### **Abstract**

Far-field noise and flow field over a novel curved trailing-edge serration (named as *iron-shaped* serration) are investigated. Spectra of the far-field broadband noise, directivity plots and the flow-field over the iron-shaped serration are obtained from numerical computations performed using a compressible Lattice-Boltzmann solver. The new design is compared to a conventional trailing-edge serration with a triangular geometry. Both serration geometries were retrofitted to a NACA 0018 airfoil at zero degree angle of attack. The iron-shaped geometry is found to reduce far-field broadband noise of approximately 2 dB more than the conventional sawtooth serration for chord-based Strouhal numbers  $St_c < 15$ . At higher frequencies, the far-field broadband noise for the two serration geometries has comparable intensity. Near-wall velocity distribution and surface pressure fluctuations show that their intensity and spectra are independent on the serration geometry, but a function of the streamwise location. It is found that the larger noise reduction achieved by the iron-shaped trailing-edge serration is due to the mitigation of the scattered noise at the root. This effect is obtained by mitigating the interaction between the two sides of the serration, by delaying toward the tip both the outward (i.e., the tendency of the flow to deviate from the centerline to the edge of the serration) and the downward (i.e., the tendency of the flow to merge between the upper and bottom side of the serration) flow motions present at the root of the sawtooth.

**Keywords:** trailing-edge serration, turbulent boundary-layer trailing-edge noise, aeroacoustics, noise reduction.

## 1. Introduction

Broadband trailing-edge noise generated by the scattering of a turbulent flow convecting over the trailing edge of an airfoil [1,2] is a relevant contributor to wind-turbine noise [3].

Many passive mitigation strategies have been proposed to reduce this source of noise. Acoustic measurements, carried out both in wind tunnels and in-field, reported that sawtooth trailing-edge serrations offer the most effective noise reduction per simplicity of design [4–11]. Far-field noise reductions with respect to the straight trailing-edge configuration, expressed as difference in Sound Pressure Level (SPL), of approximately 7 dB and 3 dB were measured in both wind tunnel [12] and in-field applications [4].

Many analytical approaches have been proposed [13–17] to predict trailing-edge noise in presence of sawtooth trailing-edge serrations. Howe [13,16] formulated the first analytical model to estimate broadband noise generated by a low Mach number turbulent flow over a flat plate at zero angle of attack with sawtooth trailing-edge serrations. The model predicts an asymptotic noise-reduction intensity, at relatively high frequencies, of  $10\log_{10}[1+(4h/\lambda)^2]$  dB where  $\lambda$  and  $2h$  are the serration wavelength and length, respectively. When compared to experimental results [4,7,10,11], the current triangular designs are not able to match the predicted noise reduction intensity. Moreover, the model cannot explain the characteristic *cross-over* frequency  $f_c$ , corresponding to a Strouhal number  $St_\delta = f_c\delta/U_\infty \approx 1$  (based on the free-stream velocity  $U_\infty$  and boundary layer thickness  $\delta$  estimated with XFOIL [18] in the study of Gruber *et al.* [19]), after which noise increases again. Recently, Lyu *et al.* [14,17] developed a new semi-analytical model applying Amiet’s trailing-edge noise theory [20] to sawtooth trailing edges. Results showed that the predicted noise reduction are closer to the

one experimentally measured. Lyu *et al.* [14,17] detected two non-dimensional parameters that substantially affect noise reduction:  $k_1 \times 2h$  and  $l_{zp}(f)/\lambda$ , where  $k_1$  is the wavenumber in the chordwise direction and  $l_{zp}(f)$  is the spanwise correlation-length of the surface pressure fluctuations. The studies of Lyu *et al.* concluded that far-field noise can be reduced when both  $k_1 \times 2h$  and  $l_{zp}(f)/\lambda$  are much larger than unity. This implies that the serration should be long enough to ensure a considerable phase difference of the scattered pressure waves at the edge of the serration. In addition, if the spatial range of the phase difference, i.e.  $\lambda$ , is sufficiently small compared to the correlation length in the spanwise direction, radiated sound waves may destructively interfere with each other.

More recent investigations on the actual flow fields [7,10,21,22] have shown that the flow past serrated airfoils is strongly three dimensional, with vortical structures developing along the edges of the serrations. Because of the complex flow field and of the streamwise varying pressure gradient, both aerodynamic effects and acoustic scattering are mutually dependent [3,23,24]. Flow measurements [7,10,24] and computations [22,25] showed that, even at small angles of attack, the turbulent flow tends to seep into the empty space in between serrations. More in details, both an outward (i.e., from the centerline toward the edge) and an inward (i.e., from the edge toward the centerline of the serrations) flow motions characterize the flow field respectively at the root and the tip of the sawtooth trailing-edge serrations [10,24]. This flow distortion is found to reduce the effective angle seen by the turbulent flow convecting over the edge of the serrations thus reducing the effectiveness of the serrations in mitigating far-field noise [21].

Aiming at reducing the broadband far-field noise even further, several variations of the serration geometry were proposed and tested, e.g. brushed [26], sinusoidal [15], slitted [27,28] and even randomly-shaped trailing edges [29]. More recently, it was shown that broadband far-field noise can be reduced, with respect to conventional serrations, by filling the empty

space in between serrations with combs or slits [3]. A first attempt to give a physical explanation behind the achieved noise reduction was reported by van der Velden & Oerlemans [30].

Based on previous experimental observations [7,10], curved trailing-edge serrations may reduce the far field noise by mitigating the negative effect due to the outward and downward flow motions at the root. In this manuscript, curved trailing-edge serrations are investigated with the commercial Lattice-Boltzmann Method (LBM) solver *Exa PowerFLOW*. The iron-shaped serrations are compared to more conventional sawtooth trailing-edge serrations with same length ( $2h$ ) and wavelength ( $\lambda$ ). A similar shape was patented by Vijgen *et al.* [31] with the purpose of improving lift and drag of lifting surfaces and by Oerlemans [32] for noise reduction. Aim of this paper is to investigate the physical reasons behind the larger noise reduction achieved by the iron-shaped serrations with respect to the conventional sawtooth serrations. In the following study, the serrations are retrofitted to a NACA 0018 airfoil placed at zero angle of attack, similarly as in the reference experiments [7,27].

## 2. Methodology and solver

The commercial software package *Exa PowerFLOW* 5.3b was used to solve the discrete Lattice-Boltzmann equations for a finite number of directions. For a detailed description of the equations used for the source field computations the reader can refer to Succi [33] or van der Velden *et al.* [34].

The discretization used for this particular application consisted of 19 discrete velocities in three dimensions (known as the D3Q19 model) involving a third-order truncation of the Chapman-Enskog expansion to retrieve the Navier Stokes equations. For three dimensional computations of low Mach number ideal gas flows, this was found to accurately reproduce the flow field [33]. The distribution of particles was solved using the kinetic equations on a

Cartesian mesh, with the conventional Bhatnagar-Gross-Krook (BGK) collision term operator [35]. A Very Large Eddy Simulation (VLES) was implemented as viscosity model to locally adjust the numerical viscosity of the scheme [36]. A sub-grid scale model is essential to obtain solutions of transient high Reynolds flow problems within feasible turn-around times. The model consists of a two-equations  $k-\varepsilon$  Renormalization Group (RNG) modified to incorporate a swirl based correction that reduces the modeled turbulence in presence of large vortical structures, required for stability of the code.

Due to the limitations of the discretization model D3Q19, the cells, further denoted as voxels, are equally sized in each direction. This makes challenging to perform wall-resolved simulations. Hence, a turbulent wall-model was used to resolve the near-wall region [37]. The particular choice of the model allowed to obtain, for this particular configuration, a reliable estimate of the boundary layer till the viscous sub-layer.

Due to the fact that the LBM is inherently compressible and it provides a time-dependent solution, the sound pressure field was extracted directly from the computation domain. Sufficient accuracy is obtained when considering at least 16 cells per wavelength for the LBM [38]. The obtained far-field noise was further compared with noise estimated by using an acoustic analogy. For this purpose, the Ffowcs-Williams and Hawkings (FWH) [39] equation was employed. The time-domain FWH formulation developed by Farassat [40] was used to predict the far-field sound radiation of the serrated trailing-edge in a uniformly moving medium [41,42]. The input to the FWH solver is the time-dependent pressure field over the surface mesh of the airfoil provided by the transient LBM simulations [43].

To further detect the location of the noise sources in the near field, the dynamics of co-rotating flow structures was investigated [44]. The Flow-Induced Noise Detection (FIND) tool was used to detect and track the co-rotating flow structures in the flow field. Starting from three dimensional time solved data, it is possible to detect the coherent structures, their

location and their size. As a consequence, co-rotating vortex pairs, responsible for airfoil self-noise, are tracked in time and their intensity is estimated following the theory of vortex sound [45].

### 3. Computational test-case

Computations were performed on a NACA 0018 airfoil with chord length  $c = 200$  mm and 80 mm span (Figure 1). The simulation domain size was  $12c$  in both the streamwise and the wall-normal directions. The outer  $2c$  were modeled as an anechoic outer-layer to damp down acoustic reflections. In spanwise direction, cyclic boundary-conditions were used. A variable mesh resolution in the computational field was employed. The grid size was changed by a factor two between adjacent resolution regions. The boundary layer was represented by two refinement regions, while the other regions were placed in uniform flow conditions in the far field. Ten refinement regions allowed the first cell to be placed in the viscous sub-layer at  $3.9 \times 10^{-4}c$  above the trailing-edge location, corresponding to  $y^+ = 3$ . In total, around 150 million voxels were used for the discretization of the domain. Data sampling started after reaching a steady standard deviation of the lift and drag coefficient in the solution (approximately 10 full flow-passes over the airfoil chord). The Courant–Friedrichs–Lewy (CFL) number is dependent on the wave propagation velocity and on the smallest voxel size in compressible simulations. With the current cell size and a unit CFL number, the resulting time-step was  $1.3 \times 10^{-7}$  s. The wall-pressure probes had the same size of the local voxel (i.e.  $3.9 \times 10^{-4}c$  at the trailing-edge location and  $7.8 \times 10^{-4}c$  along the rest of the airfoil). Flow data were sampled with frequency  $f = 30$  kHz for 20 flow passes. The prescribed methodology was validated in a previous study by van der Velden *et al.* [34].

The trailing-edge thickness of the airfoil was kept sharp with  $t = 1$  mm ( $t/c = 5 \times 10^{-3}c$ ) in order to minimize the tonal noise component due to the vortex shedding ( $t/\delta \approx 0.1$  where  $\delta$  is

the boundary layer thickness discussed below) [46]. The free-stream velocity was  $U_\infty = 20$  m/s, and the angle of attack was  $\alpha = 0^\circ$ . Boundary-layer transition to turbulence was forced at  $x/c = 0.2$  by means of a serrated strip of height  $3 \times 10^{-3}c$  and length  $1.5 \times 10^{-3}c$  on both sides of the airfoil [34].

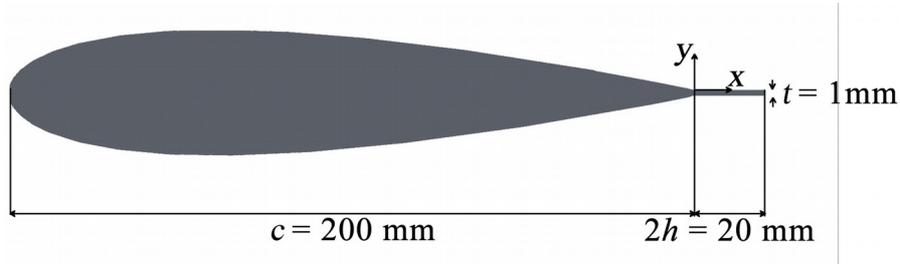

Fig. 1. Sketch of the airfoil (side view).

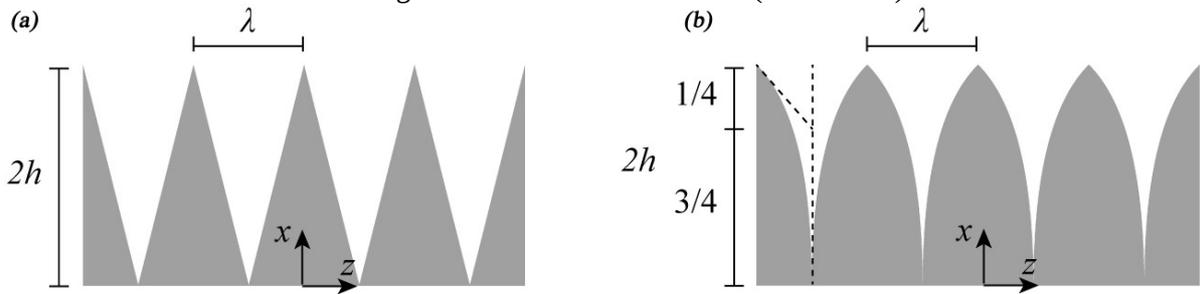

Fig. 2. Sketch of the conventional (a) and iron-shaped (b) trailing-edge serrations.

The airfoil trailing-edge was retrofitted with two serrated trailing-edges: a conventional sawtooth and an iron-shaped geometry (Figure 2). The latter was designed with a spline curve. At the root, it is perpendicular to the baseline trailing-edge while, at the tip, it is tangent to the line obtained as intersection of the tip point with the point at  $\frac{3}{4} \times 2h$  (see dashed line in Figure 2 b). Both serrations had length  $2h/c = 0.2$  ( $2h = 40$  mm) and wavelength  $\lambda/c = 0.1$  ( $\lambda = 20$  mm). The serration length was approximately four times the boundary layer thickness  $\delta$  [7,27]. The airfoil shape and the geometry of the sawtooth trailing-edge were chosen as in the experiments performed by Arce León *et al.* [7,27] used as reference throughout the entire manuscript.

The adopted Cartesian coordinate system (Figure 1 and Figure 2) for each configuration is defined as follows: the origin is chosen at the location of the baseline airfoil trailing-edge (i.e., the airfoil with the straight trailing-edge); the  $z$ -axis coincides with the airfoil

trailing-edge; the  $x$ -axis is aligned with the chord of the airfoil (i.e., aligned with the serration surface); and the  $y$ -coordinate is perpendicular to the surface of the serrations. In presence of serrations, the origin coincides with the projection along the chord direction of a serration tip on the trailing edge of the baseline model (Figure 2).

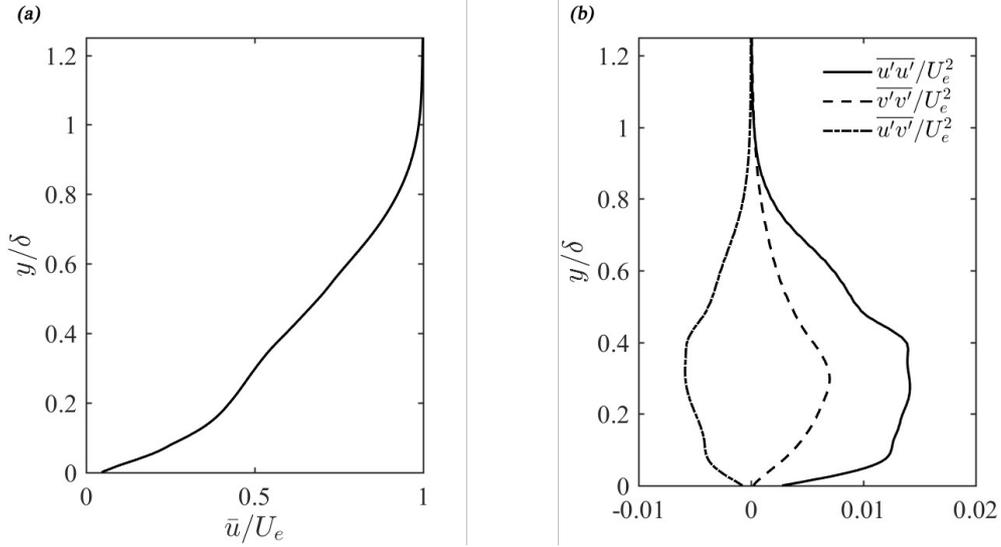

Fig. 3. (a) Mean streamwise velocity component and (b) time-averaged turbulent statistics for the baseline airfoil at  $x/c = 0$ .  $U_e$  is the local edge velocity.

Boundary-layer profiles of the mean streamwise velocity component and time-averaged turbulent statistics [47] were inferred from the computed velocities. They are reported in Figure 3 and summarized in Table I. More in detail,  $\delta_{95} = 7.9$  mm and  $\delta = 9.5$  mm are the boundary-layer thickness parameters defined by the  $y$ -location corresponding to 95% and 99% of the local edge velocity ( $U_e$ ), respectively.  $\delta^* = 3.3$  mm and  $\theta = 1.5$  mm are the displacement and momentum thickness, respectively. This results in a shape factor  $H = \delta^*/\theta$  of approximately 2.2.  $\delta$ ,  $\delta^*$  and  $\theta$  obtained from the computations are similar to the ones reported by Arce León *et al.* [7] thus allowing the comparison. Table I also lists the corresponding Reynolds numbers for the length scales addressed above.

Table I. Boundary layer characteristics at  $x/c = 0$

Parameter		Quantity
Free-stream velocity	$U_\infty$	20 m/s
Edge velocity	$U_e$	18.75 m/s
Displacement thickness	$\delta^*$	3.3 mm
Momentum thickness	$\theta$	1.5 mm
Boundary layer thickness	$\delta$	9.5 mm
	$\delta_{95}$	7.9 mm
	$Re_c$	280,000
Reynolds number	$Re_{\delta^*}$	4,600
	$Re_\theta$	2,100
	$Re_\delta$	13,300
	$H$	2.2

Given the flow similarities over the different serrations present in the computational domain and in order to further reduce the uncertainty on the velocity fields, the computed fields were spatially averaged along the spanwise direction at points with the same relative spanwise location with respect to the serration root. This procedure reduces the uncertainty by increasing the number of samples available for averaging [22].

## 4. Results

### 4.1 Far-field noise

The acoustic power spectra ( $\Phi_{aa}$ ) are obtained from the time series of the pressure fluctuations sampled by a microphone located above the trailing edge of the baseline airfoil ( $x/c = 0$ ,  $z/c = 0$  and  $y/c = 10$ ). Far-field pressure spectra ( $\Phi_m$ ) are extracted from the FWH analogy [39], and converted to acoustic far field spectra as described in Section 2. Results presented in Figure 4 are scaled as reported in equation 1:

$$\Phi_{aa} = \Phi_m + 20 \log_{10} \left( \frac{R_m}{R_{ref}} \right) + 10 \log_{10} \left( \frac{b_{ref}}{b_m} \right) + 50 \log_{10} \left( \frac{M_{\infty ref}}{M_{\infty m}} \right) \quad (1)$$

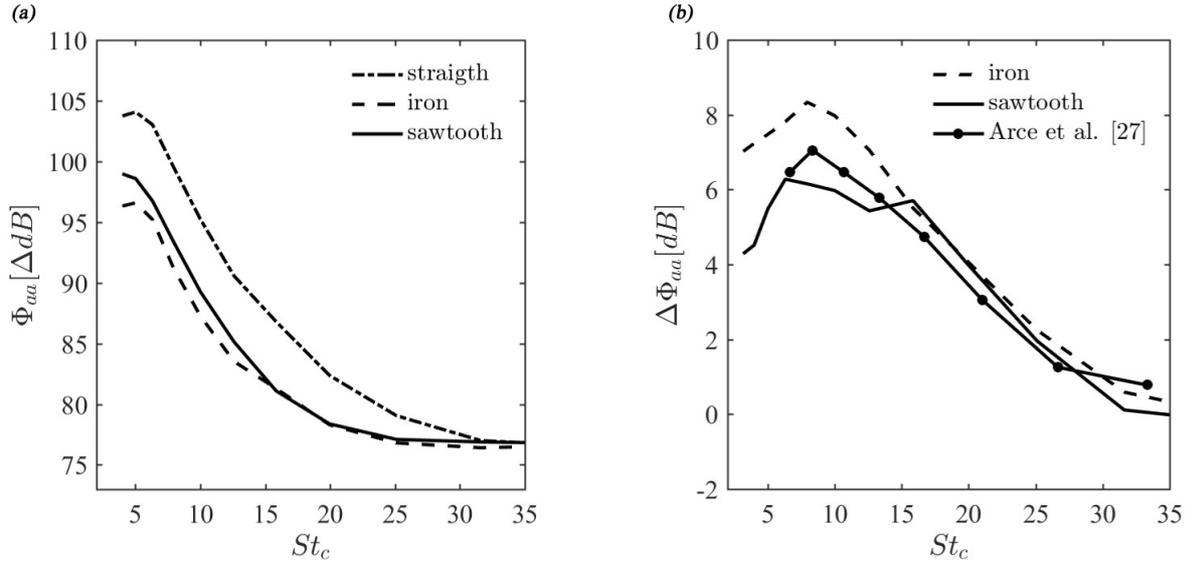

Fig. 4. (a) Power spectra of the far-field pressure fluctuations ( $\Phi_{aa}$ ) for the straight, sawtooth and iron-shaped trailing-edge serrations. (b) noise reduction ( $\Delta\Phi_{aa}$ ) with respect to the straight trailing-edge noise. Experimental data are taken from Arce *et al.* [27] at  $U_\infty = 30$  m/s with the same sawtooth geometry. Computational data are obtained by a microphone located above the trailing edge of the baseline airfoil ( $x/c = 0$ ,  $z/c = 0$  and  $y/c = 10$ ).

Here, the subscript  $m$  indicates the measured value while the subscript  $ref$  indicates the reference values. The reference values are: Mach number  $M_{ref} = 1$ , observer radius  $R_{ref} = 1$  m and spanwise length  $b_{ref} = 1$  m. The adopted scaling is conventionally used in literature for trailing-edge noise studies, where non-compact noise sources are the most relevant contributors [48,49].

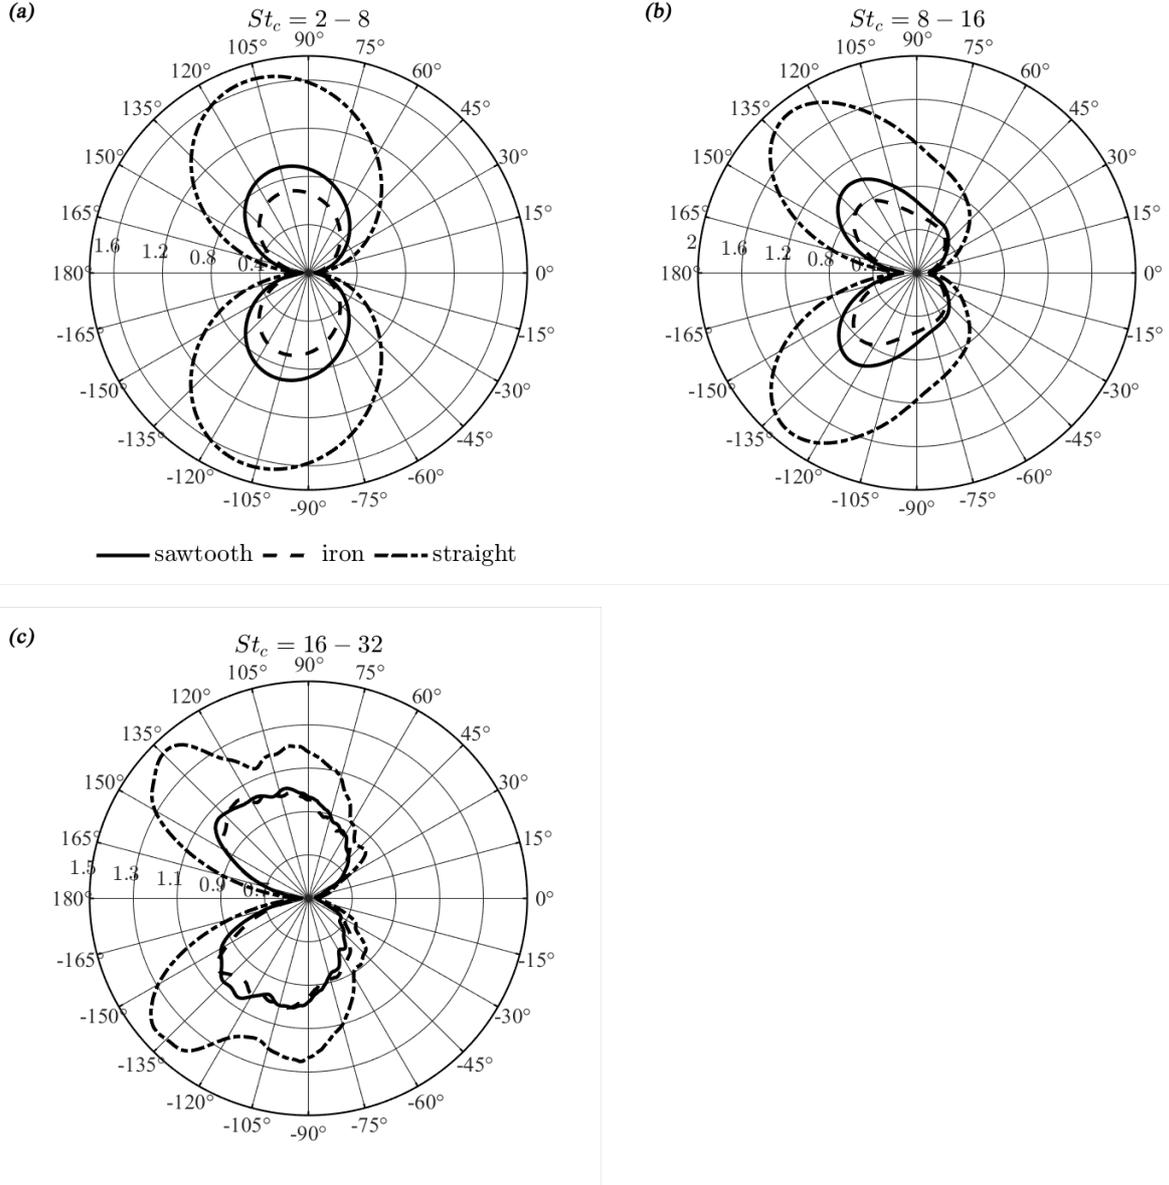

Fig. 5. Directivity plot for the straight, sawtooth and iron-shaped trailing-edge serrations. Data is obtained from microphones positioned in a circle of radius  $10c$  at the mid-span plane of the baseline trailing edge. Results are further averaged over the frequency band reported in each plot: (a):  $2 < St_c < 8$ , (b)  $8 < St_c < 16$  and (c)  $16 < St_c < 32$ .

The scaled acoustic power spectrum ( $\Phi_{aa}$ ) for the baseline airfoil and the ones with the sawtooth and iron-shaped trailing-edge serrations are plotted in Figure 4 (a). Spectra were evaluated by using Hanning windows of 500 elements and 50% of overlap, thus resulting in a frequency resolution of approximately 20 Hz. Results in Figure 4 were further integrated over 1/10 decade bandwidths. Spectra show broadband noise without a tonal component induced by the vortex shedding at the trailing-edge (see Section 3). Figure 4 (b) quantifies the noise

reduction with respect to the baseline airfoil ( $\Delta\Phi_{aa}$ ). In the same figure, the far-field noise reduction measured by Arce León *et al.* [27] at  $U_\infty = 30$  m/s using the same sawtooth geometry is added for comparison. The measured noise reduction is comparable with the computed one. Focusing on the computation results, the iron-shaped geometry reduces the far-field broadband noise more than the conventional sawtooth geometry in the range of Strouhal number based on the chord  $5 < St_c = fc/U_\infty < 15$ . Both geometries show maximum noise reduction at approximately  $St_c = 10$ . The maximum noise reduction is equal 8 dB for the iron geometry while it is equal to 6 dB for the sawtooth one. The comparison between the two serrated trailing-edges shows that the variation of the shape has a positive effect on the far-field noise, especially in the low frequency range.

To further compare the two serrated trailing-edges, directivity plots are shown in Figure 5. Data was obtained from microphones positioned in a circle of radius  $10c$  at the mid-span plane around the baseline trailing-edge. Results were further averaged over the frequency band reported in each plot. As expected, at low frequencies (Figure 5 a), a compact dipole source is seen at the trailing edge. Increasing the frequency (Figure 5 b), the dipole is tilted toward the leading edge of the airfoil. Further increasing the frequency (Figure 5 c), a non-compact behavior appears only for the straight trailing-edge with different upstream oriented lobes. In this frequency range, no lobes are visible for the serrated cases. It is argued that this change is generated by the addition of the serrated geometry, thereby locally transferring non-compact sources back to compact ones. Noise reductions with respect to the baseline airfoil are observed at all angles with maximum for angles between 105 and 135 degrees. When comparing the two investigated serration geometries, it is evident that, at the highest simulated frequency, the two geometries generate the same noise intensity. It is also clear that the modification of the serration geometry does not alter the directivity pattern in the simulated frequency range.

## 4.2 Mean and turbulent flow features

In order to identify the physical mechanisms responsible for the larger noise reduction in presence of the iron-shaped serration, the mean and statistical flow fields are investigated.

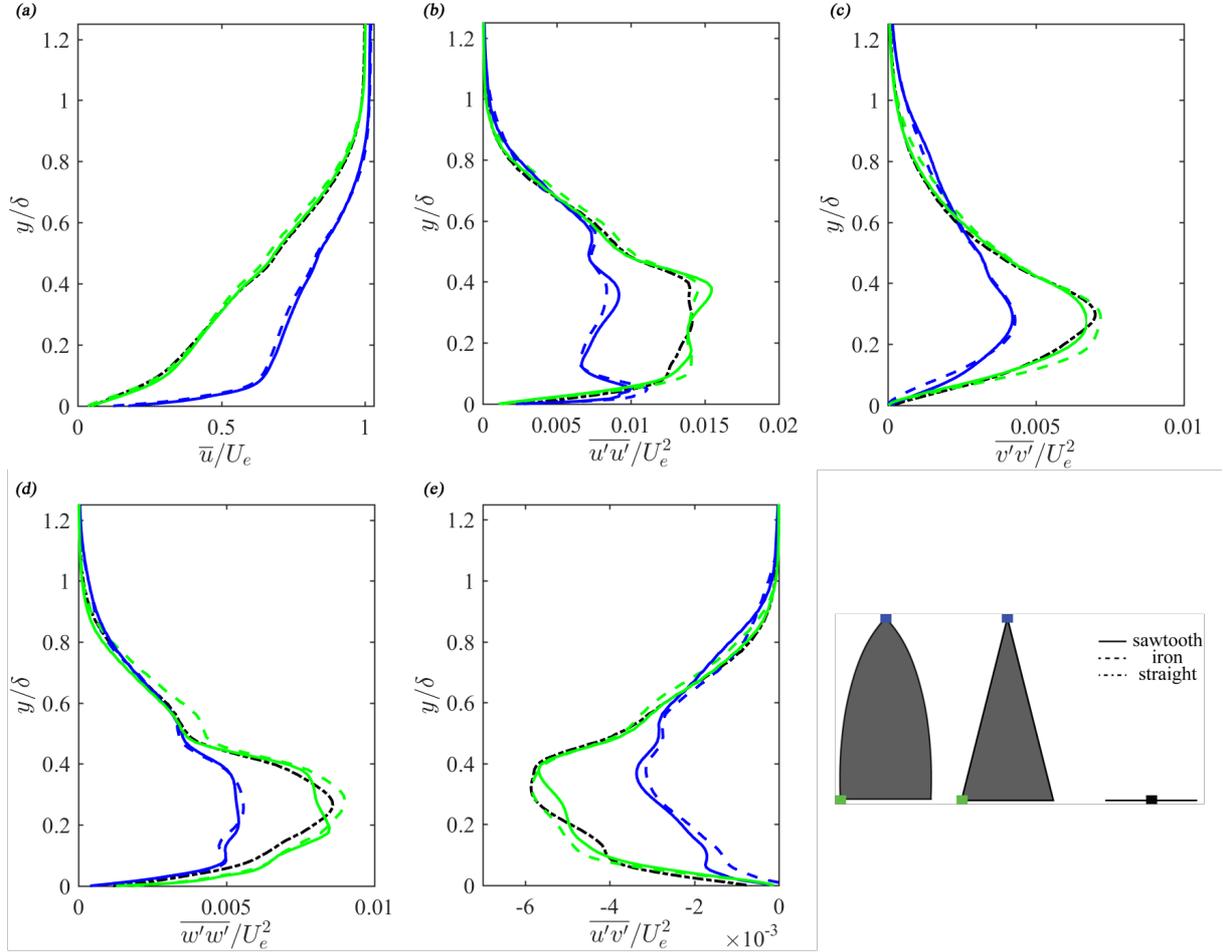

Fig. 6. Comparison of the time-averaged mean streamwise-velocity component (a) and of the time-averaged mean turbulent fluctuations (b-e) at  $x/2h = 0$  (blue line) and  $x/2h = 1$  (green line). Profiles of the baseline configuration are extracted at  $z/c = 0$  (black line).

Profiles of the time-averaged mean streamwise velocity component and of the time-averaged turbulent fluctuations are plotted in Figure 6. Wall-normal profiles at two points located at the root ( $x/2h = 0$ ) and at the tip ( $x/2h = 1$ ) of the investigated serrations are shown. The results obtained from the baseline configuration at the mid-span location ( $z/c = 0$ ) are reported for the sake of completeness.

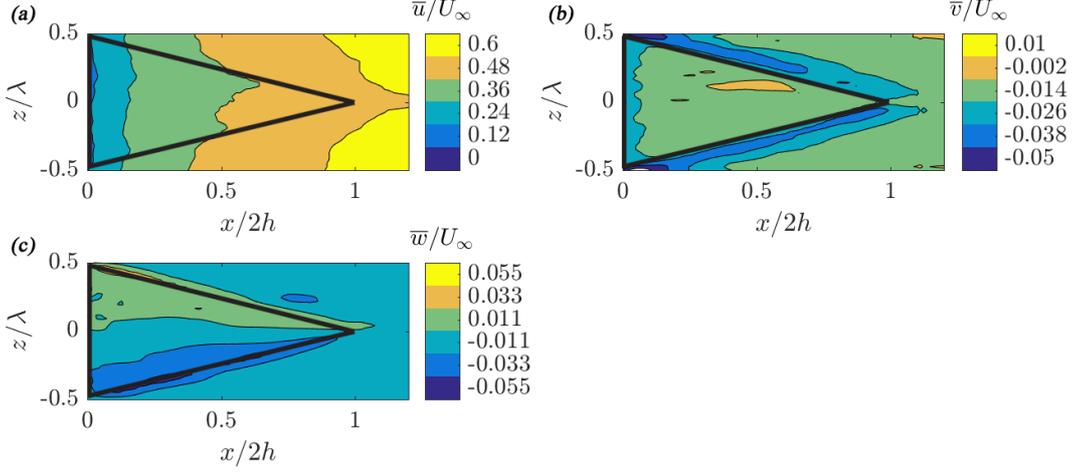

Fig. 7. Contour of the mean velocity component over the sawtooth serration at  $y/\delta = 0.05$ : (a)  $\bar{u}$ , (b)  $\bar{v}$  and (c)  $\bar{w}$  velocity components. Projections of the serration on the  $x$ - $z$  plane are indicated by means of continuous black lines.

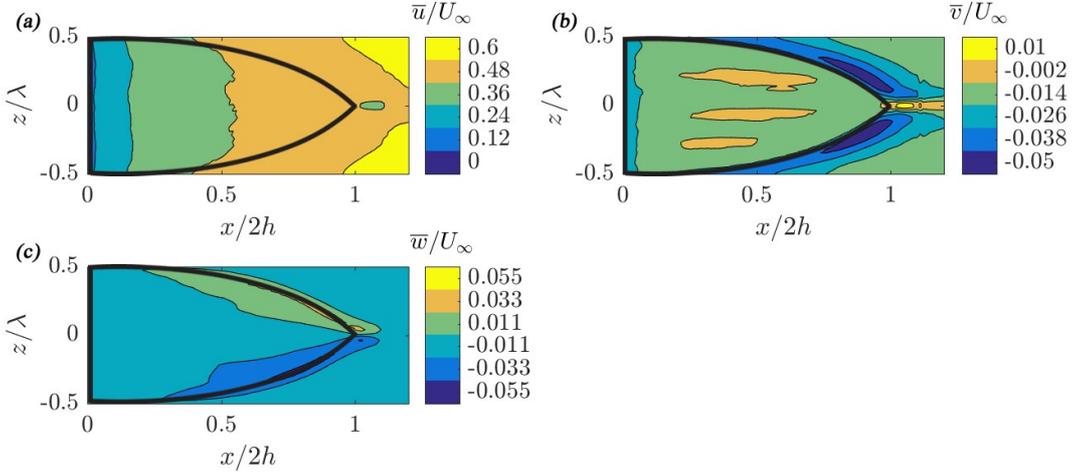

Fig. 8. Contour of the mean velocity component over the iron-shaped serration at  $y/\delta = 0.05$ : (a)  $\bar{u}$ , (b)  $\bar{v}$  and (c)  $\bar{w}$  velocity components. Projections of the serration on the  $x$ - $z$  plane are indicated by means of continuous black lines.

Data shows that the serrations mildly affect the boundary layer time-averaged mean and turbulent statistics at  $x/2h = 0$  with respect to the baseline airfoil. Similar results were reported in the experiments carried out by Chong & Vathylakis [21] and Gruber *et al.* [19]. Strong similarities are present also at the tip ( $x/2h = 1$ ). These results suggest that the turbulent flow convecting over the serration centerline is weakly sensitive to the serration geometry but it depends mainly on the streamwise location along the serration [10].

In presence of spanwise variable geometries, such as the conventional sawtooth geometry, the spanwise flow variation may form a three dimensional mixing layer

consequently responsible for the streamwise oriented structures [50,51]. Previous studies [10,24,25] showed that the sawtooth trailing-edge serrations induce distortion of the near-wall streamlines. Following Chong & Vathylakis [21], the distortion of the streamlines may reduce the effective angle seen by the turbulent flow convecting over the serrations and thus may locally increase the scattered noise with respect to an ideal flow over a sawtooth geometry.

In order to compare the two investigated serrations and inspect the physical reasons behind the computed far-field noise intensity, the near-wall spatial distributions of the time-averaged mean velocity components are discussed. They are reported in Figure 7 and Figure 8 for the conventional sawtooth and the iron-shaped geometry, respectively. Data is extracted at  $y/\delta = 0.05$  ( $y = 0.5$  mm above the serration). The mean streamwise velocity component increases from the root to the tip, corresponding to an acceleration of the flow with a thinning effect of the boundary layer. Most notably, the flow tends to seep into the empty space in between serrations (downward motion) as evidenced by the negative mean wall-normal velocity component ( $\bar{v}$ ). As a direct consequence, the flow exhibits an outward motion as visible from the contour of the spanwise velocity component ( $\bar{w}$ ) [7,10,22].

Similar flow features, but at a more downstream location ( $x/2h > 0.5$ ), are present when retrofitting the airfoil with the iron-shaped serration. At the root, the reduced free space due the tangent constraint delays both the downward and the outward motions discussed above. More in detail, up to  $x/2h = 0.25$  the flow is characterized by  $\bar{w} = 0$ . At approximately  $x/2h = 0.75$ , both the upward and downward motions are enhanced and larger values of both  $\bar{v}$  and  $\bar{w}$  are measured. A second major difference between the two serrations is present at the tip. While the sawtooth serration is characterized by  $\bar{v}$  approximately equal to zero (i.e., flow approximately parallel to the serration surface), the iron-shaped geometry is

characterized by a strong upwash. It may be caused by the interaction between the vortical structures generated at the edge of the serration.

### 4.3 Wall-pressure fluctuations

The far field noise is generated by the scattering of turbulent flow convecting over the edge of the serrations. To further understand the reasons behind the lower far-field noise generated by the iron-shaped geometry, the time-averaged wall-pressure fluctuations ( $\overline{p'p'}$ ) are discussed (Figure 9). Both the spatial distribution and the intensity of the wall-pressure fluctuations do not depend on the serration geometry. The intensity of the time-averaged wall-pressure fluctuations is a function of the streamwise location while it is a weak function of the spanwise location. It decreases from the root to the tip suggesting variable intensity of the scattered pressure waves. In both cases, the intensity of  $\overline{p'p'}$  is more than two times larger at the root than at the tip. It might be caused by the flow deviation imposed by the presence of the serration and the consequent variation of the pressure gradient. This assumption is supported by the mean wall-normal velocity component shown in Figure 7 and Figure 8, where  $\overline{v}$  approximately equal to zero is measured for both configurations at  $0 < x/2h < 0.1$ .

The fact that  $\overline{p'p'}$  do not depend on the serration geometry suggests that the lower far-field noise generated in presence of the iron-shaped geometry (Figure 4) is mainly due to the effective angle seen by the turbulent flow approaching the edge of the serrations and to the interference between scattered waves. To further confirm that the pressure fluctuations are only a function of the streamwise location, narrowband spectra of the wall-pressure fluctuations ( $\Phi_{pp}$ ) are plotted in Figure 10. Spectra were evaluated as described in Section 4.1. Three reference points along the edge of the serrations are taken at  $x/2h = 0, 0.5$  and  $1$ .

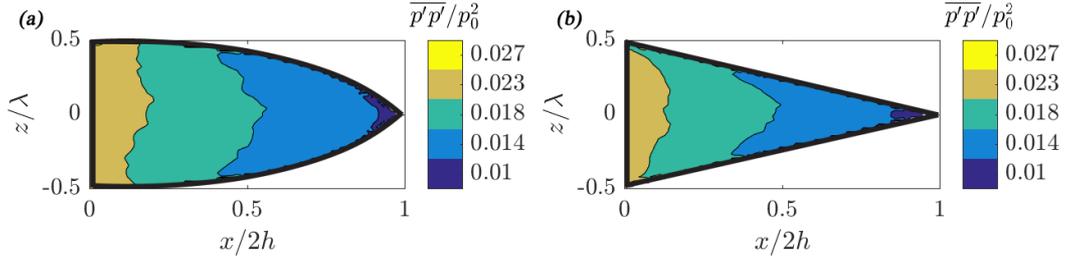

Fig. 9. Intensity of the mean wall-pressure fluctuations ( $\overline{p'p'}/p_0^2$ ): (a) iron-shaped serration, (b) sawtooth serration. The serration on the  $x$ - $z$  plane are indicated by means of continuous black lines.

Spectra of the wall-pressure fluctuations show strong similarities between the two investigated geometries. In particular, no difference is measured at  $x/2h = 0.5$  and 1, while minor differences are visible at  $x/2h = 0$ . At this location, the intensity of  $\Phi_{pp}$  is slightly larger (approximately 2 dB) for the iron-shaped geometry in the low frequency range ( $5 < St_c < 7$ ). Differently, at relatively higher frequencies ( $St_c > 10$ ) the iron-shaped geometry shows lower intensity of approximately 0.5 dB.

A deeper analysis of Figure 10 suggests that far-field noise intensity benefits by both the reduced scattering efficiency due to the serration angle, and by the streamwise variation of  $\Phi_{pp}$  with respect to the root location ( $\Delta\Phi_{pp} = \Phi_{pp}^{root} - \Phi_{pp}^{stream}$ , where  $\Phi_{pp}^{root}$  and  $\Phi_{pp}^{stream}$  are the power spectra intensity at the root location and at the other streamwise points, respectively). As a matter of fact, in the frequency range where the  $\Delta\Phi_{pp}$  between streamwise locations is larger (Figure 10), the estimated far-field noise reduction is higher.

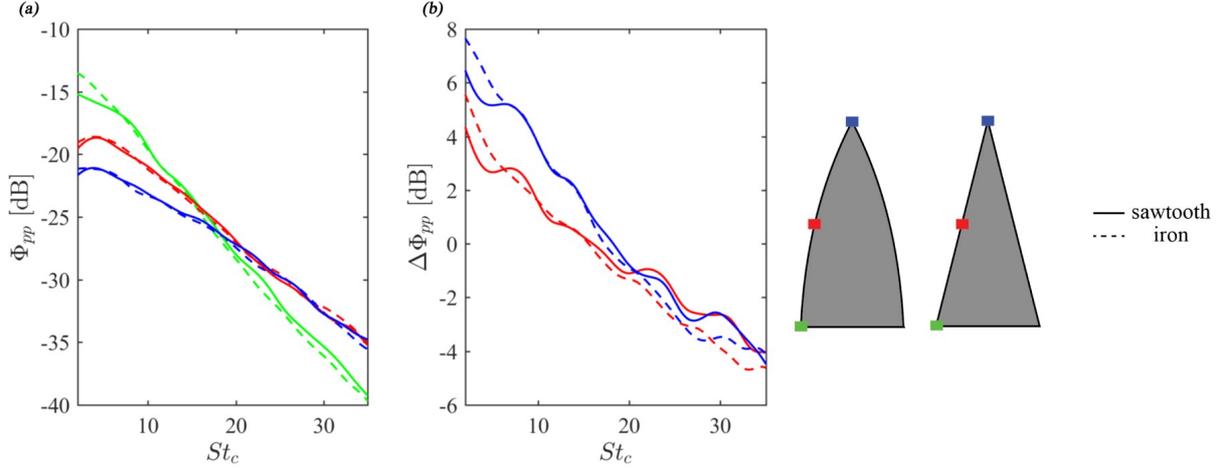

Fig. 10. (a) Spectra of the wall-pressure fluctuations ( $\Phi_{pp}$ ) at three streamwise locations corresponding to  $x/2h = 0$  (green), 0.5 (red), 1 (blue). The continuous and dashed lines represents the sawtooth and the iron-shaped serrations respectively. (b)  $\Delta\Phi_{pp} = \Phi_{pp}^{root} - \Phi_{pp}^{stream}$ , where  $\Phi_{pp}^{root}$  and  $\Phi_{pp}^{stream}$  are the power spectra intensity at the root location and at the other streamwise points, respectively.

The overall good agreement further confirms that the wall-pressure fluctuations are only dependent on the effective length of the serration and not on the actual shape. These findings support the assumption behind the shaped geometry as discussed in the introduction. The effect of the introduced curvature is to reduce the scattered noise at the trailing-edge root by mitigating both the interaction between the two sides of the airfoil and the negative effect induced by the outward and downward flow motions at this location (see Figures 7 and 8) [21]. The new geometry delays this effect downstream where the intensity of the pressure fluctuations is lower, thus contributing less to the far-field noise.

#### 4.4 Detection of noise source

The above discussion showed that the iron-shaped trailing-edge serration reduces noise in the low frequency range by mitigating noise sources at the root. In order to confirm these considerations, iso-surface of the noise sources, as detected using the FIND tool discussed in Section 2, are plotted in Figure 11 and Figure 12 for  $St_c = 4$  and 10, respectively [44,45].

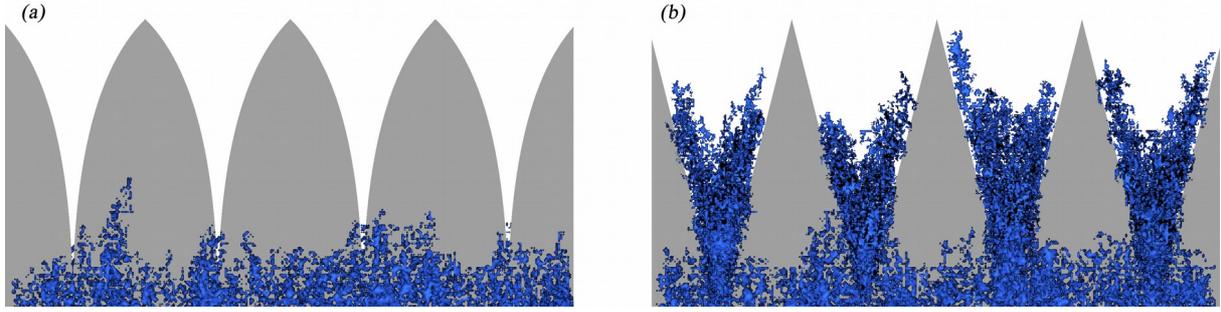

Fig. 11. Iso-surface of noise sources, as detected using the FIND tool discussed in Section 2, at  $St_c = 4$  ( $f = 400$  Hz) for the iron-shaped (a) and sawtooth (b) trailing-edge serrations.

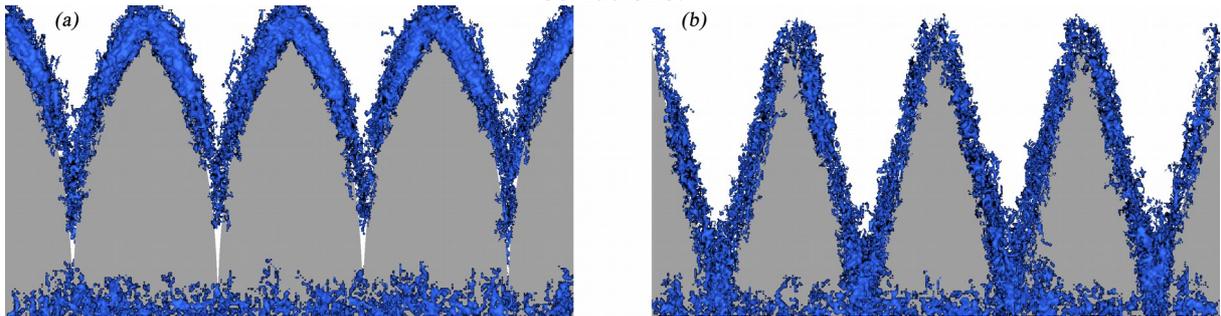

Fig. 12. Iso-surface of noise sources, as detected using the FIND tool discussed in Section 2, at  $St_c = 10$  ( $f = 1000$  Hz) for the iron-shaped (a) and sawtooth (b) trailing-edge serrations.

Figure 11 shows that at low frequency, the sawtooth trailing-edge serrations present noise sources near at the root. They are strongly mitigated in presence of the iron-shaped geometry. As discussed above, this fact can be related to the outward flow motion strongly reduced at the root location and to a more gradual interaction between the flow coming from the two sides of the airfoil. At higher frequencies (Figure 12), noise sources are more uniformly distributed along the edges of the sawtooth serrations. Similarly, as above, the iron-shaped geometry shows reduced noise sources at the root. In this case, noise sources are stronger and located toward the tip where, as discussed in Section 4.2, the downward and the outward flow motions are dominant.

## 5. Conclusions

In this manuscript, computations of the flow convecting over a conventional sawtooth and an iron-shaped serration geometries were performed using the compressible, transient and

explicit Lattice Boltzmann Method. The two investigated geometries had same length and wavelength and were retrofitted to a NACA 0018 airfoil. They were inspected in terms of both far-field noise and flow field.

The iron-shaped geometry reduces far-field noise more (approximately 2 dB) than the conventional sawtooth geometry in the range  $5 < St_c < 15$ , without modifying the directivity of the noise propagation in the similar frequency range. The analysis of the time-averaged near-wall velocity components shows that the main effect of the proposed geometry is to mitigate both the outward and downward flow motions near the root of the serration. It results in a milder interaction between the two sides of the airfoil at the root location, and, in a larger effective angle seen by the turbulent flow approaching the edges. On the other hand, stronger outward and downward flow motions are present near the serration tip. However, at this location, the intensity of wall-pressure fluctuations is lower, thus scattering less noise. In order to confirm that the achieved lower far-field noise is mainly due to the above mentioned flow effects, the time-averaged wall-pressure fluctuations and their spectra were inspected. It is found that they do not depend on the serration geometry, for a given serration aspect ratio, but that they are a function of the streamwise location. This finding confirms that the intensity of the scattered pressure waves depends on the streamwise location. Finally, iso-surfaces of the noise sources confirm that the achieved noise reduction is mainly due to the mitigation of the noise sources at the root location.
