2. DESCRIPTION OF MEASUREMENTS
3. ELABORATION OF THE RESULTS
4. DISCUSSION OF THE RESULTS
5. CONCLUSIONS AND RECOMMENDATIONS

1. INTRODUCTION

The calculations of bottom changes presented in our report "Terminal do Seixal Hydro-morphological study", February 1982 were based on a calibrated sediment transport formula. This formula was calibrated with the results of measurements made by Hydronamic in September 1981. These measurements were executed during one of the driest summers Portugal ever have had.

Because of this exceptional summer there was some doubt on the reliability of the calibrated formula for winter situations. From a theoretical point of view one can justify that the influence of the sediments transported by the Tagus river is negligible in the Seixal area, because of the large distance between the point where the river enters the estuary (Vila Franca de Xira) and the Seixal area.

But in theories one makes always certain assumptions and it is therefore better to make additional measurements in winter. Hydronamic b.v. was commissioned by Siderurgia E.P. by telex nr. 1004/gc on January 29th, 1982 to execute an additional measurement campaign in winter.

This report deals with these additional measurements which were executed in the period from February 2nd until February 9th, 1982. The backbone of the equipment was the Hydronamic Sediment Transport Meter which encompasses a frame with sensors and a calculator-unit.

The survey-vessel and the crew were supplied by Hidrotop Lta. Mr. A.C. Starink from Hydronamic supervised the operation.

Because in our report of February 1982 the principles of the Hydronamic Sediment Transport Meter and the calibration method were discussed extensively, this discussion is not repeated in this report.

All 90 profiles are registered. These profiles were measured each half hour during 9-10 hours a day, so almost one tidal cycle could be covered.

For calibration purposes every day one watersample was taken out at a water depth of -2.5 m from the water surface.

All measurements were executed according the planning.

4. DISCUSSION OF THE RESULTS

The results of the measurements show that the water in wintertime is much clearer than it is in summer. This is in contradiction with the usual visual observation of the estuary.

For location 5 three measurements have been made on three different dates:

date	concentration grams/m ³
81 09 04	46.1
81 11 13	17.8
82 02 04	3.3

We have checked if these values were correct or that an error in the sediment-meter did occur. It proved that the same tendency to clearer water was also found in the samples we have taken and tested in the laboratory.

Also interesting are two measurements in the Cala do Montijo:

data	concentration grams/m ³
81 11 11	51.9
82 02 09	49.6

It can be seen that at that location there is not very much difference in concentration.

In fig. 7 the concentration and the velocity is given, both as functions of time. The concentration is constantly decreasing until the velocity reaches the value of approx. 0.5 m/sec. Then stirring up will start again. On the tidal flats (points 1 and 2) the maximum velocities are respectively 0.48, and 0.41 m/s.

Point 5 shows values between these two groups.

5. CONCLUSIONS AND RECOMMENDATIONS

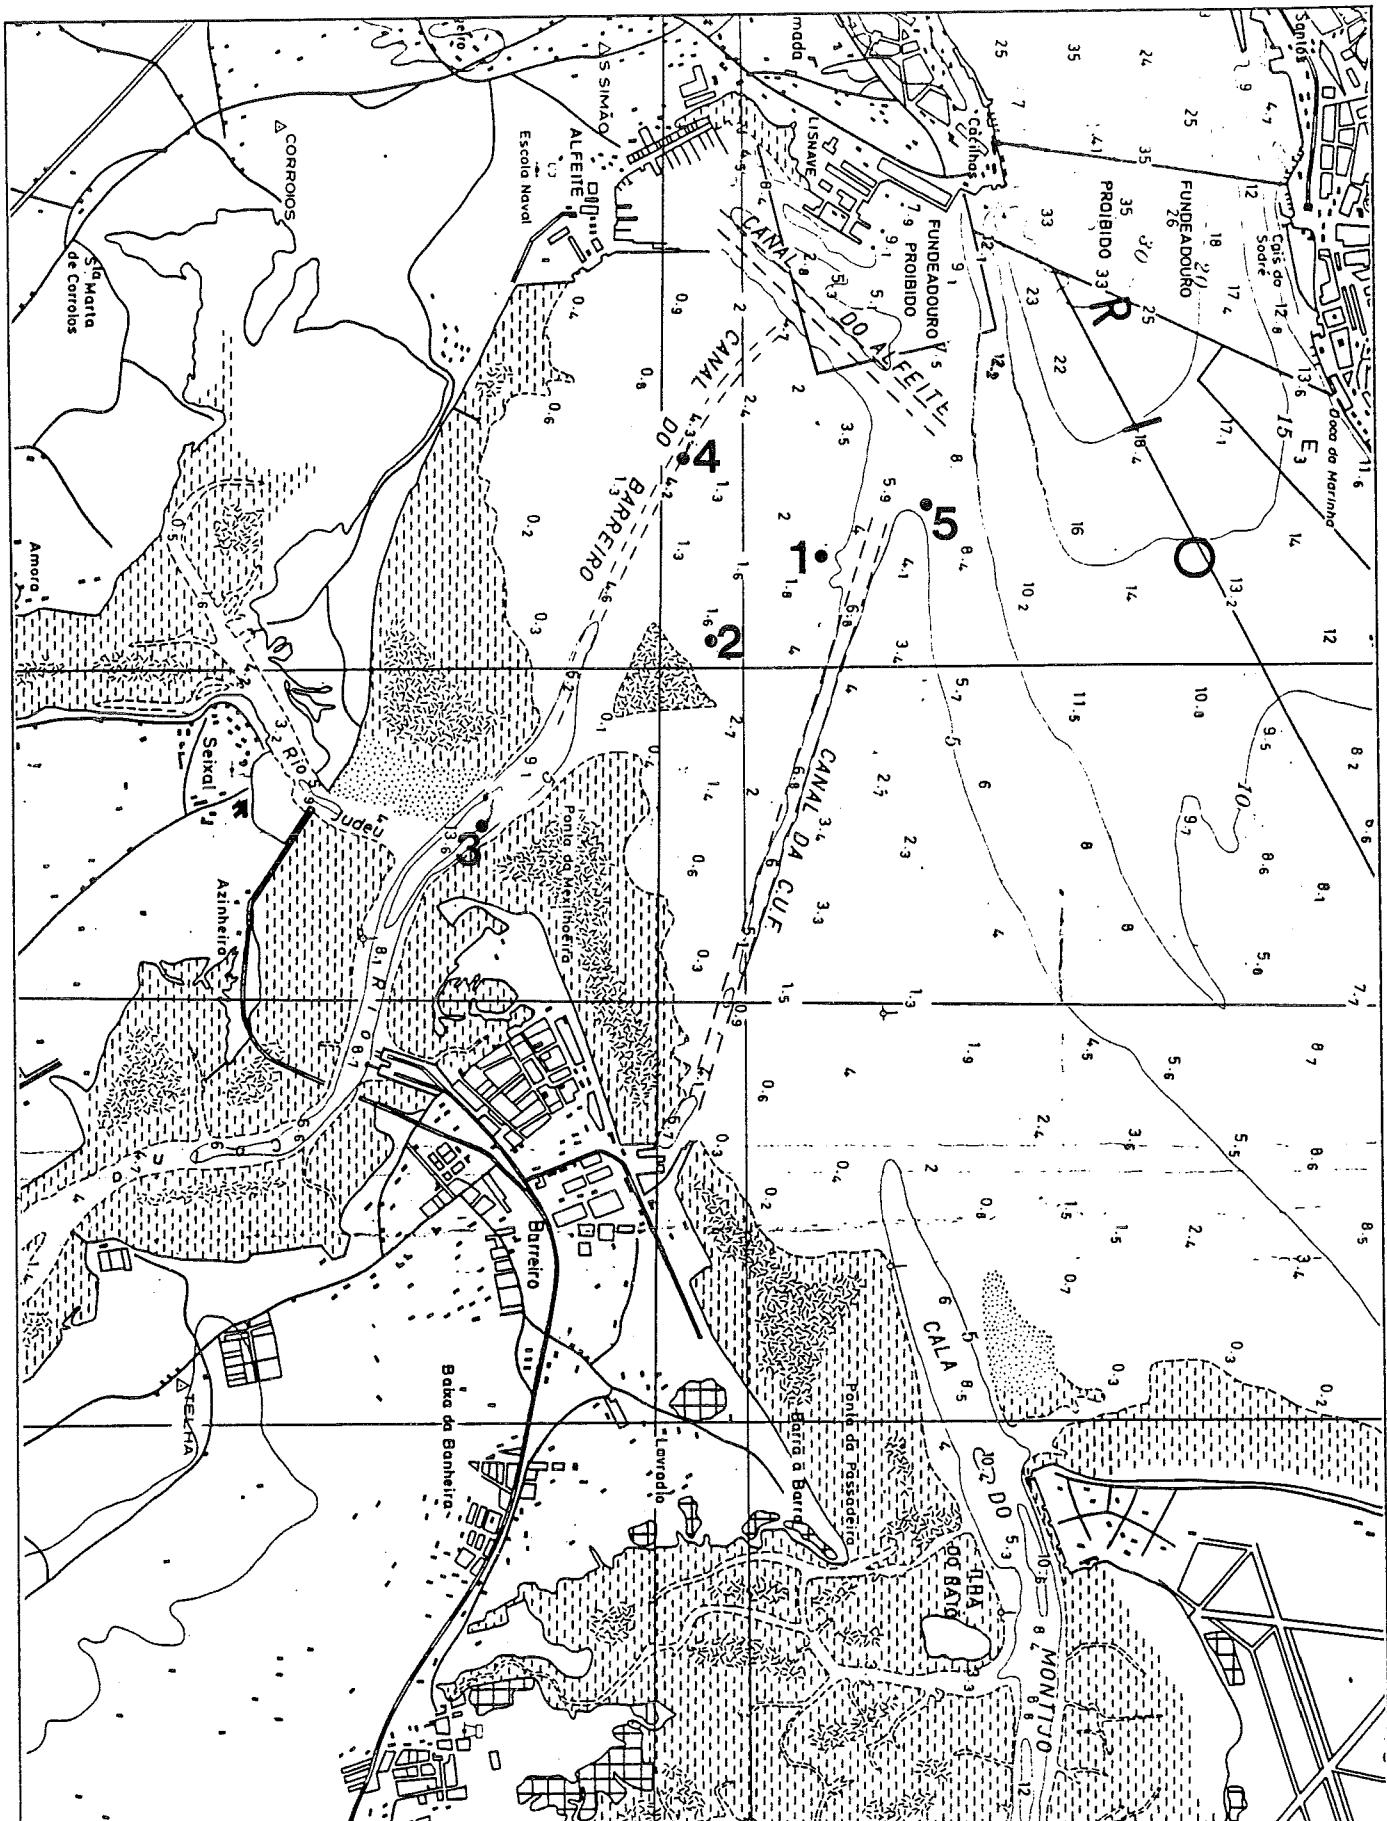

Due to seasonal influences the total siltation in the new channel will be less than calculated in the main report. It has been shown that in the Siderurgia area the concentration is lower in winter than it is in summer.

All measurements were made during calm weather, thus the influence of the waves has not been measured.

It is therefore still advisable to do some measurements during waves conditions.
