Interactive Discussion

Abstract

A four year data set of MAX-DOAS observations in the Beijing area (2008–2012) is analysed with a focus on NO₂, HCHO, and aerosols. Two very different retrieval methods are applied. Method A describes the tropospheric profile with 13 layers and makes use of the optimal estimation method. Method B uses 2–4 parameters to describe the tropospheric profile and an inversion based on a least-squares fit. For each constituent (NO₂, HCHO and aerosols) the retrieval outcomes are compared in terms of tropospheric columns, surface concentrations, and “characteristic profile heights” (i.e. the height below which 75 % of the vertically integrated tropospheric column resides).

We find best agreement between the two methods for tropospheric NO₂ columns, with a standard deviation of relative differences below 10 %, a correlation of 0.99 and a linear regression with a slope of 1.03. For tropospheric HCHO columns we find a similar slope, but also a systematic bias of almost 10 % which is likely related to differences in profile height. Aerosol optical depths (AODs) retrieved with method B are 20 % high compared to method A. They are more in agreement with AERONET measurements, which are on average only 5 % lower, however with considerable relative differences (standard deviation ~ 25 %). With respect to near surface volume mixing ratios and aerosol extinction we find considerably larger relative differences: $10 \pm 30 \%$, $-23 \pm 28 \%$ and $-8 \pm 33 \%$ for aerosols, HCHO and NO₂ respectively. The frequency distributions of these near-surface concentrations show however a quite good agreement, and this indicates that near-surface concentrations derived from MAX-DOAS are certainly useful in a climatological sense. A major difference between the two methods is the dynamic range of retrieved characteristic profile heights which is larger for method B than for method A. This effect is most pronounced for HCHO, where retrieved profile shapes with method A are very close to the a priori, and moderate for NO₂ and aerosols which on average show quite good agreement for characteristic profile heights below 1.5 km.

Interactive Discussion

2010; Wagner et al., 2011; Vlemmix et al., 2011; Sinreich et al., 2012). Especially in relation to satellite validation there is a great need for simultaneously measured trace gas and aerosol profiles, and MAX-DOAS is one of the few remote sensing methods which can provide in this need. At the same time it is well known that the MAX-DOAS profiles are only first-order estimates, due to the fact that the information content of MAX-DOAS observations with respect to the vertical distribution of aerosols and trace gases is very limited (Vlemmix et al., 2011).

Comparatively few studies have been published however which directly address the quality of MAX-DOAS tropospheric profiles obtained from real observations. This is largely due to the fact that suitable long-term (multi-year) data sets which can serve as golden standard in a comparison (e.g., profiles measured with high vertical resolution) do not exist. In turn, the lack of a thorough validation of MAX-DOAS profiles limits their use of MAX-DOAS profiles in validation studies where MAX-DOAS itself would be the reference.

The present study is highly motivated by the need for further assessment of the quality of MAX-DOAS profiles. Our approach is based on three pillars. First, the use of two very different profile retrieval algorithms, both run with various a priori profile shape assumptions. Second, the use of a four year data set covering a wide range of conditions (e.g., pollution levels, seasons, meteorological conditions). Third, analysis of profiles for three different species: formaldehyde, NO₂ and aerosols. With this we address in this work the following specific questions: How consistent are the retrievals of individual profiles with different algorithms? How consistent are the retrievals on average? Do the columns and profiles – on average – show a diurnal and seasonal variation? How strong or weak is the dependence on a priori assumptions? Which atmospheric conditions most critically limit the quality of the profile retrieval? What is the agreement between the profile shapes retrieved for the different constituents?

Since it is not straightforward to mutually compare a wide range of possible profile shapes, we compare profiles based on their “characteristic profile heights” H_{75} , which we define in this work as the height below which 75 % of the integrated profile

Interactive Discussion

resides (75 % of the tropospheric column). The advantage of this is that H_{75} is a scalar, and together with the tropospheric column and the near-surface concentration it gives a characterization of the profile that suits the typical first order profile approximation for constituents that mainly reside in the boundary layer.

The paper is structured as follows: In Sect. 2 we describe the data set of MAX-DOAS observations that is used: the instrument characteristics and measurement sites; the settings of the DOAS fitting procedures for the UV and visible; the two MAX-DOAS profile retrieval algorithms, both of which are run with different “internal” settings to test the dependence on a priori assumptions. The last part of this section describes the criteria that are applied to select data with sufficient quality. Results for selected days and the statistical analysis based on the entire data set are shown and discussed in Sect. 3. Section 4 contains a discussion, and the final conclusions are listed in the last section.

2 MAX-DOAS measurements and profile retrieval algorithms

The retrieval of vertical profiles from spectral measurements with MAX-DOAS typically consists of three steps. First, differential slant columns (of O_4 , NO_2 and HCHO) are derived by applying the DOAS spectral fitting technique to the measured spectra. Second, differential slant columns of O_4 are used as input for the aerosol extinction profile retrieval algorithms. Third, differential slant columns of the trace gas of interest (in this work: NO_2 and HCHO) are used as input for the trace gas profile retrieval algorithm, together with the estimated aerosol extinction profile. In this section each of those steps is described in more detail.

2.1 Instrument and measurement site

The MAX-DOAS instrument used in this study has been designed and assembled by BIRA, see Clémer et al. (2010). It consists essentially of a telescope mounted on

2.3 Method A – algorithm developed at BIRA

The first algorithm (method A) has been developed at BIRA Clémer et al. (2010); Hendrick et al. (2014); Wang et al. (2014) and makes use of the optimal estimation method (Rodgers, 2000). Forward simulations of differential slant columns are performed using the LIDORT radiative transfer model (Spurr, 2008). Trace gas and aerosol profiles are described by partial columns of 13 layers in a fixed altitude grid: the first ten layers (below 2 km) each have a vertical extent of 200 m, between 2 and 3 km there are two layers of 0.5 km, and the most upper layer of the profile goes from 3 to 4 km. An important input parameter for retrieval model A is the a priori profile, which is the initial profile from which the profile retrieval code iteratively searches for a more optimal solution. Retrieved profile shapes can in principle be very different from the a priori, but only if the information content of the measurements is sufficiently high (depending on trace gas and measurement conditions). If this is not the case, the retrieved profile shape will be very similar to the a priori. In the original implementation of the retrieval code (Clémer et al., 2010) this a priori profile concentration profile $n(z)$ was described by an exponential function which is characterized by a certain a priori scale height H_{scale}^{prior} :

$$n(z) = \frac{N_{prior}^V}{H_{scale}^{prior}} \cdot \exp\left(-\frac{z}{H_{scale}^{prior}}\right). \quad (1)$$

For trace gases, the profile shape is scaled such that the integrated profile corresponds to the first order estimate of the tropospheric trace gas column (N_{prior}^V), namely the differential slant column measurement at 30° elevation. The corresponding geometrical differential air mass factor (see e.g. Brinksma et al., 2008) is equal to one. For aerosols the initial column estimate (the AOD) was set to 0.15 for all retrievals.

A second important input parameter is the a priori error estimate for each layer. Tests have shown that setting this value high – this would give the algorithm most flexibility to realize diverse profile shapes – leads to frequent retrievals of profile shapes showing

Interactive Discussion

oscillations that are not likely to be realistic. For this reason a relatively low value (20 %) of the a priori is chosen, although this limits the potential of the algorithm to deviate significantly from the a priori, see also the discussion in Sect. 4.2.

Tests performed prior to the study presented here, have shown that the interplay between the a priori profile and its error estimate, combined with the fact that the sensitivity of MAX-DOAS decreases with altitude, leads to an undesired effect for relatively high a priori scale heights (> 1.5 km), namely that the retrieved tropospheric column (of trace gas or aerosols) is systematically too high.

This unwanted mechanism works as follows: for a priori scale heights higher than 1.5 km, the exponentially decreasing a priori profile does not go to (almost) zero in the upper part of the altitude grid (4 km). Because above approximately 1.5 km the information content of the observation is low, the retrieval will have a tendency to stay close to the a priori and not be allowed to go to zero. As a consequence, the retrieved profiles will have a considerable part of the partial column above ~ 1.5 km, even when this is not the case in reality. This effect will lift up the mean profile height, and this goes together with a systematic overestimation of the integrated trace gas column (or AOD).

By modifying the definition of the a priori profile shape such that it goes to zero at the top of the altitude grid, the overestimation of columns and AOD is greatly reduced. The following profile shape definition is forced to low values above 1.5 km and even zero at the top of the altitude grid:

$$n(z) = \left[\frac{N_{\text{prior}}^V}{H_{\text{scale}}^{\text{prior}}} \cdot \exp\left(-\frac{z}{H_{\text{scale}}^{\text{prior}}}\right) \right] \cdot (4 - z). \quad (2)$$

Figure 2 shows a priori profile shapes obtained with this definition, for $H_{\text{scale}}^{\text{prior}} = \{0.5, 1.0, 1.5\}$ km. Note that the range in terms of H_{75} is different: $\{0.6, 1.0, 1.3\}$ km.

The impact of the a priori profile shape on the retrieved profile can be quite high. For this reason the profile retrieval with method A is performed with three different a priori scale heights ($H_{\text{scale}}^{\text{prior}} = \{0.5, 1.0, 1.5\}$), leading to three versions: A1, A2 and A3.

Interactive Discussion

The final product that is compared to method B is a composite of the retrievals with these three a priori: for each retrieval quantity (see Sect. 2.6) the mean of the values obtained with A1–A3 is taken as the solution, and the difference between the maximum and minimum as the uncertainty. The reason to follow this approach is that the impact of the a priori is substantial and there is no external information available instead which justifies the choice for one specific a priori.

2.4 Method B – algorithm developed at KNMI

The profile retrieval approach of method B (Vlemmix et al., 2011) is quite different from method A: it makes use of a profile shape parametrisation with just a few (2–4) free parameters; forward simulations are performed by making use of a look-up table which has been created with the DAK radiative transfer model (De Haan et al., 1987; Stammes et al., 1989); a standard least-squares algorithm is used, without any form of regularization. The main reason to use a low number of free parameters is that the information content of MAX-DOAS observations with respect to the vertical distribution of aerosols and trace gases is quite limited (see Fig. 3). With a suitable choice of free parameters a sufficiently wide range of possible profile shapes can be retrieved, especially in combination with the ensemble approach described below. Compared to the description in Vlemmix et al. (2011) the algorithm has been modified in the following ways: the profile shape parametrization is slightly different, this is described below; the look-up table is compiled to allow for more extreme aerosol optical thicknesses (τ) needed in China with $\tau = 3.2$ as maximum; the look-up table is expanded with a UV component (central wavelength: 360 nm); no correction is applied to compensate for the temperature dependence of the differential cross section of NO_2 (similar strategy for method A), a fixed temperature is used (296 K). This will affect the accuracy of both retrieval methods similarly. The up to four free parameters that are used to parametrize the profile (see Fig. 2) are: (i) the tropospheric column for trace gases and the AOD in case of aerosols; (ii) the top height of the mixing layer; (iii) the “shape parameter”, which determines the linear increase or decrease of the trace gas concentration or

Interactive Discussion

difficult to get optimal agreement between simulations and measurements (i.e., to obtain low residuals) than with method A (13 profile layers). Therefore, and also because there is no a priori to fall back on, the individual retrievals with method B tend to be more unstable with respect to one or more retrieval parameters.

It is important to note that this instability is not necessarily an unwanted effect: it is an expression of the fact that (under some conditions) the MAX-DOAS observations contain very limited information about the profile shape. For such conditions it is desirable to have a good estimate of the uncertainty. This is obtained by making use of an ensemble approach: the retrieval code is run 50 times, each time with slightly different input. The differential slant column measurements are perturbed by adding Gaussian noise with a standard deviation corresponding to 10% of the original differential slant column (obtained with the semi-simultaneous zenith measurement). For each scan an ensemble of solutions is obtained, and for each retrieval quantity the median is taken as the final result. The width of the distribution for each parameter (e.g., described by the end of the first and beginning of the fourth quartile) provides an estimate for the retrieval uncertainty. Note however, that this retrieval uncertainty does not account for the uncertainty with respect to the profile shape parametrization. For this reason the retrieval is run for several profile shape parametrizations at the same time (see Table 2) and a composite retrieval product is constructed a posteriori. A-posteriori selection of plausible profile shape parametrizations (among B1–B4) is done by considering the distribution of the reduced χ^2 (χ_v^2). This parameter is defined as:

$$\chi_v^2 = \frac{\chi^2}{(N - M)}, \quad (4)$$

where N is the number of observations (differential slant columns at various elevations) minus the number of model parameters (i.e., 2 to 4). If the median value of the χ_v^2 distribution (after 50 runs) for a certain profile shape parametrization is approximately equal to one, then the selected retrieval model is capable of producing simulations that agree with the observations within the estimated measurement error.

Interactive Discussion

After the algorithm is run 50 times for all four models, it is determined which models are included in the a posteriori composite retrieval product, namely all models which have a median $\chi_v^2 < 1.5$. For each model individually the retrieval outcomes for a certain quantity (e.g., surface concentration) is defined as the median value of the distribution (after 50 runs) for that particular quantity. The lower limit of the corresponding uncertainty estimate is defined as the value which marks the transition from the first to the second quartile of the distribution. The upper limit is defined similarly as the value which marks the transition from the third to the fourth quartile of the distribution. This implies that 50 % of the retrievals is within the error bar. The composite product is constructed simply by averaging the medians of the selected models, and the error bars are constructed by averaging the lower limits and upper limits separately. The procedure that is followed here (including all models among B1–B4 which have sufficiently low median of χ_v^2) yields a more realistic uncertainty estimate than if only the model with lowest median χ_v^2 would be used, because it takes into account the uncertainty with respect to the profile shape.

2.5 Selection criteria and uncertainty estimates

Comparison of methods A and B is done only for profile pairs which satisfy three criteria: they should pass the quality control criteria of method A, those of method B and they should coincide with AERONET observations. The third criterium provides an indirect way of selecting cloud free periods. MAX-DOAS profiles are only included in the comparison if at least 3 AERONET level 2.0 (cloud screened, quality controlled) measurements are taken within an hour around the MAX-DOAS measurement time. Quality control for method A is based on two quantities: the size of the residual of the profile fit and the degrees of freedom for signal (DOFS, see Rodgers, 2000). The residuals are defined as the sum of squared differences between simulations and measurements, divided by the simulated differential slant column for an elevation of 30° (this quantity

provides a first-order estimate of the tropospheric vertical column):

$$\delta = \sum_{i=1}^8 \left(\frac{\Delta N_{\alpha_i}^S - \widehat{\Delta N_{\alpha_i}^S}}{\widehat{\Delta N_{\alpha_i=8}^S}} \right)^2, \quad (5)$$

Figures 3 and 4 show the histograms of these two parameters before the quality control is applied. These figures illustrate clearly that in general profile retrieval is more challenging for HCHO than for NO₂: the DOFS for HCHO is often well below 2, whereas for NO₂ the DOFS is often > 2. Also the residuals for HCHO are considerably higher for a considerable fraction of all data (note that Fig. 4 shows the logarithm of the residual). The same is illustrated in Fig. 5: the averaging kernels for HCHO are lower than for NO₂ and are less orthogonal with respect to one another. Profile pairs of A and B are excluded from the comparison if the minimum value of the DOFS is < 1 for one or more of the models A1–A3. Also they are excluded if the maximum residual of A1–A3 is larger than 0.1. Quality control for method B consists of selecting only those profiles where the median value of the reduces χ_v^2 for the profile fit of method B is < 1.5. For aerosols only the median χ_v^2 of the aerosol profile fits is considered, for the trace gas retrieval also the median χ_v^2 of the trace gas profile fits.

The impact of the quality control criteria defined above is discussed in Sect. 4.1.

2.6 Retrieval quantities

We compare results mostly based on three quantities: the tropospheric vertical columns (N^V), the concentration (n_{surf}) or volume mixing ratio (X_{surf}) of trace gases near the surface and the characteristic height (or H_{75} , see Sect. 1) of the retrieved profile. Similar quantities are used in case of aerosols: aerosol optical depth (τ_{aer}), aerosol extinction near the surface e_{surf} , and H_{75} . A fourth quantity that is used is the a posteriori scale height (not to be confused with the scale height of the a priori profile of method A $H_{\text{scale}}^{\text{prior}}$, see Sect. 2.3). This scale height $H_{\text{scale}}^{\text{post}}$ is a first order profile

Interactive Discussion

height estimate derived from column (or AOD) and surface concentration (or aerosol extinction):

$$H_{\text{scale}}^{\text{post}} = \frac{N^V}{n_{\text{surf}}} \quad (6)$$

5 for the trace gases, and

$$H_{\text{scale}}^{\text{post}} = \frac{\tau}{e_{\text{surf}}} \quad (7)$$

for aerosols. The reason to consider this first order profile height estimate in addition to H_{75} is that, as will be shown in Sect. 3.2, for method A it depends less on the a priori than H_{75} . This indicates to some extent that the measurements contain information
10 about the profile height that is not extracted in an optimal manner in this particular retrieval set-up.

3 Results

3.1 Example day

15 Figures 6–8 show retrieval results for 19 May 2012. The individual profiles obtained with method A and B (Fig. 6) show good agreement in the sense that in the morning they are all quite low, and in the afternoon they are all quite high. Nevertheless, this example also illustrates that retrieved profile shapes can be very different: not only the four versions of method B show considerable differences but also the two versions of
20 method A, especially those retrieved after 12:00 LT (bottom row).

Time lines for the different quantities that can be derived from the profile retrieval are shown in Fig. 7 for the same example day. Both for the aerosol retrieval (left column) and the NO_2 retrieval (right column) the χ_v^2 are quite low for most of the day, indicating a good quality of fit. On this particular day, the retrievals agree quite well for

Interactive Discussion

most quantities, especially for the columns (row 1) and surface concentrations (row 3). Agreement is worst for $H_{75}^{\text{NO}_2}$ and $H_{\text{scale}}^{\text{NO}_2}$ in the afternoon, where method B occasionally shows sometimes much higher values. This is a consequence of the fact that the retrieval is not regularized, in combination with relatively low surface concentrations in the afternoon. Because the surface concentration is the denominator in Eq. (6), one can understand that a small change (error) in the surface concentration can lead to a much larger change in $H_{\text{scale}}^{\text{NO}_2}$. This figure also clearly demonstrates the potential impact of different profile shape assumptions on $H_{75}^{\text{NO}_2}$.

Figure 8 shows results for the same day, but this time for the aerosol and HCHO retrieval in the UV. In general there is much more disagreement compared to NO_2 . There is on this day almost no retrieval where the agreement is good for all quantities at the same time. The agreement between most quantities is especially low between 10.00 a.m. and 4.00 p.m. High values for χ_v^2 in the aerosol retrieval indicate that the aerosol retrieval with method B is not successful and therefore this period is flagged with grey bars on top of each figure. Quite remarkable is the disagreement in terms of HCHO columns in the remaining part of the day (before 10.00 a.m. and after 4:00 p.m.). In the morning of this day the higher columns (for method B compared to A) seem to go along with higher H_{75}^{HCHO} .

3.2 Statistical analysis

Results of both retrieval methods are compared for sixteen quantities in terms of correlation, slope and intercept of linear fit, and median, mean and standard deviation of relative differences, see Table 3. The comparison of twelve of these quantities is also shown in Figs. 10, 14, 15 and 21. We will discuss these results separately in terms of tropospheric columns (AOD for aerosols), profile heights, and surface concentrations (or aerosol extinction).

3.2.1 Columns

Figure 9 shows the monthly median values for the column quantities: AOD, tropospheric NO_2 and HCHO columns. Note that measurements before 2010 are made in Beijing, from 2010 onwards, the observations are made in Xianghe. A clear seasonal cycle with a winter minimum of about $5 \times 10^{15} \text{ molec cm}^{-2}$ and a summer maximum roughly five times as high can be seen for HCHO. Compared to NO_2 and aerosols, the variability per month is quite small. A weaker, but similar seasonal cycle can be seen for aerosols, with typical winter values around 0.2 and a summer median between 0.5 and 1.0. For NO_2 the seasonal cycle of monthly median values is quite weak as well. Winter medians are roughly between 20×10^{15} and $30 \times 10^{15} \text{ molec cm}^{-2}$, summer medians between 10×10^{15} and $20 \times 10^{15} \text{ molec cm}^{-2}$. Noteworthy is the fact that especially the peak values in winter can be high with values above 100×10^{15} . Peaks in tropospheric NO_2 columns in midsummer do not exceed 30×10^{15} . Figure 10 and Table 3 show that very good agreement is found for tropospheric NO_2 columns with correlation 0.99, slope 1.03, intercept $-0.6 \times 10^{15} \text{ molec cm}^{-2}$, and mean relative difference 0.25 %. The standard deviation of relative differences is however considerable: 9.26 %. The third and fourth columns of Fig. 10 show that the relative difference increases with increasing tropospheric column and with increasing profile height. Also for tropospheric HCHO columns, the agreement is good with correlation 0.95, slope 1.02 and intercept $0.67 \times 10^{15} \text{ molec cm}^{-2}$. Relative differences are however considerably larger than for NO_2 , with mean 9.43 % and standard deviation 12.14 %. The dependence of relative differences on the tropospheric column itself (second row, third column) shows opposite behaviour as for NO_2 , whereas the dependence of relative differences on the profile height shows a similar increase as for NO_2 . Despite the quite high correlation in the AOD (0.92 in the UV, and 0.91 in the visible), the agreement between method A and B is moderate, with slopes 1.20 (UV) and 1.39 (visible), and mean relative differences 22.81 % and 23.07 %. Figure 10 (bottom row), shows for the visible that these differences in AOD are strongly related to the difference in aerosol

Interactive Discussion

profile height, but also tend to increase with the AOD itself. The agreement between method B and AERONET is much better, which provides confidence in the AOD retrievals obtained with method B. The frequency distributions of AERONET and AODs retrieved with method B show good agreement and differ with respect to method A in the fact that they include much more cases with AOD between 1.5 and 3.5. Only for the highest 25 % of characteristic profile heights, method B seems to overestimate the AOD systematically by about 20 %. Figure 11 shows for NO₂ and HCHO the relation between AOD (as measured by AERONET) and tropospheric trace gas columns for different seasons. There are clear seasonal differences with largest differences for NO₂ vs. AOD between summer and winter. The two models show good agreement, with only moderate systematic differences for HCHO columns in spring and summer. This is in line with the example day (Fig. 8) which shows considerable differences between tropospheric HCHO columns retrieved method A and B. Note that on this example day the AOD is high, and the differences in characteristic HCHO profile height are considerable. The quite linear relationship between NO₂ and AOD, and HCHO and AOD illustrate that trace gas emissions are often accompanied by aerosol emissions. From that perspective the flattening of the curves for high AOD's (mainly in summer and autumn) is remarkable. Possibly this is related to aerosols from natural sources (dust) emissions of which do not go along with emissions of trace gases. Another explanation would be that high AOD's cause systematic underestimation of the tropospheric column, but the flattening of the curves is not seen in winter and spring, even for higher AOD's.

3.2.2 Profile heights

Figures 12 and 13 show for methods A and B monthly median values of characteristic heights, with a distinction between retrievals before 10 a.m. (red) and retrievals after 12 p.m. (blue). For all three species and both retrieval methods, we find higher profiles in the afternoon than in the morning, especially with method B. Only for H_{75}^{HCHO} obtained with method A the differences between morning and afternoon are negligible.

This is most likely an artefact, which is also seen in Fig. 14, and which is discussed in Sect. 4.2. The morning to afternoon differences found in all other cases are qualitatively in agreement with the expected diurnal variation in the mixing layer height, and provide a first order check to see if the algorithms behave as expected. Variability per month and between months is however much larger with method B. Highest monthly median characteristic profile heights are found with method B for aerosol profiles in summer. This is in agreement with the general expectation that mixing layers are more shallow in winter and grow deeper in summer (see e.g. Luo et al., 2014). That this effect is weaker for NO₂ might be related to the shorter lifetime of NO₂ in summer which limits the effective transport of NO₂ from the surface to the higher parts of the mixing layer, see also Halla et al. (2011) and Mendolia et al. (2013). Figure 14 and Table 3 show that the agreement between the two methods in terms of profile heights is considerably lower than the agreement in terms of columns, which is to be expected because the information content of MAX-DOAS with respect to the vertical distribution is limited. The best agreement is found again for NO₂, with for the profile heights correlation 0.76, slope 1.44, intercept -0.20 km, and mean relative difference 6.51 %. The standard deviation of relative differences is high: 33.18 %. It can be seen in Fig. 14 that the dynamic range of NO₂ profile heights found with method A is somewhat lower than with method B. Especially the fraction of profiles with height above 1 km is significantly higher with method B. For the HCHO profile height we have correlation 0.62. This is quite surprising because the dynamic range of profile heights found with method A is very small compared to method B and this also explains the exceptional slope (7.47) and intercept (-5.33 km). Even though no independent data is available, it is quite safe to conclude that this very limited dynamic range is unrealistic, and therefore these HCHO profiles should be used and interpreted with great care. As a result of this effect, it is difficult to judge the quality of the HCHO profile heights obtained with method B. One can see that here the dynamic range is comparable to that of NO₂ and aerosols, but the mode of the histogram has shifted to higher altitudes compared to NO₂. Also for aerosols (visible) the dynamic range found with method A is limited compared to method B.

[Title Page](#)[Abstract](#)[Introduction](#)[Conclusions](#)[References](#)[Tables](#)[Figures](#)[Back](#)[Close](#)[Full Screen / Esc](#)[Printer-friendly Version](#)[Interactive Discussion](#)

The correlation (0.62) is somewhat lower than for NO_2 and HCHO, but the slope and intercept are less extreme than for HCHO (2.82 and -1.31 respectively). Figure 15 demonstrates that in terms of the other estimator of the average profile height ($H_{\text{scale}}^{\text{post}}$) the agreement between methods A and B is better. Especially for HCHO, the slope is less extreme for $H_{\text{scale}}^{\text{post}}$ than for H_{75} which is in line with the higher dynamic range seen for method A in Fig. 15 compared to Fig. 14. We see a similar effect for aerosols. This might indicate a retrieval artefact for method A which causes that information about the profile height that is actually contained in the MAX-DOAS measurements is not efficiently converted into a noticeable effect on $H_{75}^{\text{NO}_2}$.

A different view on the quality of the profile height retrieval obtained with both methods is given by Fig. 16. From the first left panel we can conclude that for both methods the internal consistency (UV vs. visible) of aerosol profile heights below 1.5 km is quite good, especially for method A. Above 1.5 km we have only very few cases with method A, and all of these cases show a strong bias between UV and visible. For method B the bias appears to be quite constant over the entire range, with UV profiles that are approximately 25% lower than profiles in the visible. The middle panel of Fig. 16 shows a comparison of NO_2 and aerosol profiles. In contrast to aerosols, we do not expect a strong agreement beforehand. What we hope to see, and this is partially the case, is that the general pattern is similar for both methods. Below 1.5 km the agreement is remarkably good, and this is certainly a confirmation that the results obtained with both methods make some sense. As mentioned before, the limited dynamical range of method A makes it almost impossible to draw conclusions on the reliability of profile heights above 1.5 km found with method B. Nevertheless, a possible explanation for the bias between NO_2 and aerosol profile heights in this regime is the same as mentioned earlier: higher aerosol profiles occur in summer, but then the lifetime of NO_2 can be very short, which leads to more shallow NO_2 profiles. Figure 17 shows for different seasons the characteristic aerosol, NO_2 and HCHO profile heights as a function of the AOD. For aerosol profile heights, we see a much stronger seasonal cycle with method B than with method A. In principle a seasonal cycle is also

Interactive Discussion

expected: higher boundary layers occur in summer, when the thermal convection is strongest. A possible interpretation of the results seen on the top row (decline of H_{75}^{aer} with increasing AOD) is that growth of the boundary layer through convection is weakened by the presence of high aerosol loadings (see also Barbaro et al., 2013). Without independent simultaneous observations with other techniques, it can however not be excluded that this effect is related to the measurement technique itself (i.e., a retrieval artefact). Method B shows a weaker seasonal variation in NO_2 than in aerosol profile heights and highest NO_2 profiles occur in spring. This might be due to the fact that in spring the NO_2 lifetime is not as short as in summer (allowing more time for vertical transport), whereas at the same time vertical transport through convection is stronger than in winter. Results for HCHO are more difficult to interpret. Because the lifetime is longer than for NO_2 , and because formaldehyde sources can be biogenic and anthropogenic (the relative contribution varies by season) the profile shapes can be very different from those of NO_2 . A quantity that is especially important in the context of satellite validation and satellite retrievals is the relative difference in NO_2 and aerosol profile height. The impact of the relative characteristic profile heights on the slant column measurement can be high, and lead to systematic biases if not accounted for in the retrieval. This quantity is shown for both methods as a function of season in Fig. 18 (also for HCHO). Similar as for the characteristic heights themselves, we see in Fig. 18 a higher dynamic range for method B than for method A. This is partly explained by the lower stability of method B, but also by the ability to retrieve a wider range of profile heights. Both methods detect in spring higher characteristic aerosol than NO_2 profile heights. In summer method B finds systematically higher values for $H_{75}^{aer} - H_{75}^{\text{NO}_2}$ than method A. In winter and autumn, the systematic bias between H_{75}^{aer} and $H_{75}^{\text{NO}_2}$ is smaller. As argued above, results for HCHO are more difficult to interpret (because of the artefact affecting the retrieval with method A). However, based on the results obtained with method B it appears as if aerosol profiles are higher than HCHO profiles in spring and summer, and lower in fall and winter.

3.2.3 Aerosol extinction and trace gas volume mixing ratios near the surface

Seasonal variations of volume mixing ratios and aerosol extinction near the surface are shown in Figs. 19 and 20 for methods A and B respectively. For NO_2 a systematic difference is seen between morning and afternoon values, and this is clearly related to the dynamics of the mixing layer. For aerosols a similar effect is found. For HCHO however, this contrast is almost absent. This is related to fact that HCHO profiles shapes retrieved with method A show almost no deviation from the a priori (Sect. 3.2.2). As a consequence, the main driver of the surface concentration is the tropospheric column of HCHO. This explains why for HCHO retrieval with method A the seasonal variation in volume mixing ratios is so similar to the seasonal variation in columns. For method B (not shown) the results are quite different in winter months, when morning values are about three to four times higher than afternoon values of the HCHO volume mixing ratio. In summer months, this effect appears to be less pronounced, unlike for NO_2 . It is difficult to draw conclusions based on method B only, but this weaker diurnal variation in HCHO surface volume mixing ratios compared to winter could indicate that in summer local emissions on the surface have a relatively small impact. Based on this data set only, it can however not be excluded that absence of a strong morning to afternoon contrast for HCHO volume mixing ratios in summer is an artefact of the retrieval. Figure 21 shows the results of the comparison of methods A and B in terms of trace gas volume mixing ratios and aerosol extinction near the surface (lowest profile layer). In contrast with the results found for the profile heights, the agreement is reasonable, with quite similar histograms for all three constituents. Nevertheless, the systematic relative differences are considerable. For NO_2 we have a mean relative difference of -7.92% with a standard deviation of 32.97% . For HCHO the relative differences are larger (-20.70% , $\pm 27.71\%$) which is mostly explained by the differences in profile shape, because in terms of columns the relative difference is smaller and of opposite sign (9.43%). With respect to aerosol extinction near the surface, the agreement between methods A and B is good, with correlation 0.93 , slope 1.33 and intercept -0.08 .

Interactive Discussion

in H_{75}^{aer} increases from 2.74 % to 12.35 %), but quite small for the trace gas retrieval. For example, the mean relative difference in $H_{75}^{NO_2}$ increases from 8.71 % to 9.85 %, and the mean relative difference in the volume mixing ratio for NO_2 decreases from -7.92 % to -4.4 %, which is a small change compared to the standard deviation (32.97 %).

There are no sign changes for quantities in Table 3 that are significantly different from zero. It should be noted that the results for the aerosol retrieval obtained with these relaxed constraints are clearly considered to be less representative for ideal clear sky conditions. With every set of quality criteria, the results presented here will change slightly (largely due to a different the sampling of the full data set), however the settings used here are considered to be reasonable balance between maintaining sufficient data pairs and rejection of data pairs which are likely to be affected through clouds.

4.2 Strength and weaknesses

In Sect. 3.2 it was shown that both methods show good agreement in terms of tropospheric NO_2 and HCHO columns: the correlation is high, the slopes of linear fit are close to 1 and the intercepts are relatively close to zero. The agreement of characteristic profile heights is reasonable for NO_2 and aerosols, despite clear biases, especially above 1.5 km. The main strength of method A is its robustness (stability). This is a clear advantage especially when differential slant columns are close to the detection limit, or when the assumptions that are made about fixed parameters (or cloud free conditions) do not hold. In such cases, the retrieval can rely on the a priori. The characteristic profile height retrieval with method B is only stable under cloud free conditions, and if assumptions about fixed parameters are not too far from the truth. The number of profiles which passes the quality control (Sect. 2.5) for method B is significantly smaller than for method A. A disadvantage of method A is that the combination of a profile parametrization based on 13 layers and a relatively low information content of the MAX-DOAS observations forces one to take measures to stabilize the retrieval. These measures are: (1) a relatively conservative estimate of the a priori error (for each

Interactive Discussion

profile layer 20 % of the a priori profile estimate), (2) a profile which goes to zero rapidly above 1 km. A consequence of this approach is that the absolute values of the a priori error estimate become very low above 1 km. This is believed to be the main reason why it is almost impossible for profiles to grow higher than the a priori. In most cases sufficient agreement between observations and simulations can be achieved by modifying the profile shape (compared to the a priori) only below 1.0 km. This explains why for NO₂ and aerosols shrinking of profiles compared to the a priori is seen much more often than growing. This is not seen for HCHO. For HCHO it appears that the information content is too low to obtain profiles (with method A) which deviate much from the a priori. A strong aspect of method B is that it can realize a high range of quite different profile shapes, with just a few free parameters. It can more easily realize profiles which have a characteristic height (H_{75}) well above 1.0 km. In this study, it is however not possible to fully judge the quality of these profiles because these cannot be retrieved with method A. Nevertheless, the monthly averaged morning to afternoon difference in profile height and the seasonal cycle of aerosol profile heights (Fig. 13) correspond to the expected behaviour and this is at least an indirect indication of the quality of the profiles obtained with method B. Independent (e.g., lidar) observations at the same measurement site would be needed to say more about the quality of individual profiles.

This study makes clear also that the main disadvantage of method B is its instability, despite the limited number for free parameters and the ensemble approach. Note however that the retrieval is certainly not always unstable, see for example the retrievals in the visible on 15 May 2012 (Fig. 7). The advantage of the ensemble approach taken with method B is that most often the instabilities go along with high uncertainty estimates, and this provides a means for additional quality control. Unlikely retrievals with a low uncertainty estimate occur also, but these can most often be excluded based on high values for χ^2 , either in the aerosol or in the trace gas part of the retrieval.

4.3 Recommendations for algorithm improvements and further validation

Both profile retrieval algorithms have specific strengths and weaknesses, as described above. The challenge for improved algorithms is to combine the stability and precision of method A with the ability of method B to retrieve a high dynamic range of characteristic profile heights. A possible but not so practical solution could be to use method B to obtain an initial estimate of the a priori scaling height for method A and then as a next step to perform a retrieval with method A. This will work however only under strict cloud free conditions because of the limitations for method B. Also it would transfer the impact of instabilities (for individual cases) from method B to method A. An alternative is to use the profile parametrization of method B in the framework of the optimal estimation method. Such a retrieval algorithm could be better capable of retrieving a wide range of profile heights and at the same time be more stable than the present implementation of method B. This would also lead to an algorithm which is considerably faster because there would be no need for an ensemble approach. Improving the stability of the retrieval by making use of a priori data (in combination with the optimal estimation approach) brings a certain risk, which is that systematic biases in the a priori climatology remain present in the a posteriori climatology. An advantage of more simple retrieval schemes (e.g., method B) is that they are predominantly driven by the observations themselves and therefore less prone to inheritance of systematic biases in the a priori, despite a low precision. It is almost impossible to make a choice which combines the best of both worlds: a very stable retrieval (i.e., precision of individual profiles) without introducing systematic biases in a climatological sense. Stability is important for comparison with satellite observations if the number of available cases is very limited, accuracy over a wide range of profile heights is important if MAX-DOAS would be used to provide a climatology of profile heights for better a priori estimates in the satellite retrieval. The recent work by Hartl and Wenig (Hartl and Wenig, 2013) provides indications that the Phillips-Tikhonov retrieval can potentially be used for MAX-DOAS profile retrievals which are both stable and unbiased in a climatological sense. To our best

relative differences is 12.1 %. Relative differences in formaldehyde columns are found to be related to differences in profile height: overestimations of the tropospheric column (for method B compared to method A) often correspond to overestimations of the characteristic profile height (for method B compared to method A). Volume mixing ratios near the surface are systematically lower for method B compared to method A: 8 % relative difference for NO₂ and 21 % for HCHO. The differences can again be related to the differences in profile heights between method A and B. The standard deviation of relative differences of surface volume mixing ratios is much higher than for tropospheric columns: 33 % for NO₂ and 28 % for HCHO. Characteristic profile heights are systematically higher for method B than for method A. The mean relative differences are 6.5 % for NO₂, 15.7 % for HCHO and 2.7 % for aerosols (visible). The high standard deviation of relative differences (33 %, 37 % and 44 % for NO₂, HCHO and aerosols respectively) shows that the precision of characteristic profile heights is low. We find with method B that in spring and summer aerosol profiles are systematically higher than NO₂ profiles. Also we find that in winter and summer mornings HCHO profiles are systematically higher than aerosol profiles, and vice versa in summer afternoons. Note however that these findings are only indicative, because the limitations with method A prevent confirmation of the results obtained with method B. Altogether this study gives some indications about the quality of tropospheric columns, surface concentrations and profile heights retrieved with MAX-DOAS. Since this study is based solely on MAX-DOAS observations the scope is limited and a more thorough validation is needed. In order to obtain robust validation results which can entangle differences related to accuracy and/or precision for a wide range of pollution and sky conditions, it is recommended to station MAX-DOAS instruments close to continuously monitoring surface in-situ monitors (e.g., for NO₂), sun photometers and lidars which are sufficiently sensitive to boundary layer aerosols.

Table 3. Statistical comparison of method A and B. The last two columns refer to median, mean and standard deviation (std.) of percentual relative differences (RD). The linear fit results are defined for method A on the x axis. Relative differences have a sign determined by B–A. Note that the intercepts have unit km for H_{75} and $H_{scale}^{apost.}$, unit 10^{15} molec cm^{-2} for the tropospheric columns, unit ppb for the vmr near the surface, and unit km^{-1} for the aerosol extinction near the surface.

Quantity	N	corr.	slope	interc.	median (mean) of RD (%)	std. of RD (%)
UV, aerosols						
AOD	2734	0.92	1.20	−0.02	17.16 (22.81)	24.92
H_{75}	2723	0.77	4.08	−2.42	7.55 (6.69)	47.17
$H_{scale}^{apost.}$	2735	0.88	1.50	−0.37	10.92 (10.25)	25.91
Extinction near surface	2734	0.93	1.12	0.01	11.44 (14.93)	20.07
UV, HCHO						
Trop. Column	2509	0.95	1.02	0.67	9.64 (9.43)	12.14
H_{75}	2498	0.67	7.47	−5.33	22.34 (15.65)	36.93
$H_{scale}^{apost.}$	2498	0.77	3.01	−1.47	41.96 (37.87)	35.57
vmr near surface	2504	0.80	0.95	−0.32	−23.03 (−20.70)	27.71
Visible, aerosols						
AOD	4001	0.91	1.39	−0.05	18.26 (23.07)	23.54
H_{75}	3936	0.62	2.82	−1.31	5.67 (2.74)	43.63
$H_{scale}^{apost.}$	3821	0.63	1.20	0.11	12.65 (14.40)	36.64
Extinction near surface	3907	0.93	1.33	−0.08	11.24 (10.27)	30.43
Visible, NO ₂						
Trop. Column	3360	0.99	1.03	−0.56	0.51 (0.25)	9.26
H_{75}	3298	0.76	1.44	−0.20	8.71 (6.51)	33.18
$H_{scale}^{apost.}$	3309	0.80	1.79	−0.35	18.71 (17.30)	38.03
vmr near surface	3313	0.76	1.16	−2.25	−11.82 (−7.92)	32.97

Figure 1. Schematic of profile parametrizations for methods A (left) and B (right). Method A uses 13 layers (not drawn) between 0 and 4 km. The number of free variables for method B varies, see Table 2.

Comparison of
profile retrieval
algorithms for
MAX-DOAS

T. Vlemmix et al.

Figure 3. Histograms of showing the degrees of freedom for signal (DOFS) for the profile fits obtained with methods A1–A3, based on all MAX-DOAS scans analyzed for the Xianghe station. The upper row shows results for the UV, the bottom row shows results for the visible. The dashed line indicates the threshold that is used for the quality control: retrievals with $\text{DOFS} < 1$ are excluded from the comparison.

profile retrieval
algorithms for
MAX-DOAS**

T. Vlemmix et al.

Figure 4. Histograms of residuals of the profile fits obtained with methods A1–A3, based on all MAX-DOAS scans analyzed for the Xianghe station. The upper row shows results for the UV, the bottom row shows results for the visible. The dashed line indicates the threshold (0.1, or -1 on a logarithmic scale) that is used for the quality control: retrievals with residuals above this threshold are excluded from the comparison.

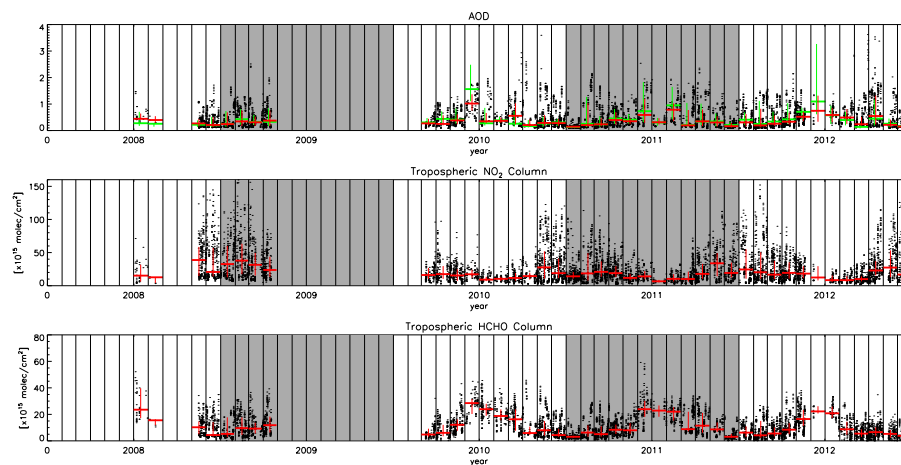

Figure 9. Time series of individual data points and monthly medians of AOD (VIS), and tropospheric columns of NO₂ and HCHO, obtained with method A. The black dots refer to individual profiles and the red lines refer to monthly medians. AOD from AERONET is shown in green (upper row). In 2008/09 the instrument was installed in Beijing, from 2010 onwards it was stationed in Xianghe.

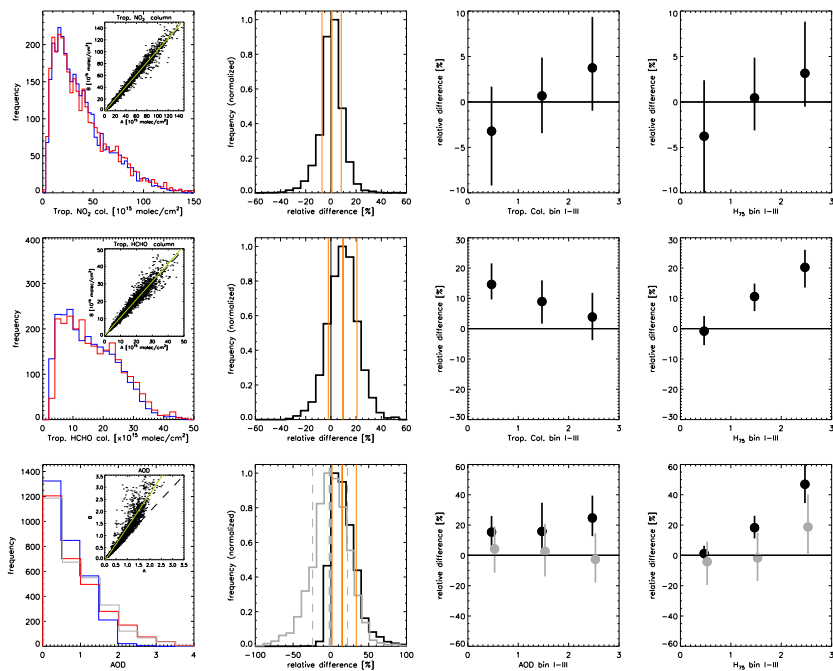

Figure 10. Statistics of column retrievals. The three rows refer to tropospheric columns of NO_2 , HCHO and aerosols respectively. Left column: frequency distributions obtained with method A (blue) and B (red). Second column: frequency distribution of relative differences (B minus A). Lines in orange indicate the quartiles. Column 3: relative difference sorted as a function of the tropospheric column (AOD for row 3) where the three bins refer to the lowest 25%, middle 50% and highest 25% respectively. Columns 4: similar to column 3, but here sorted as a function of the profile height (H_{75}). The grey line on the bottom row refers to AOD's from AERONET. The relative differences indicated in grey (bottom row, columns 2–4) refer to method B minus AERONET.
