zhang and El-Gohary, 2017). Despite the prevalence of BIM technology and the adoption of Industry Foundation Classes schema (IFC) as an industry standard, achieving a machine-readable representation of the design that contains all semantic information required for ACC, remains a challenging task that often leads to manual preprocessing of the BIM models.

Moreover, matching regulatory concepts to those represented in the computer-readable design remains highly reliant on human understanding. Recent research proposed implementing ML approaches for ACC, eliminating the need for compiling explicit rule sets (Bloch et al., 2023). However, the efficacy of ML-based code checking is contingent on comprehensive input information. As BIM models often lack the necessary highly rich semantic information, semantic enrichment offers an automated solution for supplementing it.

Complex code clauses typically require querying the topological relationships among building elements, for example, checks of wall continuity across security rooms in Israeli Home Front Command regulations, rules of accessible route and line of visibility in the New Zealand Building Code, checks on support of plaster skins in the International Residential Code, rules related to the travel path and distance in the ADA Standards for Accessible Design and the International Building Code.

Verifying building regulations necessitates a thorough understanding of the complex relationships among various elements throughout the building's structure. Consequently, code checking requires extended data structures or a proof-of-solution describing how the design proves compliance rather than merely fulfilling prescribed criteria. For example, graph processors can be integrated to address implicit spatial properties (Solihin and Eastman, 2015). In this work, we decompose the ACC task into a series of semantic enrichment tasks aiming to automatically supplement needed information for the checking process, focusing on complex requirements that involve relational aspects of the design. We turn to graph-based semantic enrichment techniques to address these specifications, leveraging the inherent relational structure within the design data.

Semantic enrichment

Semantic enrichment of BIM models emerged as a solution for lifting the need for multiple domain-specific Model View Definitions (MVDs) by reasoning over explicitly represented information to derive new facts about the model (Belsky et al., 2016). While some efforts previously focused on querying BIM to extract implicit information stored in models (Borrmann et al., 2006; Mazairac and Beetz, 2013; Wülfing et al., 2014), they often fell short in providing explicit representations of inferred information as part of the building information, limiting downstream applications. The SEEBIM system, proposed by Belsky et al. (2016), leveraged domain expert knowledge, represented as logical statements, to infer new facts and explicitly add them to the model. Wu and Zhang (2019) also implemented a rule-based, iterative method for classifying BIM objects in IFC, leveraging geometric features to identify objects with similar geometric representations. They also recognized that pure geometry, without contextual information is limited in the ability to distinguish between elements with similar geometry. In parallel, semantic enrichment solutions that are based on semantic web technology have been suggested and illustrated as well. In fact, one of the motivations for using the Web ontology, as presented by Pauwels et al. (2017), is utilizing logical inference and proofs, which involves the use of First Order Logic (FOL) to derive new insights from the initial building model. Combining inferred information with the original data represents the core objective of semantic enrichment.

Departing from the FOL methodology, Bloch & Sacks (2018) explored different methods for semantic enrichment. Their work compares a rule-based and a ML-based approach for semantic enrichment by demonstrating both for classifying room types in residential apartments. They found machine learning worked better than rules for this specific task. With the recent developments in the ML domain, and the introduction of Graph Neural Networks (GNNs) (W. L. Hamilton et al., 2017), the applicability and benefit of such models has been demonstrated for the same room type classification problem (Wang et al., 2022). The major benefit of such models is the ability to leverage not only geometric but also contextual information about the building elements. Motivated by limitations in existing BIM software regarding semantic representation and interoperability, the authors proposed leveraging graph-based data structures coupled with enhanced GNN architectures that incorporate both node and edge features. They develop the SAGE-E algorithm and generate the Room Graph dataset containing apartment layouts. Experiments demonstrate the superior performance of SAGE-E over conventional ML methods for room type classification, validating the promise of GNNs for BIM semantic enrichment. This groundbreaking effort establishes a research foundation for applying GNNs to augment BIM semantics. As suggested in Bloch and Sacks (2020), different semantic enrichment tasks can benefit from different approaches to solution. Until now, the more classic graph-based methods remain mostly unexplored in the context of semantic enrichment.

Graph representation of building design information

Building models encapsulate a wealth of architectural and engineering design knowledge, along with specific native design intentions tailored to meet the predefined requirements. In the realm of representing the embedded design properties and the complex topological relationships among building elements, graph structures have emerged as a prevalent tool (Vilgertshofer and Borrmann, 2017).

The adoption of graph-based methodologies facilitates the transformation of building models of structures into networks. These networks comprise nodes and edges, which represent building objects and interrelationships. The graph representation hinges on the specific nature of the building's design structure and the intended application scenarios. Furthermore, the choice of the graph structures depends on the varying objectives of the query. For example, dependency graphs are utilized to predict the clash change components (Hu et al., 2023), and parametric building graphs are employed to match detailing patterns (Abualdenien and Borrmann, 2021).

Method

In this work, we propose a comprehensive, hybrid approach for addressing the challenges of ACC. We demonstrate the approach through a case study, focusing on the effectiveness of graph-based semantic enrichment in addressing the requirements defined by the Israeli Home Front Command regulations for security rooms (Home Front Command, 2010). The experiment described below is structured to fulfill two essential tasks integral to the checking process. The first task is to correctly identify the security rooms in the BIM model. As previous work on the subject demonstrated effective solutions under the assumption that we can isolate individual apartments in the building, we implement community detection to automatically isolate spatial groupings representing individual apartments. The second task addressed in the described experiment is automatically recognizing the ratio of vertical connectivity between the walls of the security rooms. Recognizing the complexity of calculating this ratio, we propose a ML-based classification approach using GNNs. The GNN model was trained to categorize the ratio of vertical continuity into predefined ranges specified by the regulations, streamlining the checking process without the need for precise numeric calculations. The checking process is then complete using a set of logical statements. By implementing diverse computational techniques, we demonstrate an enhanced ACC process with no additional information requirements for the modeler.

Experiment and results

Israeli regulations for security rooms

Security rooms (bomb shelters) are designated spaces within a building specifically designed and constructed to provide protection during emergency situations related to military actions. These spaces are fully constructed from reinforced concrete and equipped with specialized windows and doors that are designed to withstand shrapnel from a blast. As per Israeli Home Front Commands regulations (2010), there are several restrictions for the components of the individual security rooms, such as room dimensions, thickness of slabs and walls, dimensions of openings, etc. However, collections of security rooms are also examined together. The security rooms must be vertically stacked so that the reinforced concrete walls are continuous and reach the foundations. Due to functional design requirements, parking, storage, or other non-protective spaces (security space) often reside above or below the security rooms, where reinforced concrete walls may interfere with the functionality of these spaces. Alterations like wall removals, added openings, or weaker materials in those spaces can disconnect the security room from its base.

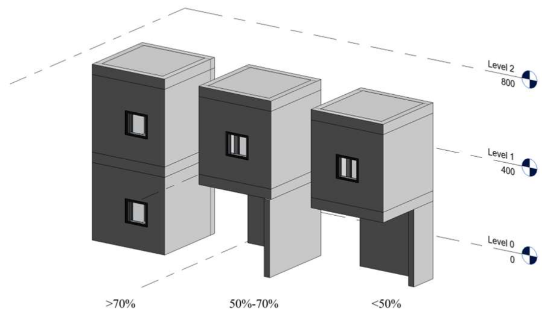

Figure 1: Ratio of vertical continuity of security room walls.

Regulations thus allow for some vertical discontinuity contingent upon certain conditions. One key determinant that dictates additional measures required is the percentage of the security room walls that are continuous and reach the foundation. We will refer to this as the "ratio of vertical continuity."

The regulations delineate three ranges, as illustrated in Figure 1, for the ratio of vertical continuity: spaces with over 70% continuous walls require no further enhancements, effectively extending the requirements for individual security rooms through all associated levels. Spaces with 50-70% vertical continuity and spaces showing less than 50% vertical continuity must incorporate thicker structural walls and slabs and are restricted in the accepted sizes of openings. Note that the ratio of vertical continuity can be calculated per wall individually, thereby dictating additional constraints on the permissible horizontal displacement between walls. And can be calculated for the entire space as the sum of the inner boundaries defined by the walls that compose the space. The ratio of vertical continuity for spaces determines the requirements for the concrete thickness of slabs and walls in the security shaft. The ability to check the compliance of a design to the concrete thickness requirements is the focus of this work. The calculation of the ratio of vertical continuity for walls and spaces involves a large set of guidelines, conditions, and exceptions. The topology of the walls supporting the security rooms, their orientation, sizes of openings and distances between them, and their proximity to existing wall corners, etc., can impact the calculation of the vertical continuity ratio since, under specific conditions, openings must be subtracted from it.

To automate this complex calculation based on BIM data, parametric and relational details of building components that are not explicitly present in the models must be considered. While some of the needed information is intrinsic to individual components, some rely on relationships between model elements, which may be more difficult to retrieve.

In this work, we demonstrate a workflow towards a highly automated compliance checking of these regulations using a case study of a residential building that includes overall five security shafts.

Community detection and room classification

As explained in the previous sections, any kind of ACC routine is contingent upon information requirements that are not always given in the BIM model in their explicit form. Spaces are the most primitive building elements that are crucial for many checks. Given that there are no standards or enforced naming conventions, the room names provided by designers become unreliable, which poses challenges for downstream applications. Given that our goal is to avoid introducing information specifications to the design process, the implementation of semantic enrichment to support ACC emerges as a promising solution. In the context of automated space function classification, it has been demonstrated that semantic enrichment for classifying abstract elements, such as spaces, is better addressed with ML than rules (Bloch and Sacks, 2018). Later, a graph-based approach for room type classification has also been demonstrated using GNNs (Wang et al., 2022). In both cases, however, the basic assumption was that we operate within the boundaries of an apartment, and the question of how we can isolate the apartments without additional information requirements for the designers remained open. We propose an automatic solution by implementing a community detection algorithm.

Community detection algorithms are useful for analyzing complex networks to identify subgroups within them. In the context of buildings, where spatial relationships and connectivity are crucial, algorithms for community detection can help uncover distinct spatial groupings indicative of separate apartments. In this test case, we implement the Girvan-Newman algorithm (Girvan and Newman, 2002) for community detection, which was originally designed for social networks. The principle of this algorithm is isolating communities in a graph by

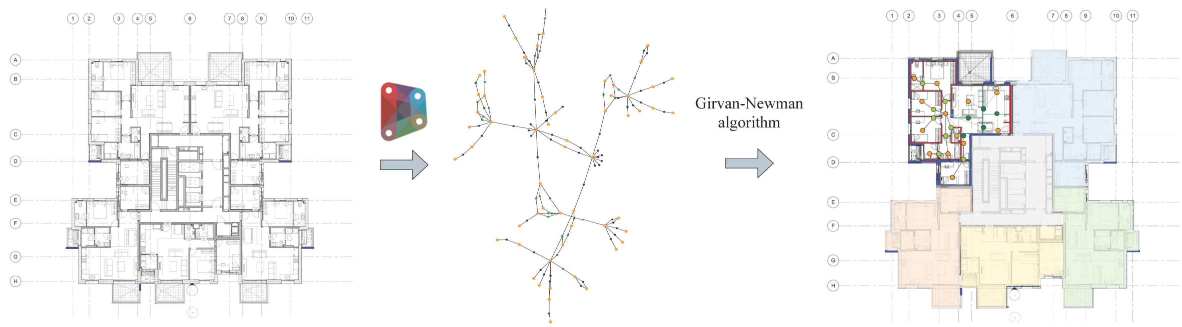

Figure 2: Graph representation of individual floors and community detection for isolating apartments.

iteratively removing edges with high *betweenness centrality,* a measure of how often an edge lies on the shortest path between two nodes. It is important to note that while the Girvan-Newman algorithm is considered relatively slow, it has been determined that it can be effectively used on graphs with less than 1000 edges (Fortunato, 2010). As we are concerned with floorplan layouts that translate into small graphs (in our case, no more than 200 edges), the algorithm provided accurate results within seconds. Other community detection algorithms were not examined.

To implement the suggested technique, we followed the workflow described in Figure 2. Utilizing the API of the BIM authoring tool (Autodesk Revit) and Dynamo (Autodesk, 2022), we collect the building elements that engage in any connection relationship within the spatial layouts, including spaces and doors. Additionally, designers typically use separation lines to divide distinct functional areas within shared spaces. Thus, both the connecting doors, typically situated in boundary walls, and separation lines are recognized as accessible or connecting elements. Furthermore, we perform topological queries on the BIM model to determine the relationships between spaces and accessible elements, forming the undirected edges within the graph structure. For each selected element, the spatial data (floor level) and the associated semantic data (element type) are queried and attached to the related graph node. Within the graph structure representing the whole building model, the elements that belong to each floor are determined by grouping the unconnected subgraphs. As a result, each floor plan of the model is individually processed, leading to the automated generation of accessibility graph structures for our test case.

Once graph extraction was complete, the Girvan-Newman algorithm for community detection was applied on the typical floors, and all individual apartments were correctly identified, after which the previously developed methods for room type classification can be applied. At the end of this stage, we assume all the security rooms in the model are identified and correctly tagged.

Graph Neural Networks for semantic enrichment

Calculating the ratio of vertical connectivity is a complex task. However, the absolute numerical value itself holds minimal significance. What is important is discerning the category of further requirements associated with the ratio—whether it falls within the 70%, 50-70%, or below 50% range. In essence, complex calculation can be avoided by implementing a ML model tailored specifically for this classification task. Given that the calculation heavily relies on the relationships between walls, GNNs emerge as a valuable tool for this classification task. Unlike traditional models, GNNs possess the unique ability to account for and leverage the complex interconnections among building elements.

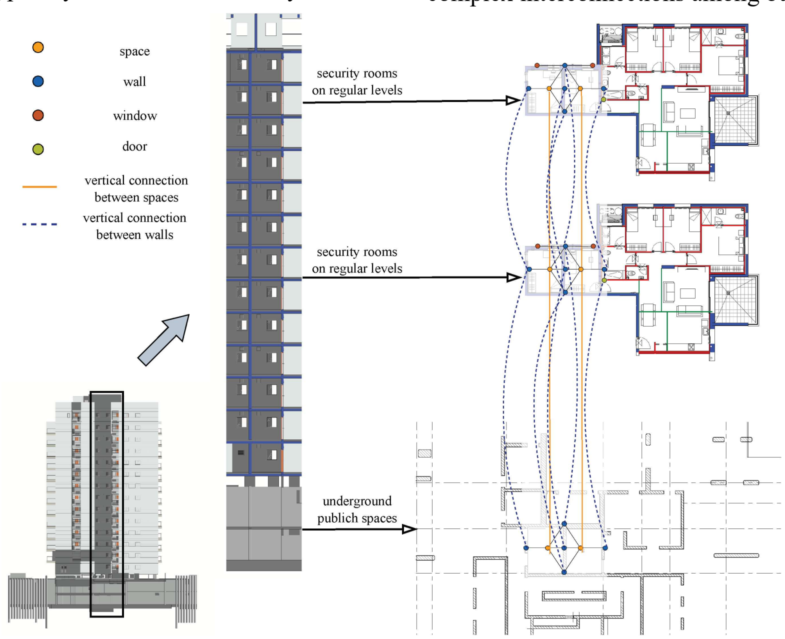

Figure 3: Graph representation of security shafts - extracting the vertical graphs.

To enable the application of GNNs, two steps are implemented. First, we aggregate all security rooms within a single shaft and link them to any continuous walls that support the security rooms. Given the high complexity of the interconnections among security-room-related elements, we interpret the design model to generate a shaft-centered graph structure utilizing the authoring tool's API via Dynamo (Autodesk, 2022). The topological query analyzes all shaft-related building elements across all floors.

By taking the bounding box coordinates of all shafts as horizontal references, we identify all security spaces that align horizontally with the shafts on all floors. We then filter out the irrelevant spaces and perform a bounding box geometric analysis at the space level to calculate the connecting relationships in the vertical direction. To achieve this, we vertically extend the space bounding boxes with a pad dimension threshold, which equals to the identified slab thickness. We also analyze the bounding relationships, including the boundary interactions between spaces and walls and the hosting relationships between walls and openings like windows and doors. This analysis translates the topological relationships of building elements and their hosts into the graph structure. Similarly, we apply the bounding box analysis to the selected walls to provide edge information about whether the structural walls of security rooms are continuously stacked until the foundations are reached. The abovementioned topological queries and geometric calculations are accomplished in an automated manner by taking the shaft-related building elements extracted from the design authoring tool as a basis.

The generated shaft-centered graph structure includes nodes that correspond to the individual components from the building models - walls, spaces, doors, and windows (Figure 3). Each node contained continuous geometric features like minimum and maximum x, y, z coordinates, area, length, height, and width, as well as intrinsic categorical features indicating the specific component type. The graph edges represent connection relationships between components based on the BIM layouts. Within the security shaft, each space is connected to the spaces above and below. Moreover, these spaces link with the associated walls, while the doors and windows are connected to the host wall. The walls of each space are linked with the aligned walls above and below that belong to security rooms on a level above and level below.

and the resulting graph representation was used to train a GNN model for node classification to categorize shaft components by vertical connection length ratio. To train the model, a set of 710 BIM models of shafts representing security rooms and other components that may be found in these shafts were generated and labeled manually using the Revit platform. To introduce realistic design variations into the models, the researchers received guidance from one of Israel's building control companies, in addition to reviewing several building control reports. One example of such a design variation is interconnected security shafts (where two security rooms share a wall) versus shafts comprising individual security rooms. Overall, the data set consists of 51,630 nodes and 78,811 edges, capturing the connections and relationships between the various components in the shafts.

The use of synthetic data comes in response to the great challenge of collecting relevant data, as industry stakeholders are usually reluctant to share BIM models. Hence, we follow the workflow suggested by (Bloch et al., 2023), where fully synthetic data was used for training a GNN model for ACC. It could be shown that the trained model had similar accuracy rates when applied for making predictions for real design.

In this case, the labels correspond to the three distinct classes characterized by the proportions of vertical connection ratios, as defined in the regulations. Namely, 70%, 50-70% range, and less than 50%. As illustrated in Figure 4, there are four types of elements represented as nodes in the graphs: spaces, walls, doors, and openings. Hence, we introduce an additional class that is related to "not applicable" (NA) nodes representing windows and doors.

The graph representations of these models were obtained using an automated workflow based on data extracted from the models to a spreadsheet. Since the synthetic data includes only individual security room shafts, the graph extraction process was different, but the resulting graph representation structure is identical to the structure obtained by the process depicted in Figure 4.

Using the described synthetic data set, a two-layer Graph Attention Network (GAT) model (Veličković et al., 2017) was trained to perform a node classification task. The training set was split into 70% for training, 15% for validation and 15% for testing. The testing phase provided a comprehensive assessment of the model's capabilities, even though the test phase was performed using a portion of the synthetic data set. The testing accuracy achieved 94.58% reflecting the model's proficiency in correctly classifying nodes within the graph. Precision, recall, and F1 score further validate the model's effectiveness, with values exceeding 94%. The described results are the outcome of iteratively evaluating multiple configurations of GNN models (such as GCN (Kipf and Welling, 2016) and SAGE (W. Hamilton et al., 2017)), model architectures and graph structures. Within the variations in graph structure, we evaluated graphs with different building elements to node mappings and with different feature vectors assigned to each node.

Table 1 illustrates the confusion matrix providing the results of predictions vs. actual labels of the test set. It provides insights into the model's classification behavior, with high counts along the diagonal indicating accurate predictions with a notable emphasis on correctly identifying all the 2025 instances in the "not applicable" class (class 4). For class 1 (>70%), the total count of nodes was 3,778, among these 3,650 instances were correctly predicted. However, 62 instances were misclassified as class 2 (50-70%) and additional 66 instances were misclassified as class 3 (<50%).

Table 1 Confusion matrix for synthetic test set

		Actual			
		>70%	**50-70%**	**<50%**	**NA**
Predicted	**>70%**	3650	62	66	0
	50-70%	196	449	19	0
	<50%	74	3	1201	0
	NA	0	0	0	2025

Class 2 (50-70%) showed the lowest accuracy, with 664 instances, out of which 449 instances correctly predicted, but 196 misclassified as class 1, and 19 misclassified as class 3. These misclassifications can be attributed to the imbalanced data set and insufficient number of examples covering these cases. Class 3 (<50%) predictions reached a better classification accuracy in comparison to class 2.

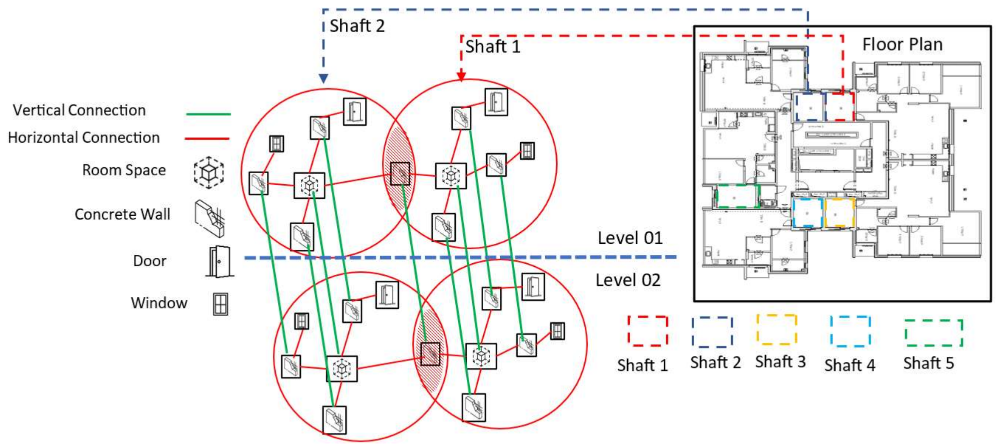

Figure 4: Graph representation of security shafts.

The total count of true class was 1278, out of which 1201 instances were correctly predicted. However, 74 instances were misclassified as Class 1, and an additional three instances were misclassified as Class 2. This also indicates the difficulty in identifying class 2 as it has high similarity to both class 1 and class 3. A better representation of this class can improve the results. In case the model is still not accurate enough in identifying class 2, we might think of a slightly different workflow that relies on distinguishing between the common case (>70% continuity) and the other cases.

After testing the model using a portion of the synthetic data, it was utilized to generate classifications on a real test case model. The real model is a residential building comprising 11 floors. Each floor accommodates five apartments, while the ground and first floors contain extra common and technical service areas. Additionally, the building includes two underground levels dedicated to parking, storage, and technical rooms. Each apartment in the building features a dedicated security room.

Notably, the model has five security shafts, where the first and second shafts are interconnected, as are the third and fourth shafts, via a shared separating wall (see Figure 4). The fifth shaft stands independently. Applying the classifier to the described real case, the model predictions achieved an accuracy of 86.84%. The confusion matrix for predictions is described in Table 2.

Table 2 Confusion matrix for the real case

		Actual			
		>70%	**50-70%**	**<50%**	**NA**
Predicted	**>70%**	208	6	6	0
	50-70%	9	21	9	0
	<50%	23	2	32	0
	NA	0	0	0	102

The complexity of the chosen test case is a result of aiming to maximize the available parking spaces, making the configuration of the walls on the lower levels of the building is not a standard case. While most of the elements follow the preferred guidelines of at least 70% vertical connection ratio, we can see representation of the other cases as well. It's noteworthy that the real-world instances include unique configurations that are not encountered and were not present in the training data.

Results of classification were injected back into the BIM model to be used for further checking requirements for reinforced concrete elements' thickness. Based on the predicted class for the spaces, a set of logical rules was inactivated to check the model for compliance with requirements for reinforced concrete element thickness. The overall checking process thus becomes "hybrid" by relying partially on graph-based and rule-based techniques. The supporting wall ratio for each space determines what requirements are applicable for the walls and slabs in the safety areas. Obviously, a misclassification of the elements by the GNN can lead to incorrect checking results. In this case, 90% of the security rooms in the model (nodes representing spaces) were classified correctly by the GNN model. The overall checking results based on this classification showed that out of a total of 265 walls and slabs checked, only 27 elements were incorrectly identified as "not compliant" while they truly are compliant with the code. Namely, 27 false positive cases. Zero false negative cases were identified. In the context of ACC, this distinction is very important since the non-compliant cases will have to be reevaluated by the designer\checker, but the false negatives may be approved despite not adhering to the code. ML models are not deterministic and may provide unreliable results. This limitation can be mitigated by further development of data sets, refinement of the models, and by constant validation against real cases. Additionally, by incorporating human oversight into the process, a more robust and reliable compliance-checking framework can be established.

Discussion and Conclusions

The extensively researched ACC domain may benefit from a significant shift in the overall approach. Hard-coded rules, being explicitly predefined and manually encoded, are often too restrictive. Furthermore, there is a tendency to confine the entire process to one single method, predominantly relying on rule-based systems. As a result, we miss opportunities for leveraging mutually beneficial methods that may lead to higher levels of automation in the overall process. Such approaches may incorporate learning techniques in addition to the human coded predetermined rules. The flexibility provided by the learning techniques is crucial in the field of ACC, where building regulations can be ambiguous or complex. One of the main limitations of such models is that they are not deterministic therefore, may be unreliable in the process of ACC. However, with large enough data sets and continuous exposure to diverse examples, these models can enhance their performance, making them well-suited for handling tasks from the code compliance checking domain. This work introduces a novel approach for ACC, leveraging semantic enrichment to enhance the level of automation that can be achieved. The approach is based on the capacity to decompose regulatory clauses into distinct semantic enrichment tasks, each addressed by a suitable solution. We demonstrate this approach with a test case, addressing specific requirements of Israeli regulations for security rooms. As described in this paper, most of the methods implemented in this case are based on graph theory, including community detection algorithms, and Graph Neural Networks. The introduced workflow is highly automated, with very little information requirements for the designers, showcasing the ability to reach a higher level of automation in the process by implementing diverse methods for every code clause. Although the training process includes manual work, it is not part of the checking as the model can be pretrained. The checking process itself relies on minimal data requirements and minimal manual BIM preprocessing, mainly making sure that the spaces have been created and that the security rooms are properly tagged.

Limitation

Several limitations are acknowledged in this study. Firstly, the transformation of the accessibility and connectivity relationships into graphs requires a well-defined BIM model, where space elements are comprehensively placed and correctly separated in the building layouts. While we aim not to add information requirements or specifications, good quality modeling practice is expected. The utilized building graphs, which are only parts of the various graph structures, are selected according to the topological features of the envisaged regulatory requirement. Thus, the applicability of the proposed graph-based enrichment for code checking on other regulations is to be justified.

Second, while we demonstrate the potential of GNNs for ACC, we acknowledge the limitation of the developed classifier, which is tailored to the context of the Israeli regulations for security rooms. Implementing a similar technique for different regulations would necessitate the collection or creation of new, context-specific synthetic datasets for training the models. Furthermore, the automated routines for data extraction must be modified to generate graphs with needed structures. Another limitation of using a synthetic data set for training is that real-world data may follow assumptions that are not well represented in the synthetic set. While we tried to limit this problem by working under the guidance of a building control company, our access to the design documents was limited. This underscores the importance of future efforts to address the scalability of the approach to accommodate a broader spectrum of regulations, including generating graph datasets tailored to support various requirements. The demonstrated promising model performance across various evaluation metrics is encouraging to continue developing this research direction.

Contribution

This work contributes to the ACC domain, addressing several existing challenges and paving the way for a more automated and adaptable approach to code compliance checking. The proposed approach for code checking, which leverages graph representation, introduces a novel way of thinking about ACC processes, where we do not have to be confined solely to rules. This approach facilitates a more comprehensive investigation of design knowledge. It has the capacity to elucidate not only the instances of non-compliance but also to subsequently link other elements that may be interconnected with these issues. Such enriched results empower designers with detailed insights, enabling more effective resolution strategies (Wu et al., 2023). This approach lays the groundwork for the advanced automated design adaptation method known as "Design Healing." By providing a more nuanced understanding of the design and its compliance with building codes, designers can leverage this foundational data to make informed adjustments, enhancing the overall efficacy and compliance of the building model.

This work lays the groundwork for future research on automated code checking, encouraging the exploration of hybrid models that harness the strengths of diverse computational techniques for enhanced regulatory compliance. The proposed workflow is fully automated, with minimal information requirements to be supplemented by users. The success of the approach underscores the potential of semantic enrichment to enhance the level of automation achieved in ACC.

Abstract

One of the main challenges in building management is dealing with the large amount of unstructured data produced throughout the asset's life cycle. At handover, Building Information Models often provide low-quality, incomplete data, necessitating extensive manual rework to elicit information from many sources. To minimize this manual rework, this study proposes an automated *Information Extraction* (IE) procedure, applied to the design and construction documents to extract information, enrich a model (COBie format), and maximize the transfer of structured data to the client. The proposed approach is based on *Natural Language Processing (NLP)* and adopts *Transformer-based Named Entity Recognition* (NER) and *Relation Extraction* (RE) methods for IE. It was evaluated and achieved good performance, with average F1 scores of 0.73 for NER and 0.91 for RE, representing a step toward a reliable tool for an enhanced data handover process.

Introduction

During the design and construction phase, a significant number of text documents are produced, not only by the design team but also by the contractor, suppliers, client, and consultants. Design documents and specifications are followed by building performance reports (structural safety, energy, acoustics...), contractor's method statements, risk assessments, health, safety, and maintenance plans, inspection and commissioning reports, product sheets and declarations, etc. However, all these documents contain poorly accessible, unstructured information that can only be retrieved through manual searches (Marzouk and Enaba, 2019).

Building Information Modelling (BIM) has emerged as the leading digital solution in the Architecture, Engineering, and Construction (AEC) industry to support the design, construction, and subsequent management phases, as facility managers can use the same physical and functional information defined in the early phases to plan and manage maintenance operations. However, the actual situation is not ideal. On the one hand, digital models are often unable to easily incorporate all the data produced (also because of the low digital readiness of stakeholders and their models). On the other hand, the information created is often incomplete, inaccurate, inconsistent, complex, large, and poorly standardized. As a result, BIM, as an enabler for providing reliable information for building management, faces numerous challenges (Tsay *et al.*, 2022; Ullah *et al.*, 2019).

In response to these issues, US agencies, with the help of the National Institute of Building Sciences, have developed a standard digital data schema known as Construction Operations Building Information Exchange (COBie) to streamline access and manipulation of BIM data. A COBie file can be exported as an Excel spreadsheet or IFC STEP file from any BIM model. However, a COBie file reflects the quality of the BIM model from which it was generated. In addition, some of the information in the BIM model dataset is not exported in the COBie file (Kumar and Teo, 2020), increasing the manual effort required to have complete information to support the management of maintenance and operations planning.

Recognizing these challenges, this study uses NLP to enhance the handover process, as shown in Figure 1, by developing a methodology in three steps: data preparation (1), information extraction (2), and integration into COBie (3).

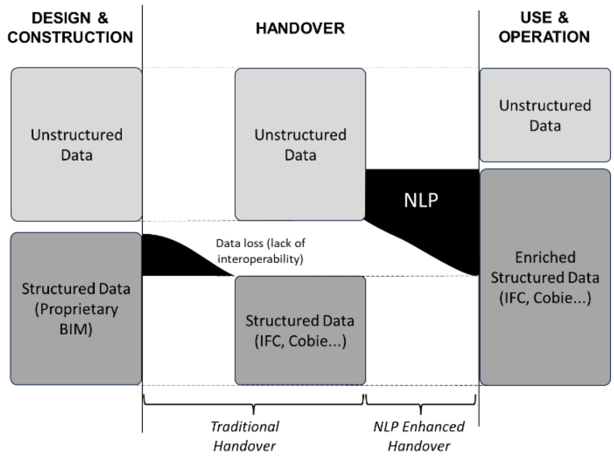

Figure 1: Handover problem statement and proposed solution

This paper is organized as follows: an introductory *State of the Art*, a *Methodology* section detailing the proposed approach, a third section for *Experiments*, and, eventually, a *Conclusion* and *References* section.

State of the Art

NLP and Data Management in the AEC Industry

NLP joins linguistics with computer science, empowering our lives with tools and techniques to perform machine reading, comprehending, and analyzing human-written documents (Salama and El-Gohary, 2013). As a result of these capabilities, NLP has been widely applied in a highly documented sector as the AEC industry (Marzouk and Enaba, 2019) to improve the management of many processes such as safety (Zhang *et al.*, 2019), risk assessment (Zou *et al.*, 2017), quality control (Jeon *et al.*, 2021), document management (Qady and Kandil, 2014), and code compliance checking (Zhang and El-Gohary, 2013; Zhang and El-Gohary, 2015).

The cornerstone of improving construction management is built on the efficiency and effectiveness of data management through transforming unstructured texts into structured information, enabling organizing and analyzing information, and identifying patterns supporting the enhancement of planning and decision-making. This transformation from unstructured data into structured information, as shown in Figure 2, is executed through a suite of NLP tools, such as tokenization, part-of-speech (POS) tagging, phrase structure analysis (PSG), stemming and integrating with machine learning (ML) and deep learning (DL) techniques to perform advanced tasks such as Text Classification (TC), Document Clustering (DC), Information Extraction (IE), and Information Retrieval (IR) to support data management.

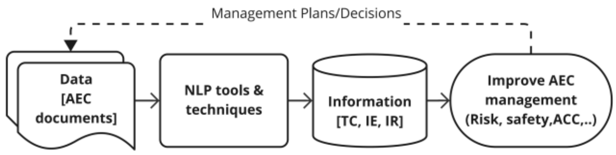

Figure 2: Methodology of NLP application in the AEC industry

Information Extraction (IE)

IE is a process that aims to automatically extract specific information from unstructured data and represent such information in a structured format (Salama and El-Gohary, 2013). IE includes sub-tasks such as *Named Entity Recognition* (NER), which recognizes and classifies entities into predefined categories, and *Relation Extraction* (RE), which extracts the semantic relations between these entities (Zhang and El-Gohary, 2013). IE methods include rule-based, machine learning (ML)-based, and deep learning (DL)-based approaches.

In rule-based approaches, the target information is extracted based on pattern-matching rules coded by experts. These rules utilize NLP tools such as POS and PSG for sentence analysis, term matching, and semantic analysis (Zhang and El-Gohary, 2015). For example, (Zhang and El-Gohary, 2013) proposed a semantic and rule-based approach to extract information from building codes to support compliance checking. Also, (Li *et al.*, 2016) developed a rule-based approach to extract spatial rules and check compliance of utility spatial specifications with requirements. (Liu and El-Gohary, 2021) proposed a dependency parsing model to extract dependency relations between the semantic information elements from bridge inspection reports and represent them in semantic information sets. Although rule-based approaches have low scalability and flexibility and require manual efforts for pattern formalization, they have high accuracy.

In ML-based approaches, models rely on learning from data (Russell and Norvig). For example, (Zhang and El-Gohary, 2016) developed an approach to classify relations between BIM and regulations concepts using ML classifiers (SMV, NB, DT, K-NN). ML-based approaches are more flexible for modifications, less costly, and require fewer manual efforts than rules-based approaches. However, manual work is still necessary for preprocessing and preparing datasets for training and testing.

DL-based models comprise multiple neural network layers from various algorithms, allowing them to deeply understand and represent complex and unstructured data for NLP tasks (Lecun *et al.*, 2015). Recently, sequence-to-sequence models such as Recurrent Neural Networks (RNNs), LSTM and RGU, along with Convolutional Neural Networks (CNNs), have been used extensively for IE. For example, (Zhong *et al.*, 2020) proposed an approach to support quality management checking using a Bi-LSTM-CRF-based NER model to identify and label entities in the clauses and an LSTM-MLP-based RE model to classify relations between entities into five predefined groups. (Zhang and El-Gohary, 2022) used a Bi-LSTM-MLP-based RE model to extract the semantic relations of building code sentences. (Wang and El-Gohary, 2023) proposed a CNN and RNN-based method to extract relations between entities that describe fall protection requirements from safety regulations and represent entities with their relations in query graphs.

Most recently, transformer-based models have gradually become a trend, utilizing multi-headed self-attention mechanisms to deeply understand text context and representation (Vaswani *et al.,* 2017) and enabling the development of pre-trained models (e.g., BERT) (Devlin *et al.*, 2018). For example, (Zhang and El-Gohary, 2023) used a BERT–based model to determine the semantic relation probability between regulatory and IFC concepts. DL-based approaches are more effective in handling various data types that exhibit high levels of complexity, achieving a high semantic analysis and word representation.

Data Handover for Building Management

There is a paramount interest in using project data for the life cycle with the evolution of Building Information Modelling, which promotes the incremental collection of data (Lindkvist and Whyte, 2013). Nevertheless, limited studies have focused on effective and automated building information sharing during the commissioning and close-out stage for efficient building handover, operations, and maintenance through its life cycle (Singh and Anumba, 2023). As a result of this lack of research in the field, the automated digital practices to perform the commissioning and handover process are still largely unknown.

Many studies (Cavka *et al.*, 2017; Tan *et al.*, 2018) collectively underscore the importance of knowledge trans-

fer, information flow, and the use of technology in enhancing information management during handover for better asset and facility management. COBie, a specification for the Construction Operations Building Information Exchange, aims to streamline data handover from design and construction to facility management (Schwabe *et al.*, 2018). It is a Model View Definition (MVD) of the Industry Foundation Classes (IFC) as defined in ISO (ISO 16739-1:2018) and was first introduced by the US Army Corps of Engineers to enable organizations to electronically capture and record important project data at the point of origin. Because the fundamental purpose of COBie is to efficiently obtain information (relevant to facility management) generated in the design and construction phases, an Excel-based spreadsheet that anyone can easily access and handle is often used (Shin *et al.*, 2022). A COBie datasheet consists of 20 workbooks in which data about the facility is stored systematically. The columns and their location in the workbooks are fixed, and changing the location of columns is restricted. Different colors are used to define data inside workbooks (Kumar and Teo, 2020). Although COBie has been widely used (Maltese *et al.*, 2017)(Kumar and Teo, 2020) (Asare *et al.*, 2023) in practice, creating COBie deliverables can be problematic due to misunderstandings among end users and insufficient software implementation. This can ultimately lower acceptance among practitioners.
COBie data capturing and compiling is a complex process; after each project phase ends, a COBie sheet deliverable is required, which needs to be verified with the project stage requirements known as COBie "data drops" (Love *et al.*, 2014). A typical data drop process requires, among other activities, extracting IFC models from native BIM models from different disciplines, merging and verifying for consistency, updating missing information through documents, and verifying that the dependency and links are maintained. This implies that data needs to be entered manually inside the COBie datasheet. The transfer of information from as-built documents is one of the biggest problems, as much of the information is not transferred in COBie format or is transferred with errors. Natural Language Processing (NLP) tools can improve the information management process by increasing the amount of structured data transferred to the client via COBie.

Methodology

In this section, we outline the proposed data enrichment methodology, which comprises three steps, as depicted in Figure 3: data preparation, information extraction, and integration into COBie. Recently, NLP has offered many DL-based tools to automate text analysis and process large batches of documents, so the proposed methodology exploits NLP techniques for language analysis to automate IE and integration.

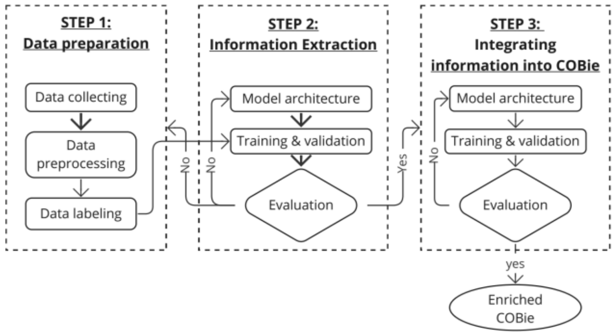

Figure 3: Methodology framework

Step 1: Data Preparation

Given the use of deep learning, a data-driven technique, ground truth data is required to train and evaluate the proposed models. This step, which includes data collection, preprocessing, and labeling, is crucial for the model's development.
For data collection, a corpus of unstructured documents for design and construction was collected from case studies provided by one of Italy's largest engineering companies in Milan and converted into plain text format for easier processing.

Table 1: Categories of the Information Entities

Entity Category	Definition
Object ID	Identify the ID code of an entity "Wall 01"
Object	Identify an entity "internal wall"
Description	Clarify a description for an entity, action, attribute
Section	Identify the geographical location of an object "north-facing windows"
Action	Identify an activity for an object "demolishing", "building", "painting"
Attribute	Identify a character that distinguishes an object's "thickness," "airtightness," and "or strength."
Value	Identify value "15", a class "U", or category "GBK(A)" for an attribute.
Unit	Identify a unit measure for attribute value "cm", or "REI" for fire resistance.
Constraint	Identify a specific condition for an attribute or value or action "equal to", "in a range", "partially, completely, "fully".
Reference	Identify a regulation, standard, or code explaining how the attribute must be evaluated or measured and the object or action must be realized.

After collecting the raw documents, data preprocessing was conducted to remove non-textual parts like figures, headers, and footers, and sentence segmentation was applied to isolate the individual sentences. Labeling involves annotating a specific word or more with the corresponding label or the relation between two entities. This process begins with defining labels for the target information entities and relation types the proposed models intend to recognize and extract. In this research, the defined categories for the information entities and their relation types are presented in Tables 1 and 2 and illustrated in Figure 4.

Table 2: Relation types between entities

Relation Type	Definition
Identifies	Links the unique identifier code (*Object ID)* to the corresponding *Object*
PartOf	Links an *Object* to another *Object*, establishing a parent-child relationship and the hierarchical structure
DescribedBy	Links an *Object* or *Action* to a *Description* that provides more details
LocatedIn	Links an *Object* to a specific geographical location (*Section*) in a building
RequireAction	Links an *Object* to an *Action* that specifics the activities or tasks to be realized
HasAttribute	Links an *Object* to an *Attribute* that specifies its characteristics
HasValue	Links an *Attribute* with a specific *Value* for its characteristics
MeasuredIn	Links a *Value* to a *Unit*, specifying the unit of measurement for the value
HasConstraint	Links an *Action* or *Value* to a *Constraint*, specifying the conditions for this value or action.
Referenced	Links either an *Object*, *Action*, or *Value* to a *Reference* establish the connection between a regulation, standard, or code and its application to an object, action, or value.

An open-source data labeling platform, "Label Studio" was used to facilitate manual labeling, applying two distinct notations. For the NER task, the Beginning-Inside-Outside (BIO) labeling schema was used, where each word in a sentence was labeled manually to indicate whether it was the beginning or inside of a specific entity or not a part of any entity (outside). In the RE task, a single relation type was assigned between each input pair of entities using the tagging schema of the SemEval 2010-Task 8 datasets to mark the entity's positions with <e1> and </e2> XML-like tags, as shown in Figure 6.b.

Step 2: Information Extraction (IE)

In this study, we introduce a modular IE pipeline comprising two respective tasks: 1) *Named Entity Recognition* (NER) to process a plain text document or a specific segment and extract all entities that exist in the text according to Table 1; and 2) *Relation Extraction* (RE) to extract and classify the relation between each pair of entities following Table 2. By iteratively applying these two steps across the entire document corpus, we methodically construct a comprehensive and structured knowledge base that encapsulates atomic entities and delineates their interrelations, as shown in Figure 5. This step consists of three sub-steps: model development, training, and evaluation, as discussed below.

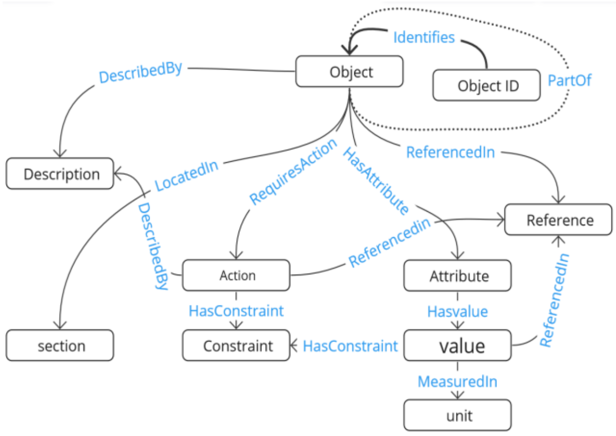

Figure 4: Entity categories and Relation types

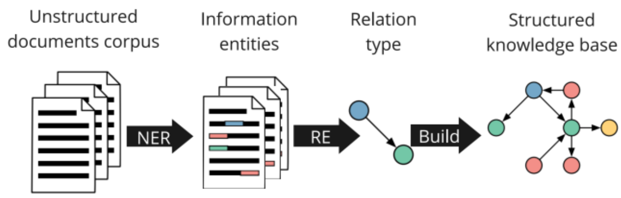

Figure 5: Information Extraction (IE) pipeline

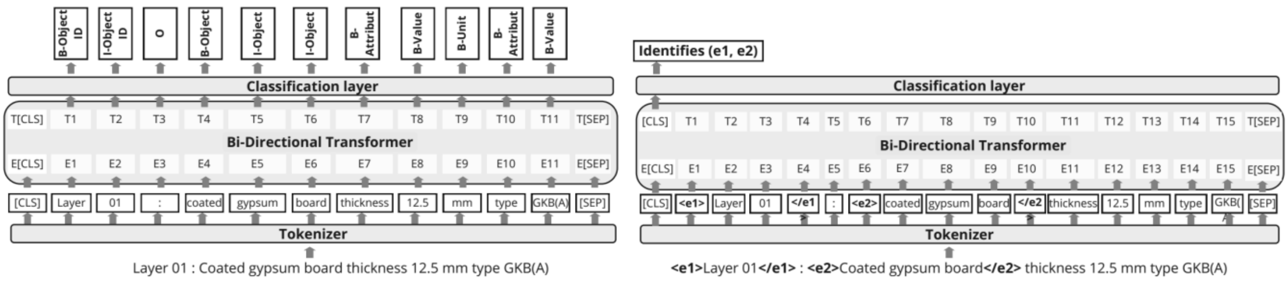
Model development

Following current state-of-the-art NLP applications built using a transformer neural network, pre-trained language models were selected as the base for the NER and RE tasks composing the pipeline. As a classification task, a bi-encoder architecture is more suitable where the model architecture consists of an input, encoding, and output layer, as shown in Figure 6 and described below:
Input (embedding) Layer: converts each word in the input text to a vector representation by tokenizing sentences, padding, converting tokens to IDs, adding an attention mask and two special tokens [CLS] and [SEP] to determine the starting and ending of each sentence.
Encoding Layer: feeds the embedding vectors of tokens from the input layer into transformer encoder blocks passing with the multi-head attention followed by the feed-forward network, with add & normalize layers, and the output of each block is passed to the next one as input. As a result, the final output from the last block represents a highly contextual embedding vector (hidden state), considering both the left and right contexts, semantics, and synthetic relationships.
Output (classification) layer: takes the final hidden states from the last layer as input, applying a SoftMax function to calculate probabilities.
In the NER task, as depicted in Figure 6. a, given a piece of text passing through the input and encoding layers, the

language model computes a probability distribution over the class labels for each input token and selects the most probable class label associated with each token. The class label indicates whether the token corresponds to the beginning, inside, or outside of a specific entity. Once a text is tagged, named entities are extracted, searching for the beginning of each entity and taking that first token with all the inside tokens associated with that same entity.

In the RE task, as illustrated in Figure 6. b, the input piece of text has four additional tokens to mark the beginning and end of the first and second entities; passing through the input and encoding layers, the language model computes a probability distribution over the class labels and selects the most probable class label associated with the input text to tag the relation type between the two marked entities.



a. Transformer-based NER model

b. Transformer-based RE model

Figure 6: Architecture of the language model for the NER and RE tasks

Model training

As pre-trained language models on a large general domain corpus, there is a need to fine-tune these models for specific downstream tasks (i.e., NER and RE). The objective is to minimize the negative log-likelihood of the target class(es) associated with the input text. Cross-entropy, serving as a cost function, calculates the discrepancy between the actual and predicted labels/relations, assessed after the model's forward pass; during the backpropagation, the optimizer updates the model weights based on the gradient of the loss and learning rate scheduler.

Evaluation

In the realm of IE, there are three common metrics for performance evaluation: Precision (P), Recall (R), and F1-score (Zhai and Massung, 2016), as delineated in Equations 1 to 3, with their values ranging from 0 to 1, where 0 is the worst score, and 1 is the best. For instance, R = 1 signifies that the model correctly identified all actual positives, P = 1 indicates that all positive predictions were correct, and F1 = 1 indicates a perfect harmonic balance between R and P.

$$Recall\ (R)\ = \frac{TP}{TP+FN} \quad (1)$$

$$Precision\ (P)\ = \frac{TP}{TP+FP} \quad (2)$$

$$F1 = 2\ x\ \frac{P\ x\ R}{P+R} \quad (3)$$

Step 3: Information integration into COBie

In this step, we merge the extracted information with the COBie format, where the relations, as depicted in Table 2 , establish interactive connections and contextual associations between the entities, creating a semantic-structured knowledge base to support the integration process. To achieve this, two models will be developed: 1) a Transformer-based model to classify the extracted entities from Step 2 into COBie sheets, 2) a Rule-based model to match the entities with COBie sheets, and embed information into COBie data fields. Further details and experiments on this step will be pursued in future research directions.

An example to illustrate the application of the proposed methodology to enrich the COBie schema is shown in Figure 7.

Experiments

In this section, we describe the implementation of the IE pipeline, training settings, and evaluation results.

Data preparation

Wall specification documents from the collected corpus were used as a case study to prepare the dataset to train and test the models. These documents include detailed information regarding wall layers, materials, characteristics, and state-of-the-art construction procedures. Following the procedure outlined in Step 1, a dataset was developed encompassing approximately 2400 entities and 1000 relations representing all entity categories and relation types in Figure 4.

Implementation

The proposed IE pipeline was implemented using two prominent bidirectional language models, BERT (Devlin *et al.*, 2018) and RoBERTa (Conneau *et al.*, 2019), from the Transformers library in the Hugging Face model hub. Table 3 Provides the considered models' variants and reference names; some were pre-trained on multiple languages, while others were pre-trained on Italian. The implementation was conducted using PyTorch, built with Python 3, and executed on a T4 GPU provided by Google Colaboratory.

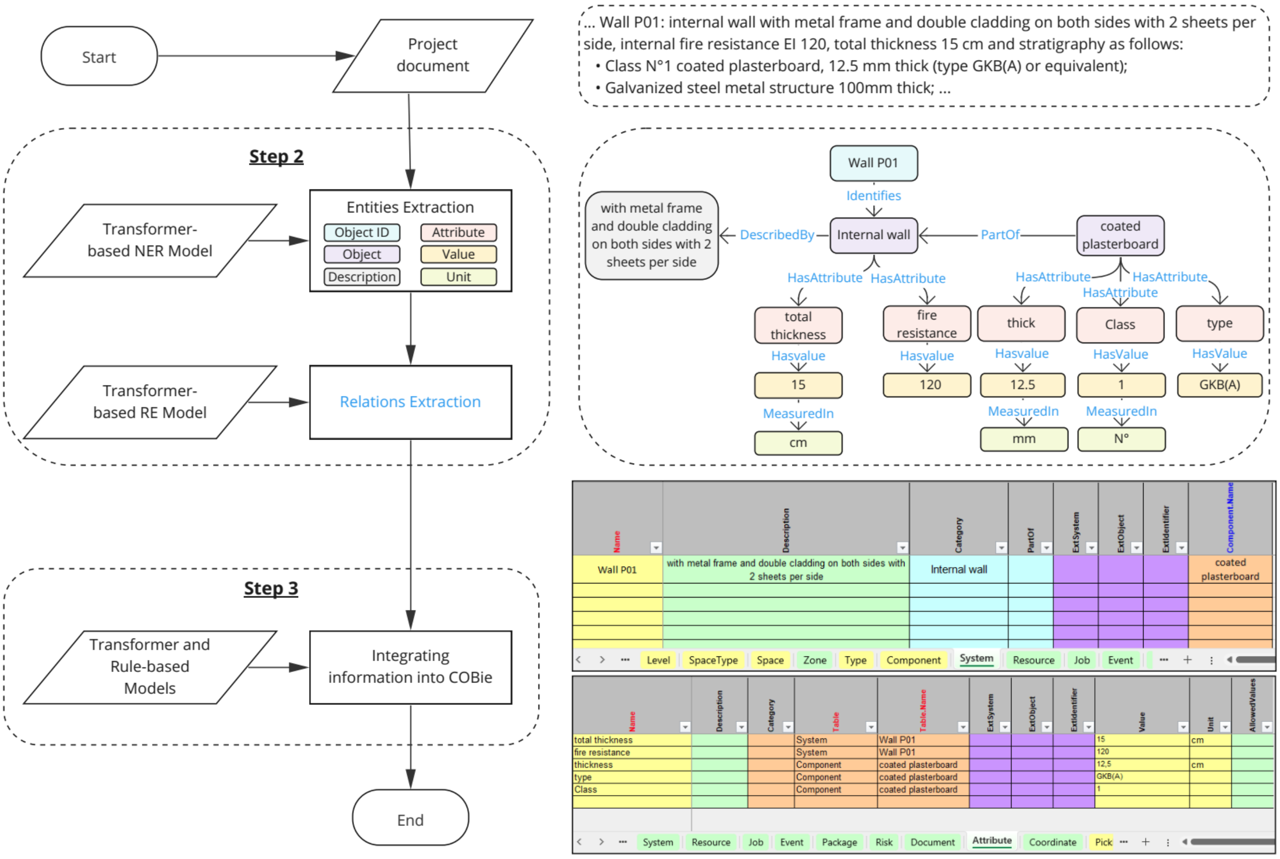


Figure 7: Enriche COBie schema using the proposed methodology

Table 3: Variants of BERT and RoBERTa models for the NER and RE tasks

Reference Name	No. of Layers	Parameters
Multilingual Bert (Cased - Uncased)	12 layers	110M
XLM-Roberta Large	24 layers	550M
Italian ALBERTO (Uncased) (Polignano *et al.*, 2019)	12 layers	110M
dbmdz-Italian Bert -XXL (Cased - Uncased)	12 layers	110M

Training

The language models were fine-tuned using the labeled dataset, which was split into training, validation, and testing sets with 80%,10%, and 10%, respectively, for the NER task and 64%, 12%, and 24%, respectively for the RE task. The configuration and hyperparameters stayed the same for the models, as provided in Table 4.

Evaluation and results

The evaluation was conducted using the testing dataset alongside selected transformer-based models. Table 5 Provides the results of the experiments where the "*xlm-roberta-large*" model emerges as the most effective in the IE pipeline, achieving the highest precision, recall, and F1 scores for both tasks. It achieved F1 scores of 0.73 for NER and 0.91 for RE, respectively, outperforming other models with an average increase of 8.8% for NER and 5.2% for RE tasks.

Table 4: Values of the hyperparameters of the language models

Hyperparameter	Value
Maximum length	128
Batch size of data loader	32
Adam learning rate	1e-5
Dropout Rate	0.1
Early stopping condition	5 epochs

Regarding the results of the RoBERTa model, the model indicated a good capability in identifying entities "Object", "Value", "Attribute", and "Unit", achieving relatively high F1-scores ranging from 0.75 to 0.90; conversely, it encountered challenges in recognizing entities "Description", "Action", and "Constraint" as reflected by lower F1-scores from 0.33 to 0.62. For the RE task, the model demonstrated a robust performance across various relation types achieving high F1-scores ranging from 0.88

to 0.97 for relations "HasValue","DescribedBy","HasAttribute","Partof","ReferencedIn", and "MeasuredIn" and moderate F1- scores from 0.67 to 0.78 for "LocatedIn", "RequiresAction", and "ConstrainedBy" ones. The limitations in the model's performance in identifying and recognizing these entities or relation types can be attributed to restricting their examples in the training dataset. Consequently, the model encountered interpretation complexities when distinguishing within the text. These results are satisfactory given the current volume of the dataset and underscore the potential for enhancing the performance once more data becomes available.

Table 5: Results of the proposed IE pipeline (NER and RE tasks) with the language models

Model	NER			RE		
	P	R	F1	P	R	F1
Bert-base-multilingual-cased	0.63	0.69	0.64	0.89	0.89	0.89
Bert-base-multilingual uncased	0.64	0.64	0.62	0.83	0.84	0.83
xlm-roberta-large	**0.74**	**0.74**	**0.73**	**0.91**	**0.91**	**0.91**
Bert_uncased_ italian_alb3rt0	0.69	0.68	0.67	0.86	0.86	0.86
dbmdz/bert-base-italian-xxl-cased	0.64	0.68	0.63	0.87	0.86	0.86
dbmdz/bert-base-italian-xxl-uncased	0.67	0.69	0.65	0.85	0.86	0.85

Conclusion

This study contributes to building management by enhancing information management during the handover process, enabling effective planning and management of maintenance operations. It proposed a methodology aiming to provide an enriched data schema (COBie) that integrates information from both the design and construction phases with less manual effort and time consumption, overcoming some of the prevalent challenges, such as data interoperability issues and the high level of documentation in the construction sector. The methodology comprised three main steps: data preparation, information extraction (IE), and integration into the COBie format. Entity categories and relation types were identified to prepare the labeled data, and two transformer-based models, BERT and RoBERTa, with their variants, were utilized to implement the proposed IE pipeline, automating *Named Entity Recognition* (NER) and *Relation Extraction* (RE) tasks. The proposed IE pipeline was tested using wall specification documents as a case study, and the "*xlm-roberta-large*" language model delivered the highest performance on both tasks, achieving an average F1-score of 0.74 in the NER task and 0.91 in the RE. These scores can be considered good results given the current data volume.

Future research directions include: 1) Implementing Step 3 to integrate the extracted entities and their relations into the COBie format; 2) Expanding the labeled dataset by considering a broader range of design and construction documents to improve the models' performance, scalability, and robustness; 3) Large Language Models (LLMs) will be used for the NER and RE tasks, and evaluated for their effectiveness in the given context, and 4) Performing a comparison to a COBie data extraction tool.

CONNECTING OBJECT DATA IN NATURAL STONE RENOVATION PROJECTS

Alex Donkers[1], Marijn Janssen Steenberg[1,2], and Pieter Pauwels[1]
[1]Eindhoven University of Technology, Eindhoven, The Netherlands
[2]Aannemingsbedrijf Nico de Bont B.V., Vught, The Netherlands

Abstract

Industry experts working on renovation projects rely on a wide range of information. Standards to connect this information are lacking, as well as tools to communicate the data with the industry expert. This study researches the application of semantic web technologies to connect heterogeneous data in renovation projects. Based on this connected data, we present a web-based linked building data viewer through which practitioners can ask relevant questions about a project. Close collaboration with industry experts led to time improvements and a positive attitude towards data-driven support systems.

Introduction

Historical buildings hold significant cultural and economic value and are key elements of a country's cultural heritage. Governments implement policies and regulations to safeguard and preserve those buildings. To do so, practitioners rely on a lot of information about the monument. This information is, however, often documented using various standards, data formats, and software systems, resulting in a situation of fragmented information that is difficult to manage.

The construction industry is increasingly adopting Building Information Modeling (BIM) as a method to digitize information in collaborative workflows. The Industry Foundation Classes (IFC) is a widely recognized standard to store information about objects in BIM models. Common Data Environments (CDE) provide ways to collaboratively use IFC-based BIM models and other information. However, the capabilities of those CDEs to provide users with an integrated overview of information are often limited, as the lack of data integration standards and the vendor lock-in of these systems make it difficult to link related information across different systems and stakeholders.

Semantic web technologies promise to alleviate some of those issues, as they enable connecting and structuring the currently fragmented datasets from various domains and stakeholders (Pauwels et al., 2017), and applying those technologies to integrate BIM models with built heritage information could help in structuring, validating, visualizing, and sharing information in monumental restoration and preservation projects. Efforts in this direction have already been made by other researchers. Hamdan et al. (2019) developed a modular ontology for defining damaged objects and their topology. Bonduel (2021) contributed to the development of a network of new and existing modular ontologies to integrate heterogeneous built heritage information. These works both conclude that more research is needed to apply linked data in real projects and that a better translation from real-world processes to semantic web technologies is necessary.

Next to the necessary development of more data integration standards, Hamdan et al. (2019) suggest that those standards should also be linked to practical actions so that integrated data can actually answer the questions of end users. Bonduel (2021) suggested the development of demo applications to translate the integrated data to end users. Various initiatives to build web-based linked building data viewers exist, such as LBDviz (Donkers et al., 2023), LD-BIM[1], RUB-IP (Hagedorn et al., 2023), BIM-SIM (Chamari et al., 2022), and ConSolid (Werbrouck et al., 2024). However, the current functionalities of those viewers are limited and use in a heritage context requires specific functionalities that are related to the requirements of end users in this specific domain (see Figure 2).

Other research has already made efforts that could help in structuring, validating, visualizing, and sharing data in the context of restoration projects. However, in practice, there still exists a research gap in structuring and visualizing such data in the construction phase of heritage projects. The created solution should use these new techniques while being integrated with existing processes and tools on site. This paper investigates the capabilities of applying semantic web technologies to integrate information from BIM models with other files and information used by practitioners. This work hereby focuses on the integration of data that is not exclusively restricted to RDF graphs. Instead, a software solution is relied upon that combines multiple datasets of multiple types, sometimes referred to here as 'connected data'. This setup and approach is not much different from several recent digital twin implementation initiatives.

This paper presents an ontology and a software tool to integrate data related to built heritage and make this data accessible to practitioners. Section 2 first presents state-of-the-art built heritage data integration, with a specific focus on natural stone renovation projects in the Netherlands. The processes in natural stone renovations, including the relevant information streams, are then

[1] https://ld-bim.web.app/

analyzed, including the relevant end users and their requirements. Those requirements are then translated into a software architecture. The information requirements are also translated into a network of ontologies, combining both existing ontologies and a newly developed extension. These methods are then finally used to develop a web-based tool that enables different end users to interact with the integrated information. The tool is validated in a real-world case study at the Dam Square in Amsterdam, The Netherlands.

Related Work

Conservation of Natural Stone Built Heritage

Historical buildings in the Netherlands hold cultural and economic value, attracting tourists and preserving the country's heritage. The conservation of these buildings is regulated through self-regulation and guidelines established by the Dutch Cultural Heritage Agency (RCE) and the Foundation ERM (Naldini & Hunen, 2019). The ERM guidelines provide technical specifications and quality standards for restoration work, ensuring the preservation of historical value. The process involves inspections, damage assessment, identification of cultural-historical value, determination of appropriate materials and techniques, and decision-making using the "Conservation ladder" (Lubelli et al., 2021). The whole conservation cycle should be documented to provide valuable information for future restoration projects. For natural stone restoration projects, aspects such as cultural-historical value, damage assessment, damage identification, material type, and shape need to be documented (ERM, 2020). Documenting these aspects is done using a wide range of standards and data formats, creating a situation that is difficult to manage.

Connected Data

Several initiatives have aimed to develop web-based building data. One of the first initiatives was the creation of ifcOWL, which translated the IFC schema into an RDF-based schema using semantic web technologies (Beetz et al., 2009; Pauwels & Terkaj, 2016). However, as it mirrors the IFC EXPRESS schema, it inherits the same complex structure and size. The Linked Building Data Community Group of the World Wide Web Consortium (W3C LBD CG) was created to identify and align ontology development initiatives for building data. The approach they took was to create a set of interoperable, flexible, and open standards covering different aspects and domains (Rasmussen et al., 2020). Rasmussen et al. (2017) took the first step in creating the Building Topology Ontology (BOT), which is a flexible and lightweight ontology to define the relationship between elements within a building. This is a basic ontology that describes building structures using the classes bot:Building, bot:Storey, bot:Space, and bot:Element. Implementing this ontology would result in a shift from file-based collaboration to data-centered collaboration using RDF, directly linking data instead of referring to other documents.

While the use of RDF graphs is immensely powerful to create a semantically rich cloud of linked data, several other types of data exist that typically do not fit this RDF graph principle. Several hybrid methods have therefore been proposed and deployed in the last few years that combine semantic web technologies with 3D models, pictures, point clouds, and so forth, e.g. Werbrouck et al. (2020). Another example is the use of semantic web technologies to describe information that does not fit into the BIM exchange schema IFC, for instance describing information about damages on objects while linking to the actual object in the IFC model (Hamdan et al., 2019). Also smart building implementations, e.g. based on Brick, adopt this approach to connect to telemetric data (Chamari et al., 2023). The adoption of semantic web technologies for the description of heritage buildings could help in integrating the different data sources into a full virtual representation. These hybrid methods, which integrate semantic web technologies with BIM models and other files, are considered a highly promising route for handling the data heterogeneity challenges in the built heritage domain.

Existing Ontologies Related to Natural Stone Restoration

Researchers proposed various ontologies that enable the representation, classification, and relationship modeling of historical buildings, their components, damages, inspections, interventions, geometry, and additional properties. Bonduel (2021) proposes the Construction Tasks Ontology (CTO), as an extension to BOT, providing terminology for construction tasks. The Damage Topology Ontology (DOT) contains classes and properties that define topological relations between the damage and the affected building components (Hamdan et al., 2019). Based on the same principles as BOT, DOT, and CTO also support the creation of extensions in a specific domain. Bonduel (2021) used this principle when converting the MDCS damage atlas into an ontology that extends DOT. Another example is the Natural Stone Damage Ontology (NSD), which is based on a different damage atlas (Hamdan, 2023; Seeaed & Hamdan, 2019). Seeaed & Hamdan (2019) have also developed the Stone Component Ontology (SCO), as an extension ontology of BOT, for semantically modeling natural stone facades. Furthermore, the Ontology for Managing Geometry (OMG) provides generic concepts for managing geometry descriptions in a semantic web context (Wagner et al., 2019). It focuses on general-purpose functionalities that allow the handling of single, multiple, and versioned geometry descriptions. OMG can be extended by the File Ontology for Geometry formats (FOG), which extends the OMG to describe file format, versioning, and object identifier information for geometry data (Bonduel et al., 2019). All these ontologies were developed using the principles of the W3C LBD CG, creating modular data structures that can be used following a plug-and-play principle to represent information in for example a natural stone restoration project.

These evolutions also happened in practice. The Dutch Cultural Heritage Agency (RCE) has published its registry of national monuments[2] as a large RDF graph or knowledge graph. This dataset is also linked with a registry of all buildings and addresses in the Netherlands[3] (BAG), which is one of the registries that is published and maintained as a knowledge graph by the Dutch cadaster. The RCE has also published thesauri terms as linked data using SKOS (CHT)[4]. This includes, for example, different types of damages and materials.

Methodology

This paper starts with natural stone renovation projects and investigates the use of the presented technologies and workflows (connecting data) for this data challenge. This paper first reviews the existing processes in natural stone renovation projects. Expert interviews with a project leader, planner, BIM coordinator, and BIM manager resulted in a list of competency questions which is translated to a use case diagram. Based on those competency questions and the processes in natural stone renovation projects, a network of ontologies is created that can support integrating the available data. The use case diagram is then translated into a system architecture that enables the end users to interact with the various types of information through a web application: Heritage LBDviz. A prototype of this application is tested using a real-world renovation project of the Dam Square in Amsterdam, The Netherlands, and validated against the competency questions in collaboration with the industry professionals. The development and validation of this tool was an iterative process with industry professionals where different functionalities were created and validated through three iterations: definition of the competency questions and use case diagram, development of the user interface, and validation.

Natural Stone Restoration Processes

The process of natural stone facade restoration consists of a series of tasks depending on the type of intervention that needs to be performed. To visualize this process, a BPMN schema was created, see Figure 1. The ERM guidelines (ERM, 2020) specify that information should be documented throughout the conservation cycle of a heritage property. The data column in Figure 1 shows when this data is collected. This gives an insight into when information is generated so that it can be associated with specific parts of the process. The schema does not show every possible workflow. However, it gives a clear overview of the main steps that are part of the process and the different types of workflows that are possible.

Firstly, an inspection of each object in the building is carried out in two steps. The first is aimed mainly at gathering information about the object. This information is often gathered in a spreadsheet. In the second step, it is decided what intervention is needed. This information is then used to produce a cost estimation, including the type of replacement material, which creates an additional spreadsheet of information. Once the interventions and costs are known, the actual work on the construction site begins. Three types of workflows are used in the execution of the interventions. Some interventions can be carried out in situ, creating a simple process with only one task: the repair. However, it is often necessary to carry out an intervention in the masonry workshop, which results in a series of additional tasks. In this case, the object must be dismantled from the building and then transported to the masonry workshop. Once the object has been repaired or reconstructed, it can be transported back to the site where it is reassembled in the building. Dismantling an object can require some of the surrounding objects to be dismantled as well. These are then transported to a location for temporary storage and, when the time is right, transported back to the site and used in a reassembly task. Progress is recorded at different steps by taking photos of the object. When all the work has been carried out and all the objects are back in place, a check is performed to ensure that the result meets the desired quality. Throughout the process, the multiple sources of data are passed on to different stakeholders to meet their information needs. This creates a situation where multiple sources of data exist in different places.

End User Requirements

During interviews with the industry experts about what information they need throughout the process, several competency questions were identified. Below are some of the most pressing ones.

CQ1 What is the location of the object in the building?

CQ2 What photos are available of a specific object?

CQ3 What is the volume, material, and shape of the object?

CQ4 What interventions are conducted on an object?

CQ5 How to give an overview of all relevant information on an object?

CQ6 What is the height of the object relative to ground level?

CQ7 What is the progress status of every object in the building?

The various competency questions were translated into use cases to be implemented as functionalities in the system (Fig. 2). They thus inform the normal user requirement definition stage of a regular software development process. These functionalities can then be developed during the different iterations of the prototype

[4] https://data.cultureelerfgoed.nl/term/id/cht.html

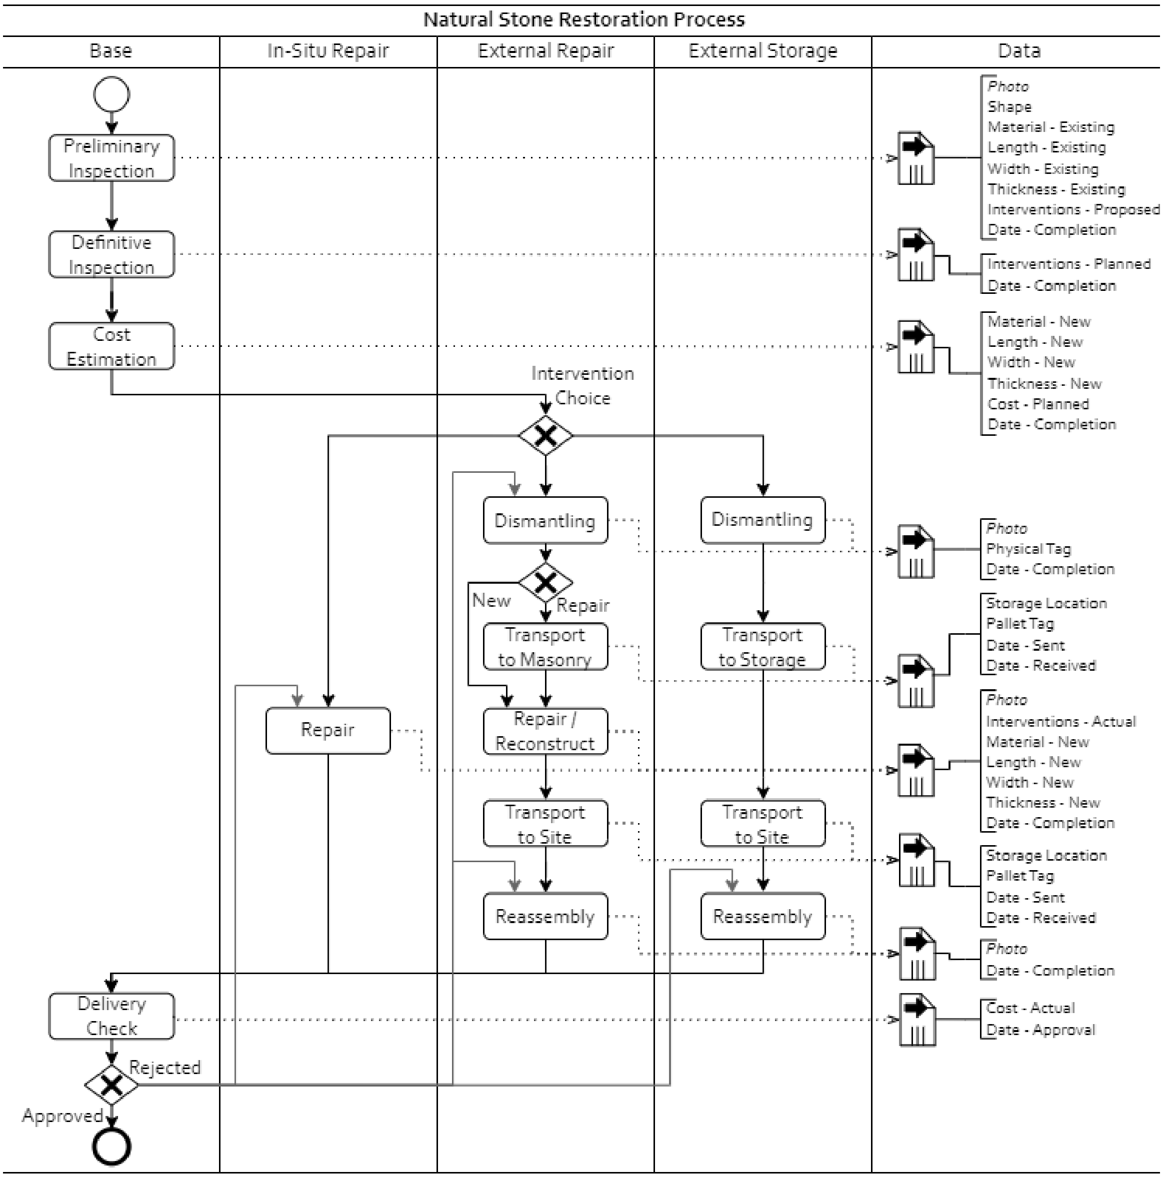

Figure 1: BPMN schema of a natural stone renovation process

development. Each use case either supports another use case or provides an answer to one of the competency questions. Multiple types of users are considered in the use cases being developed. The use cases for the beginner user focus on recognizable output, extended with new possibilities that introduce the user to the system. A more advanced user is provided with functionalities to find traditional information through the system. Finally, a pro user is also provided with the ability to create queries based on their extensive knowledge of the data structure.

System Architecture

Based on the existing processes and the end user requirements, a 5-layer conceptual system architecture was established for combining the RDF graphs with 3D models and other files, see Figure 3, following earlier found best practices (Donkers et al., 2023). The resources layer contains the heterogeneous data produced in the data layer in Figure 1, including BIM models, photos, and states. The data is structured using a network of ontologies. An ETL procedure then transforms some of the source information to RDF and loads the data into the RDF graph. The Connected Data layer combines an RDF graph in the backend with links to the 3D BIM model and other files. As said, this is similar to recurring Digital Twin development projects. A services layer provides capabilities to query data from the connected data layer and ask questions about this information. Users can interact with this information via user interfaces. This paper presents a 3D model viewer - Heritage LBDviz - and a spreadsheet exporter as user interfaces that implement functionalities based on the described use cases. The architecture defines the components independently of the selected solutions, focusing on the responsibilities of these different layers in the system. Implementation of the system architecture must include considerations for communicating between different layers.

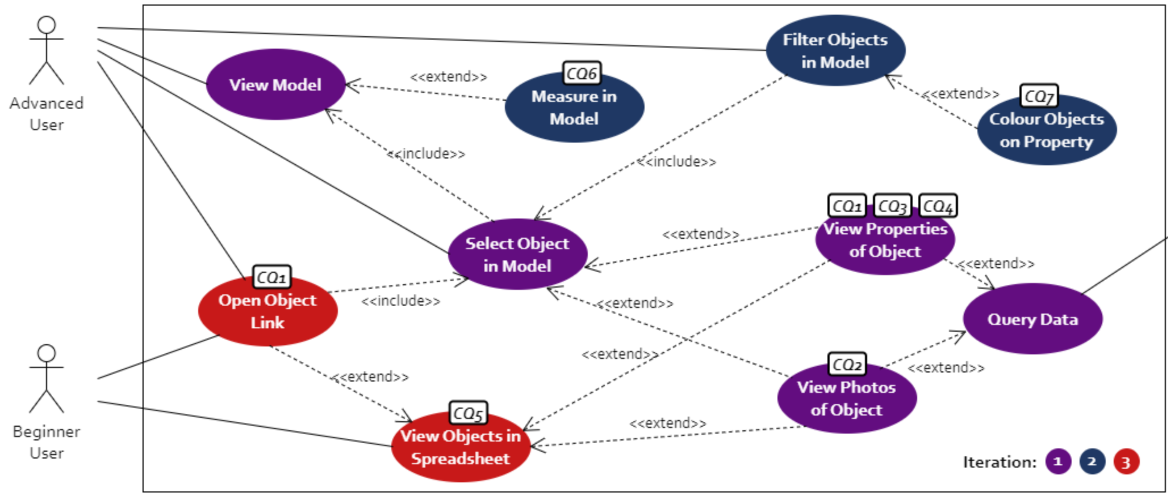

Figure 2: Use case diagram

Results

After development, the prototype was validated in a real-world setting. The restoration of the National Monument on Dam Square was chosen as a case study. The monument consists of a pylon with statues and a memorial wall with reliefs. In front of the monument, two lion figures stand as sentinels. The twenty-two-meter-high pylon, that is made of concrete, the memorial wall and the lions are cladded in travertine, a marble-like porous limestone from Tuscany, Italy. The last restoration took place in 1997. In 2022, 25 years later, the National Monument needed to be repaired or restored. During the restoration, the travertine elements were dismantled and transported to the stonemasonry workshop, where they were cleaned, repaired, and replaced where necessary, minimizing disruption to the Dam Square. The dataset provided does not include all the data described in the process schema, but the project offers a realistic representation of the current way in which practitioners operate and collect and manage data. The following data sources were available for this research: a Revit model and PDF elevations to give an insight into the geometry of the building objects; the Autodesk Build system used to carry out the inspection, which contains data on object properties and photographs; the actual set of photographs taken during the process; and finally some data documented in several spreadsheets, such as the interventions carried out on the elements and the dimensions of all the objects.

Network of Ontologies

Based on all the available data, a mapping was done to find all the classes for the case project data in the BOT ontology and all its extensions, such as CTO, DOT, and OMG. However, some of the data available in this case study could not be described using these existing ontologies. The Restoration Intervention Information (RII) ontology was created to define a set of classes and relationships to fill this gap. The ontology focuses on the interventions that are carried out on the heritage assets and the different properties of elements that are used as information in this process. The ontology describes classes of interventions based on the conservation ladder, defining the class rii:Intervention and its subclasses rii:Preservation, rii:Repair, rii:Reconstruction (Fig 4). These interventions are then linked to the cto:InspectionTask for which they were selected and the dot:Damage they are intended to cover. Finally, the cto:hasTaskContext is used to group the various cto:RepairTask instances that are performed to carry out the rii:Intervention. In addition to interventions, the ontology is also used to add external resources to the graph, specifically photos. The DOT ontology already defines a dot:ExternalResource, but this is specifically described as documentation that should only be damage-related. As not all information is damage-related, it was decided to use the class rii:ExternalResource with the subclass rii:ExternalImage, which is used in combination with the data property rii:filePath to link to externally stored images (Fig. 4).

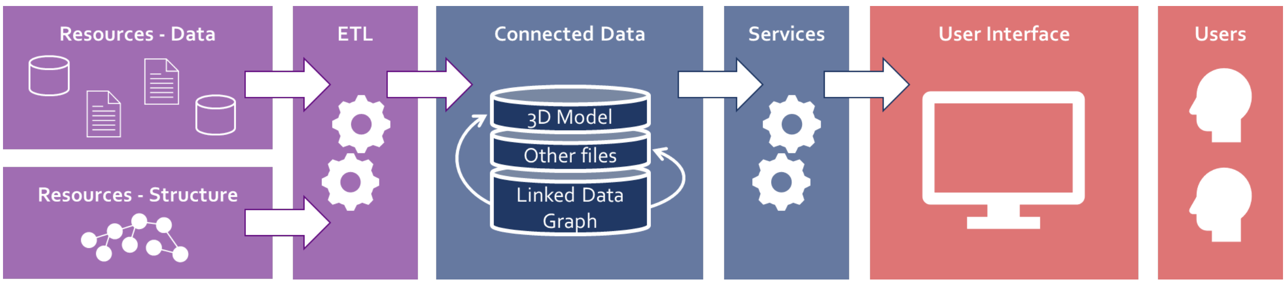

Figure 3: System architecture of Heritage LBDviz

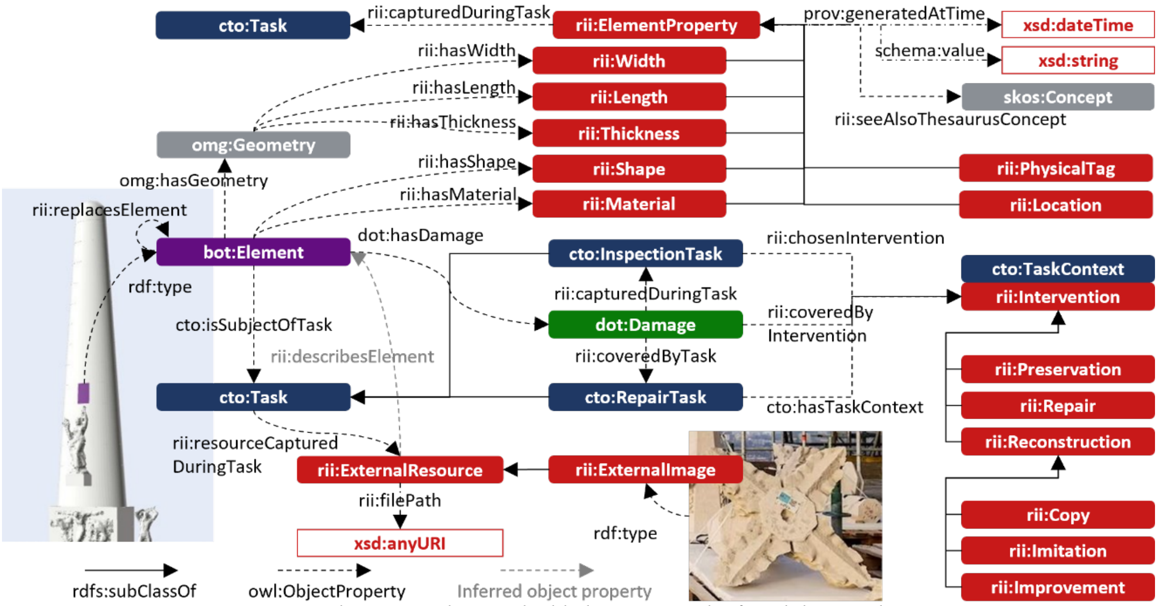

Figure 4: The RII ontology embedded in a network of modular ontologies

The ontology also includes an OWL property chain based on cto:isSubjectOfTask and rii:capturedDuringTaks, creating the relation rii:hasDescriptionInResource with the inverse rii:describesElement. The RII ontology is available at https://marijnjanssensteenberg.github.io/rii#.

Heritage LBDviz

To demonstrate the possibilities of our method in the context of restoration projects, a web application has been developed, serving as an easily accessible user interface that practitioners can visit through their browsers. This application - Heritage LBDviz - is an extension of the already existing LBDviz (Donkers et al. 2023). The tool (Figure 5) is a single-page web application combining an IFC viewer with several menu windows. IFC files are loaded through the IFC.js library, a JavaScript library that allows users to load, view, and edit IFC models in the browser. It also parses the IFC file to JSON so that one can interact with it through JavaScript. Behind this IFC file is a backend with the data, including RDF graphs and non-RDF data. This data can be accessed via Comunica.js, a meta query engine that can be used to execute SPARQL queries against multiple SPARQL endpoints or RDF files simultaneously. Heritage LBDviz[5] and a guide to recreate the tool[6] are available on GitHub.

Heritage LBDviz aims to fulfill the competency questions suggested by practitioners by adding the functionalities as shown in the use case diagram (Figure 2). First, beginner users can open the URI of a specific object, which will automatically open the viewer and highlight the specific object (CQ1). One can then use the various query functionalities to ask for information about this object, either by manually creating SPARQL queries or by using the predefined SPARQL queries hidden behind buttons in the user interface. This allows users to query information from the RDF graph, such as an object's material, size, and other properties (CQ2) and current and historical interventions on the object (CQ4), as well as non-RDF data such as photos (CQ3). All photos linked to an object can be queried and will be printed in the user interface (Figure 5). Next to printing results of queries in the user interface, Heritage LBDviz also allows users to export the results into spreadsheets. Those spreadsheets replace the traditionally manually created spreadsheets, saving time, while also allowing interaction between the spreadsheet and the viewer through hyperlinking cells with the URIs of objects (CQ5). Finally, users can interact with the IFC model in the viewer, for example by measuring distances in the 3D model (CQ6) and by highlighting objects. Using the ontology, Heritage LBDviz can also perform live reasoning and infer the current status of all elements in an IFC model after which all elements are highlighted using associated colors (CQ7).

Heritage LBDviz was validated using the Dam Square monument and the system was tested together with industry experts. Firstly, the tool seems to significantly save time in finding information on a specific object. Construction workers now don't need to go down to the workmen's shelter to find information on a block, and the normally manually created spreadsheets are now automatically generated. The fact that heterogeneous information can be accessed via one user interface is also expected to reduce errors. Inconsistent information regularly causes elements to contain errors after repair, delaying the process and increasing failure costs. The vendor-neutral approach makes projects less reliant on specific software, especially in multi-stakeholder projects. Finally, using the tool enhanced the awareness of the available data and its value, and industry experts could easily come up with suggestions on innovative functionalities of the tool.

Discussion

This paper discusses an approach to integrating data related to renovation projects and making this data available to industry professionals. This paper is not the first paper to present data integration methods related to the topic of renovation projects. This project builds on these earlier projects and re-uses several existing ontologies. Furthermore, this paper presented an extension in the form of the RII ontology to define knowledge on interventions in restoration projects and specific properties that are commonly used in practice. The ontology follows best practices that suggest a modular approach and extends already existing ontologies. Although this ontology is tested in a natural stone renovation case study, its modularity should enable extensions toward other types of projects.

Secondly, this project confirms the feasibility and usefulness of making different types of data available through the appropriate use of semantic web technologies (RDF graphs) and state-of-the-art web development practices (service-oriented architecture). Moreover, it can be experienced that this approach to data integration reduces the gap between developers and data on the one hand, and practitioners on the other hand. As suggested in Donkers et al. (2023), co-creating the Heritage LDBviz environment together with practitioners significantly reduces barriers to using these data fittingly in practice. Validating the tool together with industry experts triggered ideas for more complex functionalities. This shows future opportunities for using such integrated data in restoration projects, and it shows that co-creating such tools in iterative cycles together with industry experts can create more awareness and engagement toward data-driven decision support systems.

Further to the above contributions, two points for further development were identified. First, Heritage LBDviz mainly focuses on visualizing data to answer the competency questions of users. However, validating the quality of the data is essential to make sure that the information is reliable. Future research in quality control methods, such as using SHACL, is needed to improve the reliability of the tool. Second, it is believed that access to a complete dataset of past restorations can create many opportunities for subsequent cycles of conservation. This may be better in reach using the proposed way of working, as it has a high level of modularity and scalability. More research is needed to understand how such long-term data preservation can be organized.

Conclusion

Conserving built heritage is a complex process that involves a lot of information. This research identifies two important challenges: we lack methods to integrate this information, especially beyond the RDF formatting, and we lack tools to make this information accessible and useful to practitioners working on renovation projects. This paper applies semantic web technologies and novel web development techniques to solve these challenges in close collaboration with the industry experts. After a thorough review of existing processes in natural stone renovations, using both literature and discussion sessions with industry experts, seven competency questions were defined. These led to the development of a network of ontologies, extended with the newly developed RII ontology. The knowledge from the review of renovation processes was translated to a use case diagram, based on which a system architecture for a web app was created. This web-based BIM viewer - Heritage LBDviz - aims to help the industry experts in answering their competency questions. The tool was validated together with those industry experts in a case study at the Dam Square. This validation showed that Heritage LBDviz was able to answer the competency questions and that it had the positive side effect of creating more engagement and awareness of such data-driven support systems.

The developed network of ontologies shows that it is possible to integrate heterogeneous data related to restoration projects. The web application shows that communicating this data via a simple user interface can help industry experts in their daily work and improve their understanding of the value of these data for future use cases. While the methods presented in this paper are specifically tested on natural stone renovation projects, we believe that the system architecture can be used in a much wider range of contexts, as long as there is a need to connect, structure, and communicate data.

KNOWLEDGE DRIVEN RULE-BASED BUILDING GEOMETRIC DIGITAL TWIN CONSTRUCTION – STATE OF ART REVIEW

Ya Wen[1], Mudan Wang[1], Mahendrini Ariyachandra[1], Ran Wei[1], Ioannis Brilakis[1] and Lizhao Xiao[2]
[1]University of Cambridge, Cambridge, United Kingdom
[2]University of Hong Kong, Hong Kong SAR

Abstract

Automatic construction of the building geometric digital twins (gDTs) is implemented based on the scanned data from the existing buildings. The highly detailed gDTs necessitates the top-down construction method informed by the predefined building knowledge. This paper reviews the building rules used for the model-driven building indoor environment gDTs construction. It is found that these knowledge is fragmented and lacks systematic analysis. The research categorise these rules into three groups and proposes an Ontology-based knowledge graphs (KGs) approach for organising this knowledge. This method aims to integrate rules for gDT construction to establish a knowledge system for the further research.

Introduction

The emergence of gDTs sheds light on both academic and practical perspectives in the digitalisation journey of the AECO industry (Dou et al., 2023). DTs are the virtual replicas of physical assets, processes, or systems that enable stakeholders to visualise, monitor, and analyse their projects with unprecedented precision. gDTs focus on the static information in the model, and these are meanly the geometric information (Pan et al., 2023). An accurate and semantically-rich gDT ensure a foundation decision-making system for the building condition real-time monitoring, simulation and optimisation.

The process of gDTs construction of existing buildings typically involves the steps of: 1) scanned data collection, 2) scanned data processing, and 3) gDTs recreation. There are numerous methods for surveying and data acquisition (Volk et al., 2014). Subsequently, the collected data should be detected, segmented, and classified efficiently. The first two steps involve most of the technically complex tasks to form the essential prerequisites for gDTs construction. Numerous studies focus on the data collection and processing workflow, while fewer research work assesses the gDT recreation process. The gDTs creation work is regarded to be the 'last mile' process and a simple procedure to convert the information extracted from collected data into a structured format. However, the efficient gDT recreation requires the prior knowledge of the buildings, which including the object shapes, the identifications of objects and their relationships. The rule-based construction method can help avoid the obvious irrationality in the gDT construction process (P. Tang et al., 2010). However, there is no research focuses on reviewing and analysing the building rules that frequently used in gDTs construction to the authors' knowledge.

Building grammar is utilised to present the common building design logic and the structural topology of the building objects (Hu et al., 2019). During the gDTs construction process, building grammars are mentioned in the literatures emphasising the rules that are related architectural design principle. These can be summarised as multiple rules being employed as pre-established knowledge to minimise the dependence on the accuracy of the scanned data. This knowledge serves as the crucial supports to gDTs construction and inference.

KG plays a crucial role in the knowledge management field. Ontology-based KG is a method of representing knowledge, which utilises ontological structures to categorise and interconnect the various entities and their relationships (Bassier et al., 2020). There are some existing ontology-based KGs that can present the building topology and its semantic information (Rasmussen et al., 2020). However, there is still a gap in how to present the knowledge transferring from the scanned data to create the gDTs and to integrate the gDTs with the specific building domain knowledge.

The research objective of this paper is to review the rules used in gDTs construction phase. In addition, the conceptual framework of an ontology-based KG is then introduced to not only present the model-driven gDTs construction rules but also allow the further domain knowledge integration. The proposed KG shall benefit the researchers with direct and intuitive access to the building knowledge as a top-down gDTs creation guidance. Based on the objective, the research questions are listed: a) what knowledge is frequently used as a guide of gDTs creation process, and b) how to organise them in an ontology-based KG as the knowledge base. The proposed KG will be further enriched in the following research with the detailed description of the entities, properties and the reasoning and querying rules, which will facilitate the construction of the semantically-rich gDTs and the inference of hidden objects that are occluded during the data collection process.

Methodology

State of art review is an important knowledge capture method to design a domain KG (Wang et al., 2022). This paper conducts a systematic review and concludes the knowledge utilised for the rule-based indoor environment gDT construction (see Figure 1). Leveraging the keywords that precisely encapsulate the target papers, the searches for 'digital twin generation' and 'scan to BIM' is implemented within the databases like Web of Science and Google Scholar, covering the past decade (2014 – early 2024). After excluding studies outside the relevant fields, a total of 825 papers were initially identified. Through further selection stages, which involved assessing content completeness and scrutinizing abstracts, only 18 papers that introduce the rules for model-driven gDTs construction of building indoor environment were chosen for further detailed analysis.

This knowledge is categorised into three perspectives, which are shape rules, topological rules and semantic rules. Different categories of rules work on the various aspects of information. The shape rules typically work on the geometric attribute of the one category of building element, including the building components and space. The topological rules contribute to the establishment of the spatial relationships between the building elements. While the semantic rules refer to the guidelines or constraints based on the underlying model's semantics. The semantic information can support to the realisation of various potential functions of gDTs, such as the hidden elements inference. Some of the rules are analysed and visualised through a case of the Civil Engineering Building in the University of Cambridge.

Based on that, we developed the conceptual framework of an ontology-driven KG. These rules shall be transformed into the key components of the gDTs construction KG, which are class, properties, constraints, and reasoning rules. The KG acts as a reusable knowledge base, offering a structured representation of the current state of knowledge during the gDT construction process.

Knowledge-driven rules of gDT construction

Knowledge-driven gDTs construction approach emphasises the top-down concep from the required output information. The quality of the scanned data is not a primary factor influencing the output, but the rules adopted during the creation process. Architectural grammar can be considered as the fundamental principle of the building design. In 1994, the knowledge-based computational method for architecture design was explored. It represents a complex procedure grounded in primitive elements and design rules (Carrara et al., 1994). Currently, the knowledge-driven rules based on the building grammars can be used for the building asset remodelling (Nikoohemat et al., 2021), prediction of the building componence configurations (Chen & Liu, 2023), building compliance checking and interior space navigation (Nikoohemat et al., 2021). The Table 1 concludes the key research about the knowledge-driven rule-based methods, and the corresponding target elements.

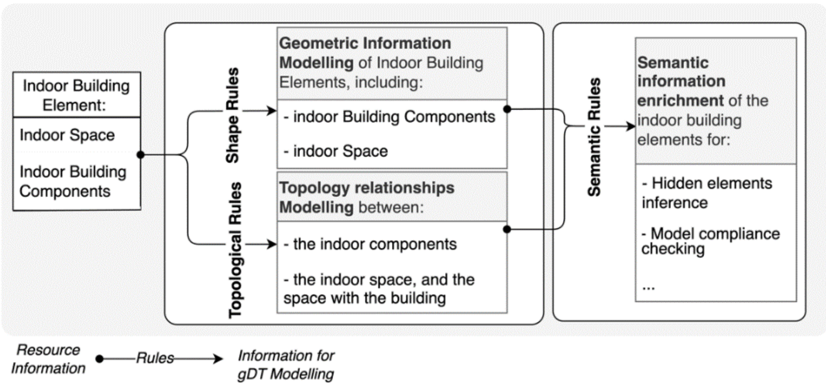

Table 1 Rules of building indoor environment gDTs construction

Research	Elements	Model-driven reconstruction method
(Khoshelham & Díaz-Vilariño, 2014)	interior walls	**shape-driven** rules for indoor wall layout reconstruction
(Becker et al., 2015)	interior hallway, rooms, staircase	three **topology-driven** rules for indoor layout and staircase reconstruction
(Ning et al., 2015)	Walls, windows, doors and roofs	**shape-driven and topology-driven rules** for the object-oriented in the scenes
(Abdollahi et al., 2023; Thomson & Boehm, 2015)	Interior walls	**shape-driven rules** for the geometric restrictions of interior walls
(Hu et al., 2019)	indoor room type inference	sixteen indoor room **topology-driven** rules to infer the room type from room layout
(Yang et al., 2019)	interior walls, roof, ceilings, doors, windows, stairs	**semantic-driven** representation for indoor environment reconstruction, especially the semantic representation of stair space

(Bassier & Vergauwen, 2020; Tran et al., 2019; Tran & Khoshelham, 2020)	interior walls	**topology-driven** rules for interior walls construction
(Nikoohemat et al., 2021)	indoor environment	eight **topology-driven** rules for building indoor component
(Cai & Fan, 2021)	interior rooms, doors	six **topology-driven** rules of the doors' position in the wall to infer spatial relationship of rooms
(Tang et al., 2022)	interior walls, roof, ceilings, doors, windows	**shape-driven** rules of planes and **semantic-driven** rules for 3D object-based indoor environment modelling
(Park et al., 2022)	indoor environment including main structural elements and furniture	**shape and topology-driven** rules of the boundary boxes of the indoor environment objects including floor, wall, column, door, window, table, chair, sofa and bookcase
(Chen & Liu, 2023)	indoor room layout inference	six **semantic-driven** rules to infer interior room layout from exterior building boundaries
(Kellner et al., 2023)	interior walls, windows and rooms	**shape-driven and topology-driven rules for the geometric features of the walls, windows and rooms;**
(Yang et al., 2023)	interior walls and indoor rooms	**topology-driven** rules of two walls, three walls and four walls
(Drobnyi et al., 2024)	interior components and space	**topology-driven rules** ('same-space', and 'same-object') for the indoor components and space

Shape rule-driven construction

The common building objects, such as the walls, floors, roofs, doors, windows, and space should be object-oriented constructed in the gDT creation process. The shape rules can be applied in both building elements modelling and interior spaces modelling.

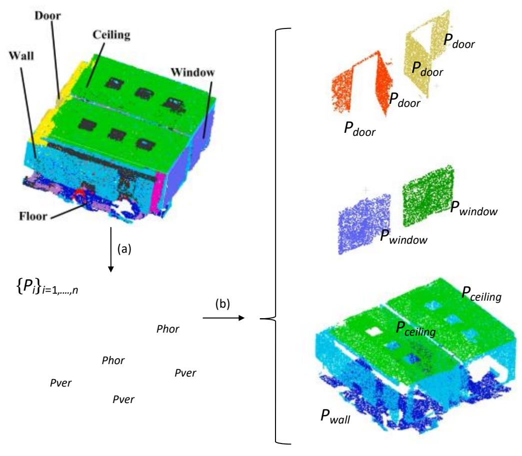

Figure 2 Shape rule-driven for building components construction (Tang et al., 2022) *(a) Decompose the data into planar primitives (b) semantic information enrichment to the planar primitives for further refinement.*

Shape rules for the building components

Wall modelling is an important task in the indoor gDT construction, typically requiring fitting with parallel and smooth surfaces rather than tessellated-as modelling. Bassier & Vergauwen (2020) defined a set of positional relationships as the foundational rules for the multiple cuboid walls. These relationships can serve as the prior knowledge for wall object creation, including: 1) intersection, 2) orthogonality, 3) blending, and 4) direct connection. Thomas and Boehm (Thomson & Boehm, 2015) proposed three geometric restrictions while the wall is generated, which are reject small wall, extend large wall and merge close planes with similar normal. Tang et al. (2022) utilised a grammar-enhanced method to decompose the entire scene into planar primitives using a two-level shape rule, based on the segmented point cloud clusters (refer to Figure 2). The first level of rules divides all planar primitives $\{P_i\}_{i=1,\ldots,n}$ into three categories according to their orientation: vertical planes (P_{ver}), horizontal planes (P_{hor}), and other planes (P_{oth}). The second level of rules further select the planar primitives that exhibit structural characteristics of the interior model and assign the semantic information to them. The characteristics are confirmed based on the geometric constrains and spatial orientation to identify doors (P_{door}), windows (P_{window}), ceilings ($P_{ceiling}$) and walls (P_{wall}).

The shape-based rules for identifying building components aim to discern the features of specific object categories. This approach is efficient as a reason of considering the ground truth shape of building elements. However, there is a lack of consistency in defining primitives and their geometric relationships across various building elements. Different researchers have adopted distinct methods for defining shape features. For instance, the positional relationships of interior walls are defined differently in the study by Bassier and Vergauwen (2020) and Khoshelham and DíazVilariño (2014). Despite these differences, both studies essentially describe the same real-world relationship between interior walls. In such scenarios, ontology-based KG holds the significant potential to facilitate the fusion of these diverse definition methods via unifying terminology.

Shape rules for the building internal space

Shape rules can be effectively applied to generate parametric indoor spaces (Abdollahi et al., 2023; Khoshelham & Díaz-Vilariño, 2014; Tran et al., 2019). This approach involves positioning cuboids within a zone defined by enclosing points to identify the space. Subsequently, topology relationship rules are typically employed in the next stage of space modelling.

The 4-tuple, $G = \{I,N,T,R\}$ is used to define a space in shape rules (Tran et al., 2019). Among that, I, represents the initial shape, providing the foundational form from the beginning of modelling. It serves as the baseline and starting point for further transformations. N denotes non-terminal shapes, which are intermediary forms during the modelling process. And T signifies terminal shapes, marking the end shape of space division. R refers to the production rules that indicate the transformation process. The relationships of these parameters can be presented as: $R : A \rightarrow B : cond., A \in N, B \in V, V = N \cup T$. The rules ($R$) can be categorised to different types, such as the initial shape place rule (R_{place}), the merging rule (R_{merge}) for two non-terminal shapes and the split rule (R_{split}) for space decomposition (Khoshelham & Díaz-Vilariño, 2014; Tran & Khoshelham, 2020). For instance, the R_{place} is presented through a transformation H, applied to the initial cuboid S, *where* $R_{placecuboid} : S \rightarrow HS$.

Shape rules can also define the relationship between building component and space as $G = \{N,T,R,S\}$, which represent the non-terminal space, terminal space, grammar axiom and starting symbol, respectively (Nikoohemat et al., 2021). With the basic elements defined, the relationship between two or more components can be further explored using topology rules. These two 4-tuples represent typical shape rules used for space construction, established on the similar conceptual basis but expressed in varying ways. Knowledge fusion is essential to merge similar concepts across different 4-tuples, aiming to realize a consistent workflow in the shape rule-driven space construction method.

Topology rule-driven construction

The logic applying topology rules for indoor 3D construction lies in establishing constraints on the interrelated topological connections of space and building structural elements. This method effectively addresses the challenges posed by incomplete and occluded elements in scanned point cloud data (PCD) (Ning et al., 2015; Tran et al., 2019; Yang et al., 2019).

Topology rules for indoor components

The building indoor environment comprises spaces and the building components, including structural elements, furniture and building service equipment. The allocation of walls is important for constructing the building indoor environment. The topological relationships between two walls (*collinear, perpendicular and intersect*), three walls (*T shape and pseudo T-shape*) and four walls (*cross shape*) are discussed (Yang et al., 2023). These relationships are important to overcome the occluded points at the corner in the collected PCD. Besides, the room boundary surface parameters can be adjusted based on the associated wall objects and the room object will be accurately rebuilt accordingly. Nikoohemat et al. (2021) highlighted the 8 potential relationships between 3D objects in building indoor elements, which are *disjoint, meet, equal, overlap, contain, cover, inside* and *coveredBy*. Furthermore, within the '*meet*' relationship, three sub- relationships are defined: support, supported and attachment.

The topological relationships between windows and walls are discussed by Kellner et al. (2023). These relationships can be utilised to not only generate the wall elements with attached door and windows, but also represented in the constructed gDT model. In addition, the integration of shape and topological relationships among the indoor building elements optimise the PCD semantic segmentation results to help with the high accuracy gDT construction. Park et al. (2022) define relationships of the indoor building element based on the boundary boxes of the objects, the spatial vectors of the boxes, and their referenced objects and referenced vectors. Except for the definition about the relationships between the objects, the topological relationships between planer surfaces are also explored (Drobnyi et al., 2024). The relationships of '*same-space*' and '*same-object*' are defined as a basis to form the topological relations between objects and spaces.

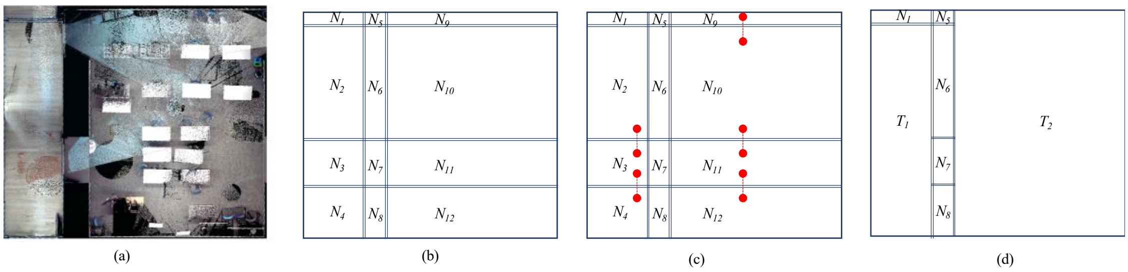

Figure 3 Merging non-terminal connected spaces (Civil Engineering Building in UOC as a case presenting the merge rules from (Tran et al., 2019): (a) top view of the selected scanned data, (b) top view of the cuboid shapes classified as the interior spaces, and defined as N (Non-terminal space), (c) find the adjacent spaces that without the common wall, and (d) the result with the merged cuboid defined as T (Terminal space).

Different research defines the various aspects of topological relations between the building indoor environment elements, which are laser scanning points, planer, object with the same or different semantic classification. The objectives of most of the rules are creating the semantic label to the disordered point cloud to construct the gDTs with not only the geometric, but also the topologic information. All the building elements with the same architecture style share the similar sets of features. However, the rules are fragmented. The systematic fusion of the rules can boost the knowledge-driven gDTs construction workflow.

Topology rules for indoor space

The indoor environment of a building not only consists of the building components but also the space. A room is defined as the terminal space enclosed by the walls, and it can be defined by the topological relationships of the spaces that compose them, and the building components, such as door or walls. These relationships are crucial for knowledge-driven gDT construction and inference. Tran et al. (2019) proposed a procedure for the room configuration rebuild including six rules: *placement, classification, adjacency, connectivity, merge and containment* rules. Three of the rules show the topological relationships of spaces including terminal and non-terminal spaces, which are: *adjacency, connectivity, and containment*. These relationships can be presented as: $R[t]: \{A1,A2\} \rightarrow \{A1[t],A2[t]\}: cond$, where, $R[t]$ is one of the constraints rules; $A1$ and $A2$ are terminal shapes or non-terminal shapes; and *cond* is the condition that identifies the topology relationship between shapes. The application of merge rule to combine two non-terminal spaces is exemplified in Figure 3, using UOC civil engineering building as an example.

The topological rules for the indoor space not only aid in room construction but can also facilitate the identification of further semantic enrichment (Cai & Fan, 2021; Tran et al., 2019). For instance, if two rooms are connected through an adjacency relationship, they share one common wall or a segment of it. Conversely, if a room partially shares a common wall with several rooms, it might indicate that this room is a corridor or hall space. Additionally, more semantic information can be inferred from the identification of room functions, such as the navigability of the space, and the existence of a door element. However, these relationships and the causation among these rules are not systematically organised. Integrating these into a KG could streamline the space construction and further support the reasoning of semantic information as proposed earlier.

In multi-story scenarios, the stair space is analysed by Yang et al. (2019). It is characterised as the composite space that connects two storeys. The stair space, denoted as S_{stair}, comprises two components: the stair-occupied space S_{sto} and the stair connection space S_{stconn}. The definitions of S_{sto} (green space) and the S_{stconn} (blue space) are illustrated in the Figure 4. Furthermore, the stair space connects with the slab free space S_{sf}, and the stair connection space, intersects with the associated slabs S_{slab}. This relationship can be expressed as: $S_{stair} = \{S_{sto}, S_{stconn}\}$, $S_{sf} = S_{slab} \cap S_{stconn}$.

Becker et al. (2015) emphasised the significance of hallway as critical elements within the building indoor environment. They proposed a strategy for constructing L-system hallway using spatial split rules and characteristics unique to hallway areas in buildings. Three functional control approaches are identified based on the topology relationships of segmented space, which are the *ActivationControl, LayoutSetting* and the *ConsistencyConstraints*.

The rooms, hallways or corridors and staircases are the typical indoor space. Tran et al. (2019) and Cai & Fan (2021) focused their research on individual rooms and corridors. Yang et al. (2019) examined the relationships of staircase spaces. However, current research lacks an integrated approach that encompasses the entire building interior space. The management of knowledge from these state- of-the-art studies could significantly enhance the capacity for indoor space construction in gDTs and provide robust evidence for subsequent semantic information retrieval.

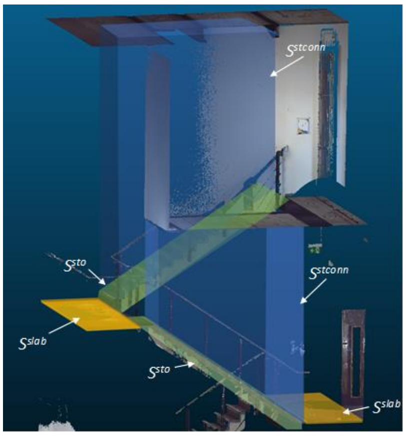

Figure 4 Definition of a stair connection space (Yang et al. 2019) *shown in the UOC case.*

Semantic rule-driven construction

The parametric and semantic properties of indoor spaces and components are pivotal information sources in current gDT construction practices (Jarząbek-Rychard & Maas, 2023; Liu et al., 2023). Semantic rules are commonly applied following the detection of building elements through shape rules, and the assessment of the topological relationships. For a comprehensive gDT, it is crucial to consider the unified and consistent characteristics of the entire indoor model, rather than focusing on isolated parts such as walls, doors or staircases (Yang et al., 2019). The importance of semantic rules is to generate the attributes for building elements beyond the parametric information that facilitate further utilisation. For example, the semantic rules are defined as classification and declassification to determine whether a room is an interior space or external space by Tran and Khoshelham (2020). This categorisation aids in supporting functions like indoor path planning. This research elaborates how semantic rules power the hidden element inference in the gDT construction process. Furthermore, this section reviews the key literature on the semantic rules applications and summarises the main semantic rules.

Hidden element inference

The knowledge-driven construction methods help with the prediction of space types (Hu et al., 2019; Xie et al., 2021). It provides a robust framework for building model construction, fostering a detailed and nuanced understanding of hidden objects and spaces within a 3D model. Chen and Liu (2023) underscored the importance of space syntax theory and design conventions, especially in the context of Singaporean dwelling units. This approach facilitates the inference of room types within a building.

Currently, most of the methods for inferencing building indoor environments focus on space or room predication. However, with semantic rules, further predication can be conducted. Hidden element inference, for instance, can be realised if default semantic information is available as prior knowledge. For example, the paths of the building pipeline could be predicted as guided by semantic rules by knowing the locations of the MEP (mechanical, electrical and plumping) terminals, and the spatial relationships between the equipment rooms and these terminals. However, there is less research contributing to this workflow.

Knowledge graph for gDT construction

A KG is a network of interconnected entities such as objects, events, concepts, represented in a graph format. In this graph, nodes typically symbolise entities or concepts, while edges represent the relationships between them (Bassier & Vergauwen, 2020). KGs utilize ontologies to define their structure, with Resource Description Framework (RDF) serving as a standard for describing the relationships (edges) within the graph.

The KGs can be utilised in building the knowledge of object identification and 3D model construction, and contributing to the knowledge fusion to the specific domains after the gDTs are constructed. Park and Cho (2022) develope the Entity-relationship diagram (ERD) to bridge the connections among point cloud, point, object, material, location. This semantic information is stored and converted in the point dimension to guide the information modelling of the building. The rules used to generate the gDTs can also be modelled in the KG, they can be regarded as the prior knowledge to facilitate the gDTs construction process. Hmida et al. (2013) propose the knowledge-based PCD detection and annotation strategy with an OWL ontology language, the Semantic Web Rule Language (SWRL) and the 3D processing built-ins. They divide the scene into various domain concepts depends on their characteristics and geometric relationships. This solution was tested in the railway objects. The knowledge from Geographic Information System (GIS) system is also integrated in the OWL structure for the further information enrichment to the 3D model. In addition, the approach of 'scan-to-graph' (STG) is proposed by Werbrouck et al. (2020). The STG method aims to integrate the Scan-to-BIM results with the sources of real-world asset via the semantic web technologies to overcome the uncertainties (occlusions, internal structure, etc.) of the collected data.

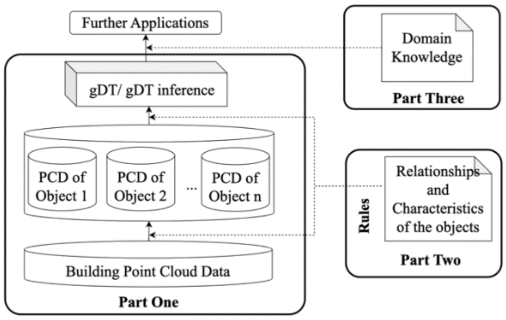

Figure 5 Conceptual framework of gDT construction KG

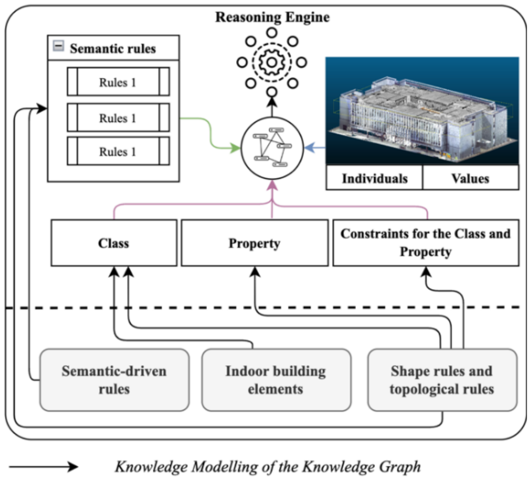

Figure 6 Key components of gDTs construction KG

Currently, there are less literatures focus on the KG development on both: 1) gDTs construction process and 2) the knowledge fusion for the further gDT applications, especially for the indoor building objects. Moreover, there are only limited rules are stored in the current KGs. In this paper, we developed the initial conceptual diagram of the knowledge graph to meet the two requirements with the considerations of shape, topological, and semantic rules. The structure of the ontology-based gDT knowledge graph is shown in Figure 5.

The first part of the framework focuses on transforming building PCD to object PCDs, and then the PCDs are converted to be the gDTs. The shape, topological, and semantic rules can be derived from the characteristics from the objects, and the relationships between the objects. Additionally, this step involves inferring parts of the building that might be occluded or hidden in the scan data based on the prior knowledge. The second part aims to establish the knowledge base (including the object characteristics and relationships) for the rules generations to facilitate the process of part one. This mainly involves the rules that discussed in the review parts of this paper. The establishment of the knowledge base of the rules can also be integrated with the existing ontologies that are commonly used, such as the Building Topology Ontology (BOT) (Rasmussen et al., 2020). In the third part, domain knowledge is utilised to enrich the gDTs for further development. This includes integrating the gDTs with other databases, such as energy consumption or environmental data, and refining the model for specific applications like simulation or analysis. The continuous improvement and updating of the gDTs are crucial to ensure they remain an accurate and useful representation of the physical structure.

Figure 6 presents the key components of the KG and the knowledge modelling mapping relationships from the building knowledge to the ontology-based KG. To enrich the ontology-based KG, building elements shall be converted to the classes, and the shape-driven and topology-driven rules will be presented as the classes, properties, constrains or the reasoning rules for the classes and properties of the KG. The semantic rules shall be expressed with the rules for the gDTs processing, semantic information enrichment and occluded gDTs inference. The objective of the proposed KG framework is to offer a comprehensive approach to enhance the gDTs construction workflow by incorporating the shape, topological, and semantic rules, ultimately paving the way for more sophisticated and accurate model-driven gDTs construction of building indoor environment.

Discussion

Understanding the indoor architectural rule and modelling it in a structured framework can support the recreation the building elements and the prediction of unreachable places in buildings. However, there are still some challenges in the current rule-based gDTs construction approaches. For example. the construction of the nonplanar surfaces and the non-Manhattan buildings are one of the big challenges (Tang et al., 2022; Tran et al., 2019). Moreover, the important connection building elements like doors and stairs are often manually added. Besides, some rules may only be applicable for specific types of buildings, such as churches or small-scale residential houses. The knowledge driven rule-based gDTs construction methods are important and should be further developed to compensate for the imperfections in the data collected from the physical world.

Conclusions

This paper has reviewed and analysed the rules in knowledge driven rule-based gDTs construction workflows from the perspectives of shape, topological, and semantic rules. It also proposes an initial conceptual KG framework for the structured representation of these rules and their interrelationships. Further development on the KG will encompass a broader range of building objects. Additionally, the continuous development of information reasoning and querying rules will also be conducted to facilitate the inference of hidden building objects and the enrichment of semantic gDTs.

AUTOMATIC HVAC TOPOLOGY GENERATION USING BIM GEOMETRY CHECKING AND KNOWLEDGE GRAPH TECHNOLOGIES

Meng Wang[1], Georgios Lilis[1], Dimitris Mavrokapnidis[1], Kyriakos Katsigarakis[1], Ivan Korolija[1], Dimitrios Rovas[1]

[1]Institute for Environmental Design and Engineering, University College London, UK

Abstract

Developing digital twins of buildings can enhance the design process and streamline operational management. This study presents an automated framework designed to establish HVAC topologies of buildings using IFC-BIM data inputs. It achieves this by detecting geometric relationships among HVAC elements and generating a knowledge graph that captures their interconnections. A case study involving a recently constructed building in the UK was conducted to validate this framework. The resulting HVAC topology was compared against design drawings to identify any disparities, demonstrating the workflow's efficacy. This framework shows promising potential and generalization ability for application in various types of buildings.

Keywords

Building digital twins, Geometric relation check, Knowledge graph, HVAC topology

Introduction

A building digital twin is an advanced concept that can be used to improve building design, facilitate a building's operational management, and bridge the gap between building information and building simulation models. A seamless framework to establish Heating, Ventilation, and Air Conditioning (HVAC) topology automatically from BIM data exploits the latter potential and supports the automation of the generation of Building Energy Models, especially for the active components in building performance simulation. This HVAC topology generation involves multiple tasks such as the crafting of appropriate building-centric ontologies, the extraction of semantic relationships among HVAC elements, and finally the generation of semantic graphs conforming to the ontological schemes, capturing the HVAC topology.

Towards this direction, researchers established several building-oriented ontologies to enhance the building management system, e.g., BrickSchema developed by Brick Consortium (2019), to describe fluid flows through MEP distribution elements, e.g., Flow Systems Ontology (FSO) developed by Kukkonen et al. (2022), and to model connections between spaces and elements, e.g., Building Topology Ontology (BOT) Rasmussen et al. (2021). Seidenschnur et al. (2022) proposed a common data environment to represent a BIM-based model with the virtual commissioning, to establish a common data environment for HVAC design. They conducted two case studies to achieve the co-simulations between Modelica and EnergyPlus. Mavrokapnidis et al. (2023) used the Geometric Relation Checker (GRC) tool to identify pairs of IFC geometric instances and to generate an HVAC topology in knowledge graph form. They also briefly compared the applicability of BrickSchema, BOT, and FSO on data from the building domain. Many researchers tried to introduce ontologies as the bridge between building information and building energy modelling to achieve building simulation automatically. Wu et al. (2022) proposed an ontology-based framework for building performance simulation by integrating various data sources including building information modelling, building management systems, and weather stations. Their results showed a considerable reduction in modelling time but appropriate assumptions could not be avoided.

Different data sources of building information can be introduced into the HVAC-related Building Information Modelling to Building Energy Models (BIM2BEM) transformation. Not limited to IFC-based BIM models, CityGML can also serve as a data source and be integrated into the BIM2BEM workflow. Deng et al. (2023) developed a tool for district-scale urban building energy modelling in which the geometric information of buildings was extracted from CityGML data. To facilitate the BIM2BEM generation process, González et al. (2021) integrated BIM and BEM methodologies to conduct an energy performance analysis of a residential building. Their work mainly depended on the Revit platform considering many variables including lighting efficiency, plug-load efficiency, and HVAC systems. In their study, an architectural BIM model provided the majority of necessary data, enabling non-geometric information to be derived from experimental design. Ramaji et al. (2020) devised an extension for OpenStudio that converts IFC-based BIM models into building simulation models. Validation of their algorithm was conducted through a case study involving a three-story office building in the US, revealing several advantages and limitations. Their findings highlighted certain drawbacks of the current semi-automated BIM2BEM process, particularly when dealing with large and intricate structures.

As the number of BIM2BEM-related studies grew, researchers started to summarize the related developments investigating potential topics that require to be addressed in the future, e.g., Kamel and Memari (2019) and Farzaneh et al. (2019). They concluded that there was still work to be done, to reach a seamless workflow from BIM to BEM. In this context, two specific tasks were proposed to facilitate the development of an automatic BIM2BEM framework. The first task focuses on integrating models, while the second task revolves around creating a process map to seamlessly connect work and data flows. Researchers primarily concentrated on bridging the gap between BIM and BEM architectural data focused on the generation of the second-level space boundary topology Ying and Lee (2021), Rose and Bazjanac (2015), Lilis et al. (2017), rather than addressing data translation issues specific to MEP data, like those appearing in the HVAC data domain. A potential explanation for this decision might stem from the difficulties encountered when attempting to automatically generate an HVAC topology directly from BIM data—a crucial step in translating HVAC information within a BIM2BEM process. Achieving this automated HVAC topology generation requires employing multiple ontologies describing mechanical equipment (e.g., BrickSchema Brick Consortium (2019)) and material flows (e.g., FSO ontology Kukkonen et al. (2022)), within MEP networks. Additionally, various issues and errors in BIM models lead to challenges in achieving an accurate HVAC topology, often requiring labour-intensive manual corrections.

To tackle these challenges, this work develops a framework that automatically generates the HVAC topology of a building that can be used to mirror real-world conditions. To demonstrate its efficacy and feasibility, we apply this framework to a recently built structure with complex HVAC systems. Concurrently, the proposed framework seeks to enhance any automated BIM2BEM conversion process by providing a fast and efficient translation method for possible MEP data that could be part of this process.

To introduce this approach the structure of the paper is as follows: The methodology section outlines the framework and its pertinent stages. The case study section provides an in-depth overview of the chosen building and its HVAC setup. Following this, the results and discussions section delves into the generated HVAC topology, highlighting the strengths and limitations. Finally, the conclusion section summarizes the findings and proposes avenues for future research.

Methodology

The proposed HVAC topology generation process involves three major steps as illustrated in the block diagram of Figure 1. These steps are: (1) Extraction of information from BIM (IFC) files related to architectural (ARC) and mechanical, electrical, and plumbing (MEP) data, (2) Checking of the extracted BIM content to detect geometric (2a) and semantic (2b) relations among HVAC elements and space volumes, and (3) Establishment of the HVAC topology via knowledge graph generation and path-finding.

- In step 1 (Extraction), the IFC geometry exporter is used to extract the geometric representations (parametric and non-parametric) of the building space and MEP elements from the ARC-IFC and MEP-IFC files. These representations are then used to form XML files that are used as input to a geometric relation-checking (GRC) tool. These XML files contain the detailed geometric representations of each entity to be checked, together with their IFC global unique ID. Additionally, in this step, the IfcOpenShell is used for parsing the MEP IFC file to extract the semantic connectivity data.

- In step 2 (Checking), connectivity and containment entity pairs are extracted via geometric (step 2a) and semantic (step 2b) relation checks. In case semantic relations are absent from the BIM data, the GRC tool is applied to identify geometric relations among the solid representations of the MEP elements (containment, clash, and adjacency) and infer the missing semantics. Finally, the Oriented Bounding Box (OBB) method is introduced to address the HVAC elements that can not be handled by the GRC tool. Hence, a hierarchy of checks (BIM context - GRC - OBB) is formed to extract all connectivity and containment relations among the involved elements.

- In Step 3 (Establishment), an ontology-based knowledge graph is created to represent the HVAC elements and their connectivity, leveraging the outcomes of Step 2. Subsequently, a path-finding method is implemented to establish logical links from terminals to systems and from pumps to units, thereby simplifying the knowledge graph of the HVAC topology.

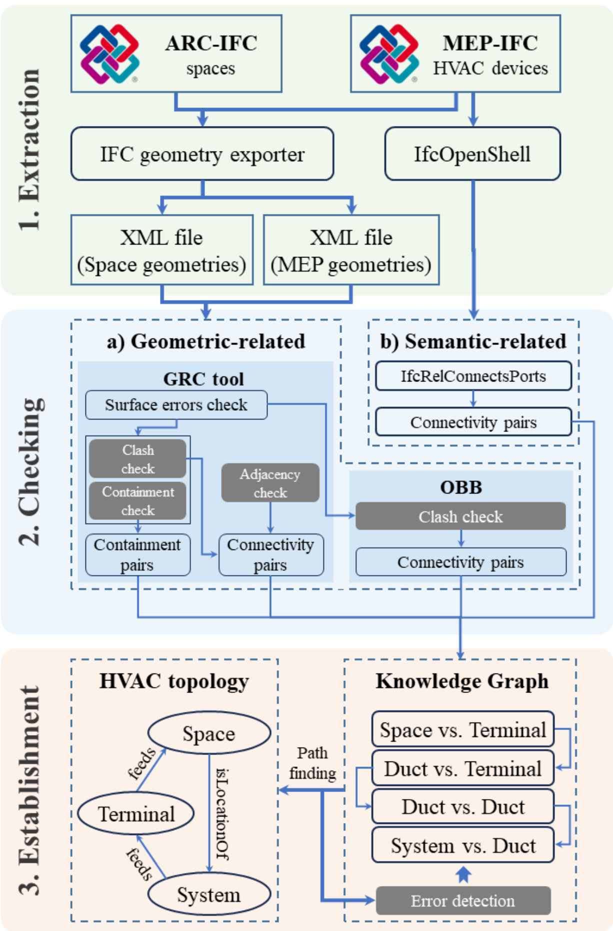

Figure 1: Introduced three-step framework

Information extraction from BIM - Step 1

The proposed workflow used two types of BIM models, i.e., ARC-IFC and MEP-IFC files. From the ARC-IFC file, only the class of IfcSpace was extracted and transferred to a set of entities in the knowledge graph that are detailed in the following sections. To extract the MEP information related to the duct network, data from multiple IFC classes were gathered, including (1) the classes of IfcAirTerminal, IfcDuctSegment, IfcDuctFitting, IfcAirToAirHeatRecovery, IfcBuildingElementProxy that are used to construct the air loop network of the HVAC system, and (2) the classes of IfcPump, IfcValve, IfcPipeFitting, IfcPipeSegment, and IfcFlowMeter that are used to construct the water loop network of the HVAC system. Instances of the previous classes that are contained in the IFC files were mapped, in a one-to-one manner, to entities in the knowledge graph.

Furthermore, the IFC Geometry Exporter Katsigarakis et al. (2021), was used to extract geometric descriptions of the elements from input IFC files, which is the prerequisite to implement the geometric relationship check that is conducted using low-level C++ geometric routines. The exporter extracted serialized geometric descriptions from the two types of IFC files, transformed them into a hierarchical tree-structured format, and created two XML files containing these transformed descriptions. The generated XML files were then used as input to the Geometric Relation Checker (GRC) tool, to identify the geometric relationship among the building's MEP and space elements.

Geometric relation checking - Step 2a

Three types of geometric relationships are defined: containment, clash, and adjacency to deduce semantic connections among the elements within the ARC and MEP IFC files. Detailed explanations of these relationships are provided in subsequent subsections.

Containment

A containment relationship between two solids exists when the surfaces enclosing one solid are entirely within the 3D boundaries of the other. Consequently, this relationship serves as a means to identify semantic links between spaces and terminals. It enables the detection of the specific space to which an HVAC terminal belongs. This association is particularly relevant, as numerous air terminal units, such as diffusers and grilles, are typically entirely enclosed within the volume of the building space, as depicted in Figure 2 a).

Clash

A clash relationship between two solids exists when surfaces or parts of the surfaces of the boundary representation of one solid are entirely within the 3D boundaries of the other. Figure 2 b) illustrates the clash relationship between two elements. This is the most common geometric relationship among many pairs of elements within the air loops, including spaces vs. terminals, terminals vs. ducts, ducts vs. ducts, and ducts vs. systems. Similarly, within the water loops, it also extends to relationships between terminals vs. pipes, pipes vs. pipes, pipes vs. pipe fittings, and pipes vs. pumps. Clashes can be used to infer connectivity between elements as well as containment when a portion of one element is inside another.

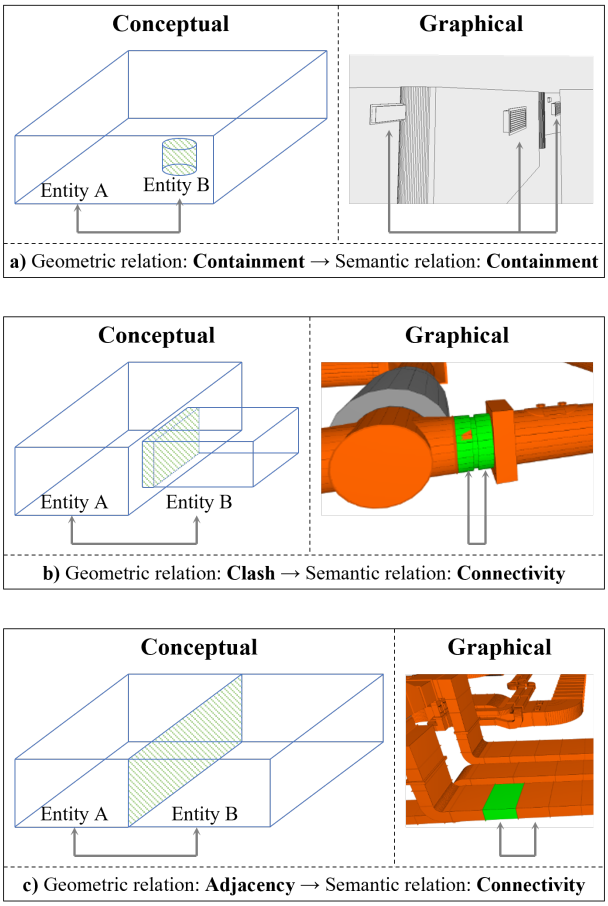

Figure 2: Conceptual and graphical illustration of a containment relationship.

Adjacency

Two solids share an adjacency relationship when the surfaces of one solid's boundary representation lie in the same plane and intersect with the surfaces of the other solid's boundary representation. Figure 2 c) illustrates the adjacency between two elements that frequently appear in pairs of ducts and ducts and systems, especially in rectangle-shaped ducts. Unlike the previous geometric relationships, a threshold value (0.01 m in this case) is used to check adjacency. This value sets the allowable distance between the planes of the intersecting surfaces that define the adjacency. If the distance between these planes exceeds this value, intersection and adjacency are not detected.

GRC tool

To detect the presence of the previous geometric relations among the solid representations of the BIM elements, a geometric relationship-checking tool, named Geometric Relation Checker (GRC), is introduced. The performance of this tool is validated on BIM elements from the architecture and construction domains. GRC is a domain-agnostic application that can be used to identify predefined geometric relationships in any IFC element pair. To achieve the necessary execution speed, the GRC tool is implemented in C++ and uses binary space partitioning to carry out fast Constructive Solid Geometry (CSG) set operations on polyhedra, required for clash detection, using multithreaded executions. GRC can not only identify relationships including containment, clash, and adjacency, but also the surfaces at which the related elements intersect or touch each other. Moreover, a threshold of the gap between each element can be set to define the adjacency and to address potential element mismatching issues.

Oriented bounding box

If surface errors are present in the solid representations of the compared BIM elements, certain Geometric Relation-checking processes like clash and containment detection cannot be performed. Surface errors refer to surface inversions and missing surfaces that form wholes in the boundary representations. To address such scenarios, the study introduced the oriented bounding box (OBB) method to carry out the relevant geometric relationship checks. The GRC tool identifies these cases and automatically routes the problematic elements to the OBB-based clash-checking process. Furthermore, inflation is used during the OBB-based clash-checking process to expand the bounding box in the direction of each face, with the inflation threshold aligned with the gap threshold used by the GRC tool. This method ensures that the OBB-based clash-checking process complements the GRC method, facilitating comprehensive geometric relationship checks for all elements within the IFC file.

Entity linking via semantic checking - Step 2b

Although numerous IfcRelationship entities exist within the BIM context to depict relationships among MEP entities, they often fail to encompass all entities within air loops and water loops. The previously described geometric relationship check processes were introduced to address this gap, enabling the deduction of missing semantics between pairs of MEP elements. Thus, the proposed GRC-OBB-BIM workflow streamlines the extraction of existing and potential containment/connectivity pairs, enhancing the linkage between HVAC elements and helping to finalize the generated HVAC topology.

HVAC topology establishment - Step 3

The HVAC topology establishment process was divided into knowledge graph generation, pathfinding, and error detection, as analyzed in the following subsections. Firstly, knowledge was transferred directly on the basis of the detected geometric relationships to the knowledge graph. At the same time, the path-finding algorithm was used to enrich the semantic linking between the critical HVAC components (e.g., terminal2VAVbox, VAVbox2system, system2pump). The knowledge graph generation was based on the integration of two open-source ontologies, named BrickSchema Brick Consortium (2019) and FSO Kukkonen et al. (2022), as described next.

Knowledge graph generation

BrickSchema, developed by Brick Consortium, standardizes semantic descriptions of the buildings' assets/devices and their inner relationships, which was introduced into this work to represent the HVAC components with a series of Brick entities (`brick:Room`, `brick:Terminal_Unit`, `brick:AHU`, `Brick:DOAS`, `brick:Chiller`, `brick:HX`, `brick:Pump`, and so on). As a supplement, the Flow Systems Ontology (FSO), which focuses on interconnected systems and their energy flows, was incorporated to model both pipework and ductwork segments by using FSO entities (`fso:Segment` and `fso:Fitting`). Furthermore, within the scope of geometric relationships among HVAC elements, `brick:isAssociatedWith` is used to denote connectivity relationships, that is, connectivity pairs resulting from clashes and adjacencies because these detected geometric relationships were downstream/upstream direction agnostic. Regarding the containment pairs, `brick:isLocationOf` was introduced to indicate the containment relationships with specific directions (e.g. space - isLocationOf - system).

Path-finding

In this study, a path-finding algorithm was utilized to discover routes between distinct entities within the knowledge graph by analyzing multi-hop connections. These routes were established among terminal units (such as air terminals), source systems (such as AHUs), and potential nodes (like VAV boxes) that might exist between the source and terminal units within air loops. Similarly, connections were formed between AHUs/FCUs, pumps, and heat exchangers or chillers within the water loops. These routes collectively formed the final HVAC topology. In this topology, the `brick:isFedBy` relation was used to replace the `brick:isAssociatedWith` relation between the critical HVAC components connected via path-finding. The flow direction along these connection links was determined by the ID of the connected elements, wherein each element's ID contains a specific string indicating whether it pertains to an air supply or an air return unit. Figure 3 illustrates how path-finding contributes to the generation of an HVAC topology instance.

In terms of algorithmic methodology, the Depth-First Search (DFS) path-finding algorithm was introduced to convert the generated knowledge graph into the final HVAC topology. DFS prioritizes depth, exploring as deeply as possible along each branch of the graph before backtracking. Additionally, DFS offers the flexibility to omit particular nodes from the search process. For example, when seeking a route from Terminal 1 to AHU 1, other AHUs can and should be excluded. It is essential to prevent path-finding processes from entangling within water loops and air loops. Two simple approaches to accomplish this are splitting the knowledge graph into distinct subgraphs or assigning a specific attribute to knowledge graph links to distinguish connection relationships.

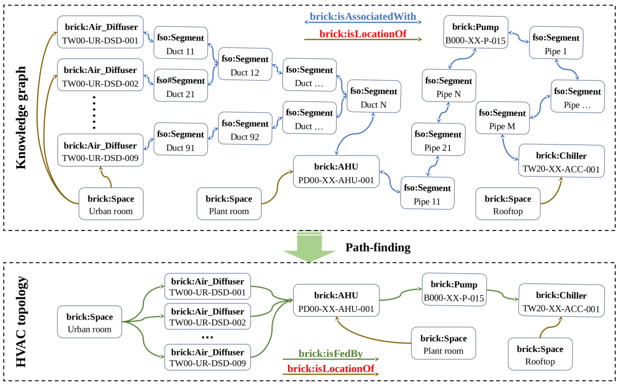

Figure 3: Illustration of the path-finding process to transform the knowledge graph into the HVAC topology.

BIM error handling

Although the preceding workflow's processes are executed automatically, errors within the BIM data can result in either zero or multiple paths detected, from the supply to terminal units. Alternatively, it might be found that one air terminal unit is linked to multiple AHUs or FCUs. These errors manifest in four distinct types, as illustrated in Figure 4, which include:

(a) An abnormal clash is an incorrect intersection among MEP elements that is due to design errors.

(b) A missing element is the absence of an MEP element in a sequence of connected elements.

(c) A geometric mismatch is a misalignment of MEP elements that leads to connection absence.

(d) A space containment issue occurs when a building space volume does not contain or does not intersect, at least, with a solid geometric representation of a terminal unit.

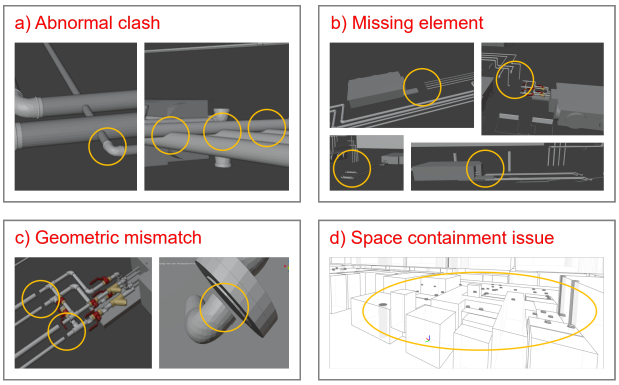

Figure 4: BIM error-type illustration examples

Error types (a), (b), and (c) impact the established routes from the supply to the terminal units within the HVAC domain, while error type (d) influences the containment connection between terminal units and their corresponding building spaces. Visual inspection is applied on the detected paths from supply to terminal units, and on the building space volume geometries, to pinpoint these errors. Subsequently, manual corrections are implemented on the produced knowledge graph to rectify the affected graph nodes and edges.

Case study

The introduced process was applied to BIM data from a new building, named One Pool Street (OPS) located at the UCL East Campus. OPS is a multi-function building that uses a state-of-the-art energy supply and management system. This work concentrated on the automatic generation of the HVAC topology of the podium part of the OPS building. The HVAC topology of this building part is ideal for demonstration purposes, as its energy supply system is complex and includes a set of diverse ventilation units. For cooling purposes, several Air Handling Units (AHUs) are installed with chilled water and hot water units that supply thermostatic air via hundreds of air terminals during the summer and winter periods. Additionally, Fan Coils (FCUs) are also used in some rooms to meet their cooling and heating requirements. Door heaters (DHs) and air curtains (ACs) are also installed for heating purposes only. Besides, Mechanical Ventilation Heat Recovery (MVHR) systems are installed to recycle the waste heat and improve energy performances in several building spaces. Consequently, the manual generation of the HVAC topology for these complex systems is a time-consuming and error-prone process. Hence, the OPS podium was selected as a case study to illustrate the effectiveness of the proposed workflow.

Figure 5 illustrates the 3D representations of the contents found in the ARC-IFC and MEP-IFC files, which encompass both air loops and water loops of the OPS podium. In terms of data quality, the Level of Development (LOD) for the IFC4 file varies between LOD 300-400 (following US standards) and LOD 4-5 (according to UK standards). This file comprises over 22,000 MEP elements, posing a significant challenge due to memory limitations on standard computers when handling MEP-IFC files. To address this challenge, it was imperative to divide the MEP-IFC file of the OPS building into two smaller IFC files, specifically focusing on air loops and water loops.

Results and discussions

In this section, the performance of the proposed workflow and its limitations are also discussed.

Established HVAC topology

The proposed workflow was conducted on a laptop computer, and the geometric relationship checking process consumed the most computing resources of the workflow. The geometric relationship checking between air terminals and spaces took several minutes and involved approxi-

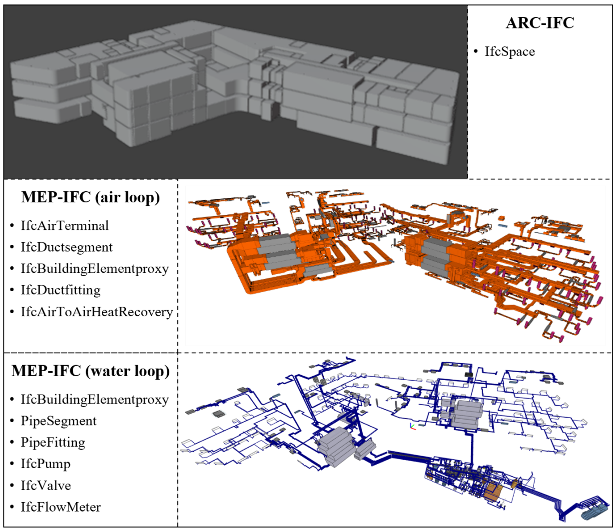

Figure 5: Visual representation of the content of ARC-IFC and MEP-IFC files.

mately 84,000 element pairs. The checking process among the HVAC elements took a few hours and involved approximately 38,000,000 pairs within air-loop elements and 101,000,000 pairs within water-loop elements. In addition, the path-finding process to link terminals, systems, and pumps, took dozens of minutes.

Figure 6 displays a part of the generated HVAC topology referring to Room 101. In this figure, the return air terminals are hidden because they are not as significant as the supply air terminals from the energy simulation perspective. Within the air loops, the air terminals (displacement diffusers) were identified successfully, and the VAV boxes within the duct network were also detected, defining the paths from the system (AHU) to air terminals (DSDs). Since the air terminals had IDs with the special string (DSD: displacement supply diffuser), the directional relations `brick:Feeds/brick:isFeedBy` were determined, linking the air terminals with the system. In the context of water loops, Figure 6 highlights the connection of four chilled water pumps and two hot water pumps with this AHU. However, the uncertain status of the valves, particularly the bypass valves, presents a challenge. This uncertainty makes it impossible to ascertain which pumps are on standby and which are operational, or to determine their positioning relative to the AHU, whether upstream or downstream. Hence, in the HVAC topology, the directional relations `brick:Feeds/brick:isFeedBy` were determined to illustrate the links between pumps and AHUs. Similarly, this approach was also applicable to establishing links from heat exchangers to pumps. The entity inventory of the original IFC files and the HVAC topology are both depicted in the right portion of Figure 6. The podium section of the OPS building comprises approximately 8,800 air-loop MEP entities and over 13,900 water-loop MEP entities, which are integrated into the proposed workflow. Approximately 7,000 of the air-loop entities are modelled using boundary representations and require ad-

ditional checks by the GRC tool for potential surface errors. However, this step will become unnecessary in the future if boundary representations are substituted with parametric ones.

MEP element - Space containment issues

Accuracy is one of the critical indicators for validating the performance of this HVAC topology-generation workflow. In this case, the HVAC design drawings of the OPS building were also obtained and acted as a reference point for validation. Figure 7 shows the statistical results of the semantic linking between the air terminals and the podium spaces. More than 70% of the air terminals were linked to their correct spaces. However, about 18% of them were not linked to any spaces because there are design errors in the geometry of the spaces in the IFC file, e.g. some spaces are not extended high enough to reach the ceiling surfaces. Additionally, elements with surface errors caused delays when conducting the GRC executions since pairwise element clash checking requires at least one of the elements in a pair, to be surface error-free. Meanwhile, nearly 8.5% of the air terminals intersected with more than one space, requiring manual work to decide the correct space. The reasons for these misalignments are mainly surface errors (requiring the OBB check) and design errors (human errors), both of which are related to the data quality of the geometric representations of the elements. The suggested workflow can efficiently identify the geometric containment relationships between air terminals and spaces, as long as the input IFC file reaches LOD-4 level or beyond.

MEP element connectivity issues

Another critical aspect of an HVAC topology pertains to the connection between air terminals and systems. Figure 8 illustrates the efficacy of the proposed workflow in identifying paths from air terminals to systems within the air loops. Initially, only half of the air terminals were accurately linked to the correct AHU, MVHR, and FCU, as depicted in Figure 8 (a), before addressing the errors. This discrepancy arose due to the dense arrangement of ducts,

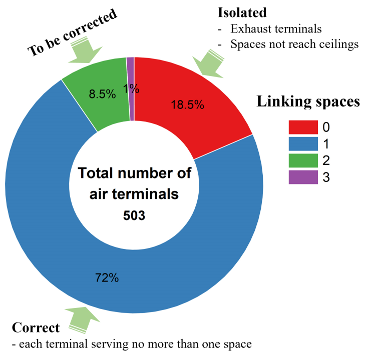

Figure 7: The distribution of air terminals and the number of their linking spaces.

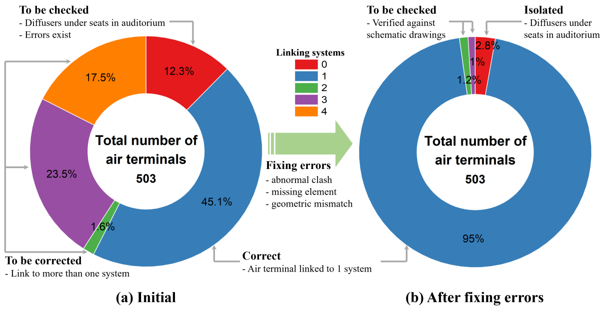

Figure 8: The distribution of air terminals and the number of their linking systems.

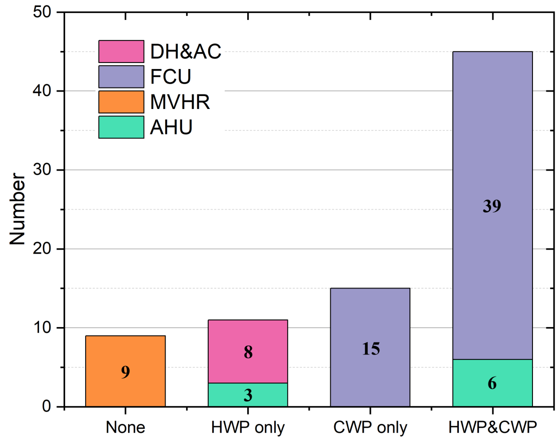

Figure 9: The distribution of units and their HWP/CWP connections.

often closely positioned near the systems. The GRC tool's capability to manage such placements is hindered by surface errors affecting these elements. Consequently, in situations where both elements of a pair exhibit surface errors, rendering clash detection impractical, the OBB method serves as an alternative, albeit less precise than the GRC tool. Furthermore, around 12% of air terminals faced challenges in establishing connection paths with systems. This hurdle arose from certain terminals being designed independently from other air-loop elements, such as diffusers situated beneath seats in auditoriums. Additionally, some instances involved design errors, evident in Figure 4 b) and c), where gaps exist between these elements and adjacent ducts. Adjusting the GRC threshold for adjacency checking proved effective in addressing this issue, although it carries the risk of detecting connections that do not actually exist.

Moreover, the initial results revealed that approximately 40% of air terminals remained connected to more than one system due to BIM design errors as previously defined. Most of these instances stemmed from the alternative OBB method, which erroneously identified nonexistent intersections between bend ducts positioned in parallel and very close proximity to each other. After manual efforts to correct the detected errors in the generated knowledge graph, the path-finding process was reexecuted on the updated knowledge graph. The statistical results of this process can be found in Figure 8 (b). Notably, 95% of the air terminals were accurately linked to the systems (AHU/MVHR/FCU), while only 2% still required verification against schematic drawings. It is advisable to verify the remaining 2.8% (isolated air terminals) against schematic drawings to ensure the completeness of the HVAC topology.

Furthermore, Figure 9 illustrates the results (after error correction) of the water-loop units in the established HVAC topology. In the OPS building, there are a total of 80 water-loop units, including AHU, MVHR, FCU, DH, and AC, within the water loops, supplied by Hot Water Pumps (HWPs) or Chilled Water Pumps (CWPs). Using the path-finding method, it is possible to determine connections between each unit and HWPs, CWPs, or both.

As depicted in Figure 9, among the 9 AHUs, 6 are linked to both HWPs and CWPs, while the remaining 3 are solely connected to HWPs. None of the 9 MVHRs are connected to either HWPs or CWPs. Of the 54 FCUs, 39 are connected to both HWPs and CWPs, with the remaining 15 solely linked to CWPs. All DHs and ACs are connected exclusively to HWPs. Additionally, this path-finding method could be extended to examine the 93 Radiators (RADs) in the OPS building for their connections to HWPs, although this is not detailed here due to length constraints. Finally, all mentioned results have been validated against the schematic drawings.

Limitations and implications

The effectiveness of the framework was assessed through a case study involving a complex HVAC system, revealing various challenges related to the accuracy and completeness of the HVAC topology when dealing with imperfect MEP-BIM data. Initial inaccuracies were attributed to human errors in BIM design and surface errors in the solid geometric representations of certain MEP-BIM elements, which hindered the effectiveness of the GRC tool. Additionally, a complication arose from adjacent duct entities in the BIM model that were not physically connected, a discrepancy not detectable through geometric relationship checking alone. While this study successfully identifies and locates these errors, manual correction remains necessary and time-consuming.

Conclusions

To automate the creation of an HVAC topology, this study introduced a framework utilizing ARC-IFC and MEP-IFC files as BIM input data sources. Initially, semantic checks were conducted using relevant IFC relationship classes to extract connectivity pairs. A hierarchical checking workflow was then employed to infer missing semantic relations. In the workflow's initial stages, the Geometric Relation Checking (GRC) tool facilitated pairwise adjacency, clash, and containment relation checks among MEP and space BIM entities. If surface errors were reported in the geometric representations of BIM elements by the GRC tool, the clash and containment detection were carried out using the OBB process. Ultimately, this process yielded a set of connectivity and containment pairs. Subsequently, a knowledge graph-based HVAC topology, encompassing air loops and water loops, was generated by applying the DFS path-finding algorithm to the obtained connectivity and containment pairs. A case study involving a newly constructed building was conducted to test the framework's performance, demonstrating its feasibility in various and intricate modern HVAC systems.

In the future, significant improvement can be achieved by incorporating a module that converts the IFC geometries to watertight solid boundary representations. This can speed up the process substantially by reducing the need for surface error checking. Meanwhile, beyond the current building case, the plan is to implement the framework in other scenarios to enhance its generalization capabilities. Besides, further investigation will be undertaken to determine how the generated HVAC topology can be leveraged to enhance BEM models that contain information related solely to the building fabric. This effort aims to support the automatic establishment of active components within the HVAC domain, thereby supporting the development of BEM2BEM research.

NAVIGATING BUILDING STANDARDS AND BUILDING WARRANT PROCESSES IN SCOTLANDBUILDING INFORMATION REPOSITORIES

Daria Belkouri[1], Ho Man Yau[1], Theodoros Dounas[2], Jamie Yorkston[1]
[1]Robert Gordon University, Aberdeen, United Kingdom
[2]University of Antwerp, Antwerpen, Belgium

Abstract

Our paper explores the improvements needed in navigating building standards and workflows for building warrant processes in Scotland. We examine this optimization through the lens of user experience, information and data flow, with the directive of improving the service provided to citizens by the Scottish government. We utilized the development of a web application and a digital process map as vehicles for engagement, developing knowledge for improvements and optimization through qualitative methods. The paper concludes with a discussion and proposals for improving the process, including the use of linked data, BIM, ontologies, and blockchain in an upgrade of the process.

Introduction

Governments establish laws, rules, and regulations relating to the built environment in order to safeguard the well-being and safety of their citizens. In the UK, the multitude and complexity of technical requirements and associated legislation for reviewing construction designs and providing building warrants as well as inspections during construction ensure that the building warrant issued for the structure is constructed according to design (Fauth et al. 2023). Acquiring a building warrant holds significant importance in any construction project, serving as a foundational requirement for its lawful execution. On a global scale, the issuance of construction permits remains a complex and error-prone procedure, often characterised by a substantial time commitment and influenced by subjective judgments (Malsane et al., 2015). One contributing factor to the limited implementation of quick complete automation in public administration is the absence of a comprehensive legislative framework, as well as a lack of societal acceptability. Furthermore, building officers responsible for overseeing building permit processes express reservations about the integration of digitization and the use of digital tools such as Building Information Modelling (BIM) models (Fauth, 2023). Additional reasons might be the lack of comprehensive and commonly agreed-upon standards for the processing of information, the lack of interoperability between data pools and databases, and the need to keep the process accessible to non-experts. For this particular reason, the acquisition of a building warrant holds significant importance in any construction project, serving as a fundamental requirement for the lawful execution of the project.

This research project involves the development of a map for navigating the building standards (BS) and building warrant (BW) process of the Scottish government, in the auspices of a larger project that aims to improve the digital delivery of the building standards and regulations. We used two vehicles of engagement to enhance our understanding of the building standards and the building warrant process: a prototype of a web application for the BS and a procedural map for the BW. The paper examines the knowledge and output from these two engagement tools.

Background

Building Standards in Scotland and the United Kingdom – relationship between government and local authorities

The digitisation processes of managing data in the Architecture, Engineering, and Construction (AEC) industry have been recently widely encouraged (Hobeika et al. 2022; European Commission 2021). The Building Standards division in Scotland is driving the digital transformation of building standards and the building warrant process. The traditional way of manually handling and assessing the building warrant applications can be prone to error - an activity that requires a high level of effort from all parties from different disciplines involved (Ullah et al. 2022). There has been a need to improve the building warrant completion process recognized, and this research acknowledges the many disjointed data landscapes – i.e fragmentation between the planning process and design, and a lack of orchestration between data pools/data silos needed to create a well-coordinated digitized system that has all the required functions to smoothly handle the process of building permit acquisition – from online submission, review and management of the applications. In 2017, the e-development platform was introduced (and managed by the Scottish Government in partnership with all Scottish local and planning authorities), providing the ability to digitally submit planning and building warrant applications. The portal is a complimentary digital service established by the Scottish Government in collaboration with all Scottish local authorities. It enables users to fill out and submit online building warrant applications, completion certificates and other relevant forms relating to the entire building standards system process. Yet, the current process of applying for approval documents - building warrants and completion certificates, comes with a myriad of complexities associated with the process that involves many stages and stakeholders along the journey. The e-development portal acts as a digital transition point between the applicants and local authorities but comes with its limitations (for example the size of data that can be uploaded onto the portal or communication of the inspection services) that need to be overcome by using complimentary data transfer options and direct email correspondence between the verifiers and applicants/agents outside the e-development portal.

The building standards as an information repository

This project aimed to create innovative processes for digitising the delivery of building standards information and processes associated with building warrant application, up to obtaining the completion certificate at the end of the permission journey. Additionally, the project focused on understanding the experiences and journeys of various stakeholders as they navigated building regulations and building warrant processes, which involved the provision of inspection services.

To achieve the objective, the research team started with the creation of a persona corresponding to each stakeholder group, which was then prioritised for testing purposes – with a focus on the less technically inclined. A customer journey mapping exercise followed, which determined the measures for success. In the second phase, we developed a minimum viable product (MVP) app and a map of the building warrant processes, using digital frameworks including Figma and WIX.

We focused on creating a web application prototype that will allow a range of stakeholders to navigate the building standards on their mobile phone or laptop/desktop computer in a swift and efficient, manner. The prototype allowed the usability testing of the navigation of the information repository of the Scottish Building Standards while allowing for various types of linkages to be developed following linked data and embedding approaches.

Research Questions

The project seeked to answer the following questions to achieve the objective, by conducting a thorough investigation into the requirements of navigating the building standards and the inspection services throughout the building permit journey.

- How can we improve the navigation of the expanded universe of the Scottish Buildings Standards, for all stakeholders, using an application, enhancing the enabling vectors, and minising restrictions in the day-to-day usage of the building standards?
- How can the building warrant journey and inspection services in Scotland be improved and streamlined?

Methodology

We used a mixed methods approach involving both the development of personas from social sciences but also design science research where we developed a computing prototype and a digital map that we then used as an engagement tool to arrive at recommendations. Our adopted methods for this study were based on a hybrid model of combining the development of digital prototypes - web applications and a digital map of the BW process with the engagement of a focus group of professionals that would use the app and then respond live to questions and a discussion, and then interviews with lay people who would also use the app and respond to a semi-structured set of questions. Essentially, the process of developing computer prototypes was interwoven with qualitative data collection methods derived from social science and user experience research. The framework diagram (Figure 01) is available on Github [1].

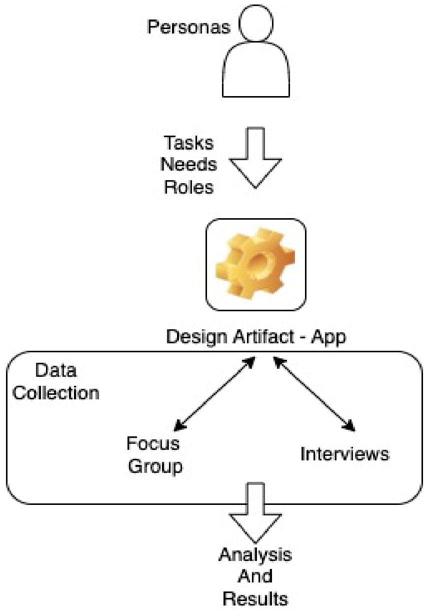

Figure 1: Overall Framework Diagram

Vehicles for research

Personas

Our qualitative methods for this study encompassed various stakeholder engagement activities (focus groups, interviews and, questionnaires) as well as the creation of PERSONAS for each key user group which helped to provide context to [web and mobile] application design for Building Standards navigation and streamline processes involved in the building warrant completion process. The engagement strategy was tailored to pinpoint the specific profile of each user type [for lay people, the general public, and professionals] and their anticipated interaction with the digital tools [web and mobile application] for data management and to develop a series of improved workflows for building warrant completion.

The method of personas creation in user experience research helps to define and understand users' needs, goals, pain points, challenges, and behaviours. The user profiles help make more informed decisions and designs that takes into account diverse user perspectives fostering a user-centred design approach. In this study, through our stakeholder engagement strategy and iterative design processes, we have created different user profiles of professionals: agents [architects, architectural technologists, surveyors, and engineers], verifiers - building officers, consultants [environmental, fire etc] and the general public in order to tailor the proposed digitisation technology and address the various user behaviours and diverse preferences. During the iterative process of engagement (using various qualitative methods – focus groups, interviews, and questionnaires) the stakeholders were asked about their occupation and objectives related to their work [Context]. They were also requested to provide information on the challenges and obstacles related to the building warrant process [Actions, Motivations, and Pains] as well as best practices and motivations [Values] that could drive the improvements in the process (Figure 2). The information gathered from personas helped to inform the design approach of our engagement tools. Essentially our methods are firmly based on social sciences, using however the design of the web application and the map of the digitised process as design artefacts and engagement tools, with which we build knowledge via the engagement with the participants. Further knowledge building took place through a search through the design space for the web application and the gaps highlighted in the map of the digitised process of the building warrant.

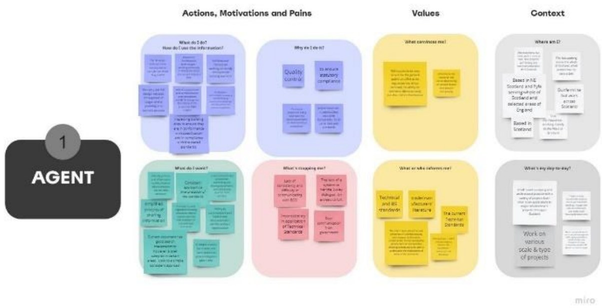

Figure 2: Personas map showing and example of an agent involved in the building warrant process.

Web App

Application Development Stage

Figure 3 showcases the initial web prototype developed in Figma. The proposed mobile application prototype was presented and tested through focus group interviews with professionals in the building construction industry. This prototype was being tested and feedback from different personas was. This prototype was mainly focused on testing the performance of the UI and UX. The structure of the prototype followed the proposed swimlane diagram and the customer journey issued by the Scottish Government: Stage 1 Before you apply for a building warrant; Stage 2 Apply for a building warrant; Stage 3 Local authority assesses your building warrant application; Stage 4 Building warrant is granted by your local authority; Stage 5 Building work (or conversion) starts; Stage 6 Changes to the building warrant design; Stage 7 Building work (or conversion) is complete; Stage 8 Local authority accepts your completion certificate.

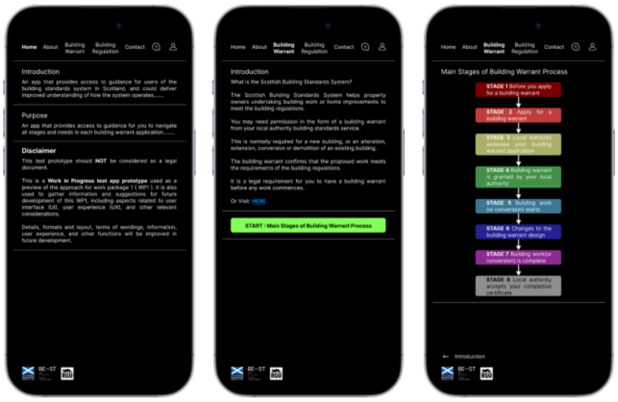

Figure 3: Showcasing Screenshots from Figma Prototype

The feedback from the participants was positive and overall UI and UX were easy to understand and follow. However, there were few participants who pointed out the accessibility of the application. There would be an issue for users to access from the office since they would be mainly accessing from desktops/laptop devices rather than mobile devices. Therefore, based on the feedback, the approach of the development is also considered to improve the accessibility of the prototype.

The Web Application (Web App) was further developed using the wix.com platform, utilized in this project in order to maximise the accessibility for different users from mobile devices, tablets, and desktops that is able to optimize accessibility across various platforms. The web app prototype focused on navigating the building standards for building warrant applications for the general public. The structure of the application is illustrated in Figure 4, while its interface on Figure 5.

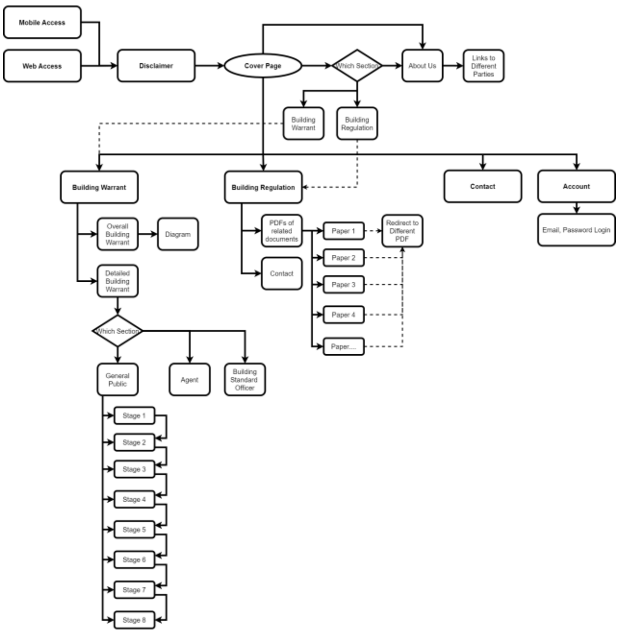

Figure 4: Overall WebApp prototype structure using Wix.com

In order to make the web app more interactive and user-friendly, simplified languages and guidelines of the application, highlighting key actions, and related building standard documents are being added during the web app development (Figure 5). The web app prototype is available on Wix.com [02].

Figure 5: Showcasing Screenshots (Left: mobile, Right: website) from WebAPP (Wix.com) Prototype

The Building Warrant Process

Investigating and recreating the swimlane diagram helps visualise and explain the whole process of all parties involved in building warrant applications. Figure 6 illustrates the full process of the building warrant application, and Figure 7 showcases an overview process of building warrant application. Both application processes followed the stages written in the document issued by the Scottish Government, with meetings and discussions with members from the Building Standards Division of the Scottish Government to prepare and finalise the process of building warrant application.

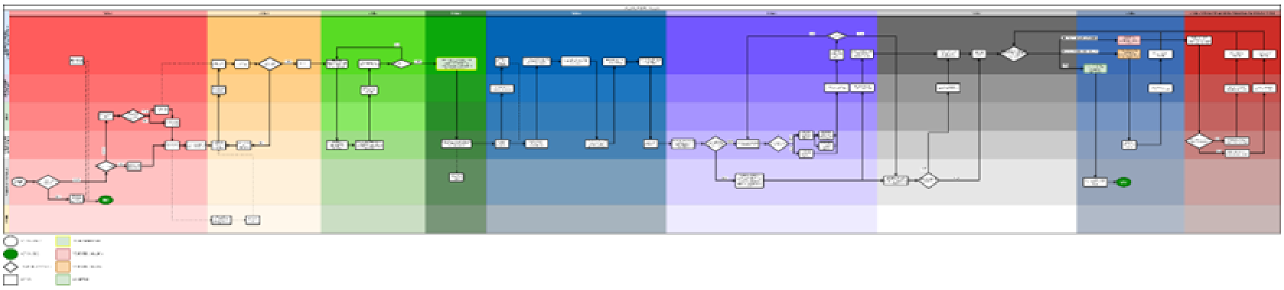

Figure 6: Whole Process of Building Warrant Application

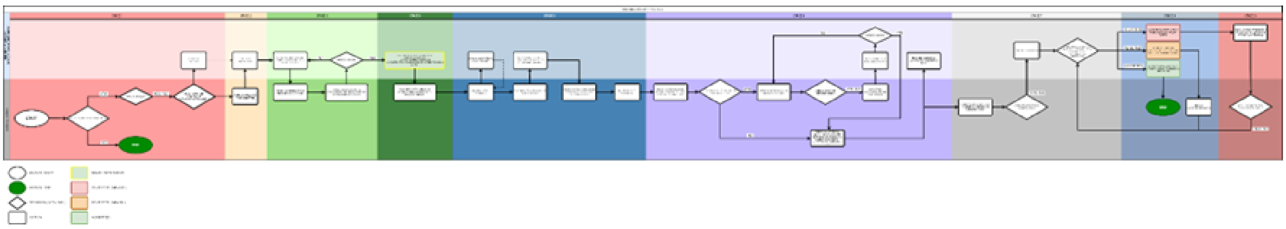

Figure 7: Overview Process of Building Warrant Application

The swimlane diagram uses mainly three shapes to identify the actions for the readers to understand. (1) an Oval shape, representing the starting and ending action, (2) a Diamond shape, representing the decision needed to be made, and (3) a Square, Action happened.

Figures 6, and 7 illustrate the whole process of building warrant application, the process was divided into 8 + 1 stages:

1. Before you apply for a building warrant.
2. Apply for a building warrant.
3. Local authority assesses your building warrant application.
4. A building warrant is granted by your local authority.
5. Building work (or conversion) starts.
6. Changes to the building warrant design.
7. Building work (or conversion) is complete.
8. Local authority accepts your completion certificate.
9. Local authority rejects your completion certificate.

Moreover, the swimlane diagram includes all sections carried by all parties being involved in the process, from a top darker colour to button lighter colour: (1) Building standard officer/ Local authority; (2) eDevelopment Scotland; (3) Agent, a professional who handles the application on behalf of the client; (4) Shared action (Agent/ General public), actions are similar on both parties; (5) Member of the public; and (6) Other, Specialist that involved during the application.

Through several structured dialogues with members from the Digital Strategy and the Building Standards Division, our team analysed the BW process and developed a swimlane diagram of it. While analysing the process of building warrant applications, it was essential to identify all actions (being carried out by different parties), and stakeholders being involved in the application process. Despite the rich documentation published by the Scottish government, none of it was comprehensive and integrated, confusing and misleading its users. Furthermore, the application varies between different councils in Scotland, each council has a slightly different set of explanations and technical requirements. Moreover, eDevelopment Scotland mainly acts as a digital mailbox between applicants and councils, i.e there is no central storage of the data. eDevelopment lacked connections between both platforms and applicants and may lead to a slower process of applications, as the applicants submit to eDevelopment, but receive answers from each particular council which is responsible for their application. Furthermore, building regulations may be interpreted subjectively by different building standard officers, leading to inconsistent application of rules. This creates confusion and unfairness for the applicants.

Data collection and analysis

Focus Group

The initial data collection was conducted through an open invitation online focus group that was distributed through social media channels (LinkedIn and Eventbrite). The focus group participants that signed up for the workshop involved an expert group representing the built environment industry including architects, technologists, quantity surveyors, building physicists, building inspectors, and sustainability consultants working on a variety of project types and scales (interiors, existing buildings, retrospective works, or large-scale education projects) offering full design services throughout all RIBA stage (Figure 8).

Figure 8: Focus group participants

Questionnaire

The questionnaire was issued in the advanced phase of developing the engagement tools timeline which allowed the research team to refine the questions and gather valuable feedback for both work packages. The questionnaire respondents were asked to review the streamline diagram embedded into the survey. The majority of respondents were aware of the overall process of getting a building warrant permission, however only 60% were familiar with the official documents explaining the process. This suggests that an online platform or indeed an interactive diagram with embedded links/images/explanatory documents and videos could be a future useful improvement in making the customer journey through the building warrant process more approachable and easier to understand when asked about the challenges associated with the permission process the participants indicated 'Contacting officers to discuss points raised " and "Technical innovation / alternative approaches", timescales - 'lengthy process', individual interpretation of technical observations and general interaction with the local authority as issues contributing to the complexity of the process. The direct impressions from the diagram indicated that the simplification could be considered as one of the participants commented: 'Far too complex, much simpler in practice/not needed to be explained in that much detail'. Additional comment was raised about the wording of certain stages in the process not adhering to the RIBA Plan of Work Stages. This, however, was predetermined in the official document released by the Scottish Government - 'Making a quality building warrant application - what you need to know' *gov.scot (www.gov.scot).*

The issues of acceptability and potential client-agent relation issues were also raised due to the possibility of progress tracking ability and potential liability of delays in the process being shifted to the agents: 'Any direct involvement from the client in this process would likely only result in further client-agent relation issues. [...] I feel it only opens the chance for a client/BCO to be able to lay blame on the agent unnecessarily. This whole idea could result in overconfident homeowners not appointing an agent.'

However, the overall functionality, clarity, and usefulness of the building warrant timeline were positively rated noting that the relevant information was included within the diagram and that the schematic was relatively easy to follow with legible content. Most of the participants were also in agreement that the best practice to move forward in the process would be an online platform to comprehensively process the application with improved liaison with the building inspector (and local authority prior to submitting the application); reminder of scheduled inspection, automated reporting on the status of the application with the ability to track progress and be aware of the 'next steps' in the application. The mobile [web] application was also mentioned together with notification of the required actions and responsibilities for those involved in the process as useful features that could be embedded in future digitisation of the customer journey diagram (Figure 9).

Results and Discussion

In this project, we designed and published a web app prototype focused on providing a platform for the general public to navigate the Scottish building warrant application processes and other related documents of the Scottish building regulation. The prototype streamlined the application process and made the application process more accessible and interactive for members of the public. Through prototype testing and a series of interviews, it shows the potential of web application prototypes to enhance the accessibility and user-friendliness of the navigation process of Building Standards and Building Warrants for the general public. The outcomes of this phase of the prototype show a huge potential for further exploration and development for impact. Through the interviews, we have observed that by simplifying the content of the building standard and building warrant application into illustrations and or plain language we can help a broader audience (members of the public and professionals) to understand easier, without requiring professional high level skills. These enhanced by interactive elements in the app provide clarity to the user experience.

The proposed web app prototype would be beneficial for users to navigate and understand the process of the building warrant applications and other building standards. However, for this project, we recognize that the approach of the research has the following limitations. The navigating framework mainly focused on the members of public access. The needs and usage habits of professionals such as: architects, architectural technologists, building standards authorities, etc. will be different compared to lay people. This prototype used a no-coding platform as the approach of the framework, thus not allowing full customization of all parameters as a full-from the ground -up application would provide.

Beyond the limitations presented here, the proposed web application prototype and interviews show the potential of developing a building standards hub or platform for different stakeholders to navigate the Scottish building regulations integrated with the process of building warrant application. There is different research (Kim, et al, 2020., Zhong, et al, 2018., Zentgraf, et al, 2023) showing that the frameworks are available to fill the gap and to develop a more effective navigation platform for building standards.

We summarise here the directions that this platform could encapsulate: Personalised user profiles where one can save searches, encourage users to revisit topics, easily picking up their trail from a previous visit, along with bookmarking frequently used documents or sections of the documents. Additionally the use of linked data approaches between the text of the regulation and building standard and real examples or guidelines of application would enhance the experience of the user and reduce ambiguity in the regulations. Further, a focus on navigation on building types could be developed. At the moment, when navigating the standards, the user has to choose between domestic or non-domestic regulations and there are cases where categories span both texts. Any platform of course would have to Consider mobile and web applications (user dependent). In order to maximise the flexibility of this application, both mobile and web applications for navigating Scottish building regulations and warrant content enhance the accessibility in the building environment community. Mobile applications such as smartphones, or tablets allow users to access the navigation app in different locations; websites otherwise were designed aimed at office users. Cross-platform allows users to choose their preferred platform and enhance accessibility. Although this prototype has not explored the potential of a Progressive Web App (PWA), such an approach allows offline access in the mobile background that benefits users offshore, and in highland, areas that have no internet connections; Installing the app into the mobile devices, PWA also allow users to download the app and access the content even when there are no internet connections (web. dev, 2023).

Finally, Design compliance tracking tools. Implementing tracking tools in the future development of the web app enables monitoring updates of building regulations and responses from building standard officers. For example, questions on clarifying unclear sections of action during applications or anticipating results of the submission of applications. Furthermore, a direct mailbox as a single point of contact between the user and the authorities, helps individuals to keep track of all actions that have been taken. Additionally, automated alerts are another potential feature that would help guide the applicants to stay on track and generate alerts when deviations are being detected. Such features may help to minimise errors during application.

Conclusions

Within this research study, we analysed the navigation of the building standards of the Scottish government and identified the actions and stakeholders involved during the application process of a building warrant in Scotland. We used a web application and a digital schematic diagram appropriately developed. Our work produced a number of key critical inflection points in the building warrant application and developed a set of guidelines for improving the navigation of the building standardfs.

Further work could include holistic implementation of thorough digitization and standardisation process in the planning process, ie starting from planning permission to the building warrant, a journey that should include a set of newer technologies such as building information modelling, linked data and potentially the use of blockchain for the data that need it.

In this context, different potential digital applications may assist and improve the technological barriers during building warrant application processes. Blockchain and Ontology offer a different approach for future improvement, in improving the quality of the application processes, and user-friendly experience. Blockchain offers a secure and shared system for storing information (Dounas, 2022). Ontology helps to organise and standardise information and data management (Zentgraf, 2023). These approaches provide a huge potential in improving the current system of building warrant applications, improving the application processes, and the security of the data.

Authorship & acknowledgements

HMY and DB wrote most of the report and the present paper, DB developed the engagement methods -personas, focus group, interviews, and the questionnaire, conducted data analysis and provided recommendations; HMY build the engagement tools – web & mobile application and streamline diagram; conducted analysis of the engagement tools and provided recommendations; JY developed the outline of the process for the building warrant in WP2 and contributed to the personas, questionnaire and data analysis, TD conceived, organised and directed the research, determined the structure of outputs and their quality and contributed to the authorship of the report and papers. HMY and DB can both claim first authorship of this paper.

HARMONIZING INPUT DATA FOR DIGITAL BUILDING TWIN: ENERGY EFFICIENCY USE CASE

Audrey Bouet[1], Nicolas Bus[1], Stoyan Danov[2], Eloi Gabaldon[2], Edgar Martínez-Sarmiento[2], Nicolas Pastorelly[1] and Guillaume Picinbono[1]

Abstract

In this article, we present a "Harmonizer module", based on RML mapping language, SPARQL[1] and RDF, which allows importing heterogeneous data sources into a unique Building Energy Analysis-oriented ontology. This work is being performed in the context of the H2020 BIGG project[2]. The Reference Architecture Framework designed by the project leverages the specific ontology which is used as a harmonized input for the unique BIGG Data Analytics Toolbox that creates various building-energy related insights. The Harmonizer module receives inputs from different kind of building energy analysis data (such as: location, building structure, sensor data, time series), formats them and maps them to the concepts defined in the BIGG ontology. This paper will introduce the objectives of the BIGG project, a description of the BIGG ontology before describing the workflow and the functionalities of the Harmonizer module, it's implementation and current results.

Introduction

Prominent parts of the National Energy Efficiency Action Plans of the EU countries are dedicated to strategies for increasing the energy efficiency in buildings. These plans include overviews of countries' building stock, policies for stimulating the renovation rate, including estimates and projections about the energy savings and carbon dioxide emission reductions from applications of different measures.

The increasing availability of data from smart meters and digital sensors in buildings has enormous potential to support the more efficient use of buildings. However, this requires the capability to collect, harmonize, and jointly process data from a variety of different sources. This problem is tackled by the H2020 BIGG project which has the objective to substantially facilitate the deployment of energy-related big data analytics for buildings and to support a large variety of business cases. BIGG develops a Reference Architecture and an Analytics Toolbox, supported by a common data model (BIGG Ontology) and a Harmonizer module for aligning data from different sources and providing them as an input for the common Analytics Toolbox.

This paper focuses on the presentation of the Harmonizer module designed for the conversion of external heterogeneous data formats into RDF complying with a targeted ontology. It has been created and exemplified in the context of the BIGG ontology for Energy Oriented Building Digital Twin but can be applied to any other ontology. The BIGG ontology is briefly addressed, but a detailed discussion on it is out of the scope of this paper.

Related works

The BIMERR (Boutouni et al., 2021) project is a research project aimed at developing and promoting the use of Building Information Modelling (BIM) in the construction industry. This project provides a tool called BIMERR Interoperability Framework (BIF) to ensure data exchange among applications. BIF utilizes mechanisms that enable semantic and syntactic interoperability. BIF uses the RMLMapper library (Dimou et al.,2014) and benefits from RML mapping to convert and align heterogeneous data into interoperable RDF data. Unfortunately, BIF neglects how to convert data based on an external taxonomy to a common interoperable taxonomy.

Similar attempts to populate Digital Building Twin ontology from heterogeneous data have been initiated through the COGITO platform (Katsigarakis et al., 2022). COGITO mainly uses transformation tools based on RML mapping to transforms data concerning building description such as IFC and store them in a knowledge graph. Data collected by sensors are stored separately in a dedicated time series database. This approach doesn't benefit from knowledge graph to ensure interoperability between static data and timestamped observations.

Several solutions have been proposed to map semi-structured data to RDF. The SweoIG taskforce has built a list of implementations also called RDFizer (Iglesias et al., 2020). Most of them are dedicated to a specific format or model. We focused our analysis on those who reach the project requirements: extensible language with call to user defined functions, model agnostic and fully compliant with W3C recommendations.

RML is one of the approaches that allows mapping between various sources toward RDF. RML is an extension of the R2RML vocabulary to describe logical

[1] SPARQL. https://www.w3.org/TR/sparql11-query/
[2] Building Information aGGregation, harmonization and analytics platform, H2020 funded project. https://www.bigg-project.eu/

sources. It generates RDF from JSON, CSV, or XML sources.

SPARQL-GENERATE (Lefrançois et al., 2017) is based on a query language that queries the combination of an RDF dataset and a set of documents. Various formats can be supported thanks to the extensible set of SPARQL 1.1 binging functions and SPARQL-Generate iterator functions. SPARQL-Generate is appropriate for engineers that are familiar with SPARQL query language.

OpenRefine[3] (formerly Google Refine) helps make sense of tabular data through a set of tools to clean, transform and merge several datasets together. RDF Refine is an extension of Open Refine meant to align the tabular data loaded in Open Refine with existing ontologies, while reconciliating the obtained URIs with third party RDF data sets. The data management part of Open Refine as well as the alignment towards RDF in RDF Refine are fully performed through a Web user interface. Unfortunately, RDF Refine does not allow to map CSV input files to RDF. Open Refine can also handle JSON data but does not implement multi-level iterators that make the mapping complicated when processing deep structures.

The BIGG H2020 Project

General presentation of the BIGG project

The BIGG project aims at demonstrating the application of big data technologies and data analytic techniques for the complete building life cycle of more than 4000 buildings in 6 large-scale pilot test beds. The proposed solutions will be deployed and tested as a pilot with country validation of at least two business scenarios in Spain and Greece. For that, the project has developed: 1) The Open Source Architecture (BIGG Data Reference Architecture 4 Buildings) for collecting, funneling, processing and exchanging data from different sources (smart meters, sensors, BMS, existing data sets); 2) An interoperable buildings data specification (the BIGG Ontology); 3) An extensible, open, cloud-compatible service (BIGG Data Analytics Toolbox of service modules) for batch and real-time analytics that supports effective decision and policy making.

In that context the reference architecture framework (RAF) (Pastorelly et al., 2022) has been designed (see Figure 1) and implemented, and the BIGG consortium has developed open source BIGG components enabling big data analytics for different business cases: Benchmarking and building portfolio management; Energy certification in residential and tertiary buildings; Building life-cycle data interoperability: from planning to renovation; Energy Performance Contract support; Building optimisation for occupants; Flexibility potential of buildings.

Presentation of the overall architecture

The Reference Architecture Framework (RAF) can be seen as a dedicated implementation of the Digital Twin concept. The detailed RAF concept is presented in Figure 1.

The RAF consists in a pipeline of several components which can be orchestrated in different ways. The first step uses BIGG ingestion modules (1) that are software components acquiring specific data (2) from different custom sources using standard protocols like HTTP or MQTT. These ingested data are stored in data lakes for later processing and/or directly pushed through an event message bus like Apache Kafka[4] to the harmonization module (3). The harmonization module is flexible enough to only require a standardized mapping file (4) to enable conversion of the initial specific data to the BIGG Standard Data Model 4 Building (5) required as input by the BIGG Data Analytics Toolbox (6). Harmonized data are instances of the BIGG data model, expressed in RDF format, containing only information needed for a specific use case. They can be stored in "harmonized data lakes" (ex: triple stores) and/or directly pushed through an event bus to the toolbox. The toolbox leverages several data analytics and AI/ML curated technologies to process the building/energy related data and produce insights output and push them back into the BIGG Standard Data Model 4 Building (7). The Toolbox uses machine learning techniques to produce valuable predictions. The knowledge created by the toolbox can be stored in "harmonized lakes shores" and is used by specific dashboard and external system software components (8) that will transform back the harmonized data into the data formats required by external dashboards or systems.

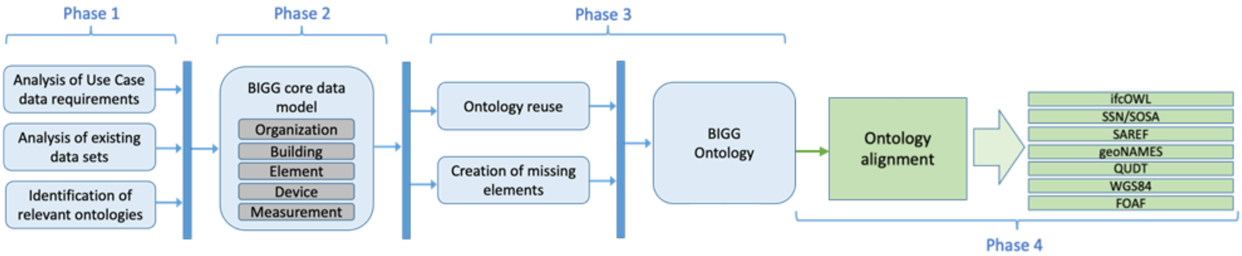

Figure 2: Methodological process for development of the BIGG Ontology.

BIGG Ontology for Energy Oriented Building Digital Twin

The creation of the BIGG ontology is rooted in the necessity to ensure harmonised input for the common Analytics Toolbox that allows developing data-driven services by using heterogeneous datasets generated within different business activities in the built environment. Conceived initially as a common data model developed in UML, it evolved to a graph data structure described in the Web Ontology Language (OWL) to benefit from the standardisation and data processing power offered by the semantic technologies.

The development process of the BIGG ontology followed a methodological approach similar to that suggested in (Radulovic et al., 2015). It is schematically illustrated in Figure 2 and has four phases, including the ontology alignment as a last step (once validated by the implementation of the business cases, BIGG ontology was aligned with already existing ontologies concepts coming from ifcOW, SAREF, SSN/SOSA, BOT, etc, and properly documented and published).

Overall, the BIGG ontology provides a standardised way to describe and organise data for buildings and applications requiring comparison and analysis of data related to performance of buildings, their systems, elements, and their usage.

Table 1: Main classes of the BIGG Ontology

Class	Description
bigg:Building	A building for which data is provided
bigg:BuildingSpace	A space that can represent one or more rooms, floors, or zones of a Building
bigg:Element	Generic element of the building
bigg:Device	Any meter, sensor, or actuator that can capture a signal or assume a state
bigg:Sensor	A collection of Measurements from the same Device
bigg:Measurement	Any time series record registered by a Device.

Currently, the BIGG ontology contains 100 classes, 181 DataProperties and 108 ObjectProperties. Table 1 provides a description of some of the main classes.

The BIGG Harmonizer

The Digital Building Twin involves a multitude of data models and formats coming from different sources such as open data providers, asset management software and sensors. Regarding data formats, relational databases and XML are still present, Open Data portals heavily rely on CSV, and web APIs on JavaScript Object Notation (JSON). The RDF data model is used as a federated model to reach semantic interoperability and querying of data having heterogeneous formats (Michel, 2017).

Presentation of the overall concept and input data

The BIGG harmonizer aims at converting any data in scope of energy performance of building, that fit with the BIGG Ontology, into RDF. Data that are not needed for use cases are filtered. As possible inputs in our approach, we focus on JSON for data coming from sensors (timeseries) and asset management software (building and systems description) as well as CSV coming from Open Data (geolocation) and RDF (data aligned on SAREF, SOSA or IFC) for alignment with existing ontologies (see Figure 3).

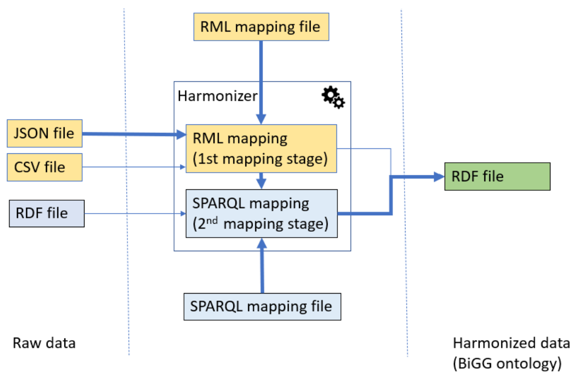

Figure 3: General workflow of the Harmonizer module

The harmonizer must generate data respectful of W3C recommendations and BIGG Ontology by providing the following functionalities: (F1) Converts JSON files into RDF compliant with BIGG Ontology; (F2) Converts CSV files into RDF compliant with BIGG Ontology; (F3) Aligns Data described using standard ontologies covering the same scope (ifcOWL, SAREF, SSN/SOSA, GeoNames, QUDT, WGS84, FOAF); (F4) Allows to map input objects with BIGG classes; (F5) Allows to map input attributes with BIGG data properties; (F6) Interprets implicit links between objects through object properties; (F7) Reconciles input values with open registers, BIGG taxonomies and enumerations; (F8) Materializes data context and generate 5-stars data. The next parts describe how the harmonizer provides these functionalities.

Converting input formats to RDF (F1, F2)

The Digital Building Twin necessitates high-quality data known as 5-star data, as originally introduced in (Berners-Lee et al., 2009). Frequently, the raw data obtained by the Digital Building Twin necessitates cleaning and enrichment to enable full interoperability. The levels established by Tim Berners-Lee are: availability (level 1), structuring (level 2), openness (level 3), universal identification (level 4), and linkage to other data (level 5). In our case, raw data is mainly provided as JSON, but the same methodology could be applied to CSV-formatted data. In this project, the 5-star level is achieved by following the RDF specifications.

First stage of the harmonizer extracts inputs from a JSON file and a RML mapping file in order to produce a first RDF file matching the BIGG scope (see Figure 3). The RML mapping files are composed of iterators to identify data sources and class mapping declarations that refer to iterators. Mapping files can either be produced manually or by using dedicated tools that simplify the mapping process such as RMLEditor[5] or Matey[6]. This procedure is detailed in the Implementation section.

The RML processing is based on the RMLMapper library developed by Ghent University. Firstly, the relevant parts of the JSON are identified according to iterators declared in the mapping file. Then the mapping itself is performed by creating, for each mapping data, an instance of the mapped ontology class, by generating a URI, and by generating triples according to data properties. Each URI is generated from the context (provider or building owner and building) and the local ID defined in the JSON.

Interpreting implicit link (F6)

The underlying structures of JSON are arrays and trees. Relations between objects are implicitly declared by using the native parent-child relation provided by the tree structure. As BIGG Ontology defines several relations, the harmonizer needs to match the parent-child relation between two JSON objects with one of the BIGG Ontology relation. Figure 4 illustrates how two parent-child relation from the same JSON file can be interpreted as distinct relations in the BIGG Ontology.

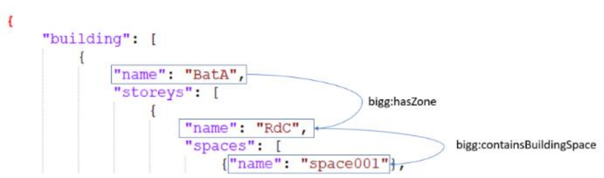

Figure 4: Sample of JSON file describing building structure.

The materialization of implicit links is also ensured by the harmonizer's first mapping stage. Object properties (as declared in the mapping file) map instances with each other's by using their URI. As for instance generation, JSON samples corresponding to the subject and the object of a triple are identified using absolute or relative expressions. As URI are always generated by using the same convention, URIs remain consistent. This way, URIs generated when populating instances match with URIs generated when building relations between instances.

Reconciliating data with enumerations (F7)

The BIGG harmonizer uses GeoNames as a universal register for public buildings. By reconciling GeoNames buildings with BIGG building descriptions, the project allows for the federation of data provided by building owners with data provided by the Open Data community. This is achieved by querying the GeoNames endpoint to retrieve the building's public URI, official name, and address, using the building location as a reference. The harmonizer's first stage generates a graph, which is then used to execute a federated SPARQL query in the second stage to replace the temporary building URI with the GeoNames URI and insert complementary information requested from GeoNames. Alternative public endpoints can be used to provide data on building height, roof inclination, and envelope materials.

The BIGG Ontology is a valuable resource that provides taxonomies for the classification of various objects, including buildings, spaces, and sensors. Within the context of building usage classification, an excerpt of the building usages taxonomy is presented in Figure 5, which outlines the primary services provided by a building.

In situations where the classification of raw data differs from the BIGG classification, the harmonizer's second stage is used to translate between the two. For example, the French building classification term "Université" must be converted to its corresponding term in the BIGG taxonomy, namely "University".

Property	Taxonomy 1st level	Taxonomy 2nd level
buildingSpaceUseType	EducationAndResearch	ExtracurricularEducationCenter
		Laboratory
		MilitaryOrPoliceAcademy
		OtherEducationAndResearch
		Preschool
		PrimarySchool
		ResearchCenter
		SecondarySchool
		University
		(empty)
	Healthcare	DayCareHospital
		HomelessShelter

Figure 5: Sample of one of the BIGG taxonomies classifying building space usages.

A thesaurus is embedded in the BIGG ontology. It employs the SKOS ontology to describe taxonomies (skos:scheme), translations (rdf:label "Université"@fr, "University"@en) and cross-taxonomy semantic links

[5] RMLEditor, https://rml.io/tools/rmleditor/

[6] Matey, https://rml.io/yarrrml/matey/#

(<medical center> skos:match <hospital>). In the harmonizer's second stage, the reconciliation process is accomplished through a federated query that utilizes the thesaurus to translate from the taxonomy used in the raw data to the harmonized taxonomy.

Materializing data context (F8)

When describing energy consumption as JSON time series (Figure 6), the contextual information regarding the source (Who), location (Where), and method (How) of measurement is often overlooked or indirectly specified in the file name. A standardized approach is required to extract and retrieve this contextual information from the pre-existing database or other data sources. The identification of data providers and building owners can be incorporated into the mapping file (in the SPARQL mapping), which can be further utilized by the harmonizer to enhance the graph. In instances where the timestamp is absent, the current date and time can be used to trace the incoming data. As an additional improvement, the harmonizer can also extract pertinent data, such as building and sensor identification, from the file name to further augment the graph.

```

```

Figure 6: Example of JSON time series missing building or provider context

Aligning data (F3)

In addition to the raw data collected by the Digital Twin as a JSON file, the harmonizer enables the ingestion of RDF data that implements standardized ontologies.

The BIGG Ontology has been aligned with several existing ontologies related to Digital Building Twins, such as BOT (for building topology description), SAREF (for energy system description), and SSN/SOSA (for sensor and timeseries description).

This alignment consists of triples that declare corresponding classes and corresponding predicates from one ontology to the other. The data alignment is generally performed on a given opportunity via a semantic reasoner embedded in the triple store but, if necessary, the harmonizer can materialize class and properties alignments by substituting the original vocabulary with BIGG vocabulary.

The BOT ontology is a minimal ontology that defines relationships between the sub-components of a building. It has been suggested as an extensible baseline for use with more domain-specific ontologies, following general W3C principles of encouraging reuse and keeping the schema no more complex than necessary. The BIGG Ontology defines some classes that are equivalent to BOT classes. For example, bigg:BuildingElement, which describes building components, is equivalent to bot:Element, and bigg:Zone is equivalent to bot:Zone. With respect to object properties, bigg:hasZone is defined as an equivalent property to bot:containsZone, and bigg:containsBuildingSpace is an equivalent property to bot:hasSpace.

SAREF is an ontology supported by the ETSI SmartM2M standard that enables interoperability among IoT projects and can be extended to any IoT vertical domains, such as smart buildings or energy. The BIGG Ontology reuses a few SAREF concepts, such as saref:Device, saref:Sensor, and saref:UnitOfMeasure, to describe sensor networks and time series. In the BIGG Ontology, a sensor is located (bigg:isContainedInSpace) in a space, observes a building element (bigg:featureOfInterest), and provides measurements (bigg:hasMeasurements).

There are two ways to extend the harmonizer's alignment capabilities. The first way is to extend the ontology with new class and property equivalences. The second way is to add SPARQL mapping queries that will convert classes and properties from one vocabulary to another (2nd mapping stage in Figure 3).

Implementation

The harmonizer is a generic way to convert any building energy related data into BIGG digital twin compliant data. As it would be too much effort to code serializers for each kind of source by using generic programming language, the harmonizer is based on the RML mapping language that simplify mapping specification for data providers.

Choice of the mapping language

The BIGG project focuses on RML as a mapping language for the following technical reasons: 1) RML is based upon RDF that is consistent with the harmonized data; 2) RML mappings are reproducible and maintainable; 3) RML is an extension of a W3C specifications: R2RML (Das et al., 2012); 4) RML is not limited to one type of input format and can easily handle JSON, CSV and XML format. But mostly, in the scope of the BIGG project, it was important that the mapping files can be generated (or at least updated) by non-informatician persons responsible for the different business cases. In this perspective, we have concluded that RML was the best option, thanks to the YARRRML language and Matey tools that offers the most suitable solution of our project. To this, we added a second mapping stage based on SPARQL to align URIs controlled values and taxonomies.

Development of the mapping files

YARRRML[7] is a human-readable mapping language developed by the University of Ghent, it allows to define rules and to convert them into RML or R2ML mapping language. Therefore, the generated RML mapping file contains rules to be used to transform input data into an RDF format. The web-based tool named Matey offers the

Figure 7: Example of a JSON input file (top left) with the corresponding YARRRML mapping (right) and the RDF file created by the mapping (bottom left)

possibility to write YARRML rules in a user-friendly way.

Matey user interface consists of 4 windows. Top left window contains input data (for example a JSON file). Top right window is the YARRRML editor, where user can write the YARRRML mapping script. Pushing the "Generate RML" button will automatically translate YARRRML script to RML and fill in the bottom right windows. Finally, pushing the "Generate LD" button will fill in the bottom left window with the RDF file resulting from the mapping of the input data using RML rules.

In the case of the BIGG harmonizer, Matey is used to develop and test the mapping rules in YARRRML language, generate RML rules and export them into a file. The YARRML mapping file is composed of three main parts (see Figure 7):

<u>The declaration of prefixes:</u> Some prefixes and namespaces are predefined by default in YARRRML, and a set of customs ones can be added by adding the '*prefixes*' collection to the root of the document (for example prefixes for the BIGG Ontology).

<u>The declaration of sources:</u>

Under the tag "sources" are listed all the "entry points" into the input data. Each entry point is defined by the file name, the format and an iterator acting as a regular expression to filter data. For example:

- Iterator: "$.building[*]" will iterate over all "building" entities in the file.
- Iterator: "$..contents[?(@.type=="SITE"&& @.categoryCode=="BUILDING")]" will iterate over all "contents" entities at any level in the JSON tree, and which have specific values of "type" and "categoryCode" properties.

<u>The mapping rules:</u>

Finally, the '*mappings*' collection contains the declaration of the mapping rules explaining how to translate the current entity pointed by the iterator into triples (subjects, predicates, objects) of the BIGG Ontology. For the example of Figure 7, the mapping named "building" takes as an input source the iterator "data1", and instantiate an object named "$(name)" as a bigg::Building, which as a bigg::name egal to "$(name)" and has a relation to a space declared as "space_$(name)". Instantiation of the bigg::BuildingSpace will be done in the next mapping rule.

Providing the harmonizer as a service

SDM-RDFizer is an interpreter of mapping rules that allows the transformation of (un)structured data into RDF knowledge graphs. The current version of the SDM-RDFizer assumes mapping rules are defined in the RDF Mapping Language (RML). The SDM-RDFizer

```
python harmonizer.py --input inputFile [--mapping RMLFile] [--sparql SparqlFiles] [--output outputFilename]
```

Figure 8: Command line calling the Harmonizer module.

implements optimized data structures and relational algebra operators that enable an efficient execution of RML triple maps even in the presence of big data. SDM-RDFizer is able to process data from heterogeneous data sources (CSV, JSON, RDB, XML) processing each set of RML rules (TriplesMap) in a multi-thread safe procedure.
RocketRML (Simsek et al., 2019) is also an implementation of the RML mapper specification based on NodeJS. Whereas RocketRML appears to be faster than RMLMapper library, it only supports a subset of the RML specification that is needed for our use cases.
RMLMapper developed in java (*rmlmapper.jar*) is the reference implementation of the RML mapper specification as it covers all the features. Furthermore, it is more widely used and benefits from a more active community regarding version control insights (Heyvaert et al., 2018). For those reasons, RMLmapper is the one used in BiGG to process RML mapping rules on a selected dataset to generate an RDF document. The integration of this library into a Python module allows to experiment the harmonization of input data from multiple sources automatically. The Python module created to harmonize input data with the BIGG Ontology is composed of two stages, the first one is related to the RML mapping file, and the second one is related to the alignment of standards ontologies with the BIGG Ontology.
The conversion step is the first stage of the Python module, it corresponds to the use of the java library to convert an input JSON file into an RDF file thanks to the mapping rules defined in the RML file. The module can output two serialization formats of RDF, the TTL (Turtle) or the JSON-LD format.
The second stage of the Python module, corresponds to the use of SPARQL queries in order to add, translate or complete the RML stage. The second stage can also be used to align data based on standardized Ontology into the BIGG compliant RDF. For instance, it allows to align data based on standards ontologies like ifcOWL, SOSA or SAREF, with the BIGG Ontology.
The execution and test of the Python module can be done in a Jupiter Notebook, with the command line of Figure 8.

Experimentation with data provided by pilot sites

The harmonizer process can be illustrated with a simple example of a building containing storeys, spaces, and some devices. Figure 7 shows the corresponding JSON input file on the top left, and the YARRRML mapping file on the right. Once the RML mapping file is generated, we can use it to convert the input file into an RDF file aligning with the BIGG Ontology (bottom left).
The Python module allows the use of the RML mapping rules to align the input data with the BIGG Ontology into an RDF document. Automatically, it generates instances of BIGG objects like bigg:Building, bigg:BuildingSpace and bigg:Device with the related relations (Figure 9).
The same approach has been successfully applied with input data from other sources: group, systems and sensors structure exported from exploitation control software, or time series coming directly from sensors. Each specific data is mapped to instantiate a specific part of the BIGG ontology.
In a second phase, the harmonization module is also used to create rules to include import data in standard format (e.g. ifcOWL) into an instance of BIGG model. Indeed, the harmonizer second stage allows to execute SPARQL queries to specify correspondences between ontologies (Figure 10).

IFCOWL	BIGG
:IfcBuilding	bigg:Building
:IfcSpace	bigg:BuildingSpace
:IfcZone	bigg:Zone
:IfcDistributionElement	bigg:Device

Figure 9: Example of Alignment between ifcOWL Ontology and BIGG Ontology

Discussion & perspectives

The BIGG harmonizer implements and orchestrates transformations on heterogeneous data. This article demonstrates how the harmonizer can convert any data covering building and sensors description as well as energy related time series. It is fully compliant with W3C recommendations by composing an RML transformation with SPARQL transformations. This solution is extensible as any data providers can add his own mapping files to process his own data stream to the unified BIGG data toolbox. The main limitation of the current implementation is the use of files as data buffers between providers and the digital twin.

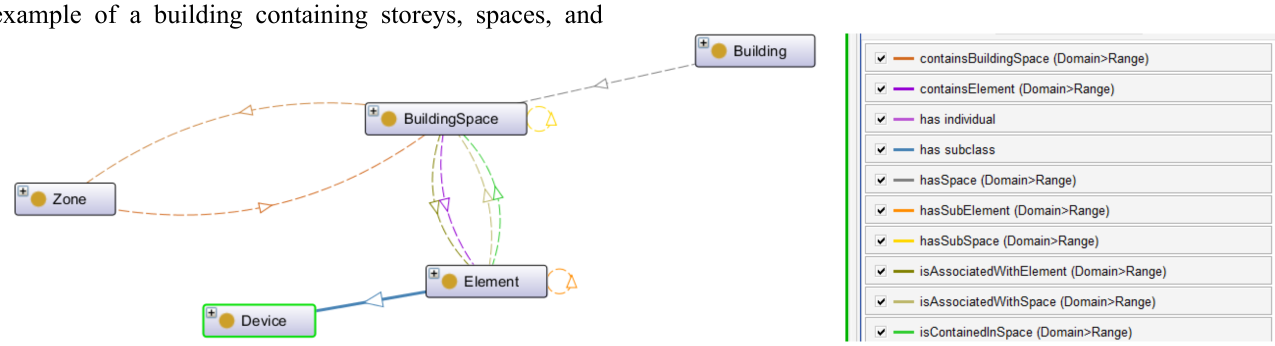

Figure 10: Visualization of objects from the BIGG Ontology to be instantiated with the Python module.

At this stage of the project, a dozen of RML mapping files have been developed for real input data (several initial tests were done with manually developed input files), covering 5 different Use Cases. Two of the involved partners were able to generate these mapping file quite easily using Matey tool, and three other partners have been trained to learn YARRRML language and are now able generate their own mapping files.

Matey tool and YARRRML language allowed us to develop most of the mapping we need. We encountered mapping difficulties on only one input file, which have a more complex structure: the depth of element decomposition depends on the type of element. This requires implementing some “Conditions” in YARRRML and managing “Iterators” in a different way. These aspects have been investigated during the last months of the project and seems very promising.

From a data integration point of view, the main objective of the BIGG project was to design, develop, and test a specific architecture allowing to address as many use cases as possible through a common data analysis pipeline. By designing a dedicated BIGG ontology, and developing a generic data harmonization tool, based on RML mapping language, to feed it from heterogeneous data sets, we achieved our objective, while using standard, open, and extensible technical solutions.

The RAF describes BIGG components and state-of-the-art techniques to coordinate BIGG components, may the actual architecture deployment on a local server or on a cloud infrastructure. The next step is the integration of the harmonizer into the whole stream-oriented architecture. Each BIGG component implements its business logic using specific technologies and specific supporting open sources libraries or frameworks (e.g., Kafka (Noac'H et al., 2017) (Hiraman et al., 2018)). Then business logic code is containerized using Docker (Wan et al., 2018). Components get their features accessible via APIs (Application Programming Interface), with event message compatible interface. For the latter point, the Kafka event streaming message system and RMLStreamer (Min et al., 2022) has been chosen to allow the platform to process continuous data streams.

Abstract

Human-Data Interaction is central to the dynamic nature of the construction industry and its growing reliance on substantial data sets. In this paper, we evaluate literature on the topic of Human-Data Interaction across several technologies and concepts within the built environment with the aim of identifying underlying aspects that can lead to an underpinning theory of Human-Data Interaction in the built environment to support advancement of the research in the field. Those aspects were identified as trust, game theory, empowerment of humans, human control, safety, accessibility, enhancing understanding, and the three pillars of Human-Data Interaction of agency, legibility, and negotiability.

Introduction

The evolution from specialised to ubiquitous and interconnected computing has instigated a profound transformation within the construction sector impacting every facet of the design, construction and operation of buildings and infrastructure. During the design phase, the adoption of tools such as Building Information Modelling (BIM) has revolutionised approaches by enabling collaborative planning and precise 3D modelling in real time. This technological advancement continues into the construction phase with the use of devices like smartphones and tablets along with devices and sensors that monitor progress and site conditions. These innovations contribute to decision making and efficient resource management. In the operations phase, integrating building technologies and data analytics plays a crucial role in optimising maintenance, energy usage and overall facility management. This promotes sustainability and cost effectiveness.

The widespread use of various devices and networks, along with their technological interactions, results in the creation of extensive data trails with considerable consequences. Data are under constant revision and extension or transformation and do not only concern the individual who provided the data or about whom the data is, but also other stakeholders that might have different interpretations of the data (Hornung *et al.*, 2015).

Considering the dynamic nature of the construction sector and its growing reliance on substantial data sets, it becomes crucial to delve into the study of Human-Data Interaction (HDI), particularly in the construction informatics domain. The aim of this paper is to make progress towards establishing a theory of HDI to underpin subsequent research into construction informatics.

HDI described as interdisciplinary encompassing "*data visualization, user interface design, and interaction as well as psychology, behavioral science, and human cognition*" (Widjojo *et al.*, 2017, p. 3). In this paper, we uncover some of these aspects through investigations into HDI across the built environment (BE). In the next section, HDI is positioned in the context of its evolution from HCI and offer an understanding of the role of data in the construction sector. The methodology describes how the study was conducted and is followed by the findings of a literature review on HDI across several technologies and concepts in the BE. Analysis of the identifies potential elements that could contribute to development of a theory of HDI for the BE leading to a roadmap to support development of such a theory. The paper end with a discussion and conclusions.

From Human-Computer Interaction (HCI) to Human-Data Interaction (HDI)

Human-Computer Interaction (HCI) has been a cornerstone in our interaction with technology, focusing on the design and use of computer technology alongside the interactions between humans and computers (Dix, 2017). HCI's evolution has shifted from viewing computers merely as devices to a complex understanding of these interactions (Grudin, 1990), encompassing psychology (Card, 2018), hardware, software, interface, and even deeper organisational aspects. This expanded view transcends the simple operator-hardware relationship, leading to a more in-depth exploration of user-computer system interrelationships, particularly as systems become more integrated within organisations (Bowers and Rodden, 1993).

An emerging dynamic ecosystem, marked by both collaborative and competitive interactions, revolves around data creation and usage by individuals (Brown, 2013). This dynamic ecosystem along with advanced machine learning (ML) and artificial intelligence (AI) has initiated a transition towards HDI (Crabtree and Mortier, 2015). Unlike HCI, HDI focuses on the interaction between humans and data, moving beyond traditional interfaces. HDI's realm extends to the subtle and often passive engagement of individuals with complex infrastructures that are typically misunderstood or ignored (Haddadi *et al.*, 2013). Although the concept of *data* is nebulous (as will be discussed below), it is arguably less important than the elements of *human interaction*. HDI views data as a boundary object, open to diverse interpretations and relevant to a broad spectrum of stakeholders, including those it concerns, collectors, legal custodians, and users (Mortier *et al.*, 2015). The challenge of HDI lies not just in usable ("user-friendly") interfaces but in making complex data comprehensible, actionable, and ethically managed. Its core themes include *Legibility, Agency*, and *Negotiability*. *Legibility* aims to make data and algorithms transparent and understandable, balancing intellectual property protection. *Agency* empowers individuals to manage their data, including opting in or out, without necessitating constant engagement but offering the choice for those interested or concerned. *Negotiability* addresses the evolving perceptions and relationships around data, societal responses, social norms, legal frameworks, and the ambiguity in data's subject and meaning (Mortier *et al.*, 2015).

As the era of big data in the construction sector progresses, HDI's themes become more pertinent, signifying a shift from mere interaction with technologies (e.g., BIM, IoT, Digital Twins, etc.) to a deeper engagement with data and its implications.

What is data and where is it produced in the construction sector?

According to the Mirriam-Webster (2023) dictionary, data is "*factual information (such as measurements or statistics) used as a basis for reasoning, discussion, or calculation*", "*information in digital form that can be transmitted or processed",* and *"information output by a sensing device or organ that includes both useful and irrelevant or redundant information and must be processed to be meaningful*".

The definition in data science might be extended beyond the use of data, as a data application acquires its value from data and produces more data as a result (Loukides, 2011). The meaning is that data do not only function as input in data driven applications or services but also outputs data that need to be processed or transmitted. On the other hand, big data can be defined as an overall term for a "*complex and substantial collection of data, which needs advanced engineering strategies and analytics systems to process, store and manage*" (Li *et al.*, 2023). Big data includes a data transformation flow and is produced in the construction sector from sites and procedures within the entire construction process, consisting of modelling, designing, planning, scheduling, and management. Big data in construction, therefore, has different sources such as BIM as a main source of data supporting planning, design, building and operation (Li *et al.*, 2023), in addition to sensors and embedded devices, operational and maintenance data including text, audio, video and more (Bilal *et al.*, 2016; Li *et al.*, 2023). In this context, there is a role of project participants in data input, acquisition, modification, and integration of information leading to information exchange as well as integration (Li *et al.*, 2023). Furthermore, construction digital twin is distinguished from BIM because of its connection to the physical twin and updates when the physical one changes throughout the process (Sacks *et al.*, 2020). The digital twin would allow for 'data centric' construction management with a flow of information between the physical and virtual models in a cycle of Plan-Do-Check-Act where 'check' marks the significant difference with current construction control if the data can be capably interpreted and automatically produce accurate and comprehensive information (Sacks *et al.*, 2020). So, data function in a process of input, processing, output in a flow of various types of information in constant interaction with the human at any point of any process.

Methodology

This inductive study conducted a literature review of HDI across several themes related to the BE and the focus of the HDI Committee of the European Council on Computing in Construction (EC3). The framework under which the literature review was conducted stemmed from the mission of the HDI Committee (EC3, n.d.) across the three research perspectives in Figure 1. This is devised to avoid the risk of developing an unordered and incomplete list of research directions omitting important areas.

HDI Research Perspective	Description
i) Understanding and evaluation (end user-oriented)	• Users and their behaviours. • Individual and societal implications of emerging interactions. • Novel/emerging uses of ICT and AI-related applications.
ii) Development (technology-oriented)	• Platforms, architectures or component technologies. • Interactions between human actors and the data systems within projects and the built environment. • Testing methods for existing technologies and design methodologies.
iii) Foundation (theory building-oriented, supported by or supporting i) and ii)	• Theories, methodologies and methods involved in emerging HDI. • Paradigms and frameworks for analysis, design and application of HDI. • Ethics and Regulations.

Figure 1: Factors of the HDI Committee Mission

Literature specific to the concept of HDI and the six themes of blockchain; machine learning (ML) and deep learning (DL); robotics for industrialised construction; sensored construction sites; smart buildings; and virtual reality (VR) and augmented reality (AR) were reviewed. These themes follow the topics of the HDI Committee's seminal white paper (Kassem and Kifokeris, forthcoming) as key considerations for the BE. We acknowledge these themes are not exhaustive to the concept of HDI in the BE, however, they provide a springboard from which to commence discussions on development a theory of HDI *for* the BE. The purpose of the review was to identify similarities across these themes that could begin to form a working theory for HDI in the BE and specifically computer informatics. Inclusion criteria included papers considering the factors above with a particular focus on users, their behaviour, their interaction with data, and the testing and/or development of technology that integrates both user data and humans. The findings of the study were consolidated to propose key elements for consideration when developing a theory of HDI in the BE and are supported by a roadmap to support achieving that theory.

Literature review

This section presents the literature reviewed across the six themes and is followed by Figure 2 showing the HDI research perspectives across each theme. The themes are ordered alphabetically with no one theme having more importance over another. Literature on each of these themes with a specific focus on HDI is limited within and outwith the BE. That which is present has been carefully selected and reviewed to highlight the components that could be relevant to overarching HDI theory in the BE.

Classifying robot traits, identifying robot types, and categorising level of robot autonomy (LoRA). Proposing safety mechanisms for HRI that involve the robotic side.	Human-related factors in respect to safety: (i) mental workload, (ii) situation awareness, (iii) trust in automation, and (iv) (physical) ergonomics.
Liu et al. (2021)	Proposing a human-centred collaborative framework that enables robots to interpret human agents' cognitive loads to improve HRC.	Enabling robotic agents to capture and predict human psychological behaviour through developing machine learning models.	Acknowledging the need for reducing the cognitive and mental load imposed on human agents involved in working with robotic agents.
Fu et al. (2024)	Understanding the impacts of HITL collaboration in off-site construction that employ robots.	Alluding to the need for training various robot types in actual work environments rather than in experimental environments.	Recognising the need for respecting the value of human skills and strengths to empower human agents over robotic agents.
Zhang et al. (2023)	Understanding risks imposed on human agents in HRC in on-site construction (e.g., physical and psychology-related risks).	Understanding risks imposed on robotic agents in HRC in on-site construction (e.g., program failure and maintenance-related risks).	focus is needed on safety and management issues of HRC in on-site construction with an implicit emphasis on empowering the human side.
Sensored Construction Sites (SCS)			
Tang et al. (2020)	Evaluates worker PPE compliance using computer vision.	Develops a new vision-based system for PPE compliance.	N/A
Park et al. (2016)	Evaluates detection of unsafe conditions and collects and analyses the trajectories of workers with respect to potential safety hazards.	Develops a Bluetooth and BIM system for safety monitoring.	N/A
Kim et al. (2021)	Evaluates compliance levels and informs site managers about non-compliance.	Develops an autonomous detection method based on sensor technology for hard hat non-use.	N/A
Jebelli et al. (2018)	Evaluates early detection of workers' stress feasibility.	Develops a wearable EEG-based field stress recognition procedure.	N/A
Aryal et al. (2017)	Evaluates workers' real-time fatigue.	Develops a multi-sensor approach using heart rate monitor, infrared temperature sensors and an EEG sensor.	N/A
Shanti et al. (2022)	Evaluates workers' safety compliance at-height activities.	Develops a novel system integrating DL and drones to monitor workers in real-time Personal Fall Arrest System components compliance such as safety harness, lifeline, and helmet.	N/A
Smart Buildings			
Konstantakopoulos et al. (2019)	Incorporates HITL modelling by creating an interface to allow building managers to interact with occupants and potentially incentivize energy efficient behaviour.	Develops a gamification application to motivate humans toward energy efficient behaviour.	Introduces a smart building social game concept based on a friendly competition between occupants. Game theory concepts are used to learn models of players' decision-making in residential buildings.
Kim et al. (2022; 2023)	Incorporates user's baseline thermostat usage and allows users to set up thermostat schedules.	Develops a cloud-based eco-feedback and gaming platform (MySmartE app) that aims to promote energy conserving thermostat adjustment behaviours in multi-unit residential buildings.	Introduces a mathematical framework through a new methodology for personalized eco-feedback design integrated with a collaborative social game to assist residents in enhancing thermostat use while promoting community-level energy-savings.
Jenkins et al. (2019)	Enables occupants to take an active role in monitoring and managing plug loads via a mobile application.	Develops web and mobile applications for building administrators and users for plug load management.	Incorporates occupant engagement, gamification, automation, and machine learning for enabling occupants to take an active role in monitoring and managing their plug loads.
Virtual Reality (VR) & Augmented Reality (AR)			
Widjojo et al. (2017)	Human perception, cognition and decision-making are deeply subjective. Systems should aim to enhance humans' understanding of big datasets through enhanced visualisation.	Systems must be scalable in terms of quantity of data and dimensionality/complexity. The focus of a technological system must be in simple accessibility of data to the human.	Systems for Visual Analytics need to exploit the respective strengths of humans (perception and reasoning) and computers (computation and visualisation) and consider meaningful ways for humans to understand data through visualisation.
Alhakamy et al. (2021)	Humans can potentially interact with data using their whole bodies.	Tested two styles of interacting with data: using gestures and body movements in a large (semi-immersive) environments versus a joypad.	The mode of interacting with data affects the easing and conclusions drawn from the data.
Schiavi et al. (2022)	N/A	N/A	It is important to develop data flows between the systems used in construction (BIM, CDE, Digital Twins) and VR/AR systems.
Grübel et al. (2022)	N/A	Situated analytics allows the anchoring of data in its spatial context, which is particularly important in built environment applications of AR/VR.	N/A

Figure 2: Literature considered against the framework of HDI research perspectives

Blockchain

Blockchain was established as a technology to challenge capitalist power structures that have existed for many years (Ekblaw *et al.*, 2016). Research has demonstrated its potential to challenge many economic structures, business models, operations and much more. For the BE, and particularly the construction sector, the focus of research generally is heavily rooted in data and how they can be leveraged to make efficiencies and increase productivity whilst still maintaining an advantage over competitors (Li and Kassem, 2021). Such capitalist systems have resulted in challenges including predatory business models (e.g., underbidding for projects, using projects funds for cashflow), the justification of competitive advantage to limit information sharing, and a general lack of trust between contracting parties (Li and Kassem, 2021). Combined with new insights gained from [big] data, a new level of exploitation of individual actors from such actions drove enactment of the General Data Protection Regulation (GDPR) and highlighted the need to rethink companies' collection and use of data. Blockchain is presented as a way to support this rethinking, particularly from a Web3 perspective where focus is on giving *agency* back to the individual.

Lockwood's (2021a; 2021b) research focuses on self-sovereign identify (SSI) as an inevitable aspect of Web3. Privacy and its importance in society is central to the discussion and understanding that centralisation removes agency of personal data. The solution focuses on *agency*, *legibility* and *negotiability*, and the principles for an SSI technology: existence of the user; control and access by the user; transparency within the system; persistence of identities; portability of information and services about the data; interoperability to ensure wide usability; consent from users to use their identity; minimalization of disclosure of claims; and protection of users' rights. From a trust perspective, Becherer *et al.* (2020) present an exploration of human data engineering (HDE) for operational risk management with blockchain. Human-centred design of a blockchain-based system generates trust between it and humans. Public key infrastructure (PKI) is used to manage data centrally. While this goes against the decentralised nature of blockchain, its key HDI considerations put trust and human-centricity at the centre of the big data-designed system.

Specific to construction, Calvetti *et al.* (2021) address HDI for sensored construction sites (SCS) proposing the use of blockchain to facilitate data in contractual arrangements by investigating the perceptions of HDI and SCS. A use case enhances the relationships between workers, sensing technologies, performance, systems and methodologies, human factors, and on-site conditions where data are collected about the individual. Standards of transparency between workers and companies of data collection is raised as a result of implementing their proposed HDI information process. Li *et al.* (2019) proposed a socio-technical framework encompassing dimensions of technology, process, policy and society that gives consideration to the users of the system and the interactions they have with the technology to achieve the desired outputs and benefits. Finally, Hunhevicz *et al.* (2021) and Wang *et al.* (2022) present an alternative to the current model of ownership of assets shifting it away from the human (or organisation) to the asset. *no1s1* (no one's one) is a prototype for self-owning assets facilitated by a decentralised autonomous organisation (DAO) that increase cooperation and coordination between transacting parties whilst removing profit-seeking intermediaries returning some agency to the individual.

Machine Learning (ML) and Deep Learning (DL)

Much of AI subfields function by studying data and making decisions such as ML, computer vision, optimisation, and knowledge-based systems (Abioye *et al.*, 2021). AI has been gradually advancing in the construction sector with different aspects including health and safety, BIM, supply chain management and other (Abioye *et al.*, 2021). The subfields of AI can vary but they share one characteristic of being dependent on input data and result in output data whether this output is a prediction, a recommendation, or an automatic procedure (Allen, 2020). Human-in-the-loop ML (HITL-ML) is a concept situating the human in the process of ML in terms of the human's role in developing an AI system which is determined by the level of control humans and machines have in the learning process, in explaining the outcome to humans, and in the usability and usefulness of AI systems (Mosqueira-Rey *et al.* 2023). An HDI theory should explicit the relationship of its principles between the human and the data at any point where interaction takes place.

Urquhart *et al.* (2019) focused on how inhabitants interact with their buildings that adapt with the environment and its inhabitants through a series of IoT devices integrated with ML or DL technologies. The analysis discusses the challenges of adaptive architecture in dimensions of physical and information security, establishing responsibility, rights over personal data, sensitivity of visible emotions and bodies, and continuous monitoring. From a user perspective, Schia *et al.* (2019) presented an AI scheduling system at an early stage of implementation and conducted interviews about the system and compared it to other well-implemented digital tools. Interviewees with low AI knowledge working in construction projects indicated that trust in AI is conditioned by knowing the AI is based on the right dataset of BIM, and visualisation of why and how the output was made will help understanding of causality and trust. Moreover, AI technology and other digitalised applications are successfully used when they fulfil maturity in terms of technology, process, and culture. Hanafy (2023) investigated the use of general-purpose technology text-to-image generative AI images was used for architecture. The interaction of the user with the AI system showed that there is a behaviour of refinement as the user did not opt to create the perfect query from the start but built the best one by choosing the best version of adding extra terms. The study found the most suitable aspect of such a tool to be in the early design phase. These tools can be seen as augmenting creativity and visualisation within architecture. In interior design, the tool has potential to allow the user flexibility in design to explore different choices which indicates that the users interact with the output in a form of judgement and learning.

Robotics for Industrialised Construction

In the field of robotics research, Bock (2015) and Sun *et al.* (2023) predicted that the future of construction projects will rely on both robotic and human agents working together to execute construction-related activities. Since the functional operation of robots pivots on embedded sets of data within them (i.e., data are their lifeblood), human-robot interaction (HRI) can be considered a specific instance of HDI. Despite the plethora of research efforts on robotics in construction, only a limited number of studies could be analysed with the goal of distilling a set of specific themes that underlie HRI focusing on the human (Fu *et al.*, 2024).

The psychological and physical safety of human agents in HRI has been the focus of three studies. In their conceptual study, Sun *et al.* (2023) reveal HRI could result in negative psychological impacts on involved human agents including (i) anxiety and acute stress, (ii) cognitive load, (iii) negative emotional state, and (iv) visual and cognitive distraction. These impacts tend to cause increased likelihood of physical accidents, thereby impacting the physical safety of human agents. In the same vein, Rodrigues *et al.* (2023) underline the importance of understanding HRI to protect health and safety of human agents as well as to create an enhanced task environment. Resonating with Sun *et al.* (2023), the authors identify human-related factors that can impact the effectiveness of HRI: (i) mental workload, (ii) situation awareness, (iii) trust in automation, and (iv) (physical) ergonomics. The materialisation of any factor highlighted by Sun *et al.* (2023) and Rodrigues *et al.* (2023) may undermine the perceived benefits of employing robots on construction sites. To this effect, Liu *et al.* (2021) make an attempt at reducing the cognitive and mental load imposed on human agents involved in HRI. They proposed a solution that enables robots to recognize psychological signals of human brains with the goal of adjusting their robotic performance. Such an adjustment is argued to enhance the physical and psychological safety of the involved human agents, thereby improving the efficiency of human-robot collaboration (HRC).

Scholarly suggestions to empower human agents over robotic agents are evident in two studies. Within the context of HRC for modular construction manufacturing (MCM), Fu *et al.*, (2024) place emphasis on the impact of 'human-in-the-loop collaboration' concluding that involved human agents can take on a range of collaborative roles and interact with robotic agents at varying levels. These roles and levels depend on a combination of factors: requirement of the MCM tasks, capacity of robotic agents, and preferences of the human agents. The latter alludes to the value of humans in HRC. Zhang *et al.*, (2023) illuminate this in a recent review on HRC for on-site construction where human agents are tasked with working with robots. They suggest designing human-led systems for HRI to empower humans to control and manipulate robotic agents.

These studies draw our attention to the importance of empowering the human side of the HRI as a proactive measure to enhance interaction efficiency. It can be inferred that the optimization of HRI as a specific instance of HDI relies on human-centric system designs that need to take account of four induced factors: psychological health, physical safety, explicit human value, and empowerment of human agents. These factors can be translated into the three HDI principles as: *legibility*: empowerment of human agents; *agency*: human value and empowerment of human agents; *negotiability*: psychological health and physical safety.

Sensored Construction Sites (SCS)

Information communication technologies (ICT) such as wireless sensors networks, wearables, CCTV, robotics and mobile BIM technologies are increasingly adopted on construction sites (Rossi *et al.*, 2019). Construction sites are challenging environments due to their inherently dynamic, complex, and dangerous nature involving complex interactions between various parties, each with human actors, equipment, and products.

HDI-relevant studies exist across several areas such as safety (e.g., monitoring, compliance, inspection), worker ergonomics (e.g., stress, fatigue), productivity measurement/monitoring, and activity monitoring/ recognition. Common themes include the development and evaluation of technologies like computer vision, sensor technology, and machine learning for safety and compliance monitoring on construction sites. There is a notable gap in addressing human-centred aspects. Many studies do not document participant feedback, assumptions about data ownership, transparency, or algorithm bias. Where participant involvement is mentioned, it often lacks depth in their perspectives or considerations about data matters. Another notable gap is the lack of theories produced or used to support the studies within this domain. This highlights a significant gap in the current research, emphasising the need for more human-centred approaches than human interactions (e.g., consequences/implications/feelings from or when using the developed systems, user acceptance), and data matters (e.g., ethical use, bias, consent, confidentiality, compliance with regulations, etc.).

While the list of papers reviewed is not exhaustive, the trend of insufficient attention to human-centred aspects in safety-related research is indicative of a broader issue in the field. Indeed, safety is a domain where human-centricity is expected to be prominent, and the lack of depth in addressing HDI aspects in these studies suggests a likely widespread gap in the field at large. This trend likely reflects a general oversight in the digitalisation of construction sites, underscoring the need for more comprehensive research that considers HDI, particularly in areas as critical as safety.

Developments in this field will often collect data actively or passively, including workforce location, movements, gestures, physiological levels, and physical efforts (Joshua and Varghese, 2014; Aryal *et al.*, 2017; Park *et al.*, 2017; Jebelli *et al.*, 2018; Tang *et al.*, 2020; Kim *et al.*, 2021; Shanti *et al.*, 2022). However, distinguishing between task analysis and the analysis of the individual performing the task is a delicate matter. It is challenging to determine which data pertain to the project tasks and which data truly reflect the physical and motor abilities of the workers themselves (Calvetti *et al.*, 2021). This complexity underscores the fine line between performance metrics and personal data.

Smart Buildings

As technology continues to advance, a growing interest is observed for integrating cutting-edge technologies and interconnected systems into buildings to enhance their efficiency, functionality, and sustainability. These *smart buildings* leverage various sensors, devices, and automation to create intelligent and responsive spaces that optimize resources, improve occupant comfort, and reduce environmental impact. Subsequently, smart connected devices and advancements in sensing, actuation, and communication bring new modes of interaction within the BE across different contexts and scales. The most common robust examples that illustrate this interaction in smart buildings are interactive systems, which require IoT devices to enable occupants to interact with the building environment actively. Among these systems, automatic climate controllers autonomously regulate indoor air temperature, relative humidity, and air quality in a designated BE (Favero *et al.*, 2022; Lee *et al.*, 2019). Lighting control systems fine-tune the luminous environment and ensure the desired illumination level (Rossi *et al.*, 2015; Cho *et al.* 2020) whereas automatic window systems respond dynamically by automatically opening and closing windows based on fluctuations in indoor air temperature, relative humidity, CO_2 levels, VOC concentrations, as well as PM2.5 and PM10 particles (Cheng *et al.*, 2016; Kim *et al.*, 2019). Most of these systems aim at improving occupant satisfaction, perceived service quality and indoor air quality in buildings.

Recent advancements in this domain evolved around user experience and user-centric features, such as intuitive or guided wayfinding systems, interactive kiosks, and personalised environmental controls. For example, Target retail stores in the United States installed LED lighting systems integrated with Visible Light Communication capabilities. Through the coupling of these LEDs with Visible Light Positioning and the incorporation of image sensors on smartphones, in-store shoppers can navigate in the stores via maps and find the locations of specific products via the directions sent by the retailer's app (Halper, 2019). The EDGE building in Amsterdam exemplifies advanced utilisation of human-building interaction (HBI) data to enhance the user experience via a seamless integration of individual preferences and real-time environmental adaptability. For example, occupants at EDGE find themselves effortlessly connected through an integrated system, with the application aligning with their daily agendas and informing the building of their arrival. The building's advanced system promptly detects incoming vehicles, guiding occupants to designated parking areas. Users have access to a diverse range of work environments and the system, finely tuned to individual preferences, adjusts lighting and temperature within these environments to ensure maximum comfort and efficiency (Randall, 2015).

The current state of smart buildings shows that incorporating human knowledge, behaviour, needs, and preferences into the operational phase is crucial for achieving optimal performance in buildings. Even in automated buildings where users lack direct control over systems, integrating the human dimension through feedback mechanisms can enhance perceived control, leading to higher satisfaction levels. Therefore, HBI emerges as a viable alternative, introducing consensus-based decision-making for building operations to potentially minimize conflicts. It is noteworthy, however, that despite endeavours to create 'smart buildings', this objective remains unattainable without 'smart users'. Users need to be active participants in the building ecosystem rather than passive recipients, engaging with the data available to them in the most effective manner.

Virtual Reality (VR) and Augmented Reality (AR)

With its focus on 3D space on a large scale, the BE is a natural application domain for VR and AR, arguably comparable to entertainment and tourism. Literature on VR/AR within and outwith the BE disciplines presents applications to visualise the 3D BE or abstract data which is somehow related to the design/construction/ operation of buildings but with no natural 3D mapping. Data visualisation is often broadly classified into *information visualisation* and *scientific visualisation*; the former focuses on abstract data, whereas the latter deals with datasets mapped to space and time.

In their position paper, Widjojo *et al.* (2017) define HDI in slightly narrower terms than elsewhere in the literature, drawing an analogy to HCI, but focusing specifically on data. They coin the term *Visual Analytics (VA)* as the integration of human efforts and computation in the analysis of data. They argue that VR technology is particularly suited to VA as it overcomes the challenge of limited display real estate. Coupled with innovative interaction design, VR can facilitate the visual analysis of complex data, such as high-dimensional and multivariate data. The authors highlight the importance of understanding human cognition when exploiting it for VA. They go on to cite various interaction patterns that can inform the design of VR systems for HDI, such as selection, manipulation and viewpoint control. In the case of 3D spatial data, clearly of interest in the BE, Widjojo *et al.* highlight three components of the immersion enabled by VR that are particularly beneficial: head tracking, field of regard, and stereoscopic rendering. These help enable a sense of presence and spatial awareness. The paper culminates with a research agenda framed in an abstract way: research on the required understanding of a specific data set, and on the VR visualisation/interaction functionality that would enable this understanding.

Outside the BE, Alhakamy *et al.*, (2021) study how users perceive correlation and causation in numerical data. They compare two styles of interacting with the data: using gestures and body movements in a large (semi-immersive) environment versus a joypad, similar to the controller used in games. It is reported that participants tended to agree more with statements that portray correlation and causation in data after using the semi-immersive system. The conclusions are presented in the light of theories of embodied learning/cognition.

Two applications of VR/AR in the BE seem implicitly to address the interaction of humans with data, but without explicitly using the term HDI: data for construction safety (Schiavi *et al.*, 2022) and data fused from digital and physical twins to provide spatial context in a smart city (Grübel *et al.*, 2022). The general themes emerging from these are that both VR and AR offer benefits for BE applications in particular because of the 3D orientation of most digital content; VR is used preferentially for office uses whereas AR is more often used with tablets and mobile devices 'in the field'; data flow between the systems used in design, construction and operation of the BE and VR/AR systems remains an issue.

Potential elements for a theory of HDI in the built environment (BE)

Following a review of the literature, the papers were mapped to the framework in Figure 1, as shown in Figure

2. *Understanding and evaluation* focused on what the studies are trying to achieve from the technologies and their potential impact on the end-user in the context of HDI. *Development* focused on any development of the technologies to achieve improvements in HDI for the end-user. *Foundation* considered any proposed frameworks or theories specific to HDI that could lead to an underpinning theory of HDI for the BE that may be applicable across all technologies and concepts.

Trust appears to be a central facet of a system when considering interaction of humans and data. This is applicable in terms of human-centred systems as well as humans knowing the correct data are being used when data-driven decisions are made *about* or *for* them without human input, especially when related to wellbeing. ***Game theory*** is considered as a way to encourage engagement with data. This relates to ***empowerment of humans*** when collaborating with technologies (e.g., robots, surveillance systems) and moving toward automation that (partially) removes ***human control***. Humans are often wary of new technologies and can result in an unwillingness to collaborate. This links to potential issues of ***safety*** of the human from both physical and psychosocial perspectives when humans work with hardware (e.g., robots, wearables) and/or software where concerns may be less detectable. ***Accessibility*** considers how humans interact with data and affects how they make sense of correlation and causation of those data. ***Enhancing understanding*** of data via visualisation can increase accessibility and willingness to engage. The three pillars of ***agency***, ***legibility***, and ***negotiability*** appear across much of the literature, though agency appears more than the other two. Acknowledgement and inclusion of these pillars could be as a result of research offered by Mortier *et al.* (2015) representing seminal work in the field and offering empirical contributions to the term.

Discussion and conclusions

With the pervasive nature of technology and the increasing volume of data produced and then used to drive decision-making in the BE, consideration is required in terms of how humans interact with data, at which levels this takes place, and for what purposes those data are used. Analysis of literature on the theme of HDI sees the emergence of key issues requiring further attention before a theory of HDI for the BE can be conceived. Of the technological themes and concepts evaluated (blockchain; ML and DL; robotics for industrialised construction; sensored construction sites; smart buildings; and VR and AR), there are some interesting elements that can begin to form the basis of such underpinning theory including trust, human empowerment and control, safety, accessibility and understanding of data, and of course agency, legibility and negotiability. However, we are at the beginning of the journey to propose a robust theory for HDI as highlighted by the literature and the many gaps that exist when analysed against a framework of HDI research perspectives spanning i) understanding and evaluation (end user-oriented), ii) development (technology-oriented), and iii) foundation (theory building-oriented). It seems that research has a grasp of understanding and evaluation in terms of the HDI benefits a system or concept is attempting to do for humans, but developments in technology that specifically consider and integrate HDI concepts and foundations to support theory building are somewhat lacking. Also missing across the literature is acknowledgement of education, policy and standardisation that would have implications for HDI, and consideration of the Digital Services Act.

Encapsulating the induced human-driven considerations in a theory will likely extend our understanding of HDI within the context of the analysed technologies and concepts. As an initial step toward building such a theory, future work is proposed as follows: 1) broaden the analysis of literature that considers elements of HDI, whether or not so-called, to further understand the challenges of HDI and the extent to which current technological systems and concepts address issues of HDI within and outwith the BE; 2) establish the array of purposes for which data are collected and/or used by technologies in the BE, for example, to make decisions on behalf of humans or to influence human behaviour, that will enhance our understanding of the true implications of humans' interaction with data; 3) survey individuals and organisations about production, collection, processing and storage of data to achieve such purposes as identified in 2) to identify the benefits, challenges and areas requiring attention in future studies; 4) consider the education, policy and standardisation aspects surrounding HDI; and 5) evaluate any emerging theory against technologies and concepts such as those in this paper and beyond (e.g., BIM, IoT, GIS) to establish its robustness and suitability for computer informatics in the BE.

Abstract

Despite intensive research efforts in developing automated compliance checking (ACC) systems for improved health and safety (H&S) outcomes, existing research has mainly focused on the technical aspects and the building sector, whilst research focusing on the social and organisational aspects of ACC in the infrastructure sector is lacking. To address this gap, this study used a case study to explore the issues and readiness to implement ACC in H&S in a design organisation in the UK's infrastructure sector. The findings show there is low readiness with issues in four main aspects, where suggestions were proposed. This research contributes to the body of knowledge by identifying the gaps and proposing ways to achieve better readiness for implementing ACC in design organisations in the UK's infrastructure sector.

Introduction

The architectural, construction and engineering (AEC) industry is widely exposed to numerous health and safety (H&S) concerns (Anwer et al., 2021). Fatalities in the AEC industry are significantly higher than the all-industry rate in the UK. H&S concerns are especially prominent in infrastructure projects that are complex, dynamic and involve many workers and plant on site (Alhammadi et al., 2022).

In the design stage, safety by design has proven to play a key role in achieving better H&S outcomes in infrastructure projects by identifying H&S hazards during the design stage (Hardison and Hallowell, 2019). With the technological advancement in the AEC industry, there have been many digital tools developed to improve the industry's H&S performance, including knowledge-based systems, hazard visualisation, safety training, and automated compliance checking (ACC) systems.

Among these developments, ACC systems dealt with compulsory regulatory requirements and have shown promising results in improved H&S compliance (Zhang et al., 2013a). Despite some existing ACC research for H&S management that mainly focused on the technical aspect, little is known regarding the social and organisational aspects of implementing such ACC systems, which focuses on the readiness of ACC adoption, and inter- and intra-organisational factors affecting such readiness. To address this research gap, this study aims to explore the ACC situation in H&S aspects in the UK's infrastructure sector, using a design consultancy organisation as an example. Specifically, the objectives are to identify the gaps and issues, and evaluate the readiness of ACC for H&S at a design consultancy organisation in the UK's infrastructure sector and propose some potential improvements. As part of an ongoing project, this paper will outline the initial findings about the current situation, readiness and gaps in implementing ACC in H&S aspects in the UK's infrastructure sector.

The remainder of the paper is structured as follows. The next section presents the literature review related to the research objectives. The third section details the methodology used in this paper. Next, the results and findings are presented. The fifth section discusses the results. The last section concludes this paper with remarks for future work.

Literature review

Digitalisation in the construction industry

Digitalisation is the gradual process of widespread adoption of digital technologies to generate new revenue streams or to improve the value-generation capacity of existing business workflows (Bajpai and Misra, 2022). With the advent of the "digital revolution", digital transformation has been one of the key trends in businesses over the last few decades. In the AEC industry, digitalisation is also seen as one of the primary means to improve the industry's overall value delivery performance, and eventually "modernise" construction by today's standards.

With external factors such as changing market requirements, technological advancements, decreasing hardware and software costs, increasing complexity of projects, a new generation of digitally adept workforce, growth of start-ups, supportive and demanding trends (e.g., digital mandates) induced by governments, policymakers and clients, digitalisation in construction is progressing at a pace. This is also due to internal drivers such as the strategic rhetoric for digital transformation to be the main solution for inefficiencies, increased profitability expectations with efficiencies gained through digitalisation and building a "modern" company image.

To this end, several factors and adoption frameworks for digitalisation have been outlined in the literature. Many studies of technology adoption in construction use theories drawn from the established body of knowledge in information systems. The digitalisation adoption process has been studied from a socio-technical, organisational and psychological (individual) perspective (Sepasgozar et al., 2016). For construction organisations, among the many factors affecting digitalisation, external factors (e.g., legislation and regulation, mandates, and pressure from clients and competitors, market demand, and standards and specifications) (Aghimien et al., 2022; Liu et al., 2023) are important. Also, organisational factors (e.g., organisational culture, structure, leadership, and internal processes) (Zulu et al., 2023) are pivotal. Finally, availability of resources (human resources, hardware and software, organisational knowledge and experience, integration of different systems and platforms across the supply chain, standardisation of data, systems, and workflows) (Li et al., 2018) come to fore.

Automated compliance checking

ACC has been an area attracting global research interests and commercial development efforts for more than 60 years. In the ACC literature, most research efforts focused on technical aspects, including two main themes: target design model and rule representation.

Research on the target design model topic mainly focused on developing various lightweight data schema or data retrieval or query methods to extract useful data from the design model due to the difficulty of data exchange and filtration for ACC tasks. Examples include using graph databases to represent design information (Ismail et al., 2017a). Nevertheless, efficient retrieving and querying BIM model data remains a challenge. Methods that enable spatial query of Industry Foundation Classes (IFC) data are especially scarce.

Rule representation methods aim to represent building rules in a machine-readable form by interpreting and capturing rules. Early research developed decision tables, object-oriented and logic-based representations (Yabuki and Law, 1993; Fenves et al., 1995; Han et al., 1998).

More recently, researchers have proposed domain-specific languages to represent building requirements, including text-based languages (Lee et al., 2015; Sydora and Stroulia, 2020) and visual programming languages (Preidel and Borrmann, 2016; Kim et al., 2019). They both aimed to develop easy-to-use methods for domain experts to write codes that represent building requirements. Other researchers focused on semantic web technology-based methods, which used query or rule languages such as SPARQL (Jiang et al., 2022) or SWRL (Beach et al., 2015) to represent building rules. Nonetheless, most existing rule representations are not able to capture the full meaning of the building rules and the rule interpretation process still relies on some manual efforts (Zhang et al., 2023b).

Several studies have focused on rule classification and organisation to support rule representation. Solihin and Eastman (2015) classified building requirements into four classes based on their computational complexity. Zhang et al. (2022) proposed a more comprehensive four-criteria (i.e., semantic constructs, intensity, self-contained or linked explanatory, prescriptive or performance-based) classification to categorise building rules.

The recent advancements in natural language processing (NLP) and machine learning (ML) have made full automation of compliance checking possible. Zhang and El-Gohary (2017) used NLP techniques to automatically generate a logical representation of the building codes. Nisbet et al. (2023a) proposed a rule-based approach using RASE to automatically generate SPARQL queries for rule representation. Nevertheless, ACC based on NLP methods has not yet achieved 100% accuracy. Extra efforts are still required to review and check the results. Also, many methods can only deal with quantitative rules.

There have also been several studies assessing ACC implementation readiness and efficiency. For example, Beach et al. (2020) used questionnaire surveys to understand the obstacles of adopting ACC in the UK. Results showed that the top three challenges are: shared open standards for regulation clauses are lacking, no tool can be used for complete pre-submission checks, and difficulties of making brief and regulatory requirements contractually enforceable. They also provided a roadmap based on interviews with experts, highlighting that 1) there have been some interest in ACC adoption from the UK government and government commitment would be crucial; 2)ACC checking results should be used with expert review; and 3)ACC may be more suitable to be used for conventional projects instead of multi-use, complex ones. Zou et al. (2022) conducted a case study to assess New Zealand's offsite manufacturing industry's readiness for ACC implementation. They suggested that improving readiness of ACC requires assessing ACC systems in different scenarios, further improving technical maturity and promoting education and training. Their later research captured lessons learned from the implementation of ACC globally (Zou et al., 2023), which highlighted the relatively low readiness for ACC adoption and the importance of governments' role in promoting ACC adoption.

Automated compliance checking for health & safety management

There have not been many research efforts on using ACC for H&S regulations. One of the earliest ones were Zhang et al. (2013a) and Zhang et al. (2013b), where rule sets for ACC against Occupational Safety and Health Administration (OSHA) regulations were developed (Occupational Safety and Health Administration, 2023) based on existing safety in design best practices. These two studies selected geometry-related rule sets, such as workways and egress rule sets. Geometrical attributes were used for compliance checking, including the dimensions of holes in slabs and openings in walls. Similarly, Qi et al. (2014) developed rule sets for fall protection using both Solibri Model Checker (Solibri, 2024) and BIM Server as model-checking platforms. More recently, a study by Getuli et al. (2017) used parametric tables to represent Italian Construction H&S normative texts.

The literature shows that the studies regarding ACC for H&S regulations are limited, and they have mainly focused on the technical aspects. To the best of the authors' knowledge, there has been no practical implementation of the developed ACC systems on H&S aspects in the AEC industry. Especially, there has been no substantial research on ACC with respect to the Construction (Design and Management) Regulations 2015 (CDM), which are important H&S regulations in the UK's infrastructure sector and particularly no research on this from a social and organisational perspective.

ACC affecting parameters and success factors

Drawing on insights from prior scholars, the effectiveness of ACC for H&S regulations is subject to key factors. Kamara et al. (2002) highlighted "effective knowledge representation" as a crucial element, the need for standardised approaches, minimising inconsistencies, and fostering interoperability. Emphasising the importance of "oversight for performance-based criteria", Amor and Dimyadi (2021) stressed clear guidelines and human expert involvement to reduce subjectivity in H&S compliance assessments. This is echoed by Zhang et al. (2023a), where the importance of interpreting ambiguous clauses correctly was highlighted. Fuchs and Amor (2021) highlighted the challenge of "accuracy in information classification", suggesting the importance of mapping criteria against information models in ACC. Advocating for "adaptable information modelling approaches", Ismail et al. (2017b) and Nawari (2019) suggested fostering interoperability and collaboration in diverse construction projects. In addition, ensuring the "accurate generation of BIM data" is emphasised by Ismail et al. (2017b), who also suggest robust quality control should be involved to reinforce reliability in H&S compliance assessments. Beach et al. (2020) underscored the "quality and transparency of compliance information", urging advanced techniques in NLP and ML for ACC. Streamlining "quality assurance and control processes", as identified by multiple scholars, is another success factor for ACC. The process must involve strategic approaches to balance process validation and practical implementation, thereby enhancing the overall H&S compliance assessment (Beach et al., 2020; Amor and Dimyadi, 2021). Addressing these factors collectively can elevate the reliability, efficiency, and overall effectiveness of ACC systems tailored for H&S regulations.

Methodology

In this paper, the authors adopted a qualitative approach. An exploratory case study method was used to explore and gain a deeper understanding of the current issues and requirements of automated H&S regulatory compliance in the infrastructure sector. The exploratory case study method is suitable for this study as it allows more in-depth understanding of a scarcely researched topic in its own context (Yin, 2009). It also allows collecting and analysing both primary (interviews, questionnaire surveys) and secondary data (documents) (Eriksson and Nilsson, 2008; Zuo et al., 2013), which is the case for this study.

To achieve the research objectives, the authors targeted one organisation to 1) have a snapshot of the current issues, gaps and requirements in digital H&S management in the infrastructure sector, and 2) gain a more in-depth understanding of their digital H&S management processes and assess their readiness for ACC in H&S aspects. This organisation is a large multi-national design consultancy in the UK's infrastructure sector, which usually takes principal designer and designer duties as specified in the CDM regulations.

Primary and secondary data was collected, including data collected from a 5-month observation while working within the organisation and 50 questionnaire surveys answered by project managers (PMs) (or other senior employees working on 21 small- medium- or large-sized projects). Five individual interviews with CDM designer managers were also conducted to complement the data gathered from the questionnaires. In addition, one design risk management schedule (DRMS) and one H&S compliance audit document were collected for review.

All collected data was then analysed using thematic analysis to elicit the emerging themes. The thematic analysis process generally includes 6 steps, namely data familiarisation, coding, generating themes, reviewing themes, defining and naming themes and writing up (Braun and Clarke, 2006). The next section presents the results and findings.

Results

Based on the data analysis, the authors found that overall, some gaps exist in implementing ACC in the H&S aspects of the UK's infrastructure sector and some existing issues need to be addressed before ACC is ready to be implemented. This section first presents the general H&S management process of the organisation, followed by four themes that emerged from the collected data, namely regulation, technology, human factors and culture, and external environment aspects, as presented in Table 1 and detailed below.

General Design Risk Management Process

As a design organisation, the most important H&S management processes are those relating to the design risk management (DRM) process. In the organisation, the DRM processes generally include obtaining relevant pre-construction information, identification of constraints, production of a DRM schedule (DRMS) to identify hazard and risk levels, developing mitigations with an emphasis on hazard elimination or reduction, reviewing the DRMS, and handing over the residual risks register to the principal contractor. To facilitate the implementation of the DRM processes, there are some organisational-level guidance documents available, which are applicable to all projects regardless of sub-sector (e.g., highways, water) or project size. Some documents need updating, resulting in partial implementation and some fragmentation of processes on some projects. Based on the observation, how well the process is followed in practice and whether the actual processes comply with the CDM regulations mainly depends on the quality of DRM (the risks identified, proposed mitigations, whether the risk levels are addressed) and the process of reviewing DRMS. The DRMS is typically reviewed at an Integrated Design Review (IDR) with the CDM principal designer manager, Design Manager and design discipline leads. As such, the DRM processes heavily rely on DRM experts' competency (e.g., skills, experience, and knowledge). Although several lessons learned workshops are held periodically, more workshops would capture more tacit knowledge of the experts to assist the development of a unified and comprehensive digital CDM compliance checking tool, which will complement the current DRM system.

Table 1: Main themes and subthemes emerged

Themes	Sub-themes
Regulation	Understanding and interpretation of regulations
	Metrics for assessing compliance against regulations
Technology	Awareness of ACC and the required technical capabilities
	Related digital systems and technical capabilities
	Data availability for ACC
Human factors and culture	Competency and upskilling of employees (CDM duty holders)
	Standardisation for risk mitigation methods and severity ratings at an organisational level
	Culture and behaviour changes in safety by design and CDM compliance
	Awareness of digital technology and tools
External environment	External initiatives from government bodies and client organisations

Regulation Aspects

A good understanding of the CDM regulations is imperative in achieving CDM compliance. From the interview and questionnaire survey responses, staff within the design team have various levels of knowledge, experience and understanding of the CDM regulations. Employees who specialise in the CDM and DRM (e.g., CDM principal designer managers) have excellent knowledge, while some other designers only have a basic understanding of CDM regulations. It was also observed that some ambiguous expressions in the CDM clauses lead to differences in understanding and interpretation of the regulations.

A similar issue is that as the CDM regulations are performance-based and not very descriptive in nature, it is difficult to produce specific metrics that directly assess CDM compliance. Ideally, detailed metrics would help the design team understand what specific measures or aspects of hazard mitigation to pay attention to. This resonates with the suggestion by Amor and Dimyadi (2021) on providing clear guidelines. The current CDM Compliance Audit form refers to the general clauses provided in the CDM regulations, such as "ensure the client makes suitable arrangements for managing a project", which renders the interpretation subjective based on the auditor's experience. However, this subjectivity is alleviated as the CDM Compliance Audit makes reference to the check sheets in DRMS as evidence.

As such, first, for organisations adopting a similar approach, improving the granularity of their compliance audit forms will better support their ACC efforts by reducing the potential subjectivity in assessment. Second, improving the metrics and providing detailed duty definitions for the requirements to ensure standardisation in practice will be useful.

Technology Aspects

Generally, the technology for the key tasks of ACC (i.e., data retrieval from and semantic enrichment of BIM models, knowledge representation and natural language processing) is relatively mature, although no system has achieved ACC fully automatically. Within the organisation, although there are existing expert systems for H&S management, no ACC system or similar is currently in use. In addition, employees across the design delivery workstreams are not familiar with ACC nor the underlying technologies of ACC. Apart from several experts, they also lack awareness regarding what can be achieved using ACC and what level of automation can be achieved based on the organisation's current technological capabilities.

In addition, the questionnaire responses show that three main methods for H&S management on projects exist, with different levels of digital implementation and technical capabilities. These methods include 1) A spreadsheet based DRMS; 2) A spreadsheet based DRMS linked to hazard triangles on drawings with reference number; and 3) A GIS-driven digital CDM system, where the spreadsheet-based DRMS can be imported or exported. All three methods can be used on various sizes of projects, while the third method is mainly used on large projects. Technical skills and experience in developing digital DRM systems may be helpful for developing an

ACC system, as there are similar elements (such as functionalities for manipulating BIM information). Some of the data required for ACC may also be available in the DRM systems. Currently, new processes are in development across the organisation to cater for different project sizes.

Nevertheless, data availability seems to be an issue in automating CDM compliance checking. Although all projects must be CDM compliant, data required for ACC is stored across several standard forms used on the projects which are not directly linked. This makes it less efficient to demonstrate compliance, especially when considering the lack of definition and ambiguous nature of some of the clauses. Despite being complex to acquire, high quality data is crucial for successful implementation of ACC, as suggested by Ismail et al. (2017b).

Human Factors and Culture Aspects

DRM is an essential part of achieving CDM compliance. It requires competent CDM duty holders to make endeavors to finish the tasks to a high quality. From the interviews with designers and CDM managers and the authors' observations, the current situation and gaps are summarised, as follows.

First, some more junior members of staff may face challenges in fulfilling their tasks due to potential gaps in skills, experience, and/or knowledge. For instance, designers might encounter difficulty in identifying all risks or suggesting appropriate mitigation methods. This suggests a need for more support and efforts for training and upskilling some of the duty holders involved. There can also be inefficiencies in determining the competency of employees when appointing competent duty holders. It was noted that a new digital competency system had been developed to improve recording of the skills, experience and knowledge of employees which will improve the efficiency of the project personnel selection process.

Second, at a national and organisational level, the standardisation for risk mitigation methods and severity ratings for different risks should be improved. Various designers have employed diverse severity and mitigation approaches. This presents a challenge in compliance verification, particularly when considering automated checks. It was noted that work to address this matter is being championed by the organisation at a company and national level.

Third, it was observed that some designers tend to see the CDM compliance as mostly a safety related matter and do not fully understand the health implications engendered by construction work. There needs to be a cultural change at a national level to truly embracing the benefits of improving health and safety by design.

Fourth, there have been varied awareness and expectations of digital tools in H&S. Some have high expectations of such tools, thinking their functionality will be so powerful that most requests can be achieved. Others, however, are more skeptical about digital tools, arguing that the results produced by digital systems may not always be reliable and must be reviewed by experts. Regarding their expectations for ACC, they expect ACC systems to not only check compliance but also highlight where the non-compliance lies and suggest how to achieve compliance. In addition, Some CDM experts expressed their concerns regarding the use of digital technologies in CDM compliance, as such automation may result in the future generation of designers lacking basic knowledge regarding H&S risk identification and mitigation.

External Environment Aspects

There has been increasing support from the UK government in digitalisation generally and the H&S aspects in the construction industry specifically. The UK government published a new digital strategy in 2022, which set out the visions and continuous support the government will provide. The Health and Safety Executive (HSE) has established the Discovering Safety programme, where there have been a handful of projects focusing on improving H&S performance in the construction industry (Health and Safety Executive, 2023a). Fundings were provided for H&S technology companies to develop novel solutions via the Industrial Safetytech Regulatory Sandbox. Recently, there has been further funding secured for the HSE's Regulatory Technology sandbox to demonstrate use cases of ACC and help innovators bring new ACC products to market (Health and Safety Executive, 2023b). The HSE also recently commissioned ACC experts in the UK to deliver an ACC workshop for regulators, showing their great interest in ACC and their aspirations in achieving ACC.

There are also various initiatives driven by large client organisations in the UK's infrastructure sector, such as National Highways' Digital Roads 2025 initiative. They work with various industrial and academic partners to improve outcomes in the whole life cycle of their projects. In H&S aspects, this initiative aimed to achieve enhanced onsite safety using data and digital tools, reducing fatalities and proactively managing risk by the end of 2023. This highlights National Highways' commitment to future digitalisation in construction H&S.

Overall, the favourable external environment provides great opportunities for developing tools or systems for automated CDM regulatory compliance and client or internal process compliance.

Discussion

The results and findings of this research highlighted the current lack of readiness for developing and implementing ACC systems in H&S aspects in design organisations of the UK's infrastructure sector. There has not been much literature focusing on the social and organisational aspects of ACC. In comparison with the limited existing literature, findings of this research is consistent with previous findings in the UK construction sector in general, which mirrors similar earlier findings in New Zealand's offsite manufacturing industry (Beach et al., 2020; Zou et al., 2022). This relatively low level of readiness is attributed to various causes, including regulation, technology, human factors and culture and external environment aspects. In this section, the authors discuss the existing issues and suggest some potential solutions that could improve such readiness.

First, the difficulty of having unified interpretations of H&S regulations in general and CDM regulations in specific has hindered the development of ACC tools for such regulations. The possible confusion and multiple interpretations were highlighted in the recent HSE digital regulatory compliance workshop report (Nisbet et al., 2023b). To alleviate this issue, design organisations could initiate more detailed internal review meetings and workshops on the CDM regulations with the wider CDM team and with the assistance of the legal team. Such internal review meetings aim to 1) share knowledge related to the interpretation and practical CDM compliance experience; 2) agree on an organisational-level standard of unified interpretations for ambiguous expressions in the CDM regulations; 3) standardise some elements related to CDM compliance such as risk severity definitions (risk matrix); 4) better define the detailed matrix for CDM compliance checking; and 5) produce a "traffic light" system that highlights which CDM regulations can (or are easier to) be checked automatically.

More fundamentally, a CDM regulations review from the ACC perspective by regulators at the HSE could be helpful. This review could 1) analyse the previous incidents that are directly or indirectly occurring because of the lack of understanding of ambiguous expressions in the CDM regulations (e.g., so far as is reasonably practicable); 2) check if any clause needs to be updated; 3) revise clauses that are not very clear and/or provide official guidance and examples for those clauses; 4) suggest what changes can be made to make the CDM regulations both human- and machine-readable, which is aligned with the HSE's digital regulatory compliance agenda.

Regarding the technological aspect, design organisations could analyse technological capabilities to automate CDM regulation compliance, which will highlight the gaps and opportunities. This can be reviewed in line with digital DRM systems to identify information gaps, and how the DRM and ACC systems can help each other to achieve enhanced CDM compliance outcomes. Care should be taken to consider the different sizes of projects, as the suitability of the CDM compliance processes and methods may be different. In addition, existence of a multitude of digital systems, platforms, and initiatives used across different projects make it more difficult for standardising and integrating (both from a technology and process perspective) an ACC approach in practice. There seems to be a "noise" in digitalisation in the AEC industry, where many ongoing efforts and ideas, and external factors compete for attention and resources.

Nevertheless, the advancement in technology cannot guarantee the successful adoption of digital CDM compliance solutions alone. It faces similar challenges as adopting other digital technologies in the infrastructure sector, where changing the culture and people's behaviour is one of the most prominent issues. Design organisations should take the initiative to promote and highlight the importance and the value of the health and safety by design approach, with evidence from other pioneering organisations to demonstrate feasibility and incentives for designers to facilitate behavioural changes. Design organisations could also organise more specific training sessions for their employees to showcase the available digital innovations in this area. This would highlight what functions are achievable and/or only speculative, to calibrate the expectations from digital tools in general and ACC in specific. Senior managers should understand and communicate clearly what ACC means, how it is performed and what could be practically expected from such systems. This would also guide their subordinates' conduct.

In addition, despite the encouraging external environment for digitalisation in the infrastructure sector, developing a new digital solution in the commercial world requires business justification. Hence, such an ACC system needs to demonstrate its tangible benefits such as efficiency, productivity gain, and cost-savings for the design organisation. This needs to be supported by organisational investment and resources (e.g., testbed projects for pilot and feasibility studies). If the existing ACC systems around the world are proven to be efficient, government policy incentives or mandates could also help achieve digital compliance. Some government initiatives to review the regulatory framework and regulation clauses could also facilitate its digitalisation process. The current regulatory framework could be improved to provide more guidance on achieving improved H&S outcomes. Firstly, the UK BIM framework has little guidance and focus on H&S aspects (CIRIA, 2023). Currently, there is only PAS 1192-6 available (British Standards Institution, 2024), with ISO 19650-6 out for consultation. More comprehensive guidance needs to be provided. Secondly, the CDM 15 regulations are performance-based and objective-oriented documents where guidance on paths to compliance is lacking. Some design examples could be provided to further explain and clarify how the requirements could be met.

Conclusions

This research presents an exploratory single case study of a design consultancy in the UK's infrastructure sector to understand the issues, gaps and readiness for implementing ACC in its H&S aspects. The results show that the readiness for implementation could be improved.

The issues and gaps mainly lie in aspects that include regulation, technology, human factors and culture, and the external environment. Suggestions are proposed for the design organisations to raise employees' awareness of technological advancements and enhance organisational knowledge sharing, training, standardisation and facilitation of culture changes, especially related to the H&S management and CDM compliance domain. The authors also suggested that the regulatory framework and regulations could be reviewed by regulators to facilitate digitalisation.

This study is one of the first studies looking at the readiness of implementing ACC in the H&S aspect of the UK's infrastructure sector. Unlike most existing ACC studies that focus on technical issues of ACC systems, it studied ACC from a socio-technical perspective to understand the readiness and how to facilitate better implementation from social and organisational perspectives. The results would be helpful for design organisations in the UK's infrastructure sector towards better development and implementation of digital regulatory compliance tools for CDM regulations.

This paper has limitations. An exploratory single case study is conducted in this paper, which may not reveal the wider H&S management situation in the UK's infrastructure sector. Our future study will conduct more case studies in similar contexts and look at the topic from different analysis units (e.g., sectoral, supply chain, organisational, departmental, team and individual) to obtain a better assessment and understanding of the situation and propose more comprehensive suggestions to improve this situation.

Acknowledgments

Appreciation is expressed to the company and all participants for their support in this study. The authors would also like to thank UKRI, as this investigation was developed through a Knowledge Transfer Partnership (KTP) project supported by Innovate UK.

Abstract

Tackling the need of large organizations for a proactive Asset Information Management (AIM) System, a methodological approach to knowledge management applied to built assets portfolios is proposed. It aims at synergically leveraging Knowledge Graphs (KGs) and Artificial Intelligence (AI) technologies to enable analytics on input data. In the theorized pipeline Large Language Models (LLMs) are meant to be used both in the graph creation phase, extracting data from unstructured sources and organizing them according to domain ontologies, as tested on a use-case sample, and in the knowledge extraction phase via queries.

Introduction

Asset Management (AM) is defined by international standardization as "coordinated activity of an organization to realize value from assets", where an asset is identified as an "item, thing or entity that has potential or actual value to an organization" (ISO 55000, 2014). It can be applied to the construction sector in terms of balancing of financial aspects, extraordinary interventions, operations and maintenance, in order to provide the most cost-effective, sustainable, well-engineered and efficient solution. The operational phase of buildings and infrastructures (ISO 19650-1, 2019), represents that time span when a continuous stream of minor interventions take place and the asset itself both delivers value to the organization and represents a source of costs. Asset owners with large portfolios typically manage numerous facilities, having the majority of them in the operational phase (UK BIM Framework, 2021).

An AMS, "whose function is to establish the asset management policy and asset management objectives" (ISO 55000, 2014), bases its performance on data exploitation, since assets can be considered data-rich environments, or recollections of a multitude of data and documents depicting information about each building's lifecycle (LC) step. From a data management perspective, future availability and accessibility of information is required, for at least as long as the life of the asset, jointly with pre-agreed Master Data Management (MDM) (ISO 8000-100, 2016) procedures internal to the organization, to support the effective management of data quality and deliver benefits across various LC phases.

Provided the output of this investigation is suggesting an Asset Information Management (AIM) approach to support the managerial processes, information ought to be regarded as a precious asset itself, whose structure and consistency provide measurable performance indicators and insights for decision-making purposes (KPMG, 2021). The main challenges associated with managing built asset data are related to their heterogeneous and siloed nature, being their structure and storage format quite often not regulated and then handled by multiple users. These dynamics determine a loss of value related to the information managed per each step of the process (Eastman, 2011), proving to be obstacles to the extraction of valuable and complete information in a timely manner. Managers and other stakeholders involved should be enabled to store, access and query information regarding their portfolio, ranging from documents to spatial information, 3D models or activity-related materials, no longer dealing with inaccurate, incomplete or even undiscoverable pieces of documentation. Inappropriate creation and maintenance of data sources, as well as interoperability issues foster higher management costs and a lack of trust in the final user, who's trying to gain a deeper insight. Recently, with the advent of Big Data (Ajah and Nweke, 2019), innovative technology solutions enable organizations to improve operational efficiency (Gomolluch, 2023), strengthen stakeholder relations, reduce costs and provide demonstrable legal compliance. Big Data Analytics, as a topic, has found some application also in the built environment to foster decision making (Farghaly et al., 2017, Demirdöğen et al., 2023). Limiting their implementation with BIM tools might not be the most efficient way to manage such intense streams of data, due to inadequate storage capabilities of those technologies. The goal of the current research is to suggest a holistic (Gomolluch, 2023) practical approach to knowledge management, applied to extended built assets portfolio, such as buildings and private or public infrastructures, through the adoption of Knowledge Graphs (KGs), as well as Large Language Models (LLMs) automating otherwise lengthy manual workloads. This proposition stems from a real use-case scenario, which is the extended built assets portfolio managed by the University of Turin. In this public institution an AMS (Di Giuda et al., 2023) is currently under development, dealing with the above mentioned limitations related to siloed documental resources and data quality. The proposed methodology is willing to enable the extraction of knowledge from heterogeneous data sources and their proactive interrogability, therefore improving the understanding of how real estate assets are used, along with decision-making at every stage of the asset's LC.

Literature background

Scientific literature in the field of AM in the built environment lacks a unitary vision and covers the topic of Information Management through sectorial applications. AM is often investigated employing BIM (Farghaly et al., 2017, Moretti et al., 2022) or through Digital Building Logbook as documental repositories of a building's lifecycle data, with a focus on sustainability and energy efficiency (Signorini et al., 2023, Malinovec Puček et al., 2023). When it comes to applying KGs and Linked Data to the built environment (Pauwels et al., 2022), it is often related to the definition of ontologies fit for specific use cases and their application to BIM models: sensors and mechanical systems (Quinn et al., 2020, Eleftheriou et al., 2022); building components (Sobhkhiz and El-Diraby, 2023); operation and maintenance (Xie et al., 2022); thermal comfort and energy analysis (Esnaola-Gonzalez et al., 2022); construction phase (Farghaly et al., 2021), even considering the integration of open source BIM models (IFC based) (Elshani et al., 2022). Others investigated link validation in ICDDs (Information Containers for Linked Document Delivery), meant for linking information in documents with Resource Description Framework (RDF) data (Hagedorn, Liu, et al., 2023, Hagedorn, Pauwels, et al., 2023), or exploited Shapes Constraint Language (SHACL) applied to distributed Linked Building Data for building model checking and constraint validation (Nisbet et al., 2023). Differently, KGs as a representation of Digital Twins has been studied in other sectors, mainly in industry 4.0 (Yahya et al., 2021, Tamašauskaitė and Groth, 2023), while text-based knowledge discovery techniques (i.e., Text Mining, Text processing, and Natural Language Processing) are hardly applied to the building sector. Natural Language Processing (NLP), which is branch of Artificial Intelligence (AI) has found application in text analysis and compliance checking related to contracts and legislation (Locatelli et al., 2023). In the field of AI and LLMs, algorithms are being developed to deal with the extraction of content from multiple kind of sources, both structured databases (Sequeda et al., 2023) and text-like documents, proving promising in assisted and semi-automated KG construction pipelines (Zhu et al., 2023).

Research context and aim

In compliance with studies stating that organizations can benefit from implementing AMS conforming to the ISO 55000 normative series (Almeida et al., 2022, Maletič et al., 2023), the proposition of a practical AIM approach should consider some recurrent characteristics in big organizations managerial praxis:

- Widespread organizations usually store large volumes of data and documentation, heterogeneous in types and formats, in centralized repositories. So called data lakes ingest all types of data from any source, ranging from structured (database tables, .xlsx sheets) to semi-structured (XML, webpages) to unstructured (images, audio files, PDFs), in their original raw form. Due to data lakes scalable architecture, a variety of applications can be compatible (Sawadogo and Darmont, 2021), from big data analytics to machine learning (ML) or predictive analytics, therefore greater value can be extracted from stored data.
- Inside an organization, analogous or related tasks are not always systematically carried out using harmonized terminology or producing consistent documentation, resulting in misalignments in both structure and content of files. Semantic enrichment of raw data would ensure clear interpretation and understanding, enabling the adoption of a graph structure (Pan et al., 2024) to interconnect individual records in a network and overcome inconsistencies.
- Structuring a uniform framework of machine-readable data generates benefits (Gomolluch, 2023) both in the short term, providing a Knowledge Base (KB) agile to interrogate, and in the long term, posing the basis for further ML implementations, which might include prediction algorithms and automatizations, optimizing managerial processes.

The theorized approach aims at multiplying the advantages provided by AI-powered technologies in Information Management, especially in decision-making processes at a managerial level. In a dual sided technological pipeline, from one side there's an AI system automatically extracting information from document sources and structuring a KB as a graph, while on the other side there's a human user interrogating another AI agent, capable of performing neural-symbolic reasoning (Zhang et al., 2021). This system, enriched by structured knowledge and logic-based inference from ontologies, based on the relevant facts retrieved from the KB, should enable informed decision making.

Methodology

As previously stated, the core idea of this research project deals with the development of a methodology to gather all sources of knowledge regarding multiple built assets in a unique interrogable environment, structured as a KG. The methodology (*Figure 1*) is composed of two parts: an *automated text-to-KG pipeline* and a *chatbot for human-machine interaction*. The former is responsible for the extraction of every bit of information existing in the organization's documents corpora, for their labeling according to pre-established sets of terms and for their interrelation to generate a KB with a graph structure. The latter assists users in finding the information they require from the KG. It should act as user-friendly interface and extract information from the KG through an NLP agent, which transforms natural language queries into query language (e.g. SPARQL), drawing inference and returning search results in human readable form. Its purpose is to perform those analytics typically carried out manually and visualizing them through graphical forms and set Key Performance Indicators (KPIs) into the AMS digital boardroom, although its proposition will be subject to future developments.

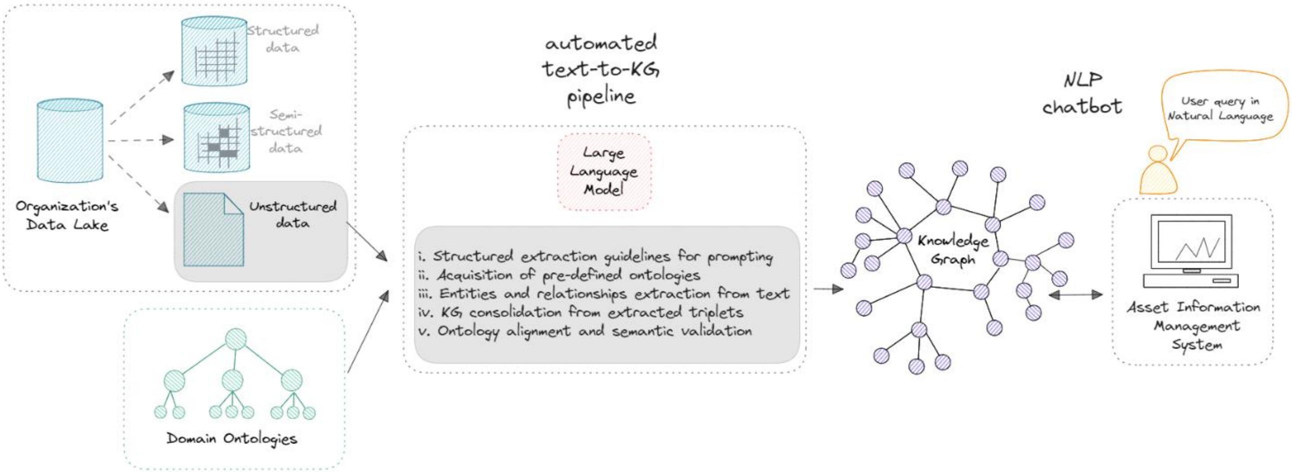

Figure 1. Theorization of an Asset Information Management approach

Prior to the tools development stage, some considerations ought to be made, regarding the intended scope of an AIM digital tool, according to the organization's administrative activities related to its use. For this purpose, a team of experts should identify one or more Domain Ontologies relevant to AIM scopes, creating those that match the organization's requirements, formulated in terms of competency questions (Keet, 2020). In addition to specifically created ontologies, existing and validated ones could be reused.

The definition of the methods to be applied in order to extract a KG from the enterprise Data Lake, based upon heterogeneous data sources, both structured and non-structured, strongly depends on the use case scenario and it has been chosen to deal with text documents. The suggested methodology aims at integrating what seems to be two distinct technologies, LLM and KGs, which though aim both at capturing a detailed representation of a portion of the world. Their different knowledge representation formats complement each other, overcoming individual limitations. A so called *text-to-KG* pipeline will be implemented, exploiting literature-tested solutions, and it involves:

- a Large Language Model (LLM), which acquires world knowledge by pre-training on massive text corpora and is capable of understanding and transforming human language, although with severe likelihood of hallucinations or logical leaps, showing limitations in domain-specific performance, trustworthiness, controllable generation or content quality assessment.
- KGs, which directly store factual knowledge as interconnected networks via relationships of real-world entities and provide structured, symbolic knowledge and deterministic logic, but struggle at handling nuanced language. They ground LLMs in factual knowledge, ensuring truthful text generation, while, on the other hand, LLMs capabilities in text processing and fact extraction mitigate their rigidity.
- Ontologies, which represent structured formal knowledge, including commonsense knowledge lacking in LLMs, and are used to define concepts, properties, relationships, constraints, and axioms in a machine-readable format, using standards like RDF and Web Ontology Language (OWL). They play the role of "organizing principle", as they provide agreed sets of hierarchies and terminologies, harmonizing the content handled and permitting entity disambiguation, as well as describing with the required level of detail the domain of interest. Ontologies act as a bridge between the unstructured textual knowledge of LLMs and the structured world knowledge represented in KGs, improving symbol grounding and enabling formal logic reasoning (Keet, 2020), such as inference through querying protocols.

The exploitability of the LLM-driven *text-to-KG* pipeline is strictly dependent on the domain ontology, as, in the first place, they will help the AI algorithm extract the correct entities and relationships. Although their outlining is an activity that requires time and the involvement of many stakeholders, it can be seen as a more formal task, upon which the technological pipeline can be built, as in the two steps described onwards.

Domain Ontologies development: the organizing principle

AM information ought to be systematized with the help of domain-specific ontologies, through classes, their properties and relations. Since "an ontology is a formal, explicit specification of a shared conceptualization" (Studer et al., 1998), the task of ontology engineering has to be demanded to a group of domain experts, jointly with professionals competent in RDF and OWL ontologies matter. Considering that concepts to be harmonized are already in use among the organization's practitioners, a bottom-up approach is suggested (Keet, 2020). Core concepts and relationships, as they tend to appear in datasets, are to be stated and formalized in the main ontology first, along with formal definitions via ontological axioms. Local ontologies and their alignment will be implemented only after the whole framework and its applicability have been validated, resulting in an incremental approach.

It is to be remarked that the core aim of the methodology is to create KGs conforming to a specific ontology, in order to guide accordingly to the schema all queries posed to the resulting graph, as well as to process a large number of documents though multiple prompts, due to computational size limitations.

LLMs for Knowledge Graph generation from text: the technological pipeline

Given recent advancements of LLMs and foundation models, they could be leveraged to alleviate time-consuming tasks, dealing with a great amount of unstructured files stored in the organization's repositories. To better understand how the *text-to-KG* pipeline could prove successful, a disaggregation of its procedure (*Figure 1*) is therefore outlined:

i. Creation of Structured Extraction Guidelines, whose scope it's the definition of the types of entities, properties and relationships the LLM needs to recognize and extract, referring to the formal content of the use-case ontology. Guidelines will be supported with input samples from the target domain and examples of the expected output structure in ontology language, to teach the LLM how to correctly encode human logic and to avoid inconsistencies in information extraction.
ii. Use of a LLM to transform unstructured text to KG in compliance with a pre-defined ontology. This task could be accomplished using either a LLM pre-trained with standard ontologies, a LLM fine-tuned with a custom ontology, a LLM prompted with a custom ontology, or a hybrid of a fine-tuned (with a custom ontology) and pre-trained (with a standard ontology) LLM. A comparative analysis investigating the most fit-for-purpose model should be conducted, evaluating benefits and limitations of each of the four plausible approaches outlined, taking into account token costs, response times, training and tuning datasets required. A hybrid approach is considered more suitable for high-quality KG construction (Wang et al., 2023), relatively to its accurate extraction of domain ontology components.
iii. Extraction of entities and relationships from large volumes of text sources via LLM, automating the process of KG extraction through text chunking, extraction of triplets, their normalization and enrichment. Subsequently text mining techniques and NLP algorithms (Van Assche et al., 2023, Zhao et al., 2023) operate on entities and their relationships.
iv. KG consolidation, merging nodes and edges extracted from all sources into a unified set and enhancing them with metadata and provenance information, to allow topological analysis on communities and centralities. The resulting KG is ready to be uploaded to a storage database, becoming a unitary source of data, over which complex analytics and queries could be carried out. Further integrations of departmental KGs, deriving from other domain ontologies, are allowed through an incremental approach.
v. Ontology alignment or ontology matching (OM) takes ontologies as input and determines as output a set of correspondences between semantically related entities, dealing with semantic heterogeneity problems (Li et al., 2019) and enabling navigation over KGs.

A few-shot prompting framework has been tested, to guide LLMs in performing NLP tasks, finalized at KG creation, exploiting GPT-3.5 (gpt-3.5-turbo), despite it being a closed-source model. The authors tried to define an ad-hoc chaining prompts to guide the LLM through a series of smaller, more manageable tasks to ultimately achieve a complex goal, which is the conversion of an unstructured paragraph into a structured graph, where each node corresponds to an entity, and the interconnecting edges depict the relationships linking them, matching those defined in a sample ontology. An exploratory trial-and-error experiment has been conducted, feeding a use-case textual source, in which university spaces are listed and assigned to organizational units and their occupants, and a reduced version of the RealEstateCore (REC) Ontology. The prompts engineered go through the following steps:

1. Task definition: the LLM is given a role as expert and is told to perform information extraction from textual documents, converting it into triplets made as: Source_Node, Relationship, Target_Node. Additional instructions are here provided, concerning how to maintain consistency in entities and handle numerical data, property formats, naming conventions.
2. Ontology ingestion: the LLM is fed with an ontology in RDF compatible .ttl format, being instructed on which entities and relationships to look for in the following tasks. Due to tokens limitations, a small ontology, composed only of use-case related entities and relationships, has been exploited.
3. Unstructured paragraph input: the LLM is given as input the text containing data aimed at being converted to KG. It is preferably accompanied by an example of how information should be correctly extracted, stating a small paragraph and the desirably outputted list of triples that could be identified in that paragraph.
4. RDF serialization: the LLM is asked to serialize the list of extracted entities and relationships according to RDF format, in this case in .ttl, enabling compatibility with graph databases.

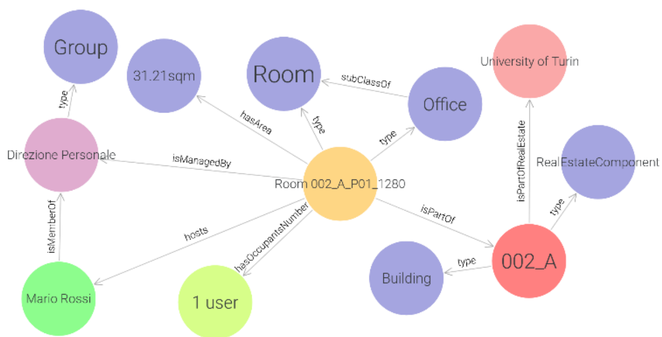

Figure 2. Visualization of nodes connected to a room entity in Ontotext GraphDB.

The resulting file was imported into an open source graph store, namely Ontotext GraphDB, where triplets consistency with the original NL source has been verified. As an example, nodes and relationships connected the one of the room entities extracted from text has been visually displayed as a graph (*Figure 2*).

Discussion

Theoretical contributions

Literature demonstrates that a single technology platform can be exploited to create accurate and transparent records of organizations' reference data (including buildings, assets, people, and contracts) and it can be integrated in internal business processes (e.g. contract and project management, strategic planning, environmental reporting, preventative and reactive maintenance) (Hanley and Brake, 2016, Geisler et al., 2021). However, a strategic approach to implementation, which must align to business process change and strong data governance, is required.

From an Information Management perspective, the process as a whole should be applied proportionally to the scale and complexity of the organization and of its asset portfolio, reflecting concepts and principles from ISO 19650-1 (UK BIM Framework, 2021). Accordingly, agreed methods and procedures should be internally standardized, to ensure the production of compliant set of data and information deliverables. Agreed schemata would ensure compatibility when federating data produced by different internal departments, which can then be used and maintained during the asset's operational life for analysis, reporting and decision-making.

Practical implications and limitations

The proposed methodological approach to knowledge management, applied to built assets' portfolios, aims to leverage a KG structure and AI technologies to enable analytics on input data for a proactive Asset Information Management System in large organizations. From an enterprise management perspective, a KG approach could solve data analytics challenges related to data quality or complex properties, exploiting intrinsic characteristics of Data Lakes storing the sources of knowledge related to accessibility, enabling scalability through a domain oriented structure and integration across all domains of the organization's network.

The main advantages deriving from the exploitation of semantic web technologies, in particular of KGs and ontologies, can be recognized in the automatic interrelation of information content, without having a human operator search for a specific document in a multitude of folders, and in its being univocally classified, reducing data creators' margins of personalization. With an incremental approach, from a single KB might stem several use-case applications, as multiple domain-specific ontologies can coexist in the same KG, putting in place an iterative construction of the KG introducing "just enough" semantics as each use case demands.

Integrating ontologies enable formal logical inference, complementing the inductive reasoning of LLMs with description logics and enhancing their generalization capabilities, as symbol grounding explicitly links language to formal conceptual representations. Moreover, a coexistence of standard and custom ontologies is feasible, as well as both independent and cross equivalence queries across domains. Additional benefits could be given by the adoption of FAIR (Findable, Accessible, Interoperable, Reusable) Data Principles, as they provide a data management framework, enabling findability of data and metadata through persistent digital object identifier (DOI); accessibility to trusted repositories; interoperability of knowledge representation language and dictionaries; reusability of data, thanks to accurate provenance information and clear usage license (Martorana et al., 2022).

Other potential advantages of using an automated methodology for KG construction from unstructured data at scale resides on saving a great amount of hours otherwise required for manual reading, labeling and linking of documents, as for inconsistencies and redundancies checking in their content. LLM integration further differentiates this methodology from traditional KG creation, accomplishing the main aim of the final KG, namely inference and query answering according to explicitly defined schema and properties, along with ensured high volume scalability, easier model retraining, debugging and dataset or prompt fixings.

According to the authors observations during the testing phase, the accuracy of the generated knowledge graph clearly relies on the underlying model leveraged, as the extracted information might be affected by biases and hallucinations, given by the LLM's ability to correctly interpret its tasks. Prompt development involved an interactive process of writing, testing, and refinement, based on feedback and experimentation. Tailoring the prompt to use-case specific application required giving the LLMs sufficient context to generate the desired output. This includes writing clear step-by-step instructions, as detailed as possible about the outcome format. Instead than zero-shot prompting (when the LLM relies solely on its pre-existing knowledge and on the instructions in the prompt to perform the task), adopting few-shot learning enabled the LLM to recognize patterns from little examples provided and to generalize to unseen task variations, also avoiding time-consuming data labeling. It emerged how the model tends to assign all relationships extracted from text to the ontology proposed, even those not standardized by it, and it struggles to infer transitive and inverse relationships from the ontology, if not explicitly declared in the example as well. Other limitations encountered testing this prompting framework rely on computational limits, which, in the case of GPT-3.5, are set to 4'096 tokens per prompt. Therefore textual sources to be analyzed must be pre-processed and split into smaller size compliant chunks, taking care of adequately preventing the loss of context and the separation of related entities (Carta et al., 2023). In order to ensure scalability for larger datasets, an algorithm devoted to chunking text and automatically and iteratively prompting the LLM should be implemented.

The proposed methodology presents intrinsic limitations, related to the time and expertise required to develop a proper domain ontology, as well as to the implementation and testing phase of the technological pipeline. It will be highly dependent on the application use-case, mainly caused by the uncertainty generated by the sample size and to the unreliability of its data sources. Due to the lack of prior research studies on this precise topic, it will be difficult to compare results and asses their validity, requiring the establishment of validation methods.

Future directions

The potential offered by this approach in the field of Knowledge Representation and Reasoning (KRR) is manifest, since KGs have emerged as key technologies for representing knowledge in a variety of domains and supporting intelligent applications, such as chatbots, question answering systems, and recommendation systems (Hu et al., 2023). An NLP agent devoted to answering a natural language question, by reasoning over facts in a KB, could potentially deal with text-to-SPARQL tasks and multi-hop reasoning, appropriately querying the organization's KG on user’s behalf. These technologies should provide also faster access to continuously-updating data like sensor readings, getting closer to real-time analytics.

Other future developments might consider multiple domains integration, differential privacy policies, implementing user-based restrictions on visualization, as well as the integration of ML algorithms for predictions. Reinforcement learning from human feedback and automatic updates to the KG as new document are ingested, will make the methodology more versatile.

As previously stated, the research project will leverage a practical use-case methodological approach, not only suggesting a plausible use of digital technologies to tackle AM processes inside the University of Turin, but also aiming at providing a scalable, generalizable and reusable set of tools, which might solve similar knowledge-related problems in other domains. Relatively to the applicative use-case, textual documents containing information regarding ownership and occupancy of the building are employed. The implementation of a *text-to-KG* will extract and interconnect factual knowledge, applying a customized ontology as “organizing principle”. The resulting KG’s consistency will be evaluated through recall and precision metrics based on confusion matrix entries, obtained from manual evaluation campaigns.

Aligning with past projects at the University of Turin, where Business intelligence (BI) tools have been implemented as means of data-driven decision making (Di Giuda et al., 2023), an integration of AI and BI would be desirable, to drive faster, automated and predictive insights. The use of AI powered analysis tool could overcome traditional BI tools limitations regarding analysis at a more granular level, benefitting the end user in terms of automating data cleaning to ensure accuracy in the procedure, integrating multidimensional analysis as well, to detect clusters or similarities across hierarchies, attributes and metadata stored in the graph database.

Conclusions

The paper tackled the proposition of a methodological approach to AIM, leveraging technological pipelines whose task is the automation of truthful knowledge extraction from a large organization’s documental corpora, to enable informed decisional processes. The pivotal element is the human user, as it determines specific information needs guiding the ontology creation, as well as practical decision-making goals and problem-solving context defined by the organization it represents. KGs provide structured knowledge by encoding concepts and relationships in machine-readable ontologies, therefore they can deliver accurate, safe and responsible AI applications, as they drive reasoning and semantics. However, the creation of an enterprise KGs manually might involve gigantic and cost-inefficient workload, hence the automation of ontology extraction from unstructured corpora through LLMs could be a viable solution. As it has been outlined, the incorporation of ontologies in the pipeline can significantly strengthen LLMs reasoning capabilities and structure accurate KGs, overcoming present challenges in reasoning and symbol grounding, granting a significant increase in the value of an organization’s knowledge graph. The authors tested a semi-automated approach to KG construction for the AIM domain, leveraging few-shot LLM prompting with GPT-3.5 model. The chaining prompting technique dealt with triplets extraction from unstructured sources, semantically aligning them with a pre-processed ontology acting as T-Box. The resulting KG showed GPT-3.5 proficiency in NLP tasks applied to closed-domain settings, taking advantage from clearly stated tasks explanation, although hallucinating ontology classes. Since being tested only on a small dataset, the authors intend to conduct more in-depth experimentation, to properly evaluate reliability and fitness to the intended purpose of the approach, qualifying replicability and generalizability, also evaluating alternative LLMs. Future developments will likely integrate other AI systems on the inference side of the pipeline, capable of dealing with continuously changing data and forecasting plausible event scenarios.

Acknowledgements

It is to be remarked that sensitive data contained in sources provided by the University of Turin have been anonymized prior to AI tools exploitation. The authors also want to thank Dr. Mirko Locatelli for sharing his knowledge on NLP and for engaging in enriching conversations on the topic.

ENHANCING BUILDING MAINTENANCE EFFICIENCY THROUGH BIM-LIDAR INTEGRATION

Hamidreza Alavi[1], Weiwei Chen[1,2], Mudan Wang[1], Soheila Kookalani[1] and Ioannis Brilakis[1]
[1]University of Cambridge, United Kingdom
[2]University College London, United Kingdom

Abstract

Facility Maintenance Management constitutes a significant portion of building costs, emphasizing the need for innovative approaches to enhance efficiency. This paper introduces a novel methodology for transforming point cloud data into Industry Foundation Classes (IFC) models. This method involves a meticulous point cloud classification and a subsequent conversion into a visually appealing mesh representation. This mesh is then linked to IFC entities, enabling the creation of comprehensive and semantically rich BIM models. A case study on the Civil Engineering Building at the University of Cambridge demonstrates the methodology's effectiveness, showcasing improved visualization and supervision of maintenance tasks. The contribution lies in the refined point cloud classification, mesh conversion, and seamless integration with IFC, providing a novel and efficient solution to existing challenges. The results underscore the potential for revolutionizing maintenance practices in existing buildings.

Introduction

The aging of buildings accentuates the imperative for effective maintenance, constituting over 65% of total building costs (Matos *et al.*, 2020; Alavi, Bortolini and Forcada, 2022). Despite this, facility managers frequently depend on conventional methods which can be inefficient and time-consuming (Juricic, Krstić and Čulo, 2021; Alavi and Forcada, 2022).

The integration of BIM with various technologies allows for the creation of 3D information models for facility maintenance and administration work, ultimately enhancing productivity. However, one major challenge in utilizing BIM for maintenance activities is the lack of a BIM model for existing buildings (Alavi and Forcada, 2019). This paper addresses this gap by introducing a novel "Scan-to-BIM" methodology. The implementation of LiDAR technology confidently converts point cloud data into a mesh format, providing a solid foundation for creating extremely accurate as-built BIM models (Antah *et al.*, 2021). The proposed methodology aims to enhance maintenance activities in existing buildings where there is no BIM model available. The paper aims to outline the utilization of LiDAR technology to obtain point cloud data of existing buildings and convert it into a mesh format, which can serve as a foundation for assigning relevant Industry Foundation Classes (IFC) information to different building components.

This method enables the development of an as-built BIM model that precisely depicts the current state of the building. Once created, this model can be integrated with a Computerized Maintenance Management System (CMMS) to simplify maintenance tasks. Each maintenance request from the CMMS can be associated with the applicable components in the as-built BIM model, making it easy for maintenance personnel to find and evaluate maintenance needs.

Literature Review

To enable effective maintenance activities during the O&M stage, a diverse range of data is required in BIM (H. Alavi *et al.*, 2021; Fan *et al.*, 2023). Furthermore, Nicolle and Cruz (Nicolle and Cruz, 2011), emphasize the need for precise data on installed components in buildings to achieve effective BIM implementation in the O&M phase. These kinds of data might not be available in many existing buildings due to imperfect and deficient, obsolete, or disintegrated building information (Gursel *et al.*, 2009). The significant difference between enabling BIM for FM in new buildings and existing buildings is the lack of as-built, CAD files as well as insufficient and outdated information of the buildings (Becerik-Gerber *et al.*, 2012; Hamidreza Alavi *et al.*, 2021). Missing this kind of information might lead to ineffective building management, uncertain process results and time loss or cost increases in facility management processes (Alavi and Forcada Matheu, 2022).

In recent years, the integration of BIM and LiDAR has emerged as a promising approach to create as-built BIM models for existing buildings and maximize building maintenance efficiency (Shin and Cha, 2023). This integration offers a robust framework for capturing detailed building information and leveraging it for effective maintenance processes. One of the key advantages of this integration is the ability to create 3D information models for facility maintenance (Wang, Guo and Kim, 2019; Liu, 2022). By integrating LiDAR data in BIM, it becomes possible to enhance the productivity of maintenance and administration work in facilities. This approach allows for a more rapid detection of faults or potential faults and a significant reduction in maintenance costs.

Multiple studies have explored the benefits and limitations of using LiDAR technology in combination with BIM for facilities management. These studies have highlighted the importance of accurately capturing the existing building conditions through LiDAR scans and converting them into BIM models (Brilakis *et al.*, 2010; Juan, Hwang and Kim, 2020; Liu, 2022). The study conducted by Hong Kong researchers focused on utilizing Scan-to-BIM, which combines terrestrial laser scan data with BIM, to perform quantity take-offs for estimating building maintenance costs (Sing *et al.*, 2022). This demonstrates the potential of LiDAR technology and BIM integration in enhancing maintenance activities by providing precise information for cost estimation and planning. Additionally, another study emphasizes the automation of the Scan-to-BIM process through semantic labeling. This study proposes an integrated system called Auto-Scan-To-BIM that automates the generation of a complete BIM model from scanned point cloud data. The Auto-Scan-To-BIM system utilizes region segmentation methodology and enhanced plane boundary line detection methods to accurately identify and analyze building elements from the point cloud data (Suprun *et al.*, 2022). Furthermore, research has also focused on the integration of BIM and LiDAR technology for quality management during the maintenance phase (Begić and Galić, 2021). Moreover, scan-to-BIM technology supports the creation of accurate as-built models that can be used by facility managers and stakeholders in maintenance operations. The integration of scan-to-BIM technology extends the value of BIM to the lifecycle of buildings, contributing to improved facility management and maintenance practices. The practicality of implementing the Scan-to-BIM approach in maintenance projects for existing buildings has not been widely explored, despite its potential benefits for creating accurate as-built models and improving facility management practices (Sing *et al.*, 2022). To address these limitations, this article proposes a methodology for enhancing maintenance activities in existing buildings using LiDAR technology and the scan-to-BIM process.

Methodology

The methodology involves utilizing LiDAR technology to capture point cloud data of the existing building. It is important to note that when processing point clouds, several challenges arise, including occlusions, misclassification, and identifying hidden elements. Occlusions occur when objects obstruct parts of the building, leading to incomplete or distorted point cloud data. Misclassification refers to the incorrect labeling of point cloud points, which can result in inaccuracies in subsequent modeling processes. Similarly, identifying hidden elements, such as structural components obscured from view, poses challenges in capturing comprehensive building information. To address these challenges, innovative approaches, such as deep learning and machine learning algorithms, were used to improve the identification of hidden elements and enhance the overall accuracy of the resulting BIM model.

The existing point cloud data is then processed and converted into a mesh representation of the building. Then, the methodology oversees creating IFC instance models to store building components created out of a laser scan. It is divided into four parts, as illustrated in Figure 1: (i) point cloud classification; (ii) point cloud conversion; (iii) the IFC model creation; and (vi) CMMS integration and visualization.

The first step in the methodology is point cloud classification. During this step, the point cloud data is classified and labeled to identify different building elements such as walls, floors, ceilings, doors, windows, and some MEP elements. Models created using the data contained in point clouds can be used for constructing an accurate representation of existing facilities by measuring their geometry and appearance.

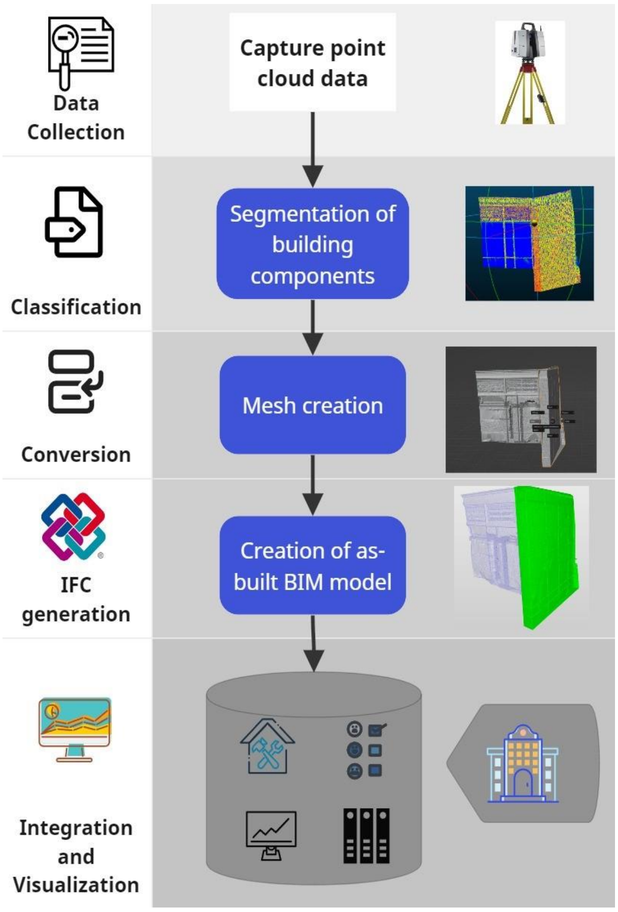

Figure 1. Methodology

The second step is point cloud-to-mesh conversion. During this step, the classified point cloud data is converted into a mesh representation of the building. This mesh representation allows for a more visually appealing and interactive view of the building, making it easier for maintenance workers to identify different elements and their locations. The third step in the methodology is the generation of an IFC model. During this step, the mesh representation of the building is assigned relevant Industry Foundation Classes entities. This involves mapping the building elements identified in the point cloud data to their corresponding IFC entities, such as walls, floors, doors, and windows. Once the relevant IFC entities are assigned, a complete IFC model is generated for the entire building. This IFC model contains all the necessary information about the building, including its geometry, spatial relationships, and attributes. The final step in the methodology involves using Dynamo in Revit to link maintenance requests from the building maintenance management system to the IFC model. By integrating the building maintenance with the generated IFC model, each maintenance request can be linked to the corresponding element in the building model. A filter can be applied to visualize the priority of each maintenance request on the model, dynamically representing their level of urgency or importance with different colors or indicators.

Case Study Implementation

To demonstrate the effectiveness of this methodology, a case study was conducted on the Civil Engineering Building in University of Cambridge, United Kingdom. The Cambridge University Engineering Department's (CUED) Civil Engineering Building, completed in 2019, stands as a pioneering example of modular and flexible laboratory and research infrastructure on the eastern fringe of the University's West Cambridge Campus. Encompassing approximately 5000m², the facility seamlessly integrates laboratory, research, and office spaces. LiDAR technology was utilized to capture a detailed and accurate point cloud of the building, shown in Figure 2.

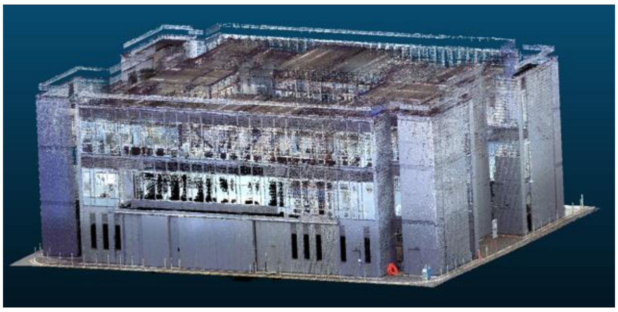

Figure 2. Point Cloud of the Civil Engineering Building

Point Cloud Classification

The point cloud data was then processed and classified to identify various building elements. The classification of the point cloud data enabled the identification of different building elements such as walls, floors, ceilings, doors, windows, and some MEP elements. Once the point cloud was segmented and the noise omitted, the next step involved the conversion of the classified point cloud data into a mesh representation of the building.

Point Cloud Conversion

The point cloud was converted into a mesh representation of the building. Using the innovative Python Ball Pivoting Algorithm, we were able to convert the raw point cloud data into a detailed mesh structure. This algorithm effectively handles challenges such as occlusions and hidden points, guaranteeing that the resulting mesh-based geometry accurately portrays the intricate details of the building's structure. The mesh representation provided a more intuitive and visually appealing view of the building, making it easier for maintenance workers to understand and interact with the model. Figure 3 shows the created mesh based on the point cloud data.

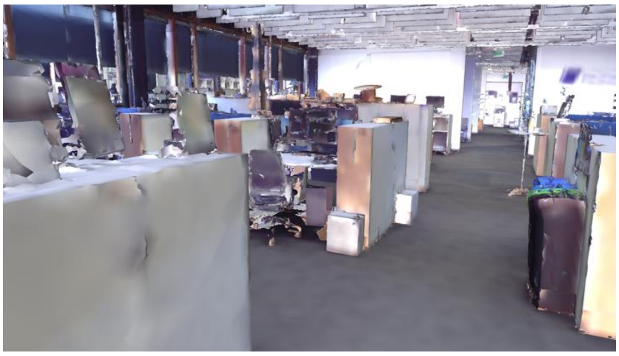

Figure 3. Mesh of the building

IFC Creation

Next, the classified point cloud data was mapped to relevant IFC entities, such as walls, floors, and doors. The IFC model was created using the ifcopenshell package in Python. This package allows for the manipulation and extraction of data from IFC files, enabling the assignment of relevant IFC entities to the classified point cloud data. The ifcopenshell library provides a set of tools and functions for working with IFC files, including the ability to create, read, and modify IFC models programmatically. Using the ifcopenshell package, the classified point cloud data was mapped to their corresponding IFC entities, such as walls, floors, doors, and windows. This process involved creating IFC elements for each building component, ensuring that the IFC model accurately represented the geometry and attributes of the existing building. The ifcopenshell package facilitated the generation of a complete IFC model that contained all necessary information about the building, allowing for spatial relationships and properties to be incorporated into the model.

By leveraging the capabilities of ifcopenshell in Python, the methodology successfully assigned relevant IFC entities to the classified point cloud data, resulting in the creation of a comprehensive and semantically rich IFC model for the existing building. Figure 4 illustrates ifcopenshell package for assigning relevant IFC to segmented mesh.

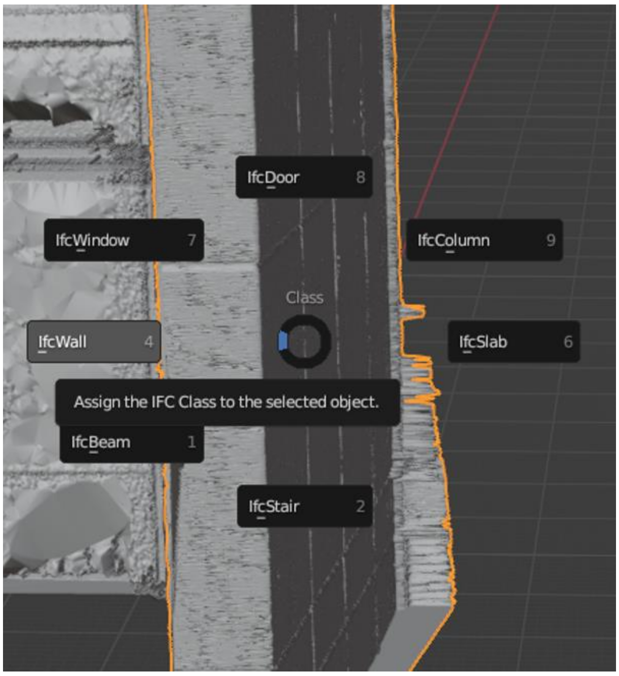

Figure 4. Process of assigning relevant IFC to mesh

CMMS Integration and Visualization

The process of linking maintenance requests from the CMMS to the generated IFC model involved several steps. First, the maintenance data obtained from the CMMS in an Excel file format was imported into Dynamo, a visual programming extension for Autodesk Revit as shown in Figure 5. Each row in the Excel file represented a different maintenance work order, with columns containing specific information such as issue, priority, and equipment codes. Table 1 shows examples of maintenance requests received by facility management department of west campus.

In this study, the shared parameter was utilized to allow BIM models to contain EquipmentID and Priority parameters. The shared parameter is a Revit term that can be added to the Revit family for custom data fields. It can also be accessible for any project due to holding parameters in a separate file. This enables the integration of maintenance data from the building maintenance management system with the BIM model, allowing for better coordination and planning of maintenance activities.

Table 1. Examples of maintenance requests for West Campus

Issue	**Date reported to Facilities**	**Priority**
Air Conditioning is still playing up	07 March 2023	Medium
remove alarm on back door	08 August 2023	low
repaint bike shed & compounds where w/shop exit is and where skips are	09 August 2023	low
The gas boiler in the plant room wont switch on	18 October 2023	medium
AC not working in the workshop	20 October 2023	medium
light inside study room not working	23 October 2023	medium
A leaking pipe in office	30 October 2023	high

To map maintenance requests to the BIM model for visualization, the following steps can be taken. First, the Excel file obtained from CMMS is imported in Dynamo, a visual programming extension for Autodesk Revit. In this file, each row corresponds to a different maintenance work order, and each column contains specific information such as issue, priority, and equipment codes. The parameters from the file are then grouped by type and mapped to each equipment (depending on the code) using the SetParameterbyName node in Dynamo. This step

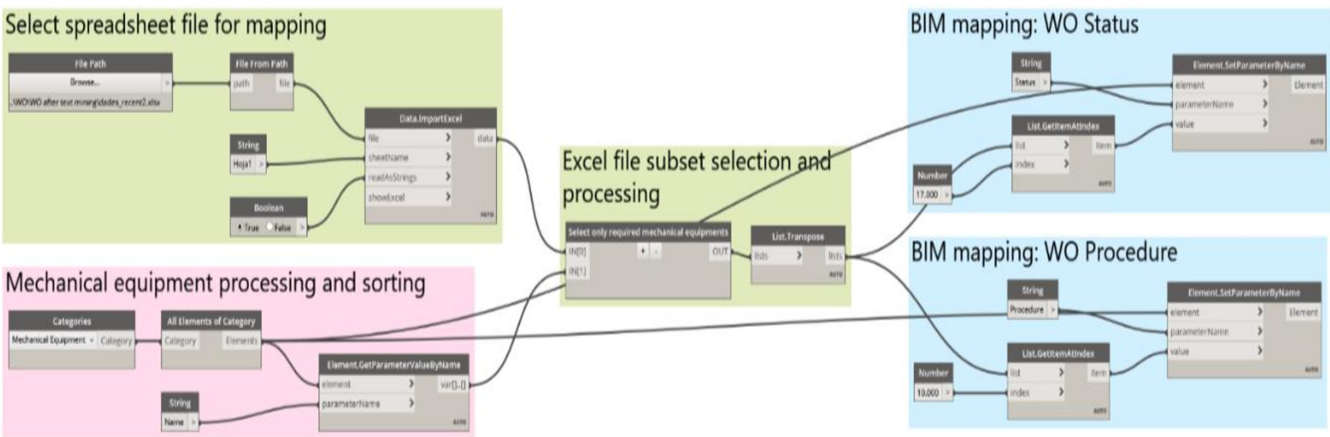

Figure 5. Dynamo code to import the maintenance requests to the mechanical equipment of the IFC model

involves linking the maintenance information to the corresponding elements in the BIM model. Using a Dynamo script, the information from the selected columns of the file can be saved in each parameter. This script contains two key Python code blocks. The code block "Reorganize room objects into Revit ordering" creates a list of all rooms and their room numbers, which are then organized to match the element numbering set by Revit. Developing custom Dynamo scripts specifically for this purpose made integrating maintenance activities into the BIM model easier. These scripts, using unique Python code blocks, showing our dedication to creating solutions that meet the specific needs of maintenance tasks in facility management. By using these custom scripts, we ensured that maintenance information was accurately mapped to corresponding rooms in the BIM model, improving the efficiency of maintenance planning and execution.

This integration allowed for the linking of each maintenance request to the corresponding element in the building model, with the ability to visually represent the priority of each maintenance request on the model. By dynamically indicating the urgency or importance of maintenance requests with different colors or indicators, the maintenance team gained an efficient and effective tool for managing and prioritizing maintenance activities.

Results and Discussion

The use of the proposed methodology for enhancing maintenance activities in existing buildings without a BIM model can greatly improve efficiency and accuracy. By utilizing LiDAR technology to capture point cloud data, maintenance workers can have access to detailed and accurate information about the building's geometry. This data is then transformed into a mesh representation using the Python Ball Pivoting Algorithm to ensure precise modeling that includes intricate details, such as holes in walls, thus enhancing the fidelity of the resulting BIM model. This BIM model can then be linked to the CMMS, enabling maintenance requests to be directly connected to the corresponding elements in the model.

The methodology involves using the ifcopenshell package in Python to convert the mesh representation into an IFC file. Unlike conventional approaches, ifcopenshell offers a versatile and general solution, providing greater flexibility in manipulating and extracting data from IFC files. This contributes to advancing the field by offering a more accessible and adaptable framework for generating IFC models from point cloud data.

In addition, we have developed custom Dynamo scripts designed to integrate maintenance tasks into Revit, enhancing the usefulness of BIM models in facility management. The unique Python code blocks within these scripts, especially the "Reorganize room objects into Revit ordering" code, demonstrate our dedication to creating solutions tailored for maintenance activities. This customization enables accurate mapping of maintenance information to respective rooms in the BIM model, leading to significant improvements in maintenance planning and execution efficiency.

The proposed visualization tool aligns with the case study's findings, illustrating how the seamless integration of LiDAR technology with BIM models effectively facilitates more efficient and accurate maintenance practices. By implementing the visualization tool, Facility Management and Maintenance teams can better organize and prioritize maintenance tasks. The clear visualization of maintenance requests directly on the 3D model of the building enables FMM personnel to assess the urgency and allocate resources effectively. Figure 6 illustrates examples of two maintenance requests on the West Campus of Cambridge University. As shown in the figure, each maintenance request is depicted by a colored marker on the BIM model. For instance, a red marker indicates a high-priority maintenance request, while a yellow marker represents medium-priority requests. A leaking pipe in the office is an example of a high-priority maintenance request and is represented as a red marker in the BIM model. On the other hand, a light in the study room constitutes a medium-priority request and is symbolized by a yellow marker. This color-coded representation not only improves the efficiency of maintenance workers in addressing urgent issues promptly but also allows for better planning and allocation of resources to address less urgent maintenance requests. In addition, this integration provides maintenance workers with a clear understanding of the location and status of each maintenance request, facilitating their decision-making process and streamlining the overall maintenance workflow.

The process of implementing the visualization tool involves the utilization of LiDAR technology to capture comprehensive point cloud data, enabling the creation of a detailed and visually rich BIM model. This model, integrated with the CMMS, enhances the clarity and accessibility of maintenance requests, streamlining the overall maintenance workflow while ensuring accurate documentation and spatial representation of the building's elements.

The comparison of the current maintenance management approach, where maintenance work orders are received in Excel files, with the proposed visualization tool clearly demonstrates the potential for improvement. The visualization tool provides a more intuitive way to manage maintenance tasks, moving away from traditional tabular data towards a spatially enriched representation of the building's elements. This transition can significantly enhance the FMM's ability to plan, coordinate, and execute maintenance activities effectively.

The implementation of the visualization tool, as evidenced by the successful integration of LiDAR technology, point cloud data, and BIM models in the case study, presents a compelling opportunity to revolutionize the management of maintenance tasks in existing buildings.

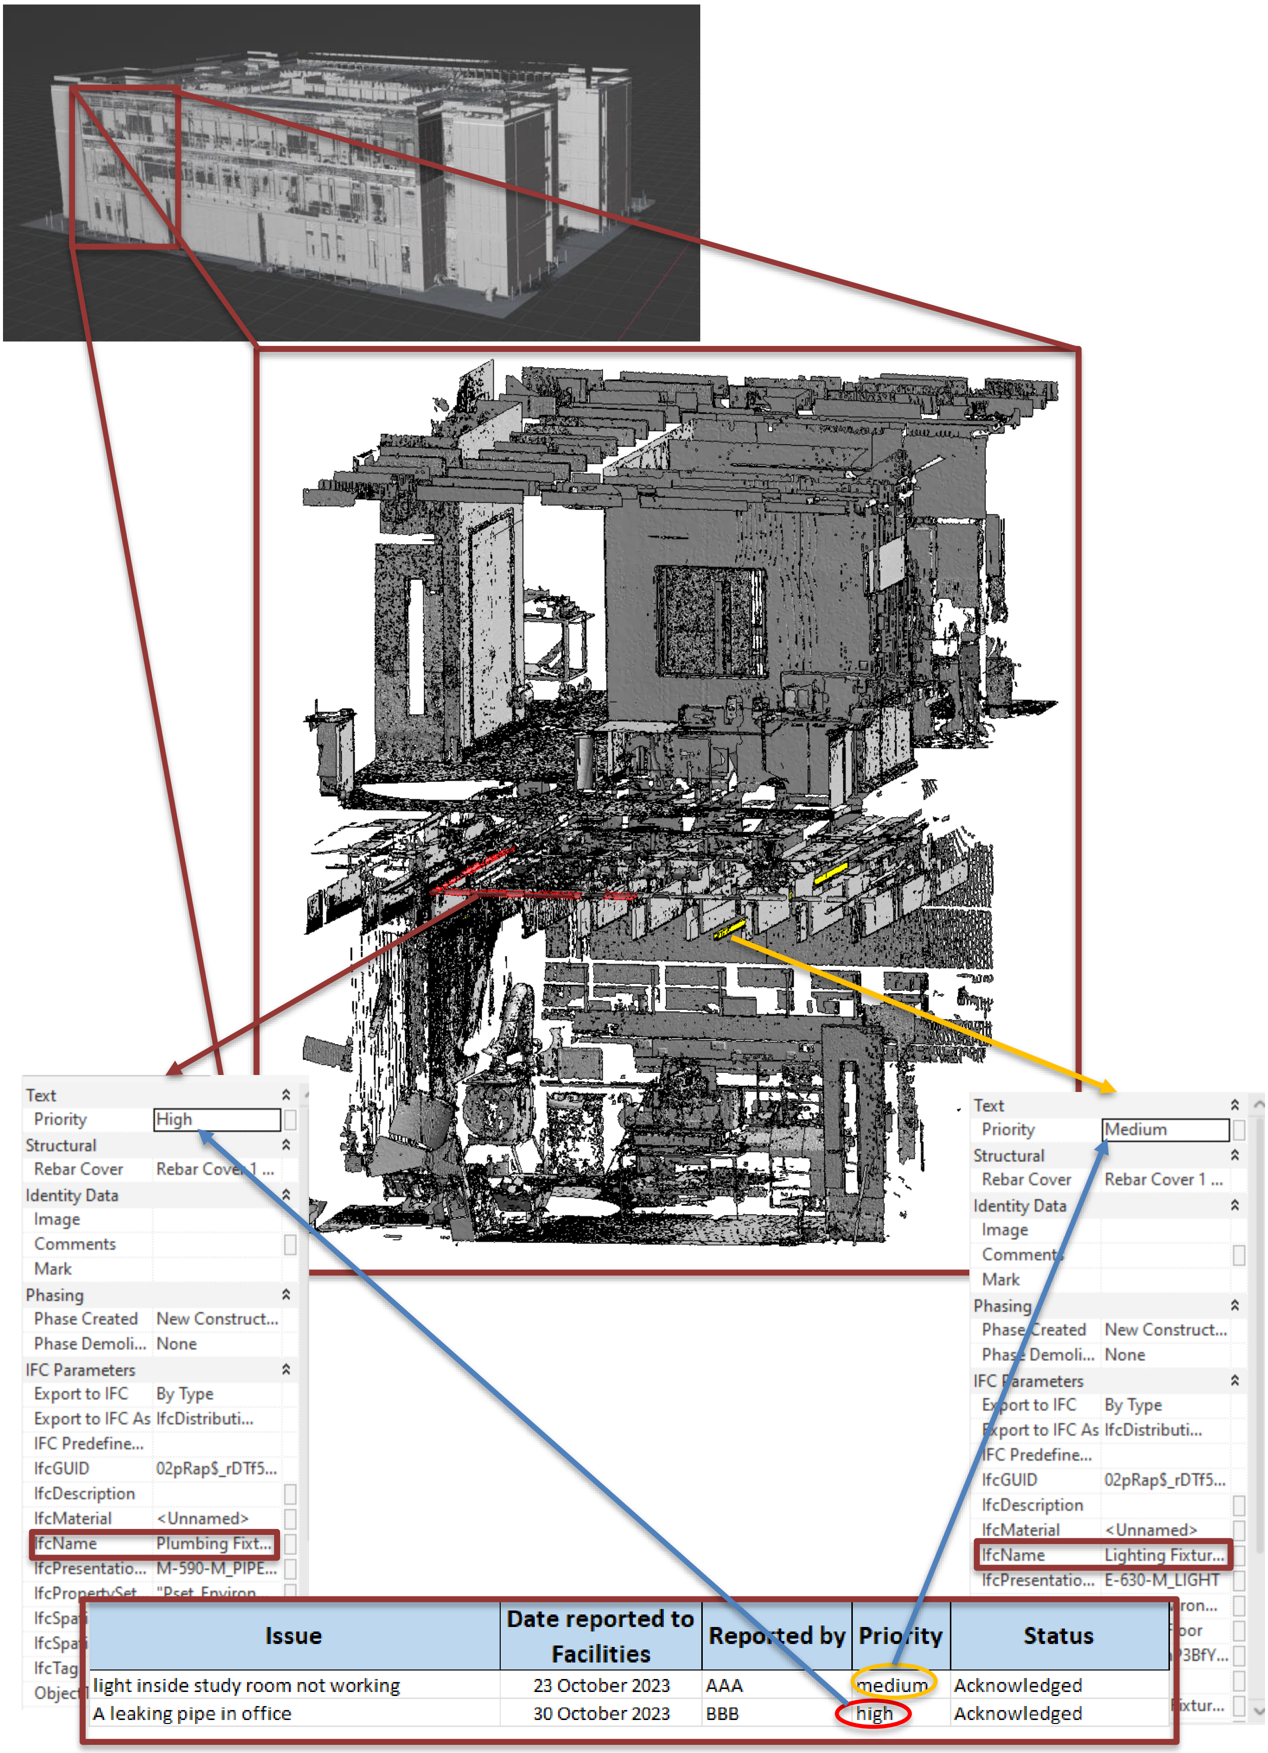

Figure 6. Example of the equipment visualization based on the priority of maintenance requests

The visualization tool not only fosters a more organized and informed approach to maintenance but also elevates the overall understanding of the building's conditions and facilitates well-informed decision-making for maintenance and rehabilitation efforts. This methodology not only improves the maintenance process but also enhances the overall management of the building. With the integrated system of LiDAR technology, point cloud data, and BIM models, facility managers can easily access and analyze important information about the building's condition, identify potential issues, and make informed decisions regarding maintenance and repairs. This approach also enables better communication and collaboration among stakeholders involved in the maintenance process.

Conclusion

The use of LiDAR technology and point cloud data to enhance maintenance activities in existing buildings without a BIM model offers significant advantages.

It allows for the creation of detailed and accurate as-built BIM models, which can be linked to maintenance management systems to streamline the maintenance workflow. By assigning relevant IFC entities and color-coding maintenance requests based on priority level, maintenance workers have a clear understanding of the location and status of each maintenance request, improving efficiency and effectiveness. Moreover, the integration of point cloud data and BIM models provides facility managers with valuable information for better decision-making and overall building management. For instance, various kinds of data can be linked to IFC models to improve maintenance activities. This includes information about equipment specifications, maintenance history, warranty details, and any other relevant data that can assist in planning and executing maintenance tasks. By leveraging the power of LiDAR technology and point cloud data, facility management teams can transform the way they approach maintenance in existing buildings. This innovative approach not only improves the accuracy and efficiency of maintenance tasks but also enhances the overall management of building conditions and facilitates informed decision-making processes. The combination of LiDAR technology, point cloud data, 3D models created with BIM in the context of maintaining activities for existing buildings presents a significant opportunity to revolutionize traditional approaches towards conducting property upkeep while improving their overall performance as well as longevity.

The development of custom Dynamo scripts highlights the potential of this methodology in the future. These scripts form the basis for potential projects, such as creating APIs for seamless integration with emerging digital twin platforms. Future work could focus on advancing the use of BIM and point cloud data in maintenance activities for existing buildings. One potential future direction is the refinement of automated algorithms and machine learning techniques to streamline the process of converting point cloud data into parametric BIM models. This advancement can significantly reduce the manual effort required, making the generation of BIM models from point cloud data more time-efficient and scalable. Additionally, future work in this area could explore the integration of Internet of Things data with BIM models to enable real-time monitoring of building components and systems. This integration would allow for proactive maintenance, where sensor data from IoT devices triggers maintenance alerts directly within the BIM model, enabling facility managers to address issues before they escalate. Moreover, the role of BIM in predictive maintenance can be explored in existing buildings. By leveraging historical maintenance data, sensor information, and building performance data within the BIM environment, predictive maintenance strategies can be employed to anticipate and plan for maintenance activities, maximizing the operational efficiency of existing buildings.

AN ONTOLOGY CONCEPT FOR THE TOPOLOGICAL ABSTRACTION OF INFRASTRUCTURE NETWORKS

Jens Bartnitzek[1], and Al-Hakam Hamdan[1]
[1]A+S Consult GmbH, Dresden, Germany

Abstract

Infrastructure planning requires the use of various geometric representations of traffic nets thus exchanging different data models during a project that all refer to the same domain object. In order to provide a common data basis for a BIM-based workflow, this article proposes a topological model for representing traffic nets based on the parametric planing objects. Therefore, a concept for connecting the topology with alignment geometry data is described. Furthermore, the proposed concept allows the abstraction of multiple macro topologies for various use cases that all refer to the same lower level micro topology. Additionally, the approach is implemented by utilizing Semantic Web Technologies and therefore developing an OWL ontology concept for representing traffic topologies. Subsequently the concept is exemplified through an ontology that defines the topology representation of a simple rail switch.

Introduction

Due to the inherent curvature of the earth of the engineering alignment and the large-scale expansions of rail networks, different types of georeferenced representations of the rail network are required. The alignment planning is based on projected geodetic coordinate reference systems such as Universal Mercator Projection (UTM) where the site planning is separated from the height planning. Consequently, a common base model is required to which the various geometric representations could refer. This is especially required when applying methods of Building Information Modeling (BIM) in infrastructure planning, whereby various stakeholders and domain-specific project participants are involved.

One possible approach would be the use of a model that represents only the topological relations of the infrastructure network. This way, different geometric representations could reference or be linked to the same consistent topology, thus preserving data integrity in digital planning processes.

An infrastructure topology allows disparate geometric datasets to integrate with a single logical network representation, avoiding inconsistencies. The topological connectivity also enables sophisticated network analysis for tasks like routing, vulnerability assessment, and optimization. Since the topology is decoupled from physical geometry, it supports flexibility in aligning to different coordinate projections or levels of detail.

A new concept for modeling a topology that represents traffic nets of any kind is proposed in this article. Theoretically, this concept could be implemented in a variety of data structures, e.g. as an SQL database or using BIM standards such as the Industry Foundation Classes (IFC). Since topologies can be represented well as graphs and in order to integrate the underlying logic-based concepts in the model, the developed topology concept is implemented as a graph-based ontology using the Web Ontology Language (OWL). The proposed concept is demonstrated on an exemplary ontology that defines the topology representation of a simple rail switch.

Related Work

Various ontological approaches exist that aim for a topological representation of constructions. According to Gruber (2009), an ontology in the context of computer and information sciences is defined as a set of representational elements that can be used to model a domain of knowledge or discourse. These representational elements include classes, properties, and relationships or relations. Furthermore, the representational elements of an ontology contain information about their meaning as well as constraints for their logically consistent application. Ontologies can be created in various formats, of which the most prominent one is OWL that is also W3C-standardized[1]. OWL is based on the Resource Description Framework (RDF)[2] and Resource Description Framework Schema (RDFS)[3], which are also W3C standardized and allow the formulation of logical statements about any things (referred to as resources in RDF) in the form of triples consisting of subject, predicate and object. In this regard, OWL adds further concepts that enable the representation of knowledge on the basis of description logic (Baader et al., 2017). Since based on description logic, OWL-based ontologies are divided into two separate systems, one of which describes the Terminological Component (TBox) and the other the Assertional Component (ABox). In the TBox the knowledge concepts used in the ontology are defined including classes and properties. It establishes the hierarchy of classes and the specifications on properties, such as domain and range specifications, class equivalences, and property characteristics. The ABox contains assertions about instances of the classes defined in the TBox, essentially the factual knowledge. By reasoning the ABox against a TBox by an OWL-compatible reasoning engine, implicit information can be inferred based on the asserted facts in the ABox.

For buildings the Building Topology Ontology (BOT) (Rasmussen et al., 2021) can be used to define topological relations between digital representations of building zones and elements. Consequently, no geometry is involved in the topology, however references to geometry data can be

[1]https://www.w3.org/OWL/ (accessed: April 03, 2024)

[3]https://www.w3.org/TR/rdf-schema/ (accessed: April 03, 2024)

made through links on BOT resources. A similiar approach can be realized for bridges with the Bridge Topology Ontology (BROT) (Hamdan and Scherer, 2020). Both approaches have in common that the structure of a construction is realized through classes for zones and components. Comparatively, a traffic net is described on a more abstract level and wider scale consisting of stations and connecting tracks.

An ontology for representing this kind of structure has been developed by Lorenz et al. (2005) as Ontology of Transportation Networks (OTN). Thereby, not only stations and their respective connections are modeled but also corresponding land areas or built structures. Furthermore, the connections could be typed via classes, e.g. a connection can be classified as waterway, road or railway. Another ontology for representing the topology of rails has been developed as Rail Topology Ontology (RTO) by Bischof and Schenner (2021). RTO is an OWL representation of the RailTopoModel (RTM), which has been released as International Railway Standard 30100 and is defined as UML model. Compared to OTN, RTM and RTO allow the definition of different aggregation levels such as nano, micro or macro for modeling the topology in various detail levels, e.g. for visualizing the network in a broader scale. However, parallel definition of higher level topologies that refer to the same lower level topology are usually not supported by RTM or lead to inconsistencies. Furthermore, OTN as well as RTM and RTO define no alignment strategies in their respective topology concepts for connecting topological data objects exactly to related geometry background by using the geometric alignment stations.

Besides ontological approaches, also general concepts for realising topologies in infrastructure have been developed. For instance, according to Bendfeldt (2005) a railway station can be divided:

- by operational technology in the areas of train transportation and train formation,
- operationally in the areas of route junctions and track groups or
- by type of transport in the areas of rail passenger transport and rail freight transport

Furthermore, Bendfeldt (2005) investigates how stations can be broken down into elementary nodes and elementary stations in order to derive standardization's and design principles for optimized operational and infrastructural aspects.

Methodology

In order to develop the topology and subsequently the prototypical ontology, core requirements must first be identified that have to be fulfilled by the resulting concepts. In this regard, a fundamental principle of traffic planning that needs to be considered for the topology is the need for specific traffic routes that result from the distribution of potentials. A location for a potential is defined as the position of an individual settlement or business location as well as an agglomeration of these locations. Topologically these (combined) locations are abstracted as nodes. Traffic potentials exist between the nodes, which as directed edges describe the potential for a traffic relationship in the form of travel or goods transportation between the nodes. Lill's law of travel (see eq. 1) provides a simplified way of evaluating this potential (Lill, 1891).

$$V_{AB} := k \cdot \frac{P_A \cdot P_B}{d(A,B)^2} \quad (1)$$

The size of the possible traffic flow V_{AB} is proportional to the product of the size of the agglomerations P_A, P_B to be connected and inversely proportional to the square of their distances $d(A,B)$. Furthermore, k is an additional constant correction value (Lill, 1891).
