Abstract

We present a high resolution model of the linear trend in the Earth's mass variations based on DMT-2 (Delft Mass Transport model, release 2). DMT-2 was produced primarily from K-Band Ranging (KBR) data of the Gravity Recovery And Climate Experiment (GRACE). It comprises a time series of monthly solutions complete to spherical harmonic degree 120. A novel feature in its production was the accurate computation and incorporation of stochastic properties of coloured noise when processing KBR data. The unconstrained DMT-2 monthly solutions are used to estimate the linear trend together with a bias, as well as annual and semi-annual sinusoidal terms. The linear term is further processed with an anisotropic Wiener filter, which uses full noise and signal covariance matrices. Given the fact that noise in an unconstrained model of the trend is reduced substantially as compared

to monthly solutions, the Wiener filter associated with the trend is much less aggressive compared to a Wiener filter applied to monthly solutions. Consequently, the trend estimate shows an enhanced spatial resolution. It allows signals in relatively small water bodies, such as Aral sea and Ladoga lake, to be detected. Over the ice sheets, it allows for a clear identification of signals associated with some outlet glaciers or their groups. We compare the obtained trend estimate with the ones from the CSR-RL05 model using (i) the same approach based on monthly noise covariance matrices and (ii) a commonly-used approach based on the DDK-filtered monthly solutions. We use satellite altimetry data as independent control data. The comparison demonstrates a high spatial resolution of the DMT-2 linear trend. We link this to the usage of high-accuracy monthly noise covariance matrices, which is due to an accurate computation and incorporation of coloured noise when processing KBR data. A preliminary comparison of the linear trend based on DMT-2 with that computed from GSFC_global_mascons_v01 reveals, among other, a high concentration of the signal along the coast for both models in areas like the ice sheets, Gulf of Alaska, and Iceland.

Keywords: Time varying gravity field, GRACE, KBR, DMT-2, Coloured noise

1. Introduction

Temporal variations of the Earth's gravity field at various spatial scales are known to be caused by mass re-distribution due to megathrust earthquakes (e.g., Han et al., 2006, 2011), accumulation and depletion of continental water stocks (e.g., Wahr et al., 1998; Swenson et al., 2003; Klees et

6 al., 2007, 2008a), postglacial rebound (e.g., van der Wal et al., 2008; Gunter
 7 et al., 2014), ice mass losses in the polar areas (e.g., Luthcke et al., 2006;
 8 Wouters et al., 2008; Baur and Sneeuw, 2011; Rignot and Mouginot, 2012;
 9 Siemes et al., 2013), and the subsequent sea level rise (e.g., Bamber et al.,
 10 2009). The primary tool to observe the large-scale mass variations is currently
 11 the Gravity Recovery And Climate Experiment (GRACE) satellite mission,
 12 which has been operational since March 2002 (Tapley et al., 2004a,b). The
 13 K-Band Ranging (KBR) data, collected by this mission, in conjunction with
 14 its other measurements, i.e., GPS (Global Positioning System), attitude, and
 15 accelerometer data, are processed by different research centres, and various
 16 models of time-variations are computed (e.g., Bettadpur, 2007, 2012; Flecht-
 17 ner, 2007; Watkins and Yuan, 2007, 2012; Kurtenbach et al., 2009; Dahle et
 18 al., 2012; Bruinsma et al., 2010; Liu, 2008; Liu et al., 2010; Mayer-Gürr et al.,
 19 2010a,b, 2014; Meyer et al., 2012; Chen et al., 2015). The majority of models
 20 make use of spherical harmonics (e.g., Heiskanen and Moritz, 1967) and are
 21 complete to degree 60 – 120, which corresponds to spatial scales larger than
 22 165 – 330 km (half-wavelength). Some other models, e.g., those produced
 23 by Luthcke et al. (2013) and Watkins et al. (2015), are based on mass con-
 24 centration blocks, i.e., so-called mascons parametrization. They are vastly
 25 believed to improve the spatial resolution further as compared to spherical
 26 harmonic models of the mass transport (Watkins et al., 2015). The temporal
 27 sampling of GRACE-based models is typically one month.

28 Recently, Delft University of Technology, in collaboration with the GNSS
 29 Research Centre of Wuhan University, has compiled and released a new spher-
 30 ical harmonic model entitled DMT-2: Delft Mass Transport model, release

31 2 (Farahani, 2013). Similar to its predecessor DMT-1 (Liu, 2008; Liu et al.,
 32 2010), the new model consists of a time series of monthly solutions complete
 33 to degree 120. Both unconstrained and constrained (i.e., filtered) solutions
 34 are available. In the latter case, an anisotropic Wiener-type filter devel-
 35 oped by Klees et al. (2008b) is applied to suppress noise, which is primarily
 36 caused by an anisotropic sensitivity of the KBR data and manifests itself in
 37 the form of pronounced along-track artifacts, i.e., the well-known “stripes”.
 38 The filter is based on the full signal and noise covariance matrices. It is
 39 designed as a mean square error filter of monthly mass re-distribution. It
 40 is a spatially-varying filter, meaning that the smoothing is minimal in areas
 41 where signal is strong (i.e., the lower the noise, the less smoothing, and vice
 42 versa). Unlike in DMT-1, degree-1 coefficients are restored in the DMT-2
 43 monthly solutions using a modified version of the approach of Swenson et
 44 al. (2008), which is described in (Sun et al., 2016). A novel feature of the
 45 methodology designed to produce DMT-2 is an accurate computation and
 46 incorporation of stochastic properties of coloured noise when processing KBR
 47 data. This leads to an accurate computation of noise covariance matrices,
 48 which enter Wiener filters. With this manuscript, we use DMT-2 to compute
 49 new models of the long-term linear trend in mass variations, which vary in
 50 terms of maximum spherical harmonic degree. To that end, we follow the
 51 methodology developed by Siemes et al. (2013). It is, in essence, a further
 52 development of the filtering idea of Klees et al. (2008b). It is realized by a
 53 design and application of an anisotropic Wiener-type filter to the linear trend
 54 obtained from unconstrained monthly solutions. That is, it is designed as a
 55 mean square error filter of linear trends in mass re-distribution. For com-

56 parison, we additionally produce a filtered linear trend from the CSR-RL05
 57 monthly solutions (Bettadpur, 2012) and their noise covariance matrices,
 58 using the same methodology. In addition, we compute the linear trend in
 59 line with a commonly-used approach, i.e., using monthly solutions subject
 60 to DDK de-correlating non-isotropic filtering (Kusche, 2007; Kusche et al.,
 61 2009). We assess the models of the linear trend with satellite altimetry data.
 62 The comparison allows us to study the added value of the applied Wiener
 63 filter. It additionally allows for an analysis of the added value of accounting
 64 for coloured noise when processing KBR data, which is currently done in
 65 the production of only a few spherical harmonic time-varying gravity field
 66 models, namely, DMT-2 and those produced in line with Mayer-Gürr (2006)
 67 and Mayer-Gürr et al. (2010a). Finally, we make a preliminary comparison
 68 of the linear trend model based on DMT-2 with one produced with a latest
 69 mascon implementation, namely, GSFC_global_mascons_v01 (Luthcke et al.,
 70 2013).

71 The manuscript is outlined as follows. Section 2 (in conjunction with
 72 Appendix A) describes the computation of DMT-2 monthly unconstrained
 73 solutions. In Section 3, we compute and assess the model of the linear trend.
 74 A brief description of how it is computed from the monthly solutions is also
 75 presented there. Finally, in Section 4, we conclude by emphasizing the main
 76 findings and identifying topics for future research.

77 **2. DMT-2**

78 DMT-2 consists of monthly gravity field solutions spanning the time in-
 79 terval February 2003 – December 2011. Three months (June 2003, January

80 2011, and June 2011) are excluded due to a complete or a partial lack of
 81 GRACE data. The solutions consist of residual spherical harmonic coeffi-
 82 cients with respect to the static gravity field model DGM-1S: Delft Gravity
 83 Model, release 1, satellite-only (Farahani et al., 2013a,b). The coefficients
 84 were estimated by a stand-alone inversion of KBR data. The unconstrained
 85 procedure consisted of two steps: (1) transforming KBR data into residual
 86 gravity data (cf. Appendix A) with respect to the a priori model; and (2)
 87 inverting these residuals into residual spherical harmonic coefficients using
 88 the least-squares adjustment in a statistically optimal manner. The first step
 89 was done mostly in the same way as in the case of DMT-1. For the complete-
 90 ness, we briefly describe it in Appendix A. A novel element of the second
 91 step was an accurate computation and parameterization of coloured noise in
 92 KBR data, which is described below.

93 Residual range combinations are contaminated by frequency-dependent
 94 (i.e., coloured) noise (e.g., Liu et al., 2010). To account for this, frequency-
 95 dependent data weighting (e.g., Klees et al., 2003; Klees and Ditmar, 2004)
 96 was used. This ensures a statistically optimal inversion of the residual data,
 97 provided that (i) an accurate realization of their noise is obtained and (ii) the
 98 stochastic properties of the noise are modeled properly. To realize the lat-
 99 ter, Auto-Regressive Moving-Average (ARMA) noise models, whose Power
 100 Spectral Densities (PSDs) best fit PSDs of the noise, were built (Klees and
 101 Broersen, 2002; Klees et al., 2003). Noise realizations were produced iter-
 102 atively as described in the following. The residual data themselves were
 103 assumed to be initial noise realizations. This allowed initial ARMA models
 104 to be produced, which resulted in preliminary monthly gravity field solu-

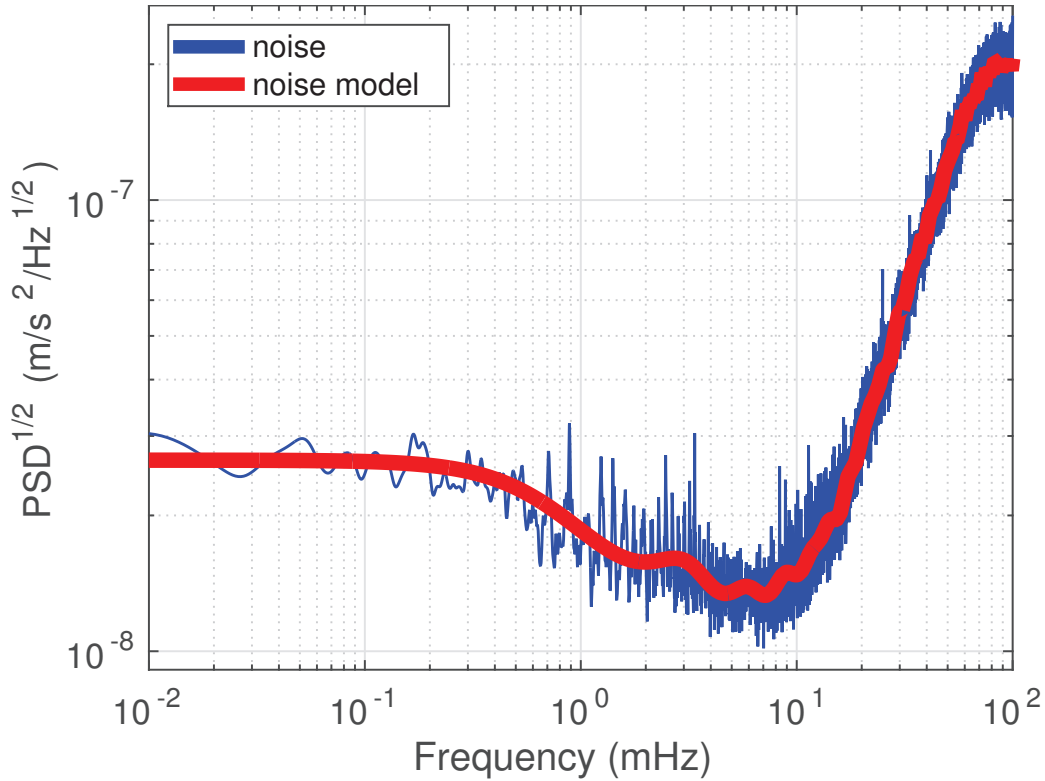

Figure 1: The $\text{PSD}^{\frac{1}{2}}$ of noise and of stochastic model of noise in residual range combinations for July 2006.

105 tions. The corresponding sets of a posteriori residuals were used as improved
 106 realizations of noise. No additional iterations of this kind were necessary, as
 107 further changes in the estimated noise properties were found to be negligible.
 108 As an example, Fig. 1 shows the $\text{PSD}^{\frac{1}{2}}$ of noise in residual range combina-
 109 tions in July 2006 together with its best-fitting ARMA model, which is in
 110 this instance an Auto-Regressive (AR) one of order 79. Such a model of
 111 noise was built for each month individually. In this way, gradual changes
 112 in the noise characteristics were captured. We found that those changes are
 113 particularly pronounced in the frequency range 0.5 – 10 mHz (3 – 54 cycles

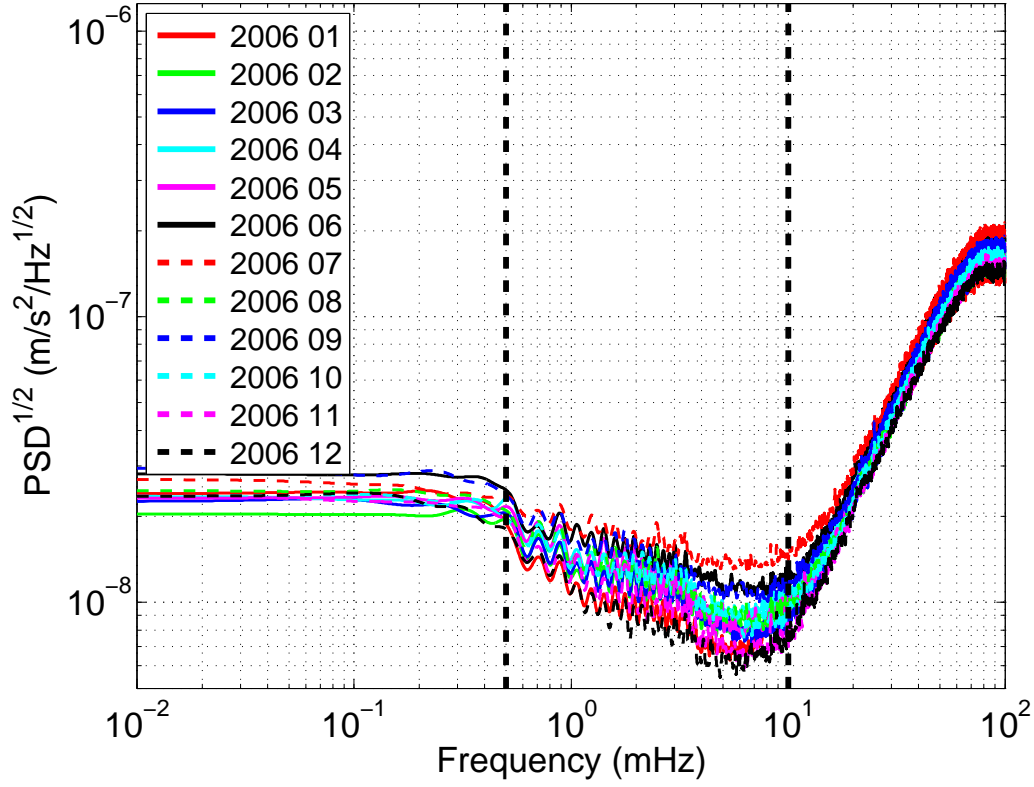

Figure 2: The noise $\text{PSD}^{\frac{1}{2}}$ s in the residual range combinations in 2006. The vertical lines mark the frequencies 3 and 54 cpr.

per revolution, cpr). This frequency range corresponds to signals at spatial
scales of 400 – 7200 km (half-wavelength), which comprise a significant part
of the time-varying gravity field. In Fig. 2, for instance, noise $\text{PSD}^{\frac{1}{2}}$ s of
residual range combinations are shown for different months in 2006. Further
details about the adopted procedure can be found in (Farahani et al., 2014).

119

120 **3. Linear trend**

121 We begin with a brief description of the methodology followed to compute
 122 different variants of the linear trend (Section 3.1). The comparison of the
 123 results are provided in Section 3.2.

124 *3.1. Methodology*

125 We compute the constrained linear trend in line with the methodology
 126 developed by Siemes et al. (2013). To that end, we first compute an uncon-
 127 strained model of the linear trend, together with a bias, as well as annual and
 128 semi-annual (co-) sinusoidal terms, from the unconstrained DMT-2 monthly
 129 solutions. Furthermore, we propagate noise covariance matrices of the un-
 130 constrained monthly solutions onto the linear trend noise covariance matrix.
 131 In doing so, so-called formal noise covariance matrices are used, i.e., those ob-
 132 tained from the estimation process without any correction or scaling. Finally,
 133 we compute the constrained model of the linear trend with the Wiener-type
 134 filter of Klees et al. (2008a)

$$\mathbf{F} = \{(\mathbf{C}_{\hat{\mathbf{x}}})^{-1} + \mathbf{D}^{-1}\}^{-1}(\mathbf{C}_{\hat{\mathbf{x}}})^{-1}, \quad (1)$$

135 or equivalently

$$\mathbf{F} = \mathbf{D}\{\mathbf{C}_{\hat{\mathbf{x}}} + \mathbf{D}\}^{-1}, \quad (2)$$

136 based on the full signal covariance matrix \mathbf{D} and the full noise covariance
 137 matrix $\mathbf{C}_{\hat{\mathbf{x}}}$ of the linear trend. To compute \mathbf{D} as reliably as possible, the time
 138 span for which the linear trend is to be estimated is divided into multiple
 139 intervals of the same length. This allows us to obtain multiple intermediate
 140 samples of the linear trend, from which an estimate of \mathbf{D} can be obtained.

141 Then, this estimate is improved iteratively. It is not subjected to any scaling
142 or other corrections. Details are documented by Siemes et al. (2013). This
143 way of computing the linear trend is motivated by the fact that noise in an
144 unconstrained model of the linear trend is substantially reduced as compared
145 to that in unconstrained monthly solutions. Thus, a Wiener-type filter tai-
146 lored for the linear trend is much less aggressive than those associated with
147 monthly solutions. Therefore, the trend produced in this way as opposed
148 to that derived from constrained monthly solutions shows a higher spatial
149 resolution (Siemes et al., 2013).

150 For comparison, we produce another constrained estimate of the linear
151 trend using CSR-RL05 monthly solutions and their noise covariance matrices
152 with the same methodology. The CSR-RL05 solutions are complete to
153 degree 96, whereas DMT-2 solutions extend to degree 120. To ensure a fair
154 comparison of them, we additionally compute the linear trend in the case
155 of DMT-2 to degree 96. This requires computing clones of DMT-2 monthly
156 unconstrained solutions to degree 96. This does not necessarily require a re-
157 processing of KBR data from scratch. These clones can be easily computed
158 using DMT-2 unconstrained solutions and their noise covariance matrices.
159 Technical aspects of these computations are provided in Appendix B. For
160 brevity, we hereafter refer to the trend estimated from DMT-2 unconstrained
161 solutions complete to degree 96 as “DMT-2-DEG-96”. Moreover, we compute
162 models of the linear trend following the standard approach by first filtering
163 the monthly solutions before the linear trend is estimated. To that end, we
164 use CSR-RL05 monthly solutions subsequent to the DDK-5 and DDK-8 de-
165 correlating non-isotropic filter (Kusche, 2007; Kusche et al., 2009). These

estimates of the linear trend are, hereafter, referred to as “CSR-RL05-DDK-5” and “CSR-RL05-DDK-8”, respectively. Their computation includes a co-estimation of a bias, as well as annual and semi-annual (co-) sinusoidal terms to be consistent with other estimates noted earlier. Given the fact that the DDK-8 filter in terms of the smoothing radius of an approximately equivalent Gaussian filter is smaller than the DDK-5 one (Kusche et al., 2009), an analysis of the results associated with these two filters allows the effect of the corresponding Gaussian smoothing radius to be studied in the side line.

3.2. Results

In this manuscript, we produce models of the linear trend in the time interval February 2003 – December 2008. This time interval is chosen since we compare results against, among others, surface elevations from ICESat laser altimeter data, which are available only to October 2009. Furthermore, a computation of GRACE-based linear trends with the Wiener filter of Siemes et al. (2013) requires dividing the time interval into multiple two-year segments. Hence, currently we can compute the linear trend for either February 2003 – December 2008 or February 2003 – December 2010. Only the former time interval allows for a consistent comparison of our results with those based on ICESat data.

In this section, we primarily focus on a comparison of the spherical harmonic models mentioned earlier, namely, DMT-2, “DMT-2-DEG-96”, CSR-RL05, “CSR-RL05-DDK-5”, and “CSR-RL05-DDK-8” (section 3.2.1). However, to provide an idea on how spherical harmonic and mascons parametrizations compare, we close this section with a comparison between linear trends based on DMT-2 and GSFC_global_mascons.v01 (section 3.2.2). The com-

191 putation of the linear trend in the latter case also includes a co-estimation
192 of a bias, as well as annual and semi-annual (co-) sinusoidal terms to be
193 consistent with the estimates based on DMT-2.

194 *3.2.1. Comparison with spherical harmonic models*

195 Figure 3 shows the five spherical harmonic linear trend estimates in the
196 time interval February 2003 – December 2008 in terms of equivalent water
197 heights (EWH).

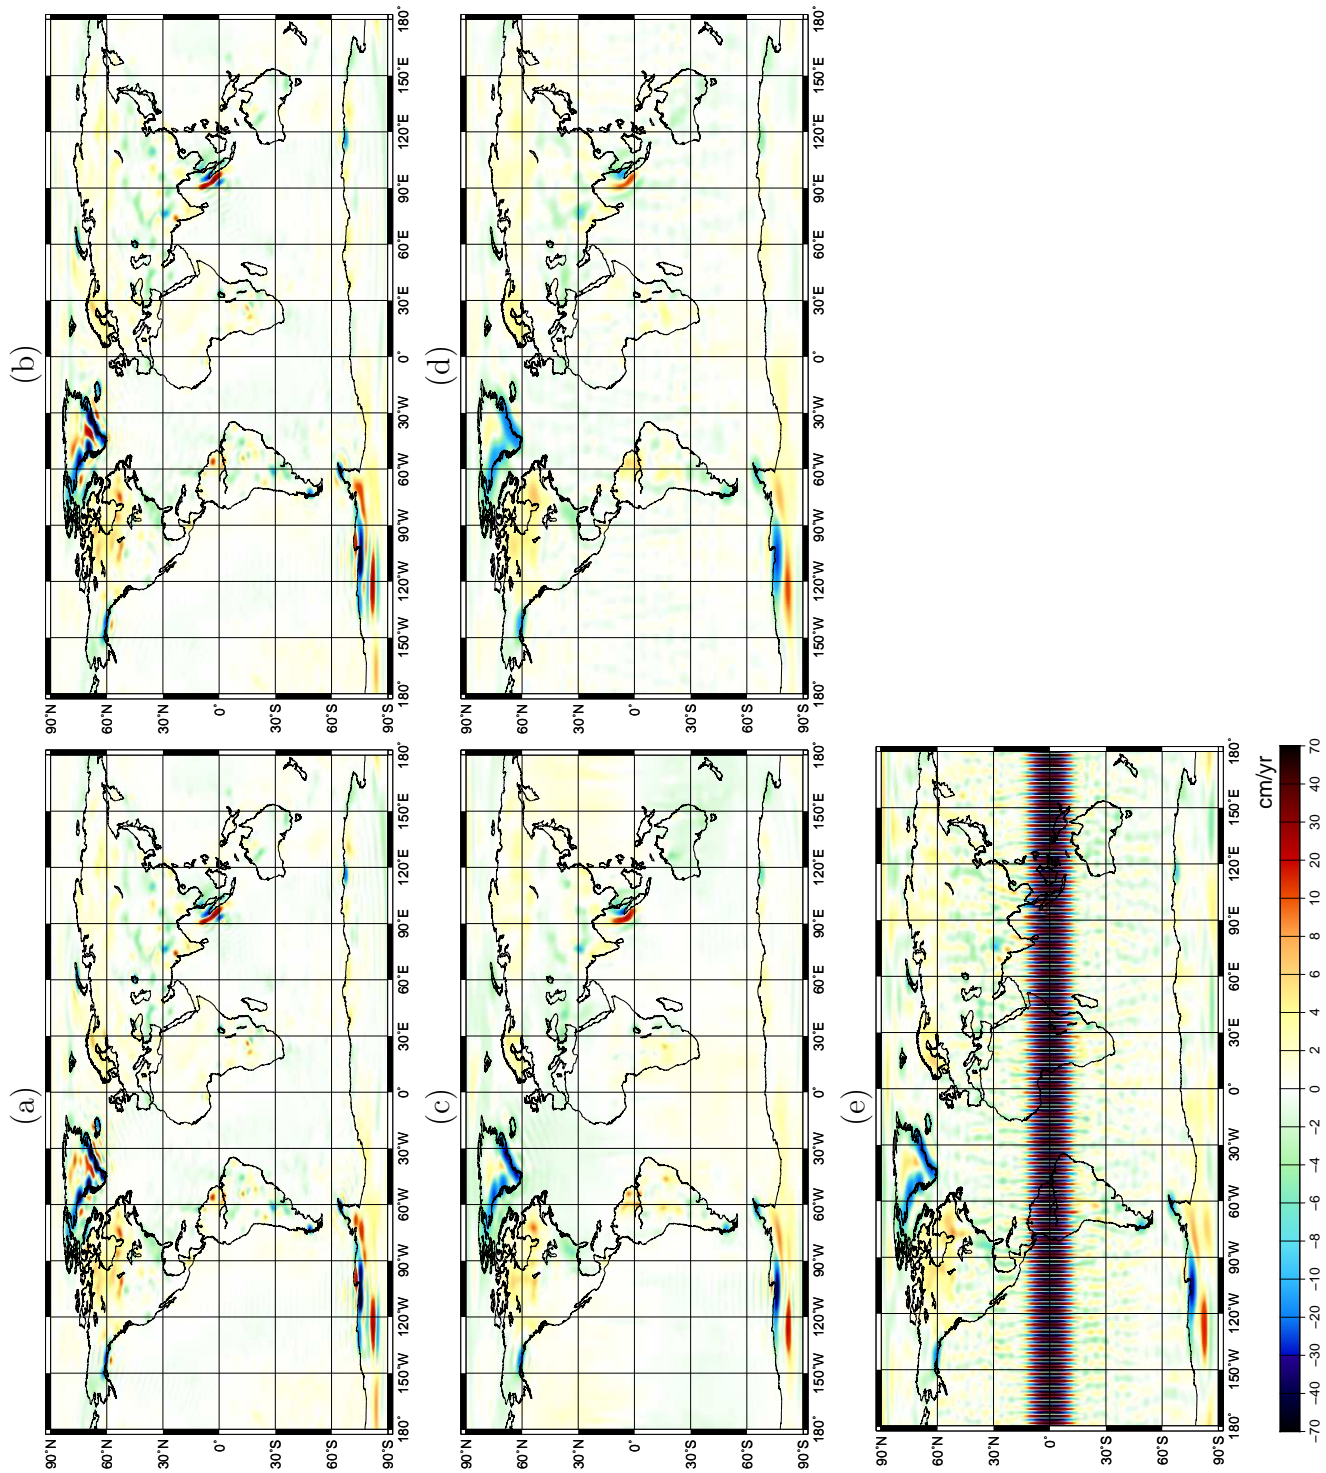

Figure 3: The linear trend computed in the time interval February 2003 – December 2008 in the cases of (a) DMT-2, (b) “DMT-2-DEG-96”, (c) CSR-RL05, (d) “CSR-RL05-DDK-8”, and (e) “CSR-RL05-DDK-8”. The maps are in terms of EWH. Their Root Mean Square (RMS) values are (a) 3.2 cm/yr, (b) 2.9 cm/yr, (c) 2.2 cm/yr, (d) 1.9 cm/yr, and (e) 2.4 cm/yr. Water heights bounded by latitudes $\pm 10^\circ$ are excluded when computing RMS in the latter case.

198 The improved spatial resolution of Wiener filter estimates DMT-2, “DMT-
 199 2-DEG-96”, and CSR-RL05 compared to “CSR-RL05-DDK-5” is clearly vis-
 200 ible, particularly, in Greenland, Antarctica, and Gulf of Alaska. Moreover,
 201 the former two trend estimates show much more power compared to “CSR-
 202 RL05-DDK-5”. This is obvious when looking at the Root Mean Square
 203 (RMS) EWH, which are provided in the caption of Fig. 3. The situation is
 204 different when comparing the linear trend Wiener filter estimates with “CSR-
 205 RL05-DDK-8”. The latter also reveals an improved spatial resolution and
 206 increased signal power. However, “CSR-RL05-DDK-8” compromises results
 207 with stripes in equatorial areas bounded by latitudes $\pm 10^\circ$ (Fig. 3e). This is
 208 the reason why those areas were excluded when calculating the RMS EWH
 209 in case of “CSR-RL05-DDK-8”. These results indicate that when comput-
 210 ing the linear trend from DDK-filtered monthly solutions, the filter variant,
 211 i.e., the corresponding Gaussian smoothing radius, needs to be chosen in line
 212 with the geographical area in interest. Further evidences to support this
 213 statement will be provided later.

214 A zoom-in at selected locations provides further insight into the differ-
 215 ences between the five linear trend estimates. To that end, we focus on two
 216 selected lakes (Section 3.2.1.1) and on the ice sheets (Section 3.2.1.2).

217 3.2.1.1 *Lakes*

218 We select two relatively small water bodies: Ladoga lake and the Aral sea.
 219 The five estimates of the linear trend over these areas are respectively pre-
 220 sented in Figs. 4 and 5. The trends produced from DMT-2 and its clone to
 221 degree 96 clearly demonstrate a gain of water mass in the Ladoga lake and a

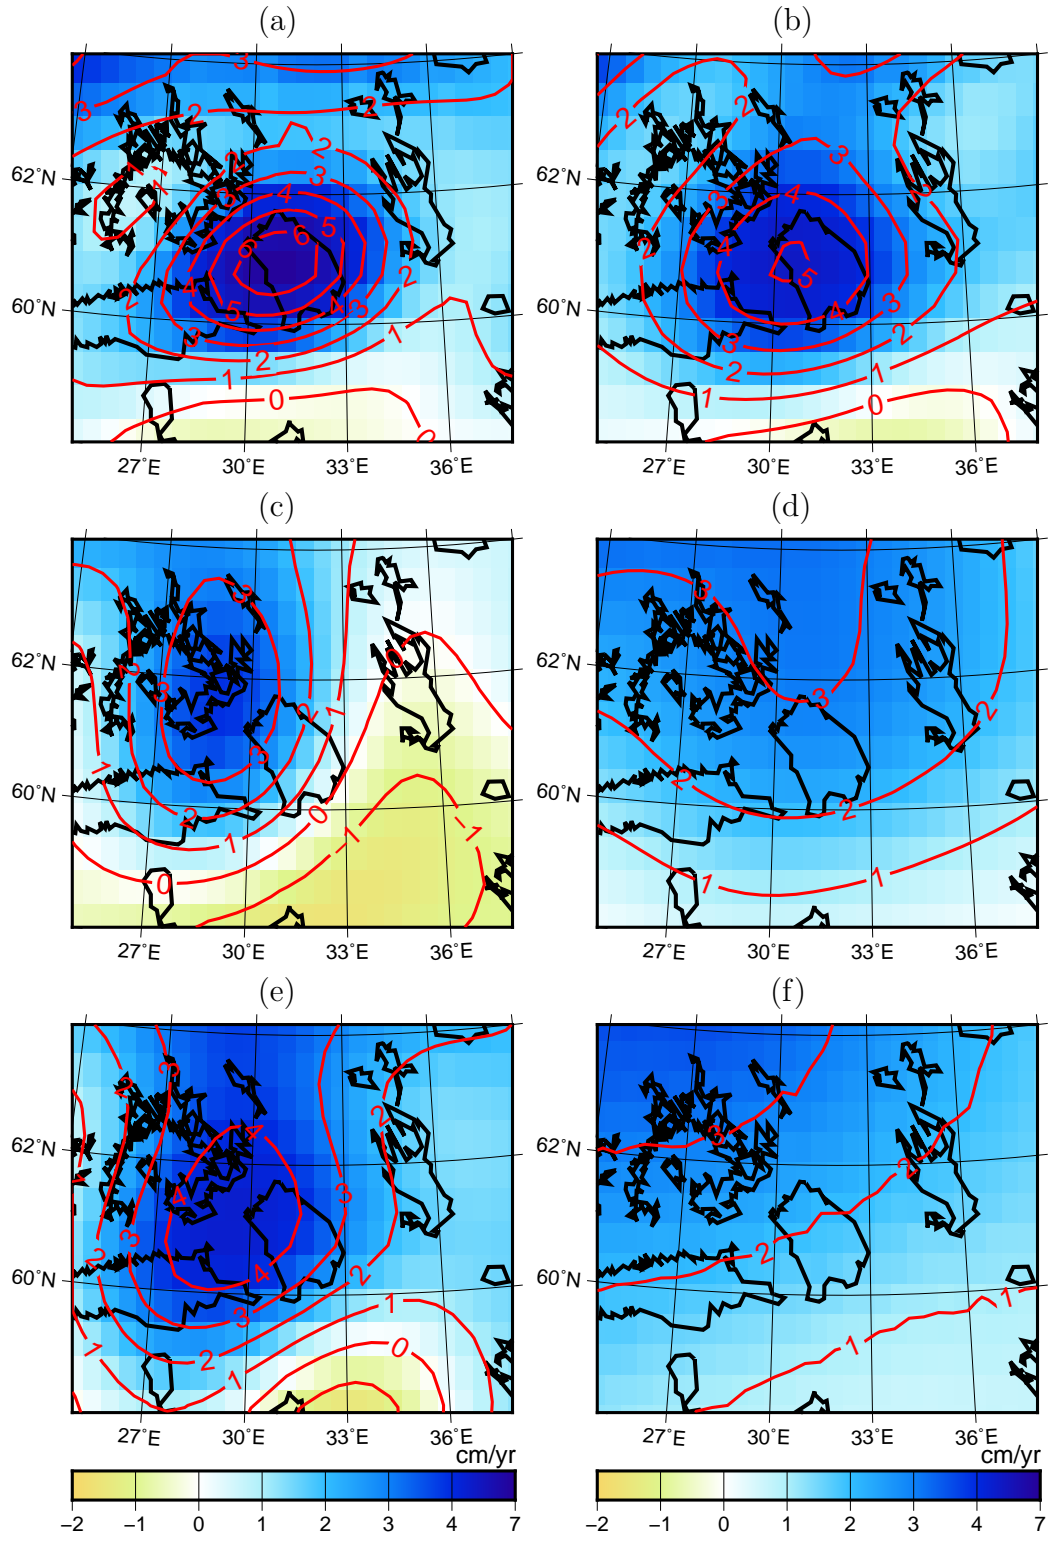

Figure 4: Linear trend in terms of EWH over the Ladoga lake computed in the time interval February 2003 – December 2008 from (a) DMT-2, (b) “DMT-2-DEG-96”, (c) CSR-RL05, (d) “CSR-RL05-DDK-5”, (e) “CSR-RL05-DDK-8”, and (f) GSFC_global_mascons_v01.

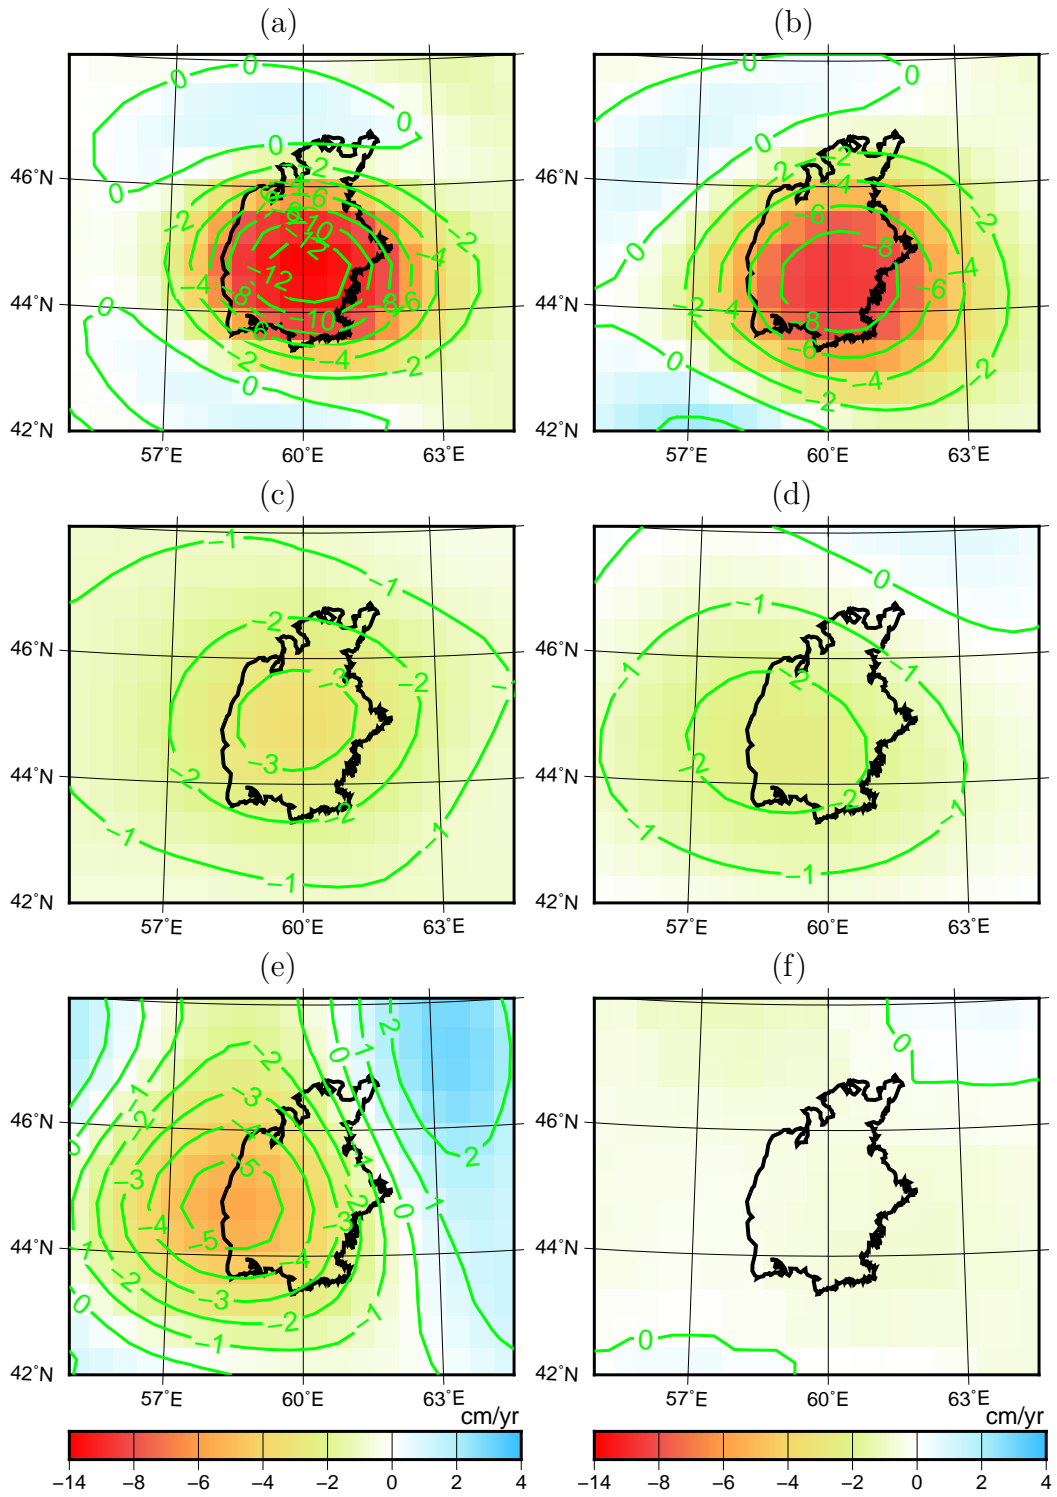

Figure 5: Linear trend in terms of EWH over the Aral sea computed in the time interval February 2003 – December 2008 from (a) DMT-2, (b) “DMT-2-DEG-96”, (c) CSR-RL05, (d) “CSR-RL05-DDK-5”, (e) “CSR-RL05-DDK-8”, and (f) GSFC_global_mascons_v01.

222 loss of water mass in the Aral sea. Signal amplitudes are much larger in those
 223 cases compared to CSR-RL05, “CSR-RL05-DDK-5”, and “CSR-RL05-DDK-
 224 8”. In order to make an independent validation of the results, we consider
 225 water levels extracted from TOPEX/Poseidon and Jason-1 radar altimeter
 226 data over the period February 2003 – December 2008. From these mea-
 227 surements, we estimate linear trends together with a bias, as well as annual
 228 and semi-annual terms, to be consistent with the GRACE-derived estimates.
 229 Figure 6 shows the water height variations as a function of time and the
 230 computed mean linear trends over the Ladoga lake and Aral sea. A compar-
 231 ison with the GRACE-based estimates reveals that only DMT-2 provides a
 232 signal amplitude close to the radar altimeter-based estimates. The ampli-
 233 tude in case of “DMT-2-DEG-96” is reduced by about 20%. The estimates
 234 based on CSR-RL05, “CSR-RL05-DDK-5”, and “CSR-RL05-DDK-8” also
 235 show mass variations in both areas, but the signal is smeared over a much
 236 larger region and dramatically reduced. Correspondingly, linear trends are
 237 highly underestimated in those cases for both the Ladoga lake and the Aral
 238 sea. This is to be expected for “CSR-RL05-DDK-5” and “CSR-RL05-DDK-
 239 8”, because both lakes occupy a relatively small area (about 18000 km² in
 240 2004). The poor performance observed in case of CSR-RL05 is likely caused
 241 by an insufficiently accurate noise covariance matrix, which yields an inad-
 242 equate Wiener filter. We also notice that the peak mass variations are not
 243 centred on the target lakes in case of CSR-RL05, “CSR-RL05-DDK-5”, and
 244 “CSR-RL05-DDK-8” (an exception is CSR-RL05 for the Aral sea) unlike
 245 DMT-2 and “DMT-2-DEG96” (Figs. 4a and 5a). We additionally show in
 246 Fig. 7 the Aral sea region observed by the Landsat in summer months in 2003

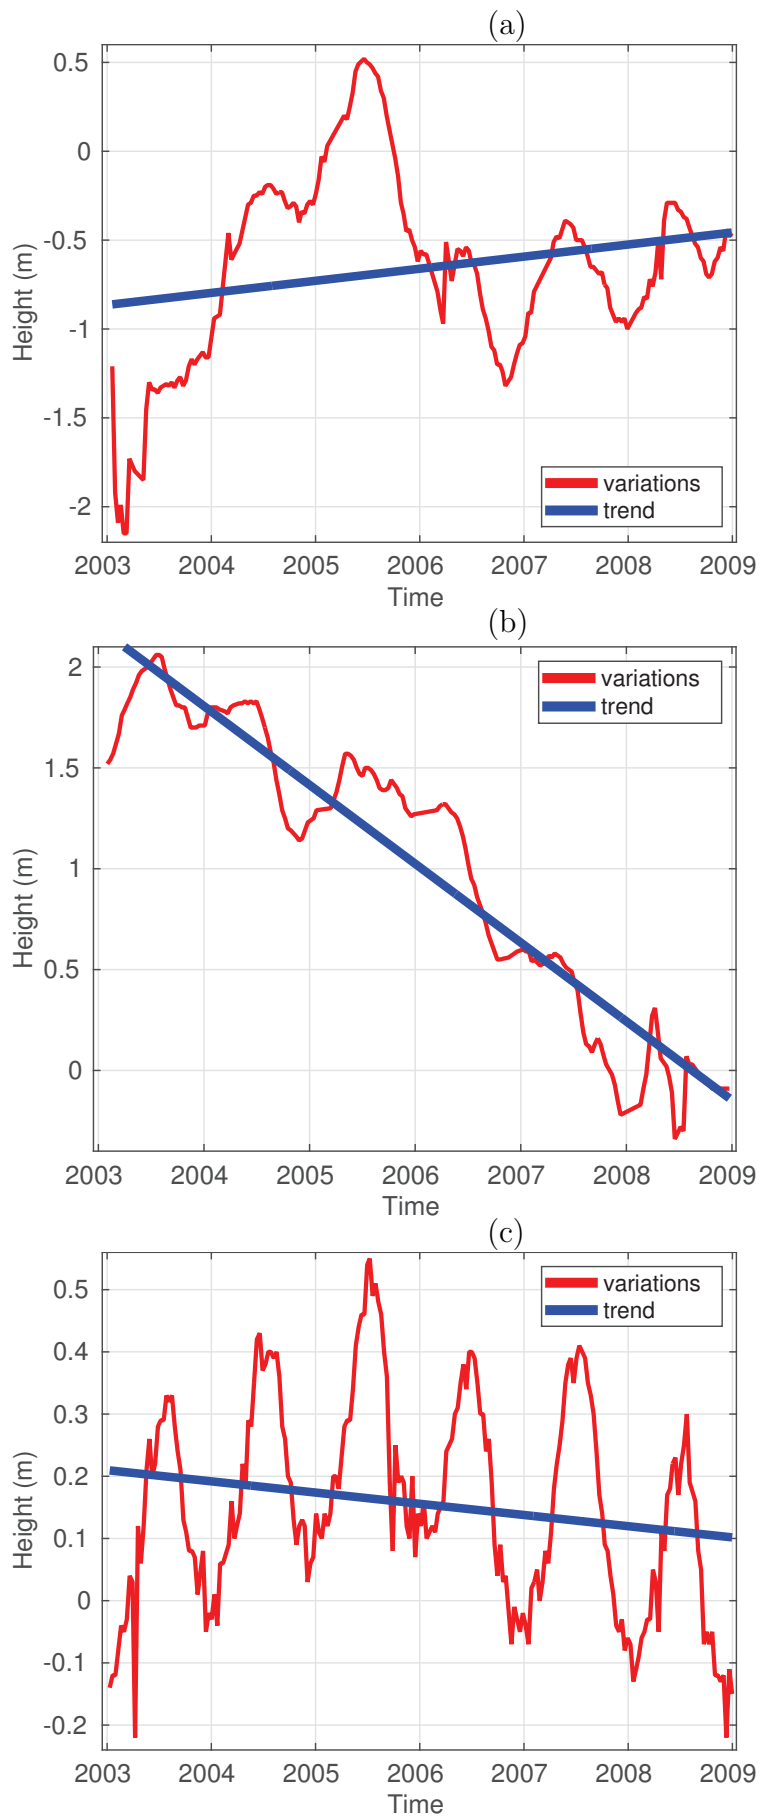

Figure 6: Water height variations and mean linear trend over (a) Ladoga lake, (b) Aral sea, and (c) Caspian sea in the time interval February 2003 – December 2008 from TOPEX/Poseidon and Jason-1 radar altimeter data. The mean linear trends are 6.92 cm/yr, -38.89 cm/yr, and -1.64 cm/yr for the Ladoga lake, Aral sea, and Caspian sea, respectively.

247 – 2008. This time interval corresponds to that for which the linear trend is
 248 computed. Summer months are chosen because they offered a clear sky. The
 249 figure reveals the presence of a massive water loss. This loss is primarily
 250 pronounced in the main water body, i.e., the one centred in the exhibited
 251 Landsat pictures. The radar altimeter data exploited in Fig. 6b are collected
 252 just over this water body, too.

253 Finally, a comparison between “CSR-RL05-DDK-5” and “CSR-RL05-
 254 DDK-8” (Fig. 4d versus Fig. 4e and Fig. 5d versus Fig. 5e) clearly reveals
 255 an improved spatial resolution when choosing a smaller DDK filter. At the
 256 same time, stripes are barely present in case of “CSR-RL05-DDK-8” esti-
 257 mates. Nevertheless, even a small DDK filter could not lead to a spatial
 258 resolution achievable with the Wiener filter.

259 3.2.1.2 *Ice sheets*

260 We compare the five spherical harmonic estimates of the linear trend over
 261 the Greenland and Antarctica. The linear trend estimates in EWH in the
 262 time interval February 2003 – December 2008 are shown over Greenland and
 263 Antarctica in Figs. 8 and 9, respectively. The linear trends in physical height
 264 changes acquired from ICESat laser altimeter data in the same time interval
 265 are provided in Figs. 8f and 9f. These ICESat-based trends are computed
 266 using the overlapping footprint approach described in (Felixson et al., 2016)
 267 and (Gunter et al., 2014) for Greenland and Antarctica, respectively. In both
 268 cases, they have a spatial resolution of about 20 km. We smooth them with
 269 a 75 km (half-width) Gaussian filter (Jekeli, 1981) to facilitate a comparison
 270 of them with the GRACE-based estimates (Figs. 8g and 9g).

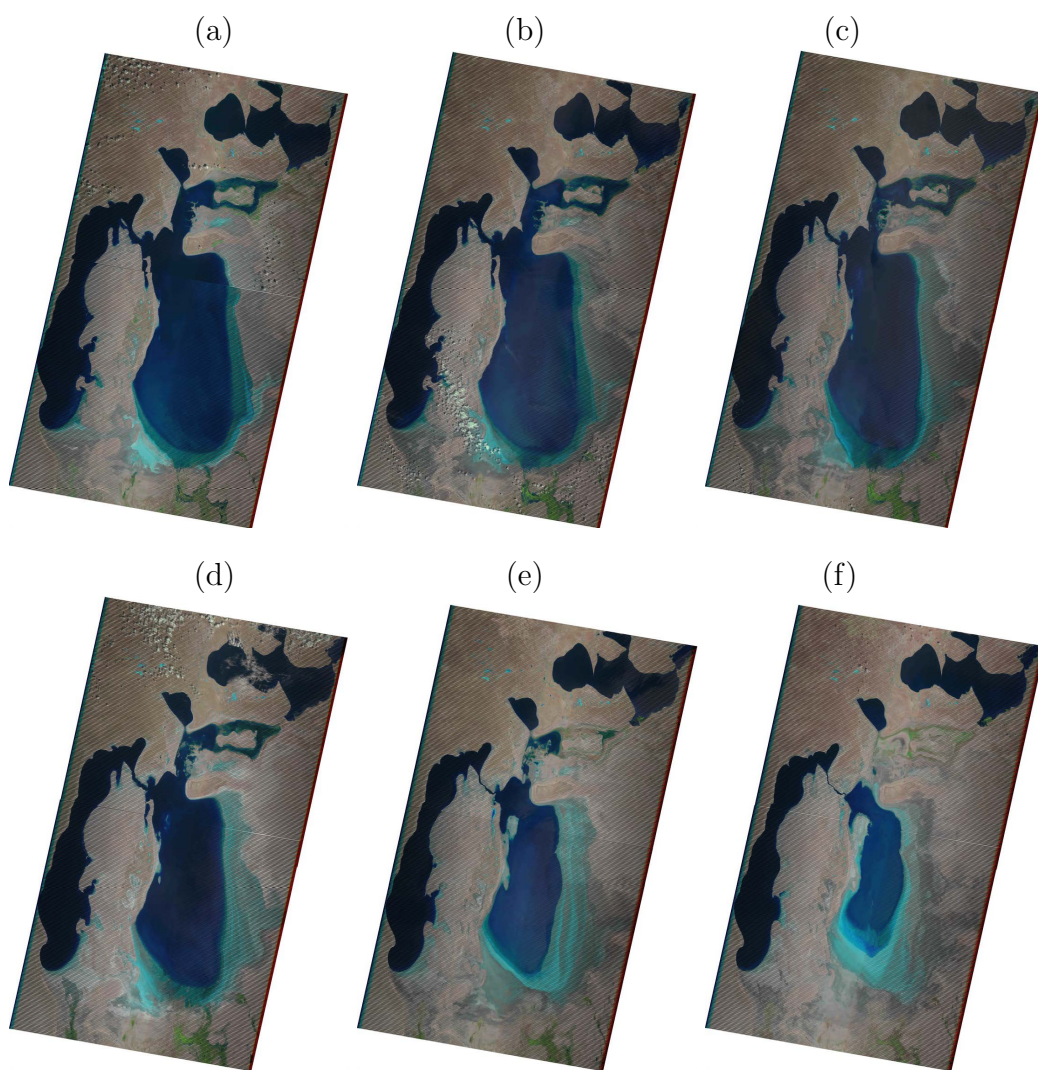

Figure 7: Aral sea region observed by Landsat in 2003 (a) – 2008 (f) in summer months.

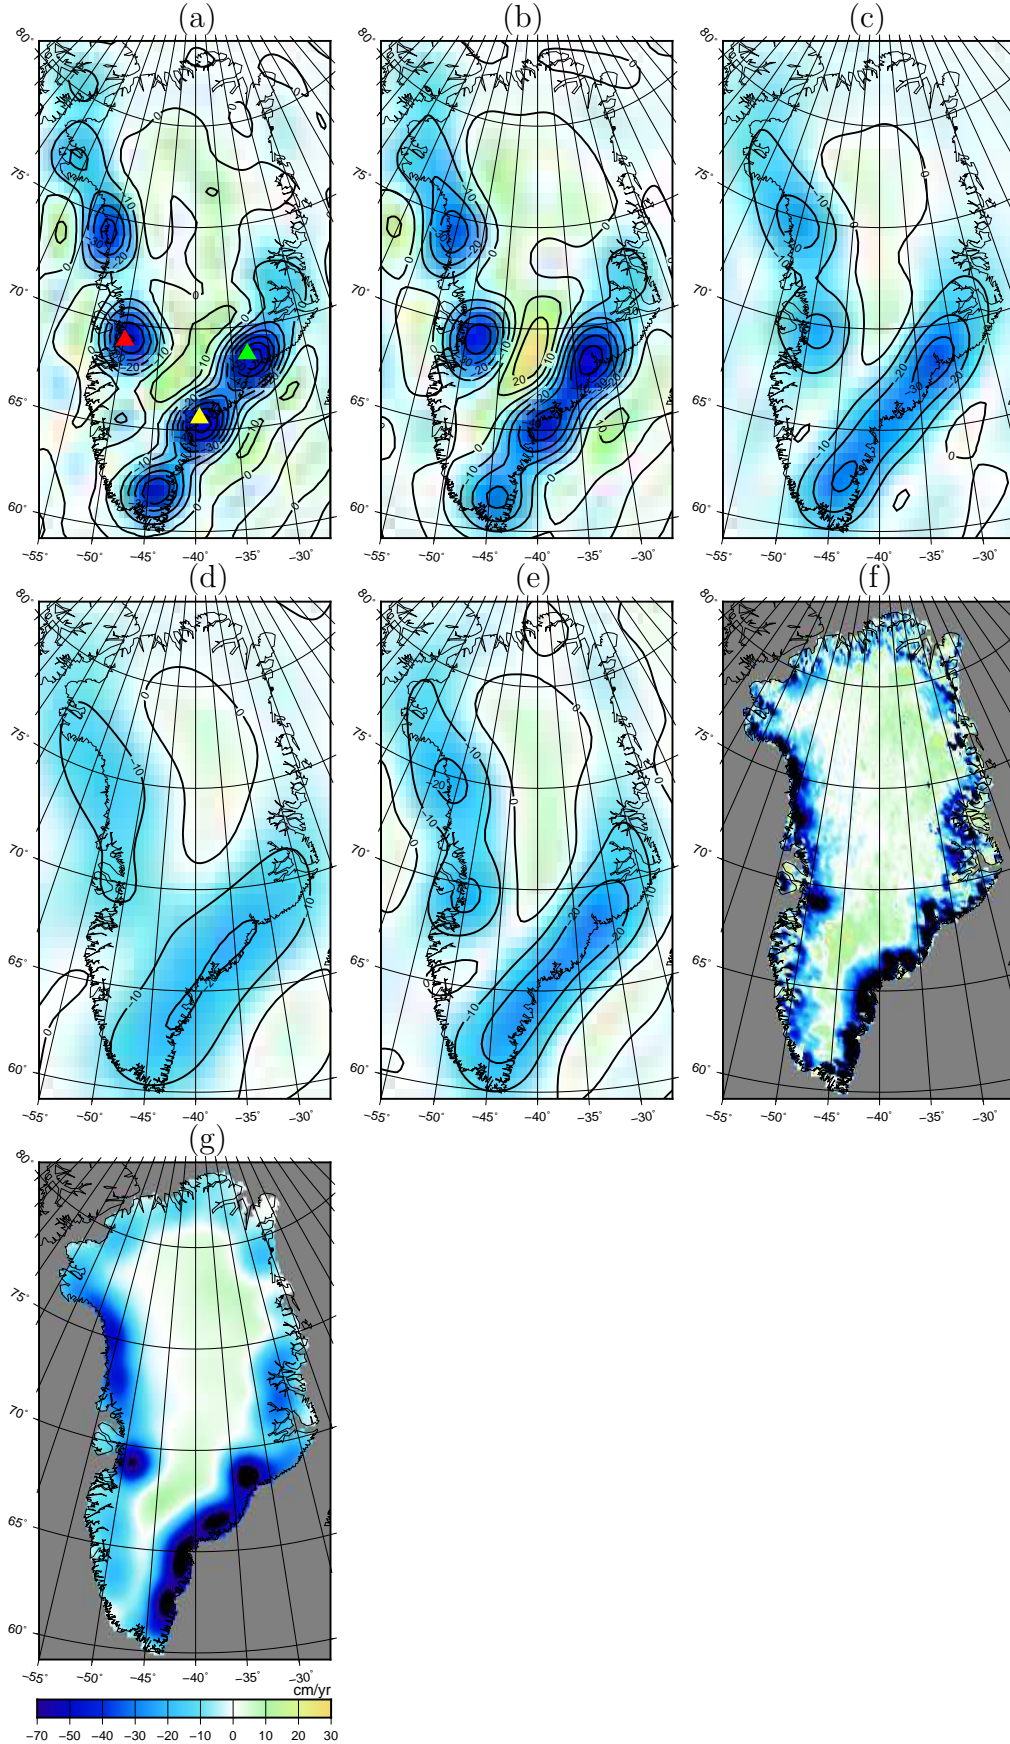

Figure 8: Linear trend over Greenland computed in the time interval February 2003 – December 2008 from (a) DMT-2, (b) “DMT-2-DEG-96”, (c) CSR-RL05, (d) “CSR-RL05-DDK-5”, and (e) “CSR-RL05-DDK-8” as well as ICESat data (f) without and (g) with a 75 km (half-width) Gaussian smoothing. The GRACE-based estimates are in EWH, whereas those based on ICESat are in physical heights. The location of Jakobshavn and Kangerdlugssuaq glaciers are marked in the top left picture with red and green triangles, respectively. The average location of Helheim, Ikertivaq, and Koge Bugt glaciers is marked in the same picture with a yellow triangle.

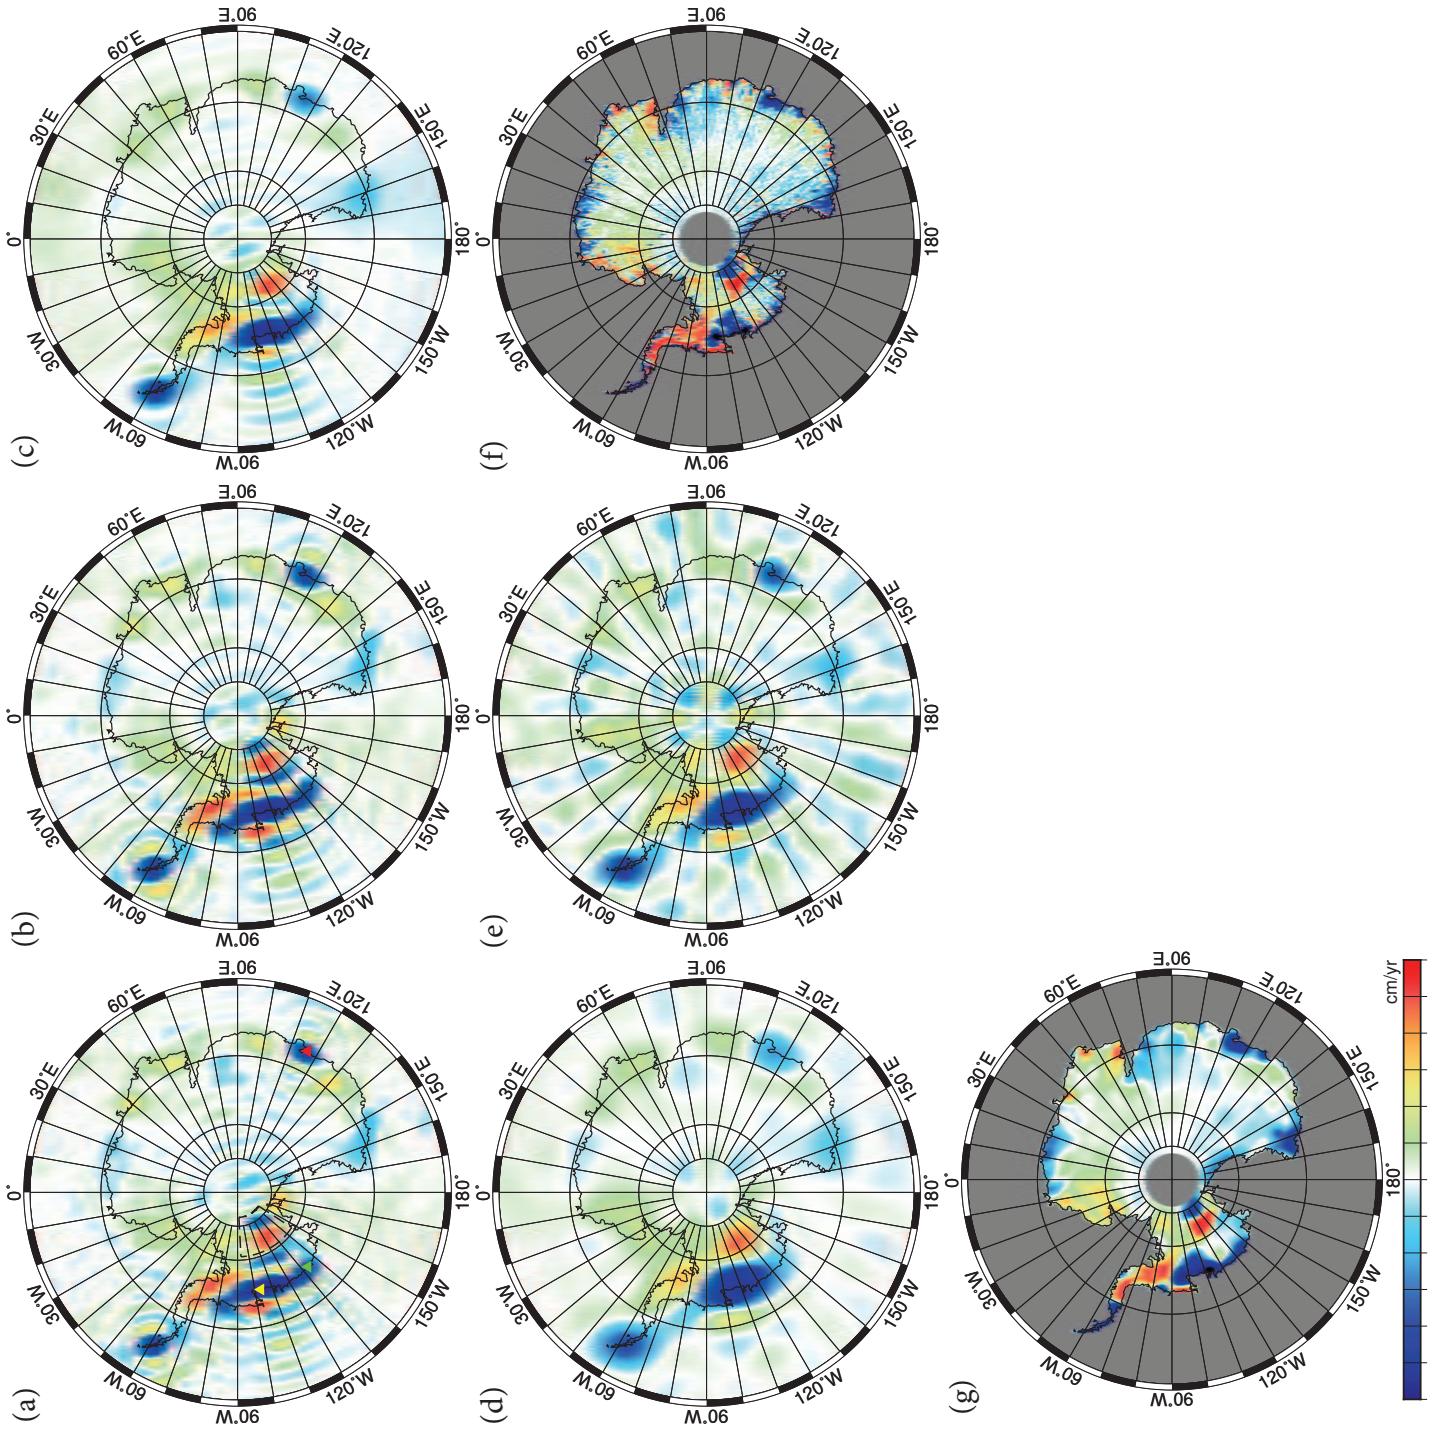

Figure 9: Same as Fig. 8, but for Antarctica. The location of Totten glacier is marked in the top left picture with a red triangle. The average location of Pine Island and Thwaites glaciers as well as that of Getz Ice Shelf and Land Glacier are marked in the same picture with yellow and green triangles. The selected area in West Antarctica is marked with a dashed, black box.

271 One can see from Figs. 8 and 9 that DMT-2 and its clone computed to
 272 degree 96 have the highest spatial resolution allowing for a clear distinction
 273 of signals related to individual glaciers. For instance, signals associated with
 274 the Jakobshavn and Kangerdlugssuaq glaciers, as well as those related to the
 275 combination of Helheim, Ikertivaq, and Koge Bugt glaciers can be clearly seen
 276 in Greenland. We also want to point to the good agreement of trend patterns
 277 over Antarctica from DMT-2 and “DMT-2-DEG-96” with results based on
 278 the ICESat data. Examples are signals associated with (i) Totten glacier
 279 in East Antarctica, (ii) the combined signal of Pine Island and Thwaites
 280 glaciers, and (iii) the combined signal of Getz Ice shelf and Land glacier
 281 in West Antarctica. Another notable example is the area near the pole in
 282 West Antarctica that is marked by a dashed, black box in Fig. 9a. We zoom
 283 in on this region in Fig. 10. DMT-2, “DMT-2-DEG-96”, and ICESat data
 284 consistently reveal a positive and a negative anomaly there located close to
 285 each other. The positive anomaly there is most likely associated with an
 286 accumulation of ice, which is in accordance with some earlier findings (e.g.,
 287 Joughin and Tulaczyk, 2002). Though the CSR-RL05 Wiener filter estimate
 288 and its DDK filter variants reveal a similar pattern, the signal amplitude
 289 retrieved is somewhat reduced.

290 At the same time we admit that linear trends from DMT-2 and “DMT-2-
 291 DEG-96” suffer from some high-frequency errors. They show up in the form
 292 of ringing artifacts in the vicinity of locations with strong mass variations.
 293 For instance, in Greenland, they are as large as about 12% of the signal. We
 294 consider them as noise given the fact that they are present not only over the
 295 ice sheets, but also over the oceans, where mass variations are expected to be

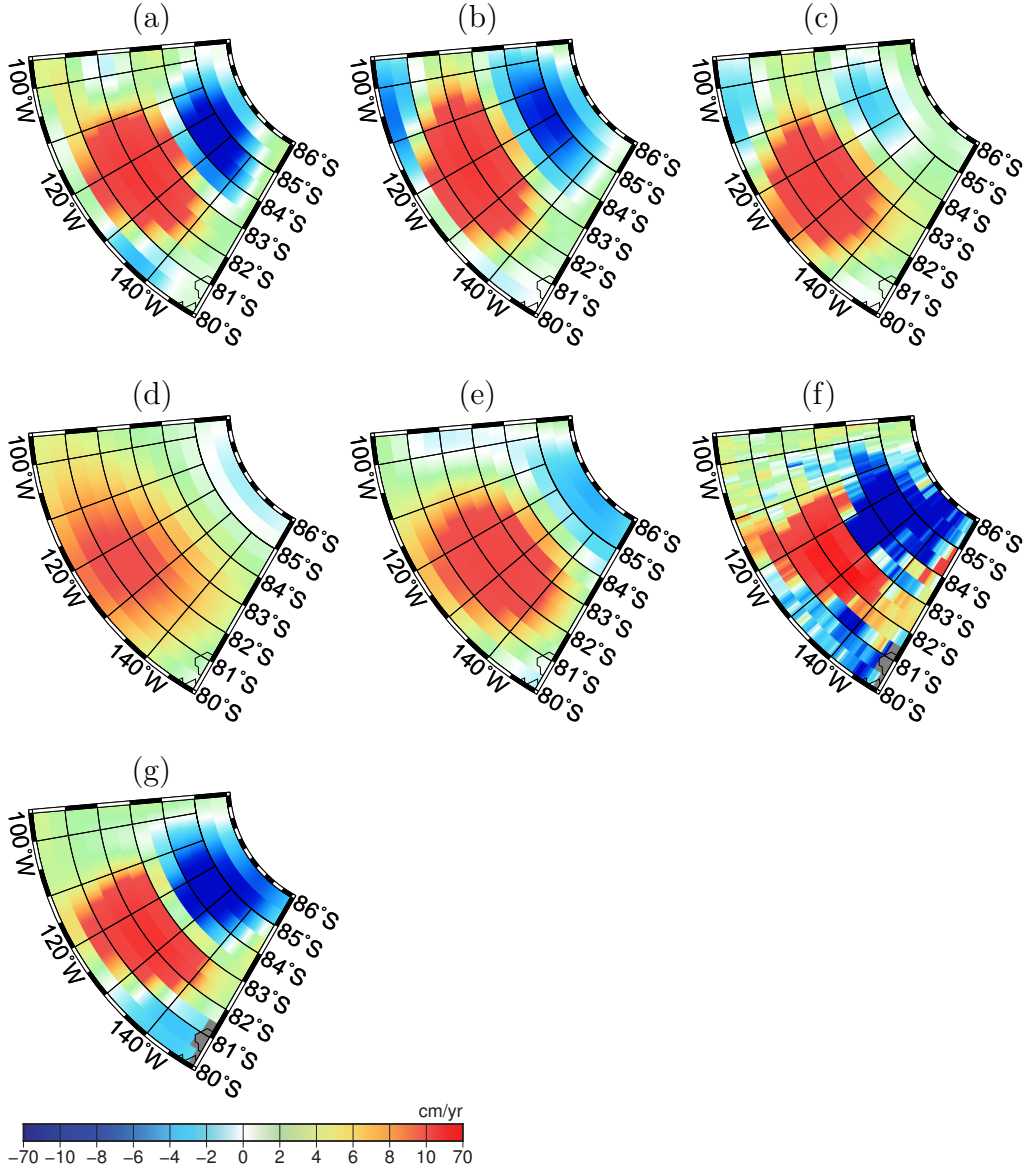

Figure 10: Linear trends over the selected area in West Antarctica, marked with a dashed black box in Fig. 9a. They are computed in the time interval February 2003 – December 2008 from (a) DMT-2, (b) “DMT-2-DEG-96”, (c) CSR-RL05, (d) “CSR-RL05-DDK-5”, and (e) “CSR-RL05-DDK-8” as well as ICESat data (f) without and (g) with a 75 km (half-width) Gaussian smoothing. The GRACE-based estimates are in EWH, whereas those based on ICESat are in physical heights.

296 minor, if not zero. The likely origin of this phenomenon is an abrupt signal
 297 truncation in the frequency domain at the maximum degree (degree 120 and
 298 96, respectively). The best way to solve this problem is still a topic of active
 299 research.

300 The DDK-filtered linear trend estimates do not offer the spatial resolution
 301 achieved in cases of DMT-2 or its clone to degree 96. “CSR-RL05-DDK-8”
 302 as compared to “CSR-RL05-DDK-5” reveals a higher spatial resolution in
 303 both Greenland and Antarctica. Results related to “CSR-RL05-DDK-8” in
 304 Antarctica are somewhat polluted with stripes. In Greenland, however, no
 305 sign of stripes is present. This means that a further improvement of spatial
 306 resolution could be achieved there when using a smaller DDK filter than the
 307 DDK-8 one.

308 Furthermore, we validate the GRACE models over the Antarctica quan-
 309 titatively by comparing the results to those derived from laser altimetry
 310 (Gunter et al., 2009). To that end, we transform the ICESat-based linear
 311 trend estimate from physical heights into EWH in line with the methodology
 312 described by Gunter et al. (2014). This approach takes into account sur-
 313 face mass changes from the regional atmospheric climate model RACMO2
 314 (Lenaerts et al., 2012) and the accompanying firn densification model (Ligten-
 315 berg et al., 2011) as well as the Glacial Isostatic Adjustment model of White-
 316 house et al. (2012). Figure 11 exhibits RMS reductions of the ICESat-
 317 based linear trend EWH by the GRACE-based ones in percentages, i.e.,
 318 $100 \times \left(\frac{\text{RMS}_{\text{ICESat}} - \text{RMS}_{\text{ICESat-GRACE}}}{\text{RMS}_{\text{ICESat}}} \right)$, subsequent to a Gaussian smoothing of the
 319 ICESat-based results at different widths. For computing the RMS reduction
 320 in percent, the entire ice sheet is seen as a time series. This comparison

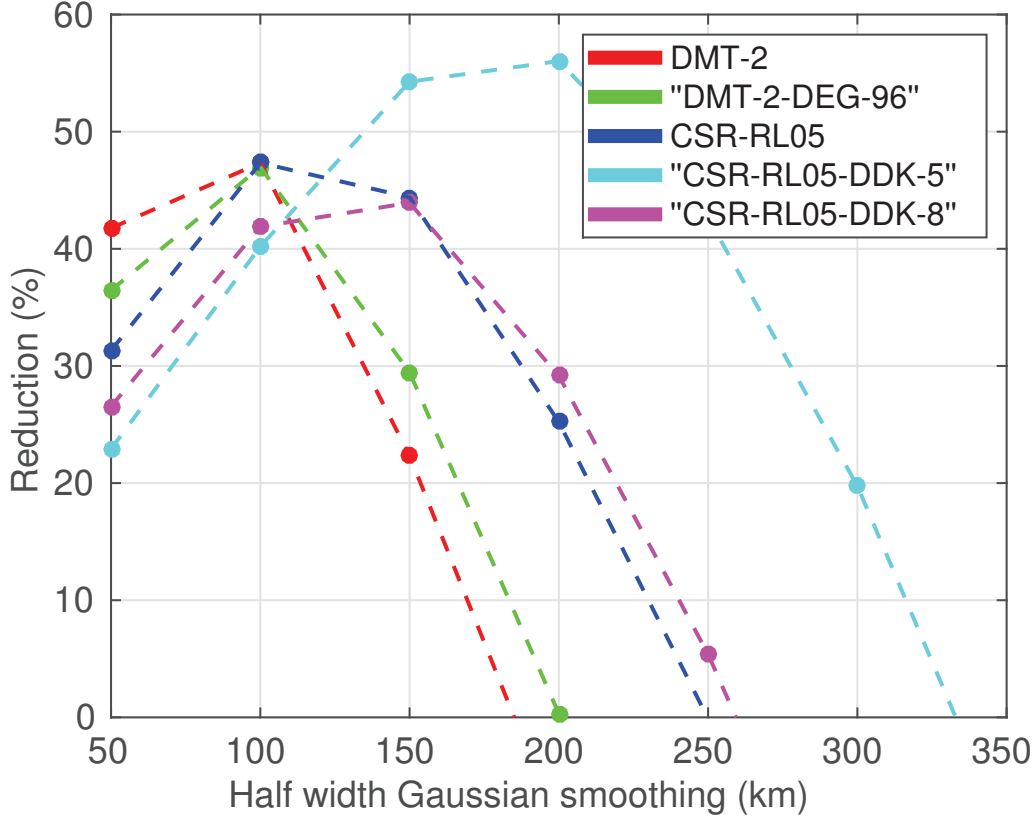

Figure 11: The RMS signal reductions (in percentages) of the ICESat-based linear trend EWH by the GRACE-based ones, i.e., $100 \times \left(\frac{\text{RMS}_{\text{ICESat}} - \text{RMS}_{\text{ICESat-GRACE}}}{\text{RMS}_{\text{ICESat}}} \right)$, subsequent to the Gaussian smoothing of the ICESat-based results at different widths over Antarctica.

321 considers both the spatial pattern as well as the magnitude of the signal.
 322 The Gaussian smoothing of the ICESat-based results is performed at dif-
 323 ferent widths and compared to the GRACE-derived trend to approximately
 324 determine the spatial resolution of the GRACE. The peaks in Fig. 11 are
 325 interpreted as the spatial resolution of the respective GRACE solution in
 326 terms of the Gaussian smoothing filter. Compared to CSR-RL05, the com-
 327 puted signal reductions are slightly larger for DMT-2 and “DMT-2-DEG-96”

328 at spatial scales smaller than about 100 km (half-width). The opposite is ob-
 329 served at larger spatial scales. We interpret this observation as an evidence
 330 that the spatial resolution of the DMT-2 model and its clone is higher. To
 331 understand this behaviour, we emphasize that only the ICESat-based results
 332 are subject to the Gaussian smoothing. Hence, the spatial resolution of those
 333 results reduces as the spatial scale increases. Consequently, for GRACE es-
 334 timates with higher spatial resolution, the peak in their signal reductions of
 335 the ICESat-based EWH occurs at smaller smoothing radii.

336 Furthermore, it is worth noting that the signal reductions in the case of
 337 the CSR-RL05 Wiener filter estimate are much higher than in case of the
 338 DDK-filtered ones at spatial scales smaller than 100 – 150 km (half-width).
 339 We interpret this as a consequence of a higher spatial resolution of the Wiener
 340 filter compared to the DDK filters. This is also supported by the maps shown
 341 in Figs. 8, 9, and 10.

342 On the other hand, as it can be seen from Fig. 9, the higher the spatial
 343 resolution of a GRACE solution, the higher its noise content. The ringing
 344 artifacts can be clearly seen for the Wiener filter estimates in Fig. 9 and they
 345 are also reflected in the lower values of RMS reduction for these solutions
 346 compared to the DDK-filtered estimates at relatively large spatial scales.

347 Finally, it is important to note that DMT-2 as compared to its clone com-
 348 puted to degree 96 reveals a slightly better agreement with the ICESat-based
 349 estimates at spatial scales smaller than 100–150 km (half-width). However,
 350 it should be noted that this must be almost entirely attributed to a higher
 351 maximum degree considered at the filtering stage and not to information
 352 content of KBR data (Farahani, 2013).

353 3.2.2. *A preliminary comparison with a mascon parametrization*

354 Figure 12 shows the linear trends estimated based on the DMT-2 spheri-
355 cal harmonic (to degree 120) and GSFC_global_mascons_v01 mascon models
356 in the time interval February 2003 – December 2008 in terms of EWH at
357 the global scale. The colore scale is intentionally saturated in order to re-
358 veal model differences more clearly. Both models demonstrate a high spatial
359 resolution. This is, in particular, notable in areas where substantial mass
360 variations occur, e.g., Antarctica, Greenland, Gulf of Alaska, Iceland, Cana-
361 dian Arctic archipelago, Novaya Zemlya archipelago, and Svalbard (Spitsber-
362 gen) archipelago. DMT-2 and GSFC_global_mascons_v01 both demonstrate
363 a high concentration of the signal along the coast in these areas. This is
364 typically expected in the case of mascon models due to a priori information
365 imposed, for instance, by defining the mascon geometry consistently with
366 coast lines. We find this, however, remarkable in the case of DMT-2 in view
367 of the fact that no such a priori information is imposed.

368 DMT-2 as compared to GSFC_global_mascons_v01 suffers from somewhat
369 larger inaccuracies in the so-called “quite areas”, i.e., areas void of substantial
370 temporal gravity field variations (e.g., oceans and deserts), which is partly
371 explained by the presence of the previously noted ringing artifacts. Finding
372 the best way to suppress those inaccuracies will be the subject of a future
373 research. This, for instance, could be done by additional filtering of spherical
374 harmonic coefficients by preventing the signal variances (i.e., diagonal ele-
375 ments in matrix \mathbf{D}) in “quite areas” from exceeding a predefined threshold.

376 Finally, one can identify numerous differences between the DMT-2 and
377 GSFC_global_mascons_v01 models at small spatial scales. Examples are Lake

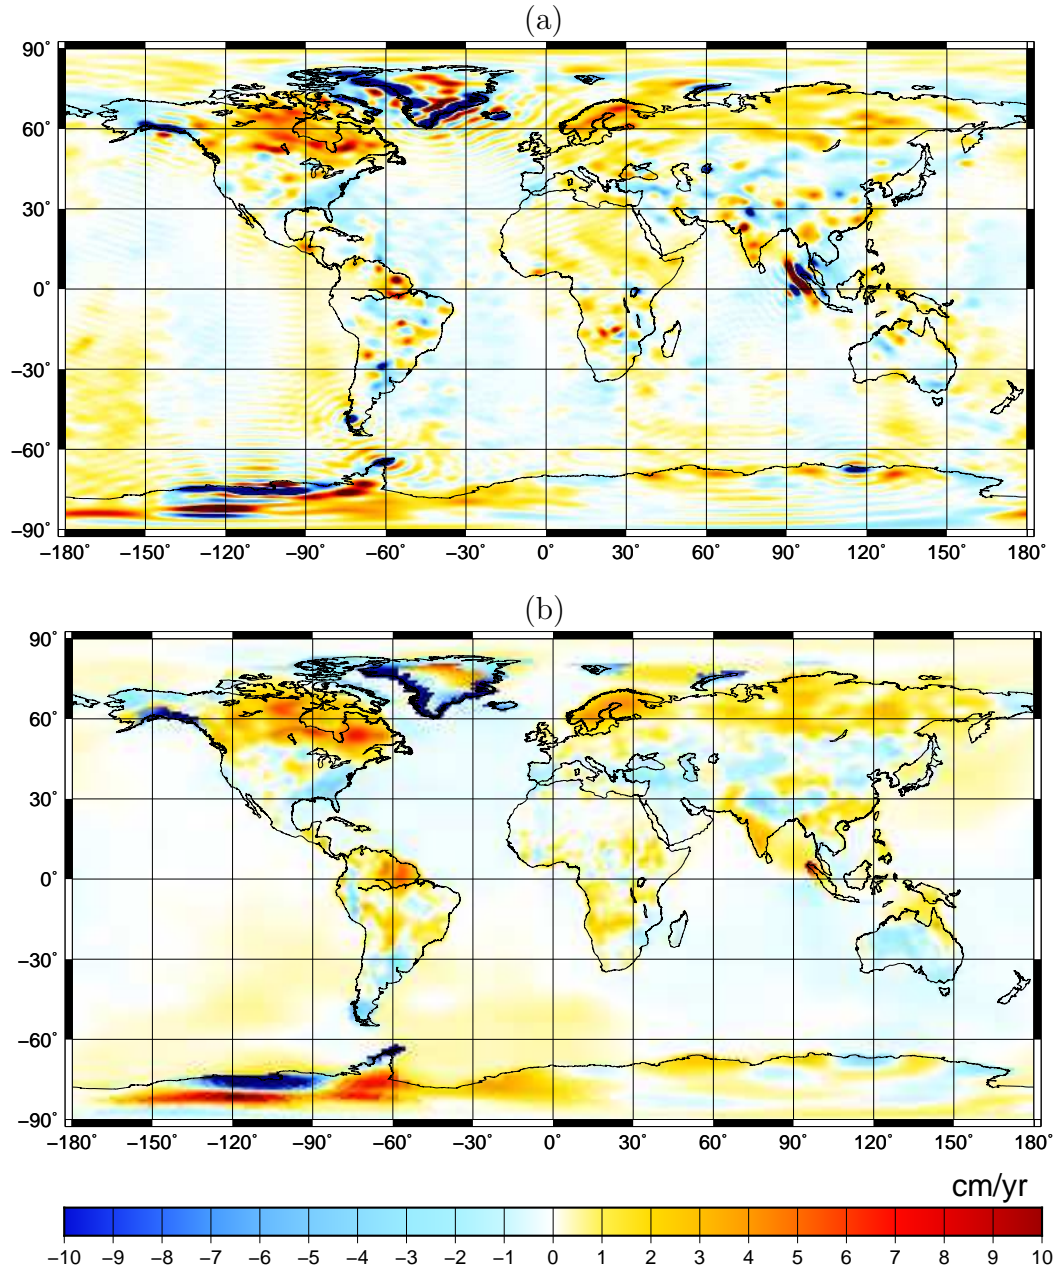

Figure 12: The linear trend computed in the time interval February 2003 – December 2008 in the cases of (a) DMT-2 and (b) GSFC_global_mascons.v01. The maps are in terms of EWH. Their RMS values are (a) 3.19 cm/yr and (b) 1.58 cm/yr. The Color scale is intentionally saturated.

378 Victoria, Ladoga lake, Aral sea, Caspian sea, Amazon river basin, and Patag-
 379 onia. A comprehensive analysis of such differences demands a separate re-
 380 search, which we postpone to a later stage. Here, we limit ourselves to only
 381 three water bodies: Aral sea, Ladoga lake, and Caspian sea. In Ladoga
 382 lake and Aral sea, GSFC_global_mascons_v01, unlike DMT-2, fails to cap-
 383 ture respective water gain and water loss signals (see Fig. 4a versus Fig. 4f
 384 and Fig. 5a versus Fig. 5f as well as Fig. 6a and Fig. 6b). On the contrary,
 385 GSFC_global_mascons_v01 reveals the water loss in the Caspian sea. DMT-
 386 2 fails in that respect and, by the way, so do all other spherical harmonic
 387 models considered in our manuscript (cf. Fig. 3c – Fig. 3e). The reason for
 388 this is yet to be investigated. It is worth noting that the loss of water in the
 389 Caspian sea in the time interval under consideration is captured by radar
 390 altimetry data, too (cf. Fig. 6c).

391 **4. Conclusions**

392 We computed new estimates of the long-term linear trend in mass re-
 393 distribution based on the DMT-2 model, which comprises monthly gravity
 394 field solutions and corresponding full noise covariance matrices complete to
 395 spherical harmonic degree 120. A novel feature of the DMT-2 model is the
 396 accurate computation and incorporation of stochastic properties of coloured
 397 noise when processing KBR data, which also accounts for gradual variations
 398 of the noise characteristics in time. This ensures a statistically optimal inver-
 399 sion of KBR data, and more importantly, an accurate computation of noise
 400 covariance matrices of monthly solutions. These matrices play a key role in
 401 the design of Wiener-type filters, including that proposed by Siemes et al.

402 (2013) for estimating the linear trend. For comparison, we produced esti-
 403 mates of the linear trend from CSR-RL05 monthly solutions and their noise
 404 covariance matrices using the same methodology to build the linear trend
 405 Wiener filter. The linear trend estimate based on DMT-2 demonstrates a
 406 higher spatial resolution, even if we lower the maximum degree in the DMT-
 407 2 model to degree 96 to be consistent with the CSR-RL05 model. It allows
 408 for a clear detection of mass variation signals in relatively small water bodies
 409 and individual outlet glaciers of the ice sheets. Moreover, it shows a much
 410 better fit to actual water level and surface elevation variations extracted
 411 from radar and laser altimeter data. We attribute the higher spatial resolu-
 412 tion of the DMT-2 linear trend estimates compared to that estimated from
 413 CSR-RL05 to an accurate computation of monthly noise covariance matri-
 414 ces, which was possible due to a proper handling of coloured noise in KBR
 415 data. However, there is still space for further improvements. The linear trend
 416 estimates based on DMT-2 or its clone computed to degree 96 suffer from
 417 some high-frequency inaccuracies. Those inaccuracies manifest themselves
 418 in the form of ringing artifacts in the vicinity of locations with strong mass
 419 variations. The best way to deal with this problem is still under investiga-
 420 tion. The estimates of the linear trend obtained from DMT-2 are publicly
 421 available for download.^{1,2} The linear trend models analysed and presented
 422 in this manuscript are related to a six-year time interval (February 2003 –
 423 December 2008). Similar models for longer time intervals are to be produced
 424 and released subsequently.

¹www.citg.tudelft.nl

²www.researchgate.net/profile/Hassan_H_Farahani

425 Furthermore, we produced additional variants of the linear trend with a
 426 commonly-used approach: from CSR-RL05 monthly solutions subject to the
 427 DDK-5 and DDK-8 de-correlating non-isotropic filters. As compared to the
 428 Wiener filters, these variants showed a reduced spatial resolution and signal
 429 power. In a comparison with the altimetry-based results over Antarctica,
 430 the linear trends obtained in this way showed peak spatial resolutions about
 431 twice (in case of DDK-5 filtering) and 1.5 times (in case of DDK-8 filtering) as
 432 coarse as those after the Wiener filtering. Thus, the DDK-8 filtering showed a
 433 notably higher spatial resolution than the DDK-5 filtering. Near the equator,
 434 nevertheless, the DDK-8-filtered results showed strong stripes. This implies
 435 that a smaller DDK filter cannot be successfully applied uniformly over the
 436 entire globe. We conclude that when estimating the linear trend based on
 437 DDK-filtered time series of solutions, one needs to choose different DDK
 438 filters for different geographical areas.

439 A comparison of DMT-2 with GSFC_global_mascons_v01, a recent global
 440 mascon model, suggests that both models demonstrate a high spatial res-
 441 olution in areas known for substantial temporal gravity field changes (e.g.,
 442 Antarctica, Greenland, Gulf of Alaska, Iceland, Canadian Arctic archipelago,
 443 Novaya Zemlya archipelago, and Svalbard archipelago). DMT-2 compared
 444 to GSFC_global_mascons_v01 showed somewhat larger inaccuracies in areas
 445 known for minor mass variations (e.g., ocean and deserts). The absence of
 446 such inaccuracies in GSFC_global_mascons_v01 is explained by a priori infor-
 447 mation typically imposed in such areas, for instance, by defining the mascon
 448 geometry consistently with coast lines (e.g., Watkins et al., 2015). Such a
 449 priori information was never used when computing DMT-2. To the knowl-

edge of authors, they are absent in all spherical harmonic models produced
 so far. An incorporation of such a priori information in the production of
 future spherical harmonic models could be the subject of future research en-
 deavours. This could be incorporated at the a posteriori stage, i.e., when
 filtering spherical harmonic coefficients. More specifically, this could be done
 by predefining and enforcing relatively small signal variances in areas with
 minor mass variations when building and applying a Wiener-type filter. Fi-
 nally, the comparison revealed numerous differences between DMT-2 and
 GSFC_global_mascons_v01 at small spacial scales. A verification of a few of
 those features, namely, in Ladoga lake, Aral sea, and Caspian sea, led to
 mixed conclusions in favour of either model in each instance. An in-depth
 comparison of other small scale differences is postponed to further publi-
 cations. It is worth noting that spherical harmonic and mascon models use
 vastly different parametrizations. That is, they belong to two vastly different
 classes of time-varying gravity field models. Hence, an in-depth comparison
 of them deserves a separate research in any way.

Acknowledgments

The research was financially supported by the Nederlandse organisatie
 voor Wetenschappelijk Onderzoek (Netherlands Organization for Scientific
 Research, NWO). High-performance computing facilities were provided by
 the Stichting Nationale Computerfaciliteiten (National Computing Facilities
 Foundation, NCF). GRACE level-1B data were provided by the Jet Propul-
 sion Laboratory (JPL). The CSR-RL05 unconstrained monthly solutions as
 well as those constrained by the DDK-5 and DDK-8 filters were provided by

474 the International Centre for Global Earth Models (ICGEM). The CSR-RL05
 475 monthly noise covariance matrices were provided by the Center for Space Re-
 476 search (CSR) at the University of Texas at Austin. Landsat pictures as well
 477 as TOPEX/Poseidon and Jason-1 radar altimeter data were made available
 478 by the US Geological Survey (USGS) and the US Department of Agriculture
 479 (USDA), respectively. GSFC_global_mascons.v01 was provided by Goddard
 480 Space Flight Center (GSFC). These supports are gratefully acknowledged.
 481 We are thankful to Natthachet Tangdamrongsub for an assistance in com-
 482 piling the Landsat pictures. We thank the editor, Volker Klemann, and two
 483 anonymous reviewers for their constructive remarks and corrections, which
 484 helped us to improve the quality of the manuscript.

485 **Appendix A. Residual data**

DMT-2 like its predecessor DMT-1 used a variant of the acceleration
 approach. So-called “range combinations” were obtained from bias-corrected
 inter-satellite ranges at three successive epochs with a three-point double
 differentiation scheme (Liu, 2008; Liu et al., 2010)

$$\begin{aligned}
 \bar{a}(t) = & \frac{\mathbf{e}(t - \Delta t) \cdot \mathbf{e}(t) \rho(t - \Delta t) - 2 \rho(t)}{(\Delta t)^2} \\
 & + \frac{\mathbf{e}(t) \cdot \mathbf{e}(t + \Delta t) \rho(t + \Delta t)}{(\Delta t)^2}, \quad (\text{A.1})
 \end{aligned}$$

486 with Δt the sampling rate, $\rho(t)$ the bias-corrected inter-satellite ranges, and
 487 $\mathbf{e}(t)$ the line-of-sight unit vectors pointing from the trailing to the leading
 488 satellite, and t the measurement epoch. It is, in essence, similar to a scheme
 489 developed earlier by Ditmar and van Eck van der Sluijs (2004) and Ditmar

et al. (2006) to determine the Earth’s gravity field from kinematic orbits of low Earth orbiters.

To reduce KBR data into residual range combinations, the following background force models were used:

- (i) Static gravity field with DGM-1S (Farahani et al., 2013a,b).
- (ii) Third-body perturbations from the JPL DE405/LE405 lunar and planetary ephemerides (Standish, 1998).
- (iii) Solid Earth and pole tides in line with the 2003 conventions of the International Earth Rotation and Reference Systems Service (IERS) (McCarthy and Petit, 2004).
- (iv) Ocean tides according to EOT11a to spherical harmonic degree 80 (Savcenko et al., 2012).
- (v) Non-tidal atmospheric and oceanic variations from the fifth release of the Atmosphere and Ocean De-aliasing level-1b (AOD1B) product to spherical harmonic degree 100 (Dobslaw et al., 2013).
- (vi) Ocean pole tide defined by the model of Desai (2002) to spherical harmonic degree 30.
- (vii) General relativity corrections in line with the IERS 2003 conventions (McCarthy and Petit, 2004).
- (viii) Non-gravitational perturbations from the second release of GRACE accelerometer and attitude data, which are provided as a part of GRACE level-1B data (Case et al., 2004).

Additionally, the background force models were iteratively improved. The production of the monthly solutions involved three iterations, in all of which

514 the gravity field retrieval was performed to degree 120. The first two itera-
 515 tions were executed in line with Liu et al. (2010). That is, the unconstrained
 516 solutions computed at a given iteration were truncated at degree 13 and in-
 517 cluded into the list of background force models used in the next iteration.
 518 In the third iteration, the solutions of the previous iteration were treated
 519 differently. Instead of a truncation, they were processed by applying the
 520 Wiener-type filter (Klees et al., 2008b). They were then included into the
 521 list of the background force models to obtain the unconstrained solutions at
 522 the third (i.e., final) iteration. The GRACE satellites in several time inter-
 523 vals, namely, September – October 2004, November – December 2009, and
 524 January – February 2010, followed an orbit with a relatively short repeat pe-
 525 riod. This leads to relatively high inaccuracies in the unconstrained solutions
 526 for these months (e.g., Farahani et al., 2014). These inaccuracies occur in the
 527 entire range of degrees, including those below degree 13. Thus, performing
 528 the second iteration as described above would not lead to optimal results.
 529 Hence, DMT-2 solutions for these months were computed by performing the
 530 second iteration in the same manner as the third one, so that noise in un-
 531 constrained solutions, however large, was efficiently suppressed in the entire
 532 range of degrees.

533 The background force models entered a dynamic orbit computation in
 534 line with Zhao (2004). The orbital arc length was set equal to six hours. The
 535 orbit computation included a least-squares estimation of the initial state
 536 vector elements and accelerometer’s bias parameters per arc as well as of
 537 accelerometer’s scaling factors per month. This estimation was done by fit-
 538 ting the orbits to input kinematic orbits or reduced-dynamic orbits. For the

539 time interval February 2003 – December 2005, reduced-dynamic orbits were
 540 exploited as input, which were kindly provided by Kroes et al. (2005). For
 541 the rest of the time interval, kinematic orbits were exploited, which were
 542 produced in the GNSS Research Center of Wuhan University in line with
 543 Zhao (2004).

544 Observed inter-satellite ranges were obtained from the second release of
 545 GRACE level-1B data. These data are biased due to phase ambiguities. The
 546 dynamic orbits were used to estimate a bias per continuous data segment
 547 by least-squares. In addition, the dynamic orbits were used to compute a
 548 priori inter-satellite ranges. Subsequently, residual inter-satellite ranges were
 549 obtained by subtracting the a priori inter-satellite ranges from the observed
 550 bias-corrected ones. Finally, the residual inter-satellite ranges were used to
 551 compute residual range combinations in line with Eq. A.1.

The obtained residual range combinations suffer from a low-frequency noise below 2 – 3 cycles per revolution (cpr) (e.g., Liu, 2008), which is mainly caused by dynamic orbit errors (Ditmar et al., 2012). This noise was approximated per orbital revolution with a seven-parameter function used earlier in (e.g., Kim, 2000; Liu et al., 2010):

$$r(t) = x_0 + x_1 t + x_2 \cos \omega t + x_3 \sin \omega t + x_4 t \cos \omega t + x_5 t \sin \omega t + x_6 t^2. \quad (\text{A.2})$$

552 Herein, $\omega = \frac{2\pi}{T}$ is the orbital angular velocity with T being the orbital pe-
 553 riod. The unknowns $x_0 \dots x_6$ were estimated from residual data using least-
 554 squares. Thereafter, the estimated model was removed from the residuals.
 555 Note that time-varying gravity field signals, which are to be retrieved at a

556 later stage, play a role of noise in the context of this least-squares adjustment.
 557 If the presence of this noise is ignored, as it was done when computing DMT-
 558 1, the estimated function will tend to explain not only the low-frequency
 559 noise in the residuals, but also a part of time-varying gravity field signals.
 560 Consequently, these signals may be partly removed from the data. In partic-
 561 ular, this concerns signals associated with spherical harmonic degrees below 4
 562 (Farahani et al., 2013a). To mitigate this effect, the least-squares adjustment
 563 was performed with a spatially-dependent data weighting, whose details are
 564 provided in (Farahani et al., 2014). The scheme ensures that residual data
 565 collected over areas with minor mass variations (e.g., in the oceanic areas
 566 and deserts) get the largest weights in this adjustment.

567 **Appendix B. Computing DMT-2 clone to degree 96**

568 To compute clones of DMT-2 monthly gravity field solutions to degree
 569 96, we begin with the original DMT-2 unconstrained solutions, which are
 570 complete to degree 120, and their noise covariance matrices. We first compute
 571 the right-hand side vectors of the systems of linear equations associated with
 572 the monthly unconstrained solutions to degree 120

$$\mathbf{u}_{(k)}^{120} = (\mathbf{C}_{\hat{\mathbf{x}}(k)}^{120})^{-1} \hat{\mathbf{x}}_{(k)}^{120}, \quad (\text{B.1})$$

573 with $\hat{\mathbf{x}}_{(k)}^{120}$ and $\mathbf{C}_{\hat{\mathbf{x}}(k)}^{120}$ being respectively the unconstrained solution to degree
 574 120 and its noise covariance matrix for month k . A truncation of $\mathbf{u}_{(k)}^{120}$ and
 575 $(\mathbf{C}_{\hat{\mathbf{x}}(k)}^{120})^{-1} = \mathbf{N}_{(k)}^{120}$, i.e., the corresponding normal matrix, at degree 96, which
 576 can be done with ease, allows monthly unconstrained solutions to degree 96
 577 to be computed

$$\hat{\mathbf{x}}_{(k)}^{96} = \mathbf{C}_{\hat{\mathbf{x}}(k)}^{96} \mathbf{u}_{(k)}^{96}, \quad (\text{B.2})$$

578 with $\mathbf{C}_{\hat{\mathbf{x}}^{(k)}}^{96} = \left(\mathbf{N}_{(k)}^{96}\right)^{-1}$ being the noise covariance matrix of $\hat{\mathbf{x}}_{(k)}^{96}$. Herein,
 579 $\mathbf{N}_{(k)}^{96}$ and $\mathbf{u}_{(k)}^{96}$ respectively symbolize the monthly normal matrices and right-
 580 hand-side vectors truncated at degree 96.
