Adaptive Vector Field Guidance Without *a Priori* Knowledge of Course Dynamics and Wind

Ximan Wang, Spandan Roy, *Member, IEEE*, Stefano Farì, and Simone Baldi, *Senior Member, IEEE*

***Abstract*—The high maneuverability of fixed-wing unmanned aerial vehicles (UAVs) exposes these systems to several dynamical and parametric uncertainties, severely affecting the fidelity of modeling and causing limited guidance autonomy. This article shows enhanced autonomy via adaptation mechanisms embedded in the guidance law: a vector-field method is proposed that does not require *a priori* knowledge of the UAV course time constant, coupling effects, and wind amplitude/direction. Stability and performance are assessed using the Lyapunov theory. The method is tested on software-in-the loop and hardware-in-the-loop UAV platforms, showing that the proposed guidance law outperforms state-of-the-art guidance controllers and standard vector-field approaches in the presence of significant uncertainty.**

***Index Terms*—Adaptive guidance, adaptive sliding-mode control, fixed-wing unmanned aerial vehicles (UAV), unknown dynamics, vector field (VF).**

I. Introduction

FIXED-WING unmanned aerial vehicles (UAVs) are emerging in several fields, due to their aerodynamic efficiency as compared to standard aircrafts built under the constraints imposed by the presence of a human pilot [1]–[3]. To replace the human pilot, autopilot software suites for fixed-wing UAVs (ArduPilot, PX4, DJI, NAVIO2, AscTec Trinity, just to name a few) use measured/reconstructed states [4]–[8] to control aileron, rudder, elevator, and thrust, so as to reach the set points provided by the *guidance law* [9]. Proposed guidance laws include geometric approaches [10], [11], acceleration-based control [12], model predictive control [13], and many more [14], [15]. This work focuses on *vector-field (VF) guidance*, a method originally proposed in [16] and further improved [17]–[19], based on the generation of a field of desired courses as set points to the autopilot. Accordingly, we follow the modeling and control architecture from the book of the proposers of VF guidance [9], noting that a similar architecture is adopted by most of the aforementioned autopilot software suites. The VF method has become standard even beyond UAV applications: extensions of the method have appeared for n-dimensional navigation [20], localization [21], obstacle avoidance, and formation control [22].

Typical guidance laws are designed under the assumptions that UAV parameters (e.g., roll/pitch/course time constants) are known, course dynamics are linear, longitudinal, and lateral motions are not coupled [9]. However, high maneuverability exposes fixed-wing UAVs to unmodeled dynamics and parametric uncertainties, which affect the fidelity of the UAV model and degrade the ideal performance [23], [24]. Studies on wind compensation [25]–[27] and guidance [28], [29] have shown that guidance performance is severely compromised by uncertain dynamics. *Adaptive* guidance ideas have been shown to compensate different levels of uncertainty: a not-exhaustive list comprises estimation methods [30]–[32], model reference adaptive control [33]–[35], switching control [36], $\mathcal{L}_1$ adaptive control [37], deep learning [38], [39], among others. Despite the progress in the field, no VF approach has been proposed for the relevant problem of guidance with *no a priori knowledge of UAV course dynamics and wind environment*. Previous studies by the same authors [33], still required knowledge of course time constant, nominal knowledge of wind, and *a priori* bounded unmodeled dynamics. The main contributions of this article are follows:

1) Achieving VF path following without structural knowledge of the unmodeled coupling effects and without *a priori* knowledge of the course time constant and of wind amplitude/direction.
2) Connect the adaptive VF method to the uncertainty framework of adaptive sliding mode (cf., [40]–[43] and

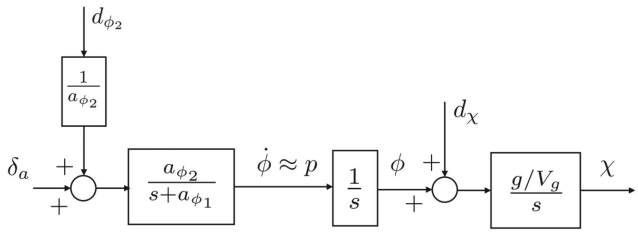

Fig. 1. Block diagram for simplified course dynamics (adapted from [9, Fig. 5.3]).

references therein), while extending it to consider unmodeled dynamics without *a priori* constant bound.

The first contribution is made possible by including estimation in the guidance laws, to compensate the uncertain terms. The second contribution is possible by considering a state-dependent uncertainty bound. Stability and performance (in the sense of uniformly ultimately boundedness, i.e., convergence of the tracking error to a tunable bound) is proven using the Lyapunov theory, and effectiveness is tested on software-in-the-loop and hardware-in-the-loop platforms comprising full UAV dynamics, wind effects, and Ardupilot/PX4 autopilots. The proposed method outperforms the state-of-the-art VF approaches in dealing with significant uncertainty.

The rest of this article is organized as follows: Section II describes the uncertainty setting for UAV dynamics, Section III recalls the standard VF guidance, Section IV presents the proposed adaptive VF guidance, simulations are in Section V, and finally, Section VI concludes this article.

II. UAV Uncertainty Setting

Fixed-wing UAVs can be modeled using 6-DOF Euler-Lagrange equations of motion [9, ch. 3]. However, to the purpose of guidance, the overall dynamics are usually simplified: after ignoring coupling effects, the dynamics of the roll angle ϕ can be described by [9, ch. 5]

$$\dot{\phi} = p + d_{\phi_1} \tag{1}$$

where p is the roll rate, and d_{ϕ_1} is an aggregate disturbance

$$d_{\phi_1} = q \sin\phi \tan\theta + r \cos\phi \tan\theta \tag{2}$$

where θ is the pitch angle and r the yaw rate.

After differentiating (1), the block diagram in Fig. 1 can be obtained, showing how the aileron input δ_a and the disturbance d_{ϕ_2} affect the dynamics of the course angle χ

$$d_{\phi_2} \triangleq \dot{d}_{\phi_1} + \Gamma_1 pq - \Gamma_2 qr + \frac{1}{2}\rho {V_a}^2 Sb \times \left[C_{p_0} + C_{p_\beta}\beta - C_{P_p}\frac{b}{2V_a}(d_{\phi_1}) + C_r \frac{br}{2V_a} + C_{p_{\delta_r}}\delta_r \right] \tag{3}$$

where β is the side slip angle, q is the pitch rate, V_a the airspeed, ρ the air density, S and b are geometric parameters of the aileron, $\Gamma_{(\cdot)}$ are coefficients related to the inertia matrix of the UAV, and $C_{(\cdot)}$ are coefficients related to the aerodynamics of the UAV.

Fig. 1 and (3) clearly show that unmodeled state-dependent terms are aggregated in d_{ϕ_2}, and similar holds for the disturbance d_χ shown in Fig. 1 (the interested reader can refer to the details in [9, ch. 6]). These disturbances take a very complex form and depends on many parameters. However, despite the presence of state-dependent terms, it is common in the literature (refer to [9, ch. 9 and 10] or to [16], [17], [21], [22], and [44]) to assume the disturbance to be *bounded a priori* and the course dynamics to be the following *ideal dynamics* for guidance purposes

$$\dot{\chi} = \alpha(\chi^c - \chi). \tag{4}$$

Here, χ is the course of the UAV, representing the angle between the north and the ground velocity V_g; χ^c is the command course from the controller; and α is a positive constant that defines the response speed of the course-hold loop (a cascaded PID not shown in Fig. 1 but present in most autopilot software suites for fixed-wing UAVs). Two comments with respect to (4) are as follows:

1) The dynamics (4) *rely on the assumption that longitudinal and lateral dynamics are decoupled:*
   in this work, we consider more realistic course dynamics
   $$\dot{\chi} = \alpha(\chi^c - \chi) + \Delta(\chi) \tag{5}$$
   where $\Delta(\chi)$ is an uncertainty term. The disturbances (2) and (3) reveal that finding a closed-form structure for the term $\Delta(\chi)$ is difficult. We follow an approach motivated by the control-theoretic framework of sliding mode [45, Assumption A2 and eq. (8)], showing that for a first-order system $\dot{x} = f(x) + u + \Delta(x)$, nonlinear unmodeled dynamics $\Delta(x)$ can be represented as
   $$||\Delta(x)|| \leq c_0 + c_1||x|| \tag{6}$$
   where c_0 and c_1 are some constants. We will consider unmodeled course dynamics as in (13) in Section IV.
2) The steps in [9] and [44] show how α in (4) is *affected in a complex way by aerodynamic coefficients which cannot be perfectly known*, and can even change depending on the altitude and velocity. Therefore, the parameter α in (5) should be considered as uncertain or even unknown.

Fig. 2 shows that the wind affecting the airspeed V_a comprises a constant component (with magnitude W and angle ψ_W, giving the nominal groundspeed V_g) and time-varying perturbation (with amplitude $A(t)$ and angle $\psi_A(t)$, giving the actual groundspeed V_g'). Time-varying wind perturbations are typically neglected, resulting in the guidance dynamics

$$\begin{aligned} \dot{x} &= V_a \cos\psi + W\cos\psi_W = V_g \cos\chi \\ \dot{y} &= V_a \sin\psi + W\sin\psi_W = V_g \sin\chi \end{aligned} \tag{7}$$

where ψ is the heading angle between the north and the airspeed velocity V_a, x and y are the coordinate of the earth frame. A third comment follows:

3) The wind introduces another source of uncertainty. The uncertainty in (7) is reflected in the fact that *the ground speed V_g is not known* since a possibly unknown wind component influences it, as shown in Fig. 2.

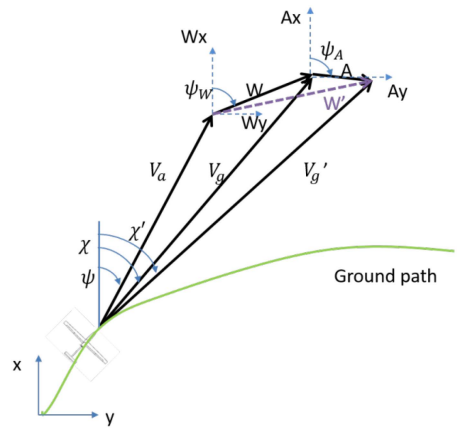

Fig. 2. Wind triangle for a fixed-wing UAV. Note that calculating the groundspeed V_g or V_g' requires *a priori* knowledge of the wind.

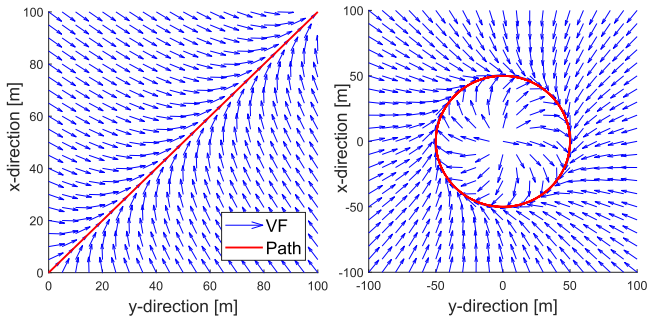

Fig. 3. VFs for straight-line and orbit paths.

It is worth mentioning that aspects 2) and 3) are overlooked both in the standard guidance literature, and also in the aforementioned framework of sliding mode, thus requiring a different design departing from existing frameworks.

III. Standard VF Guidance

The VF is based on specifying a desired course at a certain coordinate, to guide the UAV toward some paths. Two primitive paths are considered: the straight-line and the orbit path, with fields of desired courses shown in Fig. 3.

A. Straight-Line Guidance

As in [16], let us consider without loss of generality a straight-line parallel to the x-axis. The VF that describes the reference course to drive the UAV on the line is

$$\chi^d(e_y) = -\chi_\infty \frac{2}{\pi} \tan^{-1}(k e_y) \tag{8}$$

where e_y is the tracking error (distance in the y-direction), $\chi_\infty \in (0, \frac{\pi}{2}]$ is the course reference when the error is large, and k governs the VF smoothness. If the straight line is not parallel to the x-axis as in Fig. 3, it suffices to use the rotation matrix from inertial to path frame. In [16], it is shown that the control law that is able to let $\chi \to \chi^d$ and $e_y \to 0$ as $t \to \infty$ is

$$\chi^c = \chi - \chi_\infty \frac{2}{\pi} \frac{\beta_s V_g}{\alpha} \sin(\chi) - \frac{\kappa}{\alpha} \operatorname{sat}\left(\frac{\tilde{\chi}}{\varepsilon}\right) \tag{9}$$

where $\tilde{\chi} = \chi - \chi^d$, $\beta_s = k/(1 + (k e_y)^2)$, κ and ε are parameters governing control aggressiveness and counteracting a possible chattering in the control action, and

$$\operatorname{sat}(x) = \begin{cases} x, & \text{if } |x| < 1 \\ \operatorname{sgn}(x), & \text{otherwise.} \end{cases} \tag{10}$$

It is worth mentioning that the continuous sat function is used in [16] to approximate the behavior of a sgn function and avoid discontinuity in the closed-loop solutions.

B. Orbit Guidance

The strategy for orbit guidance builds course VF around the desired orbit (cf., Fig. 3)

$$\chi^d(\tilde{d}) = \gamma + \lambda \left(\frac{\pi}{2} + \tan^{-1}(k\tilde{d})\right) \tag{11}$$

where is $\tilde{d} = d - R$, d is the UAV distance from the orbit center, R is the orbit radius, and γ is the angle between the north and the UAV position with respect to the orbit center. For easiness of analysis, the UAV position is expressed in polar coordinates: λ is 1 for clockwise path and -1 for counter-clockwise path. In [16], it is shown that the control law, which is able to let $\chi \to \chi^d$ and $\tilde{d} \to 0$ as $t \to \infty$ is

$$\chi^c = \chi + \frac{V_g}{\alpha d} \sin(\chi - \gamma) + \beta_o \frac{\lambda V_g}{\alpha} \cos(\chi - \gamma) - \frac{\kappa}{\alpha} \operatorname{sat}\left(\frac{\tilde{\chi}}{\varepsilon}\right) \tag{12}$$

where $\beta_o = k/(1 + (k\tilde{d})^2)$, and the parameters k, κ, and ε are similar to the straight-line case. The proof of the Lyapunov stability for (9) and (12) is given in [16] and will not be further discussed. One crucial observation on (9) and (12) follows.

Remark 1: The guidance laws (9) and (12) require knowledge of the course time constant α, and of the groundspeed V_g. Fig. 2 and (7) show that the groundspeed requires knowledge of the wind. No guidance law has been proposed in VF literature [20], [21], [46] in the absence of such prior knowledge.

IV. Adaptive VF Guidance

To depart from the ideal assumptions in the literature, the following state dependence of uncertainty Δ is considered:

$$|\Delta(\chi)| \le c_0 + c_1 \left|\tilde{\chi} + \chi^d\right| \le \kappa_0 + \kappa_1 |\tilde{\chi}| \tag{13}$$

For some scalars κ_0, $\kappa_1 \in \mathbb{R}^+$. We have used (6) and the fact that χ^d is bounded by definition. Under the assumption that κ_0 and κ_1 are known, the modeling approach (13) was proposed in sliding-mode literature (cf., [45, eq. (8)] and related works) as a way to model complex (state-dependent) disturbances. Notice that (13) includes the fact that $\Delta(\chi)$ *may not be bounded a priori by a constant*. However, we want to deal with κ_0 and κ_1 being unknown, which is not considered in the standard sliding-mode literature. It is worth mentioning that even *adaptive* sliding-mode literature (cf., [40]–[43] and related works) models uncertainty as $|\Delta(\chi)| \le \kappa_0$, with possibly unknown κ_0: state dependencies entering through the course cannot be fully captured by this approach.

For state-dependent uncertainties, the following is a standard notion of stability [47, Definition 4.6].

Definition 1: The solutions of a nonlinear system $\dot{x} = f(x)$ are uniformly ultimately bounded (UUB) with ultimate bound b if there exist positive constants b and c and for every $a \in (0, c)$, there is a time $T(a, b)$ such that

$$\|x(0)\| \leq a \Rightarrow \|x(t)\| \leq b \quad \forall t \geq T(a, b). \tag{14}$$

We now propose an adaptive VF with the distinguishing feature of compensating for lack of knowledge of α, of V_g and of state dependent $\Delta(\chi)$. We introduce appropriate estimators and refer to the approach as *adaptive VF guidance*. It will be proven that the proposed approach achieves UUB solutions, with the ultimate bound being a performance indicator.

A. Straight-Line Adaptive Guidance

Since $\alpha > 0$, (5) can be written as

$$\overline{\alpha}\dot{\chi} = -\chi + \chi^c + \overline{\Delta} \tag{15}$$

where $\overline{\alpha} \triangleq 1/\alpha, \overline{\Delta} \triangleq \Delta/\alpha$. For control design purposes, the derivative of (8) is calculated in [16] as

$$\dot{\chi}^d = -\chi_\infty \frac{2}{\pi}\beta_s V_g \sin(\chi). \tag{16}$$

Being V_g unknown, $\dot{\chi}^d$ is not available for control deign. Then, observing (13) and (15), we have

$$\left|\overline{\Delta}\right| \leq \kappa_0^* + \kappa_1^* \left|\tilde{\chi}\right| \tag{17}$$

where $\kappa_0^* \triangleq \kappa_0/\alpha$ and $\kappa_1^* \triangleq \kappa_1/\alpha$ are unknown positive constants. For ease of controller design, let us also define $\kappa_2^* \triangleq \overline{\alpha} V_g$, which is also an unknown positive constant.

Based on the uncertainty structure (17), a guidance law is proposed as

$$\chi^c = -\Lambda\tilde{\chi} + \chi - \hat{\kappa}_2 \chi_\infty \frac{2}{\pi}\beta_s \sin(\chi) - \rho\,\mathrm{sat}\left(\frac{\tilde{\chi}}{\varepsilon}\right) \tag{18a}$$

$$\rho = \hat{\kappa}_0 + \hat{\kappa}_1 |\tilde{\chi}| \tag{18b}$$

where $\Lambda \in \mathbb{R}^+$ is a user-defined scalar, and $\hat{\kappa}_i$ are the estimates of κ_i^* $i = 0, 1, 2$, evaluated via the following adaptive laws:

$$\dot{\hat{\kappa}}_0 = |\tilde{\chi}| - \zeta_0 \hat{\kappa}_0 \tag{19a}$$

$$\dot{\hat{\kappa}}_1 = |\tilde{\chi}|^2 - \zeta_1 \hat{\kappa}_1 \tag{19b}$$

$$\dot{\hat{\kappa}}_2 = \chi_\infty \frac{2}{\pi}\beta_s \sin(\chi)\tilde{\chi} - \zeta_2 \hat{\kappa}_2 \tag{19c}$$

$$\text{with } \hat{\kappa}_i(0) > 0,\ i = 0, 1, 2 \tag{19d}$$

where $\zeta_i \in \mathbb{R}^+$ are user-defined scalars.

The following result can be derived.

Theorem 1: By employing the guidance law (18), the resulting trajectories of the UAV (15) and the parameters in the adaptive law (19) are UUB.

Proof: See the Appendix. Tunability of the ultimate bound is elaborated at the end of the proof according to (39) and (40) and standard Lyapunov arguments [47, Sec. 4.8]. □

B. Orbit Adaptive Guidance

For control design purposes, the derivative of (11) is calculated in [16] as

$$\dot{\chi}^d = V_g \left(\frac{\sin(\chi - \gamma)}{d} + \lambda\beta_o \cos(\chi - \gamma)\right). \tag{20}$$

The corresponding guidance law is defined as

$$\chi^c = -\Lambda\tilde{\chi} + \chi + \hat{\kappa}_2 \left(\frac{\sin(\chi - \gamma)}{d} + \lambda\beta_o \cos(\chi - \gamma)\right) - \rho\,\mathrm{sat}\left(\frac{\tilde{\chi}}{\varepsilon}\right) \tag{21a}$$

$$\rho = \hat{\kappa}_0 + \hat{\kappa}_1 |\tilde{\chi}| \tag{21b}$$

with the following adaptive laws:

$$\dot{\hat{\kappa}}_0 = |\tilde{\chi}| - \zeta_0 \hat{\kappa}_0 \tag{22a}$$

$$\dot{\hat{\kappa}}_1 = |\tilde{\chi}|^2 - \zeta_1 \hat{\kappa}_1 \tag{22b}$$

$$\dot{\hat{\kappa}}_2 = -\left(\frac{\sin(\chi - \gamma)}{d} - \lambda\beta_o \cos(\chi - \gamma)\right)\tilde{\chi} - \zeta_2 \hat{\kappa}_2 \tag{22c}$$

$$\text{with } \hat{\kappa}_i(0) > 0,\ i = 0, 1, 2 \tag{22d}$$

with similar design parameters as before.

The following result can be derived.

Theorem 2: By employing the guidance law (21), the resulting trajectories of the UAV (15) and the parameters in the adaptive law (22) are UUB.

Proof: See the Appendix. Tunability of the ultimate bound is elaborated at the end of the proof according to (47) and standard Lyapunov arguments [47, Sec. 4.8]. □

Remark 2: Differently from (9) and (12), no a priori knowledge of course time constant, wind, and unmodeled dynamics is required; the gains $\hat{\kappa}_0$ and $\hat{\kappa}_1$ compensate online the uncertainty term (17), stemming from the unmodeled term (13); the gain $\hat{\kappa}_2$ plays the role of an estimator for the ground velocity. The course time constant α is estimated jointly via $\hat{\kappa}_0$, $\hat{\kappa}_1$, and $\hat{\kappa}_2$ (as κ_0^*, κ_1^*, and κ_2^* all contain $1/\alpha$). These estimation actions mark a difference with the standard adaptive-free VF and with other adaptive-free robust methods.

Remark 3: The adaptive laws in (19) and (22) reveal that the control gains adjust automatically according to the tracking error, thanks to the effect of the stabilizing leakage terms $-\zeta_i\hat{\kappa}_i$, $i = 0, 1, 2$. In other words, the adaptive laws keep a balance between increasing the estimates when the error is large, and keep the estimates bounded. As $\zeta_0, \zeta_1,$ and ζ_2 become smaller, adaptation is faster. However, this might lead to larger gains $\hat{\kappa}_0, \hat{\kappa}_1$, and $\hat{\kappa}_2$ (i.e., the uncertainty can be overestimated) and high control input. This indicates a tradeoff between small control inputs and robustness to unmodeled dynamics.

Remark 4: The proposed guidance laws (18) and (21) share a structure similar to (adaptive) sliding mode

$$\chi^c = \chi - \Lambda\tilde{\chi} + \dot{\chi}^d - \rho\,\mathrm{sat}\left(\frac{\tilde{\chi}}{\varepsilon}\right). \tag{23}$$

The main differences are that $\dot{\chi}^d$ is given a priori in adaptive sliding-mode control (whereas we include adaptation due to the uncertainty in V_g), and that ρ estimates a constant bound for the uncertainty (whereas we estimate a state-dependent bound). First-order dynamics (5) usually assume the rudder loop to be well tuned and damped. If this is not the case and sideslip dynamics generate moderately damped second-order Dutch roll dynamics (e.g., triggered by cross wind) [48], one can in principle consider such effects as additional unmodeled dynamics. Accordingly, one could consider a more complex description of the uncertainty by adding extra terms, e.g., a quadratic term

$$|\Delta(\chi)| \leq \kappa_0 + \kappa_1 |\tilde{\chi}| + \kappa_q |\tilde{\chi}|^2 \tag{24}$$

with unknown scalars κ_0, κ_1, and κ_q. Besides the previously introduced adaptive laws for $\hat{\kappa}_0$ and $\hat{\kappa}_1$, this eventually leads to an additional adaptation term

$$\rho = \hat{\kappa}_0 + \hat{\kappa}_1 |\tilde{\chi}| + \hat{\kappa}_q |\tilde{\chi}|^2 \tag{25a}$$

$$\dot{\hat{\kappa}}_q = |\tilde{\chi}|^3 - \zeta_q \hat{\kappa}_q. \tag{25b}$$

Structural knowledge can be embedded in the upper bound (24), provided that the upper bound is linear in the uncertain parameters. Alternatively, the structure (23) can be modified in the sense of sliding mode for second-order dynamics

$$\chi^c = \chi - \Lambda \tilde{\xi} + \ddot{\chi}^d - \rho \,\mathrm{sat}\left(\frac{\tilde{\xi}}{\varepsilon}\right) \tag{26}$$

with $\tilde{\xi} = \dot{\tilde{\chi}} + \Lambda_2 \tilde{\chi}$, for $\Lambda, \Lambda_2 > 0$. This road is not explored here to avoid departing too much from the original VF idea, and it can be a relevant future work.

V. Experimental Results

The performance of the proposed adaptive VF is assessed, as compared to the standard VF and to an ideal VF method, which differ for the following *a priori* knowledge (cf., Fig. 2).

1) Standard VF: Knowledge of the time constant α is needed, and only the constant wind component is known, i.e., $V_g(t) = ||V_a(t) + W(t)||$.
2) "Ideal" VF: Knowledge of the time constant α is needed, and both constant and time-varying wind components are known, i.e., $V_g(t) = ||V_a(t) + W'(t)||$ (we put "ideal" in quotes because this approach still relies on simplified course dynamics, leading to degraded performance).
3) Adaptive VF: The time constant α and all wind components are estimated.

The standard and ideal VF are inspired by the recent works [19], [33], where it is further illustrated that the VF in general does not give optimality guarantees in the sense of "optimal control." However, as the final goal of any guidance law is the minimization of a tracking error, such a tracking error can be considered a measure of optimality and evaluated experimentally. Experiments are carried out on a software-in-the-loop UAV platform where the functionalities of the ArduPilot autopilot are replicated in MATLAB, and on a hardware-in-the-loop UAV platform where a PX4 autopilot hardware is connected to a Gazebo/ROS environment. Therefore, the experiments include the autopilot inner loop dynamics (cascaded loops) embedded in ArduPilot/PX4, and allow to capture realistic effects of the inner loop on the guidance layer. Note that ArduPilot and PX4 are open-source suites constantly updated by a large UAV community, i.e., they represent the newest state of the art in the field.

TABLE I
Flight Environmental Conditions

Scenario	Constant wind	Turbulence
#1	No	No
#2	Yes	No
#3	Yes	Yes

TABLE II
Parameters of the Guidance Laws

χ^∞	k	ε	κ	ζ_0, ζ_1	ζ_2
$\pi/2$	0.1 m^{-1}	1 rad	$\pi/2$ $\mathrm{rad}^2/\mathrm{s}$	0.01	0.001

The experiments offer a way to compare different sliding-mode techniques in view of the following facts.

1) The standard VF is essentially a sliding-mode control method that assumes parametric knowledge of the course time constant and the nominal wind.
2) The "ideal" VF is also a sliding-mode control method, but with more knowledge of the wind disturbance.
3) Our adaptive VF is an advanced adaptive sliding-mode control without parametric knowledge. Yet, it is different from standard adaptive sliding-mode control since the latter still requires nominal parametric knowledge and assumes the uncertainty to be bounded *a priori*.

A. Software-in-the-Loop Experiments

The six-degrees-of-freedom fixed-wing UAV and wind dynamics have been implemented in a MATLAB software-in-the-loop UAV platform developed at TU Delft, which replicates the open-source ArduPilot autopilot code (cf., [49] for implementation details and for all the details about the UAV model, which is a based on a Hobby-King Bixler UAV). We take the following environmental conditions: constant wind amplitude is $W = 4$ m/s with wind angle $\psi_W = 230°$; and a Dryden turbulence [9, Sec. 4.4]. To draw conclusions on the effectiveness of adaptation in different conditions, all environmental conditions have been combined to obtain three wind scenarios, summarized in Table I.

The reader is referred to previous work by the same authors [33] to see how high-order state-dependent unmodeled dynamics arise from approximating the Bixler course dynamics as first-order dynamics (5). The first-order time constant of the course dynamics can be estimated as $\alpha = 0.4578$. Both the standard and the ideal VF use this time constant.

The performance of the standard, adaptive, and ideal VF are first evaluated on primitive paths (straight line and orbit), using the root-mean-square (RMS) steady-state tracking error calculated in the last portion of the path when e_{py} or $\tilde{d}$ have converged. The parameters χ^∞, k, ε, κ, ζ_0, ζ_1, and ζ_2 in Table II have been tuned so as to find a good compromise between convergence speed and smooth response.

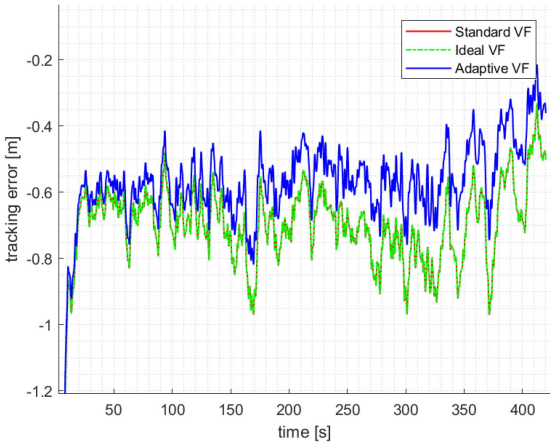

Fig. 4. Straight line, Scenario 3: Tracking error (the standard and ideal VF have similar performance and their lines overlap).

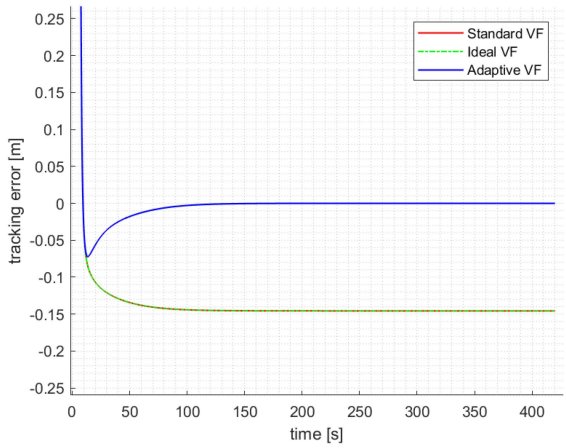

Fig. 5. Orbit, Scenario 1: Tracking error (the standard and ideal VF have the same performance and their lines overlap).

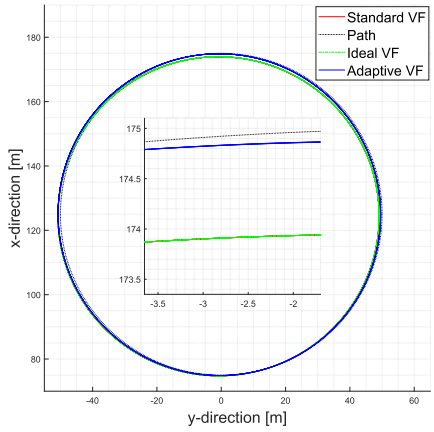

Fig. 6. Orbit, Scenario 2: Path in the x–y plane (the small box is a zoom to highlight the improved tracking of the adaptive VF).

Tables III and IV (straight line and orbit, respectively) highlight how the proposed adaptive VF outperforms, in all scenarios, the standard and the ideal VF. Note that in Scenarios 1 and 2, the standard and the ideal VF have exactly the same performance since there is no wind perturbation. For the straight-line case, Fig. 4 clearly shows that the adaptive VF better counteracts with time the effect of the wind in Scenario 3 (38% improvement). Even with exact knowledge of the wind, the ideal VF performs quite poorly, due to the inaccurate knowledge of α (the adaptive VF again gives 38% improvement). Something similar also occurs in Scenario 2 (constant wind) and will not be shown due to space limitations.

For the orbit case, Fig. 5 clearly shows that the standard and the ideal VFs have a steady-state tracking error: such error is completely removed by the adaptive VF. A significant reduction of the tracking error (76–89%) by the adaptive VF also occurs in Scenarios 2 and 3, which are depicted in Figs. 6–9 in terms of tracking error and path in the x–y plane. In all cases, it can be seen that the adaptation mechanism reduces the oscillations of the error: oscillations are present due to the fact that the wind effect changes when the UAV is travelling along the orbit. Due to space limitations, the adaptive gains κ_0, κ_1, and κ_2 are not shown, but one can verify the boundedness of the gains directly from the adaptive laws (19) and (22): if the tracking error $\tilde{\chi}$ is bounded, then $\hat{\kappa}_i$s are bounded using bounded-input-bounded-output notions, as ζ_is are positive constants.

B. Hardware-in-the-Loop Experiments

A hardware-in-the-loop UAV platform is set up using the PX4 open-source flight controller with Raspberry Pi 3B+, ROS with MAVROS communication node (to communicate with PX4), and Gazebo as a 3-D UAV simulator [cf., Fig. 10(left)]. PX4 is another popular autopilot suite: its inner loop dynamics implement an TECS-L1 guidance law[1]: also, it allows to program in C++ other control laws: in this study, we programmed both the standard VF and the adaptive VF in the PX4/Raspberry Pi 3B+ hardware (the ideal VF could not be programmed because the Gazebo wind environment can provide the wind time-varying component as a measurement).

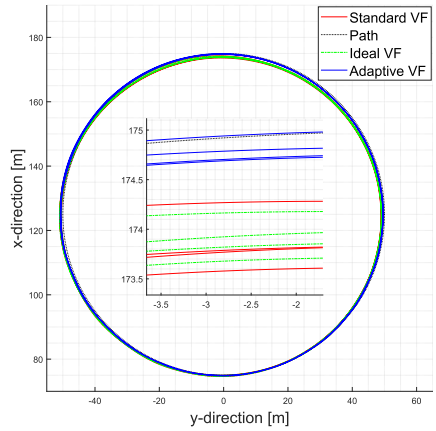

Fig. 7. Orbit, Scenario 3: Path in the x–y plane (the small box is a zoom to highlight the improved tracking of the adaptive VF).

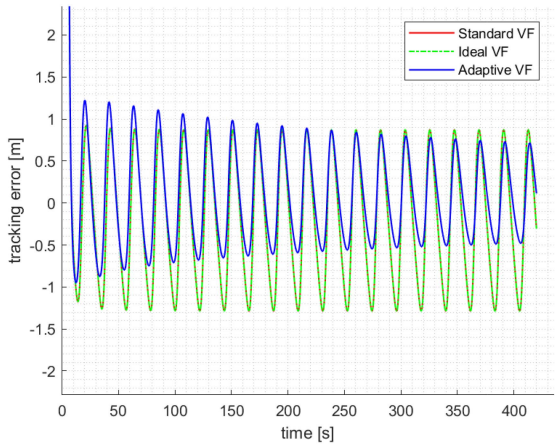

Fig. 8. Orbit, Scenario 2: Tracking error (the standard and ideal VFs have the same performance and their lines overlap).

Gazebo is used not only as a 3-D simulator for rendering of environments, but also as a physical simulator of the UAV dynamics in six degrees of freedom. The UAV model is generated in Gazebo following the tutorial[2]: it is a 1.5-kg standard structure fixed-wing UAV including aileron, rudder, and elevator. The rotor is one puller at the head of the UAV and the airspeed is in the range [10–25]m/s (refer to the template[3]). The subsystems are connected as follows: Gazebo simulates and visualizes the world environment and the UAV, and it provides the sensor data to PX4; PX4 calculates the guidance commands depending on the embedded algorithm and send them back to Gazebo; finally, Gazebo delivers the commands to the UAV after simulating the actuator dynamics. As compared to the software-in-the-loop experiments, the hardware-in-the-loop UAV platform is also able to simulate state estimation errors (GPS and IMU measurement errors and the sensor fusion layer), which, therefore, add more realism to the experiments.[4]

TABLE V
3D SIMULATION RMS TRACKING ERRORS (IN PARENTHESES IS THE LOSS OF PERFORMANCE AGAINST THE ADAPTIVE VF)

	TECS-L1 RMS error	Standard VF RMS error ($\alpha = 0.4578$)	Standard VF RMS error (optimized α)	Adaptive VF RMS error
Line				
#4	5.161 (**+462%**)	1.419 (**+54%**)	1.036 (**+13%**)	0.919
#5	11.62 (**+102%**)	12.20 (**+112%**)	5.932 (**+3%**)	5.762
Orbit				
#4	2.319 (**+1%**)	2.613 (**+14%**)	2.370 (**+3%**)	2.300
#5	5.810 (**+102%**)	6.105 (**+112%**)	2.966 (**+3%**)	2.881
Combi.				
#4	6.705 (**+333%**)	4.416 (**+185%**)	1.839 (**+19%**)	1.548
#5	18.95 (**+233%**)	16.68 (**+194%**)	5.804 (**+2%**)	5.683

Similarly to the software-in-the-loop experiments, we define several wind scenarios and paths to test the performance in different environments. We have a scenario with average wind 2 m/s with variance of 0.5 m/s and direction $\psi_W = 45°$ (Scenario #4), and a scenario with average wind of 5 m/s, direction $\psi_W = 45°$, variance of 0.5 m/s, and gusts up to 7 m/s (Scenario #5). We define three paths: a straight-line path, an orbit path, and a combined path with lines and orbits [cf., Fig. 10(right)]. The results of the guidance laws are shown in Table V in terms of RMS error. Notice that the standard VF is implemented in two conditions: one with $\alpha = 0.4578$, and one where α has been carefully tuned so as to improve the performance. Because the adaptive VF is able to improve even over the optimized standard VF, this further validates the effectiveness of the proposed strategy: even if the optimized α makes the standard VF at least four times better, still 3–19% improvements are observed thanks to adaptation. As compared to the previous tables, it can be seen that Scenario #5 is quite extreme for the UAV, but still the proposed adaptive VF outperforms all strategies. The TECS-L1 guidance works good for orbit following under low wind (Scenario #4, only 1% degradation) but is less effective for straight line and high wind, 102–462% degradation).

Overall the simulations show that the proposed adaptive VF, by compensating for the lack of knowledge in course dynamics

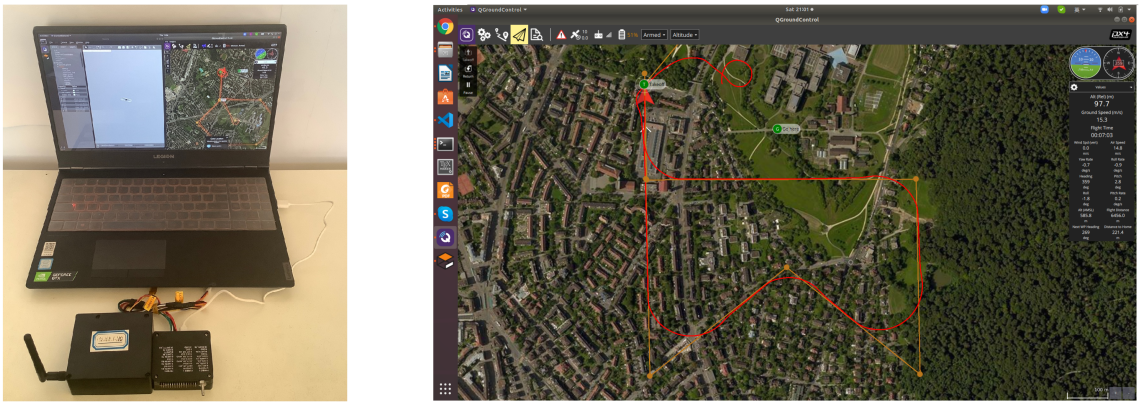

Fig. 10. Setup for hardware-in-the-loop experiments: A PX4/Raspberry Pi 3B+ controller uses MAVROS node to share data with a Gazebo 3-D simulator.

and wind environment, can bring to improved guidance performance in several wind and path scenarios.

VI. Conclusion

As compared to state-of-the-art guidance for fixed-wing UAVs, this work has proposed a novel guidance law that does not require precise knowledge of the course time constant, while the course dynamics can be affected by state-dependent uncertainty representing couplings. A dedicated control design and stability analysis was given to address these challenges. The effectiveness of the proposed method in handling such uncertainty was tested on software-in-the-loop and hardware-in-the-loop UAV platforms, showing that the proposed method outperforms several guidance approaches relying on precise UAV dynamics. An interesting question is the level of uncertainty that makes the system fail: to the best of our experience, failure will be largely dependent on how the underlying autopilot layer (low-level control) is tuned. For our autopilot (tuned via the AutoTune procedure[5] of Ardupilot), we never experienced system failure. It is intuitive to expect that when the autopilot layer is poorly tuned, any guidance algorithm can do little to cope with this situation: investigating this point in an analytic or numerical way could be an interesting future work. Further connecting the VF idea to higher order (adaptive) sliding mode [42], [50] is another interesting topic for further study.

Appendix

Before starting the analysis, let us notice that the combination of the adaptive laws (19a), (19b), (22a), and (22b) and the initial conditions (19d) and (22d) imply that

$$\hat{\kappa}_0(t), \hat{\kappa}_1(t) \geq 0 \forall t \geq 0 \tag{27}$$

for both straight-line and orbit path.

[5][Online]. Available: https://ardupilot.org/plane/docs/automatic-tuning-with-autotune.html

A. Proof of Theorem 1 (Straight-Line Case)

The closed-loop stability in the straight-line case is analyzed using the following Lyapunov function:

$$W = \frac{1}{2}\overline{\alpha}\tilde{\chi}^2 + \frac{1}{2}\sum_{i=0}^{2}(\hat{\kappa}_i - \kappa^*)^2. \tag{28}$$

Define an overall uncertainty term

$$\Delta^c \triangleq \overline{\Delta} + \kappa_2^* \chi_\infty \frac{2}{\pi}\frac{k}{1+(ke_y)^2}\sin(\chi). \tag{29}$$

Observing the structure of $\mathrm{sat}(\cdot)$ as in (18a), the overall stability analysis is carried out for the following two cases, using the common Lyapunov function (28).

Case (1): $|\tilde{\chi}| \geq \epsilon$.

Using (15) and (18), the time-derivative of (28) yields

$$\begin{aligned}\dot{W} &= \tilde{\chi}(-\chi + \chi^c + \Delta^c) + \sum_{i=0}^{2}(\hat{\kappa}_i - \kappa_i^*)\dot{\hat{\kappa}}_i \\ &\leq -\Lambda\tilde{\chi}^2 - (\hat{\kappa}_0 - \kappa_0^*)|\tilde{\chi}| - (\hat{\kappa}_1 - \kappa_1^*)|\tilde{\chi}|^2 \\ &\quad - (\hat{\kappa}_2 - \kappa_2^*)\chi_\infty\frac{2}{\pi}\beta_s\tilde{\chi}\sin(\chi) + \sum_{i=0}^{2}(\hat{\kappa}_i - \kappa_i^*)\dot{\hat{\kappa}}_i. \end{aligned}\tag{30}$$

From (19a)–(19c), we have

$$\sum_{j=0}^{1}(\hat{\kappa}_j - \kappa_j^*)\dot{\hat{\kappa}}_j = (\hat{\kappa}_j - \kappa_j^*)|\tilde{\chi}|^{j+1} - \zeta_j\hat{\kappa}_j^2 + \zeta_j\hat{\kappa}_j\kappa_j^* \tag{31}$$

$$(\hat{\kappa}_2 - \kappa_2^*)\dot{\hat{\kappa}}_2 = (\hat{\kappa}_2 - \kappa_2^*)\chi_\infty\frac{2}{\pi}\beta_s\tilde{\chi}\sin(\chi) - \zeta_2\hat{\kappa}_2^2 + \zeta_2\hat{\kappa}_2\kappa_2^*. \tag{32}$$

The following simplifications can be made for $i = 0, 1, 2$

$$\begin{aligned}\hat{\kappa}_i\kappa_i^* - \hat{\kappa}_i^2 &= -\left(\frac{\hat{\kappa}_i}{\sqrt{2}} - \frac{\kappa_i^*}{\sqrt{2}}\right)^2 - \frac{\hat{\kappa}_i^2}{2} + \frac{\kappa_i^{*2}}{2} \\ &\leq -\left(\frac{\hat{\kappa}_i}{\sqrt{2}} - \frac{\kappa_i^*}{\sqrt{2}}\right)^2 + \frac{\kappa_i^{*2}}{2}. \end{aligned}\tag{33}$$

Substituting (31)–(33) into (30) yields

$$\dot{W} \leq -\Lambda\tilde{\chi}^2 - \sum_{i=0}^{2}\left(\frac{\zeta_i(\hat{\kappa}_i-\kappa_i^*)^2}{2} - \frac{\zeta_i\kappa_i^{*2}}{2}\right). \tag{34}$$

Using the definition of W in (28) yields

$$\dot{W} \leq -\overline{\varrho}W + \frac{1}{2}\sum_{i=0}^{2}\zeta_i\kappa_i^{*2} \tag{35}$$

where $\overline{\varrho} \triangleq \frac{\min_i\{\Lambda,\zeta_i/2\}}{\max\{\overline{\alpha}/2,1/2\}} > 0$ by design.

Define a scalar $0 < \delta < \overline{\varrho}$. Then, $\dot{W}$ in (35) simplifies to

$$\dot{W} \leq -\delta W - (\overline{\varrho}-\delta)W + \frac{1}{2}\sum_{i=0}^{2}\zeta_i\kappa_i^{*2}. \tag{36}$$

Defining a scalar $\mathcal{B}_1 \triangleq \frac{\sum_{i=0}^{2}\zeta_i\kappa_i^{*2}}{2(\overline{\varrho}-\delta)}$, it can be noticed that $\dot{W} \leq -\delta W$ when $W \geq \mathcal{B}_1$.

Case (2): $|\tilde{\chi}| < \epsilon$.

Using (15) and (18), for this case, we have

$$\begin{aligned}\dot{W} &\leq -\Lambda\tilde{\chi}^2 - \rho\frac{|\tilde{\chi}|^2}{\epsilon} + |\bar{\Delta}||\tilde{\chi}| \\ &\quad + (\hat{\kappa}_2-\kappa_2^*)\beta_s\tilde{\chi} + \sum_{i=0}^{2}(\hat{\kappa}_i-\kappa_i^*)\dot{\hat{\kappa}}_i \\ &\leq -\Lambda\tilde{\chi}^2 + \kappa_0^*|\tilde{\chi}| + \kappa_1^*|\tilde{\chi}|^2 + (\hat{\kappa}_2-\kappa_2^*)\chi_\infty\frac{2}{\pi}\beta_s\sin(\chi)\tilde{\chi} \\ &\quad + \sum_{i=0}^{2}(\hat{\kappa}_i-\kappa_i^*)\dot{\hat{\kappa}}_i.\end{aligned} \tag{37}$$

Then, following the same lines of proof as in Case (1), we have

$$\dot{W} \leq -\delta W - (\overline{\varrho}-\delta)W + \frac{1}{2}\sum_{i=0}^{2}\zeta_i\kappa_i^{*2} + \hat{\kappa}_0|\tilde{\chi}| + \hat{\kappa}_1|\tilde{\chi}|^2. \tag{38}$$

In Case (2), we have $|\tilde{\chi}| < \epsilon$. From (19a) and (19b), it can be noted that $|\tilde{\chi}| \in \mathcal{L}_\infty \Rightarrow \hat{\kappa}_0, \hat{\kappa}_1 \in \mathcal{L}_\infty$. Therefore, $\exists\varsigma \in \mathbb{R}^+$ such that $(\hat{\kappa}_0|\tilde{\chi}| + \hat{\kappa}_1|\tilde{\chi}|^2) \leq \varsigma$, yielding

$$\dot{W} \leq -\delta W - (\overline{\varrho}-\delta)W + \frac{1}{2}\sum_{i=0}^{2}\zeta_i\kappa_i^{*2} + \varsigma \tag{39}$$

and $\dot{W} \leq -\delta W$ holds when $W \geq \mathcal{B}_2 \triangleq \frac{\frac{1}{2}\sum_{i=0}^{2}\zeta_i\kappa_i^{*2}+\varsigma}{\overline{\varrho}-\delta}$.

Observing the results of Cases (1) and (2) [see (36) and (39)], we get $\dot{W} \leq -\delta W$ when $W \geq \max\{\mathcal{B}_1, \mathcal{B}_2\}$ and the closed-loop system is UUB, implying $\tilde{\chi}, \hat{\kappa}_i \in \mathcal{L}_\infty$ for $i = 0, 1, 2$. Furthermore, the Lyapunov function as in (28) yields $W \geq (1/2)\overline{\alpha}\tilde{\chi}^2$. Therefore, following the definition of ultimate bound as in [47, Sec. 4.8], the ultimate bound $\mathcal{B}_s$ on the straight-line path tracking error $\tilde{\chi}$ is found to be

$$\mathcal{B}_s = \sqrt{\frac{2\max\{\mathcal{B}_1, \mathcal{B}_2\}}{\overline{\alpha}}}. \tag{40}$$

Tunability: The ultimate bound on the path tracking error can be considered as a performance indicator. From the structures of the error bounds $\mathcal{B}_1$ and $\mathcal{B}_2$ [as after (36) and (39)], one can derive that a high value of Λ and low values of ζ_i improve the tracking accuracy. However, it should be noticed that increasing Λ or decreasing ζ_i result in higher control input (due to the larger values of ρ): the tradeoff between tracking error and control effort is standard in control, and requires to tune these parameters according to the application requirements.

B. Proof of Theorem 2 (Orbit case)

The stability analysis for the orbit path follows similar steps of straight path case, with the Lyapunov function (28) and *overall uncertainty term* for the orbital path as

$$\Delta^c \triangleq \overline{\Delta} + \kappa_2^*\left(\frac{\sin(\chi-\gamma)}{d} + \lambda\beta_o\cos(\chi-\gamma)\right). \tag{41}$$

Observing the structure of $\mathrm{sat}(\cdot)$ as in (21a), the overall stability analysis is carried out for the following two cases, using the common Lyapunov function (28).

Case (1): $|\tilde{\chi}| \geq \epsilon$. Using (15) and (20), we get

$$\begin{aligned}\dot{W} &= \tilde{\chi}(-\chi + \chi^c + \Delta^c) + \sum_{i=0}^{2}(\hat{\kappa}_i-\kappa_i^*)\dot{\hat{\kappa}}_i \\ &\leq -\Lambda\tilde{\chi}^2 - (\hat{\kappa}_0-\kappa_0^*)|\tilde{\chi}| \\ &\quad - (\hat{\kappa}_1-\kappa_1^*)|\tilde{\chi}|^2 + \sum_{i=0}^{2}(\hat{\kappa}_i-\kappa_i^*)\dot{\hat{\kappa}}_i \\ &\quad + (\hat{\kappa}_2-\kappa_2^*)\left(\frac{\sin(\chi-\gamma)}{d} + \lambda\beta_o\cos(\chi-\gamma)\right)\tilde{\chi}.\end{aligned} \tag{42}$$

From (22a)–(22c), we have

$$\sum_{j=0}^{1}(\hat{\kappa}_j-\kappa_j^*)\dot{\hat{\kappa}}_j = (\hat{\kappa}_j-\kappa_j^*)|\tilde{\chi}|^{j+1} - \zeta_j\hat{\kappa}_j^2 + \zeta_j\hat{\kappa}_j\kappa_j^* \tag{43}$$

$$\begin{aligned}(\hat{\kappa}_2-\kappa_2^*)\dot{\hat{\kappa}}_2 &= (\hat{\kappa}_2-\kappa_2^*)\tilde{\chi}\left(\frac{\sin(\chi-\gamma)}{d} + \lambda\beta_o\cos(\chi-\gamma)\right) \\ &\quad - \zeta_2\hat{\kappa}_2^2 + \zeta_2\hat{\kappa}_2\kappa_2^*.\end{aligned} \tag{44}$$

The same simplifications (33) apply to the orbit case, leading along similar steps to

$$\dot{W} \leq -\delta W - (\overline{\varrho}-\delta)W + \frac{1}{2}\sum_{i=0}^{2}\zeta_i\kappa_i^{*2}. \tag{45}$$

Defining the scalar $\mathcal{B}_1$ as before, we have $\dot{W} \leq -\delta W$ when $W \geq \mathcal{B}_1$.

Case (2): $|\tilde{\chi}| < \epsilon$. Using (15) and (20), for this case, we get

$$\begin{aligned}\dot{W} &\leq -\Lambda\tilde{\chi}^2 - \rho(|\tilde{\chi}|^2/\epsilon) + |\bar{\Delta}||\tilde{\chi}| + \sum_{i=0}^{2}(\hat{\kappa}_i-\kappa_i^*)\dot{\hat{\kappa}}_i \\ &\quad + (\hat{\kappa}_2-\kappa_2^*)\left(\frac{\sin(\chi-\gamma)}{d} + \lambda\beta_o\cos(\chi-\gamma)\right)\tilde{\chi} \\ &\leq -\Lambda\tilde{\chi}^2 + \kappa_0^*|\tilde{\chi}| + \kappa_1^*|\tilde{\chi}|^2 + \sum_{i=0}^{2}(\hat{\kappa}_i-\kappa_i^*)\dot{\hat{\kappa}}_i\end{aligned}$$

$$+ (\hat{\kappa}_2 - \kappa_2^*) \left(\frac{\sin(\chi - \gamma)}{d} + \lambda \beta_o \cos(\chi - \gamma) \right) \tilde{\chi}. \quad (46)$$

We obtain that $\exists \varsigma \in \mathbb{R}^+$ such that $(\hat{\kappa}_0 |\tilde{\chi}| + \hat{\kappa}_1 |\tilde{\chi}|^2) \leq \varsigma$, giving

$$\dot{W} \leq -\delta W - (\overline{\varrho} - \delta) W + \frac{1}{2} \sum_{i=0}^{2} \zeta_i \kappa_i^{*2} + \varsigma \quad (47)$$

and $\dot{W} \leq -\delta W$ when $W \geq \mathcal{B}_2$. The results (45) and (47) reveal that $\dot{W} \leq -\delta W$ when $W \geq \max\{\mathcal{B}_1, \mathcal{B}_2\}$ and the closed loop is UUB, implying $\tilde{\chi}, \hat{\kappa}_i \in \mathcal{L}_\infty$ for $i = 0, 1, 2$.

Tunability: Following similar lines of Theorem 1, the ultimate bound $\mathcal{B}_o$ on path tracking error is analogous to (40), i.e.,

$$\mathcal{B}_o = \sqrt{\frac{2 \max\{\mathcal{B}_1, \mathcal{B}_2\}}{\overline{\alpha}}}. \quad (48)$$

Therefore, similar tradeoffs arise: increasing Λ or decreasing ζ_i result in smaller ultimate bound but may result in higher control.

Ximan Wang received the B.Sc. degree in control system engineering from Taiyuan University, Taiyuan, China, in 2014, and the M.Sc. degree in automotive control system engineering from University of Sheffield, Sheffield, U.K., in 2016. He is currently working toward the Ph.D. degree with the Delft Center for Systems and Control, Delft University of Technology, Delft, Netherlands.

He was a Senior Engineer with Systems Engineering Research Institute, Beijing, China. His research interests include adaptive optimization for control and unmanned aerial vehicle adaptive control.

Spandan Roy (Member, IEEE) received the B.Tech. degree in electronics and communication engineering from Techno India (Salt Lake), West Bengal University of Technology, Kolkata, India, in 2011, the M.Tech. degree in mechatronics from the Academy of Scientific and Innovative Research, New Delhi, India, in 2013, and the Ph.D. degree in control and automation from the Indian Institute of Technology Delhi, New Delhi, India, in 2018.

He is currently an Assistant Professor with Robotics Research Center, International Institute of Information Technology Hyderabad, Hyderabad, India. Previously, he was Postdoc Researcher with Delft Center for System and Control, Delft University of Technology, Delft, The Netherlands. His research interests include artificial delay-based control, adaptive-robust control, and switched systems and its applications in Euler–Lagrange systems.

Stefano Farì received the B.Sc. and M.Sc. degrees in automation engineering from Politecnico di Milano, Milan, Italy.

He performed his master thesis as a Guest Researcher with the Delft Center for Systems and Control, Delft University of Technology, Delft, The Netherlands. He has worked with Piaggio Aerospace, Savona, Italy, as a Flight Control System Engineer. He is currently working as GNC engineer with German Aerospace Center, Bremen, Germany.

Simone Baldi (Senior Member, IEEE) received the B.Sc. degree in electrical engineering, and the M.Sc. and Ph.D. degrees in automatic control engineering from the University of Florence, Florence, Italy, in 2005, 2007, and 2011, respectively.

He is currently a Professor with the School of Mathematics and School of Cyber Science and Engineering, Southeast University, Nanjing, China, with guest position with Delft Center for Systems and Control, Delft University of Technology, Delft, The Netherlands, where he was an Assistant Professor. His research interests include adaptive and learning systems with applications in unmanned vehicles and smart energy systems.

Dr. Baldi was the recipient of outstanding reviewer award for *Applied Energy* (2016) and *Automatica* (2017). He is a Subject Editor for *International Journal of Adaptive Control and Signal Processing* and an Associate Editor for IEEE CONTROL SYSTEMS LETTERS.
